Sodium [1-^{14}C]acetate was obtained from New England Nuclear Corporation, Boston, MA. Sodium [1-^{13}C]-, [2-^{13}C]-, and [1,2-^{13}C]acetates (all 90% ^{13}C) were supplied by Merck, Sharp and Dohme Canada, Ltd., Pointe Claire, P.Q. Sodium [2-^{13}C, 2-^{2}H$_3$]acetate (90% ^{13}C; >95% ^{2}H) was prepared by dissolving sodium [2-^{13}C]acetate (90% ^{13}C; 37.1 mmol) in sodium deuteroxide solution (7.42 mmol sodium in 22.5 mL $^{2}H_2O$ (99.7% ^{2}H)) and heating in a sealed stainless steel tube for 20 h at 137°C to exchange protons for deuterons (10). This exchange process was repeated four times. After each treatment the solution was taken to dryness and the residue of partially deuterated sodium acetate was redissolved in a fresh aliquot of the sodium deuteroxide solution. The final sample of deuterated sodium acetate was dissolved in 10 mL $^{2}H_2O$ and acidified with H_2SO_4 to pH 2–3. This acidic solution was transferred to a microdistillation apparatus and the fraction distilling at 100°C was collected. A further 5 mL $^{2}H_2O$ was added to the remaining solution and the distillation repeated. Neutralization of the combined distillates with sodium hydroxide (pH 9.0–9.5) and removal of the solvent gave the required product in good yield (32.9 mmol) and with a high deuterium content (>95%) as determined by ^{1}H and ^{13}C nmr analyses.

Isotope Measurement

Radioactivity was determined with a Nuclear Chicago ISOCAP/300 liquid scintillation counter. Carbon-13 (25.16 MHz) and ^{2}H (15.36 MHz) spectra were obtained with a Varian XL-100/15 Fourier transform nmr spectrometer at 29°C, using 0.4 mL of solution in a 5 mm tube. Broadband (^{1}H)-decoupling at 100 MHz was achieved by phase modulation of the decoupling field ($\gamma H_2/2\pi$ ca. 3500 Hz) from 0 to 180° at 150 Hz; for ^{2}H-decoupling at 15.36 MHz, $\gamma H_2/2\pi$ was ca. 310 Hz, with phase modulation at 40 Hz.

Other experimental conditions for observing ^{13}C were as follows: (*a*) **3** at natural abundance (NA) or enriched with [1-^{13}C]- or [2-^{13}C]acetate: sweep width (SW) 5120 Hz, acquisition time (AT) 1.6 s (16384 data points), flip angle (FA) 30°, time constant (TC) for weighting free induction decay −0.4 s, sample concentration 130 mg/mL in C^2HCl_3, internal ^{2}H lock, {^{1}H} decoupled; high resolution (HR) spectrum of NA material, TC −0.8 s, decoupler off during AT, on for a pulse delay (PD) of 1.6 s; (*b*) **3** enriched with [1,2-^{13}C]acetate: conditions as for (*a*) but FA 55°, PD 1.6 s; (*c*) **4** at NA or from [1-^{13}C]- or [2-^{13}C]acetate: as for (*a*) but AT 0.8 s (8192 data points), TC −0.8 s, 142 mg/mL; (*d*) **4** from [1,2-^{13}C]acetate: as for (*a*) but FA 41°, TC −0.8 s, 140 mg/mL; (*e*) elsinochrome D triacetate (**6**) at NA: as for (*a*) but FA 54°, 226 mg/mL; (*f*) **6** from [2-^{13}C, 2-^{2}H$_3$]acetate: SW 5120 Hz, AT 3.2 s (32768 data points), FA 25°, TC −1.6 s, 141 mg/mL in C^1HCl_3/C_6F_6 (4:1), internal ^{19}F lock, {^{1}H} and {^{1}H, ^{2}H} decoupled.

Conditions for observing the ^{2}H spectrum of **6** biosynthesized from [2-^{13}C, 2-^{2}H$_3$]acetate (solution from (*f*) above) were: SW 500 Hz, AT 2.0 s (2000 data points), FA 90°, TC −0.8 s, internal ^{19}F lock, {^{1}H} decoupled.

Isolation of Elsinochromes

Mycelium, separated by vacuum filtration, was leached with acetone until the reddish-orange pigments were completely extracted. The aqueous concentrate from removing the acetone *in vacuo* was diluted with water and extracted several times with ethyl acetate. The solid residue left after removing the solvent *in vacuo* was redissolved in a small volume of ethyl acetate and chromatographed on a silicic acid column. Elution with a 3:1 ethyl acetate – acetone mixture gave **3**, whereas **4** was eluted by acetone–methanol (9:1). Both pigments crystallized from 2:1 chloroform–hexane. Their physical properties were identical to those reported previously (5, 6) and were confirmed by direct comparison with specimens kindly provided by Dr. R. J. J. Ch. Lousberg, Organisch Chemisch Laboratorium, Rijksuniversiteit te Utrecht.

Elsinochrome D (**4**) (0.093 mmol), dissolved in a mixture of pyridine (1.0 mL) and acetic anhydride (1.2 mL), was kept for 8 h at room temperature. The acetyl derivative (**6**) was isolated in the usual manner. It was purified by thin-layer chromatography (tlc) on silica gel 60 T-254 (E. Merck, Darmstadt). The chromatogram was developed three times with an 8:1:1 mixture of chloroform–benzene–methanol and the orange zone containing **6** was extracted with chloroform. The chloroform solution, washed with a 1 m*M* aqueous solution of ethylenediamine tetraacetic acid to remove paramagnetic impurities, was taken to dryness and the residue crystallized from 2:1 chloroform–hexane to give **6** (0.086 mmol) as orange needles, mp 114–115°C; $[\alpha]_D^{24}$ −733° (*c* 0.023, acetone); λ_{max} (log ε) (95% ethanol): 223 (4.63), 247 (4.43), 266 (4.34), 291 (shoulder) (4.07), 347 (broad) (3.96), 359 (3.97), 442 (4.29); ms *m/e*: 672 (M^+), 630 (*M* − 42).

Results

Production of Elsinochromes and Incorporation of [1-^{14}C]Acetate

Yields of **3** and **4** as a function of incubation time showed the most rapid accumulation to be in the interval from 3 to 8 days after inoculation. This information, combined with the measurement of radioactivity incorporated from [1-^{14}C]acetate given in Table 1, established that cultures should be supplemented on the third day with potential precursors at 5 m*M* concentration.

Incorporation of Sodium [1-^{13}C]-, [2-^{13}C], and [2-^{13}C, 2-^{2}H$_3$]Acetate

Procedures used to calculate ^{13}C-enrichment have been discussed in detail elsewhere (11). The distribu-

TABLE 1. Incorporation of radioactivity from sodium [1-^{14}C]-acetate into elsinochromes C (**3**) and D (**4**)

Sodium [1-^{14}C]acetate added[a]		Specific incorporation (%)[b]	
(day)	(m*M*)	**3**	**4**
1	5	8.5	8.6
2	5	10.7	10.4
3	5	16.5	24.9
	2	5.0	10.7

[a]Cultures (1 L) were supplemented at the time of inoculation with [1-^{14}C]acetate (20 μCi) plus unlabelled carrier to a final concentration of 2 or 5 m*M*.
[b]Specific incorporation estimated as 100 times specific activity of pigment divided by specific activity of precursor.

tion of isotopic label derived from [1-^{13}C]- and [2-^{13}C]acetates was determined by comparing ^{13}C nmr spectra of the enriched and natural abundance metabolites recorded under identical conditions.

Positions enriched by sodium [1-^{13}C]acetate were, in **3**: C-13, C-15, 0.6%; C-2a, C-12a, 0.5%; C-4b, C-12c, 0.6%; C-7, C-8, 0.4%; C-5, C-10, 0.3%; C-4, C-11, 0.3%; error ± 0.15%; in **4**: C-13, 2.5%; C-15, 2.3%; C-2a, 1.8%; C-12a, 1.8%; C-4b, 1.9%; C.12c, 2.2%; C-7, 1.5%; C-8, 1.8%; C-5, 1.6%; C-10, 1.7%; C-4, 2.2%; C-11, 1.8%; error ± 0.3%. Sites enriched by sodium [2-^{13}C]acetate were, in **3**: C-14, C-16, 1.1%; C-1, C-2, 1.0%; C-4c, C-12b, 1.2%; C-7a, C-7b, 1.7%; C-6, C-9, 0.9%; C-4a, C-10a, 1.5%, C-3, C-12, 1.3%; error ± 0.3%; in **4**: C-14, 4.7%; C-16, 4.7%; C-1, 4.3%; C-2, 4.3%; C-4c, 1.7%; C-12b, 2.2%; C-7a, 2.2%; C-7b, 2.4%; C-6, 4.9%; C-9, 4.3%; C-4a, 4.2%; C-10a, 3.4%; C-3, 3.2%; C-12, 3.0%; error ±1.1%.

The overall average enrichments at sites labelled by [1,2-^{13}C]acetate were determined by quantitative analysis of the multiplet patterns arising from ^{13}C—^{13}C spin–spin coupling in ^{13}C nmr spectra of the enriched metabolites. Sodium [1,2-^{13}C]acetate is nominally 90% ^{13}C-enriched and therefore contains the following mixture of isotopic species: $^{13}CH_3{}^{13}CO_2Na$, 81%; $^{13}CH_3{}^{12}CO_2Na$, 9%; $^{12}CH_3{}^{13}CO_2Na$, 9%; $^{12}CH_3{}^{12}CO_2Na$, 1%. Incorporation of this precursor into **3** and **4** was detected by one-bond ^{13}C—^{13}C spin–spin coupling which results in the presence of pairs of equally spaced doublet signals (total intensity I_d) as satellites of singlet resonances (intensity I_c) arising from isolated ^{13}C nuclei. Pairs of bonded carbons incorporated as ^{13}C—^{13}C were identified by matching coupling constants (Table 2). Both C-3 and C-12 were ^{13}C-enriched in **4** but neither was present as part of a ^{13}C—^{13}C unit.

Additional components of quartets (total intensity I_m), due to spin–spin coupling with two adjacent carbons, were observed about the resonances for C-1, C-2, C-4a, C-5, C-6, C-9, C-10, C-10a, C-11, and C-13 of **4**. Overlap of signals prevented quartets accompanying other carbon signals from being detected. The presence of the quartets demonstrated that a proportion of **4** had been biosynthesized from a precursor pool containing a high concentration of doubly labelled acetate. Thus $I_m/(I_m + I_d)$ for C_B of C_A—C_B—C_C gives the ^{13}C-probability at C_C (11) before the highly enriched **4** was diluted with natural abundance material, where C_A—C_B is an intact ^{13}C—^{13}C unit and C_B is any one of the carbons exhibiting quartet components. The main signal for C-3 was accompanied by low-intensity doublet ^{13}C—^{13}C satellites arising from approximately equal coupling to C-2a and C-4; similar satellites were symmetrically located about the signal for C-12 due to coupling with C-11 and C-12a. Probabilities of ^{13}C at carbons adjacent to C-3 and C-12 were determined from $I_d/2(I_c - I_{NA} + I_d)$ where I_{NA} is the ^{13}C natural abundance contribution to I_c, and the 2 in the denominator takes into account the superposition of satellites arising from equal coupling of C-3 and C-12 to adjacent carbons. Similar measurements on **3** enriched by doubly labelled acetate were not possible because the signal/noise ratio in the ^{13}C nmr spectrum was inadequate. The average enrichment at sites in ^{13}C-labelled **3** and **4** after in vivo dilution with natural abundance material may be calculated as reported previously (11) from $\%^{13}C = 1.11(I_d + I_m)/[I_c - f(I_d + I_m)]$, where $f = 1/9$. Enrichment data are reported in Table 2.

Incorporation of Sodium [2-^{13}C, 2-$^{2}H_3$]Acetate

The culture conditions used to obtain ^{13}C-enriched elsinochromes were also used to obtain **4** enriched with label from sodium [2-^{13}C, 2-$^{2}H_3$]acetate. At a ^{2}H content of 95% the methyl group of the precursor would possess the following mixture of isotopic species: $^{13}C^{2}H_3$, 77.16%; $^{13}C^{2}H_2H$, 12.18%; $^{13}C^{2}HH_2$, 0.64%; $^{12}C^{2}H_3$, 8.57%; $^{12}C^{2}H_2H$, 1.35%; $^{12}C^{2}HH_2$, 0.02%. As the enriched material contained carbons bonded to both hydrogen and deuterium, simultaneous ^{1}H- and ^{2}H-broadband decoupling was used to remove ^{13}C—^{1}H and ^{13}C—^{2}H spin–spin couplings and thus obtain singlet resonances in the ^{13}C nmr spectrum. The spectrometer was field-frequency locked to ^{19}F in hexafluorobenzene. Since the latter substance considerably reduces the solubility of **4** in chloroform, the more soluble triacetate derivative **6** was used. The ^{13}C chemical shifts for unlabelled **6** in chloroform were not significantly different from those obtained with 4:1 chloroform–hexafluorobenzene, the solvent mixture used for ^{13}C nmr spectral analysis of enriched **6**.

[2-^{13}C, 2-$^{2}H_3$]Acetate labelled the same sites in **6** as were previously found to be enriched in **4** by

[a]Average enrichments calculated from $1.11(I_d + I_m)/[I_c - f(I_d + I_m)]$ (see text). Average value ± standard deviation was 2.7 ± 0.2 for **4** and 0.80 ± 0.2 for **3**. In **4**, C-3 (2.3% ^{13}C) and C-12 (2.5% ^{13}C) were enriched but were not parts of $^{13}C—^{13}C$ units; labelling at the corresponding sites in **3** was not estimated because the signal/noise ratio in the ^{13}C spectrum was low.
[b]Values determined from $I_m/(I_d + I_m)$ (see text). Average value ± standard deviation for **4** was 42 ± 4% ^{13}C. Values were not determined for **3** because the signal/noise ratio in the ^{13}C spectrum was low.
[c]Data accuracy ± 0.3 Hz but error in $^1J_{cc}$ reduced by interpolation to peak centres between data points.

sodium [2-^{13}C]acetate. ^{13}C-enrichments were once again determined by comparing the ^{13}C nmr spectra of the enriched and natural abundance samples (11). Signal enhancements were observed for C-14 (3.0%), C-16 (3.0%), C-1 (2.0%), C-2 (2.0%), C-12b (1.9%), C-7b (2.0%), C-7a (2.0%), C-9 (1.9%), C-6 (1.8%), C-10a (1.8%), C-4a (2.0%), C-12 (2.1%), and C-3 (2.0%) (error ca. ±0.2%). Also, both side-chain methyl groups in **6** gave rise to a set of four singlet resonances (Fig. 1), one due to CH_3 and the others originating from methyl carbons bonded to deuterium and chemically shifted by an amount proportional to the number of deuteriums (12) (−0.27 ($^{13}C^2HH_2$), −0.52 ($^{13}C^2H_2H$), and −0.73 ppm ($^{13}C^2H_3$)). The latter resonances appear as a broad hump on the baseline of the ^{13}C nmr spectrum when the ^2H-decoupling field is removed because they are split into multiplets by $^{13}C—^2H$ spin–spin coupling. Intensity measurements on a spectrum in which nuclear Overhauser effects were suppressed with the relaxation reagent $Cr(acac)_3$ (13) and gated decoupling (14, 15) indicated that the methyl signals had the following fractional composition: $^{13}CH_3$, 0.33; $^{13}C^2HH_2$, 0.16; $^{13}C^2H_2H$, 0.21; $^{13}C^2H_3$, 0.31 (all ±0.02). Thus the methyl groups of **6** retained 53% [100 × (0.31 + 2/3 × 0.21 + 1/3 × 0.16) ÷ (0.86 + 2/3 × 0.14 + 1/3 × 0.01)] of the deuterium at C-2 of the precursor. Four-fifths of the intensity of the $^{13}CH_3$ signal has a natural abundance origin, enrichment accounting for the remainder. The C-1, C-2, C-6, and C-9 methine groups contained no deuterium although also derived from the methyl group of acetate.

The ^1H-broadband-decoupled ^2H nmr spectrum confirmed that only the methyl groups contained deuterium. Deuteriums bonded to ^{13}C appeared as a broad doublet ($^1J_{C^2H} \approx 20$ Hz) due to $^{13}C—^2H$ coupling whereas those bonded to ^{12}C gave a broad singlet. The line widths are determined mainly by the viscosity of $CHCl_3$ which influences the correlation times for molecular motion (16) although chemical shift nonequivalence of resonances due to the different isotopic species probably contributes.

Discussion

Assignment of Carbon Resonances

Resonances were identified from concordant evidence provided by chemical-shift trends, by characteristic multiplicities and $^{13}C—H$ spin–spin couplings in the high-resolution ^{13}C nmr spectrum and by $^{13}C—^{13}C$ spin–spin coupling introduced when **3** and **4** were labelled with [1,2-^{13}C]acetate.

For symmetry reasons each of the fifteen resonances observed for **3** arises from an equivalent pair of carbons. The assignment of signals due to carbons bearing hydrogen was straightforward as their nmr parameters (Tables 3 and 4) were different and distinctive. Four resonances at lowest field clearly originated from two equivalent pairs of carbons bearing oxygen. Geminal coupling of C-5 (C-10) to H-6 (H-9) distinguished these carbons from C-4, C-11 which give singlet resonances. Carbons bearing methoxyls were observed as multiplets due to three-bond coupling with the methoxy hydrogens and two-bond coupling to H-6, H-9 (C-7, C-8) or three-bond coupling to H-1, H-2 (C-12, C-3). Shielding by

[a]The assignments for C-13 and C-15 in **4**, and for the pairs C-14, C-16; C-18, C-19; and C-3, C-12 in **4** and **6**, may be interchanged.

adjacent hydroxyl groups (17) also distinguished the C-3, C-12 from the C-7, C-8 resonance. Furthermore, matching coupled carbons (Table 2) in the ^{13}C nmr spectrum of **3** enriched with [1,2-^{13}C]acetate identified the following pairs: C-13, C-14, (C-15, C-16); C-1, C-12a (C-2, C-2a); C-7b, C-8 (C-7a, C-7); C-9, C-10 (C-6, C-5); C-10a, C-11 (C-4a, C-4). The resonances for C-12b (C-4c) and C-12c (C-4b) which form a coupled AB system can be distinguished because C-12b (C-4c) is coupled to H-1 (H-2) whereas C-12c (C-4b) is not coupled and gives a singlet resonance. Methoxyl signals could be assigned by comparing the spectra of **3** and **4**.

Separate resonances are observed for thirty carbons in the unsymmetrical **4** (Table 3). In the spectrum of **6** three pairs of signals overlap; these arise from C-13 and C-15 and the methyl and carbonyl carbons of the acetate groups at C-13 and C-15. Coupled pairs of carbons in **4** enriched with [1,2-^{13}C]-acetate were matched in the same way as for **3**, but some assignments were ambiguous because chemical shifts and $^1J_{cc}$ values for similar carbons (e.g. C-7a, C-7b; C-7, C-8) were not significantly different. As expected, conversion of **4** to **6** influenced the chemical shifts of C-7b through C-12c more than those of other aromatic ring carbons (Table 3). This chemical shift correlation, combined with the ^{13}C—^{13}C spin–spin coupling information, provides reasonable grounds for our assignments. The methylenedioxy carbon gave a characteristic triplet resonance in the high resolution spectrum and the three-bond coupling of C-4 to the methylenedioxy hydrogens distinguished it from its counterpart C-11.

Assembly Pattern of Acetate in 3 and 4

Data for **4** enriched from [1,2-^{13}C]acetate indicate that the polyketide chains were formed from a precursor pool highly enriched (≈30%; Table 2) with doubly ^{13}C-labelled acetate, and that an additional ten-fold dilution with natural-abundance material occurred at a later stage in the biosynthetic pathway to give a final average enrichment of 2–3% at individual sites. As the same feeding conditions were used for all precursors, isotopic dilution must follow the same pattern with singly labelled precursors. If dilution occurred after **4** was formed, ^{13}C—^{13}C spin–spin coupling should be observed between the three pairs of directly bonded carbons (C-1, C-2; C-12b, C-4c; C-7b, C-7a) joining the two halves of the molecule. This coupling should be more easily detected with the sample enriched from [2-^{13}C]acetate because the ^{13}C nmr spectrum would not be complicated by one-bond spin–spin interactions between other pairs of carbons. Since, for these carbon pairs, chemical shift differences are comparable with $^1J_{cc}$ (Table 3), any ^{13}C—^{13}C coupled carbon resonances present would form an AB quartet. The expected average ratio I_s/I_c of intensity I_s of each half of the quartet to the corresponding central resonance intensity I_c (after subtraction of the component due to natural-abundance material) would be ca. 0.4 ($=0.3 \times 0.3 \div 0.3 \times 0.7$) under conditions identical to those used

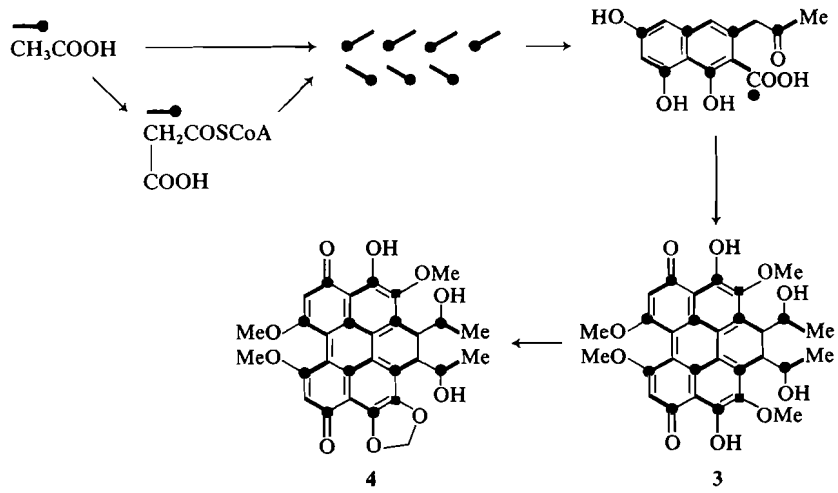

SCHEME 1. Plausible route for the biosynthesis of elsinochromes C and D.

for incorporation of the ^{13}C—^{13}C label. The inner components of such quartets are indeed visible for **4** labelled with [2-^{13}C]acetate, the outer components being masked by noise. Couplings of $^{1}J_{C\text{-}4c,C\text{-}12b} = 63 \pm 8$ Hz; $^{1}J_{C\text{-}7a,C\text{-}7b} = 61 \pm 9$ Hz were obtained from the spacings of the inner quartet components and $\Delta\nu$, but $^{1}J_{C\text{-}1,C\text{-}2}$ was not measurable. The average I_s/I_c was 0.6 ± 0.1, comparable with the expected value and confirming that no further dilution of label had occurred between the formation of the polyketide chains and the dimerization process. It is not possible to confirm this result for **3** labelled with [2-^{13}C]acetate since the pairs of nuclei which would be coupled are chemically equivalent.

Information on the fate of acetate hydrogens during elsinochrome biosynthesis was obtained from the ^{13}C and ^{2}H spectra of **6** enriched from [2-^{13}C, 2-$^{2}H_3$]acetate. Simultaneous ^{1}H- and ^{2}H-broadband decoupling ensured that carbons gave singlet resonances in the ^{13}C nmr spectrum. Carbons bearing deuterium were identified by the presence of one-bond deuterium isotope chemically-shifted ^{13}C signals which became multiplets if the ^{2}H-decoupling field was removed. Each methyl group of **6** gave a set of four signals arising from $^{13}CH_3$, $^{13}C^{2}HH_2$, $^{13}C^{2}H_2H$, and $^{13}C^{2}H_3$ and calculations show that approximately 47% of the original ^{2}H was exchanged for ^{1}H during biosynthesis. It is noteworthy that the C-1, C-2, C-6, and C-9 methine groups contained no deuterium although also derived from the methyl group of acetate. Acetyl coenzyme A – malonyl coenzyme A interconversion (23) can account for loss of deuterium at the acetyl groups but the complete removal of deuterium at other sites suggests facile exchange between the protons of water and the deuterium at activated methylene groups in malonyl coenzyme A (24, 25) or in the polyketide chain bound to the enzyme surface. The presence of deuterium at the methyl groups of **6** but not elsewhere was also confirmed by the ^{2}H spectrum, in which signals (intensity I_{13}) arising from deuteriums bonded to ^{13}C of the methyl groups were well separated by ^{13}C—^{2}H coupling from the corresponding signal (intensity I_{12}) of ^{2}H bonded to ^{12}C. The absence of additional signals clearly indicated that deuterium was not retained at other sites in the molecule. The ratio $I_{12}/(I_{12} + I_{13})$, determined from integrals and peak heights (with allowance for overlap of broadened peaks), is 0.19 + 0.01. Since the same ratio in the 90% ^{13}C-enriched precursor is 0.111, some of the ^{2}H lost from [^{13}C, ^{2}H] labelled acetate in forming malonate is not mixed with the medium but is sequestered by endogenous malonate to yield [^{12}C, ^{2}H] acetate. We observed similar behaviour in our study of fusarubin biosynthesis.[3]

Labelling patterns determined by ^{13}C nmr analysis of the metabolites following isotopic incorporation from [1,2-^{13}C]acetate suggest strongly that the carbocyclic rings and alkyl side chains were formed initially from 14 intact two-carbon units, two of which cleaved subsequently with the loss of a carbon to give C-3 and C-12. Singly enriched acetates labelled alternate carbons as expected (7) and showed that C-3 and C-12 originated from the methyl group of acetate. The distribution of two carbon units in **3** and **4** is incompatible with their biosynthesis via a single polyketide chain processed as in Fig. 1B and indicates that two chains, formed either *de novo* or by processing as in Fig. 1C, were involved. A decision between these alternatives can be based on the number of chain-initiating units detectable at C-13, C-14

and C-15, C-16 in **4**. That these two-carbon groups represent two "starter" acetate units is established by the significant proportion of trideuteromethyl groups from [2-^{13}C, 2-$^{2}H_3$]acetate incorporated intact at C-14 and C-16. Thus the biosynthesis of **3** and **4** involves two heptaketide chains formed via the acetate–polymalonate pathway (18). A plausible pathway is suggested in Scheme 1. The chains first cyclize to a substituted naphthalene, two molecules of which oxidatively couple (19), before or after decarboxylation, to give **3**. A subsequent reaction between the C-3 methoxy and C-4 hydroxy groups (20, 21) would convert **3** to **4**. As noted earlier (5), apart from the dimerization process, the biosyntheses of elsinochromes and fusarubin,[3] or more correctly 4a,10a-dihydrofusarubin (22), appear to have many features in common.

Acknowledgements

We thank Dr. R. J. J. Ch. Lousberg of the University of Utrecht, and Dr. U. Weiss of the National Institute of Health, Bethesda, MD for specimens of elsinochromes. Mrs. S. Kurobane and C. Mofford provided valuable technical help. The work was supported by a research grant (to L.C.V.) from the National Research Council of Canada.

The photochemical addition of *N*-haloamides to olefins: the influence of various factors on the competition between 1,2-addition and hydrogen abstraction[1-3]

JEAN LESSARD, MARTINE MONDON (IN PART), AND DANIEL TOUCHARD[4]

Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received May 22, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

JEAN LESSARD, MARTINE MONDON, and DANIEL TOUCHARD. Can. J. Chem. **59**, 431 (1981).

In the photodecomposition of *N*-haloamides (ZCONRX) in the presence of olefins, the 1,2-addition chain competes with the hydrogen abstraction chain(s) leading to the parent amide (the quantum yields for these processes are greater than unity). The following factors were shown to have an influence on this competition as measured by the yield of 1,2-addition and the yield of parent amide in methylene chloride solutions: (*i*) the *N*-halogen (higher yields of addition with X = Cl than with X = Br); (*ii*) the electronegativity of Z (increase of the yield of addition as the electronegativity of Z increases); (*iii*) the temperature (higher yields of addition at lower temperatures, and at −70°C, better yields of addition (>90%, R = H) for X = Br than for X = Cl); and (*iv*) the size of R (dramatic decrease of the yield of 1,2-addition in going from R = H to R = CH_3). Surprisingly, the presence of a scavenger for HX had no influence on the yield of 1,2-addition. Both the size and electronegativity of Z had an effect on the stereochemistry of 1,2-addition to cyclohexene. High yields of addition to a variety of olefins were obtained with *N*-chloroamides such as $ClCH_2CONHCl$, $C_2H_5OCONHCl$, $CF_3CONHCl$. Their addition to enol ethers at −70°C led to the synthesis of α-amido acetals or ketals (aldehydes or ketones) and to an α-amido glycoside in good yields.

JEAN LESSARD, MARTINE MONDON et DANIEL TOUCHARD. Can. J. Chem. **59**, 431 (1981).

Lors de la décomposition photochimique de *N*-haloamides (ZCONRX) en présence d'oléfines, l'addition-1,2 est en compétition avec l'abstraction d'hydrogène (ce sont des processus radicalaires en chaîne comme le montrent des rendements quantiques supérieurs à l'unité). On a démontré que les facteurs suivants exercent une influence sur cette compétiton en mesurant les rendements en addition-1,2 et en amide: (*i*) l'halogène X (rendements en addition plus élevés avec X = Cl qu'avec X = Br); (*ii*) l'électronégativité de Z (augmentation du rendement en addition avec l'électronégativité de Z); (*iii*) la température (rendements d'addition plus élevés à basse température et, à −70°C, les rendements en addition deviennent meilleurs (>90% pour R = H) avec les dérivés *N*-bromés qu'avec les dérivés *N*-chlorés); et (*iv*) la grosseur du substituant R (une diminution très marquée du rendement en addition en remplaçant l'hydrogène par un méthyle). Etonnamment, l'utilisation d'un capteur de HX n'a eu aucun effet sur le rendement en addition. La grosseur de même que l'électronégativité de Z influencent la stéréochimie de l'addition-1,2 au cyclohexène. On a obtenu d'excellents rendements d'addition à une grande variété d'oléfines avec les *N*-chloroamides suivants: $ClCH_2CONHCl$, $C_2H_5OCONHCl$, $CF_3CONHCl$. Leur addition aux ethers d'énol à −70°C à permis d'obtenir des α-amido acétals (aldéhydes ou cétones) et un α-amido glycoside en bons rendements.

Introduction

The photochemical decompositon of *N*-haloamides should lead to an amidyl radical and a halogen atom (reaction [1]).

[1] $ZCONR{-}X \xrightarrow{h\nu} ZCO\dot{N}R + X^{\cdot}$

In the presence of an olefin, three main radical chain processes can be operating and compete with each other: the 1,2-addition process and two halogenation processes. The 1,2-addition process should involve the nitrogen centered radical as the chain carrier (reactions [2] and [3]) and its addition

[2] $ZCO\dot{N}R + \rangle C{=}C\langle \rightarrow ZCONR{-}\overset{|}{C}{-}\overset{|}{C}{\cdot}$

[3] $ZCONR{-}\overset{|}{C}{-}\overset{|}{C}{\cdot} + ZCONR{-}X \rightarrow ZCONR{-}\overset{|}{C}{-}\overset{|}{C}{-}X + ZCO\dot{N}R$

to the carbon–carbon double bond (reaction [2]). The two halogenation processes should involve abstraction of hydrogen atoms (mainly allylic) from the olefin: (*i*) by the nitrogen centered radical (the Bloomfield (5) mechanism proposed for *N*-bromosuccinimide):

[4] $ZCO\dot{N}R + \rangle C{=}\overset{|}{C}{-}CH{-} \rightarrow \rangle C{=}\overset{|}{C}{-}\dot{C}\langle + ZCONHR$

[5] $\rangle C{=}\overset{|}{C}{-}\dot{C}\langle + ZCONR{-}X \rightarrow \rangle C{=}\overset{|}{C}{-}CX{-} + ZCO\dot{N}R$

and/or (*ii*) by the halogen atom (the Goldfinger (6) mechanism proposed for *N*-chloro and *N*-

bromosuccinimide):

[6] $X^{\cdot} + \rangle C{=}C{-}CH{-} \rightarrow \rangle C{=}C{-}\dot{C}\langle + HX$

[7] $ZCONRX + HX \rightarrow ZCONHR + X_2$

[8] $\rangle C{=}C{-}\dot{C}\langle + X_2 \rightarrow \rangle C{=}C{-}CX{-} + X^{\cdot}$

Both halogenation processes lead to the parent amide.

The purpose of our studies on the radical reactions of *N*-haloamides with olefins was to try to determine the relative importance of the above three radical chain processes and to determine the main factors which may affect the competition between them. This paper reports some of the results on the photochemical decomposition of ZCONRX (R = H: *N*-halo-*N*-hydroamides; R = alkyl: *N*-alkyl-*N*-haloamides) in the presence of olefins. We are going to examine the effect of X (X = Cl and Br), the influence of the electronegativity of Z, the effect of temperature, the effect of R (R = H and CH_3), and the effect of a scavenger for HX on the yield of 1,2-addition and the yield of the parent amide that is on the competition between the 1,2-addition process and the hydrogen abstraction processes (halogenation).[5] We will also try to evaluate the scope and limitations of the photochemical addition of *N*-haloamides to olefins for the synthesis of *N*-(2-haloalkyl)-amides (Scheme 1).

$$ZCONR{-}X + \rangle C{=}C\langle \xrightarrow{h\nu} ZCONR{-}C{-}C{-}X$$

SCHEME 1

Other methods of radical additon of *N*-haloamides to olefins (7, 8) are the thermal addition of *N*,*N*-dichlorourethane (9–11*a*, 11*c*), the photochemical addition of *N*-chlorourethane (11), and the chromous chloride promoted addition of *N*-halo-*N*-hydrocarboxamides and *N*-halo-*N*-hydrocarbamates (3, 12). Closely related are the photochemical addition to olefins of *N*-halo-succinimides (13, 14) and -glutarimides (13), of *N*,*N*-dichlorosulfonamides (15), of *N*-alkyl-*N*-chlorosulfonamides (16, 17), of *N*-chloro-*N*-methylcyanamide (17), and the spontaneous addition of *N*,*N*-dihalophosphoramides (18).

Results

Additions to Cyclohexene (Scheme 2)

To study the effect of various factors on the competition between the 1,2-addition process and

$$ZCONRX + \bigcirc \rightarrow \underset{X}{\overset{NRCOZ}{\bigcirc}} + ZCONHR$$

1 **2** *cis* **3** *trans*

SCHEME 2

the hydrogen abstraction processes, we have chosen cyclohexene as a representative olefin in order to give a fair chance to the hydrogen abstraction processes. Indeed, cyclohexene has allylic hydrogens which are quite reactive towards electrophilic radicals, more reactive per se than those of a terminal olefin (19, 20), and has an internal double bond which is normally less reactive than terminal ones in radical additions (20, 21). Furthermore, it was interesting to see if the various factors studied would have an effect on the stereochemistry of 1,2-addition.

The ultraviolet spectra of *N*-haloamides show a maximum in the 250–260 nm region with tailing up to about 260 nm (22). The photolyses were carried out in a Rayonnet reactor, under a nitrogen atmosphere, using Vycor glassware with the 254 nm lamps and Pyrex glassware with the 300 nm and 350 nm lamps. The results of Table 1 (entries 1 to 6) show that the more energetic the radiation, the shorter is the reaction time as expected. The wavelength has practically no effect on the relative yields of 1,2-adducts[6] and acetamide, and on the *cis*(**2**)/*trans*(**3**) ratio.

The photochemical addition of *N*-chloroacetamide (NCA, **1***b*) to cyclohexene was studied in three different solvents and in neat cyclohexene. In acetonitrile, the yield of 1,2-addition was comparable to that obtained in methylene chloride but the *cis*(**2***b*)/*trans*(**3***b*) ratio was much lower (compare entries 4 and 7 of Table 1). In methylene chloride, the *cis* isomer predominates (**2***b*/**3***b* = 2.7) whereas in acetonitrile, the *trans* isomer predominates (**2***b*/**3***b* = 0.65). This is due to the electrophilic chlorination of cyclohexene by the chlorine formed in the Goldfinger type hydrogen abstraction process (reaction [7]) and/or by NCA itself (Scheme 3); such ionic reactions should be favored in the more polar acetonitrile. Evidences for the occurrence of electrophilic chlorination in acetonitrile were provided (*i*) by the formation of the *trans* adduct **3***b* (Scheme 3, R^1 = H) in 18% and 19% yield respec-

[5]A detailed study of the influence of these factors on the halogenation products will be reported in a forthcoming paper.

[6]Many of the addition products to cyclohexene (12*a*) and to the other olefins (12, 23) have already been described. All new compounds had ir, ^{1}H nmr spectra, and elemental analysis, and/or a mass spectrum consistent with their structures. The ir and ^{1}H nmr spectra of the new adducts were similar to those of the known adducts (12, 23) except for the protons of R and Z.

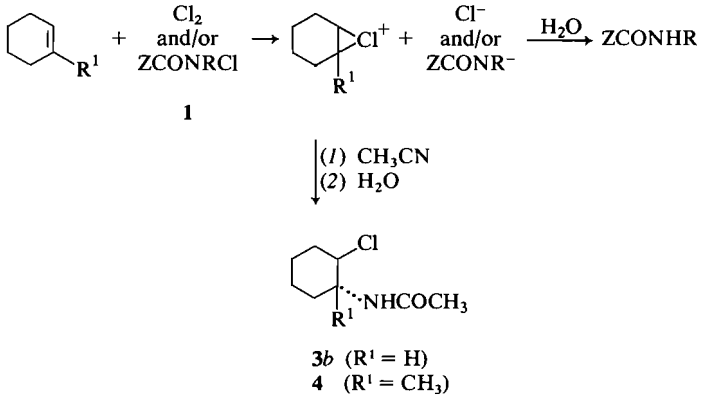
[a]Methylene chloride and acetonitrile were distilled over phosphorous pentoxide and benzene was distilled over sodium.
[b]The irradiations were carried out at 15–20°C and were stopped when the starch – iodide paper test was negative.
[c]The yields are based on the *N*-haloamide and represent yields of isolated pure products (preparative layer chromatography (plc)).
[d]Acetanilide was isolated in an 8% yield (material balance, 99%).



SCHEME 3

tively in the photolysis of *N*-chlorochloroacetamide (NCCA, **1***h*) and of *N*-chloro-*N*-methylacetamide (NCMA, **1***u*) in the presence of cyclohexene, and (*ii*) by the formation of the *trans* adduct **4** (Scheme 3, $R^1 = CH_3$) in 7 and 16% yield respectively in the photolysis of NCA and NCMA in the presence of 1-methylcyclohexene. In the ^1H nmr spectrum of **4**, the signal of the proton at δ 4.68 (dd, ΣJ = 14.5 Hz) was not altered by *N*-deuteriation. The NH signal at δ 5.85 is narrow (no vicinal proton) compared to the NH signal of adducts **11***b* and **12***b*[6] (see Table 8, entry 4 for their structures). The *trans* stereochemistry was assigned on the basis that, in the case of cyclohexene, *trans* **3***b* only was formed with NCMA (**1***u*) under the same reaction conditions (Scheme 3).

The photodecomposition of NCCA (**1***h*) in acetonitrile in the presence of cyclohexene gave, in addition to **3***b*, 72% of 1,2-adducts **2***h* and **3***h*[6] and 12% of chloroacetamide; NCMA (**1***u*) gave 68% of *N*-methylacetamide,[7] no 1,2-adduct being detected. With 1-methylcyclohexene, in addition to **4**, NCA (**1***b*) gave 54% of 1,2-adducts **18***b* and **19***b*[6] and 39% of acetamide; in the case of NCMA (**1***u*) no 1,2-adduct was formed and 76% of *N*-methylacetamide[7] was isolated. It is noteworthy that the *cis*/*trans* ratio is somewhat larger in acetonitrile (**2***h*/**3***h* = 5; **18***b*/**19***b* = 5) than in methylene chloride (**2***h*/**3***h* = 3.9, Table 2, entry 3; **18***b*/**19***b* = 4.8, Table 8, entry 4). In the dark, other conditions being the same as in Table 1, the reaction of NCA (**1***b*) with cyclohexene in acetonitrile took 35 days and gave about 14% of *trans* adduct **3***b*.

In benzene (Table 1, entry 8), the photochemical reaction of NCA with cyclohexene was slower and the yield of 1,2-addition lower than in methylene

[7]For the photolyses of NCMA (**1***u*) in acetonitrile, the 254 nm lamps were used. We found later (see Table 4) that, in methylene chloride, a better recovery of *N*-methylacetamide was obtained with the 300 nm lamps.

[a]Reaction conditions: 15–20°C, 254 nm lamps with ZCONHCl, 300 nm lamps with ZCONHBr, solutions 0.2 to 0.5 *M* in *N*-haloamide, 2 mol of olefin per mol of *N*-haloamide, CH_2Cl_2 as solvent.
[b]Yield of chromatographically (plc) pure products based on the *N*-haloamide.
[c]From Table 1, entry 4.
[d]The dark reaction took 45 days and no 1,2-adduct could be detected.
[e]By vapor phase chromatography (vpc). The two isomers were not separated by plc.
[f]From Table 1, entry 2.
[g]The dark reaction took 30 h and gave 30% of 1,2-adducts ($2q/3q = 0.5$).
[h]Only 70% of the material could be recovered from the silica gel plates. The fractions containing products other than **2***r*, **3***r*, and trifluoroacetamide were not investigated. The dark reaction took 2 days and led to 24% of *trans* adduct **3***r*. The *cis* adduct **2***r* could not be detected. Again the recovery of material from the plates was poor (65%) and the other products formed were not investigated.

chloride, the *cis*(**2***b*)/*trans*(**3***b*) ratio being about the same. The addition of NCA to benzene, leading to acetanilide (8%) after loss of hydrogen chloride, does compete with the addition to cyclohexene (42%). In neat cyclohexene, the reaction was still slower than in benzene, the yield of addition and the *cis*/*trans* ratio being practically the same (Table 1, entry 9).

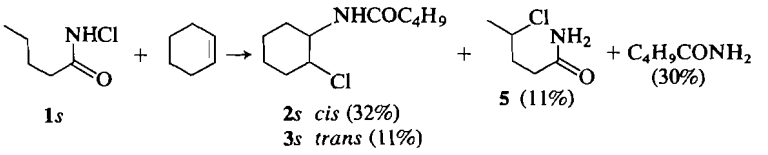
From the results of Table 1, we selected methylene chloride as solvent to carry out the study of various factors on the competition between 1,2-addition and hydrogen abstraction. The reaction conditions are specified in footnote *a* of the various tables. The material balance (1,2-adduct(s) plus parent amide) was generally very high: 92–100%. The dark reactions either did not occur at all or occurred to a very small extent during the time required for the photochemical reaction to be completed. In a few cases, the dark reaction was allowed to go to completion and the results were quite different from those of the photochemical reaction (see Table 2, footnotes *d*, *g*, and *h*).

In the absence of an olefin, methylene chloride does react with the radicals formed in the photodecomposition of *N*-haloamides. Indeed, NCMA (**1***u*) led to the formation of substantial amounts of chloroform (>95%) and traces of 1,1,2,2-tetrachloroethane according to vpc analysis. The recovery of *N*-methylacetamide was low (about 8%) and some *N*-methyl-*N*,*N*′-methylenebisacetamide ($CH_3CON(CH_3)CH_2NHCOCH_3$), resulting probably from the addition of *N*-methylacetamide to $CH_3CON{=}CH_2$, was isolated in low yield (~6%). Other products were formed but were not investigated. The structure of the methylenebisacetamide was determined from its ir, ^1H nmr, and mass spectra (see Experimental section).

Effect of the Halogen (X)

The results of Table 1 and Table 2 show that the yields of 1,2-addition[6] are higher with *N*-chloro-*N*-hydro amides than with the corresponding *N*-bromo derivatives. Thus, the nature of X has an influence on the competition between 1,2-addition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



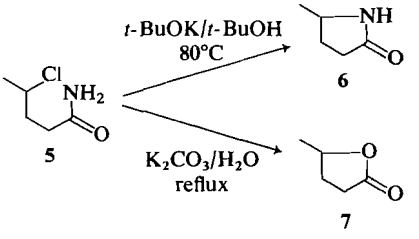
SCHEME 4

and hydrogen abstraction, the latter being less important when X = Cl than when X = Br. The *N*-halogen does have an influence also on the *cis*/*trans* ratio, the **2**/**3** ratio being larger for X = Cl than for X = Br as observed in the chromous chloride promoted addition of *N*-haloamides to cyclohexene (12*a*). Finally the reactions were faster in the case of the *N*-bromo derivatives.

Effect of Z

The results recorded in Table 2 show that, in the case of the *N*-chloro derivatives, the yield of 1,2-addition increases by changing Z in the order $(CH_3)_3C < CH_3CH_2 < CH_3 < ClCH_2CH_2 < H < BrCH_2 < ClCH_2 < FCH_2 < Cl_2CH < CCl_3 \sim CF_3$. A quantitative yield of addition was obtained for Z = CCl_3 and Z = CF_3 (entries 10 and 11). Steric effects are probably responsible for the lower yield of addition with Z = $(CH_3)_3C$ as compared to Z = CH_3CH_2 (entries 1 and 2). For the rest of the series, the increase of the yield of 1,2-addition parallels the acidity of the corresponding carboxylic acids (ZCOOH) (24) and the acidity of the *N*-chloro-*N*-hydro carboxamides themselves (25). Therefore, an increase of the electron-withdrawing power of the ZCO group favors 1,2-addition over hydrogen abstraction. *N*-Chlorourethane (NCU, **1***m*) (entry 2) led to a much better yield of addition than NCA (entry 3). Thus a carboalkoxy group appears to be more electron-attracting than an acetyl group, probably as a result of the inductive effect of the alkoxy group, although NCU is less acidic (pK_a = 8.02) than NCA (pK_a = 7.22) (25) due to the stabilization of the carboalkoxy group by resonance. Another interesting feature of Table 2 is the variation of the *cis*(**2**)/*trans*(**3**) ratio with Z. Both the size and electronegativity of Z appear to have an influence on this ratio. For instance it is much larger for Z = $(CH_3)_3C$ than for Z = CH_3CH_2 (entries 1 and 2): size effect. It increases in the order Z = $BrCH_2 < ClCH_2 < FCH_2$ (entries 6, 7, and 8) and it is larger for Z = C_2H_5O than for Z = CH_3CH_2 (entries 12 and 2): electronegativity effect. It is somewhat larger for Z = CCl_3 than for Z = CF_3, the size effect being probably more important than the electronegativity effect.

An interesting case is that of *N*-chloropentanamide (**1***s*) where the alkyl chain is long enough for intramolecular halogenation[8] to compete with the 1,2-addition process. These two processes involve the amidyl radical as the chain carrier and it is noteworthy that the intermolecular process is about 4 times faster than the intramolecular one as shown by the yields of 1,2-adducts **2***s* and **3***s* and of 4-chloropentanamide (**5**) (Scheme 4). The 4-chloro derivative **5** could not be separated from pentanamide by plc. Its yield was determined by microanalytical determination of chlorine. The mixture of **5** and pentanamide was treated with potassium tertiobutoxide in tertiobutanol at 80°C under nitrogen to afford pentanamide (22%) and 5-methyl-2-pyrrolidinone (**6**) (9%) (Scheme 5). Alkaline hydrolysis of a mixture of pentanamide and **5** obtained by photolysis of *N*-chloropentanamide (**1***s*) in the absence of olefin afforded pentanoic acid (15%) and γ-valerolactone (**8**) (59%) (Scheme 5).



SCHEME 5

The yield of addition of the *N*-bromo-*N*-hydrocarboxamides to cyclohexene and the *cis*(**2**)/*trans*(**3**) ratio also increase with Z in the order: $CH_3 < ClCH_2 \simeq FCH_2 < Cl_2CH < CCl_3$ (Table 2, entries 13 to 17). However, the behavior of *N*-bromotrifluoroacetamide (**1***r*) was quite unexpected (entry 18). Not only the yield of 1,2-addition and the *cis*/*trans* ratio were much lower than in the case of *N*-bromotrichloroacetamide (**1***q*) (entry 17),[9] but the material balance was very poor in contrast

[8]The photolysis of *N*-chlorohexanamide in methylene chloride at ca. 20°C was reported to give, after alcaline hydrolysis of the crude product, 49% of γ-lactone arising from 4-chlorohexanamide (26).

[9]*N*-Bromotrichloroacetamide (**1***q*) and *N*-bromotrifluoroacetamide (**1***r*) were reported to undergo thermal addition (not in the dark) to neat cyclohexene (reaction exothermic enough to bring cyclohexene to a boil) (27). The yield of addition and the *cis*/*trans* ratio were also lower in the case of **1***r* (38%, **2***r*/**3***r* = 0) than in the case of **1***q* (60%, **2***q*/**3***q* = 2).

to the addition of all the other *N*-haloamides of Table 2.[10] Processes other than 1,2-addition and halogenation must be involved but they were not investigated.

Finally, the rate of the photochemical decomposition of the *N*-halo-*N*-hydrocarboxamides in the presence of cyclohexene, as measured roughly by the reaction time, increases as the electronegativity of Z increases.

Effect of Temperature

As shown in Table 3, we have found that lowering the temperature favors the 1,2-addition of *N*-halo-*N*-hydrocarboxamides (**1**, R = H) over the hydrogen abstraction processes. The effect is less important in the case of NCA (**1***b*) (entries 9 and 10) than in the case of *N*-bromoacetamide (NBA, **1***a*) (entries 1 to 5) and *N*-bromochloroacetamide (**1***n*) (entries 6 and 7).[11] Thus very high yields of addition can be obtained with simple *N*-bromo-*N*-hydrocarboxamides. The 91% yield of addition with NBA is particularly worth noting since the photolysis in refluxing carbon tetrachloride was reported to give, as the primary product, *trans*-2-bromocyclohexyl-*N*-bromoacetamidate resulting from the ionic addition of *N*,*N*-dibromoacetamide and only 1% of *trans* 1,2-adduct **3***a* (28). The temperature has little influence on the *cis*(**2**)/*trans*(**3**) ratio. The smaller ratio observed at −70°C can probably be attributed to the presence of a significant amount of methanol (more than 2%) as in pure methanol, this ratio is much smaller (compare entries 7 and 8). All the irradiations of Table 3 were carried out with solutions 0.06 *M* in *N*-halocarboxamide which represents approximately a nine-fold dilution with respect to the conditions given in Table 2. Such a dilution had no effect on the relative importance of the competing radical chain processes: compare entries 1, 6, and 9 of Table 3 with entries 10, 11, and 1 respectively of Table 2. At low temperatures, methanol was added in order to ensure complete dissolution of the *N*-halocarboxamide. This led to the formation of *trans* 3-halomethoxycyclohexane through electrophilic halogenation of cyclohexene. In pure methanol as much as 27% of this product was formed (entry 8).

Effect of R

A comparison of the results of Table 4, entries 1 to 7, with those of Table 2, entries 13, 3, 7, and 11, shows that the replacement of the *N*-hydrogen by an *N*-methyl group has a drastic effect on the competition between 1,2-addition and hydrogen abstraction. The former is suppressed in the case of the *N*-methyl derivatives **1***t* and **1***u* even at −70°C (entries 1 to 5); it is suppressed also in the case of the *N*-methyl derivative **1***v* (entry 6). While the yield of addition of *N*-chlorotrifluoroacetamide (**1***l*) to cyclohexene was quantitative (Table 2, entry 11), the yield of addition of the corresponding *N*-methyl derivative **1***w* was 20% only (Table 4, entry 7). The fact that *N*-chloro-*N*-methyltrifluoroacetamide (**1***w*) does add to cyclohexene shows again that an electron attracting Z group favors

[10]The chromous chloride promoted addition of *N*-bromotrifluoroacetamide (**1***r*) to cyclohexene under the standard reaction conditions (12*a*) gave much better results than the photochemical reaction yielding 80% of 1,2-adduct **2***r* and **3***r* (**2***r*/**3***r* = 1.2) and 20% of trifluoroacetamide.

[11]A similar temperature effect has been reported recently for the photochemical reaction of *N*-bromosuccinimide with cyclohexene in acetonitrile and in the presence of ethylene oxide (14).

the 1,2-addition process. The ^1H nmr spectrum of *N*-(2-chlorocyclohexyl)-*N*-methyltrifluoroacetamide (**2***w* and/or **3***w*) shows a complex absorption at δ 3.7–4.3 for protons H_1 and H_2 and two 1:3:3:1 quartets for the *N*-methyl group, one at δ 3.03 ($^5J_{H,F}$ = 1.5 Hz) and the other at δ 2.93 ($^5J_{H,F} < 1$ Hz, not completely resolved). These two quartets arise from two different orientations around the CO—N bond, the CH_3 and CF_3 being *syn* in one and *anti* in the other (29).

Effect of a Scavenger for HX

We have seen in the Introduction that one of the competing mechanisms in the photochemical decomposition of *N*-haloamides in the presence of olefins could be hydrogen abstraction via the halogen atom–HX–X_2 chain (the Goldfinger mechanism). The formation of substantial amounts of dichlorocyclohexane[5] in the photolysis of NCA (**1***b*) and of NCMA (**1***u*) in the presence of cyclohexene indicates that this mechanism is probably operating and also that the olefin acts as a scavenger for chlorine. With the aim of suppressing completely the chlorine atom–HCl–Cl_2 chain and hoping to increase the yield of 1,2-addition, we studied the effect of 2,4,6-trimethylpyridine (TMP) and cyclohexene oxide as HCl scavengers on the photodecomposition of NCA and NCMA in the presence of cyclohexene. TMP was used successfully by Johnson and Greene (22) to repress the chlorine atom–HCl–Cl_2 chain in the light-initiated chlorination of alcanes with *N*-chloroamides. Epoxides have been used to scavenge HBr in the bromination of ketones (30) and alkyl benzenes (31), and in the photochemical decomposition of *N*-bromosuccinimide in the presence of olefins (14). The results of Table 5 show that, contrary to our expectation, the presence of a scavenger for HCl did not favor the 1,2-addition process over hydrogen abstraction. No addition of NCMA was observed in the presence or in the absence of a scavenger (entries 4 to 7). The yields of 1,2-addition of NCA were even lower in the presence of a scavenger. NCA and NCMA as well as the 1,2-adducts **2***b* and **3***b*, dichlorocyclohexane, 3-chlorocyclohexene, and 4-chlorocyclohexene were stable toward TMP and cyclohexene oxide under the reaction conditions. The photodecomposition was slowed down by the addition of TMP and cyclohexene oxide. The most striking result of Table 5 is the large amount of HCl scavenged (see entries 5, 6, and 7). The yield of *trans* chlorocyclohexanol (entry 7) shows that cyclohexene oxide was effective in scavenging HCl.

Additions to 1-Dodecene

The reaction is depicted in Scheme 6. The structure of the 1,2-adducts **8** shows that the amido

8 **9**

SCHEME 7

group attached itself to the terminal carbon of the olefin. The spectral characteristics of adducts **8** where R = H are very similar to those of the 1,2-adducts to 1-octene (12*a*). Treatment of 1,2-adduct **8***w* by potassium carbonate in aqueous methanol gave the *N*-methyloxazolidone **9** (Scheme 7).

The results of Table 6 confirm the trends observed with cyclohexene: the yields of addition are higher with the *N*-chloroamides than with the corresponding *N*-bromo derivatives (compare entries 1 and 2 with entries 2 and 4); the 1,2-addition is favored by increasing the electron-attracting power of Z (entries 1 and 2, 3 and 4); lowering the temperature favors the 1,2-addition process (entries 6 and 7); the replacement of an *N*-hydrogen by an *N*-methyl group diminishes drastically the amount of 1,2-addition (entries 3 and 6); and, finally, the presence of a scavenger for HX (TMP) does not promote the 1,2-addition process (compare entries 8 and 9).

It is noteworthy that the yields of addition of *N*-chloro-*N*-methylchloroacetamide (**1***v*) and *N*-chloro-*N*-methyltrifluoroacetamide (**1***w*) to 1-dodecene (17 and 70% respectively, entries 6 and 10) are significantly higher than those obtained with cyclohexene (0 and 18% respectively, see entries 5 and 6 of Table 4). On the other hand, in the case of the *N*-halo-*N*-hydrocarboxamides, the yields of 1,2-addition are comparable with both olefins (e.g. compare entries 1 and 2 of Table 6 with entries 14 and 17 of Table 2).

Additions to Norbornene

Norbornene is an interesting olefin since it has a reactive double bond and no readily abstractable hydrogens. The reaction is depicted in Scheme 8

and the results are recorded in Table 7. The amido group in the 1,2-adducts **10** and **11** has the *exo* orientation. A number of features of Table 7 parallel those observed with cyclohexene: both the yield of 1,2-addition and the *cis*(**10**)/*trans*(**11**) ratio are higher when X = Cl than when X = Br (entries 1 and 3) and increase with the electronegativity and/or the size of Z (entries 2 to 4).[12] The 42% yield of addition of NCMA (**1***u*) (entry 5) is noteworthy since no addition was observed with cyclohexene (Table 4, entry 3) or 1-dodecene (Table 6, entry 5). For the *N*-halo-*N*-hydrocarboxamides (entries 1, 2, and 3), the yield of 1,2-addition is similar to that obtained with cyclohexene (Table 2) and 1-dodecene (Table 6). Entries 5 to 8 show that the size of the *N*-alkyl group has a marked effect on the

[12]A similar increase of the *cis*/*trans* ratio with Z was observed also in the chromous chloride promoted addition of *N*-halo-*N*-hydro amides to norbornene (12*a*).

[a]Unless stated otherwise, the reactions were carried out at 15–20°C in methylene chloride solutions 0.5 *M* in *N*-haloamide, with an excess of olefin (2 mo per mol of *N*-haloamide) using the 254 nm lamps with *N*-chloro derivatives and the 300 nm lamps with *N*-bromo derivatives. In the case of the enol ethers (entries 8 to 11) the reaction temperature was −70°C and the solutions were 0.06 *M* in *N*-haloamide.
[b]Yields of isolated (plc) products based on the *N*-haloamides unless otherwise indicated.
[c]After 80 h of irradiation, 95% of unreacted NCA (1*b*) was still present. Reduction of the reaction mixture by sodium bisulfite allowed the recovery of 96% of acetamide.
[d]By vpc.
[e]The photolysis was followed by the addition, at −70°C, of 1 equiv. of sodium ethoxide in dry ethanol.
[f]Not determined.
[g]Photolysis followed by the addition of water.
[h]α-Chlorocyclohexanone was formed in a 9% yield according to vpc analysis.
[i]Besides the parent amide, α-bromocyclohexanone was the sole product identified (57% by vpc).
[j]The 350 nm lamps were used.

1,2-addition process: 42% of addition for R = CH_3 compare to 10% for R = C_2H_5 then 0% for R = *i*-C_3H_7 and R = *t*-C_4H_9.

Additions to Various Mono-olefins

We chose mainly NCCA (1*h*), *N*-chlorotrifluoroacetamide (1*l*), and NCU (1*m*) to evaluate the scope and limitations of the method for the synthesis of *N*-(2-haloalkyl)amides since they gave a high yield of addition with the three olefins studied so far. The results are shown in Table 8. Styrene inhibited completely the photodecomposition of NCA (1*b*) (entry 1). The yield of addition of *N*-chlorotrifluoroacetamide (1*l*) to the isomeric 3-hexenes (entries 2 and 3) was somewhat lower than that obtained with cyclohexene (Table 2, entry 7). The

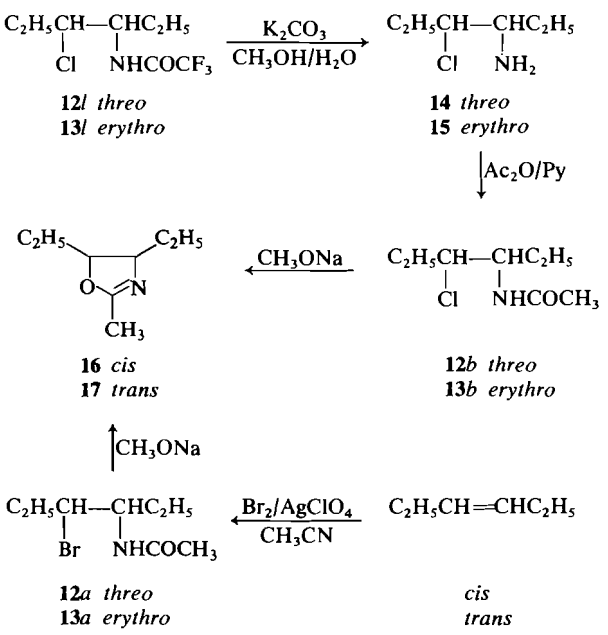


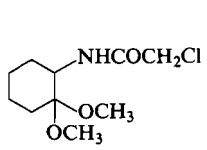
SCHEME 9

same *threo*(**12***l*)/*erythro*(**13***l*) ratio was obtained irrespective of the configuration of the olefin, thus showing that equilibration of the intermediate radical adduct, through inversion at the radical center and/or rotation around the central carbon–carbon bond, was much faster than its reaction with a molecule of *N*-chloroamide (chlorine-atom transfer, reaction [3]). The structure of **12***l* and **13***l* was proven by their conversion to the oxazolines **16** and **17** respectively as shown in Scheme 9. Authentic samples of **16** and **17** were obtained by the bromoacetamidation (32) of *cis*-3-hexene and *trans*-3-hexene respectively followed by treatment of the resulting β-bromoamide with sodium methoxide (Scheme 9).

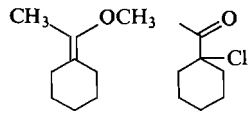
For the additions to 1-methylcyclohexene (Table 8, entries 4 to 6), the yields were comparable to those obtained with cyclohexene but the *cis*(**18**)/*trans*(**19**) ratios were higher as observed in the chromous chloride promoted additions (12*a*). As with cyclohexene, both the yield of addition and the *cis*/*trans* ratio are higher for X = Cl than for X = Br and increase with the electronegativity of Z. No adduct could be detected with a tetrasubstituted olefin (entry 7) in contrast to the chromous chloride promoted additions (12*a*).

The addition of *N*-chlorotrifluoroacetamide (**1***l*) and NCU (**1***m*) to pregnenolone acetate (**20**) (equimolar quantities of *N*-chloroamide and olefin) is depicted in Scheme 10. The addition was regiospecific, the amido group being attached to the less substituted carbon atom (C-6) of the olefin. The transfer of chlorine onto the intermediate radical at C-5 was stereospecific giving the more stable *trans* A/B ring fusion. The predominant formation of the *trans* adduct with the amido group at C-6 β and axial shows the strong preference for the axial attack of the 5,6-double bond by an amidyl radical. The yields of addition were quite good (those between brackets take into account the recovery of pregnenolone acetate)[13] and the *cis*(**21**)/*trans*(**22**) ratio appears to vary with Z. The ^{1}H nmr spectra of **21***l* and **22***l* were similar to those of **21***m* and **22***m* whose structure has been unambiguously determined (12*a*). In particular, they show clearly that the proton at position 3 is axial in both isomers (*trans* A/B ring fusion) and that the proton at position 6 is axial in **21***l* and equatorial in **22***m* (see Experimental section).

The radical addition of *N*-haloamides to enol ethers followed by solvolysis of the intermediate α-haloether (1,2-adduct) should provide a way to synthesize α-amido acetals or ketals (aldehydes or ketones). *N*-Bromoamides cannot be used for that purpose since electrophilic bromination was much faster than light-initiated addition even at −70°C (Table 8, entry 11). With *N*-chloroamides however, electrophilic chlorination was usually negligible at −70°C and excellent yields of α-amido acetals **23** and α-amidocyclohexanone **24***h* were obtained from ethoxyethylene and 1-methoxycyclohexene respectively (Table 8, entries 8 to 10). When the photochemical addition of NCCA (**1***h*) to 1-methoxycyclohexene was followed by methanolysis of the intermediate α-chloroether, the α-amido ketal **25***h* was isolated in a 78% yield. Its hydrolysis to α-chloroacetamidocyclohexanone (**24***h*) was quantitative.



25*h*



26 **27**

Neither NCCA (**1***h*) nor NCU (**1***m*) could be added to (1-methoxyethylidene)cyclohexane (**26**), a fully substituted enol ether, the parent amide being isolated in 95 and 93% yield respectively after treatment of the photolysate with water.[14] Beside

[13]The photochemical addition of NCU to cholesteryl acetate and to androst-5-en-3β-ol-17-one was reported to give only the corresponding *trans* 1,2-adduct in 34% and 9% yield respectively (33). The chromous chloride promoted addition of NCU in excess to pregnenolone acetate led to 21% of **21***m* and 79% of **22***m* (12*a*).

[14]In contrast, the chromous chloride promoted addition of NCU to **23** gave 62% of the expected α-amido ketone, 1-acetyl-1-ethoxycarbonylaminocyclohexane (23).

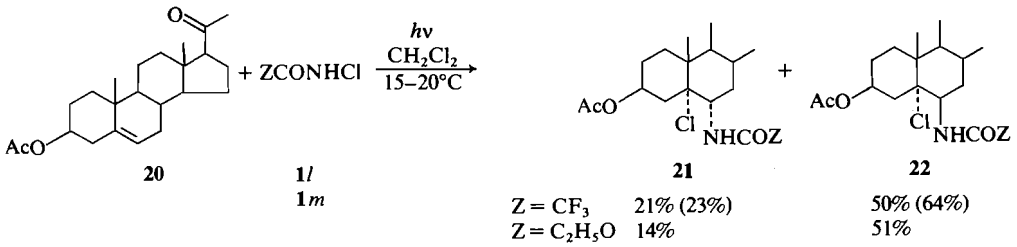
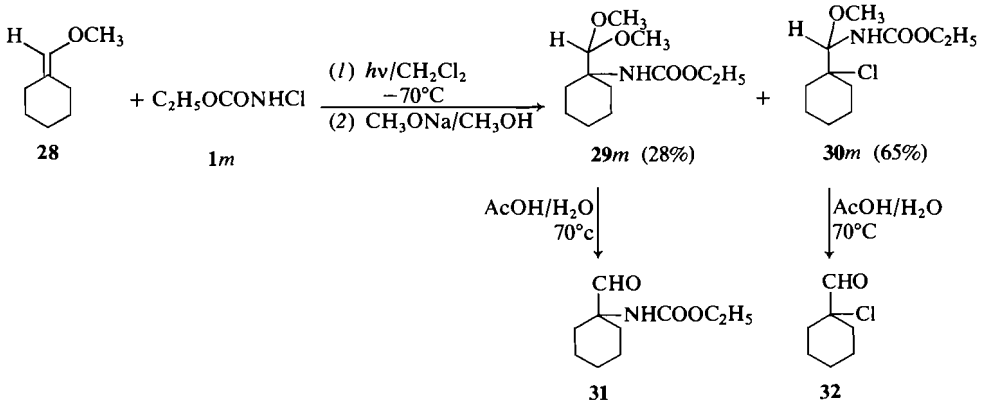
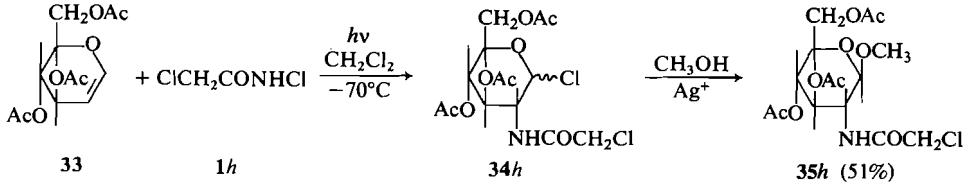


SCHEME 10



SCHEME 11



SCHEME 12

the parent amide some 1-acetyl-1-chlorocyclohexene (**27**), resulting from electrophilic chlorination of **26** was formed according to vpc analysis (~10–20%). The addition of NCU (**1***m*) to methoxymethylenecyclohexane (**28**) gave 28% only of α-amido acetal **29***m* but 65% of 1,2-adduct **30***m* resulting from the attack of the amidyl radical on the less substituted carbon atom of enol ether **29***m* (Scheme 11). The α-amido acetal **29***m* and the 1,2-adduct **30***m* were treated with 70% aqueous acetic acid at 70°C for 2 h to afford respectively the α-amido aldehyde **31** (88%, fully characterized as its 2,4-DNP derivative) and the known (34) α-chloro aldehyde **32** (70%) (Scheme 11).

We applied the reaction to triacetyl-D-glucal (**33**) and NCCA (**1***h*) using a slight excess of glucal (1.1 mol per mol of **1***h*). The reaction is described in Scheme 12. The 1,2-adduct **34***h* was not isolated. The crude product was treated with methanol under Koenigs–Knorr conditions to afford the α-amido β-D-glucoside **35***h* (23) in 51% yield (88% by taking into account the amount of unreacted **33** recovered). Thus the amidyl radical preferentially adds on the α face of triacetyl-D-glucal (**33**) as found in the chromous chloride promoted additions (23) and in contrast to the preferential addition of the thioacetyl radical on the β face (35).

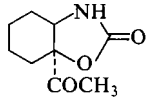
The radical addition of *N*-chloroamides to ketene acetals should lead to α-amido esters (hence to α-amino acids) after hydrolysis of the 1,2-adducts. Unfortunately, with such electron-rich olefins (e.g. ketene diethyl acetal), electrophilic chlorination was very fast even at −70°C.

The addition of NCCA (**1***h*) to the electron-poor olefin 1-chlorocyclohexene (Table 8, entry 12) was less efficient than its addition to cyclohexene as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

expected. However, the addition of NCCA and NCU (**1***m*) to 1-acetylcyclohexene, which is also an electron-poor but a conjugated olefin, was quite efficient (~70%; Table 8, entries 13 and 14). The *trans* adduct **38***m*, upon heating at 185°C under nitrogen, was converted to the oxazolidone **40**.



40

Under the same conditions, the *cis* isomer **37***m* was recovered unchanged. We have no satisfactory explanation for the fact that adduct **39***m* where X = H was the major product in the case of NCU whereas no such product was isolated in the case of NCCA. Finally, NCCA did not add to 1-octyne (Table 8, entry 15).

Additions to Dienes

The photodecomposition of NCCA (**1***h*) was inhibited by 1,3-cyclohexadiene. Indeed, after irradiating for 45 h, 94% of *N*-chloro derivative **1***h* was still present according to iodometric titration. Treatment with sodium bisulfite led to the recovery of 95% of chloroacetamide.

As depicted in Scheme 13, the addition of NCA (**1***b*) to norbornadiene led to a 66% yield of three isomeric 3,5-disubstituted nortricyclenes **42***b*, **43***b*, and **44***b* and to a small amount (7%) of 1,2-adduct **41***b*. The stereochemistry of the nortricyclene adducts has not been determined. They have already been described (12*b*). Hydrogenation of 1,2-adduct **41***b* over Adam's catalyst in ethyl acetate afforded the corresponding norbornane derivative **45***b* (Scheme 13) which was different from either of the 1,2-adducts **10***b* and **11***b* obtained from the photochemical addition of NCA (**1***b*) to norbornene (see Scheme 8). Therefore, the chloroacetamido group of **45***b* must be *endo*. The orientation of the chlorine substituent was not determined.

We have already reported that the photochemical addition of *N*-halo-*N*-hydro amides to 1,6-heptadiene gives rearranged 1,7-adducts as well as unrearranged 1,2-adducts (1). In contrast, the addition of NCCA (**1***h*) to 1,5-cyclooctadiene gave 50% of 1,2-adduct **46***h* and 44% of chloroacetamide (Scheme 14). No bicyclic compound resulting from transannular cyclization of the primary radical adduct was detected. Such bicyclic derivatives have been obtained in radical additions to 1,5-cyclooctadiene (36). The ^{1}H nmr spectrum of **46***h* shows a multiplet centered at δ 5.84 for the two olefinic protons and a complex absorption centered at δ 4.45 for the protons on the carbons bearing the substituents. The stereochemistry of adduct **46***h* was not determined.

Discussion

The following observations indicate that the photochemical 1,2-addition of *N*-haloamides to olefins involves the attack of the π-bond by an amidyl radical (reaction [2]) followed by halogen-atom transfer onto the resulting adduct radical (reaction [3]): (*i*) the failure of the dark reactions; (*ii*) the orientation of the addition to unsymmetrical olefins (the amido group is attached to the less substituted carbon atom) and to norbornene (the amido group is *exo* (37)); (*iii*) the formation of rearranged adducts in the additions to norbornadiene and to 1,6-heptadiene (1); (*iv*) the inhibition of the 1,2-addition process by oxygen (see below); (*v*) quantum yields greater than unity for the formation of the addition products (see Table 9).

We have seen that, under a nitrogen atmosphere, the photoaddition of *N*-bromochloroacetamide (**1***n*) to cyclohexene in methanol – methylene chloride (1:25) at −70°C was complete after 12 h and gave 95% of 1,2-adducts **2***n* and **3***n* (**2***n*/**3***n* = 1.1) (Table 3, entry 7). Under the same conditions but bubbling oxygen instead of nitrogen through the solution, there was still 18% of unreacted *N*-bromoamide after 63 h and the yield of 1,2-addition was low (20%, **2***n*/**3***n* = 1.0). The main reaction products were 2-bromomethoxycyclohexane (48%) resulting from electrophilic bromination of cyclohexene and chloroacetamide (57%). Thus, the 1,2-addition process is inhibited by oxygen.

Quantum yields greater than unity are indicative of chain processes. From the values of the quantum yields for the formation of 1,2 adducts, Φ(addn), given in Table 9, entries 1 and 2, the 1,2-addition process involves a chain mechanism. The chain appears to be longer with a *N*-bromoamide than with its *N*-chloro analogue because bromine-atom transfers are faster than chlorine-atom transfers. We have indeed shown, using 1,6-heptadiene as the olefin, that the transfer step [3] of the 1,2-addition process is faster with an *N*-bromoamide than with its *N*-chloro analogue (1). The relatively low quantum yields could result from short chains[15] and/or from low efficiency of the primary processes.

TABLE 9. Quantum yields for the photolysis of *N*-haloamides in the presence of cyclohexene

Entry	*N*-Haloamide	Quantum yields[a] Φ(N—X)[b]	Φ(addn)[c]
1	$ClCH_2CONHCl$ (**1***h*)	2.4	2.4
2	$ClCH_2CONHBr$ (**1***n*)	16	10
3	$CH_3CON(CH_3)Cl$ (**1***u*)	6.2	[d]
4	$CH_3CON(CH_3)Br$ (**1***t*)	61	[d]

[a]Based on potassium ferioxalate actinometry, see ref. 38.
[b]Quantum yield for the disappearance of *N*-haloamide (iodometric titration).
[c]Quantum yield for the formation of 1,2-adducts 2 and 3 (isolated).
[d]No addition product was detected.

The quantum yields for the disappearance of *N*-haloamide, Φ(N—X), given in entries 3 and 4 (Table 9) where the addition process could not be detected, are larger than the Φ(addn) values of entries 1 and 2, thus showing that the hydrogen abstraction chain(s) is(are) longer than the 1,2-addition chain. This is shown also by the fact that in entry 3 where the yield of 1,2-addition was of the order of 60%, Φ(N—X) is larger than Φ(addn). In entry 1, the yield of 1,2-addition was greater than 90% and Φ(N—X) has the same value as Φ(addn).

Interestingly, while Φ(N—X) in entry 3 is about 2.6 times larger than Φ(addn) of entry 1 (*N*-chloro derivatives), Φ(N—X) in entry 4 is about 6 times larger than Φ(addn) in entry 2 (*N*-bromo derivatives). Therefore, in the case of *N*-bromoamides, hydrogen abstraction appears to compete more effectively with 1,2-addition than in the case of *N*-chloroamides. This would then explain why the yields of 1,2-addition of *N*-bromoamides are lower than those of the corresponding *N*-chloro derivatives (*Effect of X*). It also might indicate that the main hydrogen abstraction species is not the same whether the *N*-haloamide is an *N*-bromo or an *N*-chloro derivative as would be the case if hydrogen abstraction occurs mainly through the Goldfinger type mechanism (reactions [6] to [8]) when X = Br as well as when X = Cl.[16]

An increase of the electron-withdrawing power of the acyl group (ZCO) should increase the reactivity of the amidyl radical towards the π-bond of an olefin (reaction [2]) by rendering the radical more electrophilic.[17] Furthermore, we have shown that the reactivity of ZCONHX as an halogen-atom transfer agent towards a carbon radical (reaction [3]) increases with the electron-withdrawing power of ZCO (1). Therefore, both the rate of step [2] and that of step [3] of the 1,2-addition chain increase as the ZCO moiety becomes more electronegative and, then, the 1,2-addition process can compete more effectively with hydrogen abstraction. Ex-

[15]We did not isolate any product resulting from the coupling of two amidyls or the coupling of two intermediate adduct-radicals and other reactions are probably involved as chain-termination steps of the 1,2-addition chain.

[16]A more elaborate discussion on the nature of the hydrogen abstraction process(es) is outside the scope of this paper and will be given in a forthcoming paper.

[17]For an interpretation of the electrophilic character of radicals and of their reactivity towards alkenes in terms of frontier orbital interactions, see refs. 39 and 40. An application to the reactivity of alkoxy radicals towards olefins is given in ref. 41.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

perimentally, this is translated into better yields of 1,2-addition (Tables 2 and 4) and shorter reaction times (Table 2). An alkanesulfonyl group should be more electron-withdrawing than an alkanoyl group and it is noteworthy that irradiation of *N*-chloro-*N*-methylethanesulfonamide in the presence of 1-hexene led to a 58% yield of addition (14) whereas NCMA (**1***u*) did not add to 1-dodecene (Table 4).

A conjugated olefin like styrene and conjugated dienes should be more reactive towards an electrophilic radical than an alkene.[17] Unfortunately, the photodecomposition of *N*-chloroamides at 254 nm were inhibited by styrene and 1,3-cyclohexadiene. This could be attributed to the fact that all the light was absorbed by the olefin which could not transfer its energy to the *N*-haloamide. We have not tried to use longer wavelengths. On the other hand, an electron-poor olefin like 1-acetylcyclohexene should be less reactive towards an electrophilic radical than a simple alkene.[17] However, the photochemical addition of NCCA (**1***h*) and NCU (**1***m*), using the 350 nm lamps, was quite efficient (~60%, Table 8). We do not know whether the photodecomposition occurs by direct excitation of the *N*-chloroamide or by indirect excitation, 1-acetylcyclohexene (present in excess) absorbing all the light ($n \rightarrow \pi^*$ excitation) and acting as a sensitizer. The lower yield of addition of NCCA (**1***h*) to 1-chlorocyclohexene (35%) as compared to cyclohexene (91%) is in agreement with the amidyl radical being electrophilic and 1-chlorocyclohexene being poorer in electrons than cyclohexene due to the inductive effect of chlorine.[17] The yields of addition to norbornene should be higher than those to cyclohexene and 1-dodecene since norbornene has a reactive double bond but no reactive allylic hydrogens (minimization of the hydrogen abstraction process(es)). In agreement with this, NCMA (**1***u*) did add to norbornene (42%) whereas it could not be added to cyclohexene or 1-dodecene and the addition of *N*-bromochloroacetamide (**1***n*) was somewhat more efficient with norbornene (77%) than with cyclohexene and 1-octene (62%). However, the yields of addition of NCA (**1***b*) to norbornene and to cyclohexene were exactly the same (50%).

The effect of temperature on the yield of 1,2-addition (Table 3) shows that the hydrogen abstraction process(es) is(are) retarded more than the 1,2-addition process as the temperature is lowered; and more so for an *N*-bromoamide than for its *N*-chloro analogue. This implies that the activation enthalpy of the hydrogen abstraction process(es) is higher than that of the 1,2-addition process. It also implies that the activation energy for hydrogen abstraction is higher with an *N*-bromoamide than with the corresponding *N*-chloro derivative, which could be readily explained: (*i*) if the main hydrogen abstractor is not the same whether X = Br or X = Cl (as suggested above from the Φ(N—X)/Φ(addn) ratio) and (*ii*) if the hydrogen abstractor is the halogen atom (Goldfinger mechanism, reactions [6] to [8]) since a bromine atom is less reactive than a chlorine atom (42).

The replacement of the *N*-hydrogen by an alkyl group (*Effect of R*) should decrease the reactivity of the amidyl radical towards the π-bond of an olefin (reaction [2]) mainly because an *N*-alkyl amidyl is bulkier than its *N*-hydro analogue at the reacting center. On the other hand, the effect of such a replacement on the halogen-atom transfer step [3] should be much smaller. In fact we do not know whether or not an *N*-halo-*N*-alkylamide is a better halogen atom donor than its *N*-hydro analogue. Therefore, the dramatic effect of an *N*-methyl group on the yield of 1,2-addition to cyclohexene ($CH_3CONHCl$, 55% and $CH_3CON(CH_3)Cl$, 0%; $CF_3CONHCl$, 97%, and $CF_3CON(CH_3)Cl$, 18%) and to 1-dodecene ($ClCH_2CONHCl$, 95%, and $ClCH_2CON(CH_3)Cl$, 17%) is most probably due to the retardation of the addition step [2]. The 1,2-addition chain would thus compete less effectively with the hydrogen abstraction chain(s) which should not be affected so much by the presence of an *N*-methyl substituent. Indeed, hydrogen abstraction by the amidyl radical (reaction [9], Bloomfield mechanism) should not be very sensitive to the steric bulk at the nitrogen and the Goldfinger chain (reactions [6] to [8]) should not be affected by the size of the nitrogen radical. The decrease of the yield of addition of $CH_3CONRCl$ to norbornene with R in the order $H > CH_3 > C_2H_5 > i\text{-}C_3H_7$ (Table 7) is in agreement with the addition step [2] being sensitive to the steric bulk of the nitrogen radical. However, contrary to our expectation, the decrease in yield was more pronounced in going from $R = CH_3$ (42%) to $R = C_2H_5$ (10%) than from R = H (56%) to $R = CH_3$ (42%).

We have seen that the yield of addition was lower for X = Br than for X = Cl, that the Φ(N—X)/Φ(addn) ratio was larger for X = Br than for X = Cl, and that the temperature had a more pronounced influence on the competition between 1,2-addition and hydrogen abstraction when X = Br than when X = Cl. These facts can be readily explained, as already pointed out, if hydrogen abstraction involves mainly the halogen atom (Goldfinger chain, reactions [6] to [8]) with both an *N*-bromo and an *N*-chloroamide. We would then expect that efficient scavenging of HX should at

For personal use only.

least diminish the importance of the Goldfinger chain ($X^{\cdot}$–HX–X_2 chain) if it does not suppress it completely. As a result, the 1,2-addition chain (reactions [2] and [3]) should become more important or even take over and the yield of addition should increase. The scavenging of HCl by 2,4,6-trimethylpyridine and by cyclohexene oxide was quite efficient (40 to 55%) as we have seen. But, contrary to our expectation, it had no influence on the yield of 1,2-addition of *N*-chloroamides to cyclohexene (Table 5) or to 1-octene (Table 6, entries 8 and 9), although it did have an effect on the total amount and relative proportion of the halogenation products.[5] A similar observation has been recently reported concerning the effect of ethylene oxide as a scavenger for HBr in the photodecomposition of NBS in the presence of cyclohexene (14): the scavenger had practically no effect on the yield of addition but did affect the relative proportions of 3-bromocyclohexene and dibromocyclohexane.

Summary and Conclusions

The present work allowed us to show that the photochemical addition of *N*-haloamides (ZCONRX) to olefins is a radical chain process. An increase of the yield of addition was observed: (*i*) when replacing X = Br for X = Cl, (*ii*) when increasing the electron-withdrawing power of the ZCO moiety, and (*iii*) when lowering the temperature. Thus high yields of addition to a variety of olefins were obtained with *N*-chloro-*N*-hydroamides (R = H, X = Cl) such as $ClCH_2$-CONHCl (**1***h*), $CCl_3CONHCl$ (**1***k*), $CF_3CONHCl$ (**1***l*), and NCU (**1***m*) at 15–20°C. By carrying out the light-initiated reactions at ca. −70°C, it was possible to get excellent yields of addition with *N*-bromo-*N*-hydroamides (R = H, X = Br) even in the case of NBA (**1***a*). Therefore, the photochemical method can lead to almost quantitative yields of 1,2-addition of *N*-halo-*N*-hydroamides (ZCONHX) to olefins and can be useful to synthesize *N*-(2-haloalkyl)amides. From enol ethers and ZCONHCl, we have prepared α-amido acetals and ketals (aldehydes and ketones) and a 2-amido glycoside in good yields.

We have shown that replacing the *N*-hydrogen by an *N*-methyl group did cause a dramatic decrease in the yield of 1,2-addition which was attributed to a steric effect on the rate of addition of the amidyl radical to the double bond of the olefin (reaction [2]).

We have found that the *cis* isomer predominates over the *trans* isomer in the addition of ZCONHX to cyclohexene, 1-methylcyclohexene, and norbornene as in the chromous chloride promoted additions (12*a*), and furthermore that the *cis*/*trans* ratio varies with the electronegativity and the size of Z.[18]

Finally, although some of the facts (e.g. the variation of the Φ(N—X)/Φ(addn) ratio with X, the difference in the amplitude of the temperature effect with X) could be best explained by a competition between an addition chain involving the amidyl radical as the chain carrier and a halogen atom – HX – X_2 chain (Goldfinger mechanism) for hydrogen abstraction, the presence of an efficient HCl scavenger had practically no effect on the yield of 1,2-addition of *N*-chloroamides (it did have an effect, however, on the halogenation products).[5] Further work is necessary to clearly identify and recognize the pathways competing with the 1,2-addition process.

Experimental Section[19]

Most of the pertinent general information is the same as that given in ref. 12*a*. In addition to an OS-138 column, SE-30 (5% on dimethylsilylated Chromosorb W) and Carbowax 20 M (10% on dimethylsilylated Chromosorb W) columns were used for analytical and preparative vapor phase chromatography (vpc).

Olefins

They were obtained commercially except for 1-methoxycyclohexene which was prepared from cyclohexanone according to the method described by Schmidt and Grafin (44) in a 94% yield after distillation, bp 49°C/22 Torr (lit. (44) 36°C/12 Torr), and (1-methoxymethylene)cyclohexane (**26**) which was prepared from cyclohexanone by the method described by Wittig (45) in a 60% yield after distillation, bp 46–50°C/20–25 Torr (lit. (45) 74°C/48 Torr). The preparation of (1-methoxyethylidene)-cyclohexane (**26**) has been described (46).

Amides

With the exception of pentanamide, the amides were obtained commercially and were used without purification. Pentanamide was prepared from pentanoyl chloride and concentrated ammonium hydroxyde, and recrystallized from methylene chloride, mp 105–107°C (lit. (47) 106°C).

N-*Halo*-N-*hydroamides*

With the few exceptions given below, they were prepared by the sodium hypohalite method (48), their iodometric purity was greater than 94% except for *N*-chloroformamide (**1***f*) (86%), *N*-chloropentanamide (**1***s*) (83%), and *N*-bromo-2,2-dichloroacetamide (**1***p*) (83%). *N*-Chloro-2,2-dimethylpropionamide (**1***c*) was prepared from the parent amide and tertiobutylhypochlorite according to the method of Beckwith and Goodrich (26): yellow liquid, 98% iodometric purity, 65% yield. *N*-Bromo-2,2,2-

[18]The results of a study of the stereochemistry of the radical 1,2-addition of ZCONHX to a variety of acyclic and cyclic (conformationally rigid and flexible) olefins (43) will be reported later.

[19]For the new products not described in the Experimental section, the melting points together with the microanalytical and/or mass spectral data and the ir and ^1H nmr characteristic absorptions are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

trichloroacetamide (**1***q*) was prepared from the parent amide and acetylhypobromite (49): mp 123–124°C (lit. (27) 125°C), 99% iodometric purity, 92% yield. The latter method was used also to prepare *N*-bromo-2,2,2-trifluoroacetamide (**1***r*) which was purified by sublimation: mp 61–62°C (lit. (27) 62°C), 100% iodometric purity, 82% yield.

N-*Halo*-N-*alkylamides*

Most of *N*-chloro-*N*-alkyl amides were prepared by treatment of a stirred solution (magnetic stirring) of the parent amide (0.02 mol) in water (25 mL) containing sodium bicarbonate (0.03 mol, not completely soluble) with chlorine at ca. 0°C (ice bath) until the solution was yellow. The *N*-chloroamide separated out as a deep yellow liquid. Methylene chloride was added. The two phases were separated and the organic phase washed once with water then dried. Evaporation under reduced pressure afforded the *N*-chloroamide as a colorless or slightly yellow liquid. *N*-Chloro-*N*-methylacetamide (**1***u*) was distilled under reduced pressure: bp 45–46°C/16 Torr (95% active chlorine, 73% yield). The other *N*-chloroamides were used without purification: *N*-chloro-*N*-ethylacetamide (**1***y*), 96% active chlorine, 75% yield; *N*-chloro-*N*-isopropylacetamide (**1***z*), 100% active chlorine, 70% yield; *N*-chloro-*N*-tertiobutylacetamide (**1**α), 95% active chlorine, 75% yield; *N*-chloro-*N*-methylchloroacetamide (**1***v*), 95% active chlorine, 60% yield.

N-Chloro-*N*-methylethylcarbamate (**1***x*) was prepared by treating the parent carbamate in methylene chloride with excess sodium hypochlorite (2*a*): 83% active chlorine (sample containing methylene chloride and unreacted parent amide according to the ^{1}H nmr spectrum), 80% yield. *N*-Chloro-*N*-methyltrifluoroacetamide (**1***w*) was obtained from the parent amide by the tertiobutylhypochlorite method (26) and purified by distillation: bp 65–70°C/170 Torr, 94% active chlorine, 60% yield.

N-Bromo-*N*-methylacetamide (**1***t*) was prepared directly in the photochemical cell from equimolar amounts of *N*-methylacetamide and tertiobutyl hypobromite according to the method described by Neale *et al.* (50) for the *N*-bromination of *N*-alkylcarboxamides except that methylene chloride was used as the solvent instead of carbon tetrachloride.

Photochemical Reactions

The uv irradiations were carried out in a Rayonnet RPR-100 reactor using Pyrex cells with the 300 and 350 nm lamps and Vycor cells with the 254 nm lamps. For the reactions at 15–20°C, the cells were cooled with tap water. For the reactions at lower temperatures, jacketed cells of the type described in ref. 1 were used. The reaction temperatures were measured with a copper–constantan thermocouple. The solvents used were dry: methylene chloride and acetonitrile freshly distilled from P_2O_5, absolute methanol. The *N*-haloamide (usually 5 mmol) and the solvent were placed in the cell and cooled to the desired temperature as nitrogen was passed through the solution (10 to 15 min). The olefin (usually 10 mmol), neat or dissolved in the solvent, was added slowly. The reaction mixture was degassed for a further 10 min before irradiating. The resulting solution was normally 0.2 to 0.5 *M* in *N*-haloamide for the reactions at 15–20°C and 0.06 *M* in *N*-haloamide for the reactions at low temperature. A slow stream of nitrogen was maintained throughout the irradiation which was stopped when no more *N*-haloamide was present (negative starch – iodide paper test). The reaction mixture was transferred into a volumetric flask. Aliquots were used for chromatographic separations, vpc, and other analyses.

(a) In the Presence of Cyclohexene

Aliquots were separated by preparative layer chromatography (plc) on silica gel to isolate the *cis* and *trans* adducts **2** and **3** and the parent amide (order of increasing polarity). The yields are recorded in Tables 1, 2, 3, and 4 and in Scheme 4.

An aliquot was treated with silver nitrate (10% ethanolic solution) in the dark at room temperature for 0.5 h. Under these conditions, 3-bromo- and 3-chlorocyclohexene as well as 4-chlorocyclohexene reacted completely to form AgX which was filtered, washed with water, and dried in an oven at 100°C to constant weight. Dichloro- and dibromocyclohexane, *trans* chloro- and bromomethoxycyclohexane, *trans*-chlorocyclohexanol, and the 1,2-adducts **2** and **3** did not react significantly with $AgNO_3$ under the same conditions. Thus the amount of AgX formed was related to the total yield of 3-halo- and 4-halocyclohexene. For the reactions carried out in the presence of 2,4,6-trimethylpyridine (TMP), the TMP hydrochloride formed also led to the formation of AgCl (Table 5).

Finally another aliquot was analysed by vpc for *trans*-chlorocyclohexanol (Carbowax 20 M) formed in the reactions carried out in the presence of cyclohexene oxide (Table 5), *trans*-chloro- and bromomethoxycyclohexane (OS-138) formed in the reactions carried out in the presence of methanol, 3-chloro- (SE-30 or Carbowax 20 M) or 3-bromocyclohexene (OS-138), 4-chlorocyclohexene (SE-30 or Carbowax 20 M), dichloro- or dibromocyclohexane (OS-138), and bicyclohexenyl (OS-138). Authentic samples either commercially available or readily prepared from well known methods were used as standards. The compounds were isolated by preparative vpc for full identification and spectral comparison with the authentic samples. The yields of 3-halocyclohexenes, 4-chlorocyclohexene, dihalocyclohexanes, and bicyclohexenyl will be reported and discussed in a forthcoming paper.

(b) In the Presence of cis *and* trans *3-Hexene*

The pure addition products were obtained by separation of aliquots by preparative vpc on OS-138. The yields were determined by analytical vpc on OS-138 using the pure products as standards (Table 8, entries 2 and 3).

(c) In the Presence of Enol Ethers

The reactions were carried out at −70°C. After the *N*-haloamide had reacted completely, 1 equiv. of sodium methoxide or ethoxide in methanol or ethanol (2 to 3% solution) was added and the reaction mixture was allowed to warm to room temperature. The solvent was removed and the crude product separated by plc on silica gel to isolate the adducts and the parent amide (see Table 8, entries 8 and 9, and Scheme 11). Alternatively, water was added to the reaction mixture which was then allowed to warm to room temperature. The solvent was evaporated and the crude product separated by plc on silica gel to yield the α-amido carbonyl derivative and the parent amide (see Table 8, entry 10). The α-haloketones resulting from electrophilic halogenation were separated by preparative vpc (OS-138) and compared with authentic samples. Their yield was determined by vpc using the pure samples as standards (see Table 8, entry 10, and 1-acetyl-1-chlorocyclohexane (**27**)).

(d) In the Presence of the Other Olefins

Aliquots were separated by plc or silica gel to isolate the addition product(s) and the parent amide. In the case of cyclic olefins (norbornene, 1-methylcyclohexene, pregnenolone acetate) the *cis* adduct was less polar than the *trans* isomer as in the case of cyclohexene. The yields are reported in Tables 6, 7, and 8 and in Schemes 10, 13, and 14.

Typical Procedures for the Photochemical Addition of N-*Haloamides to Olefins*

(a) Addition of N-*Chloropentanamide (1s) to Cyclohexene*

A solution of *N*-chloroamide **1***s* (732 mg, 83% active chlorine, 5 mmol) in CH_2Cl_2 (10 mL) was placed in a Vycor cell cooled with tap water. Nitrogen was bubbled through the solution for 10 min then cyclohexene (1 mL, ~10 mmol), freshly passed through alumina, was added. After degassing for a further

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

10 min, the solution was irradiated (254 nm lamps) until the starch–iodide paper test was negative (20 h) while maintaining a slow stream of nitrogen. The reaction mixture was transferred into a 25 mL volumetric flask with methylene chloride. The resulting solution was analyzed by vpc: dichlorocyclohexane, 22%; 3-chlorocyclohexene, 8%; 4-chlorocyclohexene, 3%; bicyclohexenyl, 9%. A 10 mL aliquot was treated with $AgNO_3$ (20 mL of a 10% alcoholic solution) for 30 min in the dark. The precipitate was filtered, washed with water, and dried: 38 mg of AgCl (13%). The remaining solution (15 mL) was evaporated *in vacuo*. The residue was separated by plc (ether–pentane 1:1) to give three main fractions. The less polar fraction consisted of cis N-*(2-chlorocyclohexyl)pentanamide* (**2***s*), mp 47–52°C (212 mg, 32%). Recrystallization from pentane afforded the analytical sample, mp 50–51°C; $\nu_{max}(CHCl_3)$ 3440 (NH), 1730 (C=O), 1520 cm^{-1} (NH); $\delta(CDCl_3)$, 0.91 (t, J = 6.5 Hz, 3H), 1.0–2.4 (6H), 4.10 (m, $\Delta\nu_{1/2}$ = 27 Hz, $\Delta\nu_{1/2}$ = 19 Hz after exchange with D_2O, H_1), 4.51 (q, $J \simeq$ 2.5 Hz, H_2), 6.33 ppm (br d, J = 8 Hz, NH); *m/e* 217, 219 (3:1, M^+). *Anal.* calcd. for $C_{11}H_{20}ClNO$: Cl 16.28; found: Cl 16.26.

The second fraction consisted of trans N-*(2-chlorocyclohexyl)pentanamide* (**3***s*), mp 83–86°C (70 mg, 11%). Recrystallization from pentane–ether afforded the analytical sample, mp 87°C; $\nu_{max}(CHCl_3)$ 3430 and 3320 (free and bonded NH), 1665 (C=O), 1520 cm^{-1} (NH); $\delta(CDCl_3)$, 0.90 (t, J = 6.5 Hz, 3H), 1.0–2.5 (6H), 3.84 (m, $\Delta\nu_{1/2} \sim$ 21 Hz, $H_1 + H_2$), 6.38 ppm (br, NH); *m/e* 217, 219 (3:1, M^+). *Anal.* calcd. for $C_{11}H_{20}ClNO$: Cl 16.28; found: Cl 16.06.

The third fraction (219 mg) consisted of a mixture of pentanamide and 4-chloropentanamide **5** which could not be separated. A microanalytical determination of chlorine gave 5.40% from which the relative proportion of pentanamide and **5** could be evaluated as 70:30 (30% yield of pentanamide, 11% yield of **5**). The ^1H nmr spectrum ($CDCl_3$) showed a doublet at 1.52 ppm (J = 6 Hz) for the methyl group of **5**. The mixture was dissolved in dry tertiobutanol (5 mL) then treated with *t*-BuOK (100 mg of K in 2.5 mL of *t*-BuOH) at 80°C for 12 h under a nitrogen atmosphere. Water was added and the mixture extracted with methylene chloride (2 × 25 mL). The organic phases were washed with water then dried. The solution was concentrated then analysed by vpc using pure samples as standards: pentanamide, 22%; 5-methyl-2-pyrrolidinone (**6**), 9%. The pure samples were obtained by preparative vpc and compared (ir and ^1H nmr) with authentic samples obtained commercially.

Alternatively, 5 mmol of *N*-chloropentanamide (**1***s*) was photolysed under the same conditions as above but in the absence of cyclohexene. The crude product was treated with base according to the procedure described by Beckwith and Goodrich (26) and the resulting mixture separated by plc (ether) to afford valeric acid (76 mg, 15%) and γ-valerolactone (295 mg, 59%). The lactone was purified by distillation and compared (ir and ^1H nmr) with an authentic sample.

(b) Addition of N-*Chloro-trifluoroacetamide (1l) to Pregnenolone Acetate (20)*

The reaction was carried out as in (*a*) with the following quantities: **1***l*, 263 mg, 100% active chlorine, 2 mmol in CH_2Cl_2 (5 mL); **20**, 717 mg, 2 mmol in CH_2Cl_2 (5 mL). The reaction took 1.75 h. The solvent was evaporated *in vacuo* and the crude product separated by plc (ether–pentane 1:1) to give three main fractions. The less polar fraction consisted of pregnenolone acetate, mp 147–150°C (137 mg, 19%), identical (ir, ^1H nmr) to that of an authentic sample.

The second fraction consisted of *3β-acetoxy-5α-chloro-6α-trifluoroacetylaminopregnan-20-one* (**21***l*), mp 183–185°C (201 mg, 21%). Recrystallization from ether afforded the analytical sample, mp 185–186°C; $\nu_{max}(CHCl_3)$ 3420 (NH), 1735 and 1710 (C=O of amide and acetate), 1250 and 1030 (acetate), 1170 cm^{-1} (CF_3); $\delta(CDCl_3)$ 0.63 (s, $18CH_3$), 1.19 (s, $19CH_3$), 2.02 (s, $COCH_3$), 2.11 (s, $OCOCH_3$), 4.36 (t, ΣJ = 20 Hz, H_6 axial; becomes a d, J = 9.5 Hz, upon irradiating the NH), 5.24 (m, $\Delta\nu_{1/2}$ = 33 Hz, H_3 axial), 6.41 ppm (br d, J = 9.5 Hz, NH). *Anal.* calcd. for $C_{25}H_{30}F_3ClNO_4$: C 59.34, H 6.97, N 2.76; found: C 59.12, H 7.14, N 2.63.

The third fraction consisted of *3β-acetoxy-5α-chloro-6β-trifluoroacetylaminopregnan-20-one* (**22***l*), mp 210–211°C (516 mg, 50%). Recrystallization from methylene chloride – methanol afforded the analytical sample, mp 205–206°C; $\nu_{max}(CHCl_3)$ 3460 (NH), 1740 and 1710 (C=O of amide and acetate), 1535 (NH), 1250 and 1035 (acetate), 1175 cm^{-1} (CF_3); $\delta(CDCl_3)$, 0.65 (s, $18CH_3$), 1.24 (s, $19CH_3$), 2.02 (s, $COCH_3$), 2.12 ($OCOCH_3$), 4.45 (dd, ΣJ = 14 Hz, H_6 equatorial; becomes a d, J = 3.8 Hz, upon irradiating the NH), 5.35 (m, $\Delta\nu_{1/2}$ = 32 Hz, H_3 axial), 6.52 ppm (br d, J = 9.5 Hz, NH). *Anal.* calcd. for $C_{25}H_{30}F_3ClNO_4$: C 59.34, H 6.97, N 2.76; found: C 59.28, H 6.81, N 2.80.

(c) Addition of N-*Chlorochloroacetamide (1h) to Triacetyl-*D-*glucal (33)*

A solution of *N*-chloroamide **1***h* (242 mg, 96% active chlorine, 2 mmol) in CH_2Cl_2 (80 mL) was placed in a Vycor jacketed cell (1) cooled with methanol saturated with dry ice. Nitrogen was bubbled through the solution for 10 min, then a solution of glycal **33** (599 mg, 2.2 mmol) in CH_2Cl_2 (20 mL) was added slowly. After degassing for a further 10 min, the reaction mixture was irradiated (254 nm lamps) for 3.25 h. The solvent was evaporated *in vacuo* at ca. 5–10°C. The residue was dissolved in absolute methanol (40 mL). Silver carbonate (3 g) and Drierite (3 g) were added and the mixture stirred for 12 h at room temperature. Filtration through celite, washing with methanol, and evaporation to dryness gave a crystalline residue (905 mg). Recrystallization from methylene chloride – ether afforded *methyl-2-deoxy-2-chloroacetylamino-3,4,6-tri-*O-*acetyl-β-*D-*glucopyranoside* (**35***h*), mp 148–152°C (351 mg, 44%). Further recrystallization gave a sample melting at 156–157°C; $[\alpha]_D^{25}$ −5° (*c* 1.0, $CHCl_3$) (lit. (51) mp 154–156°C; $[\alpha]_D^{0}$ −6.67 (*c* 0.75)); it proved identical (ir, ^1H nmr) to that of an authentic sample (23). Separation of the mother liquors by plc (ether) gave two fractions. The less polar fraction consisted of triacetyl-D-glucal (**33**), mp 43–48°C (251 mg, 42%) identified (ir, ^1H nmr) with an authentic sample. The second fraction consisted of β-glucopyranoside **35***h*, mp 150–156°C (97 mg, 12%; total yield: 56% (51% based on glucal **33**).

N-*Methyl Oxazolidone* **9**

N-(2-Chlorododecyl)-*N*-methyltrifluoroacetamide (**8***w*) (100 mg, 0.3 mmol) was treated with a 7% solution of potassium carbonate in methanol–water (5:2, 10 mL) at room temperature overnight. The reaction mixture was extracted with methylene chloride, the organic phases washed with water then dried. Removal of the solvent *in vacuo* afforded the N-*methyloxazolidone* **9**, mp 40–42°C (62 mg, 85%). Two recrystallizations from hexane afforded a sample melting at 44–44.5°C; $\nu_{max}(CHCl_3)$ 1760 cm^{-1} (C=O); $\delta(CDCl_3)$ 0.89 (m, terminal CH_3), 1.0–2.0 (18H), 2.88 (s, $\geq N—CH_3$), 3.01–3.74 (six lines, 2H), 4.44 ppm (m, $\Delta\nu_{1/2} \sim$ 30 Hz, 1H); *m/e* 241 (M^+).

cis-*Oxazoline* **16**

(a) From Bromoacetamidation of cis *3-Hexene*

A solution of bromine (3.2 g, 0.02 mol) and silver perchlorate (4.14 g, 0.02 mol) in acetonitrile (25 mL, distilled over P_2O_5) was cooled in an ice bath and *cis*-hexene (2.5 mL, ~0.02 mol) was added dropwise while stirring. The precipitation of silver bromide was immediate. After a few minutes, sodium hydroxide (10 mL of 0.01 *N* solution) was added. The mixture was extracted with methylene chloride and the organic phases washed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

with water then dried. The solvent was removed *in vacuo* (2.30 g, 52%). Part of the residue (1.0 g) was dissolved in absolute methanol (25 mL). Sodium methoxide (0.105 g of sodium in 5 mL of methanol) was added and the mixture heated at 60°C for 12 h under nitrogen. Part of the methanol was evaporated *in vacuo* and the resulting solution treated with brine (10 mL) and then extracted with methylene chloride (3 × 25 mL). The combined organic phases were dried and the solvent evaporated to give cis-*4,5-diethyl-2-methyloxazoline* (**16**) (0.65 g, 94%) which was purified by microdistillation for analyis: $\nu_{max}(CHCl_3)$ 1665 (C=N), 1438 (C—N), 1268 cm^{-1} (C—O—C); $\delta(CDCl_3)$ 0.8–1.8 (10H); 1.93 (d, J = 1.5 Hz, N—CH_3), 3.85 (br sext, J = 7 and 9 Hz, H-4), 4.40 ppm (sext, J = 7 and 9 Hz, H-5). *Anal.* calcd. for $C_9H_{15}NO$: C 68.04, H 10.70, N 0.91; found: C 68.48, H 11.06, N 9.22.

(b) From threo N-*(4-Chloro-3-hexyl)trifluoroacetamide (12l)*

The *threo* 1,2-adduct **12***l* (462 mg, 2 mmol) was stirred with potassium carbonate (20 mL of a 7% solution in methanol–water 5:2) for 3 h at room temperature. The mixture was extracted with methylene chloride. The solvent was evaporated and the residue treated in acetic anhydride – pyridine at room temperature for 4 h. The solvent was removed *in vacuo* and the crude product treated with sodium methoxide (46 mg of sodium in 10 mL of methanol) at 65°C for 24 h. Work up as in (*a*) followed by microdistillation of the product gave the pure cis-*oxazoline* **16** (214 mg, 70%), identical (ir, ^1H nmr) to the sample obtained in (*a*).

trans-*Oxazoline* ***17***

(a) From Bromoacetamidation of trans *3-Hexene*

The procedure was exactly the same as that described in (*a*) above using the same quantities except that treatment with sodium methoxide was carried out on the whole crude β-bromoamide to give trans-*4,5-diethyl-2-methyloxazoline* (**17**) (2.97 g, 97%) which was purified by microdistillation: $\nu_{max}(CHCl_3)$, 1670 (C=N), 1440 (C—N), 1250 cm^{-1} (C—O—C); $\delta(CDCl_3)$, 0.95 (t, J = 7.5 Hz, 3H), 1.53 (m, 4H), 1.95 (d, J = 1.2 Hz, N—CH_3), 3.56 (br q, J = 6 Hz, H-4), 4.05 ppm (q, J = 6 Hz, H-5). *Anal.* calcd. for $C_9H_{15}NO$: C 68.04, H 10.70, N 9.91; found: C 68.07, H 10.92, N 9.40.

(b) From erythro N-*(4-Chloro-3-hexyl)trifluoroacetamide (13l)*

The procedure was exactly the same as that described in (*b*) above using the same quantities to give the *trans*-oxazoline **17** (236 mg, 77%), identical (ir, ^1H nmr) to the sample obtained in (*a*).

Hydrolysis of α-*Amido Acetal* ***29***m

The acetal **29***m* (95 mg, 0.39 mmol) was treated at 70°C with 70% aqueous acetic acid (5 mL) for 2 h. Evaporation to dryness in the presence of benzene gave an oil (70 mg, 88%); $\nu_{max}(CHCl_3)$ 3420 (NH), 2810 and 2710 (CH of aldehyde), 1730 (C=O of carbamate), 1710 (C=O of aldehyde), 1500 (NH), 1240 and 1100 cm^{-1} (C—O of carbamate); $\delta(CDCl_3)$ 1.24 (t, J = 7 Hz, OCH_2CH_3), 4.10 (q, J = 7 Hz, OCH_2CH_3), 5.24 (br, NH), 9.20 ppm (s, CHO); *m/e* 199 (M^+). The 2,4-DNP derivative (prepared in methanol) melted at 158–159°C.

Hydrolysis of ***30***m

The hydrolysis was carried out as above (95 mg of **30***m*, 0.4 mmol) except that the reaction was carried out in the presence of 2,4-dinitrophenylhydrazine (198 mg, 1 mmol) to give directly the 2,4-DNP derivative of α-chloro aldehyde **32** (104 mg, 80%), mp 214–215°C (lit. (34) mp 220–221°C).

Hydrogenation of ***41***b

Compound **41***b* (46 mg, 0.25 mmol) was hydrogenated over prehydrogenated platinum oxide (3 mg) in ethyl acetate (2 mL) over 1 h (3.6 mL of H_2 was absorbed). Filtration over celite and evaporation to dryness gave N-(endo-*3-chloro*-endo-*2-norbornyl)acetamide* (**45***b*), mp 127–128°C (40 mg, 100%). Recrystallization from ether – methylene chloride afforded the analytical sample, mp 129–130°C; $\nu_{max}(CHCl_3)$ 3430 (NH), 1670 (C=O), 1515 cm^{-1} (NH); $\delta(CDCl_3)$ 1.1–2.3 (6H), 1.98 (s, CH_3), 2.42 (m, $H_1 + H_4$), 2.42 (m, $H_2 + H_3$), 6.52 ppm (br, NH); *m/e* 187, 189 (3:1, M^+). *Anal.* calcd. for $C_9H_{14}ClNO$: C 57.60, H 7.57, N 7.46; found: C 57.45, H 7.70, N 7.65.

N-*Methyl*-N,N′-*methylenebisurethane* ($C_2H_5OCON(CH_3)CH_2COOC_2H_5$)

Urethane (7.12 g, 80 mmol), *N*-methylurethane (4.62 g, 40 mmol), formaldehyde (10 mL of a 37% solution, 123 mmol), and hydrochloric acid 0.1 *N* (120 mL) were stirred at room temperature for 4 days. The crude product obtained after methylene chloride extraction (3 × 150 mL) followed by the usual work up was distilled under reduced pressure. The fraction collected at 80–130°C (0.4 Torr) was redistilled to afford a fraction (1.4 g, 95–110°C/0.6 Torr) containing the desired product. An aliquot (0.350 g) was separated by plc on silica gel (hexane–ether 2:1) to give N-*methyl*-N,N′-*methylenebisurethane* (0.274 g, 16%) which was purified by microdistillation (90–100°C, 0.1 Torr) for analysis: $\nu_{max}(CHCl_3)$ 3460 (NH), 1730 and 1700 (C=O), 1505 (NH), 1235 and 1190 cm^{-1} (C—O—C); $\delta(CDCl_3)$ 1.24 (t, J = 7 Hz, 6H), 2.94 (s, $>$N—CH_3), 4.08 (q, J = 7 Hz, 4H), 4.59 (d, J = 7 Hz, $>$N—CH_2—NH—), 5.88 ppm (br, NH); *m/e* 204 (M^+). *Anal.* calcd. for $C_8H_{16}N_2O_4$: C 47.05, H 7.90, N 13.72; found: C 47.11, H 7.86, N 13.86.

The photochemical addition of *N*-chloro-*N*-methylethylcarbamate (0.83 g, 83% active chlorine, 5 mmol) to 1-octene (1.6 mL, 10 mmol) in CH_2Cl_2 (30 mL) was carried out in the usual way. Separation by plc on silica gel (ether–hexane 1:1) afforded two fractions. The less polar fraction consisted of the 1,2-adduct **8***x* (0.26 g, 21%) (see Tables 10, 11, and 12 for its characterization).[19] The other fraction (0.47 g) consisted of a mixture of *N*-methylethylcarbamate and *N*-methyl-*N*,*N*′-methylenebisurethane, the relative proportions of which were determined by ^1H nmr (see Table 6 for the yields). Further separation of the second fraction by plc allowed the isolation of a small amount of bisurethane identical (ir, ^1H nmr) to the authentic sample prepared above.

N-*Methyl*-N,N′-*methylenebisacetamide*

Attempts to prepare that compound from *N*-methylacetamide, acetamide, and formaldehyde in acidic medium as above were unsuccessful. *N*-Chloro-*N*-methylacetamide (**1***u*) was treated with triethylamine in the presence of *N*-methylacetamide in methylene chloride but no bisacetamide could be detected.

N-Chloro-*N*-methylacetamide (**1***u*) (565 mg, 95% active chlorine, 5 mmol) in CH_2Cl_2 (25 mL) was irradiated at 254 nm for 4 h. Vapor phase chromatography analysis showed the presence of a substantial amount of chloroform (>95%) and traces of 1,1,2,2-tetrachloroethane (SE-30 column, 35°C) and about 8% of *N*-methylacetamide (OS-138 column, 130°C). The solvent was evaporated and the residue separated by plc on silica gel (ether–hexane 4:1) to afford N-*methyl*-N,N′-*methylenebisacetamide* (21 mg, 6%) as an oil which was not purified further: $\nu_{max}(CHCl_3)$ 3430 and 3300 (free and bonded NH), 1672 and 1650 (C=O), 1510 cm^{-1} (NH); $\delta(CDCl_3)$ 1.98 (s, $COCH_3$), 2.06 (s, $COCH_3$), 3.14 (s, $>$N—CH_3), 4.71 (d, J = 7.5 Hz, $>$N—CH_2—NH), 6.67 ppm (br, NH); *m/e* 144.0903 (calcd. for $C_6H_{12}N_2O_2$, 144.0899).

A more polar fraction still contained some bisacetamide along with polymeric material according to the ^1H nmr spectrum and was not further investigated.

Effects of protonation and hydrogen bonding on carbon-13 chemical shifts of compounds containing the >C=N̈— group[1,2]

MALWINA ALLEN[3] AND JOHN D. ROBERTS[4]

The Gates and Crellin Laboratories of Chemistry, California Institute of Technology, Pasadena, CA 91125, U.S.A.

Received March 4, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

MALWINA ALLEN and JOHN D. ROBERTS. Can. J. Chem. **59**, 451 (1981).

The effects of hydrogen bonding and protonation produced by changing solvent from chloroform to 2,2,2-trifluoroethanol to trifluoroacetic acid were determined for the ^{13}C chemical shifts of fourteen imines, four oximes, and two pyridines. Downfield shifts relative to chloroform were observed for the C=N carbon of the imines and oximes in both trifluoroethanol and trifluoroacetic acid, ranging from 1.5 to 27.5 ppm, which contrasts with upfield C_α shifts for the pyridines in trifluoroacetic acid. Substantial downfield and upfield shifts of from +10 to −15 ppm were found for the *para* and *ipso* carbons, respectively, of the aromatic rings attached to the C=N group in trifluoroacetic acid. Possible explanations of these shift changes are considered as well as their relation to the corresponding changes in ^{15}N shifts with the identical variations in solvent.

MALWINA ALLEN et JOHN D. ROBERTS. Can. J. Chem. **59**, 451 (1981).

Utilisant le chloroforme, la trifluoro-2,2,2 éthanol et l'acide trifluoroacétique comme solvants, on a déterminé les effets de la liaison hydrogène et de la protonation résultant du changement de solvant sur les déplacements chimiques du ^{13}C de 14 imines, de 4 oximes et de deux pyridines. On a observé des déplacements chimiques vers les champs faibles (allant de 1,5 à 27,5 ppm) du carbone C=N des imines et des oximes dans le trifluoroéthanol et dans l'acide trifluoroacétique; ces résultats contrastent avec les déplacements chimiques vers les champs forts observés pour les C_α des pyridines dans l'acide trifluoroacétique. Dans l'acide trifluoroacétique, on a observé des déplacements importants vers les champs faibles et vers les champs forts allant de +10 a −15 ppm pour les carbones respectivement en positions *para* et *ipso* des cycles aromatiques liés au groupe C=N.

On considère des explications probables de ces déplacements aussi bien que leur relation avec les changements correspondants dans les déplacements chimiques du ^{15}N avec des changements identiques de solvants.

[Traduit par le journal]

Introduction

In the preceding paper (1), we reported the changes in ^{15}N chemical shifts associated with the sequence of solvent changes, chloroform → 2,2,2-trifluoroethanol → trifluoroacetic acid for a number of imines, oximes, and pyridines. The corresponding changes in ^{13}C chemical shifts are discussed here.

Previous studies of the protonation of azaaromatics (2), amino acids (3), aliphatic amines (4), benzenamine (5), and nitriles (6) have demonstrated a general trend of upfield ^{13}C shifts, ranging from 1 to about 17 ppm, for the carbons directly attached to the nitrogens. Because imines, oximes, azaaromatics, and nitriles all have multiple bonds between nitrogen and carbon, and because the ^{15}N shifts of all of the substances move strongly *upfield* on protonation, it was of interest to determine whether the ^{13}C shifts of the carbons multiply bonded to the nitrogens change in a similarly uniform way.

Experimental Section

The compounds used were the same as in the earlier investigation (1). The ^{13}C spectra of 4 mol% solutions were taken with a Varian XL-100-15 spectrometer operating at 25.4 MHz in the Fourier-transform mode, with 12-mm od sample tubes, 20-μs pulses (45° flip angle), and 5-s repetition rates. Good signal-to-noise ratios could usually be obtained for all of the carbons with 200–300 scans. Tetramethylsilane (TMS) was used as internal reference, and a 5-mm coaxial tube containing deuterium oxide provided the external field frequency lock signal. The samples were at the ambient probe temperature, about 28°C. The data length was 8192 points for a spectral width of 5000 Hz. The reproducibility of the shifts was about ±0.05 ppm.

Results and Discussion

The ^{13}C chemical shifts of all of the compounds studied in this work in chloroform solution are summarized in Tables 1 to 4, wherein the compounds are grouped in accord with common structural features. Values for the shifts of some of these compounds have been reported previously (2, 7–9), but were redetermined to ensure constant experimental conditions. The assignments of resonances to particular carbons were generally

confirmed by single-frequency off-resonance decoupling, relative peak intensities, and comparisons with shift assignments already made for appropriately substituted benzene derivatives. For the imine, **3***a*, the phenyl rings attached to the C=N carbon are nonequivalent; the set of resonances similar to those of **3***b* was assigned to the *anti* phenyl carbons. This assumes the *anti* configuration of **3***b* suggested by Yoshida *et al.* (9) is correct. The resonances of **3***c* and **3***d* were made by analogy with those of the corresponding oximes (7).

The ^{13}C shifts of the imines of Table 1 and of the oximes of Table 4 have been discussed previously (7, 8). The C=N carbons of the imines in Table 2 are very similar to those of Table 1, and are rather insensitive to substituents, 4-nitro vs. 4-methoxy, in **2***a*–**2***b*, and to the various alkyl groups in **2***c*–**2***e*.[5]

The resonances of the C=N carbons of imines listed in Table 3 are farther downfield than those of Tables 1 and 2 (analogous to ketones vs. aldehydes) with deshielding increasing with the number of the aliphatic groups. Perhaps surprisingly, the change in ring size from six to five between **3***c* and **3***d* causes as large a shift change as going from **3***a* to **3***c*.

The *changes* in ^{13}C shifts (Δδ) which occur on changing the solvent from chloroform to trifluoroethanol and from chloroform to trifluoroacetic acid are listed in Tables 5 to 9.[6] The assignments of the resonances of the 2′ and 3′ carbons of **1***a*–**1***f* in trifluoroacetic acid and of the aliphatic carbons of **3***c*, **3***d*, and **4***b*, in trifluoroacetic acid are tentative, as therefore will be the Δδ values for these substances. Concentration effects on the ^{13}C resonances of representative compounds in the 2, 4, 8, and 10 mol% range were within 0.1 ppm (more

[5]The insensitivity of imines to substituents on adjacent rings is similar to that reported for acetophenones (10*a*), styrenes (10*b*), and chalconnes (10*c*).

[6]The reasons for choosing chloroform as the standard solvent were discussed earlier (1).

substantial changes were noted at 20 mol%) and it appears that the shifts at infinite dilution are already well approximated by those at the 10 mol% level.

It will be seen from Tables 5 to 9 that changing from chloroform to either trifluoroethanol or trifluoroacetic acid produces substantial changes in many of the carbon chemical shifts of the compounds studied. Both upfield and downfield shift changes are observed, and it is especially interesting and significant that trifluoroethanol and trifluoroacetic acid may have effects which are not only different in magnitude but in sign as well. It is not wholly surprising that this be the case, because, as we have pointed out when discussing the ^{15}N shifts (1), trifluoroethanol is primarily a hydrogen-bonding solvent, while trifluoroacetic acid is a protonating solvent for imines. Protonation with trifluoroacetic acid is firmly established by observation of proton–^{15}N couplings with imines (1).

For the ^{15}N resonances of C=N nitrogens, both

trifluoroacetic acid and trifluoroethanol uniformly cause *upfield* shifts, with the protonation shifts being several times the hydrogen-bonding shifts. These shift changes accord with the expected increases in the $n \rightarrow \pi^*$ transition energies, which are associated with very substantial second-order paramagnetic contributions to the chemical shifts of $>C{=}\ddot{N}-$ nitrogens. This does not mean to say that other effects on the ^{15}N chemical shifts are negligible, only that they appear to be largely

masked by the changes in second-order paramagnetic effects associated with partial or full bonding to the unshared electron pair on nitrogen. Because the carbons with which we are concerned have no unshared pairs, it is to be expected that different considerations are likely to apply in rationalizing the positions of their resonance signals.

In the following discussion, we will give special attention to the ^{13}C shift changes which are associated with hydrogen bonding and protonation of the carbons of the structural units, C—C=N—C of imines and pyridines, and C—C=N—OH of oximes. Perusal of Tables 5 to 9 shows that the aromatic carbon resonances, except for those of the *ipso* carbons, move downfield on both hy-

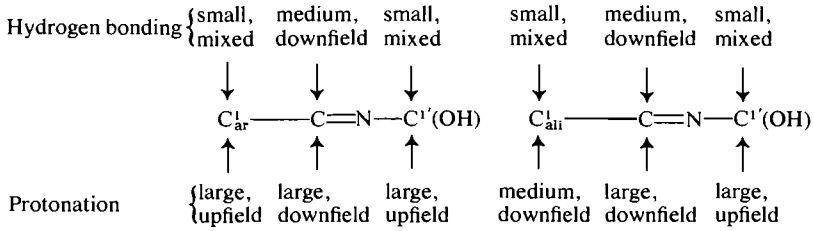
drogen bonding and protonation, as befits conversion of the C=N groups into more electron-attracting groups. The changes in shift of these aromatic carbons are often large, especially on protonation, but there are no surprises in their general trends. The aliphatic carbon-shift changes outside of the structural units, C—C=N—C or C—C=N—OH, are generally small and somewhat erratic and will not be considered further.

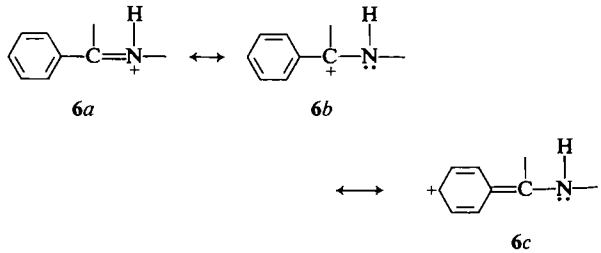
One interesting aspect of the shift changes in Tables 5 to 9 is the fact that hydrogen bonding or protonation uniformly causes the resonances of C=N carbons in imines and oximes to move *downfield* while, in contrast, the resonances of C2,6 of pyridine move *upfield*. 2,6-Dimethylpyridine is different from pyridine in that its C2,6 resonances move downfield on hydrogen bonding and upfield on protonation. Also significant are the large and uniform *upfield* protonation shifts of aromatic *ipso* carbons which we shall henceforth designate as C1 and C1′ in the structural unit C^1—C=N—$C^{1'}$. When C1 is a saturated carbon, as in **3***b–d* and **4***b–d*, the corresponding protonation shifts (here, of the carbon actually labeled in the formulas variously as C8, C2,5, C2,6, or C2) are medium in size and *downfield*. However, as with **2***c–e*, when C1′ is aliphatic, the shift changes are medium and *upfield*.

The hydrogen-bonding shifts of the C1 and C1′ resonances are generally quite small compared to those of the C=N carbon resonances and may or may not have the same sign as the protonation shifts. To summarize (where C_{ar} = *ipso* aromatic ring carbon and C_{ali} = saturated carbon):



What sense can be made out of these patterns of shift changes? Let us consider the effects on the C=N carbon resonances first, remembering that the α-carbon resonances of pyridine go upfield on hydrogen bonding or protonation — opposite to the imine and oxime C=N resonances.

Partial or complete bonding to the lone pair of a C=N nitrogen by a proton donor is expected to raise the $n \rightarrow \pi^*$ transition energy and cause a very substantial upfield shift of the ^{15}N resonance. Such bonding will also be expected to change the character of the C=N bond, as can be rationalized by an increase in the contribution of resonance structures such as **6***b*. (The resonance structures, **6**, are written for convenience to correspond to full protonation, but the extension to a hydrogen-bonding situation should be obvious.)



6*a* **6***b* **6***c*

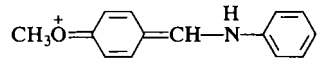
If an aromatic ring is attached to the carbon of the C=N bond, then both hydrogen bonding and protonation could be expected to lead to electron delocalization from the ring, as symbolized by **6***c*, and this, of course, is expected to affect the shieldings of the ring carbons in a significant way in the *downfield* direction, as is observed. An important question is what part, if any, of the shift change at the C=N carbon could be a neighboring anisotropy effect arising from the decrease in the paramagnetic shielding of the nitrogen nucleus associated with hydrogen bonding or protonation. Such neighboring anisotropy effects have been used to account for the shielding of acetylenic and non-hydrogen bonded H—O, H—N, and H—F protons (11). Whether a change in the electron circulation around the nitrogen should be expected to shield or deshield a directly attached C=N carbon nucleus is not easy to predict with molecules as complex as the ones considered here. However, shielding at nitrogen and deshielding at carbon of C=N atoms as the result of changing the second-order paramagnetic contributions by hydrogen bonding to, or protonation of, the nitrogen is certainly not unreasonable.

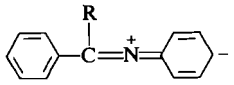
Experimentally, for the compounds in Tables 5 to 8, the ratios of the changes produced by hydrogen bonding and protonation on the C=N carbon resonances are substantially smaller than are the ratios of the corresponding effects on the C4 resonances of the aromatic carbons. This fact, at least naively, seems to suggest a sizeable contribution to the downfield shift in the C=N shifts through the diamagnetic change in the nitrogen shielding as the result of hydrogen bonding. On full protonation, this contribution would be expected to be enhanced, but then might be masked by an opposing shift associated with drastic changes in the overall electron distribution ascribable to resonance structures **6***b* and **6***c*. These notions are in good agreement with the fact that the shifts of C1 and C1′ are only very slightly changed by hydrogen bonding but are greatly changed by protonation, as would be expected if there is not in fact much charge transfer on hydrogen bonding. Pyridine and 2,6-dimethylpyridine (Table 9), where the C=N atoms are part of aromatic rings, could well be different from imines and oximes because of different anisotropies of the second-order paramagnetic effect at their nitrogen atoms.

The results with compounds **1***a*–**1***d* indicate a qualitative relationship between shift changes on protonation and relative contributions of **6***b* and **6***c*. With **1***a* and **1***b*, which can enhance the contribution of **6***c*, the C4 shifts are larger and the C7 shifts smaller than for **1***d* with its 4-nitro group, which should favor **6***b* over **6***c*. That both the C7 and C4 shifts of **1***a* are smaller than **1***b* is expected because of electron delocalization from the methoxy group, **7**.



7

The large upfield shifts of the resonances of C1 and C1′ on protonation have several parallels in compounds where a positive center is generated adjacent to carbon. For example, formation of the conjugate acid of acetophenone with trifluoromethanesulfonic acid causes an upfield shift of the *ipso* carbon of 8 ppm (5), ionization of triphenylmethanol in sulfuric acid results in an upfield shift of 9.9 ppm for the *ipso* carbons (12), conversion of benzenamine to its salt with methanesulfonic acid gives an upfield C1 shift of 17.6 ppm (5). In all of these substances, as with the compounds studied here, the other ring-carbon resonances move downfield. The upfield shift changes produced by attachment of carbon to an atom undergoing a loss of electronic charge seems very likely to be largely an inductive effect. Clearly, conjugative unsaturation is not necessary, because conversion of a carboxylate salt to the acid results in an upfield shift of the carboxyl carbon (13) and the change of an aliphatic amine to the ammonium ion causes an upfield shift of the α carbon (4). The fact that protonation of imines is expected to call for an increase in conjugation involving C1 (**6***c*) and a decrease in conjugation involving C1′ (**8**) adds further weight to postulation of a nonconjugative origin to the resulting shift changes.



8

It has been pointed out to us by Reynolds that the π-inductive effect is likely to be especially important in these systems in determining the shifts of the *ipso* carbons and, furthermore, can help to account for the smaller shift changes of the *ortho* relative to the *para* carbons of the unsubstituted phenyl rings of **1***a*–**1***f*, **2***c*–**2***e*, and **3***b*–**3***d* on protonation (14, 15).

The twist angle approach to the stereoselectivity in reduction of ketones

MICHAEL R. GIDDINGS AND JOHN HUDEC

Department of Chemistry, The University, Southampton S09 5NH, Great Britain

Received July 3, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

MICHAEL R. GIDDINGS and JOHN HUDEC. Can. J. Chem. **59**, 459 (1981).

Semiempirical MO calculations show that the π^* orbital of the carbonyl carbon of asymmetric ketones deviates from orthogonality. These small deviations, measured by twist angles, are used to predict the configurations of the diastereoisomeric alcohols formed on reduction of the ketones with complex metal hydrides. The method is particularly suitable for predicting the changes in stereoselectivity when the carbonyl compound is substituted. This is illustrated by a number of examples of reduction of substituted rigid polycyclic ketones. It is proposed that a nucleophile approaches a carbonyl group preferentially from the side of obtuse angle with respect to the O—C bond. The twists incorporate the electronic nature of the substitent and help to understand the steric effect. The application of the twist angle approach to other reactions is briefly mentioned.

MICHAEL R. GIDDINGS et JOHN HUDEC. Can. J. Chem. **59**, 459 (1981).

Les calculs semi-empiriques de OM montrent que l'orbitale π^* du carbone du carbonyle des cétones asymétriques dévie de l'orthogonalité. On a utilisé ces petites déviations, mesurées par les angles de torsion, pour prédire les configurations des alcools diastéroisomères qui proviennent de la réduction des cétones par les hydrures métalliques complexes. Cette méthode convient particulièrement à la prédiction des changements de stéréosélectivité quand le composé carbonylé porte un substituant. Un grand nombre d'exemples de réductions des cétones polycycliques rigides substituées illustrent cette méthode. On propose qu'un nucléophile approche le groupe carbonyle préférentiellement du côté de l'angle obtus par rapport à la liaison O—C. Les torsions incorporent la nature électronique du substituant et aident à comprendre l'effet stérique. On mentionne brièvement l'application de l'angle de torsion d'approche à d'autres réactions.

[Traduit par le journal]

The search for a set of rules that would predict the stereoselectivity in the reduction of ketones by complex metal hydrides has been under continuous study since their introduction in the early 1950's. Virtually all the rationalisations, based on experimental data, incorporate some kind of steric effect. However, their predictive ability is very limited for the following reasons: (*i*) they are all based on the results obtained on substituted cyclohexanones (or acyclic ketones with assumed preferred conformations), (*ii*) the only substituent that is seriously considered is the methyl group, and (*iii*) the approach of the reagent nucleophile to the carbonyl group is assumed to be strictly perpendicular to the C—O bond from either side of the π/π^* MO's. For the sake of brevity, we do not discuss the merits and disadvantages of the various earlier proposals and refer the reader to a very recent review (1) in which the question of stereoselectivity is discussed and critically evaluated. We concentrate on the presentation of a different approach that incorporates some aspects of earlier proposals (2–4) and promises to be much more general.

We have shown recently (5) that the cd of the n→ π^* transition of a chiral carbonyl compound can be easily obtained by evaluating the twists of the n and π^* orbitals (HOMO and LUMO) localised on oxygen from an output of a simple program such as CNDO/2 (6). More importantly, these calculations predict quite accurately the *relative* changes in cd, both in sign and magnitude, when any one of the hydrogen atoms of the ketone is replaced by a substituent. Although our analysis showed that the π^* MO contributed very little to the overall rotary strength because it is mainly localised on the C=O group, it nevertheless interacts with the σ^* orbital of the substituent C—X bond. As the π^* orbital on the C atom of the carbonyl group is involved in the reactions with nucleophiles, we have re-examined it in order to see whether it undergoes any distortions (twists) on substitution. Such twists (Fig. 1), if present, should be a most useful guide for predicting the change in the ratio of diastereoisomeric alcohols on reduction of ketones, and more generally, in any reaction in which an electron deficient atom is present or produced that subsequently reacts with a nucleophile.

In principle, there can be two twists generated, one in the *xz* and one in the *xy* planes, either of which can be positive or negative.[1] Assuming that the nucleophile will react preferentially with the C=O group from the side of the "obtuse angle"

[1]The twist angles (all in minutes of a degree) are defined as

$$\text{tg}\,\theta_{(\pi^*xz)} = C(\pi^*z)/C(\pi^*x); \qquad \text{tg}\,\theta_{(\pi^*xy)} = C(\pi^*y)/C(\pi^*x)$$

where the coefficients C are the eigenvectors on the carbonyl carbon in the π^* (LUMO) molecular orbital. It should be noted that $\theta_{(\pi^*xz)}$ will have the same sign for any pair of antipodal ketones but $\theta_{(\pi^*xy)}$ will have opposite signs. Standard bond angles and bond lengths as well as idealised geometries were used in all calculations.

(2), it will come from the top preferentially if $\theta_{(\pi^*xz)}$ is negative and from the bottom if $\theta_{(\pi^*xz)}$ is positive. As there is still some doubt about the reduction of flexible cyclohexanones (1, 4), we have limited our analysis to rigid carbonyl systems.

The first systems we examined were norbornene 2- and 7-ketones and the corresponding saturated analogues (7) (Figs. 2 and 3). The increase in the *endo* alcohol of the 2-ketone was ascribed to the steric (and electrostatic) effect of the π electrons being larger than that of the ethano bridge. However, such a conclusion is immediately negated by the results of the 7-ketone. The change in the $\theta_{(\pi^*xz)}$ twist of the unsaturated ketones *relative* to the saturated ones reflect the change in the distribution of the alcohols: the positive twist in the 7-one series parallels preferential attack from the *syn* side, and the increased negative twist on going from saturated to the unsaturated compounds in the 2-one series parallels the increased attack from the *exo* side. Interestingly, in this case the change in twists reflects the change in the relative rates of reduction from the *exo* and *endo* sides — an increase in obtuse angle is proportional to the increase in relative rate. The dramatic decrease in the rate of addition from the *anti* side in the 7-one series is probably a reflection of the twist, the angle of attack becoming more acute. The decrease in rate from the *syn* side (instead of an increase) may be due to electrostatic and/or steric interaction between the π electrons of the double bond and the incoming nucleophile, BH_4^-. It thus appears that both the experiment and theory concur and indicate that a double bond as a substituent interacts with a carbonyl group in a variable way that is very strongly orientationally dependent (for another example, benzobicyclo-[2:2:2]octanone, see ref. 8).

We turned our attention next to 2-adamantanone system, which because of its symmetry (in the same way as 7-norbornanone), should show clearly the effect of substituents (F and Cl) at positions 4_{eq}- (9) and 5. The analysis of the $\theta_{(\pi^*xz)}$ twists provided an unexpected surprise as they predicted not only that fluorine and chlorine should give different isomers as the major products in both 4 and 5 substituted series but that the major fluoro alcohol in the 4-series will be *trans* with respect to the cyclohexane that carries both substituents and *cis* in the 5-series (vice versa for Cl). As no such results were available in the literature, we checked these predictions experimentally ourselves and found them to be in full agreement (Scheme 1).[2] The only surprising

[2]From general properties of halogens, Br and I are expected to follow progressively the enhanced trend of Cl. Unfortunately, our program is not parametrised for these elements.

point about the experimental results is the larger inverse ratio of the fluoro isomers in the 5-series than in the 4-series. This is most likely due to differing steric requirements of the two reagents used; $LiAl(OBu^t)_3H$ was forced on us in the 4-series as

SCHEME 1

$LiAlH_4$ or $NaBH_4$ gave in all cases (except X = H) the bicyclic unsaturated alcohol formed by Grob-type elimination.

In order to gain a better understanding of these results, we carried out the twist analysis on a γ-substituted pentanone that could serve as a model for *anti*-π-substituted camphors (10). Again, the $\theta_{(\pi^*xz)}$ twists predicted unexpected results that had to be checked experimentally. The $\theta_{(\pi^*xz)}$ twists showed the same trend as the 4-substituted adamantanone series and, gratifyingly, these predictions were borne out experimentally, despite the steric effect of the *syn*-7-methyl group. The apparent decrease in steric bulk of this methyl group on going from X = F to X = Cl can be explained by the utilisation of the twist in the *xy*-plane, $\theta_{(\pi^*xy)}$; its sign suggests that the nucleophile approaches the carbonyl carbon along a path between C-1 and C-7-*syn* methyl groups. An inspection of molecular models does agree that this direction of *exo* approach is less hindered than any other one (Scheme 3).

These results show that electronic substituent effects, transmitted through bonds, are responsible for the changes in the product ratios, as well as for the changes in the cd of the corresponding ketones; in fact, they parallel one another. For the same given orientation of a substituent X, as in 4-substituted adamantanones and in *anti*-π-substituted camphors, F has a dissignate contribution and Cl a consignate contribution to the cd of the parent unsubstituted ketone.

However, the behaviour of the $SnMe_3$ group, a strong σ-electron donor as observed in the cd of ketones (11), is at present difficult to rationalise, even though the result was predicted by the calculations. In this instance, $SnMe_3$ group acts in the same way as F, as a net electron acceptor, in contrast to Cl which is a net electron donor (12) (the balance between the σ-withdrawal and π-donation, both effects being conformationally dependent (5, 11)). In order to test this hypothesis, we calculated butanone and pentanone-2 with different electronegativities of the starred H atoms (Scheme 4).

The best way to assess the data in Scheme 4, so that they can be compared with the calculated data in Schemes 1 and 3, is to use twists relative to H of normal electronegativity, i.e. $\delta\theta = \theta^R_{(\pi^*)} - \theta^H_{(\pi^*)}$ where $\theta^R_{(\pi^*)}$ is H* with altered electronegativity. It then becomes immediately apparent that F in both series produces the twists of the same signs as the more electronegative H; Cl parallels the behaviour of the more electropositive H. As has been already mentioned, SiH_3 group (Scheme 3) behaves anomalously.

SCHEME 3. Preferred conformation of the substituted *anti*-π-methyl group, as shown, is corroborated by X-rays on *anti*-π-trimethyltin camphor (unpublished work — we thank Dr. L. Alexander, Open University, for the information) and on substituted *anti*-π-camphor sulphonic acid derivatives (36).

The last system that we investigated computationally was the recently studied 3-substituted bicyclo[2:2:2]octanone-2 (13, 14). The results (Scheme 5) of reduction with $LiAlH_4$ (13) are startling — with R = H and Me, the ratio of *trans* to *cis* alcohols is 1, it increases on going from R = Et to Pr^i and then drops below 1 for R = Bu^t. This suggests that the steric bulk of Me is equal to H, Et and Pr^i get progressively smaller than Me, and only Bu^t is greater than H. The same trend is observed when the reduction is carried out with a much bulkier reagent, $LiAl(OBu^t)_3H$, when all *trans*/*cis* ratios are reduced by a nearly constant factor.

The calculations on a model molecule, R substituted acetone, in correct conformation help to understand the results. The twists, $\theta_{(\pi^*xz)}$, is negative (increasing from Me to Bu^t) for Me, Bu^t, and all conformations of Et and Pr^i, and thus we would expect the *trans* alcohol as the major product. However, the twist, $\theta_{(\pi^*xy)}$, is changing its sign on going from Me to Bu^t, leaning away from the substituent in the case of Me and towards it in the case of Bu^t. The results for the $LiAlH_4$ reduction can be explained on the following basis: the same *trans*/*cis* ratio of alcohols for the unsubstituted and the methyl ketone indicates that the steric interaction between the Me group and the incoming reagent is offset by the preferred lower energy approach from the side of the obtuse angle and away from the Me ($\theta_{(\pi^*xy)}$). The average of the $\theta_{(\pi^*xz)}$ increases for the two likely conformations of the Et group and hence an increase in the *trans* alcohol. There is a further increase in this angle for the single preferred conformation of the Pr^i group which should give considerably increased proportion of the *trans* alcohol. However, the change in sign of the $\theta_{(\pi^*xy)}$ twist now increases the steric interaction between the substituent and the incoming reagent and thus reduces the effect of the $\theta_{(\pi^*xz)}$ twist. The increase in the $\theta_{(\pi^*xz)}$ for Bu^t group is very small but the change in $\theta_{(\pi^*xy)}$ towards the substituent quite large, generating a big steric interaction with the approaching reagent; this leads to a dramatic decrease of the *trans* alcohol.

Perhaps the most revealing is the recent kinetic study of this system using the bulky $LiAl(OBu^t)_3H$ (14). It can be seen (Fig. 4) that the rate of reaction gradually decreases (relative to H when $\theta_{(\pi^*xz)} = 0$) for the *cis* alcohols, i.e. an approach from opposite side to the substituent. This must mean that the energy of the transition state increases as the angle of attack becomes more acute on going from R = H to Bu^t. The fact that the rates for the *syn* attack, leading to *trans* alcohols, for Me, Et, and Pr^i are all identical, means that there is a balancing effect between the increasing obtuse angle, which should lower the transition state energy (twist $\theta_{(\pi^*xz)}$), and the increasing steric interaction between the substituent and the incoming reagent (twist $\theta_{(\pi^*xy)}$), which should increase the energy. In these cases, they just balance. It is now possible to predict that the rate profile for the reduction of this system with $LiAlH_4$ should be virtually identical for the *anti* approach by the reagent. However, all the rates for

the *syn* approach would be faster, i.e. raised, so that the rates for the *syn* and *anti* approach for R = Me coincide.[3]

The steric effect of substituents is one of the basic concepts used by organic chemists in rationalising, and sometimes predicting, the outcome in reactions. Our calculations shed some light on its subtle changes which may arise as a consequence of a substitution in other parts of a molecule, e.g. in the *anti*-π-substituted camphors, which result in a change of the twist angles at the reaction centre. Similarly, we would like to suggest that the "buttressing effect" (7) which is responsible for a larger rate reduction of the attack from the *endo* side camphor relative to the norbornanone-2 is the consequence of the change in $\theta_{(\pi^*xz)}$. Our present work should also adequately account for the recently proposed anisotropic inductive effect (14) of alkyl groups.[4]

Another effect which is often invoked in reductions is electrostatic repulsion of the substituent (18) — our calculations have shown this to be unimportant in the substituted adamantanones. In fact, we predict that 3-chlorobicyclo[2:2:2]-

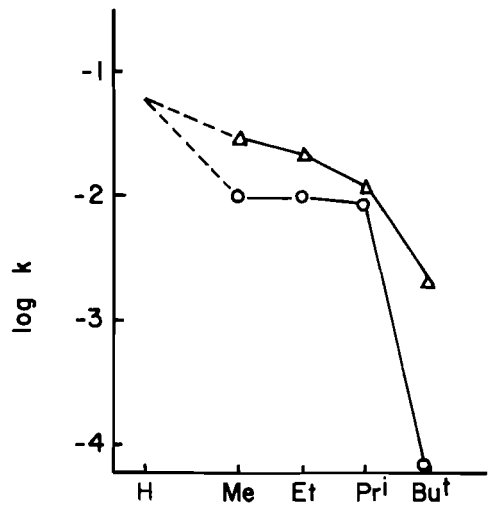

FIG. 4. log (rate) (○) for the formation of the *trans* alcohols and log (rate) (△) for the formation of the *cis* alcohols as a function of the substituent R in the reduction of 3-substituted bicyclo[2:2:2]octan-2-one with $LiAl(OBu^t)_3H$.

[3]Our calculations on the optical activity of the 3-alkylbicyclo[2:2:2]octan-2-ones indicate again a rough correspondence between the reduction and the magnitude of the Cotton effect — the Bu^t groups should behave anomalously in terms of the strict application of Octant Rule (15, 16).

[4]We have also carried out calculations on 4 ax-substituted adamantanones but the results did not warrant experimental product study unless detailed rate study was undertaken as well. The twists (reported as $\theta_{(\pi^*xz)}$, $\theta_{(\pi^*xy)}$) for F and Cl were 7; −11 and 10; −19 respectively, indicate a preference for the formation of the axial alcohol (with respect to the cyclohexane that carries the axial F and Cl). In terms of the rate studies, we would expect the rate of formation of the diaxial alcohol to be accelerated relative to half the rate of reduction of adamantanone, as would have been predicted on the basis of the inductive effect of an electron-withdrawing substituent (17). The twists of 4 ax-methyladamantanone were −3; 7 — these allow us to predict larger amounts of the diaxial alcohol at a retarded rate on the basis of the arguments already presented, again as might be predicted on the basis of an inductive effect of an electron donating substituent (17).

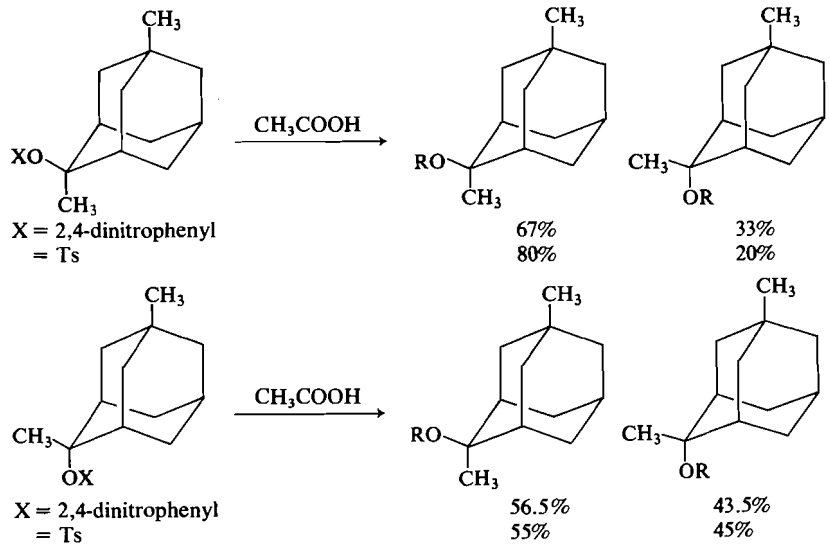

FIG. 5. Solvolysis of 2,5-dimethyladamantyl-2-(leaving group).

octanone-2 should give *trans* alcohol as the major product. On the other hand, the fact that the phenyl group leads to predominantly *cis* alcohol on reduction of 3-phenylbicyclo[2:2:2]octanone-2 (13) is mainly due to its restricted rotation — the balance between the favoured *syn* attack (negative $\theta_{(\pi^*xz)}$) is more than offset by the twist (negative $\theta_{(\pi^*xy)}$) that leads to steric hindrance to the approach. When such rotational restriction is removed, as in 2-phenylindanone-1 (13) or 1-phenylindanone-2 (13), the *trans* alcohol is the major isomer observed.[5]

Our preliminary investigations show that the application of the twist principle can be of help in other reactions, such as solvolysis. It was reported that both isomers of 2,5-dimethyladamantyl-2-(leaving group) (19) give more of the *cis* product on solvolysis (Fig. 5). This means that the compound with the *trans* leaving group solvolyses, under pseudo S_N1 conditions, with more inversion and the *cis* compound largely with retention of configuration. The same result is obtained in the methanolysis of the two epimeric 2-chloro-2-ethynyl-5-phenyladamantanes (20) — both give the same mixture of methoxy compounds (Fig. 6). The calculations on 5-methyl and 5-phenyl-2-adamantyl cation show a small $\theta_{(\pi^*xz)}$ twist towards the substituent (Me, − 1.5; Ph, − 3, which varies in magnitude but not in sign when the phenyl group is rotated). This result could be interpreted in terms of the involvement of solvent-separated ion-pairs which collapse into the product preferentially from the side of the obtuse angle, i.e. *cis* to the substituent.

Previous calculation on the reduction of ketones (2*b*) confirmed the experimentally derived conclusion (2*a*) that a nucleophile approaches the carbonyl group from the obtuse angle which varied from ca. 109° to 118° depending on the distance

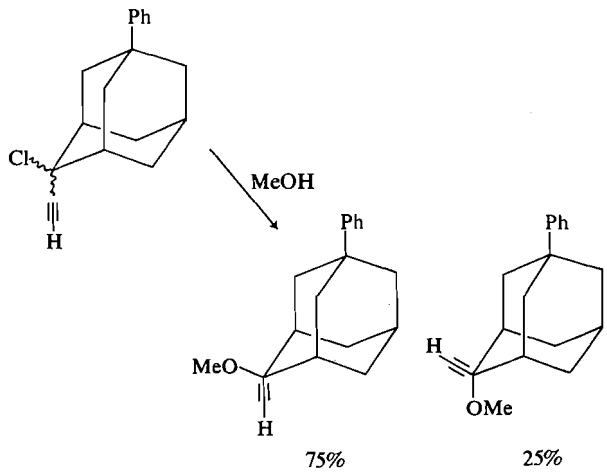

FIG. 6. Methanolysis of the two epimeric 2-chloro-2-ethynyl-5-phenyladamantanes.

[5]It should be pointed out that the twist angles vary not only when an asymmetric substituent X is rotated about the C—X bond but also with the rotation about O=C—C_α bond. Indeed, we find that $\theta_{(\pi^*xz)}$ changes its sign in the region of O=C—C—X dihedral angle of 80° to 100° for many substituents. Thus generalisations of preferred attack of a nucleophile on a carbonyl group in an acyclic system is difficult. The twist $\theta_{(\pi^*xy)}$ in a conformation of minimum energy may hinder the approach of the reagent from the obtuse angle side, thus raising the energy of the transition state to such an extent that a lower energy transition state may be obtained in a conformation of higher energy in which the twist $\theta_{(\pi^*xz)}$ has changed in sign.

between the nucleophile (H^-) and the carbonyl carbon (of formaldehyde). Thus the potential energy surface was evaluated. The stereochemistry of reduction was studied by considering the energy difference between two assumed and geometry unrelaxed reaction complexes some way along a reaction co-ordinate at an optimised angle of approach of 90° (4).

In contrast to these approaches, our calculations involve the evaluation of the twist angles (θ_{π^*}) of a ketone whose carbonyl group is perturbed asymmetrically by a substituent relative to the parent unsubstituted ketone or a suitably substituted analogue). Whilst it is relatively easy to appreciate the usefulness of calculations of the former approach vis-à-vis stereoselectivity and the mechanism of the reaction, it is, as yet, difficult to appreciate that an asymmetric ketone should have information built into its ground state as to how stereoselectively it will react with certain nucleophiles. Such an approach raises several questions that we will attempt to answer.

Perhaps the most important question is whether the twist approach has any physical significance and if so, how it governs the stereoselectivity. Extensive calculations on selected ketones have shown that the twist angles relate to the electron density distribution about an atom. The three dimensional shape of the electron density of the three 2*p* bonding electrons for the carbonyl carbon (2*s* electron has been omitted because of its spherical contribution) shows a flattening on the two diastereotopic sides which in turn have small indentations in them, representing a decrease in electron density — in effect small electron deficient wells. These indentations move relative to one another when the orientation (or position) of the substituent attached to the parent ketone is altered; the twist angles represent their relative positions with respect to the C—O bond.[6] Thus a nucleophile approaches the carbonyl carbon aiming for one of the electron deficient wells, preferably the one that is further away from the electron-rich oxygen in order to minimize the electrostatic repulsion.

The electron density distortion observed above is very similar to an early rationalisation for the reduction of cyclohexanones (3) based on orbital interactions. It was suggested that the π-electron density of the C=O bond is dissymmetrically distributed on the two faces because of the dissymmetric interaction with the α axial hydrogens on one side and the "axial" C_α—C_β bonds. This was later confirmed by more sophisticated calculations (21).

The next question that needs to be answered is the question of reaction rates. The calculations show quite clearly that net electron-withdrawing substituents (e.g. F) lower the energy of the LU molecular orbital of the C=O, resulting in an increased rate of reduction (17), whilst net electron-donating substituents (e.g. Me and other alkyl groups) hardly effect the LUMO energy or slightly raise it and hence decrease the rate of reaction (17) (the change is conformationally dependent). It is thus difficult at the moment to decide how much of the experimentally observed rate changes can be ascribed to the change in the LUMO energy (which should affect both diastereotopic sides of the carbonyl groups equally) and how much to the change in the twist angles. This aspect was investigated by another set of calculations on asymmetric ketones by bending the oxygen of the carbonyl group out of the plane. It was found that when the bending (up to 2° out of the plane) was in the direction that resulted in the decrease of the obtuse angle $\theta_{(\pi^*xz)}$, the ground state energy rose much more steeply than when the bending was in opposite direction (i.e. an increase in the obtuse angle). In some cases a small decrease in energy was observed which suggests that strongly perturbed carbonyl groups need not necessarily be strictly coplanar with the α-carbon atoms. Such experimental evidence is currently difficult to abstract from the X-ray crystallographic literature. Similar relaxations of molecular geometry were observed in carbonium ions (22). This would suggest that for any given partially bonding distance between the carbonyl carbon and the nucleophile, there will be more rehybridisation at lower energy cost when the nucleophile approaches from the obtuse angle side. Taken to limit, the transition state resulting from attack at an obtuse angle should be slightly more product-like irrespective of the final diastereoisomeric product distribution.

Another question of importance to organic chemists must be whether the twist angle approach is applicable not only to reductions with complex metal hydrides but also to other addition reactions to the carbonyl group. In order to classify the reagents, we have carried out calculations on protonated ketones and found that the twist angles of the protonated species are very different from those obtained on the corresponding ketones. Furthermore, the twist angles are different for ketones that do not contain a vertical plane of symmetry and that

[6]The same electron density distortion is observed on the oxygen of chiral ketones. This distortion, measured by $-(\theta_n - \theta_{\pi^*})$ is proportional to the rotatory strength of the $n \rightarrow \pi^*$ transition (5). Thus it must represent the direction as well as the relative magnitude of the electric transition moment.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

are protonated from either side. We therefore conclude that any reactants, such as Grignard reagents, aluminium alkoxides, etc. that co-ordinate first to the carbonyl oxygen, will produce quite different stereoselectivity than those which add directly. Thus we do not distinguish between $NaBH_4$, $LiAlH_4$, modified complex hydrides, KCN (23), etc. Although the details of the mechanism of reduction of ketones with complex metal hydrides have yet to be fully established, it is beginning to be accepted that the transition state in sodium borohydride reductions has considerably more product developed character than the lithium aluminium hydride one (1). Our calculations do not tell us anything about it. The relative changes in the ratio of the products (with respect to H as a substituent) may arise partly to the changing steric requirements of the reagents and partly to their different degree of "hardness" (24), as has already been suggested (4).

Finally there is a question how the twist angles arise. This happens when *p* orbital on an atom mixes into itself a small amount of character from a second *p* orbital on the same atom, even though they are mutually orthogonal. Such mixing is possible when these two orthogonal orbitals can interact simultaneously with orbital on another atom; this phenomenon takes place extensively in aliphatic systems. Orbital mixing analyses have been performed on a number of systems in order to gain a better understanding of various chemical processes (25–27) and have been generalised in an Orbital Mixing Rule (27). The twist angles represent a simple way of evaluating the extent of orbital mixing both in magnitude and sign. We have attempted the orbital mixing analyses on our systems in order to derive some rules for predicting the twists; unfortunately, we have failed so far in this instance, even though we were quite successful in deriving rules for the prediction of the optical activity of chiral ketones (5) without recourse to the Octant Rule (15), which has sometimes failed to predict the correct absolute configuration (28). The same lack of predictability applies to the suggestion that the π electron density on the diastereotopic faces of a cyclohexanone is unequal (3) as has already been pointed out (29). We therefore hope that these simple semiempirical MO calculations will soon be utilised by practising organic chemists as they will not only help to rationalise many unexpected results,[7] but will also predict them.

Our work in this area strongly indicates that the twist approach can rationalise, and put on a semiquantitative basis, the recently proposed "Approach Vector Analysis" to stereoselectivity (31). It can also rationalise many other stereochemical outcomes of various reactions in which the effect of a differently oriented substituent has hitherto been explained in terms of opposing or reinforcing dipole–dipole and steric interactions (32). The twist angle approach will also be extremely useful in rationalising some aspects of chiral discrimination (33), in particular enantiomeric (34) and diastereomeric interactions — in the latter case, the application of the twist angle approach is obvious.

Experimental

General Procedure

The ketones (0.5 m*M*) were dissolved in a solvent (2 mL; Et_2O or MeOH), cooled to 0°C and the reducing agent (1 m*M* equiv.) added. The reactions were allowed to stand overnight at 0°C and worked up in the usual way (saturated aq. Na_2SO_4 for $LiAl(OBu^t)H$ and $LiAlH_4$ and aq. AcOH for $NaBH_4$). The worked up reaction solutions were then analysed by glc. The solvents were evaporated and changed to $CDCl_3$ for the nmr analyses. ^1H nmr spectra were run on Varian HA-100 or XL-100. The chemical shifts are quoted in ppm from TMS (internal); s = singlet, d = doublet, t = triplet, q = quartet, dt = double triplet, dq = double quartet. All J_{HF} coupling constants were confirmed by F decoupling.

[7]For further example of an identical problem, see ref. 30*a*. Our understanding of our own CNDO/2 calculations on norbornene differs slightly from the interpretation of the explanation that is given in ref. 27 (ref. 3 of the above publication). The π electron density, which is equal on both *exo* and *endo* sides of the double bond, is concentrated into a smaller volume of space on the *exo* side. This can be seen from the θ_π twists (i.e. the $p\sigma$ components of the C_2—C_3 σ bond mix into the π system with such phasing as to create twists on C_2 and C_3 which tend to parallel C_1—C_7 and C_4—C_7 bonds respectively). We also observe from the twist angles, θ_π, that the *exo*-π electron density is tilted towards the C_7 bridge. The consequence of this latter tilt is that the energy minimizes when the hydrogens attached to the double bond are bent down (towards the ethano bridge — energy minimum at 3.9–4.0) and then rises again. The energy rises quite steeply on bending towards the C_7 bridge. The bending was carried out only in a plane perpendicular to the plane of the double bond — we have not examined the energy change when the hydrogens are at the same time pushed together. The less energy demanding rehybridisation in the *endo*-direction (for the C_2 and C_3 hydrogens), a consequence of orbital mixing, does account, in our opinion, not only for the preferential *exo*-addition of norbornene (also norbornyl cation) but also for the enhanced rates in cases when the reaction is controlled by HO(diene)/LU(norbornene) or LU(diene)/HO(norbornene) interactions. (θ_{π^*} is tilted away from the C_7 bridge, on the other side of the symmetry plane of the double bond with a very slightly more concentrated "electron hole" on the *exo*-side.) Bach *et al.* (30*b*) also reach the same conclusions in different systems.

Received July 22, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

KYOICHI A. WATANABE, AKIRA MATSUDA, and TSUNEO ITOH. Can. J. Chem. **59**, 468 (1981).

Pentopyranine B and D, pentopyranosylcytosine nucleosides elaborated by *Streptomyces griseochromogenes*, have been synthesized from the common intermediate, methyl 4-*O*-benzoyl-3-deoxy-3-iodo- β-D-xylopyranoside (**1**). The synthetic products, 1-(2,3-dideoxy-β-D-*glycero*pentopyranosyl)cytosine (**18**) and 1-(3-deoxy-β-D-*erythro*pentopyranosyl)cytosine (**7**) were identical with the natural products, pentopyranine B and D, respectively.

KYOICHI A. WATANABE, AKIRA MATSUDA et TSUNEO ITOH. Can. J. Chem. **59**, 468 (1981).

Utilisant le *O*-benzyl-4 déoxy-3 iodo-3 β-D-xylopyrannoside de méthyle (**1**) comme intermédiaire commun, on a synthétisé les pentopyranines B et D, des nucléosides du type pentopyrannosylcytosine, élaborées par les *Strepstomyces griseochromogenes*. Les produits synthétiques (didéoxy-2,3 β-D-*glycéro*pentopyrannosyl)-1 cytosine (**18**) et (déoxy-3 β-D-*érythro*pentopyrannosyl)-1 cytosine (**7**) sont respectivement identiques aux produits naturels pentopyranine B et D.

[Traduit par le journal]

Nine nucleosides (Fig. 1) were isolated by Seto *et al.* (see ref. 1) from the culture filtrate of *Streptomyces griseochromogenes* during their studies on the biosynthesis of the important nucleoside antibiotic, blasticidin S, a potent antifungal agent against rice blast disease (2). The structures of pentopyranine A and C were proposed (3) as 1-(2,3-dideoxy-α-L-*glycero*pentopyranosyl)cytosine and 1-(3-deoxy-α-L-*threo*pentopyranosyl)-cytosine, respectively, and were confirmed by total syntheses (4, 5). Pentopyranine E, F, and G were identified by direct comparison with the known nucleosides, 1-(α-L-arabinopyranosyl)cytosine (6), 1-(β-D-xylopyranosyl)cytosine (6), and 1-(β-D-glucopyranosyl)cytosine (7), respectively. The total syntheses of pentopyranic acid (8) and pentopyranamine D (9), which is the nucleoside moiety of blasticidin H (10), have also been achieved. This report describes the total syntheses of the two remaining nucleosides, pentopyranine B and D (11).

The starting material for the syntheses of both pentopyranine B and D was methyl 4-*O*-benzoyl-3-deoxy-3-iodo-β-D-xylopyranoside (**1**) which was obtained in 7 steps from D-arabinose by the method

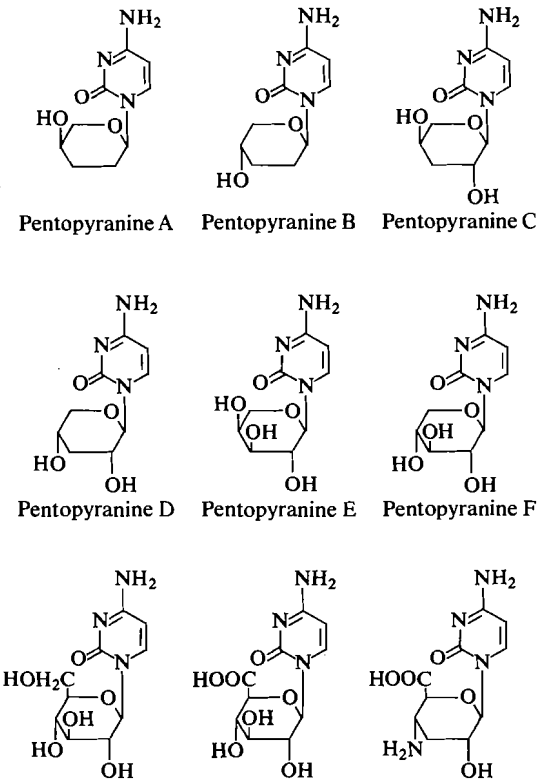

FIG. 1.

reported for the preparation of the β-L-counterpart by Lemieux *et al.* (12). Acetylation of the iodohydrin afforded the crystalline acetate **2**. Hydrogenation of **2** over Pd/C gave a product which was contaminated with considerable amounts of 2,3- and 3,4-dideoxysugars (13). However, reduction of **1** gave the corresponding 3-deoxysugar (**3**) which was acetylated to give the crystalline methyl 2-*O*-acetyl-4-*O*-benzoyl-3-deoxy-β-D-*erythro*pentopyranoside (**4**) in good yield. Compound **4** was treated with HBr/HOAc to give the corresponding glycosyl bromide (**5**) which was then condensed with trimethylsilylated N4-anisoylcytosine (5) to afford the crystalline protected nucleoside **6**. Deacylation of **6** with NaOMe/MeOH afforded the corresponding free nucleoside **7**, which was identical with the natural product, pentopyranine D.

The synthesis of pentopyranine B was achieved as follows: selective de-*O*-acetylation of **6** was achieved by treatment with HCl/MeOH, and the crystalline product **8** was mesylated to give the 2-*O*-mesylate **10**. Treatment of **10** with NaOMe under various conditions, however, did not afford the desired anhydronucleoside **13**, but always gave an intractable mixture. Compound **8** was, therefore, deaminated with aqueous HOAc to give the uracil nucleoside **11**. Compound **11** could also be prepared by condensation of the bromosugar **5** with trimethylsilylated uracil followed by de-*O*-acetylation of the protected nucleoside **9**. Mesylation of **11**, and subsequent base treatment of the mesylate **12**, afforded the desired 2,2′-anhydronucleoside **14** in good yield. Treatment of **14** with HBr–DMF complex in tetrahydrofuran gave the 2′-bromo-2′-deoxynucleoside **15**. Reductive debromination of **15** with *n*-Bu_3SnH (14) afforded the 2′,3′-dideoxy derivative **16**. Thiation of **16** with P_4S_{10} in dioxane and amination of the 4-thio nucleoside **17** with NH_3/MeOH gave the free cytosine nucleoside **18**, which exhibited identical uv, ir, and ^1H nmr spectral properties as those of the natural product, pentopyranine B.

Experimental

Microanalyses were performed by Galbraith Laboratories, Inc., Knoxville, TN, or by Spang Microanalytical Laboratory, Eagle Harbor, MI. Melting points were determined on a Thomas-Hoover capillary apparatus and are uncorrected. The ^1H nmr spectra were obtained on a Jeol PFT-100 spectrometer with Me_4Si as the internal standard for organic solvents and $Me_3Si(CH_2)_3SO_3Na$ for D_2O; chemical shifts are reported in parts per million (δ), and signals are quoted as s (singlet), d (doublet), t (triplet), q (quartet), or m (multiplet); *J* values are first order. Infrared spectra were recorded on a Perkin-Elmer Infracord using pressed KBr pellets.

Methyl 2-O-Acetyl-4-O-benzoyl-3-deoxy-3-iodo-β-D-xylopyranoside (2)

Compound **1** (21.3 g, 0.056 mol, prepared from D-arabinose according to Lemieux *et al.* (12)) was acetylated in pyridine (210 mL) with Ac_2O (15 mL). After 3 h the reaction mixture was diluted with CH_2Cl_2 (450 mL), MeOH (50 mL), and water (500 mL). The organic layer was washed with water (2 × 500 mL), dried (Na_2SO_4), and evaporated *in vacuo*. The residue was crystallized from EtOH to give 23 g (97%) of **2**, mp 105–106°C; ^1H nmr ($CDCl_3$) δ: 2.13 (3H, s, CH_3CO), 3.49 (3H, s, OCH_3), 3.44 (1H, q, H-5a, $J_{5a,5e}$ = 11.9, $J_{4,5a}$ = 8.3 Hz), 4.23 (1H, t, H-3, $J_{3,4} = J_{2,3}$ = 9.5 Hz), 4.36 (1H, q, H-5e, $J_{5a,5e}$ = 11.9, $J_{4,5e}$ = 3.9 Hz), 4.39 (1H, d, H-1, $J_{1,2}$ = 6.4 Hz), 5.20 (1H, t, H-2, $J_{1,2} = J_{2,3}$ = 6.4 Hz), 5.29 (1H, sextet, H-4, $J_{4,5a}$ = 8.3, $J_{3,4}$ = 8.5, $J_{4,5e}$ = 4.6 Hz), 7.2–8.2 (5H, m, aromatic). *Anal.* calcd. for $C_{15}H_{17}IO_6$: C 42.86, H 4.05, I 30.24; found: C 42.91, H 4.13, I 30.04.

*Methyl 4-O-Benzoyl-3-deoxy-β-D-*erythro*pentopyranoside (3)*

Compound **1** (20 g, 0.053 mol) was hydrogenated over 10% Pd/C (1 g) in EtOAc (250 mL) containing Et_3N (5.3 g). The catalyst was removed by filtration, and the filtrate was washed successively with water, 0.1 *M* $Na_2S_2O_3$, and water (250 mL each), dried (Na_2SO_4), and evaporated to dryness *in vacuo*. The colorless residue 11.8 g (89%) of **3** was sufficiently pure to be used in the next step; ^1H nmr ($CDCl_3$) ($^1C_4$ conformation) δ: 2.10 (1H, m, H-3e, $J_{3a,3e}$ = 14.7, $J_{2,3e} = J_{3e,4}$ = 4.5, $J_{1,3e} = J_{3e,5e}$ = 1.0 Hz), 2.30 (1H, dt, H-3a, $J_{3a,3e}$ = 14.7, $J_{2,3a} = J_{3a,4}$ = 4.00 Hz), 3.48 (3H, s, CH_3O), 3.68 (1.4H, m, H-2 and a part of H-5e), 3.81 (0.6H, q, part of H-5e, $J_{5a,5e}$ = 13.0, $J_{4,5e}$ = 3.4, $J_{3e,5e}$ = 1.8 Hz), 4.07 (1H, q, H-5a, $J_{5a,5e}$ = 13.0, $J_{4,5a}$ = 2.5 Hz), 4.57 (1H, d, H-1, $J_{1,2}$ = 2.7 Hz), 5.16 (1H, quintet, H-4, $J_{4,5a} = J_{4,5e} = J_{3a,4} = J_{3e,4}$ = 3.2 Hz), 7.3–8.2 (5H, m, aromatic).

An analytical sample (syrup) was purified by chromatography on a silica gel G60 column using C_6H_6–EtOAc (9:1) as the eluent. *Anal.* calcd. for $C_{13}H_{16}O_5$: C 61.90, H 6.35; found: C 61.69, H 6.53.

*Methyl 2-O-Acetyl-4-O-benzoyl-3-deoxy-β-D-*erythro*pentopyranoside (4)*

Acetylation of **3** (13 g, 0.052 mol) with Ac_2O (10 mL) in a mixture of CH_2Cl_2 (100 mL) and pyridine (30 mL) gave the acetate **4** which was crystallized from EtOH – *n*-heptane to afford 12.5 g (82%) of pure **4**, mp 66–67°C; ^1H nmr ($CDCl_3$) ($^1C_4$ conformation) δ: 2.01 (3H, s, CH_3CO), 2.27 (2H, m, H-3a,3e), 3.45 (3H, s, CH_3O), 3.73 (1H, dt, H-5e, $J_{5a,5e}$ = 12.8, $J_{4,5e} = J_{3,5e}$ = 2.0 Hz), 4.06 (1H, dd, H-5a, $J_{5a,5e}$ = 12.8, $J_{4,5a}$ = 2.1 Hz), 4.67 (1H, d, H-1, $J_{1,2}$ = 0.5 Hz), 4.80 (1H, quintet, H-4), 5.07 (1H, narrow m, H-2), 7.4–8.2 (5H, aromatic multiplet). *Anal.* calcd. for $C_{15}H_{18}O_6$: C 61.22, H 6.12; found: C 61.07, H 6.37.

*2-O-Acetyl-4-O-benzoyl-3-deoxy-D-*erythro*pentopyranosyl Bromide (5)*

Compound **4** (1.18 g, 4 mmol) was dissolved in 30% HBr/HOAc (10 mL); the mixture was stirred for 2 h at room temperature and partitioned between CH_2Cl_2 (100 mL) and water (50 mL). The organic layer was washed with water (2 × 50 mL), dried (Na_2SO_4), and concentrated to dryness *in vacuo*. Compound **5** was obtained in quantitative yield as a slightly yellow syrup which was not further purified but used directly in the next step.

*1-(2-O-Acetyl-4-O-benzoyl-3-deoxy-β-D-*erythro*pentopyranosyl)-N4-anisoylcytosine (6)*

$SnCl_4$ (0.7 mL, 6 mmol) was added to a mixture of the above bromo sugar **5** and crude N4,O2-bis(trimethylsilyl)-N4-anisoylcytosine (prepared from 1.47 g (6 mmol) of N4-anisoylcytosine (5)) in dry CH_2ClCH_2Cl (25 mL). The mixture was stirred at room temperature for 1 h, and then heated at 60°C for 20 min. The mixture was diluted with CH_2Cl_2 (25 mL) and poured into saturated $NaHCO_3$ (100 mL); the suspension was passed through a Celite pad. The filtrate was washed (water), dried (Na_2SO_4), and evaporated to dryness *in vacuo*. The residue was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

crystallized from EtOH to give 879 mg (43.2%) of **6**, mp 240–242°C; ^{1}H nmr ($CDCl_3$) δ: 2.02 (3H, s, CH_3CO), 2.06 (1H, q, H-3′a, $J_{3'a,3'e} = J_{2',3'a} = J_{3'a,4'} = 11.6$ Hz), 2.75 (1H, m, H-3′e), 3.65 (1H, t, H-5′a, $J_{5'a,5'e} = J_{4',5'a} = 10.7$ Hz), 3.89 (3H, s, CH_3O), 4.37 (1H, dd, H-5′e, $J_{5'a,5'e} = 10.7$, $J_{5'e,4} = 5.2$ Hz), 5.36–4.69 (2H, m, 10 lines, H-2′,4′), 6.00 (1H, d, H-1′, $J_{1',2'} = 9.5$ Hz), 6.99 (1H, d, H-5, $J_{5,6} = 8.8$ Hz), 8.08–7.37 (6H, m, benzoyl and H-6), 8.58 (1H, broad s, NH). *Anal.* calcd. for $C_{26}H_{25}N_3O_8$: C 61.53, H 4.97, N 8.28; found: C 61.36, H 4.97, N 8.13.

*1-(3-Deoxy-β-D-*erythro*pentopyranosyl)cytosine (7)*

A suspension of **6** (177 mg, 0.35 mmol) in absolute MeOH (20 mL) was treated with 1 *N* NaOMe (1 mL). The reaction mixture was stirred overnight at room temperature and then neutralized with Amberlite IRC-50 (H^+). The resin was removed by filtration, and the filtrate was evaporated to dryness *in vacuo*. The residue was dissolved in water (20 mL) and extracted with $CHCl_3$ (2 × 20 mL). The aqueous phase was evaporated *in vacuo* to dryness. The residue was crystallized from MeOH–Et_2O to give 66.5 mg (84%) of **7**, mp 255–257°C (dec.) (lit. (11), mp 261°C (dec.)). A mixture mp with the natural sample was unchanged; ^{1}H nmr (DMSO-d_6) δ: 1.41 (1H, dd, H-3′a, $J_{2',3'a} = J_{3'a,3'e} = J_{3'a,4'} = 10.7$ Hz), 2.20 (1H, m, H-3′e), 3.06 (1H, t, H-5′a, $J_{5'a,5'e} = J_{4',5'a} = 9.0$ Hz), 3.70 (3H, m, H-2′, 4′, 5′e), 5.03 (2H, broad s, dissociable, 2′- and 4′-OH), 5.28 (1H, d, H-1′, $J_{1',2'} = 9.2$ Hz), 5.68 (1H, d, H-5, $J_{5,6} = 7.5$ Hz), 7.14 (2H, broad s, NH_2), 7.53 (1H, d, H-6, $J_{5,6} = 7.5$ Hz). The ^{1}H nmr spectrum taken in concentrated DCl was identical with that of the natural sample supplied by Dr. Seto.

*1-(4-O-Benzoyl-3-deoxy-β-D-*erythro*pentopyranosyl)-N4-anisoylcytosine (8)*

A solution of **6** (254 mg, 0.5 mmol) in 3% HCl/MeOH (50 mL) was stirred for 6 h at room temperature and then the mixture was stored at 4°C for 3 days. The solvent was removed *in vacuo* and the residue dried by several azeotropic distillations with EtOH. The residue was crystallized from EtOH to give 189 mg (81%) of **8**, mp 229–230°C; ^{1}H nmr (DMSO-d_6) δ: 1.85 (1H, q, H-3′a, $J_{2',3'a} = J_{3'a,3'e} = J_{3'a,4'} = 11.2$ Hz), 2.50 (1H, m, H-3′e), 3.56 (1H, t, H-5′a, $J_{4',5'a} = J_{5'a,5'e} = 10.4$ Hz) 3.84 (3H, s, CH_3O), 4.00 (1H, m, H-2′), 4.13 (1H, m, H-5′e), 5.21 (2H, m, H-4′ and 2′-OH), 5.58 (1H, d, H-1′, $J_{1',2'} = 9.2$ Hz), 7.05 (1H, d, H-5, $J_{5,6} = 8.9$ Hz), 7.31–8.26 (10H,m, aromatic and H-6). *Anal.* calcd. for $C_{24}H_{23}N_3O_7$: C 61.93, H 4.98, N 9.03; found: C 61.81, H 5.00, N 8.91.

*1-(4-O-Benzoyl-3-deoxy-2-O-mesyl-β-D-*erythro*pentopyranosyl)-N4-anisoylcytosine (10)*

A cold (0°C) solution of **8** (233 mg, 0.5 mmol) in dry pyridine (5 mL) was treated with MsCl (0.12 mL, 1.5 mmol). After 2 h, the mixture was poured into an ice–water mixture (100 mL). The precipitate was collected and washed with water and EtOH to give 261 mg (96%) of **10**, mp 155–157°C; ^{1}H nmr (DMSO-d_6) δ: 2.26 (1H, q, H-3′a, $J_{2',3'a} = J_{3'a,3'e} = J_{3'a,4'} = 11.9$ Hz), 2.81 (1H, m, H-3′e), 3.15 (3H, s, CH_3SO_2), 3.79 (1H, t, H-5′a, $J_{4',5'a} = J_{5'a,5'e} = 10.7$ Hz), 3.85 (1H, s, CH_3O), 4.22 (1H, dd, H-5′e, $J_{4,5e} = 4.8$, $J_{5'a,5'e} = 10.7$ Hz), 5.26 (2H, m, H-2′,4′), 5.99 (1H, d, H-1′, $J_{1',2'} = 8.9$ Hz), 7.05 (1H, d, H-5, $J_{5,6} = 8.9$ Hz), 8.32–7.36 (10H, m, aromatic and H-6), 11.18 (1H, broad s, NH). *Anal.* calcd. for $C_{25}H_{25}N_3O_9S$: C 55.24, H 4.64, N 7.73, S 5.90; found: C 55.03, H 4.53, N 7.68, S 6.04.

*1-(2-O-Acetyl-4-O-benzoyl-3-deoxy-β-D-*erythro*pentopyranosyl)uracil (9)*

A room temperature solution of **5** (prepared from 1.89 g, 6.43 mmol of **4**) and 2,4-bis(trimethylsilyloxy)pyrimidine (prepared from 1.08 g of uracil) in dry CH_2ClCH_2Cl (50 mL) was treated with $SnCl_4$ (0.53 mL, 4.5 mmol). After 3 h, saturated $NaHCO_3$ solution (100 mL) was added to the mixture, and the resulting suspension was filtered through a Celite pad. The filtrate was washed with water, dried (Na_2SO_4), and evaporated to dryness *in vacuo*. The residue was dissolved in $CHCl_3$ and placed on a column of silica gel G60 (4 × 31 cm), and the column was washed successively with $CHCl_3$ (500 mL), 0.5% EtOH in $CHCl_3$ (500 mL), and 1% EtOH in $CHCl_3$ (1000 mL). Compound **9** was obtained from the last fraction and was crystallized from EtOH to give 1.2 g (50%), mp 190–191°C; ^{1}H nmr ($CDCl_3$) δ: 2.04 (3H,s, CH_3CO), 2.07 (1H, q, H-3′a, $J_{2',3'a} = J_{3'a,3'e} = J_{3'a,4'} = 11.6$ Hz), 2.76 (1H, m, H-3′e), 3.63 (1H, t, H-5′a, $J_{4',5'a} = J_{5'a,5'e} = 10.7$ Hz), 4.33 (1H, ddd, $J_{5'a,5'e} = 10.7$, $J_{4',5'e} = 5.2$, $J_{3'e,5'e} = 2.0$ Hz), 5.08 (2H, m, H-2′, 4′), 5.73 (1H, d, H-1′, $J_{1',2'} = 9.2$ Hz), 5.81 (1H, dd, H-5, $J_{5,6} = 8.2$, $J_{5,NH} = 2.1$ Hz), 7.26–8.07 (6H, m, aromatic and H-6). *Anal.* calcd. for $C_{18}H_{18}N_2O_7$: C 57.75, H 4.85, N 7.48; found: C 57.52, H 4.95, N 7.35.

*1-(4-O-Benzoyl-3-deoxy-β-D-*erythro*pentopyranosyl)uracil (11)*

A mixture of **9** (450 mg, 1.2 mmol) in 3% HCl/MeOH (50 mL) was stirred at room temperature for 4.5 h and then evaporated to dryness *in vacuo*. The residue was coevaporated several times with EtOH until colorless crystals were obtained. The crystals were collected by suction filtration and washed with Et_2O to give 352 mg (88%) of **11**, mp 235–238°C; ^{1}H nmr ($CDCl_3$ – DMSO-d_6 4:1) δ: 1.86 (1H, q, H-3′a, $J_{2',3'a} = J_{3'a,3'e} = J_{3'a,4'} = 11.8$ Hz), 2.58 (1H, m, H-3′e) 3.53 (1H, t, H-5′a, $J_{4',5'a} = J_{5'a,5'e} = 10.4$ Hz), 3.81 (1H, m, H-2′), 4.23 (1H, m, H-5′e), 4.97 (1H, m, H-4′), 5.43 (1H, d, H-1′, $J_{1',2'} = 9.2$ Hz), 5.66 (1H, d, H-5, $J_{5,6} = 8.2$ Hz), 7.47–8.03 (6H, m, aromatic and H-6), 11.29 (1H, broad s, NH). *Anal.* calcd. for $C_{16}H_{16}N_2O_6$: C 57.83, H 4.85, N 8.43; found: C 57.81, H 4.85, N 8.38.

*1-(4-O-Benzoyl-3-deoxy-2-O-mesyl-β-D-*erythro*pentopyranosyl)uracil (12)*

A cold (0°C) solution of **11** (352 mg, 1.06 mmol) in dry pyridine (5 mL) was treated with MsCl (0.25 mL). After 3 h, the mixture was poured into an ice–water mixture, and the precipitate was collected and crystallized from EtOH to give **12** (391 mg, 90%), mp 158–159°C; ^{1}H nmr ($CDCl_3$) δ: 2.18 (1H, q, H-3′a, $J_{2',3'a} = J_{3'a,3'e} = J_{3'a,4'} = 11.0$ Hz), 2.90 (1H, m, H-3′e), 3.02 (3H, s, CH_3SO_2), 3.65 (1H, t, H-5′a, $J_{4',5'a} = J_{5'a,5'e} = 11.0$ Hz), 4.36 (1H, ddd, H-5′e, $J_{5'a,5'e} = 11.0$, $J_{4',5'e} = 5.3$, $J_{3'e,5'e} = 2.4$ Hz), 4.82 (1H, octet, H-2′, $J_{1',2'} = 8.9$, $J_{2',3'a} = 11.0$, $J_{2',3'e} = 5.2$ Hz), 5.23 (1H, 7 lines, H-4′, $J_{4',5'a} = 11.0$, $J_{4',5'e} = J_{3'e,4'} = 5.3$ Hz), 5.78 (1H, d, H-1′, $J_{1',2'} = 8.9$ Hz), 5.85 (1H, dd, H-5, $J_{5,6} = 8.4$, $J_{5,NH} = 2.1$ Hz), 7.27–8.07 (6H, m, H-6 and aromatic). *Anal.* calcd. for $C_{17}H_{18}N_2O_8S$: C 49.75, H 4.42, N 6.83, S 7.81; found: C 49.86, H 4.35, N 6.75, S 7.79.

*2,2′-Anhydro-1-(4-O-benzoyl-3-deoxy-β-D-*threo*pentopyranosyl)uracil (14)*

A suspension of **12** (511 mg, 1.25 mmol) in dry MeCN (100 mL) was treated with 1,8-diazabicyclo[5,4,0]undec-7-ene (0.25 mL, 1.6 mmol). The mixture was heated at reflux for 1 h and then cooled to room temperature. The solvent was removed *in vacuo*, and the residue was crystallized from EtOH to give 370 mg (94.4%) of **14**, mp 199–203°C; ^{1}H nmr ($CDCl_3$) δ: 2.23 (1H, octet, H-3′ down, $J_{3'down,\ 3'up} = 15.0$, $J_{2',3'down} = 7.9$, $J_{3'down,4'} = 3.7$ Hz), 2.99 (1H, octet, H-3′up, $J_{3'down,\ 3'up} = 15.0$, $J_{2',3'up} = 3.7$, $J_{3'up,4'} = 7.3$ Hz), 3.90 (2H, m, H-5′, 5″), 5.13–5.33 (2H, m, H-2′,4′), 5.89 (1H, d, H-1′, $J_{1',2'} = 6.1$ Hz), 6.11 (1H, d, H-5, $J_{5,6} = 7.6$ Hz), 7.26–8.09 (6H, m, H-6 and aromatic). *Anal.* calcd. for $C_{16}H_{14}N_2O_5$: C 61.15, H 4.49, N 8.91; found: C 61.23, H 4.40, N 8.84.

*1-(4-O-Benzoyl-2-bromo-2,3-dideoxy-β-D-*erythro*pentopyranosyl)uracil (15)*

A mixture of DMF–HBr complex (230 mg) and **14** (104 mg, 0.33 mmol) in dry THF (10 mL) was heated at reflux for 40 min. The solvent was removed *in vacuo*, and the residue was dissol-

For personal use only.

ved in a small volume of THF and spotted on 2 sheets of glass plates (20 × 20 cm) coated with silica gel PF_{254} which were then developed in $CHCl_3$–EtOH (170:7). The major band was removed and extracted with EtOAc. After evaporation of the solvent, compound **15** (110 mg, 84%) was obtained as colorless crystals, mp 201–202°C; ^{1}H nmr ($CDCl_3$) δ: 2.34 (1H, q, H-3′a, $J_{2',3'a} = J_{3'a,3'e} = J_{3'a,4'} = 11.5$ Hz), 3.12 (1H, m, H-3′e), 3.73 (1H, t, H-5′a, $J_{4',5'a} = J_{5'a,5'e} = 11.5$ Hz), 4.08 (1H, octet, H-2′, $J_{1',2'} = 9.5$, $J_{2',3'a} = 11.5$, $J_{2',3'e} = 4.6$ Hz), 4.38 (1H, ddd, H-5′e, $J_{5'a,5'e} = 11.5$, $J_{4',5'e} = 5.2$, $J_{3'e,5'e} = 2.4$ Hz), 5.16 (1H, 7 lines, H-4′, $J_{3'e,4'} = J_{4',5'e} = 5.2$, $J_{3'a,4'} = J_{4',5'a} = 11.5$ Hz), 5.82 (2H, 2 doublets for H-1′ and H-5, $J_{1',2'} = 9.5$ Hz), 7.22–8.06 (6H, m, H-6 and aromatic). *Anal.* calcd. for $C_{16}H_{15}BrN_2O_5 \cdot 0.5H_2O$: C 47.54, H 3.98, Br 19.77, N 6.93; found: C 47.75, H 3.74, Br 19.75, N 6.85.

1-(4-O-Benzoyl-2,3-dideoxy-β-D-glycero-pentopyranosyl)uracil (16)

A mixture of **15** (271 mg, 0.69 mmol), *n*-Bu_3SnH (0.24 mL, 0.9 mmol), and 2,2′-azobis(2-methylpropionitrile) (~10 mg) in dry MeCN (40 mL) was heated under reflux for 5 h. The solvent was removed *in vacuo*, and the residue was crystallized from EtOH to give 191 mg of **16** (88%), mp 188–190°C; ^{1}H nmr ($CDCl_3$) δ: 1.79–2.20 (3H, m, H-2′a,2′e,3′a), 2.39 (1H, m, H-3′e), 3.63 (1H, t, H-5′a, $J_{4',5'a} = J_{5'a,5'e} = 10.7$ Hz), 4.31 (1H, ddd, H-5′e, $J_{5'a,5'e} = 10.7$, $J_{4',5'e} = 4.9$, $J_{3'e,5'e} = 2.1$ Hz), 5.09 (1H, m, H-4′), 5.72 (1H, q, H-1′, $J_{1',2'a} = 8.6$, $J_{1',2'e} = 2.0$ Hz), 5.80 (1H, q, H-5, $J_{5,6} = 8.2$, $J_{5,3NH} = 2.0$ Hz), 7.38–8.07 (6H, m, H-6 and benzoyl), 8.60 (1H, broad s, 3NH). *Anal.* calcd. for $C_{16}H_{16}N_2O_5$: C 60.75, H 5.10, N 8.85; found: C 60.66, H 5.18, N 8.76.

1-(4-O-Benzoyl-2,3-dideoxy-β-D-glycero-pentopyranosyl)-4-thiouracil (17)

To a stirred suspension of **16** (158 mg, 0.5 mmol) in dry dioxane (20 mL) was added P_4S_{10} (200 mg), and the mixture was heated under reflux for 45 min. A second charge of P_4S_{10} (100 mg) was added and the mixture refluxed for a further 45 min. The solvent was removed *in vacuo*, the residue extracted with $CHCl_3$ (10 mL), and the extract placed on a column of silica gel G60 (2.4 × 13 cm). The column was washed with $CHCl_3$, the uv absorbing fractions collected and evaporated, and the residual yellow powder purified by preparative tlc (20 × 20 cm glass plate coated with silica gel PF_{254}, C_6H_6–EtOAc 6:1 system) to give 58 mg of **17** which was sufficiently pure to be used directly in the next step.

1-(2,3-Dideoxy-β-D-glycero-pentopyranosyl)cytosine (18)

Compound **17** (58 mg, 0.17 mmol) was dissolved in saturated NH_3/MeOH (3 mL) in a test tube which was sealed and heated at 100°C for 36 h in a steel container. The yellow mixture was concentrated to dryness, the residue extracted with $CHCl_3$, and then crystallized from EtOH to afford 16 mg (43%) of **18**, mp 233–234°C (lit. (11) mp 241°C). When this compound was admixed with a sample of the natural product, no depression of melting point was observed; ^{1}H nmr (DMSO-d_6) δ: 1.49–1.78 (3H, m, H-2′a,2′e,3′a), 2.04 (1H, m, H-3′e), 3.16 (1H, t, H-5′a, $J_{4',5'a} = J_{5'a,5'e} = 9.9$ Hz), 3.54 (1H, m, H-4′), 3.87 (1H, m, H-5′e), 4.92 (1H, d, 4′OH), 5.48 (1H, m, H-1′), 5.69 (1H, d, H-5, $J_{5,6} = 7.5$ Hz), 7.14 (2H, broad s, NH_2), 7.57 (1H, d, H-6, $J_{5,6} = 7.5$ Hz). The ^{1}H nmr spectrum of this sample taken in concentrated DCl was identical with that of pentopyranine B supplied by Dr. Seto. The ir spectrum (KBr) of the synthetic compound **18** was not identical to that of the natural product. An approximately 10:1 mixture of the natural product and synthetic **18** gave an ir spectrum which was identical to that of the synthetic product. The reverse (an approximately 1:10 mixture of the natural product and synthetic **18**) did not alter the ir spectrum of the synthetic product.

Acknowledgements

The authors are indebted to Dr. Jack J. Fox for his warm and continued interest and encouragement. They also wish to thank Professor Haruo Seto of the Institute of Applied Microbiology, the University of Tokyo, for samples of pentopyranine B and D and the ir and ^{1}H nmr spectra of these natural products.

Reçu le 26 juin 1980

Ce papier et dédié au Prof. Raymond U. Lemieux à l'occasion de son 60ème anniversaire

J. M. LACOMBE, A. A. PAVIA et J. M. ROCHEVILLE. Can. J. Chem. **59**, 473 (1981).

La réaction à froid, dans le dichlorométhane ou l'acétonitrile, d'un dérivé benzylé d'un monosaccharide réducteur avec un hydroxyaminoacide convenablement protégé, en présence d'anhydride trifluorométhanesulfonique comme agent de condensation conduit avec un rendement variant entre 55 et 90% au mélange des *O*-glycosylaminoacides dans lequel les anomères α sont prépondérants. Les α et β *O*-D-galactosyl, D-glucosyl, D-xylosyl-et L-arabinosyl-L-sérine, -L-thréonine et -L-hydroxyproline ont été ainsi obtenus purs par cristallisation ou chromatographie sur colonne. Leur structure et leur stéréochimie s'appuient essentiellement sur la rmn du ^{13}C.

J. M. LACOMBE, A. A. PAVIA, and J. M. ROCHEVILLE. Can. J. Chem. **59**, 473 (1981).

When 2,3,4,6-tetra-*O*-benzyl-D-glucopyranose, -D-galactopyranose and 2,3,4-tri-*O*-benzyl-D-xylopyranose were allowed to react in the cold in dichloromethane or acetonitrile as solvent in the presence of trifluoromethanesulfonic (triflic) anhydride, with methyl or benzyl esters of the *N*-(benzyloxycarbonyl)-L-serine, -L-threonine, and -L-hydroxyproline, an anomeric mixture of the corresponding *O*-glycosylaminoacids was obtained (55 to 90% overall yield), with the α-anomer being predominant. The same experimental procedure was successfully applied to the condensation of the benzyl ester of the *N*-(benzyloxycarbonyl)-L-hydroxyproline with 2,3,4-tri-*O*-benzyl-L-arabinopyranose and 2,3,5-tri-*O*-benzyl-L-arabinofuranose affording the corresponding condensation products with similar yield. Pure α and β anomers were obtained after column chromatography or crystallization with 30 to 65% yield. Hydrogenolysis of benzyl derivatives afforded the unprotected compounds. Optical rotation, ^1H and ^{13}C nmr were the main methods used to assess structure and stereochemistry.

Introduction

La nature de la jonction entre la copule glucidique et le squelette peptidique constitue un des aspects essentiels de la chimie et de la biochimie des glycoprotéines et protéoglycanes. Les deux types de liaisons rencontrées diffèrent par leurs propriétés chimiques, leur stabilité vis-à-vis des bases en particulier (1). La liaison *N*-glycosidique entre le 2-acétamido-2-désoxy-β-D-glucopyranose et la L-asparagine, mise en évidence pour la première fois par Marshall et Neuberger au début des années 60 dans l'ovalbumine et fréquemment trouvée depuis dans un grand nombre de glycoprotéines, est stable en milieu basique. A l'exception de celles impliquant une liaison glycosidique avec l'hydroxylysine et l'hydroxyproline, les *O*-glycoprotéines sont fragiles en milieu basique. La liaison osidique entre le galactose et l'hydroxylysine est présente dans le collagène et les polymères apparentés (1); celle entre la sérine et/ou la thréonine et le 2-acétamido-2-désoxy-α-D-galactose prédomine dans de nombreuses mucoprotéines (1), les substances des groupes sanguins (1, 2), les immunoglobulines (1, 2), les glycoprotéines "antigel" (1, 3), et les glycoprotéines membranaires comme la glycophorine par exemple (1, 4).

Nous avons décrit récemment (5) la synthèse des 3-*O*-(2-acétamido-2-désoxy-α-D-galactopyranosyl)-L-sérine et L-thréonine qui constituent l'unité de base de ces macromolécules. De nombreux autres glycopeptides dans lesquels la sérine et la thréonine sont liés au D-glucose (6), L-fucose (7), D-galactose (8), D-mannose (6, 9, 10) et D-xylose (10) ont été décrits dans les toutes dernières années. Par ailleurs, le D-galactose (11, 12) et le L-arabinose (11, 13) sont présents dans la nature sous la forme de *O*-galactosyl et *O*-arabinosyl-L-hydroxyproline dans certaines glycoprotéines de la paroi des cellules végétales (11, 13).

Il apparait évident qu'une connaissance approfondie des propriétés physiques, chimiques et conformationnelles des glycoprotéines est nécessaire pour mieux apprécier les relations existant entre d'une part leur structure et d'autre part leur métabolisme, leur rôle biologique et leur pathologie (14, 15). Dans cette optique il nous a semblé important de développer une méthode permettant d'accéder à ces glycosylaminoacides et glycopeptides de base.

Résultats et discussion

Nous avons décrit récemment (16) la synthèse en une seule étape des dérivés benzylés du tréhalose et des analogues *galacto*, *manno*, *xylo*, *arabino*, *fructo* par autocondensation des monosaccharides

SCHÉMA 1

appropriés dans le dichlorométhane à froid en présence d'anhydride trifluorométhanesulfonique comme agent de condensation. Nous avons pu montrer que la réaction était du type acido-catalysé et que l'anhydride trifluorométhanesulfonique jouait le double rôle de "source de protons" et de "piège à eau".

Nous avons pu montrer également (16) que si la réaction était conduite en présence d'un excès (3 à 4 moles pour une) d'un hydroxyaminoacide, la réaction d'autocondensation était minimisée au profit de la formation des glycosylaminoacides. Le travail que nous rapportons ici représente la généralisation de l'observation précédente et l'extension de la méthode à la préparation des α et β-*O*-glycosylaminoacides naturels.

La réaction est effectuée dans le dichlorométhane ou dans un mélange dichlorométhane–acétonitrile, à froid, en présence d'anhydride trifluorométhanesulfonique (voir Partie expérimentale). Dans ces conditions, le dérivé benzylé du monosaccharide réducteur réagit en quelques minutes avec un excès de l'hydroxyaminoacide convenablement protégé pour donner avec un bon rendement (55 à 90%) le mélange des deux anomères du *O*-glycosylaminoacide correspondant. La chromatographie du mélange réactionnel sur gel de silice, permet d'une part de séparer les anomères α et β et d'autre part de récupérer la majeure partie de l'aminoacide qui n'a pas réagi.

La condensation des 2,3,4,6-tétra-*O*-benzyl-D-gluco (**1**) et galactopyranose (**2**) avec les esters méthyliques de la *N*-(benzyloxycarbonyl)-L-sérine (**6**), -L-thréonine (**7**) et -L-hydroxyproline (**11**) dans le dichlorométhane entre −70 et 0°C conduit au mélange des *O*-glycosylaminoacides correspondants, dans lequel l'anomère α est toujours prépondérant ou parfois même exclusif. La chromatographie sur colonne de gel de silice, des mélanges réactionnels permet d'isoler les anomères α (**13**, **15**, **17**, **19**, **35** et **37**) purs avec un rendement variant entre 32 et 65%.

En dehors de l'utilisation possible de ces composés comme preuve non ambiguë de structure, ou comme haptène, un des objectifs majeurs de notre travail est l'étude de leurs propriétés conformationnelles en solution aqueuse et à l'état solide.

SCHÉMA 2

Il était donc nécessaire de prévoir des agents protecteurs qui puissent être éliminés facilement. C'est la raison pour laquelle nous avons choisi de protéger la fonction acide par l'ester benzylique. Dans une seconde série d'expériences la condensation a été réalisée entre −20° et +20°C dans un mélange dichlorométhane–acétonitrile. La réaction dure en moyenne 30 minutes et conduit avec un rendement compris entre 70 et 90% au mélange des deux anomères. C'est ainsi qu'ont été condensés les esters benzyliques des *N*-(benzyloxycarbonyl)-L-sérine (**8**) et -L-thréonine (**9**) avec les monosaccharides **1**, **2** et **3** pour conduire aux glycosylaminoacides correspondants de configuration α (**21**, **23**, **25**, **27**, **29** et **31**) et β (**22**, **24**, **26**, **28**, **30** et **32**) obtenus purs après chromatographie sur colonne avec des rendements variant entre 30 et 50% pour les anomères α, 30 et 40% pour les anomères β.

D'autre part, l'ester benzylique de la *N*-(benzyloxycarbonyl)-L-hydroxyproline (**12**) a été condensé selon le même protocole expérimental avec le 2,3,4,-tri-*O*-benzyl-L-arabinopyranose (**4**) pour donner les produits de condensation de configuration β-L- (**39**) et α-L- (**40**). Dans le cas du 2,3,5-tri-*O*-benzyl-L-arabinofuranose (**5**), seul l'anomère α-L- (**41**) a été isolé (rdt. 55%).[2]

[2]Le pouvoir rotatoire fortement négatif et la position du carbone anomère sont en faveur du composé de configuration α-L. Depuis l'envoi de ce manuscrit, nous avons pu synthétiser le β-L-arabinofuranosyl-L-hydroxyproline caractérisé en rmn du ^{13}C par δ(C-1) 100,90 ppm au lieu de 107,30 pour l'anomère α (voir Tableau 1).

Dans l'optique d'un allongement éventuel de la chaîne peptidique du côté C-terminal de l'aminoacide nous avons vérifié que la condensation pouvait être réalisée avec des aminoacides "activés" comme montré précédemment (18). Les esters *O*-nitrophénoliques de la *N*-(benzyloxycarbonyl)-3-*O*-(2,3,4,6-tétra-*O*-benzyl-D-glucopyranosyl)-L-thréonine α (**33**) et β (**34**) ont pu être obtenus de cette façon.

La déprotection est effectuée en une seule étape par hydrogénation du composé protégé en présence de palladium sur charbon dans le mélange éthanol–eau – acide acétique (17). Nous avons obtenu de façon quantitative les composés *O*-D-glucopyranosyl-L- thréonine α (**42**) et β (**43**), *O*-D-glucopyranosyl-L-sérine α (**46**) et β (**47**), *O*-D-galactopyranosyl-L-thréonine α (**44**) et β (**45**), *O*-D-galactopyranosyl-L-sérine α (**48**) et β (**49**), *O*-D-xylopyranosyl-L-thréonine α (**50**) et β (**51**), *O*-D-

SCHÉMA 4

xylopyranosyl-L-sérine α (**52**) et β (**53**) et α-L-arabinofuranosyl-L-hydroxyproline (**54**) à partir des composés **21–32** et **41**.

La structure et la stéréochimie des composés décrits dans ce travail s'appuient fondamentalement sur les pouvoirs rotatoires, la rmn du proton et du ^{13}C. Le tableau 1 en résume les données essentielles.

L'examen des valeurs rapportées dans le tableau 1 appelle plusieurs commentaires.

(*1*). Pour les composés protégés (**13** à **41**), la stéréochimie de la liaison glycosidique est facilement déterminée à partir des déplacements chimiques des carbones anomères. Il faut noter néanmoins que la différence de déplacement chimique qui est en moyenne de 5 ppm pour les dérivés de la sérine ou de l'hydroxyproline n'est plus que de 3 ppm pour ceux de la thréonine. Dans ces derniers les C-1 dans la configuration β sont blindés d'environ 2,5 ppm par rapport à ceux de leurs homologues de la sérine ou de l'hydroxyproline.

(*2*). Parallèlement, le déplacement chimique du méthyl de la thréonine est très sensible à la stéréochimie de la liaison glycosidique et on observe une différence remarquablement constante de 1,5 ppm entre les deux valeurs. Le CH_3 des anomères β est blindé par rapport à ceux des anomères α, y compris dans les produits déprotégés **42–45** et **50–51**. Etant donné le petit nombre de groupements qui absorbent entre 10 et 20 ppm (voir le cas de la glucoamylase (6) par exemple), le méthyl de la thréonine pourrait servir de *sonde* et être d'une *aide considérable* dans l'étude des glycoprotéines pour (*i*) distinguer les résidus thréonine non glycosylés ($\delta CH_3 = 20,3$ ppm pour la thréonine) de ceux qui sont liés à des chaînes oligosaccharidiques ($\delta CH_3 < 19,3$ ppm); (*ii*) parmi ces derniers, identifier et doser ceux qui sont liés à la chaîne peptidique par des liaisons α ($\delta CH_3 \simeq 19,1$ ppm) et β ($\delta CH_3 \simeq 17,5$ ppm).

(*3*). La comparaison des valeurs relatives aux composés déprotégés semble montrer que (*i*) la position des carbones anomères de configuration β varie très peu après déprotection: 100,8 ppm pour **43** au lieu de 101,0, 101,5 et 101,3 dans **16**, **24** et **34**; 101,3 ppm pour **45** au lieu de 102,02 dans **20** et **28**; (*ii*) par contre, la déprotection s'accompagne d'un déblindage du carbone α d'environ 3 ppm. Il en résulte des déplacements chimiques extrêmement voisins entre les dérivés α (**42**, **44**, **50**) et les dérivés β (**43**, **45**, **51**); (*iii*) dans la mesure où cette observation peut être extrapolée aux spectres ^{13}C rmn de glycoprotéines natives, il apparait peu raisonnable d'utiliser les valeurs des déplacements chimiques des carbones anomères pour préciser la nature des monosaccharides liés à la protéine et la stéréochimie de la jonction entre la partie saccharidique et le squelette peptidique.

(*4*). Il faut enfin signaler que les dérivés de la L-hydroxyproline (**35–41**) présentent un dédoublement de certains signaux. Ce phénomène n'est pas le résultat d'une racémisation survenue lors de la condensation, puisque la *N*-(benzyloxycarbonyl)-L-hydroxyproline (**A**) possède un azote tertiaire qui interdit la formation de l'oxazolone intermédiaire. Par ailleurs, l'absence de racémisation est confirmée par le fait que (*i*) le dédoublement des signaux apparait déjà dans le composé **A** et s'accentue dans l'ester méthylique de la *N*-(benzyloxycarbonyl)-L-hydroxyproline (**B**); (*ii*) l'hydrogénolyse de **A** conduit à la L-hydroxyproline dont le spectre du ^{13}C rmn et le pouvoir rotatoire sont identiques à ceux du produit de départ; (*iii*) le pouvoir rotatoire $[\alpha]_D^{22} -71°$ et le point de fusion pf 106°C de **A** sont identiques à ceux rapportés dans la littérature (23). Ces valeurs sont fondamentalement différentes de celles données pour la D-allo ($[\alpha]_D^{22} +26,5°$) et L-allothréonine ($[\alpha]_D^{22} -23,7°$).

L'explication la plus plausible est celle d'un ralentissement de la vitesse d'inversion de l'atome d'azote intracyclique avec le remplacement de l'atome d'hydrogène. Le ralentissement a comme conséquence première une augmentation du temps

[a]Tous les spectres des composés protégés **13** à **41** ont été enregistrés dans le chloroforme-*d*, avec le TMS comme référence interne; ceux des composés **42** à **47** dans l'oxyde de deutérium avec comme référence interne le dioxane dont la position par rapport au TMS a été prise égale à 67,4 ppm.
[b]Voir le texte pour l'origine du dédoublement des signaux dans les dérivés de la L-hydroxyproline.

de vie des deux conformères possibles qui deviennent observables par rmn.

Partie expérimentale

Méthodes générales

Le déroulement des réactions ainsi que l'homogénéité des composés décrits ont été contrôlés par chromatographie sur couche mince (ccm) de gel de silice (Merck F 254, Merck, Darmstadt, Allemagne), la révélation des plaques étant assurée par vaporisation d'une solution 10% d'acide sulfurique suivie du chauffage à 100°C. Les purifications ont été réalisées par chromatographie sur colonne de gel de silice (Merck 60). Les points de fusion ont été mesurés sur appareil Tottoli et sont rapportés non corrigés. Les pouvoirs rotatoires ont été mesurés sur un micro polarimètre Jobin-Yvon 11230. Les microanalyses ont été effectuées par le Service Central de Microanalyse du C.N.R.S., division de Montpellier. Les spectres de rmn ^1H ont été enregistrés à 80 MHz sur un appareil Bruker WP 80; sauf indications particulières ils ont été réalisés dans le chloroforme-*d* et les déplacements chimiques sont donnés en δ par rapport au tétraméthylsilane pris comme référence interne. Les spectres de rmn ^{13}C ont été enregistrés sur un appareil Bruker WP 80 à 20,115 MHz, les déplacements chimiques sont exprimés par rapport au tétraméthylsilane en référence interne. Dans le cas des solutions aqueuses, le déplacement chimique du dioxane utilisé comme référence est de 67,4 ppm.

Les 2,3,4,6-tétra-*O*-benzyl-D-glucopyranose (**1**), galactopyranose (**2**), 2,3,4-tri-*O*-benzyl-D-xylopyranose (**3**) et L-arabinopyranose (**4**) ont été préparés selon la technique de Koto *et al.* (19). Le 2,3,5-tri-*O*-benzyl-L-arabinofuranose (**5**) a été préparé selon le protocole expérimental décrit par Glaudemans et Fletcher (19). Les produits ont été purifiés par recristallisation ou chromatographie sur colonne de gel de silice et leurs caractéristiques physiques conformes à celles rapportées dans la littérature. Les dérivés méthylés **6**, **7**, **11** et benzylés **8**, **9**, **12**, des *N*-(benzyloxycarbonyl)-L-sérine, -L-thréonine et -L-hydroxyproline ont été préparés par les méthodes classiques (20–23) et leurs propriétés physiques conformes à celles rapportées (24–28). L'ester *O*-nitrophénylique de la *N*-(benzyloxycarbonyl)-L-thréonine (**10**) a été préparé selon la méthode de Bodansky *et al.* (29) et est conforme à celui décrit précédemment (18).

Conditions générales de glycosylation

Aucune condition particulière n'est à prendre concernant l'anhydricité des solvants et réactifs.

Première variante (utilisée pour la synthèse des composés **13–19**, **35–38**)

Le monosaccharide benzylé et l'aminoacide *N* et *C* protégé (2 à 3 mol par mol de monosaccharide) sont dissous dans le dichlorométhane (environ 15 mL pour 6 mmol de réactif) et la solution est refroidie à −70°C. A cette solution refroidie est ajouté l'anhydride trifluorométhanesulfonique en une seule fois de sorte que la proportion des réactifs dans le milieu réactionnel soit approximativement de 1,5 équivalents d'anhydride par mole de sucre. Le mélange ci-dessus est maintenu pendant cinq minutes à la température de −70°C puis le vase réactionnel est sorti du bain. On laisse la température revenir vers la température ambiante en suivant la disparition du monosaccharide benzylé en chromatographie couche mince. Lorsque la réaction est terminée (généralement de 10 à 25 min) le vase réactionnel est plongé dans le bain à −70°C et le mélange repris par l'eau puis extrait par du chloroforme, de l'éther ou du dichlorométhane. La phase organique est lavée par une solution d'hydrogénocarbonate de sodium, de l'eau jusqu'à neutralité, séchée sur sulfate de sodium et le solvant évaporé sous vide. Le produit brut est obtenu sous forme d'une huile que l'on purifie par chromatographie sur colonne de gel de silice (solvant B).

Seconde variante (utilisée pour la synthèse de tous les esters benzyliques)

L'aminoacide *N* et *C* protégé (4 mmol) est dissous dans l'acétonitrile (30 mL). A cette solution refroidie à −20°C est ajouté l'anhydride trifluorométhanesulfonique (1,5 mmol). Au mélange ci-dessus on additionne goutte à goutte la solution du monosaccharide benzylé (1 mmol) dans le dichlorométhane (10 mL) pendant environ 15 min, puis le vase réactionnel est sorti du bain froid et laissé réagir jusqu'à ce que le contrôle en ccm (solvant A) montre la disparition totale du monosaccharide (environ 30 min). Le mélange réactionnel est ensuite traité comme précédemment et le produit brut chromatographié (solvant B) ou recristallisé; le lavage de la colonne par du méthanol permet de récupérer 75 à 85% de l'aminoacide en excès.

Solvants utilisés pour la chromatographie; solvant A: chloroforme–éther, 90:10, v/v; solvant B: chloroforme–éther, 96:4, v/v.

Ester méthylique de la N-*(benzyloxycarbonyl)*-O-*(2,3,4,6-tétra*-O-*benzyl-D-glucopyranosyl)-L-sérine : α (13) et β (14)*

A une solution de Z-Ser-OMe (**6**) (1,020 g, 4 mmol) et de tétrabenzylglucose (**1**) (1,080 g, 2 mmol) dans le dichlorométhane (15 mL) refroidie à −70°C est ajouté l'anhydride trifluorométhanesulfonique (0,5 mL, 3 mmol). Après 15 min à température ambiante le mélange réactionnel est traité puis chromatographié sur gel de silice (250 g). L'élution par le solvant B donne une huile (0,87 g, 55%) qui est un mélange de deux anomères (2 spots en ccm, solvant A). Le composé **13** cristallise dans un mélange éther/éther de pétrole (0,500 g, 31,5%); pf 79–80°C; $[\alpha]_D^{22}$ +32 (*c* 1,7, $CHCl_3$); ^1H rmn: 4,72 (d, $J_{1,3}$ = 3,9 Hz, (H-1)), 3,51 (q, $J_{1,2}$ = 3,9 Hz, $J_{2,3}$ = 10 Hz, (H-2)), 5,97 (*J* = 9 Hz, (N—H)); ^{13}C rmn: 170,43 (CO ester), 156,11 (CO uréthane), 98,67 (C-1), 71,00 (C-5), 54,70 (C-α-Ser), 52,52 (CH_3 ester). *Anal.* calc. pour $C_{46}H_{49}N$: C 71,22, H 6,32, N 1,80; trouvée: C 70,90, H 6,34, N 1,85.

Les liqueurs mères de recristallisation contiennent un mélange de **13** et de son anomère β (**14**) dont le spectre ^{13}C est caractérisé par un signal à 103,85 (C-1) et 54,62 (C-α-Ser).

Ester méthylique de la N-*(benzyloxycarbonyl)*-O-*(2,3,4,6-tétra*-O-*benzyl-D-glucopyranosyl)-L-thréonine : α (15) et β (16)*

A une solution de Z-Thr-OMe (**7**) (1,068 g, 4 mmol) et de tétrabenzyl glucose (**1**) (1,080 g, 2 mmol) dans le dichlorométhane refroidie à −70°C est ajouté l'anhydride trifluorométhanesulfonique (0,5 mL, 3 mmol). Après 20 min à température ambiante le mélange réactionnel est traité puis chromatographié sur gel de silice (250 g) élué par le solvant B. Le composé **15** est obtenu pur (1,0 g, 64%) sous forme d'un solide blanc qui cristallise dans un mélange éther/éther de pétrole: pf 86–88°C; $[\alpha]_D^{22}$ +25,3 (*c* 1,8, $CHCl_3$); ^1H rmn: 4,85 (d, $J_{1,2}$ = 3,6 Hz, (H-1)), 3,43 (q, $J_{1,2}$ = 3,6 Hz, $J_{2,3}$ = 9 Hz, (H-2)), 4,36 (m, $J_{\alpha,\beta}$ = 7,2 Hz, (H-β-thr)), 4,32 (q, $J_{\alpha\text{-NH}}$ = 8,7 Hz, (H-α-thr)); ^{13}C rmn: 171,23 (CO ester), 156,84 (CO uréthane), 98,04 (C-1), 79,19 (C-β-thr), 71,13 (C-5), 68,54 (C-3), 67,13 (CH_2-benzyloxycarbonyl), 59,07 (C-α-thr), 52,38 (CH_3 ester), 19,07 (CH_3-thr).

Le spectre de rmn du produit contenu dans les liqueurs de recristallisation montre un signal à 101,0 (C-1), 59,0 (C-α-thr) et 17,63 (CH_3-thr).

Ester méthylique de la N-*(benzyloxycarbonyl)*-O*(2,3,4,6-tétra*-O-*benzyl-D-galactopyranosyl)-L-sérine: α (17) et β (18)*

A une solution de Z-Ser-OMe (**6**) (1,020 g, 4 mmol) et de tétrabenzyl galactose (**2**) (0,540 g, 1 mmol) dans le dichlorométhane (10 mL) refroidie à −70°C est ajouté l'anhydride trifluorométhanesulfonique (0,25 mL, 1,5 mmol). Après 5 minutes à −70°C le mélange réactionnel est sorti du bain et laissé

revenir à température ambiante (10 min). Le contrôle en chromatographie sur couche mince (solvant A) montre que le tétrabenzyl galactose a complètement réagi. Après traitement, l'huile obtenue (0,650 g, 80%)[3] est chromatographiée sur gel de silice (100 g), éluée par le solvant B. Deux fractions correspondant respectivement à l'anomère α (0,390 g, 45%) et au mélange d'anomères α et β (0,205 g, 30%) sont récupérées.

La première fraction cristallise dans un mélange éther/éther de pétrole pour donner **17**, pf 70–72°C; ^{13}C rmn: 170,50 (CO ester), 156,11 (CO uréthane), 99,44 (C-1), 54,6 (C-α-Ser), 52,38 (CH_3 ester).

Dans la deuxième fraction l'anomère β (**18**) est identifié par son spectre ^{13}C rmn: 170,89 (CO ester), 156,16 (CO uréthane), 104,46 (C-1), 54,4 (C-α-Ser), 52,43 (CH_3 ester).

Ester méthylique de la N-*(benzyloxycarbonyl)*-O-*(2,3,4,6-tétra*-O-*benzyl-*D*-galactopyranosyl)-*L*-thréonine: α (19) et* β *(20)*

A une solution de Z-Thr-OMe (**7**) (0,80 g, 3 mmol) et de tétrabenzyl galactose (**2**) (0,54 g, 1 mmol) dans le dichlorométhane (10 mL) refroidie à −70°C est ajouté l'anhydride trifluorométhanesulfonique (0,25 mL, 1,5 mmol). Après 5 minutes à −70°C et 20 min à température ambiante, le composé **2** a complètement disparu (ccm, solvant A). Le mélange réactionnel est traité et l'huile obtenue après évaporation (0,68 g, 90%) est chromatographiée sur gel de silice (150 g) éluée par le solvant B.

On obtient ainsi trois fractions correspondant respectivement à l'anomère α **19** (0,380 g, 49%), au mélange α et β (**19** et **20**) (0,121 g, 15%) et au composé β **20** (0,135 g, 17%). *Composé 19*: $[\alpha]_D^{22}$ +26,14 (*c* 1,075, $CHCl_3$); ^{13}C rmn: 171,17 (CO ester), 156,8 (CO uréthane), 98,27 (C-1), 58,60 (C-α-thr), 52,33 (CH_3 ester), 19,07 (CH_3-thr). *Anal.* calc. pour $C_{47}H_{51}N$: C 71,41, H 6,46; trouvée: C 70,64, H 6,35. *Composé 20*: $[\alpha]_D^{22}$ +0,257 (*c* 1,66, $CHCl_3$); ^{13}C rmn: 170,9 (CO ester), 156,7 (CO uréthane), 102,27 (C-1), 58,9 (C-α-thr), 52,33 (CH_3 ester), 17,90 (CH_3-thr).

Ester benzylique de la N-*(benzyloxycarbonyl)*-O-*(2,3,4,6-tétra*-O-*benzyl-*D*-glucopyranosyl)-*L*-sérine: α (21) et* β *(22)*

A une solution de Z-Ser-OBzl (**8**) (1,31 g, 4 mmol) dans l'acétonitrile (30 mL) refroidie à −20°C on ajoute 0,25 mL (1,5 mmol) d'anhydride trifluorométhanesulfonique. On additionne peu à peu (20 min) le tétrabenzyl glucose (**1**) (0,54 g, 1 mmol) en solution dans le dichlorométhane (10 mL) et le vase réactionnel est sorti du bain froid. Après 50 min **1** a disparu (ccm solvant A) et on traite le mélange réactionnel. L'huile obtenue est chromatographiée sur gel de silice (éluant B). On obtient trois fractions (rdt. global 0,75 g, 88%). La première fraction contient l'anomère α (**21**) (0,4 g, 48%) sous forme d'huile. La seconde fraction contient un mélange des anomères α et β (0,035 g, 4%). La troisième fraction contient l'anomère β (**22**) (0,31 g, 36%) qui cristallise. Le lavage de la colonne au méthanol permet de récupérer 80% (0,78 g) de l'excès d'aminoacide. *Composé* **21**: $[\alpha]_D^{22}$ +33 (*c* 1,1, $CHCl_3$); ^{1}H rmn: 6,05 (d, *J* = 8,5 Hz (NHCbz)); 7,25 (30H, C_6H_5); ^{13}C rmn: 170,1 (CO ester), 156,2 CO uréthane), 98,78 (C-1), 54,70 (C-α-Ser). *Anal.* calc. pour $C_{52}H_{53}O_{10}N$: C 73,32, H 6,22, N 1,64; trouvée: C 72,85, H 6,57, N 1,70. *Composé 22*: pf 80–81°C (éther – éther de pétrole); $[\alpha]_D^{22}$ +16,3 (*c* 0,55, $CHCl_3$); ^{1}H rmn: 7,25 (30H, C_6H_5), 5,75 (d, *J* = 6,3 Hz (NHCbz)); ^{13}C rmn: 170,0 (CO ester), 156,1 (CO uréthane), 103,9 (C-1), 69,7 (C-β-Ser), 68,8 (C-6), 54,62 (C-α-Ser).

Ester benzylique de la N-*(benzyloxycarbonyl)*-O-*(2,3,4,6-tétra*-O-*benzyl-*D*-glucopyranosyl)-*L*-thréonine: α (23) et* β *(24)*

A une solution de Z-Thr-OBzl (**9**) (1,38 g, 4 mmol) dans l'acétonitrile (30 mL) refroidie à −20°C, on ajoute 0,25 mL (1,5 mmol) d'anhydride trifluorométhanesulfonique. On additionne peu à peu (15 min) à la solution précédente le composé **1** (0,54 g, 1 mmol) dans le dichlorométhane (10 mL). Après la fin de l'addition on sort le vase réactionnel à température ambiante et on contrôle l'évolution par ccm (solvant A). Après traitement le mélange réactionnel est chromatographié sur gel de silice (solvant B). On obtient ainsi trois fractions: la première (0,380 g, 44%) sous forme d'huile correspond à l'anomère α (**23**), la deuxième (0,040 g, 5%) est un mélange des anomères α et β, la troisième (0,32 g, 37%) sous forme d'huile correspond à l'anomère β (**24**). *Composé 23*: $[\alpha]_D^{22}$ +40 (*c* 0,4, $CHCl_3$); ^{1}H rmn: 1,2 (d, *J* = 6 Hz (CH_3-thr)), 5,75 (d, *J* = 8,5 Hz (NH-Cbz)), 7,15 (30H, C_6H_5); ^{13}C rmn: 180,67 (CO ester), 155,4 (CO uréthane), 98,03 (C-1), 59,44 (C-α-thr), 19,16 (CH_3-thr). *Anal.* calc. pour $C_{53}H_{55}O_{10}N$: C 73,52, H 6,35, N 1,61; trouvée: C 73,35, H 6,55, N 1,44. *Composé 24*: $[\alpha]_D^{22}$ +14,5 (*c* 0,53, $CHCl_3$); ^{1}H rmn: 1,2 (d, *J* = 6 Hz (CH_3-thr)), 5,65 (d, *J* = 8,5 Hz (NH-Cbz)), 7,1 (30H, C_6H_5); ^{13}C rmn: 170,3 (CO ester), 155,6 (CO uréthane), 101,5 (C-1), 59,26 (C-α-thr), 17,6 (CH_3-thr).

Ester benzylique de la N-*(benzyloxycarbonyl)*-O-*(2,3,4,6-tétra*-O-*benzyl-*D*-galactopyranosyl-*L*-sérine: α (25) et* β *(26)*

A une solution de Z-Ser-OBzl (**6**) (1,31 g, 4 mmol) dans l'acétonitrile (30 mL) refroidie à −20°C sont ajoutés l'anhydride trifluorométhanesulfonique (0,25 mL, 1,5 mmol) puis lentement (15 min) le composé **2** (0,54 g, 1 mmol) en solution dans le dichlorométhane (10 mL). Trente minutes après avoir sorti le ballon du bain froid le composé **2** a disparu (ccm, éluant A). Après traitement habituel et chromatographie de l'huile résiduelle sur colonne (éluant B) on obtient trois fractions: l'anomère α **25** (0,34 g, 40%), un mélange des deux anomères α et β (0,13 g, 15%) et l'anomère β (**26**) (0,34 g, 40%). Le composé **6** est récupéré (0,8 g, 80%) par lavage de la colonne au méthanol. *Composé 25*: $[\alpha]_D^{22}$ +21 (*c* 1,1, $CHCl_3$); ^{1}H rmn: 6,15 (d, *J* = 8,5 Hz (NH-Cbz)), 7,25 (30H, C_6H_5); ^{13}C rmn: 170,19 (CO ester), 156,36 (CO uréthane), 99,65 (C-1), 69,03 (C-6), 55,07 (C-α-Ser). *Anal.* calc. pour $C_{52}H_{53}O_{10}N$: C 73,32, H 6,22, N 1,64; trouvée: C 73,68, H 6,26, N 1,48. *Composé 26*: $[\alpha]_D^{22}$ +5,2 (*c* 1,2, $CHCl_3$); ^{1}H rmn: 5,95 (d, *J* = 8,5 Hz (NH-Cbz)), 7,25 (30H, C_6H_5); ^{13}C rmn: 170,01 (CO ester), 156,32 (CO uréthane), 104,35 (C-1), 68,71 (C-6), 54,84 (C-α-Ser).

Ester benzylique de la N-*(benzyloxycarbonyl)*-O-*(2,3,4,6-tétra*-O-*benzyl-*D*-galactopyranosyl)-*L*-thréonine: α (27) et* β *(28)*

A une solution de Z-Thr-OBzl (**7**) (1,38 g, 4 mmol) dans l'acétonitrile (30 mL) refroidie à −20°C sont ajoutés 0,25 mL, 1,5 mmol d'anhydride trifluorométhanesulfonique et une solution de **2** (0,54 g, 1 mmol) dans le dichlorométhane (10 mL). Après 40 min traitement habituel et chromatographie, le composé **27** est obtenu sous forme d'huile (0,44 g, 50%) ainsi que le composé **28** (0,260 g, 30%). *Composé 27*: $[\alpha]_D^{22}$ +29 (*c* 2,8, $CHCl_3$); ^{1}H rmn: 1,3 (d, *J* = 6 Hz (CH_3-thr)), 6,0 (d, *J* = 8,5 Hz (NH-Cbz)), 7,3 (30H, C_6H_5); ^{13}C rmn: 170,78 (CO ester), 158,8 (CO uréthane), 98,55 (C-1), 59,36 (C-α-thr), 19,11 (CH_3-thr). *Anal.* calc. pour $C_{53}H_{55}O_{10}N$: C 73,52, H 6,35, N 1,61; trouvée: C 72,71, H 6,49, N 1,53. *Composé 28*: $[\alpha]_D^{22}$ −5,5 (*c* 1,8, $CHCl_3$); ^{1}H rmn: 1,25 (d, *J* = 6 Hz (CH_3-thr)), 5,85 (d, *J* = 8 Hz (NH-Cbz)), 7,3 (30H, C_6H_5); ^{13}C rmn: 170,42 (CO ester), 157,5 (CO uréthane), 102,02 (C-1), 59,22 (C-α-thr), 17,52 (CH_3-thr).

Ester benzylique de la N-*(benzyloxycarbonyl)*-O-*(2,3,4-tri*-O-*benzyl-*D*-xylopyranosyl)-*L*-sérine: α (29) et* β *(30)*

A une solution de Z-Ser-OBzl (**6**) (1,32 g, 4 mmol) dans l'acétonitrile (30 mL) refroidie à −20°C on ajoute 0,25 mL (1,5 mmol) d'anhydride trifluorométhanesulfonique, puis la solution de **3** (0,42 g, 1 mmol) dans le dichlorométhane (10 mL). Après disparition de **3** (20 min) traitement habituel et

[3]Dans tout ce qui suit le rendement global ainsi exprimé correspond en fait à celui obtenu après séparation de l'excès d'aminoacide, par chromatographie.

For personal use only.

chromatographie on obtient les composés **29** (0,220 g, 30%) et **30** (0,220 g, 30%) sous forme de solides ainsi qu'un mélange de **29** et **30**. Après une nouvelle chromatographie des fractions en mélange la quantité totale de composés α est de (0,338 g, 45%) et β (0,27 g, 37%). *Composé 29*: pf 105–106°C ($CHCl_3$ – éther de pétrole); $[\alpha]_D^{22}$ +41 (*c* 1,4, $CHCl_3$); ^1H rmn: 5,8 (d, *J* = 8,5 Hz (NH-Cbz)), 7,3 (25H, C_6H_5); ^{13}C rmn: 170,14 (CO ester), 156,6 (CO uréthane), 98,32 (C-1), 54,86 (C-α-Ser). *Composé 30*: pf 76–78°C (éther-éther de pétrole); $[\alpha]_D^{22}$ +9 (*c* 1,1, $CHCl_3$); ^1H rmn: 5,62 (d, *J* = 8,2 Hz (NH-Cbz)), 7,3 (25H, C_6H_5); ^{13}C rmn: 170,01 (CO ester), 156,5 (CO uréthane), 104,48 (C-1), 54,75 (C-α-Ser). *Anal.* calc. pour $C_{44}H_{45}O_9N$: C 72,22, H 6,15, N 1,91; trouvée: C 72,08, H 6,30, N 1,80.

Ester benzylique de la N-*(benzyloxycarbonyl)*-O-*(2,3,4-tri*-O-*benzyl*-D-*xylopyranosyl)*-L-*thréonine: α (31) et β (32)*

La réaction de **7** (1,38 g, 4 mmol) dans l'acétronitrile (30 mL) à −20°C avec **3** (0,42 g, 1 mmol) en présence de l'anhydride trifluorométhanesulfonique (0,25 mL, 1,5 mmol), conduit après traitement habituel et chromatographie sur colonne de gel de silice (éluant B) à trois fractions dont une constituée d'un mélange d'anomères α **31** et β **32**. Après chromatographie de cette fraction on obtient **31** pur, sous forme d'huile avec un rendement de 50% et **32** cristallise avec un rendement de 34%. *Composé 31*: $[\alpha]_D^{22}$ +35 (*c* 3,2, $CHCl_3$); ^1H rmn: 1,3 (d, *J* = 6 Hz (CH_3-thr)), 5,95 (d, *J* = 8,2 Hz (NH-Cbz)), 7,3 (25H, C_6H_5); ^{13}C rmn: 170,72 (CO ester), 155,6 (CO uréthane), 97,76 (C-1), 59,12 (C-α-thr), 19,25 (CH_3-thr). *Anal.* calc. pour $C_{45}H_{47}O_9N$: C 72,48, H 6,30, N 1,87; trouvée: C 71,48, H 6,25, N 1,74. *Composé 32*: pf 71–72°C (éther – éther de pétrole); $[\alpha]_D^{22}$ −10 (*c* 0,8, $CHCl_3$); ^1H rmn: 1,25 (d, *J* = 6 Hz (CH_3-thr)), 5,55 (d, *J* = 8,5 Hz (NH-Cbz)), 7,3 (25H, C_6H_5); ^{13}C rmn: 170,42 (CO ester), 156,1 (CO uréthane), 102,34 (C-1), 58,99 (C-α-thr), 17,70 (CH_3-thr). *Anal.* calc. pour $C_{45}H_{47}O_9N$: C 72,48, H 6,30, N 1,87; trouvée: C 72,67, H 6,29, N 1,88.

Ester-O-*nitrophénolique de la* N-*(benzyloxycarbonyl)*-O-*(2,3,4,6-tétra*-O-*benzyl*-D-*glucopyranosyl)*-L-*thréonine: α (33) et β (34)*

A une solution de l'ester *O*-nitrophénolique de la *N*-(benzyloxycarbonyl)-L-thréonine (18) (0,75 g, 2 mmol) dans l'acétonitrile (15 mL) refroidie à −20°C sont ajoutés 0,125 mL (0,75 mmol) d'anhydride trifluorométhanesulfonique puis lentement la solution du composé **1** (0,270 g, 0,5 mmol) dans le dichlorométhane (5 mL). Après être sorti du bain froid la réaction est terminée au bout de 30 min (ccm, solvant. A, révélation par uv). Après traitement le résidu huileux, jaune est chromatographié sur colonne de gel de silice pour donner **33** (0,18 g, 40%) et **34** (0,14 g, 30%). *Composé 33*: $[\alpha]_D^{22}$ +17 (*c* 2,4, $CHCl_3$); ^{13}C rmn: 168,5 (CO ester), 155,3 (CO uréthane), 98,74 (C-1), 60,04 (C-α-thr), 19,3 (CH_3-thr). *Anal.* calc. pour $C_{52}H_{52}O_{12}N_2$: C 69,64, H 5,80, N 3,12; trouvée: C 69,52, H 5,92, N 2,92. *Composé 34*: $[\alpha]_D^{22}$ +12 (*c* 2,8, $CHCl_3$); ^{13}C rmn: 168,27 (CO ester), 155,36 (CO uréthane), 101,3 (C-1), 59,68 (C-α-thr), 17,24 (CH_3-thr). *Anal.* calc. pour $C_{52}H_{52}O_{12}N_2$: C 69,64, H 5,80, N 3,12; trouvée: C 69,22, H 5,83, N 3,02.

Ester méthylique de la N-*(benzyloxycarbonyl)*-O-*(2,3,4,6-tétra*-O-*benzyl*-D-*glucopyranosyl)*-L-*hydroxyproline: α (35) et β (36)*

A une solution de Z-Hyp-OMe (**8**) (1,116 g, 4 mmol) et de tétrabenzyl glucose (**1**) (1,080 g, 2 mmol) dans le dichlorométhane (15 mL) refroidie à −70°C est ajouté l'anhydride trifluorométhanesulfonique (0,5 mL, 3 mmol). Après 15 min à température ambiante le mélange réactionnel est traité et l'huile obtenue (1,95 g, 90%) purifiée par chromatographie sur colonne de gel de silice (250 g). L'élution par le solvant B permet de recueillir trois fractions. La première fraction (0,760 g, 47%) qui cristallise dans un mélange éther – éther de pétrole correspond à **35**: pf 59–62°C; ^{13}C rmn[4]: 172,98 (CO ester), 154,69 (CO uréthane), 96,1 et 96,70 (C-1), 57,84 et 58,08 (C-α-Hyp), 52,04 et 52,33 (CH_3 ester). *Anal.* calc. pour $C_{48}H_{51}O_{10}N$: C 71,91, H 6,36, N 1,74; trouvée: C 71,97, H 6,38, N 1,80. *Le composé 36*: pf 75–76°C (éther – éther de pétrole); ^{13}C rmn[4]: 172,78 (CO ester) 102,42 et 102,28 (C-1), 57,50 et 57,69 (C-α-Hyp), 52,04 et 52,33 (CH_3 ester). *Anal.* calc. pour $C_{48}H_{51}O_{10}N$: C 71,91, H 6,36, N 1,74; trouvée: C 71,85, H 6,36, N 1,82.

Ester méthylique de la N-*(benzyloxycarbonyl)*-O-*(2,3,4,6-tétra*-O-*benzyl*-D-*galactopyranosyl)*-L-*hydroxyproline: α (37) et β (38)*

A une solution de Z-Hyp-OMe (**8**) (0,84 g, 3 mmol) et de tétrabenzyl galactose (**2**) (0,54 g, 1 mmol) dans le dichlorométhane (7,5 mL) refroidie à −60°c est ajouté l'anhydride trifluorométhanesulfonique (0,25 mL, 1,5 mmol). Après 5 min à −60°C la réaction est laissée 20 min hors du bain froid. Le composé **2** ayant complètement disparu, le mélange réactionnel est alors traité comme précédemment. L'huile obtenue (0,570 g, 70%) est chromatographiée sur gel de silice (125 g) éluée par le solvant B. L'anomère α **37** (0,480 g, 60%) a été isolé pur; ^{13}C rmn[4]: 173,09 (CO ester), 97,76 et 97,04 (C-1), 58,03 et 58,26 (C-α-Hyp), 52,02 et 52,25 (CH_3 ester). *Anal.* calc. pour $C_{48}H_{51}O_{10}N$: C 71,91, H 6,36; trouvée: C 70,74, H 6,34. Le composé **38**, n'a pas été isolé pur. Le spectre ^{13}C du mélange montre un carbone anomère à 103,3 ppm.

Ester benzylique de la N-*(benzyloxycarbonyl)*-O-*(2,3,4-tri*-O-*benzyl*-L-*arabinopyranosyl)*-L-*hydroxyproline: β (39) et α (40)*

A une solution de Z-Hyp-OBzl (**12**) (1,42 g, 4 mmol) dans l'acétonitrile (30 mL) à −15°C sont ajoutés l'anhydride trifluorométhanesulfonique (0,25 mL, 1,5 mmol) et le composé **4** (0,42 g, 1 mmol) dissous dans le dichlorométhane (10 mL). Après 30 min à −15°C la réaction est terminée (ccm, solvant A). Après traitement habituel et chromatographie sur colonne de gel de silice, on obtient ainsi 0,65 g (rdt. 85%) du mélange des composés β **39** et α **40** qu'il ne nous a pas été possible de séparer. Les déplacements chimiques des carbones anomères mesurés sur le spectre du mélange sont rapportés dans le tableau 1.

Ester benzylique de la N-*(benzyloxycarbonyl)*-O-*(2,3,5-tri*-O-*benzyl*-α-L-*arabinofuranosyl)*-L-*hydroxyproline: (41)*

A une solution de **12** (1,42 g, 4 mmol) dans l'acétonitrile (30 mL) à −15°C est ajouté l'anhydride trifluorométhanesulfonique, (0,25 mL, 1,5 mmol) puis en 15 min le composé **5** (0,42 g, 1 mmol) en solution dans le dichlorométhane (10 mL). La réaction est terminée après 20 min à −15°C. Le contrôle de la réaction en ccm (solvant A) montre la présence de deux composés de R_f différents. Après traitement du milieu réactionnel et chromatographie, un seul des anomères subsiste isolé pur sous forme d'huile (0,38 g, 55%); $[\alpha]_D^{22}$ −62,4 (*c* 2,1, $CHCl_3$); ^{13}C rmn: 172,3 (CO ester), 155,1 (CO uréthane), 105,3 (C-1), 69,6 (C-5), 58,17 (C-α-Hyp).

Méthode générale de déprotection. Synthèse des composés 42–54

Le composé protégé (1 mmol) est dissous dans l'éthanol (40 mL), auquel est ajouté l'acide acétique (10 mL), l'eau (10 mL) et le Pd/C 10% (2,5 g). L'hydrogénation est réalisée à température ambiante sous une pression de 4 bars, pendant 24 h. Après filtration sur Célite et lavage du catalyseur avec de l'eau

Ce papier est dédié au Prof. Raymond U. Lemieux à l'occasion de son 60ème anniversaire

ANDRÉ A. PAVIA et SAK N. UNG-CHHUN. Can. J. Chem. **59**, 482 (1981).

Le caractère acido-catalysé de la réaction de synthèse des glycosylglycosides symétriques par autocondensation des dérivés benzylés des monosaccharides réducteurs en présence d'anhydride trifluorométhanesulfonique a été établi grâce à la rmn du fluor à basse température. L'efficacité de la méthode est justifiée par la propriété particulière de l'acide trifluorométhanesulfonique de former un sel d'hydroxonium $CF_3SO_3^- H_3O^+$ stable, insoluble dans le milieu réactionnel, permettant de déplacer l'équilibre vers la formation du glycoside. L'anhydride joue dans cette réaction le double rôle de source de protons et de piège à eau. Il est montré par ailleurs que le mécanisme le plus probable est celui passant par un intermédiaire oxonium cyclique et que l'α-stéréosélectivité résulte essentiellement de l'anomérisation *in situ* des composés β en composés α thermodynamiquement plus stables.

ANDRÉ A. PAVIA and SAK N. UNG-CHHUN. Can. J. Chem. **59**, 482 (1981).

The acid-catalysed mechanism of the reaction using trifluoromethanesulfonic anhydride to synthesize symmetrical 1,1′-glycosyl-glycosides such as trehalose and *galacto*, *manno*, *arabino*, *xylo* etc. analogues has been elucidated. The authors were able to prove by ^{19}F nmr study at low temperature that the efficiency of the system is due to the peculiar property of trifluoromethanesulfonic acid generated *in situ* to form a stable, insoluble hydroxonium trifluoromethanesulfonate $CF_3SO_3^- H_3O^+$. The procedure satisfies the two necessary conditions for a glycosylation reaction being workable: (*i*) the presence in catalytic amounts of free acid which is regenerated during the condensation step; (*ii*) a very efficient trapping of the water liberated during the protonation step which displaces the equilibrium towards the formation of the glycoside. The α-stereoselectivity of the reaction is discussed in terms of anomerisation of the β-anomers on to the thermodynamically more stable α ones, through a cyclic oxonium intermediate.

Introduction

Depuis les premiers travaux d'Haszeldine et coll. (1–3), l'acide trifluorométhanesulfonique et ses dérivés ont été de plus en plus utilisés en chimie organique (4, 5) et parmi eux les trifluorométhanesulfonates principalement comme agents d'alkylation. Ces dérivés sont connus pour être de très bons groupes partants et leur réactivité a été mise à profit dans des réactions de solvolyse impliquant des substrats réputés très peu ou pas réactifs. Ces esters constituent un moyen simple et efficace d'activer les groupements hydroxyles aussi leur utilisation dans la chimie des carbohydrates va en augmentant (6–14). Dans certains cas, l'anhydride trifluorométhanesulfonique a été utilisé pour promouvoir la formation *in situ* d'intermédiaires 1-*O*-trifluorométhanesulfonates comme dans le cas de la synthèse en une seule étape d'α-D-glucosides rapportée récemment (13, 14) par Leroux et Perlin.

Lorsque nous avons appliqué le protocole expérimental décrit par ces auteurs à la synthèse de *O*-glycosylaminoacides nous avons pu mettre en évidence dans le milieu réactionnel des quantités très faibles, mais décelables de 1,1′-glycosyl-glycosides. Cette observation nous a incité à reconsidérer le rôle de l'anhydride trifluorométhanesulfonique à la fois comme source de protons et comme agent de déshydratation, ces deux conditions étant nécessaires pour qu'une réaction de glycosylation acido-catalysée soit possible et efficace. C'est ainsi qu'ont pu être synthétisés par un processus simple, rapide et avec des rendements quasi-quantitatifs (≥95%) les mélanges d'α,α et α,β-tréhalose et ses analogues *galacto*, *manno*, à partir respectivement des dérivés benzylés du D-glucopyranose, D-galactopyranose, D-mannopyranose (15*a*). Dans chaque cas les anomères α,α sont obtenus de façon prépondérante.

De plus, quand la réaction est effectuée en présence d'un excès (deux à trois moles pour une) d'un second "alcool" (hydroxyaminoacide convenablement protégé ou monosaccharide non réducteur), le produit de condensation majoritaire est le *O*-glycosylaminoacide ou le disaccharide mixte (55 à 90%) (15*a*, *b*). Dans ce cas aussi l'anomère prépondérant et parfois même exclusif est l'anomère α. Nous sommes maintenant en mesure d'établir le mécanisme de la réaction.

Résultats et discussion

Les résultats décrits précédemment (15*a*) ont été confirmés par la synthèse des dérivés benzylés de l'α-D-xylopyranosyl-α-D-xylopyranoside (**1**), β-L-arabinopyranosyl-β-L-arabinopyranoside (**2**), β-L-

arabinopyranosyl-α-L-arabinopyranoside (**3**), β-D-fructofuranosyl-β-D-fructofuranoside (**4**), α-D-fructofuranosyl-α-D-fructofuranoside (**5**). On peut à priori envisager deux modes de formation pour ces glycosides.

(*1*) Glycosylation directe par réaction entre une mole du monosaccharide réducteur et le dérivé 1-*O*-trifluorométhanesulfonate ou la paire d'ions correspondante, selon le schéma 1. Il est vraisemblable qu'en absence de base, la formation du triflate est très limitée. En fait un tel dérivé n'a jamais été décelé. Notons que dans cette hypothèse le milieu réactionnel doit s'enrichir en acide trifluorométhanesulfonique CF_3SO_3H.

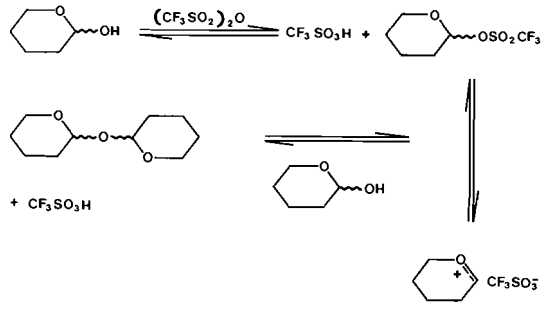

SCHÉMA 1

(*2*) Condensation par réversion acide. L'acide nécessaire pour catalyser la réaction peut être contenu à l'état d'impureté dans l'anhydride (cf. mode d'obtention (2)) soit provenir d'une hydrolyse partielle de l'anhydride par l'eau existant dans le solvant, soit encore d'une réaction d'estérification nécessairement limitée entre le sucre et l'anhydride (schéma 1). Cet acide est régénéré au cours de la réaction de condensation proprement dite. La différence essentielle avec le processus précédent réside dans la formation d'eau qui peut donner avec l'anhydride un sel d'hydroxonium (schéma 2).

La condensation dite par réversion acide ne représente qu'un cas particulier de la glycosylation acido-catalysée utilisée couramment pour la préparation des alkyl-glycosides simples. Dans ce cas l'alcool est utilisé en grand excès et l'équilibre est ainsi déplacé vers la formation du glycoside. Dans tous les autres cas où les réactifs sont en proportions voisines de la stoechiométrie, l'efficacité de la méthode dépend strictement de celle avec laquelle l'eau formée au cours de la réaction de condensation est éliminée du milieu réactionnel. Par l'étude en rmn du Fluor-19, nous apportons la preuve que l'efficacité de notre système est essentiellement due à la propriété particulière de l'acide trifluorométhanesulfonique libéré par hydrolyse de former avec l'eau un hydrate ou plus précisément un trifluorométhanesulfonate d'hydroxonium dont la formation résulte globalement de l'équation ci-dessus (schéma 2).

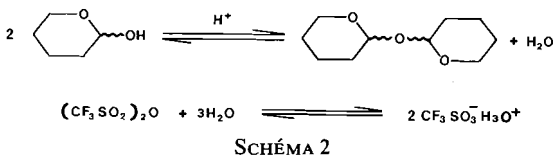

SCHÉMA 2

Vis-à-vis d'un acide aussi fort que l'acide trifluorométhanesulfonique, l'eau se comporte comme une base et sa "capture" est d'autant plus efficace que "l'hydrate" ainsi formé est insoluble dans le dichlorométhane, comme nous avons pu le montrer, à partir d'échantillons authentiques. Dans ces conditions, non seulement on minimise les dégradations que pourraient subir les sucres en présence d'un tel acide, mais on déplace l'équilibre de façon quasi-irréversible vers la formation du glycoside.

En dehors de ce sel d'hydroxynium stable, isolable (F 34°C) décrit dès les premiers travaux d'Haszeldine (1–3) sont également connus d'autres dérivés du même type. Les structures cristallines de $CF_3SO_3^-$ H_3O^+, $CF_3SO_3^-$ $H_5O_2^+$, $CF_3SO_3^-$ $H_3O^+ \cdot CF_3SO_3H$, que l'on peut assimiler sur le plan de la stoechiométrie à des monohydrate, dihydrate, hémihydrate, ont été déterminées par diffraction des rayons X (16). Les études cristallographiques montrent que dans $CF_3SO_3^-$ H_3O^+ et $CF_3SO_3^-$ H_3O^+, CF_3SO_3H, l'ion hydroxonium H_3O^+ est lié par liaison-hydrogène à 3 atomes d'oxygène appartenant à 3 ions trifluorométhanesulfonates selon un arrangement pyramidal. Dans l'hémihydrate il n'y a pas de liaison-hydrogène entre H_3O^+ et la seconde molécule d'acide qui est liée par son hydroxyle à l'un des trois ions $CF_3SO_3^-$ entourant H_3O^+. Il est probable qu'en solution aqueuse on peut envisager tout un éventail de combinaisons entre la molécule d'acide et les molécules d'eau.

L'hypothèse de la réversion acide est confirmée par les résultats suivants. Trois espèces fluorées sont susceptibles d'intervenir: l'anhydride $(CF_3SO_2)_2O$ (**A**), l'acide non dissocié CF_3SO_3H (**B**) et le sel d'hydroxonium $CF_3SO_3^-$ H_3O^+ (**C**). Les déplacements chimiques du groupement CF_3 dans **A**, **B** et **C**[2] en solution dans le dichlorométhane ont

[2]En fait **C** qui a été préparé comme indiqué (2) est à peu près insoluble dans le dichlorométhane. Le spectre de rmn a été réalisé sur une suspension obtenue par agitation de **C** avec le solvant. Malgré cette hétérogénéité la valeur du déplacement chimique est reproductible.

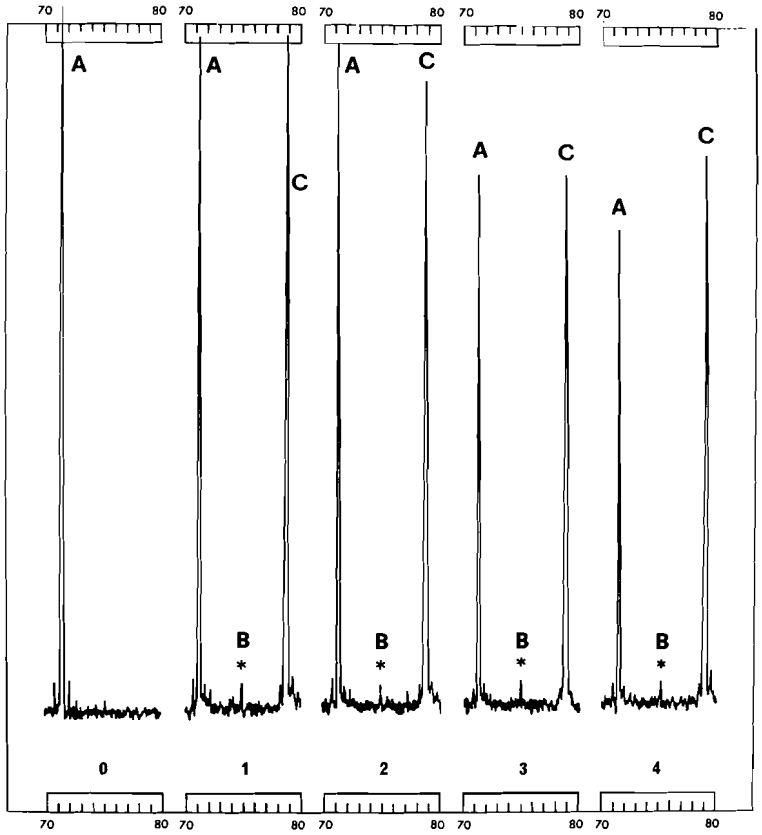

FIG. 1. Hydrolyse de l'anhydride trifluorométhanesulfonique contrôlé par les spectres de ^{19}F rmn (voir texte pour les explications).

été obtenus dans des conditions de concentration et de température (−40°C) identiques à celles utilisées pour le contrôle de la réaction proprement dite. Par rapport au trichlorofluorométhane utilisé en référence interne on note δ_A +71,5 ppm, δ_B +75,3 ppm, δ_C +78,8 ppm. Ces valeurs se retrouvent à ±0,4 ppm près dans le mélange **A** + **B** et dans le milieu réactionnel.

Lorsque les solutions de **A** et **B** dans le dichlorométhane sont agitées à température ambiante avec un égal volume d'eau, le contrôle en ^{19}F rmn montre que la phase organique ne contient plus ni **A** ni **B**. Par contre le spectre de la phase aqueuse montre dans les deux cas un signal CF_3 situé à +2,82 ppm par rapport à celui de l'acide trifluoroacétique pris comme référence interne. Dans les mêmes conditions, les spectres de **B**, **C** et du mélange des deux en solution aqueuse présentent le même signal CF_3 à +2,84 ppm.

Par ailleurs le spectre enregistré immédiatement après avoir agité à froid la solution **A** avec une goutte d'eau (la solution se trouble) fait apparaitre un changement significatif: l'intensité du signal CF_3-**A** a diminué tandis qu'apparait le signal **C** à 78,8 ppm. De plus, un troisième signal de faible intensité est présent à 75,3 ppm. A −40°C, dans les dix minutes qui suivent l'enregistrement du premier spectre, on note une diminution progressive du signal CF_3-**A** puis une stabilisation et une augmentation concomittante de CF_3-**C**, l'intensité de CF_3-**B** restant faible et apparemment constante (fig. 1).

Ces observations montrent que (*a*) l'acide trifluorométhanesulfonique est plus soluble dans l'eau que dans le dichlorométhane; (*b*) l'hydrolyse de l'anhydride est relativement rapide même à basse température; (*c*) le produit principal de l'hydrolyse est le sel d'hydroxonium; (*d*) le milieu ne contient que des quantités faibles (catalytiques) d'acide libre.

La réaction du tétrabenzylglucose avec l'anhydride triflique a été étudiée dans les conditions ci-après: on réalise le mélange comme décrit précédemment à −80°C, puis on laisse remonter la température en sortant le vase réactionnel hors du bain carboglace–acétone. L'évolution de la réaction est contrôlée de dix degrés en dix degrés, parallèlement par ccm et ^{19}F rmn. Les spectres sont

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

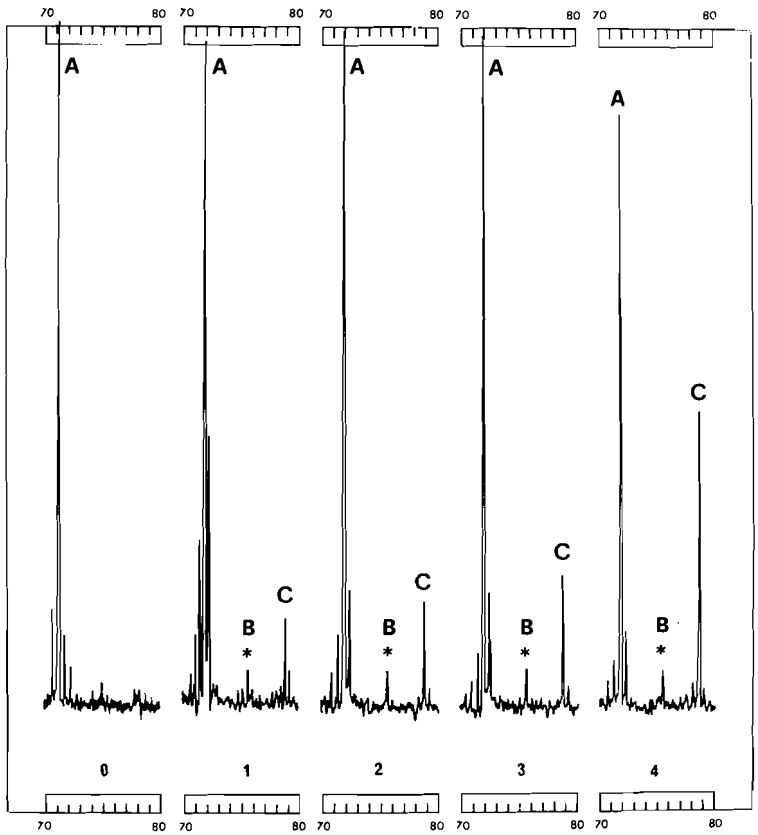

FIG. 2. Spectres de rmn du fluor de la réaction du 2,3,4,6-tétra-*O*-benzyl-D-glucopyranose en présence de $(CF_3SO_2)_2O$ au moment du mélange (0), en cours de réaction (1, 2, 3) et en fin de réaction (4).

réalisés à −46°C de façon à bloquer la réaction et minimiser les dégradations éventuelles pendant la durée de l'enregistrement. La figure 2 montre les modifications du spectre dans la région d'absorption des groupements CF_3. Elles sont analogues à celles observées dans l'expérience précédente.

La formation des disaccharides, confirmée par ccm s'accompagne de la diminution de la quantité d'anhydride au profit du sel d'hydroxonium. On note également l'apparition du signal à 75,3 ppm de faible intensité. La réaction est terminée lorsque la température du milieu réactionnel atteint ~+15°C et dure en moyenne 15 à 30 min selon le volume de la solution. La formation du sel d'hydroxonium implique nécessairement la libération d'eau et confirme la validité du mécanisme acido-catalysé.

Par ailleurs comme nous l'avions noté précédemment (15*a*) la réaction peut être réalisée en présence d'acide trifluorométhanesulfonique moyennant un contrôle strict des temps de réaction et des conditions de température, afin de minimiser les réactions de dégradation. L'examen de la réaction réalisé simultanément par ccm et ^{19}F rmn entre −80 et −40°C, montre que (*a*) à −60°C, 5 minutes seulement après que le mélange ait été sorti du bain froid, la moitié environ du D-glucose a été transformé en un mélange d'α,α et α,β-tréhalose, (*b*) à cette même température le milieu réactionnel ne contient déjà plus d'acide trifluorométhanesulfonique; le seul signal visible est celui situé à 78,8 ppm attribué à CF_3-**C**, d'intensité équivalente à celle du signal CF_3-**B** de la solution témoin, mesuré avant d'ajouter le tétrabenzylglucose. L'obtention de ce signal est une preuve supplémentaire de la libération d'eau en cours de réaction. Abstraction faite des traces d'eau susceptibles d'être contenues dans le solvant, la quantité d'acide est au moins égale à la quantité d'eau qui pourra être libérée par la réaction de condensation. Au moment du 1er contrôle il y a normalement un excès d'acide puisque la réaction n'a progressé que de moitié. Malgré celà, tout l'acide a disparu du milieu réactionnel. Il est probable que ce dernier s'est solubilisé dans la "phase aqueuse" correspondant à l'eau libérée au cours de la condensation.

Par ailleurs, si, en fin de réaction, on ajoute l'acide au milieu réactionnel, on ne voit apparaitre le signal à 75,6 ppm caractéristique de l'acide non

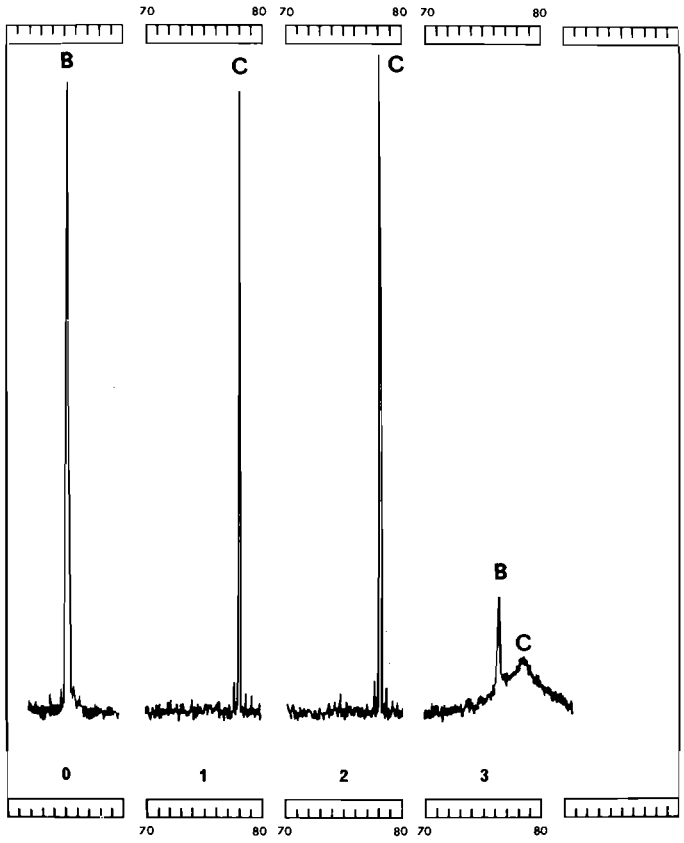

FIG. 3. Spectre de rmn du fluor de la réaction du 2,3,4,6-tétra-*O*-benzyl-D-glucopyranose en présence de CF_3SO_3H au moment du mélange (0), en cours de réaction (1, 2) et en fin de réaction (3).

dissocié, que lorsque ce dernier est ajouté en excès. Dans le même temps le signal à 78,8 ppm évolue sous forme d'un signal élargi.

Les résultats ci-dessus, s'ils confirment la validité d'un mécanisme acido-catalysé, ne nous permettent pas de trancher entre les deux voies possibles, celle passant par un oxonium acyclique (schéma 3A) et celle qui passe par un oxonium cyclique (schéma 3B).

Ces deux mécanismes ont été souvent discutés dans le cadre des réactions d'hydrolyse de glycosides simples (17, 18) bien qu'il soit difficile de les distinguer expérimentalement (19). Mora et Wood (20) s'appuient sur l'hypothèse 3A pour expliquer la polycondensation du glucose alors que Banks *et al.* (21) concluent en faveur du mécanisme 3B après étude de la méthanolyse des phénylglycopyranosides et des effets isotopiques mesurés lors de l'hydrolyse du méthyl-α-D-glucopyranoside. Cet ion oxonium cyclique n'est pas exclusivement capturé par l'eau puisque Overend *et al.* (22) notent la formation (5 à 10%) de disaccharides au cours de l'hydrolyse du méthyl α et β-D-glucopyranoside. Par ailleurs, l'addition de glucose au milieu réac-

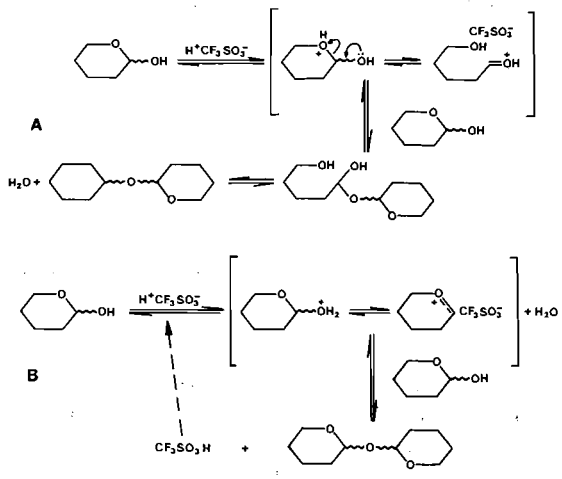

SCHÉMA 3

tionnel provoque une augmentation de la concentration en disaccharide sans que la vitesse d'hydrolyse soit modifiée. Cet intermédiaire est également impliqué dans les réactions d'alcoolyse d'halogénures de glycosyle (23).

Dans l'optique du choix entre les deux hypothè-

ses ci-dessus, nous avons réalisé l'autocondensation du 2,3,4,6-tétra-*O*-benzyl-5-thio-D-glucopyranose (**6**)[3] et du 2,3,6-tri-*O*-benzyl-D-glucopyranose. Dans le premier cas la réaction conduit au bout de 30 min au mélange des trois anomères de l'octa-*O*-benzyl-5,5′-dithiotréhalose (rdt. global 90%) d'où l'anomère α,α (**7**) a été isolé pur avec un rendement de 38% et caractérisé par les données de rmn[4] (H-1, 5,16 ppm, $J_{1,2}$ = 2,5 Hz). Dans l'hypothèse du schéma 3A, le remplacement d'un atome d'oxygène par un atome de soufre moins basique aurait dû se traduire par une diminution sensible de la vitesse de la réaction; en fait il n'en est rien.

De même, dans le cas du 2,3,6-tri-*O*-benzyl-D-glucopyranose il était possible d'envisager la formation de dérivés du type furanoside si la réaction obéissait au mécanisme du type 3A.

Pour tenir compte de la fragilité relative des formes furanoses, nous avons effectué des prélèvements en cours de réaction à des températures inférieures à 0°C, ces aliquots étant traités comme habituellement. En aucun cas nous n'avons pu mettre en évidence ni isoler des composés de condensation du type furanoside. Le mécanisme utilisant la voie passant par l'oxonium cyclique (schéma 3B) semble être le plus plausible et les résultats de l'anomérisation décrits ci-après plaident en sa faveur.

Tout au long de ce travail nous avons constaté (^{13}C rmn et ccm) que les anomères β(α,β et β,β) sont relativement abondants en début de réaction et que leur concentration diminue au fur et à mesure que la réaction progresse. Le processus d'anomérisation a été souvent mis en avant (18, 24, 25, 26) dans d'autres circonstances; il fait intervenir selon les auteurs un mécanisme du type 3A ou 3B. Si l'anomérisation des glycosides simples a donné lieu à de nombreux travaux, peu d'efforts ont été consacrés à celle de disaccharides et aucun à notre connaissance à celle des glycosyl-glycosides. Deux types d'expériences ont été réalisés: le premier en présence d'acide trifluorométhanesulfonique, le second, en reproduisant les conditions mêmes de la réaction de glycosylation en présence d'anhydride (15*a*). Les expériences ont été réalisées sur les substrats suivants: l'octa-*O*-benzyl-*galacto*-tréhalose α,α (**8**), α,β (**9**) et β,β (**10**), l'octa-*O*-benzyl-tréhalose α,β (**11**) et β,β (**12**), l'hexa-*O*-benzyl-L-*arabino*-tréhalose α,β (**3**) et l'octa-*O*-benzyl-1-thio-*galacto*-tréhalose β,β (**13**). En présence d'acide, on n'observe pas d'anomérisation proba-

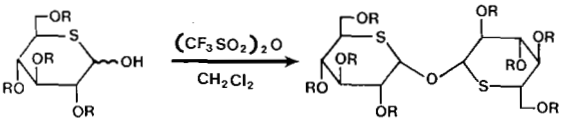

SCHÉMA 4

blement masquée par la réaction d'hydrolyse qui prédomine.

Les résultats obtenus en présence d'anhydride sont résumés dans le tableau 1 et appellent les commentaires suivants. (*a*) Comme on pouvait s'y attendre, le *galacto*-tréhalose α,α (**8**) reste inchangé, sans dégradation ni transformation. Par contre les anomères α,β et β,β sont convertis avec un bon rendement en anomère α,α, même en présence de quantités catalytiques d'anhydride (exp. 3). (*b*) l'α,β-L-*arabino*-tréhalose (**3**) est converti quantitativement en anomère β,β (**2**). (*c*) L'octa-benzyl-1-thio-D-*galacto*-tréhalose β,β (**13**) reste inchangé lorsqu'il est placé dans des conditions qui transforment son homologue **10** en son anomère α,α (**8**). Par ailleurs le contrôle de la réaction ne permet pas de mettre en évidence le produit d'hydrolyse. Cette expérience qui a été répétée plusieurs fois est particulièrement significative dans la mesure où elle indique clairement que l'étape déterminante dans le processus d'anomérisation comme dans celui de la glycosylation est bien la protonation de l'hétéroatome interglycosidique. Le remplacement de l'oxygène par un atome de soufre moins basique défavorise ce processus en diminuant considérablement la vitesse. L'ensemble des résultats discutés ci-dessus nous autorise à proposer le schéma réactionnel 5.

Les données rapportées dans ce travail sont toutes en faveur d'un mécanisme acido-catalysé.[5] L'efficacité de la méthode est expliquée par la "capture" de l'eau libérée au cours de la condensation sous la forme d'un sel d'hydroxonium, insoluble dans le dichlorométhane. Il a été montré également que l'α-stéréosélectivité est renforcée

[3]L'expérience a été réalisée pour le compte du laboratoire du Professeur Defaye de Grenoble et sur un échantillon de 2,3,4,6-tétra-*O*-benzyl-5-thio-D-glucopyranose fourni par ce laboratoire.

[4]J. Defaye, H. Driguez et B. Henrissat, résultats non publiés.

[5]On peut ajouter aux observations rapportées ci-dessus les précisions suivantes. (*a*) Si la réaction passait par un intermédiaire 1-*O*-triflate qui est extrêmement réactif il ne serait pas nécessaire de laisser la réaction évoluer jusqu'à température ambiante (~ +15°C) pour qu'elle soit complète, alors que toutes les réactions impliquant un tel intermédiaire sont faites à −78°C (8, 9, 10). (*b*) Seule l'hypothèse acido-catalysée permet d'expliquer (*1*) que la réaction ne se fasse pas (disaccharides à l'état de trace seulement, < 5%) lorsqu'elle est conduite en présence de pyridine ou collidine, alors que la formation du triflate devrait être favorisée dans de telles conditions; (*2*) que la réaction ait lieu et soit beaucoup plus rapide encore lorsque l'on remplace l'anhydride par l'acide; (*3*) que la réaction ait lieu lorsque l'on remplace l'anhydride triflique par l'anhydride phosphorique (résultats non encore publiés); (*4*) l'anomérisation des disaccharides-1,1,α,β et β,β en disaccharides α,α en présence d'anhydride trifluorométhanesulfonique.

par l'anomérisation *in situ* des dérivés α,β et β,β en dérivés α,α.

Sur le plan du mécanisme proprement dit, le choix en faveur d'un processus réactionnel faisant intervenir un oxonium cyclique intermédiaire s'appuie sur différentes preuves chimiques dont (*a*) l'absence de dérivés furanosiques lorsque le substrat est un dérivé non protégé en position-4; (*b*) la non diminution de la réactivité et de la vitesse lorsque la réaction met en jeu un substrat du type 5-thio-glucose; (*c*) l'absence d'anomérisation du 1-thio-*galacto*-tréhalose β,β alors que l'α,β et le β,β-*galacto*-tréhalose sont, dans les mêmes conditions convertis en leur isomère α,α.

Partie expérimentale

Méthodes générales

Le déroulement des réactions ainsi que l'homogénéité des composés décrits ont été contrôlés par chromatographie sur couche mince (ccm), de gel de silice (Merck F 254, Merck, Darmstadt, Allemagne), la révélation des plaques étant assurée par vaporisation d'une solution 10% d'acide sulfurique suivie du chauffage à 100°C. Les purifications ont été réalisées par chromatographie sur colonne de gel de silice (Merck 60). Les points de fusion ont été mesurés sur appareil Tottoli et sont rapportés non corrigés. Les pouvoirs rotatoires ont été mesurés sur un polarimètre Jobin-Yvon, 11230. Les microanalyses ont été effectuées par le Service Central de Microanalyses du C.N.R.S., division de Montpellier. Les spectres de rmn du ^1H ont été enregistrés à 80 MHz sur un appareil Bruker WP 80; sauf indications particulières ils ont été réalisés dans le chloroforme-*d* et les déplacements chimiques sont donnés en δ par rapport au tétraméthylsilane pris comme référence interne. Les spectres de rmn du ^{13}C ont été enregistrés sur un appareil Bruker WP 80 à 20,115 MHz, les déplacements chimiques sont exprimés par rapport au tétraméthylsilane en référence interne. Dans le cas des solutions aqueuses, le déplacement chimique du dioxane utilisé comme référence interne est de 67,4 ppm.

Les monomères ont été obtenus selon les méthodes déjà décrites. Leurs caractéristiques physiques sont les suivantes.

2,3,4-Tri-*O*-benzyl-D-xylopyranose: F 129–130°C; $[\alpha]_D^{22}$ +18,5° (*c* 0,59, $CHCl_3$); ^{13}C rmn ($CDCl_3$): 92,65 ppm (C-1 anomère β), 91,44 ppm (C-1 anomère α).

2,3,4-Tri-*O*-benzyl-L-arabinopyranose: F 69–70°C; $[\alpha]_D^{22}$ +36,6° (*c* 1,83, $CHCl_3$); ^{13}C rmn ($CDCl_3$): 90,02 ppm (C-1 anomère α), pas de signal correspondant à l'anomère β.

Le 1,3,4,6-tétra-*O*-benzyl-D-fructofuranose a été obtenu par hydrolyse de l'octabenzyl saccharose en présence d'acide trifluorométhanesulfonique: $[\alpha]_D^{22}$ −12,5° (*c* 0,4 $CHCl_3$); ^{13}C rmn: 105,40 ppm (C-2 anomère β, 20%), 102,66 ppm (C-2 anomère α, 80%).

Les glycosyl-glycosides ont été préparés selon le protocole expérimental décrit précédemment (15*a*).

(2,3,4-Tri-*O*-benzyl-α-D-xylopyranosyl)-2,3,4-tri-*O*-benzyl-α-D-xylopyranoside (**1**): (rdt. 90%), $[\alpha]_D^{22}$ +96,10 (*c* 0,77, $CHCl_3$); ^{13}C rmn: 94,22 ppm (C-1). *Anal.* calc. pour $C_{52}H_{54}O_9$: C 75,91, H 6,56; trouvée: C 75,81, H 6,53.

(2,3,4-Tri-*O*-benzyl-β-L-arabinopyranosyl)-2,3,4-tri-*O*-benzyl-β-L-arabinopyranoside (**2**): (rdt. 97%): F 134–135°C; $[\alpha]_D^{22}$ +142° (*c* 1,15, $CHCl_3$); ^1H rmn: 5,75 (d, $J_{1,2}$ 3,5 Hz (2H, H-1), 4,08 (q, H-2) ppm; ^{13}C rmn: 94,66 ppm (C-1). *Anal.* calc. pour $C_{52}H_{54}O_9$: C 75,91, H 6,56; trouvée: C 75,69, H 6,55.

(2,3,4-Tri-*O*-benzyl-β-L-arabinopyranosyl)-2,3,4-tri-*O*-benzyl-α-L-arabinopyranoside (**3**). $[\alpha]_D^{22}$ +84,13 (*c* 0,72, $CHCl_3$); ^{13}C rmn: 102,91 ppm (C-1, α-L), 99,54 ppm (C-1 β-L). *Anal.* calc. pour $C_{52}H_{54}O_9$: C 75,91, H 6,56; trouvée: C 75,80, H 6,45.

1,2,4,6,1′,2′,4′,6′-Octa-*O*-benzyl-fructofuranosyl-fructofuranoside β,β (**4**) et α,α (**5**): le mélange réactionnel (rdt. global 53%) contient environ 85% du composé **4** et 15% de **5**. La chromatographie ne nous a pas permis de les séparer; ^{13}C rmn: 108,5 ppm (C-1 anomère β,β), 104,70 ppm (C-1 anomère α,α).

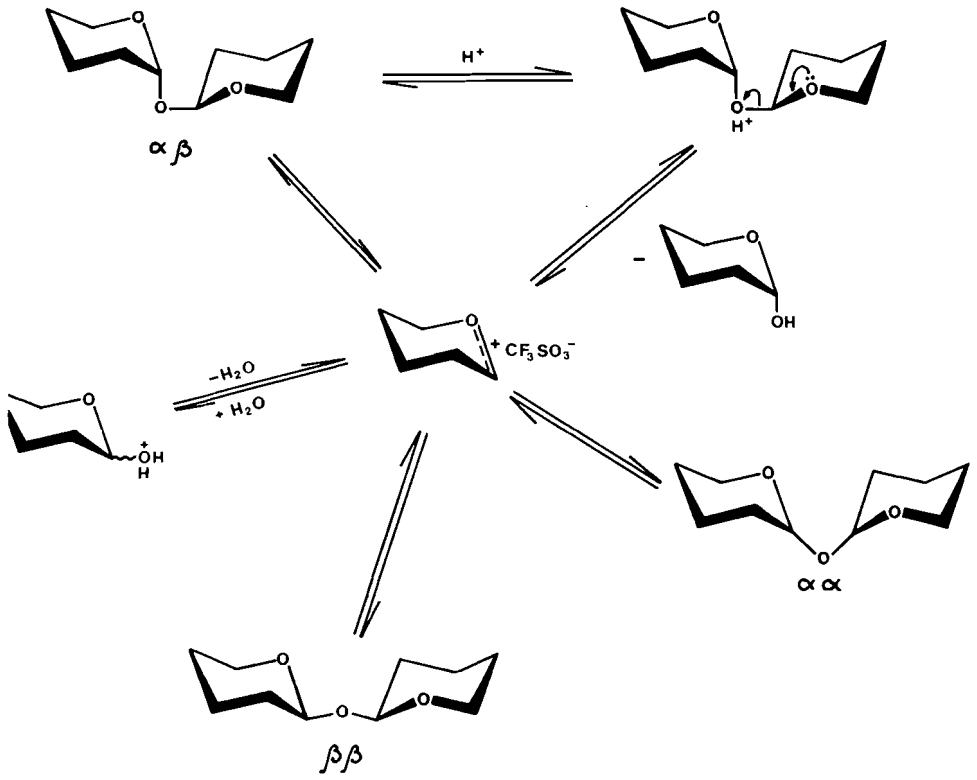

SCHÉMA 5

Réactions d'anomérisation

Les disaccharides α,α, α,β ou β,β octabenzylés (0,5 mmol) purs ou sous forme de mélange sont mis en réaction en présence de l'anhydride trifluorométhane sulfonique (1 à 1,5 mole par mole de sucre) dans le dichlorométhane (≈8 mL) de la même façon que pour les réactions de condensation des monosaccharides. La réaction est conduite, contrôlée et traitée comme précédemment (15*a*).

Remerciements

Les auteurs remercient la Mairie d'Avignon et le Conseil Général du Vaucluse pour l'aide matérielle qu'ils leur ont si généreusement accordée ainsi que Monsieur J. L. Durand, Technicien responsable du laboratoire de rmn pour sa collaboration technique.

A relative extrusibility scale and its application to the thermal fragmentation patterns of 5-membered ring diazenes[1]

ANTHONY JAMES PAINE[2]

Xerox Research Centre of Canada, 2480 Dunwin Drive, Mississauga, Ont., Canada L5L 1J9

AND

JOHN WARKENTIN

Received August 18, 1980

ANTHONY JAMES PAINE and JOHN WARKENTIN. Can. J. Chem. **59**, 491 (1981).

Extrusion of a stable molecular fragment (like N_2, CO_2, SO_2, CO, etc.) is a common chemical process. Using thermodynamic additivity concepts, group values, and heat of formation data, a Relative Extrusibility Scale (ΔH_{ex}^0) has been defined for these fragmentations:

$$\underset{\text{GMF}}{\text{R—X—R}} \rightarrow 2\text{R} + \text{X} \qquad \Delta H_{ex}^0(\text{X}) = \Delta H_f^0(\text{X}) - \Delta H_f^0(\text{GMF})$$

(GMF = generalized molecular fragment, can be cyclic or chain)

Twenty-four such extrusions spanning 150 kcal mol^{-1} have been compiled. Typical values include N_2 (−42.0), CO_2 (−2.6), HCN (13.8), CO (15.4), H_2CO (18.3), C_2H_4 (32.2), and $^1CH_2$ (109). Among other theoretical and mechanistic applications, this list should be useful when designing synthetic routes involving extrusion reactions.

In a particularly effective illustration of the usefulness of the scale, it rationalizes, for the first time, the variety of product types obtained from thermolyses of 14 different kinds of 5-membered ring diazenes. Heat of formation data on most of these compounds do not exist and they contain such sufficiently complicated functional group arrangements that most of the thermodynamic group equivalents are also unknown. This problem can be circumvented by thermodynamic cycles based on the Relative Extrusibility Scale, suitable models, and interfragment resonance corrections. Within an error framework of less than ± 5 kcal mol^{-1}, enthalpy estimates are sufficiently accurate to give heats of reaction capable of predicting which of the potential fragmentation routes actually occur. Formation of a 3-membered ring must be exothermic by at least 30 kcal mol^{-1} to contribute to the products, but 3-piece fragmentation and 1,3-dipolar cycloreversion will contribute to the observed products when the process is either thermoneutral or exothermic. The unimportance of entropy is also discussed.

ANTHONY JAMES PAINE et JOHN WARKENTIN. Can. J. Chem. **59**, 491 (1981).

L'expulsion d'un fragment moléculaire stable (comme N_2, CO_2, SO_2, CO, etc.) est un procédé chimique courant. Faisant appel à des concepts d'additivité thermodynamique, à des valeurs de groupe et à des données de chaleur de formation, on a défini une échelle relative d'expulsion (ΔH_{ex}^0) de ces fragments:

$$\underset{\text{FMG}}{\text{R—X—R}} \rightarrow 2\text{R} + \text{X} \qquad \Delta H_{ex}^0(\text{X}) = \Delta H_f^0(\text{X}) - \Delta H_f^0(\text{FMG})$$

(FMG = fragment moléculaire généralisé; peut être cyclique ou à chaîne ouverte)

On a compilé 24 exemples de telles expulsions couvrant une variation de 150 kcal mol^{-1}. Les valeurs typiques comprennent N_2 (−42,0), CO_2 (−2,6), HCN (13,8), CO (15,4), H_2CO (18,3), C_2H_4 (32,2) et $^1CH_2$ (109). Cette liste, parmi d'autres applications mécanistique et théorique, devrait être utile quand il s'agit de synthèse impliquant des réactions d'expulsion.

L'utilité de cette échelle est illustrée d'une façon particulièrement appropriée par le fait qu'elle rationalise pour la première fois la variété des produits obtenus au cours de la thermolyse de 14 sortes différentes de diazènes à cinq chaînons. Les données de chaleur de formation de la plupart de ces composés n'existent pas et ils contiennent tant d'arrangements de groupes fonctionnels compliqués que les équivalents de groupe thermodynamique sont également inconnus. Ce problème peut être évité en utilisant des cycles thermodynamiques basés sur l'échelle relative d'expulsion, sur des modèles appropriés et sur des corrections de résonance interfragment. Dans les limites d'erreur de ±5 kcal mol^{-1}, les évaluations d'enthalpie sont suffisamment précises pour donner les chaleurs de réaction susceptibles de prédire la voie de fragmentation qui serait potentiellement suivie. La formation d'un cycle à 3 chaînons doit être exothermique (au moins 30 kcal mol^{-1}) pour contribuer à la formation des produits; toutefois les fragmentations conduisant à des chaînons à 3 unités et la cycloinversion dipolaire-1,3 contribueront aux produits observés quand le processus est soit thermoneutre, soit exothermique. On discute également du fait que l'entropie n'est pas importante.

[Traduit par le journal]

Introduction

Thermodynamic considerations place a strong quantitative constraint on kinetics, but are often overlooked as criteria of chemical reactivity. Through the efforts of Benson *et al.* (1, 2) and others (3), additivity schemes have been developed which permit reasonably accurate estimation of thermodynamic parameters (ΔH_f^0, S^0, C_p^0) for many organic compounds. These estimates facilitate calculation of

thermodynamic state function changes associated with a very large number of reactions.

Nevertheless, there remain numerous reactions for which the heat of formation of a reactant or product is not only unmeasured, but the structure is also sufficiently complex that ΔH_f^0 cannot be estimated directly by summing group contributions. This paper demonstrates that some of these previously inestimable heats of formation can be crudely obtained from appropriate cycles based on a Relative Extrusibility Scale and Table of Interfragment Interactions developed herein. Although the method is more general, it is useful to develop the discussion in the context of rationalizing 5-membered ring diazene chemistry.

Extrusion Reactions

Extrusion of a stable molecular fragment like N_2, CO, CO_2, SO_2, etc., is a common chemical process. In the most general sense,[3] an extrusion reaction may be defined as a process whereby a molecule of some kind, either cyclic or acyclic, undergoes unimolecular thermal fragmentation to liberate a small molecule, X, together with some other stable molecular product(s) and/or short-lived intermediates, such as dipoles, diradicals, or biradicals, for example. Typical examples of extrusion reactions would be cycloreversions, diazene fragmentations, decarbonylations, and decarboxylations.

For a variety of reasons (synthetic, theoretical, mechanistic), it is desirable to know the relative ease of extrusion of various small molecules. For example, which of CO, SO_2, or SO is most easily extruded by the cheleotropic process in eq. [1]? Suppose a certain radical, R•, were a synthetic target. What fragments could be extruded together with R• to drive the synthesis?

[1]  X = CO, SO, SO_2,...

The first part of this paper uses thermodynamics to derive a Relative Extrusibility Scale which addresses these kinds of questions. Such an approach ignores very important kinetic and mechanistic factors, but has several advantages. The thermodynamic scale is more generally applicable because the complicating variety of (often unknown) mechanistic types can be ignored. Furthermore, the relative thermodynamic scale may be anchored (made into an absolute scale) for a given reaction series using one known heat of reaction, thereby allowing computation of approximate values for other cases in the series. If such a calculation reveals that a specific extrusion is excessively endothermic, the relative scale will have predicted that the corresponding extrusion is kinetically inaccessible.

A Relative Extrusibility Scale from Group Values

Consider eq. [2] to describe a general extrusion reaction which releases a fragment X. The thermodynamic driving force for the extrusion is the free energy change, ΔG^0. If various X are to be compared for constant R and R′, however, entropy changes will be approximately independent of X, making differences between ΔG^0 and ΔH^0 very similar.

It is both convenient and instructive to arbitrarily define eq. [3] as the model process. Here, the end groups R and R′ of the more general eq. [2] have been set equal to carbon fragments whose group equivalents are readily available.[4] Structure **1** is obviously not a molecule in this formalism, but rather something we define as a generalized molecular fragment, whose heat of formation, ΔH_f^0 (GMF:X), can be calculated by summing the group equivalents for two [C—(X)(C)$(H)_2$] and one [X—$(C)_2$] (eq. [4], examples to come).

[2] R—X—R′ → R + X + R′

[3] C—CH_2—X—CH_2—C → 2″C—CH_2″ + X

GMF **1**

[4] ΔH_f^0(GMF:X) = [X—$(C)_2$] + 2[C—(X)(C)$(H)_2$]

[5] $\Delta H_{ex}^0(X) = \Delta H_f^0(X) - \Delta H_f^0$(GMF:X)

With eq. [3] as the model process, we arbitrarily define a *relative* scale of extrusibility, ΔH_{ex}^0 (X), as the difference between the heat of formation of X and the GMF containing X (eq. [5]). Such a definition intentionally ignores the constant contribution of the cofragments.

One advantage of this kind of relative enthalpy scale for a related set of reactions is that enthalpy contributions from ring strain, gauche interactions, solvent effects, or other factors are all approximately constant and cancel when two extrusions are compared.

Because additivity principles have been introduced in the thermodynamic calculation, the scale is really only defined for the gas phase. However, in most cases the results can be safely applied in solu-

[3]This definition differs from an earlier definition by Duke and Stark (4) by including acyclic cases.

[4]The thermodynamic additivity concepts of Benson and particularly the group values found in his 1976 text (2) together with heat of formation data in his 1969 review (1) and a text by Cox and Pilcher (3) have been used extensively throughout the present work. Whether directly measured, or reliably computed from group equivalents, all unreferenced heats of formation used in the following discussion are available from these sources. Space limitations prohibit including details of any straightforward computations. Units are universally assumed to be kcal mol^{-1} for *G* and *H* and cal mol^{-1} K^{-1} for *S*, and will not always be explicitly carried.

		ΔH_{ex}^0(CH≡CH) = 46.53	

$$\Delta H_{ex}^0(N_2) = \Delta H_f^0(N_2) - \Delta H_f^0(\text{GMF}) = -42.0$$

SCHEME 1

tion if products and reactants are nonpolar. Whereas solvent can alter the kinetics quite considerably, particularly in the case of dipolar intermediates or dipolar transition states on a path to nonpolar products, it has a much less significant effect on the thermodynamics. If a solvent effect is severe, one can always calculate corrections for solvation differences between starting materials and products with greater ease than for transition states.

If similar extrusions occur by a concerted mechanism, then differences in ΔH_{ex}^0 may be used to predict or explain differences in $\Delta H_{obs}^{\ddagger}$, using the Hammond Postulate (5), thereby achieving a bridge between thermodynamics and kinetics. Even if the extrusion mechanisms are not concerted, or are not even the same, the Relative Extrusibility Scale may still be anchored to give approximate reaction enthalpies.

By way of example, consider the cases for extrusion of molecular nitrogen versus its carbon analogue, acetylene. For nitrogen, Scheme 1 shows the generalized azo compound, then sums the appropriate set of group equivalents to give ΔH_f^0 (GMF:N_2). Following eq. [5], the relative extrusibility of N_2, ΔH_{ex}^0 (N_2) is found to be −42.0 kcal mol^{-1}.

On the other side of Scheme 1, the generalized olefin is subjected to a similar calculation to yield the relative extrusibility of acetylene as 46.5 kcal. This little example shows that, all other factors being equal, the extrusion of molecular nitrogen (formation of an NN triple bond) from azo compounds is 88.5 kcal more exothermic than extrusion of acetylene (formation of a CC triple bond) from olefins.

Similar calculations may be performed for a number of different fragments (although not all the ones of interest, since key group equivalents are not available). Twenty-four such extrusions spanning 150 kcal have been compiled in Table 1. These ΔH_{ex}^0 do not correlate at all with the heat of formation of the extruded fragment; both ΔH_f^0 (GMF) and ΔH_f^0(X) are important. The last two columns of the table show the effect of methyl or phenyl substitution on ΔH_{ex}^0, in cases where enough group equivalents exist. Substitution typically lowers ΔH_{ex}^0 by conjugation with the newly-formed bond: a methyl group is worth 2 to 4 kcal; a phenyl typically 8–13. These corrections are reasonably significant, but are not available for key cases. In those instances, typical values for $\delta\Delta H$ may be used, but this will introduce additional error into the estimate of ΔH_{ex}^0.

In their 1967 book on extrusion reactions, Duke and Stark empirically ranked the ease of extrusion of inorganic molecules as $N_2 > CO_2 \gtrsim CO \gtrsim SO > SO_2 > O_2 \gtrsim S > O$, provided the mechanisms remain comparable (4). In reasonable agreement, Table 1 quantifies their qualitative observations.

Intergroup Interaction, ΔH_{int}^0 (Table 2)

Another important factor which must be considered when attempting thermodynamic estimates is the effect of intergroup interaction or resonance. This correction factor is employed when the extruded fragment is not bound to two CH_2 groups (as defined in the GMF), but rather is adjacent to another functional group. Intergroup interactions may either stabilize or destabilize a molecule, thereby affecting ΔH_{ex}^0. For example, if two adjacent functional groups X and Y are both -CH=CH-, then a resonance interaction will lower the energy of R—X—Y—R, increasing ΔH_{ex}^0(X) or ΔH_{ex}^0(Y). On the other hand, in peroxides (X = Y = O) and hydrazines (X = Y = NR) adjacency is destabilizing, and ΔH_{int}^0 is positive (Table 2).

Interfragment interaction corrections, ΔH_{int}^0, are defined here as the difference between heats of formation of a GMF containing the two functional groups in contact and one with an intervening 2-carbon bridge. For example, ΔH_{int}^0 (C=O/O) = ΔH_f^0 (**2**) − ΔH_f^0 (**3**) = −91.5 + 67.9 = −23.6 (eq. [6]; row 1, column 4 in Table 2).

m	-NH-C(=O)-	−49.0	HNCO	−27.90[d]	21.1		—

System **2** contains the same atoms as **3**, but is stabilized by 23.6 kcal by the interaction between carbonyl and oxygen groups. Both **2** and **3** may, in principle, decompose to the same products by eliminating one ketene plus one formaldehyde molecule in a multiextrusion reaction, but decomposition of **3** will be 23.6 kcal less endothermic (or more exothermic) than decomposition of **2**.

Significantly, ΔH_{int}^0 is only taken into consideration of ΔH_{ex}^0 when the bond between X and Y in R—X—Y—R is broken in the reaction. Again, not all the desirable numbers are available, and the estimation of missing values, even when facilitated by Table 2, can be somewhat crude.

Thermal Fragmentation Patterns of 5-Membered Ring Diazenes

In the second part of this paper, the concepts advanced in the previous section are developed to permit thermodynamic estimates which contribute to understanding the variety of product types arising from fragmentation of 5-membered ring diazenes. Among the product patterns observed in this series, three major fragmentation routes emerge: 3-membered ring formation, 1,3-dipolar cycloreversion, and 3-piece ($\sigma 2s + \sigma 2s + \sigma 2s$) fragmentation (Scheme 2).[5] In focussing on these three major routes, other

[5]It is possible that for certain cases, 3-piece fragmentation is not a distinct third option, but rather that the products result from further decomposition of a three-membered ring or diazo species formed in an earlier step. In none of the known cases of 3-piece fragmentations of these diazenes does the experimental evidence favour the intermediacy of a 3-membered ring. On the other hand, highly reactive diazo species like $A{=}\overset{+}{N}{=}\bar{N}$ could be short lived, high energy intermediates (e.g. $O{=}C{=}\overset{+}{N}{=}\bar{N}$) on the way to final products (e.g. CO + N_2). It is important to remember, however, that the present focus is on the insight *thermodynamics* offers, and therefore, the kinetic and mechanistic details of how the products are ultimately obtained are irrelevant to the present discussion.

[a] See text for definitions and discussion. All units kcal mol^{-1}.
[b] The effect of methyl substitution on ΔH_{ex}^0.
[c] The effect of phenyl substitution on ΔH_{ex}^0. In cases where missing data prevent calculation, a dash is found.
[d] Reference 37.
[e] Due to the lack of available data for unsubstituted compounds, this X contains a methyl group.
[f] $\Delta H_{ex}^0(^1O_2) = \Delta H_{ex}^0(^3O_2) + 22$ kcal mol^{-1} (ref. 6).
[g] Calculated from group equivalents.
[h] Benson's compilation lists only one thiocarbonyl group equivalent, [CS—(N)$_2$] for thiourea, which is an assigned value (2). A crude estimate for the difference in ΔH_f^0 between a thiocarbonyl compound and the corresponding carbonyl compound may be obtained from the following (admittedly poor) models: $\Delta H_f^0(CS_2) - \Delta H_f^0(COS) = 61.9$; $\Delta H_f^0(COS) - \Delta H_f^0(CO_2) = 60.2$; $\Delta H_f^0(HNCS) - \Delta H_f^0(HNCO) = 57.9$; and $\Delta H_f^0(\text{thiourea})_s - \Delta H_f^0(\text{urea})_s = 57.6$. The average is 59.4 ± 2 kcal, giving [CS—(X)(Y)] ≡ [CO—(X)(Y)] + 59.4, assuming [X—(CS)( )...] = [X—(CO)( )...].
[i] Following footnote *h* above: $\Delta H_f^0(H_2CS) \simeq \Delta H_f^0(H_2CO) + 59.4 = -26.0 + 59.4 = 33.4$.
[j] $\Delta H_{ex}^0(^1CH_2) = \Delta H_{ex}^0(^3CH_2) + 8$ kcal mol^{-1} (ref. 7).

less frequent products (olefins from H or R migration in biradicals, bicyclic products, any products from bimolecular mechanisms, etc.) are ignored. The present discussion is meant to be quite general, and enthalpy estimates for specific alternative processes can usually be obtained in the conventional way.

Table 3 summarizes the various experimental observations on thermal fragmentation patterns of 14 types of 5-membered ring diazenes. Δ^1-Pyrazolines (**4**), Δ^3-1,3,4-oxadiazolines (**5**), and thiadiazolines (**6**) give 3-membered rings with stereochemistries consistent with the intervention of 1,3-biradicals. Although these rings are often synthesized by 1,3-dipolar cycloadditions, the synthesis is usually not reversible, except in very rare cases involving extremely large steric effects or very strongly-electron-withdrawing substituents. In contrast to these three systems, 3-*H* pyrazoles (**7**) are thermally stable. The less well-known series of carbonyl diazenes, **8** to **10**, is characterized by very facile 3-piece fragmentation, without the intervention of 3-membered rings. From pyrazoline **8**, the products are nitrogen, carbon monoxide, and olefin, in good yield at low temperature. The additional double bond in **9** lowers the yield of the thermal unimolecular process to form an alkyne, but the other two processes have been ruled out. In contrast to the case for structurally similar **9**, 3-piece fragmentation of **10** is a high yield process.

Warkentin and co-workers (26–34) have shown that a series of 3 triazolines (**12–14**) gives exclusive 3-piece fragmentation, whereas iminooxadiazoline **15**

and oxadiazolinone **16** demonstrate competing independent mechanisms for 1,3-dipolar cycloreversion and 3-piece fragmentation. In examining these systems over the past decade, it has been very unclear why such highly varied reactivity patterns have been observed. What gross molecular features influence the direction of fragmentation from case to case? Why do triazolines **12** to **14** not undergo 1,3-dipolar cycloreversion? Why do more highly-functionalized pyrazolines not form 3-membered rings? Why is there competition in some systems but not others?

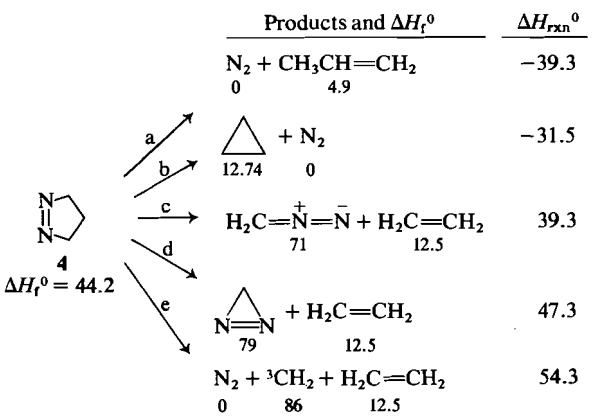
Mechanistic work on **15** and **16** has determined how factors such as temperature, solvent, and substituent can affect the (kinetic) competition within a molecular type (30, 32–34), but it would be useful to develop generalizations capable of rationalizing all of the diverse chemistry in Table 3, and predicting product types for as-yet-unknown cases.

In this regard, it is extremely useful to examine the thermochemistry of the three major competitive fragmentation routes in these cyclic diazenes. To do this, however, is not simple; some potential 3-membered ring products are experimentally unknown, and only two relevant heats of formation have been reported: those of 3,3,5,5-tetramethylpyrazoline (**4***a*; ref. 35) and 5,5-dimethyloxadiazolinone (**16***a*; ref. 33). Many of the systems in Table 3 are too complex for normal additivity schemes to work; too many group equivalents are not available. Most of these problems can be overcome by applying the Relative Extrusibility Scale and the Table of Interfragment Interactions. These numbers can be manipulated with the scarce available data and with data for appropriate model compounds to estimate thermodynamic quantities of interest for these diazenes and their reactions. The reliability of the method will be established by a suitable test, estimating the heat of formation of **16***a*.

The Breakdown of Ordinary Additivity

Engel (35) measured the gas phase heat of formation of **4***a* as 9.4 kcal mol^{-1}, from which one may readily calculate, using ordinary additivity rules, the value for the unsubstituted pyrazoline (**4**) with eq. [7]. With this value, it is a routine matter to calculate the reaction enthalpies for the 5 different processes in Scheme 3.

[7] $\Delta H_f^0(\mathbf{4}) = \Delta H_f^0(\mathbf{4a}) - 4[\text{C—(C)(H)}_3] - 2[\text{C—(N}_A\text{)(C)}_3] + 2[\text{C—(N}_A\text{)(C)(H)}_2]$
$= 9.4 - 4(-10.20) - 2(-3.0) + 2(-6.0) = 44.2$ kcal



SCHEME 3. Thermochemistry of Δ^1-pyrazoline

TABLE 3. Classification of thermal fragmentation patterns of 5-membered ring diazenes

	Ring type[a]	3-Membered ring formation	1,3-Dipolar cycloreversion	3-Piece fragmentation	Temperature[b] comments, ref.
4		Dominant	—	—	200–250°C Some olefin (8–11)
5		Dominant	Only with CF_3 substituent (12)	—	30–120°C Other reactions (12–14)
6		Dominant	Only with extremely bulky substituent (15)	—	50–100°C (15, 16)
7		—	—	—	Thermally stable (17)
8		Ruled out	—	Almost quantitative N_2 + CO + olefin	−30°C Stereospecific (18–22)
9		Ruled out	—	1.3% N_2 + CO + alkyne	20°C Much dimeric and polymeric material (23)
10		—	—	95–99% N_2 + CO +nitrile	20°C (24)
11		—	Only observed product, trapped in unstated yield (25)	—	150°C (25)
12: Z = O **13**: Z = S **14**: Z = NPh		—	—	Quantitative :C=Z + N_2 +	100–200°C (26–28)
15		—			100°C Competition between independent mechanisms (29–31)
16		Ruled out		N_2 + CO + R_2C=O	85°C Competition between independent mechanisms (32–34)

[a]Specific substituents are not shown on these ring type structures unless only one compound was studied. In spite of these generalized structures, the parent (unsubstituted) compounds have seldom been isolated and studied. Alkyl or aryl substitution adjacent to the N=N is necessary to prevent tautomerization to cyclic hydrazone-like derivatives.
[b]In some cases, particularly for **8**, **9**, and **10**, the reaction temperature actually refers to the temperature at which the compound was formed *in situ* (usually by oxidation) and subsequently rapidly decomposed. As such then, these temperatures offer only a rough guide to relative reactivity.

Clearly, the thermodynamics are only favourable for olefin or 3-membered ring formation (paths a and b, respectively), which are exothermic by 30 to 40 kcal. Indeed, these are the only types of observed products in the vast majority of simple pyrazoline thermolyses. Other potential fragmentation routes, such as diazoalkane formation (path c), diazirine formation (path d), and 3-piece fragmentation (path e), are disfavoured by some 70–100 kcal, and are too endothermic to be feasible. The thermodynamics account for the chemistry. Such a successful result urges further application, for example, to oxadiazoline **5**, Table 3. Unfortunately, additivity eq. [8] cannot be solved because the group equivalent [C—(O) (N_A) $(H)_2$] is unknown. The situ-

[8] $\Delta H_f^0(\mathbf{5}) = \Delta H_f^0(\mathbf{4}) - 2[C—(N_A)(C)(H)_2] - [C—(C)_2(H)_2] + 2[C—(O)(N_A)(H)_2] + [O—(C)_2]$

ation worsens when one attempts to calculate the heat of formation of dimethyloxadiazolinone (**16***a*; Scheme 4). In this case, half of the required group equivalents are not known, and there is no way to estimate them. Group values are not intrinsic properties; Benson's scales are anchored by numerous assigned values, making it extremely hazardous to estimate values for missing groups because there are no patterns among the tabulated numbers. This is a major drawback of conventional application of Benson's additivity method. What can be done?

SCHEME 4. Heat of formation of dimethyloxadiazolinone

Thermodynamic Cycles Based on the Relative Extrusibility Scale

Equation [9] represents a thermodynamic cycle in which model pyrazoline **4***a*, whose heat of formation has been measured, extrudes isobutene, while the target molecule extrudes CO_2 in the other direction. Equations [10]–[12] summarize the algebra (recalling the definition in eq. [5] for the final step) to express the heat of formation of the target molecule in terms of GMF switches and an intergroup interaction term. Although Table 2 does not contain a value for ΔH_{int}^0 (N=N/CO_2), this method has the advantage that it is much easier to estimate this value by examining the other systems in Table 2 than it is to estimate 3 missing group equivalents in Scheme 4. At the present time, the approximation ΔH_{int}^0 (N=N/CO_2) ~ ΔH_{int}^0 (C=C/CO_2) = −3.4 kcal seems the most reasonable. This gives the numerical result at the end of eq. [12].

[9] 
	Model (**4***a*)		Target (**16***a*)	
ΔH_f^0:	9.4	−94.05	?	−4.04

[10] $\Delta H^0 = \Delta H_f^0$ (target) + ΔH_f^0(>=) − ΔH_f^0 (CO_2) − ΔH_f^0 (model)

$= \Delta H_{ex}^0$(>=) − ΔH_{ex}^0(CO_2) + ΔH_{int}^0(N=N/CO_2)

so:

[11] ΔH_f^0 (target) = ΔH_{ex}^0(>=) − ΔH_{ex}^0(CO_2) + ΔH_{int}^0(N=N/CO_2) − ΔH_f^0(>=) + ΔH_f^0(CO_2) + ΔH_f^0 (model)

[12] ΔH_f^0 (target) = ΔH_f^0 (model) + ΔH_f^0 (GMF: new fragment) − ΔH_f^0 (GMF: old fragment) + ΔH_{int}^0

$= 9.4 + \Delta H_f^0$(C—CH_2—COO—CH_2—C) − ΔH_f^0(C—CH_2—C(Me)$_2$—CH_2—CH_2—C) + ΔH_{int}^0(N=N/CO_2)

$= 9.4 + (-91.5) - (-34.69) + (-3.4) = -50.8$

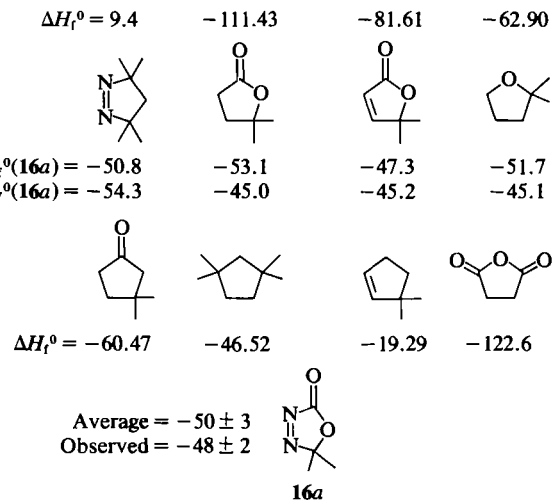
One is not restricted to any particular model, and Scheme 5 shows the results of similar calculations for 8 different models for oxadiazolinone, ranging from pyrazoline **4***a*, through various oxygenated rings, to cyclopentene and cyclopentane. Even the hydrocarbons (which require two fragment swaps) are reasonable models for **16***a*.

All eight models yield very similar estimates[6] for the heat of formation of the target molecule, the average being -50 ± 3 kcal, which is within experimental error of the measured value (33). The successful application of simple models, used with either one or two fragment switches, has severely challenged the GMF method, proving its utility in cases where errors of up to 5 kcal can be tolerated.



16*a*

SCHEME 5. Estimates for the heat of formation of dimethyloxadiazolinone from various models (34)

Reaction Enthalpies for 5-Membered Ring Diazenes

Similar calculations, summarized in the Appendix, have been performed for the other 5-membered ring diazenes in Table 3, permitting the first examination of some of their interesting thermochemistry. Table 4 contains the estimated reaction enthalpies for the three different processes for all 14 systems; circled values correspond to major observed routes.

As discussed earlier, pyrazoline (**4**) fragments to cyclopropane, releasing more than 30 kcal, while 1,3-dipolar cycloreversion and 3-piece fragmentation, at 39 and 54 kcal, are too endothermic to be feasible. Likewise, oxadiazoline (**5**) and thiadiazoline (**6**) form 3-membered rings by very exothermic processes, and the other alternatives are thermodynamically forbidden, at 25 to 60 kcal.

On the other hand, 3-*H* pyrazole (**7**) is much more stable because cyclopropene formation is thermoneutral, disfavoured by 30–40 kcal relative to analogous processes in systems **4**–**6**. Its alternatives are even worse.

Estimates for the three carbonyl diazenes **8**–**10** demonstrate that the observed 3-piece fragmentation is thermodynamically favoured. Thermal decomposition of pyrazolinone **8** to N_2 plus CO plus olefin is exothermic by 22 kcal. Although cyclopropanone formation is also slightly exothermic (by 10 kcal), it is still much less favourable than cyclopropane formation from pyrazoline, and would not be expected to compete with 3-piece fragmentation of **8** at the lower temperature.

The presence of the double bond in **9** shifts all values upwards from those for **8**, much the same as the result of switching to **7** from **4**. In this example, 3-piece fragmentation is roughly thermoneutral, but yield was only 1.3% (Table 3). Cyclopropenone is less accessible than cyclopropanone, and it is not possible to write a 1,3-dipolar cycloreversion without invoking an unlikely, high-energy N_2CO intermediate.

Nitrile formation by 3-piece fragmentation of **10** is also very exothermic, by 35 kcal. Table 1 shows that extrusion of HCN is one of the more favourable processes. The bracketed value of 14 kcal under 3-membered ring formation reflects the assumption that this value equals that for **9** (see Appendix).

Interestingly, phenyl substituted methylene oxadiazoline (**11**) undergoes thermoneutral 1,3-dipolar cycloreversion in preference to exothermic (by 14 kcal) 3-membered ring formation. However, the estimates predict that without C5 phenyl substitution, 1,3-dipolar cycloreversion and 3-piece fragmentation will be much more endothermic, perhaps inaccessible (footnote *c* in Table 4).

Now the discussion narrows to **12**–**16**, which spurred our initial interest. Like systems **8**–**10**, triazolines **12**–**14** have very exothermic 3-piece fragmentation routes. There are almost no data available for thiocarbonyl compounds, so that the error in the values for **13** is likely quite large, although it apparently fits the patterns. In this series, as in **8** and **11**, it seems that 3-membered ring formation is insufficiently exothermic to compete.

The last two systems in Table 4 show the interesting competition between independent mechanisms for 1,3-dipolar cycloreversion and 3-piece fragmentation. It is gratifying to see that amongst all the

[6]Some of these differences reflect differences in strain energy for the 9 systems in Scheme 5. This can be seen from the known ring strain contributions (1): THF (6.7), cyclopentanone (6.0), succinic anhydride (1.1). Subtraction of this factor would reduce the *scatter* in ΔH_f° (target), but it would give no greater *certainty* to that value because the ring strain contribution in **16***a* is unknown. Therefore, it is preferable to include this uncertainty in the apparent scatter in Scheme 5.

TABLE 4. Reaction enthalpy estimates for thermal fragmentation of 5-membered ring diazenes[a]

Compound		ΔH^0 (3-membered ring formation)	ΔH^0 (1,3-dipolar cycloreversion)	ΔH^0 (3-piece fragmentation)
4		(−31.5)	39	54
5		(−32)	25	40
6		(−39)	45	60
7		−1	58	73
8		−10	51	(−22)
9	R = Ph	14	Certainly ≫ 0	(2[b])
10		(14)	Certainly ≫ 0	(−35)
11	 R = Ph[c]	−14	(0)	15[d]
12	Z = O	−3	12	(−31)
13	Z = S	(−3)	(12)	< (−8)
14	Z = NPh	(−3)	19	(−23)
15	*a* R = Me	(−14)	(−9)	(−21)
	b R = Ph	(−14)	(−26)	(−38)
16	*a* R = Me	2	(1)	(−30)
	b R = Ph	2	(−16)	(−47)

[a]Estimates refer to the gas phase (kcal mol^{-1}). Circled values correspond to observed products (Table 3). Values in parentheses are assumed the same as some other value in the table. See the Appendix for details.
[b]For R = H (**9***a*) this is −2 kcal.
[c]For R = H (**11***a*) these values are: −14, 24, and 39 kcal.
[d]This value, based on forming diphenylcarbene, assumes that the difference between 1,3-dipolar cycloreversion and 3-piece fragmentation in **11** is the same as in **4**, **5**, **6**, and **7**.

molecules in the table, only these two satisfy apparent thermodynamic criteria for both reactions; three-piece fragmentation is exothermic by the usual large amount and 1,3-dipolar cycloreversion is exothermic or thermoneutral. The unobserved 3-membered-ring-forming reactions, although slightly exothermic, are insufficiently so to compete with the other two processes.

As the details in the Appendix show, many of the heats of reaction appearing in Table 4 are crude and numerous approximations were necessary. Even though some of the final results may be in error by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

more than ± 5 kcal, the differences among the numbers from system to system, and from reaction to reaction, are much greater, and the following gross trends are apparent: 3-membered ring formation must be exothermic by some 30 kcal or more in order for it to be important, but thermoneutral or exothermic 1,3-dipolar cycloreversion or 3-piece fragmentation can contribute to the observed products.

By identifying processes which are too endothermic to be reasonable, the reaction enthalpy estimates obtained from the Relative Extrusibility Scale are able to account for the gross features of the fragmentation patterns of 5-membered ring diazenes. *As thermochemical information, however, such data cannot explain why two processes, which differ in exothermicity by* 10–30 *kcal in systems* **15** *and* **16**, *have transition states of similar energy.* That is a kinetic problem which is no doubt related to the fact that the two processes have different mechanisms.

On Entropy and Temperature Dependence

As the introduction to the Relative Extrusibility Scale noted, entropy contributions cancel when comparing *similar* extrusions, for example, epoxide vs. cyclopropane formation, and differences in ΔH^0 parallel differences in ΔG^0. However, it may seem that comparing 2-piece to 3-piece fragmentations in Scheme 3 and Table 4 is rather akin to comparing apples to oranges. Typical values of the thermodynamic entropy change on forming two fragments from a 5-membered ring are about $+40$ eu. For 3-piece fragmentation this rises to about $+70$ eu. Should this difference be accounted for when estimating the thermodynamic driving force? Is it meaningful to compare ΔH^0 for 3-membered ring formation from pyrazolinone at -25°C to that for pyrazoline at 250°C?

In spite of large thermodynamic entropy changes associated with multipiece fragmentations, $\Delta S^{\neq}$ is usually quite small for these processes, on the order of 10 eu or less, and sometimes negative. This apparently reflects the fact that, regardless of the mechanism, the ring of atoms is largely unbroken at the transition state. Since it is the activation entropy which affects the competition between processes, and since these activation entropies are all similar, and smaller than the thermodynamic entropy changes, it is reasonable to view these irreversible fragmentation reactions as enthalpy driven. This differs from the situation in the reverse direction, where the driving force for cycloadditions is the free energy change. Because $\Delta S^{\neq}$ is large and negative, both enthalpy and entropy contribute to the barrier for cycloaddition.

Analogous arguments greatly reduce the effect of the heat capacity term to the subjective concept of "*driving force*", leaving ΔH^0, calculated at 25°C, as a reasonably valid index of thermodynamic influence over fairly wide temperature ranges, perhaps even the 300° span in Table 3. In most cases then, one does not have to be too concerned with entropy factors when comparing reactions carried out at different temperatures, or when comparing reactions which give different numbers of products.

For personal use only.

tribution due to aromaticity, the heat of formation of cyclopropenone is estimated by eq. [6],[8] and then used in Scheme 10.

[A 6] ΔH_f^0() $\simeq \Delta H_f^0$() + ΔH_f^0() − ΔH_f^0() + ΔH_{int}^0(C=C/C=O)

$= -1.5$ (ref. 36) + 66.6 − 12.74 + (−8.8) = 43.6

For **9** itself, phenyl substitution would be expected to have a negligible effect on cyclopropenone formation, but an effect of $2\delta\Delta H_{Ph}^0$ for acetylene extrusion (see Table 1), raising ΔH^0 by 4.0 kcal.

*6. Triazolinone **10***

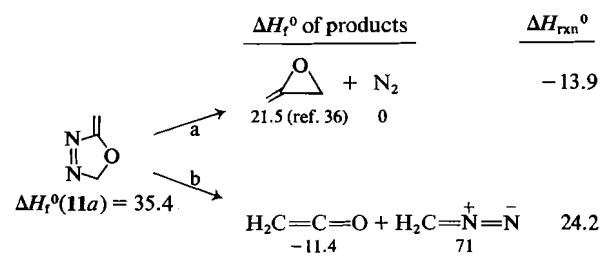
Here, 3-membered ring formation and resonance energy are assumed to be the same as for **9***a*. Then, the difference between 3-piece extrusion of **10** and **9***a* is equal to the difference between HCN and acetylene extrusion in the Relative Extrusibility Scale:

[A 7] ΔH^0 (3-pce; **10**) $\simeq \Delta H^0$ (3-pce; **9***a*) + ΔH_{ex}^0 (HCN) − ΔH_{ex}^0 (HC≡CH) = −1.8 + 13.8 − 46.5 = −34.5

*7. Methylene Oxadiazoline **11**; Scheme 11*

Assuming ΔH_{int}^0 (N=N/CO_2) $\simeq \Delta H_{int}^0$ (N=N/C=C/O):

[A 8] ΔH_f^0 (**11***a*) $\simeq \Delta H_f^0$ (**16***a*) − ΔH_f^0 (C—CH_2—CMe_2—O—CH_2—C) + ΔH_f^0 (C—CH_2CH_2—O—CH_2—C) − ΔH_f^0 (C—CH_2COOCH_2—C) + ΔH_f^0 (C—CH_2—C(=CH_2)—O—CH_2—C) = −48.0 − (−63.23) + (−44.33) − (−91.5) + (−26.97) = 35.4



SCHEME 11

Phenyl substitution will have a negligible effect on the 3-membered ring forming reaction (path a) because no new double bonds are formed. On the other hand, phenyl groups will greatly favour 1,3-dipolar cycloreversion (path b), mostly by stabilizing the diazoalkane. Although the absence of necessary group values makes it difficult to quantify this effect, one may compare to carbonyl compounds. In the series H_2CO, PhCHO, Ph_2CO (ΔH_f^0 = −26.0, −6.0, 12.3), the second phenyl group has an effect 1.7 kcal less than the first, due in part to the nonplanarity of the rings. If one combines this fact with an assumption that $\delta\Delta H_{Ph}^0$ for diazoalkane extrusion is the same as that for ketone extrusion, then the two C5 phenyls should lower ΔH_{ex}^0 by 12.7 + 11.0 = 23.7 kcal, in the absence of any steric effect. This yields ΔH_b^0 (**11**) $\simeq$ 0.5 kcal mol^{-1}, which can be rounded down to zero by the steric effect and ketene phenyl effect.

*8. Triazolinone **12**; Scheme 12*

[A 9] ΔH_f^0 (**12**) $\simeq \Delta H_f^0$ (**16***a*) + ΔH_f^0 (C—CH_2—NPh—CH_2—C) − ΔH_f^0 (C—CH_2—O—CH_2—C) + ΔH_{int}^0 (C=O/NPh) − ΔH_{int}^0 (C=C/O) = −48.0 + 29.0 − (−39.4) + (−16.4) − (−23.6) = 27.6

In Scheme 12, ΔH_f^0 (PhNCO) $\simeq \Delta H_f^0$ (PhCHO) − ΔH_f^0 (H_2CO) + ΔH_f^0 (HNCO) = −6.0 − (−26.0) + (−27.90) = −7.9 kcal mol^{-1}. Apparently the α-lactam phenyl group is not coplanar, as in amides (36), so ΔH_{int}^0 (C=O/NPh) is lost on 3-membered ring formation. Equation [10] estimates the heat of formation of **17**.

[8]A referee has suggested that two C=C/C=O interactions should be included in eq. [6]. Although it is difficult to be certain about a unique group like cyclopropenone, interaction energies are generally not additive: ΔH_{int}^0 (C=O/O/C=O) is −23.8 kcal, but may be compared to $2\Delta H_{int}^0$ (C=O/O) = 2 (−23.6) = −47.2; and ΔH_{int}^0 (C=C/C=O/O) is −17.0 kcal, but ΔH_{int}^0 (C=C/C=O) + ΔH_{int}^0 (C=O/O) = −8.8 − 23.6 = −32.4 kcal. (Note that ΔH_{int}^0 (C=C/C=O/O) is not the same as ΔH_{int}^0 (C=C/CO_2): each slash represents a separating ethylene group in a structure analogous to **3**.) Although the interaction of three functional groups is an imperfect model for the situation in cyclopropenone, it is interesting to note that the total interaction is roughly equal to the *mean*, rather than the sum, of the two isolated interactions, apparently legitimizing the assumption made in eq. [6] of the Appendix.

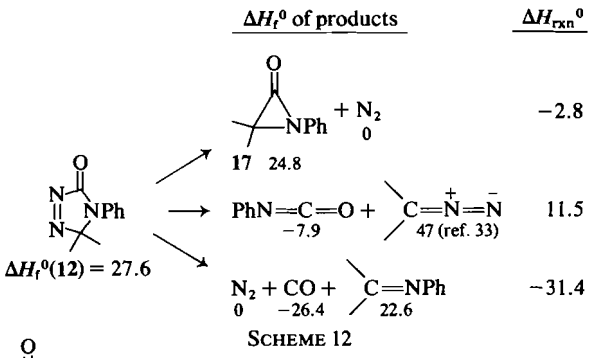
For personal use only.



SCHEME 12

[A 10] ΔH_f° (**17**) $\simeq \Delta H_f^\circ$ (H_2C—NH) $- \Delta H_f^\circ$ (C—$CH_2CH_2CH_2$—C) $+ \Delta H_f^\circ$ (C—CH_2—CMe_2—CH_2—C) $- \Delta H_f^\circ$ (C—CH_2NHCH_2—C) $+ \Delta H_f^\circ$ (C—CH_2—NPh—CH_2—C) = 13 (ref. 36) − (−14.79) + (−29.76) − 2.2 + 29.0 = 24.8

9. Triazolinethione 13

[A 11] ΔH° (3-pce; **13**) $\simeq \Delta H^\circ$ (3-pce; **12**) $+ \Delta H_{ex}^\circ$ (CS) $- \Delta H_{ex}^\circ$ (CO) = −31.4 + 38.5 − 15.4 = −8.3

Since the resonance energy in **13** is likely to be less than in **12**, eq. [11] probably represents an upper limit. Without other group equivalents, the 3-membered ring formation and 1,3-dipolar cycloreversion must be equated to system **12**.

10. Iminotriazoline 14

[A 12] ΔH° (3-pce; **14**) $\simeq \Delta H^\circ$ (3-pce; **12**) $+ \Delta H_{ex}^\circ$ (PhN≡C) $- \Delta H_{ex}^\circ$ (CO) = −31.4 + 24.0 − 15.4 = −22.8

Equation [12] assumes that $\delta\Delta H_{Ph}^\circ \simeq 0$ for this triple bond: compare to −2.1 in HCN and +2.0 in HC≡CH. For 1,3-dipolar cycloreversion, eq. [13] proceeds analogously:

[A 13] ΔH° (1,3-dpcr; **14**) $\simeq \Delta H^\circ$ (1,3-dpcr; **12**) $- \Delta H_{ex}^\circ$ (H_2CO) $+ \Delta H_{ex}^\circ$ (H_2C=NH) = 11.5 − 18.3 + 25.3 = 18.5

Finally, 3-membered ring formation is assumed equienergic to system **12**.

*11. Oxadiazolinone 16*a

Reaction enthalpy estimates for 1,3-dipolar cycloreversion and 3-piece fragmentation have been reported earlier (33), as 1 and −30 kcal, respectively. The heat of formation of dimethyl α-lactone (**18**) is estimated in eq. [14],

[A 14] ΔH_f° (**18**) $\simeq \Delta H_f^\circ$ $- \Delta H_f^\circ$(C—$CH_2CH_2CH_2$—C) $+ \Delta H_f^\circ$(C—$CH_2CMe_2CH_2$—C) = −31 (ref. 36) − (−14.79) + (−29.76) = −46.0

leading to a reaction enthalpy of −2 kcal for 3-membered ring formation. The differences between **16***b* and **16***a* were set equal to the difference between **15***b* and **15***a* (next section).

12. Iminooxadiazoline 15

Assuming resonance energies in **15** and **16** are the same, eqs. [15] and [16] estimate reaction enthalpies for **15***a* (dimethyl substituted) and eqs. [17] and [18] for **15***b* (diphenyl substituted). 3-Membered ring formation is assumed equienergic to system **11** at −14 kcal.

[A 15] ΔH° (3-pce; **15***a*) $\simeq \Delta H^\circ$ (3-pce; **16***a*) $- \Delta H_{ex}^\circ$ (CO) $+ \Delta H_{ex}^\circ$ (PhNC) = −30 − 15.4 + 24.0 = −21.4

[A 16] ΔH° (1,3-dpcr; **15***a*) $\simeq \Delta H^\circ$ (1,3-dpcr; **11***a*) $- \Delta H_{ex}^\circ$ (H_2C=C=O) $+ \Delta H_{ex}^\circ$ (HNCO) $+ \delta\Delta H_{Me}^\circ$ = 24.2 − 15.6 − 11.15 − 6.8 = −9.4

[A 17] ΔH° (3-pce; **15***b*) $\simeq \Delta H^\circ$ (3-pce; **15***a*) $+ 2(\delta\Delta H_{Ph}^\circ - \delta\Delta H_{Me}^\circ)$ = −21.4 − 23.7 (see section 7, above) + 6.8 = −38.3

[A 18] ΔH° (1,3-dpcr; **15***b*) $\simeq \Delta H^\circ$ (1,3-dpcr; **15***a*) $+ 2(\delta\Delta H_{Ph}^\circ - \delta\Delta H_{Me}^\circ)$ = −9.4 − 23.7 + 6.8 = −26.3

These calculations illustrate how the Relative Extrusibility Scale, the Table of Interfragment Interactions, and substituent effect corrections can be used to obtain either heats of formation of complicated molecules, or heats of reaction for their decomposition. The latter approach is useful when the heat of formation of one or more of the products is also unknown.

P. S. NEUDORFL, R. A. BACK, and A. E. DOUGLAS. Can. J. Chem. **59**, 506 (1981).

The vacuum ultraviolet absorption spectrum of *trans*-diimide (N_2H_2) in the gas phase has been re-examined between 1800 and 1300 Å, using diimide prepared by the thermal decomposition of sodium tosylhydrazide. Two band systems were observed, designated $\tilde{B} \leftarrow \tilde{X}$ and $\tilde{C} \leftarrow \tilde{X}$, with origins at 1727 and 1473 Å, which have been assigned to the Rydberg transitions $3p_\pi(b_u) \leftarrow n_+$ and $4p_\pi(b_u) \leftarrow n_+$ respectively. Both systems show long progressions in ν_2', the N—N—H symmetric bending frequency, and short progressions in ν_3', the symmetric N—N stretching frequency.

The $\tilde{B} \leftarrow \tilde{X}$ system has well-resolved rotational *J* type structure in some bands, and the rotational analysis showed that the ground state is a totally symmetric singlet state of C_{2h} symmetry (planar *trans*-N_2H_2 isomer), and that the system arises from a $^1B_u \leftarrow {}^1A_g$ transition. Rotational constants obtained for the 0–0 band of the $\tilde{B}$-state were $A = 15.63$, $B = 1.32$, and $C = 1.22$ cm^{-1}, and the values of $r_{H—N} = 1.028$ Å, $r_{N—N} = 1.167$ Å, and $\angle$H—N—N = 127.6° were estimated from them assuming a planar *trans* conformation.

P. S. NEUDORFL, R. A. BACK et A. E. DOUGLAS. Can. J. Chem. **59**, 506 (1981).

On a étudié de nouveau le spectre ultraviolet à vide de la *trans*-diimide (N_2H_2) en phase gazeuse entre 1800 et 1300 Å en utilisant une diimide préparée par la décomposition thermique de la tosylhydrazide de sodium. On a observé deux systèmes de bandes que l'on désigne par $\tilde{B} \leftarrow \tilde{X}$ et $\tilde{C} \leftarrow \tilde{X}$ et qui prennent naissance à 1727 et 1473 Å; on les a attribués respectivement aux transitions de Rydberg $3p_\pi(b_u) \leftarrow n_+$ et $4p_\pi(b_u) \leftarrow n_+$. Les deux systèmes montrent de longues progressions pour ν_2', la fréquence de déformation symétrique N—N—H et de courtes progressions pour ν_3' la fréquence d'élongation symétrique N—N.

Le système $\tilde{B} \leftarrow \tilde{X}$ a une structure rotationnelle de type *J* bien résolue dans quelques bandes et l'analyse rotationnelle a montré que l'état fondamental est un état singulet complètement symétrique de symétrie C_{2h} (isomère plan du N_2H_2 *trans*) et que le système provient d'une transition $^1B_u \leftarrow {}^1A_g$. Les constantes de rotation obtenues pour la bande 0–0 de l'état $\tilde{B}$ sont: $A = 15{,}63$, $B = 1{,}32$ et $C = 1{,}22$ cm^{-1} et les valeurs de $r_{H—N} = 1{,}028$ Å, $r_{N—N} = 1{,}167$ Å et $\angle$H—N—N = 127,6° ont été évaluées à partir de ces constantes en admettant une conformation plane *trans*.

[Traduit par le journal]

Introduction

The vacuum ultraviolet spectrum of diimide (N_2H_2) was first studied by Trombetti (1) in 1968, using a microwave discharge through flowing hydrazine vapor as a source of this metastable molecule. The spectrum showed a resolved rotational *J*-structure, and from its apparent intensity alternation it was concluded that the ground electronic state of diimide is not totally symmetric, which by analogy with the isoelectronic molecule O_2, indicated a triplet ground state. Subsequently, however, esr and magnetic susceptibility measurements (2) showed that diimide is not strongly paramagnetic, while analysis of the infrared (3) and near ultraviolet (4) spectra, as well as numerous theoretical calculations (5–7), provided strong evidence against a triplet ground state. It has in fact been established beyond reasonable doubt that the ground state of *trans*-diimide, the most stable N_2H_2 isomer and the only one positively identified experimentally, is a totally symmetric singlet state, ^1A_g. The vacuum ultraviolet spectrum, however, has remained unexplained. It is a strong, reproducible absorption system, and the critical intensity alternation originally observed in a flow system was confirmed in static experiments (2). Suggestions that the spectrum arises from a longlived excited triplet state or from one of the other possible isomers of diimide seem highly improbable (2, 3). The spectrum observed was complicated at some wavelengths by overlapping bands of ammonia, which is unavoidably present in large excess when diimide is prepared by a microwave discharge through hydrazine vapor (2). Wiberg and his colleagues (8) have shown that almost pure diimide can be produced by the thermal decomposition of alkali metal tosylhydrazides, and have also argued that the *cis*-diimide or aminonitrene rather than the *trans* isomer is formed, at least initially, by this method (9). It appeared that a re-examination of the vacuum ultraviolet spectrum using diimide prepared in this way might resolve some of its anoma-

lous features, or if indeed other isomers were present, might yield a totally new spectrum. The present paper describes such a re-examination.

Experimental

Diimide, generated continuously by the thermolysis of sodium tosylhydrazide (8) at 70–100°C, was mixed with helium carrier gas at a pressure of 1 to 5 Torr and passed through a trap at −78°C into an 80 cm long absorption tube fitted with LiF windows and cooled at −78°C. Continuous pumping maintained a steady concentration of diimide in the absorption tube, kept at the desired value (of about 0.1 to 0.7 mTorr) by controlling the thermolysis temperature and the helium flowrate.

The absorption spectrum in the wavelength regions 1240–2000 Å and 1370–1550 Å was photographed in the first and seventh orders of a 10 m Eagle spectrograph equipped with gratings with 1200 and 600 lines/mm and reciprocal dispersions of 0.75 and 0.21 Å/mm, using slit widths of 0.10 and 0.02 mm respectively. Third and fourth order iron lines from a hollow cathode source were superimposed on the seventh order spectrum as wavelength standards. A Lyman discharge provided the continuum light source, and spectra were photographed on Ilford Q2 and Kodak SWR plates.

Results

A comparison of the absorption spectra obtained in the present experiments with those of Trombetti (1) and Willis and Back (2) leaves no doubt that the same absorbing species was observed throughout. The virtual absence of ammonia, however, dramatically improves the quality of the spectra, permitting not only measurements of N_2H_2 absorption over a much broader range of wavelengths than before but also much better resolution of the rotational structure. A microdensitometer trace of the absorption spectrum between 1800 and 1350 Å is shown in Fig. 1. The spectrum consists of at least two band systems, one extending from about 1730 to 1520 Å and the other from about 1470 Å to shorter wavelengths. The first system is the one previously described by Trombetti (1), and consists of at least 17 bands, about half of which show a resolved rotational structure. The bands of the 1470 Å system, not previously reported, are much weaker and their rotational structure is not resolved. For convenience, these two systems will be denoted as the $\tilde{B} \leftarrow \tilde{X}$ (following Trombetti (1)) and $\tilde{C} \leftarrow \tilde{X}$ transitions respectively.

In addition to these systems, some rather weak diffuse bands were observed between 1800 and 1730 Å which do not seem to belong to the $\tilde{B} \leftarrow \tilde{X}$ system, whose possible origin will be discussed later. No further absorption was seen up to 2000 Å.

Vibrational Analysis

The $\tilde{B} \leftarrow \tilde{X}$ *System (1730–1520 Å)*

The vibrational assignments, shown in Fig. 1, are the same as Trombetti's (1), although almost twice as many bands were observed in the present spectrum. There are three progressions with $\Delta\nu = 1150 \pm 30\ cm^{-1}$ assigned to the totally symmetric HNN bending vibration, ν_2', in the upper electronic state.[2] The first progression, which consists of seven bands, is the most intense, with the first member at about 1727 Å. The origin of the second progression is blue-shifted by about 1875 cm^{-1} and that of the third progression by another 1845 cm^{-1}. The second progression consists of six bands; the third progression is much weaker, and only four members are observed. The three progressions in ν_2' are assumed to correspond to the excitation of 0, 1, or 2 quanta of the totally symmetric N—N stretching vibration, ν_3'. These progressions account for virtually all the bands of the $\tilde{B} \leftarrow \tilde{X}$ system (with two exceptions, see below), and no further members were observed at longer wavelengths, confirming Trombetti's assignment of the 1727 Å band as the origin. No "hot" bands corresponding to transitions from vibrationally excited levels of the ground state were observed, and because only ν_2' and ν_3' were excited, a simplified band notation, (v_2', v_3'), has been adopted, in which it is implicit that all other vibrational modes in both states are unexcited. The vibrational assignments for the $\tilde{B} \leftarrow \tilde{X}$ band system are given in Table 1; the wavenumbers shown are band origins determined by rotational analysis (see below) or estimated from the gross features of the diffuse bands.

Two additional weak absorption bands were observed in high resolution spectra lying just to the short wavelength side of the (1,1) and (2,1) bands. These showed virtually the same rotational structure as the latter (Table 4, below), but blue-shifted by 58 and 83 cm^{-1} respectively. The weak band adjacent to the (2,1) band shows much sharper rotational structure than the latter, which is quite diffuse, indicating that a different vibrational transition is responsible. The most probable source of these two weak bands, with origins at 61 019 and 62 191 cm^{-1}, would appear to be excitation of the symmetric N—H stretching vibration, ν_1', with the two bands corresponding to $v_1' = 1$, and to $v_1' = 1$, $v_2' = 1$, respectively, with all other vibrations in both states in their zero levels. This assignment leads to values of ν_1' of 3092 and 3085 cm^{-1} in the $\tilde{B}$ state, which may be compared with $\nu_1'' =$

[2]In accordance with the established ground-state frequencies, ν_2 is the symmetric HNN bending vibration, and ν_3 the N—N stretching vibration (3, 4). This is the opposite notation to that used originally by Trombetti (1).

†Less certain because of overlap with other bands.

$3128\ cm^{-1}$ for the ground state (10). While these values seem reasonable, the assignment must remain tentative because the bands are weak and partially overlapped.

The $\tilde{C} \leftarrow \tilde{X}$ System (1470–1350 Å)

This band system shows many similarities to the $\tilde{B} \leftarrow \tilde{X}$ system, and very similar vibrational assignments in terms of ν_2' and ν_3' have been made (Fig. 1, Table 2). The bands are weaker and diffuse, with no resolved rotational structure, and the wavenumbers estimated for the band origins in Table 2 are therefore less accurate. Although many more absorption bands can be observed at wavelengths below 1360 Å, they are weak, badly overlapped and diffuse, and no assignments have been attempted.

Table 3 summarizes the fundamental vibrational frequencies measured for the $\tilde{B}$ and $\tilde{C}$ states, together with the values determined previously for the $\tilde{X}$ and $\tilde{A}$ states of diimide, and those for the ground-state $N_2H_2^+$ ion.

Rotational Analysis of the $\tilde{B} \leftarrow \tilde{X}$ System

Typical high-resolution plates are shown in Fig. 2 for the (0,0) and (1,0) bands. It is clear from these spectra that two strong sub-bands are present, and comparison with the previous spectra (1, 2) reveals that the apparent intensity alternation in the latter arose from fortuitous overlap of unresolved lines from these two sub-bands. It will be seen that the rotational structure is in complete accord and only compatible with the ^1A_g ground state of *trans*-diimide whose structure and rotational levels are well established from its infrared spectrum. The molecule of *trans*-N_2H_2 has three different moments of inertia ($I_A \neq I_B \neq I_C$), and as such it should be classified as an asymmetric top; however, since $I_A < I_B \approx I_C$, the molecule is not too far removed from a limiting case of the prolate symmetric top and, with a good approximation, its rotational structure can be described in terms of J and K quantum numbers.

The J-structure

Rotational assignments for the (0,0) and (1,0) bands are shown on the spectra in Fig. 2. In each band two sub-bands are present, one corresponding approximately to a parallel transition with $K' = 0$ and $K'' = 0$, and the other approximately to a perpendicular transition with $K' = 0$ and $K'' = 1$. The assignments of the rotation line can be determined unambiguously from the known rotational structure of the ground state.[3] From the wavenumbers of the lines of the P branch of the $\Delta K = 0$ sub-band those of the R branch were calculated using ground-state combination differences. Since the $\Delta K = -1$ sub-band has the same upper state as the $\Delta K = 0$ sub-band, the line positions for the P, Q, and R branches of the former could be calculated from the measured line positions of the latter and the known combination differences of the ground state. Agreement between calculated and observed line positions for both sub-bands was very good,

[3]We are grateful to Dr. J. W. C. Johns for providing these ground-state data.

usually within the accuracy of the measurement of the line centres (±0.03 cm^{-1} for the sharpest lines).

Similar rotational analysis was carried out for all bands with resolved *J*-structure, and the wavenumbers (cm^{-1} *in vacuo*) and assignments are given in Table 4. Essentially all the observed lines are accounted for in this analysis or as known lines of ammonia (11) which was still present in low concentration. From the line positions for the P and R branches in Table 4, values for the upper-state rotational constant B_v' were determined for each of the observed vibrational levels. The B_v' values reported in Table 5 are averages, calculated by a simplified formula, $\Delta_2F_v'(J) = R_v(J) - P_v(J) \simeq 4B_v'(J + \frac{1}{2})$, from the lines of the two sub-bands (12*a*).

The K*-structure*

All levels with $K > 0$ in the upper state appear to be greatly broadened by predissociation and no *J* type rotational structure arising from these levels can be observed. Nevertheless in N_2H_2 a weak and diffuse *K*-structure is clearly visible. Table 6 lists approximate positions of several sub-bands in six vibrational bands; wavenumbers were estimated from prints of first-order spectra, and refer to assumed positions of Q branches in a diffuse *K*-structure. To aid in these assignments, comparison was made with spectra of N_2D_2 in which the *K*-structure is better resolved.[4] From the data in Table 6, values of the upper-state rotational constant, A_v', were determined, using the symmetric rotor formulas (12*b*) and the molecular constants for the ground state (3). The values of A_v' are reported in Table 7, and were used to estimate the geometry of the $\tilde{B}$ state, Table 3.

Discussion

The Nature of the Electronic Transitions

The rotational analysis of the $\tilde{B} \leftarrow \tilde{X}$ system has confirmed that the lower state of the transition is the same as that of the infrared spectrum (3), i.e., a totally symmetric singlet state, ^1A_g, with planar *trans* geometry (C_{2h} symmetry). The strength of the absorption indicates that the electronic transition is symmetry allowed. If the $\tilde{B}$ state also has C_{2h} symmetry, it can be shown that it must belong to the ^1B_u species. Thus for C_{2h} symmetry and a ^1A_g ground state, the selection rules allow either ^1B_u or ^1A_u for the upper state; when the symmetry of the rotational levels is considered, only for a ^1B_u upper state is a $\Delta K = 0$ sub-band allowed as was observed. The $\tilde{B} \leftarrow \tilde{X}$ system can therefore be assigned to a $^1B_u \leftarrow {}^1A_g$ electronic transition.

Robin (13) has argued convincingly that the first strong absorption in the vacuum ultraviolet region in diimide and the alkyl azo compounds should come from the $3p \leftarrow n_+$ Rydberg transitions. In Table 8 are listed in order of increasing excitation energy the singlet states that can be derived from the valence-shell and lower Rydberg orbitals of *trans*-diimide. Experimental and theoretical (5) estimates of vertical transition energies are shown in columns 3 and 4, and lend support to Robin's arguments. The $3s \leftarrow n_+$ transition is symmetry forbidden and should be very weak. The 3*p* Rydberg orbitals are split into three components, σ, $\pi(a_u)$, and $\pi(b_u)$, by the geometry of the core molecule, and only two of these, the $3p_\sigma$ and $3p_\pi(b_u)$ components, have the required B_u symmetry. The CI vertical transition energies calculated by Vasudevan *et al.* (5) for the $3p \leftarrow n_+$ states lie well below that observed for the $\tilde{B} \leftarrow \tilde{X}$ system. Their value for the vertical transition energy for the $\tilde{A} \leftarrow \tilde{X}$ system is also lower then the experimental value, by about 0.6 to 0.7 eV, and if their calculated energies for all transitions originating from the n_+ orbital were increased by this amount, the value for the $3p_\pi(b_u) \leftarrow n_+$ transition would become about 7.6 eV, close to the central maximum of the $\tilde{\tilde{B}} \leftarrow \tilde{\tilde{X}}$ band system.[5]

[4]Unpublished spectra, R. A. Back and C. Willis, N_2D_2 generated by microwave discharge in N_2D_4; cf. Trombetti (1).

[5]If the calculated vertical energy for the $3p_\sigma \leftarrow n_+$ transition is similarly adjusted upward by 0.65 eV, an absorption maximum at about 1790 Å is predicted, and it seems possible that the weak diffuse bands observed in this region might be attributed to this transition. Other weak diffuse bands in the 1480–1512 Å region might correspond to the next member, the $4p_\sigma \leftarrow n_+$ transition, in the Rydberg series. Both these assignments are very tentative.

*Overlapped lines.

From considerations of orbital overlap, the $3p_\pi(b_u) \leftarrow n_+$ transition, with the Rydberg orbital and the n_+ orbital both in the plane of the molecule, should be much stronger than the transitions involving the $3p_\sigma$ and $3p_\pi(a_u)$ orbitals. It appears reasonable therefore to assign the strong $\tilde{B} \leftarrow \tilde{X}$ absorption system to this transition.

The possible involvement of the $\pi^* \leftarrow n_-$ and $\pi^* \leftarrow \pi$ states in the present absorption spectra requires some comment. The proper positions of

these states in Table 8 are in some doubt. The CI calculations by Vasudevan *et al.* (5) (column 4) place the former at 7.47 eV and the latter much higher, at 11.67 eV. The photoelectron spectrum reported by Frost *et al.* (14), on the other hand, puts the π-orbital 0.6 eV *below* the n_--orbital, and when combined with the observed value of 3.6 eV for the $\pi^* \leftarrow n_+$ vertical transition (4), leads to estimates of 8.0 and 8.6 eV for the $\pi^* \leftarrow \pi$ and $\pi^* \leftarrow n_-$ states respectively (column 3). These energies are close to those of the $\tilde{B}$ and $\tilde{C}$ states and the $\pi^* \leftarrow \pi$ state has the B_u symmetry observed for the $\tilde{B}$ state. The $\tilde{B} \leftarrow \tilde{X}$ system can nevertheless be safely identified with a Rydberg transition, on the basis of its strength and relative sharpness, and the increase in ν_3 frequency and decrease in N—N bond length relative to the ground state (cf. Table 3); the exact reverse changes would be expected for both $\pi^* \leftarrow$

π and $\pi^* \leftarrow n_-$ transitions (see below). It must be concluded that these valence-shell transitions are probably buried under the stronger $\tilde{B}$ and $\tilde{C}$ systems where they would be difficult to detect photographically, especially if the spectra are diffuse. Some weak diffuse bands are in fact observed between the two systems which cannot be assigned to either, and there is also a maze of unresolved unassigned bands to the blue of the $\tilde{C} \leftarrow \tilde{X}$ system.

The second absorption system observed in the present study, $\tilde{C} \leftarrow \tilde{X}$, shows no resolved rotational fine structure, hence no rigorous information about its electronic configuration or symmetry is available. The vibrational structure, however, and the

derived frequencies, show much similarity to the $\tilde{B} \leftarrow \tilde{X}$ system, and it can be assigned with some confidence to the next member in the Rydberg series, the $4p_\pi(b_u) \leftarrow n_+$ transition. When the origins of the $\tilde{B}$ and $\tilde{C}$ systems (57 926.45 and 67 893.9 cm^{-1} respectively) are fitted to the well-known Rydberg formula, $\nu = IP - R/(n-\delta)^2$, taking $n = 3$ and 4 and assuming a constant quantum defect, δ, values of IP = 9.62 eV and $\delta = 0.639$ are obtained. The former is in close agreement with recent measurements of the ionization potential of N_2H_2 of 9.65 ± 0.08 eV (15) and 9.7 ± 0.1 eV (16) by mass spectrometry, and 9.59 ± 0.01 eV (14) from its photoelectron spectrum. The quantum defect is of the size expected for *p*-Rydberg orbitals (17), and its value agrees well with estimates by Frost *et al.* (14), who used a term value approach based on the photoelectron spectrum to assign the $\tilde{B} \leftarrow \tilde{X}$ system to a $3p \leftarrow n_+$ Rydberg transition.

3	1.263	1.258	

*In cm^{-1}; $\bar{B}_v' = \frac{1}{2}(B_v' + C_v')$.

The Geometry of the $\tilde{B}$ *State*

The geometry of the $\tilde{B}$ state was calculated from the rotational constants A_v' and $\bar{B}_v'$ (where $\bar{B}_v' = \frac{1}{2}(B_v' + C_v')$) assuming a planar *trans*-configuration of C_{2h} symmetry, and the same N—H bond length as in the ground state. The latter assumption is supported by the very weak excitation of ν_1', the symmetric N—H stretching vibration, in the spectrum. Table 3 reports values of the N—N bond length and the HNN bond angle obtained for the (0,0) vibrational band. The HNN bond angle is increased by almost 21° from its ground-state value. As in the $\tilde{A} \leftarrow \tilde{X}$ system (4, 18), the long progressions in ν_2' in the spectrum are consistent with a large change in the HNN angle on excitation. The N—N bond distance in the upper state is shorter by about 0.09 Å (i.e., ~7%) than in the ground state; because of its dependence on the assumed N—H bond length, this value is only approximate. A shortening of the N—N bond length is expected from the excitation of one electron from the n_+ orbital, which is considerably N—N antibonding, to a largely nonbonding Rydberg orbital. Associated with this change in bond length, excitation of ν_3' is observed in the spectrum and its frequency increases to 1875 cm^{-1} from 1529 cm^{-1} in the ground state.

In Table 3 are summarized all the available data on the geometry and frequencies of the three symmetric vibrations in the $\tilde{X}$, $\tilde{A}$, $\tilde{B}$, and $\tilde{C}$ states of

trans-diimide and the ground state of the $N_2H_2^+$ ion. All the excited species and the ion show large increases in bond angle and decreases in ν_2 arising from removal of one electron from the angle-sensitive n_+ orbital. Such an effect was predicted by Walsh (19) and supported by more recent quantitative calculations of potential energy curves by Vasudevan *et al.* (5), and leads to strong excitation of the ν_2' bending vibration in the spectra.

Both the $\tilde{C}$ state and the ion show increases in ν_3' (and presumably therefore decreases in the N—N bond length) relative to the ground state, very similar to those discussed above for the $\tilde{B}$ state, for similar reasons. The $\tilde{A}$ state, by contrast, shows an *increased* N—N bond length and a little change in ν_3', as expected for excitation of an electron to the N—N antibonding π^* orbital, and the $\pi^* \leftarrow n_-$ and $\pi^* \leftarrow \pi$ states would be expected to show even larger changes in the same direction.

Predissociation in the $\tilde{B}$ *State*

The $\tilde{B} \leftarrow \tilde{X}$ absorption spectrum is very much sharper than the $\tilde{A} \leftarrow \tilde{X}$ system, which showed only a trace of coarse rotational structure at the longest wavelengths. The diffuseness of the latter system has been attributed to a rapid internal conversion to the ground state facilitated by a very low torsional barrier in the excited state (4). The $\tilde{B}$ state, with strong N—N π-bonding, should have a large torsional barrier, and perhaps the lack of an easy torsional route to internal conversion may account for its much greater stability. The $\tilde{B}$ state is nevertheless strongly predissociated, even for the relatively sharp $K' = 0$ levels; for the (0,0) and (1,0) bands very approximate minimum line widths of $\sim 0.8\ cm^{-1}$ can be estimated corresponding to a lifetime of ~ 7 ps (based on the uncertainty principle formula $\Delta\nu\Delta t = 1/2\pi$). With increasing vibrational excitation the bands become progressively more diffuse, with rotational structure barely discernible, for example, in the (4,0) or (3,1) bands. The $\tilde{B} \leftarrow \tilde{X}$ spectrum of N_2D_2 is notably sharper than that of N_2H_2, which was not true for the $\tilde{A} \leftarrow \tilde{X}$ system, suggesting that dissociation of an N—H bond is directly involved in the predissociation.

Summary

(*1*) Rotational analysis of a well-resolved vacuum ultraviolet absorption spectrum of relatively pure diimide produced from the thermolysis of sodium tosylhydrazide has shown that the $\tilde{B} \leftarrow \tilde{X}$ system previously studied by Trombetti arises from the ^1A_g ground state of *trans*-diimide that has been well characterized by its infrared spectrum. No evidence was found for the presence of other isomers or triplet states of diimide. The spectrum is essentially the same as that of diimide produced by a microwave discharge through hydrazine vapor, although almost free of the strong ammonia impurity absorption that obscured much of the latter.

(*2*) The $\tilde{B}(^1B_u) \leftarrow \tilde{X}(^1A_g)$ system and a second new $\tilde{C} \leftarrow \tilde{X}$ system, with origins at 1727 and 1473 Å respectively, are believed to correspond to the Rydberg transitions, $3p_\pi(b_u) \leftarrow n_+$ and $4p_\pi(b_u) \leftarrow n_+$, members of a series converging to an ionization potential of 9.62 eV with a quantum defect of 0.639.

(*3*) Excitation of the $\tilde{B}$ state leads to an increase of 21° in the HNN bond angle and a decrease in the N—N bond length of about 0.09 Å. Associated with these changes in geometry are a decrease in ν_2', the symmetric bending frequency, and an increase in ν_3', the symmetric N—N stretching frequency, in both the $\tilde{B}$ and $\tilde{C}$ states, while both the ν_2' and ν_3' vibrations are excited in the transitions.

Synthesis, characterization, and X-ray structural analysis of the Cu(I) derivative, $[Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7]Cu \cdot PPh_3$

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received July 28, 1980

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **59**, 518 (1981).

The Cu(I) complex $[Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7]Cu \cdot PPh_3$ has been synthesized and its fluxional behavior in solution probed. Attempts have been made to isolate the analogous Cu(I) carbonyl complex. Crystals of [dimethyl(3,5-dimethyl-1-pyrazolyl)(*N*,*N*-dimethylethanolamino)gallato (*N(2),O,N(3)*)](triphenylphosphine)copper(I) are monoclinic, $a = 18.871(2)$, $b = 9.464(1)$, $c = 18.374(2)$ Å, $\beta = 109.62(1)°$, $Z = 4$, space group $P2_1/c$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.028$ and $R_w = 0.035$ for 2729 reflections with $I \geq 3\sigma(I)$. The copper atom is bonded to the phosphine and to the tridentate $Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7^-$ ligand resulting in a distorted tetrahedral coordination geometry. The Cu—P distance of 2.156(1) Å is unusually short. Other important bond distances (corrected for libration) are: Cu—O, 2.163(2), Cu—N(pyrazolyl), 2.025(3), Cu—N(amino), 2.144(3), Ga—O, 1.896(3), Ga—N, 2.005(3), and Ga—C, 1.972(5) and 1.987(5) Å.

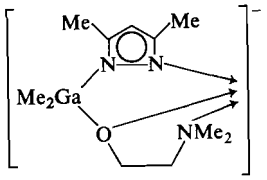
KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **59**, 518 (1981).

On a synthétisé le complexe de Cu(I)$[Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7]Cu$ et on a prouvé son comportement fluxionnaire en solution. On a essayé d'isoler les complexes carbonylés analogues du Cu(I). Les cristaux de [diméthyl(diméthyl-3,5 pyrazolyl-1)(*N*,*N*-diméthyléthanolamino)gallato(*N(2),O,N(3)*)] triphénylphosphine Cu(I) sont monocliniques et appartiennent au groupe d'espace $P2_1/c$ avec $a = 18,871(2)$, $b = 9,464(1)$, $c = 18,374(2)$ Å, $\beta = 109,62(1)°$, $Z = 4$. On a résolu les structures par les méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0,28$ et $R_w = 0,035$ pour 2729 réflexions avec $I \geq 3\sigma(I)$. L'atome de Cu est lié à la phosphine et au ligand tridentate $Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7^-$ conduisant ainsi une géométrie de coordination tétraédrique déformée. La distance Cu—P de 2,156(1) Å est inhabituellement courte. Les autres longueurs importantes de liaison (corrigée pour la libration) sont: Cu—O, 2,163(2), Cu—N(pyrazolyl), 2,025(3), Cu—N(amino), 2,144(3), Ga—O, 1,896(3), Ga—N, 2,005(3) et Ga—C, 1,972(5) et 1,987(5) Å.

[Traduit par le journal]

Introduction

Tridentate chelating gallate ligands (incorporating pyrazolyl and ethanolamino moieties) that impart an asymmetry in their complexes with metallic species and create electron-rich metal centres have been the subject of a number of recent publications (1). This type of ligand has now been used to stabilize the Cu(I) centre in the complex $[Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7]Cu \cdot PPh_3$ and also in attempts to prepare isolable Cu(I) carbonyl derivatives. ^1H nmr results indicate that the title compound is fluxional in solution. In the solid state the title compound has been shown by X-ray structural studies to possess the Cu(I) centre in a tetrahedral environment.



1

Experimental

Starting Materials

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free dry nitrogen or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) and diethyl ether were dried by refluxing over sodium/benzophenone and were used immediately following distillation. Toluene was dried by refluxing over potassium followed by distillation. The gallium ligand, $Na^+Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7^-$, **1**, was prepared as described earlier (2). $Ph_3P \cdot CuBr$ was prepared from Ph_3P and CuBr (3).

Preparation of $[Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7]Cu \cdot PPh_3$

A THF solution of the ligand **1** (1.6 mmol) was added to a slurry of $Ph_3P \cdot CuBr$ (0.649 g, 1.6 mmol) in the same solvent. The mixture was stirred overnight and the solvent then removed *in vacuo*. The remaining white solid was extracted with toluene and the extracts filtered. Slow evaporation of the filtrate gave large colorless crystals of the product in approximately 80% yield. *Anal.* calcd. for $[Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7]Cu \cdot PPh_3$: C 57.2, H 6.3, N 6.9; found: C 57.6, H 6.4, N 7.0. Room temperature ^1H *nmr* (C_6D_6 solution): τ = 9.97 s ($GaMe_2$), 8.15 s (NMe_2), 7.85 s (pz—Me), 7.66 s (pz—Me), 7.90 t and 5.97 t ($—CH_2—CH_2$) ($J \approx 5$ Hz), 4.01 s (pz—H(4)), 2.95 m and 2.41 m (PPh_3) ($\tau_{C_6H_6} = 2.84$ ppm; s = singlet, t = triplet; pz = pyrazolyl). *Mass spectrum*: the parent ion was not observed, the highest mass signal arising from the ion $[Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7]Cu^+$. Other strong signals observed were due to the ions $[MeGa(OCH_2CH_2NMe_2)N_2C_5H_7]Cu^+$, $[MeGa(N_2C_5H_7)O]Cu^+$, PPh_3^+, PPh_2^+, and PPh^+.

Attempted Preparation of $[Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7]Cu \cdot CO$

CuCl (0.099 g, 1.00 mmol) was suspended in diethyl ether saturated with carbon monoxide. A solution of the ligand **1** (1.00 mmol) in THF was added dropwise over a period of 30 min. Slowly a flocculent white precipitate formed and after the reac-

tion mixture had been stirred overnight (under an atmosphere of CO) the mixture was filtered. The ir spectrum of the solution showed a ν_{CO} band at ~2070 cm^{-1} (free CO, ν_{CO} 2143 cm^{-1}). However, after removal of volatiles *in vacuo* the remaining white solid showed no evidence for a Cu—CO moiety in its ir spectrum. When this white solid was treated with CO gas, the ir spectrum of the resulting residue showed a weak ν_{CO} band at ~2078 cm^{-1}. Again this band disappeared when the solid was pumped *in vacuo*. The white solid decomposed slowly to yield in part the previously characterized five-coordinate gallium dimer $(Me_2GaOCH_2CH_2NMe_2)_2$ (4). The propensity of this Cu compound to decomposition and its extreme sensitivity to air curtailed the study of this reaction.

Spectra

The mass spectrum was collected on a Varian MAT CH4 spectrometer at 70 eV with an ion source temperature of 100–180°C and the ^1H nmr spectra on a Varian XL-100 spectrometer using FT techniques.

X-ray Crystallographic Analysis of [Dimethyl(3,5-dimethyl-1-pyrazolyl)(N,N-dimethylethanolamino)gallato-(N(2),O,N(3))](triphenylphosphine)copper(I)

A crystal ca. 0.21 × 0.35 × 0.35 mm in size was mounted in a general orientation. Parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Mo K_α radiation (λ = 0.71073 Å). Crystal data at 22°C are:

$C_{29}H_{38}CuGaN_3OP$ fw = 608.89
Monoclinic, a = 18.871(2), b = 9.464(1), c = 18.374(2) Å, β = 109.62(1)°, V = 3091.0(5) Å^3, ρ_m = 1.30 (by flotation in aqueous KI), Z = 4, ρ_c = 1.308 g cm^{-3}, $F(000)$ = 1264, μ(Mo K_α) = 16.3 cm^{-1}. Absent reflections: $h0l$, $l \neq 2n$ and $0k0$, $k \neq 2n$ uniquely indicate the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured with graphite-monochromatized Mo K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 0.96–10.06° min^{-1} over a range of (0.70 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 50°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, remained constant to within ±4%. After data reduction, an absorption correction was applied using the Gaussian integration method (5, 6). Transmission factors ranged from 0.574 to 0.777 for 190 sampling points. Of the 5415 independent reflections measured, 2729 (50.4%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

The structure was solved by direct methods, the coordinates of the Ga, Cu, and P atoms being determined from an E-map and those of the remaining non-hydrogen atoms from a subsequent Fourier synthesis. After refinement of the non-hydrogen atoms with anisotropic thermal parameters to R = 0.044, a difference map revealed the positions of 35 of the 38 hydrogen atoms. Idealized positions were calculated for all hydrogen atoms which were included as fixed atoms in subsequent calculations (C(sp^3)—H = 0.98, C(sp^2)—H = 0.95 Å, $U_H = xU_C$ where x = 1.25 for methyl H and 1.15 for all others).

The scattering factors of ref. 7 were used for non-hydrogen atoms and those of ref. 8 for hydrogen atoms. Anomalous scattering factors from ref. 9 were used for the Ga, Cu, and P atoms. The weighting scheme, $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. Convergence was reached at R = 0.028 and R_w = 0.035 for 2729 reflections with $I \geq 3\sigma(I)$. For all 5415 reflections R = 0.094 and R_w = 0.035. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts correspond to 0.06 and 0.45σ respectively. The mean error in an observation of unit weight was 1.043. A final difference map showed maximum fluctuations of ±0.28 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (10) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0034 Å^2. Six successful analyses were carried out; three tetrahedra centered at Ga, Cu, and N(3), two PPh moieties and a 12 atom group consisting of the P atom plus the atoms comprising the system of three fused rings (rms ΔU_{ij} = 20, 22, 20, 33, 27, and 70 × 10^{-4} Å^2). Analysis of the phenyl ring containing C(24) and P gave a non-positive-definite libration tensor. The appropriate bond distances have been corrected for libration (11), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values and corrected bond angles are not different from the uncorrected values listed in Table 4 by more than one standard deviation. Intra-annular torsion angles defining the conformations of the chelate rings are listed in Table 5.

Results and Discussion

The compound $[Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7]Cu \cdot PPh_3$ was found to be air stable in the solid state and also stable in hydrocarbon solvents under a nitrogen atmosphere. However, on exposure of such solutions to air or on dissolution of the solid in halogenated solvents, decomposition is evidenced by the formation of blue solutions.

The rt ^1H nmr of the title compound in C_6D_6 solvent displayed one signal due to the —$GaMe_2$ protons, one signal due to the —NMe_2 protons, and two pseudo-triplets due to the —CH_2 —CH_2 protons (see Fig. 2). This spectrum is suggestive of a *meridionally* coordinated gallate ligand and consequently a square-planar Cu(I) derivative. A tetrahedral arrangement about the Cu atom in the complex in solution would lead to two signals for each of the —$GaMe_2$ and —NMe_2 groups of protons. However, a square-planar geometry is very unusual for a Cu(I) centre and our previous experience with a related four-coordinate Ni nitrosyl derivative (12) prompted us to investigate the present Cu(I) complex for fluxional behavior in solution.

The —$GaMe_2$ signal was monitored as the temperature of an acetone-d^6 solution was lowered. The sharp singlet at rt gradually broadened at tem-

[1]The structure factor table and Table 2 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

peratures below ~ −40°C, "disappeared", and reappeared as two signals in positions on either side of the position of the original singlet. These two signals were sharp at the lowest temperature attainable (−75°C) and were separated by about 0.2 ppm. This evidence suggests that the Cu(I) centre is indeed tetrahedrally coordinated but that at temperatures above −40°C in solution the molecule undergoes a rapid (on the nmr time scale) fluxional process to give an "average" square-planar environment about the Cu atom.

Two plausible mechanisms might explain the fluxional process. The first possibility involves a simple inversion at the metal centre without dissociation of any of the ligand atoms from the metal. This would give an intermediate square-planar environment about the Cu atom. The second possibility (see Fig. 3) involves a three-coordinate intermediate formed by dissociation of the —NMe_2 part of the gallate ligand from the Cu(I) centre. In this intermediate the —NMe_2 and —$GaMe_2$ groups would also give rise to one signal each in the ^1H nmr spectrum. The expected tetrahedral nature of the Cu(I) complex suggested by these low temperature ^1H nmr studies has been confirmed in the solid state by X-ray crystallographic studies (see below).

At the outset of this study it was thought entirely possible that the compound $[Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7]Cu \cdot CO$ should exist and be moderately stable. Effectively in this complex the CO ligand formally replaces the Ph_3P ligand of the title compound. It was thought that the ability of the gallate ligands to create electron-rich metal centres in its complexes (13) would help to stabilize a Cu(I) carbonyl derivative. Thus the only stable Cu(I) carbonyl complexes to have been reported contain ancillary ligands capable of creating increased electron density at the copper centre with

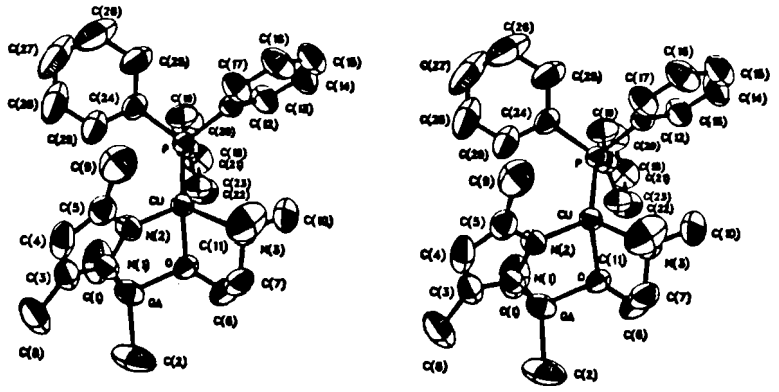

FIG. 1. Stereo view of the [dimethyl(3,5-dimethyl-1-pyrazolyl)(*N,N*-dimethylethanolamino)gallato(*N(2),O,N(3)*)](triphenylphosphine)copper(I) molecule. 50% thermal ellipsoids are shown for the non-hydrogen atoms.

*Corrected distances are referred to throughout the discussion, esd's for these values are assumed to be equal to those for the uncorrected values.

concomitant stronger Cu—CO binding. The first of these incorporated a pyrazolyl borate ligand, viz. $[HB(N_2C_3H_3)_3]Cu \cdot CO$ (14), the complex being air stable with a ν_{CO} ir band at 2083 cm^{-1}. The nature of the tridentate borate ligand necessarily imparts a tetrahedral structure at the Cu(I) centre in this complex, and this was confirmed in a structure determination (15). More recently a number of stable "amine" Cu(I) carbonyl complexes have been reported. These include the diethylenetriamine complex $[Cu(dien)(CO)]^+BPh_4^-$ (16) with a ν_{CO} ir band at 2080 cm^{-1} and a series of ethylenediamine Cu(I) carbonyl complexes (17). In the present study the reaction of $Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7^-$ with CuCl in the presence of CO in diethyl ether did generate a species in solution giving an expected low ν_{CO} ir band at ~2070 cm^{-1}. However, isolation of a copper carbonyl complex from solution did not prove feasible. It is evident that only weak coordination of CO occurs in this experiment and although the clear possibility of reversible CO binding exists with this system, the unstable nature of the product from the reaction discouraged any further studies.

Crystal Structure of [Dimethyl(3,5-dimethyl-1-pyrazolyl)(N,N-dimethylethanolamino)gallato(N(2),O,N(3))](triphenylphosphine)copper(I)

The crystal structure of $[Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7]Cu \cdot PPh_3$ consists of discrete molecular units separated by normal van der Waals distances. The copper atom is bonded to the phosphorus and to the oxygen and two nitrogen atoms of the tridentate $Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7^-$ ligand resulting in a distorted tetrahedral coordination geometry. The mean bond angle at copper involving phosphorus is 122.5°, and the remaining bond angles average 92.9°.

The Cu—P distance of 2.156(1) Å is unusually short, the normal range for tetrahedral Cu(I)—P distances being 2.19–2.35 Å with a mean value of 2.270 Å for 61 independent observations. The only known Cu(I)—P bond shorter than that in the present structure is the distance of 2.136(9) Å observed in the pseudotetrahedral complex $(\eta^5\text{-}C_5H_5)Cu \cdot PEt_3$ (18). Two interrelated factors are believed responsible for this short Cu—P distance. Steric constraints of chelation by the ligand **1** cause hybridization changes at the metal which result in increased *s* character of the fourth bond in tetrahedral complexes. This, combined with the enhancement of electron density at the metal centre (13), results in unusually short bond distances, as noted for the tetrahedral complex $[Me_2Ga(OCH_2CH_2NMe_2)N_2C_5H_7]Ni(NO)$ (12). The Cu—O and Cu—N distances are as expected.

The gallium atom has distorted tetrahedral coordination geometry with bond angles ranging from 97.7(1) to 124.9(3)°. The internal geometry of the gallate ligand is in good agreement with that observed in related structures (1) and the ligand conformation is similar to other structures in which the ligand is facially coordinated (12, 19–21). The

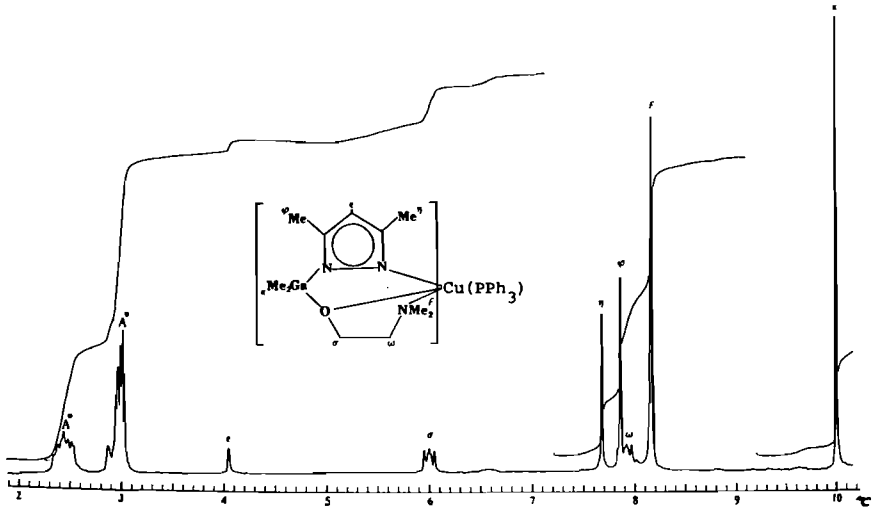

FIG. 2. 100 MHz ^{1}H nmr spectrum of $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_5H_7)]Cu \cdot PPh_3$ in C_6D_6 solution (A* signals due to PPh_3 ligand).

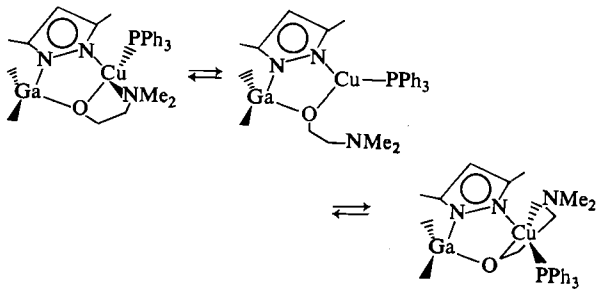

FIG. 3. A possible mechanism for the fluxional process observed for $[Me_2Ga(OCH_2CH_2NMe_2)(N_2C_5H_7)]Cu \cdot PPh_3$ in solution.

pyrazolyl group is planar ($\chi^2 = 0.04$ for N_2C_3) with the metal atoms considerably displaced from the mean plane (Ga by − 0.2540(5) and Cu by −0.1950(5) Å).

The geometry of the phosphine ligand is normal. The phenyl ring containing C(12) is planar within experimental error ($\chi^2 = 8.5$) while the two other phenyl rings are slightly, but significantly, non-planar ($\chi^2 = 19.8$ and 13.7 for rings containing C(18) and C(24), respectively). The phosphorus atom is significantly displaced from each of the three phenyl mean planes (by −0.243(1), 0.087(1), and −0.057(1) Å from the rings containing C(12), C(18), and C(24), respectively). There is a possible weak intramolecular hydrogen bond between the oxygen atom and a phenyl hydrogen (C(23)···O = 3.456(5), H(23)···O = 2.55 Å, C—H···O = 158°).

Crystal structure of a stemodin intermediate

RICHARD A. PAUPTIT AND JAMES TROTTER

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received July 25, 1980

RICHARD A. PAUPTIT and JAMES TROTTER. Can. J. Chem. **59**, 524 (1981).

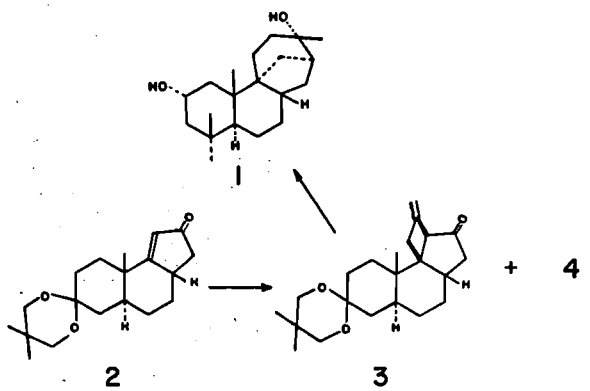
Crystals of the title compound, $C_{22}H_{32}O_3$, are monoclinic, $P2_1/n$, $a = 11.832(1)$, $b = 11.423(1)$, $c = 14.637(1)$ Å, $\beta = 98.71(2)°$, $Z = 4$. The structure was solved by direct methods and was refined to $R = 0.035$ for 2052 reflexions with $I \geq 3\sigma(I)$. The X-ray study was carried out in order to determine the structures of two diastereomeric products obtained from a key step in a projected synthesis of the diterpenoids aphidicolin and stemodin. The product examined is the stemodin intermediate.

RICHARD A. PAUPTIT et JAMES TROTTER. Can. J. Chem. **59**, 524 (1981).

Les cristaux du composé du titre, $C_{22}H_{32}O_3$, sont monocliniques, $P2_1/n$, $a = 11.832(1)$, $b = 11.423(1)$, $c = 14.637(1)$ Å, $\beta = 98.71(2)°$, $Z = 4$. On a résolu la structure par les méthodes directes et on a l'affinée jusqu'à une valeur de $R = 0.035$ pour 2052 réflexions avec $I \geq 3\sigma(I)$. On a fait l'étude par X-rayon pour déterminer les structures de deux produits diastéréomères qu'on a obtenu d'un pas dominant dans une synthèse projetée des diterpenoids aphidicolin et stemodin. Le produit qu'on a examiné est l'intermediaire de stemodin.

Introduction

In connection with a research program directed towards the total synthesis of the tetracyclic diterpenoids aphidicolin and stemodin (**1**), the photochemically-induced cycloaddition of allene to the cyclic enone **2** was investigated (1). Thus, irradiation (4.5 h, low-pressure mercury lamp) of a cold (−72°C) solution of **2** and allene in dry, deoxygenated tetrahydrofuran gave a mixture of two isomeric photoadducts, **3** and **4**, which were separated by column chromatography on silica gel (elution with 10:5:2 cyclohexane – hexane – ethyl acetate). The diastereomer which was eluted from the column first (39% yield) exhibited mp 132–133°C, while the second isomer (42% yield) had mp 134–135°C. In order to determine the structures of these two diastereomeric adducts, prior to continuing the syntheses, the first-eluted isomer has been studied by X-ray methods, and proves to be **3** (and its enantiomorph, since the synthetic materials are racemates).



SCHEME 1.

Experimental

Crystal data are as follows:

$C_{22}H_{32}O_3$ fw = 344.5

Monoclinic, $P2_1/n$, $a = 11.832(1)$, $b = 11.423(1)$, $c = 14.637(1)$ Å, $\beta = 98.71(2)°$, $V = 1955.5$ Å^3, $Z = 4$, $\rho_c = 1.17$ g cm^{-3}.

The intensity data were collected on an Enraf-Nonius CAD-4 automatic diffractometer with an ω–θ scan technique and graphite-monochromatized MoKα radiation. The ω-scan angle $\Delta\omega$ was $(1.00 + 0.35 \tan\theta)°$ and was extended by 25% on either side for background counts. The aperture was $(2.50 + \tan\theta)$ mm wide and 4 mm high. The intensities of three standard reflections were measured every 1 h of X-ray exposure time and showed no variation during data collection. The same three reflections were checked for orientation every 100 reflections; automatic reorientation occurred if the scattering vectors differed from the calculated positions by more than 0.05°. Of the 3432 unique reflections collected in the range $0 < \theta \leq 25°$, 2052 (60%) had $I/\sigma(I) \geq 3.0$ ($\sigma^2(I) = S + B + (0.04S)^2$ and S and B are the scan and background counts), and were classified as observed. Only the observed reflections were included in the refinement.

The 500 highest renormalized E's, obtained by using the minimum profile of a K-curve, were input into the MULTAN program (2) and the resulting E-map revealed all the non-H atoms. After three isotropic and three anisotropic full-matrix least-squares refinement cycles a difference map revealed 31 of 32 H's; the position of the remaining H was calculated. Two more refinement cycles with H atoms isotropic, non-H atoms anisotropic, and with use of a polynomial weighting scheme (3) resulted in the final $R = 0.034$ and $R_w = 0.046$, and after several more cycles the H atom parameters had converged. The scattering factors of ref. 4 were used for non-hydrogen atoms and those of ref. 5 for hydrogen atoms. Final atomic positional parameters are given in Table 1.[1]

Discussion

The X-ray study has established that the first-eluted isomer is the β-cyclobutyl species **3**, which

[1]Thermal parameters, bond lengths involving hydrogen atoms, the packing diagram, and the structure factor table are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

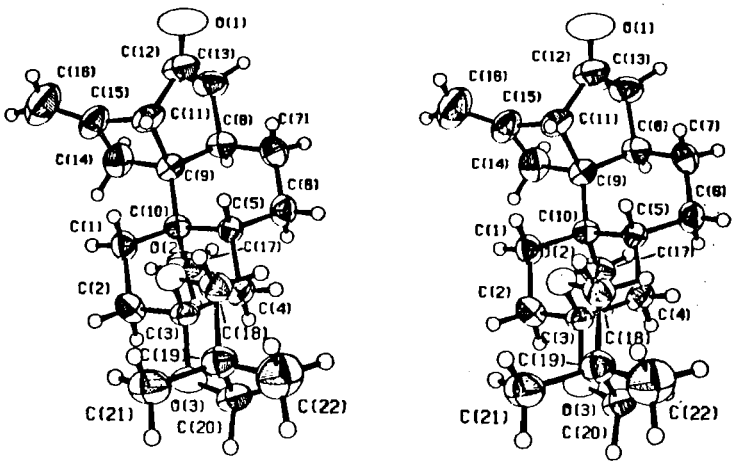

FIG. 1. A stereoview of the molecule (this is the enantiomorph of (3) in Scheme 1).

may prove to be a useful intermediate in a synthesis of stemodin (1). The molecular structure is shown in Fig. 1, and bond lengths and angles are given in Table 2. Bond distances are representative of those expected for C—C, C=C, C—O, and C=O bonds; bond angles are fairly close to those expected for 4-, 5-, and 6-membered rings, with some deviations resulting from strain in the polycyclic molecule. Intermolecular distances[1] are unexceptional.

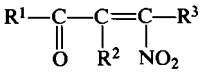
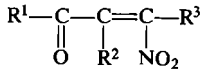
The electrochemical reduction of compounds of the type



has been investigated in hydroorganic medium between pH 0 and 7. For **3** ($R^1 = R^2 = R^3 = C_6H_5$), the 3,4,5-triphenylisoxazole is obtained at pH 1. **3** in neutral medium, **1** ($R^1 = CH_3$, $R^2 = R^3 = C_6H_5$) and **2** ($R^1 = C_2H_5$, $R^2 = R^3 = C_6H_5$) lead to 4,5-dihydroxy-2-isoxazoline (only one of such compounds is described in the literature). The structure of these compounds has been determined by the usual spectroscopic methods (ir, nmr, mass spectrometry) and by radiocrystallography. A mechanism which accounts for the whole set of our results is proposed: it involves an intermediate α,β-nitrosoethylenic compound which cyclizes into a 4,5-dihydroxy-2-isoxazoline or gives an 1,3-diketone oxime upon reduction; this last compound cyclizes into an isoxazole.

CHRISTIAN BELLEC, PIERRE MAITTE, JOSEPH ARMAND et CLAUDE VIEL. Can. J. Chem. **59**, 527 (1981).

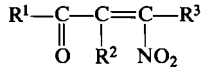
La réduction électrochimique de composés du type



a été étudiée en milieu hydroorganique entre pH = 0 et pH = 7. Pour **3** ($R^1 = R^2 = R^3 = C_6H_5$) on obtient à pH = 1 le triphényl-3,4,5 isoxazole. Dans le cas de **3** en milieu neutre, de **1** ($R^1 = CH_3$, $R^2 = R^3 = C_6H_5$) et de **2** ($R^1 = C_2H_5$, $R^2 = R^3 = C_6H_5$) on isole des dihydroxy-4,5 isoxazolines-2 composés dont un seul est décrit dans la littérature. La structure de ces composés a été déterminée par les méthodes spectroscopiques usuelles (ir, rmn, spectrométrie de masse) et par radiocristallographie. Un mécanisme en accord avec l'ensemble de nos résultats est proposé: il fait intervenir un intermédiaire nitrosé α,β-éthylènique susceptible de se cycliser en dihydroxy-4,5 isoxazoline-2 ou d'être réduit en oxime de dicétone-1,3, celle-ci se transformant ultérieurement en isoxazole.

Introduction

The electrochemical reduction of α,β-ethylenic ketones and α,β-ethylenic nitro derivatives has been the subject of a number of papers (ref. 1, p. 399, ref. 2, p. 81). But, to the best of our knowledge, no investigation of compounds of the type



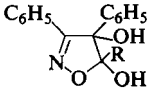
has ever been carried out. We now report the results obtained with **1** ($R^1 = CH_3$, $R^2 = R^3 = C_6H_5$), **2** ($R^1 = C_2H_5$, $R^2 = R^3 = C_6H_5$), and **3** ($R^1 = R^2 = R^3 = C_6H_5$) in hydroorganic medium (CH_3CN 50%). This study is performed at pH < 7 as these compounds decompose rapidly at higher pH values.

Polarography and Electrolysis of 1 and 2

Between pH 1 and 7, both compounds evidence a 2e cathodic wave followed, until pH 4, by a second 4e wave. The $E_{1/2}$ are pH-dependent (Fig. 1).

An electrolysis in dilute solution performed at the potential of the first plateau (pH 1.2, $C = 2 \times 10^{-3}$ *M*, $E = -0.4$ V) consumes 2 electrons per molecule. The polarogram of the electrolyzed solution only shows the second wave of the starting compound. At the same time, the strong uv band of the conjugated system (λ_{max} = 310 nm for **1** and 315 nm for **2**) disappears; the electrolyzed solution evidences another strong band with a λ_{max} at shorter wavelength (λ_{max} = 255 nm for **1** and λ_{max} = 260 nm for **2**).

A preparative electrolysis carried out under similar conditions allows the isolation of the 4,5-dihydroxy-3,4-diphenyl-2-isoxazolines **4** and **5**.



4 R = CH_3
5 R = C_2H_5
7 R = C_6H_5

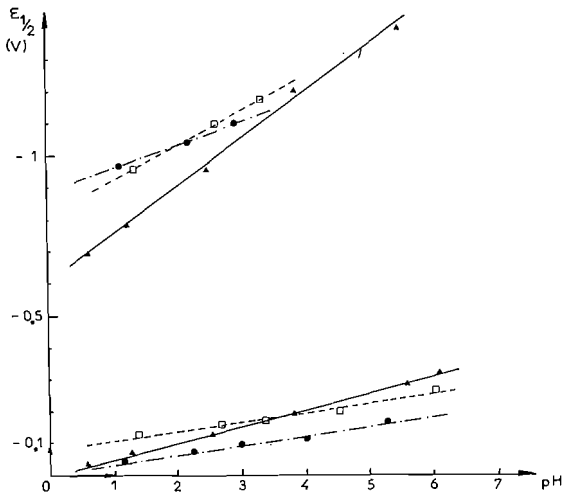

FIG. 1. Plot of $E_{1/2}$ vs. pH: ●, **1**; □, **2**; ▲, **3**.

The usual spectroscopic methods (ir, nmr, mass spectrometry) do not permit assignment of an unambiguous structure to **4** and **5**. However, the spectra clearly show that **4** and **5** are homologous products. The structure of **4** has been determined by radiocrystallography (3) as the *cis*-4,5-dihydroxy-5-methyl-3,4-diphenyl-2-isoxazoline. As for **5**, the nmr spectrum points to a mixture of similar amounts of *cis* and *trans* isomers and not to a single stereoisomer.

Compounds **4** and **5** present a 4 F wave identical to the second wave of **1** and **2**. Preparative electrolysis of **4** and **5** only led to gummy products.

Polarography and Electrolysis of 3

Between pH 1 and 7, **3** shows a first wave, the height of which decreases with increasing pH (Fig. 2) from 4e at pH 1 to 2e at pH 6. Its $E_{1/2}$ is pH-dependent (Fig. 1). It is followed by a second 4e wave.

The consumption of electricity during the electrolysis of a dilute solution at a potential corresponding to the first plateau (pH = 1.4, $c = 2 \times 10^{-3}$ *M*, $E = -0.5$ V) is near 4e per molecule. The height of the second wave decreases during the electrolysis and disappears completely at the completion of the electrolysis. A preparative electrolysis performed under similar conditions gives the 3,4,5-triphenylisoxazole **6**.

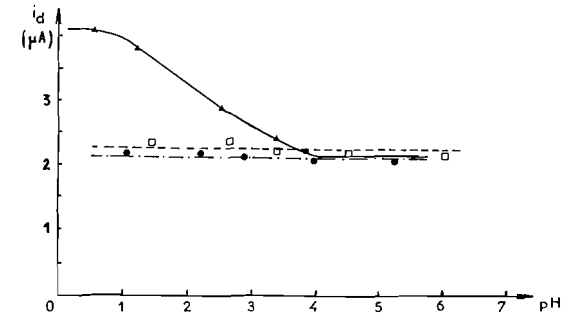

FIG. 2. Plot of i_D vs. pH; ●, **1**; □, **2**; ▲, **3**.

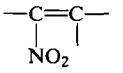
At pH 6.1 ($c = 2 \times 10^{-3}$ *M*, $E = -0.5$ V) coulometry consumes 2e per molecule. The polarogram of the electrolysed solution evidences a single wave identical to the second wave of **3**. A preparative electrolysis leads to the 4,5-dihydroxy-3,4,5-triphenyl-2-isoxazoline, **7**.

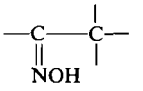
Discussion

Reduction of 3 in Acidic Medium

The formation of the isoxazole **6** can be explained by Scheme 1: the



group is reduced into a saturated oxime



(**8**) according to the classical reduction of α,β-nitroethylenic derivatives (2). The 1,3-diketone monoxime (**8**) obtained cyclizes into a 5-hydroxy-2-isoxazoline (**9**) (4) which then dehydrates spontaneously into the isoxazole **6** (5).

The assignment of the second wave of **3** is more difficult; it can be due to the oxime (**8**) (C_6H_5—C(=NOH)CH_3 gives a 4 F wave with an $E_{1/2}$ near that of **8** (6)) or to isoxazoline **9** as **4** and **5** also present a 4 F wave at similar $E_{1/2}$ (Fig. 1).

A preparative electrolysis at the level of the second waves of **3** (pH 1.20, $E = -1.0$ V) only leads to the trisubstituted isoxazole **6**. We have observed, as it had been noticed before, that the behaviour of unstable compounds may be different by polarography and during an electrolysis: the overall electroreduction of **8** (or **9**) is faster by polarography than the transformation into the isoxazole, while the reverse is true during an electrolysis.

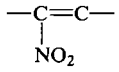
Reduction of 3 in Neutral Medium and of 1 and 2

The nature of the products isolated, the stepwise change with the pH from a 4e to a 2e process in the case of **3** and the absence of discontinuity on $E_{1/2}$ vs. pH plot for **3** point to the existence of a common 2e intermediate for both processes.

This intermediate would be the nitrosoethylenic ketone **10** which, according to the conditions and the nature of R, would be further reduced or would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

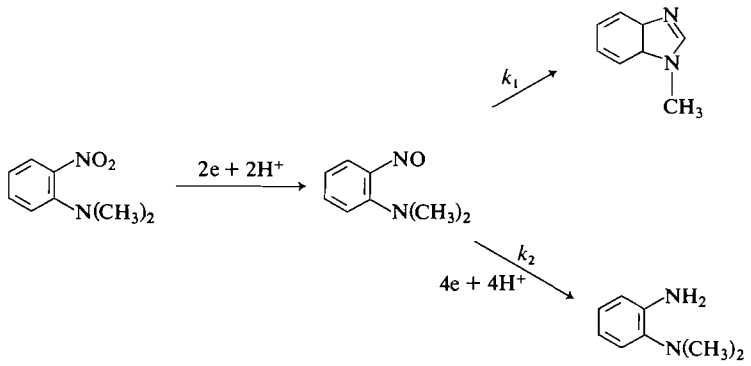
cyclize (Scheme 1). In support of this hypothesis, it should be noted that the $E_{1/2}$ of **1**, **2**, and **3** are very near that of nitrostyrene (8): this is in favour of a reduction mechanism involving only the



group and not the carbonyl group.

The mechanism for the electrochemical reduction of α,β-nitroethylenic derivatives into saturated oximes is still unknown. However, a mechanism similar to that of nitroaromatics (9) can be considered. It is shown that the electrochemical reduction of nitroaromatics leads to a nitroso derivative after consumption of 2 F per mol; nitrosopyridines have been recently evidenced in the reduction of nitropyridines (10). The nitroso derivative is generally reduced into the corresponding hydroxylamine.

Besides, in the electrochemical reduction of *N*,*N*-disubstituted *o*-nitroanilines, the results can be explained (11) by the intermediacy of a nitroso derivative which undergoes two competitive reactions: a cyclization and an electrochemical reduction.



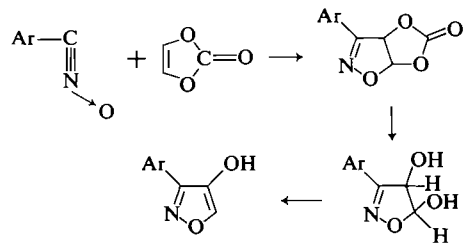
A similar nitroso intermediate undergoing a cyclization has been postulated in the reduction of *o*-nitrobenzoylhydrazide (12).

In the frame of our hypothesis, one can rationalize the different behaviours of **3** and **1**, **2**: the overall rate of the electrochemical reduction of nitroso derivative increases with the acidity of the medium (ref. 2, p. 131); in the case of **3** but not in the case of **1** and **2**, the reduction rate would exceed the cyclization rate at low pH. This can be explained in the following manner: the cyclization takes place through an attack of the N=O group on the carbonyl which is less reactive with an α-phenyl group than with an α-alkyl group.

Conclusion

A mechanism is presented to account for the formation of 4,5-dihydroxy-2-isoxazoline. In a previous study (14) it had been shown that the chemical reduction of **1**, **2**, and **3** leads to different compounds: this, together with the fact that a single 4,5-dihydroxy-2- isoxazoline is described in the literature (15), brings forward the synthetic interest of the electrochemical reduction.

This 4,5-dihydroxy-2-isoxazoline (15) has been prepared by reaction of a nitrile oxide according to:



The dehydration of the intermediate 1,2-diols is very easy and it is only in the case where Ar = *p*-NO_2—C_6H_4 that the 4,5-dihydroxy-2-isoxazoline can be isolated.

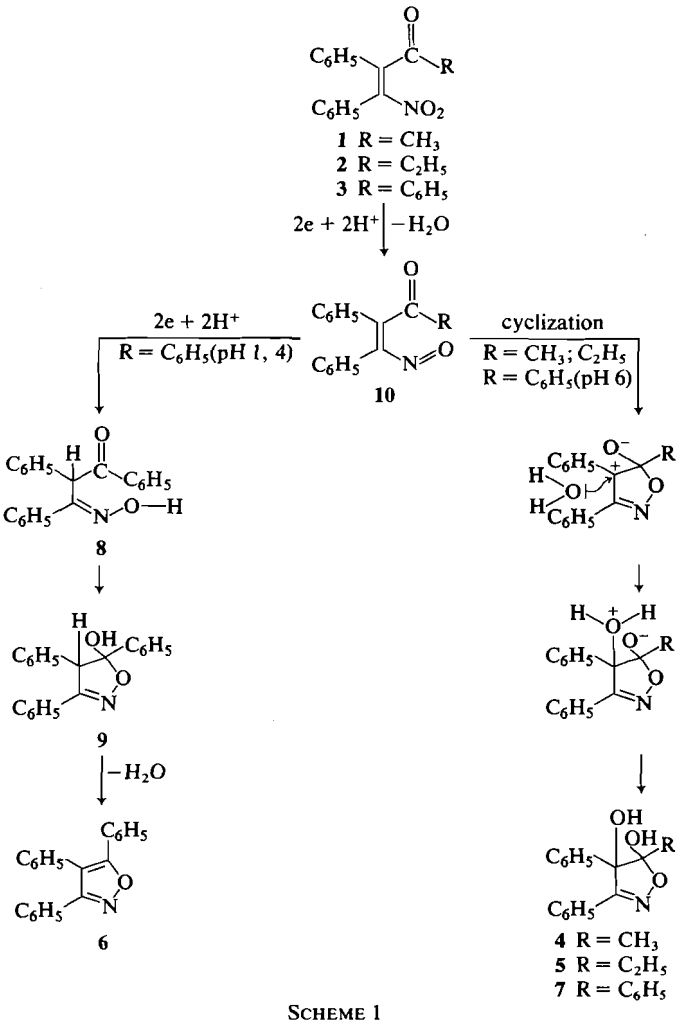
A general method for the chemical synthesis of 4,5-dihydroxy-2-isoxazoline substituted on the -4 and -5 positions can be designed by reaction of nitrile oxides with disubstituted vinylidene carbonates or with enediol ethers.

Experiments are now in progress to synthesize 4,5-dihydroxy-2-isoxazolines by this route.

Experimental

Techniques

The apparatus and techniques used in hydroorganic medium have been described previously (16, 17). The reference electrode was a saturated calomel electrode. The pH values were measured with a Radiometer model 4 pH-meter equipped with a combined glass–calomel electrode model GK 2302 B standard-



SCHEME 1

ized in aqueous buffer. The microanalyses were performed by the "Service de Microanalyse du CNRS" (Gif sur Yvette). All the compounds described gave correct elemental analysis. The following abbreviations are used in reporting nmr results: s = singlet, d = doublet, t = triplet, q = quadruplet, and m = multiplet.

Preparation of Compounds 1, 2, and 3

Nitroethylenic ketones **1**, **2**, and **3** were prepared according to ref. 14 by reaction of the corresponding ethylenic ketone with dinitrogentetroxide.

Preparative Electrolysis

Electrolysis of 3-Nitro-1,2,3-triphenyl-2-propene-1-one (3) in Acidic Medium

Preparation of 6. Solution (250 mL) is prepared from 125 mL of acetonitrile, 25 mL of a 1 *N* solution of sulfuric acid, and water. This solution (200 mL) and 882 mg (2.5×10^{-3} mol) of **3** are used to fill the cathodic compartment while the remainder is used in the anodic compartment; pH = 1.34, $E = -0.5$ V. During the electrolysis a white solid precipitates in the cell. After consumption of 850 C (4e per mol correspond to 925 C) the current drops to 4 mA. The electrolysis is stopped and the solution is filtered. The precipitate is washed with water and dried over P_2O_5. A white solid, **6**, 560 mg, 76% yield, is obtained; anal. (297) $C_{21}H_{15}NO$; mp 214°C (C_6H_6–ligroïn 50/50) (lit. (18) mp 211–212°C) nmr ($CDCl_3$) 3-Ph + 4-Ph + 5-Ph, m between 6.9 ppm and 7.8 ppm.

Electrolysis of 1-Nitro-1,2-diphenyl-1-butene-3-one (1)

Preparation of 4. The electrolysis was carried out on 200 mL of 0.1 *N* sulfuric acid solution containing 50% of acetonitrile (pH = 1.12) and 1.07 g (4×10^{-3} mol) of **1** at $E = -0.4$ V. After consumption of 835 C (2 F per mol correspond to 775 C) the current decreases to 6 mA. The electrolysis is stopped, and acetonitrile is evaporated to give an oil which crystallizes into a white solid, **4**, 4,5-dihydroxy-3,4-diphenyl-5-methyl-2-isoxazoline, 929 mg, 91% yield, mp 144°C (C_6H_6–ligroïn 75/25). Anal (269) $C_{16}H_{15}NO_3$. The ir spectrum (KBr pellet) ν_{OH} free: 3380 cm^{-1}, $\nu_{OH\ assoc.}$ = 3300 cm^{-1}, $\nu_{C=N}$ = 1600 cm^{-1}; nmr (acetone-d_6)—CH_3, s, 1.1 ppm (3 H); 4-OH + 5-OH, s, 5.3 ppm (2 H) which disappears on the addition of D_2O; 3-Ph + 4-Ph, m between 7.15 and 7.9 ppm (10 H). Nmr ^{13}C ($CDCl_3$)—CH_3, q, 20.63 ppm; 5-C, s, 106.4 ppm; 4-C, s, 90.48 ppm; 3-C, s, 163.12 ppm; phenyl group on 3-C: C bonded to 3-C, s, 136.63 ppm; 3-Ph + 4-Ph, m between 125.4 and 130.5 ppm; mass spectra (10 and 70

eV) 235, M − 34 (loss of 20H); 220 (loss of CH_3). After these peaks, principal peaks of diphenylisoxazoles are observed (previously reported in the literature (7, 13)).

Electrolysis of 1-Nitro-1,2-diphenyl-1-pentene-3-one (2)

Preparation of 5. A solution is prepared as in the case of **3**. Compound **2** (1.125 g, 4×10^{-3} mol) is reduced in 200 mL of this solution, pH: 1.40, at $E = -0.4$ V. After consumption of 830 C (2e per mol corresponds to 800 C) the current decreases to 3 mA and the electrolysis is stopped. Acetonitrile is evaporated to give a yellow oil which crystallizes into a while solid. A yield of 980 mg of 4,5-dihydroxy-3,4-diphenyl-5-ethyl-2-isoxazoline **5** is obtained (~90%); mp 147–148°C (C_6H_6-ligroïn 60/40); anal. (283) $C_{17}H_{17}NO_3$. Nmr (acetone-d_6)—CH_3, t centered at 0.9 ppm (3H); —CH_2— q centered at 1.42 ppm, (2H); 4-OH + 5-OH, s, 5.05 ppm, s broad, 6.2 ppm (2H) which both disappear upon addition of D_2O; 3-Ph + 4-Ph, m between 7.2 and 7.95 ppm (10H). The ir spectrum (KBr pellet); ν_{OH} 3440 and 3350 cm^{-1}; $\nu_{C=N}$ = 1600 cm^{-1}. Mass spectra (70 eV) 266, M − 17 (loss of OH) 249, M − 34 (loss of 20H), 220 (loss of C_2H_5) and all peaks of diphenylisoxazoles (7, 13).

Electrolysis of 3-Nitro-1,2,3-triphenyl-2-propene-1-one (3) in Neutral Medium

Preparation of 7. Solution (250 mL) is prepared from 125 mL of acetonitrile, 50 mL of a 0.5 *M* solution of phosphoric acid, 30 mL of a 1 *M* solution of sodium hydroxide, and water. This solution (200 mL) and 1.18 g (3.6×10^{-3} mol) of **3** are used to fill the cathodic compartment while the remainder is used in the anodic compartment; pH = 6.10, $E = -0.5$ V. After consumption of 715 C (2 F per mol correspond to 690 C) the current drops to 5 mA. The electrolysis is stopped, acetonitrile is evaporated, and the oil which is formed crystallizes slowly into a white solid. A yield of 1.02 g of 4,5-dihydroxy-3,4,5-triphenyl-2-isoxazoline (**7**) is obtained (87%); mp 159°C (C_6H_6–ligroïn 75/25 vol.). Anal. (331): $C_{21}H_{17}NO_3$. Nmr (acetone-d_6) 4-OH + 5-OH, s broad, 2.95 ppm (2H); 3-Ph + 4-Ph + 5-Ph, m between 7.35 and 8.3 ppm (15H); mass spectra (70 eV): 314, M − 17 (loss of OH); 297, M − 34 (loss of 20H).

Fission fragment radiolysis of carbon dioxide

YASUMASA IKEZOE, SHOICHI SATO, AND SABURO SHIMIZU
Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki, Japan

Received April 10, 1980

YASUMASA IKEZOE, SHOICHI SATO, and SABURO SHIMIZU. Can. J. Chem. **59**, 532 (1981).

The fission fragment radiolysis of CO_2 and the CO_2–C_3H_8, CO_2–NO_2 systems is studied in comparison with the γ radiolysis. Two kinds of back reactions (re-oxidation of carbon monoxide to carbon dioxide) are operative in the fission fragment radiolysis. One (a rapid back reaction) is the unidentified ionic chain reaction which proceeds at low CO concentrations, and the other (a slow back reaction) is assigned to a radical reaction ($CO + O + CO_2 \rightarrow 2CO_2$ [3′]). This slow back reaction is a characteristic of the fission fragment radiolysis. The analysis of results gives an upper limit of the radius of fission fragment tracks in the reaction system, $r\rho < 1.04\ \mu g\ cm^{-2}$.

YASUMASA IKEZOE, SHOICHI SATO et SABURO SHIMIZU. Can. J. Chem. **59**, 532 (1981).

On a étudié la radiolyse par fragmentation de fission des systèmes CO_2, CO_2–C_3H_8 et CO_2–NO_2 et on a comparé les résultats à ceux obtenus par radiolyse gamma. Au cours de la radiolyse par fragmentation de fission, il se produit deux sortes de réaction en retour (réoxydation du CO en CO_2). L'une (une réaction en retour rapide) est une réaction ionique en chaîne non identifiée qui a lieu à de faibles concentrations de CO et l'autre (une réaction en retour lente) qui est attribuée à une réaction radicalaire ($CO + O + CO_2 \rightarrow 2CO_2$ [3′]). Cette réaction en retour lente est caractéristique de la radiolyse par fragmentation de fission. L'analyse des résultats donne une limite supérieure du rayon de parcours des fragments de fission dans le milieu réactionnel, $r\rho < 1{,}04\ \mu g\ cm^{-2}$.
[Traduit par le journal]

Introduction

The radiolysis of carbon dioxide has been studied extensively (1) from a variety of viewpoints, such as radiation stability of carbon dioxide as a nuclear reactor coolant (2), radiation energy conversion to chemical energy (3–5), radiation synthesis (6, 7), and ionic reactions in the Martian atmosphere (8). Primary process yields estimated by Willis and Boyd (9) and a numerical model by Kummler *et al.* (10) provide a good understanding of the radiolysis.

In almost all of the preceding papers, an unidentified back reaction, in which the carbon monoxide formed is re-oxidized to carbon dioxide, has been a common subject of interest. It is known that the back reaction is suppressed during the high dose rate irradiation using pulsed electrons (11). There should be a similarity between the fission fragment and the high dose rate radiolysis (12), for the concentration of active species during the irradiation, in either case, reaches a value some orders of magnitude higher than in the γ radiolysis.

The fission fragment radiolysis of carbon dioxide has been studied by several workers (3, 4, 13), and the effects of temperature, pressure, and additives on the yield of carbon monoxide have been examined. But the back reaction in the fission fragments radiolysis has not been reported. In the fission fragment radiolysis, product formation is closely related to the structure of fission fragment tracks in the reaction system. A theoretical track model for water has been proposed by Mozumder and co-workers (14, 15), and fission fragment tracks in the dense gas have been studied experimentally by Meisels *et al.* (16).

In this paper, we attempt to investigate chemical reactions, especially the back reaction, involved in the fission fragment radiolysis of gaseous carbon dioxide. The structure of the fission fragment tracks will be discussed in connection with an LET effect observed experimentally.

Experimental

Reactants and Reaction Vessel

Carbon dioxide (Nihon Sanso, stated purity >99.99%), propane (Takachiho Chemicals, stated purity >99.7%), and nitrogen dioxide (Matheson Co., stated purity 99.5%) were used as reactant gas without purification. The reaction vessel (an inner capsule, 43 mL, stainless steel), which has a needle valve gas inlet at one end and a rupture plate at the other end, was washed with ethanol and with distilled hot water repeatedly, and dried before use.

Fission Fragment Irradiation

A piece of thin uranium–palladium alloy foil[1] was set in an inner capsule which was then filled with reactant gas. Three inner capsules were loaded in an outer capsule, which was irradiated in the Low Temperature Fissiochemical Loop (17) in the Japan Research Reactor 3. The reactant gas in the inner capsule was irradiated by mixed radiations of fission fragments, fast neutrons, and γ rays (FFnγ).

Dosimetry

The absorbed dose was determined by ethylene dosimetry (18) and by calculation (19) using the known thermal neutron

[1]The uranium–palladium alloy foil used in this work was given to our group by the courtesy of Messrs. B. Manowitz and M. Steinberg of the Brookhaven National Laboratory. The foil contained 0.503 mg ^{235}U per 1 cm^2 foil, and the 2.1 μm thick alloy layer was covered on both sides with 0.2 μm thick platinum layers.

flux. Ethylene was charged in the inner capsule of the same kind and irradiated under the same conditions as the reactant gas. The absorbed dose in ethylene was determined by the yield of hydrogen ($G(H_2) \equiv 1.3$). The absorbed dose in the reactant gas was then obtained by taking into account the stopping power ratio of the secondary electrons and the fast neutrons.

The thermal neutron flux was determined by the activation of ^{59}Co. Two pieces of ^{59}Co metal pellet (7 mg) were attached to the outer capsule. The absorbed dose rate (rad h^{-1}) due to fission fragments was calculated by eq. [1].

$$[1] \qquad (\text{Dose rate})_{FF} = Nf\sigma E\varepsilon_0 K^{-1} W^{-1}$$

where N is the number of ^{235}U atoms in the foil, f the thermal neutron flux (cm^{-2} s^{-1}), σ the cross section of ^{235}U for fission (580×10^{-24} cm^2), E the initial kinetic energy of fission fragments per fission (170 MeV), ε_0 the ratio (0.325) of energy absorbed by the reactant gas to E (19, 20), K is the conversion factor from rad h^{-1} to MeV g^{-1} s^{-1}, and W the weight of the reactant gas in the inner capsule (g).

Absorbed doses determined by the two methods were consistent with each other. Under standard conditons (6 atm CO_2, 1.89 mg ^{235}U); $(\text{dose rate})_{FF} = 6.8$, $(\text{dose rate})_{\gamma} = 3.4$, and $(\text{dose rate})_n < 0.1$ Mrad h^{-1}. Details are described elsewhere (19, 20).

Product Analysis

The inner capsule was punctured at the rupture plate in a vacuum line, and reaction products were analysed by a Toepler pump, a mass spectrometer, or by gas chromatography.

Results and Discussion

CO Formation from CO_2

Formation of carbon monoxide in pure CO_2 by FFnγ and by γ-rays is shown in Fig. 1. Formation of carbon monoxide by γ-rays is saturated at low CO concentrations, and apparent G(CO) at 10 Mrad is less than 0.1. This small G(CO) is explained by the back reaction. On the other hand, formation of carbon monoxide by FFnγ is larger than that by γ-rays. The apparent G(CO) at 10 Mrad, 0.7, lies between the low value for γ-rays (less than 0.1) and a high value reported (7.8) by pulsed electrons (11). With respect to the back reaction, it is less effective under FFnγ irradiation than under γ irradiation, but not suppressed as in the pulsed electron irradiation.

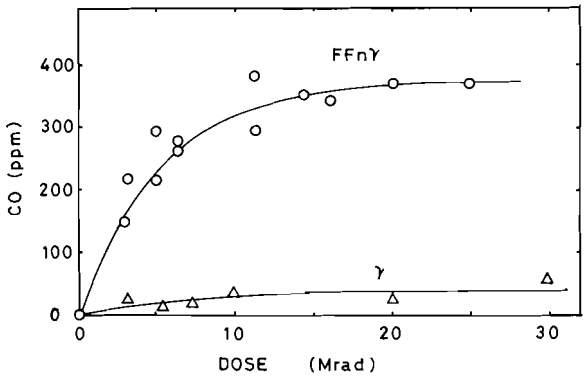

FIG. 1. CO formation from pure CO_2 by FFnγ and by γ. FFnγ: 10.2 Mrad/h (FF; 6.8, $n < 0.1$, and γ; 3.4 Mrad/h), γ: 1.1 Mrad/h. CO_2 6 atm at 298 K in 43 mL stainless steel capsules.

NO_2 Addition

The effect of NO_2 addition on G(CO) and $G(O_2)$ is shown in Fig. 2. G(CO) by FFnγ is higher than by γ-rays in the whole range of NO_2 concentration, 0–1.0%. The difference in G(CO) between the two types of radiation may be attributed to the forward reactions, because the back reaction in the CO_2–NO_2 system (NO_2 1%) may be considered suppressed. Initial decomposition of carbon dioxide by FFnγ is greater than by γ-rays.

The sharp increase in G(CO) with the addition of a small amount of NO_2 (0.2%) is due to the suppression of the back reaction. The increase under irradiation with FFnγ (0.7 to 5.3) was greater than that under γ-irradiation (0.1 to 3.6). This means that the back reaction in pure CO_2 consumes more carbon monoxide under irradiation with FFnγ than under γ-ray irradiation.

The values of $G(O_2)$ were smaller than expected from mass balance, but approached half of G(CO) at low NO_2 concentration.

Pressure Effect

The concentration of active species in fission fragment tracks will increase with the total pressure of the reactant gas, since the range and radius of fission fragment tracks are inversely proportional to the total pressure (14, 15). The pressure depen-

For personal use only.

dence of G(CO) is shown in Fig. 3. G(CO) in pure CO_2 increased slightly with pressure, and that in the CO_2–NO_2 mixture was constant within experimental error in the pressure range examined, 4–14 atm. This tendency is in qualitative agreement with that observed by Cusack and King (13). They reported an appreciable increase in G(CO) in pure CO_2 and little or no increase in the CO_2–NO_2 mixture.

G(CO) by Fission Fragments

G(CO) by FFnγ, $G_{FFn\gamma}$, is a composite average value due to fission fragments, fast neutrons, and γ-rays. G(CO) attributed solely to fission fragments, G_{FF}, can be estimated by eqs. [2] and [3].

$$[2] \quad G_{FFn\gamma} = \varepsilon_{FF} G_{FF} + \varepsilon_{n\gamma} G_{n\gamma}$$

$$[3] \quad \varepsilon_{FF} + \varepsilon_{n\gamma} = 1$$

where ε_{FF} or $\varepsilon_{n\gamma}$ is the normalized ratio of dose rate of the fission fragments or the fast neutron and the γ dose rate to the total dose rate. The values of ε_{FF} and $\varepsilon_{n\gamma}$ were determined by dosimetry. G_{FF} thus obtained for CO_2–C_3H_8 system is shown in Table 1. It should be mentioned that eq. [2] is correct only when the chemical reactions induced by fission fragments are independent of those by nγ. In the CO_2–C_3H_8 system (21), this condition seems satisfied at low absorbed doses, but in pure CO_2 it is not satisfied as will be shown in the later discussion concerning the rapid back reaction.

The value of G_{FF} in CO_2–C_3H_8, 6.3, is smaller than those found by Cusack and King, 8.7–11.9 (13). The reason for this discrepancy is not clear. It might be attributed to different experimental conditions, such as irradiation temperature, dose rate, and additives. In any event, it is affirmed again that G(CO) by fission fragments is greater than that by γ-rays.

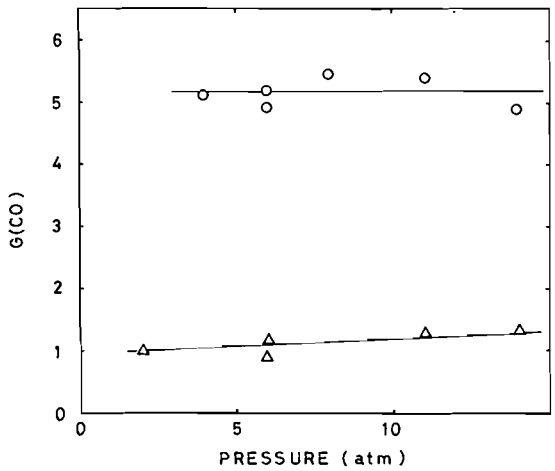

FIG. 3. Pressure dependence of G(CO) of pure CO_2 (△) and of CO_2–NO_2 (0.2%) (○) by FFnγ. Dose rate of FFnγ: 9.9–10.9 Mrad/h. Amounts of ^{235}U controlled to keep the ratio, (dose rate)$_{FF}$/(dose rate)$_{n\gamma}$ = 1.9 ± 0.1. G values determined at the absorbed dose of 5 Mrad.

TABLE 1. G(CO) of pure CO_2 and CO_2–C_3H_8 system and ΔG(CO) by different radiations

Radiations (dose rate)	G(CO)[a] CO_2	G(CO)[a] CO_2–C_3H_8 (0.2%)	ΔG(CO)[b]
γ (1.1 Mrad/h)	0.1	4.7	4.6
nγ (3.4 Mrad/h)	0.3	4.9	4.6
FFnγ (10.2 Mrad/h)	1.5	5.8	4.3
FF (6.8 Mrad/h)	—	6.3[c]	—

[a]Obtained experimentally at the absorbed dose less than 3 Mrad.
[b]Difference between G(CO) in pure CO_2 and in CO_2–C_3H_8 system (0.2%).
[c]Calculated by eq. [2] in text.

Formation and Consumption of CO

Figure 1 shows a saturation curve for the formation of carbon monoxide. At an absorbed dose of more than 10 Mrad, CO formation by reaction [4] and its consumption [5] are balanced.

$$[4] \quad CO_2 \rightsquigarrow CO + \text{others}$$

$$[5] \quad CO + X \rightarrow CO_2 + Y$$

Equation [6] can be written for the formation of carbon monoxide.

$$[6] \quad d[CO]/dt = G(CO)(\text{dose rate}) - k_3[X][CO]$$

CO concentration is expressed as a function of irradiation time by

$$\ln\left\{1 - \frac{[CO]k_3[X]}{G(CO)(\text{dose rate})}\right\} = -k_3[X]t$$

The theoretical curve which best fits the experimental data of Fig. 1 is obtained when G(CO) = 1.47 and $k_3[X] = 5.2 \times 10^{-4}$ s^{-1} for the FFnγ irradiation. G(CO) thus obtained is the initial G value when the back reaction [5] does not contribute. It is notable that Harteck and Dondes have already obtained similar G(CO) values, 0.091–1.26, in the fission fragment radiolysis of carbon dioxide (3). The initial G(CO), 1.47, by our experiments is still smaller than G(CO) in the CO_2–NO_2 or the CO_2–C_3H_8 system. This indicates that there must be another kind of back reaction which operates at a very early stage of FFnγ irradiation when reaction [5] does not take place.

It must be remembered that X in reaction [5] is a complex function of the pressure, dose rate, and impurity level in the reaction system. The initial G(CO) would depend on the irradiation conditions.

Slow and Rapid Back Reactions

Two kinds of back reaction are considered for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

FFnγ irradiation of carbon dioxide; the slow back reaction [5] and the rapid one. For the slow back reaction, reaction [5′] seems plausible, which predominates over reaction [7] under our experimental conditions.

[5′] $CO + O + CO_2 \rightarrow 2CO_2$

where $k = 5.6 \times 10^{-36}$ cm^6 s^{-1} (22).

[7] $O + O + CO_2 \rightarrow O_2 + CO_2$

where $k = 3.0 \times 10^{-33}$ cm^6 s^{-1} (23).

In the extremely high dose rate experiment of Willis, Boyd, and Binder (11), reaction [5′] would become negligible compared with reaction [7] because of high steady state concentration of oxygen atoms. In such a case reaction [5′], as well as the rapid back reaction, will be suppressed. The high CO yield obtained by fission fragments and the comparatively low steady state concentration of oxygen atoms are the reasons why the slow back reaction [5′] is clearly evident in these experiments.

It is commonly presumed that the rapid back reaction is an ionic chain reaction (1, 10). In Table 1, the increase in G(CO), ΔG(CO), with the addition of 0.2% propane to pure CO_2 is ascribed to the suppression of the rapid back reaction. ΔG(CO) values lie in a small range between 4.3 and 4.6 for various radiations.

Considering the chain length, m, of the rapid back reaction, the increase, ΔG(CO), may be expressed as eq. [8].

[8] $\Delta G(CO) = mG(Z)$

where $G(Z)$ is the G value of the unidentified ionic oxidizing species, Z.

In the high dose rate radiolysis (11), the ionic species were destroyed by reaction [9] and they could not initiate the rapid back reaction.[2]

[9] $CO_2^+ + e^- \rightarrow CO + O$

The local concentration of ionic species in the fission fragment tracks is estimated to be higher than their steady state concentration in the high dose rate radiolysis using pulsed electrons. Thus in the fission fragment radiolysis, reaction [9] may be considered fast enough to quench the rapid back reaction in the tracks.

However, from Table 1 it is obvious that by the rapid back reaction a nearly equal amount of carbon monoxide is consumed in the FFnγ radiolysis as in the γ-radiolysis. This may be explained as follows: the ionic species formed outside of fission fragment tracks by nγ have a lifetime sufficient to initiate the rapid back reaction and they consume carbon monoxide which is formed not only outside but also inside of the tracks. This means that radiation chemical reactions induced by FF cannot be separated from those by nγ and eq. [2] becomes invalid.

Ionic Reaction in the Fission Fragment Tracks

The G(CO) by FFnγ was greater than that by γ-rays in every system examined. This is a clear LET effect in the gas phase. This result supports the mechanism inferred previously (4, 21): that is to say, reaction [9] predominates over reaction [10] in the fission fragment tracks.

[10] $CO_2^+ + M \rightarrow CO_2 + M^{+*}$

In the γ-radiolysis, on the other hand, CO_2^+ transfers its charge to additive M (reaction [10]), and does not contribute to the formation of carbon monoxide.

In the γ-radiolysis of the CO_2–C_3H_8 system, reaction [10′] is followed by reactions [11] and [12] (25), and $G(CH_4)$ becomes higher than that by FFnγ.

[10′] $CO_2^+ + C_3H_8 \rightarrow C_3H_8^{+*} + CO_2$

[11] $C_3H_8^{+*} \rightarrow C_2H_5^+, CH_3\cdot, C_2H_4^+, CH_4, \cdots$

[12] $CH_3\cdot + C_3H_8 \rightarrow CH_4 + C_3H_7\cdot$

The constant G(CO) obtained when the total pressure is varied (Fig. 3) may be explained by assuming that, in these experiments, reaction [9] predominates over reaction [10] in the fission fragment tracks.

Fission Fragment Tracks

Reaction [9] being faster than reaction [10], eq. [13] can be written for the reactions in the fission fragment tracks.

[13] $k_9[CO_2^+][e^-] > k_{10}[CO_2^+][M]$

where $[CO_2^+] = [e^-] = n/\pi r^2$ concentration of ions in the tracks, [M] = concentration of additive M (n is the number of ionizations per unit track length ($1.68 \times P \times 10^6$ cm^{-1}, P in atm),[3] and r the average track radius at the time when reaction [9] is taking place). From eq. [13], we obtain an upper limit of the track radius.

[14] $r < (nk_9/\pi k_{10}[M])^{1/2}$

Using appropriate values of k_9 (2×10^{-7} cm^3

[2]The recombining species are probably $CO_2^+(CO_2)_n$ (24) and e^- or $O_2^-(CO_2)_m$ (10). For brevity, $CO_2^+(CO_2)_n$ is represented by CO_2^+, and e^- or $O_2^-(CO_2)_m$ by e^-.

[3]$n = L/W$, where L is the average LET value of fission fragments in carbon dioxide and W the W value (energy required to produce a pair of ions) of carbon dioxide.

s^{-1}),[4] k_{10} (1×10^{-10} cm^3 s^{-1}) (26), and [M] (1.48×10^{18} cm^{-3}; 1% NO_2 in 6 atm CO_2 at 298 K), eq. [15] is obtained.

[15] $r\rho < 1.04$ μg cm^{-2}

This value compares favorably with the range of 100 eV electrons (0.15 ~ 0.51 μg cm^{-2}) (14, 27). Meisels *et al.* gave experimental track radii, 70 ~ 120 nm for ethylene at densities of 0.0795–0.0259 g/cm^3 (16). The corresponding thickness will be 0.56 ~ 0.31 μg cm^{-2}.

This simple estimation for the upper limit of the radius of fission fragment tracks seems qualitatively consistent with Mozumder's track model, in which the track radius is given by the range of 100 eV electrons in the reactant system.

[4]A precise value for k_9 has not been reported. A comparatively low value, 2×10^{-7} cm^3 s^{-1} (10) is adopted tentatively, because recombination of CO_2^+ with O_2^- but not with free electrons is expected in the presence of an appreciable amount of oxygen.

Vacuum-ultraviolet (147.0 nm and 123.6 nm) photolysis of 1,1-dimethylcyclopropane

JOSEPH B. BINKEWICZ, MICHAEL KAPLAN, AND RICHARD D. DOEPKER
Department of Chemistry, University of Miami, Coral Gables, FL 33124, U.S.A.

Received August 20, 1980

JOSEPH B. BINKEWICZ, MICHAEL KAPLAN, and RICHARD D. DOEPKER. Can. J. Chem. **59**, 537 (1981).

The gas-phase photolysis of 1,1-dimethylcyclopropane has been investigated using xenon (147.0 nm) and krypton (123.6 nm) resonance radiation. Major products observed in order of decreasing importance were isobutene, ethylene, hydrogen, 1,3-butadiene 2-methyl-1,3-butadiene, propylene, allene, methylacetylene, and acetylene. Radical scavengers, NO and O_2, and radical interceptors, H_2S/D_2S and HI, were used to determine the relative importance of radical and molecular processes. CH_3, C_2H_3, C_3H_5, and C_4H_7 radical species were identified and quantified. Ten primary reaction channels were postulated, of which the elimination of methylene was the most predominant, accounting for 34% of the photo-decomposition at 147.0 nm and 39% at 123.6 nm. Although ionization was established at 123.6 nm ($\eta = 0.10$) the nature of a charge transfer or other ion-molecule reaction channel leading to the formation of 2-methyl-1-butene and 2-methyl-2-butene could not be determined.

JOSEPH B. BINKEWICZ, MICHAEL KAPLAN et RICHARD D. DOEPKER. Can. J. Chem. **59**, 537 (1981).

On a étudié la photolyse en phase gazeuse du diméthyl-1,1 cyclopropane en utilisant la radiation de résonance du xénon (147,0 nm) et du krypton (123,6 nm). Les principaux produits observés sont par ordre décroissant d'importance: l'isobutène, l'éthylène, l'hydrogène, le butadiène-1,3 le méthyl-2 butadiène-1,3, le propène, l'allène, le propyne et l'acétylène. On a utilisé les pièges à radicaux NO et O_2 et les intercepteurs de radicaux H_2S/D_2S et HI pour déterminer l'importance relative des processus radicalaire et moléculaire. On a identifié et quantifié les espèces radicalaires CH_3, C_2H_3, C_3H_5 et C_4H_7. On postule la présence de dix chemins réactionnels primaires dans lesquels l'élimination de méthylène prédomine; cette élimination correspond à 34% lors de la photodécomposition à 147,0 nm et de 39% à 123,6 nm. Bien qu'on ait établi la présence d'ionisation à 123,6 nm ($\eta = 0,10$), on ne peut pas déterminer la nature d'un processus de transfert de charge ou d'une autre réaction ion-molécule conduisant à la formation du méthyl-2 butène-1 et du méthyl-2 butène-2.

[Traduit par le journal]

Introduction

Throughout the past years, a series of investigations had been initiated in order to identify the primary and secondary reaction channels for the neutral excited (8.4 eV and 10.0 eV) substituted cyclopropane molecules. The most recent study, the photolysis of *trans*- and *cis*-1,2-dimethylcyclopropane (1) disclosed that the elimination of methylene, reaction [1], was of minor importance

[1]  $+ h\nu \longrightarrow CH_2 + C_4H_8$

with a quantum efficiency of 0.10 at 147.0 nm. This is compared to a quantum efficiency of 0.32 for ethylcyclopropane (2*a*) and methylcyclopropane (2*b*). Methylenecyclopropane (2*c*) produced a quantum efficiency of 0.06 for the methylene elimination process. Additional information concerning the photolysis of substituted cyclopropanes has been reported by Collin (3).

An investigation of the photolysis of 1,1-dimethylcyclopropane has been reported recently by Collin *et al.* (4). Their study covered the wavelengths 163.3 nm, 147.0 nm, 123.6 nm, and 106.7–104.8 nm. Although the results reported here closely agree with the investigation of Collin *et al.* at 147.0 nm the 123.6 nm results show considerable important differences.

Experimental Section

Materials

1,1-Dimethylcyclopropane (DMCP), obtained from K and K Laboratories, was purified by vapor phase chromatography using a 12 ft column of 30% squalane on Chromosorb P. at room temperature. Analysis of the resulting DMCP disclosed an impurity of 0.03% *trans*-2-butene. Purification of the other materials used have been described elsewhere (1, 2).

Irradiation and Analysis

The vacuum ultraviolet photolysis of DMCP was investigated at room temperature (25°C) in a standard static system using a 600 cm^3 reaction vessel and a "gettered" xenon (147.0 nm) or krypton (123.6 nm) resonance lamp. Irradiation procedures including photoionization have been reported previously (2, 5). Analysis was performed by vapor chromatography (25 ft, 30% squalane at 60°C, and 6 ft phenyl isocyanate/Porasil C) and mass spectrometry (CEC-21-103 C) as also reported earlier (2, 5).

Actionometry

The chemical actinometers used at 147.0 nm were cyclobutene ($\Phi_{C_4H_4} = 0.23$) (6) and cyclopentene ($\Phi_{C_2H_4} = 0.24$) (5). At 123.6 nm only cyclopentene ($\Phi_{C_2H_4} = 0.19$) (5, 7) was used. The ionization efficiency (η) of 0.16 was assumed for cyclopentene (5, 7) at 123.6 nm. The value was used in order to determine the ionization efficiency of DMCP.

Results

The quantum yields of the major products of the photolysis DMCP at 147.0 nm and 123.6 nm reported in Tables 1–4 are representative data collected under a variety of experimental conditions. In addition to these data, the following observations and controls should be reported.

(*1*). Irradiation times were selected as to hold the conversion below 0.05% for the experiments where quantum yields were obtained, except in those cases where hydrogen yields were simultaneously determined through mass spectrometry. Conversions of the order of 0.2% were needed here for sufficient hydrogen production.

(*2*). The quantum yield of ethylene exhibits no pressure sensitivity in the photolysis of DMCP between 0.2 to 4.1 Torr nor was it affected by a tenfold change in irradiation time.

(*3*). Small amounts ($\Phi = 0.02$) of isobutane were observed at both 147.0 nm and 123.6 nm when the photolysis was carried out without scavenger. 1,2-Butadiene was always present to an average quantum yield of 0.02 at 147.0 nm and 0.01 at 123.6 nm.

(*4*). Extensive use of the radical interceptors H_2S/D_2S (8, 9) and HI (10) were employed in this investigation. HI was found to be a more effective radical interceptor than H_2S as suggested by Ausloos *et al.* (10). Increasing the concentration of HI from 3 to 15% revealed that the optimum concentration of HI for radical interception is between 5 and 10% (7% normally used). This corresponds to the maximum in the radical quantum yields vs. HI concentration curve. H_2S, on the other hand, required at least a 10% addition to produce similar effects. Nonradical production was unaffected by the addition of HI, while 1,3-butadiene was reduced in the presence of H_2S. Although the reason for this anomalous result is unclear, it has been observed previously (*2a*, 11). When D_2S (20%) was used, stable products were isolated and determined

through mass spectrometry. In the 123.6 nm photolysis of DMCP (5.0 Torr) mass spectral analysis of the hydrogen (H_2 = 45, HD = 52, D_2 = 3), methane (CH_4 = 44, CH_3D = 52, CH_2D_2 = 4), propylene (C_3H_6 = 54, C_3H_5D = 46), and butene (C_4H_6 = 82, C_4H_7D = 18) were carried out. Unfortunately, the results obtained when D_2S is used must be considered diagnostic since total radical yields were consistently less than those determined through the use of H_2S or HI addition.

(5). The ionization energy of DMCP, 9.08 eV (12), is below the photoenergy of the krypton (10.0 eV) resonance radiation. The ionization efficiency for DMCP was determined at 123.6 nm and found to be $\eta = 0.10$. Although no product yield vs. applied collector voltage studies were made, the production of 2-methyl-1-butene (Φ = 0.04) and 2-methyl-2-butene (Φ = 0.04) at 123.6 nm is believed to be formed through an ion-molecule pathway (4).

Discussion

147.0 nm

Collin *et al.* (4) reported seven primary processes involving the 147.0 nm photolysis of DMCP. The data presented in Tables 1 and 2 of this work agree within experimental error to that presented by Collin.

Isobutene is clearly the most abundant product produced in the photolysis of 1,1-dimethylcyclopropane. The isobutene yield is unaffected by the presence of nitric oxide or oxygen, although it is slightly increased in the presence of hydrogen iodide. The elimination of methylene from the cy-

[2] DMCP + $h\nu \rightarrow CH_2$ + iso-C_4H_8

clopropyl ring (reaction [2]) is the sole reaction channel for isobutene formation, when the photolysis is carried out in the presence of NO or O_2. The quantum efficiency of this pathway is equal to the quantum yield of isobutene (Table 5) $\phi_2 = \Phi_{C_4H_8} = 0.34$. This compares well with a value of 0.35 presented by Collin *et al.* (4).

The formation of 1,3-butadiene and 1,2-butadiene occurs through the elimination of a methyl group and a hydrogen atom (reaction [3]).

[3] DMCP + $h\nu \rightarrow CH_3 + H$ + 1,3/1,2-C_4H_6

This reaction pathway was found to be the sole reaction channel for the production of the butadienes in the photolysis of 1,2-dimethlycyclopropane (1). If the assumption is again made here that reaction [3] is the exclusive pathway for butadiene formation then the quantum efficiency for reaction [3] is equal to the sum of the quantum yields of 1,3- and 1,2-butadiene, $\phi_3 = \Phi_{1,3\text{-}C_4H_6} + \Phi_{1,2\text{-}C_4H_6} = 0.09$. Collin *et al.*'s (4) value was 0.08.

The photolysis (147.0 nm) of *trans*-1,2-dimethylcyclopropane (1) revealed that a portion of the C_4H_7-fragments, resulting from the elimination of a methyl radical, was stable within the pressure range of 0.2 to 25 Torr (1).

[4]  + $h\nu \longrightarrow CH_3 + C_4H_7$

The presence of the C_4H_7 radical species was determined through the use of HI as a radical interceptor (9). The difference in yield of C_4H_8 in the presence of HI with its yield in the presence of NO evaluates the quantum yield of the C_4H_7 radical. For DMCP the quantum efficiency of the parallel reaction pathway is 0.03.

TABLE 5. Photolysis of 1,1-dimethylcyclopropane, a summary of quantum yields

Product	Quantum yield at wavelength 147.0 nm	123.6 nm

C_4H_7	0.03	0.11

[a] Methylacetylene.
[b] Allene.
[c] 1,3-Butadiene + 1,2-butadiene.

[5] DMCP + $h\nu \rightarrow CH_3 + C_4H_7$

This reaction channel was not reported by Collin *et al.* (4).

Methylacetylene and allene are produced through the elimination of two methyl radicals from the photoexcited state of DMCP and is quantified by the sum of the quantum yields of

[6] DMCP + $h\nu \rightarrow 2CH_3 + C_3H_4$

methylacetylene and allene. It must be assumed that isomerization occurred in the formation of methylacetylene. $\phi_6 = 0.06 + 0.05 = 0.11$. A value of 0.10 was reported by Collin *et al.* (4).

The formation of ethylene ($\Phi_{C_2H_4} = 0.26$) may result from the direct cleavage of the 1,2 and 1,3 carbon bonds of the cyclopropane ring, eliminating ethylene and a CH_3CCH_3 species. The CH_3CCH_3 species will rearrange to propylene or decompose to a C_3H_5 radical.

[7] DMCP + $h\nu \rightarrow C_2H_4 + (CH_3CCH_3)^*$

[8] $(CH_3CCH_3)^* \rightarrow CH_3CHCH_2$

[9] $\rightarrow CH_3CCH_2 + H$

The formation of the 2-propenyl radical is demonstrated by the increased formation of propylene in the presence of H_2S (13), since H_2S will intercept the vinyl form but not the allyl structure. HI, on the other hand, will intercept both structures. Isomerization of the C_3H_5 can be demonstrated by the small increase that is observed in the propylene yield when the photolysis is carried out in the presence of HI over that when H_2S is used. The quantum yield of propylene for the DMCP–HI system will dictate the C_3H_5 quantum yield.

Considering reactions [8] and [9], two reaction channels involving the formation of ethylene can be postulated.

[10] DMCP + $h\nu \rightarrow C_2H_4 + C_3H_6$

[11] DMCP + $h\nu \rightarrow C_2H_4 + C_3H_5 + H$

The quantum efficiency of reaction channel 11 may be quantified from the quantum yield of the C_3H_5 radical, which in turn is evaluated through the difference between the quantum yields of propylene with HI and that with NO. $\phi_{11} = \Phi_{C_3H_5} = 0.13$. Collin *et al.* (4) found a value of 0.16 for this pathway.

Although acetylene quantum yields are small its formation reveals a second pathway for the formation of propylene. Reaction [12] is of major impor-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

[12] DMCP + $h\nu \rightarrow C_2H_2 + H_2 + C_3H_6$

tance in the 147.0 nm photolysis of *trans*-1,2-dimethylcyclopropane (1) with a quantum efficiency of 0.24. Here though due to structural changes in the intermediate fragments the quantum efficiency of reaction [12] is greatly reduced. $\phi_{12} = \Phi_{C_2H_2} = 0.02$. If it can be assumed that the formation of propylene is restricted to reactions [10] and [12], the quantum efficiency of reaction channel 10 may thus be evaluated. $\phi_{10} = \Phi_{C_3H_6} - \phi_{12} = 0.06$. Collin *et al.* (4) reported a value of 0.08 for this reaction but did not include reaction channel 12, although their data are consistent with the values reported here.

Ethylene may also be produced through a pathway involving the elimination of a methyl radical and the "splitting" of the resulting C_4H_7 fragment into a vinyl radical and ethylene. This process was reported to have a quantum efficiency of 0.11 for ethylcyclopropane at 147.0 nm (2*a*). Reaction [13]

[13] DMCP + $h\nu \rightarrow CH_3 + C_2H_3 + C_2H_4$

may be evaluated from the quantum yield of vinyl radical formation reported in Table 5. The quantum yield of vinyl radical formation is determined by the difference in ethylene yield when NO is used as a radical interceptor with that when either HI or H_2S is used. $\phi_{13} = \Phi_{C_2H_3} = 0.07$. The formation of ethylene, $\Phi_{C_2H_4} = \phi_{10} + \phi_{11} + \phi_{13} = 0.06 + 0.13 + 0.07 = 0.26$, is indeed consistent with the independent evaluation of reaction channels 10, 11, and 13.

The elimination of two hydrogen atoms or molecular hydrogen from the photoexcited state of

[14] DMCP + $h\nu \rightarrow 2H(H_2) + C_5H_8$

DMCP results in the formation of 2-methyl-1,3-butadiene and 2-methyl-1,2-butadiene depending upon which hydrogen atoms are eliminated. The total quantum efficiency for reaction channel 14 would be the sum of the quantum yield of the two methyl-butadienes. $\phi_{14} = \Phi_{C_5H_{8\text{-}1,3}} + \Phi_{C_5H_{8\text{-}1,2}} = 0.11$. Collin *et al.* (4) reported a value slightly higher at 0.13, which is still within the expected experimental error.

123.6 nm

The primary reaction channels discussed and applied to the 147.0 nm photolysis of 1,1-dimethylcyclopropane are expected to be applicable at 123.6 nm (Tables 3 and 4). The methylene elimination reaction channel 2 again may be evaluated through the scavenged value of isobutene formation, $\phi_2 = \Phi_{C_4H_8} = 0.39$. Similarly, reaction channel 3 is evaluated through the quantum yield of 1,3- and 1,2-butadiene, $\phi_3 = \Phi_{C_4H_{6\text{-}1,3}} + \Phi_{C_4H_{6\text{-}1,2}} = 0.06$, while reaction channel 5 which results in the C_4H_7 radical production has a quantum efficiency of 0.11. It may be noted that the presence of the C_4H_7 radical was further demonstrated at 123.6 nm through the use of D_2S. Here 18% of the resulting butene was mono-deuterated.

The formation of methylacetylene and allene again would be associated with reaction [6], $\phi_6 = 0.05 + 0.05 = 0.10$. As in the lower energy photolyses, propylene is produced through reaction channels 10 and 12, with reaction channel 12 being set equal to the quantum yield of acetylene, $\phi_{12} = \Phi_{C_2H_2} = 0.02$. Reaction channel 10 is quantified through the difference in the quantum yield of propylene and acetylene. $\phi_{10} = 0.08 - 0.02 = 0.06$.

The formation of the 2-propenyl radical again is demonstrated by the increased propylene in the presence of HI/H_2S. Further, when D_2S is used nearly 45% of the propylene was mono-deuterated. This is in good agreement with the quantum efficiency of reaction [11] being assigned a value of 0.07 (47%) and that of the nonradical propylene production of 0.08.

The formation of vinyl radicals at 123.6 nm is again demonstrated through the use of HI/H_2S. The quantum efficiency for the production of vinyl radical at 123.6 nm, reaction [13], was found to be 0.05. Again the check of the quantum yield of ethylene $\Phi_{C_2H_4} = 0.19$ and the sum of the quantum efficiencies for reaction [10] ($\phi_{10} = 0.06$), reaction [11] ($\phi_{11} = 0.07$), and reaction [13] ($\phi_{13} = 0.05$) is within the experimental uncertainty of the method, $\phi_{10} + \phi_{11} + \phi_{13} = 0.18$.

The elimination of two hydrogen atoms or molecular hydrogen again leads to the formation of 2-methyl-1,3-butadiene and 2-methyl-1,2-butadiene (reaction [14]) with a quantum efficiency of 0.10 at 123.6 nm.

At 123.6 nm (10.0 eV) ionization of the parent molecule occurs. The ionization efficiency re-

[15] DMCP + $h\nu \rightarrow (C_5H_{10})^+ + e^-$

ported here was determined to be 0.10 while Collin *et al.* (4) reported a value of 0.28. Collin *et al.* did not report primary reaction channel quantum efficiencies for 123.6 nm but did for the argon (106.7–104.8 nm) resonance study. Although we have also carried out additional experiments with the argon resonance lamp no quantum yields were determined at the time so these results are not reported here. It is assumed that the isomerization of DMCP to the reported methyl butenes directly involve the parent $(C_5H_{10})^+$ ion.

Summary and Conclusion

The vacuum-ultraviolet photolysis of 1,1-dimethylcyclopropane may be described by ten

TABLE 6. Quantum yields for the primary reaction channels of the vacuum-uv photolysis of 1,1-dimethylcyclopropane

Reaction	Quantum yield at wavelength (nm) 147.0	123.6	~106[a]
$\triangle + h\nu \xrightarrow{[2]} CH_2 + i\text{-}C_4H_8$	0.34 (0.35)[b]	0.39	0.22
$\xrightarrow{[3]} CH_3 + H + C_4H_6\text{-}1,3/1,2$	0.09 (0.08)	0.06	0.04
$\xrightarrow{[5]} CH_3 + C_4H_7$	0.03 (—)	0.11	—
$\xrightarrow{[6]} 2CH_3 + C_3H_4$	0.11 (0.10)	0.10	0.15

[a] ~106 nm results are by Collin *et al.* (4).
[b] Values reported by Collin *et al.* (4).

primary reaction channels. Quantum efficiencies obtained in this study are reported in Table 6 along with values obtained by Collin *et al.* (4). The product quantum yields summarized in Table 5 were collected with an estimated accuracy of better than 10%, with the exception of hydrogen. Here due to the method required, a 15% error can be expected. Larger error limits might be expected to apply for radical yields, since the resulting quantum yields were obtained as a difference between two quantum values with their own errors limits. Although there were some discrepancies between this work and that of Collin *et al.* (4) with regards to the 123.6 nm photolyses, the 147.0 nm results demonstrated the reproducibility of such studies.

Mass spectral studies of symmetrical and unsymmetrical dialkyl disulfides

DINESH GUPTA, ARTHUR R. KNIGHT, AND PETER J. SMITH[1]

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received March 13, 1980

DINESH GUPTA, ARTHUR R. KNIGHT, and PETER J. SMITH. Can. J. Chem. **59**, 543 (1981).

The mass spectra for thirteen symmetrical and thirty-five unsymmetrical dialkyl disulfides have been determined at 70 eV. Carbon–sulfur bond cleavage to give hydrocarbon ions was observed as well as the formation of RS^+ ions. Factors affecting these two processes are discussed. The most favoured decomposition pathway for the molecular ions of most of the dialkyl disulfides (RSSR′) studied was intramolecular hydrogen transfer to give RSSH and R′SSH. The effect of varying the structure of the alkyl groups on this process has been investigated.

DINESH GUPTA, ARTHUR R. KNIGHT et PETER J. SMITH. Can. J. Chem. **59**, 543 (1981).

On a déterminé à 70 eV les spectres de masse de 13 disulfures d'alkyles symétriques et de 35 disulfures non symétriques. On a observé la rupture de la liaison C—S qui conduit aux ions hydrocarbonés ainsi que la formation des ions RS^+. On discute des facteurs qui affectent ces deux processus. Le mode de décomposition le plus favorisé des ions moléculaires de la plupart des disulfures d'alkyles (RSSR′) étudiés est un transfert intramoléculaire d'hydrogène qui donne RSSH et R′SSH. On a étudié l'effet d'un changement de structure des groupes alkyles sur ce mode de fragmentation.

[Traduit par le journal]

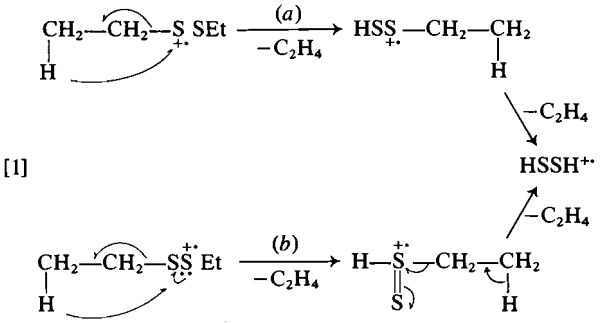
Introduction

Organic disulfides have been the subject of extensive investigations (1). This class of compound is found in nature as constituents of essential oils, natural pesticides, and insect pheromones (2, 3). As well, organic disulfides have been studied in considerable detail due to their ability to give protection against ionizing radiation (4).

Several investigations (5–7) of the photochemically induced exchange reactions of aliphatic disulfides have been carried out in our laboratories. Accordingly, it was considered of interest to study the mass spectra of these compounds and, hence, thirty-five unsymmetrical and thirteen symmetrical disulfides were prepared and the results are discussed herein.

Until recently (1) there had been very little reported on the mass spectrometry of aliphatic disulfides. Disulfides which contain sites of unsaturation (e.g., diallyl disulfide and aromatic disulfides) were shown to decompose to a large extent with skeletal rearrangement (8). The major fragmentation pathway for aliphatic disulfides where the alkyl groups are saturated and larger than methyl is the elimination of a neutral alkene molecule. This is the only process considered in detail by other workers (9, 10) and can be represented by either reaction [1*a*] or [1*b*] where sequential loss of two alkene molecules leads to the formation of HSSH.

Block *et al.* (10) considered the detailed mechanism of alkene loss by determining the mass spectrum of bis(ethyl-1,1-d_2)disulfide. It was found



[1]

(reaction [2]) that the molecular ion, *m/z* 126, fragmented by a one-step nonspecific hydrogen transfer to give both *m/z* = 96 and 97. Since *m/z* 96 was the more intense ion (87%), it was concluded that the hydrogen transfers shown in reaction [1] are more favourable than the 1,2 shift presumably responsible for the *m/z* 97 species.

[2] $[CH_3CD_2SSCD_2CH_3]^{+\cdot}$ (*m/z* 126) → $CH_3CD_2SSH^{+\cdot}$ (*m/z* 96) (87%); $CH_3CD_2SSD^{+\cdot}$ (*m/z* 97) (13%)

Alonso *et al.* (11) have recently investigated the fragmentation of a series of unsymmetrical disulfides in order to determine the factors affecting the competing loss of alkene processes taking place in each side of the unsymmetrical system. The fragmentation of unsymmetrical disulfides can lead to two sets of hydrogen transfer derived fragment ions.

It was concluded that the 1,2-H shift is an unfavourable process since $HSSR^{+\cdot}$ was not observed in the mass spectra of the methyl alkyl disulfides studied. Furthermore, the hydrosulfide intermediate, $CH_3SSH^{+\cdot}$, did not fragment to $HSSH^{+\cdot}$

via a second H transfer. The observation of significant fragment ions from several *t*-butyl alkyl disulfides, formed by transfer of hydrogen from the *t*-butyl group, was concluded to give support to the 1,3-hydrogen migration process observed by Block *et al.* (10).

Alonso *et al.* (11) measured the relative intensity of both RSSH and R′SSH formed from a series of unsymmetrical dialkyl disulfides, RSSR′. A marked preference for RSSH over R′SSH was noted depending on the structure of R and R′ and it was concluded that the position occupied by the migrating hydrogen is very important.

The availability of the large number of both symmetric and unsymmetric alkyl disulfides in the present investigation allows us to quantitatively study the factors associated with the ease of hydrogen transfer to sulfur with loss of the alkene molecule. The intensity ratio $(RSSH)^{+\cdot}/M^{+\cdot}$ was determined and the results discussed in the light of the type and number of hydrogens transferred as well as a consideration of the stability of the resultant alkene molecule. As well, factors affecting various possible competing processes to the alkene loss fragmentation are considered. Such processes have not been discussed previously in the literature.

Results and Discussion

The mass spectra[2] were determined for thirteen symmetrical alkyl disulfides, series 1, at 70 eV and lower ionization energies as well as for thirty-five unsymmetrical alkyl disulfides, series 2–7 (Table 1).

A noteworthy feature of the spectra of the forty-eight disulfides studied is the presence of a significant molecular ion at 70 eV. Only di-*t*-butyldisulfide, **8**, had a molecular ion with relative intensity less than 10% (8%). The significant molecular ions observed for this class of compound, even for high molecular weight disulfides, is useful for both detection and identification.

A favoured decomposition pathway for the molecular ions of thioethers, aliphatic ethers, and aliphatic amines is β-cleavage, reaction [3].

$$[3] \quad [RSCH_2—R']^{+\cdot} \rightarrow RS^+=CH_2 + R'^{\cdot}$$

β-Cleavage, however, was not observed for the disulfides examined in the present study even when there was branching at the α-carbon, e.g., di-*t*-butyldisulfide, **8**. Presumably, the formation of the β-cleavage ion from the disulfides is unfavourable due to the presence of an electronegative sulfur atom adjacent to the positive sulfur in the β-cleavage ion, $RS\overset{+}{S}=CH_2$.[3] This ion does not appear to be stabilized by partial π-bond formation between the two sulfur atoms. The failure of the disulfides to undergo β-cleavage could account to some extent for the relatively intense molecular ions.

A feature of the mass spectrum of aliphatic thioethers (ref. 9, p. 280) is the observation of an ion formed by cleavage of the carbon–sulfur bond with charge retention on sulfur. It has been noted (ref. 9, p. 280) that this process is more favourable for thioethers than for the oxygen analogues. This observation was rationalized as being due to the greater ability of sulfur to stabilize the electron deficiency by participation of its inner shell electrons. However, there was no analogous carbon–sulfur bond rupture observed in the present investigation to give RSS^+. This observation is consistent with the explanation presented for the failure to observe the β-cleavage ions.

Hydrocarbon ions corresponding to R and R′ of both the symmetric and unsymmetric disulfides RSSR and RSSR′ are significant, contrary to ref. 9, p. 292, in the spectra of all the compounds studied except the di-*n*-heptyl and di-*n*-octyl disulfides where hydrocarbon fragments smaller than R are significant. For the symmetric disulfides of series 1 the relative abundance of R varies between 28 and

TABLE 1. List of RSSR′ studied

Series 1	R = R′ = methyl, ethyl, *n*-propyl, *i*-propyl, *n*-butyl, *i*-butyl, *s*-butyl, *t*-butyl, *n*-amyl, *i*-amyl, *n*-hexyl, *n*-heptyl, *n*-octyl; compounds **1–13**, respectively.
Series 2	R = methyl; R′ = ethyl, *n*-propyl, *i*-propyl, *n*-butyl, *i*-butyl, *s*-butyl, *t*-butyl, *n*-amyl, *i*-amyl; compounds **14–22**, respectively.
Series 3	R = ethyl; R′ = *n*-propyl, *i*-propyl, *n*-butyl, *i*-butyl, *s*-butyl, *t*-butyl, *n*-amyl, *i*-amyl, compounds **23–30**, respectively.
Series 4	R = *n*-propyl; R′ = *n*-butyl, *i*-butyl, *s*-butyl, *n*-amyl, *i*-amyl; compounds **31–35**, respectively.
Series 5	R = *i*-propyl; R′ = *n*-butyl, *i*-butyl, *s*-butyl, *n*-amyl, *i*-amyl; compounds **36–40**, respectively.
Series 6	R = *n*-amyl; R′ = *n*-butyl, *i*-butyl, *s*-butyl, *t*-butyl; compounds **41–44**, respectively.
Series 7	R = *i*-amyl; R′ = *n*-butyl, *i*-butyl, *s*-butyl, *t*-butyl; compounds **45–48**, respectively.

[2]A complete listing of the mass spectral peaks for all the compounds down to 3% relative intensity is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[3]This explanation was put forth by Block (12) who studied the solvolysis of chloromethyl methyl disulfide.

TABLE 2. Mass spectral data of hydrocarbon fragment ions (R) derived from dialkyldisulfides at 70 eV

Compound		R^+	$M^{+\cdot}$	$R^+/M^{+\cdot}$ intensity ratio
$CH_3SS(CH_2)_2CH_3$	(**15**)	43(65)	122(75)	0.87
$CH_3SSCHCH_3$ (CH$_3$ branch)	(**16**)	43(57)	122(55)	1.04
$CH_3SS(CH_2)_3CH_3$	(**17**)	57(63)	136(73)	0.86
$CH_3SSCHCH_2CH_3$ (CH$_3$ branch)	(**19**)	57(53)	136(45)	1.18
$CH_3SSCH_2CHCH_3$ (CH$_3$ branch)	(**18**)	57(100)	136(57)	1.75
$CH_3SSC(CH_3)_3$	(**20**)	57(100)	136(32)	3.13
$CH_3SS(CH_2)_4CH_3$	(**21**)	71(14)	150(31)	0.45
$CH_3SSCH_2CH_2CHCH_3$ (CH$_3$ branch)	(**22**)	71(27)	150(28)	0.96

100%. These hydrocarbon ions can be formed directly by simple carbon–sulphur bond cleavage.

Another pathway leading to the hydrocarbon ions R and R′ is decomposition of the odd electron ions $RSSH^{+\cdot}$ and $R'SSH^{+\cdot}$, formed by intramolecular hydrogen transfer, with subsequent loss of $HS_2^{\cdot}$, reaction [4]. The loss of HS_2 has been

$$[4]\quad [RSSR']^{+\cdot} \rightarrow RSSH^{+\cdot} \xrightarrow[*]{-HS_2^{\cdot}} R^+ \qquad [RSSR']^{+\cdot} \rightarrow R'SSH \xrightarrow[*]{-HS_2^{\cdot}} R'^+$$

confirmed in most cases by the observation of a metastable peak. This process, like the simple cleavage process to give R^+, appears to be favoured only when the hydrocarbon ion is reasonably stable; i.e. loss of $HS_2^{\cdot}$ was not observed from RSSH when R = *n*-heptyl and *n*-octyl.

In order to gain a measure of the relative contribution of the two competing processes to give R^+, the ratio $R^+/M^{+\cdot}$ at 70 eV was determined for several dialkyl disulfides, Table 2. Compounds **15–22** cannot give R^+ via decomposition of RSSH since it has recently been shown (11), and confirmed in the present study, that a 1,2-H shift to give RSSH does not occur for methyl alkyl disulfides, CH_3SSR. Consequently, the ratio $R^+/M^{+\cdot}$ should provide a measure of the direct cleavage process to give R^+. It is noted that the ratio increases with increased branching within a series where the size of R is kept constant; i.e., $R^+/M^{+\cdot}$ = 0.86 and 3.13 for CH_3SS-*n*-Bu (**17**) and CH_3SS-*t*-Bu (**20**), respectively. Presumably this increase in ratio reflects a preference for the formation of the branched ion, *t*-butyl as compared with the *n*-butyl cation. Similarly, the ratio increases from 0.45 to 0.96 when R is changed from *n*-amyl (**21**) to isoamyl (**22**).

The hydrocarbon ions R and R′ can be formed by the two competing processes from the compounds shown in Table 3. The intramolecular hydrogen transfer reaction[4] can produce both RSSH and R′SSH which, on loss of $HS_2^{\cdot}$, give R^+ and R'^+. It is noted, however, that for substrates **43** and **47** only R′SSH, *m*/*z* = 136, is formed which fragments to give *m*/*z* 71. The ratios $R^+/M^{+\cdot}$ and $R'^+/M^{+\cdot}$ are similar for both **43** and **47**. This indicates that *m*/*z* 71 is enhanced by decomposition of R′SSH (*m*/*z* 136) since $R^+/M^{+\cdot}$ is significantly greater for **19** than for either **21** or **22**, Table 2.

The ratios are appreciably altered when both RSSH and R′SSH are formed, compounds **41** and **45**. When the relative abundance of RSSH (*m*/*z* 122) is greater than for R′SSH (*m*/*z* 136), compound **41**, the ratio $R^+/M^{+\cdot}$ is greater than $R'^+/M^{+\cdot}$, 3.67 and 1.57, respectively. When, however, RSSH and R′SSH are formed in essentially equal amounts, compound **45**, then $R^+/M^{+\cdot}$ is less than $R'^+/M^{+\cdot}$, 1.43 and 2.43, presumably due to the preference for the formation of the isoamyl cation to that of the

[4]This process will be discussed in more detail in a subsequent section of this manuscript.

n-butyl ion by the direct cleavage process. This is supported by the data for **22** and **17**, Table 2.

Hydrocarbon ions smaller than R and R' are noteworthy in the spectra of all the compounds studied where the alkyl groups of the disulfides were butyl or larger. Table 4 shows the hydrocarbon ions observed when the symmetrical normal alkyl disulfides were examined at 70 eV. Fragmentation of both R and R' by the well established pathway, reaction [5], leads to smaller hydrocarbon ions.

[5] $CH_3CH_2CH_2CH_2{-}\overset{\curvearrowright}{CH_2}{-}\overset{+}{C}H_2 \xrightarrow{m^*} CH_3CH_2CH_2\overset{+}{C}H_2$

However, significant ions smaller than R are observed which cannot be rationalized by the process represented in reaction [5]; i.e. *m/z* 43 with a relative intensity of 100% found in the spectrum of the di-*n*-hexyl substrate (**11**). Similarly, the ions at *m/z* 29 for **9**, *m/z* 57 for **12**, and *m/z* 71 for **13** cannot be accounted for by the loss of ethylene from R. Accordingly, it is suggested that to some degree δ-cleavage occurs with the formation of a cyclic disulfide radical and the hydrocarbon ion, reaction [6].

[6] $[CH_3(CH_2)_5SSCH_2CH_2CH_2CH_2CH_2CH_3]^{+\cdot}$

$$\longrightarrow CH_3CH_2CH_2^+ + CH_3(CH_2)_5{-}\dot{S}{-}S{-}CH_2CH_2CH_2$$

Sulfur–sulfur bond rupture with formation of RS^+ ions has been observed for methyl phenyl disulfide and diphenyl disulfide (ref. 9, p. 292). An examination of the spectra of the symmetric di-*n*-alkyl disulfides in the present study shows also ions resulting from sulfur–sulfur bond cleavage. The relative intensity of the RS^+ ions varies from 16% (di-*n*-octyl disulfide) to 9% (di-*n*-amyl disulfide) and are negligible for the lower molecular weight disulfides. These ions could be formed by a combination of simple sulfur–sulfur bond rupture and decomposition of RSSH ions formed by intramolecular hydrogen transfer, reaction [4]. The loss of $SH^\cdot$ from RSSH to give RS^+ is confirmed by the observation of the appropriate metastable peak. It appears that direct sulfur–sulfur cleavage to give RS^+ is not significant in the case of the dialkyl disulfides, as compared with diphenyl disulfide, since the relative intensity of such ions is negligible for the lower molecular weight disulfides where

*In all cases, this process was confirmed by the observation of the appropriate metastable peak.

decomposition of RSSH leads to HSSH rather than RS^+.

As indicated in reaction [4], odd electron ions $RSSH^{+\cdot}$ and $R'SSH^{+\cdot}$ can be formed from $[RSSR']^{+\cdot}$ by intramolecular hydrogen transfer. Since it has been shown (10, 11) that the process is essentially a 1,3-H transfer (reaction [7]) it was of

[7]  $\longrightarrow [HSSEt]^{+\cdot} + C_2H_4$

interest to determine the factors associated with this process. The mass spectral data of fragment ions derived from 1,3-intramolecular hydrogen transfer for several selected dialkyl disulfides are shown in Table 5 together with the intensity ratio, $[RSSH]^{+\cdot}/M^{+\cdot}$, which provides a measure of the facility of the hydrogen transfer reaction.

It is seen from the data in Table 5 that 1,2-H migration does not occur for the methyl alkyl disulfides, CH_3SSR', **14**, **15**, **17**, **19–21**, to give $R'SSH$. Accordingly, a measure of the ease of hydrogen transfer from R′ to give $RSSH(CH_3SSH)$ can be obtained by considering the ratio, $[RSSH]^{+\cdot}/M^{+\cdot}$. Transfer of a primary hydrogen from **14** appears to be less favourable than transfer of a secondary hydrogen from **15**, **17**, and **21** to give $CH_3SSH^{+\cdot}$ and the terminal alkene; i.e. $[RSSH]^{+\cdot}/M^{+\cdot} = 1.00$ for **14** and 1.33, 1.37, and 1.42 for **15**, **17**, and **21**, respectively. Similarly, transfer of a primary hydrogen from the *t*-butyl group in **20** is not favoured even though there are nine identical hydrogens as $[RSSH]^{+\cdot}/M^{+\cdot} = 0.59$. The stability of the alkene which is formed also must be considered as a factor which determines the ease of hydrogen migration since H-transfer from **19** gives 2-butene whereas 1-butene is obtained from **17**; $[CH_3SSH]^{+\cdot}/M^{+\cdot} = 2.22$ and 1.37 from **19** and **17**, respectively.

Intramolecular hydrogen transfer from the ethyl alkyl disulfides, CH_3CH_2SSR', **23–25**, **27–29**, can lead to both $CH_3CH_2SSH^{+\cdot}$ and $R'SSH^{+\cdot}$. It is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

noted that only **28**, where we have found that H transfer from the *t*-butyl group is not favourable, gave an ion resulting from hydrogen transfer from the ethyl group to sulfur. It appears, therefore, that the initial H migration occurs preferentially from the larger alkyl side chain to give $CH_3CH_2SSH^{+\cdot}$. This can be accounted for by a combination of the ease of H-transfer, secondary preferred over primary, and the stability of the resultant alkene. In all cases, the initially formed $CH_3CH_2SSH^{+\cdot}$ ions underwent a subsequent 1,3-H migration to give $HSSH^{+\cdot}$.

It is seen once again that the ratio $[RSSH]^{+\cdot}/M^{+\cdot}$ depends on the structure of the dialkyl disulfide. Transfer of a secondary hydrogen is preferred over primary; i.e. $[RSSH]^{+\cdot}/M^{+\cdot} = 1.64$ and 1.47 for **23** and **24**, respectively where the alkyl group is changed from *n*-propyl to isopropyl. As well, formation of 2-butene is preferred over 1-butene, $[RSSH]^{+\cdot}/M^{+\cdot} = 2.94$ and 2.38 for **27** and **25**, respectively.

The results obtained for the CH_3CH_2SSR' compounds are similar to those found for $CH_3CH_2CH_2SSR'$. Only in the case of **31**, $CH_3CH_2CH_2SS(CH_2)_3CH_3$, does transfer of a hydrogen occur initially from both alkyl groups to give $RSSH^{+\cdot}$ and $R'SSH^{+\cdot}$. Transfer of hydrogen from the larger alkyl group is preferred. The variation in $[RSSH]^{+\cdot}/M^{+\cdot}$ ratio with structure of the butyl group, **31–33**, can be rationalized by a consideration of the stability of the alkene formed together with the number and type of transferred hydrogen.

Experimental

All symmetrical disulfides were obtained commercially. Unsymmetrical disulfides were prepared by the co-photolysis of two disulfides. Equimolar mixtures of RSSR and R'SSR', using 200–300 μL samples, were irradiated in the liquid phase in quartz cells using a Vycor 7910 filtered low pressure mercury lamp. At the end of the reaction the photolysates were analyzed using a thermal conductivity or flame ionization gas chromatograph. The unsymmetrical disulfides after separation, using a preparative g/c, were directly examined using a MS-12 mass spectrometer at 70 eV with a source temperature of 100°C. All the collected samples were reinjected into the gas chromatograph to establish their purity. As well, there was no variation in the mass spectra when the source temperature was varied between 100°C and 150°C. Consequently, it was established that the disulfides used in the present study are stable under the experimental conditions employed.

RAFIK O. LOUTFY. Can. J. Chem. **59**, 549 (1981).

The optical absorption spectra of small particles of α-, β-, and *x*-form of metal-free phthalocyanine (H_2Pc) and vanadyl phthalocyanine (VOPc) surrounded by a dielectric (polymers) have been studied. The true bulk absorption can be obtained by measuring the difference in transmittance of two films of identical composition but different thicknesses. This approach eliminates effectively light reflection losses. Comparison between the absorption spectra measured by direct vs. difference in transmittance revealed a number of differences: shift in the absorption frequencies, change in absorption intensities, and change in peak-to-valley ratio. These differences are due to light scattering which can be significantly minimized by using the differential transmittance method. The true peak absorption of *x*-H_2Pc particles located at 770 and 615 nm had an absorption coefficient of 35.3 and 34.2 μm^{-1}, respectively. The absorption minimum occurs at 477 nm. The peak-to-valley ratio was 27.

The absorption spectra of VOPc particles did not correspond to any one polymorph, but are due to a mixture of two known polymorphs. Some discrepancies between the particle absorption of α-H_2Pc or β-H_2Pc and the corresponding evaporated film absorption were observed. These discrepancies are attributed to the spread in particle size and also to local agglomeration of the particles.

RAFIK O. LOUTFY. Can. J. Chem. **59**, 549 (1981).

On a étudié les spectres d'absorption de petites particules des formes α, β et *x* de la phtalocyanine dépourvue de métal (H_2Pc) et de la vanadyl phtalocyanine (VOPc) entourées d'une substance diélectrique (polymères). On peut évaluer la vraie absorption globale en mesurant la différence de transmission de deux films de composition identique mais d'épaisseur différente. Cette approche élimine effectivement les pertes de lumière par réflexion. La comparaison entre les spectres d'absorption mesurées par transmission directe et par différence de transmission révèlent un certain nombre de différences soit le déplacement des fréquences d'absorption, les variations des intensités d'absorption et les variations du rapport pic-vallée. Ces différences sont dues à la dispersion de la lumière qui peut être minimisée de façon significative en utilisant la méthode de transmission différentielle. Les vrais pics d'absorption des particules *x*-H_2Pc situés à 770 et 615 nm ont respectivement un coefficient d'absorption de 35,3 et 34,2 μm^{-1}. L'absorption minimum se produit à 447 nm. Le rapport picvallée est de 27.

Les spectres d'absorption des particules de VOPc ne correspondent à aucune variété polymorphique, mais ils sont dus à un mélange de deux variétés polymorphiques connues. On observe quelques différences entre les absorptions des particules α-H_2Pc ou β-H_2Pc et l'absorption du film évaporé correspondant. On a attribué ces différences à l'étalement de la dimension de la particule et également à l'agglomération locale des particules.

Introduction

It has been recognized for some time that a method of characterizing the optical properties of particulate materials is needed. For example, information about the actual spectral absorption characteristics of metal-free phthalocyanine pigment particles is required to adequately analyze the action spectra of solar cells (1).

Several studies have been carried out in the past to determine the optical characteristics of various organic pigments (2). The most fundamental work is that of Sharp and Lardon (3), where the optical absorption spectra of several phthalocyanines were determined by measuring the transmittance of a series of vacuum deposited thin film of these materials. It is assumed that the absorption characteristics of a pigment in the form of a thin film is the same as that displayed by pigment crystallites. Unfortunately, the pigment properties are frequently changed during the deposition process. Thin films are probably amorphous whereas pigment powders are usually crystalline and thus optically dichroic and bi-refringent (4). Another limitation of this approach is that many pigment materials cannot be successfully vacuum deposited without thermal decomposition or without the occurrence of polymorphic transformation. For instance, the *x*-polymorph of metal-free phthalocyanine (*x*-H_2Pc) cannot be prepared by vacuum deposition. The optical absorption of a thin film of *x*-H_2Pc prepared from a suspension in hydrocarbon or in polymer resin was reported (3). However, no attempts were made to eliminate scattered light contributions. Photoacoustic spectroscopy is emerging as an extremely sensitive detection method which can be applied to study absorption of most kinds of materials including powders, crystals, gels, living biological specimens, gaseous and liquid samples (5). This technique is based on measuring acoustic waves generated when modulated light is absorbed by a sample, rather than observing transmitted or reflected light. This avoids problems that can arise from light scattering. However, a major disadvantage of this technique is the difficulty of quantita-

tion as well as defining standards for spectrometric performance (6). An alternative quantitative method of measuring the optical properties of pigments in particulate form is still needed. Such a technique should account satisfactorily for effects related to light scattering. At the same time, the measurement should not induce modification in the chemistry or crystal structure of the pigment particles and it should be simple.

In this paper, we report the measurements of the optical absorption spectra of particles of α-, β-, and *x*-metal-free phthalocyanine (H_2Pc) and vanadyl phthalocyanine (VOPc). The influence of particle size and shape, and the dielectric constant of the surrounding medium on the absorption frequency and intensity were studied.

Experimental

Materials

β-H_2Pc was obtained from ICI as monolite fast blue GS. It was purified by slurrying and working with hot dimethylformamide. The pigment was milled in isopropanol using stainless steel balls for 72 h in order to reduce the particle size. Acid pasting of β-H_2Pc followed by ice dilution gave a fine powder of α-H_2Pc. This product could be converted to *x*-H_2Pc by neat milling with flintstone for one week (2). Vanadylphthalocyanine was obtained from the reaction of phthalonitrile and vanadyltetrachloride. The deep blue product was acid pasted in sulfuric acid to give submicron size particles.

Sample Preparation

General Procedure

The pigments to be tested were prepared as a series of dilute suspensions in a solution of polyvinylacetate in methylene chloride. The pigment-to-polymer weight ratio was varied from 10 to 60%; the mixture was ball-milled using 1/4 in. stainless steel balls for at least 1/2 h to ensure uniform suspensions. The suspensions were then coated on 2 mil Mylar film using wire wound rods #4, 6, 8, and 16 having a 9, 13.7, 18.3, and 36.6 μm gaps respectively, giving various film thicknesses. The wet coating was allowed to dry and then the apparent film thickness was measured using a Talystep thickness monitoring device. In one experiment, pigment particles suspended in methylene chloride without a polymer binder were used. In this case, the dried film showed excellent uniformity; however, it was mechanically fragile. The dry pigment film was covered with a sheet of Tedlar and then passed through a pressure roller (at 250 lb/sq. in.). This treatment resulted in highly compact, uniform, and mechanically durable films. No transfer of the pigment to Tedlar was observed.

Thin evaporated films of α-, β-H_2Pc, and VOPc were obtained by vacuum depositing onto a glass slide using Balzer vacuum system.

Optical Measurements

The optical absorption spectra of the samples were recorded on a Cary 17 Spectrophotometer at room temperature. The spectra were obtained using the differential technique in order to eliminate reflection and scattering losses. In this technique, a film of the pigment with a thickness $(X - \Delta X)$ was placed in the pass of the reference beam, while another film of the same composition but with a thickness X was placed in the sample compartment. The absorption spectrum is that of a film with thickness ΔX. With this technique, the reflection losses were significantly minimized in particular for pigment samples with particle size < 1 μm such as *x*-H_2Pc, α = H_2Pc, and VOPc. From the absorbance (A) measured at various wavelengths α, the absorption coefficient, was calculated via the following equation:

$$[1] \quad \alpha = 2.303A/NV\Delta Xf$$

In this equation N is the number of particles per unit volume, V is the volume of one particle (NV is the fractional volume concentration of particles), ΔX is the film thickness in cm, and f is a correction factor necessary because the mass density of the film is not equal to the true bulk density. This correction factor was found to relate to the ratio of pigment to polymer as will be discussed later. We have shown that pigment powders can be compressed into dense, mechanically stable films with surfaces having essentially optical quality. In these cases, mass densities in excess of 90% of the true pigment bulk densities are possible. Thus, in absence of agglomeration and when the surface coverage is uniform the absorption coefficient of pigment particles can be obtained using eq. [1] and $f \simeq 1.0$.

The reflectance spectrum of polycrystalline compacts film of *X*-H_2Pc was recorded on Cary 17 Spectrophotometer using the Specular reflectance attachment. Electron micrographs of the pigment samples were made using a Phillips E200 Transmission electron microscope after a proper preparation.

Results and Discussion

Electron micrographs of *x*-H_2Pc, α-H_2Pc, and β-H_2Pc particles are shown in Fig. 1. The particles of *x*-H_2Pc are in the form of needles, the majority of which have a length of ~0.1 μm. α-H_2Pc particles exists as a mixture of needles and flakes. The particle size varies enormously from 0.02 to 0.2 μm. β-H_2Pc particles are large needles varying in length from 2 to 8 μm. Vanadyl phthalocyanine particles are similar to those of *x*-H_2Pc. The variation in particle size and shape is expected to cause a marked effect on the particle absorption. The effective absorption and scattering which accounts for the change in intensity of a light beam passing through the pigment layer is a complicated function of the refractive index of the pigment, the refractive index of the binder, and the particle size. The particle absorption is greatest for small particles when the particle and the medium refractive index match. Also the relative scattering is largest for small particles when the particle and medium indices are matched. Figure 2 shows the specular reflectance spectrum of an *x*-H_2Pc film. A specular reflectance as high as 15% was observed, with maxima at 850, 810, 650, and 480 nm. The reflectance and absorption maxima are quite dissimilar causing the strong dichroic properties of the material.

The Optical Absorption of x-H_2Pc Particles

The problem of determining the fundamental optical properties of pigment materials is difficult because most pigments can only be obtained in particulate form. However, as described above, the absorption of these pigments was measured by preparing a thin film of the particles in a polymer binder

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

and measuring the difference in transmittance between two films of different thickness. Figure 3 shows the optical absorption spectra of 0.23 μm films of x-H_2Pc particles embedded in polyvinyl

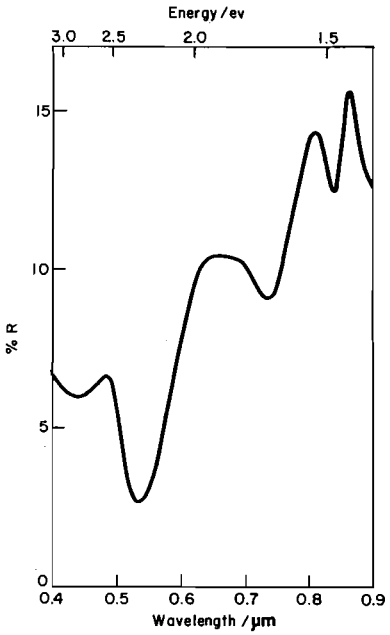

FIG. 2. Reflectance spectrum of a film of polycrystalline x-H_2Pc.

acetate (the pigment concentration corresponds to NV of 0.53). These were obtained by using the direct transmission (curve 1) and by the difference in transmittance (curve 2) technique. A number of differences are apparent: first, a change in intensity of absorption is noticed, particularly in the ir and blue regions of the spectrum. Second, a shift in the absorption frequency, and third a change in the ratio of peak intensities. Curve 1 represents the transmittance and reflectance of the pigmented film, while in curve 2 a significant amount of the reflectance component has been eliminated using the technique of differential transmittance. The success of this technique rests on the high optical quality and uniformity of the x-H_2Pc particulate films.

The absorption coefficient α as defined by eq. [1] was determined for x-H_2Pc films as a function of the volume concentration fraction (NV) and the results are given in Table 1. The assumption that the fraction f is unity for all films gives α's which increase with volume fraction. The dependence of α on the volume fraction must be due to the difference in surface mass density compared to the true material density. The estimated values of f required to give a constant α at any given wavelength as a function of NV are given in Table 1. These values were computed from the ratio of α for a given volume fraction to that at $NV = 1.0$.

Figure 4 shows the absorption spectrum of thin films of x-H_2Pc particles (ΔX = **60 nm**). The ab-

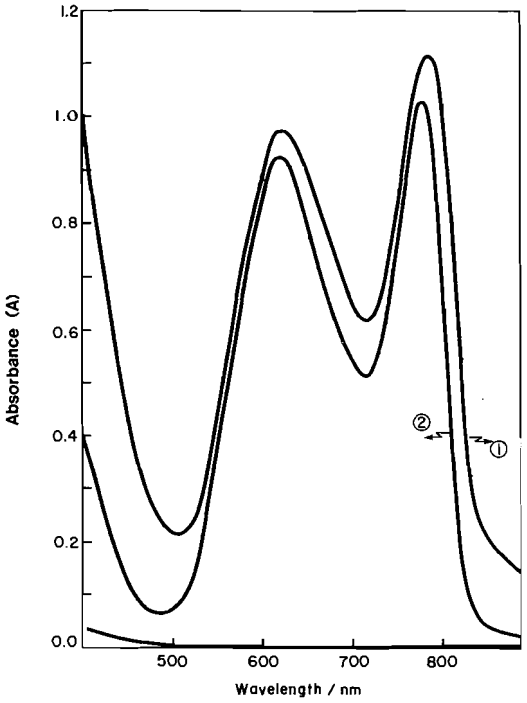

FIG. 3. Optical absorption spectra of x-H_2Pc particles embedded in polyvinylacetate (NV = 0.53): (*1*) a 0.23 μm thick film vs. mylar and (*2*) a 0.46 μm film vs. 0.23 μm films.

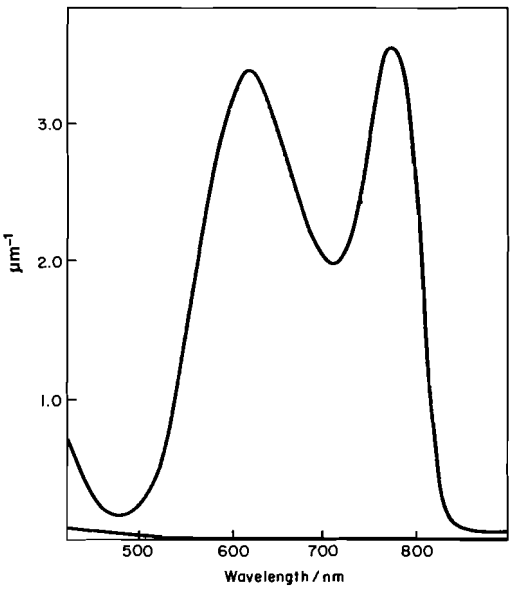

FIG. 4. The absorption spectrum of 60 nm x-H_2Pc particles.

sorption coefficients α corresponding to the absorption maxima at 770 and 615 nm are 35.3 μm^{-1} and 34.1 μm^{-1}, respectively. The absorption minimum in the green occurs at 477 nm. An important aspect of the spectrum is the depth of the absorption minimum at 477 nm. This is best described by the peak-to-valley absorption ratio. This ranges typically from 25 to 35. The α615/α480 ratio for our sample is 27.

Optical Absorption of Vanadyl Phthalocyanine Particles

Vanadyl phthalocyanine (VOPc) exhibited a strong absorption in the ir region of the spectrum at λ = 830 nm, which coincides with the GaAs laser wavelength. Consequently, this material is of considerable interest as a potential infrared photoreceptor material.

The absorption spectra of a number of samples of VOPc particles have been measured using the procedure described in detail in the preceding section. Figure 5 shows the absorption spectrum of compressed thin film of VOPc particles (ΔX = 63 nm) measured using the differential transmittance technique. The absorption coefficient at the absorption maxima 830, 690, 650 nm are 34.4, 31.0, and 31.4 μm^{-1}, respectively. The absorption minimum in the green occurs at 480 nm. The α650/α480 ratio is 21.4. The absorption spectrum of a dispersion of VOPc in polyvinylacetate was quite similar to that of a compressed film with no binder. The estimated fraction, f, for NV = 0.52 was 0.42 which agrees well with that found for similar films of x-H_2Pc.

The absorption of VOPc particles does not correspond to any one of the known polymorphs (see Fig. 6). The peak at 830 nm corresponds to the high

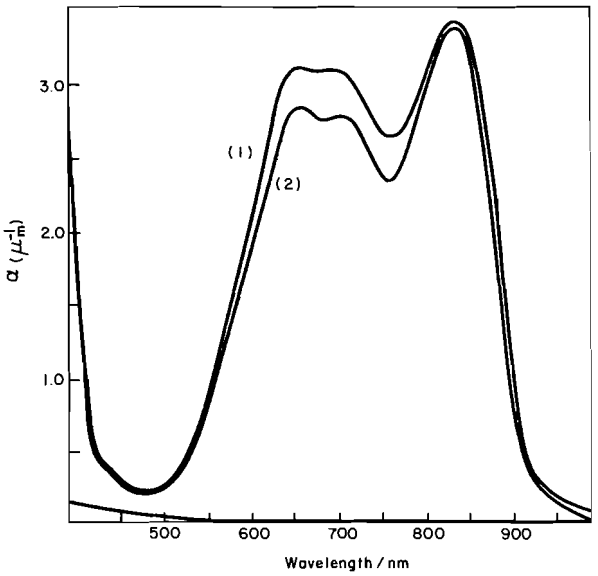

FIG. 5. The absorption of VOPc particles: (*1*) $NV = 1.0$ and (*2*) $NV = 0.51$ in polyvinylacetate ($f = 0.46$).

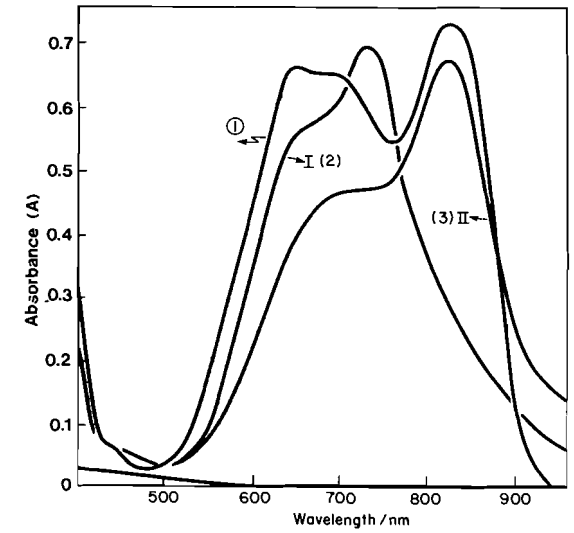

FIG. 6. The absorption spectra of VOPc: (*1*) particles; (*2*) polymorph I, and (*3*) polymorph II.

temperature polymorph II, while the peaks at 650 and 720 nm correspond to the low temperature polymorph I. Therefore, the VOPc particles appear to be a mixture of polymorphs I and II.

The Optical Absorption of α-H_2Pc and β-H_2Pc Particles

The absorption spectra of α-H_2Pc and β-H_2Pc particles were determined by the technique described previously. The peak absorption (620 nm for α-H_2Pc and 645 nm for β-H_2Pc) increased with increasing pigment concentration and ranged from 8 μm^{-1} for a pigment volume fraction of 0.073, 15 μm^{-1} for $NV = 0.53$ to a value of 28 μm^{-1} for a $NV = 1.0$. This corresponds to a ratio of surface mass density to true bulk material density of 0.29 for $NV = 0.073$ and 0.54 for $NV = 0.53$, which are in good agreement with those estimated for x-H_2Pc and VOPc particle/polymer blends.

Comparison of Thin-film Absorption with Particle Absorption Spectra

We have seen that the differential absorption technique minimizes light scattering in the absorption of x-H_2Pc and VOPc particles. It is of interest to compare this technique to that of evaporated thin-film absorption.

Evaporated thin-film absorption and differential particle absorption spectra for α- and β-H_2Pc are shown in Figs. 7 and 8, respectively. Although the shapes of the spectra are similar, there is one major difference. The α-H_2Pc differential particle absorption spectra indicate considerably more absorption in the valley region and less in the peak region than does the evaporated film. The peak-to-valley ratio here is typically 10–15 compared to 31 for the evaporated film. In the case of β-H_2Pc particles there is a general enhanced absorption and softening in the absorption maxima. We have experienced great difficulty in the preparation of β-

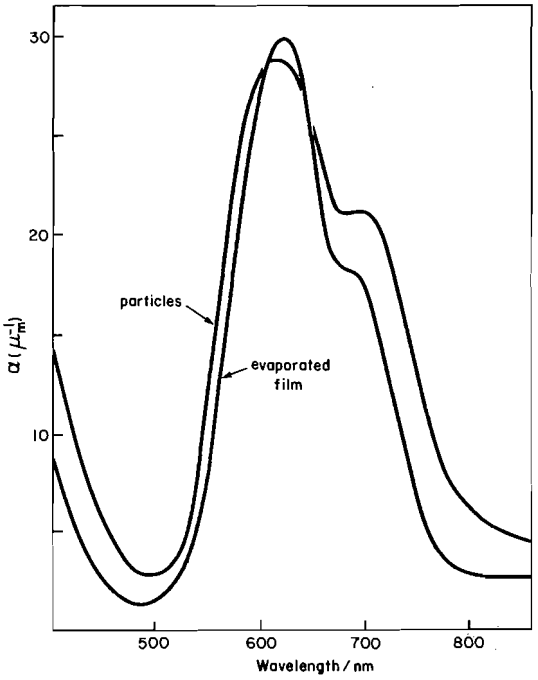

FIG. 7. Comparison of the absorption spectra of α-H_2Pc particles and evaporated film.

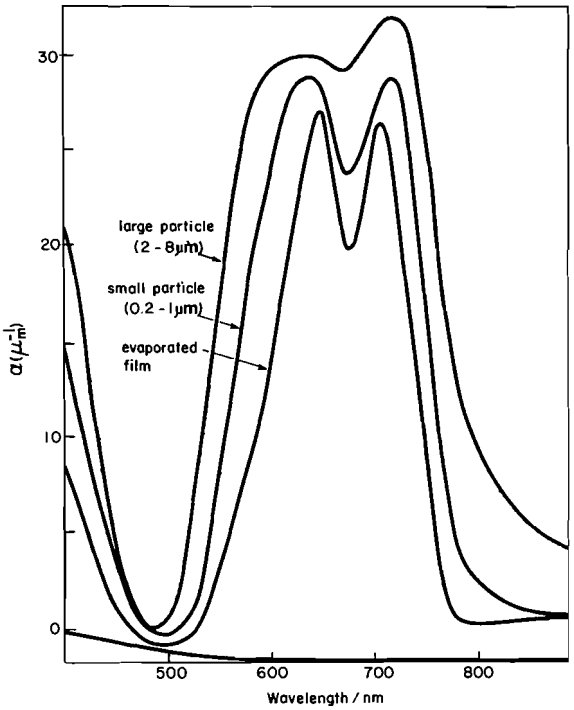

FIG. 8. Comparison of the absorption spectra of β-H_2Pc particles and evaporated film.

H_2Pc particle films due to a strong tendency for agglomeration of the pigment. The fact that the particles are large and are not widely separated due to agglomeration probably leads to a wavelength-dependent scattering which results in additivity failure, particularly in high optical density regions. The agreement between β-H_2Pc particles and evaporated films improves significantly when smaller particles are used, see Fig. 8.

Conclusion

In this work we have attempted to show that the spectroscopic properties of pigment particles are better determined by difference than by direct transmission. This technique minimizes reflection losses and allows the true bulk absorption to be determined. The absorption spectra of *x*-H_2Pc and VOPc particles were successfully determined.

Comparison between the absorption of evaporated and particulate films of α-H_2Pc showed general similarity; although the particle absorption spectra absorbed more strongly in the valley region (480 nm) and less strongly in the peak region (620 nm) than does the evaporated film. A larger discrepancy between the particle and evaporated film absorption of β-H_2Pc was observed. This was attributed to the particle size and also to the local agglomeration of the particles which leads to wavelength-dependent scattering.

Apparent stability constants of proton and metal ion complexes of glycine, iminodiacetic acid, nitrilotriacetic acid, and triethylenetetramine in aqueous methanol

TERRENCE B. FIELD[1] AND W. A. E. MCBRYDE

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received November 30, 1979[2]

TERRENCE B. FIELD and W. A. E. MCBRYDE. Can. J. Chem. **59**, 555 (1981).

Conditional formation constants were determined at 25°C and with a background electrolyte of 0.1 mol dm^{-3} $NaNO_3$ for the proton, nickel(II), copper(II), and zinc(II) complexes of glycine, iminodiacetic acid, and nitrilotriacetic acid in 0, 20, 50, 80, and 95 volume percent methanol mixed with water. Similar measurements were made for triethylenetetramine in all but 95% methanol, and the formation constants so determined were used to determine K_{MNTA} by a competitive method.

The variation of all constants with solvent composition was examined from the point of view that complex formation is accompanied by solvent displacement. Accordingly it should be possible to correlate the observations by means of an over-all formation constant, valid for any solvent concentration. It was concluded that for two solvents as similar as water and methanol, both of which appear to be involved in solvation or desolvation in the reaction, the correlations sought could not very precisely fix the amounts of solvents displaced or taken up. The goodness of fit to the attempted correlations suggests that they would be useful for interpolations to solvent compositions other than those studied.

TERRENCE B. FIELD et W. A. E. MCBRYDE. Can. J. Chem. **59**, 555 (1981).

Opérant à 25°C et utilisant comme électrolyte de base une solution de $NaNO_3$ à 0,1 mol dm^{-3}, on a déterminé les constantes de formation conditionnelle des complexes du proton, du nickel(II), du cuivre(II) et du zinc avec la glycine, les acides iminodiacétique et nitritotriacétique dans des mélanges méthanol–eau à 0, 20, 50, 70 et 95% en volume. On a fait des déterminations identiques pour la triéthylamine mais sans recourir au mélange méthanol–eau à 95% et on a utilisé les constantes de formation ainsi obtenues pour déterminer K_{MNTA} par une méthode compétitive.

On a examiné la variation de toutes les constantes avec la composition du solvant en tenant compte du fait que la formation des complexes s'accompagne d'un déplacement du solvant. En conséquence il devra être possible de faire concorder les observations au moyen d'une constante globale de formation, valable pour n'importe quelle concentration de solvant. On a conclu que pour deux solvants aussi semblables que l'eau et le méthanol, qui semblent être impliqués dans la solvatation ou la désolvatation au cours de la réaction, les corrélations recherchées ne peuvent pas fixer avec précision les quantités de solvant déplacé ou éliminé. Les meilleurs corrélations obtenues suggèrent qu'elles seraient utiles pour faire des interpolations dans les compositions de solvant différentes de celles étudiées.

Introduction

The formation constants of proton and metal ion complexes with organic ligands undergo appreciable changes when measured in mixed solvents containing water compared to their values when measured in solely aqueous solutions. An understanding of this *solvent effect* would be desirable from a purely theoretical standpoint, but also would be of practical value in interpreting or correlating data obtained in solutions other than strictly aqueous. Some success in accounting for the solvent effect has been achieved (1, 2) by adopting the concept of the complete equilibrium constant (3) in which the solvent or solvents associated with the reactant and product molecules is/are included in the complex-forming reaction and its equilibrium constant. Thus in a binary solvent, molecules of one or both components are regarded as excluded or incorporated when an association reaction takes place, and so the activity (concentration) of these participating solvents is included in the equilibrium expression.

The present investigation was planned to test this concept further by examining the progressive effect of added methanol in the solvent upon the formation constants of the complexes of a series of ligands with increasing numbers of donor atoms. In such a series the increase in number of chelate rings formed might be expected to result in a progressively increased rejection of solvent. The essential reaction (omitting charges) is assumed to be

$$\mathrm{M(solv) + Chel(solv) = MChel(solv) \pm solvent}$$

Solvent would probably be displaced in consequence of the direct bonding between metal ion and ligand. Conventional formation constants were measured for the ligands glycine (gly), iminodiacetic acid (IDA), and nitrilotriacetic acid (NTA) reacting with hydrogen ions and the bivalent ions of nickel, copper, and zinc. Additional measurements were made with triethylenetetramine (trien) as a

competing ligand. The effectiveness of relationships developed previously (1) for interpreting the effect of solvent composition on the apparent stability constants was tested with the results of these determinations.

Experimental

Solvents and Solutions

All solutions were prepared in distilled, deionized water, stored under nitrogen, with addition as indicated of Baker's Analyzed methanol (100%). All salts and acids used to prepare solutions were of reagent grade; alkali solutions were prepared from Baker Dilut-it ampoules (carbonate free) and stored under nitrogen. As necessary, solutions were standardized by published titration methods. The acid content of stock metal ion solutions was determined by means of ion-exchange displacement.

Ligands

Glycine, iminodiacetic acid, and nitrilotriacetic acid were recrystallized from water; solutions prepared from the purified acids were standardized by conductance titration. Triethylenetetramine was prepared as the tetranitrate salt (4), and its purity checked by titration (observed molar mass 398.24 g mol^{-1}).

Titrations

These were carried out in a thermostatted cell (at 25°C), continuously purged with nitrogen, and provided for magnetic stirring of the contents. A Beckman glass electrode (39301) and an Orion solid-state electrode (94-29A) were calibrated and used as concentration probes respectively for hydrogen ions and copper(II) ions. These were used, as appropriate, with various reference electrodes: Leeds and Northrup calomel (117208) filled with saturated KCl or NaCl solution, or Orion single-junction (90-01) filled with Orion solution 90-00-01 or with a home-made filling solution. This last consisted of 0.001 mol dm^{-3} NaCl + 0.099 mol dm^{-3} $NaNO_3$ (or KNO_3) in water, 20% methanol, 50% methanol, etc., and rendered just cloudy by addition of $AgNO_3$. The electrodes were connected through a good-quality switch so that as many as three reference electrodes and two copper-ion electrodes could be used at a time for checks of consistency. The glass – reference electrode pair was applied to an Orion Model 801 digital pH meter, and the solid-state – reference electrode pair to a null-point Radiometer Model 4 pH meter. The solutions to be titrated were of the order of 10^{-3} mol dm^{-3} in ligand or metal ion concentration, and 10^{-1} mol dm^{-3} in background electrolyte in a total volume of 50 cm^3. The titrant was either 1.0 or 2.0 mol dm^{-3} alkali or acid delivered from a micrometer syringe.

Results

The data from the titrations carried out as described were used to calculate the acidity and stability constants for the selected metals and ligands in water–methanol solutions of selected compositions. The large number of results have, for the sake of brevity of this report, been placed with the Depository of Unpublished Data and those for iminodiacetate are plotted in Fig. 1 to illustrate the general trends observed.[3] Unless otherwise noted

[3]Complete set of data may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

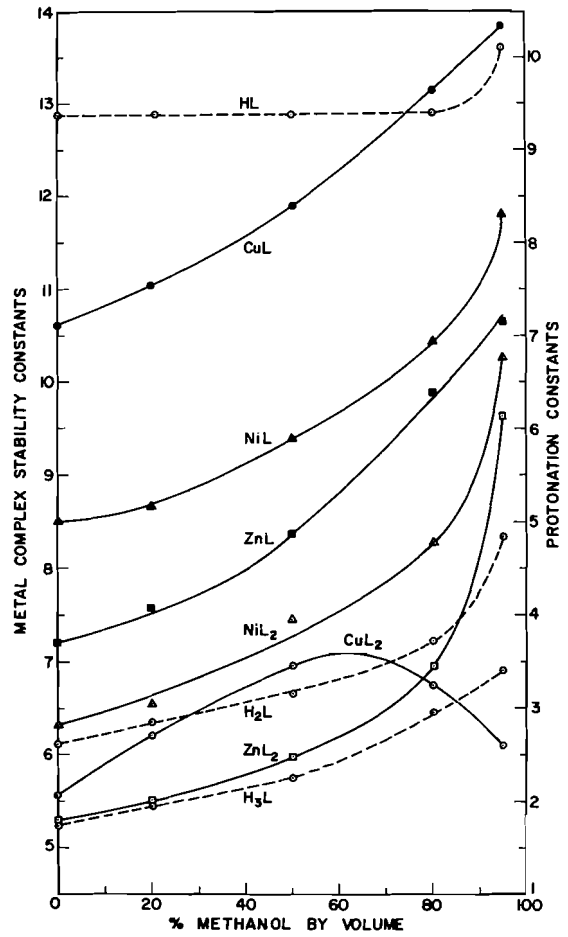

FIG. 1. Metal complex stability constant and protonation constants of iminodiacetate in water–methanol solutions.

all equilibrium constants were calculated from the experimental data by the computer program SCOGS (5), and the various species included for each combination of reactants were those which yielded minimum standard deviations between observed and calculated titers.

Owing to the great stability of some metal–NTA complexes direct determination of their formation constants from pH-titration data is difficult, and is often avoided by carrying out titrations with a competing ligand (6). Both approaches were followed in this study; the second required determinations of stability constants of trien (as competing ligand) in the same media, the values of which are in the Depository of Unpublished Data. There is limited solubility of KNO_3 in aqueous methanol, and of trien$(NO_3)_4$ in methanol-rich solvents, these facts account for the use of $NaNO_3$ as background electrolyte, and for the absence of trien data in 95% methanol. To displace metal ions from a MNTA complex by hydrogen ions requires a high concen-

tration of the latter; accurate measurement of this concentration becomes increasingly difficult as pH is lowered below 2, since the emf of the measuring cell is then increasingly affected by liquid junction potentials. Because of this and also because the ionic strength of the analyte may be affected by added electrolyte the relationship between emf and $-\log [H]$ no longer remains linear. There are four protonation constants for NTA, though most authors have only reported three; at low pH the effect of the fourth protonation must be taken into account. Finally, because of the formation of a weak sodium–NTA complex values of K_i^0 for this ligand are somewhat different in sodium salts than in potassium salts as background electrolytes. Regrettably, in spite of having taken all foreseeable precautions, the values of $\log K_1$ for NiNTA obtained by direct determination must be regarded as unsatisfactory. For purposes of all correlations with solvent composition the values calculated from competitive titrations with trien were used.

Discussion

With increasing methanol content in the solvent, amine protonation constants were found first to decrease and then to increase. This effect has been noted for 24 nitrogen bases in methanol–water mixtures as well as numerous other solvents mixed with water (7). All carboxyl protonation constants and the stability constants of most of the metal–ligand complexes increased with the methanol content of the solvent. This regular increase was not found among the formation constants of protonated (MHL) or deprotonated (MOHL) complexes. Also, when the coordination number of the metal was exceeded, with the addition of a second molecule of ligand, $\log K_2$ did not show the same increase with additional methanol in the solvent.

Following an earlier approach to interpretation of the solvent effect in such ionic equilibria (1) an attempt was made to correlate the results from this study in terms of a total equilibrium constant (3). For the reaction

$$aA + bB = A_aB_b + wH_2O + sMeOH$$

$$K_{total} = K_{observed}[H_2O]^w[MeOH]^s$$

In this expression concentrations of water and methanol appear although, strictly speaking, activities of the solvents should have been put in instead. If the total number of solvent molecules displaced is represented by t $(= w + s)$ then it can be shown that

$$[1] \quad \log K_{total} + w \log ([MeOH]/[H_2O]) = \log K_{observed} + t \log [MeOH]$$

a value of t can then be sought which yields the best straight line when the right-hand side of [1] is plotted against $\log ([MeOH]/[H_2O])$. (In this instance only integral values of t were considered, but it is possible to achieve even better fits to the data with fractional values of t.) From the slope and intercept of the straight line, values of w and K_{total} can be found. The results of such correlations for the iminodiacetate complexes are shown in Table 1; corresponding tables giving correlation parameters and total equilibrium constants for the other systems are available from the Depository of Unpublished Data. The quantity R shown in this table is the conventional statistical correlation coefficient.

When all the data are examined this way, it is clear that good to very good correlations (in the sense of R being very close to unity) can be obtained by use of the two-parameter relationship [1]. However, the success of such correlations affords no proof of the validity of the model of solvent exclusion from which [1] was derived. In fact the absence of any consistent pattern among the values of t for some comparatively similar systems (e.g., Table 1) makes it difficult to associate any physical significance with them. Some limited conclusions might be drawn from the correlation parameters. For example, in the protonation of nitrogen centres s values are greater than w values, whereas for oxygen centres the reverse is true; this had previously been found with ethylenediamine and glycine (1). It might be concluded therefore that methanol is preferentially solvated at nitrogen centres; however, equally well this balance of w and s values may simply be an artifact created by the minimum in pK that is typical of nitrogen bases in aqueous methanol. In the case of glycine and IDA the formation of metal complexes, with a single exception, is characterized by negative s values; such values could be interpreted to signify that the metal complexes bind methanol to a greater extent than the reactants. However, that this seeming regular-

ity is not sustained among metal–NTA complexes places this physical interpretation in doubt. Where $w > t$, values of s are negative and the physical situation corresponding to that would be that the complex binds methanol to a greater extent than the reactants. The solvent exclusion idea, as a basis for explaining the solvent effect on ionic equilibria, was most successfully applied to binary solvents in which one partner exhibited markedly preferential solvation over the other, e.g., water with dioxane (1), or benzene with cyclohexane (2). Methanol is obviously active in solvation, and the simple model used may be incapable of resolving the relative extent to which the two solvents are engaged in the reactions examined. To set a unique value of t for some of these systems is not clear-cut; when experimental variance is taken into account the value of t is often uncertain by 1, and therefore the derived parameters w and s are correspondingly uncertain. Moreover, it is not known whether the solvent molecules postulated to have been displaced or added are from the primary or secondary layer of solvation. It had originally been our supposition that the formation of metal–ligand bonds would liberate solvent molecules from the primary solvation layer. However, in a recent study of partial molar volumes (8), formation of the Ni–EDTA complex in solution was found to be accompanied by a significant increase in volume; this was interpreted to indicate incorporation of electrostricted solvent within the complex.

Finally, we have applied the correlation method based on [1] to data obtained by other workers who have measured some of the same equilibria in aqueous methanol (1, 9–14). The particulars are available in a university thesis (14). It was of some interest to check the correspondence between the present work on glycine and that previously reported from this laboratory. The two lots of values for the equilibrium constants are in reasonably good agreement but did not in a number of cases lead to the same value of t in [1]. As we have said, the goodness of fit of the data is not particularly sensitive to the choice of t value, but the choice of t value can lead to widely differing values of w and s (even to the point of changing sign).

As an example of the uncertainty attending any physical interpretation of the correlation parameters based on [1], we offer in Table 2 the values of these for the stepwise protonation of trien based (*a*) on this work and (*b*) on the measurements of Rohrobacher *et al.* (12). Apart from the fourth-stage protonation constants, the values obtained in the two studies were in reasonable agreement, yet the correlation parameters and complete equilibrium constants differ appreciably.

TABLE 2. Correlation constants for eq. [1]: trien complexes

Species formed	t	w	s	K_{total}	R
HL	1*	0.30	0.70	10.68	1.000
H_2L	1*	0.22	0.78	9.94	0.999
H_3L	1*	0.29	0.71	7.51	1.000
H_4L	3*	1.41	1.59	6.61	1.000
HL	4†	1.44	2.56	14.32	0.999
H_2L	4†	1.43	2.57	13.49	0.999

H_4L	4†	1.11	2.89	7.03	0.999

*This study.
†Data from ref. 12.

In conclusion it must be conceded that while this investigation has added some carefully measured stability constants for the systems examined, it has failed to uphold earlier hopes that the solvent effect might be explained to a large extent on the basis of relative activity of the solvent partners.

Kinetics and mechanism of the thermal decomposition of *N*-nitrosodiphenylmethylimine

MICHAEL T. H. LIU

Department of Chemistry, University of Prince Edward Island, Charlottetown, P.E.I., Canada C1A 4P3

AND

TOSHIKAZU IBATA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka, Japan

Received August 17, 1980

This paper was presented at the Symposium in honour of Prof. K. J. Laidler, 63rd Canadian Chemical Conference, Ottawa, June 8–11, 1980, and is dedicated to him on the occasion of his sixty-fifth birthday

MICHAEL T. H. LIU and TOSHIKAZU IBATA. Can. J. Chem. **59**, 559 (1981).

The thermal decomposition of *N*-nitrosodiphenylmethylimine has been investigated in various solvents. The decomposition products are benzophenone and nitrogen. The $\Delta H\dagger$ and $\Delta S\dagger$ parameters for these first-order decompositions have been determined. The experimental evidence is consistent with the hypothesis that the thermolysis of *N*-nitrosodiphenylmethylimine involves the formation of a cyclic transition state via an electrocyclic ring closure mechanism.

MICHAEL T. H. LIU et TOSHIKAZU IBATA. Can. J. Chem. **59**, 559 (1981).

On a étudié dans différents solvants l'effet de la décomposition thermique de la *N*-nitrosodiphénylméthylimine. Les produits de décomposition sont la benzophénone et l'azote. On a déterminé les paramètres $\Delta H\dagger$ et $\Delta S\dagger$ de ces décompositions du premier ordre. La preuve expérimentale concorde avec l'hypothèse qui stipule que la thermolyse de la *N*-nitrosodiphénylméthylimine devrait faire intervenir un état de transition cyclique impliquant un mécanisme électrocyclique d'annellation.

[Traduit par le journal]

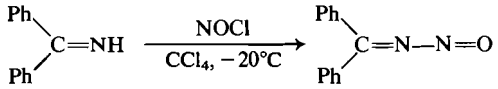
Introduction

Since the report of Thoman and Hunsberger on the synthesis and characterization of *N*-nitrosoimines (1), there has been a growing interest in the chemistry of this class of compounds (2–4). These authors reported that the decomposition of *N*-nitroso-2,4′-dimethylbenzophenonimine is first-order and a cyclic mechanism based on observed chemical and spectral properties was suggested for the decomposition of these compounds. However, very little work has been done on the kinetics of reaction of *N*-nitrosoimines. In this paper we wish to report kinetic results for the decomposition of *N*-nitrosodiphenylmethylimine (**1**) in various solvents.

Experimental

Preparation of N-*Nitrosodiphenylmethylimine (1)*

A suspension of anhydrous sodium acetate (14.8 g, 0.18 mol) in 40 mL of dry carbon tetrachloride was cooled to −20°C in a Dry Ice – acetone bath. Nitrosyl chloride (4.0 g, 60 mmol) was added with stirring, followed by a solution of diphenylketimine (7.24 g, 40 mmol) in 15 mL carbon tetrachloride at −20°C.



Blue color appeared as soon as the ketimine was added. The mixture was stirred vigorously for 20 min at −20°C and quickly washed with 200 mL of ice cold 10% $NaHCO_3$, followed by 200 mL of ice water. The solution was dried over anhydrous $MgSO_4$, and 30 mL cold *n*-pentane at −20°C was added to the dried CCl_4 solution. The solution was left overnight at −80°C and blue crystal of the *N*-nitrosoimine separated out. **1** was recrystallized from a mixed solvent of ether–*n*-pentane at −70°C, mp 57.5–58.5°C. The melting point (lit. mp 53°C) and spectral data are in good agreement with the reported values (1). Accurate measurements of ε values are difficult because of the rapid decomposition of *N*-nitrosoimine. The values for ε at 0°C in various solvents are the following: CH_3OH, 590 nm (ε54); C_2H_5OH, 590 nm (ε66); and CH_3CN, 596 nm (ε87).

All solvents were distilled before use: C_2H_5OH from $MgOC_2H_5$; CH_3OH from $MgOCH_3$; *i*-PrOH from *i*-PrONa; CH_3CN from P_2O_5 and then K_2CO_3; THF from NaOH and then $LiAlH_4$. Ethyl acetate was washed with saturated NaCl solution, dried, and distilled over $MgSO_4$.

Kinetics Procedure

The kinetics were determined by following the change of absorbance with time at the wavelength of maximum absorption in the visible (590 nm) region. The reaction was monitored by using a Hitachi uv-vis spectrophotometer equipped with a thermostated cell holder. 5–8 mg of **1** were added to the thermostated solvent (4 mL) contained in a 1 cm quartz cell. The cell was shaken vigorously for several seconds and was returned to the cell holder for repetitive scanning. The first-order rate constants were determined graphically from the plot of $\log (A_t - A_\infty)$ against time. Good isosbestic points were observed.

Results and Discussion

The thermal decomposition of *N*-nitrosodiphenylmethylimine, **1**, in various solvents gave benzophenone and nitrogen as the only products. In order to confirm that the oxygen atom in

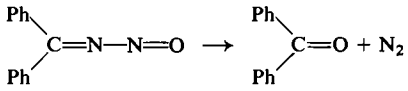
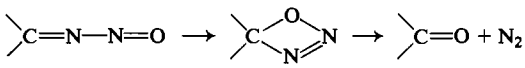
benzophenone is not incorporated from an external reagent, we have carried out the following control experiment. Compound **1** was thermolyzed in carbon tetrachloride under a nitrogen atmosphere, once again the products were nitrogen and benzophenone. Although **1** is kinetically stable ($t_{1/2} \sim$ 1/2 h) at ambient temperature, thermodynamically, it is highly unstable. We suggest that this compound is best handled in dilute solution. In all our experiments the concentration of nitrosoimine is approximately 0.01 *M*.

In the temperature range of 25–60°C, **1** undergoes a first-order decomposition in all solvents studied according to the equation:



First-order kinetics were obeyed for well over 80% decomposition. Typical first-order plots are given in Fig. 1. The results are shown in Table 1. From the least-squares analysis of the rate constants in Table 1, the activation parameters were determined. The values in various solvents, are summarized in Table 2. A plot given in Fig. 2 of $\Delta H\dagger$ versus $\Delta S\dagger$ shows a linear relationship; this indicates that the same mechanism is operating in various solvents. Nevertheless there is a solvent effect. It is noted in Table 1 that the rate increases with increasing solvent polarity. This effect is also reflected in a lower value for $\Delta H\dagger$ in methanol, as seen in Table 2. The negative entropies of activation in all solvents (Table 2) are indicative of a net loss of rotations in **1** going from ground state to the transition state.

In view of the first-order kinetics, Thoman and Hunsberger (1) suggested that the decomposition of *N*-nitrosoimines might involve an intra- rather than an inter-molecular transition state.



In the light of chemical properties, these authors have also suggested that there is a substantial contribution of the 1,4-dipolar structure (**1′**) to the ground state.

1 **1′**

If, as suggested, the structure of the starting material is a hybrid of **1** and **1′**, then there is double bond character to all of the bonds shown, and hence no free rotation about the CN, NN, and NO bonds. Therefore, no rotational degrees of freedom are lost in proceeding to the cyclic transition state, a feature contrary to our observation. We suggest, therefore, that the contribution of **1′** to the ground state is not significant. Further support for this statement can be seen in the following discussion. The E_t values (5–7) were used as a scale of solvent ionizing power in studying the effect of solvent on the decomposition rate. The solvent parameters and the corresponding calculated rate constants at 30°C are given in Table 3. As illustrated in Fig. 3, the plot of log k against E_t values shows a linear

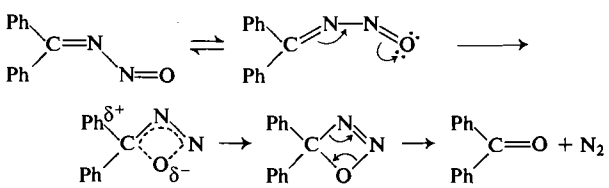
relationship. From the equation $\log k = aE_t + b$, the value of the slope, a, is 7.5×10^{-2}. Large values of a have been attributed to the formation of an ion-pair in the transition state (8). However, the small value of a in the present case suggests a mechanism in which there is little change in charge separation between the ground state and the transition state. This conclusion further affirms that the contribution of **1′** to the ground state is minimal.

In order for the O atom to migrate to the C atom there must be a cyclic transition state at some stage. To account for the negative $\Delta S\dagger$ values and the small a value in the $\log k$ vs. E_t plot, we would like to consider an electrocyclic ring closure mechanism, which is thermally (and also photochemically) allowed by Woodward–Hoffman rules (9):



Such a mechanism is in agreement with our results.

It is interesting to note the formation of the four-membered transition state and its similarity to the 1,2-dioxetane system (10–13). The thermochemical data for **1** are unknown. However, an estimate of the heat of reaction from **1** to benzophenone and nitrogen can be made on the basis of bond energy data (14). The reaction is approximately 75 kcal mol^{-1} exothermic. The value of ΔH_f (Ph_2CO) is 12.5 kcal mol^{-1} and the present estimates appear to support the view that ΔH_f (**1**) is of the order of 88 kcal mol^{-1}. Since the combined estimated heat of reaction (~75 kcal) and measured enthalpy of activation (~17 kcal) exceed the energy required for benzophenone excitation, formation of excited states of benzophenone and of nitrogen are possible.

Since the rate of intersystem crossing for the singlet excited benzophenone is fast, no fluorescence should be observed even if the singlet state of benzophenone is produced (15). The benzophenone produced from the thermal reactions of *N*-nitrosodiphenylmethylimine may be in a triplet state. If this is so, then the photoreduction reaction of benzophenone would take place to yield benzopinacol for the thermolysis of **1** in isopropanol. Several attempts were made to detect benzopinacol but it was not found. In addition, solutions of **1** containing a fluorescer such as 9,10-dibromoanthracene were allowed to warm up to room temperature, no luminescence was observed. This means that the branching ratio for energy transfer to the singlet or triplet states of benzophenone is small.

The thermolysis of **1** in acetic acid was also studied. The intense blue color of the *N*-nitrosodiphenylmethylimine disappeared within

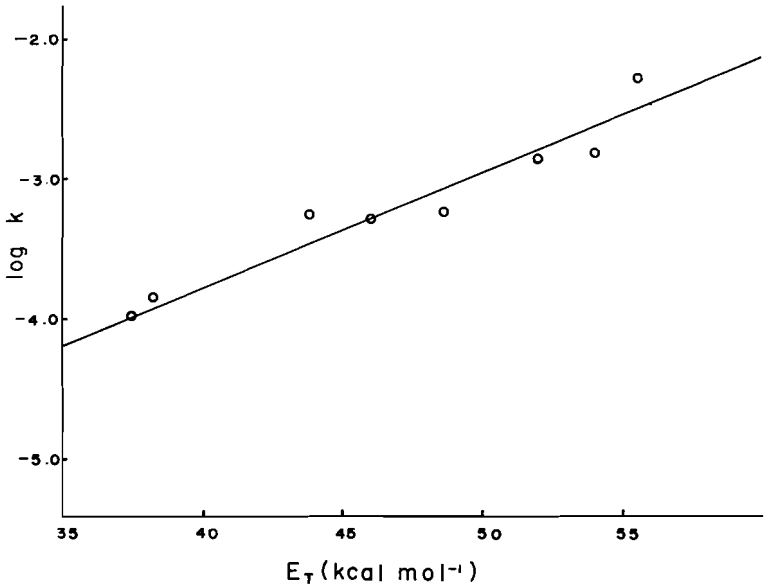


FIG. 3. Plot of log k vs. E_t for the decomposition of **1**.

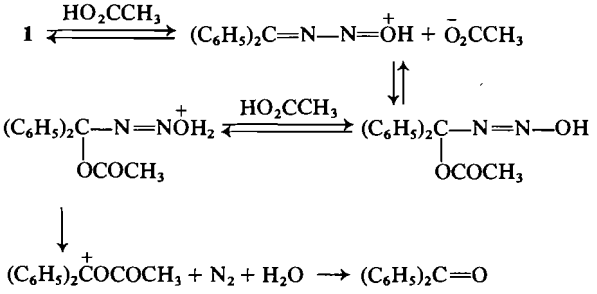
seconds at room temperature and the products were benzophenone and nitrogen. For this decomposition, the following mechanism is proposed:



Further investigation of this system is in progress.

Thiotungstate isopolyanions: an electrometric study

SHIVA PRASAD

Departamento de Engenharia Química, Centro de Ciências e Tecnologia, Universidade Federal da Paraíba Campina Grande, Paraíba, Brasil

Received July 29, 1980

SHIVA PRASAD. Can. J. Chem. **59**, 563 (1981).

The stoichiometry of the various polyanions formed during the reaction between sodium thiotungstate and sulphuric acid has been investigated by pH and conductance measurements, which have revealed the formation of different polymerized species, viz. $(W_4S_{15})^{6-}$, $(W_2S_7)^{2-}$, and possibly $(W_4S_{13})^{2-}$ in the vicinity of pH 6.2, 4.4, and 2.7 respectively. The formation of $(W_4S_{13})^{2-}$ is, however, not evidenced by the pH investigations. It was observed that at higher hydrogen ion concentration (pH < 2.4), thiotungstate decomposes into hydrated tungsten trisulphide.

SHIVA PRASAD. Can. J. Chem. **59**, 563 (1981).

Faisant appel à des mesures de pH et de conductivité, on a étudié la stoechiométrie des différents polyanions qui se forment au cours de la réaction du thiotungstate de sodium avec l'acide sulfurique. Ces mesures ont permis de mettre en évidence la formation de différentes entités polymérisées comme $(W_4S_{15})^{6-}$, $(W_2S_7)^{2-}$ et possiblement $(W_4S_{13})^{2-}$ respectivement à des pH voisins de 6,2, 4,4 et 2,7. Les études de pH ne prouvent cependant pas qu'il y a formation du polyanion $(W_4S_{13})^{2-}$. On a observé qu'à une concentration plus forte en ions hydrogènes (pH < 2,4), le thiotungstate se décompose en trisulfure de tungstène hydraté.

[Traduit par le journal]

Introduction

There is no reference in the literature to the study of acid–thiotungstate system by electrometric techniques. A few references (1–3) are, however, available concerning the preparation of tungsten trisulphide by the action of acid on thiotungstate, but no light has been thrown by the earlier workers on the constitution of various intermediate species formed during the process of acidification of thiotungstate. With a view to studying in detail the chemistry of the decomposition of sodium thiotungstate on acidification it is considered worthwhile to make a careful and precise study of the acid–thiotungstate system by electrometric techniques, which have provided more conclusive evidences on the condensation processes of oxyanions of tungsten(VI), molybdenum(VI), vanadium(V), arsenic(V), and thioanions of molybdenum(VI) (4–10).

Experimental

Merck's guaranteed extra-pure reagents, tungstic acid, ammonium sulphide, sodium sulphide, and sulphuric acid were used. The sulphide content of the solutions was checked iodometrically by titrating against a standard solution of sodium thiosulphate.

The solution of sodium thiotungstate, was prepared by digesting WS_3 with a solution containing an equivalent amount of Na_2S. Tungsten(VI) contents in WS_3 were determined by 8-hydroxyquinoline as tungsten oxinate (11*a*) and sulphur contents as $BaSO_4$ (11*b*).

pH measurements were carried out on Metrohm Herisau (Switzerland) pH-meter using a wide range glass electrode in conjunction with a sce. Conductance values were recorded by employing a Metrohm Herisau (Switzerland) conductometer. The thiotungstate solution (40 mL) was placed in the cell each time and thermostated at 25 ± 0.1°C.

Job's method of continuous variation was employed for determining the composition of polyanions. This consists of plotting the differences in specific conductivities (the sum of observed specific conductivities of the constituent solutions minus the observed specific conductivities of the mixture) against composition of mixtures.

Results and Discussion

Tungsten trioxide dissolves in sodium hydroxide solution to form sodium tungstate (Na_2WO_4) which, on passage of hydrogen sulphide gas, for a long time acquires a brown colour via yellow and orange. The development of the colour depends on pH, temperature, and time of reaction. The slow development of colour indicates the formation of intermediate thio-oxy compounds by displacement of oxygen by sulphur. The equilibria (12) may be represented as follows:

$$(WO_4)^{2-} \xrightarrow[-H_2O]{H_2S} (WO_3S)^{2-} \xrightarrow[-H_2O]{H_2S} (WO_2S_2)^{2-} \xrightarrow[-H_2O]{H_2S} (WOS_3)^{2-} \xrightarrow[-H_2O]{H_2S} (WS_4)^{2-}$$

The final solution $(WS_4)^{2-}$ on treatment with dilute acid decomposes into tungsten trisulphide with a gradual change in colour intensity and evolution of H_2S. These observations lead us to believe that the addition of the acid to thiotungstate solution causes the formation of different polyanions before

*A and B represent the end-points observed from pH and conductometric titrations respectively.

the final decomposition to WS_3. This phenomenon appears to be identical with polymerisation of alkali tungstate on acidification. The formation of polymerised thiotungstate anions has, therefore, been studied by pH and conductometric titrations, the results of which are summarized in Table 1.

A perusal of the pH titration curves (Fig. 1) indicates that the addition of 1/4 mol of sulphuric acid per mol of sodium thiotungstate yields a pronounced maxima in dpH/dV curves in the region of formation of $(W_4S_{15})^{6-}$. Further action with the acid yields one more inflection in curves shown by the marked change in dpH/dV at the point where the molecular ratio of H_2SO_4:Na_2WS_4 is as 1:2, corresponding to the formation of dithiotungstate anion $(W_2S_7)^{2-}$. It is noted that in the case of higher concentration of solutions the curves are steeper and dpH/dV is more pronounced than for dilute reactants.

Conductometric titrations between sulphuric acid and sodium thiotungstate were also carried out using solutions of the same strengths for the sake of comparison of results. The plots (Fig. 2) of corrected conductance as a function of volume of titrant (H_2SO_4) yielded three defined breaks corresponding to the removal of 0.25, 0.50, and 0.75 mol (as H_2S) of Na_2S per mol of Na_2WS_4. The first two breaks indicate the formation of $(W_4S_{15})^{6-}$ and $(W_2S_7)^{2-}$ as suggested by the preceding pH study. The third break at a WS_4^{2-}:H^+ ratio of 1:1.5 indicated the formation of $(W_4S_{13})^{2-}$. A similar break was, however, not obtained in the pH titration curves, which may be ascribed to the little difference in the pH values of sulphuric acid and of this polyanion.

The decomposition of thiotungstate by sulphuric acid was also followed by Job's method of continuous variation using electrical conductance measurements. Plots of differences in specific conductivity values against composition of the mixture indicated a sharp maximum (Fig. 3) corresponding to a molar ratio for H_2SO_4:Na_2WS_4 of 1:2; this

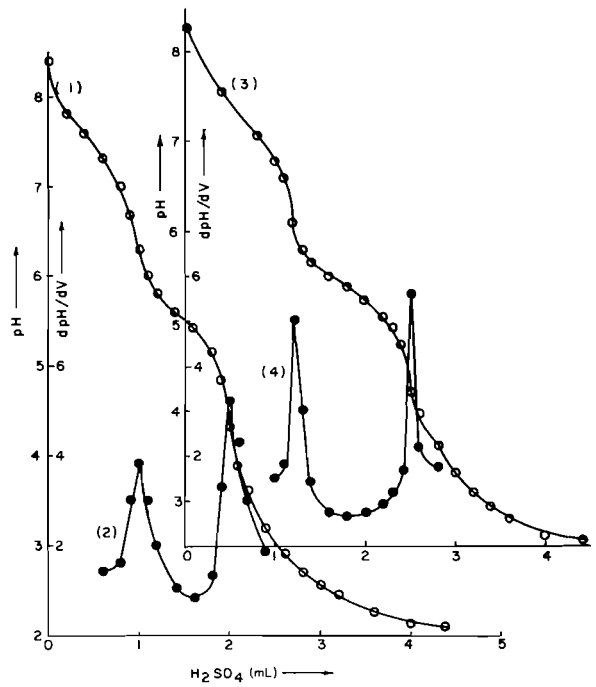

FIG. 1. pH titrations of Na_2WS_4 with H_2SO_4. Curves *1* and *2*: amount of *M*/5 H_2SO_4 (mL) added to 40 mL of *M*/50 Na_2WS_4; curves *3* and *4*: amount of *M*/10 H_2SO_4 (mL) added to 40 mL of *M*/80 Na_2WS_4.

provides further evidence for the formation of dithiotungstate, $(W_2S_7)^{2-}$.

When a basic thiotungstate solution containing WS_4^{2-} and Na^+ is acidified, the thiotungstate ions condense in definite steps, as evidenced by the foregoing electrometric experiments, to form different polythiotungstate anions. The overall condensation process may be considered formally at least to begin with partial neutralization of thiotungstate ions followed by the elimination of H_2S to form a thiobridge in analogy with the oxotungsten(VI) compounds.

$$(WS_4)^{2-} + H^+ \rightarrow [WS_3(SH)]^-$$

$$2[WS_3(SH)]^- \rightarrow (S_3W—S—WS_3)^{2-} + H_2S$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

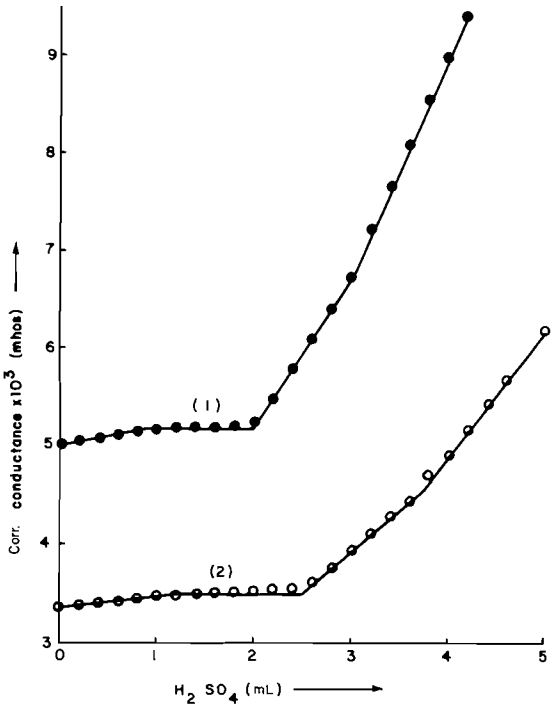

FIG. 2. Conductometric titrations of Na_2WS_4 with H_2SO_4. Curve *1*, amount of *M*/5 H_2SO_4 (mL) added to 40 mL of *M*/50 Na_2WS_4; curve *2*, amount of *M*/10 H_2SO_4 added to 40 mL of *M*/80 Na_2WS_4.

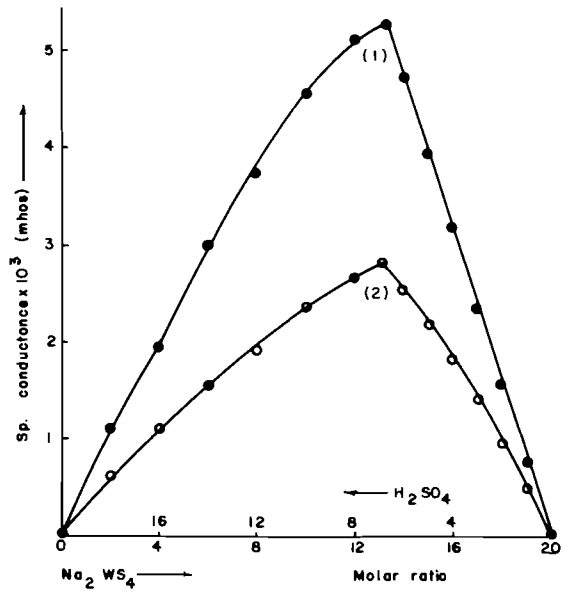

FIG. 3. Continuous variation study by Job's method using equimolar solutions. Curve *1*, *M*/50 H_2SO_4 and *M*/50 Na_2WS_4; curve *2*, *M*/100 H_2SO_4 and *M*/100 Na_2WS_4.

The addition of acid to Na_2WS_4 thus neutralizes 0.25, 0.50, and 0.75 mol of Na_2S per mol of Na_2WS_4, liberating an equivalent amount of H_2S. Further acidification decomposes Na_2WS_4 finally into WS_3, a brown precipitate. The stepwise decomposition of sodium thiotungstate may be represented by the following set of stoichiometric equations:

$$4(Na_2S{\cdot}WS_3) + H_2SO_4 \rightarrow (3Na_2S{\cdot}4WS_3) + Na_2SO_4 + H_2S$$

$$(3Na_2S{\cdot}4WS_3) + H_2SO_4 \rightarrow 2(Na_2S{\cdot}2WS_3) + Na_2SO_4 + H_2S$$

$$2(Na_2S{\cdot}2WS_3) + H_2SO_4 \rightarrow (Na_2S{\cdot}4WS_3) + Na_2SO_4 + H_2S$$

$$(Na_2S{\cdot}4WS_3) + H_2SO_4 \rightarrow 4WS_3 + Na_2SO_4 + H_2S$$

During the preliminary steps of the titrations 2–3 min are required for each pH and conductance value to become steady. This may be due to vigorous evolution of H_2S. A thorough stirring of the cell contents in the vicinity of the end-points has been found necessary.

The results evidently suggest the formation of two different polymerized intermediate species, viz. $(W_4S_{15})^{6-}$ and $(W_2S_7)^{2-}$ in the vicinity of pH 6.2 and 4.4 respectively, before the complete decomposition of thiotungstate into WS_3. The formation of $(W_4S_{13})^{2-}$ at pH 2.7 is indicated by conductometric investigations but could not be evidenced by the pH titrations.

On the existence of intramolecular hydrogen bonds in methyl *o*-mercaptobenzoate and 2-methoxymethylbenzenethiol

TED SCHAEFER, DAVID M. MCKINNON, RUDY SEBASTIAN, AND BERT KRAWCHUK

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received July 14, 1980

TED SCHAEFER, DAVID M. MCKINNON, RUDY SEBASTIAN, and BERT KRAWCHUK. Can. J. Chem. **59**, 566 (1981).

Full analyses of the ^1H nmr spectra of methyl *o*-mercaptobenzoate and of 2-methoxymethylbenzenethiol yield spectral parameters suggesting that the *trans* conformer of the former is preferred by 1.6 ± 0.7 kJ/mol in free energy in solution at 305 K. Both *cis* and *trans* conformers can be reasonably discussed in terms of "planar" conformations. The ether displays nearly equal concentrations of *cis* and *trans* conformers. However, these conformers display considerable conformational freedom of the sulfhydryl group. These results are compared to previous infrared data. It is suggested that in the ester the small tendency towards intramolecular hydrogen bonding involves the carbonyl oxygen. Any S—H···O interaction in the ether must surely occur for conformations in which the S—H and C—O bonds are far from the ring plane.

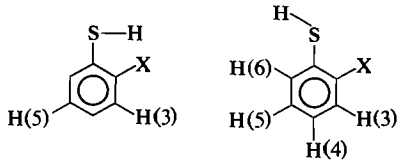
TED SCHAEFER, DAVID M. MCKINNON, RUDY SEBASTIAN et BERT KRAWCHUK. Can. J. Chem. **59**, 566 (1981).

L'analyse détaillée des spectres rmn du *o*-mercaptobenzoate de méthyle et du méthoxyméthyl-2 benzènethiol conduit à des paramètres spectraux suggérant que la différence d'énergie libre en solution à 305 K favorise le conformère *trans* du premier composé de $1,6 \pm 0,7$ kJ/mole. On peut raisonnablement discuter des deux conformères *cis* et *trans* en fonction de conformations "planes". Dans le cas de l'éther les concentrations des conformères *cis* et *trans* sont presqu'égales. Cependant le groupe sulfydryle jouit d'une liberté conformationnelle considérable. On a comparé ces résultats aux données infrarouges obtenues antérieurement. On croit que la faible tendance a former des liaisons hydrogènes intramoléculaire implique l'oxygène du carbone de l'ester. Toute interaction S—H···O dans l'éther doit sûrement se produire dans des conformations où les liaisons S—H et C—O sont éloignées du plan du cycle.

[Traduit par le journal]

Introduction

Because the S—H bond is much less polar than the O—H bond, weaker hydrogen bonding ability is anticipated for thiophenol than for phenol and its derivatives. In particular, *ortho*-substituted thiophenols are discussed in terms of *cis*, **1***a*, and *trans*, **1***b*, conformations (1). Absence of intramolecular hydrogen bonding favors **1***b* on steric grounds, whereas its presence will stabilize **1***a*. Infrared spectroscopy (2, 3) and dipole moment measurements (3) suggest, for example, that when X = NO_2, **1***a* is the predominant form in solution. On the other hand, stereospecific long-range spin–spin coupling constants strongly imply that **1***b* is favored by 2.1 ± 0.8 kJ/mol in $CDCl_3$ and C_6D_6 solutions at 305 K (4). The population ratio of **1***a* and **1***b* is found on the assumption that the long-range coupling constants over five bonds, $^5J_m^{H(3),SH}$ in **1***a* and $^5J_m^{H(5),SH}$ in **1***b*, vanish, and are finite for the all-*trans* arrangement of the intervening bonds, i.e., $^5J_m^{H(5),SH}$ in **1***a*, and $^5J_m^{H(3),SH}$ in **1***b*. This assumption has been investigated (4–7).



1*a* **1***b*

The twofold barrier to internal rotation in thiophenol (8) is ca. 3 kJ/mol, comparable to thermal energies at ambient temperatures, and much less than the 14.4 kJ/mol in phenol (9). Accordingly, unless the substituent increases the internal barrier substantially by conjugative perturbations, as it does in *para* and *ortho* nitrothiophenol (4, 10), nonplanar conformations should be considered in addition to **1***a* and **1***b*; a complication not encountered with phenol derivatives (6, 11). If the barrier to internal rotation is relatively large, say 12 kJ/mol or more, $^6J_p^{H,SH}$ will be very small (4, 10). For a barrier of 3 kJ/mol, as in thiophenol, $^6J_p^{H,SH}$ is -0.33 Hz (12). In 2-nitrothiophenol, $^6J_p^{H,SH}$ effectively vanishes (4). If the S—H group is held perpendicular to the benzene plane, $^6J_p^{H,SH}$ can become as large in magnitude as 1 Hz (7).

Substantial out-of-plane motion of the S—H group occurs in 2-methoxythiophenol (6) and in some 2-halothiophenol derivatives (5). Indeed, again on the basis of long-range coupling constants, it was shown (7) that 2-hydroxythiophenol in CCl_4 exists mainly as a conformer in which the S—H bond prefers a plane perpendicular to the benzene nucleus; the hydroxyl group hydrogen bonds to the directional lone pair on the sulfur atom.

The stretching frequencies of the S—H bond in the ethyl ester of thiosalicylic acid have been attributed to **2***a* and **2***b* (2). Similarly (2), in dilute solu-

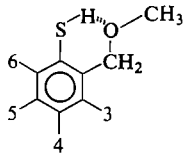
tion in CCl_4, a benzyl ether is thought to exist in conformation **3**.



3

In this paper, the long-range coupling constants are determined for **2** (R = CH_3) and **3** in solution. The couplings involving H-3, H-5, and S—H yield information about the relative stability of *cis* and *trans* conformers, while the coupling to H-4, $^6J_p^{H,SH}$, indicates the importance of out-of-plane motion of the mercapto group. The couplings involving the methylene protons in **3** provide a rough measure of the flexibility of the ether fragment.

Experimental

2-Mercaptobenzoic acid (Aldrich) was esterified in acidic methanol containing some acetyl chloride. The product, **2** (R = CH_3), gave the correct mass spectrum and the ^1H nmr spectrum was consistent with **2**.

2-Methoxymethylbenzenethiol, **3**, has previously been prepared from 2-aminobenzyl methyl ether (2). Here **3** was prepared from 2-methylthiobenzyl chloride (13) via 2-methylthiobenzyl methyl ether (14) and oxidation of the latter to the sulfoxide. The sulfoxide was rearranged to the thiohemiacetal acetate with acetic anhydride. Mild basic hydrolysis yielded **3**; bp 75°C/0.2 Torr. *Anal.* calcd. for $C_8H_{10}OS$: C 62.34, H 6.49, S 20.78; found: C 62.09, H 6.58, S 21.02.

Samples of **2** were prepared as ca. 2 mol% solutions in CCl_4 and C_6D_6 and contained some tetramethylsilane (TMS). After transfer to 5 mm od Pyrex tubes, the samples were degassed by five freeze–pump–thaw cycles and were flame-sealed. A similar procedure gave a ca. 3 mol% solution of the ether, **3**, in CCl_4 solution. All solutions contained Linde type 3A sieve.

The ^1H nmr spectra of the three samples were calibrated in the frequency sweep mode at 100.001 MHz (centerband) on an HA100 spectrometer at a probe temperature of 305 K. Markers were placed at ca. 5 Hz intervals, their frequencies relative to the lock frequency were recorded, and the peak frequencies of this procedure yielded peak positions whose rms deviation was $\leq$ 0.02 Hz. The ^1H nmr spectrum of **3** was calibrated under single resonance conditions, as well as in the presence of decoupling fields placed at the S—H band, at the CH_2 band, and at the CH_3 peak.

Results and Discussion

Spectral Analyses

These utilized the computer program LAME (15, 16). The ensuing spectral parameters are given in Tables 1 and 2. The CCl_4 solution of **2** (R = CH_3) gave a spectrum with a chemical shift difference of only 1 Hz between H-5 and H-6, whereas these protons are coupled by 8 Hz. In consequence, there occurs a correlation coefficient of −0.698 between $^4J_o^{H,SH}$ and $^5J_m^{H(5),SH}$, meaning that their individual values are uncertain. For this reason the benzene solution was also examined. As can be seen in Table 1, the chemical shift dispersion of the ring protons is increased and the correlation between $^4J_o^{H,SH}$ and $^5J_m^{H(5),SH}$ decreases, but only to −0.382. Therefore, these parameters are still not as reliably known as their standard deviations would indicate. For **3**, the chemical shifts of H-4 and H-5 differ by 2 Hz and $^6J_p^{H,SH}$ and $^5J_m^{H(5),SH}$ are correlated by −0.399. These facts must be considered in the conformational analysis to follow.

Figure 1 illustrates the spectral quality, displaying the S—H multiplet of **2** in CCl_4 solution. In C_6D_6 the S—H band approximated to a doublet, each component having some structure. The different appearance arose simply from the change in dispersion of the ring proton spectra (see ref. 4 for a similar example).

The Conformational Preference of the S—H Group in the Ester, 2

In CCl_4, the S—H stretching band occurs at 2585 cm^{-1} for benzenethiol (2). In the ethyl ester of 2-mercaptobenzoic acid, the two bands at 2556 and 2523 cm^{-1} (2) were assigned to **2***a* and **2***b*. On the other hand, in the methyl ester one band is tabulated at 2534 cm^{-1} in CCl_4 solution (3). The shifts in frequencies are rather small compared to analogous phenol derivatives but the intensities of the bands are considerably higher than that in thiophenol.

As argued for 2-nitrothiophenol (4), the vanishing $^6J_p^{H,SH}$ in **2** is a strong indication that the S—H conformational preference can be usefully discussed in terms of planar *cis* and *trans* forms. Conjugation with the substituent increases the double-bond character of the C—S bond and raises the internal barrier, perhaps to as much as 10 to 12 kJ/mol (10).

It follows that, because $^5J_m^{H(3),SH}$ is 0.29 ± 0.01 Hz (this coupling does not correlate significantly with any other spectral parameter), a substantial population of the *trans* form exists at 305 K in CCl_4 solution. A similar statement holds for the C_6D_6 solution, in which $^5J_m^{H(3),SH}$ is 0.35 ± 0.02 Hz (the error limits assume that the standard deviations are to be multiplied by three). Now, although $^5J_m^{H(5),SH}$ correlates with $^4J_o^{H,SH}$ in both solutions (but less

[a]Calibrated while decoupling S—H proton.
[b]Calibrated while decoupling CH_2 protons.
[c]Decoupling CH_3.
[d]In Hz at 100.001 MHz to low field of internal TMS; numbers in parentheses are standard deviations in the last one or two places.
[e]These two parameters are correlated by 0.78, accounting for the variation in their values in the different analyses.

strongly in the C_6D_6 solution), the sums of the two ^5J values are close to the sums in 2-methoxythiophenol (6) and in thiophenol itself (12). Furthermore, while the correlations are different in the two solutions, $^5J_m^{H(5),SH}$ does not change significantly. It appears rational, therefore, to attach significance to the $^5J_m^{H(5),SH}$ of 0.17 ± 0.03 Hz in **2** and to deduce a population for the *cis* form. The ratio of *trans* to *cis* populations is then 1.7 to 1 and 2.0 to 1 in CCl_4 and C_6D_6 respectively, yielding a free energy preference for the *trans* conformer of 1.3 ± 0.5 and 1.8 ± 0.5 kJ/mol. In view of the doubt about $^5J_m^{H(5),SH}$ it seems safe to state that the preference is 1.6 ± 0.7 kJ/mol in both solutions.

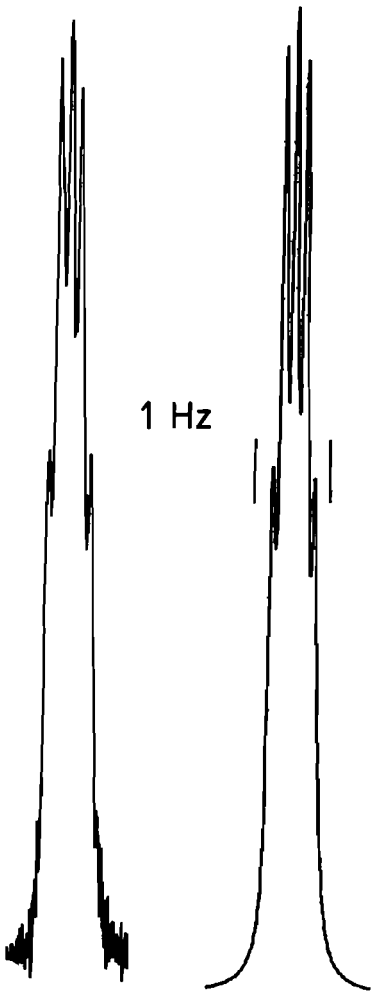

FIG. 1. The ^1H nmr spectrum of the sulfhydryl proton in methyl *o*-mercaptobenzoate as a ca. 2 mol% solution in CCl_4 at 100 MHz and 305 K. The calculated spectrum on the right assumes the parameters in Table 1 and a linewidth at half height of 0.10 Hz. The separation between the midpoints of the outer peaks is 0.58 Hz.

Purely steric interactions might well cause a larger preference for the *trans* conformation (intermolecular association is unimportant (17)). Accordingly, a small degree of hydrogen bonding apparently exists. This conclusion is consistent with the δ_{SH} of 5.39 ppm in the CCl_4 solution, its value being 3.23 ppm for benzenethiol (12). Conjugative electron withdrawal by the ester moiety will increase δ_{SH} somewhat, perhaps by as much as 0.3 ppm (18), leaving ca. 1.9 ppm as a hydrogen-bond shift. The deshielding of the hydroxyl proton in methyl salicylate, relative to phenol in CCl_4, is 6.2 ppm (19, 20). The salicylate exists as the *cis* form to the extent of at least 95%. To a first approximation, if ca. 33% of **2** exists in the *cis* conformation (as indicated by the long-range couplings) and if the deshielding is caused mainly by the time varying electric fields and the large magnetic anisotropy of the ester moiety in this conformer, the observed deshielding of ca. 2 ppm in **2** is rationalized. Of course, the S—H bond is more polarizable than the O—H bond and the geometry will be somewhat different in the *cis* conformers of the two compounds, so that δ_{SH} in **2** can only be said to be roughly consistent with a 2:1 ratio of *trans* to *cis* conformers. (A similar comparison between δ_{OH} and δ_{SH} for 2-methoxyphenol and 2-methoxythiophenol (6) is also consistent with the *cis*/*trans* distribution based on coupling constants.)

These adumbrations imply that the S—H group hydrogen bonds to the carbonyl group in the methylester. Certainly the carbonyl group is a stronger proton acceptor than the ether function in phenol derivatives (6, 21). The two S—H stretching bands reported (2) for the ethyl ester may arise from the *cis* and *trans* forms rather than from **2***a* and **2***b*. Only one stretching frequency was tabulated for the methyl ester (3), yet the reported spectrum apparently consists of two very broad overlapping bands (Fig. 3 of ref. 3), rather similar in appearance to the ethyl ester spectrum (2).

A recent analysis (22) of the ^1H nmr spectrum of **2** in $CDCl_3$ at 360 MHz reports $^5J_m^{H(3),SH}$ as 0.4 Hz and $^5J_m^{H(5),SH}$ as < 0.2 Hz; presumably the latter was not observed as a splitting because of larger linewidths than those in the present analysis. The chemical shifts of H-5 and H-6 were apparently identical (22). The deuterium quadrupole coupling constant (DQCC) in the S—D bond was 133 kHz (22), smaller than the 146 kHz in thiophenol (23). Hydrogen bonding will cause a decrease in the DQCC. If 33% of **2** exists in the *cis* form and if the DQCC of the *trans* form is that in thiophenol, then the *cis* form has a DQCC of ca. 107 kHz. This number also assumes that interconversion of the conformers is faster than about 10^4 Hz but slower than rotational diffusion; a reasonable assumption because the barrier to interconversion must lie in the region of 8 to 12 kJ/mol (10). On the other hand, the observed DQCC in the ester could arise from increased ionicity of the S—D bond caused by electron withdrawal by the ester group, a possibility testable by examination of the *para* isomer.

The Conformational Behaviour of the S—H Bond in 2-Methoxymethylbenzenethiol, 3

In CCl_4 solution, the S—H stretching band at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

2560 cm^{-1} is assigned to the hydrogen bonded S—H group (2). No other band was observed.

The coupling data in Table 2 show that motion of the S—H group in **3** is much less restricted than in **2**, 2-nitrothiophenol (4), or in 2-methoxythiophenol (6). $^6J_p^{H,SH}$ is -0.35 ± 0.02 Hz, hardly different from the -0.33 ± 0.02 Hz in benzenethiol (12). The twofold barrier to out-of-plane rotation in the latter is not below 3.2 kJ/mol (8, 12), implying that **3** cannot be discussed simply in terms of *cis* and *trans* conformers.

Furthermore, $^5J_m^{H,SH}$ values indicate a very slight preference for conformations in which the S—H bonds avoid the other substituent. Their sum is the same to within experimental error as in 4-methylthiophenol (10) and somewhat larger than in thiophenol (12), indicating a $\sigma-\pi$ contribution to $^5J_m^{H,SH}$ (6, 10), in agreement with substantial out-of-plane populations deduced from $^6J_p^{H,SH}$.

The long-range couplings to the sulfhydryl proton are consistent with a relatively weak intramolecular hydrogen bond to the ether oxygen atom. Of course, the structure **3** has an H··O distance of only 1.2 Å, much too short for a stable hydrogen bond. Accordingly, the *cis* conformation would require, say, an out-of-plane twist of about 60° by the S—H and C—O bonds so as to reach the H··O distance of 2.2 Å in the *cis* conformation of 2-methoxythiophenol. In fact, in the latter compound, the *cis* conformer is also slightly less abundant (43%) and δ_{SH} is 3.66 ppm, whereas it is 3.69 ppm in **3**. Naturally, the twist angle of 60° is not meant quantitatively. Nevertheless, the long-range couplings involving the S—H proton are consistent with a skewed *cis* conformation.

The conformational looseness of the S—H bond should be reflected in a similar property of the ether substituent. The barrier to internal rotation of the CH_2OH moiety in benzyl alcohol is very likely less than 1 kJ/mol (24–26) and $^6J_p^{H,CH_2}$ is -0.59 Hz (24). In 2,6-dichlorobenzyl methyl ether (27), where the barrier to rotation about the exocyclic C—C bond must be substantial, $^6J_p^{H,CH_2}$ is -0.20 ± 0.02 Hz; in line with a conformation in which the C—O bond prefers a plane perpendicular to the ring. In **3**, $^6J_p^{H,CH_2}$ is -0.45 ± 0.01 Hz, indicative of an intermediate restriction to motion about the C—C bond. Certainly, if the C—O bond were constrained to the ring plane by a strong hydrogen bond, then $^6J_p^{H,CH_2}$ would be expected (25) to be about -0.85 Hz. It seems unlikely, therefore, that the single stretching band (2) can be identified solely with such a conformer. Furthermore, the two $^5J_m^{H,CH_2}$ numbers are effectively equal, consistent with weak conformational preferences about the exocyclic C—C bond.

The coupling of $+0.32$ Hz between the methylene and sulfhydryl protons (the sign was confirmed by double resonance experiments and simulation with the computer program DOR (28) modified for use with up to 8 spins (29)) has the same magnitude as $^4J_o^{H(6),SH}$, which is -0.31 Hz. This result implies a predominant $\sigma-\pi$ mechanism for $^4J_o^{H,SH}$ (6, 10).

Conclusions

The planar *trans* conformer in methyl *o*-mercaptobenzoate is twice as abundant as the *cis* conformer in solution at 305 K, suggesting only a small degree of intramolecular hydrogen bonding and comparable to that in 2-nitrothiophenol. The *cis* and *trans* conformers in 2-methoxymethylbenzenethiol are equally abundant but display relatively free motion of the sulfhydryl group, comparable to that in benzenethiol itself.

Synthèse totale des acides (+) et (−) nonactique à partir de carbohydrates[1]

ROBERT E. IRELAND ET JEAN-PAUL VEVERT

Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, CA 91125, U.S.A.

Reçu le 17 juin 1980

ROBERT E. IRELAND et JEAN-PAUL VEVERT. Can. J. Chem. **59**, 572 (1981).

La synthèse des acides (−) et (+) nonactique **2***a* et **2***b* a été réalisée à partir respectivement de D-mannose (**7**) et de D-gulono-γ-lactone (**22**). Elle fait intervenir comme étape clé le réarrangement [3,3]-sigmatropique de cétène-acétals silylés IV qui permet le contrôle de la configuration du C-2 de l'acide nonactique. Ces cétène-acétals sont préparés à partir d'esters aliphatiques de glycals furanoïques II, qui sont eux même synthétisés en dix étapes à partir du carbohydrate précurseur. Les centres chiraux de ces glycals proviennent de la conservation durant cette suite de transformations des centres correspondants du monosaccharide de départ. Effectué avec ce genre de cétène-acétals le réarrangement de Claisen conduit à des composés comportant l'enchaînement du type aldol désiré. On tire également parti de la connaissance de la configuration absolue des carbones chiraux de l'acide nonactique pour déterminer la conformation (chaise ou bateau?) de l'état de transition du réarrangement [3,3]-sigmatropique.

ROBERT E. IRELAND and JEAN-PAUL VEVERT. Can. J. Chem. **59**, 572 (1981).

The synthesis of (−) and (+) nonactic acids (**2***a*) and (**2***b*) has been achieved starting from D-mannose (**7**) and D-gluono-γ-lactone (**22**) respectively. The key step in the synthesis is the [3,3]-sigmatropic rearrangement of the silylated ketene-acetals IV leading to control of the C-2 configuration of nonactic acid. The ketene-acetals were prepared from aliphatic esters of furanoid-glycals II, which were prepared in ten steps from the carbohydrate precursor. The chiral sites of the glycals arise from the corresponding centres in the starting monosaccharide. This type of ketene-acetal Claisen rearrangement leads to products containing the aldol portion required. At the same time knowledge of the absolute configuration of the chiral carbon atom of nonactic acid allows for the determination of the chair or boat form of the transition state of the [3,3]-sigmatropic rearrangement.

Introduction

La nonactine (**1**) macrotétrolide isolé pour la première fois en 1955 par Prelog, Keller-Schierlein et coll. (1) représente l'homologue le plus simple d'une famille de tétraesters macrocycliques à 32 membres, connus sous le nom de nactines (2) et produits à partir de cultures de streptomyces (3). L'intérêt biologique suscité par ces composés résulte en partie de leurs propriétés antimicrobiennes (G+, fungi) mais surtout de leur capacité à agir comme transporteurs d'ions à travers les membranes biologiques (4). Les nactines forment des complexes 1:1 avec de nombreux ions des métaux alcalins et alcalino-terreux et plus particulièrement avec le potassium (5) qui se trouve littéralement englobé par coordination des huit oxygènes des carbonyles et cycles tétrahydrofuraniques à l'intérieur du squelette carboné (6). Ces propriétés de transporteurs d'ions font entr'autre de ces composés de puissants inhibiteurs de la phosphorilation oxydative de l'ADP en ATP (3). La structure de la nonactine a été élucidée par Prelog, Gerlach et coll. (7). Le macrocycle est formé de quatre subunités d'acides nonactique (**2**) reliés entr'eux par des liaisons ester, avec alternance des énantiomères (−) (**2***a*) et (+) (**2***b*) de telle sorte qu'il présente une configuration *méso*. Son hydrolyse conduit à un mélange racémique d'acides nonactique dont la configuration absolue des quatre carbones chiraux a été déterminée (8). La synthèse de la nonactine a été réalisée par Ger-

lach et coll. à partir de l'acide nonactique racémique (9) et par Schmidt et coll. (10) à partir de l'acide (−) nonactique (**2***a*) et de dérivés des épimères (−) (**4***a*) et (+) (**4***b*) en position 8 (Schéma 1). La plupart des synthèses de l'acide nonactique publiées à ce jour conduisent à un mélange racémique (10–14).[2] Elles font généralement intervenir dans l'étape clé pour contrôler la configuration *cis* du tétrahydrofurane-2,5 disubstitué l'hydrogénation catalytique d'un cycle furanique. Seule celle rapportée par Schmidt et coll. permet d'isoler l'acide (−) nonactique (**2***a*) à partir d'un mélange de quatre diastéréoisomères. Par inversion de Walden du C-8 des trois diastéréoisomères restants ces auteurs ont obtenus un mélange duquel l'acide (+) nonactique (**2***b*) a pu être séparé (10, 13). Cette synthèse ne présente toutefois pas un très haut degré de stéréosélectivité. L'oxyde de S (−) propylène, non commercialement disponible, étant d'autre part utilisé comme produit de départ, elle nécessite la préparation de ce composé avec une grande pureté optique à partir d'acide lactique (15).

En raison de l'intérêt grandissant porté aux sucres dans divers laboratoires dont le nôtre (16) en tant que produits de départ chiraux relativement peu onéreux pour la synthèse de produits naturels comportant un nombre élevé de carbones assymétriques, il nous est apparu intéressant d'élaborer une synthèse des énantiomères de l'acide nonactique à partir de cette classe de composés.

Résultats et discussion

Un dérivé du type V (Schéma 2) peut être considéré comme un précurseur intéressant de l'acide nonactique.[3] La synthèse d'un tel composé peut être envisagée par formation de la liaison entre les atomes de carbone chiraux 2 et 3 des deux entités encerclées. De précédents travaux dans notre laboratoire ont démontré que la formation de telles liaisons carbone–carbone, pour l'obtention de dérivés du type aldol apparentés à V, pouvait être réalisée par un réarrangement de Claisen de cétènes-acetals silylés (17). Ceci permet de considérer l'alcool allylique hétérocyclique II comme un intermédiaire clé de cette synthèse. Il permet en effet d'obtenir le cétène-acétal silylé IV devant conduire après le réarrangement [3,3]-sigmatropique au précurseur désiré. Alors que la configuration du carbone 3 de V découle directement de celle du carbone 3 de IV, la configuration du carbone 2 résulte de la géométrie du cétène-acétal silylé et il devient donc important de contrôler celle-ci lors de la formation de IV.

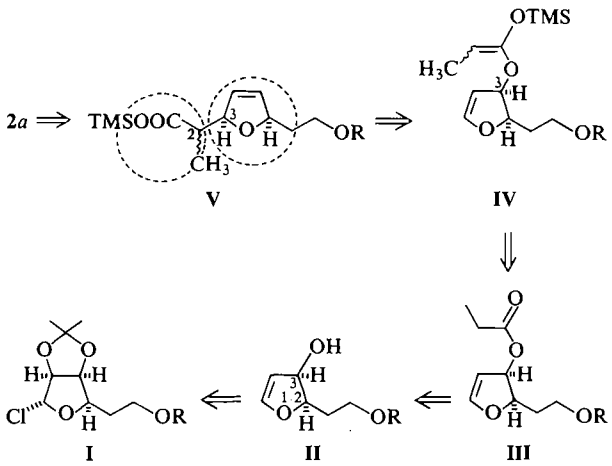

SCHÉMA 2

Des résultats antérieurs obtenus dans ce laboratoire font apparaître que suivant le solvant ou la base employée, la déprotonation à −78°C de l'ester **6** (Schéma 3) conduit à un mélange de proportions variables des énolates *Z* et *E* (17, 18). Ainsi lorsque la déprotonation est effectuée par le diisopropylamidure de lithium (LDA) à −78°C dans le THF l'anion-énolate de type *Z* est formé préférentiellement, tandis que la formation de l'anion-énolate de type *E* est favorisée quand cette déprotonation a lieu dans un mélange de 23% d'hexaméthylphosphotriamide (HMPA) dans le THF.

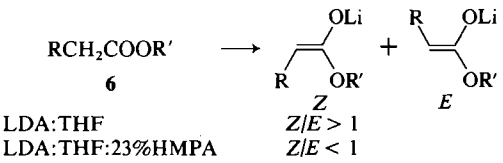

SCHÉMA 3

Le réarrangement de Claisen des cétènes-acétals silylés tels que IV, obtenus par silylation du mélange d'énolates correspondant, conduit à deux esters de silyle γ,δ insaturés diastéréoisomères V. Il a été montré qu'en série acyclique en l'absence d'effets stériques particuliers ce réarrangement s'opérait suivant un état de transition du type chaise (18). La proportion des deux diastéréoisomères formés ne dépend donc que de la proportion relative des deux énolates *E* et *Z* et peut de ce fait être prévue et orientée par un contrôle des conditions dans lesquelles la déprotonation est effectuée. Les résultats préliminaires obtenus en série cy-

[3]Pour des raisons de clarté nous n'avons représenté que les précurseurs de l'énantiomère (−).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

clique semblaient indiquer le passage pour le réarrangement [3,3]-sigmatropique par un intermédiaire du type bateau. L'application de ce réarrangement à la synthèse de produits naturels de configuration connue tels que les deux énantiomères de l'acide nonactique semblait donc devoir de plus fournir des renseignements plus précis quant à la nature de l'état de transition. Les résultats concernant la formation prépondérante de l'énolate *Z* dans le THF et celle prépondérante de l'énolate *E* en présence de HMPA semblant pouvoir être transposés en série cyclique, l'obtention d'une forte proportion de l'un des diastéréoisomères par rapport à l'autre devrait indiquer le passage pratiquement exclusif pour le réarrangement de ce diastéréoisomère majoritaire par un état de transition unique, soit chaise, soit bateau. La comparaison ultérieure de ce diastéréoisomère avec le produit naturel, devrait indiquer par lequel de ces deux états de transition le réarrangement a eu lieu. Par contre l'obtention des deux diastéréoisomères dans des proportions tendant vers 50:50 devrait indiquer le passage compétitif par ces deux états de transition.

L'étape clé de la synthèse proposée devrait donc permettre d'obtenir de façon spécifique la configuration désirée des carbones 3 et 6 et sélectivement celle du carbone 2. Une méthode générale de synthèse de glycals optiquement actifs du type II à partir de sucres a été précédemment mise au point dans notre laboratoire, utilisant la réduction par le lithium dans l'amoniac des chlorures du type I (17*b*, *c*, 19).

Le D-(+)-mannose (**7**) (Schéma 4) a été choisi comme produit de départ pour la synthèse de l'énantiomère (−) (**2***a*). Il est en effet possible d'obtenir pour un prix modique des quantités importantes de l'isomère (+) de ce sucre qui possède la configuration désirée des carbones 4 et 3 appelés à devenir respectivement les carbones 2 et 3 de l'alcool allylique II. Par une série de transformations connues, diacétonisation, benzylation, séparation des deux anomères et hydrolyse sélective de l'un des acétonides, le mélange d'anomères α et β **7** conduit avec un rendement global de 76% à l'α-D-mannofuranoside de benzyle (**8**) (20). En présence de diméthylacétal du diméthylformamide celui-ci est transformé quantitativement en acétal du DMF (**10**) qui par chauffage dans l'anhydride acétique fournit l'oléfine **11***a* (76,5% après chromatographie) et 17,5% d'un composé **9** correspondant à une diacétylation des alcools en position 5 et 6 de **8** (21). La réduction par $LiAlH_4$ de ce diacétate permet de regénérer le diol **8** conduisant à un rendement de 93% en oléfine **11***a* sur la base du diol récupéré.

Une modification de la méthode précédente, introduite par Hanessian et coll. consiste à transformer **10** en iodure d'amonium par traitement par l'iodure de méthyle, et à chauffer le sel obtenu dans le toluène (22). Contrairement à la méthode originale, cette variante appliquée à **10** ne conduit pas à l'oléfine désirée mais à un iodo-formate résultant d'une substitution par l'ion iodure de l'oxygène en position 6 de **10**. Cette réaction est probablement dûe au faible encombrement stérique de cette position et devient la réaction attendue dans le cas des acétals des *N*,*N*-diméthylamides autres que ceux du DMF (28).

L'alcool **12***a* obtenu après hydroboration oxydative de **11***a* par le 9-BBN (96,5% après chromatographie) est protégé quantitativement sous forme de méthoxyméthyléther (MOM) (**13***a*) par réaction de l'alcoolate de potassium correspondant avec l'éther chlorométhylméthylique dans le THF à 0°C. Une tentative de mise en place de ce groupe protecteur suivant un mode opératoire consistant à faire réagir l'alcool et du diméthoxyméthane en présence de P_2O_5 (23) n'a conduit qu'à des rendements médiocres (40% après chromatographie) bien qu'employée avec succés dans notre laboratoire avec des substrats analogues. Le furanoside de benzyle (**13***a*) traité par le lithium dans l'amoniac à −78°C permet d'isoler le lactol **14***a* avec un rendement de 79%. Celui-ci est transformé en chlorure de mannofuranosyle (**15***a*) par le CCl_4 et la PPh_3 dans le THF à reflux (91,5% après distillation). La réduction par le lithium dans l'amoniac à −78°C de ce dernier conduit, comme prévu en série furanique, à un mélange (10:1 d'après le spectre de ^1H rmn du distillat) du glycal **17***a* (70%) et du dérivé **16***a* résultant d'une réduction non suivie de fragmentation de **15***a* (17*c*, 19). Le réarrangement [3,3]-sigmatropique est effectué sur le mélange précédent, le glycal se décomposant partiellement sur gel de silice et Florisil.

Postulant le passage par un intermédiaire du type bateau pour le réarrangement de Claisen, la configuration du carbone 2 de l'acide nonactique nécessite la formation majoritaire de l'énolate de type *Z*. Celui-ci est obtenu par traitement par le diisopropylamidure de lithium dans le THF à −78°C du propionate résultant de l'estérification du chlorure de propionyle par l'alcoolate (*n*-BuLi, THF, −78°C) correspondant de l'alcool allylique **17***a* du mélange précédant. Le mélange d'énolates est piégé a −78°C par le chlorure de triméthylsilyle (TMSCl) et le réarrangement s'opère durant le

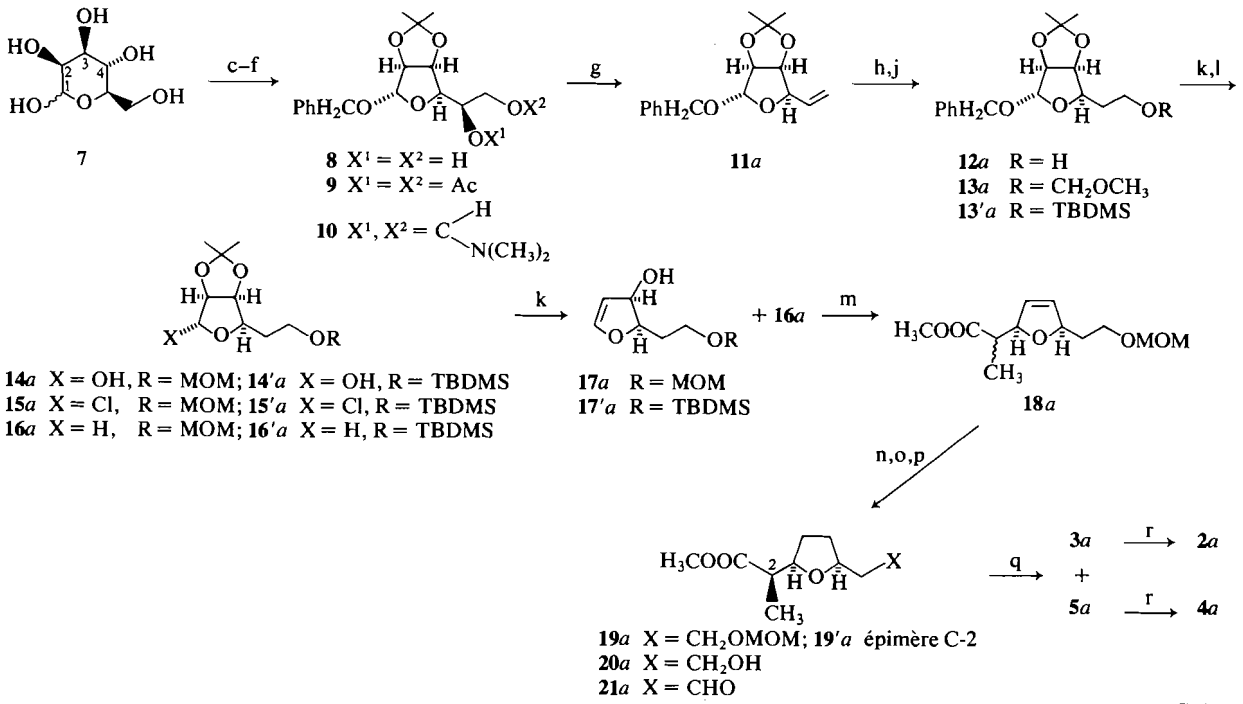
For personal use only.

réchauffement jusqu'à la température ambiante. Après hydrolyse des esters de triméthylsilyle, le mélange d'acides traité par le diazométhane conduit aux deux esters γ,δ insaturés diastéréoisomères **18***a*, qui présentent le même R_f en ccm et ne peuvent être séparés à ce stade. L'hydrogénation de la double liaison est réalisée en présence de rhodium sur charbon. Toutefois une faible quantité de produits résultant d'hydrogénolyse et d'isomérisation de la double liaison étant également formés, l'emploi de platine sur charbon lui est préféré. Contrairement à leurs analogues insaturés les deux esters diastéréoisomères **19***a* et **19**′*a* peuvent être séparés par chromatographie sur gel de silice. L'examen du mélange par cpv révèle qu'ils ont été formés dans un rapport de 89:11. Ce rapport élevé semble indiquer d'après le raisonnement précédent le passage par un état de transition unique pour le diastéréoisomère majoritaire et cet état de transition semble avoir été du type bateau. Dans l'attente d'une confirmation univoque par comparaison de l'acide nonactique synthétique avec le composé naturel, différentes constatations semblent soutenir cette hypothèse. Après séparation le spectre de ^{1}H rmn du diastéréoisomère majoritaire présente une résonance du méthyle en position 2 à champ plus élevé (1,11 ppm) que le méthyle correspondant du diastéréoisomère minoritaire (1,20 ppm) et son R_f est d'autre part plus petit. Les différents dérivés et analogues de l'acide nonactique synthétisés ont de même toujours présenté un R_f plus petit et une résonance du méthyle en C-2 à champ plus élevé que les épimères correspondants en C-2 (*7b*, 10*a*, 12). Les probabilités que le diastéréoisomère majoritaire présente comme prévu la même configuration en C-2 que l'acide nonactique étaient donc élevées et semblaient confirmer nos hypothèses. La synthèse a donc été poursuivie avec ce diastéréoisomère, isolé avec un rendement de 48,5% à partir de **17***a*.

La même suite de réactions avait été initialement entreprise à partir de **13**′*a*, l'alcool primaire étant protégé sous forme d'éther de *tert*-butyldiméthylsilyle (TBDMS). Le rendement après le réarrangement de Claisen est toutefois très faible (quelques %). Une explication à ce fait pourrait être l'échange de l'éther de TBDMS avec l'alcoolate de lithium de **17**′*a*, conduisant à des produits se décomposant durant l'hydrolyse. Un argument en faveur de cette explication découle de l'observation suivante. Lors de la formation du glycal **17**′*a* on observe à côté des produits attendus un composé résultant d'un tel échange de l'éther de TBDMS. Voisine de 50% lorsque la réduction est effectuée dans l'amoniac à −33°C, sa formation peut cependant être ramenée à moins de 5% à −78°C. Il semble toutefois que dans le THF cet échange ne puisse être évité.

L'alcool en position 8 de **20***a* est libéré par chauffage de **19***a* dans l'acide chlorhydrique à 2% dans le méthanol anhydre (96,5% après chromatographie) et oxydé en aldéhyde **21***a* avec un rendement de 90% (24). L'introduction du méthyle en position 8 a été effectuée par le diméthylcuprate de lithium à −20°C. Il a été montré que ce réactif, inerte vis-à-vis des cétones et esters carboxyliques, réagit avec les aldéhydes (25). Les deux alcools diastéréoisomères sont obtenus dans des proportions comparables. Le plus polaire devant correspondre à l'ester méthylique de l'acide (−) nonactique (**3***a*) (12) est isolé avec un rendement de 39,5% et son épimère en C-8 (**5***a*) avec un rendement de 45%. L'hydrolyse séparée de ces deux épimères par une solution aqueuse 2 *N* d'hydroxyde de potassium s'effectue en quelques minutes à température ambiante. Elle conduit à l'acide (−) nonactique (**2***a*) et à son épimère en C-8 (**4***a*) avec un rendement de 96% sans qu'aucun produit résultant d'une épimérisation en C-2 ou C-3 ne puisse être détecté par ccm. Les caractéristiques analytiques et spectrales de l'acide (−) nonactique et de son ester méthylique sont en accord avec celles publiées à partir du produit résultant de l'hydrolyse de la dinactine, et plus particulièrement en ^{1}H rmn avec les déplacements chimiques et constantes de couplage du méthyle en C-2 (3, *7b*). Comme prévu (12), des deux épimères en C-8 le plus polaire présente les caractéristiques de l'acide nonactique. Le pouvoir rotatoire négatif obtenu pour **3***a* et **5***a* corrobore les déductions faites après le réarrangement de Claisen, l'épimère en C-2 (*S*,*R*,*S*,*S*) de l'acide nonactique présentant un pouvoir rotatoire positif (*7b*).

L'énantiomère (+) de l'acide nonactique (**2***b*) a été synthétisé suivant le même schéma. Bien que commercialement disponible le L-(−)-mannose n'a pas été choisi comme produit de départ en raison de son prix élevé et la D-gulono-γ-lactone (**22**) (Schéma 5) présentant les configurations désirées des carbones 2, 3 et 4 lui est préférée. Après conversion de **22** en diacétonide et réduction de la lactone par l'hydrure de diisobutyl aluminium (DIBAL) dans l'éther, les deux lactols anomères obtenus sont protégés par benzylation et séparés par chromatographie. L'hydrolyse sélective de l'un des acétonides de l'anomère majoritaire β conduit au diol **24** avec un rendement global de 50%. Celui-ci est diastéréoisomère du diol **8**, la configu-



(c) H_3CCOCH_3, H^+; (d) NaH, $PhCH_2Cl$, DMF; (e) HCl conc., CH_3OH; (f) $(CH_3)_2NCH(OCH_3)_2$, CH_2Cl_2; (g) $(H_3CCO)_2O$, 130°C; (h) 9-BBN; NaOH, H_2O_2; (j) KH, $ClCH_2OCH_3$; (k) Li, NH_3, −78°C; (l) Ph_3P, CCl_4; (m) *n*-BuLi; *n*-C_2H_5COCl; LDA, THF, −78°C; TMSCl; 25°C; H_2O, OH^-; CH_2N_2; (n) H_2, Rh/C; (o) 2% HCl, CH_3OH; (p) $(COCl)_2$, DMSO; Et_3N; (q) $Li(CH_3)_2Cu$; (r) 2 *N* KOH, H_2O.

SCHÉMA 4

ration du carbone 5 appelé à perdre sa chiralité lors de l'étape suivante étant la même pour ces deux composés. Sa conversion en oléfine **11***b* énantiomère de **11***a* est effectuée suivant la séquence précédemment décrite. Par une série de réactions identiques à celles utilisées pour obtenir l'énantiomère (−), l'oléfine **11***b* est transformée en aldéhyde **21***b*. L'introduction du méthyle en C-8 par réaction de **21***a* avec le diméthylcuprate de lithium ayant conduit précédemment à un mélange des deux diastéréoisomères légèrement plus riche en l'épimère non désiré (47:53 en produits isolés), nous avons envisagé son incorporation possible par un autre réactif. La réaction de **21***b* avec un équivalent de bromure de méthyl-magnésium dans l'éther à basse température conduit à des rendements en produits isolés aprés chromatographie de 53,5% pour le (+) nonactate de méthyle (**3***b*) et 40% pour son épimère en C-8 (**5***b*). Bien que tendant cette fois encore vers un rapport voisin de 1:1 (57:43 en produits isolés) l'utilisation du réactif de Grignard semble toutefois favoriser légèrement la formation du diastéréoisomère désiré comme le montre l'examen du mélange brut par ccm, et conduire à un rendement sensiblement supérieur (93,5%). Ces résultats font apparaître une stéréoselectivité très faible, et sont en accord avec ceux récemment rapportés par Still et Schneider relatifs à l'addition d'organométalliques sur des β-alkoxyaldéhydes non substitués en α (29). L'hydrolyse comme précédemment de ces deux esters offre l'acide (+) (*S*,*S*,*R*,*R*) nonactique et son épimère en C-8 en tout point équivalents au signe près du pouvoir rotatoire, aux énantiomères précédemment obtenus.

Conclusion

La synthèse des deux énantiomères de l'acide nonactique que nous venons de décrire montre une fois de plus l'intérêt présenté par les sucres comme produits de départ chiraux relativement peu onéreux. D'autre part elle souligne l'intérêt déjà précédemment démontré (18) qui peut être tiré de l'utilisation du réarrangement [3,3]-sigmatropique de cétène-acétals silylés pour la formation de liaisons entre atomes de carbone dont la chiralité peut être présélectionnée. Elle fait également apparaître son application possible à la formation de dérivés du type aldol, déjà intensivement mise à profit lors de la synthèse de l'acide lasalocide A (16). Elle présente en outre un haut degré de stéréosélectivité, le seul centre non contrôlé (C-8)

pouvant être inversé suivant une série de réactions précédemment rapportées (14). D'autre part comme nous l'avons soulignée la forte sélectivité obtenue après le réarrangement [3,3]-sigmatropique et la comparaison de la configuration du C-2 du diastéréoisomère majoritaire obtenu avec l'acide nonactique naturel a permis de confirmer le passage, pour le réarrangement de ce type de cétène-acétals silylés cycliques, par un intermédiaire du type bateau.

Partie expérimentale

Les points de fusion ont été déterminés sur un appareil Hoover à capillaires et ne sont pas corrigés. Les spectres d'absorbtion infrarouge (ir) ont été obtenus avec un spectromètre Perkin-Elmer 727 B et les spectres de résonance magnétique nucléaire ont été enregistrés sur un appareil Varian EM-390 à 90 MHz pour le proton (^1H rmn) et sur un appareil Jeol FX-90 Q pour le carbone (^{13}C rmn). Les solvants utilisés ont été $CDCl_3$ ou CCl_4. Les déplacements chimiques sont exprimés en ppm sur l'échelle δ en prenant le tétraméthylsilane comme référence interne (δMe_4Si = 0,0). Les constantes de couplage sont données en Hz. Les spectres sont décrits de la manière suivante: solvant, δ (multiplicité: s = singulet; d = doublet; t = triplet; q = quadruplet; m = multiplet. Constantes de couplage. Intégration. Interprétation). Les pouvoirs rotatoires ont été mesurés dans une cellule de 1 dm et 1 mL de capacité sur un polarimètre Perkin-Elmer 141.

Les microanalyses ont été effectuées par Spang Microanalytical Laboratory, Ann Arbor, MI. Les échantillons analytiques ont été obtenus, sauf indication contraire, par distillation dans un tube à boules à la pression indiquée.

Les chromatographies en phase vapeur (cpv) ont été effectuées sur un chromatographe Hewlett-Packard 5750 équipé avec un détecteur à ionisation de flamme utilisant l'hélium comme gaz vecteur à un débit de 60 mL/min.

L'avancement des réactions a été suivi sur des prélèvements par spectroscopie de ^1H rmn ou par chromatographie sur couche mince (ccm). Les ccm on été réalisées sur des plaques préparées de gel de silice 60F-254 Merck, de 0,25 mm d'épaisseur. Les chromatographies sur colonne ont été effectuées sur gel de silice Merck "Silica gel 60", 70–230 mesh ASTM, à l'exception de celles réalisées sur gel de silice acide Silicar CC-4 Spécial, Mallinckrodt Chemical Works, St. Louis, MO.

Les solvants et réactifs ont été séchés et distillés avant emploi. L'éther éthylique, le THF et le pentane ont été distillés sur sodium (utilisant la benzophénone comme indicateur pour les deux premiers) et sous une atmosphère d'argon sec. Le méthanol a été distillé sur méthylate de magnésium et le chlorure de méthylène sur pentoxide de phosphore. Le DMSO a été distillé sur hydrure de calcium pulvérisé, sous une pression de 30 Torr. La diisopropylamine et la triéthylamine ont été distillées sur sodium–benzophénone et sous argon juste avant emploi. Le chlorure d'oxalyle a été distillé sous atmosphère d'argon et le chlorure de propionyle sur 10% de quinoléine. Le chlorure

For personal use only.

d'amonium a été séché sur P_2O_5 à 80°C sous 1 Torr pendant deux jours.

Toutes les réactions ont été réalisées sous atmosphère d'argon sec (à l'exception des hydrogénations et réductions dans l'amoniac) en légère surpression utilisant un système permettant alternativement d'évacuer et d'introduire le gaz inerte. Les réactions (hormis les hydrolyses finales) ont été effectuées avec du matériel (réacteurs, seringues, condenseurs, etc...) préalablement séché 12 h à 140°C et refroidi dans un dessiccateur sur sulfate de calcium anhydre. Les volumes inférieurs à 30 mL ont été introduits à l'aide de seringues à travers des bouchons perforables.

Par traitement habituel on entend: lavage (3 ou 4 fois) par une solution saturée en NaCl de la phase organique, séchage sur $MgSO_4$, filtration, évaporation du solvant sous pression réduite et séchage du résidu plusieurs heures sous une pression de l'ordre de 10^{-2} Torr à température ambiante. Les distillations sur les quantités inférieures à 5 g ont été réalisées dans un tube à boules par chauffage dans un four thermostaté. Les points d'ébulition indiqués se rapportent à ces distillations.

*Phénylméthyl 2,3-*O*-(1-méthyléthylidène)-5,6-*O*-(*N*,*N*-diméthylaminométhylène)-α-*D*-mannofuranoside (**10**)*

A une solution de 51,1 g (164,7 mmol) de phénylméthyl-2,3-*O*-(1-méthyléthylidène)-α-D-mannofuranoside (**8**) (20) dans 600 mL de chlorure de méthylène, on ajoute 96 g (0,8 mol) de *N*,*N*-diméthylformamide diméthylacétal fraîchement redistillé. La solution est maintenue pendant 24 h sous atmosphère d'argon à temperature ambiante. Le solvant est évaporé sous pression réduite à température inférieure à 50°C. Le résidu conservé 12 h supplémentaires sous un vide de 0,01 Torr est utilisé sans autre purification au cours de l'étape suivante: ^{1}H rmn ($CDCl_3$) δ: 1,32 et 1,45 (2s, 2 × 3H, $C(CH_3)_2$); 2,36 (s, 6H, $N(CH_3)_2$); 5,06 (s, 1H, $PhCH_2OCHO$—); 5,40 et 5,46 (2s (diastéréoisomères), 1H, —OCHON<); 7,33 (s, 5H, C_6H_5).

*Phénylméthyl 2,3-*O*-(1-méthyléthylidène)-5,6-didéhydro-5,6-didéoxy-α-*D*-mannofuranoside (**11**a)*

Une solution du produit brut précédent dans 500 mL d'anhydride acétique est chauffée à 130°C pendant 1 heure. L'anhydrique acétique est évaporé sous pression réduite et l'huile résiduelle dissoute dans 500 mL d'éther. Après lavage avec une solution à 5% de $NaHCO_3$ (4 × 75 mL) et traitement habituel on obtient une huile, qui chromatographiée sur gel de silice (éluant: cyclohexane/AcOEt, 85:15) fournit 34,8 g (76,5% à partir de **8**; 96% sur la base du diol **8** régénéré) de **11***a* et 11,34 g (17,5%) de diacétate **9**. La réduction de ce dernier par $LiAlH_4$ permet de régénerer **8** avec un rendement de 93%; Eb: 95–100°C (0,04 Torr); R_f: 0,4 (cyclohexane/AcOEt, 75:25); $[\alpha]_D^{25}$ +56,6° (*c* 1,14, $CHCl_3$); ir ($CHCl_3$): 1020, 1090, 1230, 1385, 1390, 3010, 3030, 3090, 3110 cm^{-1}; ^{1}H rmn ($CDCl_3$) δ: 1,30 et 1,45 (s, 2 × 3H, $2CH_3$); 5,08 (s, 1H, —OCHO—); 5,20–5,53 (m, 2H, C=CH_2); 5,80–6,23 (m, 1H, C=CH); 7,30 (s, 5H, C_6H_5). *Anal.* calc. pour $C_{16}H_{20}O_4$: C 69,55, H 7,29; trouvée: C 69,49, H 7,17.

*Phénylméthyl 2,3-*O*-(1-méthyléthylidène)-5-déoxy-α-*D*-mannofuranoside (**12**a)*

A 250 mL (125 mmol) d'une solution 0,5 *M* de 9-borabicyclo[3.3.1]nonane (9-BBN) dans le THF[4] agitée magnétiquement sous atmosphère d'argon on ajoute à l'aide d'une ampoule à addition 32,5 g (117,6 mmol) de **11***a* en solution dans 130 mL de THF. La solution est maintenue 2 heures et demie à température ambiante. On ajoute successivement par l'ampoule à addition 75 mL d'éthanol, 50 mL d'une solution 6 *M* de NaOH et 25 mL d'une solution à 30% de H_2O_2 et chauffe le mélange 1 heure et demie à 60°C. La phase aqueuse refroidie est saturée en carbonate de potassium. La phase organique est séparée et traitée de manière habituelle. Le résidu chromatographié sur gel de silice (éluant: cyclohexane/AcOEt, 75:25 à 65:35) conduit à l'isolement de 33,4 g (96,5%) d'alcool **12***a* sous forme d'huile; Eb: 120°C (0,05 Torr); R_f: 0,50 (cyclohexane/AcOEt, 50:50); $[\alpha]_D^{25}$ +97° (*c* 1,03, $CHCl_3$); ir ($CHCl_3$): 1010, 1085, 1225, 1385, 1390, 3560, 3640 cm^{-1}; ^{1}H rmn ($CDCl_3$) δ: 1,30 et 1,43 (2s, 2 × 3H, $C(CH_3)_2$); 3,60–3,90 (m, 2H, CCH_2OH); 4,52 (AB, J_{AB} = 12 Hz, ν_{AB} = 13 Hz, 2H, —OCH_2Ph); 5,04 (s, 1H, —OCHO—); 7,32 (s, 5H, C_6H_5); ($CDCl_3$ + D_2O) δ: 3,72 (t, *J* = 6 Hz, 2H, CCH_2OH). *Anal.* calc. pour $C_{16}H_{22}O_5$: C 65,29, H 7,53; trouvée: C 65,19, H 7,66.

*Phénylméthyl 2,3-*O*-(1-méthyléthylidène)-5-déoxy-6-*O*-méthoxyméthyl-α-*D*-mannofuranoside (**13**a)*

Une suspension de KH à 23,6% dans l'huile[5] (16,77 g; 99 mmol) est lavée avec 3 × 100 mL de pentane sous atmosphère d'argon. On ajoute 205 mL de THF, un crystal d'imidazole, refroidit la solution dans un bain de glace et additionne lentement sous agitation magnétique à l'aide d'une ampoule à addition 24,2 g (82,2 mmol) de **12***a* en solution dans 205 mL de THF. A la fin de l'addition le mélange est agité 15 min supplémentaires à 0°C. On ajoute lentement à l'aide d'une seringue 9,43 mL (124 mmol) d'éther chlorométhylméthylique préalablement séché pendant 12 h sur chlorure de calcium, puis 2 h sur carbonate de potassium et filtré. Le bain de glace est enlevé. Le mélange réactionnel maintenu à température ambiante pendant 7 h est alors hydrolysé avec 150 mL d'une solution saturée de bicarbonate de sodium et gardé sous agitation durant la nuit. On ajoute 1 L d'éther et décante la phase organique qui est lavée avec 4 × 250 mL d'une solution saturée de bicarbonate de sodium, puis traitée de façon habituelle. On obtient 27,8 g (100%) de **13***a* (une tache en ccm) qui est utilisé sans autre purification au cours de l'étape suivante. Un échantillon analytique de 1 g est obtenu par chromatographie sur gel de silice (éluant: cyclohexane/AcOEt, 85:15); Eb: 125–127°C (0,01 Torr); R_f: 0,38 (cyclohexane/AcOEt, 75:25); $[\alpha]_D^{25}$ +89,2° (*c* 0,95, $CHCl_3$); ir ($CHCl_3$): 1020, 1050, 1090, 1120, 1165, 1220, 1385, 1390, 2960 cm^{-1}; ^{1}H rmn ($CDCl_3$) δ: 1,30 et 1,43 (2s, 2 × 3H, $C(CH_3)_2$); 2,0 (d de t, J_1 = J_2 = 6 Hz, 2H, —CH_2CH_2OMOM); 3,33 (s, 3H, OCH_3); 3,67 (t, *J* = 6,3 Hz, 2H, —CH_2OMOM); 4,03–4,30 (m, 1H, —$OCHCH_2$—); 4,61 (s large, 4H, —OCH_2O— et —OCHCHO—); 4,53 (AB, J_{AB} = 12 Hz, ν_{AB} = 17 Hz, 2H, —OCH_2Ph); 5,03 (s, 1H, —OCHO—); 7,31 (s, 5H, C_6H_5). *Anal.* calc. pour $C_{18}H_{26}O_6$: C 63,89, H 7,74; trouvée: C 63,93, H 7,68.

*2,3-*O*-(1-Méthyléthylidène)-5-déoxy-6-*O*-méthoxyméthyl-(α et β)-*D*-mannofuranose (**14**a)*

A 1,2 L d'amoniac (redistillé à partir d'une solution bleue de lithium dans l'amoniac) sous agitation à −78°C, on ajoute 1,25 g (180 mmol) de lithium en fil et après 20 min, à l'aide d'une ampoule à addition, une solution de 27,2 g (80,4 mmol) de **13***a* dans 40 mL de THF. Le bain réfrigérant est enlevé et la réaction maintenue sous reflux d'amoniac. Après 2 h, 10,7 g (0,2 mol) de NH_4Cl sec sont ajoutés par portions d'environ 0,5 g. On laisse alors lentement évaporer l'amoniac sous un courant d'argon pendant que 500 mL d'éther anhydre sont ajoutés au milieu réactionnel. Lorsque l'amoniac est totalement évaporé la suspension est filtrée sur verre fritté et l'éther évaporé sous pression réduite. Après chromatographie sur gel de silice (éluant: cyclohexane/AcOEt, 60:40) on isole 15,7 g (79%) de lactol **14***a*. Le spectre de ^{1}H rmn de **14***a* montre la présence d'un seul anomère qui en solution chloroformique s'isomérise en un mélange α et β; Eb: 105°C (0,02 Torr); R_f: 0,30 (cyclo-

hexane/AcOEt, 50:50); ir (film): 1060, 1155, 1210, 1385, 1390, 2940, 3400 cm^{-1}; ^1H rmn ($CDCl_3$) δ: 1,31 et 1,43 (anomère majoritaire), 1,35 et 1,50 (anomère minoritaire) (2 × 2s, 2 × 3H, $C(CH_3)_2$); 1,93 (d de t, $J_1 = J_2 = 6$ Hz, 2H, —CH_2CH_2OMOM); 3,35 (s, 3H, —OCH_3); 3,65 (t, $J = 6$ Hz, 2H, —CH_2OMOM); 4,25 (d de t, $J_1 = 3$ Hz, $J_2 = 6$ Hz, 1H, —$OCHCH_2$—); 4,63 (s, 2H, —OCH_2O—); 5,30 (s, "0,85H", —OCHO-anomère majoritaire). *Anal.* calc. pour $C_{11}H_{20}O_6$: C 53,22, H 8,12; trouvée: C 53,20, H 8,01.

*Chlorure de 5-déoxy-2,3-*O*-(1-méthyléthylidène)-6-*O*-méthoxyméthyl-α-*D*-mannofuranosyle (15*a*)*

On chauffe à 90°C sous agitation magnétique et sous atmosphère d'argon une solution de 993,1 mg (4 mmol) de **14***a*, 2 mL (20 mmol) de tetrachlorure de carbone et 2,1 g (8 mmol) de triphénylphosphine dans 20 mL de THF. Le milieu réactionnel homogène laisse rapidement précipiter de l'oxyde de triphénylphosphine. Après 3 h la solution refroidie est filtrée sur verre fritté et le solvant évaporé sous pression réduite. Le résidu est trituré avec du pentane sec, gardé une demi-heure au réfrigérateur, et l'oxyde de triphénylphosphine qui a cristallisé est filtré. Cette dernière opération est répétée (3 ou 4 fois) jusqu'à élimination complète de l'oxyde de triphénylphosphine. La distillation du produit brut dans un tube à boules permet d'obtenir 976 mg (91,5%) de **15***a*; Eb: 90°C (0,02 Torr); $[\alpha]_D^{25}$ +94,4° (*c* 1,04, $CHCl_3$); ir (film): 1050, 1090, 1160, 1215, 1385, 1390, 2965 cm^{-1}; ^1H rmn ($CDCl_3$) δ: 1,31 et 1,43 (2s, 2 × 3H, $C(CH_3)_2$); 2,0 (d de t, $J_1 = J_2 = 6$ Hz, 2H, —CH_2CH_2OMOM); 3,35 (s, 3H, —OCH_3); 3,63 (t, $J = 6$ Hz, 2H, —CH_2OMOM); 4,25–4,60 (partie X d'un AMX, 1H, —$OCHCH_2$—); 4,60 (s, 2H, —OCH_2O—); 4,70 (partie M d'un AMX, $J_{AM} = 6$ Hz, $J_{MX} = 3$ Hz, 1H, ClCCCH); 4,93 (partie A d'un AMX, $J_{AM} = 6$ Hz, 1H, ClCCH); 6,06 (s, 1H, —OCHCl). *Anal.* calc. pour $C_{11}H_{19}O_5Cl$: C 49,54, H 7,18; trouvée: C 49,62, H 7.29.

*Phénylméthyl 2,3-*O*-(1-méthyléthylidène)-5-déoxy-6-O-[diméthyl-(1,1-diméthyléthyl)-silyl]-α-*D*-mannofuranoside (13′a)*

Une solution de 5,88 g (20 mmol) de **12***a* dans le diméthylformamide anhydre est agitée sous atmosphère d'argon en présence de 5,7 g (84 mmol) d'imidazole préalablement sublimé et 6,33 g (42 mmol) de chlorure de *tert*-butyldiméthylsilane. Après 15 h à température ambiante 200 mL d'eau sont ajoutés au milieu réactionnel qui est extrait par 3 × 100 mL d'éther. Après traitement habituel, l'huile obtenue est chromatographiée sur gel de silice (éluant: cyclohexane/AcOEt, 75:25). On obtient 8,05 g (99%) d'éther silylé **13′***a*; Eb: 140°C (0.07 Torr); R_f: 0,34 (cyclohexane/AcOEt, 75:25); $[\alpha]_D^{25}$ +80,9° (*c* 0,93, $CHCl_3$); ir ($CHCl_3$): 840, 1015, 1095, 1230, 1265, 1385, 1390, 2875, 2950, 2970 cm^{-1}; ^1H rmn ($CDCl_3$) δ: 0,09 (s, 6H, $Si(CH_3)_2$); 0,91 (s, 9H, *t*-C_4H_9 Si); 1,28 et 1,42 (2s, 2 × 3H, $C(CH_3)_2$); 1,91 (d de t, $J_1 = J_2 = 6$ Hz, 2H, $CH_2CH_2OTBDMS$); 3,25 (t, $J = 6,5$ Hz, 2H, $CH_2OTBDMS$); 4,53 (AB, $J_{AB} = 12$ Hz, $\nu_{AB} = 18,6$ Hz, 2H, OCH_2Ar); 5,02 (s, 1H, $OCHOCH_2Ar$); 7,30 (s, 5H, —C_6H_5). *Anal.* calc. pour $C_{22}H_{36}SiO_5$: C 64,67, H 8,88; trouvée: C 64,79, H 9,00.

*2,3-*O*-(1-Méthyléthylidène)-5-déoxy-6-O-[diméthyl-(1,1-diméthyléthyl)-silyl]-α et β-*D*-mannofuranose (14′a)*

Obtenu à partir de 7,96 g (19,5 mmol) de **13′***a* suivant le mode opératoire permettant d'obtenir **14***a* à partir de **13***a*. Après chromatographie sur gel de silice on isole 5,35 g (86%) de **14′***a*; Eb: 97°C (0,02 Torr); R_f: 0,45 (cyclohexane/AcOEt, 50:50); ir ($CHCl_3$): 850, 1015, 1055, 1095, 1230, 1265, 1385, 1390, 2890, 2950, 2970, 3435, 3620 cm^{-1}; ^1H rmn ($CDCl_3$) δ: 0,09 (s, 6H, $Si(CH_3)_2$); 0,93 (s, 9H, *t*-C_4H_9Si); 1,30 et 1,43 (2s, 2 × 3H, $C(CH_3)_2$); 1,93 (d de t, $J_1 = J_2 = 6$ Hz, 2H, $CH_2CH_2OTBDMS$); 3,73 (t, $J = 6$ Hz, 2H, $CH_2OTBDMS$); 5,33 (s, 1H, $OCHOH$). *Anal.* calc. pour $C_{15}H_{30}O_5Si$: C 56,57, H 9,49; trouvée: C 56,49, H 9,36.

*Chlorure de 5-déoxy-2,3-*O*-(1-méthyléthylidène)-6-O-[diméthyl-(1,1-diméthyléthyl)-silyl]-α-*D*-mannofuranosyle (15′a)*

Obtenu à partir de 647 mg (2,03 mmol) de **14′***a* suivant le mode opératoire permettant d'obtenir **15***a* à partir de **14***a*. Obtenu après distillation: 640 mg (94%) Eb: 81°C (0,02 Torr); $[\alpha]_D^{25}$ +82,7° (*c* 0,9, $CHCl_3$); ir ($CHCl_3$): 840, 1095, 1175, 1230, 1265, 1385, 1390, 2875, 2950, 2970 cm^{-1}; ^1H rmn ($CDCl_3$) δ: 0,09 (s, 6H, $Si(CH_3)_2$); 0,93 (s, 9H, *t*-C_4H_9Si); 1,30 et 1,43 (2s, 2 × 3H, $C(CH_3)_2$); 1,96 (d de t, $J_1 = J_2 = 6$ Hz, 2H, $CH_2CH_2OTBDMS$); 3,73 (t, $J = 6$ Hz, 2H, $CH_2OTBDMS$); 4,30–4,53 (partie X d'un AMX, 1H, $OCHCH_2$); 4,73 (partie M d'un AMX, $J_{AM} = 6$ Hz, $J_{MX} = 3$ Hz, 1H, ClCCCH); 4,93 (partie A d'un AMX, $J_{AM} = 6$ Hz, 1H, ClCCH); 6,10 (s, 1H, ClCHO). *Anal.* calc. pour $C_{15}H_{29}O_4SiCl$: C 53,47, H 8,68; trouvée: C 53,35, H 8,49.

2R-cis-2-(β-Méthoxyméthylènoxyéthyl)-2,3-dihydro-3-hydroxyfurane (17a)

A 80 mL d'amoniac (redistillé à partir d'une solution bleue de lithium dans l'amoniac) sous agitation à −78°C on ajoute 110 mg (15,8 mmol; 5 éq.) de lithium en fil, et après une demi-heure à l'aide d'une seringue une solution de 845 mg (3,17 mmol) de **15***a* dans 4 mL de THF. On rince avec 2 × 3 mL de THF et garde sous agitation à −78°C pendant une heure et demie. A la solution bleue est ajouté 1,34 g (25 mmol) de NH_4Cl sec. L'amoniac est évaporé sous courant d'argon et 100 mL d'éther et 2 g de $MgSO_4$ sont ajoutés au milieu réactionnel. Lorsque l'amoniac est évaporé, la suspension est filtrée sur verre fritté et l'éther évaporé sous pression réduite. L'huile résiduelle est triturée avec un mélange d'éther et de pentane (1:1), conservée 1 heure au réfrigérateur et filtrée. La distillation du produit brut conduit à l'obtention de 441 mg d'un mélange de glycal **17***a* et de 1,5-dideoxy-2,3-*O*-(1-méthyléthylidène)-6-*O*-méthoxyméthyl-D-mannofuranose (**16***a*) dans un rapport 10:1 (^1H rmn) correspondant à un rendement de 70% en **17***a*. Différentes tentatives de chromatographie du mélange sur gel de silice ou Florisil ont conduit à une décomposition partielle du glycal; Eb du mélange: 85°C (0,005 Torr); ir (film): 1060, 1115, 1160, 1606, 3450 cm^{-1}; ^1H rmn ($CDCl_3$) δ: 1,90–2,40 (m, 2H, —CH_2CH_2OMOM); 3,35 (s, 3H, —OCH_3); 3,67 (m, 2H, —CH_2OMOM); 4,25 (d de t, $J_1 = J_2 = 7$ Hz, 1H, C=COCH); 4,60 (s, 2H, —OCH_2O—); 4,65–4,73 (m, 1H, $CHOH$); 5,20 (d de d, $J_1 = J_2 = 5,4$ Hz, 1H, —OC=CH—); 6,56 (d, $J = 5,4$ Hz, 1H, —OCH=C—).

[2R[2α(R et S*),5α]]-2,5-Dihydro-5-(2-méthoxyméthylènoxyéthyl)-α-méthyl-2-furanacétate de méthyle (18a)*

A une solution de 441 mg du mélange 10:1 de **17***a* et **16***a* (2,22 mmol de glycal **17***a*) dans 10 mL de THF à −78°C sous atmosphère d'argon, on ajoute sous agitation un crystal de phénantroline et une solution 2,4 *M* de *n*-BuLi dans l'hexane[4] jusqu'à apparition d'une coloration brunâtre (0,96 mL; 2,3 mmol). Après 5 min 0,2 mL (2,33 mmol) de chlorure de propionyle sont ajoutés. On enlève le bain réfrigérant, laisse remonter la température à −10°C et refroidit à nouveau à −78°C. La solution est alors ajoutée à l'aide d'une aiguille à double entrée à une solution 0,5 *N* de 2,33 mmol de diisopropylamidure de lithium dans le THF, maintenue à −78°C sous agitation. Après 15 min on ajoute 1,90 mL (11 mmol) du liquide surnageant obtenu après centrifugation d'un mélange 3:1 (v/v) de chlorure de triméthylsilyle et de triéthylamine, maintient le milieu réactionnel 15 min supplémentaires à −78°C, enlève le bain réfrigérant et garde à température ambiante pendant 20 h. La solution est alors hydrolysée à 0°C avec 50 mL d'une solution 0,5 *N* de NaOH. Les solvants sont évaporés sous pression réduite à température

inférieure à 30°C, la phase aqueuse extraite par 3 × 50 mL d'éther, acidifiée jusqu à pH 2,5, extraite par 7 × 100 mL d'éther et les phases éthérées réunies traitées de façon habituelle. Un excès d'une solution éthérée de diazométhane est alors ajouté à l'huile obtenue, conduisant à 382 mg de **18***a* brut, qui est directement hydrogéné sans purification ultérieure. Un échantillon analytique est obtenu par chromatographie sur gel de silice (éluant: cyclohexane/AcOEt, 75:25); Eb: 80°C (0,05 Torr); R_f: 0,3 (cyclohexane/AcOEt, 60:40); ir ($CHCl_3$): 1050, 1740 cm^{-1}; ^1H rmn ($CDCl_3$) δ: 1,11 (diastéréoisomère majoritaire) et 1,22 (diastéréoisomère minoritaire) (2 × d, J = 7,2 Hz, 3H, —CH_3); 1,65–1,96 (m, 2H, —CH_2CH_2OMOM); 2,60 (d de q, $J_1 = J_2$ = 7,2 Hz, 1H, —O_2CCH); 3,33 (s, 3H, —OCH_3); 3,63 (t, J = 6,5 Hz, 2H, —CH_2OMOM); 3,68 (s, 3H, —$COOCH_3$); 4,58 (s, 2H, —OCH_2O—); 4,73–5,06 (m, 2H, HCOCH); 5,86 (m, 2H, —HC=CH—). *Anal.* calc. pour $C_{12}H_{20}O_5$: C 59,00, H 8,25; trouvée: C 58,76, H 8,26.

[2R[2α(R),5α]] et [2R[2α(S*),5α]]-Tétrahydro-5-(2-méthoxyméthylènoxyéthyl)-α-méthyl-2-furanacétate de méthyle (19*a*) et (19′a)*

L'ester brut **18***a* en solution dans 20 mL de THF est hydrogéné dans un appareil de Parr en présence de 20 mg de rhodium (5%) sur charbon pendant 4 h sous 4 atm. Après filtration du catalyseur et traitement habituel un échantillon du produit brut est analysé par cpv (SE30 10%; T: 115°C). L'apparition de 2 pics se recouvrant partiellement (t_R: 60 et 63 min) fait apparaître que les 2 diastéréoisomères **19***a* et **19′***a* ont été formés dans une proportion de 89:11. Le produit brut chromatographié sur gel de silice (éluant: cyclohexane/AcOEt, 85:15) conduit à l'isolement de 265 mg de l'ester **19***a* (48,5% à partir du glycal **17***a*); Eb: 75°C (0,05 Torr); R_f: 0,26 (cyclohexane/AcOEt, 60:40); $[\alpha]_D^{25}$ −13,6° (*c* 1,07, $CHCl_3$); ir (film): 1050, 1120, 1160, 1205, 1742, 2970 cm^{-1}; ^1H rmn ($CDCl_3$) δ: 1,11 (d, J = 7,2 Hz, 3H, —CH_3); 2,52 (d de q, $J_1 = J_2$ = 7,2 Hz, 1H, —O_2CCH); 3,33 (s, 3H, —OCH_3); 3,58 (t, J = 6,5 Hz, 2H, —CH_2OMOM); 3,68 (s, 3H, —$COOCH_3$); 3,78–4,13 (m, 2H, —HCOCH—); 4,58 (s, 2H, —OCH_2O—). *Anal.* calc. pour $C_{12}H_{22}O_5$: C 58,52, H 9,00; trouvée: C 58,73, H 8,89.

On isole de même 29,5 mg (5,3% à partir du glycal **17***a*) de l'épimère **19′***a*; R_f: 0,3 (cyclohexane/AcOEt, 60:40); ^1H rmn ($CDCl_3$) δ: 1,20 (d, J = 7,2 Hz, 3H, —CH_3), 2,50 (d de q, $J_1 = J_2$ = 7,2 Hz, 1H, —O_2CCH); 3,33 (s, 3H, —OCH_3); 3,58 (t, J = 6,5 Hz, 2H, —CH_2OMOM); 3,65 (s, 3H, —$COOCH_3$); 3,78–4,13 (m, 2H, —HCOCH—); 4,58 (s, 2H, —OCH_2O—).

[2R[2α(R),5α]]-Tétrahydro-5-(2-hydroxyéthyl)-α-méthyl-2-furanacétate de méthyle (20*a*)*

Une solution de 240 mg (0,97 mmol) de **19***a* dans 50 mL de méthanol anhydre contenant 2,1% d'acide chlorhydrique (préparé à partir de 1,7 mL de chlorure d'acétyle et de 50 mL de méthanol) est chauffée à 45°C pendant 14 h sous atmosphère d'argon. Après évaporation des solvants sous pression réduite, l'huile obtenue est chromatographiée sur gel de silice (éluant: cyclohexane/AcOEt, 65:35). On isole 190 mg (96,5%) d'ester-alcool **20***a*; Eb: 83°C (0,06 Torr); R_f: 0,21 (cyclohexane/AcOEt, 85:15); $[\alpha]_D^{25}$ −26,3° (*c* 1,06, $CHCl_3$); ir ($CHCl_3$): 1080, 1180 1210, 1742, 2875, 3570 cm^{-1}; ^1H rmn ($CDCl_3$) δ: 1,11 (d, J = 7,2 Hz, 3H, —CH_3); 2,52 (d de q, $J_1 = J_2$ = 7,2 Hz, 1H, —O_2CCH—); 3,68 (s, 3H, —$COOCH_3$); 3,71 (t, J = 6,5 Hz, 2H, —CH_2OH); 3,83–4,20 (m, 2H, —HCOCH—). *Anal.* calc. pour $C_{10}H_{18}O_4$: C 59,39, H 8,97; trouvée: C 59,21, H 8,97.

[2R[2α(R),5α]]-Tétrahydro-5-(2-oxoéthyl)-α-méthyl-2-furanacétate de méthyle (21*a*)*

A une solution de 226 mg (0,155 mL; 1,78 mmol) de chlorure d'oxalyle dans 2 mL de chlorure de méthylène agitée à −78°C sous atmosphère d'argon on ajoute 278 mg (0,252 mL; 3,56 mmol) de DMSO et après 5 min une solution de 180 mg (0,89 mmol) de **20***a* dans 8 mL de THF. On maintient à cette température pendant 20 min, ajoute 900 mg (1,23 mL; 8,9 mmol) de triéthylamine, enlève le bain réfrigérant après 5 min et garde sous agitation pendant une heure et demie. Le mélange réactionnel est alors hydrolysé et la phase aqueuse extraite par 3 × 30 mL de chlorure de méthylène. Les phases organiques réunies sont lavées avec respectivement 2 × 20 mL d'une solution à 2% d'HCl et 2 × 20 mL d'une solution à 2% de bicarbonate de sodium, puis traitées de façon habituelle. On isole après chromatographie sur gel de silice (éluant: cyclohexane/AcOEt, 75:25), 160 mg (90%) d'aldéhyde **21***a*; Eb: 70°C (0,03 Torr); R_f: 0,25 (cyclohexane/AcOEt, 50:50); $[\alpha]_D^{25}$ −26,3° (*c* 1,06, $CHCl_3$); ir ($CHCl_3$): 1090, 1730 cm^{-1}; ^1H rmn ($CDCl_3$) δ: 1,11 (d, J = 7,2 Hz, 3H, —CH_3); 3,68 (s, 3H, —$COOCH_3$); 3,9–4,48 (m, 2H, —HCOCH—); 9,82 (t, J = 1,3 Hz, 1H, —CHO).

[2R[2α(R),5α(S*)]] et [2R[2α(R*),5α(R*)]]-Tétrahydro-5-(2-hydroxypropyl)-α-méthyl-2-furanacétate de méthyle (3*a*) et (5*a*)*

A une suspension de 162 mg (0,79 mmol) du complexe $(H_3C)_2S \cdot CuBr$ (26) dans 2 mL de pentane sous agitation à −20°C et sous atmosphère d'argon on ajoute goutte à goutte 0,93 mL (1,5 mmol) d'une solution 1,62 *M* de méthyllithium dans l'éther.[5] Après 20 min à cette température, une solution de 70 mg (0,35 mmol) de **21***a* dans 3 mL d'un mélange 1:1 (v/v) d'éther et de pentane est ajouté au milieu réactionnel qui est alors maintenu pendant 3 h à une température comprise entre −20° et −10°C. La suspension est versée dans 10 mL d'une solution à pH 8 de NH_3/NH_4Cl. La phase aqueuse est extraite par 3 × 20 mL de CH_2Cl_2 et les phases organiques réunies traitées de façon habituelle. Après chromatographie sur gel de silice (éluant: cyclohexane/AcOEt, 70:30) on isole 29,9 mg (39,5%) de **3***a* et 34,2 mg (45%) de **5***a* ainsi que 3 mg d'un mélange de ces deux produits.

(2*R*,3*R*,6*S*,8*S*) Nonactate de méthyle (**3***a*): Eb: 90°C (0,025 Torr); R_f: 0,13 (cyclohexane/AcOEt, 50:50); $[\alpha]_D^{25}$ −20,7° (*c* 0,925, $CHCl_3$); ir ($CHCl_3$): 1090, 1180, 1205, 1285, 1395, 1450, 1475, 1740, 3000, 3535, cm^{-1}; ^1H rmn ($CDCl_3$) δ: 1,11 (d, J = 7,2 Hz, 3H, —O_2CCCH_3); 1,18 (d, J = 6,3 Hz, 3H, HOCCH_3); 2,50 (d de q, $J_1 = J_2$ = 7,2 Hz, 2H, —O_2CCH et OH); 3,67 (s, 3H, —OCH_3); ^1H rmn (CCl_4) δ: 1,08 (d, J = 7,2 Hz, 3H, —O_2CCCH_3); 1,12 (d, J = 6,3 Hz, 3H, HOCCH_3); 2,43 (d de q, $J_1 = J_2$ = 7,2 Hz, 1H, —O_2CCH); 3,60 (s, 3H, —OCH_3); ^{13}C rmn ($CDCl_3$): 175,1; 81,0; 65,2; 51,7; 45,3; 42,9; 30,1; 28,8; 23,2; 13,5. *Anal.* calc. pour $C_{11}H_{20}O_4$: C 61,09, H 9,32; trouvée: C 61,18, H 9,46.

(2*R*,3*R*,6*S*,8*R*) Nonactate de méthyle (**5***a*): Eb: 90°C (0,025 Torr); R_f: 0,17 (cyclohexane/AcOEt, 50:50); $[\alpha]_D^{25}$ −33° (*c* 1,18, $CHCl_3$), ir ($CHCl_3$): identique à **3***a*; ^1H rmn ($CDCl_3$) δ: 1,12 (d, J = 7,2 Hz, 3H, —O_2CCCH_3); 1,15 (d, J = 6,3 Hz, 3H, HOCCH_3); 2,50 (d de q, $J_1 = J_2$ = 7,2 Hz, 1H, —O_2CCH); 3,67 (s, 3H, —OCH_3); ^1H rmn (CCl_4) δ: 1,07 (d, J = 6,3 Hz, 3H, HOCCH_3); 1,09 (d, J = 7,2 Hz, 3H, —O_2CCCH_3); 2,45 (d de q, $J_1 = J_2$ = 7,2 Hz, 1H, —O_2CCH); 3,62 (s, 3H, —OCH_3). *Anal.* calc. pour $C_{11}H_{20}O_4$: C 61,09, H 9,32; trouvée: C 60,94, H 9,20.

Acide [2R[2α(R),5α(S*)]]-tétrahydro-5-(2-hydroxypropyl)-α-méthyl-2-furanacétique (2*a*)*

A 19 mg (0,087 mmol) d'ester **3***a* on ajoute 0,5 mL d'une solution aqueuse 2 *N* de KOH et agite magnétiquement 40 min à température ambiante. La solution est acidifiée jusqu'à pH 1,5 et évaporée à sec à température ambiante sous pression réduite. Le résidu est trituré et filtré sur verre fritté avec 3 × 50 mL de $CHCl_3$. Après évaporation du $CHCl_3$, l'acide brut est

For personal use only.

chromatographié sur gel de silice acide (éluant: cyclohexane/AcOEt, 50:50). On receuille 17 mg (96%) d'acide (−) nonactique (**2***a*); Eb: 130°C (0,003 Torr); R_f: 0,1 (cyclohexane/AcOEt/AcOH, 50:50:2). $[\alpha]_D^{25}$ −9,3°(*c* 1,0, $CHCl_3$); ir ($CHCl_3$): 1090, 1395, 1475, 1720, 2995, 3540 cm^{-1}; ^1H rmn ($CDCl_3$) δ: 1,15 (d, *J* = 7,2 Hz, 3H, —O_2CCCH_3); 1,20 (d, *J* = 6,3 Hz, 3H, HOCCH_3); 2,48 (d de q, $J_1 = J_2$ = 7,2 Hz, 1H, —O_2CCH); 6,39 (2H, OH); ^1H rmn (CCl_4) δ: 1,12 (d, *J* = 7,2 Hz, 3H, —O_2CCCH_3); 1,14 (d, *J* = 6,3 Hz, 3H, HOCCH_3); 2,43 (d de q, $J_1 = J_2$ = 7,2 Hz, 1H, —O_2CCH). *Anal.* calc. pour $C_{10}H_{18}O_4$: C 59,39, H 8,97; trouvée: C 59,23, H 8,98.

Acide [2R[2α(R),5α(R*)]]-tétrahydro-5-(2-hydroxypropyl)-α-méthyl-2-furanacétique (4*a)

On hydrolyse de la même façon 11,5 mg (0,051 mmol) de 8-*épi* nonactate de méthyle (**5***a*) et obtient après chromatographie sur gel de silice acide 10 mg (93%) d'acide (−) 8-*épi* nonactique (**4***a*); R_f: 0,12 (cyclohexane/AcOEt/AcOH, 50:50:2); $[\alpha]_D^{25}$ −50,1° (*c* 1,0, $CHCl_3$); ir ($CHCl_3$): 1090, 1395, 1435, 1475, 1770, 2995, 3350 cm^{-1}; ^1H rmn ($CDCl_3$) δ: 1,12 (d, *J* = 7,2 Hz, 3H, —O_2CCCH_3); 1,18 (d, *J* = 6,3 Hz, 3H, HOCCH_3); 2,47 (d de q, $J_1 = J_2$ = 7,2 Hz, 1H, —O_2CCH); 5,88 (2H, OH); ^1H rmn (CCl_4) δ: 1,09 (d, *J* = 7,2 Hz, 3H, —O_2CCCH_3); 1,14 (d, *J* = 6,3 Hz, 3H, HOCCH_3); 2,42 (d de q, $J_1 = J_2$ = 7,2 Hz, 1H, —O_2CCH). *Anal.* calc. pour $C_{10}H_{18}O_4$: C 59,39, H 8,97; trouvée: C 59,49, H 8,83.

Phénylméthyl 2,3:5,6-di-O-(1-méthyléthylidène)-(α et β)-D-gulofuranoside (23) et (23')

Obtenus à partir de 92 g (0,353 mol) de 2,3:5,6-di-*O*-(1-méthyléthylidène)-(α et β)-D-gulofuranose (27) suivant le mode opératoire permettant d'isoler les mannofuranosides correspondants (20). La chromatographie du mélange brut sur gel de silice (éluant: cyclohexane/AcOEt, 80:20) permet d'isoler 110 g d'anomère β qui recristallisé dans l'éther de pétrole fournit 106,2 g (86%) de **23**; F: 88–89°C (éther de pétrole); R_f: 0,4 (cyclohexane/AcOEt, 80:20); $[\alpha]_D^{25}$ −64,9° (*c* 1,03, acétone); ir ($CHCl_3$): 855, 1015, 1090, 1160, 1230, 1380, 1390, 1465, 2960, 3000 cm^{-1}; ^1H rmn ($CDCl_3$): 1,27; 1,40; 1,43 et 1,45 (4s, 12H, 2 $C(CH_3)_2$); 4,60 (AB, J_{AB} = 12 Hz, ν_{AB} = 20,8 Hz, 2H, —OCH_2Ph); 5,15 (s, 1H, OCHOCH_2Ph); 7,31 (s, 5H, C_6H_5—). *Anal.* calc. pour $C_{19}H_{26}O_6$: C 65,13, H 7,48; trouvée: C 64,99, H 7,38.

On isole de même 6 g (5%) d'α-glycoside **23'**: F: 86–87°C (CH_3OH/H_2O); R_f: 0,17 (cyclohexane/AcOEt, 80:20); $[\alpha]_D^{25}$ −63,4° (*c* 1,08, acétone); ir ($CHCl_3$): 860, 1030, 1080, 1120, 1175, 1230, 1385, 1390, 1465, 2960, 3020 cm^{-1}; ^1H rmn ($CDCl_3$) δ: 1,32; 1,38, 1,45 et 1,50 (4s, 12H, 2 $C(CH_3)_2$); 7,2–7,5 (m, 5H, C_6H_5—). *Anal.* calc. pour $C_{19}H_{26}O_6$: C 65,13, H 7,48; trouvée: C 65,06, H 7,39.

Phénylméthyl 2,3-O-(1-méthyléthylidène)-β-D-gulofuranoside (24)

Obtenu par hydrolyse partielle de 105,8 g (0,302 mol) de **23** suivant le mode opératoire permettant d'isoler l'α-mannofuranoside **8** correspondant (20). Après neutralisation le méthanol est évaporé sous pression réduite et le résidu versé dans 2 L de CH_2Cl_2. La phase organique est séparée et traitée de façon habituelle. On obtient 92,7 g (99%) de **24**. Un échantillon analytique est obtenu par recristallisation dans un mélange AcOEt/éther de pétrole; F: 137–138°C; R_f: 0,43 (EtOAc); $[\alpha]_D^{25}$ −96,3° (*c* 1,12, acétone); ir ($CHCl_3$): 990, 1015, 1095, 1175, 1230, 1385, 1390, 2960, 3030, 3550, 3620 cm^{-1}; ^1H rmn ($CDCl_3$) δ: 1,28 et 1,45 (2s, 6H, $C(CH_3)_2$); 4,58 (AB, J_{AB} = 12 Hz, ν_{AB} = 20,8 Hz, 2H, —OCH_2Ph); 5,15 (s, 1H, —OCHOCH_2Ph); 7,31 (s, 5H, C_6H_5—). *Anal.* calc. pour $C_{16}H_{22}O_6$: C 61,92, H 7,15; trouvée: C 61,89, H 7,09.

Phénylméthyl 2,3-O-(1-méthyléthylidène)-5,6-(N,N-diméthylaminométhylène)-β-D-gulofuranoside (26)

Même mode opératoire que pour le diastéréoisomère **10** à partir de 50,7 g (0,163 mol) de **24**; ^1H rmn ($CDCl_3$) δ: 1,26 et 1,43 (2s, 6H, $C(CH_3)_2$); 2,38 (s, 6H, —$N(CH_3)_2$); 5,13 (s, 1H, —OCHOCH_2Ph); 5,43, (s, 1H, $(H_3C)_2NCH$); 7,30 (s, 5H, C_6H_5).

*Phénylméthyl 2,3-O-(1-méthyléthylidène)-5,6-didéhydro-5,6-didéoxy-β-D-gulofuranoside (11*b)

Même mode opératoire que pour l'énantiomère **11***a* à partir du formamide acétal **26** brut. Obtenu: 34,15 g (75,5% à partir de **24**); F: 36,7–37,5°C (éther de pétrole à −20°C); $[\alpha]_D^{25}$ −54,4° (*c* 0,975, $CHCl_3$). *Anal.* calc. pour $C_{16}H_{20}O_4$: C 69,55, H 7,29; trouvée: C 69,50, H 7,19.

On isole de même 12,2 g (19%) de diacétate **25** qui est recyclé en **24** après réduction par $LiAlH_4$.

*Phénylméthyl 2,3-O-(1-méthyléthylidène)-5-déoxy-β-D-gulofuranoside (12*b)

Même mode opératoire que pour l'énantiomère **12***a*, à partir de 44 g (0,16 mol) de l'oléfine **11***b*. Obtenu: 44,4 g (95%); $[\alpha]_D^{25}$ −99,0° (*c* 1,0, $CHCl_3$). *Anal.* calc. pour $C_{16}H_{22}O_5$: C 65,29, H 7,53; trouvée: C 65,15, H 7,47.

*Phénylméthyl 2,3-O-(1-méthyléthylidène)-5-déoxy-6-O-méthoxyméthyl-β-D-gulofuranoside (13*b)

Le groupe protecteur MOM est plus efficacement introduit par réaction avec l'éther chlorométhylméthylique (cf. **13***a*) et le mode opératoire suivant (23), employé dans notre laboratoire avec succès sur des substrats étroitement apparentés à **12***b*, conduit avec ce composé à des rendements médiocres.

A une solution de 42 g (0,142 mol) de l'alcool **12***b* et 60 mL de $CH_2(OCH_3)_2$ dans 600 mL de CH_2Cl_2 on ajoute sous agitation et sur une période de 20 min 100 g d'un mélange 1:1 de P_2O_5 en poudre et de Celite. Après une heure le milieu réactionnel est versé dans 500 mL d'une solution à 10% de $NaHCO_3$ et extrait par 3 × 500 mL d'éther. Les phases éthérées réunies sont traitées de façon habituelle. Le produit brut chromatographié sur gel de silice (éluant: cyclohexane/AcOEt, 90:10) conduit à l'isolement de 19,3 g (40%) de **13***b*; $[\alpha]_D^{25}$ −88,5° (*c* 1,075, $CHCl_3$). *Anal.* calc. pour $C_{18}H_{26}O_6$: C 63,89, H 7,74; trouvée: C 64,04, H 7,77.

*2,3-O-(1-Méthyléthylidène)-5-déoxy-6-O-méthoxyméthyl-(α et β)-D-gulofuranose (14*b)

Même mode opératoire que pour l'énantiomère **14***a* à partir de 18,45 g (54 mmol) de **13***b*. Obtenu: 11,1 g (82%). *Anal.* calc. pour $C_{11}H_{20}O_6$: C 53,22, H 8,12; trouvée: C 53,24, H 8,10.

*Chlorure de 5-déoxy-2,3-O-(1-méthyléthylidène)-6-O-méthoxyméthyl-β-D-gulofuranosyle (15*b)

Même mode opératoire que pour le chlorure énantiomère **15***a* à partir de 1,97 g (7,93 mmol) de lactol **14***b*. Obtenu: 1,82 g (86%); $[\alpha]_D^{25}$ −92,8° (*c* 0.905, $CHCl_3$). *Anal.* calc. pour $C_{11}H_{19}O_5Cl$: C 49,54, H 7,18; trouvée: C 49,37, H 7,06.

*2S-cis-2-(β-Méthoxyméthylènoxyéthyl)-2,3-dihydro-3-hydroxyfurane (17*b)

Même mode opératoire que pour l'énantiomère **17***a* à partir de 1,8 g (6,75 mmol) du chlorure **15***b*. Obtenu: 1,095 g d'un mélange 10:1 (^1H rmn) de glycal **17***b* et de **16***b*, correspondant à un rendement de 82% en glycal **17***b*.

[2S[2α(R et S*),5α]]-2,5-Dihydro-5-(2-méthoxyméthylènoxyéthyl)-α-méthyl-2-furanacétate de méthyle (18*b)

Même mode opératoire que pour les énantiomères respectifs

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

correspondants **18***a* à partir de 1,09 g du mélange 10:1 précédent, correspondant à 5,5 mmol de glycal **17***b*.

[2S[2α(R),5α]] et [2S[2α(S*),5α]]-Tétrahydro-5-(2-méthoxyméthylènoxyéthyl)-α-méthyl-2-furanacétate de méthyle (**19**b) et (**19'**b)*

Obtenu par hydrogénation à pression atmosphérique d'une solution de l'ester insaturé brut précédent **18***b* dans 20 mL d'AcOEt en présence de 100 mg de Pt (5%) sur charbon pendant une demi-heure. Après filtration du catalyseur et traitement habituel de la phase organique, le produit brut est analysé par cpv (SE30 10%; *T*: 118°C). Le même chromatogramme que pour les énantiomères correspondants **19***a* et **19'***a* est obtenu, indiquant que la formation des diastéréoisomères **19***b* et **19'***b* s'est effectuée dans une proportion de 86:14. La chromatographie sur gel de silice (éluant: cyclohexane/AcOEt, 85:15) du produit brut conduit à l'isolement de 596 mg de l'ester **19***b* (44% à partir du glycal **17***b*); $[\alpha]_D^{25}$ +13,8° (*c* 0,995, $CHCl_3$). *Anal.* calc. pour $C_{12}H_{22}O_5$: C 58,52, H 9,00; trouvée: C 58,67, H 9,03.

On isole de même 66,3 mg (4,9% à partir du glycal **17***b*) de l'ester épimère en C-2, **19'***b*; $[\alpha]_D^{25}$ −33,8° (*c* 1,005, $CHCl_3$). *Anal.* calc. pour $C_{12}H_{22}O_5$: C 58,52, H 9,00; trouvée: C 58,27, H 8,90.

[2S[2α(R),5α]]-Tétrahydro-5-(2-hydroxyéthyl)-α-méthyl-2-furanacétate de méthyle (**20**b)*

Même mode opératoire que pour l'alcool énantiomère **19***a* à partir de 230 mg (0,93 mmol) de **19***b*. Obtenu: 179,5 mg (95%); $[\alpha]_D^{25}$ +26,0° (*c* 1,01, $CHCl_3$). *Anal.* calc. pour $C_{10}H_{18}O_4$: C 59,39, H 8,97; trouvée: C 59,47, H 8,86.

[2S[2α(R),5α]]-Tétrahydro-5-(2-oxoéthyl)-α-méthyl-2-furanacétate de méthyle (**21**b)*

Même mode opératoire que pour l'aldéhyde énantiomère **21***a* à partir de 160 mg (0,79 mmol) de l'alcool **20***b*. Obtenu: 144 mg (91%); $[\alpha]_D^{25}$ +28,9° (*c* 1,22, $CHCl_3$). *Anal.* calc. pour $C_{10}H_{16}O_4$: C 59,99, H 8.05; trouvée: C 60,03, H 8,02.

[2S[2α(R),5α(S*)]] et [2S[2α(R*),5α(R*)]]-Tétrahydro-5-(2-hydroxypropyl)-α-méthyl-2-furanacétate de méthyle (**3**b) et (**5**b)*

A une solution de 130 mg (0,65 mmol) d'aldéhyde **21***b* dans 5 mL d'éther anhydre agitée sous atmosphère d'argon à −78°C on ajoute à l'aide d'une seringue 5,5 mL (0,66 mmol) d'une solution 0,12 *M* de CH_3MgBr dans l'éther, préparée par dilution d'une solution commerciale 3 *M* dans l'éther.[4] Le milieu réactionnel est maintenu une demi-heure à −78°C, puis une heure et demie à une température comprise entre −60 et −50°C. On laisse finalement remonter la température jusqu'à −10°C, hydrolyse par une solution saturée de NH_4Cl et extrait la phase aqueuse avec 4 × 50 mL d'éther. Les phases éthérées réunies sont traitées de façon habituelle. La chromatographie du produit brut sur gel de silice (éluant: cyclohexane/AcOEt, 70:30) conduit à l'isolement de 13 mg d'aldéhyde **21***b* n'ayant pas réagi, 67,7 mg d'alcool **3***b* (53,5% calculé à partir de l'aldéhyde recouvré) et 51 mg d'alcool épimère **5***b* (40% calculé à partir de l'aldéhyde recouvré).

(2*S*,3*S*,6*R*,8*R*) Nonactate de méthyle (**3***b*): $[\alpha]_D^{25}$ +22,1° (*c* 0.7, $CHCl_3$). *Anal.* calc. pour $C_{11}H_{20}O_4$: C 61,09, H 9,32; trouvée: C 61,13, H 9,33.

ALFRED FISCHER, GEORGE N. HENDERSON, TREVOR A. SMYTH, FREDERICK W. B. EINSTEIN, and ROGER E. COBBLEDICK. Can. J. Chem. **59**, 584 (1981).

The higher melting isomer of 1,4-dimethyl-4-nitrocyclohexa-2,5-dienol has the (*E*)-configuration. The stereospecific interconversion of the dienols and the corresponding acetates and the stereospecific conversion of dienols to methyl ethers allow the assignment of the configurations of the isomeric acetates and ethers. Parallels in physical properties allow the assignment of the stereochemistry of the isomers of 1-alkyl-4-methyl-4-nitrocyclohexa-2,5-dienyl acetates (alkyl = Et, *i*-Pr, *t*-Bu) and of 1-alkyl-4-ethyl-4-nitrocyclohexa-2,5-dienyl acetates (alkyl = Me, Et).

ALFRED FISCHER, GEORGE N. HENDERSON, TREVOR A. SMYTH, FREDERICK W. B. EINSTEIN et ROGER E. COBBLEDICK. Can. J. Chem. **59**, 584 (1981).

L'isomère du diméthyl-1,4 nitro-4 cyclohexanediène-2,5 ol ayant le point de fusion le plus élevé a la configuration (*E*). L'interconversion stéréospécifique des diénols et des acétates correspondants ainsi que la conversion stéréospécifique des diénols en éthers méthyliques permettent d'établir les configurations des acétates et des éthers isomères. En établissant un parallèle entre les propriétés physiques, on peut attribuer la stéréochimie des isomères des acétates d'alkyl-1 méthyl-4 nitro-4 cyclohexadiene-2,5 yles (alkyl = Et, *i*-Pr, *t*-Bu) et des acétates d'alkyl-1 éthyl-4 nitro-4 cyclohexadiene-2,5 yles (alkyl = Me, Et).

[Traduit par le journal]

Introduction

Aromatic compounds containing an activated *ipso* position when nitrated in acetic anhydride give, as major products, nitronium acetate adducts (1–6). The 1,4-adducts are formed as diastereoisomeric pairs. Attempts to assign the configuration of the individual members of such pairs have met with limited success (7–11). In this paper we report the assignment of the configuration of the adducts of *p*-xylene, based on the determination of the structure of (*E*)-1,4-dimethyl-4-nitrocyclohexa-2,5-dienol,[2] by X-ray crystallography.

In our earlier work we attempted to assign the configuration of the adducts through shift-reagent studies. Addition of the shift reagent *tris*-(1,1,1,2,2,3,3-heptafluoro-7,7-[$^2H_6$]dimethyl-4,6-[$^2H_3$]-octanedionato)europium(III)(Eu([$^2H_9$]fod)$_3$), which complexes at the acetate function, might be expected to move the 4-methyl protons in the (*E*)-isomer, with these protons *cis* to europium, more rapidly downfield than in the case of the (*Z*)-isomer. The method is apparently successful in the case of secondary acetate adducts, such as those from toluene, in that there is a significant difference in the relative gradients of proton chemical shifts of the appropriate protons resulting from the addition of Eu([$^2H_9$]fod)$_3$ (7). However, in the case of the *p*-xylene adducts, and more generally for tertiary acetate adducts, the relative shift gradients of the appropriate protons in the diastereoisomers are not significantly different (8–11). Similarly inconclusive results were obtained when the shift study was repeated on the diastereoisomers of 1,4-dimethyl-4-nitrocyclohexa-2,5-dienol. A 23% difference was observed between the relative shift gradients of the 4-CH_3 protons in the diastereoisomers of the 1,4-dimethyl-4-nitrocyclohexadienyl methyl ethers. On this basis the isomer with the higher relative shift gradient[3] was suggested to have the 1-methoxyl group *cis* to the 4-CH_3 (i.e. the (*E*)-diastereoisomer). However, in view of the failure of the method when applied to the corresponding dienols and dienyl acetates, it was suggested that this assignment could only be regarded as tentative (8). In this earlier work the relative configurations of the dienols and acetates were established: ace-

tate **8–1***a* and alcohol **8–2***a* have the same configurations, as do their diastereoisomers **8–1***b* and **8–2***b*. However, the configurational relationship between the ethers **8–3***a* and **8–3***b* and the alcohols **8–2***a* and **8–2***b* or acetates **8–1***a* and **8–1***b* was not determined and the tentative assignment of the configurations of the ethers did not provide even a tentative assignment of the configuration of the alcohols and acetates.

Myhre and co-workers have developed a method of synthesis of the 1,4-dialkyl-4-nitrocyclohexadienols by addition of methyllithium to a 4-alkyl-4-nitrocyclohexadienone, and of 4-alkyl-4-nitrocyclohexadienols by reduction of the nitrodienone with sodium borohydride (12). They point out that these reactions are moderately stereoselective and the predominant isomer, assumed to be the (*Z*)-isomer on the basis of an addition *trans* to the nitro group being preferred as a consequence of both steric and field effects of the latter, is the diastereoisomer which, as the acetate, is formed in smaller amount in the nitration reaction. For secondary acetate adducts the assignments based on the shift-reagent studies are in accord with those based on the nitrodienone reduction (12).

Shosenji *et al.* have recently assigned the configurations of the 1,4-dimethyl-4-nitrocyclohexadienyl methyl ethers by infrared spectroscopy (13). They reacted the nitro group in the ethers with methylmagnesium iodide and with methylmagnesium iodide in the presence of cuprous chloride to give the *N*-methylhydroxylamine and the hydroxylamine derivatives, respectively. They observed a band attributed to intramolecular hydrogen bonding between the *cis* hydroxylamine and methoxyl functions in one diastereoisomer (that obtained from compound **3***b* of ref. 8) of each pair.

On this basis they assigned the (*Z*)-configuration to **3***b* (*cis* methoxy and nitro groups) and observed that this was in conflict with the assignment based on shift-reagent studies.

Results and Discussion

Nitration of *p*-xylene in acetic anhydride at −40°C resulted in the formation of the diastereoisomers of 1,4-dimethyl-4-nitrocyclohexa-2,5-dienyl acetate in yields close to 90%. The predominant isomer **8–1***a*, shown below to be the (*E*)-isomer and constituting ca. 70% of the diene component, was crystallized from the crude product and obtained pure. The two diastereoisomers were also separated by low-temperature chromatography, as previously described (8). The nitrocyclohexadienyl acetates were stereospecifically reduced to the corresponding nitrocyclohexadienols with aluminium hydride and the dienols were stereospecifically methylated to the methyl ethers, thus establishing the configurational relationships between the diastereoisomers of the acetates, alcohols, and ethers.[4] In the 2,6-dideuterionitrocyclohexadienols (below) the (*Z*)-diastereoisomer was stereospecifically acetylated to the corresponding acetate and methylated to the corresponding ether, confirming the configurational relationships.

The nmr shift-reagent studies and chemical shift correlations (below) required the unambiguous assignment of the spectra of the adducts. We therefore synthesized the 2,6-dideuterio-1,4-dimethyl-4-nitrocyclohexa-2,5-dienols by addition of methyllithium to 2,6-dideuterio-4-methyl-4-nitrocyclohexa-2,5-dienone. The dienone was itself prepared from 2,6-dideuterio-4-methylphenol via the nitration of the corresponding aryl acetate (cf. refs. 12 and 14). The diastereoisomeric dideuteriocyclohexadienols were separated by high pressure liquid chromatography. In the proton decoupled ^{13}C nmr spectra of the (*E*)- and (*Z*)-deuteriocyclohexadienols, the (*Z*)-acetate, and the (*Z*)-ether, the C-2 and C-6 absorption was readily identified as a triplet, resulting from C–D coupling. In each of the four spectra the (triplet) C-2 and C-6 absorption occurs at lower field than the (singlet) C-3 and C-5 absorption and we assume that this is also the case in the (*E*)-acetate and (*E*)-ether and in other 1,4-dialkyl-

[4]Previously the ethers had been obtained by solvolysis (acid-catalysed methanolysis) of the acetates, a nonstereospecific process (8).

4-nitrocyclohexadienyl acetates. In previous work (10, 11) the vinyl carbons closer to the nitro group (C-3 and C-5) have been assumed to absorb at lower field than the vinyl carbons closer to the acetate group (C-2 and C-6). This assumption is clearly incorrect in the case of the dienes derived from *p*-xylene and is most probably incorrect for the dienes derived from other 1,4-dialkylbenzenes.

The ^{1}H nmr absorptions of the vinyl protons adjacent to the nitro group (3-H and 5-H) in the 1,4-dimethyl- 4-nitrocyclohexadiene adducts were also assigned unambiguously from the ^{1}H nmr spectra of the dideuteriodienes. The absorptions of the other vinyl protons (2-H and 6-H) were then assigned from the spectra of the undeuterated compounds. In the dienols, 2-H and 6-H absorb at lower field than 3-H and 5-H. In the dienyl acetates the absorptions are superimposed and in the dienyl methyl ethers 2-H and 6-H absorb at higher field than 3-H and 5-H. The chemical shifts of the vinyl protons of the dienols were incorrectly assigned in the earlier report (8).

A perspective view of the higher melting isomer of 1,4-dimethyl-4-nitrocyclohexa-2,5-dienol, derived from the parameters obtained in the X-ray structure analysis, is shown in Fig. 1. The cyclohexadiene ring is "chemically" planar, the deviations of C-1 and C-4 being 0.03(3) and 0.08(3) Å towards the same side (making the conformation a marginal boat). The methyl groups are *trans*; the molecule has the (*E*)-configuration. The molecules are linked in a spiral fashion along the three-fold screw axis by hydrogen bonding (O.....O 2.75 Å) involving the hydroxyl group. The crystals were of relatively poor quality and we associate this with the disordered diethyl ether molecules of crystallization which lie in channels parallel to *C*.

The configurational relationships previously established between acetate and dienol and confirmed in this paper and those now established between dienol and methyl ether, when combined with the X-ray analysis result, lead to the conclusions that the lower melting acetate with the more widely dispersed 1- and 4-methyl peaks in the ^{1}H nmr spectrum ($\Delta\delta$ = 0.34 ppm) has the (*E*)-configuration, as does the higher melting alcohol and as does the ether with higher field methoxyl group. Thus the compounds **1***a*, **2***a*, and **3***b* of ref. 8 are (*E*)-isomers and correspondingly **1***b*, **2***b*, and **3***a* are (*Z*)-isomers. In the case of the ethers this is the opposite assignment to that made by Shosenji *et al.* (13) but, perhaps fortuitously, it is the same as the tentative assignment based on shift-reagent studies (8). In the case of the dienols it is the same assignment as that suggested by Myhre and co-workers (12). Shosenji *et al.* reported that the photosolvolysis of **8–1***a* in methanol is significantly stereoselective, with 70% **8–3***a* and 30% **8–3***b* being obtained. Similarly **8–1***b* gives 70% **8–3***b* and 30% **8–3***a*, i.e. the photosolvolysis results in predominant inversion (15). They misassigned the stereochemistry of the diastereoisomers of both the acetates and the ethers, thus, fortuitously, making their conclusion valid.

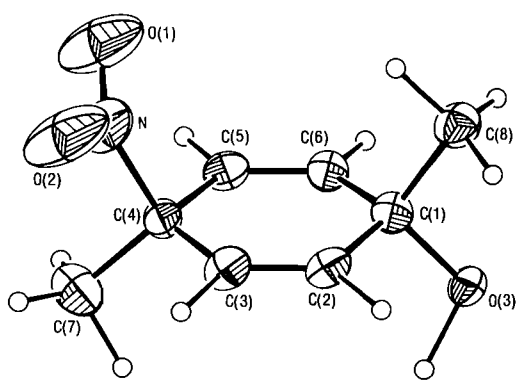

FIG. 1. Perspective view of (*E*)-1,4-dimethyl-4-nitrocyclohexa-2,5-dienol.

We have also made a ^{13}C nmr shift-reagent study, using Eu([$^2H_9$]fod)$_3$, of the 1,4-dimethyl-4-nitrocyclohexa-2,5-dienyl acetates and dienols and some related 1-alkyl-4-methyl-4-nitrocyclohexa-2,5-dienyl acetates. Results are given in Table 1. In the case of the dimethyldienyl acetates the relative shift gradient of the 4-CH_3 carbon atom in the (*E*)-isomer (**8–1***a*) is twice that of the same carbon atom in the (*Z*)-isomer (**8–1***b*), in accord with expectations. The relative shift gradients are less differentiated for the other pairs of corresponding carbon atoms in the two isomers. In the cases of the *a* isomers of 1-ethyl-4-methyl-4-nitrocyclohexadienyl acetate (**10–2**) and 1-isopropyl-4-methyl-4-nitrocyclohexadienyl acetate (**9–1**) the relative shift gradient of the 4-CH_3 carbon atom is likewise twice that of the same carbon in the *b* isomers (for the pairs of diastereoisomeric acetates the *a* isomer is that which is eluted first on chromatography). We therefore conclude that the *a* isomers all have the *E*-configuration. It is also to be noted that the shift gradient of C-4 is consistently smaller in the *a* isomers than in the *b* isomers.

Table 2 shows ^{13}C chemical shifts for the diastereoisomers of the 1-alkyl-4-methyl-4-nitrocyclohexa-2,5-dienyl acetates (**8–1**, **10–2**, **9–1**, and **11–2**) and the 4-ethyl-1-methyl- (**10–1**) and 1,4-diethyl-4-nitrocyclohexa-2,5-dienyl acetates (**10–3**). For each pair of diastereoisomers that diastereoisomer eluted first on chromatography is desig-

[a]Assignments reversed from those reported earlier (10, 11).[6]
[b]Assignments for 1-CH_2CH_3 and 4-CH_2CH_3 may be reversed.

nated as the *a* isomer. In the *a* isomers of the 1-alkyl-4-methyl series the chemical shift of the 4-methyl group is 25.5 ± 0.4 ppm, 2 ppm less than the chemical shift of the same group in the *b* isomers (27.6 ± 0.5 ppm). The chemical shift of the C-4 atom is 84.9 ± 0.3 ppm in the *a* isomers, 2 ppm larger than that of the same atom in the *b* isomers (82.6 ± 0.2). These differences are certainly significant and are consistent with the existence of a common stereochemical relationship between the *a* isomers, on the one hand, and the *b* isomers, on the other. This conclusion is buttressed by other parallels in the physical properties of *a* isomers versus *b* isomers. In the ^{13}C spectra the chemical shifts of C-1 and C-2 are larger and that of C-3 is smaller in *a* isomers than in *b* isomers. In the ^1H nmr spectrum (Table 3) the chemical shift of the 4-CH_3 protons in the *a* isomers (δ 1.78 ppm) is significantly larger than that of the corresponding protons in the *b* isomers (1.71 ppm). The chemical shift of the acetate methyl group is larger and those of the 2- and 3-protons are smaller in the *a* isomers than in the *b* isomers. The chemical shift of the 1′-H in the alkyl group is smaller in the *a* isomers than in the *b* isomers. The *a* isomers also have lower melting points than the *b* isomers. Some of the individual differences of cited physical properties between *a* and *b* isomers are probably not significant. Collectively the trends are unmistakable. Clearly, all *a* isomers have some fundamental similarity which distinguishes them from *b* isomers and this can only be a common stereochemistry. The *a* isomers must therefore have the *E*-configuration and the *b* isomers must have the *Z*.

The relationships between the physical properties of *a* and *b* isomers identified in the 1-alkyl-4-methyl-4-nitrocyclohexadienyl acetate series also extend to the 1-alkyl-4-ethyl-4-nitrocyclohexadienyl acetate series (**10–1** and **10–3**). Again the *a* isomers are those which are eluted first on chromatography. The 4-ethyl-1-methyl compounds were obtained crystalline and the *a* isomer was the lower melting. In the ^{13}C nmr spectra (Table 2) the chemical shifts of C-1, C-2, and C-4 are larger, and of C-3 and 4-CH_2CH_3 are smaller in the *a* isomers. In addition the chemical shift of 4-CH_2CH_3 is smaller in the *a* isomers. In the ^1H nmr spectra (Table 3) the chemical shifts of 2-H, 3-H, and 1′-H of 1-alkyl, are all smaller and those of the acetate methyl and 4-CH_2CH_3 are larger in the *a* isomers. In addition the shifts of 4-CH_2CH_3 are also larger in the *a* series. The exactly parallel

[a]Previously reported as 7.03 (11).
[b]Previously reported as 7.04 (11).
[c]Previously reported as 7.34 (11).

trends of the physical properties in the 4-ethyl series, with that of the 4-methyl series, argues for the same fundamental similarity between *a* isomers in both series, i.e. the *a* isomers in both series have the (*E*)-configuration. For the 4-ethyl compounds this assignment is the same as that made in the previous work on the basis of a shift reagent study of the terminal protons of the 4-ethyl group (10).

In contrast to the situation in the acetates the relative shift gradients for 4-CH_3 in the isomeric dienols **8–2***a* and **8–2***b* are not significantly different (Table 1). We have also examined the ^{13}C and ^{1}H nmr data for the pairs of isomeric 1-alkyl-4-methyl-4-nitrocyclohexa-2,5-dienols, 1-ethyl- and 1-methyl-4-ethyl-4-nitrocyclohexa-2,5-dienols, and some of their methyl ethers. Although there appear to be some systematic differences in the nmr data of diastereoisomers in these series, which can presumably be related to the stereochemistry, these differences appear to be too small to be of value for the assignment of unknown stereochemistry.

Experimental

General experimental methods have been described previously (8, 16). 4-Methylphenol and 1,4-dimethylbenzene were from Aldrich. 4-Methylphenyl acetate was prepared by acetylation of the phenol (17). 4-Methyl-4-nitrocyclohexa-2,5-dienone was prepared by nitration of the acetate in acetic anhydride at −15°C (12, 18) (the reaction mixture was prepared at −78°C and then warmed to −15°C). On slow addition of methanol at −78°C the nitrodienone was precipitated (12). After recrystallization from methanol the colourless crystals had mp 43–45°C; ^{1}H nmr ($CDCl_3$, −20°C) δ: 1.96 (s, 3, CH_3), 6.43 (d, J = 10 Hz, 2-*H* and 6-*H*), 7.19 (d, J = 10 Hz, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$, −40°C) δ_C: 25.7 (4-*C*H_3), 84.2 (*C*-4), 130.1 (*C*-2 and *C*-6), 143.4 (*C*-3 and *C*-5), 184.1 (*C*-1) ppm. 2,6-Dideuterio-4-methylphenol was obtained by deuteration of 4-methylphenol (10.8 g, 0.1 mol) by refluxing a solution in D_2O (100 g) with PBr_3 (8 cm^3, 0.08 mol) for 5 h (cf. ref. 19). 2,6-Dideuterio-4-methylphenol constituted over 90% of the isolated phenol (nmr) and had mp 31–32°C; ir (KBr): 3310 and 1240 (OH), 2260 (C—D), 2920 (CH_3) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.24 (s, 3, CH_3), 5.07 (s, 1, O*H*), 7.03 (s, 2, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 20.4 (4-*C*H_3), 115.1 (t, J_{CD} = 24.1 Hz, *C*-2 and *C*-6), 130.1 (*C*-3 and C-5), 130.1 (*C*-4), 152.8 (*C*-1) ppm. Acetylation (17) of the dideuteriophenol gave 2,6-dideuterio-4-methylphenyl acetate as an oil, ir (film): 2300 (C—D), 1765, 1220 and 1060 (OCOCH_3) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.20 (s, 3, 4-CH_3), 2.28 (s, 3, OCOCH_3), 7.14 (s, 2, 3-*H* and 5-*H*) ppm. Nitration of the 2,6-dideuterio-4-methylphenyl acetate gave 2,6-dideuterio-4-methyl-4-nitrocyclohexa-2,5-dienone as colourless crystals, mp 43–45°C; ir ($CDCl_3$): 2340 (C—D), 1670 (C=O), 1555 and 1340 (NO_2) cm^{-1}; ^{1}H nmr ($CDCl_3$, −20°C) δ: 1.96 (s, 3, CH_3), 7.21 (s, 2, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$, −40°C) δ_C: 25.8 (4-*C*H_3), 84.0 (*C*-4), 129.8 (t, J_{CD} = 26.1 Hz, *C*-2 and *C*-6), 143.0 (*C*-3 and *C*-5), 184.1 (*C*-1) ppm.

Diastereoisomers of 1,4-Dimethyl-4-nitrocyclohexa-2,5-dienyl Acetate

These were prepared by nitration of *p*-xylene in acetic anhydride at −40°C (2, 8). The diene adducts constituted ca. 88% of the nitration products with the (*E*)-isomer (ca. 70% of the diene component) being predominant. Crystallization of the crude nitration product from ether–pentane (1:5 v/v) gave (*E*)-1,4-dimethyl-4-nitrocyclohexa-2,5-dienyl acetate (**8–1***a*). After a second recrystallization the (*E*)-isomer was obtained as colourless crystals and had mp 50–52°C; ir (KBr): 1740, 1250 and 1060 (OCOCH_3), 1535 and 1345 (NO_2) cm^{-1}; ^{1}H nmr ($CDCl_3$, 0°C) δ: 1.43 (s, 3, 1-CH_3), 1.77 (s, 3, 4-CH_3), 1.97 (s, 3, OCOCH_3), 6.07 (s, 4, 2-*H*, 3-*H*, 5-*H*, 6-*H*) ppm; ^{13}C nmr ($CDCl_3$, 0°C) δ_C: 21.7 (OCO*C*H_3), 25.2 (4-*C*H_3), 27.1 (1-*C*H_3), 73.2 (*C*-1), 84.9 (*C*-4), 126.1 (*C*-3 and *C*-5), 133.6 (*C*-2 and *C*-6), 169.6 (O*C*OCH_3) ppm.[5] Chromatography of the crude nitration product at −40°C on 3% deactivated alumina and elution with ether–pentane gave the (*E*)-isomer in the earlier fractions and the (*Z*)-isomer in the later fractions. (*Z*)-1,4-Dimethyl-4-nitrocyclohexa-2,5-dienyl acetate (**8–1***b*) was obtained as colourless crystals on recrystallization from ether–pentane and had mp 57–60°C; ir (KBr): 1725, 1245

[5]The absorptions of the vinyl carbons of the (*Z*)-2,6-dideuterio dienyl acetate (below) could be assigned unambiguously. The carbons at positions 3 and 5 absorb at higher field than those at positions 2 and 6. The same assignment applies to the (*Z*)-dienyl acetate and is assumed to apply to its (*E*)-isomer. In the shift-reagent studies the higher field vinyl carbons move more slowly downfield than the lower field ones. This also suggests that the higher field carbon atoms are there at positions 3 and 5. Assignment of the 1-CH_3 absorptions is based on the assumption that the 1-CH_3 peak is the one which moves downfield more rapidly in the shift-reagent study.

and 1065 ($OCOCH_3$), 1535 and 1340 (NO_2) cm^{-1}; ^1H nmr ($CDCl_3$, 0°C) δ: 1.46 (s, 3, 1-CH_3), 1.70 (s, 3, 4-CH_3), 1.96 (s, 3, $OCOCH_3$), 6.19 (s, 4, 2-*H*, 3-*H*, 5-*H*, 6-*H*) ppm; ^{13}C nmr ($CDCl_3$, 0°C) δ_C: 21.8 ($OCOCH_3$), 27.0 (1-CH_3), 27.8 (4-CH_3), 73.0 (*C*-1), 82.4 (*C*-4), 126.3 (*C*-3 and *C*-5), 132.7 (*C*-2 and *C*-6), 169.7 ($OCOCH_3$) ppm.[5]

Diastereoisomers of 1,4-Dimethyl-4-nitrocyclohexa-2,5-dienol and 2,6-Dideuterio-1,4-dimethyl-4-nitrocyclohexa-2,5-dienol

A solution of (*E*)-dienyl acetate (30 g, 0.14 mol) in dry tetrahydrofuran (60 cm^3) was added with stirring to a solution of aluminium hydride (~ 0.28 mol) in tetrahydrofuran (850 cm^3) at −40°C under an argon atmosphere (20). The mixture was warmed to 0°C, then cooled to −40°C and excess hydride decomposed by dropwise addition of water (150 cm^3). After work-up (*E*)-1,4-dimethyl-4-nitrocyclohexa-2,5-dienol (**8–2***a*) was obtained in quantitative yield. After recrystallization (× 2) from ether–pentane a sample was sublimed at 50°C/20 Pa and had mp 107–108°C; ir (KBr): 3270 (OH), 1540 and 1335 (NO_2) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.35 (s, 3, 1-CH_3), 1.73 (s, 3, 4-CH_3), 2.06 (s, 1, O*H*), 5.98 (d, 2, *J* = 10 Hz, 3-*H* and 5-*H*), 6.12 (d, 2, *J* = 10 Hz, 2-*H* and 6-*H*) ppm; ^{13}C nmr ($CDCl_3$, 0°C) δ_C: 26.7 (4-CH_3), 27.7 (1-CH_3), 65.4 (*C*-1), 83.8 (*C*-4), 125.0 (*C*-3 and *C*-5), 137.5 (*C*-2 and *C*-6) ppm.[6]

Reduction of the (*Z*)-nitrodienyl acetate gave the (*Z*)-nitrodienol **8–2***b* which after recrystallization from ether–pentane had mp 50–52°C; ir (KBr): 3270 (OH), 1540 and 1340 (NO_2) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.30 (s, 3, 1-CH_3), 1.67 (s, 3, 4-CH_3), 2.29 (s, 1, O*H*), 5.99 (d, 2, *J* = 10 Hz, 3-*H* and 5-*H*), 6.07 (d, 2, *J* = 10 Hz, 2-*H* and 6-*H*) ppm; ^{13}C nmr ($CDCl_3$, 0°C) δ_C: 27.1 (4-CH_3), 27.8 (1-CH_3), 64.9 (*C*-1), 83.7 (*C*-4), 125.1 (*C*-3 and *C*-5), 136.7 (*C*-2 and *C*-6) ppm.[6]

The (*E*)- and (*Z*)-nitrodienols were also prepared by addition of methyllithium to 4-nitro-4-methylcyclohexa-2,5-dienone (12). The product mixture contained the (*E*)- and (*Z*)-isomers in a 1:4 ratio and these were separated by high-pressure liquid chromatography at 0°C on silica using ether as eluant. The predominant product, the (*Z*)-isomer, was eluted first.

The 2,6-dideuterionitrodienols were similarly prepared in 95% yield by the addition of methyllithium to 2,6-dideuterio-4-methyl-4-nitrocyclohexa-2,5-dienone. The ratio of (*E*)-isomer: (*Z*)-isomer was ca. 1:3 and the isomers were separated by hplc. (*Z*)-2,6-Dideuterio-1,4-dimethyl-4-nitrocyclohexa-2,5-dienol, eluted first, was recrystallized from ether–pentane as colourless needles, mp 51–52°C; ir (KBr): 3270 (OH), 2260 (C—D), 1540 (NO_2) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.27 (s, 3, 1-CH_3), 1.66 (s, 3, 4-CH_3), 3.16 (s, 1, O*H*), 6.01 (s, 2, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$, 0°C) δ_C: 27.2 (4-CH_3), 27.8 (1-CH_3), 64.7 (*C*-1), 83.5 (*C*-4), 124.6 (*C*-3 and *C*-5), 136.3 (t, J_{CD} = 24.9 Hz, *C*-2 and *C*-6) ppm. (*E*)-2,6-Dideuterio-1,4-dimethyl-4-nitrocyclohex-2,5-dienol was obtained as colourless needles from ether–pentane and had mp 107–109°C; ir (KBr): 3270 (OH), 2260 (C—D), 1535 and 1335 (NO_2) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.35 (s, 3, 1-CH_3), 1.73 (s, 3, 4-CH_3), 2.08 (s, 1, O*H*), 5.99 (s, 2, 3-H and 5-H) ppm; ^{13}C nmr ($CDCl_3$, 0°C) δ_C: 26.8 (4-CH_3), 27.8 (1-CH_3), 65.4 (*C*-1), 83.9 (*C*-4), 125.1 (*C*-3 and C-5), 137.2 (t, J_{CD} = 24.4 Hz, *C*-2 and *C*-6) ppm.

Diastereoisomers of 1,4-Dimethyl-4-nitrocyclohexa-2,5-dienyl Methyl Ether; (Z)-2,6-Dideuterio-1,4-dimethyl-4-nitrocyclohexa-2,5-dienyl Methyl Ether

A mixture of (*E*)-nitrodienol (1.7 g, 10 mmol), moist silver oxide (~ 6.8 g, 29 mmol), methyl iodide (27.8 g, 196 mmol), and potassium hydroxide (0.19 g, 3.4 mmol) was stirred at ambient temperature for 5 h (cf. ref. 21). Chloroform was added and the insoluble material filtered off. The filtrate was dried ($MgSO_4$) and refiltered. The chloroform was evaporated under reduced pressure to yield the (*E*)-nitrodienyl methyl ether **8–3***b* as an oil, ir (film): 1545 and 1340 (NO_2), 2825 and 1095 (OCH_3) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.32 (s, 3, 1-CH_3), 1.74 (s, 3, 4-CH_3), 3.03 (s, 3, OCH_3), 5.92 (d, 2, *J* = 10 Hz, 2-*H* and 6-*H*), 6.17 (d, 2, *J* = 10 Hz, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$, 0°C) δ_C: 26.7 and 27.2 (1-$CH_3$and 4-CH_3), 52.0 (1-OCH_3), 70.7 (*C*-1), 84.0 (*C*-4), 128.3 (*C*-3 and *C*-5), 135.7 (*C*2 and *C*-6) ppm.

Methylation of the (*Z*)-nitrodienol by the above procedure afforded the (*Z*)-nitrodienyl methyl ether **8–3***a* as an oil, ir (film): 1545 and 1340 (NO_2), 2830 and 1100 (OCH_3) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.28 (s, 3, 1-CH_3), 1.70 (s, 3, 4-CH_3), 3.08 (s, 3, OCH_3), 5.90 (d, 2, *J* = 10 Hz, 2-*H* and 6-*H*), 6.22 (d, 2, *J* = 10 Hz, 3-*H* and 5-*H*) ppm; ^1H nmr (CCl_4) δ: 1.22, 1.67, 3.02, 5.83 (d), 6.17 (d) pm; ^{13}C nmr ($CDCl_3$, 0°C) δ_C: 27.3 and 27.7 (1-CH_3 and 4-CH_3), 52.4 (1-OCH_3), 70.1 (*C*-1), 83.3 (*C*-4), 128.2 (*C*-3 and *C*-5), 135.0 (*C*-2 and *C*-6) ppm.

Methylation of the (*Z*)-2,6-dideuteronitrodienol gave the (*Z*)-dideuteronitrodienyl methyl ether as an oil, ir (film): 2250 (C—D), 1545 and 1340 (NO_2), 2830 and 1100 (OCH_3) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.28 (s, 3, 1-CH_3), 1.70 (s, 3, 4-CH_3), 3.08 (s, 3, OCH_3), 6.22 (s, 2, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$, −5°C) δ_C: 27.3 and 27.7 (1-CH_3 and 4-CH_3), 52.5 (1-OCH_3), 70.0 (*C*-1), 83.3 (*C*-4), 128.2 (*C*-3 and *C*-5), 134.6 (t, J_{CD} = 24.9 Hz, *C*-2 and *C*-6) ppm.

(Z)-2,6-Dideuterio-1,4-dimethyl-4-nitrocyclohexa-2,5-dienyl Acetate

The (*Z*)-dideuteronitrodienol (0.4 g, 2.3 mmol) was stirred for 52 h at 35°C with acetic anhydride (2.4 cm^3) and [$^2H_5$]pyridine (0.27 mm^3, 3.5 mmol). Cold ether (50 cm^3) was added, the organic layer was washed with ice water (5 × 50 cm^3), dried ($MgSO_4$), and the ether evaporated to afford an oil (0.37 g) containing 83 mol% of the acetate. Recrystallization from ether–pentane gave colourless crystals, mp 60–61.5°C; ir (film): 2260 (C—D), 1740, 1245 and 1065 ($OCOCH_3$), 1545 and 1340 (NO_2) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.47 (s, 3, 1-CH_3), 1.69 (s, 3, 4-CH_3), 1.94 (s, 3, $OCOCH_3$), 6.21 (s, 2, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$, 0°C) δ_C: 21.8 ($OCOCH_3$), 26.9 (1-CH_3), 27.8 (4-CH_3), 72.9 (*C*-1), 82.4 (*C*-4), 126.2 (*C*-3 and *C*-5), 132.4 (t, J_{CD} = 24.0 Hz, *C*-2 and *C*-6) ppm.

Structure Determination of (E)*-1,4-Dimethyl-4-nitrocyclohexa-2,5-dienol*

$C_8H_{11}NO_3 \cdot C_4H_{10}O$ f.w. = 243.3

Rhombohedral, space group $R\bar{3}$ (or R3) hexagonal cell *a* = 30.21(1), *c* = 5.848(2) Å, *U* = 4622 $Å^3$, *Z* = 18, ρ_o = 1.57, ρ_c ~ 1.5 (flotation), 18°C, MoKα_1 = 0.70930 Å, μ = 1.4 cm^{-1}.

A crystal of dimensions 0.25 × 0.30 × 0.40 mm was used to collect the 650 independent reflections measured ($2\theta \leq 35°$), of which 463 were observed ($I > 2.3\sigma$), on a Picker FACS-I diffractometer. The structure was determined by direct methods and refined by full-matrix least-squares techniques to $R = 7.0\%$ (assuming space group $R\bar{3}$). ($R = \sum||F_o| - |F_c||/\sum|F_o|$.) The model used did not include hydrogen atoms for the solvent molecule and a final electron-density difference map indicated the major discrepancies were in the solvent area.

Silver(I) complexes of 4,6-dimethylpyrimidine-2(1*H*)-thione

RAFFAELE BATTISTUZZI AND GIORGIO PEYRONEL
Istituto di Chimica Generale e Inorganica, University of Modena, 41100 Modena, Italy

Received July 11, 1980

RAFFAELE BATTISTUZZI and GIORGIO PEYRONEL. Can. J. Chem. **59**, 591 (1981).

The following silver(I) complexes of 4,6-dimethylpyrimidine-2(1*H*)-thione (HL) have been prepared and investigated by conductometric, infrared, and Raman methods: $Ag(HL)X$ (X = Cl, Br, I, SCN), $Ag(HL)_2X$ (X = Cl, Br, I, NO_3 (MeOH), ClO_4 ($0.25CHCl_3$), BF_4 ($0.25CHCl_3$)), $Ag_mX_n(H_2L)_{n-m}$ (X = Cl: $m = 6$, $n = 11$; Br: $m = 2$, $n = 3$; I: $m = 5$, $n = 7$), AgL, $AgL \cdot Ag(HL)NO_3$, $AgL \cdot [Ag(HL)X]_2$ (X = ClO_4, BF_4). The HL acts as N,S-chelating ligand in the $Ag(HL)X$ and $Ag(HL)_2X$ (X = NO_3, ClO_4, BF_4) complexes and partially in the $Ag(HL)_2X$ (X = Cl, Br, I) complexes in which the halide ion is still coordinated. In the $Ag_mX_n(H_2L)_{n-m}$ complexes the H_2L^+ ion is at least partially S-coordinated to some silver ions. In AgL, L^- acts as tridentate ligand N,N,S-bridging the silver ions. In the $AgL \cdot Ag(HL)NO_3$ complex the nitrate ion is coordinated.

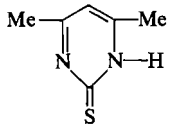
RAFFAELE BATTISTUZZI et GIORGIO PEYRONEL. Can. J. Chem. **59**, 591 (1981).

On a préparé et étudié par conductimètrie et par la spectroscopie Raman et infrarouge, les complexes suivants de l'argent(I) avec la diméthyl-4,6 1H-pyrimidinethione-2 (HL): $Ag(HL)X$ (X = Cl, Br, I, SCN), $Ag(HL)_2X$ (X = Cl, Br, I, NO_3 (MeOH), ClO_4 ($0.25CHCl_3$), BF_4 ($0.25CHCl_3$)), $Ag_mX_n(H_2L)_{n-m}$ (X = Cl: $m = 6$, $n = 11$; Br: $m = 2$, $n = 3$; I: $m = 5$, $n = 7$), AgL, $AgL \cdot Ag(HL)NO_3$, $AgL \cdot [Ag(HL)X]_2$ (X = ClO_4, BF_4). Le HL agit comme un ligand chélatant N—S dans les complexes $Ag(HL)X$ et $Ag(HL)_2X$ (X = NO_3, ClO_4, BF_4) et partiellement dans les complexes $Ag(HL)_2X$ (X = Cl, Br, I) ou l'ion halogénure est encore coordonné. Dans les complexes de $Ag_mX_n(H_2L)_{n-m}$, l'ion H_2L^+ est au moins coordonné par le soufre à quelques ions d'argent. Dans AgL, L^- agit comme un ligand tridentate dans lequel N,N,S forment un pont entre les ions argent. Dans le complexe $AgL \cdot Ag(HL)NO_3$, l'ion nitrate est coordonné.

[Traduit par le journal]

Introduction

The complexes of 4,6-dimethylpyrimidine-2(1*H*)-thione (Hdmpt = HL)



with some divalent metal ions have been previously studied (1, 2) and the crystal structure of the cobalt(III) complexes $Co(dmpt)_3$ has been determined (3). In a previous work (4) we have investigated the copper(I) complexes of the neutral, deprotonated, and protonated ligand. The silver(I) complexes have been prepared now and studied by conductometric methods and infrared and Raman spectra, in order to establish the coordinating sites of the ligand which also depend on the protonation or deprotonation state of the molecule. The coordinating behaviour of this ligand may have an interest in the context of the studies on the coordination of heavy metals to nucleotides and related components of nucleic acids and particularly of the substituted pyrimidines which may have an antitumor activity (refs. 2, 3, and references therein).

Experimental

The ligand and its hydrohalides were prepared by the methods previously described (4). The complexes were prepared as follows:

$Ag(HL)X$ (X = Cl, Br, I, SCN) and $Ag(HL)_2X$ (X = Cl, Br, I)

By refluxing under stirring for 3–4 h the freshly prepared silver salts (3 mmol) in a solution of the ligand (3 or 6 mmol) in 4/1 $CHCl_3$/MeOH (25 cm^3). After standing overnight the complexes were filtered and washed with $CHCl_3$.

$Ag_mX_n(H_2L)_{n-m}$ (X = Cl: m = 6, n = 11; Br: m = 2, n = 3; I: m = 5, n = 7)

By refluxing under stirring for 4 h the freshly prepared silver halide (3 mmol) in a solution of H_2LX (3 or 6 mmol) in 1/1 MeOH/$CHCl_3$ (20 cm^3). The compounds were washed with MeOH and $CHCl_3$.

AgL

A solution of $AgNO_3$ (3 mmol) in H_2O (5 cm^3) was added under stirring to an aqeuous solution (10 cm^3) of the ligand (6 mmol). The instantaneous precipitate was stirred for 2 h and washed with MeOH.

$AgL \cdot Ag(HL)NO_3$ and $AgL \cdot [Ag(HL)X]_2$ (X = ClO_4, BF_4)

A MeOH solution (5 cm^3) of $AgNO_3$, $AgClO_4 \cdot H_2O$, $AgBF_4$ (4 mmol) was added drop by drop under stirring to a hot solution of the ligand (4 mmol) in $CHCl_3$ (20 cm^3). After stirring for 3 h the products were washed with 1/1 MeOH/$CHCl_3$.

$Ag(HL)_2NO_3 \cdot MeOH$ and $Ag(HL)_2X \cdot O.25CHCl_3$ (X = ClO_4, BF_4)

By adding with stirring solid $AgNO_3$, $AgClO_4 \cdot H_2O$, $AgBF_4$ (3 mmol) to a solution of the ligand (6 mmol) in $CHCl_3$ (25 cm^3) for the perchlorate and fluoborate and in $CHCl_3$ + MeOH (17 + 3 cm^3) for the nitrate. After 2 h of stirring the microcrystalline products were washed with $CHCl_3$. All the products were dried *in vacuo* on KOH.

Silver was determined gravimetrically for the halide and thiocyanate complexes and volumetrically by the Volhard's method for the other compounds; carbon, hydrogen, and nitrogen by microanalytical methods (Table 1). Molar conductivities were determined on freshly prepared 10^{-3} *M* DMF solutions at

25°C with a WTW conductivity bridge type LBB. Infrared spectra (Tables 2 and 3) were recorded on the solids in KBr pellets (4000–250 cm^{-1}) and as Nujol mulls on polythene (500–50 cm^{-1}) with a Perkin Elmer 180 spectrophotometer.

Raman spectra (20–600 cm^{-1}) were recorded on the solid samples with a Jobin Yvon Ramanor HG2S spectrophotometer equipped with a Spectra-Physics 165 argon ion laser (514.5 nm line) using a rapidly rotating sample holder. The spectra were calibrated by means of the plasma lines of the laser. Satisfactory Raman spectra could not be obtained for the Ag(HL)I, $Ag_2Br_3(H_2L)$, $Ag_5I_7(H_2L)_2$, $AgL \cdot Ag(HL)NO_3$, and perchlorate complexes because these compounds were unstable or highly fluorescent in the laser beam.

The molecular weights of the compounds could not be determined because of their insolubility or very low solubility (of the order of 10^{-3} *M*) in all the solvents suitable for osmometric or tensimetric determinations. Even in DMF, which seems to be the best solvent for them, some of the compounds as indicated in Table 1 give opalescent solutions, probably with decomposition.

Results and Discussion

In the silver(I) complexes of 4,6-dimethylpyrimidine-2(1*H*)-thione here described, the ligand may be present in the neutral form HL with 1:1 and 1:2 M:HL ratios, in the deprotonated L^- and in the protonated H_2L^+ form.

Copper(I) and silver(I) complexes of Hdmpt show the same stoichiometries only for the compounds M(HL)X (X = Cl, Br, I), $M(HL)_2X$ (X = Cl, Br), ML, and $ML \cdot [M(HL)X]_2$ (X = ClO_4, BF_4).

In DMF solution the complexes Ag(HL)X (X = Cl, Br, I, SCN), $Ag(HL)_2X$ (X = Cl, Br, I), AgL, and $AgL \cdot Ag(HL)NO_3$ behave as non-electrolytes, the complexes $Ag(HL)_2X$ (X = NO_3, ClO_4, BF_4) and $Ag_2Br_3(H_2L)$ as 1:1 electrolytes (Λ_M = 65–90) (5), the complexes $AgL \cdot [Ag(HL)X]_2$ (X = ClO_4, BF_4) as 1:2 electrolytes (Λ_M = 130–170) (5) while the complex $Ag_5I_7(H_2L)_2$ has a molar conductivity intermediate between those of 1:1 and 1:2 electrolytes and the complex $Ag_6Cl_{11}(H_2L)_5$ a molar conductivity of the order or greater than those reported for 1:3 or 1:4 electrolytes (5, 6).

The infrared bands of the ligand HL and its protonated H_2L^+ forms reported and discussed in a previous work (4) were recorded with a Perkin Elmer 521 spectrophotometer. They have been recorded again with a Perkin Elmer 180 spectrophotometer in order to be better compared with the spectra of the new complexes. For this reason some of the wave numbers reported in this work for HL and H_2LCl slightly differ from those given in the previous work (4).

In the silver complexes the ligand bands lying in the ν(C=N) region (Table 2) show only very small frequency decreases which in some cases may be considered as significant for a coordination of the ligand through its ring-nitrogen atom, while for the ligand bands in the 1230–1160 cm^{-1} region, to which a ν(NCN) + ν(NCS) + ν(CS) contribution was previously assigned (4), no significant frequency change is observed. The strong ligand band at 853 cm^{-1} lying in the frequency range in which the ν(C=S) bands of several thioamides were located (7) is substituted in most of the silver(I) Hdmpt complexes by other bands at lower frequencies down to 808 cm^{-1} and this may be a clear indication of the coordination of the ligand through its thiocarbonylic sulphur atom.

In the far ir and Raman spectra (Table 3) some new bands like those in the 320–290 and 200–190 cm^{-1} region are sufficiently distinct from the ligand bands to be safely attributed to metal–ligand vibrations. Other bands like those in the 280–270 cm^{-1} region and 228–224 cm^{-1} regions very near to two strong ligand bands, are only tentatively assigned to metal–ligand bands by considering that they are present only in some complexes. Most of the ν(AgX) bands have been only tentatively assigned as they are not clearly distinct from other bands. Particularly the ν(AgCl) bands at 228–220 cm^{-1} are considered as coincident or coupled with a ν(AgS) mode.

The assignment of the bands in the 320–270 cm^{-1} region to ν(AgN) and in the 230–180 cm^{-1} region to ν(AgS) is in agreement with the assignments given for the Hdmpt complexes of copper(I) (4) ν(CuN) = 317–288 cm^{-1}, ν(CuS) = 223–191 cm^{-1}. For the 2-imino-4-oxo-1,3-thiazolidine complexes ν(AgN) at 290–270 cm^{-1} and ν(AgS) at 235 cm^{-1} were reported (8, 9). For the pyrimidine-2-thione complexes with some bivalent metal halides of the first transition series ν(ML) at 265–231 cm^{-1} were given by attributing to them an appreciable contribution of ν(MN) character (10).

Increased ν(MN) frequencies in the silver(I) Hdmpt complexes with respect to those of the pyrimidine-2-thione complexes of other metals may be due to the electron releasing effect of the 4,6-methyl groups one of which is contiguous to the nitrogen atom.

The chelation ability has been demonstrated for Hdmpt by the X-ray structure of the Co(III) $(dmpt)_3$ complex (3) and admitted for the pyrimidine-2-thione (10) and its 1,4,5-trimethyl derivative (11). The ν(AgX) frequencies reported in Table 3 are in the range of similar values given for bridging halide or for "long" silver–halide bonds (12–15).

With these assumptions and the limitations given by the uncertainty in the identification of some of the metal–ligand and particularly of the metal–halogen stretching bands an interpretation of the complexes may be tentatively done.

The presence of two ν(AgN) and two ν(AgS)

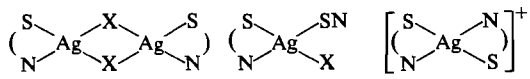
bands, all ir- and Raman-active, and of presumably two ν(AgX) bands ir- and/or Raman-active may indicate for the Ag(HL)X (X = Cl, Br, I) complexes a dimeric structure (**A**)



A **B** **C**

in which silver has a pseudo-tetrahedral coordination and the absence of a center of symmetry in the dimer allows the same bands to be ir- and Raman-active.

In the Ag(HL)SCN complex the SCN anion shows the bands ν(CN) at 2075(vs) and 2035(w) cm^{-1} and ν(CS) at 850(sm) cm^{-1} corresponding to a prevalent Ag–NCS coordination (16, 17) which does not exclude a weaker Ag–S secondary interaction. The ν(Ag—NCS) mode may be coupled with the ν(AgN) mode of the ligand in the strong bands at 288 and 271 cm^{-1} while the weaker ν(Ag—SCN) mode may be tentatively identified in the very strong band at 147 cm^{-1}; ν(M—NCS) frequencies in a tetrahedral coordination are given for terminal NCS groups in the range 330–230 cm^{-1} for transition metal complexes while, for bridging SCN groups ν(M—NCS) are given in the same range and ν(M—SCN) in the 230–213 cm^{-1} range (18). Owing to the very weak Ag—SCN bond the coordination may be considered substantially trigonal.

For the $Ag(HL)_2X$ (X = Cl, Br, I) only one strong ν(AgN) band is observed at about 300–290 cm^{-1} while two ν(AgS) bands are present if the band at 228–225 cm^{-1} is assigned to a ν(AgS) mode as for the Ag(HL)X complexes. Also a single ν(AgX) band seems to be recognisable for these complexes. A monomeric tetrahedral structure like **B** may therefore be tentatively proposed with one chelating and one terminally S-bonded ligand molecules and a terminal "long" AgX bond. An ionic structure $[Ag(HL)_2]X$ has to be excluded by the low molar conductivity of these complexes.

This structure, like type **C**, may be admitted for the $Ag(HL)_2X$ (X = NO_3, BF_4, ClO_4) complexes behaving as 1:1 electrolytes in DMF solution, and for which two ν(AgN) and two ν(AgS) (at least for the fluoborate and the perchlorate complexes) are observed. Infrared spectra do not indicate a coor-

dination of these anions in the solid state. The band at 757(m) and 755(ms) cm^{-1} observed for the perchlorate and fluoborate complexes may be assigned to a chloroform deformation mode (ν_5, *E*) (19).

The sequence **A** → **B** → **C** seems to indicate that a second ligand molecule produces a bridge-splitting of the dimer **A** in which the nitrogen atom of the ligand does not overcome the coordinating power of the halide ion in the structure **B** but excludes from the coordination the other anions in the structure **C**.

The complexes $Ag_mX_n(H_2L)_{n-m}$ behave in DMF solution as electrolytes with all or almost all the $(H_2L)^+$ ions not bonded to the anions. The presence of one ν(AgS) band (or two for the chloride) indicate that at least some of these cations should be S-bonded in the solid state. Polymeric anions $Ag_2X_3^-$, AgX_2^-, AgX_3^{2-} have a ribbon structure in which all the silver ions form AgX_4 tetrahedra with doubly or triply bridging halide ions (15). In the present complexes the Ag:X ratio diminishes from the chloride to the iodide down to a value lower than the 1:1.5 ratio. Some of the coordination sites of the silver ions may be occupied by the sulphur atom of some of the H_2L^+ cations.

It is likely that AgL has a polymeric structure in which the tridentate L^- anion bridges several silver ions through both the N-ring atoms and the thiocarbonylic sulphur atom which may itself act as a bridging atom. The band at 167–160 cm^{-1} which appears in the complexes containing the AgL group could be assigned to some weaker AgS bonds of these bridging sulphur atoms.

As shown by the non-electrolyte behaviour of the $AgL \cdot Ag(HL)NO_3$ complex in DMF solution and by the presence of the ir bands at 1290(mb), 824(wm), 742(w), and 710(w) cm^{-1} for this complex the nitrate ion is coordinated in the solid state and this explains the fact that the stoichiometry of this complex is different from that of the $AgL \cdot [Ag(HL)X]_2$ (X = BF_4, ClO_4) complexes. In the ν(C=N) region both the ir bands of the L^- and HL molecules appear separately. For the fluoroborate and perchlorate complexes a band at 256–257 cm^{-1} not present in the other complexes may be assigned to a ν(AgS) mode. The increased frequency of this band with respect to those of the first ν(AgS) band of the other complexes is attributable to the increased AgS bond strength due to the negative charge of the L^- anion.

With silver(I) and copper(I) ions (4) Hdmpt forms $M(HL)X$ and $M(HL)_2X$ complexes in which it behaves as neutral S,N-bonded ligand, ML and mixed $ML \cdot [M(HL)X]_2$ complexes in which it acts as deprotonated N,N,S-bonded ligand and $M_mX_n(H_2L)_{n-m}$ complexes in which it behaves as protonated S-bonded ligand. The ν(MN) and ν(MS) bands have almost the same frequencies for both metals. It seems likely that copper(I) ion has a great tendency to retain a more trigonal coordination with unequivalent Cu—X bonds in the case of bridging halide ions giving one high and one low ν(CuX) frequency while the greater tendency of silver ion to assume a pseudo-tetrahedral coordination makes the Ag—X bonds more equivalent giving two very close low ν(AgX) frequencies. This difference is particularly evident for the $M_mX_n(H_2L)_{n-m}$ complexes which show for the copper(I) ion only the simple $Cu^I(H_2L)X_2$ (X = Cl, Br) stoichiometry, as the Cu^I(8-mercaptopurine)Cl_2 complex with unequivalent Cu^I—Cl bonds (20), while for silver(I) ion they show much more complicated polyanions (15).

Acknowledgments

The infrared and Raman spectra were recorded in the Centro Strumenti of the University of Modena.

Stereochemical studies. IX. Acid-catalyzed rearrangement of δ- to γ-lactones

JOHN T. EDWARD, ELLEN COOKE, AND THEMISTOCLES C. PARADELLIS
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received May 13, 1980

JOHN T. EDWARD, ELLEN COOKE, and THEMISTOCLES C. PARADELLIS. Can. J. Chem. **59**, 597 (1981).

Depending on their constitution and stereochemistry, δ-lactones are converted by hot formic acid into pendant or spiro γ-lactones.

JOHN T. EDWARD, ELLEN COOKE et THEMISTOCLES C. PARADELLIS. Can. J. Chem. **59**, 597 (1981).

Sous l'influence de l'acide formique à chaud les δ-lactones se transforment suivant leur constitution et leur stéréochimie soit en lactones ouvertes ou en spiro γ-lactones.

[Traduit par le journal]

Lunn *et al.* (1) reported that treatment of 4-oxa-5β-cholestan-3-one (**1**) with hot formic acid gave a 60% yield of the spiro-γ-lactone **2**; treatment of the less reactive *trans* isomer **3** with hot trifluoroacetic acid gave a small amount of gummy product which appeared, from its spectral properties, to be a mixture of isomeric pendant γ-lactones **4**. (Two isomeric γ-lactones **4** were obtained as crystalline products by a different route.) The different products from the two isomeric δ-lactones **1** and **3** may be rationalized by the mechanism indicated, the bond migrating being anti-periplanar to the O—C bond being broken.

Other cases of acid-catalyzed isomerization of δ-lactones to spiro-γ-lactones have been reported (2, 3) but none (to our knowledge) in which the structure of the γ-lactone, spiro or pendant, depends on the stereochemistry of the starting δ-lactone. Consequently, it became of interest to look at the rearrangement of other δ-lactones, including pairs of isomers, in boiling formic acid. In fact, it was found that all the δ-lactones mentioned below were converted to varying extents into γ-lactones, as well as into small amounts of acidic material. The latter appeared, from its ir spectrum, to be made up of unsaturated acids, and was not investigated further.

The simplest model of the lactones **1** and **3**, was the δ-lactone **5**. In formic acid it gave the γ-lactone **6** (4–7), also synthesized from ethyl levulate (**7**) for comparison. The two most intense peaks in the mass spectrum of the lactone **6** were at *m/e* 99 and 43, corresponding to cleavage of the molecule at the "pendant" bond. This cleavage had been found earlier in a γ-lactone assigned the structure **4**, and serves to distinguish a pendant from its spiro isomer (1).

Cis- (**8**) and *trans*-1-oxa-10-methyldecal-2-one (**10**) offer more complete models of the δ-lactones **1** and **3**, but are available only in 2:1 mixture (8, 9).[1]

[1]Attempts to separate the lactones **8** and **10**, and the lactones **13** and **16** (see below), by vpc under various conditions failed (10).

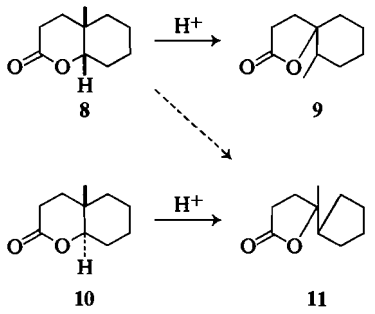
This mixture might be expected, on treatment with acid, to yield a large amount of spiro-γ-lactone **9** and a smaller amount of pendant γ-lactone **11**. In fact, the reverse proved true; the main rearrangement product was the pendant γ-lactone **11**, whose structure was established by synthesis from ethyl levulate and cyclopentyl magnesium bromide. Only a small amount of impure product was obtained which had the correct spectral properties for the spiro structure **9**: an ir peak at 1777 cm^{-1} in carbon tetrachloride (γ-lactone); nmr peaks for α and β protons of the γ-lactone ring, but none for γ

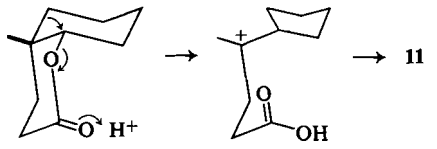


8 **9** **10** **11**

protons; and a methyl doublet (unlike lactones **8**, **10**, and **11**, which have singlet methyl peaks). A small amount of a third rearrangement product was indicated by vaporphase chromatography, but was not obtained pure.

In the mass spectrometer the lactone **11** showed the characteristic pendant-bond cleavage.

The high yield of γ-lactone **11** indicates that it is being formed from the *cis*-lactone **8** as well as the *trans*-lactone **10**. This seems plausible because in its nonsteroid conformation **8***a* the *cis* isomer can undergo antiperiplanar bond migration to give the carbonium ion **12**, the precursor to γ-lactone **11**:



8*a* **12**

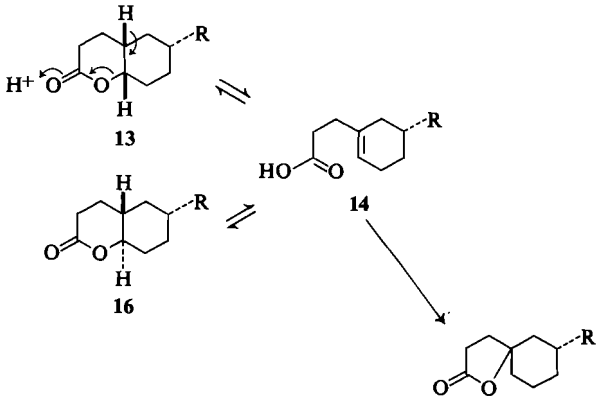
Such a possibility is not open to the rigid *cis*-lactone **1**.

The δ-lactones so far considered undergo skeletal rearrangment via tertiary carbonium ions (e.g. **12**). In the absence of an angular methyl group, this rearrangement would have to proceed via a secondary carbonium ion, and so would be less facile. This is illustrated by the effect of formic acid on the isomeric δ-lactones **13** (R = *t*-Bu) and **16** (R = *t*-Bu). Both proved less reactive than the δ-lactones **8** and **10**. The *cis* isomer **13** (R = *t*-Bu) gave a γ-lactone ($\nu_{max}(CCl_4)$: 1778 cm^{-1}) whose nmr spectrum showed peaks for α and β, but no peak for γ protons. This points to the spiro structure **15** (R = *t*-Bu), as does the mass spectrum, which excludes a pendant structure. The more stable *trans* isomer **16** (R = *t*-Bu) also gave a little of the spiro product **15** (R = *t*-Bu). A small amount of *cis* ⇄ *trans* interconversion was observed. This and the formation of the γ-lactone **15** (R = *t*-Bu), may proceed via the unsaturated acid **14** (R = *t*-Bu).

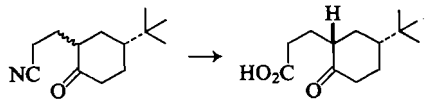
Cis- and *trans*-1-oxadecal-2-one (**13** and **16**; R = H) were available only as 1:2 mixture (10, 11). On treatment with acid this mixture gave a 54% yield of a γ-lactone ($\nu_{max}(CCl_4)$: 1780 cm^{-1}) assigned the spiro structure **15** (R = H) on the basis of spectral evidence similar to that advanced above for **15** (R = *t*-Bu).

In summary, acid-catalyzed rearrangements of δ and γ-lactones seem to be general, and both pendant and spiro structures are formed.

The δ-lactones required as starting materials have all been described previously, except for the lactones **5**, **13** (R = *t*-Bu), and **16** (R = *t*-Bu). The



latter two compounds were prepared by reduction of the oily keto-acid **18** obtained by alkaline hydrolysis of the keto-nitrile **17** (11, 12). Under these equilibrating conditions the keto acid should have (to the extent of 96% (13, 14)) the configuration shown in **18**, and hence would be expected (15, 16)



17 **18**

to yield predominantly the *cis* lactone **13** (R = *t*-Bu) when reduced by hydrogen over platinum in acidic solution, and the *trans* lactone **16** (R = *t*-Bu) when reduced by borohydride. In fact, two crystalline lactones were obtained by the two different modes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

of reduction and shown by nmr (16, 17) to have the expected configurations.

Experimental

Melting points were determined on a Kofler hot stage and are corrected. Infrared spectra were obtained with Perkin-Elmer 421, 337, or 257 spectrometers. The nmr spectra were recorded on a Varian A-60 or HA-100 spectrometer. Vapour phase chromatography was done with a Hewlett-Packard F and M 5750 or an Aerograph 705 Autoprep instrument, both equipped with flame ionization detector, and using a Honeywell 10 recorder or a Beckman 10 recorder equipped with a disc integrator. Mass spectra were recorded at 70 eV on a AEI-MS-902 instrument with the sample introduced by a heated probe at the following temperatures: **6**, 35°; **11**, 90°; **15** (R = *t*-Bu), 70°; **15** (R = H), 100°C.

General Procedure for Acid Treatment of δ-Lactones

The δ-lactone (0.5–1.0 g) in anhydrous formic acid (10–20 mL) was heated under reflux, with exclusion of moisture, for 24 h. The solution was concentrated under reduced pressure and the residue taken up in ether and washed with 2% aqueous sodium hydroxide, saturated aqueous NaCl, and dried ($MgSO_4$). The ether was removed and the neutral product purified as described below. The aqueous NaOH washings were acidified and extracted with ether. The ether solution was washed with saturated aqueous NaCl, dried ($MgSO_4$), and concentrated to yield an acid product, typically ν_{max}: 3300–2500, 1710, 1645 cm^{-1}, which was weighed but not examined further.

Treatment of the δ-lactones with trifluoroacetic acid for 24 h at room temperature gave in general the same products but in much smaller amounts.

γ,γ,δ-Trimethyl-δ-valerolactone (5)

A solution of sodium borohydride (0.73 g) and 4,4-dimethyl-5-oxohexanoic acid (6.08 g) (18) in 2*N* aqueous NaOH (19.5 mL) – ethanol (100 mL) was stirred for 24 h at room temperature. Excess sodium borohydride was destroyed with 20% aqueous HCl, and the acidified mixture stirred for 30 min. The solution was saturated with NaCl and extracted with ether. The ether was washed with aqueous $NaHCO_3$, dried ($MgSO_4$), and concentrated, and the residue distilled at reduced pressure to give the δ-lactone **5** (3.4 g; 62%), bp 63°C/0.1 Torr; n_D^{20} 1.4578; $\nu_{max}(CCl_4)$: 2955, 2925, 2860 (C—H), 1740 (C=O) cm^{-1}; $\delta(CCl_4)$: 0.98 (d, 6H, $C(CH_3)_2$), 1.23 (d, 3H, CH—CH_3), 1.66 (m, 2H), 2.46 (m, 2H), 4.21 (q, 1H). *Anal.* calcd. for $C_8H_{14}O_2$: C 67.5, H 9.9; found: C 67.4, H 9.2.

γ-Isopropyl-γ-methyl-γ-butyrolactone (6)

From Reaction of Ethyl Levulate with Isopropyl Magnesium Bromide

Isopropyl magnesium bromide, prepared from magnesium (1.2 g) and isopropyl bromide (6.6 g) in ether (40 mL), was added dropwise to a stirred solution of ethyl levulate (7.2 g) in benzene (50 mL) cooled in ice–salt. The mixture was left overnight and then worked up following Varech *et al.* (19) to yield the γ-lactone **6** (2.4 g; 34%), bp 127–128°C/31 Torr (lit. (5) bp 116°C/16 Torr); $\nu_{max}(CCl_4)$: 2960, 2940, 2880 (C—H), 1787 (C=O) cm^{-1}; $\delta(CCl_4)$: 0.95 (d, J = 4 Hz, 3H), 1.07 (d, J = 4 Hz, 3H), 1.35 (s, 3H), 1.4–2.35 (m, 3H), 2.35–2.8 (m, 2H); mass spectrum *m/e*: 127 (6.1), 99 (100), 98 (6.1), 87 (12.2), 71 (7.6), 56 (7.6), 43 (27.2), 41 (9.1), 39 (6.1). *Anal.* calcd. for $C_8H_{14}O_2$: C 67.5, H 9.9; found: C 67.1, H 9.9.

From Acid Treatment of δ-Lactone 5

The general procedure applied to the lactone **5** gave 26% of acidic material and 62% of neutral product. The latter was shown by vpc (3% OF-1, 6 ft × ¼ in. glass, 130°C, 70 mL/min N_2) to be made up of γ-lactone **6** (95%; 4 min) and recovered **5** (5%). It was distilled at 52–60°C/2 Torr to yield the lactone **6**, identical (ir, nmr, mass spectrum) to synthetic material described above.

γ-Cyclopentyl-γ-methyl-γ-butyrolactone (11)

From Reaction of Methyl Levulate with Cyclopentyl Magnesium Bromide

This was carried out by the procedure described above for the lactone **6**, and the pendant γ-lactone was obtained in 9.1% yield as a colourless oil, bp 72–73°C/1 Torr (lit. (4) bp 135–136°C/10 Torr); ν_{max}(neat): 2950, 2870 (C—H), 1770 (C=O), 1465, 1425, 1385 (C—H), 1292, 1265, 1245, 1220, 1175, 1130, 1105, 1090, 1072, 1015, 945, 918, 815 cm^{-1}; $\delta(CCl_4)$: 1.45 (s, 3H), 1.72 (m, 9H), 1.95–2.40 (m, 2H), 2.40–2.95 (m, 2H); mass spectrum *m/e*: 168 (16.4), 153 (26.2), 113 (29.5), 99 (100.0), 98 (36.1), 71 (14.7), 69 (29.5), 67 (32.8), 56 (9.8), 55 (14.7), 43 (37.8), 41 (50.8). *Anal.* calcd. for $C_{10}H_{16}O_2$: C 71.4, H 9.6; found: C 71.4, H 9.7.

From Acid Treatment of Mixture of δ-Lactones 8 and 10

The standard procedure gave 23% of acidic material and 73% of neutral product. The latter on vpc showed three components having retention times of 7.0 min (16%, A), 8.1 min (53%, B), and 8.8 min (21%, C). Preparative vpc (8% OF-1, 6 ft × ⅜ in. Al, 140°C, 140 mL/min N_2) gave: A (contaminated with some B), tentatively identified as the spiro-γ-lactone **9**, $\nu_{max}(CCl_4)$: 2950, 2880 (C—H), 1777 (C=O), 1469, 1461, 1447, 1421, 1378 (C—H), 1360, 1310, 1272, 1233, 1207, 1180, 1155, 1140, 1128, 1095, 1065, 1055, 1005, 995, 982, 953, 932, 905, 858, 811 cm^{-1}; $\delta(CCl_4)$: 0.93 (d, J = 6 Hz, 3H), 1.65 (m, 9H), 1.5–2.3 (m, 2H), 2.3–2.8 (m, 2H); B, identified (ir, nmr, mass spectrum) with the pendant γ-lactone **11** synthesized above; C (contaminated with B) $\nu_{max}(CCl_4)$: 1777, 1745 cm^{-1}; $\delta(CCl_4)$: 0.57 (s), 0.95 (d, J = 6 Hz), 1.00 (s), 1.75 (s), 1.43 (s), 1.65 (m), 1.9–2.4 (m), not identified.

4-tert-Butyl-2-(2′-hydroxycarbonylethyl) Cyclohexanone (18)

4-*tert*-Butyl-2-(2′-cyanoethyl) cyclohexanone (**17**) (10.3 g) (11, 12) was treated with refluxing 2*N* aqueous NaOH for 9 h. The solution was acidified with 20% hydrochloric acid and extracted with ether. The ether solution was extracted with aqueous sodium bicarbonate, and the latter acidified and extracted with ether. The final ether solution was washed with aqueous NaCl, dried ($MgSO_4$), and concentrated. The residue was distilled and yielded the keto-acid **18** as an oil (10.1 g; 89%), bp 151–155°C/0.5 Torr; ν_{max}(neat): 3400–2500 (bonded OH), 1710 (C=O), 1480, 1473, 1448, 1420, 1397, 1367, 1326, 1283, 1268, 1248, 1228, 1173, 1140, 1113, 1090, 1078, 983, 946, 928 cm^{-1}. *Anal.* calcd. for $C_{13}H_{22}O_2$: C 69.0, H 9.8; found: C 68.7, H 10.0.

6α-tert-Butyl-1-oxa-9β,10β-decal-2-one (13; R = t-Bu)

The keto-acid **18** (4.3 g) was hydrogenated over prereduced platinum oxide (0.5 g) in a mixture of glacial acetic acid (45 mL) and concentrated hydrochloric acid (5 mL). After absorption of one equivalent of hydrogen, the mixture was filtered and the filtrate diluted with ether. The ether solution was washed with water, aqueous sodium bicarbonate, dried ($MgSO_4$), and concentrated. The residue on distillation gave the lactone **13** (R = *t*-Bu) as an oil (2.7 g; 62%), bp 144–146°C/0.65 Torr, crystallizing to a solid. Recrystallization from hexane–ether gave colourless plates, mp 78–80°C (1.8 g), raised to 82–83°C after sublimation; $\nu_{max}(CCl_4)$: 2950, 2870, 2845 (C—H), 1742 (C=O), 1478, 1469, 1457, 1433, 1393, 1363, 1358, 1348, 1333, 1310, 1290, 1198, 1160, 1135, 1105, 1069, 1012, 1001, 935, 925, 850 cm^{-1}; $\delta(CCl_4)$: 0.88 (s, 9H), 1–2.4 (complex m, 12H), 4.38 (m, 1H) (lit. (17) δ 4.52[2]). *Anal.* calcd. for $C_{13}H_{22}O_2$: C 74.2, H 10.5; found: C 74.5, H 10.4.

[2]Value reported for isomer in a *trans–cis* 80:20 mixture (17).

2-tert-Butylcyclohexane-1-spiro-4-butyrolactone (15; R = t-Bu)

The standard procedure applied to the δ-lactone **13** (R = *t*-Bu) gave a 12% yield of acidic material and 86% yield of neutral product showing by vpc (170°C) components at 8.7 min (**15**, R = *t*-Bu; 51%), 15 min (**13**, R = *t*-Bu; 43%), and 18 min (**16**, R = *t*-Bu; 6%).

The crude lactone mixture was distilled at reduced pressure to give, as a first fraction, an oil which solidified on standing. After three recrystallizations from hexane the γ-lactone **15** (R = *t*-Bu) was obtained as colourless crystals, mp 69–72°C; $\nu_{max}(CCl_4)$: 2955, 2875 (C—H), 1778 (C=O), 1475, 1470, 1450, 1423, 1393, 1363, 1295, 1233, 1218, 1195, 1168, 1140, 1125, 1095, 1051, 1012, 960, 913, 840 cm^{-1}; $\delta(CCl_4)$: 0.92 (s, 9H), 1.05–1.95 (m, 9H), 1.95–2.35 (m, 2H), 2.35–2.8 (m, 2H); mass spectrum *m/e*: 210 (8.7), 195 (17.30), 155 (57.7), 154 (81.8), 153 (42.3), 152 (13.5), 139 (7.2), 137 (23.1), 136 (28.8), 135 (12.5), 112 (7.2), 111 (38.4), 109 (7.2), 108 (13.5), 99 (2.2), 98 (7.2), 95 (30.8), 94 (69.3), 93 (19.2), 83 (7.2), 81 (25.0), 79 (14.4), 69 (14.4), 67 (15.4), 57 (100.0), 56 (29.8), 55 (37.5), 53 (9.6), 43 (13.5), 41 (67.4). *Anal.* calcd. for $C_{13}H_{22}O_2$: C 74.2, H 10.5; found: C 74.2, H 10.5

6α-tert-Butyl-1-oxa-9α,10β-decal-2-one (16; R = t-Bu)

Sodium borohydride (0.38 g) was added to a solution of the keto acid **18** (4.5 g) in 2 *N* aqueous NaOH (20 mL) and the solution stirred for 24 h at room temperature. The excess borohydride was destroyed with dilute hydrochloric acid, and the acidified mixture stirred for 30 min to complete lactonization. The mixture was extracted with ether, and the ether solution worked up in the usual way to yield the lactone **16** (R = *t*-Bu) as an oil (3.0 g; 74%) which solidified on standing, and melted unsharply above 45°C. Recrystallization from hexane–ether, followed by sublimation at 35°C/0.2 Torr gave colourless needles, mp 73.5–75°C; $\nu_{max}(CCl_4)$: 2959, 2870 (C—H), 1740 (C=O), 1475, 1469, 1455, 1450, 1419, 1392, 1363, 1330, 1297, 1250, 1240, 1218, 1187, 1128, 1098, 1089, 1045, 990, 965, 925, 905, 862 cm^{-1}; $\delta(CCl_4)$: 0.88 (s, 9H), 0.95–2.5 (complex, 12H), 3.73 (m, 1H) (lit. (17) 3.75[1]). *Anal.* calcd. for $C_{13}H_{22}O_2$: C 74.2, H 10.5; found: C 74.0, H 10.3.

Acid Treatment of δ-Lactone 16 (R = t-Bu)

The standard procedure gave a 13% yield of acidic material and 84% yield of neutral material, shown by vpc (170°C) to be made up of the γ-lactone **15** (R = *t*-Bu) (8.7 min; 3%), an unidentified component (10.5 min; 5%), δ-lactone **13** (R = *t*-Bu) (15 min; 4%) and recovered δ-lactone **16** (R = *t*-Bu) (18 min; 88%).

Acid Treatment of Mixture of δ-Lactones 13 and 16 (R = H)

The standard procedure gave 36% yield of acidic material and 61% yield of neutral product, showing by vpc (150°C) components at 3 min (γ-lactone **15**; R = H; 90%) and at 4.9 min (mixture of δ-lactones **13** and **16**; R = H; 10%). Work-up in the usual way gave the γ-lactone **15** (R = H) as a colourless oil, bp 84°C/2.0 Torr; $\nu_{max}(CCl_4)$: 2960, 2880 (C—H), 1780 (C=O), 1445, 1420, 1368, 1358, 1348, 1333, 1287, 1217, 1190, 1147; 1123, 1043, 1030, 1002, 995, 952, 940, 920, 900, 890, 855, 840 cm^{-1}; $\delta(CCl_4)$: 1.75 (10H), 1.95–2.25 (m, 2H), 2.35–2.88 (m, 2H); mass spectrum *m/e*: 154 (31.2), 125 (9.8), 112 (18.0), 111 (10.0), 99 (14.9), 98 (29.5), 97 (2.4), 83 (9.0), 81 (11.5), 67 (8.2), 56 (12.3), 55 (18.0), 42 (8.2), 41 (14.5). *Anal.* calcd. for $C_9H_{14}O_2$: C 70.1, H 9.2; found: C 69.4, H 9.6.

Total synthesis of α- and β-himachalene by an intermolecular Diels–Alder approach

HSING-JANG LIU AND ERIC N. C. BROWNE

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 10, 1980

HSING-JANG LIU and ERIC N. C. BROWNE. Can. J. Chem. **59**, 601 (1981).

A total synthesis of α-himachalene (**2**) and β-himachalene (**3**) has been achieved in eleven steps and in an effective overall yield of 21% from 4,4-dimethyl-2-cyclohexenone (**4**). The synthesis involves keto ester **7** as a key intermediate which is conveniently prepared by the Diels–Alder addition of dienone ester **6** to isoprene.

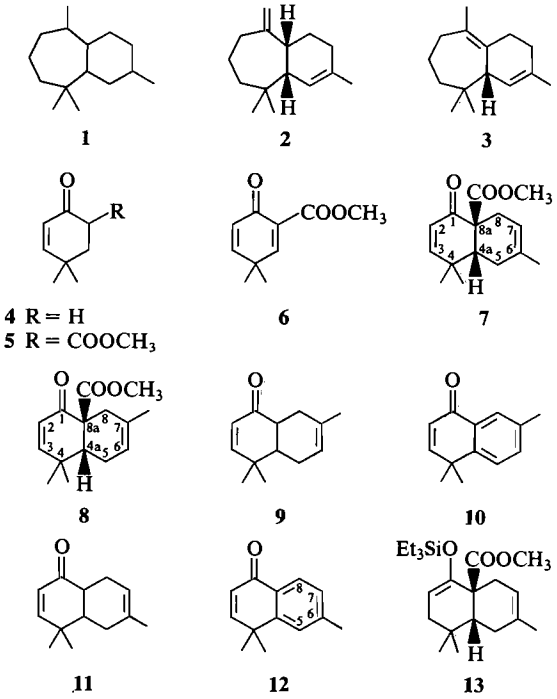
HSING-JANG LIU et ERIC N. C. BROWNE. Can. J. Chem. **59**, 601 (1981).

Partant de la diméthyl-4,4 cyclohexène-2 one (**4**) on a réalisé, en 11 étapes et avec un rendement global de 21%, une synthèse totale de l'α-himachalène (**2**) et de la β-himachalène (**3**). La synthèse fait appel à un intermédiaire clé, le cétoester **7**, qui est préparé avec facilité par une addition de Diels–Alder de l'ester diénone **6** sur l'isoprène.

[Traduit par le journal]

The himachalane carbon skeleton (**1**) is characteristic of a growing class of sesquiterpenes (1–13). The isolation of two representatives of the class was first reported by Dev and co-workers in 1952 from the essential oil of the Himalayan cedar (*Cedrus deodara Loud*) (1). The gross skeletal structure of the two new hydrocarbons, designated α- and β-himachalene, was reported almost simultaneously in 1961 by Joseph and Dev (2) and by Bredenberg and Erdtman (3) who isolated the two compounds from Atlas cedar (*Cedrus atlantica*) and from *Cedrus libani*. In 1968 Joseph and Dev were able to rigorously establish the structure (4) and the absolute stereochemistry (5) of α-himachalene as **2** and of β-himachalene as **3**. These two natural hydrocarbons have been the subject of considerable synthetic activity and several total syntheses have been accomplished during the last decade (14–17). We wish to report a fundamentally different approach to the synthesis of α- (**2**) and β-himachalene (**3**) in racemic form.

Our synthetic plan called for two critical operations, the construction of a suitably functionalized 4,4-dimethyl-1-decalone derivative (i.e. **16**) and a one-carbon ring enlargement (i.e. **16** → **17**). The former process was facilitated by a Diels–Alder approach using 2-carbomethoxy-4,4-dimethyl-2,5-cyclohexadienone (**6**) as a dienophile. The initial studies (18) on the addition of isoprene to dienone ester **6**, readily prepared from 4,4-dimethyl-2-cyclohexenone (**4**) by carbomethoxylation (**4** → **5**) followed by oxidation with selenium dioxide, employed boron trifluoride etherate as a catalyst. The reaction, carried out at room temperature in ether, resulted in the formation of what appeared to be a single adduct which showed homogeneity on tlc and four methyl singlets in the



^{1}Hmr spectrum, and to which structure **7** was assigned based on the well established rules governing the Diels–Alder reaction (19). However, further examination of the adduct by ^{13}Cmr revealed that it was in fact a mixture of two compounds (thirty carbon signals). Separation of these two compounds was possible by preparative high-pressure liquid chromatography. Surprisingly, the major component, which amounted to 70% of the mixture, was the undesired *anti-para* adduct **8**. This assignment was confirmed by decarbomethoxylation with lithium iodide dihydrate in refluxing

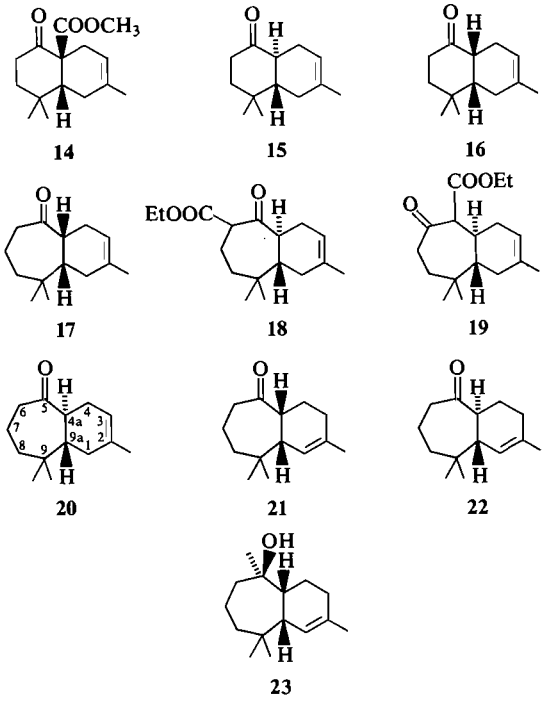
2,4,6-collidine (20) to give a mixture of the two known (21) epimeric ketones **9** and oxidation of this mixture with *N*-bromosuccinimide to the known aryl ketone **10** (21). The minor compound was shown spectroscopically to be isomeric with **8** and its structure could be logically deduced as **7**. In further proof of the structure, this compound was subjected to decarbomethoxylation with LiI·2H_2O-collidine. The resulting mixture of the epimeric ketones **11** (ca. 1:1; 97% yield) on oxidation with *N*-bromosuccinimide in carbon tetrachloride gave aryl ketone **12** in 43% yield. The ^{1}Hmr spectrum of **12** showed a signal due to a *peri*-deshielded proton (C-8 H) (22) as a doublet (J = 8 Hz) at δ 7.95. Such a coupling is only compatible with structure **12**.

Examination of a series of Lewis acids as catalyst for the Diels–Alder reaction of dienone ester **6** and isoprene indicated that, whereas BF_3 gave predominantly the undesired isomer **8**, use of stannic chloride resulted in the preferential formation of the desired regioisomer (**7**:**8** = 82:18; 99% total yield). To our knowledge, this is the first example of a Diels–Alder reaction in which the regiochemistry of the product can be reversed solely by choice of an appropriate Lewis acid catalyst.[1]

In the presence of Wilkinson's catalyst (*tris*-triphenylphosphine rhodium(I) chloride) (24) hydrosilanes have been shown (25) to add to α,β-unsaturated ketones exclusively by 1,4-addition to give silyl enol-ethers which readily undergo hydrolysis (26) to give saturated ketones. When keto ester **7** as a 25% solution in benzene was treated with triethylsilane (1 equiv.) and a catalytic amount of Wilkinson's catalyst, only a small amount of addition product was observed after 5 days. However, when finely divided solid keto ester **7** was suspended in triethylsilane in the presence of the catalyst, conversion to product was complete within 24 h. The purified product, obtained in 91% yield was identified as silyl enol-ether **13**. Hydrolysis of **13** with potassium carbonate in aqueous methanol gave the saturated ketone **14** in 88% yield. The crude silyl enol-ether **13** could conveniently be hydrolyzed to give **14** in 94% yield from keto ester **7**.

Keto ester **14** was decarbomethoxylated with LiI·2H_2O-collidine to give *trans*-ketone **15** and its epimer **16**, in 86% yield and in a ratio of ~90:10, which were easily separated by column chromatography on silica gel. In proof of the stereochemical assignment, *cis*-ketone **16** epimerized with sodium



hydroxide in aqueous methanol to give an equilibrium mixture of **15** and **16** in a ratio of 82:18 and in 95% yield.

The most direct approach to α-himachalene (**2**) from this point would appear to require homologation of *cis*-ketone **16** to the ketone **17**. However, since *cis*-ketone **16** was obtained only as a minor product of decarbomethoxylation of **14** and efficient use of the starting materials would require successive epimerizations of **15** followed by chromatographic separation of the minor component **16**, it seemed more expedient to proceed with ring expansion of the major isomer, *trans*-ketone **15** and to correct the ring junction stereochemistry at a later stage.

The ring expansion of ketones with ethyl diazoacetate (27, 28) has been shown (28, 29) to proceed via the selective migration of the less substituted carbon α to the carbonyl group. Treatment of **15** with ethyl diazoacetate and boron trifluoride etherate at 0°C for 1 h gave two chromatographically separable keto esters **18** and **19**. The major product, obtained in 90% yield showed a signal at δ 3.53 in its ^{1}Hmr spectrum characteristic of a methine proton on the α-carbon of a β-keto ester. The signal was a doublet of doublets with coupling constants of 10 Hz and 4 Hz indicating the presence of two adjacent protons. These data were consistent with the assignment of structure **18** to the major product. In the case of the minor product (10%

[1]For an approach to orientation reversal by selection of either thermal or catalytic conditions see ref. 23.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

yield), the nmr signal at δ 3.28 indicating one proton at the α-carbon of a β-keto ester, was a doublet with a coupling constant of 8 Hz indicating the presence of only one adjacent proton. This was consistent with the assignment of structure **19** to the minor product. Both **18** and **19** were single compounds (17 lines in their ^{13}Cmr spectra) existing exclusively in the keto-form. The stereochemistry at the newly introduced chiral center, however, could not be assigned with certainty.

Keto ester **18** was decarbethoxylated with LiI·2H_2O-collidine to give ketone **20** in 85% yield. The ^{1}Hmr spectrum of **20** was identical with previously reported (30) ^{1}Hmr data for **20** obtained by degradation of α-himachalene (**2**).

The synthesis of the key intermediate **21** from ketone **20** requires two operations. In one, the double bond must be moved from the C-2 to the C-1 position. In the other, the stereochemistry of the ring junction must be converted from *trans* to *cis*. Joseph and Dev (30) have reported that ketone **22**, when treated with oxalic acid in aqueous dioxan at reflux for 12 h, produces an equilibrium mixture of **20** and **22** in a ratio of 15:85 (determined by gc analysis). Furthermore it has been reported (16) that the ketone **21**, when subjected to base catalyzed equilibration (conditions unspecified), gives a 50:50 equilibrium distribution with its *trans*-isomer **22**. The sequential application of these two equilibration conditions appeared to offer an acceptable route from **20** to **21**.

It was found, however, that application of oxalic acid equilibrating conditions to ketone **20** produced no detectable (^{1}Hmr, gc) trace of any isomeric ketone and the starting material was recovered quantitatively. The application of more strongly acidic conditions was investigated. In refluxing benzene with *p*-toluenesulfonic acid an equilibrium was rapidly established within 1 h, as determined by gc and ^{1}Hmr analysis. Two peaks were observed by gc in a ratio of 65:35. The minor peak had a retention time identical with that observed for pure ketones **20** and **17**[2] while the major peak had a lower retention time corresponding to ketones **21** and **22**.[3] The product mixture was obtained in quantitative yield and ^{1}Hmr analysis showed the presence of four compounds approximately in the ratio 53:27:14:6. Three of these were identified as the known ketones (16, 30) **22** (53%), **20** (27%), and **21** (14%). The fourth, minor component was shown to be identical with ketone **17**. Flash chromatography of this mixture gave leading fractions of pure *cis*-ketone **21** in approximately 12% yield, and later fractions (in 88% yield) which were a mixture of **17** and **20–22**. In practice this mixture was subjected sequentially to the acid catalyzed equilibration conditions and flash chromatographic removal of the desired *cis*-ketone **21** in order to obtain efficient use of the starting material.

The direct conversion of *cis*-ketone **21** to α-himachalene (**2**) by a Wittig reaction appeared to be straightforward and has been briefly described (16). However, this approach using an excess of methylenetriphenylphosphorane in refluxing ether gave material identifiable as α-himachalene (**2**) (^{1}Hmr) only slowly (74% conversion after 5 days) and in poor yield (~20%) and contaminated with other inseparable hydrocarbon products.

A methylation–dehydration approach proved more effective for the conversion of ketone **21** to himachalenes. As reported (16) the addition of methyl lithium to ketone **21** proceeded smoothly and specifically from the less hindered side of the carbonyl to give 7-*epi*-himachalol (**23**) in 93% yield. The dehydration of alcohol **23** with phosphoryl chloride in refluxing pyridine for 1 h gave a mixture of hydrocarbons in 93% yield composed of α- (**2**) and β-himachalene (**3**) in a ratio of 75:25 by ^{1}Hmr integration. Separation of the two isomeric hydrocarbons by flash chromatography gave pure α-himachalene (**2**) which was identical with the naturally occurring compound by comparison of its ^{1}Hmr, ir, and mass spectra with published values (5, 6). As well, a sample of β-himachalene (**3**) (contaminated by ~20% of the α-isomer **2**) was obtained which showed ^{1}Hmr signals identical with those reported (5, 6) for the natural material.

Experimental

General

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Elemental analyses were performed by the microanalytical laboratory of this department. Infrared spectra were recorded on a Perkin-Elmer model 457 or Nicolet 7-199 FT-IR spectrophotometer and, except where otherwise stated, were obtained on solutions in chloroform. The ^{1}Hmr spectra were recorded on a Varian HA-100, HA-100/Digilab, or Bruker WH-200 spectrometer and, except where otherwise stated, were obtained on solutions in carbon tetrachloride with tetramethylsilane as internal reference. The ^{13}Cmr spectra were recorded on a Bruker WP-60/Nicolet BNC-12 system or a Bruker HFX-90/Nicolet 1085 system and were obtained on solutions in deuteriochloroform using tetramethylsilane as internal reference. Mass spectra (ms) were recorded using A.E.I. model MS9, MS12, or MS50 mass spectrometers. Gas chromatography (gc) was performed on a Hew-

[2]Ketone **17** was prepared by epimerization of **20** with aqueous sodium hydroxide in refluxing methanol for 48 h. Pure **17** was obtained from the resulting 80:20 (*trans*:*cis*) mixture by flash chromatography (31).

[3]Ketone **22** was obtained by treatment of pure **21** (*vide infra*) with aqueous sodium hydroxide in refluxing methanol to give an 80:20 equilibrium mixture of **22** and **21**.

lett Packard 5750 research chromatograph using stainless steel columns (8 ft × 1/8 in.) packed with 10% diethylene glycol succinate on 80–100 mesh Chromosorb W, acid washed, and treated with dimethylchlorosilane. Unless stated otherwise, anhydrous magnesium sulfate was used for drying organic solutions. Lithium iodide dihydrate – collidine reagent was prepared as follows. Finely divided anhydrous lithium iodide (514 mg, 3.84 mmol) was suspended in 2,4,6-collidine (3.05 mL) with vigorous stirring. Water (138 μL, 7.68 mmol) was added and the suspension rapidly dissolved. The resulting pale yellow solution had a calculated concentration of 1.28 *N* in lithium iodide dihydrate.

6-Carbomethoxy-4,4-dimethyl-2-cyclohexen-1-one (5)

Sodium hydride (50% oil dispersion, 15.65 g, 0.326 mol) was suspended in 1,2-dimethoxyethane (130 mL, freshly distilled over lithium aluminum hydride) under an atmosphere of nitrogen and dimethyl carbonate (73.4 g, 0.815 mol) was added. The suspension was brought to reflux while stirring with a mechanical stirrer. A solution of 20 g (0.163 mol) of enone **4** (32) in dry 1,2-dimethoxyethane (60 mL) was added dropwise over 1 h. Heating was continued for 4 h and then the mixture was cooled to 0°C. An aqueous 10% solution of acetic acid (200 mL) was added dropwise with stirring and the mixture was extracted with ether. The extracts were washed with water, saturated aqueous sodium bicarbonate, water, and saturated aqueous sodium chloride, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 8–20% ether in Skelly B, gave keto ester **5** (18.13 g, 61% yield) as a yellow oil. This compound existed partially (~40% by ^{1}Hmr integration) in the corresponding enol form. The following ^{1}Hmr data were attributed to the keto form: δ: 6.58 (dd, 3/5H, J = 10, J' = 2 Hz, —C*H*=CH—CO—), 5.76 (d, 3/5H, J = 10 Hz, —CH=C*H*—CO—), 3.68 (s, 3 × 3/5H, —O—CH_3), 3.41 (dd, 3/5H, J = 13, J' = 5 Hz, —CH(—CO_2—)—), 2.25 (dd, 3/5H, J = J' = 13 Hz, —CH(—*H*)—), 1.91 (ddd, 3/5H, J = 13, J' = 5, J'' = 2 Hz, —CH(—*H*)—), 1.20 (s, 3 × 3/5H, —CH_3), and 1.06 (s, 3 × 3/5H, —CH_3). The following ^{1}Hmr data were attributed to the enol form: δ: 11.75 (s, 2/5H, =C(—OH)—), 6.00 (d, 2/5H, J = 10 Hz, =C*H*—C(=CH—)—$(CH_3)_2$), 5.76 (d, 2/5H, J = 10 Hz, =C(—CH=)—), 3.72 (s, 3 × 2/5H, —OCH_3), 2.31 (s, 2 × 2/5H, —CH_2—), 1.20 (s, 6 × 2/5H, —CH_3). The following spectral data were recorded for the mixture of keto and enol forms. Infrared (neat): 1744 (ester C=O), 1680 (enone C=O), 1658 (C=C), and 1379 cm^{-1} (CH_3). *Exact Mass* calcd. for $C_{10}H_{14}O_3$: 182.0943; found (ms): 182.0936. *Anal.* calcd. for $C_{10}H_{14}O_3$: C 65.92, H 7.74; found: C 66.13, H 7.74.

2-Carbomethoxy-4,4-dimethyl-2,5-cyclohexadien-1-one (6)

Keto ester **5** (22.04 g, 0.121 mol) was dissolved in 2.204 L of a 5% solution of glacial acetic acid in *tert*-butyl alcohol under an atmosphere of nitrogen. Finely divided selenium dioxide (40.25 g, 0.363 mol) was added. The mixture was stirred with a mechanical stirrer and heated to reflux. After heating for 18 h, the mixture was cooled to room temperature, filtered, and concentrated. The residue was dissolved in ether, washed with water, saturated aqueous sodium bicarbonate and water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 50–100% ether in petroleum ether, gave keto ester **6** which was contaminated with red selenium. Molecular distillation of this material in a Kugelrohr apparatus at 120°C/0.5 Torr gave pure keto ester **6** (17.4 g, 80% yield) as a yellow oil; ir (neat): 1734 (ester C=O), 1660 (ketone C=O), 1398, 1384, and 1360 (CH_3) cm^{-1}; ^{1}Hmr δ: 7.33 (d, 1H, J = 3 Hz, —CH=C(—CO_2—)—), 6.80 (dd, 1H, J = 10, J' = 3 Hz, —C*H*=CH—CO—), 6.06 (d, 1H, J = 10 Hz, —CH=C*H*—CO—), 3.74 (s, 3H, —OCH_3), and 1.33 (s, 6H, 2 × —CH_3). *Exact Mass* calcd. for $C_{10}H_{12}O_3$: 180.07865; found (ms): 180.07834. *Anal.* calcd. for $C_{10}H_{12}O_3$: C 66.65, H 6.71; found: C 66.33, H 6.70.

8aβ-Carbomethoxy-4,4,6-trimethyl-4aβ,5,8,8aβ-tetrahydro-1(4H)-naphthalenone (7)[4] *and 8aβ-Carbomethoxy-4,4,7-trimethyl-4aβ,5,8,8aβ-tetrahydro-1(4H)-naphthalenone (8)*

From BF_3 Catalyzed Reaction

At 0°C, boron trifluoride etherate (0.68 mL, 5.55 mmol) was added to a solution of dienone ester **6** (2 g, 11.1 mmol) and isoprene (22 mL, 0.22 mol) in ether (80 mL). The reaction mixture was stirred at room temperature under an atmosphere of argon for 96 h. Saturated aqueous sodium bicarbonate (40 mL) was added and the resulting mixture was extracted with ether. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 10–12% ether in *n*-hexane, gave a 70:30 mixture (gc analysis) of keto esters **8** and **7** (2.536 g, 92% yield). A 1.70 g sample was separated by preparative high pressure liquid chromatography on a Waters Associates Prep LC/System 500 using one silica gel cartridge and eluting with 50% ether in petroleum ether. Fractions were collected by shaving the leading and trailing edges of the single peak and recycling the central portion. The combined "leading edge" fractions were concentrated to give a sample which was shown by gc analysis to be predominantly keto ester **8** (445 mg, lower gc retention time isomer). This sample crystallized on standing and three recrystallizations from ether gave colourless rhombs of pure keto ester **8**; mp 93–95°C; ir: 1744, 1730 (ester C=O), 1672 (enone C=O), 1384 and 1371 (CH_3) cm^{-1}; ^{1}Hmr δ: 6.43 (d, 1H, J = 10 Hz, —C*H*=CH—CO—), 5.76 (d, 1H, J = 10 Hz, —CH=C*H*—CO—), 5.29 (m, 1H, =CH—), 3.64 (s, 3H, —OCH_3), 2.62 (ddd, 1H, J = 5, J' = 4, J'' = 0.5 Hz, C-4a H), 2.47 (br d, 1H, J = 17 Hz, C-8 H), 2.08 (br d, 1H, J = 17 Hz, C-8 H), 2.01 (m, 2H, C-5 —CH_2—), 1.66 (br s, 3H, =C(—CH_3)—), 1.16 (s, 3H, —CH_3), and 1.00 (s, 3H, —CH_3); ^{13}Cmr δ: 197.4 (C-1), 173.0 (—CO_2—), 158.0 (C-3), 131.1 (C-7), 124.0 (C-2), 119.3 (C-6), 57.5 (C-8a), 52.4 (—OCH_3), 40.4 (C-4a), 36.0 (C-4), 33.1 (C-8), 30.4 (C-4 CH_3), 24.2 (C-5), 23.6 (C-4 or C-7 CH_3), and 23.4 (C-4 or C-7 CH_3). *Exact Mass* calcd. for $C_{15}H_{20}O_3$: 248.1413; found (ms): 248.1410. *Anal.* calcd. for $C_{15}H_{20}O_3$: C 72.55, H 8.12; found: C 72.41, H 8.08. The "trailing edge" fractions were combined and concentrated to give a sample which was shown by gc analysis to be predominantly keto ester **7** (161 mg, higher gc retention time isomer). This sample crystallized on standing and two recrystallizations from ether gave colourless rhombs of pure keto ester **7**; mp 91.5–92.5°C; ir: 1740 (ester C=O), 1667 (enone C=O), 1376 (CH_3), and 828 (C=CH) cm^{-1}; ^{1}Hmr δ: 6.41 (d, 1H, J = 10 Hz, —C*H*=CH—CO—), 5.75 (d, 1H, J = 10 Hz, —CH=C*H*—CO—), 5.34 (br s, 1H, =CH—), 3.67 (s, 3H, —OCH_3), 2.71 (dd, 1H, J = 6, J' = 3 Hz, C-4a H), 2.62 (dm, 1H, J = 19 Hz, C-8 H), 2.14 (dm, 1H, J = 19 Hz, C-8 H), 1.91 (m, 2H, C-5 —CH_2—), 1.67 (br s, 3H, =C(—CH_3)—), 1.19 (s, 3H, —CH_3), and 1.02 (s, 3H, —CH_3); ^{13}Cmr δ: 197.7 (C-1), 173.0 (—CO_2—), 157.9 (C-3), 132.2 (C-6), 123.9 (C-2), 118.5 (C-7), 56.6 (C-8a), 52.4 (—OCH_3), 41.3 (C-4a), 36.2 (C-4), 30.4 (C-4 CH_3), 29.0 (C-5 or C-8), 28.7 (C-5 or C-8), 23.5 (C-4 or C-6 CH_3), and 23.4 (C-4 or C-6 CH_3). *Exact Mass* calcd. for $C_{15}H_{20}O_3$: 248.1412; found

[4]The stereochemical designations used in this and all other chemical names in this section denote relative stereochemistry. All compounds used and obtained were racemic.

(ms): 248.1412. *Anal.* calcd. for $C_{15}H_{20}O_3$: C 72.55, H 8.12; found: C 72.71, H 8.29. A total of 1.09 g of a mixture of keto esters **7** and **8** was also recovered from the preparative liquid chromatography.

From $SnCl_4$ Catalyzed Reaction

Dienone ester **6** (1.03 g, 5.72 mmol) was dissolved in ether (20 mL) under an atmosphere of nitrogen. Anhydrous stannic chloride (745 mg, 2.86 mmol) was added with stirring followed by addition of isoprene (11.4 mL, 114 mmol). After stirring for 84 h, saturated aqueous sodium bicarbonate (10 mL) was added. The resulting mixture was extracted with ether and the extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 8–20% ether in petroleum ether, gave a mixture of keto ester **7** and its regioisomer **8** (82:18 by gc analysis, 1.37 g, 97% yield) which crystallized on standing. As an alternative to chromatographic purification the crude residue could be purified by molecular distillation in a Kugelrohr apparatus (~120°C at 0.5 Torr) to give a mixture of keto esters **7** and **8** in 99% yield. One recrystallization of this mixture from ether gave pure keto ester **7** (872 mg) as colourless crystals. Additional keto ester **7** could be obtained either by fractional crystallization from the mother liquor or by preparative high pressure liquid chromatography as described above.

4,4,7-Trimethyl-4aβ,5,8,8aβ-tetrahydro-1(4H)-naphthalenone and 4,4,7-Trimethyl-4aβ,5,8,8aα-tetrahydro-1(4H)-naphthalenone (9)

Keto ester **8** (336 mg, 1.35 mmol) was dissolved in lithium iodide dihydrate – collidine reagent (2.12 mL, 2.70 mmol) under an atmosphere of nitrogen. The mixture was stirred vigorously and heated at reflux for 3 h. The mixture was then cooled to room temperature, poured into cold aqueous 5% hydrochloric acid, and extracted with ether. The extracts were washed with cold 5% aqueous hydrochloric acid and water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 4–8% ether in petroleum ether, gave a mixture of *cis*- and *trans*-enones **9** (50:50 by ^{1}Hmr integration, 195 mg, 76% yield, 97% based on consumed starting material). Further elution with 8–25% ether in petroleum gave recovered keto ester **8** (75 mg, 22% recovery). The ^{1}Hmr spectrum of the product mixture showed two sets of signals identical to those reported for pure compounds (21).

4,4,7-Trimethyl-1(4H)-naphthalenone (10)

The 1:1 mixture of *cis*- and *trans*-enones **9** (120 mg, 0.645 mmol) obtained from the preceding experiment was dissolved in carbon tetrachloride (10 mL). *N*-Bromosuccinimide (230 mg, 1.29 mol) and benzoyl peroxide (5 mg, 0.021 mmol) were added. The mixture was refluxed for 1 h, then cooled to room temperature, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 1–2% ether in petroleum ether, gave 44 mg (37% yield) of aryl ketone **10** (21).

4,4,6-Trimethyl-4aβ,5,8,8aβ-tetrahydro-1(4H)-naphthalenone and 4,4,6-Trimethyl-4aβ,5,8,8aα-tetrahydro-1(4H)-naphthalenone (11)

Keto ester **7** (248 mg, 1.00 mmol) was dissolved in the lithium iodide dihydrate – collidine reagent (2.34 mL, 3.00 mmol) and the mixture was brought to reflux. After heating for 3 h the mixture was cooled to room temperature, poured into cold aqueous 5% hydrochloric acid, and extracted with ether. The extracts were washed with cold 5% aqueous hydrochloric acid and water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 4–10% ether in petroleum ether, gave a mixture of *cis*- and *trans*-enones **11** (43:57 by ^{1}Hmr integration, 174 mg, 91% yield, 97% based on consumed starting material). Further elution with 10–15% ether in petroleum ether gave keto ester **7** (18 mg, 7% recovery). The ^{1}Hmr spectrum of the product mixture exhibited two sets of signals. The following ^{1}Hmr data were attributed to the *cis* compound: δ: 6.29 (dd, ~2/5H, J = 10, J' = 2 Hz, —C*H*=CH—CO—), 5.68 (d, ~2/5H, J = 10 Hz, —CH=C*H*—CO—), 5.33 (m, ~2/5H, =CH—), 2.82 (m, ~2/5H, —CO—CH—), 1.58 (br s, 3 × ~2/5H, =C—CH_3), 1.30 (s, 3 × ~2/5H, —CH_3), and 1.10 (s, 3 × ~2/5H, —CH_3). The following ^{1}Hmr data were attributed to the *trans* compound: δ: 6.56 (d, ~3/5H, J = 10 Hz, —C*H*=CH—CO—), 5.72 (d, ~3/5H, J = 10 Hz, —CH=C*H*—CO—), 5.33 (m, ~3/5H, =CH—), 1.66 (br s, 3 × ~3/5H, =C—CH_3), 1.14 (s, 3 × ~3/5H, —CH_3), and 1.04 (s, 3 × ~3/5H, —CH_3). The following spectral data were recorded for the mixture: ir (CCl_4): 1686 (C=O), 1675 (C=O), 1397, 1379, 1367 (CH_3), 790 (C=CH) cm^{-1}. *Exact Mass* calcd. for $C_{13}H_{18}O$: 190.1357; found (ms): 190.1352. *Anal.* calcd. for $C_{13}H_{18}O$: C 82.06, H 9.54; found: C 82.06, H 9.55.

4,4,6-Trimethyl-1(4H)-naphthalenone (12)

A mixture of *cis*- and *trans*-enones **11** (58 mg, 0.31 mmol) obtained from the preceding experiment was dissolved in carbon tetrachloride (10 mL) and *N*-bromosuccinimide (109 mg, 0.61 mmol) and benzoyl peroxide (5 mg, 0.02 mmol) were added. The mixture was stirred vigorously and heated at reflux for 45 min, then cooled to room temperature, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 1.5–2% ether in petroleum ether, gave an impure sample of aryl ketone **12** which was subjected to a second chromatographic purification. This provided pure aryl ketone **12** (25 mg, 43% yield); ir 1661 (C=O), 1607, (aromatic C=C), 1395, 1372, 1359 (CH_3), 814 (aromatic CH) cm^{-1}; ^{1}Hmr δ: 7.95 (d, 1H, J = 8 Hz, C-8 H), 7.20 (br s, 1H, C-5 H), 7.09 (dd, 1H, J = 8, J' = 2 Hz, C-7 H), 6.72 (d, 1H, J = 10 Hz, —C*H*=CH—CO—), 6.18 (d, 1H, J = 10 Hz, —CH=C*H*—CO—), 2.40 (s, 3H, —CH=C—C*H*$_3$), and 1.44 (s, 6H, 2 × —CH_3). *Exact Mass* calcd. for $C_{13}H_{14}O$: 186.1045; found (ms): 186.1047.

8aβ-Carbomethoxy-1-triethylsilyloxy-4,4,6-trimethyl-3,4,4aβ,5,8,8a-hexahydronaphthalene (13)

Finely divided keto ester **7** (760 mg, 3.06 mmol) was suspended in triethylsilane (710 mg, 6.12 mmol) and *tris*-triphenylphosphine rhodium(I) chloride (14 mg, 0.015 mmol) was added. The mixture was stirred for 5 h after which additional triethylsilane (710 mg) was added. After a further 19 h the mixture was diluted with petroleum ether, filtered, and concentrated to give crude silyl enol ether **13** (1.28 g). Column chromatography of crude **13** on silica gel, eluting with 3–5% ether in petroleum ether, gave pure silyl enol ether **13** (1.01 g, 91% yield) as a colourless oil; ir: 1743, 1728 (C=O), 1674 (enol C=C), 1387, 1378, 1366 (CH_3), and 820 (C=CH) cm^{-1}; ^{1}Hmr δ: 5.28 (m, 1H, CH_3—C=C*H*—), 4.63 (dd, 1H, J = 6, J' = 3 Hz, —O—C=C*H*—), 3.58 (s, 3H, —O—CH_3), 2.63 (dd, 1H, $J = J'$ = 8 Hz, —CH—), 1.62 (s, 3H, =C—CH_3), 0.96 (s, 6H, —C(CH_3)$_2$), 0.96 (t, 9H, J = 7 Hz, —Si(CH_2CH_3)$_3$), and 0.61 (q, 6H, J = 7 Hz, —Si(CH_2CH_3)$_3$). *Exact Mass* calcd. for $C_{21}H_{36}O_3Si$: 364.2433; found (ms): 364.2433. *Anal.* calcd. for $C_{21}H_{36}O_3Si$: C 69.18, H 9.95; found: C 69.36, H 9.95.

8aβ-Carbomethoxy-4,4,6-trimethyl-3,4,4aβ,5,8,8a-hexahydro-1(2H)-naphthalenone (14)

Pure silyl enol ether **13** (993 mg, 2.72 mmol) was dissolved in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

methanol (50 mL) and a solution of 10% aqueous potassium carbonate (10 mL) was added. The mixture was stirred for 4 h, then poured into water and extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 3–10% ether in petroleum ether, gave keto ester **14** (598 mg, 88% yield) as a colourless oil; ir: 1743, 1731 (C=O, ester), 1710 (C=O, ketone), 1427 (—CH_2—C=O), 1388, 1367 (CH_3), and 783 (C=CH) cm^{-1}; ^{1}Hmr δ: 5.28 (m, 1H, —CH=), 3.62 (s, 3H, —O—CH_3), 1.60 (s, 3H, =C—CH_3), 1.07 (s, 3H, CH_3) and 0.97 (s, 3H, CH_3); ^{13}Cmr δ: 209.0, 173.7, 131.9, 117.7, 59.5, 52.4, 44.9, 38.4, 35.6, 33.4, 30.7, 29.6, 28.6, 23.8, and 23.5. *Exact Mass* calcd. for $C_{15}H_{22}O_3$: 250.1569; found (ms): 250.1570. *Anal.* calcd. for $C_{15}H_{22}O_3$: C 71.97, H 8.86; found: C 71.83, H 8.73.

Crude silyl enol ether **13** could be hydrolyzed using the procedure above to give keto ester **14** in 94% overall yield from **7**.

4,4,6-Trimethyl-3,4,4aβ,5,8,8aα-hexahydro-1(2H)-naphthalenone (15) and 4,4,6-Trimethyl-3,4,4aβ,5,8,8aβ-hexahydro-1(2H)-naphthalenone (16)

Keto ester **14** (966 mg, 3.86 mmol) was dissolved in 2,4,6-collidine (24 mL) under an atmosphere of nitrogen. Anhydrous lithium iodide (4.14 g, 30.9 mmol) was added to the stirred solution followed by addition of water (556 mg, 30.9 mmol). The mixture was heated under reflux for 2.5 h, then cooled to room temperature, poured into cold 5% aqueous hydrochloric acid, and extracted with ether. The extracts were washed with ice-cold 5% aqueous hydrochloric acid and water, dried, filtered, and concentrated. The gc analysis of the residue showed the presence of *cis*- and *trans*-ketones **16** and **15** in a ratio of ~10:90. Column chromatography of the residue on silica gel, eluting with 4% ether in petroleum ether, gave *trans*-ketone **15** (550 mg, 74% yield) which crystallized on standing. One recrystallization from ether gave colourless crystals of pure *trans*-ketone **15**: mp 71–71.5°C; ir: 1706 (C=O), 1387, 1380 and 1366 (CH_3) cm^{-1}; ^{1}Hmr δ: 5.33 (br s, 1H, =CH—), 1.61 (s, 3H, =C—CH_3), 1.07 (s, 3H, —CH_3), and 0.98 (s, 3H, —CH_3); ^{13}Cmr δ: 212.8, 133.1, 120.2, 48.3, 46.0, 42.2, 38.9, 33.3, 32.5, 29.7, 26.3, 24.2, and 20.0. *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found (ms): 192.1513. *Anal.* calcd. for $C_{13}H_{20}O$: C 81.20, H 10.48; found: C 80.74, H 10.55. Further elution with 4–5% ether in petroleum ether gave a mixture of *cis*- and *trans*-ketones **16** and **15** (67:33 by gc analysis, 74 mg, 10% yield). Further elution with 5% ether in petroleum ether gave *cis*-ketone **16** (16 mg, 2% yield) which crystallized on standing. One recrystallization from ether gave pure *cis*-ketone **16**; mp 51–53°C; ir: 1709 (C=O), 1390 and 1370 (CH_3) cm^{-1}; ^{1}Hmr δ: 5.22 (br s, 1H, =CH—), 2.81 (dd, 1H, $J = J' = 5$ Hz, —CH—CO—), 1.58 (s, 3H, =C—CH_3), 1.32 (s, 3H, —CH_3), and 0.98 (s, 3H, —CH_3); ^{13}Cmr δ: 211.9, 131.4, 118.9, 46.6, 43.6, 37.9, 35.6, 33.0, 29.3, 27.8, 26.9, 24.1, and 23.7. *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found (ms): 192.1522. *Anal.* calcd. for $C_{13}H_{20}O$: C 81.20, H 10.48; found: C 80.87, H 10.44.

Equilibration of trans- *and* cis-*Ketones 15 and 16*

A mixture of *trans*- and *cis*-ketones **15** and **16** (50:50 by gc analysis, 618 mg, 3.21 mmol) was dissolved in methanol (25 mL) and 1 *N* aqueous sodium hydroxide (5 mL) was added. After stirring for 1 h the mixture was extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Gas chromatographic analysis of the residue showed the presence of *cis*- and *trans*-ketones **16** and **15** in a ratio of 18:82. Column chromatography of the residue on silica gel, eluting with 3% ether in petroleum ether, gave pure *trans*-ketone **15** (401 mg). Continued elution gave a mixture of *cis*- and *trans*-ketones **16** and **15** (50:50 by gc analysis, 160 mg). Further elution with 3–5% ether in petroleum ether gave pure *cis*-ketone **16** (27 mg). The total recovery of ketones **15** and **16** was 95%.

6-Carbethoxy-2,9,9-trimethyl-1,4,4aα,6,7,8,9,9aβ-octahydro-(5H)-benzocyclohepten-5-one (18) and 5-Carbethoxy-2,9,9-trimethyl-1,4,4aα,6,7,8,9,9aβ-octahydro-(5H)-benzocyclohepten-6-one (19)

Ketone **15** (1.69 g, 8.78 mmol) was dissolved in anhydrous ether (25 mL) under an atmosphere of nitrogen in a flask wrapped in aluminum foil to exclude light. The solution was cooled to 0°C and boron trifluoride etherate (2.49 g, 17.6 mmol) was added with stirring. Then ethyl diazoacetate (2.00 g, 17.6 mmol) was added. After 1 h saturated aqueous sodium bicarbonate (5 mL) was added slowly (5 min) and the resulting mixture was extracted with methylene chloride. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 5% ether in petroleum ether, gave keto ester **18** (2.09 g, 86% yield) as a pale yellow oil; ir: 1746 (ester C=O), 1703 (ketone C=O), 1390 and 1368 (CH_3) cm^{-1}; ^{1}Hmr δ: 5.33 (br s, 1H, =CH—), 4.08, 4.06 (each q, total 2H, each $J = 8$ Hz, —O—CH_2—CH_3), 3.53 (dd, 1H, $J = 10$, $J' = 4$ Hz, —CO—CH—CO_2—), 1.65 (s, 3H, =C—CH_3), 1.21 (dd, 3H, $J = J' = 8$ Hz, —O—CH_2—CH_3), 0.95 (s, 3H, —CH_3), and 0.76 (s, 3H, —CH_3); ^{13}Cmr δ: 211.0, 170.3, 134.4, 118.4, 60.9, 54.0, 53.4, 44.1, 43.0, 35.8, 32.0, 30.4 (two carbons), 24.4, 23.5, 19.2, and 14.1. *Exact Mass* calcd. for $C_{17}H_{26}O_3$: 278.1881; found (ms): 278.1883. *Anal.* calcd. for $C_{17}H_{26}O_3$: C 73.35, H 9.41; found: C 73.45, H 9.69.

Continued elution gave a mixture of keto esters **18** and **19** (50:50 by ^{1}Hmr integration, 154 mg, 6% yield). Further elution with 5–30% ether in petroleum ether gave keto ester **19** (195 mg, 8% yield) which crystallized on standing. One recrystallization from ether gave pure white crystals of keto ester **19**: mp 92–96°C; ir: 1750 (ester C=O), 1706 (ketone C=O), 1392, 1369 (CH_3), and 783 (C=CH) cm^{-1}; ^{1}Hmr δ: 5.27 (br s, 1H, =CH—), 4.10 (q, 2H, $J = 8$ Hz, —O—CH_2—CH_3), 3.28 (d, 1H, $J = 8$ Hz, —CO—CH—CO_2—), 2.45 (m, 2H, —CH_2—CO—), 1.63 (s, 3H, =C—CH_3), 1.25 (t, 3H, $J = 8$ Hz, —O—CH_2—CH_3), 1.02 (s, 3H, —CH_3), and 0.81 (s, 3H, —CH_3); ^{13}Cmr δ: 207.5, 169.4, 134.1, 119.3, 63.6, 61.0, 49.8, 40.5, 36.7 (two carbons), 35.9, 33.6, 32.9, 31.7, 23.0, 19.5, and 14.1. *Exact Mass* calcd. for $C_{17}H_{26}O_3$: 278.1882; found (ms): 278.1886. *Anal.* calcd. for $C_{17}H_{26}O_3$: C 73.35, H 9.41; found: C 73.18, H 9.43. The overall yield of keto esters **18** and **19** was 100% and in a ratio of ~90:10 by weight.

2,9,9-Trimethyl-1,4,4aα,6,7,8,9,9aβ-octahydro-(5H)-benzocyclohepten-5-one (20)

Keto ester **18** (307 mg, 1.10 mmol) was dissolved in lithium iodide dihydrate – collidine reagent (5.00 mL, 6.60 mmol) under an atmosphere of nitrogen. The resulting mixture was heated at reflux with stirring for 1 h, then cooled to room temperature, poured into ice-cold 5% aqueous hydrochloric acid and extracted with ether. The extracts were washed with ice-cold aqueous hydrochloric acid and water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 3–5% ether in petroleum ether, gave ketone **20** (192 mg, 85% yield) which crystallized on standing. One recrystallization from ether gave colourless crystals of pure ketone **20**; mp 53–54°C; ir: 1700 (C=O), 1391, 1378, 1368 (CH_3), and 784 (C=CH) cm^{-1}; ^{1}Hmr δ: 5.32 (br s, 1H, =CH—), 2.52 (ddd, 1H, $J = J' = 10$, $J'' = 3$ Hz, —CO—CH—), 1.64 (br s, 3H,

=C(CH$_3$)—), 0.95 (s, 3H, —CH$_3$), and 0.75 (s, 3H, —CH$_3$); ^{13}Cmr δ: 216.7, 134.4, 118.8, 53.5, 45.8, 43.3, 40.2, 36.1, 32.3, 31.1, 30.7, 23.5, 22.2, and 19.0. *Exact Mass* calcd. for $C_{14}H_{22}O$: 206.1671; found (ms): 206.1676.

2,9,9-Trimethyl-1,4,4aβ,6,7,8,9,9aβ-octahydro-(5H)-benzocyclohepten-5-one (17), 2,9,9-Trimethyl-3,4,4aα,6,7,8,9,9aβ-octahydro-(5H)-benzocyclohepten-5-one (21), and 2,9,9-Trimethyl-3,4,4aα,6,7,8,9,9aβ-octahydro-(5H)-benzocyclohepten-5-one (22)

Ketone **20** (831 mg, 4.03 mmol) was dissolved in dry benzene (25 mL) under an atmosphere of nitrogen. *p*-Toluenesulfonic acid monohydrate (393 mg, 2.02 mmol) was added and the mixture heated at reflux with stirring. After 3 h the mixture was cooled to room temperature and diluted with ether. The resulting solution was washed with saturated aqueous sodium bicarbonate and water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel eluting with 6% ethyl acetate in petroleum ether gave pure ketone **21** (98 mg, 12% yield) as an oil; ir: 1693 (C=O), 1391, 1378, 1362 (CH$_3$), and 829 (C=CH) cm^{-1}; ^{1}Hmr δ: 5.48 (br s, 1H, =CH—), 2.56 (dd, 1H, J = 8, J' = 4 Hz, —CO—CH—), 1.69 (s, 3H, =C(CH$_3$)—), 1.05 (s, 3H, —CH$_3$), and 0.91 (s, 3H, —CH$_3$); ^{13}Cmr δ: 218.0, 134.5, 122.3, 48.1, 45.3, 44.7, 38.1, 36.5, 31.2, 29.9, 27.2, 25.3, 23.9, and 21.8. *Exact Mass* calcd. for $C_{14}H_{22}O$: 206.1671; found (ms): 206.1675. *Anal.* calcd. for $C_{14}H_{22}O$: C 81.50, H 10.75; found: C 81.34, H 10.40. Continued elution gave a mixture of ketones **17**, **20**, **21**, and **22** (35 mg, 4% yield). Continued elution gave a mixture of ketones **17**, **20**, and **22** (700 mg, 84% yield). The total yield of ketones **17**, **20**, **21**, and **22** obtained was 100%.

The conditions described produced an identical mixture of products in identical yield when applied to a mixture of **17**, **20**, and **22**.

Epimerization of Ketone 20

Ketone **20** (20 mg, 0.097 mmol) was dissolved in methanol (5 mL) under an atmosphere of nitrogen and 1 *N* aqueous sodium hydroxide solution (1 mL) was added. The solution was heated at reflux with stirring for 48 h, then cooled to room temperature, diluted with water, and extracted with ether. The extracts were washed with water, dried, filtered, and concentrated to give a mixture of *cis*- and *trans*-ketones **17** and **20** (20:80 by ^{1}Hmr integration). Flash chromatography of the mixture on silica gel, eluting with 6% ethyl acetate in petroleum ether, gave a mixture of **17** and **20** (16 mg, 80% yield). Continued elution gave pure *cis*-ketone **17** (2 mg, 10% yield) as an oil; ir: 1696 (C=O), 1389, 1377, 1367 (CH$_3$), and 793 (C=CH) cm^{-1}; ^{1}Hmr δ: 5.26 (m, 1H, =CH—), 2.82 (m, 1H, —CO—CH—), 1.70 (s, 3H, =C(CH$_3$)—), 1.12 (s, 3H, —CH$_3$), and 1.00 (s, 3H, —CH$_3$). *Exact Mass* calcd. for $C_{14}H_{22}O$: 206.1670; found (ms): 206.1667.

Epimerization of Ketone 21

Ketone **21** (17 mg, 0.083 mmol) was dissolved in methanol (5 mL) under an atmosphere of nitrogen and 1 *N* aqueous sodium hydroxide (0.5 mL) was added. The mixture was heated at reflux with stirring for 20 h. The reaction mixture was cooled to room temperature, diluted with water, and extracted with ether. The extracts were washed with water, dried, filtered, and concentrated to give a mixture of *cis*- and *trans*-ketones **21** and **22** (20:80 by ^{1}Hmr integration, 13 mg, 77% yield). The ^{1}Hmr of this product mixture showed two sets of signals; a minor set identical with those already reported for *cis*-ketone **21** and a major set attributed to the *trans*-ketone **22**; ^{1}Hmr δ: 5.26 (br s, 1H, =CH—), 1.70 (s, 3H, =C(CH$_3$)—), 1.04 (s, 3H, —CH$_3$), and 0.80 (s, 3H, —CH$_3$); ^{13}Cmr δ: 216.9, 135.7, 122.5, 47.8 (two carbons), 43.0 (two carbons), 37.0, 30.3, 29.8, 26.5, 24.6, 22.4, and 18.0. The following data were also recorded for the mixture of ketones **21** and **22**: ir: 1704 (C=O), 1390, 1365 (CH$_3$), and 828 (C=CH) cm^{-1}. *Exact Mass* calcd. for $C_{14}H_{22}O$: 206.1671; found (ms): 206.1669.

7-Epihimachalol (23)

A 0.25 *N* solution of methyllithium in ether (4.34 mL, 1.08 mmol) was diluted with ether (10 mL). A solution of ketone **21** (149 mg, 0.72 mmol) in dry ether (10 mL) was added dropwise with stirring over 5 min. After stirring for an additional 30 min the reaction mixture was poured into ice and water (~20 mL) and the resulting mixture was extracted with ether. The extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 5% ether in petroleum ether, gave alcohol **23** (149 mg, 93% yield) which crystallized on standing. One recrystallization from petroleum ether gave white crystals of pure alcohol **23**; mp 66–68°C; ir: 3461 (OH), 1387, 1376, 1363 (CH$_3$), and 856 (C=CH) cm^{-1}; ^{1}Hmr δ: 5.50 (br s, 1H, =CH—), 1.70 (s, 3H, =C(CH$_3$)—), 1.24 (s, 3H, —C(OH)C*H*$_3$), and 0.97 (s, 6H, 2 × —CH$_3$); ms *m/e* ($M^+ - H_2O$): 204.1880 (calcd. for $C_{15}H_{24}$: 204.1878). *Anal.* calcd. for $C_{15}H_{26}O$: C 81.02, H 11.79; found: C 81.14, H 11.55.

α-Himachalene (2) and β-Himachalene (3)

Alcohol **23** (103 mg, 0.464 mmol) was dissolved in dry pyridine (4 mL) under an atmosphere of nitrogen and the resulting solution was heated to reflux. A solution of phosphoryl chloride (142 mg, 0.928 mmol) in pyridine (1 mL) was added and the reaction mixture was refluxed for 1 h. The mixture was cooled to 0°C, poured into ice-cold 5% aqueous hydrochloric acid, and extracted with ether. The extracts were washed with ice-cold aqueous 5% hydrochloric acid and water, dried, filtered, and concentrated. Column chromatography of the residue on neutral alumina (Woelm I), eluting with petroleum ether, gave a mixture of himachalenes **2** and **3** (88 mg, 93% yield) in a ratio of 75:25 by ^{1}Hmr integration. A sample of a similar mixture (130 mg) was purified by flash chromatography on silica gel eluting with petroleum ether. The fractions obtained, in order of elution, contained (*a*) pure α-himachalene (56 mg); (*b*) α- and β-himachalene, 50:50, (40 mg); (*c*) α- and β-himachalene, 40:60, (17 mg); and (*d*) β-himachalene, 80% pure, (4 mg). α-Himachalene (**2**) showed the following spectral data: ir (neat): 3060, 1775, 1626 (C=CH$_2$), 1390, 1379, 1362 (CH$_3$), 885 (C=CH$_2$), 868 (C=CH), and 822 (C=CH$_2$) cm^{-1}; ^{1}Hmr δ: 5.43 (br s, 1H, =CH—), 4.70 (m, 2H, =CH$_2$), 1.68 (d, 3H, J = 1.5 Hz, =C(CH$_3$)—), 1.01 (s, 3H, —CH$_3$), and 0.97 (s, 3H, —CH$_3$). *Exact Mass* calcd. for $C_{15}H_{24}$: 204.1878, found (ms): 204.1874. The sample of β-himachalene (**3**) showed the following spectral data: ^{1}Hmr δ: 5.37 (br s, 1H, =CH—), 2.84 (br s, 1H, =CH—C*H*—C=), 1.74 (s, 3H, =C(CH$_3$)—), 0.99 (s, 3H, —CH$_3$), and 0.75 (s, 3H, —CH$_3$). *Exact Mass* calcd. for $C_{15}H_{24}$: 204.1878; found (ms): 204.1876.

Merostabilization in radical ions, triplets, and biradicals. 5. The thermal *cis–trans* isomerization of *para*-substituted tetraphenylethylenes[1]

WILLIAM J. LEIGH AND DONALD R. ARNOLD[2]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received July 16, 1980

WILLIAM J. LEIGH and DONALD R. ARNOLD. Can. J. Chem. **59**, 609 (1981).

The *cis*- and *trans*-isomers of four *para*-substituted (three disubstituted and one tetrasubstituted) tetraphenylethylenes have been synthesized, separated, and characterized by either dipole moment or X-ray analysis. The rates of thermal isomerization of the disubstituted derivatives in benzene solution correlate with a substituent parameter reflecting substituent effects on benzylic radical stabilities ($\sigma\cdot$), which reflects the biradical nature of the transition state for thermal isomerization in this system. A significant rate enhancement is observed for the tetrasubstituted derivative, in which merostabilization of the transition state is possible.

The Arrhenius parameters for thermal isomerization in benzene were determined. From the variation observed for the disubstituted derivatives, an estimate of 35.5 kcal mol^{-1} for the rotational barrier in tetraphenylethylene is obtained. The activation energy for thermal isomerization of the tetrasubstituted derivative is 2 kcal mol^{-1} lower than those of the other three; this provides an assessment of the importance of merostabilization in this system.

The thermal isomerization of some related olefins (e.g. bianthrylidenes and indigo derivatives) is discussed in light of these results.

WILLIAM J. LEIGH et DONALD R. ARNOLD. Can. J. Chem. **59**, 609 (1981).

On a synthétisé les isomères *cis* et *trans* de quatre tétraphényléthylènes substitués en positions *para* (trois sont bisubstitués et un est tétrasubstitué) et on les a séparés et caractérisés soit par leur moment dipolaire soit par diffraction des rayons-X. Les vitesses d'isomérisation thermique des dérivés bisubstitués dans une solution de benzène peuvent être reliées à un paramètre de substituant qui est un reflet des effets de substituant sur les stabilités du radical benzyle ($\sigma\cdot$), lesquels sont un reflet de la nature biradicalaire de l'état de transition de l'isomérisation thermique de ce système. On observe une augmentation significative de la vitesse du dérivé tétrasubstitué dans lequel une mérostabilisation de l'état de transition est possible.

On a déterminé les paramètres d'Arrhénius de l'isomérisation thermique dans le benzène. A partir de la variation observée pour les dérivés bisubstitués, on a évalué à 35,5 kcal mol^{-1} la barrière de rotation du tétraphényléthylène. L'énergie d'activation de l'isomérisation thermique du dérivé tétrasubstitué est de 2 kcal mol^{-1} plus faible que celles des trois autres dérivés; ceci donne une appréciation de l'importance de la mérostabilisation dans ce système.

A la lumière de ces résultats, on discute de l'isomérisation thermique de quelques oléfines apparentées (comme les dérivés des bianthrylidènes et de l'indigo).

[Traduit par le journal]

Introduction

It is generally accepted that the ground and first excited states of 90°-twisted ethylene have predominantly biradical character (1). The multiplicities of these states are triplet and singlet, respectively, and they correspond to the first excited triplet state of ethylene in the twisted geometry (the ^3p state (2)) and the transition state for thermal isomerization in the ground state (the ^0p state). This ordering of the p-states is frequently reversed in substituted ethylenes (2).

Substituent effects on the energies of the p-states in ethylene relative to their counterparts in the planar geometry are a result of both steric and electronic factors. Sterically bulky substituents raise the energies of the planar states relative to the p-states. One obvious result of this is the lower activation energies for thermal isomerization generally observed for sterically crowded olefins (3). An illustration of the effect on the triplet state is provided by the stilbenes; the sterically unencumbered *trans*-stilbene triplet is nearly isoenergetic with the twisted ^3p state, while the triplet energy of *cis*-stilbene is about 8 kcal mol^{-1} higher (2). Accordingly, *cis*-stilbene is observed to undergo nonvertical excitation (excitation directly to the ^3p state) while the *trans*-isomer does not (2). In cases where both planar isomers are sterically hindered, nonvertical excitation occurs for both (4).

The relative energies of the planar ground state and the ^0p state are markedly affected by electronic factors. In ethylenes which are symmetrically substituted across the double bond, the general trend observed is that this energy difference decreases the greater the ability of the substituent to stabilize a radical (3*a*, *c*). In other words, the electronic effect of a substituent is much greater on the energy of the ^0p state than on that of the planar ground states. On the other hand, it appears that any difference in stability between planar and twisted triplet states is primarily the result of steric factors (e.g. the stilbenes). Biradical stabilization of the triplet state

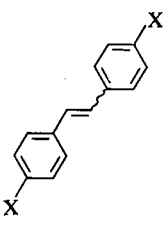
does appear, however, when one considers the difference in energy between the triplet state and the ground state (i.e. the triplet energy).

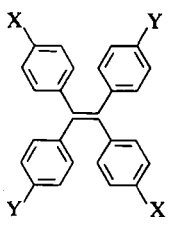
The situation is different with ethylenes which are unsymmetrically substituted about the double bond. Since the olefinic carbons are not equivalent, a certain amount of bond polarization will occur in the transition state for thermal isomerization (1). This bond polarization can be stabilized by appropriate substitution of donor and acceptor groups on the double bond. Compounds of this type have characteristically low barriers to thermal isomerization (3*a*, 5) and in extreme cases the most stable ground state conformation is in fact twisted about the double bond (5). These low rotational barriers are alternatively explained as being due to decreased double bond order as a result of the contribution from charge-separated resonance structures (in which the olefinic bond has single bond character) to the resonance hybrid structure describing the ground state of the olefin (3*a*, 5).

The transition state for thermal isomerization and the triplet state of symmetrical (across the double bond) olefins such as stilbene (**1**) and tetraphenylethylene (**2**) are thus expected to have predominantly biradical character. The energies of these states relative to the ground state should therefore be roughly as sensitive to variations in ring-substituents as is the stability of the benzyl or diphenylmethyl radical. Substituent effects on benzyl radical stability are small but clearly significant (6–9); all *para*-substituents with the exception of fluorine stabilize the benzyl radical to a certain extent. It is therefore expected that symmetrically substituted (cf. **1** and **2**) stilbenes and tetraphenylethylenes will exhibit slightly lower triplet energies and activation energies for thermal isomerization than the parent compounds. However, when X and Y in substituted tetraphenylethylenes (**2**) are substituents of opposite electron demand, these quantities may be more significantly affected.

Merostabilization (10) is receiving increased recognition as a factor contributing to the stability of free radicals. This concept accounts for the increased stability imparted to free radicals when



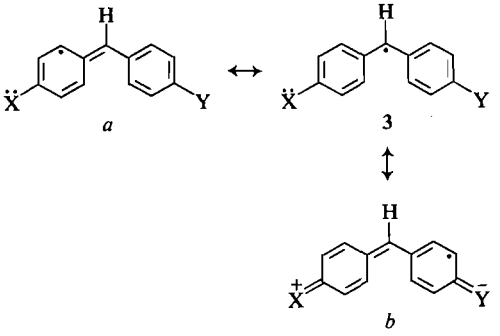
1



2

simultaneously substituted at the radical site with substituents of opposite electron demand. The effect is most commonly explained in valence bond terminology; the increased stability is a result of the contribution of low energy charge-separated resonance structures to the valence bond hybrid which enables more extensive delocalization of the unpaired electron (10), as is illustrated in [1] with

[1]

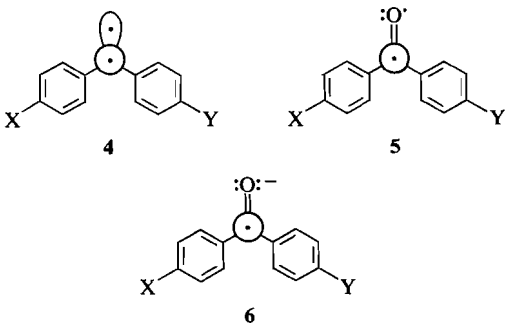


a **3** *b*

the diphenylmethyl radical **3**. The stability of diphenylmethyl is rationalized in terms of resonance structures of type **3***a*, in which unpaired electron density is delocalized onto the *ortho*- and *para*-positions of the rings. Contributions from resonance structures of type **3***b* allow delocalization of the unpaired electron onto *all* carbon atoms in the system. More rigorous explanations have employed molecular orbital theory (11, 12); in fact, the effect was first described in a derivation of a theoretical approach to free radical reactivity (11). A qualitative molecular orbital approach has recently been developed (12).

Although a large number of examples of merostabilized free radicals are now known (10, 12, 13), the effect on other systems containing unpaired electrons has generally not been explored. We have initiated a program designed to assess the importance of merostabilization as a factor contributing to the stability of radical ions, triplet states, and biradical species using the diphenylmethyl radical as the common model system. In our earlier reports in this series, we demonstrated the role of merostabilization in extending electron delocalization in triplet diphenylmethylenes (**4**) (14, 16) and its effect on the stability of benzophenone n,π^* triplets (**5**) (15, 16) and radical anions (**6**) (16).

In this report, we describe the synthesis, separation, and characterization of a series of four *para*-substituted tetraphenylethylenes **2***a–d*, and provide a detailed description of the kinetics of thermal *cis–trans* isomerization. From an analysis of the rates and energetics of the isomerization of the three disubstituted derivatives (**2***a–c*), we obtain an indication of the nature of the "normal" sub-



4 5 6

stituent effect (in the absence of merostabilization) on the rotational barrier in tetraphenylethylene. Extrapolation then enables a fairly precise estimate to be made of the rotational barrier in the theoretically important parent compound, tetraphenylethylene. We rationalize the rotational barriers in this and other heavily arylated olefins by considering radical stability arguments, comparing calculated activation energies with experimental values. The effect of merostabilization on the energy of the transition state for thermal isomerization of tetraphenylethylene is demonstrated with the tetrasubstituted derivative **2***d*. With this indication in mind, we offer a different interpretation of the low rotational barriers observed for other important olefinic systems such as indigo derivatives.

Finally, this study provides the first systematic experimental indication of the biradical-like nature of the transition state for thermal *cis–trans* isomerization of symmetrically substituted (across the double bond) olefins.

Results

The tetraarylethylenes (**2***a–d*) were synthesized from the corresponding benzophenones as illustrated in [2] (17), and were obtained as approximately equimolar mixtures of *cis*- and *trans*-isomers. Initial purification by column chromatography removed unreacted ketone and other products. The *cis–trans* isomers were then separated by medium pressure (15–20 psi) column chromatography and/or repeated fractional recrystallization. The olefins were protected as much as possible from unnecessary light, since *cis–trans* isomerization proceeds rapidly and efficiently upon direct irradiation (18*a*). The composition of isomeric mixtures of **2***b–d* could be conveniently determined by high-pressure liquid chromatography (hplc). The *cis*- and *trans*-isomers of **2***a* could not be resolved by hplc under any conditions, so the compositions of mixtures were determined by a combination of ir and ^{1}Hmr spectroscopy (see Experimental).

The gross structures of **2***a–d* were inferred from their ^{1}Hmr, ir, uv, and mass spectra and elemental analysis; with the exception of *cis*- and *trans*-**2***b* (18) they are all new compounds. The identification of *cis*- and *trans*-isomers of **2***a* was made on the basis of an X-ray crystal structure determination performed on one of the isomers.[3] *Cis*- and *trans*-isomers of **2***b–d* were identified on the basis of their dipole moments. The dipole moments were measured in benzene solution at 25°C by the dielectric constant method (19) and are collected in Table 1. Included in the table for comparison are estimates of the dipole moments calculated by vector addition of standard group moments (20). For ease of calculation, the phenyl groups were assumed to be coplanar, the olefinic bond angles were assumed to be 120°,[4] and methoxy groups were assumed to be freely rotating.[5] The large differences between the dipole moments of the *cis*- and *trans*-isomers of **2***c* and **2***d* allows unambiguous assignments to be made in these cases. The agreement between calculated and observed values is excellent considering the rather gross approximations used in the calculations. The nonzero dipole moment observed for *trans*-**2***c* may be the result of a variety of factors; it is most likely due to the presence of a small

[3] T. S. Cameron, unpublished results. The crystal structures of both *trans*-**2***a* and *trans*-**2***b* are very similar to that found for tetraphenylethylene itself (see ref. 31*a*).

[4] The method of vector analysis used can be best illustrated by pointing out that the calculation of the dipole moment of *cis*-**2***d*, for example, reduces to a calculation of that of 1,2-dicyano-4,5-dimethoxybenzene.

[5] This, though accepted nomenclature (20), is misleading. The notion of "freely rotating" methoxy groups led us to expect calculated dipole moments of zero for *trans*-**2***b* and **2***d*. The calculation, however, gives the average dipole moment of all possible conformations, which is nonzero. The calculated and observed dipole moments of *trans*-4,4′-dimethoxystilbene are 1.70 and 1.69 D, respectively (21).

amount of the *cis*-isomer (a sample of *trans*-**2***c* contaminated with just 2% of the *cis*-isomer would yield a dipole moment of 1.1 D).

We considered our assignment of *cis*- and *trans*-**2***b* to be tentative, though it agrees with that of Olsen and Buckles (18*a*). Their assignment was made primarily on the basis of melting points; they reasoned that the more symmetric *trans*-isomer should pack into a more stable crystalline arrangement and would therefore be the higher melting of the two (18*c*). We note, however, that the higher melting isomers of both **2***c* and **2***d* are in fact the *cis*-isomers. X-ray analysis of *trans*-**2***b* proved the assignment made on the basis of dipole moments to be correct.[3]

The thermal isomerizations of *cis*- and *trans*-**2***a*–*d* were carried out in degassed, sealed ampoules using benzene, benzonitrile, and pyridine (2%) – benzene as solvents. There was no evidence of competing side reactions, leading to other products, in any case. Progress of the isomerization of **2***a* was monitored by ir spectroscopy. Concentration ratios were calculated from the relative absorbances of the 607.9 cm^{-1} band of *trans*-**2***a* and the 630.6 cm^{-1} band of *cis*-**2***a* (in perdeuteriobenzene) and the ratio of the extinction coefficients of these two bands. The concentration ratios were then converted to mole fractions for the kinetic analyses. Progress of the isomerizations of **2***b*–*d* were monitored by hplc. Apparent mole fractions obtained by measurements of peak areas in the hplc trace were converted to true mole fractions with working curves.

For the isomerization of simple olefins (eq. [3]), the sum of the rate constants for forward and reverse reactions can be obtained from concentration vs. time analysis according to eq. [4], which is derived by straightforward manipulation of the standard equation for first order reversible reactions (22*a*). X_0^c, X^c, and X_e^c are mole fractions of the *cis*-isomer at time = 0, t, and equilibrium, respectively. The individual rate constants k_1 and k_2 can

$$[3]\quad \textit{trans}\text{-}\mathbf{2} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \textit{cis}\text{-}\mathbf{2}$$

$$[4]\quad \ln \frac{X_0^c - X_e^c}{X^c - X_e^c} = (k_1 + k_2)t$$

then be obtained from the equilibrium constant:

$$[5]\quad K_e = X_e^c/(1 - X_e^c) = [cis]/[trans] = k_1/k_2$$

Equivalent results are of course obtained irrespective of the direction in which equilibrium is approached.

Rate constants for the isomerization of **2***a*–*d* were obtained by regression analysis of mole fraction – time data according to eq. [4] and are compiled in Table 2. Included in the table are the values of the equilibrium constants measured at each temperature along with recalculated values obtained from regression analysis of the Gibbs equation ($\ln K_e = \Delta H^0/RT$). The individual rate constants k_1 and k_2 can then be calculated from the sums and the recalculated equilibrium constants; for the sake of brevity these are not included, however.

We have used the sum of the rate constants ($k_1 + k_2$) in our analysis of the rates and energetics of *cis*–*trans* isomerization of **2***a*–*d* which follows, and it seems necessary to give some brief justification for this procedure. Although log ($k_1 + k_2$) in fact bears no rigorous thermodynamic significance with regard to the actual rotational barriers in **2***a*–*d*, it does have several advantages over the individual rate constants log k_1 or log k_2. Firstly, the kinetic analysis yields the sum directly, and the added manipulations that are required to obtain the individual rate constants compound the errors. Secondly, the quantity log ($k_1 + k_2$), which defines the activation energy for *approach to equilibrium*, is independent of K_e, and hence is independent of differences in the relative thermodynamic stability of *cis*–*trans* isomers within the series. Variations in the individual activation energies for *cis*→*trans* or *trans*→*cis* isomerization reflect *both* variations in transition state stability and ground state stability. Since the activation energy for approach to equilibrium (E_a) is in fact a *weighted average* of the individual activation energies ($E_a = (k_1E_1 + k_2E_2)/(k_1 + k_2)$) (22*b*), consideration of log ($k_1 + k_2$) provides an indication of the variation in transition state stability only, and effectively excludes the effects of specific interactions which may alter the relative stabilities of *cis*- and *trans*-isomers within the series.

Discussion

An indication of the "normal" substituent effect

on the rates and energetics of thermal isomerization of tetraphenylethylene, in the absence of merostabilization, is provided by the model compounds **2***a–c*. As the data in Table 2 (205°, 206.7°C) reveal, the rate of isomerization in benzene solution varies slightly (but significantly) with substitution in the *para*-positions of the rings. The rates of isomerization are the same, within experimental error, in pyridine (2%) – benzene as those in benzene, which rules out the possibility of rate enhancements due to adventitious acid catalysis. It is of interest to note that the observed trend in rates (**2***a* < **2***b* < **2***c*) does not correlate with Hammett substituent constants. This is in accord with current notions of substituent effects on benzylic radical stabilities (6–9). We have used the recently measured (9) relative rates of thermal isomerization of *meta*- and *para*-substituted 2-aryl-3,3-dimethylmethylenecyclopropanes to define a scale of substituent parameters reflecting the variation in benzylic radical stability with ring substituent (16):

$$[6] \quad \sigma\cdot = \log k_x/k_H$$

These parameters were found to correlate very well with benzylic proton hyperfine coupling constants from the esr spectra of ring-substituted benzyl radicals (7*a*). To the extent that electron delocalization correlates with radical stability, these parameters appear to accurately represent substituent effects on benzyl radical stabilities.[6]

Using the Arrhenius parameters obtained from our rate constant data for isomerization of **2***a–d* in benzene (*vide infra*), we have calculated the rates of thermal isomerization at one standard temperature (207.5°C) for comparative purposes. These are shown plotted versus $\sum\sigma\cdot$ in Fig. 1.

While the significance of the correlation between $\log(k_1 + k_2)$ and $\sum\sigma\cdot$ in Fig. 1 is admittedly not as great as it could be with the inclusion of more substituents, the trend is clear. The variation in rate within the series **2***a–c* is revealed by the small slope ($\rho\cdot = 0.24$) obtained from least-squares analysis of the three-point plot (c.c. = 0.91). The tetrasubstituted derivative **2***d* deviates significantly from the best line drawn for **2***a–c*, the rate of isomerization being a factor of about two greater than that expected on the basis of the "normal" radical stabilizing effect of the substituents (as predicted by $\sigma\cdot$-values). We attribute this rate enhancement to increased stabilization of the transition state as a result of merostabilization.

[6] As we have pointed out (16), benzylic proton hyperfine constants should provide the most accurate $\sigma\cdot$-scale. Due to the current unavailability of hyperfine data for more than a handful of substituents (7*a*), however, we continue to use the scale derived from Creary's data.

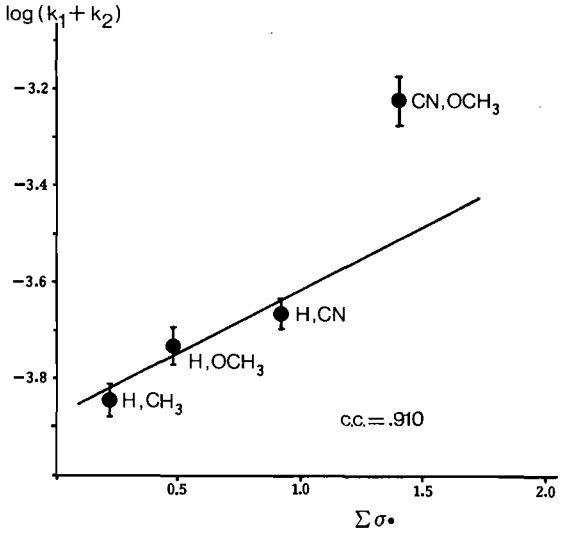

FIG. 1. The rates of thermal isomerization of 2*a*–*d* in benzene solution (207.5°C): log ($k_1 + k_2$) vs. $\Sigma\sigma\cdot$.

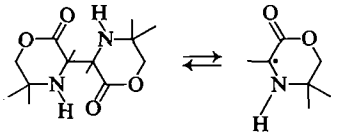
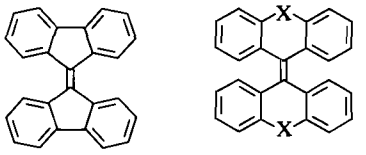
Since merostabilization is a result of the ability of the substituents to support charge separation in the free-spin system, the effect should be enhanced in more polar solvents. Koch and co-workers observed a considerable solvent effect on the enthalpy of dissociation of **7**, which exists in equilibrium with the merostabilized radical **8** (13*g*). The enthalpy of dissociation in ethanol (ΔH = 11 kcal mol^{-1}) is 10 kcal mol^{-1} less than the value of 21 kcal mol^{-1} observed in chloroform and benzene.

We therefore measured the rates of isomerization of 2*b*–*d* at 207.5°C in benzonitrile solution (Table 2). The dielectric constants of benzene and benzonitrile at 207.5°C are estimated to be about 2 and 12, respectively (23). The rate of isomerization of 2*d* is indeed enhanced (by ca. 25%) in this solvent relative to the rate in benzene. It seems unlikely, however, that this rate enhancement is attributable entirely to merostabilization: while the dicyano derivative (2*c*) showed no rate enhancement in the more polar solvent, the rate of isomerization of the dimethoxy derivative (2*b*) was significantly faster.



7 **8**



9 **10**

Arrhenius parameters for the thermal isomerization of 2*a*–*d* in benzene solution were determined from the temperature dependence of the rate constants and are compiled in Table 3, along with the ground state enthalpy differences calculated from the temperature dependence of the equilibrium constants according to the Gibbs equation. As expected, the difference in thermodynamic stability between *cis*- and *trans*-isomers is not large, being less than 0.5 kcal mol^{-1}, although the *trans*-isomer is slightly more stable in all cases. Stabilization of the *trans*- relative to the *cis*-isomers may simply be the result of dipole–dipole interactions; the difference in thermodynamic stability increases as the difference in dipole moments between the two isomers increases (2*a*,*b* < 2*c*,*d*). The equilibrium is shifted slightly in favor of the *cis*-isomers in the more polar solvent benzonitrile, though the effect is not large.

Within the series of disubstituted derivatives 2*a*–*c*, the variations in both the activation energies and pre-exponential factors are very small, as the data in Table 3 reveal. "Normal" pre-exponential factors of the order of 10^{12} are observed in each case, which indicates that the isomerization process takes place entirely within the singlet manifold (24). The observation of very low pre-exponential factors and activation energies in early studies of *cis*–*trans* isomerizations were interpreted as being due to the involvement of the triplet state; however, reinvestigation indicated more normal Arrhenius parameters in most cases (25). It is now generally accepted that triplet state involvement is unlikely (24), and that the early indications were the result of catalysis. In any case, the triplet (^3p) energies of 2*a*–*d* appear to be at least 10 kcal mol^{-1} higher than the activation energies for thermal isomerization,[7] so any mechanism for the thermal process involving the triplet state is unlikely.

The activation energies for thermal isomerization of 2*a*–*c* are very similar, varying by not more than 0.2 kcal mol^{-1} within the limits of experimental error. The small variation in activation energy is as expected considering the variation in the rates of isomerization within the series.

It has been pointed out that the difference between the activation energies for thermal isomeri-

[7]W. J. Leigh and D. R. Arnold, unpublished results. The triplet (^3p) energies of 2*a*–*d* have been estimated from a qualitative examination of the relative efficiencies of triplet-sensitized isomerization as a function of sensitizer triplet energy. The triplet energies of 2*a*–*c* are very similar (~48 kcal mol^{-1}) while that of 2*d* is significantly lower (~46 kcal mol^{-1}).

zation (gas phase) of *cis*-stilbene and *cis*-2-butene of 20 kcal mol^{-1} is approximately twice the stabilization energy of the benzyl radical (13 kcal mol^{-1}) (3*c*). The rotational barrier in tetraphenylethylene, which can be estimated to be 35.5 kcal mol^{-1} from the variation in activation energy for **2***a–c*, is therefore similarly expected to reflect the stabilization energy of the diphenylmethyl radical. These results imply additional stabilization of at least 4 kcal mol^{-1} in the diphenylmethyl radical over that in the benzyl radical. Although the bond dissociation energy of diphenylmethane is to our knowledge not available, we can obtain a reasonable estimate of the resonance stabilization energy in diphenylmethyl by considering the spin densities at the benzylic carbon calculated from the α-proton hyperfine constants in the esr spectra of the benzyl radical (ρ = 0.654 (7*a*))[8] and the diphenylmethyl radical (ρ = 0.588 (26)).[8] The spin density at the benzylic carbon decreases by about 30% on going from the ethyl radical (ρ = 0.919 (15)) to the benzyl radical, and a further decrease of about 10% occurs in diphenylmethyl. Taking 13 kcal mol^{-1} as the stabilization energy of the benzyl radical (3*c*, 27*a*), the variation in spin density implies that diphenylmethyl has 1/3 of this, or 4–5 kcal mol^{-1} more stabilization energy than the benzyl radical. This agrees with the value of 4 kcal mol^{-1} calculated from the difference in the activation energies for thermal decomposition of azobis(diphenylmethane) (27*b*) and azobis(phenylmethane) (8*c*). The rotational barrier in tetraphenylethylene is therefore expected to be 8–10 kcal mol^{-1} lower than that for *cis*-stilbene, in agreement with the observed results.

Similar arguments allow estimates of the rotational barriers in related systems such as bisfluorenylidene (**9**) and the bianthrylidenes (**10**). These olefins have been rather extensively studied due to their well-known thermo- and photochromic properties (28). The esr spectra of the 9-fluorenyl and 9-xanthenyl radicals have been determined, and from the α-proton hyperfine constants we can calculate the spin densities at the benzylic carbons to be ρ = 0.52 (29)[8] and ρ = 0.50 (30),[8] respectively. These 20–23% decreases in spin density relative to that in benzyl imply that these radicals each have 8–10 kcal mol^{-1} more stabilization energy than the benzyl radical. Restricting the phenyl rings to a coplanar arrangement effectively doubles the stabilization energy in these radicals compared to diphenylmethyl. This leads to an estimate of 26–30 kcal mol^{-1} for the rotational barriers in **9** and **10**, assuming biradical stabilization to be the major factor contributing to the activation energies for thermal isomerization in these systems.

Figure 2 illustrates the ground state conformations (as determined by X-ray analysis (31)) and the (highest energy) transition states for thermal isomerization in **2**, **9**, and **10**. The larger angle of twist about the double bond in bisfluorenylidene (**9**) compared to that in tetraphenylethylene relieves steric strain due to buttressing of the hydrogens in the 1,1′- and 8,8′-positions. These interactions are relieved in tetraphenylethylene by twisting the phenyl rings relative to one another; the angle of twist about the double bond in tetraphenylethylene is accordingly smaller than in bisfluorenylidene. While these results would imply a smaller degree of double bond order in **9** relative to **2**, it is difficult to quantitatively assess the contribution from these factors to the activation energy for thermal isomerization of **9**.

While 1,1′-substituted derivatives of **9** are known to have free energies of activation in the 20–21 kcal mol^{-1} range (32), an investigation of the thermal isomerization of 2,2′-difluorobisfluorenylidene (by nmr coalescence studies) has led to the suggestion that the rotational barrier in the parent compound is much higher than this (33). Although no indication of $\Delta G^{\ddagger}$ was given in this report, we can estimate a lower limit for the activation energy for isomerization of **9** based on the limited amount of data that

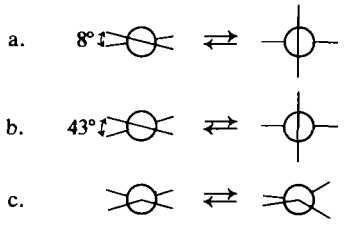

FIG. 2. Newman projections (along the olefinic bond) of the ground state and (highest energy) transition state conformations of (a) tetraphenylethylene (**2**) (31*a*); (b) bisfluorenylidene (**9**) (31*b*); (c) bianthrylidene (**10**) (31*c*).

[8]Calculated according to the McConnell equation; $a = Q\rho$, Q = 25 G.

For personal use only.

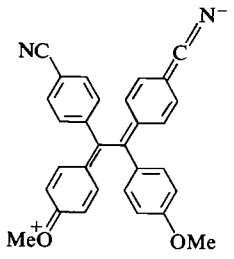
was given. The authors indicated that coalescence of the fluorine signals was expected at temperatures "considerably higher than 220°C" (33). Assuming then that $T_c \sim 250$°C, we get an estimate of 26 kcal mol^{-1} for the activation energy in this case.[9] This is in excellent agreement with the value estimated from the spin density argument above, considering that steric destabilization is also expected to contribute to some extent. The importance of biradical stabilization in the bisfluorenylidene system is further demonstrated by the low $\Delta G^{\ddagger}$ observed for thermal isomerization of bis(11*H*-benzo[*b*]fluorenylidene) (23.5 kcal mol^{-1}) (35).

The thermal isomerizations of a wide variety of 2,2′-substituted derivatives of bianthrylidene (**10**) have been studied and are known to have considerably lower activation barriers ($\Delta G^{\ddagger} \sim$ 17–21 kcal mol^{-1}) (36) than the estimate based on radical stability arguments given above. Steric destabilization of the ground state is considerable in this system. Although some of this strain is relieved by puckering of the central rings in the most stable conformer (the A form, see Fig. 2), the highest energy transition state for thermal isomerization is in fact one in which two of the phenyl rings are eclipsed (36). The 90°-twisted form corresponds to the transition state for interconversion of the B forms and is lower in energy.

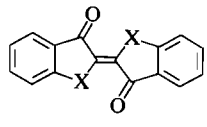
The small substituent effect on the activation energy for thermal isomerization of tetraphenylethylene is reasonable in view of the known small effect of substituents on benzylic radical stability. These have generally been investigated using relative rate studies; only in a few cases have complete rate–temperature studies been carried out. The activation energies for thermal decomposition of *para*-substituted azocumenes vary by less than 1.5 kcal mol^{-1} over a range of substituents including fluoro, chloro, methyl, and methoxy (8). Activation energies for thermal isomerization of 2-aryl-3,3-dimethylmethylenecyclopropanes were inferred from the rates of isomerization at only two temperatures (37); these vary between 27–30 kcal mol^{-1} for a wide range of substituents. A more reliable estimate can be obtained by calculating the activation energies from the rates of isomerization at 100°C (8), assuming the pre-exponential factor is constant within the series (3×10^{13} s^{-1}). This gives a variation of less than 0.9 kcal mol^{-1} within the entire range of substituents studied. The difference in activation energy between 2-(4-cyanophenyl)- and 2-(4-methylphenyl)-3,3-dimethylmethylenecyclopropane is about 0.5 kcal mol^{-1}. The variation in activation energy for thermal isomerization for **2***a–c* of $\sim$ 0.2 kcal mol^{-1} is thus consistent with the biradical nature of the transition state.

The Arrhenius parameters for thermal isomerization of the tetrasubstituted derivative **2***d* are strikingly different from those observed for **2***a–c*, the activation energy being about 2 kcal mol^{-1} lower than that of **2***c*. We attribute this pronounced lowering of the rotational barrier in **2***d* to additional stabilization of the biradical-like transition state as a result of merostabilization. Simultaneous substitution by both electron-donating and withdrawing groups in the *para*-positions allows an increased contribution from charge-separated resonance structures to the resonance hybrid describing the perpendicular, biradical transition state. The smaller pre-exponential factor observed for **2***d* is also consistent with this explanation. The same interactions which are responsible for lowering the energy of the transition state relative to the ground state also lead to increased rigidity in the transition state, and thus result in a reduction in the entropy of activation. The existence of an isokinetic relationship for thermal olefin isomerizations has been previously noted (24).

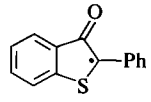
It may be argued that the lower activation energy observed for the thermal isomerization of **2***d* may be due to decreased π-bond order in the ground state, as a result of the contribution from polarized resonance structures such as **2***d*′ to the resonance hybrid. Indeed, the exceedingly low barriers to thermal isomerization observed for derivatives of indigo (**11**) have been explained in this way (38). Our data do not allow an estimate of what proportion of the 2 kcal mol^{-1} decrease in activation energy is attributable to such an effect. However, if such bond polarization is in fact important, we



2*d*′



11



12

[9]Using $\Delta\nu = 34$ Hz (33), we get $k_c \sim 76$ s^{-1} at 250°C (34). E_a is then calculated from the Arrhenius equation assuming $A \sim 10^{13}$ s^{-1}. This corresponds to $\Delta G^{\ddagger} \sim$ 26 kcal mol^{-1}, which is a reasonable lower limit in this case.

For personal use only.

would certainly expect more of a variation in the activation energies for **2***a–c*, since bond polarization should contribute in these derivatives as well, and to different extents depending on substituent. The low rotational barriers observed for indigo derivatives can alternatively be rationalized in terms of a biradical transition state.

The rate of thermal *cis–trans* isomerization (25°C) of **11** as a function of the heteroatom X decreases in the order NMe > NAc > S > Se ≫ O (38, 39), in the same order as the calculated π-bond energies increase (39*a*, 40). This is *not* the sort of trend expected simply on the basis of the ability of the heteroatom to support positive charge.

A biradical transition state, on the other hand, should enjoy considerable stabilization in this system. First of all, both carbonyl groups and heteroatoms adjacent to a radical site are strongly stabilizing (7, 9, 41). Furthermore, heteroatom radical-stabilizing effects increase in the order O < N ≤ S (42). Secondly, merostabilization should have a very pronounced effect in this case as a result of the contribution from resonance structures such as **11***a*, which enable delocalization of the unpaired electrons into the aromatic rings. Katritzky and co-workers have examined the closely analogous radical **12** by esr spectroscopy (10). This stable radical is generated by thermolysis of the dimer at 40–100°C. Analysis of the esr spectrum reveals significant spin density in the benzo-ring.

We believe that merostabilization of radical and radical-like species is a much more prevalent factor than has been recognized in the past. The well studied thermal isomerization of indigo derivatives is offered as an example where merostabilization may contribute to the lowering of the rotational barrier.

Conclusions

The rates of thermal isomerization of a series of *para,para'*-disubstituted tetraphenylethylenes correlate with a set of parameters describing substituent effects on benzylic radical stability, which is consistent with the biradical nature of the transition state. A significant rate enhancement is observed for the tetrasubstituted derivative; this is attributed to the effect of merostabilization on the energy of the transition state for thermal isomerization.

There is only a slight variation in the Arrhenius parameters for isomerization within the series of disubstituted derivatives, which allows an estimate of 35.5 kcal mol^{-1} for the rotational barrier in tetraphenylethylene. The activation energy observed for the tetrasubstituted derivative is about 2 kcal mol^{-1} less than those observed for the three model compounds; this provides an assessment of the contribution from merostabilization to the energy of the transition state for thermal isomerization of tetraphenylethylene derivatives.

Merostabilization may be the dominant factor responsible for the low rotational barriers characteristic of many indigo derivatives.

Experimental

All melting points are corrected. The ^{1}Hmr spectra were recorded on either a Varian T-60 or CFT20 nmr spectrometer and are reported in parts per million (ppm) downfield from TMS. Infrared spectra were recorded on an air-purged Perkin-Elmer 180 grating infrared spectrometer and are reported in wavenumbers, calibrated against the 1601.8 cm^{-1} polystyrene absorption. Ultraviolet–visible absorption spectra were recorded on a Cary-Varian 219 Absorption Spectrometer and are reported in nanometers. Elemental analyses were performed by Chemalytics, Inc. or Canadian Microanalytics, Inc., and agreed to within 0.3% of the calculated values. A Fisher proportional temperature control unit with an insulated silicon oil (Dow Corning 210-H) bath was used in the kinetic studies. Temperatures were recorded using a Hewlett-Packard 2802A thermometer, and did not vary by more than 0.5° during any particular run. Analyses of olefin mixtures (for **2***b–d*) were performed using a Tracor high pressure liquid chromatograph, which consists of a Tracor 995 isochromatographic pump, Model 970 variable wavelength absorbance detector, a Rheodyne model 7120 loop injection valve (20 μL volume), and a Hewlett-Packard Model 7123A strip chart recorder, in conjunction with a Whatman Partisil PXS 10/25 analytical column. The hplc solvents were hexanes (Fisher reagent, distilled) and dichloromethane (Fisher reagent, distilled from phosphorus pentoxide). Peak areas were determined by cutting and weighing, multiplying height by half-width, or planimetry; the three methods were shown to be of equal accuracy. Apparent mole fractions of the *cis*-isomers were obtained by dividing the area of the peak due to the *cis*-isomer by the sum of the areas of both peaks. These were then converted to true mole fractions with working curves, which were simply plots of apparent vs. true mole fractions constructed with ten standard solutions of accurately weighed mixtures of "pure" *cis*- and *trans*-isomers. Where necessary, the true mole fractions of the "pure" isomers were determined by dividing the hplc peak areas by the respective extinction coefficients of the two isomers obtained from their uv spectra in dichloromethane.

Analyses of mixtures of *cis*- and *trans*-**2***a* were performed by ir spectroscopy. The solution (ca. 0.15 *M*) in benzene-d_6 or pyridine-d_5 (2%) – benzene-d_6 was placed in a NaCl solution cell (0.113 mm path length, 60 μL cell volume) and placed in the sample beam of the PE 180 spectrometer. A matched cell containing solvent was placed in the reference beam. The spectrum was then scanned (3 cm^{-1} min^{-1}) through the 645–595 cm^{-1} region under conditions of high sensitivity, high S/N, and linear absorbance. No absorption in this region was evident in spectra of either solvent vs. air or solvent vs. solvent. The ratio of absorbances at 631 cm^{-1} (*cis*-**2***a*) and 608 cm^{-1} (*trans*-**2***a*) was then determined from the ratio of peak heights (average of two determinations), and converted to the concentration ratio using the ratio of extinction coefficients of the two bands. The extinction coefficient ratio ($\varepsilon_{trans}/\varepsilon_{cis}$ = 1.499) was determined by comparing the absorbance ratios of four mixtures of differing compositions with true concentration ratios determined from the integrated intensities of the methyl peaks in the ^{1}Hmr spectra (CFT 20) of the same mixtures in deuterochloroform. Concen-

For personal use only.

tration ratios were then converted to mole fractions for the kinetic analyses.

Benzene used in the dipole moment determinations and kinetic studies was Fisher reagent grade, which had been stirred with concentrated sulfuric acid for 12 h, washed thrice with distilled water, once with saturated aqueous bicarbonate, stirred over sodium for eight hours, and distilled. Pyridine was Eastman reagent grade and was used as received. Benzene-d_6 and pyridine-d_5 were purchased from Merck, Sharpe, and Dohme and used as received. Benzonitrile (Eastman, aniline free) was shaken with silica gel (2 × 100 g), filtered, stirred with calcium hydride for three hours, and decanted. It was then distilled twice from phosphorus pentoxide, taking middle fractions in each case.

The tetraarylethylenes were prepared from the corresponding benzophenones (16) by the method of Buckles and Matlack (17). The benzophenone was refluxed for 24 h with phosphorus pentachloride (1 equiv.) in dry benzene; in most cases, progress of the reaction was followed by ir spectroscopy. Following evaporation of solvent, the crude dichlorides were pumped on under vacuum for 1–3 hours, and then redissolved in fresh, dry benzene. Electrolytic copper dust (10 equiv., dried at 110°C for 12 h) was added and the mixtures refluxed for 24 h. The mixtures were cooled, filtered, and the solvent evaporated to yield the olefins as approximately equimolar mixtures of *cis–trans* isomers contaminated with unreacted benzophenone. The separation, purification, and characterization of each are described in detail below.

1,2-Di(4-methylphenyl)-1,2-diphenylethylene (2a)

The crude product from above (2 g) was chromatographed on a silica gel (65 g) column using hexane as eluant. The olefins (1.1 g, 61%) were eluted first from the column. After evaporation of solvent, the mixture of olefins was dissolved in hot hexane (~15 mL) and allowed to cool slowly in the dark. The two isomers crystallized in different crystalline forms, *needles (cis)* and *spherical clusters (trans)*, which were separated by hand, and recrystallized again. The needles dissolve more readily in warm hexane than do the clusters. A small amount of hexane could therefore be added to *trans*-rich mixtures, warmed slightly to dissolve the needles, and decanted off. A similar treatment was applied to the *cis*-rich mixtures. The *cis*- and *trans*-isomers could be obtained in roughly 90% isomeric purity after three or four careful recrystallizations. Mother liquors were combined and their volumes reduced to afford more material. The *trans*-isomer was finally recrystallized slowly from chloroform–hexane (1:4) to yield colourless plates (mp 171–175°C); ir (KBr): 3020(w), 1511(m), 1490(m), 1442(m), 811(br, m), 759(m), 748(s), 719(m), 700(s), 608(s); uv λ_{max} (ethanol): 242 (26 800), 311 (15 300); ^{1}Hmr ($CDCl_3$) δ: 2.23 (s, 3H), 6.88 (s, 5H), 7.06 (5, 4H). *Anal.* calcd. for $C_{28}H_{24}$: C 93.29, H 6.71; found: C 93.08, H 6.80. The identity of this isomer was inferred from an X-ray analysis. The *cis*-isomer was obtained as colourless needles (mp 130–134°C); ir (KBr): 3020(w), 1511(m), 1490(m), 1442(m), 821(w), 800(m), 785(w), 737(s), 727(w), 696(s), 631(m); uv λ_{max} (ethanol): 242 (25 300), 311 (14 600); ^{1}Hmr ($CDCl_3$) δ: 2.25 (s, 3H), 6.90 (s, 5H), 7.04 (s, 4H).

1,2-Di(4-methoxyphenyl)-1,2-diphenylethylene (2b)

The crude product (oily yellow solid, 33 g) was chromatographed on a silica gel (500 g) column using benzene (60%) – hexane as eluant. Evaporation of the first two material-containing fractions yielded a colourless solid (2.2 g) which was predominantly the *trans*-isomer (by hplc). Evaporation of the next five fractions yielded an oily solid (14.8 g) which was a roughly equimolar mixture of *cis*- and *trans*-isomers. The following six fractions yielded a colourless fluorescent oil (4.0 g) which subsequently crystallized; this was found to consist predominantly of the *cis*-isomer. The combined *trans*-rich mixture was recrystallized from chloroform (10%) – ethanol. A portion of this material (1 g) was chromatographed in the dark on Merck 60 PF-254 preparative layer silica gel (60 g) under a pressure of 8 psi N_2 using cyclohexane (60%) – benzene as the eluant. Fractions (20 mL) were collected and their compositions checked by hplc; those containing less than 5% of the *cis*-isomer were combined and evaporated. One recrystallization from chloroform (10%) – ethanol gave the *trans*-isomer as colourless needles (0.5 g, mp 193–194°C; lit (18*b*) mp 185–187°C).

The *cis*-rich (~75%) mixture isolated from the preliminary column was recrystallized from carbon tetrachloride – methanol, and a portion (1 g) was chromatographed in the dark on preparative layer silica gel (50 g) with cyclohexane (80%) – benzene as eluant (10 psi N_2); 10 mL fractions were collected and monitored by hplc. Those containing less than 5% of the *trans*-isomer were combined and evaporated. The resulting oil was dissolved in chloroform, four times the volume of ethanol was added, and the solution was allowed to crystallize slowly, yielding the *cis*-isomer as colourless needles (mp 134–135°C, lit. (18*a*) mp 135–136°C).

High-pressure Liquid Chromatographic Analysis of 2b

Solvent: dichloromethane (60%) – hexanes, flow rate: 0.95 mL min^{-1}; analytical wavelength: 300 nm; retention times: *trans*-**2***b*, 8 min; *cis*-**2***b*, 10.5 min.

1,2-Di(4-cyanophenyl)-1,2-diphenylethylene (2c)

The crude yellow solid (7.3 g) was dissolved in chloroform–ethanol (1:1, 60 mL), the resulting solution was evaporated to ca. 35 mL and then allowed to cool slowly. The resulting crystals (0.9 g) were collected by vacuum filtration. Ethanol (10 mL) was added to the mother liquors, and this solution was allowed to crystallize slowly. Filtration afforded a further 0.7 g of material which was combined with the first crop of crystals. The mother liquors were evaporated to ca. 30 mL, cooled slowly, and the resulting crystals (1.0 g) collected by filtration; these were shown to be rich in the *trans*-isomer by hplc. This mixture was chromatographed on preparative layer silica gel (50 g) under a pressure of 10 psi N_2 with benzene (60%) – cyclohexane as eluant. The first twenty-five 8 mL fractions contained the *trans*-isomer contaminated with less than 3% of the *cis*-isomer by hplc; these were combined and evaporated to yield a yellowish solid (0.46 g). Two recrystallizations from chloroform–ethanol afforded *trans*-**2***c* as slightly yellow needles, mp 203–204°C; ir (KBr): 2225(s), 1600(m), 1499(m), 1441(m), 859(m), 838(m), 818(m), 767(m), 758(m), 747(w), 701(s), 603(s); uv λ_{max} (ethanol): 247 (34 100), 330 (17 200); ^{1}Hmr ($CDCl_3$) δ: 6.60 (m, 7H), 6.86 (d, 2H). *Anal.* calcd. for $C_{28}H_{18}N_2$: C 87.93, H 4.74; found: C 87.86, H 4.86.

The first two crops of crystals from recrystallization of the crude product (above) consisted of the *cis*-isomer contaminated with small amounts of 4-cyanobenzophenone and the *trans*-isomer (by hplc). Three careful recrystallizations from chloroform–ethanol afforded *cis*-**2***c* as slightly yellow needles, mp 247–249°C; ir (KBr): 2225(s), 1600(m), 1499(m), 1441(m), 858(m), 820(m), 772(m), 733(m), 720(m), 698(s), 628(m); uv λ_{max} (ethanol): 242 (27 200), 294 (14 200), 328 (14 100); ^{1}Hmr ($CDCl_3$) δ: 6.57 (m, 7H), 6.88 (d, 2H). *Anal.* calcd. for $C_{28}H_{18}N_2$: C 87.93, H 4.74; found: C 87.88, H 4.68. The identities of *cis*- and *trans*-**2***c* were inferred from their measured dipole moments (*vide infra*).

High-pressure Liquid Chromatographic Analysis of 2c

Solvent: Dichloromethane; flow rate: 0.95 mL min^{-1}; analytical wavelength: 300 nm; retention times: *trans*-**2***c*, 10 min; *cis*-**2***c*, 18 min.

1,2-Di(4-methoxyphenyl)-1,2-di(4-cyanophenyl)ethylene (2d)

The crude orange solid (38.1 g) was dissolved in hot methanol (400 mL), filtered, and cooled. The resulting yellow solid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

(11.1 g) was collected by vacuum filtration and was shown to contain *cis*- and *trans*-**2***b* in roughly equimolar amounts (by hplc and ^{1}Hmr). A portion of this material (3 g) was chromatographed in the dark on preparative layer silica gel (130 g) under a pressure of 14 psi N_2 using chloroform (25%) – hexanes as eluant. The first three 30 mL fractions contained the *trans*-isomer contaminated with less than 5% of the *cis*. The next seventy-five fractions contained mixtures of the two isomers, and finally the last four were > 95% *cis*-**2***d*.

Evaporation of the first three (combined) fractions from the column yielded a yellow solid (0.32 g). Two recrystallizations from chloroform–hexanes yielded *trans*-**2***d* as bright yellow needles, mp 123–124°C; ir (KBr): 2840(w), 2225(s), 1602(s), 1509(s), 1290(m), 1244(s), 1172(s), 1030(m), 862(w), 830(m), 815(m), 679(w), 574(m); uv λ_{max} (ethanol): 261 (25 800), 353 (12 800); ^{1}Hmr ($CDCl_3$) δ: 3.76 (s, 3H), 6.67 (d, 2H), 6.86 (d, 2H), 7.13 (d, 2H), 7.42 (d, 2H). *Anal.* calcd. for $C_{30}H_{22}N_2O_2$: C 81.43, H 5.01, N 6.33; found: C 81.13, H 5.07, N 6.10.

Evaporation of the last four (combined) fractions yielded a yellowish oil which crystallized (0.23 g). Two recrystallizations from chloroform–methanol yielded *cis*-**2***d* as slightly yellow needles, mp 230–231°C; ir (KBr): 2840(w), 2225(s), 1600(s), 1509(s), 1290(m), 1244(s), 1172(s), 1030(m), 862(w), 828(m), 811(w), 652(w), 585(m); uv λ_{max} (ethanol): 260 (26 900), 279 (19 800), 354 (12 900); ^{1}Hmr ($CDCl_3$) δ: 3.76 (s, 3H), 6.67 (d, 2H), 6.90 (d, 2H), 7.10 (d, 2H), 7.41 (d, 2H). *Anal.* calcd. for $C_{30}H_{22}N_2O_2$: C 81.43, H 5.01, N 6.33; found: C 81.38, H 5.29, N 6.38.

The identities of *cis*- and *trans*-**2***d* were inferred from their measured dipole moments (*vide infra*).

High-pressure Liquid Chromatographic Analysis of 2d

Solvent: dichloromethane; flow rate: 1.5 mL min^{-1}; analytical wavelength: 360 nm; retention times: *trans*-**2***d*, 24 min; *cis*-**2***d*, 28 min.

Samples of *trans*-**2***d* can alternatively be prepared by irradiation of a 0.1 *M* solution of a *cis–trans* mixture of **2***d* in degassed benzene solution with a 1 kW medium pressure mercury lamp (10°, Pyrex filter) for 5–10 min. The resulting mixture (ca. 90% *trans*-**2***d*) can then be chromatographed and/or recrystallized as described above to yield pure samples of *trans*-**2***d*.

Dipole Moment Determinations for cis- *and* trans-2b–d

Preparation of Solutions

A 0.01 *M* solution (100 mL) of the olefin was prepared by dissolving an accurately weighed (±0.2 mg) sample of the olefin in an accurately weighed amount of dry, purified benzene. Weighed amounts of this solution were then diluted with benzene to give a total of five solutions. Concentrations were expressed as mole fractions of the olefin (X_{ol}), and ranged from ca. 2×10^{-4} to 10^{-3}. The solutions were prepared in dry 25 mL volumetric flasks, stoppered, wrapped in parafilm, and stored in the dark until use.

The capacitance of each solution was measured with a Weilheim Dipolemeter DM 01, the temperature of which was held at 25 ± 1°C by means of a thermostatted water bath. The temperature of the water bath did not vary by more than 0.1°C during a run. The cell constant was determined prior to each run by measuring the capacitances of dry air and benzene, and plotting these against dielectric constant (ε); it did not vary significantly throughout the course of the study.

The refractive indices (n) of the solutions were measured with a Fisher refractometer, the temperature of which was also held constant at 25°C with a thermostatted water bath.

A solution was placed in the cell of the dipolemeter and allowed to sit for 15 min to allow temperature equilibration. After measurement of the capacitance (average of six measurements) the cell was drained, rinsed repetitively with benzene, and dried under a stream of nitrogen. The next solution was then placed in the cell and the process was repeated. The capacitances were converted to dielectric constants using the cell constant as determined above.

The slopes obtained from least-squares analysis of plots of ε vs. X_{ol} and n^2 vs. X_{ol} were used to calculate the molecular polarizability at infinite dilution (P_μ°), which was then used to calculate the dipole moment (19). The measured dipole moments, their estimated error limits, and values calculated using standard group moments are compiled in Table 1.

Thermal Isomerization of 2a–d: *Kinetics*

Sample tubes were prepared from 5 or 7 mm Pyrex tubing which had been rinsed once with concentrated nitric acid, thrice with distilled water, soaked in 5% aqueous sodium hydroxide (1 h), rinsed again (three times) with distilled water, and dried in an oven. In the case of **2***a*, the solutions used were ca. 0.15 *M* in benzene-d_6 or pyridine-d_5 (2%) – benzene-d_6, and were degassed by bubbling dry nitrogen through the solution before placing 70 μL aliquots in each of ten tubes. The tubes were then frozen, evacuated, and sealed. In the cases of **2***b–d*, the solutions were ca. 0.001 *M* in benzene, pyridine (2%) – benzene, or benzonitrile and were degassed (three freeze–pump–thaw cycles) and sealed.

Nine tubes were then placed simultaneously in the preset insulated kinetic bath. One tube containing a solution of the other isomer was included to evaluate the equilibrium composition. The temperature of the bath did not fall by more than 0.5° during this procedure and recovered to its original value within 1.5 minutes. Samples were removed after specific time intervals, quenched immediately in an ice bath, opened, and analysed by either ir spectroscopy (**2***a*) or hplc (**2***b–d*). Prior to each run, one tube was used to check the initial composition of the sample to ensure that no accidental heating had occurred during the sealing process. Equilibrium compositions (approached from both directions) were the average of four determinations.

Rate constants were determined by linear regression analysis of the mole fraction vs. time data according to eq. [4], using the Minitab II programme (43*a*). Arrhenius parameters and ΔH^0 values were determined from the temperature dependence of the rate constants for thermal isomerization ($k_1 + k_2$) and the equilibrium constants (K_e) using a nonlinear least-squares programme (43*b*).

Acknowledgements

We wish to express our considerable gratitude to Dr. T. S. Cameron for performing the X-ray analyses. We also gratefully acknowledge the assistance of Dr. D. L. Hooper in obtaining the 80 MHz ^{1}H nmr spectra, and thank Dr. R. K. Chan (University of Western Ontario) for the use of the dipolemeter. We thank Dr. J. Saltiel for an advance copy of the manuscript (2*b*). This work was supported by a grant from the Natural Sciences and Engineering Research Council of Canada.

Halogenocyclopropanation des éthoxy-alcènes diversement alkylés. Effet *syn*-directeur des groupes éthoxy et alkyles

ROGER BARLET, RAYMOND LE GOALLER ET CLAUDE GEY

Laboratoire de Chimie Organique, Université Scientifique et Médicale de Grenoble, B.P. 53 X, 38041 Grenoble, France

Reçu le 24 avril 1980

ROGER BARLET, RAYMOND LE GOALLER et CLAUDE GEY. Can. J. Chem. **59**, 621 (1981).

Il est montré que des accepteurs faiblement nucléophiles tels que les éthers d'énols subissent pourtant facilement une réaction de cycloaddition avec les monohalogénocarbénoïdes. Les hauts rendements obtenus ainsi que la stéréosélection en faveur des adduits les plus encombrés sont interprétés par une assistance de l'oxygène du substrat auprès du métal du carbénoïde.

ROGER BARLET, RAYMOND LE GOALLER, and CLAUDE GEY. Can. J. Chem. **59**, 621 (1981).

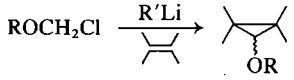
Weakly nucleophilic acceptors such as enol ethers can facilitate cycloaddition reactions with monohalocarbenoids. The high yields and stereoselection towards the more highly hindered adducts are interpreted by complexation of the oxygen atom of the substrate with the metal atom of the carbenoid.

[Journal translation]

Introduction

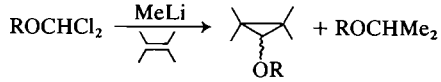
La méthode d'alkoxycyclopropanation de Schöllkopf et coll. (1, 4), largement utilisée depuis plus de 10 ans, présente un certain nombre de limitations. La plus importante consiste dans le déplacement nucléophile que subit le précurseur carbénique sous l'influence de la base utilisée.

Menée à partir des éthers monochlorés $ROCH_2Cl$ cette méthode ne conduit majoritairement au produit de pontage qu'avec *t*BuLi (1)



Remarquons cependant que l'utilisation récente de LiTMP (tétraméthyl-2,2,6,6 pipéridinure de lithium), base forte dont l'encombrement réduit l'activité nucléophile (2), permet une limitation sensible de cette réaction secondaire et autorise de bons rendements en éthers cyclopropaniques (3).

Les éthers dichlorés $ROCHCl_2$ présentent un rendement de cyclopropanation amélioré mais les réactions secondaires demeurent importantes (4).



La méthode de Schöllkopf mise en œuvre sur le bromoéthylène a cependant permis l'obtention du méthoxy-1 bromo-2 cyclopropane avec un bon rendement (58%) et une nette *syn*-stéréosélection[1] (*syn*/*anti* = 91:9) (5).

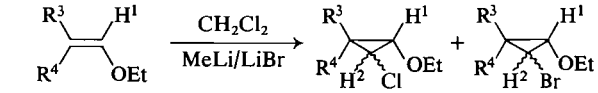
Par ailleurs, quelques alcoxyhalogénocyclopropanes ont déjà été obtenus, par réduction des composés dihalogénés correspondants, avec une nette antistéréosélection que le réducteur soit l'hydrure de tributylétain (6) ou le butyllithium (7, 8).

Désireux de préparer de tels alcoxyhalogénocyclopropanes et de vérifier l'extension possible de la réaction de monohalogénocyclopropanation sur les oléfines fonctionnalisées, telle qu'elle a déjà été développée par l'un d'entre nous (9), nous avons systématiquement soumis les éthoxy-1 éthylènes, diversement alkylés, à l'action du générateur de carbénoïde CH_2Cl_2/MeLi.

Nous présentons, dans ce travail, les résultats de la monohalogénocyclopropanation de ces éthers d'énols substitués. Nous avons obtenu une amélioration sensible des premières chlorocyclopropanations connues de vinyl-éthers non substitués (10) et nous avons pu déterminer la configuration des adduits, par étude rmn, et mettre en évidence la nette stéréosélectivité de la réaction.

Résultats expérimentaux

La réaction de cyclopropanation est pratiquement quantitative et conduit sans sous-produits[2] à la *formation préférentielle des éthoxy-1 chloro-2 cyclopropanes* cis *et* trans *accompagnés minoritairement* des composés bromés correspondants (tableau 1).



R^3, R^4 = H	**1**	**1***t* + **1***c*	**1**′*t* + **1**′*c*
R^3 = H; R^4 = Me	**2**	**2***t* + **2***c*	**2**′*t* + **2**′*c*
R^3 = Me; R^4 = H	**3**	**3***t* + **3***c*	**3**′*t* + **3**′*c*
R^3, R^4 = Me	**4**	**4***t* + **4***c*	**4**′*t* + **4**′*c*

[1]Les termes *syn* et *anti* (ou *cis* et *trans*) précisent ici et dans la suite du mémoire la position relative du groupement éthoxy et de l'halogène.

[2]Il est cependant nécessaire pour éviter la formation de produits légers d'utiliser un méthyllithium suffisamment concentré (solution dans l'éther de 0,7 à 1,0 *M*).

[a]L'analyse des multiplets dus aux protons cyclopropaniques à 100 et 250 MHz a permis de déterminer deux autres couplages de **1***t*, $J_{H^1H^4} = 4$ Hz et $J_{H^3H^4} = 7.4$ Hz.
[b]L'analyse à 100 et 250 MHz a permis de déterminer deux autres couplages de **1***c*, $J_{H^1H^4} = 4.7$ Ha et $J_{H^3H^4} = 7.4$ Hz.

L'addition du méthyllithium sur le mélange éther d'énol – chlorure de méthylène est menée à faible reflux d'éther. Le méthyllithium utilisé est associé à un équivalent de bromure de lithium (lithien préparé par action de MeBr sur Li) et doit être exempt d'ions iodures.

La valeur des déplacements chimiques et des couplages en rmn (tableau 2), l'existence de vibration de valence ν(C—H) en ir comprises entre 3025 et 3040 cm^{-1}, la mise en œuvre d'une réaction de cycloaddition déjà expérimentée sur d'autres substrats faiblement nucléophiles (9) ne laissent

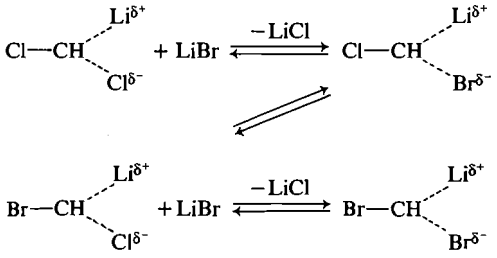
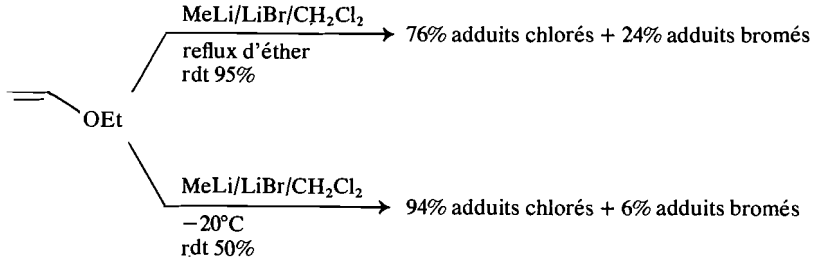
aucun doute sur la nature cyclopropanique des adduits formés.

Les adduits bromés sont des produits primaires de réaction. En effet *leur formation*, en quantité minoritaire, n'*est pas due à une réaction de substitution nucléophile des adduits chlorés par les ions* Br^- présents dans le milieu (LiBr est associé à MeLi). Nous avons en effet vérifié que, séparés et remis dans les conditions de la réaction (MeLi/LiBr + CH_2Cl_2) mais en l'absence d'éthoxy-alcène accepteur, les adduits chlorés ne conduisent pas à leurs analogues bromés. On peut interpréter cette formation des adduits bromés, comme dans le cas du pontage des dioxolannes ou des cétones éthyléniques (9), par *échange au niveau du complexe carbène–sel intermédiaire*. Ce complexe est sans doute plus probable à température ordinaire ou à reflux d'éther que le chlorométhyllithium ($CHLiCl_2$) stable seulement à basse température et dont l'évolution doit être très rapide après l'échange initial hydrogène–métal.



Cet échange est évidemment dû au fait que le lithien utilisé, formé à partir de MeBr, est constitué par une association, équivalent à équivalent, MeLi/LiBr et permet une telle incorporation de Br dans le complexe carbène–sel.

Nous avons d'ailleurs vérifié qu'il suffit d'additionner le méthyllithium à basse température pour bloquer l'échange et observer la formation pratiquement exclusive des adduits chlorés accompagnée cependant d'une chute du rendement.



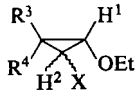
Par contre, nous n'avons pas pu augmenter le pourcentage des adduits bromés par addition d'un équivalent de LiBr au méthyllithium utilisé. Il est vrai que ce bromure de lithium ajouté à la solution lithienne reste insoluble et n'augmente pas la capacité du brome à s'incorporer au complexe carbène–sel.

Stéréochimie des adduits

Nous avons pu élucider la stéréochimie *cis* ou *trans* des adduits au moyen de la résonance magnétique nucléaire (tableau 2) par examen des couplages $^3J(cis)$ et $^3J(trans)$ de H^1 et H^2, des déplacements chimiques de H^1 et H^2 et de l'effet LIS sur ces déplacements. Nous avons pu ajouter à ces critères de configuration d'autres éléments de preuve cohérents dans toute la série.

1. *Valeur des couplages*

L'étude comparée des couplages $^3J(cis)$ et $^3J(trans)$ des hydrogènes vicinaux H^1 et H^2, nettement déblindés par rapport à R^3 et R^4, s'est avérée être le critère déterminant



$^3J(cis)_{H^1H^2} > {}^3J(trans)_{H^1H^2}$

Dans le cas de **4***t* et **4***c*, H^1 et H^2 apparaissent sous forme de doublets. La détermination du couplage ^3J est alors directe et permet l'attribution des configurations sans ambiguïté ($^3J(cis)$ = 5,1 Hz, $^3J(trans)$ = 2 Hz).

Les adduits **2***t*, **2***c* (R^3 = H, R^4 = Me) et **3***t*, **3***c* (R^3 = Me, R^4 = H) présentent plusieurs couplages ^3J entre les protons cyclopropaniques et les multiplets, relatifs à H^1 et H^2, ne permettent pas une lecture aussi directe de $^3J_{H^1H^2}$. Il convient alors de recourir soit à des expériences de double résonance lorsque l'écart des fréquences de résonance entre H^1 et H^2 est suffisant pour que l'irradiation d'un des signaux n'affecte pas l'autre (cas de **2***t* et **3***c*), soit à des déterminations approchées liées à un système ABX correspondant à H^1, H^2, H^3 (cas de **2***c*) ou H^1, H^2,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

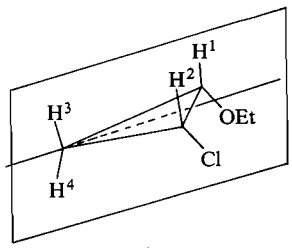
H^4 (**3***t*). L'obtention conjointe des isomères *cis* et *trans* et leur observation comparée en rmn permet cependant de conclure clairement: **3***t* présente deux multiplets différents (deux $J(trans)$ pour H^1, un $J(trans)$ et un $J(cis)$ pour H^2) alors que **3***c* présente deux multiplets identiques pour H^1 et H^2 (un $J(trans)$ et un $J(cis)$); de même **2***t* présente deux multiplets différents (deux $J(trans)$ pour H^2, un $J(trans)$ et un $J(cis)$ pour H^1) tandis que **2***c* présente deux couplages $J(cis)$.

Les adduits **1***c* et **1***t* présentent des signaux analysables au 1er ordre pour H^1 et H^2. Chaque stéréoisomère montre pour H^1 et H^2 des multiplets identiques avec mise en évidence de 3 couplages vicinaux ^3J. La présence parmi eux d'un couplage $^3J_{H^1H^2}$ de 1,4 Hz dans un cas et 5,3 Hz dans l'autre cas, permet d'attribuer ces multiplets respectivement à **1***t* et **1***c*.

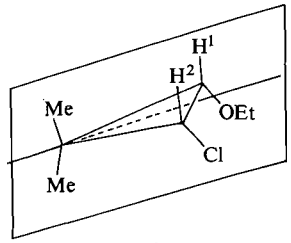
Remarquons que les couplages $^3J_{H^1H^2}$ *des protons cyclopropaniques sont nettement affaiblis par rapport aux valeurs habituelles* respectivement proches de 8 et 4 Hz pour $^3J(cis)$ et $^3J(trans)$ (9). En effet $^3J(cis)$ se trouve être compris entre 4,5 et 5,3 Hz alors que $^3J(trans)$ s'abaisse jusqu'à 1,4 Hz et n'excède pas 2,1 Hz (tableau 2). Seule l'observation simultanée des deux stéréoisomères permet ainsi d'éviter les erreurs d'attribution des configurations puisque $^3J(cis)$ se trouve alors être ici dans la zone de valeur connue de $^3J(trans)$. Un tel abaissement des valeurs de ^3J est d'ailleurs conforme à celui observé par Corey et Ulrich (5) sur le méthoxybromocyclopropane. Notons que ces abaissements n'affectent pas $^3J_{H^1H^3}$, $^3J_{H^2H^3}$ ou $^3J_{H^2H^4}$ et ne concernent que $^3J_{H^1H^2}$ avec la condition que les protons en cause soient l'un et l'autre situés sur des carbones porteurs d'atomes électronégatifs.

2. *Attribution des déplacements chimiques et effet LIS*

(*a*) Il est à noter que ces attributions de configuration fondée sur la valeur des couplages peuvent se faire indépendamment des attributions de déplacements chimiques de H^1 et H^2. *Nous avons cependant généralement attribué au proton* H^1 *le déplacement chimique le plus élevé* conformément aux effets de déblindage supérieur du groupe éthoxy, par rapport aux halogènes, tels qu'ils ressortent des incréments de Shoolery (11) dans les structures RR'—CHX où ces groupes X sont géminés avec le proton observé. En toute rigueur cette attribution n'est valable que dans les cas où la structure cyclopropanique présente une grande symétrie et où l'influence du reste du cycle reste identique.



1*c*



4*c*

Une telle attribution est confirmée par la structure des multiplets et la valeur des couplages dans **2***t*, **2***c* et **3***c*. Par contre pour **3***t* le multiplet le moins large, constitué par deux $J(trans)$, doit être attribué à H^1 bien qu'il soit moins déblindé.

(*b*) L'observation des déplacements chimiques de H^1 et H^2 sur les couples de stéréoisomères **1***c*, **1***t* et **4***c*, **4***t* permet de préciser les *effets de déblindages à travers l'espace de Cl et OEt*. La présence de deux H ou deux Me sur le 3ème carbone cyclopropanique permet d'isoler ces seuls effets sans interférence avec les effets de substituants sur ce carbone.

Le chlore exerce un effet de déblindage de 0,1 ppm sur le proton cyclopropanique vicinal H^1 cis *par rapport au proton* trans. L'estimation de cet effet est obtenue par comparaison, dans le tableau 2, de δH^1 pour les couples **1***c*, **1***t* et **4***c*, **4***t*. *Le groupe éthoxy exerce également un effet de déblindage, réduit à 0,06–0.07 ppm, sur le proton vicinal* H^2 cis *par rapport au proton* trans (comparaison, tableau 2, de δH^2 pour les couples **1***c*, **1***t* et **4***c*, **4***t*).

L'effet du chlore est conforme à celui observé en série cyclopropanique monohalogénée, par contre, l'effet de l'éthoxy est inversé par rapport à la série cyclopropanique monoéthoxylée (12).

(*c*) *L'étude de l'effet LIS* pour les protons H^1 et H^2 sur le couple de stéréoisomères **1***c* et **1***t* nous a permis de vérifier à la fois l'attribution des déplacements chimiques δ_1 et δ_2 ainsi que l'attribution des configurations *cis* et *trans* (Fig. 1). *Cet effet s'avère*, conformément à ce qu'on peut attendre, *plus important pour les isomères* trans *que pour les isomères* cis. L'approche du groupe complexant auprès de l'oxygène de l'éthoxy, siège de la complexation, est en effet rendue plus difficile dans le cas de l'isomère *cis*. L'halogène, situé du même côté que l'éthoxy, ne complexe alors pas, pour son propre compte, le chélate (13) mais le repousse pour des raisons stériques et affaiblit ainsi le degré de complexation c'est-à-dire la valeur des déplacements induits de H^1 et H^2. Il convient cependant de remarquer que le rapport entre les déplacements induits de H^1 et H^2 reste du même ordre quel que soit le stéréoisomère ce qui semble

For personal use only.

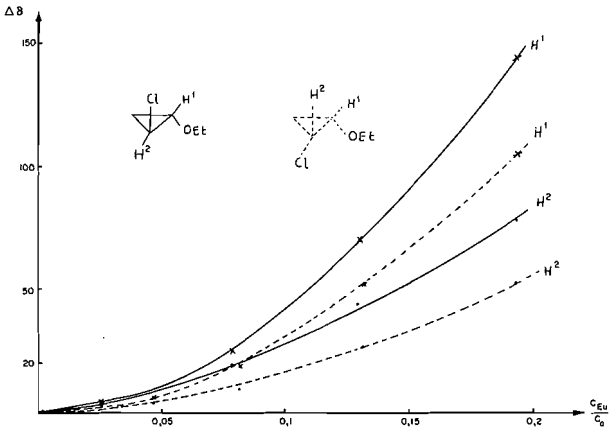

FIG. 1. Effet LIS (complexes de $Eu(dpm)_3$) sur un couple de chloroéthoxycyclopropanes *cis* et *trans*. C_{Eu} = concentration en chélate; C_0 concentration en éther.

indiquer que la position moyenne du complexe d'europium est très proche du plan du cycle. Cette position moyenne implique cependant, aussi bien pour le stéréoisomère *cis* que pour le *trans* un déplacement induit $\Delta\delta_1$ plus élevé que $\Delta\delta_2$. En effet, quelles que soient les contributions respectives des intéractions de contact ou de pseudo contact, H^1, aussi bien à travers les liaisons qu'à travers l'espace, demeure plus proche du site de complexation que H^2.

3. *Autres éléments de détermination des configurations*

Au total, indépendamment de la détermination de configuration précédente fondée sur l'analyse des déplacements chimiques et des couplages des protons cyclopropaniques, nous avons pu mettre en évidence les caractères distinctifs suivants entre les isomères *cis* et *trans*.

Les protons méthyléniques du groupe éthoxy présentent une légère inéquivalence, de l'ordre de 3 Hz, pour les isomères *cis*. Ce doublet de quadruplets fait place à un quadruplet unique pour les isomères *trans*. Cette inéquivalence est conforme à un effet de champ de l'halogène sur les deux hydrogènes voisins OCH_2—CH_3.

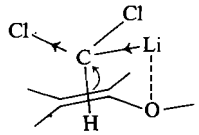
Les temps de rétention en chromatographie en phase vapeur sont toujours supérieurs pour les isomères *cis* quelle que soit la nature de la colonne.

Les isomères *trans*, chauffés à reflux de toluène, disparaissent beaucoup plus rapidement que les isomères *cis*, montrant ainsi une aptitude supérieure à l'ouverture disrotatoire, avec formation d'éthoxydiènes conformément aux règles de Woodward–Hoffman (6).

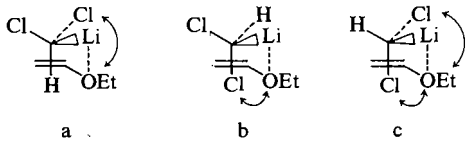
Les isomères *cis* présentent une densité et un indice de réfraction supérieurs (voir Partie expérimentale).

Discussion: effet *syn*-directeur du groupe éthoxy et des groupes méthyles

L'intérêt préparatif de cette réaction d'halogénocyclopropanation réside dans sa facile mise en œuvre et son rendement élevé. Ce rendement est inattendu puisque le groupe éthoxy désactive les doubles liaisons et les rend, à priori, moins aptes à une cycloaddition avec les halogénocarbénoïdes électrophiles. *On peut interpréter cette anomalie apparente par une assistance de l'oxygène* comme dans le cas des dioxolannes éthyléniques (9). Cette assistance serait d'ailleurs accrue dans le cas des éthoxy-alcènes puisque la distance lithium–oxygène dans l'état de transition serait plus faible. Le pouvoir électroattracteur de l'éthoxy pourrait ainsi être largement compensé par cette assistance.



On observe un très net effet syn-*directeur de l'éthoxy et des alkyles de l'accepteur de carbène* (voir tableau 1). La cycloaddition de **1** permet d'isoler l'effet *syn*-directeur de l'éthoxy. La cycloaddition de **2** cumule les effets *syn*-directeurs et entraîne une nette *syn*-stéréosélection. La cycloaddition de **3** ne montre plus qu'une très faible stéréosélection; la compensation des deux effets directeurs semble alors indiquer qu'ils sont du même ordre de grandeur. La *syn*-stéréosélectivité des alkyles par rapport à l'halogénocyclopropanation s'interprète ici de la façon habituelle: *dans l'état de transition, la position* cis *de l'halogène sera favorisée par interaction électrostatique entre l'halogène et les alkyles légèrement positifs* lors du transfert d'électrons de la double liaison vers le carbénoïde (14). Par contre l'effet *syn*-directeur du groupe éthoxy est plus délicat à interpréter. En schématisant le chlorocarbénoïde sous la forme ($LiCHCl_2$) on peut envisager les trois états de transition a, b et c.



L'état a conduira au composé *trans* tandis que b et c conduiront au composé *cis*; a est, à priori, beaucoup plus probable que b et c. La formation préférentielle du dérivé *cis* peut s'interpréter ainsi:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

la forte interaction Li–O neutralise partiellement le caractère électronégatif de l'oxygène et le groupe éthoxy se rapproche alors du comportement d'un alkyle. Cette forte interaction entraîne une torsion dans l'état de transition avec un éloignement du chlore *syn* dans b et c et un rapprochement du chlore *anti* dans a et c; a sera ainsi déstabilisé par le rapprochement chlore *anti*-oxygène (déstabilisation par effets électronique et stérique) tandis que b sera stabilisé par l'éloignement chlore *syn*-oxygène. b deviendra aussi, sinon plus probable que a. c, destabilisé par le rapprochement chlore *anti*-oxygène et stabilisé par le rapprochement chlore *syn*-oxygène, continuera, malgré la torsion, à jouer un rôle important dans l'état de transition global. Au total le rapport b + c/a deviendra supérieur à 1 et pourra rendre compte de la formation dominante du produit *cis*.

En conformité avec ce que l'on observe dans le cas des dioxolannes α-éthyléniques (9) mais contrairement au cas des oléfines non fonctionnalisées (15), la température ne joue pratiquement aucun rôle vis-à-vis de la stéréosélectivité. Le rapport **1***c*/**1***t* reste inchangé que le pontage soit effectué à reflux d'éther ou à −25°C. On peut également interpréter cette observation par la forte interaction lithium–oxygène dans l'état de transition. La stabilisation additionnelle apportée par les interactions alkyle–halogènes y sera très faible et les énergies d'activation pour la *syn* et l'*anti*-direction seront trop voisines pour que des variations de température de faible ou moyenne amplitude, jouent un rôle sensible.

Conclusion

Ce travail nous a permis d'obtenir des alcoxy halogénocyclopropanes, diversement alkylés, par action du générateur de carbénoïde CH_2Cl_2/MeLi/LiBr sur les alcoxy-alcènes correspondants. La facile mise en œuvre de la réaction à température ordinaire, ses excellents rendements ainsi que l'obtention stéréosélective des adduits complètent et améliorent les premiers résultats observés sur les vinyl-éthers non substitués où la cyclopropanation par CH_2Cl_2/BuLi s'exerçait, à basse température, avec prédominance des isomères chlorés *cis*, à l'exclusion d'isomères bromés et sans précision de rendement (10). La possibilité d'obtenir des adduits bromés, concurremment aux adduits chlorés, constitue effectivement une extension utile de cette réaction puisque de tels adduits ne sont habituellement obtenus en bons rendements que par des réactions difficiles à mettre en œuvre (16) ou peu probables sur des accepteurs faiblement nucléophiles (17).

La stéréochimie des adduits a été établie essentiellement par rmn et nous avons mis en évidence que les couplages $^3J(cis)$ et $^3J(trans)$ des protons cyclopropaniques H^1 et H^2 s'avéraient anormalement faibles.

Nous avons pu montrer et justifier le net effet *syn*-directeur du groupe éthoxy et du groupe méthyle des substrats lors de cette réaction d'halogénocyclopropanation qui conduit ainsi à la formation des adduits les plus encombrés.

Partie expérimentale

Les spectres de rmn ont été enregistrés dans CCl_4, sur appareil fonctionnant, dans la grande généralité des cas, à 60 MHz (Hitachi-Perkin-Elmer R 24) ou pour les composés **1***c* et **1***t* sur HA 100 et Cameca 250.

Les spectres infrarouge ont été réalisé sur un spectrophotomètre Perkin-Elmer 521 à deux réseaux (précision ± 0,5 cm^{-1}).

La cpv analytique a été réalisée sur Aerograph 600 D à ionisation de flamme. La cpv préparative a été effectuée sur Autoprep A 700 et A 705. Les colonnes les plus généralement utilisées ont été des colonnes Ucon Oil de 3 à 10 pieds (1/8 po ou 3/8 po).

Les analyses élémentaires ont été réalisées par le Service Central de Microanalyses du C.N.R.S., Echangeur de Solaize, B.P. 22, 69390 Vernaison, France.

Mode opératoire général

Préparation du méthyllithium associé au bromure de lithium

Dans un ballon à 3 cols on place 21 g (3 at.g) de lithium martelé et découpé en fins morceaux dans 0,5 L d'éther anhydre fraîchement distillé sur $LiAlH_4$. On additionne MeBr gazeux en contrôlant son débit avant et après le ballon réactionnel au moyen de barboteurs. Au début de l'addition l'halogénure se dissout dans l'éther puis la réaction démarre et le lithium prend un éclat métallique très vif. On ajuste le débit d'halogénure de façon à ce qu'il soit totalement consommé (contrôle au barboteur de sortie) et qu'il permette le maintien d'un léger reflux. On additionne en cours de route de l'éther jusqu'à ce que la solution totale soit de 1,5 L. L'addition d'halogénure dure 5 à 6 h. Il est nécessaire de procéder lentement pour éviter la duplication de Wurtz. LiBr reste en solution. MeLi après décantation des produits d'oxydation de Li est dosé par différence (hydrolyse avant et après action du dibromo-1,2 éthane) au moyen de 1*N* HCl. On observe ainsi 10 à 15% de EtOLi formé par rapport à MeLi total. Les quantités de lithium mises en œuvre et la concentration finale de MeLi montrent qu'on ne peut éviter, même avec faible débit d'addition de l'halogénure, 10% de duplication de Wurtz.

Halogénocyclopropanation

Les réactions sont menées sous débit d'azote à partir de 0,025 ou 0,05 mol de MeLi dont la concentration doit être comprise entre 0,7 et 1 mol/L. Le mode opératoire identique sur tous les substrats, se caractérise de la façon suivante: addition goutte à goutte du méthyllithium sur le mélange d'accepteur de carbène en léger excès (éthoxy-alcène)/MeLi ≃ 1,25) et le générateur de carbène en net excès (CH_2Cl_2/MeLi ≃ 3). L'addition est menée de façon à entretenir le reflux d'éther et dure de 1/2 h à 1 h. Après la fin de l'addition on laisse encore sous agitation 1 h à 2 heures. Dès le début de l'addition du méthyllithium le bromure de lithium trouble la solution puis précipite. Le précipité s'épaissit ensuite progressivement. L'hydrolyse est faite sur la glace pilée, la neutralisation de la phase organique par le chlorure d'ammonium en solution saturée et le sèchage par Na_2SO_4 anhydre.

Les substrats soumis à halogénocyclopropanation sont soit commerciaux (cas de **1** et du mélange **2** + **3**, produits Fluka) soit préparé, dans le cas de **4** selon la méthode de Claisen (18).

Le mélange **2**/**3** (environ 80:20) est séparé en cpv sur SE 30 20 pieds, chargée à 30% (température de colonne 40°C). Le mélange **2** + **3** soumis directement à la cycloaddition carbénique permet de mettre en évidence que **2** réagit plus facilement que **3**.

Caractérisation et identification des adduits

Tous les composés obtenus sont des composés nouveaux à l'exclusion de **1***c* et **1***t* (10). Les analyses élémentaires obtenues sont satisfaisantes (Cl ± 0,3%, Br ± 0,5%) à condition qu'elles soient faites rapidement après les séparations chromatographiques. Si ce n'est pas le cas, bien que les chromatogrammes ou les spectres de rmn restent inchangés, la libération d'halogène altère les analyses.

L'ensemble des composés présente cependant une bonne stabilité en solution. Gardés en solution éthérée les adduits présentent des analyses chromatographiques inchangées après des mois, voire des années pour certains d'entre eux.

Malgré les précautions prises, **1***c*, **2***t*, **3***t*, **3**′*t*, **4***c*, **4**′*c* se décomposent partiellement entre la séparation chromatographique et l'analyse. **1**′*t*, **2**′*t* et **4**′*t* obtenus en faible quantité n'ont pu être collectés et examinés qu'en solution dans le tetrachlorure de carbone. Les analyses que nous avons pu obtenir sont les suivantes.

Composé	Analyse (%)
1*t*	Calc. pour C_5H_9OCl : C 49,81, H 7,47, O 13,28, Cl 29,43
	Trouvée : C 49,56, H 7,63, O 13,53, Cl 29,18
1′*c*	Calc. pour C_5H_9OBr : C 36,36, H 5,45, O 9,70, Br 48,48
	Trouvée : C 36,05, H 5,62, O 9,97, Br 48,03
2*c*	Calc. pour $C_6H_{11}OCl$: C 53,55, H 8,18, O 11,90, Cl 26,37
	Trouvée : C 53,12, H 8,22, O 12,17, Cl 26,07
2′*c*	Calc. pour $C_6H_{11}OBr$: C 40,22, H 6,14, O 8,93, Br 44,69
	Trouvée : C 39,87, H 6,25, O 9,16, Br 44,36
3*c*	Calc. pour $C_6H_{11}OCl$: C 53,55, H 8,18, O 11,90, Cl 26,37
	Trouvée : C 53,39, H 8,31, O 12,11, Cl 26,11
3′*c*	Calc. pour $C_6H_{11}OBr$: C 40,22, H 6,14, O 8,93, Br 44,69
	Trouvée : C 40,01, H 6,31, O 9,07, Br 44,21
4*t*	Calc. pour $C_7H_{13}OCl$: C 56,58, H 8,76, O 10,78, Cl 23,88
	Trouvée : C 56,23, H 8,91, O 10,99, Cl 23,59

Les divers produits n'ont pas été séparés par distillation mais par cpv vu les faibles quantités sur lesquelles nous avons opéré et la complexité des mélanges obtenus. Les stéréoisomères *trans* sont moins retenus en cpv que les stéréoisomères *cis* aussi bien dans le cas des adduits bromés que des adduits chlorés et quelle que soit la colonne utilisée. Les adduits chlorés *cis* et *trans* sortent habituellement tous deux avant les adduits bromés correspondants sauf dans le cas des adduits de **1** ou il y a chevauchement (ordre de sortie **1***t*, **1**′*t*, **1***c*, **1**′*c*).

L'effet LIS a été étudié sur les adduits **1***t* et **1***c*. Le chélate, $Eu(dmp)_3$ est additionné peu à peu sur le substrat dont la concentration est déterminée une fois pour toutes au départ. On mesure les déplacements chimiques induits $\Delta\delta$ et on représente les courbes $\Delta\delta = f(C_{Eu}/C_0)$ (Fig. 1) où C_{Eu} et C_0 sont les concentrations en chélate et en substrat. Les valeurs de $\Delta\delta$ sont données ci-dessous en Hz.

Composé	$\frac{C_{Eu}}{C_0} \times 10^3$	Nature des protons			
		H^1	H^2	$O—CH_2—CH_3$	$O—CH_2—CH_3$
1*t*	30,35	3,5	3	4,5	2
	78,6	25	19	28,5	14,5
	130,4	70	45	68,5	35
	193,8	145	78,5	119	60
1*c*	46,5	6	3,5	5,5	3,5
	81,45	18,5	10	16	8,5
	131,6	53	27	46	23,5
	193,4	106	54	89	47,5

La caractérisation des adduits chlorés en spectrographie de rmn figure dans le tableau 2. Notons que dans le cas de **1***t* et **1***c* l'analyse des spectres enregistrés à 60 MHz permet la détermination des couplages $J_{H^1H^2}$, $J_{H^1H^3}$, $J_{H^2H^3}$, $J_{H^2H^4}$ auxquels il convient d'adjoindre celle des couplages $J_{H^1H^4}$ et $J_{H^3H^4}$ obtenus à 100 et 250 MHz.

Les adduits bromés présentent des spectres identiques à ceux des adduits chlorés; les couplages restent inchangés, les déplacements chimiques sont légèrement réduits (de 1 à 9 Hz). La différence la plus grande est observée pour **1**′*c* qui présente les valeurs suivantes de δ en ppm pour les protons respectifs H^1, H^2, H^3, H^4, $OCH_2—CH_3$: 3,10; 2,72; 1,12; 0,80; 3,61 et 3,59.

La distinction entre les deux types d'adduits au moyen de la densité et de l'indice de réfraction est par contre très nette. Les adduits chlorés présentent une densité légèrement supérieure à 1 et un indice voisin de 1,43 tandis que les adduits bromés présen-

tent une densité voisine de 1,35 et un indice très proche de 1,46. Dans tous les cas les valeurs sont plus élevées pour les stéréoisomères *cis* que pour les stéréoisomères *trans*. Ainsi à titre d'exemple, notons les valeurs suivantes pour les adduits de **2** (d_4^{20}; n_D^{20}): **2***t* (1,054; 1,4252), **2***c* (1,073; 1,4382), **2**′*t* (1,337; 1,4537), **2**′*c* (1,354; 1,4623).

Nuclear magnetic resonance study of addition–cyclization involving ethyl thioacetoacetate and α-nucleophiles

MICHAEL COCIVERA, SOUMEN BASU,[1] LESLIE COPP,[2] AND VINCENZO MALATESTA[3]

The Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received July 9, 1980

MICHAEL COCIVERA, SOUMEN BASU, LESLIE COPP, and VINCENZO MALATESTA. Can. J. Chem. **59**, 629 (1981).

Addition of NH_2NH_2 or NH_2OH to ethyl thioacetoacetate to form the corresponding cyclic product, 3-methylpyrazol-5-one or 3-methylisoxazol-5-one proceeds via cyclization of the carbinolamine formed by addition to the β-keto carbon, i.e., cyclization is faster than dehydration of the carbinolamine to form the imine. In contrast the corresponding carbinolamine derived from ethylacetoacetate undergoes dehydration faster than cyclization. By means of ^1H nuclear magnetic resonance spectroscopy, it is possible to detect the cyclic carbinolamine as well as another transient and measure their rates of decay. Based on these results, a mechanism is proposed.

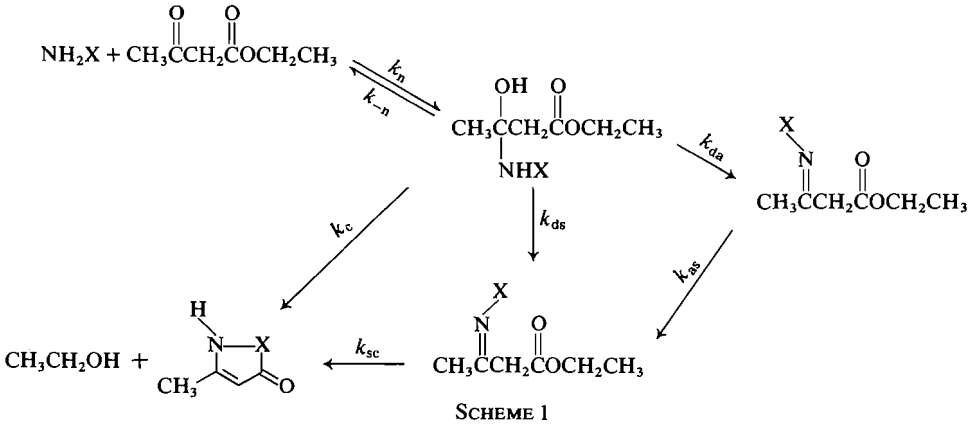
MICHAEL COCIVERA, SOUMEN BASU, LESLIE COPP et VINCENZO MALATESTA. Can. J. Chem. **59**, 629 (1981).

L'addition du NH_2NH_2 ou du NH_2OH au thioacétoacétate d'éthyle qui conduit au produit cyclique correspondant, la méthyl-3 pyrazolone-5 ou la méthyl-3 isoxazolone-5, se fait via la cyclisation de la carbinolamine obtenue par l'addition du réactif au carbone en β de la cétone; on en déduit que la cyclisation est plus rapide que la déshydratation de la carbinolamine qui conduirait à l'imine. Par opposition, la carbinolamine correspondante provenant de l'acétoacétate d'éthyle se déshydrate plus rapidement qu'elle ne se cyclise, En utilisant la spectroscopie de rmn du ^1H, il est possible de déceler la carbinolamine ainsi que les autres intermédiaires et de mesurer leur vitesse de décomposition. On propose un mécanisme en se basant sur ces résultats.

[Traduit par le journal]

Introduction

Previously (1) we have found that the addition of α-nucleophiles to β-keto esters such as ethyl acetoacetate and diethyl β-ketophosphonate involves an initial addition to the β-keto carbon followed by an intramolecular addition to the ester function. The details of the intramolecular process depend on the nature of the ester and the nucleophile. For ethyl acetoacetate the overall reaction proceeds according to the general mechanism in which X represents either the NH_2 or OH group:



SCHEME 1

For both nucleophiles the equilibrium step is fast relative to the subsequent steps. The relative rates of these steps depend on the nature of the nucleophile. For NH_2OH, k_c is negligible in comparison with k_{ds} and k_{da}. On the other hand, it is commensurate when NH_2NH_2 is the nucleophile.

As a continuation of this study, the reaction of these nucleophiles with ethyl thioacetoacetate is reported in this paper. In contrast with the oxygen ester the thioester undergoes the intramolecular step substantially faster than the dehydration step. Under these conditions, the reaction follows the mechanism:

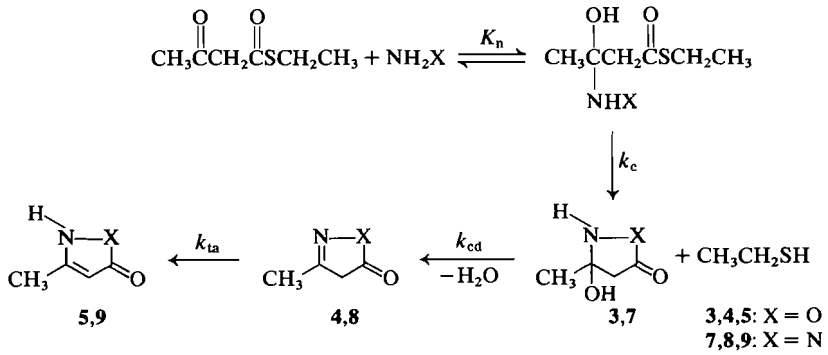

SCHEME 2

The cyclization rate constant has been determined in only a few cases because of limitations placed on the flow system; but k_{cd} and k_{ta} can be determined readily since the steps associated with these rate constants appear to follow pseudo-first order kinetics. For NH_2OH these steps appear to be more complicated since the rate constants depend on the concentration of the nucleophile, and the CH_3-protons of the cyclic imine appear to be involved in an exchange process. A mechanism consistent with these results is suggested.

Experimental

Chemicals

Ethyl thioacetate (Pfaltz and Bauer) was distilled prior to use. Ethyl thioacetoacetate was prepared from ethyl thioacetate by means of a Grignard reaction described previously (2). Sodium phosphate, imidazole, and acetohydroxamic acid were used without purification. In addition, acetohydroxamic acid and *O*-acetylhydroxlamine were prepared *in situ* by reaction of *p*-nitrophenylacetate with hydroxylamine (3) to determine chemical shifts of CH_3-proton resonances under the same conditions of solvent, ionic strength, and temperature as employed in the kinetic studies described below. Diazabicyclooctane (Dabco) was sublimed prior to use. *p*-Nitrophenyl acetate was checked by nmr spectroscopy and used without additional purification.

Solutions

To increase the solubility of ethyl thioacetoacetate, 30:70 (by volume) methanol/water was used as the solvent. To permit comparisons, this solvent was also used for ethyl thioacetate. In these studies, initial concentrations were about 0.06 *M* ethyl thioacetoacetate and 0.1 *M* ethyl thioacetate. The pH of the solution at an ionic strength of 1 *M* (KCl) was determined at 30°C according to the method of Blount and Herman (4) using a Radiometer PHM 63 digital pH meter. The following pK_a values were determined by this technique: NH_2OH, 5.90; NH_2NH_2, 8.23; Dabco, 8.97; and sodium phosphate 6.64.

Kinetic Measurements

All kinetic determinations were made by following the time dependence of the intensities of ^1H nuclear magnetic resonance (nmr) signals obtained at 100 MHz using either static samples or stopped-flow nmr (5). The flow nmr technique differed from that described earlier in that no reservoir was used to equilibrate the nuclei in the magnetic field. This modification was made to reduce the volumes employed and to reduce the chance of leaks of thioethanol into the air. As a result, reliable spectra could be obtained only about 30 s after the flow had been stopped since the internal lock signal intensity fluctuates for about that length of time.

No hydrolysis of either thioester was observed over the period of the kinetic measurements. For ethyl thioacetate the presence of acetohydroxamic acid was confirmed by addition of $FeCl_3$ solution (3, 6*a*, 7).

Results and Discussion

Ethyl Thioacetate

To ascertain the relative importance of intermolecular nucleophilic addition to the acyl carbonyl group of the β-keto thioester, nucleophilic addition to ethyl thioacetate was studied. In general, our results are similar to those obtained previously for *n*-butyl thioacetate (6) using optical spectroscopy. Thus for NH_2NH_2, the observed third order rate constant[4] (k[ester] [NH_2NH_2]^2) is 37, 19, and 21 $M^{-2}min^{-1}$ at pH 8.0, 8.5, and 9.0, respectively. For comparison, values of about 37 and 31 $M^{-2}min^{-1}$ at pH 8.0 and 8.4, respectively, have been reported (6*b*)[5] for *n*-butyl thioacetate. For NH_2OH, the third order rate constant appears to be independent of pH in the range 6.5 to 9.0 (6 pH values), having a value[4] of about 11 $M^{-2}min^{-1}$. Previous results (6*a*) indicate a pH dependence, although the values are close to those obtained in the present study. For example at pH 6.5, 7.0, and 7.5, the values are 10 [15],[6] 10 [11],[6] and 12 [7][6] $M^{-2}min^{-1}$, respectively. In addition, catalysis by phosphate, imidazole, and diazabicyclooctane (Dabco) buffers is not observed whereas imidazole was found to catalyze reaction of NH_2NH_2 with *n*-butyl thioacetate (6*b*). Although the leaving group (*n*-butyl vs. ethyl) and solvent (water/methanol (70:30) vs. water) are somewhat different in the two studies, we suspect that our study is not as precise as the previous one due to the

[4]In most cases the precision is about 15 percent.

constraints of the nmr method, i.e., the nucleophile and ester concentrations are comparable. Consequently, k is obtained by means of computer fit (1*c*) of a third order rate equation in contrast with the first order treatment used previously (6).[7]

On the other hand, an advantage of the nmr technique lies in the direct detection of *O*-acetylhydroxylamine,[8] which is produced in competition with acetohydroxamic acid, the thermodynamically favored product. Formation of the former has been inferred from the disparity between the rate of hydroxamic acid formation and the rate of ester decomposition in the pH range 5.4 to 7 (6*a*). The concentration ratio, acetohydroxamic acid/*O*-acetohydroxylamine, appears to depend on pH as well as the nature of the buffer. For Dabco buffer, the pH and ratio are: 8.0, 1.2; 8.5, 0.49; and 9.0, 0.56. At pH 8.0, this ratio is 4.6 and 1.4 for phosphate[9] and imidazole buffers, respectively. Thus, Dabco and imidazole provide the same ratio, which differs substantially from the ratio found for phosphate buffer at the same pH. Although it is possible to speculate about mechanisms consistent with these effects, the number of data do not warrant such discussions. The pH dependence of the ratio indicates that the competition between N and O addition is not altered only by the increase in amount of anion NH_2O^- as the pH is increased. Comparison of the nmr ratios with those obtained kinetically is not meaningful since no buffer other than the nucleophile was employed in the previous study (6*a*).

Ethyl Thioacetoacetate

Figure 1 illustrates the part of the nmr spectrum of ethyl thioacetoacetate that is upfield from the CH_3-proton resonance of methanol at pH 8.0 (0.2 *M* Dabco, μ = 1 *M*) obtained under various conditions. The signal assignments are indicated in the figure caption. Figure 1A illustrates the positions of the two CH_3-proton resonances of ethyl thioacetoacetate. Figure 1B illustrates that not only the thioester (labeled 2) but also a transient (labeled 3) have reacted completely in less than 5 min, in the presence of 0.40 *M* NH_2OH. In fact, the keto CH_3-proton resonance disappears in a time shorter than about 30 s, the shortest time available when the flow system is used without an equilibrating reservoir. The transient species appears to be generated as quickly since its signal intensity is largest at the first scan. We have assigned the cyclic carbinolamine structure **3** to this species because (*a*) its signal has a chemical shift expected for a methyl group that is attached to an sp^3 hybridized carbon atom and differs from that known for the *syn* and *anti* oximes (1*a*), (*b*) its formation is associated with the liberation of thioethanol at a rate that is faster than oxime formation, (*c*) this species converts to a cyclic product rather than the acyclic oxime. The broad signal 4 is not observed on the initial scan but grows to a maximum over the same period as the decay of signal 3, indicating that it is due to species that are generated by the decomposition of species **3**. The width and position of this signal depends on the concentration of NH_2OH free base remaining after the initial reaction of thioester, indicating a proton exchange process associated with a rapid equilibrium reaction involving NH_2OH. A mechanism consistent with these results is the dehydration of **3** to form **4**, which is involved in the equilibrium

[1] 
4 **10**

Evidence for the formation of the analogue of **4** is also found when NH_2NH_2 is the nucleophile; however, in this case the equilibrium constant K_{cn} appears smaller than the one for eq. [1] since the line width and chemical shift of the signal do not appear to depend appreciably upon the concentration of NH_2NH_2 (see below). Assuming that the CH_3-proton resonances of **4** and **8** have similar chemical shifts, the [NH_2OH] dependence of the chemical shift of signal 4 has been used to estimate the chemical shift δ_{NN} between the CH_3-proton resonances due to **4** and **10** and the equilibrium constant K_{cn} for eq. [1] (0.95 ppm and 1.3 M^{-1}, respectively).[10] Because only four concentrations of NH_2OH were used, these values should be considered to be semiquantitative. Nevertheless using these data along with line width data, we estimate (1) k_{cn} in eq. [1] to be 1700 $M^{-1}s^{-1}$ and k_{-cn} may be obtained from the expression $K_{cn} = k_{cn}/k_{-cn}$. These values for K_{cn} and k_{cn} are the same order of magnitude as those for the addition of NH_2OH to the keto carbonyl carbon atom of ethyl acetoacetate

[7]For NH_2NH_2, a second order term has also been detected (ref. 6*b*); however, it is sufficiently small relative to the third order term to be neglected in our fit.

[8]The CH_3-proton resonances occur at δ 2.14 and 1.93 for *O*-acetylhydroxylamine and acetohydroxamic acid, respectively.

[9]At pH 7.5, this ratio is 6.0 for phosphate buffer.

[10]Values for δ_{NN} and K_{cn} were estimated using chemical shift data for four NH_2OH concentrations and the equation $\delta - \delta_N = (\delta_{NN} - \delta_N)/K_{cn}[NH_2OH]$ in which δ, δ_{NN}, and δ_N are the chemical shifts of the exchange broadened signal and the CH_3-proton resonances of **10** and **4**, respectively.

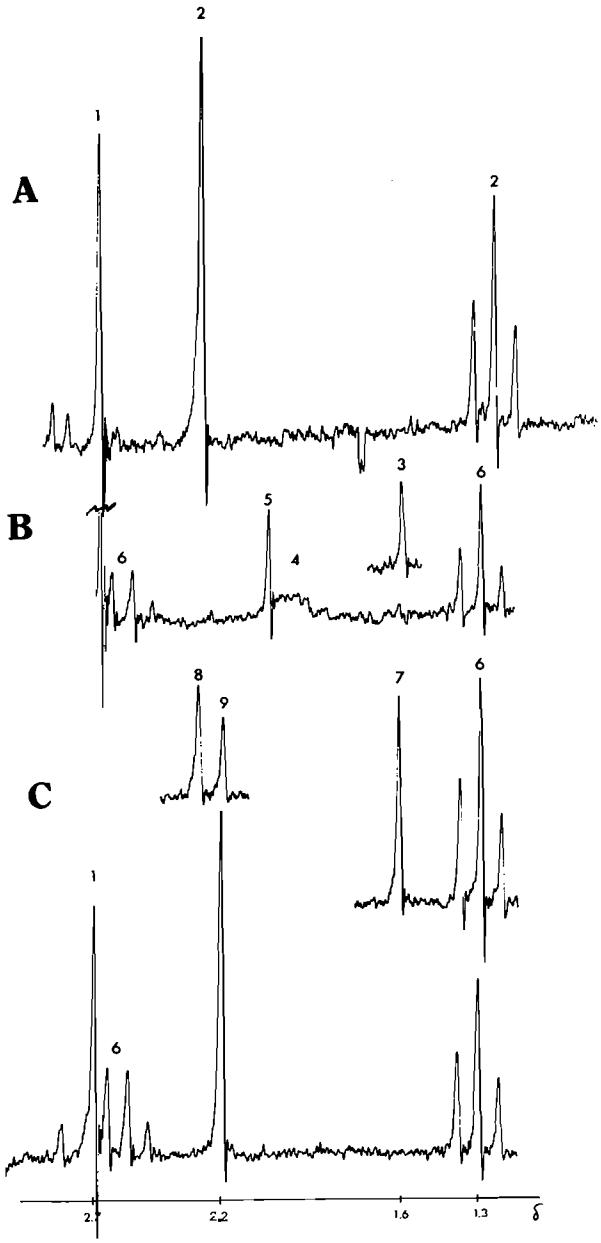

FIG. 1. (A). The upfield portion of the proton nmr spectra at 100 MHz and 30°C in 30% (by volume) aqueous methanol solution of 0.060 *M* ethyl thioacetoacetate at pH 8.0 (0.2 *M* Dabco buffer, $\mu = 1$ *M*). The methylene proton signal is masked by those due to water and methanol. (B). Same as A except that the sweep was started 4.5 min after adding 0.4 *M* NH_2OH. The inset illustrates the intensity and position of a transient signal obtained 1.7 min after mixing. The gain differs from that for A and C. (C). Same as A except that the sweep was started at the end of reaction with 0.2 *M* NH_2NH_2. The inset illustrates the position and intensity of the signals obtained 2.6 min after mixing.

Assignments and chemical shifts in ppm relative to tetramethylsilane: 1. $^{13}CH_3OH$ upfield side band, 2.67; 2. $CH_3COCH_2COSCH_2CH_3$, 2.31 and 1.24; 3.  1.58; 4. Coalescence of  and  , see text for chemical shifts; 5.  , 2.07; 6. CH_3CH_2SH, 1.29 and 2.60; 7.  , 1.60; 8. May be due to three compounds, see text; 9.  , 2.22.

(1*a*). In contrast, the line width of the oxime of ethyl acetoacetate appears to be independent of NH_2OH concentration in the range 0.1 to 0.3 *M* (1*a*).

Signal 5 is due to the CH_3-proton resonance of the final product, which is assigned structure **5**. This signal is not observed on the first scan and its growth corresponds to the same time-scale as the decay of signal 4. Previously this signal was assumed to be due to the CH_3-proton resonance of **4** (1*a*).

Figure 1C illustrates part of the spectrum obtained at an intermediate time after mixing with NH_2NH_2 (2.6 min) and one obtained at the end of the reaction. Thus, signal 6 indicates that the formation of thioethanol is already complete after 2.6 min. Consequently signals 7, 8, and 9 are not due to compounds containing the thioester group. Because signals 7 and 3 have almost the same chemical shift and 7 is observed with maximum intensity in the first scan, it is assigned to the CH_3-protons of structure **7**. Signal 9 is assigned to the CH_3-protons of **9**, the final product. Signal 8 is more complicated to interpret because it appears to be due to more than one compound, as indicated by the following observations. First, it is observed with maximum intensity in the first scan, and this initial intensity decreases as the concentration of NH_2NH_2 is increased. Simultaneously some of the thioester remains during the first scan. Second, signal 8 remains (at reduced intensity) after the thioester has disappeared (Figure 1C). Consequently, before 2.6 min have elapsed signal 8 may be due to at least two compounds, the thioester[11] and **8**. An additional complication is that NH_2NH_2

[11]The thioester is in equilibrium with acyclic carbinolamine (Scheme 1). However, the expected exchange broadening and shift in the position of the signal is small because pH values of 8.0 or less have been employed and K_n is probably about the same as that for ethyl acetoacetate (0.5 M^{-1}, reference 1*b*).

addition to the acyl carbonyl of ethyl thioacetoacetate can be appreciable. Thus at pH 8.0 a value of 6 is estimated (see below) for the ratio of the lifetime for addition to the acyl carbonyl vs. that for the process involving addition to the keto carbonyl followed by cyclization. Consequently, roughly a maximum of 14% of the ester may be converted to the hydrazide of acetoacetic acid. The absence of a separate keto CH_3-proton resonance for this compound does not preclude its occurrence since its signal may have a chemical shift that is very close to that for the thioester. Furthermore NH_2NH_2 addition to the keto carbonyl carbon of the hydrazide would be expected to result ultimately in the formation of **9**. Consequently the analysis of the time dependence of signals 7 and 9 appears complicated.

Kinetic Analysis

For both nucleophiles, the time dependence of signals 3 and 7 has been treated as a first order decay.[12] During this period, the concentration of

[12]For cases in which the decay of the thioester was not complete before the first scan of these signals, this analysis was applied to intensity data collected after the thioester had disappeared. This approach was necessary for all the NH_2NH_2 data and for NH_2OH data collected at pH 7.0 and 7.5. For NH_2NH_2, the formation of **7** was assumed to be complete when the thioester was not observed. Consequently since it is possible that **7** may also be formed from the hydrazide of acetoacetic acid, its rate constant may be less accurate.

nucleophile is constant, and its effect on the rate constant can be ascertained. Hydroxylamine appears to affect the decay rate of **3** whereas NH_2NH_2 does not appear to affect the decay of **7**. Table 1 lists values for the observed rate constant k_{cd} (Scheme 2) for NH_2NH_2. These data are averages of at least three concentrations of NH_2NH_2. The standard deviations indicate that the apparent dependence upon buffer concentration is within experimental error. In addition, there appears to be no pH dependence over the small range employed.

For NH_2OH, the second order rate constant is listed in Table 2 as $k_{cd}/[NH_2OH]$ in which k_{cd} is the observed first order rate constant. There appears to be no significant dependence upon pH or buffer concentration. The reason for the apparent second order dependence for the decay of **3** can not be decided at this time. One possibility is nucleophilic displacement by NH_2OH to form **10**; however, we are not aware of any precedent for this step.

According to Scheme 2, the formation of **5** and **9** occurs via **4** and **8**, respectively. Consequently the growth of **5** and **9** cannot be considered to obey a simple first order rate law since the time scale is comparable to that for the decay of **3** and **7**, respectively, in most cases. For this reason, k_{ta} has been calculated by means of nonlinear regression (1*b*) to fit the equation

$$[2]\quad C/C_\infty = (k_{ta}\exp -k_{cd}t)/(k_{cd} - k_{ta}) - (k_{cd}\exp -k_{ta}t)/(k_{cd} - k_{ta}) + 1$$

in which C and C_∞ are concentrations at time t and infinity, respectively, for **5** and **9**. For this fit, k_{ta} is the sole unknown.

For NH_2NH_2, k_{ta} does not appear to depend upon nucleophile concentration. The averaged values listed in Table 1 appear to be independent of Dabco concentration. There is an indication of a dependence on the phosphate concentration at pH 7.5.

For NH_2OH, k_{ta} depends on the concentration of nucleophile, and values for the second order rate constant $k_{ta}/[NH_2OH]$ listed in Table 2 appear to be dependent upon pH but independent of buffer concentration. The pH dependence is consistent with the fact that **4** is detectable at high but not low pH in the range employed. The second order nature of the rate would be consistent with a mechanism in which **4** converts to **5** via **10**. The difference in behavior between NH_2OH and NH_2NH_2 is not inconsistent with their relative reactivities for nucleophilic addition to keto carbonyl groups (1*a*, *b*, 8).

Measurement of the rate of formation of **3** and **7** has been restricted because no equilibrating reservoir (5) was employed for the flow nmr measurements (see Experimental), thus preventing intensity measurements prior to about 30 s after mixing. Consequently only approximate rates can be determined based upon the relative intensities of CH_3-triplets of the thioester and thioethanol.[13] The rate constants obtained in this manner are considered to be upper limits since they may involve a contribution from hydrazinolysis or hydroxylaminolysis of the thioester. This rate constant k_c for the formation of **3** or **7** is calculated based on the pre-equilibrium and cyclization steps of Scheme 2 taking into account the fact that the rate is not cleanly first or second order (1*b*). For this purpose, K_n is assumed to be identical to that obtained for ethyl acetoacetate (1*a*, *b*). At pH 7.0, k_c is 5.6 min^{-1} and 6.0 min^{-1} for 0.12 and 0.2 *M* NH_2OH, respectively. For 0.2 *M* NH_2NH_2, k_c is 30 $\pm$ 2 min^{-1} and 63 min^{-1} at pH 8.0 and 7.5, respectively. If it can be assumed that the rate of hydrazinolysis or hydroxylaminolysis of ethyl thioacetoacetate is comparable to that for ethyl thioacetate, the ratios of lifetime for reaction via direct intermolecular nucleophilic addition to the thioester versus that for Scheme 2 are estimated to be 7 for 0.2 *M* NH_2OH at pH 7.0 and 6 for 0.2 *M* NH_2NH_2 at pH 8.0. Consequently these results would suggest that at least 85% of the reaction proceeds via Scheme 2 in these two cases. For NH_2OH, the spectra indicate that this percentage increases with pH.

Bromination–methanolysis of 2,3-disubstituted indoles; effects of side chain structure[1]

EDWARD A. GROSS, SUSAN F. VICE, AND GARY I. DMITRIENKO[2]

Guelph–Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received March 10, 1980[3]

EDWARD A. GROSS, SUSAN F. VICE, and GARY I. DMITRIENKO. Can. J. Chem. **59**, 635 (1981).

The bromination–methanolysis of 2,3-dialkylindoles has been shown to lead in some cases to good yields of 3-methoxyindolenines via the corresponding 3-bromoindolenines. However, changes in the structure of the C-2 substituent can cause dramatic changes in the reaction pathway. Structural features expected to stabilize the "enamine" tautomeric form of an indolenine make such methoxyindolenines unstable with respect to acid catalyzed conversion to 2-methoxyalkylindole products.

EDWARD A. GROSS, SUSAN F. VICE et GARY I. DMITRIENKO. Can. J. Chem. **59**, 635 (1981).

On a montré que la réaction de bromation en présence de méthanol des dialkyl-2,3 indoles conduit dans certains cas avec de bons rendements à des méthoxy-3 indolénines par l'intermédiaire des bromo-3 indolénines correspondants. Cependant si l'on modifie la structure du substituant en C-2 il peut se produire des changements majeurs dans le processus réactionnel. Les caractéristiques structurales qui devraient stabiliser la forme tautomère de l'énamine des indolénines rendent instables de telles méthoxyindolénines vis-à-vis de la transformation en méthoxy-2 alkylindoles catalysée par un acide.

[Traduit par le journal]

We have recently reported that the bromination of 2,3-dimethylindole **1** and tetrahydrocarbazole **4** in the presence of triethylamine in methylene chloride or methanol yields the corresponding 3-bromoindolenine **2** or **5** respectively.

The bromoindolenines **2** and **5** represent the first reported 3-bromoindolenines bearing alkyl substituents at C-2 and C-3. They are moderately stable in methanol at room temperature in the presence of triethylamine, but react rapidly upon acidification to yield the corresponding methoxyindolenines **3** and **6** in good yield (1, 2).

The observation that the methanolyses of **2** and **5** were acid catalyzed prompted us to suggest the mechanism illustrated in Scheme 2.

Protonation of the indolenine **2** to give **7** would be expected to catalyze addition of methanol to the C=N bond to give the 2-methoxy-3-bromoindoline **8**. S_N1 reaction of **8** via the carbonium ion **9** would give the 2,3-dimethoxyindoline **10**.

Elimination of methanol would then yield the observed methoxyindolenines **11**. An alternative mechanism involving simple S_N1 displacement of bromide from **7** by methanol would involve creation of a carbonium ion adjacent to the positively charged C=N$^+$—H bond and, as a result, is considered unlikely. Direct S_N2 displacement from **7** was considered unlikely on steric grounds.

In order to explore the generality of this route to methoxy indolenines we have now examined the effect of alterations of C-2 and C-3 substituents on the course of the reaction. Thus 2-phenyl-3-methylindole, upon bromination as described for **1** and **4**, yields a moderately stable 3-bromoindolenine **13** which reacts with methanol to yield the methoxyindolenine **14**.

The fact that **13** undergoes methanolysis (**13** → **14**) in exact analogy with **2** and **5** is of some significance with respect to the mechanism of the methanolysis reaction. A possible mechanism not

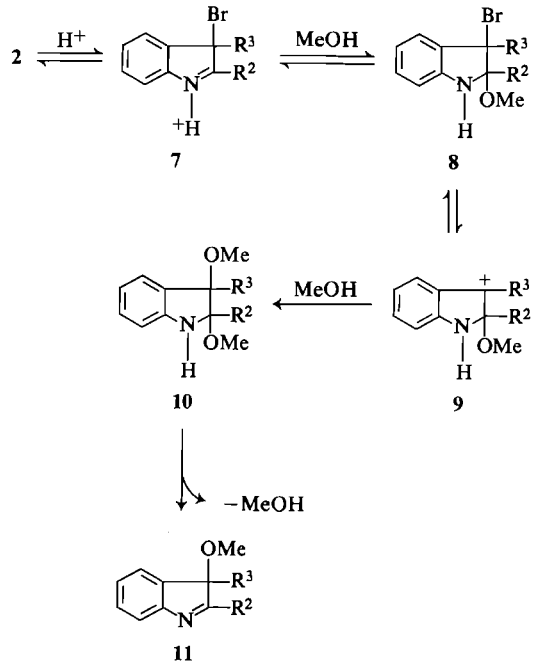
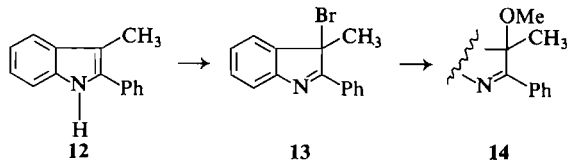
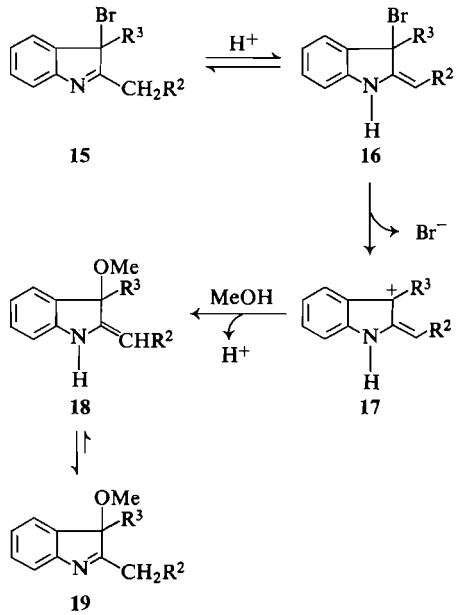


SCHEME 2



SCHEME 3



SCHEME 4

previously discussed involves acid catalyzed tautomerism of the bromoindolenine **15** to its enamine form **16**.[4]

Methanolysis of **16** perhaps via an S_N1 process would yield the methoxy analogue **18** which would be expected to rapidly tautomerize to the indolenine form **19**. The fact that **13**, for which such a pathway is not possible, undergoes facile methanolysis suggests that the mechanism of Scheme 4 is unlikely for other bromoindolenines as well.

Bromination–methanolysis of 2-ethyl-3-methylindole under the same conditions yielded none of the corresponding methoxyindolenine **22**, but instead gave a good yield of 2-methoxyethyl-3-methylindole **23**.

That the intermediate produced in the bromination step was the desired bromoindolenine **21** was clearly indicated by its nmr spectrum; δ 1.40 (t, J = 6.5, 3, C-2—CH_2—CH_3), 1.90 (s, 3, C-3—CH_3), 2.63 (q, J = 6.5, 2, C-2—CH_2—CH_3), 6.9–7.5 (m, 4, Ar-H).

It seemed very likely that the formation of **23** occurred via some variation of the general mechanism proposed some time ago by Taylor (3) (see Scheme 6). We initially suspected that the reaction involved tautomerism of the bromoindolenine **21** to the ethylideneindoline **25** ($R^3 = CH_3 = R^2$, X = Br) followed by nucleophilic attack by methanol leading to displacement of bromide, as indicated in Scheme 6 for the general nucleophile Y^-, to give, after deprotonation, the observed product **23**.

Recently, Owellen and Hartke have observed a related phenomenon in the reaction of chloroindolenines of tetrahydrocarbazoles with sodium methoxide (4). Whereas the chloroindolenine **28** (R = H), derived from tetrahydrocarbazole, gives principally the methoxyindolenine **6**, the chloroindolenine **28** (R = CO_2Me), derived from 1-carbomethoxytetrahydrocarbazole **27** (R = CO_2Me), gives the indole **30**. It was proposed that the difference in product types observed with **28** (R = H) and **28** (R = CO_2Me) was due to stabilization of the tautomer **29** of **28** (R = CO_2Me) by the C-1 carbomethoxy group, which could react by Taylor's mechanism to give **30**. A similar stabilization of the tautomer **25** ($R^2 = R^3 = CH_3$, X = Br) of **21** by the methyl substituent would explain the observation that methanolysis of **21** yields **23** whereas methanolysis of **2** gives **3**.

More recent work in our laboratory indicates that **21** in fact does not behave anomalously in the acid

[4]The authors would like to thank Professor E. W. Warnhoff for suggesting this mechanistic possibility.

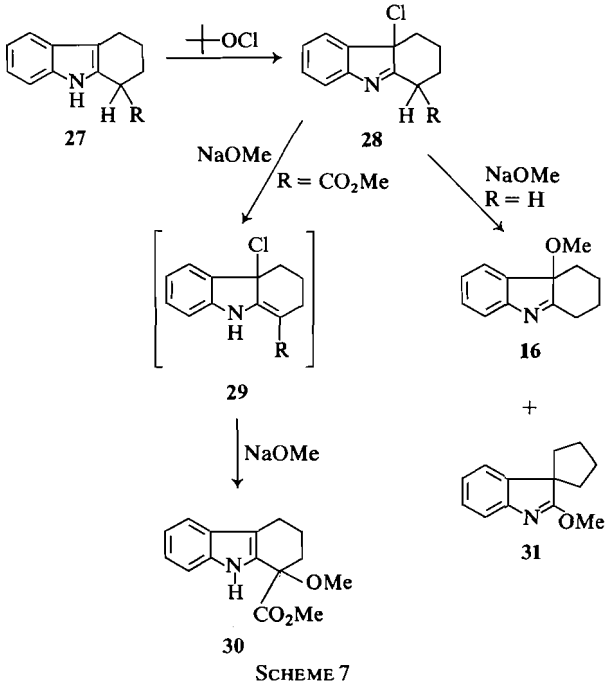


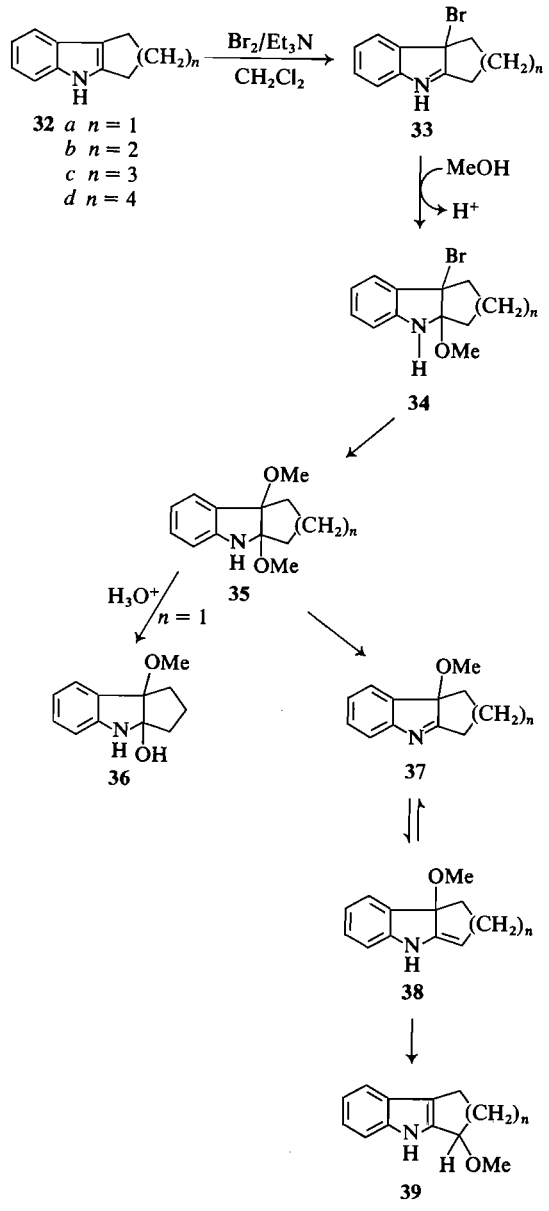
SCHEME 7

catalyzed methanolysis reaction and that under appropriate conditions the desired methoxyindolenine **22** can be isolated. Thus, we have found that acid catalyzed methanolysis of **21** at −78°C occurs rapidly to give, after basic aqueous work-up, a relatively unstable oily product with spectroscopic characteristics compatible with its formulation as 2-ethyl-3-methoxy-3-methylindolenine **22**. Treatment of **22** with acidic methanol at 0°C gave **23** very rapidly and cleanly. The failure to isolate **22** from the methanolysis of **21** at 0°C is thus readily understood.

To further test the generality of the bromination–methanolysis route to methoxyindolenines we examined the effect of ring size in the cycloalkanoindole series **32** on the outcome of the reaction. Our previous study indicated that tetrahydrocarbazole (**32***b*) reacted in the same manner as **1** giving the methoxyindolenine **6** in good yield likely via the sequence **4** → **33***b* → **34***b* → **35***b* → **6**. Bromination–methanolysis of the five-membered ring analogue **32***a* has been found to give a mixture of two products formulated as **35***a* and **36**. Thus **32***a* behaves in the same manner as **1** and **4**, giving a C-3 methoxy substituted system which in this case exists as a stable hydrate **36** or methanol addition product **35***a*. The tendency of indolenines derived from **32***a* to form stable addition products with a number of nucleophiles including alcohols has been noted previously and suggests that there is less ring strain in such a fused ring system when the C-2 carbon is sp^3 hybridized than when it is sp^2 hybridized (5, 6).

In contrast to the 5-membered and 6-membered cycloalkanoindoles, the 7- and 8-membered cycloalkanoindoles **32***c* and **32***d* yielded no detectable products bearing a C-3 methoxy substituent upon bromination–methanolysis at 0°C. Instead the major products were the methoxyindoles **39***c* (60% of the crude product estimated by nmr; 45% isolated yield) and **39***d* (49% of crude product; 28% isolated yield). As was the case with 2-ethyl-3-methylindole **20**, it was possible to isolate the methoxyindolenine **37***c* from the methanolysis of **33***c* at −78°C. The indolenine **37***c* was very labile, decomposing very rapidly in the absence of small amounts of base (triethylamine).

Treatment of crude **37***c* with methanol and acid at 0°C gave **39***c* rapidly and in good yield, presumably via **38***c*. On the other hand no conditions could be found under which **37***d* could be isolated or detected. The brominated intermediate **33***d* derived from **32***d* underwent no reaction with methanol at −78°C. At higher temperatures mixtures of unreacted **33***d* and the indole **39***d* were obtained.



SCHEME 8

There is insufficient evidence with which to formulate a clear explanation for the observed differences in reaction modes of indolenines derived from **32***c* and **32***d* relative to those derived from **1** and **4**.

It should be noted, however, that unfavourable transannular interactions expected in the medium sized ring systems are somewhat relieved by the introduction of sp^2 centers (7). This effect should favour tautomerism of **37** to **38** and thus lead to formation of the indole products **39**. It should also be noted that addition of methanol to **33***d* to give **34***d* involves conversion of an sp^2 center of a medium sized ring to an sp^3 centre. Such a structural change would increase transannular interactions and would thus be unfavourable. The failure of **33***d* to undergo methanolysis at −78°C might well be due to this effect.

It is clear now that, although bromination–methanolysis of 2,3-disubstituted indoles leads in some cases to good yields of 3-methoxyindolenines, subtle structural changes of the C-2 substituent can lead to dramatic changes in the stability of the methoxyindolenines. Methoxyindolenines incorporating structural features which lead to stabilization of the enamine tautomer are relatively unstable and are readily converted to C-2 methoxyalkylindoles on treatment with methanol and acid.

Further reactions of methoxyindolenines which are of potential synthetic utility are currently being studied.

Experimental

General

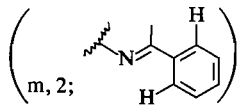
General experimental details have been described previously (2).

Indoles

2,3-Trimethyleneindole was prepared by the method of Plant and Tomlinson (8). All other indoles used were prepared by the general method of Dave and Warnhoff (9) and had physical characteristics in agreement with literature values.

Bromination of 2-Phenyl-3-methylindole

To a cooled (0°C) solution of 2-phenyl-3-methylindole (1.02 g; 4.91 mmol) in methylene chloride (40 mL) containing triethylamine (2 mL) was added dropwise a solution of bromine (1.1 equivalents) in methylene chloride (7 mL) over a period of 5 min. The solution was stirred in a nitrogen atmosphere at ambient temperature for 10 min. The mixture was washed with 5% aqueous ammonia and water. Removal of solvent from the dried organic phase gave an oily product (1.37 g; 4.79 mmol) formulated as 3-bromo-2-phenyl-3-methylindolenine. Infrared (neat): 1602 (C=N—); uv (0.1% Et_3N/CH_2Cl_2): 330 (22 570); nmr: 2.05 (s, 3), 7.00–7.70 (m, 7), 8.10–8.45.



Methanolysis of 3-Bromo-2-phenyl-3-methylindolenine (13)

The bromoindolenine (**13**) was dissolved in methylene chloride (20 mL) and methanol (90 mL) was added at room temperature. After 40 min, the mixture was diluted with water and made basic with 10% aqueous ammonium hydroxide. The mixture was extracted with methylene chloride and the organic extract washed with water, dried, and concentrated to dryness *in vacuo* to give a yellow oil (1.10 g) which consisted principally of 3-methoxy-2-phenyl-3-methylindolenine and minor impurities. A pure sample was obtained by chromatography on silica gel with elution by diethyl ether – petroleum ether (60–80) (15:85) to give **14** as a colourless oil (0.73 g; 3.08 mmol).

Infrared (neat): 1603 (C=N—); uv (0.1% Et_3N/CH_2Cl_2): 335 (27 640); nmr: 1.62 (s, 3), 7.05–7.70 (m, 7), 8.10–8.45. Mass spectra *m/e*: 237 (molecular ion). *Exact Mass* calcd. for $C_{16}H_{15}NO$: 237.1154; found (ms): 237.1143.

Bromination of 2,3-Dialkylindoles

General. To an ice-cold solution of the indole (approximately 3.1 mmol) in methylene chloride (20 mL) containing triethylamine (1.0 mL) was added a solution of bromine (1 equivalent) in methylene chloride (4 mL) over a period of 5 min. The solution was stirred for 5 min and used directly for isolation of the bromoindolenine or for acid catalyzed methanolysis as described below.

Isolation of 3-Bromo-2-ethyl-3-methylindolenine 21

To the solution of the bromoindolenine prepared as described above was added ice-cold water (75 mL). The mixture was extracted with cold methylene chloride (100 mL). The organic extract was washed with saturated aqueous sodium chloride, dried, and concentrated to give a golden yellow oily product, nmr: 1.40 (t, J = 6.5, 3, C-2—CH_2—CH_3), 1.90 (s, 3, C-3—CH_3), 2.63 (q, J = 6.5, 2, C-2—CH_2—CH_3), 6.9–7.5 (m, 4). Signals due to methylene chloride and triethylamine were also present. Further concentration of the sample *in vacuo* gave a tan coloured crystalline solid which rapidly decomposed to a purple solid with vigorous evolution of HBr upon exposure to a normal atmosphere.

*Isolation of 3-Bromo-2,3-trimethylene Indolenine 33*a

The bromoindolenine **33***a* was isolated as an oil contaminated with methylene chloride and triethylamine by the method described for isolation of **21**; nmr: 1.2–3.4 (m, —$CH_2CH_2CH_2$—, overlapped with CH_2 of triethylamine), 6.9–7.6 (m, Ar-H).

Removal of methylene chloride and triethylamine *in vacuo* led to decomposition as described for **21**.

*Isolation of 3-Bromo-2,3-pentamethylene Indolenine 33*c

The bromoindolenine **33***c* was isolated as an oil contaminated with methylene chloride and triethylamine by the method described for isolation of **21**; nmr: 1.2–2.7 (C-3—$(CH_2)_4$—), 2.8–3.1 (m, 2, C-2—CH_2—), 6.9–7.6 (m, 4, Ar-H).

Removal of the volatile contaminants *in vacuo* led to decomposition as described for **21**.

*Isolation of 3-Bromo-2,3-hexamethylene Indolenine 33*d

The bromoindolenine **33***d* was isolated as an oil contaminated with methylene chloride and triethylamine by the method described for **21**; nmr: 0.7–3.2 (m, —$(CH_2)_6$—, overlapped with —CH_2CH_3 of triethylamine), 6.9–7.6 (m, Ar-H).

Removal of volatile contaminants *in vacuo* led to decomposition.

Methanolysis of 3-Bromo-2-ethyl-3-methylindolenine 21

(a) At 0°C

Anhydrous methanol (20 mL) was added to the solution of the bromoindolenine **21** obtained from the indole **20** (0.490 g; 3.08 mmol) by the general method described above. A solution of *p*-toluenesulfonic acid monohydrate (0.780 g) in methanol (5 mL) was added dropwise over a period of 5 min. The mixture was stirred for 5 min and poured into water (75 mL). The aqueous phase was made basic with 10% aqueous ammonia and the mixture was extracted with methylene chloride (50 mL). The organic phase was washed with saturated aqueous sodium chloride. Removal of solvent *in vacuo* from the dried organic extract yielded the crude product (0.590 g) consisting principally of **23** contaminated with minor impurities as indicated by tlc and nmr. One recrystallization from ether–hexane gave 2-(1′-methoxyethyl)-3-methylindole **23** as small prisms, mp 105–109°C (0.266 g; 1.41 mmol; 46% yield).

Infrared: 3330 (N—H); uv (MeOH): 277 (sh), 282.5 (8380), 291 (6850); nmr: 1.47 (d, J = 7, 3), 2.25 (s, 3), 3.2 (s, 3), 4.58 (q, J = 7, 1), 6.8–7.6 (m, 4), 8.1 (br s, 1); ms *m/e*: 189 (molecular ion). *Anal.* calcd. for $C_{12}H_{15}NO$: C 76.15, H 7.99, N 7.40; found: C 75.82, H 8.00, N 7.31.

(b) At −78°C

A methylene chloride solution of the bromoindolenine **21** (derived from the indole **20** (0.502 g; 3.15 mmol)) was cooled to −78°C and methanol (30 mL) was added. A solution of *p*-toluenesulfonic acid monohydrate (0.79 g) in methanol (5 mL) was added dropwise over a period of 5 min. After 10 min 10% aqueous ammonia was added to the cooled mixture and the reaction was worked up as described in (*a*) above. The product **22** was an oil which contained a small amount of triethylamine. Upon removal of traces of base *in vacuo* the product partially solidified but became relatively unstable decomposing extensively even at 0°C after several hours. Infrared (neat): 1580 (C=N); nmr: 1.38 (t, J = 7, 3, C-2—CH_2—CH_3), 1.47 (s, 3, C-3—CH_3), 2.63 (q, J = 7, 2, C-2—CH_2—CH_3), 2.87 (s, 3, CH_3), 7.2–7.8 (m, 4, ArH); ms *m/e*: 189 (molecule ion).

*Methanolysis of 3-Bromo-2,3-trimethylene Indolenine 33*a *at 0°C*

The crude product obtained by methanolysis of a solution of the bromoindolenine **33***a* (derived from the indole **32***a* (0.490 g; 3.12 mmol)) as described for **21** was chromatographed on silica gel with elution by petroleum ether – diethyl ether (9:1). The major fraction obtained as a white solid, mp 63–68°C (0.320 g; 55% yield), was 2-hydroxy-3-methoxy-2,3-trimethylene indoline **36**. Infrared: 3360 (N—H, O—H); uv (MeOH): 244 (5990), 304 (1762); nmr: 1.1–2.4 (m, 6), 3.30 (s, 3), 3.5 (br, 1), 4.8 (br, 1); 6.3–7.4 (m, 4); ms *m/e*: 205 (molecular ion). *Exact Mass* calcd. for $C_{12}H_{15}NO_2$: 205.1103; found (ms): 205.1079. *Anal.* calcd. for $C_{12}H_{15}NO_2$: C 70.22, H 7.37, N 6.82; found: C 70.78, H 7.45, N 6.83.

Further elution yielded a small amount of an unstable oily product (0.008 g) formulated as 2,3-dimethoxy-2,3-trimethylene indoline **35**. Infrared (neat): 3350 (N—H); uv (MeOH): 243 (8090), 298 (2586); nmr: 1.1–2.4 (m, 6), 3.33 (s, 3), 3.40 (s, 3), 4.2 (br s, 1), 6.3–7.4 (m, 4); ms *m/e*: 219 (molecular ion). *Exact Mass* calcd. for $C_{13}H_{17}NO_2$: 219.1259; found (ms): 219.1245.

*Methanolysis of 3-Bromo-2,3-pentamethylene Indolenine 33*c

(a) At 0°C

The crude product obtained by methanolysis of a solution of the bromoindolenine **33***c* (derived from the indole **32***c* (0.562 g; 3.04 mmol)) as described for **21** was chromatographed on silica gel with elution by diethyl ether – petroleum ether (9:1). The major fraction was a white crystalline solid **39***c* (0.297 g; 1.38 mmol, 45%), mp 84–85.5°C; ir: 3400 (N—H); nmr: 1.1–3.0 (m, 8), 3.3 (s, 3), 4.1–4.4 (m, 1), 6.8–7.6 (m, 4), 8.1 (br s, 1); ms *m/e*: 215 (molecular ion). *Anal.* calcd. for $C_{14}H_{17}NO$: C 78.10, H 7.96, N 6.51; found: C 78.32, H 7.92, N 6.42.

(b) At −78°C

Acid catalyzed methanolysis of the bromoindolenine **33***c* as described for **21** at −78°C gave an oily product, **37***c*, containing traces of methylene chloride and triethylamine. Infrared: 1580 (C=N); nmr: 0.8–3.2 (m, —$(CH_2)_5$—, overlapped with signal from —CH_2CH_3 of triethylamine), 2.87 (s, 3, OCH_3), 7.0–7.6 (m, 4, ArH)). Removal of the last traces of base *in vacuo* led to rapid decomposition to a red gum.

*Methanolysis of 3-Bromo-2,3-hexamethylene Indolenine 33*d

(a) At 0°C

The acid methanolysis of the bromoindolenine **33***d* (derived from the indole **32***d* (6.17 g; 3.10 mmol)) was performed as described for **21** except that acidic methanolysis was performed for 30 min rather than 5 min. Using shorter reaction times gave complex products containing no methoxy groups as indicated by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

nmr analysis. The crude product was chromatographed on silica gel with elution by petroleum ether – diethyl ether (95:5). The major product **39***d* was obtained as a waxy solid (0.20 g; 0.87 mmol). An analytical sample was obtained by recrystallization from petroleum ether – diethyl ether, mp 103.5–105°C. Infrared (Nujol): 3310 (N—H); uv (MeOH): 291 (6308), 299 (sh); nmr: 0.8–3.2 (m, 10), 3.4 (s, 3), 4.70 (dd, $J = 3, J = 5, 1$), 6.9–7.6 (m, 4), 8.5 (br s, 1); ms *m/e*: 229 (molecular ion). *Anal.* calcd. for $C_{15}H_{19}NO$: C 78.56, H 8.35, N 6.11; found: C 78.72, H 8.50, N 6.00.

(b) At −78°C

Acid catalyzed methanolysis of the bromoindolenine **33***d* at −78°C as described for **21** gave only starting material contaminated with very minor impurities. No methoxyindolenine **37***d* could be detected by tlc or nmr analysis.

Acid Catalyzed Methanolysis of the Methoxyindolenine 22

Acid catalyzed methanolysis of the methoxyindolenine **22** as described for the bromoindolenine **21** at 0°C gave a yellow crystalline crude product which was principally **23** as indicated by tlc and nmr analysis. Chromatography of the crude product on silica gel with elution by petroleum ether – diethyl ether (9:1) yielded the pure indole **23** (0.407 g; 2.30 mmol; 73% from the indole **20**) identical in all respects with the indole prepared by methanolysis of **21** at 0°C.

*Acid Catalyzed Methanolysis of the Methoxyindolenine 37*c

Acid catalyzed methanolysis of the methoxyindolenine **37***c* (prepared from the indole **32***c* (0.502 g; 2.71 mmol)) yielded a brown oily product consisting principally of **39***c* and minor unidentified impurities. Chromatography of the crude product on silica gel with elution by petroleum ether – diethyl ether (9:1) gave the pure indole **39***c* (0.411 g; 1.89 mmol; 70% from the indole **32***c*) identical in all respects with the indole obtained by methanolysis of **33***c* at 0°C.

Structure of condensation products between isonicotinylhydrazine and reducing sugars by ^{13}C nmr spectroscopy

KEITH BAILEY AND ANDREW G. BUTTERFIELD

Drug Research Laboratories, Health Protection Branch, Tunney's Pasture, Ottawa, Ont., Canada K1A 0L2

Received July 8, 1980

KEITH BAILEY and ANDREW G. BUTTERFIELD. Can. J. Chem. **59**, 641 (1981).

The structures of the condensation products of isonicotinylhydrazine (isoniazid) with galactose, glucose, lactose, maltose, glycolaldehyde and glyceraldehyde were investigated by examination of their ^{13}C nmr spectra, determined in D_2O and DMSO-d_6 solution. Spectroscopic data and their interpretation are presented. Spectroscopic and chromatographic (hplc) evidence are combined to show that the products formed with the four sugars exist in solution predominantly as 1-(1β-pyranosyl)-2-isonicotinylhydrazines, and to a lesser extent as the analogous 1α-pyranosyl anomers. The products formed with glycolaldehyde and glyceraldehyde are normal hydrazones.

KEITH BAILEY et ANDREW G. BUTTERFIELD. Can. J. Chem. **59**, 641 (1981).

Nous avons étudié les structures chimiques des produits de condensation entre l'isonicotinyl-hydrazine (isoniazide) et le galactose, le glucose, le maltose, le glyceraldehyde et le glycolaldehyde grâce à leur spectres ^{13}C rmn en solutions dans D_2O et d_6-DMSO. Les données spectroscopiques ainsi que leurs interprétations seront présentées. Ces données spectroscopiques renforcées avec des données chromatographiques (hplc) démontrent que les produits glucidiques se trouvent surtout dans la forme de 1-(1β-pyranosyl)-2-isonicotinyl hydrazine contenant une quantité moindre d'anomères 1α-pyranosyl, tandis que les produits des deux aldéhydes sont des hydrazones ordinaires.

Introduction

Impurities in isonicotinylhydrazine (isoniazid, isonicotinic acid hydrazide) drug formulations, formed by condensation of the drug with either lactose (1) or glucose (2), have been reported. However, there has been uncertainty about the exact nature of these compounds: they have been referred to as hydrazones (1–3) or as substituted hydrazines (4), the latter implying the absence of an imino carbon at C-1 of the sugar moiety.

During the development of high-performance liquid chromatographic (hplc) methods for the determination of isonicotinylhydrazine (INH) and the lactose and glucose–INH condensation product impurities in INH formulations (5, 6), it was noted that two peaks were obtained for each impurity (6). It was postulated (6) that these two peaks are due to the 1-(1α-pyranosyl) and 1-(1β-pyranosyl)-2-isonicotinylhydrazine anomers, and that their observed interconversion is via the isomeric sugar hydrazone. These observations are to some extent at odds with the hydrazone structure heretofore assumed for these compounds. Knowledge of the structure, and possible isomeric interconversions of these compounds, may help explain their observed physical, chemical, metabolic, and pharmacological characteristics. In an attempt to resolve the uncertainty regarding their structure we studied a series of these compounds obtained from galactose, glucose, lactose, maltose, glyceraldehyde, and glycolaldehyde using carbon-13 nuclear magnetic resonance (^{13}C nmr) spectroscopy and hplc. Shortly after the completion of our work, Takeda (7) reported ^{13}C nmr and other data for the INH-glucose product and some related substances which prompts us to report the results of our studies and our interpretation of the data.

Results and Discussion

Synthesis

Methods for the preparation of various 1-pyranosyl-2-isonicotinylhydrazines have been reported (1, 4, 8). The degree of reaction between INH and the various sugars was monitored by hplc. In all cases, two product peaks were obtained and the earlier-eluting peak, **1***a*–**4***a*, was smaller than the latter, **1***b*–**4***b* (ca. 1:2–1:4). Monitoring of the reaction mixture also showed that monosaccharides reacted with INH much faster than disaccharides, apparently reaching equilibrium at 40°C after 3 and 5 days respectively.

Products obtained in crystalline form were invariably the major reaction products, **1***b*–**4***b*; these were examined by ^{13}C nmr spectroscopy. Attempts to isolate **1***a*–**4***a* using preparative hplc were unsuccessful due to interconversion of the two products in solution. C, H, and N analysis of these products closely matched the theoretical values; however, melting points were generally higher than those previously reported, presumably because of the higher purity of the hydrazines (Table 1).

High Performance Liquid Chromatography

Retention times for compounds **1**–**4**, **9**, and **10** are given in Table 1. The characteristics of the

chromatographic system have been described elsewhere (6). Changes in the chromatograms of solutions of the purified hydrazines, **1***b*–**4***b*, on standing, are interpreted as being due to isomerization to equilibrium proportions of the α and β anomers and open-chain (imino) forms and gradual hydrolysis to free INH (and presumably the respective sugar). The ^{13}C nmr spectra for aged solutions of **1***b*–**4***b*, and the results of Takeda (7) for **2***b*, support these conclusions.

^{13}C Nuclear Magnetic Resonance Spectral Assignments

The ^{13}C nmr signals of galactose, glucose, and lactose in D_2O were identified in accordance with the recent literature (9) and of maltose in accordance with the work of Colson *et al.* (10) (Table 2). The tentative assignments of signals presented in Table 2 for DMSO-d_6 solutions have been made on the assumption that the signals will appear in the same order from low to higher field as that observed

[b]These assignments may be reversed.

in D_2O. This assumption is not altogether justified since inspection of the data presented in Table 2 reveals that the signals are not precisely equally affected by the change in solvent. In the case of glucose, the assignments were supported by the observation that signals observed in 1:1 D_2O: DMSO-d_6 appeared at positions intermediate between those in D_2O and DMSO-d_6.

Spectra of hydrazones **9** and **10** clearly showed that single products were formed (Table 3). The product **10**, from glyceraldehyde, had a terminal rather than central imino carbon, since single frequency off-resonance decoupling (SFORD) of the spectrum resulted in the generation of four doublets and a triplet, two singlets remaining. The imino carbons produced signals at about 157 ppm in D_2O and 154 ppm in DMSO-d_6 (Table 3). Signals from C-4 and C=O for **9** in D_2O were not detected, presumably due to the low solubility of this compound under these conditions.

Spectra for the reaction products of INH with galactose, glucose, lactose, and maltose, **1***b*–**4***b*, were recorded in D_2O and DMSO-d_6. Data with tentative assignments are presented in Table 4. Only one signal appears within a 20 ppm-wide window centred on the position of the imino carbon determined above; this is the readily-identifiable signal from the equivalent C-2 and C-6 of the isonicotinyl ring at 152.6 and 150.4 ppm in D_2O and DMSO-d_6, respectively. There is therefore no evidence for an imino carbon in products of this type and open-chain structures **5**–**8** (Fig. 2) can be eliminated from consideration.

Spectra of INH-galactose and INH-glucose displayed only six signals from the sugar moiety in both D_2O and DMSO-d_6 solution and one anomeric

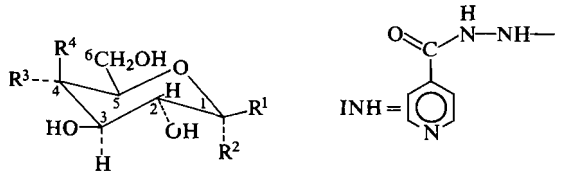
[a]A negative sign indicates a relative shielding effect at that position; assignments of C-3, C-5 of maltose derivative were uncertain in DMSO-d_6.
[b]Refer to footnotes *b* and *c*, Table 2.

configuration was therefore indicated. The spectra of INH-lactose in D_2O and DMSO-d_6 and of INH-maltose in D_2O displayed 12 signals from the sugar moiety, six of which corresponded in both cases with the chemical shifts of C-1′ – C-6′ in the free sugars (Tables 2 and 4), indicating that the glucopyranosyl rings of these materials have remained intact. Substitution of the INH residue for hydroxyl at C-1 is expected to have minimal effects on the chemical shifts of C-4, C-6, and C-1′ – C-6′ because they are remote from the site of change (11).

The signals from C-4 and C-6 were identified on this basis in all spectra (Table 4). All spectra showed a new signal ascribed to C-1 since it had a chemical shift similar to that of C-1 of the starting sugar in the pyranosyl form.

Very similar chemical shift effects occur at C-1 on formation of the four INH products (Table 5), and since only one C-1 signal was observed in these spectra, it is suggested that all have one and the same configuration at C-1 and that they are 1-pyranosyl-2-isonicotinylhydrazines (Fig. 1). The remaining discussion will be rationalized on these structural premises with an attempt to assign the remaining signals and to define the α- or β-configuration of the products in solution.

In the case of INH-glucose, signals at 72.45 and 70.51 ppm in D_2O and DMSO-d_6, respectively, correspond exactly with signals observed for C-4β in β-glucose. The positions observed in glucose for C-4α are 72.45 (D_2O) and 70.81 ppm (DMSO-d_6) and this signal is therefore assigned to C-4. The following reasoning was employed in an attempt to



Compound	R^1	R^2	R^3	R^4
β-Galactose	OH	H	H	OH
β-Glucose	OH	H	OH	H
β-Lactose	OH	H	1-β-Galactopyranose	H

1a	H	INH	H	OH
1b	INH	H	H	OH
2a	H	INH	OH	H
2b	INH	H	OH	H
3a	H	INH	1-β-Galactopyranose	H
3b	INH	H	1-β-Galactopyranose	H
4a	H	INH	1-α-Glucopyranose	H
4b	INH	H	1-α-Glucopyranose	H

FIG. 1. Structures of 1-pyranosyl-2-isonicotinylhydrazines.

solve the remaining assignments. The effects on chemical shifts at C-3 and C-5 upon formation of the INH-coupled product should be similar in magnitude since they bear the same stereochemical relationship to the anomeric C-1. Therefore, if chemical shift *differences* are measured between C-3 and C-5 of glucose itself, both α and β, and pairs are taken from the three signals which are to be assigned, then one pair should show very similar differences for C-3 and C-5 compared with others. All the possible combinations were worked out, and it was found that the conjecture applies to two combinations, in both of which C-2 is the highest-

FIG. 2. Structure of galactose isonicotinylhydrazone (**5**) and related compounds

field of the three signals and its assignment is thereby established (Table 4). The changes in position from the β-series seem to favour slightly the remaining higher-field signal being ascribed to C-3, but in regard to the α-series there is a very marked preference to ascribe the higher-field signal to C-5 in both D_2O and DMSO-d_6. The resulting assignments for INH-glucose (Table 4) agree with those tentatively proposed by Takeda (7) for the D_2O solutions; however, our chemical shifts (relative to DSS) were consistently to lower-field than those published (relative to TMS) by up to 2 ppm.

The spectra of INH-galactose and INH-lactose were interpreted (Table 4) using the same principles as those applied to INH-glucose.

The spectra of maltose in D_2O and DMSO-d_6 indicated that the β:α ratio is approximately 2:1 and 5:1, respectively. The spectrum of INH-maltose in D_2O showed signals which were easily identified as those of the INH moiety, C-1′ – C-6′ and C-1, C-4, and C-6; the C-2, C-3, and C-5 signals were identified as described for glucose. In DMSO-d_6, new C-1 signals appeared at 91.04 and 87.45 ppm with relative intensitives 2.5:1, respectively, in reasonable correspondence with the ratio of peak heights found for the two products on hplc. No imino carbon being apparent, these probably arise from the β and α anomers, respectively, since the chemical shift difference (3.59 ppm) is similar to that of C-1 in maltose (4.49 ppm). The presence of two components led to no difficulties in the identification of C-1′ – C-6′ or C-1, C-4 (partially resolved signals), or C-6, and C-2 of the major component was tentatively assigned to the remaining strong signal positioned between C-5′ and C-4′, as in the D_2O spectrum. Comparisons of chemical shifts with other compounds suggest that C-3 and C-5 of the major component produce the partially resolved signal at 76.52 ppm. A review of the spectrum of INH-maltose, after the solution in D_2O had been kept at ambient temperatures for 3 days, showed a signal at 90.01 ppm of about one tenth the intensity of the major C-1 signal at 92.55 ppm, but other minor signals were poorly resolved from the other pyranoside signals. This higher-field signal is presumably due to C-1 of the minor anomer.

In comparison with the spectra of the pyranoses, those of the INH-pyranoses show consistent effects on the chemical shifts of C-1 – C-6 (Table 5), notably so at C-1, which strongly suggests that the configuration at C-1 is the same in all cases. The chemical shift of C-4 of the INH-pyranoses is close to that in the free β-pyranose, and the shifts of C-3 and C-5 are also much closer to those of the β-pyranoses than the α-pyranoses. It is difficult to explain why the 1α-configuration should lead to de-shielding at C-3 and C-5 of some 4–7 ppm (Table 5); steric shielding might have been anticipated, as observed at C-2. Thus, the ^{13}C chemical shift evidence strongly suggests that the β-INH-pyranoside strongly predominates in both D_2O and DMSO-d_6 solutions. This contention is further supported by the observation of a small amount of the other anomer of INH-maltose in which the minor C-1 signal is upfield of the major C-1 signal; C-1α (minor) is upfield of C-1β (major) of maltose, as with the other free saccharides studied. The relatively bulky INH moiety (as compared with OH) would also be expected to prefer the equatorial 1β-configuration associated with the usual chair conformation of the pyranoses.

Takeda concluded from H-1–H-2 coupling constants that the predominant structure of INH-glucose in D_2O and DMSO-d_6 solutions was that of the 1-(1β-glucopyranosyl)-2-isonicotinylhydrazine (7). We were unable to determine $J_{H\text{-}1\text{-}H\text{-}2}$ of **1–4** in D_2O because the H-1 signal was obscured by the large HDO signal (cf. ref. 7). In DMSO-d_6, H-1 of INH-galactose was not clear but, using Takeda's assignment for INH-glucose, the H-1 signal of the predominant forms **2***b*, **3***b*, and **4***b* was tentatively identified at 3.99 ($J_{H\text{-}1\text{-}H\text{-}2}$ = 8.0 Hz), 4.00 ($J_{H\text{-}1\text{-}H\text{-}2}$ = 7.5 Hz), and 4.00 ($J_{H\text{-}1\text{-}H\text{-}2}$ = 8.0 Hz) ppm, respectively; i.e., having the 1β-configuration. Weak signals in the spectra at 4.7, 4.7, and 4.6 ppm may have been due to small proportions of **2***a*, **3***a*, and **4***a*, respectively. The results of these experiments

support the conclusion that the structure of INH-sugar products in solution is that of 1-(1β-pyranosyl)-2-isonicotinyl hydrazines.

Experimental

The ^{13}C nmr spectra were determined at 20.1 MHz on a Bruker WP 80 Fourier transform spectrometer. Spectra were recorded at ambient temperature using the deuterium resonance of the solvent as the internal lock. Solution concentration was usually about 100 mg/1.7 mL solvent, in 10 mm tubes. Protons were decoupled by broad-band irradiation (4–5 W, offset 6,000 Hz) except in SFORD experiments (4 W, offset 4,700 Hz). Usually, about 3000–6000 interferograms of 5000 Hz sweep-width were stored for output in 4K data points following transform; this gives a separation in memory addresses of 0.06 ppm. (It was noted that in those instances where spectra were determined more than once, it was very uncommon for chemical shifts to differ by more than one address.) Pulse-widths were 1.5 μs (19.2° tipping angle) with no pulse delay following data acquisition.

Elemental analysis was performed using a Perkin Elmer Model 240 Elemental Analyzer. Melting points were determined on a Thomas Hoover capillary apparatus and are uncorrected.

High performance liquid chromatography was carried out on an instrument consisting of a Beckman 110A single-piston pump, a Rheodyne 7105 injector, a Waters Associates 440 UV (254 nm) detector, and a Perkin-Elmer 56 recorder. A 4.6 × 250 mm Brownlee Laboratories column packed with Merck 10 μm DIOL bonded phase packing was used at ambient temperature. The mobile phase, consisting of pH 4.0, 0.05 *M* aqueous acetate buffer and acetonitrile (12:88), was pumped at 2 mL/min. Samples were dissolved in water (ca. 2 mg/mL) diluted 1:10 with acetonitrile, and 10–25 μL aliquots were chromatographed.

1-(1β-Galactopyranosyl)-2-isonicotinylhydrazine (1b)

Isonicotinylhydrazide (INH) (13.7 g; 0.1 mol) and 18.0 g (0.1 mol) of D (+)-galactose were stirred overnight at ambient temperature in 50 mL of water. The resulting clear solution was maintained at 40°C for 7 days. The solution was concentrated to about 25 mL on a rotary evaporator (40°C), 5 mL of methanol was added, and the solution stored at 4°C for 1 week. The product (2.5 g) was collected, washed with methanol, and dried at 40°C overnight.

1-(1β-Glucopyranosyl)-2-isonicotinylhydrazine (2b)

Compound **2***b* was prepared in a similar manner to **1***b*, except that the crystalline product (3.5 g) was obtained directly from the reaction solution after 1 week at 40°C.

1-(1β-Lactosyl)-2-isonicotinylhydrazine (3b)

Isonicotinylhydrazide (INH) (13.7 g, 0.1 mol) and 34.2 g (0.1 mol) of α-lactose were stirred overnight at ambient temperature in 75 mL of water. The product (5.3 g) was obtained after 7 days at 40°C as described for **2***b*.

1-(1β-Maltosyl)-2-isonicotinylhydrazine (4b)

Isonicotinylhydrazide (INH) (13.7 g, 0.1 mol) and 35.0 g (0.1 mol) of maltose hydrate were heated under reflux in 500 mL of methanol. After 48 h the solution was concentrated to about 100 mL on a rotary evaporator (40°C), 20 mL of acetonitrile was added and the solution stored at −10°C overnight. The crystals obtained were collected, but reverted to a straw coloured oil (2.5 g); hplc showed this liquid to contain about 1.4% INH and **4***a* and **4***b* in the ratio 1:14. ^{13}C nuclear magnetic resonance showed a large peak due to methanol, so the liquid was dried at 40°C *in vacuo* and the residue powdered and dried *in vacuo* at 100°C for 48 h. The semi-crystalline product obtained had an indistinct melting point starting at 110°C and decomposed at 190°C; ^{13}C nmr showed the absence of solvent and hplc showed that the product contained about 4.5% INH and **4***a* and **4***b* in the ratio 1:4.

Glycolaldehyde Isonicotinylhydrazone (9)

Isonicotinylhydrazide (INH) (3.4 g, 0.025 mol) and 1.5 g (0.025 mol) of glycolaldehyde were stirred for 24 h at ambient temperature in 15 mL of methanol. The solution was stored at −10°C overnight. The product was collected, washed with 2-propanol and dried at 40°C overnight.

Glyceraldehyde Isonicotinylhydrazone (10)

Compound **10** was prepared as described for **9**, except that the product was obtained with the addition of acetone prior to storage at −10°C.

Acknowledgements

We would like to thank Mr. H. Avdovich for the ^{13}C nmr spectra, and Mr. H. Séguin for the elemental analyses.

The photochemical reaction of tris(ethylenediamine)cobalt(III) ion with ferrocyanide[1]

COOPER H. LANGFORD[2] AND ROGER L. P. SASSEVILLE

Metal Ions Group, Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received April 24, 1980

COOPER H. LANGFORD and ROGER L. P. SASSEVILLE. Can. J. Chem. **59**, 647 (1981).

The photochemical formation of $[Cl(en)_2Co—N{\equiv}C—Fe(CN)_5]^{2-}$ from $Co(en)_3^{3+}$ and $Fe(CN)_6^{4-}$ is explored. Earlier evidence established that the reaction proceeds via electron transfer. Ligand field Co(III) excited states are clearly indicated to be effective. There is evidence that free $Fe(CN)_6^{4-}$ can scavenge these excited states or their successors arising in ion pairs with $Fe(CN)_6^{4-}$. This suggests that the reactive excited state lifetime is at least comparable to the rate of diffusional encounters. However, racemization does not accompany reaction if $(+)_{589}Co(en)_3^{3+}$ is the reactant. Wavelength studies indicate approximate wavelength independence as far as 647.1 nm. These results are in contrast with the behaviour of photosubstitution yields for Co(III) amines.

COOPER H. LANGFORD et ROGER L. P. SASSEVILLE. Can. J. Chem. **59**, 647 (1981).

On étudie la formation photochimique du $[Cl(en)_2Co—N{\equiv}C—Fe(CN)_5]^{2-}$ à partir du $Co(en)_3^{3+}$ et du $Fe(CN)_6^{4-}$. Les données antérieures suggèrent que la réaction se fait par l'intermédiaire d'un transfert d'électron. Il semble clair que les états excités du champ de ligand du Co(III) sont efficaces. Il existe des données à l'effet que le $Fe(CN)_6^{4-}$ libre peut piéger ces états excités ou leurs successeurs apparaissant sous forme de paires d'ions avec $Fe(CN)_6^{4-}$. Ceci suggère que la durée de vie de l'état excité réactif est au moins comparable à la vitesse des rencontres diffusionnelles. Cependant la réaction se fait sans racémisation si le réactif est le $(+)_{589}Co(en)_3^{3+}$. Des études en fonction de la longueur d'onde indiquent que les résultats sont indépendants de la longueur d'onde jusqu'à environ de 647,1 nm. Ces résultats sont contraires au comportement des rendements de photosubstitution des Co(III) amines.

[Traduit par le journal]

Introduction

When the mechanistic step shown in reaction [1]

[1] $$Co(en)_3^{3+} + Fe(CN)_6^{4-} \xrightarrow[\text{L.F.}]{h\nu} Co(en)_3^{2+} + Fe(CN)_6^{3-}$$

was first proposed (1) (en = ethylenediamine), it was an early counter example to the concept that ligand field excited states are reactive only in photochemical ligand substitution or isomerization reactions. It was instead an example of electron transfer to a ligand field excited state. With the discovery of electron transfer quenching of the ^2E state of $Cr(bipy)_3^{3+}$ (bipy = bipyridine) (2), examples of electron transfer to ligand field excited states of Cr(III) and Co(III) coordinated to rigid aromatic ligand systems have multiplied (3) and evidence for redox reactivity of ligand field excited states is no longer rare. On the other hand, cross-over from charge transfer states to ligand field states as the lowest excited state (varying with structure, or medium) often does lead to cross-over to ligand substitution from redox photo-reactivity (4, 5).

The excited states of Cr(III) complexes like $Cr(bipy)_3^{3+}$ which accept electrons from quenchers are long lived and may be regarded as fully vibrationally equilibrated "isomers" of their ground states (6). A Marcus–Hush theory account can be developed for their reactivity. For the same complexes, Stokes shifts are small so that excited states are structurally similar to ground states (7). Moreover, the complexes are resistant to facile substitution reactions (8).

In this frame of reference, the reaction discussed in this paper is different. Luminescence is not observed from the reactive species and the choice of effective reducing agents seems restricted. These facts are somewhat puzzling if the excited state in this case is long lived and can react by diffusional encounter with scavengers as we earlier suggested (1).

Experimental

Materials

Solutions were prepared from redistilled water. Analar grade NaCl was used as is, $K_4Fe(CN)_6 \cdot 3H_2O$ was recrystallized several times (until no perceptible residue remained in the filtration step). $(+)Co(en)_3Cl_3 \cdot H_2O$ was prepared, resolved, and recrystallized several times following a literature method (9).

Reaction Product

The product of photolysis was described (1, 12) as a "cherry red" product but it was not isolated. Nuclear magnetic resonance (1) signals showed it to contain diamagnetic metal centres (presumably d^6Co(III) and d^6Fe(II) as in the reactants). Nuclear magnetic resonance also indicated 2 en molecules bound to Co(III) and one free protonated en in solution (1). An extinction coefficient was estimated (incorrectly!) on the assumption that conversion of $(+)Coen_3^{3+}$ to red product was accompanied by racemization (1). Anion exchange shows the product to be anionic (1).

Samples of red product have now been isolated two ways. (*i*)

trans-$Coen_2Cl_2^+$ (9) was allowed to aquate for 0.5 h at room temperature in 50 cm^3 of water, addition of $Fe(CN)_6^{4-}$ dissolved in H_2O produced the red colour. Cooling in ice yielded a red brown solid. On redissolution this gave the familiar visible spectrum: λ_{max} = 440 nm (ε = 300 ± 10 M^{-1} cm^{-1}). The ir spectra in KBr pellets *differed* from a precipitate of $[Coen_3][Fe(CN)_6]$ in the region of CN stretch. The latter compound has a single peak at 2005 cm^{-1}. The red product has a broad CN region with a maximum at 2050 cm^{-1}. Bridging CN has been reported to show a 25–100 cm^{-1} higher frequency than the terminal ligand (10–12). (*ii*) An equivalent material was isolated from photolysis of $Coen_3^{3+}$ with $Fe(CN)_6^{4-}$ by irradiation of 10^{-2} *M* $Fe(CN)_6^{4-}$ plus 10^{-3} *M* $Coen_3^{3+}$ in 4.0 *M* NaCl to about 50% reaction with the 514.5 nm line of an Ar-ion laser ($I \simeq 10^{-7}$ einstein s^{-1}). Gradual evaporation over days yielded red–brown crystals.

The elemental analysis of neither solid was entirely satisfactory. Assuming complete conversion of *trans*-$Coen_2Cl_2^+$ to red product, the spectrum in Fig. 1 is obtained (λ_{max} 440, ε = 305 M^{-1} cm^{-1}). The formulation of the solids as $Na_2[ClCoen_2—NC—Fe(CN)_5]\cdot 5H_2O$ yields ε = 300 ± 10 M^{-1} cm^{-1}. This formulation is closer to the results of elemental analysis than any alternative considered.

Solution Preparations

Stock solutions of $Co(en)_3^{3+}$ and $Fe(CN)_6^{4-}$ were prepared in 2.0 and 4.0 *M* NaCl under dim red light from freshly recrystallized materials and filtered through 0.45 μm millipore filters. A slow thermal reaction which gives rise to a positive error in quantum yields occurred, therefore dilution and mixing was carried out just prior to photolysis to minimize the corrections.

Photolysis Procedure

Irradiations were carried out in a jacketed 10.0 cm Perkin-Elmer micro-polarimeter cell of 5.1 cm^3 capacity (facial area 0.50 cm^2) or in a 5.00 cm cyclindrical quartz spectrophotometer cell (volume = 16.0 cm^3). Irradiations were conducted at 25°C (±1°C) in dim red room light. Light sources were a 1000 W Hg–Xe lamp (Oriel optics) with a Jarrell-Ash 1/4 M monochromator (for λ = 436 nm), a Coherent Radiation 2 W Ar-ion c.w. laser (for λ = 457.9 and 514.5 nm), and a Spectra-Physics 1 W Kr-ion c.w. laser (for λ = 647.1 nm). In all experiments, except those at 647.1 nm, absorbance was adjusted so that greater than 90% of incident light was absorbed. Percent conversions to product were kept low (less than 5%) and light intensities were measured by Reineckate actinometry on *absorbance matched* solution (13). Intensity values ranged from 1–3 × 10^{-8} einstein s^{-1}. Analyses were carried out using Gilford 240 and Cary 14 spectrophotometers as well as a Perkin-Elmer Model 141 automatic polarimeter. The monitoring wavelength for the product

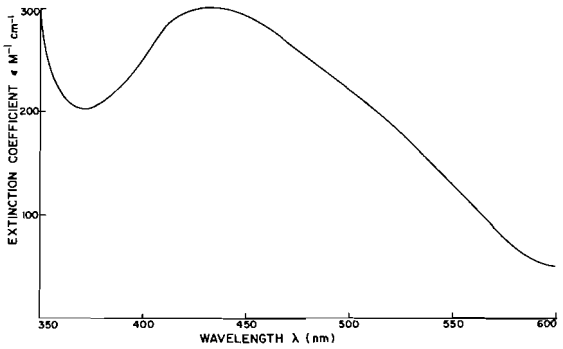

FIG. 1. The visible spectrum of the red product assigned the formulation $[Clen_2Co—N\equiv C—Fe(CN)_5]^{2-}$.

was 440 nm (ε = 300 ± 10 M^{-1} cm^{-1}). The loss of optical activity was followed at 589 nm.

Reaction Stereochemistry

The stereochemical course of the photochemical reaction (eqs. [5]–[10]) of (+)$Co(en)_3^{3+}$ with $Fe(CN)_6^{4-}$ in 2.0 *M* NaCl was investigated. Appropriate solution concentrations of (+)-$Co(en)_3^{3+}$ and $Fe(CN)_6^{4-}$ in 2.0 *M* NaCl were mixed and photolyzed as previously described. The extent of reaction was followed by (*i*) the loss of optical activity at 589 nm and (*ii*) by the spectrophotometric grow-in of product absorption at λ = 440 nm.

Ion Association Measurements

In zero and 2 *M* NaCl media, ion association is extensive. To bring ion pairing constants down to *low enough* values to measure a convenient equilibrium between free ions and pairs, it is necessary to work in media of 4 *M* NaCl. Extensive absorbance and CD measurements reveal that there are NaCl medium effects (14) so that simple interpretation of the decrease in "excess optical absorbance" of the $Coen_3^{3+}$–$Fe(CN)_6^{4-}$ mixtures with increasing NaCl concentration is not a simple guide to ion association. However, measurements in a *swamping and constant medium* are interpretable.

Spectral enhancement at 410 nm was analyzed by the well known Newton–Arcand procedure (15) to obtain ion association constants. Stock solutions of $Coen_3Cl_3$ and $K_4Fe(CN)_6$ were prepared in 4.0 *M* NaCl media filtered (0.45 μm), mixed, and allowed 15 min to come to temperature equilibrium (25.0 ± 0.2°C) in a 10 cm Cary 14 spectrophotometer cell. The molar extinction coefficients (ε) of the free ions (in 4.0 *M* NaCl!) are: $Coen_3^{3-}$, 21.1; $Fe(CN)_6^{4-}$, 2.42 M^{-1} cm^{-1} at 410 nm. Precision of the results is limited by slow thermal reaction. (This is a supplementary reason for not attempting to obtain ion association constants for media lower in NaCl. The thermal reaction correction is large and difficult in these media where thermal reaction is faster.)

Results and Discussion

When solution mixtures of $Co(en)_3^{3+}$ and $Fe(CN)_6^{4-}$ are exposed to visible light it soon becomes apparent to the naked eye that the orange colour of the original mixture is rapidly changed to a "cherry red". This red product is $[Cl(en)_2Co^{III}—NC—Fe(CN)_5]^{2-}$.

(1) Medium Dependence Experiments

Tables 1 and 2 collect quantum yields for appropriate concentrations of $Co(en)_3^{3+}$ and $Fe(CN)_6^{4-}$ mixed and photolyzed with 514.5 nm green laser light at constant intensity in 0 *M* NaCl, 2.0 *M* NaCl, and 4.0 *M* NaCl media. Note that yields are approximately 3 times larger in 0 and 2.0 *M* NaCl media. If only ion paired $Coen_3^{3+}$ excited states entities are reactive, it is easy to account for the lack of dependence of quantum yield on $Fe(CN)_6^{4-}$ concentration in 0 and 2 *M* NaCl media. The unit yield and concentration independence reflect the reactivity of pairs and nearly 100% of Co(III) complexes are ion paired. But this does not provide any test of the capacity of $Fe(CN)_6^{4-}$ to scavenge excited states. This issue is of interest since it could provide an estimate of the lifetime of the reactive

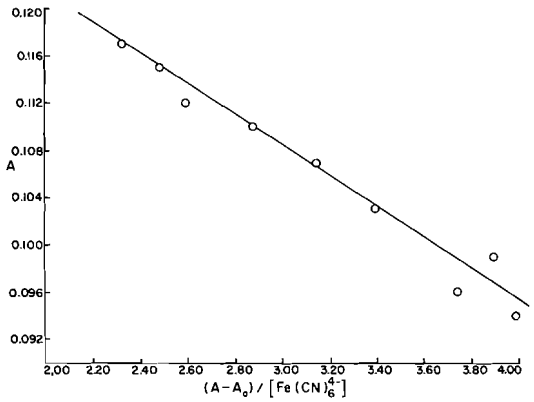

FIG. 2. Newton–Arcand plot for determination of ion association constant between $Coen_3^{3+}$ and $Fe(CN)_6^{4-}$ in the constant ionic strength swamping medium, 4.0 *M* NaCl.

Co(III) excited state. In a preliminary communication (1) on this system, we presented evidence that as ion pairing is suppressed by high ionic strength media, dependence on $Fe(CN)_6^{4-}$ emerges and we suggested an excited state lifetime long enough to permit diffusional encounters with the excited state. Quantitative analysis depends on an estimate of the extent of ion association in 4 *M* NaCl.

A plot of absorbance, A, vs. $(A - A_0)/[Fe(CN)_6^{4-}]$ where A_0 is the absorbance of free $Coen_3^{3+}$ in 4.0 *M* NaCl is shown in Fig. 2. This allows calculations of an ion pairing constant for the medium (K_{eq}) from the slope ($= -1/K_{eq}$) according to the Newton–Arcand procedure (15). The value of 78 ± 5 M^{-1} obtained seems reasonable for the very high ionic strength of the medium.

Returning to Table 2, we recognize that concentrations chosen for photolysis, which must fall between the limits of too low absorbance on the one hand and precipitation on the other, are in a concentration region where 70 ± 15% of the $Coen_3^{3+}$ is ion paired with $Fe(CN)_6^{4-}$. This conclusion is contrary to ref. 1 where it was assumed prior to careful analysis of effects of NaCl on the spectra of $Coen_3^{3+}$ that reduction in the excess absorbance with increasing NaCl implied nearly complete suppression of ion pairing.

If it is assumed that the excited state is too short lived for diffusional encounter, and that all reaction originates in ion pairs, there should be only a weak dependence of quantum yield on concentration of $Fe(CN)_6^{4-}$ in the concentration region that is suitable for photolysis experiments. Figure 3 shows a plot of quantum yields for a constant Co(III) concentration. The dependence is nearly linear in $Fe(CN)_6^{4-}$ with an intercept near zero. This suggests diffusional scavenging. A lifetime for the excited state longer than about 10^{-9} is implied. If the rate of $Fe(CN)_6^{4-}$ scavenging is diffusion-limited ($\sim 10^9$ M^{-1} s^{-1}), the slope in Fig. 3 would imply a lifetime of the order of 10^{-8} s. The effect of Co(III) seen in Table 2 may imply some self quenching. It is possible that the species scavenged is similar to an "exiplex".

(2) Reaction Stereochemistry

When the reaction was first considered (1) it was presumed that the product was racemic and that the

course of the reaction could be followed by the loss of optical activity of the chiral reactant (+)-Co(en)$_3^{3+}$. Prior to actual isolation of the product, this assumption was employed to obtain an "incorrect" value of the extinction coefficient of the product. When a solution 6.34 mM (+)Co(en)$_3^{3+}$ and 3.71 mM Fe(CN)$_6^{4-}$ in 2.0 M NaCl is irradiated (λ = 514.5 nm) and the course of the reaction is monitored (*i*) spectrally, λ = 440 nm; ε = 300 M^{-1} cm^{-1} or; (*ii*) polarimetrically, λ = 589 nm ^{d}M = 89°, the results collected in Table 3 are observed. ΔC_R, from loss of optical activity at 589 nm and, ΔC_S, from increase in absorbance at λ = 440 behave differently (ΔC represents a computed concentration change). The quantum yields determined spectrally (ϕ_S) remain constant while the quantum yields (ϕ_R) calculated by assuming that loss of optical activity corresponds to product formation decrease as the extent of reaction increases. This is strong evidence to indicate that the product is not a racemate but rather, at least partially, optically active. Mutarotation appears to take place in the primary step. Ultimate racemization occurs, presumably, in secondary photolytic and/or thermal steps.

(3) Wavelength Dependence Experiments

Since it is possible that the ligand field (L.F.) triplet (or even possibly a quintet) of the Co(III) complex is important, it was desirable to extend photochemical measurements to the red of the spin allowed singlet bands. The Kr-ion laser provided a line at 647.1 nm where absorptivity is low and concentrations must be high. Error is large, but results comparing 647.1 nm behaviour with 514.5 nm are collected in Table 4. Large correction for product absorption, made as described in ref. 16, are mainly responsible for the uncertainty. It was not possible to conduct experiments in 4.0 M NaCl media. For the moment we emphasize only that reactivity *persists* up to 647.1 nm without substantial diminution.

Conclusions

No direct luminescence evidence concerning the lifetimes of Co(III) amine excited states is available against which to check the notion that the reactive state has a lifetime longer than rates of diffusional encounter. However, there is information from the wavelength dependence experiments to suggest some difference between the ligand field redox photochemistry discussed here and the substitutional photochemistry of Co(III) amines. Several authors (4, 16–20) have reported a more or less

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

monotonic decline in substitutional quantum yield as irradiation wavelength is increased. Moreover, the $Co(NH_3)_5Cl^{2-}$ ion shows an increase in the ratio of Cl^- release to NH_3 release as wavelength increases (16). This suggests that substitution reactions occur in competition with rapid relaxation to a lower lying state. Substitution quantum yield from ligand field excited states are small. It has been suggested that the competing process is radiationless return to the $^1A_{1g}$ (approximately O_h symmetry) ground state since both singlet and triplet ligand field excited states are associated with a $t_{2g}^5e_g^1$ electron configuration which is expected to be photolabile. However, the present results and ref. 1 indicate fairly efficient relaxation at all wavelengths between 436 nm to 647 nm to a reactive state. The reactive excited state may be a thermally equilibrated excited state. This longer lived reactive state might be the quintet Co(III) ligand field state which has a configuration ($t_{2g}^4e_g^2$) appropriate for facile reduction to the Co(II) product with the $t_{2g}^5e_g^2$ configuration. Alternately, it might be a change transfer excited state of the ion pair with $Fe(CN)_6^{4-}$ which could be called an *exiplex*. The results do *not* clearly demonstrate reactions of the free $Coen_3^{3+}$ ion as distinct from an ion pair.

Received June 12, 1980

COOPER H. LANGFORD, BRYAN R. HOLLEBONE, and DANIEL NADEZHDIN. Can. J. Chem. **59**, 652 (1981).

The photovoltaic properties of palladium tetraphenylporphyrin films on n-doped SnO_2 transparent electrode in contact with a solution of quinone/hydroquinone are discussed as a function of the preparation of the film and history of its treatment with heat, H_2, or O_2/H_2O. Magnetic circular dichroism (MCD) spectra of the electrodes provide guidance on film structure. There are three important results. First, MCD spectra show that photovoltaic behaviour is *independent* of crystallinity of the film. Second, the evolution of film behaviour as "doping" by O_2/H_2O occurs shows that photoprocesses occur at *both* the interface of the film with SnO_2 and the electrolyte, leading to both photoanodic and photocathodic processes. Third, MCD spectra show that "doping" is not a surface or trace phenomenon but affects the axial ligand sensitive region of the spectra of molecules throughout the film. Transport of charge through the film by successive "redox" reactions appears to provide the simplest qualitative explanation of the results. That is, conduction is by hopping in a non-stoichiometrically oxidized film.

COOPER H. LANGFORD, BRYAN R. HOLLEBONE et DANIEL NADEZHDIN. Can. J. Chem. **59**, 652 (1981).

On discute des propriétés photovoltaiques de films de tétraphénylporphyrine de palladium sur une électrode transparente de SnO_2 dopée au n et qui est en contact avec une solution de quinone/hydroquinone, en fonction de la préparation du film et de l'histoire de son traitement par la chaleur, le H_2 ou le O_2. Les spectres de dichroisme circulaire magnétique (DCM) des électrodes fournissent une indication sur la structure du film. Il y a trois résultats importants. Premièrement, les spectres DCM révèlent que le comportement photovoltaique est indépendant de la cristalinité du film. Deuxièmement, l'évolution du comportement du film quand il se produit un dopage par O_2/H_2O indique que les processus photoélectriques se produisent à la fois à l'interface du film avec SnO_2 et avec l'électrolyte et qu'il en résulte aussi bien des processus photoanodiques que photocathodiques. Troisièmement, les spectres DCM montrent que le dopage n'est pas seulement un phénomène de surface ou de trace, mais qu'il affecte à travers tout le film la région du spectre des molécules sensibles au ligand axial. Le transport de charge à travers le film par des réactions rédox successives semblent fournir la plus simple explication qualitative des résultats. C'est à dire que la conduction se produit par sauts non stoechiométrique dans le film oxydé.

[Traduit par le journal]

Introduction

Recent efforts to develop artificial means of solar energy conversion and storage have led to a renewed interest in the problem of photovoltaic (1, 2) and photoelectrochemical (3, 4) behaviour of prophyrine and phthalocyanine films. In this laboratory, a wide range of structures is being canvassed for use in a cell based on a transparent electrode of n-type SnO_2 on glass (5). One of the more promising compounds in terms of both photovoltaic and photocurrent effects is palladium tetraphenylporphyrin (PdTPP). In this report, we describe the photovoltaic behaviour of PdTPP as a function of mode of film preparation (vacuum sublimation, or spin coating from $CHCl_3$), pretreatment of the film (heating in H_2 or exposure to moist air), and conditions of exposure during electrochemical experimentation in a cell using a quinone/hydroquinone — 1 *M* KCl electrolyte (N_2 or air saturation of the solution).

It has long been recognized that the film electronic properties of porphyrin and phthalocyanine films (which are commonly regarded as p-type organic semiconductors) depend heavily on the history of exposure of the film to oxygen and moisture (1, 6). The origin of the "doping" effects has been associated with surface adsorption and surface states in some discussions. There has also been some tendency to consider "doping" processes to involve low concentrations. In this study, the history of the electrode was recorded in terms of magnetic circular dichroism (MCD) spectra as well as photovoltaic behaviour. These spectra provide a high resolution probe. Film spectra have been assigned previously (7).

It is worth noting at the outset that the MCD probe shows that films may be crystalline or amorphous with little effect on photoelectrochemical properties. The large effects of "doping" on photoelectrochemical behaviour are associated with modification of a sufficient fraction of the film molecules (quite possibly a majority) to radically alter parts of the MCD spectrum. This alteration is similar in *both* crystalline and amorphous films.

Experimental

Photoelectrodes consisting of a film of palladium tetraphenylporphyrin deposited on *n*-SnO_2 coated glass plates (O. H. Johns Glass Co.) were prepared in two ways, either by vacuum deposition or by spin coating from chloroform solution.

Palladium tetraphenylporphyrin was prepared by reflux of palladium dichloride with tetraphenylporphyrin in glacial acetic acid and sodium acetate (8). After addition of water and filtration of the crude material final purification was by sublimation *in vacuo* at 350–400°C with rejection of the first fraction below 350°C to eliminate chlorine.

Vacuum deposited films were made by placing the PdTPP in a boat in a tube furnace and after sublimation temperature was achieved, the cleaned (2.5 mm diameter) SnO_2 surface was exposed to the vapour through a shutter for 10 to 30 min depending on the film thickness (~500–1000 Å) desired. After deposition and cooling the coated glass plate was removed from the furnace and stored until needed under dry nitrogen.

In the preparation of the spin coated electrodes the SnO_2 surface was washed successively in nitric acid, detergent, distilled water, and finally dried chloroform. The plate was mounted horizontally with the SnO_2 surface upwards in a high speed rotor, and several drops of a PdTPP solution in dried chloroform (5 m*M*/L) placed on the surface for 10 s. The plate was then spun for 20 s at 3000 rpm, resulting in an evenly spread, dry film (of thickness near 500 Å).

For both films the measurements of photovoltages were carried out in an aqueous solution of 1 *M* KCl, 1 m*M* quinone, and 1 m*M* hydroquinone buffered with a phosphate buffer (pH 5.6–5.7). The electrode was pressed to the wall of a Teflon cell from outside and was sealed with a rubber ring and silicone grease. A brass ring pressed to the dye side of the electrode served for the electrical contact. Dye was removed so that the brass ring contacted the SnO_2 layer. The contact of the light beam to the dye and electrolyte was through a 10 mm hole in the wall of the cell. A fresh portion of the solution of about 30 mL was used for each measurement. Air or purified nitrogen was bubbled through the solution as required during the measurements. A saturated calomel electrode (sce) served as a reference electrode. The cell is the "bubbling gas" cell described previously (9). Open circuit voltage was measured using a "Keithley" electrometer. As a source of illumination a 1000 W Xenon-mercury lamp with yellow uv cutoff filter was used. Light power was approximately equal to 130 mW/cm^2.

The experiments involved obtaining dependences of photovoltage (V_{ph}) upon time (t) under continuous illumination for electrodes treated in various ambients producing different stages of doping depending on the cell aeration conditions.

Absorption spectra of both types of film were measured in a Cary 14 spectrophotometer using uncoated SnO_2 plates as blanks. Magnetic circular dichroism (MCD) spectra were measured in a custom built computer operated spectrophotometer (5) with separately run background spectra again taken from uncoated SnO_2 electrode plates.

The MCD spectra were obtained at room temperature 4.7 T magnetic field in a horizontally mounted superconducting solenoid. The sign and intensity were calibrated with a standard hexaquo cobalt(II) sulphate solution (7) for the solution spectra which also provides the sign convention for the film spectra. The slit was set at 1.0 mm for constant wave number band pass.

The solution spectrum of PdTPP in α-chloronaphthalene could not be obtained beyond 23 000 cm^{-1} because of solvent absorbance.

Results and Discussion

(A) Photoelectrode Structure and Behaviour

The MCD and absorption spectra of the vacuum deposited and spin evaporated films on SnO_2 electrode plates were obtained together with a chloronaphthalene solution spectrum of PdTPP for comparison. While the absorption spectra are very similar (Table 1), the MCD film spectra are radically different as shown in Figs. 1 and 2. The vacuum deposited film (Fig. 1*b* and *c*) display a rich structure in the MCD visible region which could be resolved into a series of strong overlapping *A* terms (Fig. 1*b* and *c*) (7). As in these earlier film studies, none of this structure was observable in the broad absorption spectrum. The detailed *A* term pattern varies from one electrode to another but the same number of bands appear. There are no important changes in these spectra related to storage under nitrogen or air/moisture. On the other hand, the spectrum of the spin coated electrode film is much simpler, consisting of an isolated *A* term in the visible and another in the near-uv (Fig. 2). This pattern resembles the solution spectrum very closely (Fig. 1*a*).

These observations can be interpreted from the structural model developed for vacuum deposited

Magnetic circular dichroism spectra of palladium tetraphenylporphyrin (*a*) in chloroform solution, (*b*) vacuum deposited on SnO_2 treated glass electrode, (*c*) the same PdTPP film electrode after use for 8 h as a photoelectrode in the quinone/hydroquinone bubbled air cell. Ellipticities [θ] are in units of 5×10^{-4} G^{-1}. Region (*1*) is the Q band and region (*2*) is the Soret band of the PdTPP spectrum.

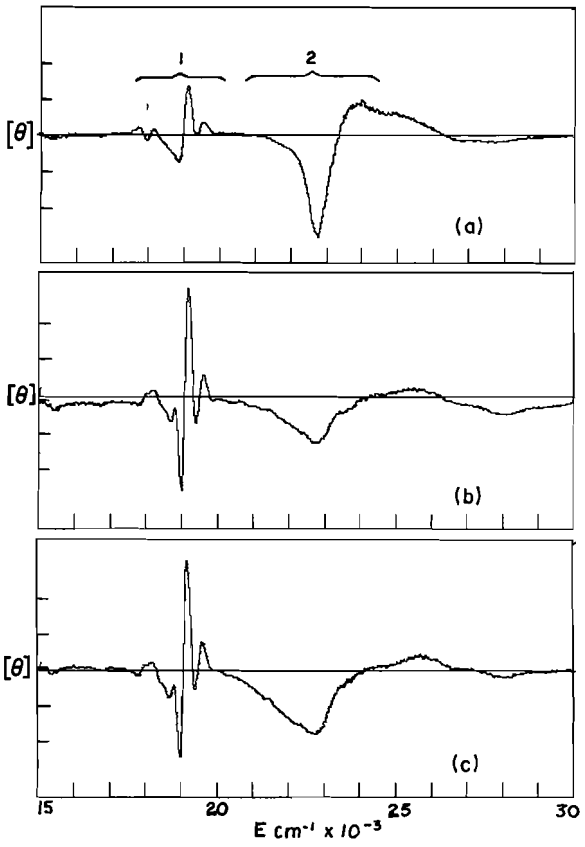

FIG. 2. Magnetic circular dichroism spectra of spin coated palladium tetraphenylporphyrin – SnO_2 electrodes (*a*) after initial preparation from chloroform solution, (*b*) after "hydrogenation" for 24 h at 215°C, (*c*) after use for 8 h as a photoelectrode in the quinone/hydroquinone bubbled air cell. Regions (*1*) and (*2*) as in Fig. 1.

metal phthalocyanine films (7). The visible spectrum of these earlier films was resolved into pairs of *A* and *B* terms which represent the exciton splittings of the electronic origin and the (0–1) vibronic state respectively. In some cases more than one pair of *A* and *B* terms became apparent, indicating that the film consisted of two or more distinct solid phases of the phthalocyanine derivative (α or β) due to the particular conditions of temperature and pressure used during sublimation. The number of MCD bands and the variation of their intensities observable in different individual preparations of the PdTPP films indicates that this compound also forms crystalline films of variable phase composition in the available range of pressure and temperature sublimation conditions.

By contrast the spin evaporated films display no discernable crystalline spectra. Instead the spectrum is nearly superimposible on the solution spectrum in chloroform even after prolonged drying at elevated temperatures. The film appears to be essentially amorphous and any intermolecular interactions must be relatively long range and lacking in regular symmetry.

Turning attention to photovoltaic properties of the films, dependence on history is quite apparent. In all cases, the dark potential settles rapidly to 0.125 V vs. sce, the equilibrium potential of the quinone/hydroquinone couple. Vacuum deposited films which have been stored under dry N_2 but handled in air initially display a *positive* photovoltage vs. sce which decreases fairly rapidly in a manner shown in curve *1* of Fig. 3 finally achieving a *negative* steady state value in 3–4 h. In contrast, both vacuum deposited and spin coated films which were "equilibrated" with moist laboratory air yielded only *negative* photovoltage (Fig. 3, curve *2*). The behaviour is related to the decrease in resistance associated with exposure of films on

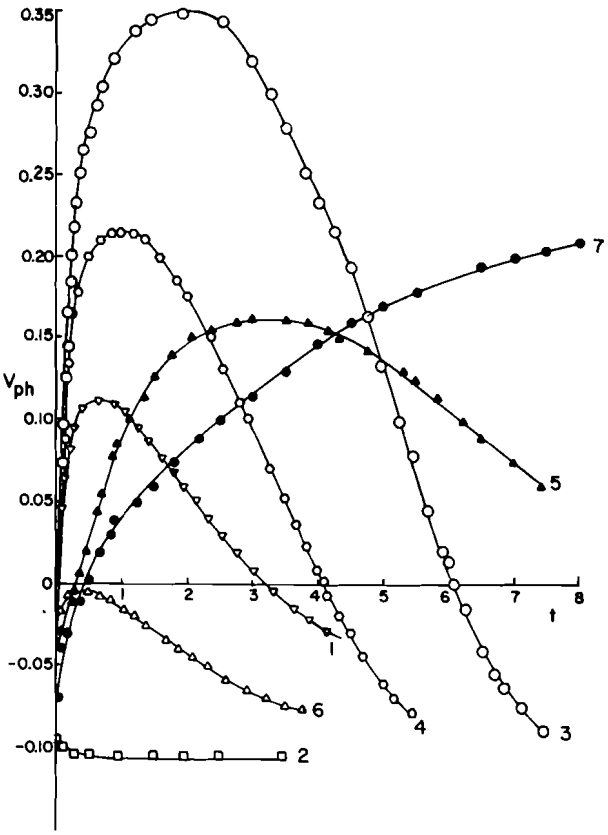

FIG. 3. V_{ph}–time records for SnO_2–PdTPP–electrolyte cell. Curves are for various electrode treatments as follows: *1*, vacuum sublimed electrode with limited exposure to air (stored under N_2 prior to use); *2*, spin coated electrode; *3*, spin coated electrode heated under H_2; *4–7* are all curves for electrodes prepared by spin coating; *4*, H_2 treated then exposed at room temperature to moist air; *5*, H_2 treated and exposed to hot dry air; *6*, H_2 treated, heated, then exposed to moist laboratory air; *7*, H_2 treated then mounted in cell which is N_2 purged to exclude O_2 exposure.

metals to air/moisture (1, 6, 10, 11). The observed photovoltage is strongly influenced by reaction of the film with oxygen and water. The vacuum deposited films have been only briefly exposed to the laboratory atmosphere during transfer from the sublimation apparatus and in mounting the electrochemical cell. They are relatively free of both O_2 and H_2O. However, exposure either to moist air for several hours or to the electrolytic solution itself permits reaction to occur and leads to negative photovoltages essentially the same as observed for the spin evaporation films which were prepared in the presence of humid laboratory air. There is *no evidence, however, of a breakdown in the solid state structure of vacuum deposited films after exposure to moist air, nor of any ordering of the spin deposited films on aging*. Thus the photovoltaic behaviour of the electrodes is *apparently unconnected* to the solid state structure of the film.

In order to more fully characterize these reactions and the accompanying photoelectrochemical behaviour, a series of pretreatments of films were carried out. Attempts to dry and degas films by heat treatments *in vacuo* gave highly variable results and are limited by the temperature of sublimation. Qualitatively, heat treatment produced results related to those described below. A reproducible technique for "drying" and/or removal of O_2 is treatment of the film at 210–215°C under one atmosphere of hydrogen gas, for 24 h. Films from any source treated in this manner yield an initial, but unstable, photovoltage near −0.05 V. This treatment, like the moist air reaction, does not result in any fundamental MCD observable rearrangement of the *film solid state structure*. The series of *A* terms assigned to intermolecular interaction (7) neither appears nor fades. There is, *however*, an increase in the ellipticity of the *visible region* A *term* in the spin deposited film. This is a strong indication of increased delocalization of the ^1E_u state of the ring resulting from removal of an axially coordinated π acid ligand from the Pd^{2+} ion (12). At the same time the first, partially resolved *A* term in the near-uv becomes more intense. This is again a good indication of a ligand change since this band is known experimentally to be sensitive to the axial environment of the metal ion (7, 12) and involves a state with a large metal atom contribution in its basis function (13).

All of these large and easily observed changes in the MCD spectra strongly indicate that reaction of the film with moist air and with hydrogen is an *extensive* phenomenon, *involving a large fraction of available* PdTPP *molecules* and independent of the detailed solid structure. The processes clearly do not represent a minor doping process which could be regarded as the introduction of the small number of defect sites as is frequently associated with production of extrinsic semiconductors.

The hydrogen treated electrodes were then exposed to oxygen and water, either independently or simultaneously, either before or during the course of electrochemical monitoring under controlled conditions. The time evolution of photovoltaic properties was followed and spectra were recorded for various important stages of treatment. The photovoltage for an H_2 treated electrode immersed in air saturated electrolyte rises from its initial negative value very rapidly to a maximum near 0.35 V within 2 h. Later the photovoltage decreases to reach −0.12 V in 8 h (Fig. 3, curve *3*). The original vacuum deposited films (Fig. 3, curve *1*) corre-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

late very closely with the decreasing branch of the hydrogen treated electrode curve, probably indicating a slight but variable degree of reaction with moist air in spite of the storage precautions.

The MCD spectra of initially H_2 treated electrodes (Fig. 2*b*) change considerably after 8 h in the electrochemical cell. The visible region shows a moderate decrease in ellipticity and the near-uv ligand sensitive band narrows again to resemble that in the initially prepared sample (Fig. 2*c*). Both changes strongly indicate recoordination of the axial sites of PdTPP by some oxygen donor ligand. A similar change was seen in the spectrum of a vacuum sublimed film after use in the electrochemical cell (Fig. 1*c*) but the analysis is complicated by overlapping exciton bands.

Curve *4* of Fig. 3 represents the electrode exposed to *wet* air after hydrogen treatment. It has generally the same shape as curve *3*, but the photovoltage maximum value is lower (ca. 0.22 V). Heating the electrode gently in air after the hydrogen treatment results in an appreciable change of shape (curve *5*); the slope of both ascending and descending branches is smaller than in other cases. The maximal value of the photovoltage (ca. 0.16 V) is reached in about 3.5 h. The electrode exposed to wet air after the treatment in hot H_2 and hot air (curve *6*) reaches the maximal value of the photovoltage relatively quickly (in about 30 min) and this value is negative, ca. −0.005 V. The slope of the descending branch is approximately equal to that in curve *5*.

In a nitrogen saturated electrolyte the electrode treated in H_2 shows increase of the photovoltage eventually approaching a limit (curve *7*) but the maximum is not reached even after 48 h of measurements. A supply of air into the electrolyte results in rapid increase of the photovoltage to the maximum and the rapid decrease of the photovoltage to negative values with a slope similar to the initial decay in Fig. 3, curve *3*. This is shown in Fig. 4, curve *1*. Finally, nitrogen purging of the air saturated electrolyte (Fig. 4, curve *2*) results in a rather small and rapid decrease and beyond in a slow increase of the photovoltage.

(B) Photoelectrode Reaction and Charge Transport

The variation of voltage from positive to negative can be given qualitative explanation from the point of view of the reaction process in a PdTPP dye. The system [*n*-SnO_2–PdTPP–electrolyte] has two photosensitive interfaces: I, between electrolyte and PdTPP film with photovoltage V_{ph}^{I}, and II, between PdTPP film and SnO_2 layer with photovoltage V_{ph}^{II}. The measurable open circuit photovoltage V_{ph} is the sum of V_{ph}^{I} and V_{ph}^{II}. We postulate that in a film of "undoped" palladium tetraphenylporphyrin, the photovoltage at the interface I is positive and at the interface II is negative. This is a consequence of electron transfer at each. An increase of axial ligation in the PdTPP film leads to an increase of the positive value of V_{ph}^{I} and the negative value of V_{ph}^{II}. The heating in H_2 results in vigorous removal of water and oxygen from the porphyrin film (6). Contact of the film with the air-saturated electrolyte leads to a reabsorption of oxygen and water by the film, first increasing the extent of coordination in molecules of PdTPP *at interface I* and *later* at *interface II* as well. This successive alteration gives the observed V_{ph} vs. t dependence with the maximum corresponding to the condition $dV_{ph}^{I}/dt = dV_{ph}^{II}/dt$. Thus the time evolution of photovoltages shown in Figs. 3 and 4 shows the diffusion of both water and oxygen from interface I to interface II with a corresponding shift of the dominant photoprocess from reaction of the "minority carrier" (1, 6, 14) (electrons) with the

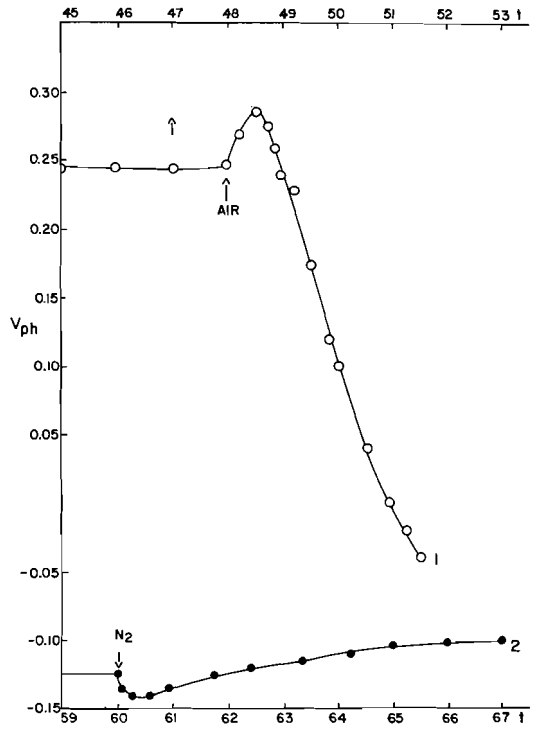

FIG. 4. This figure shows extension of two curves from Fig. 3. Curve *1* shows the effect of admitting air to the cell (curve *3* of Fig. 3) which had been protected from O_2. Curve *2* shows the effect of purging a cell (curve *2* of Fig. 3) with N_2 after it had equilibrated with O_2/H_2O.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

electrolyte to transfer of the same minority carrier (electrons) to the n-SnO_2 layer. This is similar to observations of Fan and Bard (15). As the photoprocess changes, the photoelectrode shifts from a *"photoelectrochemical" cathode to a "photovoltaic" junction driving an electrochemical anode*. This changing process however depends on the presence of both reagents since it is clear from anaerobic experiments (Fig. 3, curve 7) that the second process cannot be achieved by aqueous saturation alone although water does lead to reaction of interface I (with the electrolyte).

The extensive changes in the MCD spectra which accompany the appearance of the anodic behaviour and the observation that crystallinity does not substantially affect the electrochemistry both suggest that electrochemistry of these films is to be treated in terms of individual molecular units. It may even be appropriate to borrow the chemical language of homogeneous electron transfer. Potentially useful theories of electron transfer rate are available. From this point of view, the film appears to act as an activating support for ligand molecules which facilitate electrochemical electron transport by successive redox reactions through the film. This *hopping* mechanism may transfer electrons to quinone at the electrolyte interface with a photopotential V_I from the excited state of the coordinated PdTPP molecules as the initial cathodic process. After film saturation is complete, however, the reverse process by which electrons are transferred to the SnO_2 conduction band from the same excited state is efficient. A very recent study of porphyrin oxidation with iodine suggest partial oxidation and non-stoichiometry is important to efficient electrical processes in such films (16).

In summary, changes in solid state properties which might be expected to affect semiconductor behaviour do not correlate with changes in photovoltaic behaviour. Instead this behaviour is a function of extensive modification of the film by oxygen and water which results in well defined change in the *monomer* MCD spectra of the PdTPP. These changes are similar to those seen in solution coordination studies (12) and are susceptible to interpretation as axial ligation changes. Thus, the anodic behaviour is coupled to *coordination* and probably *activation* of *water* and *oxygen* molecules resulting in a route for successive redox reactions under photoexcitation as the main components of electron transport.

1-Chloromethyl-3-*endo*-(2′,4′-dinitrophenylthio)tricyclo[2.2.1.$0^{2,6}$]heptane, $C_{14}H_{13}ClN_2O_4S$, crystallizes in space group $P2_1/a$ with unit cell dimensions $a = 12.785(2)$, $b = 10.653(1)$, $c = 11.061(1)$ Å, $\beta = 101.54(1)°$, $Z = 4$.

The structure was solved from Patterson and Fourier maps. The parameters were refined by block-diagonal least-squares to a final $R = 0.038$ for 2063 observed reflections. The structural data provide unequivocal proof for our earlier ascertainment of configurational-specific *exo* attack upon the *endocyclic* double bond of 2-methylenebicyclo[2.2.1]hept-5-ene with homoallylic participation.

The molecule is characterized by the presence of an interaction between oxygen of the 2-nitro group and a sulphur atom, and of a weak bifurcated hydrogen bond system involving C—H···O bonds.

MARIA PRZYBYLSKA et DENNIS G. GARRATT. Can. J. Chem. **59**, 658 (1981).

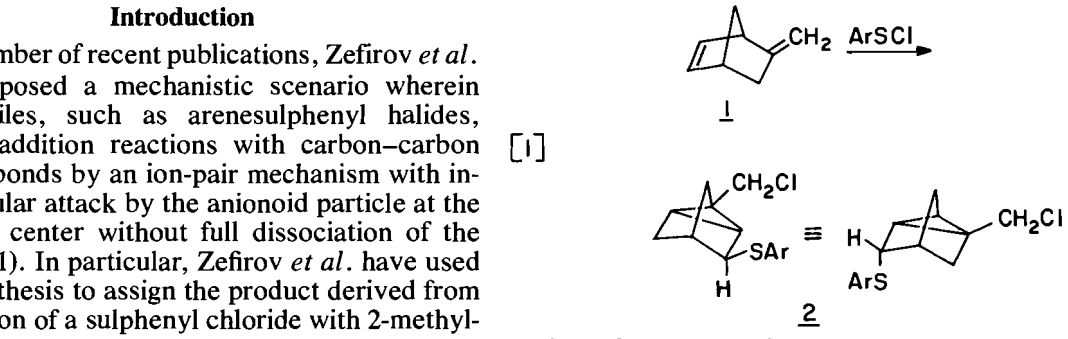
Le chlorométhyl-1 (dinitro-2′,4′ phénylthio) 3-*endo* tricyclo[2.2.1.$0^{2,6}$] heptane, $C_{14}H_{13}ClN_2O_4S$ cristallise dans le groupe d'espace $P2_1/a$ avec des dimensions de maille de: $a = 12{,}785(2)$, $b = 10{,}653(1)$, $c = 11{,}061(1)$ Å, $\beta = 101{,}54(1)°$, $Z = 4$. La structure a été résolue à partir des diagrammes de Patterson et de Fourier. Les paramètres sont affinés par la méthode des moindres carrés (matrice entière) jusqu'à une valeur finale $R = 0{,}038$ pour les 2063 réflexions observées. Les données de structure confirment d'une façon non ambigue notre conclusion antérieure à l'effet que l'attaque sur la double liaison endocyclique du méthylène-2 bicyclo[2.2.1]heptène-5 se produit d'une façon sétérospécifique par la face *exo* avec une participation homoallylique.

La molécule est caractérisée par une interaction entre l'oxygène du groupe nitro en position 2 et l'atome de soufre et une faible liaison hydrogène bifurquée impliquant des liaisons C—H· · · O.

[Traduit par le journal]

Introduction

In a number of recent publications, Zefirov *et al.* have proposed a mechanistic scenario wherein electrophiles, such as arenesulphenyl halides, undergo addition reactions with carbon–carbon multiple bonds by an ion-pair mechanism with intramolecular attack by the anionoid particle at the cationoid center without full dissociation of the ion-pair (1). In particular, Zefirov *et al.* have used this hypothesis to assign the product derived from the reaction of a sulphenyl chloride with 2-methylenebicyclo[2.2.1]hept-5-ene, **1**, as that of configurationally-specific[2] *endo* attack upon the *endocyclic* double bond with homoallylic participation of the *exocyclic* π system in the product determining step (reaction [1]), to give the *exo*-arylthionortricyclene, **2**.[3]



1 [1] 2

[1]NRCC No. 18804.

[2]The term configurational-specificity or -selectivity was originally coined in reference to a problem in allene chemistry in which it became necessary to distinguish which face or faces of the orthogonal π systems was/were being attacked (2). The extension of the use of this term to problems such as *exo* and *endo* attack seems quite reasonable and has been used in this context previously (3).

[3]We have extended the *endo–exo* terminology beyond its original usage in norbornane systems (4) to nortricyclenes in accord with the suggestion of Cristol and Lalonde (5), by referring to configurations with respect to the unsubstituted methano bridge. We agree with Cristol and Lalonde that the use of the terms *endo* and *exo* in these connotations is better than coining new terms, even though the original derivations are not precisely applicable.

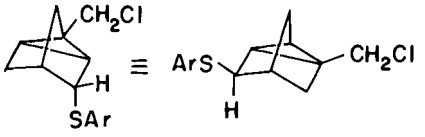
[2]



3

This interpretation, however, contrasts with results obtained in these laboratories and elsewhere (6) which predict configurationally-specific *exo* attack upon the *endocyclic* double bond of **1**. In this respect, we and others (7) have recently reported the reaction of **1** with arenesulphenyl chlorides to give the *endo*-arylthionortricyclene, **3**; the product of *exo* attack upon the *endocyclic* double bond with homoallylic participation of the *exocyclic* π system. In support of this assignment, we note the observation that adducts of type **4** isomerize to the nortricyclene, **3**, presumably by way of a thiiranium ion-like intermediate resulting from neighbouring group assistance of carbon–chlorine bond cleavage by the arylthio group (reaction [2]).

In view of the aforementioned differences in interpretation, we felt that it was necessary to unambiguously establish the configurational-specificity of this reaction. We therefore undertook a single crystal X-ray structural determination of the adduct derived from 2,4-dinitrobenzenesulphenyl chloride and diene **1**. As will be seen, the correct structure is that derived from *exo* attack: 1-chloromethyl-3-*endo*-(2′,4′-dinitrophenylthio)tricyclo-[2.2.1.0^{2,6}]heptane.

Experimental

Crystal data are as follows:

$C_{14}H_{13}ClN_2O_4S$ fw = 340.8
Monoclinic, $P2_1/a$, a = 12.785(2), b = 10.653(1), c = 11.061(1) Å, β = 101.54(1)°, V = 1476.0 Å^3, Z = 4, ρ_o = 1.51 (by flotation at 24°C), ρ_c = 1.53 g cm^{-3}, λ(Cu Kᾱ) = 1.54178 Å, μ(Cu Kᾱ) = 38.0 cm^{-1}.

Yellow prisms of mp 101–103°C were obtained from a mixture of cyclohexane and methylene chloride. The space group was established from precession films. The data were collected at room temperature with the Nonius CAD-4 procedures using a crystal of dimensions 0.21 × 0.21 × 0.12 mm and Cu Ni-filtered radiation.

The pertinent details are: ω–2θ scan; 1° < θ < 70°; ω scan angle = (0.7 + 0.2 tan θ)°; SIGPRE (the prescan acceptance parameter) = 0.7; SIGMA = 0.014. ITMAX (the maximam scan time) = 150 s. The prescan speed was 5°/min and two final scans were made in opposite directions with double the variable scan speed. A measurement of two standard reflections every 100 min revealed a decrease in intensity of < 6% during data collection. Three reflections were used as orientation controls and were measured every 60 reflections. Reorientation occurred, if the deviation of any scattering vector in any direction from calculated position was greater than 0.050°.

Out of 2800 measured reflections, 2063 (73.7%) were above threshold of 1.43σ(I_{net}). The net intensities, after scaling, were corrected for Lorentz and polarization effects but not for absorption.

The non-hydrogen atomic coordinates were obtained from Patterson and Fourier maps. Refinement for observed reflections was carried out by block-diagonal least-squares, minimizing $\Sigma w(|F_o| - |F_c|)^2$ with weights.

$$\sqrt{w} = 1/\{1 + [(|F_o| - P_2)/P_1]^2\}^{1/2} \sin^2\theta/P_3$$

where P_1 = 15, P_2 = 10, and P_3 = 0.27.

Hydrogen atoms were located on a difference map carried out when R was 0.073, and which showed no other significant peaks. The non-hydrogen atoms were refined anisotropically and isotropic temperature factors were used for H. Refinement converged at R = 0.038 and R_w = 0.042 for the 2063 observed reflections and the final mean and maximum shifts/esd for all atoms were 0.05 and 0.20, respectively. The scattering factor curves were those of Hanson, Herman, Lea, and Skillman (8) for non-hydrogen atoms and of Stewart, Davidson, and Simpson (9) for H.

All calculations were carried out with the NRCC crystallographic computer programs by Ahmed, Hall, Pippy, and Huber (10).

The final atomic coordinates are presented in Table 1.[4]

Discussion

The projection of the molecule of the nortricyclene derivative is shown in Fig. 1, in which the numbering of the atoms and the bond lengths are also presented. The values of the valency angles, together with their esd's are listed in Table 2. The C—H bonds are in the range 0.92 to 1.05 Å (mean = 0.99 and esd = 0.03 Å).

The C—C bonds of the nortricyclene moiety vary from 1.509 to 1.518 Å with the exception of the bonds to C(4), which are 1.530 to 1.539 Å. They agree well with the values previously reported for 3,5-*endo*,*endo*-dibromotricyclo[2.2.1.0^{2,6}]heptane-7-carboxylic acid (11) with the exception of C(1)—C(7) and C(4)—C(7), which in the latter are 1.541(10) and 1.560(10) Å, respectively, due to the substitution at C(7) by COOH.

The angles of the three-membered ring are 59.8, 60.1, and 60.1°. The endocyclic angles of the five-membered rings vary from 97.2 to 107.6°; the smallest being C(2)—C(3)—C(4) = 97.3°, C(6)—C(5)—C(4) = 97.2°, and C(1)—C(7)—C(4) = 97.4°.

[4]Tables of observed and calculated structure factors and of temperature factors are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

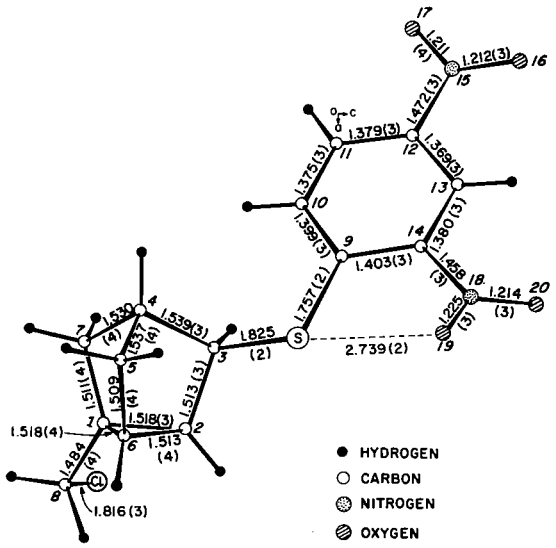

FIG. 1. The projection of the nortricyclene derivative along the *b* axis showing the stereochemistry of the molecule, the numbering scheme, and the bond lengths with their esd values in parentheses.

The S—C(3) and S—C(9) bonds are 1.825(2) and 1.757(2) Å, respectively, and they reflect the difference between S—C(sp^3) and S—C(sp^2) bonds. Similar differences were observed in, for example, dimethyl 3-*endo*-chloro-4-*exo*-phenylthiotricyclo-[4.2.2.$0^{2,5}$]dec-9-ene-7,8-*endo*,*endo*-dicarboxylate (12) (1.819(8) and 1.762(8) Å) and in 2-methylthiobenzothiazole (13) (1.82(3) and 1.77(3) Å).

The nitro groups are rotated about N—C bonds in opposite directions bringing O(16) above and O(20) below the plane of the benzene ring; the distances being 0.09 and −0.50 Å, respectively. The rotation about the C(12)—N(15) bond is ~5° and that about C(14)—N(18) is 28°. The relevant torsion angles are presented in Table 3 and the dihedral angles between the plane of the benzene ring and those of N(15) and N(18) nitro groups are 4.9 and 152.0°, respectively. In *m*-dinitrobenzene (14) both nitro groups are rotated out of the aromatic plane by about 13°, the directions of the rotations being such that the molecular symmetry is *m*. The deviation from symmetry in our structure appears to be caused by the intramolecular interaction between O(19) and S atoms. The O···S distance is 2.739(2) Å, which is considerably smaller than the sum of their van der Waals radii of 3.07 Å (r(O) = 1.42 (15); r(S) = 1.65 Å (16, 17)).

A similar strong intramolecular interaction between S of the $SOCH_3$ group and O(1) of the nitro group was reported by Hamilton and LaPlaca (18) in methyl ester of 2-nitrobenzenesulphenic acid. The structure was characterized by a very short

S···O(1) distance of 2.44 Å and the N—O(1) bond was found to be somewhat longer (1.24 Å) than N—O(2) (1.19 Å). The O—S···O(1) configuration is almost linear, which the authors considered favourable for sulfur *p*- and *d*-orbital participation in the partial bonding. In the title compound C(3)—S···O is also nearly linear. This linearity suggests a trigonal bipyramidal geometry about S, wherein C(3) and O(19) occupy apical sites and C(9) plus the two lone pairs of electrons occupy the three equatorial sites.

A similar interaction between S and O of the *ortho*-nitro group is evident in 3-*endo*-bromo-4-*exo*-(2′-nitrophenylthio)-7,8-*endo*,*endo*-dimethyltricyclo[4.2.2.$0^{2,5}$]dec-7-ene, dimethyl 3-*endo*-chloro-4-*exo*-(2′,4′-dinitrophenylthio) tricyclo-[4.2.2.$0^{2,5}$]dec-9-ene-7,8-*endo*,*endo*-dicarboxylate and in methyl (1*RS*,4*SR*,12*RS*)-4-(2′nitrophenylthio)-9-oxapentacyclo[6.4.0.$0^{2,5}$.$0^{3,7}$.$0^{6,11}$]dodeca-

10-one-12-carboxylate (19). The authors did not mention it, but the O···S distances in these structures were found to be 2.630, 2.657, and 2.634 Å, respectively.

Non-bonding interactions of this type are also probably present in two other structures involving the 2-nitrophenylthio moiety (20), as in both cases one of the NO bonds of the nitro group is somewhat longer than the other, and apparently closer to S. Unfortunately the lack of listing of coordinates in both of these publications does not allow the calculation of the O···S distances.

TABLE 3. Selected torsion angles (deg); esd is 0.4°

(*a*) Endocyclic torsion angles of five-membered rings

Ring A: C(1), C(2), C(3), C(4), and C(7)
Ring B: C(2), C(3), C(4), C(5), and C(6)
Ring C: C(1), C(6), C(5), C(4), and C(7)

Bond	A	B	C	Mean	C_s*
C(1)—C(2)	−2.3				
C(2)—C(6)		−2.6		1.7	0.0
C(1)—C(6)			−0.1		
C(2)—C(3)	34.7	−28.1			
C(5)—C(6)		32.1	−30.9	31.4	25.0
C(1)—C(7)	−31.5		31.2		
C(3)—C(4)	−55.4	49.5			
C(5)—C(4)		−51.2	51.8	52.2	40.3
C(7)—C(4)	53.6		−51.9		

*Calculated values for the envelope conformation with a puckering amplitude (q = 0.435 Å) determined from an electron diffraction study of cyclopentane (23).

(*b*) Exocyclic torsion angles

C(7)—C(1)—C(8)—Cl	69.9
C(4)—C(3)—S—C(9)	−95.4
C(3)—S—C(9)—C(10)	23.7
C(9)—C(14)—N(18)—O(19)	−28.4
C(11)—C(12)—N(15)—O(17)	−5.6

The O···S interaction causes the lengthening of N(18)—O(19) to 1.225 from the average for the other three N—O bonds of 1.212 Å. This lengthening combined with the already mentioned shortening of S—C(9) leads to changes in electron density distribution in C(9)—C(14), which is longer than its counterpart C(11)—C(12) (1.403 vs. 1.379 Å) and in C(14)—N(18) which is shorter than C(12)—N(15) (1.458 vs. 1.472 Å). Thus an alternate shortening and lengthening of bonds along the chain S—C(9)—C(14)—N(18)—O(19) is observed. Similar effects were found in, for example, ergotamine (21, 22) in a chain of 5 atoms in which the end oxygens were an acceptor and a donor in hydrogen bond formation. The shortening of C(12)—C(13) is significant and reflects similar alternate changes in electron distribution through the N(15)—C(12) —C(13)—C(14) —N(18) chain.

The endocyclic torsion angles of the nortricyclene moiety (cf. Table 3) show strain. Those involving C(4) deviate most from the calculated values for the envelope conformation with a puckering amplitude (q = 0.435 Å) as determined from an electron diffraction study of cyclopentane (23).

The benzene ring atoms including both nitrogens, but excluding C(13) are planar (χ^2 = 6.8). C(13) lies at 0.012 and S at 0.070 Å above that plane. The puckering of the benzene ring at C(13) may be due to the formation of a weak intramolecular bifurcated hydrogen bond, apparently present between C(13) and one oxygen atom of both nitro groups. Due to the presence of nitro groups the hydrogen at C(13) is relatively acidic and the H(13,1) distances to O(16) and O(20) are 2.48(2) and 2.38(2) Å, respectively. C(13)—H(13,1)···O(16)

and C(13)—H(13,1)···O(20) angles are only 93.6(1.5) and 99.4(1.6)°, but weak asymmetrical bifurcated hydrogen bonds with O—H···O angles as small as 90 and 96° were described by Newton, Jeffrey, and Takagi (24). The interaction of H(13,1) with O(20) appears to be somewhat stronger than with O(16). This difference is probably brought about by the O(19)···S interaction and is supported by the observation that the angle C(14)—C(13)—H(13,1) is smaller than C(12)—C(13)—H(13,1), 117.3(1.4)° vs. 124.3(1.4)°. A similar weak intramolecular C—H···O bond was found in 2,9-diacetyl-9-azabicyclo[4.2.1]non-2,3-ene (25).

The molecules are separated by normal van der Waals contacts. The shortest O(19)···H(3,1′) distance is 2.63(2) Å and the shortest H···H contacts are 2.48(4) and 2.55(3) Å. The shortest Cl···H approach is to H(4,1′) of 2.93(3) Å.

The photochemistry of phenanthrene in sodium dodecyl sulfate micelles in the presence of conjugated dienes having from five to eight carbon atoms has been examined using laser flash photolysis techniques. The effect of the addition of the diene quenchers on the intensity of the T–T absorptions immediately after singlet decay reflects largely the distribution of the quenchers and can be used to determine micellar properties, e.g. the aggregation number. The effect of quenchers on the lifetime of triplet phenanthrene is largely controlled by the rate constants for quencher entry and exit from the micelles. Typical rates of entry are in the $1–2 \times 10^9\ M^{-1}\ s^{-1}$ range, while the exit rates are strongly dependent on the number of carbon atoms and are different for open and cyclic molecules; for example the exit rate constants are 1.3×10^5 and $3.5 \times 10^5\ s^{-1}$ for 1,3-octadiene and 1,3-cyclooctadiene, respectively.

J. C. SELWYN et J. C. SCAIANO. Can. J. Chem. **59**, 663 (1981).

Utilisant les techniques de la photolyse flash au laser, on a étudié la photochimie du phénanthrène dans des micelles de dodécylsulfate de sodium, en présence de dienes conjugués ayant 5 à 8 atomes de carbone. L'effet de l'addition des pièges de dienes sur l'intensité des absorptions T–T immédiatement après la désintégration du singulet, reflète largement la distribution des pièges, et peut être utilisé pour déterminer les propriétés micellaires, par exemple le nombre d'aggrégation. L'effet des pièges sur la durée de vie du triplet du phénanthrène est largement contrôlé par les constantes de vitesse d'entrée et de sortie des pièges dans les micelles. Les vitesses typiques d'entrée sont de l'ordre de $1–2 \times 10^9\ M^{-1}\ s^{-1}$ tandis que celles de sortie dépendent fortement du nombre d'atomes de carbone et sont différentes selon qu'il s'agit de molécules cyclique ou à chaîne ouverte; par exemple les constantes de vitesse de sortie sont respectivement de $1,3 \times 10^5$ et $3,5 \times 10^5\ s^{-1}$ pour l'octadiène-1,3 et le cyclooctadiène-1,3.

[Traduit par le journal]

Introduction

The kinetics of chemical reactions in micellar systems frequently reflect the distribution of reactants and the kinetics of entry and exit processes, in addition to the interaction between the reagents. Several studies have shown that luminescent probes can be used in the examination of static and dynamic aspects of the behaviour of probes in micelles (1–14). Flash photolysis techniques have also been used to examine kinetic aspects of micellar processes (1, 2, 15, 16) but not to determine micellar properties, such as the aggregation number.

Few rates of exit and entry are known; for example, in the case of ground state probes the values have been determined for several cyclic azoalkanes (5), for nitromethane and diiodomethane (8), and for di-*tert*-butylnitroxide (17). In the case of excited probes, the rates of exit for triplet state probes for a series of arenes were measured by Thomas *et al.* (9) using phosphorescence techniques.

In this paper we examine the quenching of phenanthrene triplets by conjugated dienes in sodium dodecyl sulfate (SDS) micelles. The measurements were carried out by monitoring the T–T absorptions due to phenanthrene triplet using laser flash photolysis techniques.

Results

All the experiments described in this paper have been obtained using laser flash photolysis techniques and employing the pulses (337.1 nm, ~8 ns, up to 10 mJ) of a nitrogen laser for excitation. Most of our experiments have been carried out using phenanthrene as a probe, with the only exception of some runs in which we used 1-methylphenanthrene.

In carefully prepared and deaerated samples one can obtain phenanthrene triplet lifetimes (monitored at 483 nm) in the neighborhood of 300 μs; in our experiments, the quenching by conjugated dienes is always the predominant mode of triplet decay (*vide infra*). Therefore, as long as other modes of triplet decay are much slower, they do not play a role in the kinetic measurements. We have normally regarded as acceptable triplet lifetimes of 100 μs and up in the absence of added quencher.

The type of effects observed by addition of dienes can be clearly divided into two groups: static and dynamic effects. The former refers to those effects which are the result of a probe and a quencher being resident in the same micelle at the time of excitation. Dynamic effects reflect the migration of either the probe or the quencher towards the other.[3] In all our experiments the quenchers are far more mobile than the probe and only the migra-

tion of the quencher needs to be considered in the time scale of our experiments.

A similar subdivision applies to the analysis of the kinetic data. That is, static phenomena largely reflect the occupancy levels in the micellar phase, while dynamic aspects reflect kinetic processes related to the exit and entry of the quencher from and into the micelle. This subdivision is also used in the rest of this section.

Static Phenomena

The observable yield of phenanthrene triplet (18) decreases upon addition of a conjugated diene. This does not mean that the triplet state is not formed, but rather, that quenching takes place in a time domain shorter than that accessible using nanosecond techniques (~10 ns). We believe that this quenching effect reflects the presence of phenanthrene and quencher in the same micelle at the time of excitation. The analysis for a system of this type is essentially the same as that reported by Turro *et al.* (5, 6) for the quenching of fluorescent probes by cationic quenchers associated to anionic micelles and by partially-solubilized, cyclic azo compounds. If the distribution of the quencher in the micelles is determined by Poisson statistics, then the ratio of the triplet transient absorption in the absence (A^0) and presence (A) of quencher (Q) will be determined by eq. [1].

$$[1] \quad \ln (A^0/A) = [Q_m]\bar{n}/[\text{Det}] - \text{cmc}$$

where $\bar{n}$ is the aggregation number, [Det] the concentration of detergent, cmc the critical micelle concentration and the subscript (e.g. in Q_m) "m" indicates micelle solubilized.

Our experiments (*vide infra*) clearly show that dienes are far from being just static quenchers associated to the micelles, but rather, their exit and entry rates can be quite large. However, in the case of some of the larger molecules, like 1,3-octadiene, one can regard them as fully micellized static probes in the time scale required to measure the yields of triplet phenanthrene. Under these conditions, a plot of ln (A^0/A) vs. [Q] yields, from the slope, $\bar{n}/([\text{Det}] - \text{cmc})$. The data for several concentrations of surfactant can also be plotted using [Q]/([Det] − cmc) in the abscissa. Figure 1 shows the plot obtained in the case of 1,3-octadiene (using cmc = 8.2×10^{-3} *M* (19)) from which we obtained $\bar{n}$ = 63. The method can in principle be utilized in order to determine both aggregation numbers and cmc values (6).

A decrease in the observable yield of phenanthrene triplets is observed upon addition of any of the quenchers used in this study; however, for the

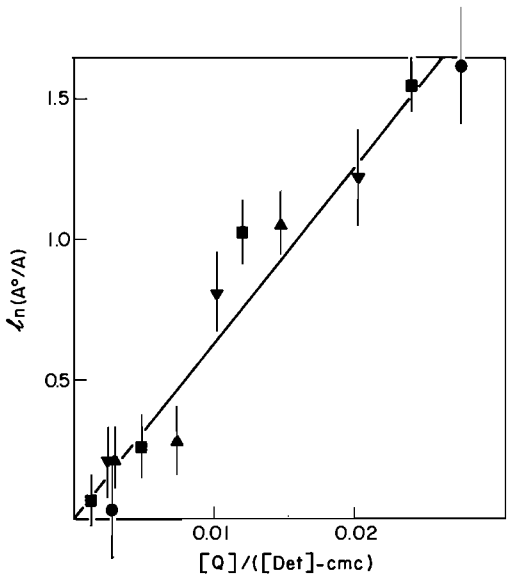

FIG. 1. Plot of the data for 1,3-octadiene according to eq. [1], for the following surfactant concentrations: (●), 0.0762 *M*; (▼), 0.102 *M*; (■), 0.152 *M*; and (▲), 0.254 *M*.

smaller molecules dynamic quenching processes are of considerably greater importance than static effects and the analysis of these is somewhat different, see Discussion.

If sufficient diene is added to a system a point is reached in which all triplets are quenched in static processes and as a result no triplets are observed in the study of transient phenomena. Under these conditions the only detectable species in the singlet state of phenanthrene, which decays with first order kinetics and a lifetime of 60 ns (based on measured values of 58 ns from absorption and 62 ns from fluorescence), and is consistent with literature values (20). Figure 2 shows the absorption spectra of the singlet and triplet states of phenanthrene in SDS micelles. The singlet spectrum has been corrected for fluorescence and measurements at $\lambda <$ 450 nm are subject to considerable error because the magnitude of the correction exceeds that of the absorption signal. Since there is considerable spectral overlap between the singlet and triplet states, it was considered convenient to carry out all experiments under conditions such that the triplet lifetime exceeded 700 ns; under these conditions the role and involvement of the singlet state can be safely ignored.

Dynamic Phenomena

While static phenomena account for quenching events which are controlled by the relative distribution of probes and quenchers (5, 6), dynamic

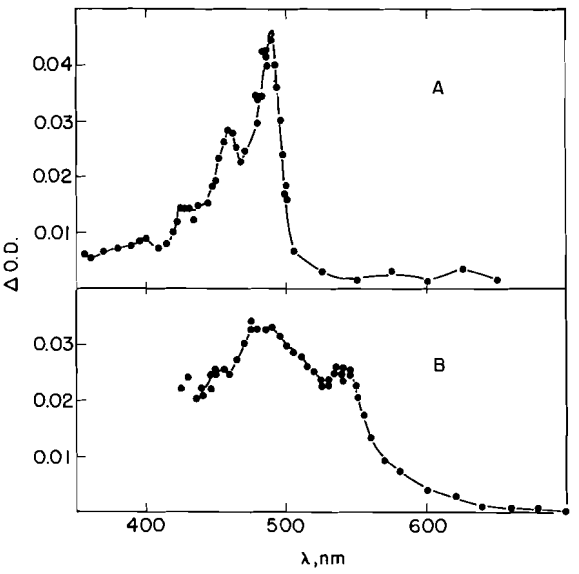

FIG. 2. Transient spectra for phenanthrene in SDS micelles. *A*: triplet state in 0.251 *M* SDS containing 0.001 *M* phenanthrene, recorded between 2 and 20 μs following excitation; *B*: singlet state in 0.30 *M* SDS containing 0.0030 *M* phenanthrene and 0.020 *M* *trans*-1,3-pentadiene, recorded immediately after excitation by the laser pulse.

processes require the migration of the probe and/or quencher, and as a result are a reflection of the mobility of these species. In our experiment the probe has been chosen so that it can be safely assumed that it will not leave the micelle in the time scale of the experiment. There is sufficient evidence in the literature to support this statement (9) and our own experiments are consistent with it.

We will assume that if a diene molecule enters a micelle where an excited phenanthrene resides, quenching occurs with a probability of 1.0. The validity of this assumption can be better understood by combining our own data with those available from the literature (8) and will be dealt with in the Discussion section.

The quenching by dienes can be expected to occur by the mechanism of Scheme 1, where Q represents the quencher and P is a phenanthrene molecule associated to a micelle. The concentrations of P are small enough that only single occupancy needs to be considered and it is important to note that when one uses the concentration term [P], it refers to the concentration of micelles which contain the probe P. The rate of triplet decay is given by:

$$[2] \quad -\partial[^3P]/\partial t = (k_0 + k_+[Q_w])[^3P]$$

That is, the decay of the triplet state of the probe can be expected to occur in a pseudo-first order

$P \xrightarrow{h\nu} {}^1P$ ${}^1P \rightarrow$ decay or $h\nu$ ${}^1P \rightarrow {}^3P$	τ_s^{-1}
${}^3P \rightarrow$ decay or $h\nu'$	$k_0[^3P]$
${}^3P + Q_w \rightarrow {}^3Q_m + P$	$k_+[Q_w][^3P]$
${}^3Q_m \rightarrow$ decay or (exit and decay) $Q_m \rightarrow Q_w$	$k_-[Q_m]$

SCHEME 1

process (k_{expt}) controlled by the concentration of quencher in the aqueous phase ([Q_w]) and the rate of quencher entry into the micelle, k_+.

$$[3] \quad k_{expt} = k_0 + k_+[Q_w]$$

Naturally, [Q_w] is not a convenient variable because what one knows is the total or bulk concentration, not [Q_w]. If the quencher concentration in the aqueous and micellar phase can be regarded as in equilibrium, then

$$[4] \quad K_{eq} = k_+/k_- = [Q_m]/[Q_w][M]$$

where [M] is the concentration of micelles, given by $[M] = ([SDS] - cmc)/\bar{n}$. Substituting in eq. [3]:

$$[5] \quad k_{expt} = k_0 + (k_-/[M])[Q_m]$$

For those molecules which are largely resident in the micellar phase, that is, $[Q_m] \gg [Q_w]$, one can replace [Q_m] for [Q], the bulk quencher concentration, which leads to:

$$[6] \quad k_{expt} \cong k_0 + (k_-/[M])[Q]$$

This equation will apply to the larger molecules, for example, the data for 2,5-dimethyl-2,4-hexadiene are shown in Fig. 3, from which we obtain $k_- = 1.9 \times 10^5\ s^{-1}$.

For those systems where the fraction of

TABLE 1. Kinetic data for the quenching of phenanthrene triplets by dienes in SDS micelles at room temperature

Quencher (units)	[SDS] range[a] (M)	k_- (s^{-1})	k_+ ($M^{-1}\,s^{-1}$)	K_{eq} (M^{-1})
cis-1,3-Pentadiene	0.051–0.253	8.9×10^6	1.2×10^9	130
trans-1,3-Pentadiene	0.051–0.253	6.9×10^6	9.5×10^8	140
1,3-Hexadiene	0.050–0.254	2.3×10^6	8.3×10^8	360
cis-2-*trans*-4-Hexadiene	0.051–0.253	1.0×10^6	(2.0×10^9)	(1900)[b]
1,3-Cyclohexadiene	0.050–0.249	5.6×10^6	1.3×10^9	240
2,4-Dimethylpentadiene	0.165	3.7×10^5	—	—
1,3-Cycloheptadiene	0.151	1.3×10^6	—	—
1,3-Octadiene	0.076–0.254	1.3×10^5	—	—
2,5-Dimethyl-2,4-hexadiene	0.165	1.9×10^5	—	—
1,3-Cyclooctadiene	0.177	3.5×10^5	—	—

[a]When a range is given the ionic strength was maintained constant at the highest value shown using sodium chloride.
[b]See text for value obtained using eq. [11].

quencher molecules in the aqueous phase cannot be neglected, the values of k_+ and k_- can be derived from a study of the kinetics of triplet decay as a function of quencher *and* surfactant concentration. In this case

$$[7] \quad [Q] = [Q_w] + [Q_m]$$

and

$$[8] \quad K_{eq} = ([Q] - [Q_w])/[Q_w][M]$$

In this case, substituting in eq. [3]

$$[9] \quad k_{expt} = k_0 + \frac{k_+[Q]}{K_{eq}[M] + 1}$$

If we call k_M the slope of plots of k_{expt} vs. [Q], i.e., $k_M = k_+/(K_{eq}[M] + 1)$, then the values of k_+ and k_- can be obtained from a plot of k_M^{-1} vs. [M] according to eq. [10].

$$[10] \quad k_M^{-1} = k_+^{-1} + [M]/k_-$$

Figure 4 shows a plot for 1,3-cyclohexadiene according to eq. [10] (at constant ionic strength), from which the parameters given in Table 1 were obtained. In the case of large molecules, e.g. 1,3-octadiene, only the value of k_- could be obtained. This is due to the fact that the intercept is too small compared with the variation of k_M^{-1} and therefore not significantly different from zero within the experimental error. This observation supports the use of eq. [6] for the larger dienes. In other words, eq. [6] is valid under the conditions where the intercept in eq. [10] can be neglected.

The data obtained applying eq. [10] to several dienes have also been included in Table 1.

In order to confirm that the mobility of phenanthrene could be disregarded we carried out a series of experiments with 1-methylphenanthrene as a probe; the exit rate for 1-methylphenanthrene triplets can be expected to be significantly different from that of phenanthrene triplets (8).[4] As a quencher we have used 1,3-octadiene, which is the slowest example examined; it is reasonable to assume that if the mobility of phenanthrene can be ignored in the case of 1,3-octadiene, the same condition will be met in all the other systems where the mobility of the quencher is considerably greater. The values of k_- for 1,3-octadiene obtained are 1.25×10^5 and 1.32×10^5 s^{-1} using 1-methylphenanthrene and phenanthrene as a probe, respectively.

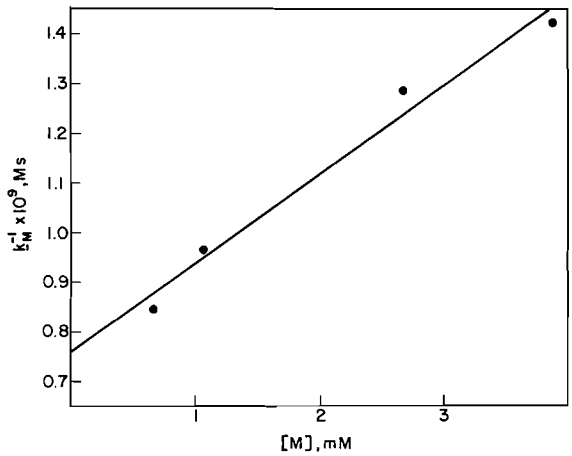

FIG. 4. Plot according to eq. [10] of the data for 1,3-cyclohexadiene.

Discussion

We start this section by noting that the kinetic parameters measured herein all correspond to the ground state of the dienes; by contrast, rate parameters based on phosphorescence quenching (e.g. ref. 8) reflect the behavior of the triplet state. The difference is probably trivial for molecules

[4]Thomas *et al.* (9) have shown that methyl substitution leads to a change of a factor of 2.5 in the rate of exit of naphthalene from SDS micelles.

(e.g. arenes) which do not suffer extensive changes upon excitation, but may be substantial where structural or dipolar changes are involved.

The rates of entry could only be determined for C_5 and C_6 dienes, since for the larger molecules the errors would be too large.

Typically we find $k_+ \sim 1\text{–}2 \times 10^9\ M^{-1}\ s^{-1}$. The value is substantially lower than that measured for methylene iodide (8) ($k_+ = 2.5 \times 10^{10}\ M^{-1}\ s^{-1}$, also in SDS micelles), but comparable with the value determined for di-*tert*-butyl nitroxide (17), $k_+ = 1.48 \times 10^9\ M^{-1}\ s^{-1}$. For 1-bromonaphthalene a value of $5\text{–}8 \times 10^9\ M^{-1}\ s^{-1}$ has been estimated (9). In the case of cyclic azoalkanes, Turro *et al.* measured entry rate constants of ca. $4 \times 10^9\ M^{-1}\ s^{-1}$ (5). Clearly small polar molecules (methylene iodide and nitromethane) enter the micelles at substantially faster rates than typical organic molecules, for which the rate constants fall in the $1\text{–}5 \times 10^9\ M^{-1}\ s^{-1}$ range. It is not entirely clear what controls the differences between the various families of substrates, although dipole moment, size, and shape are obvious candidates. More data are clearly necessary in order to reach general conclusions, in addition, it would be desirable to design experiments to test the consistency of the different experimental techniques.

In the previous section we have mentioned that one of the conditions for our kinetic analysis to apply is that if a quencher enters a micelle containing an excited probe, quenching will occur with a probability of 1.0. When a quencher enters a micelle its average residence time will equal k_-^{-1}, that is, it will be in the 0.12 to 10 μs range (Table 1). For reactions with close to diffusion-controlled rate constants in solution, Thomas *et al.* (8) have estimated an intramicellar rate constant of $7.5 \times 10^7\ s^{-1}$; i.e. reaction will occur in ca. 13 ns. Since our residence times are between 10 and 1000 times larger than the mean reaction time, we conclude that the condition mentioned above will be met in all the examples examined.

The rates of exit from the micelles seem to reflect the number of carbon atoms, a parameter that naturally must in turn correlate with the solubility of the dienes in water. In general, we find that for a given number of C-atoms the exit rates are larger for the cyclic quenchers.

In the interpretation of static phenomena we have mentioned before that while eq. [1] can be used for the larger molecules (replacing $[Q_m]$ by the bulk concentration), this approximation does not apply for those cases when a considerable fraction of the quencher molecules are resident in the water phase. In this case the partition equilibrium needs to be taken into consideration (5), which leads to eq. [11].

$$[11] \quad \ln (A^0/A) = \frac{K_{eq}[Q]}{1 + K_{eq}[M]}$$

Therefore, plots of $\ln (A^0/A)$ vs. [Q] are expected to be linear and the reciprocal of the slopes should, in turn, depend linearly on "[Det] − cmc" (replacing [M] by ([Det] − cmc)/$\bar{n}$). The slope of these plots corresponds to $\bar{n}^{-1}$ and the intercept to K_{eq}^{-1}. We find that for small molecules, where $1 \gg K_{eq}[M]$, only K_{eq} can be obtained, the slope being too small for accurate determination; even the values of K_{eq} are subject to considerable errors, reflecting largely that errors in laser flash experiments are more important in static than dynamic phenomena, as well as the logarithmic nature of eq. [11]. For example, for 1,3-cyclohexadiene the values of K_{eq} are $240\ M^{-1}$ from dynamic measurements and $580\ M^{-1}$ using eq. [11]. For large molecules (e.g. C_8), $1 \ll K_{eq}[M]$ and only the aggregation number can be obtained; the treatment being essentially the same as already described. An interesting example is the case of *cis*-2-*trans*-4-hexadiene where the two values in the denominator in eq. [11] are comparable; we obtained $\bar{n} \sim 81$ and $K_{eq} \sim 900\ M^{-1}$. While the errors are relatively large, the data are reasonably consistent with those obtained from dynamic studies or from other techniques.

It is interesting to compare the possibilities of triplet transient spectroscopy with those of fluorescence techniques for the study of micellar properties (i.e. cmc, $\bar{n}$) and kinetic properties (k_+, k_-). We find that while our approach does yield $\bar{n}$ values which are consistent with those obtained by other techniques (e.g. for SDS $\bar{n}$ values are 62 by light scattering (21), 63 by osmometry (22), 71 by fluorescence quenching (5), 60 using the luminescence from $Ru(bipy)_3^{2+}$ (6), 74 by pyrene excimer formation (23), and 63 by quenching T–T absorption in phenanthrene), it is not as simple as, e.g. luminescence quenching. For the determination of dynamic parameters the use of triplet absorption quenching has the advantage that, as a result of the longer time scales involved, it can be used to determine k_- values for quenchers that are largely resident in the micelle (e.g. 1,3-octadiene); it is also important to note that the condition of 100% efficient quenching generally assumed in the study of static phenomena is more likely to be met by triplets than by singlets, again reflecting the longer time scales involved. Also, in the case of dienes which have high energy singlet states, it would be extremely difficult to find a suitable fluorescent probe. In conclusion, both techniques

offer advantages in certain cases: luminescent probes are probably better for the study of micellar properties, while kinetic parameters, in particular for quenchers with high energy singlets, or very low solubility in water can be measured more easily and accurately using triplet transient absorptions.

Finally, it is conceivable that in some cases the *cis* and *trans* isomers of conjugated dienes may show kinetic differences (k_- and k_+) larger than those observed here for 1,3-pentadiene. In such cases it should be possible to design experiments involving the photosensitized isomerization of the dienes which would lead to *cis*/*trans* photostationary ratios substantially different from those obtained in homogeneous solution. This possibility could have considerable synthetic application and deserves further examination.

Experimental Section

Materials

Phenanthrene (Aldrich) was sublimed before the experiment. 1-Methylphenanthrene (ICN) was used as received. Sodium dodecyl sulfate (BDH, specially purified) was also used as received. In those experiments where the concentration of surfactant was changed the ionic strength was kept constant using sodium chloride (Anachemia).

When the isomer used in the case of the quenchers is not specified, it is usually because we used the commercially available isomeric mixture (where applicable). The sources of dienes were as follows: *cis*-1,3-pentadiene from Fluka, 1,3-octadiene from Chem. Samples Co., and all others from Aldrich.

Sample Preparation

The samples were contained in Suprasil cells made of 3 × 7 mm rectangular tubing (Vitro Dynamics), fitted in their upper part with tube of ca. 13 mm id which provided a convenient volume (5–7 mL) to minimize foam losses. In any case, the actual volume of solution (initially 2 mL) to which the quencher or quencher solution was added was determined by weighing the tube after deaerating with oxygen-free nitrogen.

Laser Flash Photolysis

Our facility uses the pulses from a Molectron UV-24 nitrogen laser for excitation. The system has been fully interfaced with a PDP 11-03L computer which processes the data initially acquired by an R-7912 Tektronix transient digitizer. A detailed description of the instrument can be found elsewhere (24).

JOHN S. HAYNES, JOHN R. SAMS, and ROBERT C. THOMPSON. Can. J. Chem. **59**, 669 (1981).

The iron(II) sulfonates $Fe(CF_3SO_3)_2$ and $Fe(p\text{-}CH_3C_6H_4SO_3)_2$ have been prepared and on the basis of vibrational and electronic spectra and magnetic and Mössbauer data have been assigned a layer lattice structure involving hexacoordinated iron(II) and terdentate bridging anions. The FeO_6 chromophore in these compounds is distorted by a trigonal elongation along the C_3 axis. $Fe(CH_3SO_3)_2$ has been obtained in two isomeric forms, one having a trigonal elongation of the FeO_6 chromophore, the other a trigonal compression. No structural isomerism has been found for the other iron(II) sulfonates; however, evidence for such isomerism in methanesulfonates of cobalt(II) and zinc(II) is presented. While $Fe(CF_3SO_3)_2$ and $Fe(p\text{-}CH_3C_6H_4SO_3)_2$ appear to be magnetically dilute the presence of antiferromagnetic coupling in both forms of $Fe(CH_3SO_3)_2$ is indicated. The iron(III) sulfonates, $Fe(CF_3SO_3)_3$, $Fe(p\text{-}CH_3C_6H_4SO_3)_3$, and $Fe(CH_3SO_3)_3$, have been prepared and all three are magnetically concentrated exhibiting magnetic moments which are significantly less than 5.92 BM and which decrease with decreasing temperature.

JOHN S. HAYNES, JOHN R. SAMS et ROBERT C. THOMPSON. Can. J. Chem. **59**, 669 (1981).

En se basant sur les spectres de vibration et électronique et sur des données de Mössbauer et magnétiques, on a conclu que les sulfonates de fer(II) $Fe(CF_3SO_3)_2$ et $Fe(p\text{-}CH_3C_6H_4SO_3)_2$ qu'on a préparé, ont une structure cristalline en couches faisant intervenir du fer(II) hexacoordonné et des anions tridentates agissant comme ponts. Le chromophore FeO_6 de ces composés est déformé selon une élongation trigonale le long de l'axe C_3. On a obtenu le $Fe(CH_3SO_3)_2$ sous deux formes isomères, l'une ayant une élongation trigonale du chromophore FeO_6 et l'autre présentant une compression trigonale. On n'a pas trouvé d'isomère de structure des autres sulfonates de Fe(II); cependant on rapporte des données suggérant l'existence d'une telle isomérie dans les méthanesulfonates de cobalt(II) et de zinc(II). On note la présence d'un couplage anti-ferromagnétique des deux formes de $Fe(CH_3SO_3)_2$ même si le $Fe(CF_3SO_3)_2$ et le $Fe(p\text{-}CH_3C_6H_4SO_3)_2$ semblent être magnétiquement dilués. On a préparé les sulfonates de Fe(III), $Fe(CF_3SO_3)_3$, $Fe(p\text{-}CH_3C_6H_4SO_3)_3$ et $Fe(CH_3SO_3)_3$, et tous les trois magnétiquement concentrés ont des moments magnétiques qui sont beaucoup plus faibles que 5,92 BM et qui diminuent avec la température.

[Traduit par le journal]

Introduction

Sulfonate anions, RSO_3^-, have the potential to bond to metal ions as bidentate or terdentate bridging ligands with the consequent formation of highly polymeric materials. Calcium methanesulfonate, $Ca(CH_3SO_3)_2$, has been shown by X-ray diffraction studies to have a structure in which layers of metal atoms are bridged by CH_3SO_3 groups with each anion bridging three different metal centres and each metal ion surrounded by a nearly octahedral array of oxygens from six different anions (1). Analogous structures have been proposed for a number of metal bisfluorosulfates (2) and for the methanesulfonates, trifluoromethanesulfonates, and paratoluenesulfonates of copper(II) and cobalt(II) (3).

The work described here is an extension of our earlier study of iron(II) fluorosulfate (4) and was undertaken to determine whether the structural features exhibited by $Fe(FSO_3)_2$ are common to iron(II) sulfonates in general. This research involves, primarily, the synthesis of iron(II) salts of methane-, trifluoromethane-, and paratoluenesulfonic acids and the structural characterization of these materials using ^{57}Fe Mössbauer, vibrational and electronic spectroscopy, and variable temperature magnetic susceptibility studies.

During the course of this study we discovered that two structural modifications of iron(II) methanesulfonate can be isolated and a preliminary report on this appears elsewhere (5). In an effort to investigate the possibility of structural isomerism in methanesulfonates of other divalent metals we have also prepared and investigated the bismethanesulfonates of calcium, cobalt, copper, and zinc.

Both forms of $Fe(CH_3SO_3)_2$ gave evidence of magnetic concentration and the possibility that magnetic exchange effects might be even stronger in sulfonates of iron(III) prompted a study reported here of the synthesis and magnetic properties of $Fe(CH_3SO_3)_3$, $Fe(p\text{-}CH_3C_6H_4SO_3)_3$, and $Fe(CF_3SO_3)_3$. Previous work showed the magnetic moment of $Fe(FSO_3)_3$ to be significantly below the value expected for high spin d^5 and to be both temperature and field dependent, suggesting the presence of both ferromagnetic and antiferromagnetic coupling in that compound (6).

Experimental

Starting materials and solvents were reagent grade and used without further purification unless otherwise stated. Products were found to be susceptible to atmospheric moisture and, when isolated, required handling in a nitrogen atmosphere dry box or *in vacuo*. C and H analyses were obtained by P. Borda in the

microanalytical laboratory at the University of British Columbia. Iron was determined by redox titration (7).

Preparations

Iron(II) Trifluoromethanesulfonate, $Fe(CF_3SO_3)_2$

Trifluoromethanesulfonic acid (20 mL) was freshly distilled at a pressure of 20 mm Hg at 70°C onto anhydrous iron(II) chloride (12 mmol). The product is insoluble in acid and to ensure complete reaction the reaction mixture was stirred under reflux conditions for approximately 40 h. The white solid product was vacuum filtered, washed with freshly distilled trifluoromethanesulfonic acid, and dried by heating under vacuum at 50°C.

Anal. calcd. for $FeC_2F_6S_2O_6$: C 6.78, H 0.00, Fe 15.8; found: C 6.75, H 0.00, Fe 15.9.

Iron(II) Paratoluenesulfonate, $Fe(p\text{-}CH_3C_6H_4SO_3)_2$

This salt was prepared by the reaction of aqueous solutions of silver(I) paratoluenesulfonate (17 mmol in 50 mL H_2O) with iron(II) chloride tetrahydrate (8.5 mmol in 10 mL H_2O). In order to avoid oxidation of Fe(II) to Fe(III) it was necessary to degas the water prior to use by several freeze–pump–thaw cycles. After combining the aqueous solutions the resulting mixture was stirred under a flow of nitrogen gas and the precipitated silver chloride was removed by filtration under nitrogen. The resulting solution of iron(II) paratoluenesulfonate was evaporated to dryness under vacuum and complete dehydration was accomplished by heating under vacuum at 120°C. The product is a pale green solid.

Anal. calcd. for $FeC_{14}H_{14}S_2O_6$: C 42.22, H 3.55, Fe 14.0; found: C 42.50, H 3.60, Fe 13.9.

α-Iron(II) Methanesulfonate, α-$Fe(CH_3SO_3)_2$

Silver(I) methanesulfonate (9.2 mmol in 30 mL H_2O) and iron(II) chloride tetrahydrate (4.6 mmol in 10 mL H_2O) were combined as described above for the preparation of the paratoluenesulfonate derivative. The product, a white solid, was isolated as described above and dried by heating under vacuum at 130°C.

Anal. calcd. for $FeC_2H_6S_2O_6$: C 9.76, H 2.46, Fe 22.7; found: C 9.93, H 2.48, Fe 22.5.

β-Iron(II) Methanesulfonate, β-$Fe(CH_3SO_3)_2$

An aqueous solution of iron(II) methanesulfonate, prepared as described above, was evaporated to dryness and complete dehydration of the product was obtained by prolonged (about three days) exposure to refluxing 2,2-dimethoxypropane. The product, a white solid, may also be obtained by treating the α-form with 2,2-dimethoxypropane in the same manner.

Anal. found: C 9.59, H 2.60, Fe 22.5.

Iron(II) Methanesulfonate Methanesulfonic Acid Solvate, $Fe(CH_3SO_3)_2 \cdot CH_3SO_3H$

Methanesulfonic acid (20 mL) was distilled at 165°C under pressure of 8.5 mm Hg onto anhydrous iron(II) chloride (15 mmol). A vigorous reaction occurred with the evolution of hydrogen chloride gas. The reaction mixture was heated to approximately 100°C for 8 h; the solid product was removed by vacuum filtration and then washed with several portions of freshly distilled acid. The white solid product was dried in vacuum for 24 h at 150°C. The infrared spectrum correlates well with a superposition of the spectra of α-iron(II) methanesulfonate and methanesulfonic acid (8). The elemental analysis confirms the presence of one molecule of solvent of crystallization.

Anal. calcd. for $FeC_3H_{10}S_3O_9$: C 10.53, H 2.95; found: C 10.37, H 2.86.

Infrared frequencies (cm^{-1}) are as follows: 1323 m, 1190 m sh, 1150 s, 1120 m, 1066 s, 990 s, 920 s, 787 m, 767 m, 566 s, 556 m, 542 m, 506 s, 484 w.

Iron(III) Trifluoromethanesulfonate, $Fe(CF_3SO_3)_3$

This compound was prepared from trifluoromethanesulfonic acid and iron(III) chloride by the method used to prepare the iron(II) derivative. The product, a white solid, was dried at 150°C.

Anal. calcd. for $FeC_3F_9S_3O_9$: C 7.16, H 0.00, Fe 11.1; found: C 7.04, H 0.00, Fe 11.3.

Iron(III) Methanesulfonate, $Fe(CH_3SO_3)_3$

This salt was prepared by the reaction of stoichiometric quantities of silver(I) methanesulfonate and iron(III) chloride hexahydrate as described for the preparation of α-$Fe(CH_3SO_3)_2$. The product, a light yellow solid, was dried by heating at 110°C for 24 h under vacuum.

Anal. calcd. for $FeC_3H_9S_3O_9$: C 10.56, H 2.66, Fe 16.4; found: C 10.50, H 2.80, Fe 16.1.

Iron(III) Paratoluenesulfonate, $Fe(p\text{-}CH_3C_6H_4SO_3)_3$

This salt was prepared by the reaction of silver(I) paratoluenesulfonate with iron(III) chloride hexahydrate as described for the preparation of the iron(II) derivative. The product, an orange solid, was dehydrated by heating under vacuum at 70°C.

Anal. calcd. for $FeC_{21}H_{21}S_3O_9$: C 44.29, H 3.72, Fe 9.8; found: C 44.16, H 3.85, Fe 9.7.

Bismethanesulfonates of Calcium, Cobalt, Copper, and Zinc, $M(CH_3SO_3)_2$

$Co(CH_3SO_3)_2$ and $Cu(CH_3SO_3)_2$ were prepared as described previously (3). The other compounds were prepared by the reaction of silver(I) methanesulfonate with aqueous solutions of the appropriate metal chloride as described for the preparation of α-$Fe(CH_3SO_3)_2$. All compounds were dried under vacuum at 110°C.

Anal. calcd. for $CoC_2H_6S_2O_6$: C 9.63, H 2.43; found: C 9.51, H 2.39. *Anal.* calcd. for $CuC_2H_6S_2O_6$: C 9.46, H 2.38; found: C 9.30, H. 2.48. *Anal.* calcd. for $CaC_2H_6S_2O_6$: C 10.43, H 2.63; found: C 10.52, H 2.71. *Anal.* calcd. for $ZnC_2H_6S_2O_6$: C 9.40, H 2.37; found: C 9.75, H 2.64.

Physical Methods

Infrared and electronic spectra were obtained as before (3). Magnetic susceptibilities were measured at room temperature and three different values of $H dH/dx$ using the Faraday magnetic balance described in the literature (9). The values were found to be field independent for all samples. Variable temperature magnetic susceptibilities were obtained using Gouy equipment (3). The molar magnetic susceptibilities were corrected for the diamagnetism of all atoms; the corrections used were $Fe^{2+} = 13$, $Fe^{3+} = 10$, $CF_3SO_3^- = 46$, $CH_3SO_3^- = 35$, $p\text{-}CH_3C_6H_4SO_3^- = 89$ (all 10^6 cm^3 mol^{-1}). ^{57}Fe Mössbauer spectra were measured as described elsewhere (10). Samples for Mössbauer studies were contained in nylon holders which were sealed with epoxy resin to avoid hydrolysis problems. The Doppler velocity scale was calibrated with a metallic iron foil absorber, and isomer shifts are quoted relative to the centroid of the iron foil spectrum.

Results

Iron(II) Sulfonates

The iron(II) sulfonates, $Fe(CF_3SO_3)_2$, $Fe(p\text{-}CH_3C_6H_4SO_3)_2$, and α-$Fe(CH_3SO_3)_2$, were obtained as hygroscopic powders, the first by reaction of anhydrous iron(II) chloride with trifluoromethanesulfonic acid and the other two by reaction of the silver(I) salt of the appropriate sulfonic acid with iron(II) chloride in aqueous solution followed by dehydration at elevated temperatures. A second form of the methanesulfonate, β-$Fe(CH_3SO_3)_2$, was obtained by prolonged exposure of the α form to refluxing 2,2-dimethoxypropane (DMP). To investigate the possibility of additional structural

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

isomers of iron(II) methanesulfonate we attempted to obtain a sample under anhydrous conditions by the reaction of iron(II) chloride with anhydrous methanesulfonic acid. The product obtained was a methanesulfonic acid solvate of composition $Fe(CH_3SO_3)_2 \cdot CH_3SO_3H$. Attempts to remove the solvate molecules by heating were unsuccessful.

Infrared spectra (250 to 1400 cm^{-1}) of the iron(II) sulfonates are given in Table 1 where assignments to vibrations associated with the CSO_3 groups have been made as was done previously for analogous copper and cobalt compounds (3). The two modifications of $Fe(CH_3SO_3)_2$ are clearly distinguished by their distinctive infrared spectra. Figure 1 compares the spectrum of a sample which had been treated for only a few hours with refluxing DMP with the spectra of pure α- and β-forms. The spectrum is clearly a superposition of the spectra of the two forms indicating that α converts directly to β with no other structural isomers present in the system. This is confirmed by the Mössbauer studies.

Mössbauer parameters at two temperatures are given in Table 2. Isomer shift values, δ, are rather high compared to values normally observed for high spin iron(II) (δ normally lies in the range 1.1 to 1.3 mm s^{-1}); the small temperature dependence is presumably a consequence of a second-order Doppler shift. All spectra show quadrupole splitting indicative of some distortion of the FeO_6 octahedra. The ΔE_Q values of $Fe(CF_3SO_3)_2$, $Fe(p\text{-}CH_3C_6H_4SO_3)_2$, and $Fe(FSO_3)_2$ (4) are comparable in magnitude and in temperature dependence; in contrast, the quadrupole splitting values of α-$Fe(CH_3SO_3)_2$ are significantly larger than those of the other derivatives while the ΔE_Q values of β-$Fe(CH_3SO_3)_2$ are significantly smaller. Figure 2 shows the Mössbauer spectra of pure α and β forms of $Fe(CH_3SO_3)_2$ along with the spectrum of a sample of the α form which had been refluxed in DMP for only a few hours (partial conversion to the β form). Consistent with the infrared study, these spectra show the presence of only two structural isomers in the $Fe(CH_3SO_3)_2$ system.

The electronic spectra of the iron(II) sulfonates are all similar in appearance to that reported for $Fe(FSO_3)_2$; they consist of a single broad band centred around 8600–9000 cm^{-1} with a shoulder at lower energy (Table 3).

Magnetic moments have been measured over the range 80 to 300 K and the results are listed in Table 4. The μ_{eff} values for $Fe(CF_3SO_3)_2$ and $Fe(p\text{-}CH_3C_6H_4SO_3)_2$ are in the range normally expected for high spin iron(II) and are comparable to the values shown by $Fe(FSO_3)_2$ while those of α- and particularly β-$Fe(CH_3SO_3)_2$ are anomalously low.

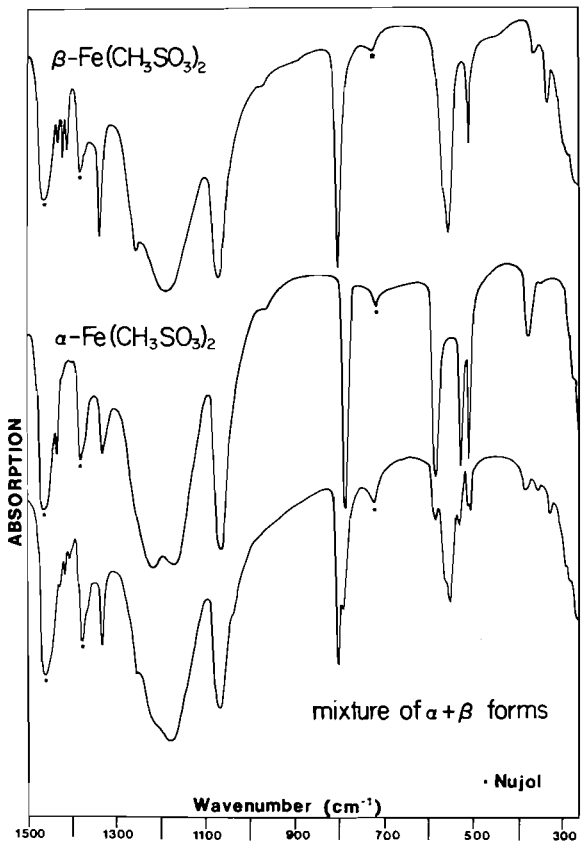

FIG. 1. Infrared spectra of α and β forms of iron(II) methanesulfonate.

The presence of structural isomerism in iron(II) methanesulfonate prompted us to look for evidence for isomerism in other $Fe(XSO_3)_2$ systems. Both $Fe(CF_3SO_3)_2$ and $Fe(p\text{-}CH_3C_6H_4SO_3)_2$ were heated under vacuum and treated with refluxing 2,2-dimethoxypropane for prolonged periods of time. The infrared spectra of different samples so treated remained unchanged, giving no evidence for conversion to isomeric forms. The sample of $Fe(CF_3SO_3)_2$ characterized here was prepared by the reaction of CF_3SO_3H with iron(II) chloride; another sample prepared by the silver salt method (analogous to the method used to obtain α-$Fe(CH_3SO_3)_2$) gave an identical infrared spectrum to that of the first sample indicating the different preparative methods yield the same structural form.

Methanesulfonates of Zn(II), Co(II), Cu(II), and Ca(II)

To pursue the question of isomerism in sulfonate polymers further we prepared methanesulfonates of other divalent metals. $Zn(CH_3SO_3)_2$ prepared by the silver salt method has a very complex infrared spectrum (Table 5 and Fig. 3). Refluxing a sample in

[b]Data from ref. 4.

2,2-dimethoxypropane yields a product the infrared spectrum of which is virtually identical to that of β-$Fe(CH_3SO_3)_2$. It seems likely that this sample, identified as β-$Zn(CH_3SO_3)_2$, is structurally similar to the β isomer of iron(II) methanesulfonate and that the original sample is another isomer or mixture of isomers. Inspection of the data in Table 5 shows that the original sample does not contain detectable quantities of β-$Zn(CH_3SO_3)_2$.

$Co(CH_3SO_3)_2$ prepared in the present work has an infrared spectrum identical to that reported previously (3). The spectrum shows reduced symmetry for the CSO_3 moiety and a pattern of lines almost identical to that observed for α-$Fe(CH_3SO_3)_2$. After refluxing this compound, identified as α-$Co(CH_3SO_3)_2$, for several days in DMP, the infrared spectrum of the α modification is replaced by a more complex spectrum indicative of conversion to another form or mixture of forms (Table 5). Interestingly, heating the DMP refluxed

[a]Data for each of the iron(II) compounds were obtained from two separate variable temperature experiments; those for the iron(III) compounds from one variable temperature experiment for each compound.

sample of $Co(CH_3SO_3)_2$ for a few hours at ~150°C results in complete reconversion to the α form as evidenced by the infrared spectra. Similar treatment of β-$Fe(CH_3SO_3)_2$ or β-$Zn(CH_3SO_3)_2$ does not cause reconversion of these materials to their α forms.

The sample of $Cu(CH_3SO_3)_2$ prepared in this work has an infrared spectrum which is identical to that reported previously (3). No amount of prolonged heating at elevated temperatures (~110°C) or treatment with refluxing 2,2-dimethoxypropane effected noticeable change in the spectrum. In view of these observations it seems unlikely that the complex spectrum observed for this material is a consequence of a mixture of different forms. It seems more likely that a single form exists for this compound in which there are non-equivalent methanesulfonate ions as was postulated previously (3).

Calcium(II) methanesulfonate, prepared by the silver salt method, shows a complex infrared spectrum (Table 5) in which more than one absorption is seen in the SO_3 symmetric stretching region. Since this is a non-degenerate A_1 vibration, splitting is not expected even in low symmetry and can be explained only by the presence of non-equivalent anions in the lattice. This is, in fact, consistent with the X-ray structure determination of Charbonnier *et al.* (1). As for copper(II) methanesulfonate, neither prolonged heating at elevated temperatures (~110°C) nor treatment with refluxing 2,2-dimethoxypropane effected noticeable change in the spectrum.

Iron(III) Sulfonates

The compounds $Fe(CF_3SO_3)_3$, $Fe(p\text{-}CH_3C_6H_4SO_3)_3$, and $Fe(CH_3SO_3)_3$ were obtained as hygroscopic powders by substituting iron(III) chloride as the iron source in preparative reactions analogous to those used to obtain the iron(II) sulfonates. The infrared spectra of the iron(III) derivatives are very similar with respect to bands arising from vibrations of the CSO_3 groups. Spectra with assignments are given in Table 1.

Mössbauer parameters are listed in Table 2. The δ values observed here all tend towards the higher limit of values normally observed for high spin iron(III) (δ normally lies in the range 0.1 to 0.6 mm s^{-1}). As for the iron(II) analogues the small temperature dependence of δ is presumably a consequence of a second order Doppler shift. Quadrupole splittings in the range 0.25–0.40 mm s^{-1} are seen for all iron(III) sulfonates studied. The splitting in these compounds shows only a small temperature dependence presumably because no thermally accessible low lying levels are present.

The magnetic moments of $Fe(CH_3SO_3)_3$, $Fe(CF_3SO_3)_3$, and $Fe(p\text{-}CH_3C_6H_4SO_3)_3$ measured over the temperature range 80 to 300 K are given in Table 4. The moments are lower than predicted for spin-free d^5 systems (though much higher than expected for spin-paired configurations) and are temperature dependent.

Discussion

Iron(II) Sulfonates

That $Fe(CF_3SO_3)_2$, $Fe(p\text{-}CH_3C_6H_4SO_3)_2$, and $\beta\text{-}Fe(CH_3SO_3)_2$ have basically the same structure as proposed for $Fe(FSO_3)_2$ (4), including a trigonally elongated FeO_6 chromophore, is suggested by the similarities in the infrared and electronic spectra and by the magnitude and temperature dependence of the quadrupole splitting. The CSO_3 groups retain C_{3v} approximate symmetry in all three compounds as evidenced by the fact that, within the limitation of resolution of the infrared spectrometer ($\sim 3\ cm^{-1}$) the $\nu_4(E)$ and $\nu_5(E)$ modes are not split (Table 1). This indicates that, as for $Fe(FSO_3)_2$, all three oxygens must be involved in equivalent coordination to iron. The electronic spectra are consistent with six-coordinate iron(II); the observed splitting of the electronic transition is best explained, as discussed previously (4), in terms of a dynamic Jahn–Teller effect.

Turning to interpretation of the Mössbauer data, a splitting of less than $\sim 2\ mm\ s^{-1}$ as shown by $Fe(CF_3SO_3)_2$, $Fe(p\text{-}CH_3C_6H_4SO_3)_2$, and $\beta\text{-}Fe(CH_3SO_3)_2$ indicates that either the ground state is a singlet and the crystal field splitting is small, or the

ground state is a doublet. The former may be obtained by a trigonal or tetragonal compression of the FeO_6 octahedron and the latter by a trigonal or tetragonal elongation. Since the quadrupole coupling constant e^2qQ is positive for tetragonal compression and trigonal elongation stereochemistries and negative for the other two possibilities, determination of the sign of the quadrupole splitting should help establish the form of coordination. Magnetic perturbation Mössbauer studies established that e^2qQ is positive in both $Fe(FSO_3)_2$ (4) and β-$Fe(CH_3SO_3)_2$ (5) and hence that the form of distortion is either trigonal elongation or tetragonal compression. A detailed fitting of the temperature dependence of the quadrupole splitting to a crystal field model for $Fe(FSO_3)_2$ (4) eliminated the possibility of tetragonal symmetry and established the distortion as a trigonal elongation along the C_3 axis of the FeO_6 octahedron and the ground state therefore as

$$[(\sqrt{2/3}|x^2 - y^2\rangle - \sqrt{1/3}|xz\rangle), (\sqrt{2/3}|xy\rangle + \sqrt{1/3}|yz\rangle)]$$

Such a form of distortion then is probable for the other three compounds under discussion and this is supported by more detailed Mössbauer studies including magnetic perturbation Mössbauer work (11). Moreover, a trigonal elongation is consistent with the infrared spectral results which show no observable lowering in the symmetry of the XSO_3 groups below C_{3v}. Anion symmetry would be expected to be lowered in the case of a tetragonally distorted FeO_6 octahedron.

The quadrupole splitting of α-$Fe(CH_3SO_3)_2$ is substantially greater than 2 mm s^{-1} and this is consistent only with an orbital singlet ground state, $|z^2\rangle$ in trigonal symmetry or $|xy\rangle$ in tetragonal symmetry. Magnetic perturbation Mössbauer studies have shown e^2qQ to be negative (5), consistent only with a trigonally compressed FeO_6 octahedron and $|z^2\rangle$ ground state. The infrared spectrum of the compound shows significant splitting of the $\nu_4(E)$ and $\nu_5(E)$ modes (Table 1) indicative of reduction of anion symmetry below C_{3v}. While this would be expected as a consequence of different Fe–O interactions brought about, for example, by a tetragonal distortion of the FeO_6 octahedron, the Mössbauer results show this is not the case here. Other possible causes include a small rhombic component superimposed on the trigonal distortion or a distortion of the $CH_3SO_3^-$ anions of a form in which the CH_3 moiety is displaced from the C_3 axis of the anion brought about, possibly, by intermolecular contacts between anions in adjacent layers of the polymeric lattice.

The high isomer shift values obtained for all the iron(II) compounds (Table 2) indicate a high degree of ionic character in the metal–ligand bonds; using the Walker–Wertheim–Jaccarino model (12) which relates isomer shift values to electron configurations the derived electron configuration for Fe(II) in these compounds is $3d^{6.00}4s^{0.00}$. The differences in isomer shift values are small and, as the isomer shifts are a function of lattice dynamics as well as the *s*-electron density, any attempt at a correlation between the isomer shifts and the base strengths of the anions would be very tenuous.

The magnetic data for $Fe(CF_3SO_3)_2$ and Fe(*p*-$CH_3C_6H_4SO_3)_2$ over the temperature range 80 to 300 K are very similar to those reported earlier for $Fe(FSO_3)_2$ over the same temperature range (4) and support the conclusion that these three compounds have very similar structures. The data could be fitted to the theoretical model described by Figgis *et al.* (13) using the following parameter values (values for $Fe(CF_3SO_3)_2$ given first, values for Fe(*p*-$CH_3C_6H_4SO_3)_2$ given second): orbital reduction factor $k = 0.8$ and 0.75, spin–orbit coupling constant $\lambda = -90$ and $-90\,cm^{-1}$ and axial field splitting paramter $v = 2$ and 3. The accuracy to which these parameters are determined is considered to be no better than ±5% in k and λ and, because of the relative insensitivity of calculated magnetic moments to small distortions, ±2 in the case of v(3). There are no significant differences (except perhaps in the value of k) between the two sets of parameters nor between these parameters and those calculated previously for $Fe(FSO_3)_2$ (4). The magnetic data support the conclusion drawn from the Mössbauer studies that the three compounds under discussion have very similar structures. The orbital reduction factor k decreases as XSO_3 varies from FSO_3 to CF_3SO_3 to *p*-$CH_3C_6H_4SO_3$ and while this may reflect an increase in electron delocalization in this series such an interpretation should be made with caution since a similar variation in λ (the value might also be expected to reflect the degree of electron delocalization) does not occur. Figgis *et al.* have in fact warned that the k values do not provide a good measure of electron delocalization (13).

Attempts to fit the magnetic moment data of α- and β-$Fe(CH_3SO_3)_2$ were less successful. To obtain magnetic moments as low as those observed for α-$Fe(CH_3SO_3)_2$ requires a k value of ~0.7 in the model and an even lower k value of ~0.5 is required for the β-isomer. Even assuming anomalously low k values, agreement between experiment and theory over the entire range of temperatures cannot be obtained with a single set of parameter values. We are forced to conclude that the methanesul-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

fonate compounds are not magnetically dilute but that, particularly in the β-isomer, exchange of an antiferromagnetic nature is taking place between iron centres. In fact, Mössbauer studies have shown β-$Fe(CH_3SO_3)_2$ to undergo an antiferromagnetic phase transition at ~23 K (5). This finding is somewhat surprising not only because of the number of bridging atoms through which such an exchange would have to be transmitted but also because of the highly ionic nature of the iron–sulfonate linkages as indicated by the Mössbauer isomer shift results. It is also not clear why the two methanesulfonate compounds should show magnetic concentration while the paratoluenesulfonate, trifluoromethanesulfonate, and fluorosulfate derivatives appear to be magnetically dilute.

Our studies have generated the following structural model for iron(II) sulfonate polymers. Planes of iron atoms are sandwiched by planes of sulfonate anions; the anions are acting as terdentate ligands, each bridging to three different metal ions; each metal ion is surrounded by oxygen atoms from six different anions. The FeO_6 chromophore is not a regular octahedron and the distortion which is present may be considered as follows. Starting with a regular FeO_6 octahedron this may be distorted by increasing the O—S—O bond angles (compress XSO_3 along its C_3 axis), resulting in a trigonal elongation of FeO_6 along a C_3 axis perpendicular to the plane of iron atoms. This is the form of distortion found in $Fe(CF_3SO_3)_2$, $Fe(p\text{-}CH_3C_6H_4SO_3)_2$, β-$Fe(CH_3SO_3)_2$, and $Fe(FSO_3)_2$. The α form of $Fe(CH_3SO_3)_2$, on the other hand, has a structure in which, relative to the β form, the $CH_3SO_3^-$ anions are elongated along their C_3 axes thus resulting in a trigonal compression of the FeO_6 chromophore.

It is interesting to compare the iron(II) sulfonates with the previously studied cobalt(II) analogues (3). Similarities in their infrared spectra suggest structural similarities in the $M(XSO_3)_2$ (where M = Fe, Co; X = F, CF_3, p-$CH_3C_6H_4$) compounds. They all have C_{3v} anion spectra and any distortion of the MO_6 chromophores from O_h symmetry is likely to be trigonal (proven to be trigonal elongation in the case of the iron compounds). The cobalt(II) methanesulfonate compound identified in the previous section as α-$Co(CH_3SO_3)_2$ has a distorted anion spectrum which is virtually identical to that of α-$Fe(CH_3SO_3)_2$. While it had been suggested earlier (3) that the distortion of the anion might be due to a tetragonal distortion of the CoO_6 octahedron, it is clear from the present work that this is not necessarily the case. It seems more likely that the compound has an octahedral MO_6 chromophore or, as for the iron compound, a trigonally compressed octahedron. Possible causes of reduction in anion symmetry below C_{3v} were discussed previously for α-$Fe(CH_3SO_3)_2$. Another important point of similarity in the iron(II) and cobalt(II) methanesulfonates is that both compounds can be obtained in more than one structural form.

Copper(II) sulfonates have also been studied before; however, direct comparison with the iron(II) analogues is less informative here since the copper salts are all very strongly distorted as expected for a d^9 configuration. One important conclusion based on the present study is that while it had always been assumed previously (3, 6) that $Cu(XSO_3)_2$ compounds contain tetragonally distorted CuO_6 octahedra, it now seems possible that the form of distortion is a trigonal elongation or compression.

Structural Isomerism

Iron(II) methanesulfonate is shown by this work to exist in two distinct structural forms, α-$Fe(CH_3SO_3)_2$ and β-$Fe(CH_3SO_3)_2$. Isomerism in methanesulfonates of this type is not restricted to iron(II). This is demonstrated by the studies on $Co(CH_3SO_3)_2$ which indicate the existence of an α form as well as at least one other isomer and by the studies on $Zn(CH_3SO_3)_2$ which suggest the presence of a β modification and at least one other isomer. Not all metal bismethanesulfonates readily show this structural isomerism, however. $Ca(CH_3SO_3)_2$ and $Cu(CH_3SO_3)_2$, which appear from their infrared spectra to be structurally related (evidence for non-equivalent anions in the lattices of both salts), have been obtained as single forms only.

Considering the proven existence of structural isomers of methanesulfonates, one might expect to find evidence for structural isomerism in other sulfonate derivatives. Thus far, no such evidence has been obtained. As described in the previous section some effort to obtain structural isomers of $Fe(CF_3SO_3)_2$ and $Fe(p\text{-}CH_3C_6H_4SO_3)_2$ has been made but without success. The lack of an α form (trigonally compressed FeO_6 octahedra) of $Fe(CF_3SO_3)_2$ may be a consequence of electronegativity effects. As the electronegativity of X increases, the extent of S—O double bonding in XSO_3^- anions should increase and this should favour larger O—S—O bond angles and therefore trigonally elongated FeO_6 chromophores (β form). For this reason it may prove difficult to obtain any divalent metal fluorosulfate or trifluoromethanesulfonate with the α-$Fe(CH_3SO_3)_2$ structure. On the other hand, one might expect to be able to obtain α isomers of divalent metal paratoluenesulfonates. The fact that we have obtained no evi-

dence for α-Fe(p-$CH_3C_6H_4SO_3)_2$ may simply reflect the lack of a suitable synthetic route to this material.

Iron(III) Sulfonates

The infrared spectra of $Fe(CF_3SO_3)_3$, Fe(p-$CH_3C_6H_4SO_3)_3$, and $Fe(CH_3SO_3)_3$ show significant splitting of the formally doubly degenerate ν_4 and ν_5 modes, consistent with reduction of CSO_3 symmetry below C_{3v} (Table 1). This in turn is consistent with six-coordinate iron(III) since the stoichiometry requires that for FeO_6 chromophores each sulfonate must utilize only two of its oxygen atoms for bonding.

The isomer shifts (Table 2) are consistent with high spin electron configurations for all three compounds with the rather high values indicating, as for the iron(II) derivatives, a rather high degree of ionic character in the iron–oxygen bonds. Again, no correlation between isomer shift and anion basicity seems possible. No quadrupole splitting is expected for octahedral high-spin iron(III) compounds yet small but significant splittings are seen for all three compounds. Any valence contribution to the electric field gradient (i.e. unequal electron distribution in either bonding or non-bonding orbitals) seems difficult to imagine here and a lattice contribution from a non-cubic distribution of charges about the Fe^{3+} ion seems much more likely to account for the observed splitting.

Spin-free iron(III) complexes should have temperature independent magnetic moments of 5.92 BM. All three compounds studied here have moments which are lower than 5.92 BM over the entire range of temperatures (80 to 300 K) and which decrease with decreasing temperature (Table 4). The presence of antiferromagnetic interaction in these compounds seems certain; moreover, the deviation from the expected value of 5.92 BM increases in the series $Fe(CF_3SO_3)_3$ < $Fe(CH_3SO_3)_3$ < Fe(p-$CH_3C_6H_4SO_3)_3$ reflecting perhaps increasing degree of covalent character in the metal–anion bonds along the series.

To summarize the results of the magnetic susceptibility studies, two of the iron(II) sulfonates, the α and β forms of $Fe(CH_3SO_3)_2$, gave evidence for weak magnetic exchange interaction while evidence for significant antiferromagnetic coupling was found for all three iron(III) sulfonates studied. The work has shown that magnetic exchange in iron sulfonate polymers is possible particularly when the metal is in the +3 oxidation state in spite of the fact that iron–sulfonate bonds are highly ionic and the exchange must take place over three atoms in the bridging ligand.

Symmetric and unsymmetric substituted 1,5-diarylthiocarbazones, and their mono- and bismercury complexes, were synthesized for spectral analysis. The first singlet–singlet transition of the mercury complexes was determined and the spectral shift produced by trifluoromethyl substitution was compared with that caused by different substituents in similar complexes. The large magnitude of the hypsochromic shift produced by the trifluoromethyl substituent can be explained by concerted steric and inductive effects, while the smaller bathochromic shift induced by the methoxy substituent is a result of opposing steric and electronic effects. In the trifluoromethyl substitution, a hypsochromic shift caused by steric influences was found to be 500 cm^{-1} in the photochromic unactivated state, and 250 cm^{-1} in the photochromic activated state. A similar shift caused by inductive influences was found to be 750 cm^{-1} in the photochromic unactivated state, and 600 cm^{-1} in the photochromic activated state. The smaller spectral shift observed in the photochromic activated state is consistent with the elucidated structure of the unsymmetric 1,5-diarylthiocarbazone, **6***d*, which was shown that the trifluoromethyl substitution was on the phenylazo portion of the molecule by chemical and spectral studies.

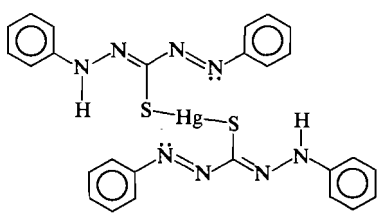
En vue d'en faire une analyse spectrale, on a synthétisé des diaryl-1,5 thiocarbazones substituées de façon symétrique et non symétrique ainsi que leurs mono et bis complexes de mercure. On a déterminé la première transition singulet–singulet des complexes de mercure et on a comparé les déplacements produits dans les spectres par le substituant trifluorométhyle avec ceux provoqués par d'autres substituants dans des complexes semblables. On peut expliquer l'ampleur du déplacement hypsochrome provoqué par le substituant trifluorométhyle en se basant sur des effets inductifs et stériques concertés alors que la valeur plus faible du déplacement bathochrome induite par le substituant méthoxy serait le résultat d'effets électronique et stérique opposés. Dans le cas du substituant trifluorométhyle, on a trouvé que le déplacement hypsochrome provoqué par des influences stériques est de 500 cm^{-1} dans l'état photochrome inactivé et de 250 cm^{-1} dans l'état photochrome activé. On a trouvé qu'un déplacement semblable provoqué par des influences inductives est de l'ordre de 750 cm^{-1} dans l'état photochrome inactivé et de 600 cm^{-1} dans l'état photochrome activé. Les déplacements plus faibles observés dans l'état photochrome activé sont en accord avec la structure trouvée pour la diaryl-1,5 thiocarbazone non symétrique (**6***d*) pour laquelle des études chimiques et spectrales on montré que le substituant trifluorométhyle se trouve sur la portion phénylazo de la molécule.

[Traduit par le journal]

Introduction

The photochromic properties of mercury bis-(1,5-diphenylthiocarbazonate) (**1**) were discovered independently by Irving *et al.* (1) and Webb *et al.* (2). Benzene or chloroform solutions of **1** are orange, and show absorption maxima at 485 nm ($\varepsilon \sim 7 \times 10^4$), 320 nm (sh, $\varepsilon \sim 1.5 \times 10^4$), and 270 nm ($\varepsilon \sim 4 \times 10^4$). When irradiated by sunlight, solutions develop an intense blue color which changes back to orange when solutions are placed in the dark. The color change upon irradiation is due to a new absorption centered at 606 nm ($\varepsilon \sim 4 \times 10^4$), and to decreased absorption at 485 nm. The photochromic change is minimized in hydroxylic solvents, organic acids, and bases, and is most dramatic in dry, nonpolar solvents (3).



1

The absorption of **1** in the visible region of the spectrum can be attributed to the ligand since a solution of 1,5-diphenylthiocarbazonate ion (**2***b*) exhibits a single strong absorption maximum at 470 nm ($\varepsilon \sim 2 \times 10^4$). 1,5-Diphenylthiocarbazone (**2***a*), however, shows well defined bands at 450 and 620 nm.

The effect of substitution in the benzenoid rings of the ligands on the spectral properties of mercury

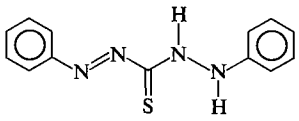
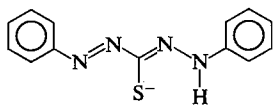
[e]Sample too insoluble.

bis(1,5-diarylthiocarbazonates) has been documented by Coleman *et al.* (5) (Table 1). They reported that *meta* substituents produced only small effects on the position of the absorption maxima and molar absorptivities, while large spectral changes were produced by *ortho* substituents. They attributed the decrease in the molar absorptivity caused by most *ortho* substituents, and the spectral blue shifts induced by 2-ethyl and 2-trifluoromethyl groups to steric influences.



2a



2b

Closer examination of the spectral blue shifts produced by *ortho* substituents reveals that only relatively bulky substituents at this position cause a spectral shift. Steric influences cannot, however, explain the large spectral blue shift produced by 2-trifluoromethyl substituents in comparison with 2-ethyl substituents. This is demonstrated spectrally in mercury bis[1,5-di(2′-methylphenyl)thiocarbazonate], which shows an absorption maximum at 475 nm (as does the 2-ethyl substituted material), since the size of a methyl group is about the same as a trifluoromethyl group.

In order to explain the large spectral shift produced by 2-trifluoromethyl substitution, an investigation of the spectral behavior of symmetric and unsymmetric mercury 1,5-diarylthiocarbazonates with trifluoromethyl substitution has been undertaken.

Synthesis of Diarylthiocarbazones

Methods for synthesis of symmetric 1,5-diarylthiocarbazones have been described by Fischer (6) and Bamberger (7). In the Bamberger method, Scheme 1, 2 mol of aryldiazonium salt are coupled with 1 mol of nitromethane at pH ~ 5 to form nitro(bisarylazo)methane (**4**). Reduction of **4** with ethanolic ammonium sulfate affords 1,5-diarylthiocarbazide (**5**), which is oxidized in alkaline solution to form 1,5-diarylthiocarbazone (**6**).

The coupling of aryldiazonium salts with nitromethane is strongly pH dependent (7). At low pH (~1), 1 mol of aryldiazonium salt couples with 1 mol of nitromethane to form 1-(nitromethylene)-2-arylhydrazine (**3**), while at higher pH (~5), 2 mol of aryldiazonium salt react with 1 mol of nitromethane to form **4**. Pupko and Pelkis (8, 9) have utilized the pH dependence of coupling to synthesize a number of unsymmetric 1,5-diarylthiocarbazones.

Employing the method of Bamberger, with modifications to improve yields, symmetric and unsymmetric trifluoromethyl substituted 1,5-diphenylthiocarbazones were synthesized. We observed that, at low pH (~1), 2-trifluoromethylphenyldiazonium salts predominantly reacted with nitromethane to give 1-(nitromethylene)-2-(2′-trifluoromethylphenyl)hydrazine (**3**, $R_1 = CF_3$), in 90–95% yield. In contrast, the coupling reaction of unsubstituted phenyldiazonium salts (**3**, $R_1 = H$) was not efficient, yields were less than 30%, and obtaining the pure product required numerous recrystallizations.

Structure Determination of 1-(2′-Trifluoromethylphenyl)-5-phenylthiocarbazone

Two isomeric products, **6***d* and **6***e*, could have been obtained in the synthesis of 1-(2′-trifluoromethylphenyl)-5-phenylthiocarbazone from oxidation of **5***d*. The absorption properties of these two isomers, and their mercury complexes, would be different. Therefore, it was important to establish whether the isolated product was a mixture of **6***d* and **6***e*, or one favored product. This was of particular importance since it had previously been demonstrated by X-ray analysis (10) that the azo and hydrazo functions in the symmetric 1,5-

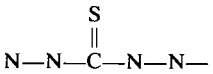
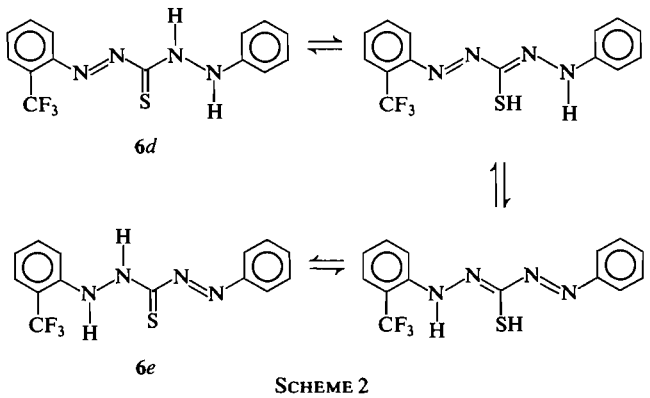
SCHEME 1

diphenylthiocarbazone showed no localized single or double bonds in the



chain and tautomerism would interconvert **6***d* and **6***e* as shown in Scheme 2. Structural analysis identified the product as **6***d*, with the 2-trifluoromethyl substituted aryl ring bound to the azo portion of the thiocarbazone group.



SCHEME 2

The structure determination, Scheme 3, was achieved by employing the reported (11) reaction of thiocarbazones with phosgene to give 1,3,4-thiodiazol-5-ones. Phosgene reacts with the hydrazo portion of thiocarbazone to afford a relatively stable 1,3,4-thiodiazol-5-one (**7***d–f*). Subsequent reduction (12) by zinc of the thiodiazolone produces an aryl amine (**9***d–f*) and a thiosemicarbazide (**10***d–f*). If the isolated thiocarbazone product were a mixture of **6***d* and **6***e*, then this sequence of reactions would yield amines **9***d* and **9***e*, and thiosemicarbazides **10***d* and **10***e* as products of reduction. Isolation of a single amine and thiosemicarbazide pair (**9***d* and **10***d* or **9***e* and **10***e*) would indicate that a single thiocarbazone product had been isolated. Further, if a single amine and thiosemicarbazide pair were produced, the position of the substituted aryl ring relative to the azo or hydrazo function of the thiocarbazone product would be established by the presence of the trifluoromethyl substituent on either the aryl amine (azo portion) or thiosemicarbazide (hydrazo portion).

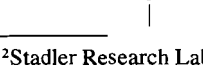
1,5-diphenylthiocarbazone (**6***f*), aniline (**9***f*) was obtained from reduction of 2-phenylazo-4-phenyl-1,3,4-thiodiazol-5-one (**7***f*), as identified by gas chromatographic and infrared spectral analyses (11). Reaction of the isolated thiocarbazone product (**6***d* and/or **6***e*) with phosgene afforded a single orange crystalline product with elemental analysis ($C_{15}H_9F_3N_4OS$) and spectral properties suggesting a thiodiazolone structure. Reduction of the thiodiazolone with zinc and NaOH afforded two major products, a solid and a liquid. Infrared and gas chromatographic analyses of the liquid, when compared with a known standard, demonstrated the presence of 2-trifluoromethylaniline (**9***d*) exclusively; no aniline was observed at the limit of detection sensitivity. The solid product melted at 198–200°C, and its infrared spectrum was identical to 1-phenyl-3-thiosemicarbazide (**10***d*).[2] The isolated thiocarbazone product was therefore a single tautomer, **6***d*, with the 2-trifluoromethyl substituted aryl ring bound to the azo portion of the thiocarbazone group.

Spectral Properties of Mercury Complexes of 1,5-Diarylthiocarbazones

A toluene solution of mercury bis(1,5-diphenylthiocarbazonate) (**1**) shows an intense absorption with a maximum at 485 nm. Upon irradiation the intensity of this band decreases, while a new absorption band appears at 606 nm, Fig. 1. Substitution of the benzenoid rings with 2-trifluoromethyl groups causes a blue shift in these maxima to 445 nm and 560 nm, Fig. 2. No spectral shift is observed when trifluoromethyl substituents are on either the *meta* or *para* positions. These results and the spectral properties of mercury complexes of 1,5-diphenylthiocarbazones with other substituents in the benzenoid rings obtained by Coleman *et al.* (5) are given in Table 1. It is observed that monosubstitution at the *meta* or *para* position does not change the position of the absorption greatly though a large spectral shift is induced by a relatively bulky *ortho* substituent or a trifluoromethyl group.

The spectral shifts produced by *ortho* substituents can be explained by steric and inductive effects. X-ray crystallography (13) shows that the atoms of both ligands in mercury bis(1,5-diphenylthiocarbazonate) exist primarily in a planar configuration. This configuration maximizes the interaction of π-electrons of the benzenoid rings and the



[2]Stadler Research Laboratories, Inc., mp 198–200°C.

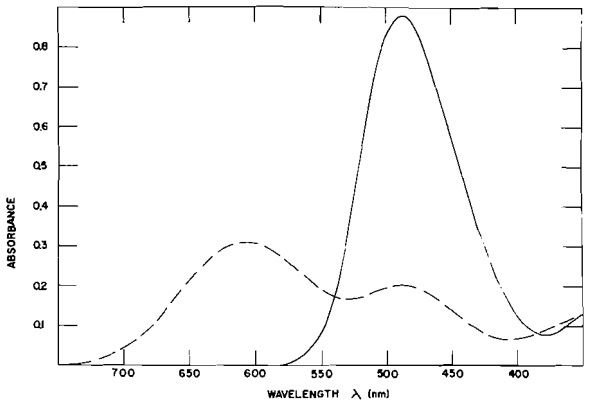


FIG. 1. The absorption spectrum of mercury bis(1,5-diphenylthiocarbazonate) (**1**) in toluene. The solid curve shows the spectrum before and the dashed curve after irradiation.

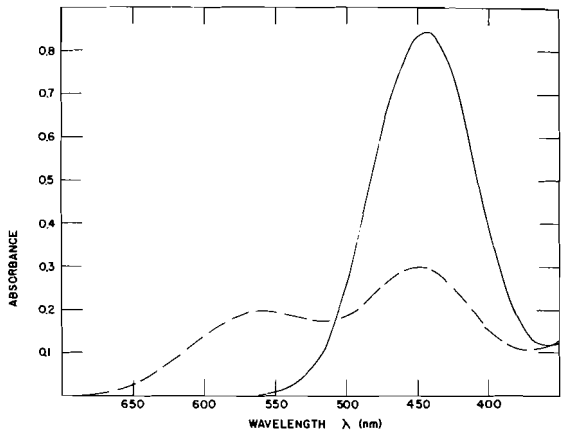

FIG. 2. The absorption spectrum of mercury bis[1,5-di(2-trifluoromethylphenyl)thiocarbazonate] (**14**) in toluene. The solid curve shows the spectrum before and the dashed curve after irradiation.

chain. It seems likely that 2-methyl or 2-ethyl substituents will force the benzenoid rings out of the

plane and increase the energy required for photochromic activation, causing the observed blue shift. This explanation is consistent with the observation that fluorine or chlorine in the *ortho* position does not cause spectral shifts (while 2-methyl substitution does) since these substituents are smaller than methyl. However, the large spectral shift caused by methoxyl and trifluoromethyl substituents cannot be accounted for by steric effects alone, as asserted by Coleman *et al.* (5).

Mercury complexes with a single 1,5-diphenylthiocarbazone ligand, e.g., phenylmercuric 1,5-diphenylthiocarbazonate (**11**), show absorption maxima at 470–475 nm, which is blue shifted by

10–15 nm relative to bis-complexes, (e.g., **1**), Table 2. This small hypsochromic shift may result from purely steric effects. Since the Hg—S—C bond angle is likely to be the same as in the bis-complex, the azo-benzenoid ring is twisted out of the chromophoric plane due to the presence of the phenyl group.

In order to assess the individual contributions of the steric and inductive effects, 1,5-diphenylthiocarbazones with a trifluoromethyl substituent in only one of the benzenoid rings, and the mono- and bismercury complexes of these ligands, were studied, Table 2. From these data, one can infer the magnitude of the blue shift produced by steric effects to be about 500 cm^{-1} in the unactivated state, and about 250 cm^{-1} in the activated state, assuming that the blue shift observed in phenylmercuric 1,5-diphenylthiocarbazonate (**11**) is only due to steric effects. The magnitude of the blue shift induced by the inductive effect of the trifluoromethyl group is about 750 cm^{-1} in the unactivated state, and about 600 cm^{-1} in the activated state, if we assume the blue shift observed in mercury bis[1-(2′-trifluoromethylphenyl)-5-phenylthiocarbazonate], **12**, is solely due to inductive effects. The observed blue shift produced by the electron-withdrawing trifluoromethyl group is adequately explained in this manner.

The bathochromic shift, 1000 cm^{-1}, observed in mercury bis[1,5-di-(2′-methoxyphenyl)thiocarbazonate], Table 1, is most likely the result of opposing steric and electronic effects. Assuming steric hindrance is responsible for a blue shift of about 500 cm^{-1}, as above, the actual electronic effect of the two methoxyl groups in this complex can be estimated to be 1500 cm^{-1}. Along these lines, the observed spectrum of mercury bis[1,5-di-(2′-methylphenyl)thiocarbazonate] is consistent with the very weak electron donating power of methyl groups.

It is interesting to note that inductive and steric effects in the activated form, e.g., phenylmercuric 1-(2′-trifluoromethylphenyl)-5-phenylthiocarbazonate (**13**), are smaller than those in the unactivated form. This is consistent with the proposed photochromic mechanism which involves a *cis–trans* isomerization of the azomethine group and a rate determining proton shift (4). Since the main chromophore responsible for absorption is on the phenylazo portion of the molecule which, upon activation, is changed to hydrazo bonding whose contribution to the observed absorption is much smaller. The benzenoid ring with the trifluoromethyl substituent is no longer conjugated with the absorbing chromophore upon activation, and the inductive and steric effects of the trifluoromethyl group are reduced.

Experimental Section

General

The absorption spectra of the mercury complexes were recorded on a Cary 14 spectrophotometer. The infrared source, a General Electric CPR tungsten lamp having a color temperature of 3075 K, of the spectrophotometer was used to irradiate the photochromic solutions and the absorption spectrum of the equilibrium mixture between the activated and unactivated forms was measured. Infrared spectra were recorded on Perkin-Elmer 567 and 180 spectrophotometers. Analytical gas-phase chromatography was performed using a Varian Aerograph Model 920 chromatograph, with a 6 ft by 1/4 in. SS 10% Carbowax 1540, 40% Chromosorb P/W PAW 80–100 mesh column. Melting points were determined on either a Thomas-Hoover capillary or Fischer-Johns melting point apparatus. Elemental analyses were determined by Galbraith Laboratories, Inc., Knoxville, TN.

Trifluoromethylanilines were purchased from Aldrich Chemical Co., Milwaukee, WI. All other chemicals were reagent grade and used without further purification.

Synthesis

(1) Preparation of 1,5-Di(2′-trifluoromethylphenyl)thiocarbazone (6a) and 1-(2′-Trifluoromethylphenyl)-5-phenylthiocarbazone (6d)

(A) Nitrobis(2-trifluoromethylphenylazo)methane (4a)

2-Trifluoromethylaniline (50 g) in concentrated HCl (250 mL) was diazotized with a solution of $NaNO_2$ (23 g) in H_2O (50 mL). NaOAc (100 g) in H_2O (330 mL), and an alkaline solution of nitromethane, prepared by slowly adding nitromethane (10 g) to a stirred cold solution of NaOH (50 g) in H_2O (300 mL) and EtOH (150 mL), were added to the filtered diazotized solution, maintaining $T < 10°C$. The pH of the mixture was about 5.

A maroon precipitate was filtered and purified by two recrys-

(C) Conversion to Thiocarbazone

Nitrobis(2′-trifluoromethylphenylazo)methane (**4***a*) (20 g) was suspended in EtOH (400 mL), treated with $(NH_4)_2S$ solution (60 mL), and stirred until the solid dissolved. The mixture was poured into 2 L of ice water, the light yellow thiocarbazide, **5***a*, was filtered and dissolved in 2% aqueous NaOH (600 mL) with heating. After cooling the solution in an ice-water bath, it was titrated with 1 *N* HCl to pH 5. A green precipitate (**6***a*) was filtered and purified by repeated dissolution and titration. *Meta* and *para* derivatives (**6***b*, **6***c*) were similarly prepared. The prominent infrared bands and melting points are tabulated in Table 5.

Compound **4***d* was converted to unsymmetric thiocarbazone in the same fashion to compound **6***d*: mp 112–114°C; ir(KBr): 3200, 1602, 1586, 1524, 1496, 1464, 1442, 1320, 1276, 1220, 1198, 1166, 1104, 1054, 1032, 752 cm^{-1}.

(2) Preparation of Mercury Complex of Thiocarbazones

The mercury complexes were prepared by reacting thiocarbazone with equal molar amounts of either phenylmercuric chloride or mercuric chloride to form mono- or bis-complex, respectively, in a CH_2Cl_2/H_2O (1:1) mixture. The organic layer was separated and the complex was precipitated out by the addition of MeOH.

The elemental analyses and melting points for the bis-complexes are tabulated in Table 6 with the infrared spectral bands in Table 7. For compound **13**: mp 177–178°C ir(KBr): 3302, 3056, 1606, 1588, 1530, 1460, 1374, 1320, 1282, 1260, 1162, 1150, 1128, 1110, 1050, 1028, 750 cm^{-1}.

Anal. calcd. for $C_{20}H_{15}F_3N_4SHg$: C 39.96, H 2.52, F 9.48, N 9.32, S 5.33, Hg 33.37; found: C 39.86, H 2.63, F 9.28, N 9.19, S 5.61, Hg 33.50.

*(3) 2-Phenylazo-4-phenyl-1,3,4-thiodiazol-5-one (7*f*)*

1,5-Diphenylthiocarbazone (**6***f*) (10 g, 0.039 mol), dissolved in a minimum of benzene, was added to a stirred solution of phosgene (5 g, 0.05 mol) in toluene (25 mL) at 0°C. The reaction mixture was stirred for 1 h, washed with H_2O until no further evolution of HCl gas, and followed with $NaHCO_3$, but kept acidic. After drying with $MgSO_4$ and evaporating the solvent,

DZ(2)	3332, 3064, 1608, 1590, 1532, 1500, 1462, 1380, 1322, 1284, 1264, 1160, 1126, 1054, 1030, 758

10.3 g (92%) of **7***f* was obtained (mp 138–141°C). Trituration with MeOH, and recrystallization from toluene/MeOH, afforded golden needles: mp 142–143°C (lit. mp 140°C) (6); ir($CHCl_3$): 1700, 1679, 1590, 1529, 1489, 1458, 1329, 1257, 1191, 1160, 1149 cm^{-1}.

Compound **7***d* was similarly prepared: mp 128–129°C; ir($CHCl_3$): 1703, 1682, 1598, 1542, 1487, 1457, 1414, 1316, 1270, 1151, 1112, 1092, 1050 cm^{-1}.

Anal. calcd. for $C_{15}H_9F_3N_4OS$: C 51.42, H 2.59, N 16.00, F 16.27, S 9.15, O 4.57; found: C 51.26, H 2.57, N 15.90, F 16.34, S 9.36.

(4) Zinc Reduction of 4-Phenyl-1,3,4-thiodiazol-5-one

2-Phenylazo-4-phenyl-1,3,4-thiodiazol-5-one, **7***f*, (1 g, 0.0034 mol) was dissolved in MeOH/20% NaOH (100 mL v/v). Zinc (0.5 g, 0.0076 mol) was added to the deep red solution and the mixture heated under reflux until no color change on exposure to air (10 min). The reaction mixture was extracted with CH_2Cl_2 and 0.05 μL of the organic extract was injected into the gas chromatograph. Two peaks were observed whose retention times matched that for solvent and aniline **9***f*. The organic layer was evaporated and the residue triturated with ether. The triturate was evaporated, affording a brown oil and an ir spectrum identical to that of commercial aniline.

Similarly, 2-(2′-trifluoromethylphenyl)azo-4-phenyl-1,3,4-thiodiazol-5-one, **7***d*, was dissolved in MeOH/20% NaOH and reduced. Gas chromatograms of the reaction mixture, the mixture with added 2-trifluoromethylaniline (**9***d*), and the mixture with added aniline (**9***f*), are shown respectively in Fig. 3 *a*, *b*, *c*. When the reaction mixture was analyzed, the instrument was set at its highest sensitivity and no aniline was detected. Only 2-trifluoromethylaniline (**9***d*) was observed, identified by a retention time identical to that of supplemented commercial 2-trifluoromethylaniline.

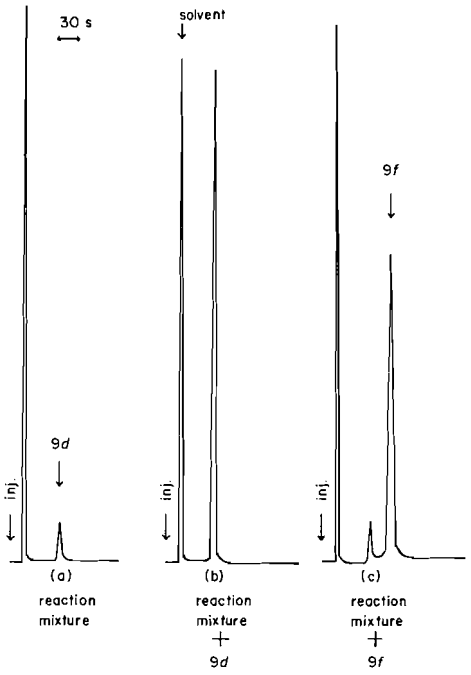

FIG. 3. Gas chromatograms of the organic layer of the zinc reduction of **7***d*. (*a*) Reaction mixture neat, (*b*) reaction mixture with added 2-trifluoromethylaniline (**9***d*), and (*c*) reaction mixture with added aniline (**9***f*).

The organic layer was evaporated and the residue washed with CS_2. The resultant residue was crystallized from benzene/EtOH and afforded white crystalline flakes, mp 198–200°C. The infrared spectrum and the mp were identical to a reported[2] infrared spectrum and mp for 1-phenyl-3-thiosemicarbazide (**10***d*).

Intramolecular hydride shift in some noncyclic isopropyl ketols

E. W. WARNHOFF, MARGARET Y. H. WONG, and P. SUNDARA RAMAN
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received August 19, 1980

E. W. WARNHOFF, MARGARET Y. H. WONG, and P. SUNDARA RAMAN. Can. J. Chem. **59**, 688 (1981).

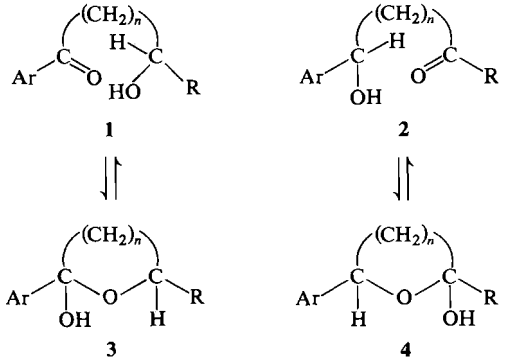
The acyclic ketols **7** ⇌ **11** and **8** ⇌ **12** have been synthesized by a Reformatsky sequence. Each ketol undergoes intramolecular hydride transfer when refluxed in KOH–H_2O–*t*-BuOH solution. When the procedure was applied to the synthesis of **34**, hydride transfer occurred during the Reformatsky reaction to yield **33** instead. With longer reaction times, **33** underwent self-acylation and β-dicarbonyl cleavage to **37**. Treatment of **33** with aqueous base gave a mixture of ketols **35** and **36** from hydride transfer and β-keto decarboethoxylation. The attempted conversion of the isobutyrate group of the Reformatsky intermediates **21** and **24** to *tert*-butyl was not practicable.

E. W. WARNHOFF, MARGARET Y. H. WONG et P. SUNDARA RAMAN. Can. J. Chem. **59**, 688 (1981).

On a synthétisé les cétols acycliques **7** ⇌ **11** et **8** ⇌ **12** en utilisant une réaction de Reformatsky. Au reflux dans une solution de KOH–H_2O–*t*-BuOH, chaque cétol subit un transfert d'hydrure intramoléculaire. Si on utilise la même méthode pour synthétiser le composé **34**, le transfert d'hydrure se produit pendant la réaction de Reformatsky et conduit de préférence au composé **33**. Si on le soumet à des temps de réaction plus longs le composé **33** subit une autoacylation ainsi qu'un clivage du β-dicarbonyle pour conduire au composé **37**. Le composé **33** réagit avec une base aqueuse et conduit à un mélange de cétols **35** et **36** provenant d'un transfert d'hydrure et d'une β-céto décarboéthoxylation. On n'a pas pu convertir le groupe isobutyrate des intermédiaires **21** et **24** du réactif de Reformatsky en un *tert*-butyle.

[Traduit par le journal]

The increasingly observed phenomenon of base-catalyzed intramolecular hydride shift in ketols (intramolecular Meerwein–Ponndorf–Verley–Oppenauer reactions) has so far only been reported across rings, simple or fused, in which the stereochemical requirements for the transfer are favored by molecular rigidity (e.g. 1–7). To survey the generality of this reaction, we have made and tested some noncyclic ketols, **1** and **2**, whose freedom of rotation and preferred conformations would retard intramolecular hydride transfer.[1]

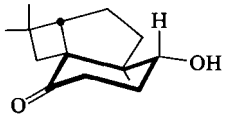


1 ⇌ **3**

2 ⇌ **4**

a R = isopropyl
b R = *tert*-butyl

The first goal was a 1,4-ketol (n = 2), which would have the least rotational freedom in this series, and which could be compared with the previously studied 4-hydroxycyclohexanone **5** (1, 4). The choice of end groups for the ketol chain was governed by two considerations. First, it was desirable to make the equilibrium for any hydride transfer lie to one side for ease of studying rates of hydride transfer. Second, it was feared that carbonyl condensation might be a serious side reaction



5

during base treatment of the ketols. By making one end group aryl and the other alkyl, it was hoped that the aroyl ketol **1** would predominate at equilibrium;[2] and by making the alkyl group isopropyl or *tert*-butyl, it was hoped to minimize condensation reactions. Unlike the cyclic ketols studied previously, acyclic ketols have the potential disadvantage of existing in equilibrium with their hemiketals **3** and **4**. However, although this factor would complicate product analysis, it could be taken into account.

Initial attempts to synthesize the ketol by alkylation of γ-phenylbutyrolactone with isopropyl Grignard reagent or *tert*-butyllithium, by alkylation of pinacolone and acetophenone with styrene oxide, and by alkylation of acetophenone with bro-

[1]Part of this work was reported at the 62nd Canadian Chemical Conference, Vancouver, B.C., June 3–6, 1979.

[2]On combustion at 25°C in a static bomb, benzyl methyl ketone gives 3 kcal/mol more heat than propiophenone (8). If this value is taken as a measure of the phenyl–carbonyl conjugative stabilization, then **1** should predominate essentially completely over **2**.

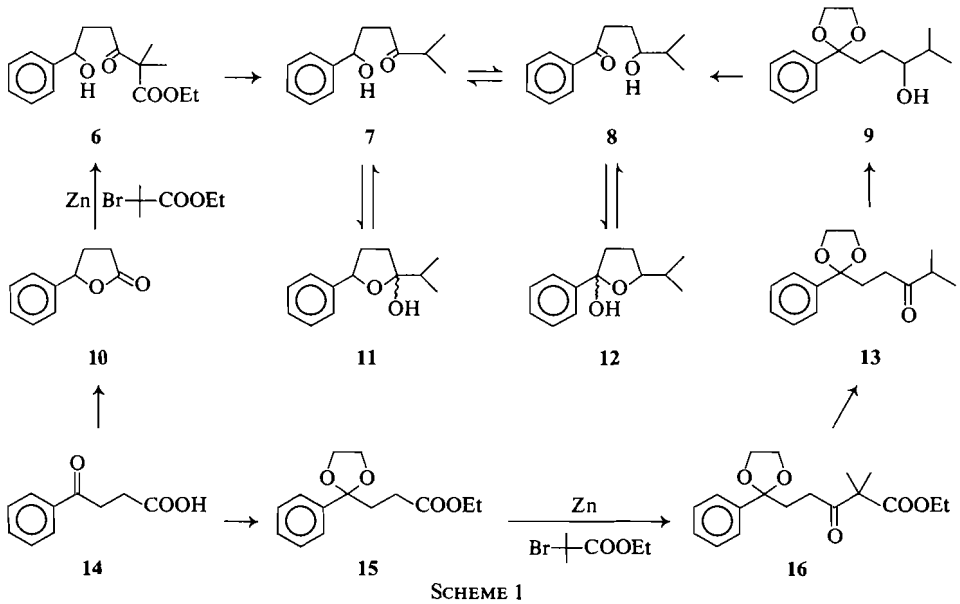


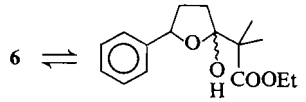
SCHEME 1

mopinacolone were unpromising. Therefore, we turned to the well developed Reformatsky procedure of Lapin and Horeau (9) because it seemed adaptable to preparation of the isopropyl and *tert*-butyl derivatives of a number of homologs (e.g. $n = 2, 3, 4$) of **1** and **2**.

Both ketols **7** and **8** were prepared from the same starting material, β-benzoylpropionic acid **14**, as outlined in Scheme 1. For **8**, the ethylene ketal of ethyl β-benzoylpropionate, **15**, was treated with ethyl α-bromoisobutyrate and zinc to obtain the known keto ester **16**. Base-catalyzed decarboethoxylation of **16** furnished the isopropyl keto ketal **13** which was reduced by $NaBH_4$ to the hydroxy ketal **9**. Acid hydrolysis gave the required phenyl isopropyl ketol **8**.

For the other ketol **7**, β-benzoylpropionic acid was dissolved in aqueous base and then reduced with $NaBH_4$;[3] acidification gave γ-phenylbutyrolactone **10**. The Reformatsky reaction with the lactone **10** and ethyl α-bromoisobutyrate produced a good yield of the hydroxy keto ester **6** which was readily separated from contaminating diethyl tetramethylsuccinate by chromatography. In $CDCl_3$ **6** existed in equilibrium with its cyclic hemiketal **17** in a ratio of ~2:1, respectively. Decarboethoxylation in 2% aqueous ethanolic KOH gave ketol **7**.

As a check on structural and spectroscopic assignments, the ethylene ketal **16** was hydrolyzed to give diketo ester **19** (Scheme 2). Saponification of **19** yielded the diketone **22**. In our hands the acidic hydrolysis of **19** as described in ref. 9 did not lead to **22** but instead gave 2-phenyl-5-isopropylfuran **18** in good yield.



17

Both ketols **7** and **8** existed in equilibrium with minor amounts of their hemiketals which were apparent in the ^{1}Hmr spectra (see Experimental); in $CDCl_3$ at room temperature the ratio of **7**:**11** was 5:1 and that of **8**:**12** was 3:1. For analytical purposes the most useful ^{1}Hmr differences between **7** ⇌ **11** and **8** ⇌ **12** were the positions of the O—C—H proton and the patterns of the aromatic protons. The hydroxymethine proton signal from **7** at δ 4.68 was shifted downfield by the phenyl group relative to the corresponding signal in **8** at δ 3.38. The phenyl protons in **7** ⇌ **11** appeared as a singlet with a broadened base at δ 7.3 and the benzoyl protons in **8** ⇌ **12** as two broad multiplets at δ 7.2–7.6 and 7.9–8.0.

Each ketol **7** ⇌ **11** and **8** ⇌ **12** was subjected to isomerization conditions found earlier to be suitable for **5** (4), KOH–H_2O–*t*-BuOH at reflux. Hydride transfer, **7** ⇌ **8**, did indeed occur[4] and at a rate comparable with that for the cyclic ketone **5**. The

[3]If the acid salt was not preformed, $NaBH_4$ reduction of the keto acid **14** apparently gave some diol from further reduction.

[4]The transfer was judged to be *intra*molecular by the absence of both diketone **22** and the diol corresponding to **22**.

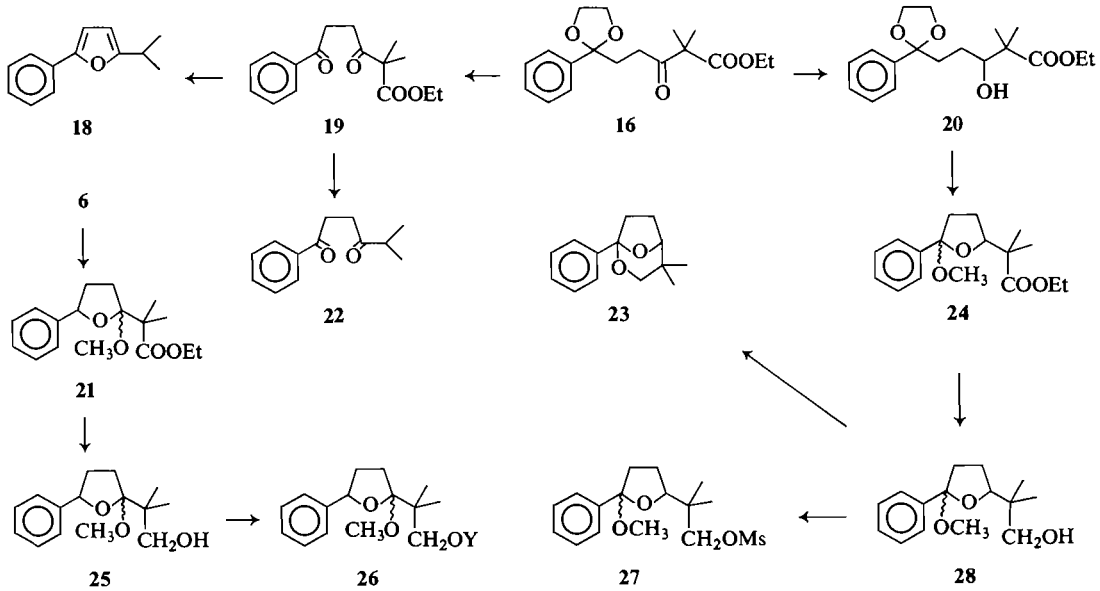
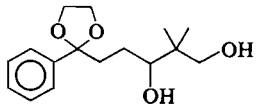


SCHEME 2

reactions were less clean than with **5**, and even under nitrogen some decomposition took place, but after chromatography the ketol fraction from each reaction was found to be a mixture of comparable amounts of **7** ⇌ **11** and **8** ⇌ **12** from glpc analysis (e.g from **7** ⇌ **11** the ratio of **7**:**8** was ~7:3, see Experimental). Although the equilibrium constant was not determined, it was clearly not one-sided. Hence, the conjugation of the carbonyl group with the phenyl group was not sufficient to tip the equilibrium position in favor of **8**,[5] and consequently these compounds were not very suitable for kinetic experiments.

In hope of diminishing hemiketal formation and possibly altering the equilibrium constant for hydride shift, we turned to the preparation of the corresponding *tert*-butyl ketols **1***b* and **2***b* ($n = 2$) by conversion of the carboethoxyl group of the Reformatsky intermediates **6** and **16** into methyl (Scheme 2). The existing ketone group in **6** was protected by formation of the cyclic ketal **21**, which appeared to be a single racemate, in acidic methanol. The isomeric cyclic ketal ester **24** was obtained as a mixture of two diastereomeric racemates by brief borohydride reduction of **16** to **20** which was then treated with acidic methanol. If the reduction mixture from **16** was allowed to stand at room temperature, the ester group began to be reduced to diol **29**, presumably by an intramolecular donation of hydride after the ketone had been reduced (10). $LiAlH_4$ reduction of the cyclic ketal esters **21** and **24** furnished the cyclic ketal alcohols **25**, which was a single crystalline racemate, mp 85°C, and **28**, which was a liquid diastereomeric mixture. Not surprisingly, with the benzylic ketal group and the possibility of intramolecular reaction, compound **28** was very sensitive to acid. Mere standing in $CDCl_3$ resulted in cyclization to the bicyclic ketal **23** with loss of MeOH. However, both ketal alcohols could be converted into the sulfonate esters **26** and **27** in pyridine solution.



29

Although some difficulty in reducing these hindered neopentyl-like sulfonates to methyl groups was anticipated, it was expected that one of the recently developed procedures (11–14) would work. However, tosylate **26***a* was recovered from the following reductive conditions: NaI/Zn/DME for 1.5 h at reflux (13), NaI/Zn/DMF for 2.5 days at 40°C (13), $NaBH_4$/DMSO for 4 h at 45–50°C (11), and $NaBH_3CN$/HMPT for 18 h at 80°C (12). Two sets of conditions did give reductive removal of tosylate from **26***a*: NaI/Zn/DME for 66 h at 80–95°C (13) and $LiEt_3AlH$/THF at reflux for 3 h (14), but in both cases the product was a mixture of

[5]The failure of carbonyl conjugation to determine the equilibrium position must be linked to the fact that the equilibration also involves the hemiketals **11** and **12**, and the relative stability of these latter would not parallel that of **7** and **8**.

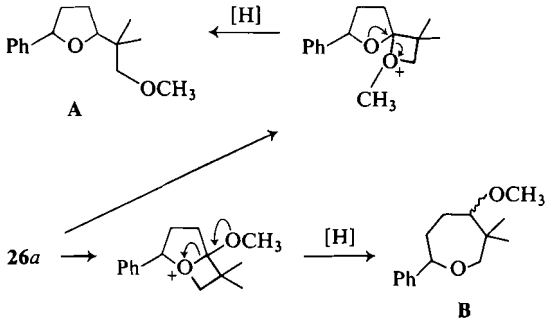
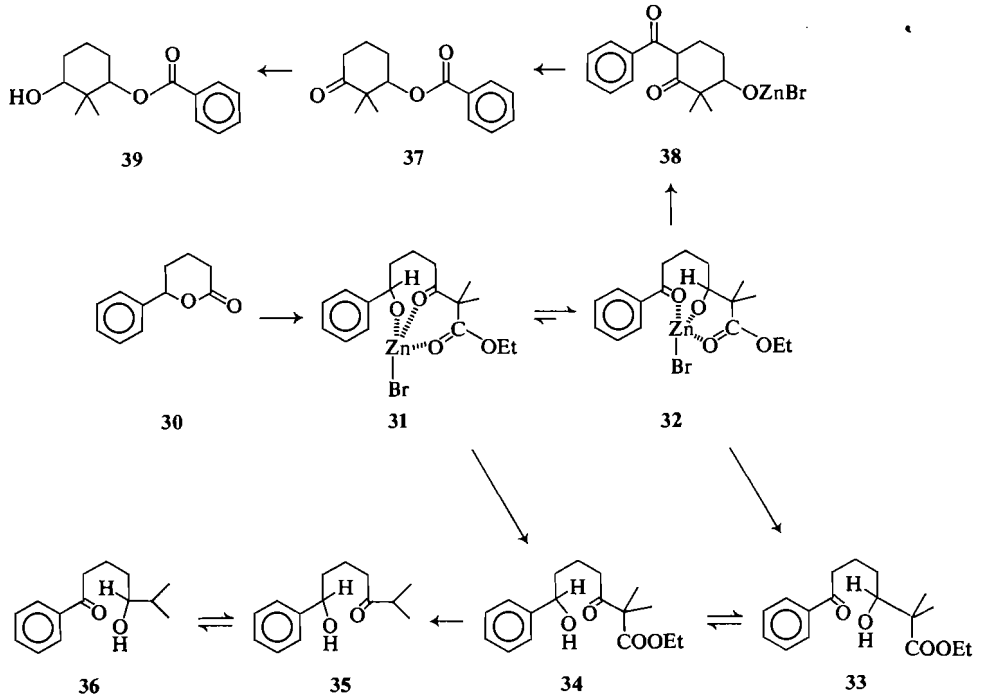
at least four components. From similarities in the ^{1}Hmr spectra of these two reduction products and the increase in number of protons on carbon bearing oxygen, it seems likely that rearrangement was occurring via intramolecular attack of the ethereal oxygen atoms followed by oxonium ion cleavage and reduction to give **A** and **B**. In agreement, the methoxyl group was not hydrolyzed by aqueous alcoholic H_2SO_4 at room temperature. After these unpromising results, the replacement of triflate from **26***c* by thiophenoxide was tried, but the yield



of (possibly rearranged) thioether in the product mixture was too low to be useful for Raney nickel reduction. At this point, the conversion of **26** and **27** into *tert*-butyl ketols was given up.

In spite of the fact that the Reformatsky intermediates were not readily amenable to preparation of *tert*-butyl ketols, the extension of this approach to the next higher isopropyl homolog **2** ($n = 3$) was examined. Surprisingly, the Reformatsky reaction of ethyl α-bromoisobutyrate with δ-phenylvalerolactone **30** (Scheme 3) in refluxing benzene for 2 h did not yield the expected product **34**, but instead the isomeric hydroxy keto ester **33** in which intramolecular hydride transfer had already occurred! Longer reaction time in refluxing benzene led to cyclization of **33** with loss of ethanol to give the rearranged ester **37**. The origin of this product is readily explained by intramolecular acylation of the zinc enolate of **33** (formed from **32**) to yield **38**, followed by intramolecular β-dicarbonyl cleavage to **37** (cf. ref. 15). Attempts to prevent these reactions and to isolate **34** were unsuccessful; at room temperature no reaction occurred, and at reflux for 20 min, although lactone remained, the product that had formed was only the rearranged **33**. With the highly touted trimethyl borate as cosolvent (16) for the Reformatsky synthesis, the only product after 19 h at room temperature was the ring opened methyl ester from δ-phenylvalerolactone.

The contrast between the reaction with δ-phenylvalerolactone and that with γ-phenylbutyrolactone, which gave no evidence of any hydride



SCHEME 3

For personal use only.

shift during longer reflux periods, must be due to the greater ease of 1,5-hydride transfer in **31**[6] relative to the 1,4-hydride transfer in **6**. This difference is a general phenomenon and is apparently a result of the greater strain imposed on the transition state in order to achieve the required geometry (17, 18) for the 1,4-hydride shift (cf. ref. 2).

Since the Reformatsky product from δ-phenylvalerolactone was pure **33**, the equilibrium between **31** and **32** must lie far toward **32**.[6] Possibly aroyl conjugation is the dominant factor in the **31** ⇌ **32** equilibration, or another possibility from a study of Dreiding models (provided that **31** and **32** are the structures of the zinc alkoxides) is that the zinc complex **32** is less strained than **31** because the quasi 6-membered ring of **32** with two sp^3-carbons is less strained than the quasi 6-membered ring in **31** with only one sp^3-carbon. In a test of the reversibility of the **31** ⇌ **32** hydride shift, ester **33** was heated with KOH–H_2O–*t*-BuOH under the conditions used to equilibrate **7** and **8**. The product was a mixture of decarboethoxylated ketols **35** and **36** in a (presumably equilibrium) ratio of ~1:1. Consequently **33** was converted by hydride shift to the β-keto ester **34** which underwent decarboethoxylation to **35** and further partial hydride shift to **36**.

At this point, although pure ketol **36** could presumably have been made from the next higher homolog of **15**, the Reformatsky reaction had lost much of its original appeal as a synthetic method for these compounds for the several reasons discussed above. Nevertheless, the Reformatsky compounds had served to demonstrate that hydride shift would occur readily in acyclic ketols and to spur the search for more suitable compounds and syntheses for a more detailed study of hydride shift in acyclic ketols. Subsequently, attention has been redirected to the use of *tert*-butyllithium and phenyllithium in a general synthesis of the *tert*-butyl series of **1** and **2** ketols. This approach has been successful and will be reported shortly.

41

Experimental

General

The instruments and chromatographic procedures are the same as in ref. 4. Mass spectra were run at 70 eV unless otherwise specified; only major fragmentation ions are given. For ^{1}Hmr spectra only well resolved signals are reported. Ultraviolet spectra were measured with a Cary Model 219 spectrophotometer. Gas–liquid partition chromatography was done on an Unilab Model 400 all-glass system with a 1.8-m column of 1% DEGS on 60–80 mesh Chromosorb W at 130°C and a hydrogen flame detector. Analyses were done by Chemalytics, Tempe, AZ. The zinc metal used was either granular (20 mesh) or dust from the Fisher Co. and was activated according to ref. 19. Ether extractions included the usual washing with acid and/or base and drying.

Ethyl 6-Hydroxy-6-phenyl-2,2-dimethyl-3-oxo-hexanoate (6)

A mixture of 1.0 g (6.2 mmol) of γ-phenylbutyrolactone (**20**), 0.81 g (12 mmol) of Zn metal, and 25 mL of dry benzene was distilled until 10 mL of benzene had been collected. A solution of 3.0 mL (3.98 g, 20 mmol) of ethyl α-bromoisobutyrate in 10 mL of dry ether was then added, and the reaction mixture was refluxed for 6 h. The Zn had dissolved and a white precipitate of Zn salt had appeared. Cooling, hydrolysis with aqueous H_2SO_4, and extraction with ether furnished 2.20 g of oily liquid. Column chromatography on 50 g of silica gel with $CHCl_3$ eluent gave 1.40 g (81%) of pure liquid hydroxy keto ester **6** which existed in equilibrium with its cyclic hemiketal **17** (**6**:**17** = 2:1 in $CDCl_3$); ir (neat): 3500 (broad strong OH) and 1710 with shoulders at 1725 and 1740 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.18 (3H, t, J = 7 Hz, $CH_3[CH_2]$), 1.32 (6H, s, *gem*-diMe), 1.6–2.7 (5H, m, OH, CH_2CH_2), 4.12 (q, J = 7 Hz, $OCH_2[CH_3]$), 4.18 (q, J = 7 Hz, $OCH_2[CH_3]$), 4.68 (0.65H, varies from bt to m, HC—[OH] of **6**), 4.98 (0.65H, bs, OH of **6**), 5.06 (0.35H, bs, OH of **17**), 5.18 (0.35H, dd, HC—OC of **17**), and 7.32 (5H, s, Ph) ppm; at 220 MHz the signals at 4.68 and 5.18 ppm were clearly resolved dds; ms *m/e*: 260 ($M^+ - H_2O$) and 233 (M^+ − OEt). M^+ calcd. for $C_{16}H_{22}O_4$: 278.1518; found: 278.1518. *Anal.* calcd. for $C_{16}H_{22}O_4$: C 69.04, H 7.97; found: C 69.13, H 7.98.

The less polar impurity eluted first from the column amounted to 460 mg of diethyl tetramethylsuccinate; ir (neat): 1725 (ester C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.23 (12H, s, Me_2C—CMe_2), 1.25 (6H, t, J = 7 Hz, $2CH_3[CH_2O]$), and 4.10 (4H, q, J = 7 Hz, 2 $OCH_2[CH_3]$) ppm; ms *m/e*: 185 (M^+ − OEt).

6-Hydroxy-6-phenyl-2-methylhexan-3-one (7)

A solution of 70 mg of pure **6** in 5 mL of a 2% solution of KOH in EtOH–H_2O (4:1) was refluxed for 0.5 h. Dilution with water and extraction with ether afforded 52 mg (100%) of colorless liquid ketol **7** which existed in equilibrium with the cyclic hemiketal **11** (**7**:**11** = 5:1 in $CDCl_3$); ir (neat): 3450 (broad intense OH) and 1705 (weak C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.08 (6H, d, J = 7 Hz, $Me_2[CH]$), 1.9–2.2 (2H, m, CH_2), 2.4–2.8 (2H, m, CH_2C=O), 2.90 (1H, bs, OH), 4.68 (0.85H, t = dd, HC—[OH] of **7**), 5.19 (0.15H, t = dd, HC—OC of **11**), and 7.33 (5H, s, Ph) ppm. At 220 MHz the signals at 4.68 and 5.19 still appeared as triplets; ms *m/e*: 188 ($M^+ - H_2O$), 163 (M^+ − *i*-Pr), and 145 ($M^+ - H_2O$ − *i*-Pr). M^+ calcd. for $C_{13}H_{18}O_2$: 206.1306; found: 206.1297. *Anal.* calcd. for $C_{13}H_{18}O_2$: C 75.69, H 8.80; found: C 75.95, H 8.54.

Ethyl 6,6-Ethylenedioxy-6-phenyl-2,2-dimethyl-3-oxohexanoate (16)

The general procedure of ref. 9 was reduced in scale. A mixture of 1.25 g (5.0 mmol) of ketal ester **15** (9), 0.65 g (10 mmol) of Zn metal, and 25 mL of dry benzene was distilled and stirred (magnetic bar) until 10 mL of benzene had been collected. A solution of 1.95 g (10 mmol) of ethyl α-bromoisobutyrate in 5 mL of dry ether was added dropwise, and the reaction mixture was stirred and refluxed for 6 h. By this time most of the Zn had dissolved and a white turbidity due to Zn salts had appeared. After cooling, the reaction mixture was poured into 50 mL of ice cold aqueous 8 *N* H_2SO_4. The organic layer was separated, washed to neutrality with water, dried, and

[6]The Reformatsky zinc alkoxide products drawn as **31** and **32** might exist as the hemiketal forms **40** and **41** or an equilibrium mixture of all four structures.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

evaporated to leave 1.86 g of crude product which was chromatographed on 50 g of neutral alumina. Benzene–hexane mixtures eluted 1.43 g (89%) of pure liquid **keto ketal ester 16**; ir (neat): 1730 (ester C=O) and 1705 (ketone C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.20 (3H, t, J = 7 Hz, $CH_3[CH_2]$); 1.34 (6H, s, *gem*-diMe), 2.10–2.30 (2H, m, CH_2), 2.46–2.70 (2H, m, CH_2C=O), 3.7–4.1 (4H, m, OCH_2CH_2O), 4.15 (2H, q, J = 7 Hz, $OCH_2[CH_3]$), and 7.26–7.54 (5H, m, Ph) ppm; ms *m/e*: 320 (M^+), 275 ($M^+ - OEt$), 205 ($M^+ - Me_2CCOOEt$), and 149 (base peak, $PhCH(OCH_2)_2^+$). *Anal.* calcd. for $C_{18}H_{24}O_5$: C 67.48, H 7.55; found: C 67.79, H 7.54.

6,6-Ethylenedioxy-6-phenyl-2-methylhexan-3-one (13)

A solution of 640 mg of keto ketal ester **16** in 10 mL of a 2% solution of KOH in EtOH–H_2O (4:1) was refluxed for 1 h. Dilution with water and extraction with ether yielded 488 mg (98%) of pure colorless liquid **keto ketal 13**; ir (neat): 1710 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.05 (6H, d, J = 7 Hz, $Me_2[CH]$), 2.1–2.3 (2H, m, CH_2), 2.4–2.7 (3H, m, CH_2C=O + $HC[Me_2]$), 3.6–4.1 (4H, m, OCH_2CH_2O), and 7.2–7.5 (5H, m, Ph) ppm; ms *m/e*: no M^+, 205 ($M^+ - i$-Pr), and 149 (base peak, $PhCH(OCH_2)_2^+$). *Anal.* calcd. for $C_{15}H_{20}O_3$: C 72.55, H 8.12; found: C 72.68, H 8.20.

6,6-Ethylenedioxy-6-phenyl-2-methylhexan-3-ol (9)

The above keto ketal **13** sample was dissolved in a few mL of aqueous MeOH and treated with excess $NaBH_4$. Dilution with water and extraction with ether afforded 462 mg (94%) of pure **hydroxy ketal 9**, mp 52–52.5°C after recrystallization from hexanes; ir (neat): 3440 (broad OH) cm^{-1} and no C=O absorption; ^{1}Hmr ($CDCl_3$) δ: 0.88 (6H, d, J = 7 Hz, $Me_2[CH]$), 1.1–2.2 (6H, m, OH, CCH_2CH_2C, $HC[Me_2]$), 3.22–3.50 (1H, m, HC[OH]), 3.64–4.18 (4H, sym m, OCH_2CH_2O), and 7.20–7.56 (5H, m, Ph) ppm; ms *m/e* (20 eV): no M^+, 207 ($M^+ - i$-Pr), and 149 (base peak, $PhCH(OCH_2)_2^+$). *Anal.* calcd. for $C_{15}H_{22}O_3$: C 71.97, H 8.86; found: C 72.26, H 8.81.

4-Hydroxy-1-phenyl-5-methylhexan-1-one (8)

The above hydroxy ketal **9** was dissolved in a few mL of aqueous MeOH containing a drop of 8 N H_2SO_4 and allowed to stand for 15 min. Dilution with water and extraction with ether gave 378 mg of crude liquid product. Chromatography on a 20-g plate of silica gel furnished 298 mg (78%) of pure liquid ketol **8** which existed in equilibrium with the cyclic **hemi ketal 12** (**8**:**12** = 3:1 in $CDCl_3$); uv (MeOH): 242 nm (10 300); ir (neat): 3450 (strong OH) and 1680 (PhC=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.92 (6H, d, J = 7 Hz, $Me_2[CH]$), 1.4–2.1 (4H, bm, CH_2, OH, $HC[Me_2]$), 3.13 (2H, dt, O=CCH_2), 3.38 (0.75H, m, HC—[OH] of **8**), 7.2–7.64 (3.5H, m, *m*- and *p*-H of PhC=O), and 7.88–8.04 (1.5H, m, *o*-H of PhC=O) ppm; ms *m/e*: no M^+, 188 ($M^+ - H_2O$), and 106 (base peak, $PhCOH^+$). *Anal.* calcd. for $C_{13}H_{18}O_2$: C 75.69, H 8.80; found: C 75.13, H 8.90.

Ethyl 6-Phenyl-2,2-dimethyl-3,6-dioxohexanoate (19)

A solution of 1.82 g of keto ketal ester **16** in 10 mL of MeOH plus 0.5 mL of 8 N H_2SO_4 was allowed to stand at room temperature for 30 min. Dilution with water and extraction with ether yielded 1.62 g (100+%) of liquid **diketo ester 19**; ir (neat): 1740 (ester C=O), 1715 (alkyl C=O), and 1690 (PhC=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.26 (3H, t, J = 7 Hz, $CH_3[CH_2]$), 1.46 (6H, s, *gem*-diMe), 2.8–3.5 (4H, m, CH_2CH_2), 4.24 (2H, q, J = 7 Hz, $OCH_2[CH_3]$), 7.3–7.7 (3H, m, *m*- and *p*-ArH), and 7.9–8.1 (2H, m, *o*-ArH); ms *m/e* (25 eV): 185 ($M^+ - H_2O$ – COOEt). *Anal.* calcd. for $C_{16}H_{20}O_4$: C 69.55, H 7.30; found: C 69.91, H 7.59.

1-Phenyl-5-methyl-1,4-hexanedione (22)

A solution of 500 mg of diketo ester **19** in 10 mL of 2% KOH in EtOH–H_2O (4:1) was refluxed for 1 h. Dilution with water and extraction with ether gave 412 mg (100%) of liquid **diketone 22**; uv (MeOH): 242 nm (12 500); ir (neat): 1710 (alkyl C=O) and 1685 (PhC=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.15 (6H, d, J = 7 Hz, $Me_2[CH]$), 2.4–3.4 (5H, m, O=CCH_2CH_2C(=O)CH), 7.0–7.4 (3H, m, *m*- and *p*-ArH), and 7.7–7.9 (2H, m, *o*-ArH) ppm; ms *m/e* (25 eV): 204 (M^+) and 161 (base peak, $M^+ - i$-Pr). M^+ calcd. for $C_{13}H_{16}O_2$: 204.1150; found: 204.1151.

2-Phenyl-5-isopropylfuran (18)

The hydrolysis procedure of Bogavac *et al.* (9) was followed. A solution of 0.5 g of **diketo ester 19** in 2.5 mL of HOAc to which was added 0.5 mL of 10% aqueous H_2SO_4 was refluxed for 1 h. Dilution with water and extraction with ether gave a single compound, the liquid **furan 18**; ir (neat): no OH or C=O absorption; ^{1}Hmr ($CDCl_3$) δ: 1.26 (6H, d, $Me_2[CH]$), 2.98 (1H, septuplet, $HC[Me_2]$), 6.02 (1H, d, J = 3 Hz, furan H), 6.52 (1H, d, J = 3 Hz, furan H), and 7.05–7.70 (5H, m, Ph) ppm; ms *m/e*: 186 (M^+) and 171 (base peak, $M^+ - CH_3$). M^+ calcd. for $C_{13}H_{14}O$: 186.1045; found: 186.1044.

Ethyl 3-Hydroxy-6,6-ethylenedioxy-6-phenyl-2,2-dimethylhexanoate (20)

A solution of 500 mg of keto ketal ester **16** in 10 mL of MeOH was cooled to 0°C and 60 mg of $NaBH_4$ was added in portions. After 15 min, 20 mL of ice water was added, and the product was extracted with ether to yield 508 mg (100+%) of colorless liquid hydroxy ketal ester **20**; ir (neat): 3480 (OH) and 1725 (ester C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.14 (6H, s, *gem*-diMe), 1.21 (3H, t, J = 7 Hz, $CH_3[CH_2]$), 1.2–2.4 (4H, 2m, CCH_2CH_2C), 2.85 (1H, b, OH), 3.3–4.2 (5H, m, OCH_2CH_2O + HC[OH]), 4.11 (2H, q, J = 7 Hz, $OCH_2[CH_3]$), and 7.26–7.54 (5H, m, Ph) ppm; ms *m/e* (25 eV): no M^+, 277 (M^+ – OEt), 207 ($M^+ - Me_2CCOOEt$), and 149 (base peak, $PhC(OCH_2)_2^+$). *Anal.* calcd. for $C_{18}H_{26}O_5$: C 67.06, H 8.13; found: C 67.19, H 7.91.

If the temperature or time of the reduction was raised, a second more polar product was formed and could be separated by chromatography on alumina. This was the crystalline **diol 29**, mp 133–134°C, from intramolecular reduction of the carboethoxy group after reduction of the ketone (10); ir ($CHCl_3$): 3460 (OH) cm^{-1}, no C=O absorption; ^{1}Hmr ($CDCl_3$) δ: 0.84 (6H, s, *gem*-diMe), 1.0–2.3 (4H, 2m, CCH_2CH_2C), 3.0–3.7 (2H, b, 2OH), 3.43 (3H, m, CH_2[OH] + HC[OH]), 3.7–4.2 (4H, sym dm, OCH_2CH_2O), and 7.26–7.54 (5H, m, Ph) ppm; ms *m/e* (25 eV): no M^+. $M^+ - (CH_3)_2CCH_2OH$ calcd. for $C_{12}H_{15}O_3$: 207.1021; found: 207.1018. $C_6H_5C(OCH_2)_2^+$ calcd. for $C_9H_9O_2$: 149.0603; found: 149.0600. *Anal.* calcd. for $C_{16}H_{24}O_4$: C 68.55, H 8.63; found: C 68.39, H 8.61.

When the ^{1}Hmr solution of **29** in $CDCl_3$ was treated with one drop of concentrated aqueous HCl, the spectrum changed to that of the bicyclic ketal **23**.

Ethyl 2-(2'-Methoxy-5'-phenyl-2'-tetrahydrofuryl)isobutyrate (21)

A solution of 186 mg of hydroxy keto ester **6** in 10 mL of dry MeOH containing two drops of concentrated H_2SO_4 was refluxed for 30 min. The acid was then neutralized by addition of excess solid $NaHCO_3$ before 50 mL of ice cold water was added. Extraction with ether yielded 186 mg of liquid **cyclic ketal ester 21**, which appeared to be a single (±) diastereomer; ir (neat): 1715 (ester C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.22 (3H, t, J = 7 Hz, $CH_3[CH_2]$), 1.35 (6H, s, *gem*-diMe), 2.01 (2H, 5 lines, $[OCH]CH_2[CH_2]$), 2.48–2.63 (2H, 4 lines, $[CH_2]CH_2[COCH_3]$), 3.19 (3H, s, OCH_3), 4.12 (1H, dd, HC—O), 4.16 (2H, q, J = 7 Hz, $OCH_2[CH_3]$), and 7.32 (5H, s, Ph) ppm; ms *m/e* (20 eV): 292 (M^+), 274 ($M^+ - 18$), 260 (base peak, $M^+ - CH_3OH$), 177 ($M^+ - Me_2CCOOEt$), 134, and 121. *Anal.* calcd. for $C_{17}H_{24}O_4$: C 69.84, H 8.27; found: C 69.71, H 7.93.

2,2-Dimethyl-2-(2'-methoxy-5'-phenyl-2'-tetrahydrofuryl)-ethanol (25)

To a stirred (magnetic bar) suspension of 100 mg of $LiAlH_4$ in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

10 mL of dry ether was added dropwise a solution of 330 mg of cyclic ketal ester **21** in 5 mL of dry ether. After 30 min (or less) at room temperature, excess $LiAlH_4$ was destroyed by the addition of cold water. Extraction with ether gave 284 mg (100%) of white crystalline solid **25**, mp 80–81°C. Recrystallization from hexanes raised the mp to 84–85°C; ir ($CHCl_3$): 3380 (OH) cm^{-1}, no C=O absorption; ^{1}Hmr ($CDCl_3$) δ: 0.85 (6H, s, *gem*-diMe), 1–2 (4H, m, CCH_2CH_2C), 3.20 (3H, s, OCH_3), 3.45 (2H, sym m, CH_2[OH]), 3.3–3.6 (1H, bs, OH), 4.06–4.26 (1H, m, HC—O), and 7.30 (5H, s, Ph) ppm; ms *m/e* (25 eV): no M^+, 219 ($M^+ - OCH_3$), 147, 134, and 121 (base peak). $M^+ - OCH_3$ calcd.: 219.1385; found: 219.1381. *Anal.* calcd. for $C_{15}H_{22}O_3$: C 71.97, H 8.86; found: C 71.32, H 9.41.

Ethyl 2-(5'-Methoxy-5'-phenyl-2'-tetrahydrofuryl)isobutyrate (24)

A solution of 342 mg of hydroxy ketal ester **20** in 10 mL of dry MeOH containing two drops of concentrated H_2SO_4 was refluxed for 30 min. The acid was then neutralized by addition of excess solid $NaHCO_3$. Dilution with 50 mL of ice cold water and extraction with ether gave 330 mg (100+%) of gummy liquid **cyclic ketal ester 24** which was a mixture of two (±) diastereomers in a ratio of ~3:1; ir (neat): 1730 (ester C=O) cm^{-1}, no OH absorption; ^{1}Hmr ($CDCl_3$) δ: 1.26 (3H, t, J = 7 Hz, $CH_3[CH_2]$), 1.24 (s, *gem*-diMe of major isomer), 1.32 (s, *gem*-diMe of minor isomer), 1.6–2.5 (4H, bm, CCH_2CH_2C), 3.00 (s, OCH_3 of major isomer), 3.04 (s, OCH_3 of minor isomer), 4.18 (q, J = 7 Hz, $OCH_2[CH_3]$ of major isomer), 4.21 (q, J = 7 Hz, $OCH_2[CH_3]$ of minor isomer), 4.35–4.60 (1H, m, HC—O of both isomers), and 7.20–7.64 (5H, bm, Ph) ppm. $M^+ - CH_3OH$ calcd. for $C_{16}H_{20}O_3$: 260.1412; found: 260.1417.

Compound **24** decomposes on standing, especially in solvents ($CDCl_3$ or $CHCl_3$) giving rise to acid.

2,2-Dimethyl-2-(5'-methoxy-5'-phenyl-2'-tetrahydrofuryl)-ethanol (28)

To a stirred (magnetic bar) suspension of 60 mg of $LiAlH_4$ in 10 mL of dry ether was added dropwise a solution of 292 mg of cyclic ketal ester **24** in 2 mL of dry ether. After 10 min at room temperature, excess $LiAlH_4$ was destroyed by the addition of cold water. Extraction with ether furnished 258 mg of colorless liquid **hydroxy cyclic ketal 28** which was a mixture of two (±) diastereomers in a ratio of ~3:1; ir (neat): 3400 (strong OH) cm^{-1}, no C=O absorption; ^{1}Hmr (acetone-d_6) δ: 0.96 (3H, s, Me), 1.00 (3H, s, Me), 1.5–2.5 (4H, m, CCH_2CH_2C), 2.97 (s, OCH_3 of major isomer), 3.02 (s, OCH_3 of minor isomer), 3.4–3.7 (3H, m, CH_2OH), 4.06–4.32 (1H, m, HC—O of both isomers), and 7.20–7.62 (5H, m, Ph) ppm; ms *m/e* (18 eV): 250 (M^+), 219 (base peak, $M^+ - OCH_3$), and 177 ($M^+ - Me_2CCH_2OH$). M^+ calcd. for $C_{15}H_{22}O_3$: 250.1569; found: 250.1570.

Although the ^{1}Hmr spectrum of a freshly prepared solution of **28** in $CDCl_3$ could be taken, on standing the compound underwent acid-catalyzed loss of MeOH and formation of the liquid **bicyclic ketal 23**, which was readily purified by thick layer chromatography on silica gel; ir (neat): no OH or C=O absorption; ^{1}Hmr ($CDCl_3$) δ: 0.80 (3H, s, Me), 1.32 (3H, s, Me), 1.5–2.5 (4H, bm, CCH_2CH_2C), 3.45–3.88 (2H, m, CCH_2O) 4.06–4.24 (1H, m, HC—O), and 7.26–7.66 (5H, bm, Ph) ppm; ms *m/e*: 218 (M^+) and 106 (base peak). M^+ calcd. for $C_{14}H_{18}O_2$: 218.1307; found: 218.1309.

2,2-Dimethyl-2-(2'-methoxy-5'-phenyl-2'-tetrahydrofuryl)ethyl p-Toluenesulfonate (26a)

To a solution of 250 mg of the hydroxy ketal **25** in 2 mL of dry pyridine at 5°C was added 200 mg of *p*-TsCl. After standing overnight at 5°C the reaction mixture was diluted with ether and washed with water. Evaporation of the ether left 396 mg (98%) of crude gummy tosylate **26*a*** which was purified by chromatography on alumina; ^{1}Hmr ($CDCl_3$) δ: 0.85 (6H, s, *gem*-diMe), 1–2 (4H, bm, CCH_2CH_2C), 2.42 (3H, s, $ArCH_3$), 3.20 (3H, s, OCH_3), 3.3–4.2 (3H, bm, —CH_2OTs and HC—O), 7.32 (5H, s, Ph), 7.34 and 7.78 (4H, J = 8 Hz, A_2B_2 of *p*-Ts) ppm; ms *m/e* (25 eV): no M^+, 373 ($M^+ - OCH_3$), 147, 134, and 121 (base peak). $M^+ - OCH_3$ calcd. for $C_{21}H_{25}O_4S$: 373.1473; found: 373.1474.

2,2-Dimethyl-2-(2'-methoxy-5'-phenyl-2'-tetrahydrofuryl) ethyl Mesylate (26b)

A solution of 125 mg of hydroxy cyclic ketal **25** and 0.5 mL of dry triethylamine in 5 mL of dry CH_2Cl_2 was cooled to −15°C and treated with 0.04 mL of freshly distilled $MeSO_2Cl$. After 0.5 h the reaction was diluted with cold water and extracted with ether to yield 185 mg of crude product, ^{1}Hmr ($CDCl_3$) δ: 0.90, 0.95, 1.00 (overlapping Me singlets), 2.96 (3H, s, CH_3SO_2), 3.20 (3H, s, CH_3O), 4.0–4.4 (m, CH_2OMs + Ph—CH—O), and 7.23 (5H, s, Ph) ppm; ms *m/e* (25 eV): 296 ($M^+ - CH_3OH$).

2,2-Dimethyl-2-(5'-methoxy-5'-phenyl-2'-tetrahydrofuryl)ethyl Mesylate (27)

A solution of 200 mg of freshly prepared hydroxy cyclic ketal **28** and 0.5 mL of triethylamine in 5 mL of dry CH_2Cl_2 was cooled to −15°C and treated with 0.08 mL of freshly distilled $MeSO_2Cl$. After 0.5 h the reaction mixture was diluted with ether and washed with water. Evaporation of the dried ether solution left 268 mg (100+%) of gummy mesylate **27**, ir (neat): 1350 and 1175 (sulfonate ester) cm^{-1}, no OH or C=O absorption; ^{1}Hmr ($CDCl_3$) δ: 1.03 (6H, s, Me_2C), 3.00 (3H, s, CH_3SO_3), 3.00 (3H, s, OCH_3), 3.3–4.3 (3H, m, —CH_2OMs, HC—O), and 7.1–7.5 (5H, m, Ph) ppm; ms *m/e* (25 eV): 328 (M^+, too weak for precise mass determination) and 296 ($M^+ - CH_3OH$). $M^+ - CH_3OH$ calcd. for $C_{15}H_{20}O_4S$: 296.1082; found: 296.1078.

Reduction of Tosylate 26a

(a) NaI/Zn/DME. A solution of 100 mg of **26*a*** in 20 mL of DME was refluxed with a large excess of NaI and Zn dust for 66 h. Cooling, dilution with ether, and filtration gave a colorless solution which was washed with water, dried, and evaporated to leave 79 mg of crude liquid product. The ^{1}Hmr spectrum indicated the loss of the tosyl group, but tlc analysis revealed several spots. Thick layer chromatography (EtOAc–hexanes, 1:4, development) gave a colorless oil from the major band, ^{1}Hmr ($CDCl_3$) δ: 0.87(s) + 1.07(s) + 1.15(s) + 1.18(s) (total ~7H), 1.4–2.0 (~4H, m, CH_2s), 3.17 (3H, s, OCH_3), 3.93–4.53 (~3H, m, OCH), and 7.17 (5H, s, Ph) ppm.

(b) $LiEt_3BH$. A solution of 86 mg of tosylate **26*a*** in 2 mL of dry THF (freshly distilled from $LiAlH_4$) cooled in an ice bath was treated with 0.42 mL of a 1.0 *M* solution of $LiEt_3BH$ in THF (Aldrich). The reaction mixture was then stirred at reflux temperature for 3 h. After addition of water, 0.2 mL of 3 *N* aqueous NaOH, and 0.2 mL of 30% H_2O_2, the product was extracted with ether to yield 64 mg of crude liquid product. The ^{1}Hmr spectrum verified the absence of the tosyl group and the presence of new peaks in the methyl region, but tlc analysis revealed that the product was a mixture of several compounds. Thick layer chromatography ($CHCl_3$ development) gave a colorless oil from the major band, ir (neat): no OH or C=O absorption; ^{1}Hmr ($CDCl_3$) δ: 1.08(s) + 1.15(s) + 1.20(s) (total ~6H), 1.4–2.0 (~4H, m, CH_2s), 3.18 (3H, s, OCH_3), 3.93–4.53 (3–4H, m, OCH), and 7.16 (5H, s, Ph) ppm.

(c) An authentic specimen of the methoxy ketal of the *tert*-butyl ketol **25** (CH_2OH=CH_3) was prepared by refluxing 85 mg of **2*b*** (Ar = Ph) in 15 mL of dry MeOH with 85 mg of *p*-TsOH for 0.5 h. Quenching with aqueous $NaHCO_3$ and extraction with ether gave 56 mg of pale yellow oily ketal, ^{1}Hmr ($CDCl_3$) δ: 1.07 (9H, s, *t*-Bu), 1.7–2.2 (2H, m, CH_2), 2.4–2.8 (2H, m, CH_2), 3.20 (3H, s, OCH_3), 4.07 (1H, t, PhCHO), and 7.20 (5H, s, Ph) ppm. M^+ calcd. for $C_{15}H_{22}O_2$: 234.1620; found: 234.1623. From the

For personal use only.

t-Bu peak position it seems likely that this ketal was one component of the reduction mixtures described in (*a*) and (*b*).

Preparation and Reaction of 2,2-Dimethyl-2-(2'-methoxy-5'-phenyl-2'-tetrahydrofuryl)ethyl Trifluoromethanesulfonate (26c)

To a solution of 57 mg of hydroxy ketal **25** in 2 mL of CH_2Cl_2 and 0.5 mL of dry pyridine at −15° to −25°C was added 0.05 mL of trifluoromethanesulfonic anhydride. After 45 min the reaction mixture was diluted with CH_2Cl_2 and washed with aqueous $NaHCO_3$. Evaporation of the dried CH_2Cl_2 solution left liquid **26c**; ^{1}Hmr ($CDCl_3$) δ: 1.02 (s, Me), 1.05 (s, Me), 1.4–2.1 (m, CH_2s), 3.67 (s, OCH_3), 4.38 (bs, CH_2—OTrf), 4.48–5.01 (m, PhCH—O), and 7.15 (Ph) ppm.

The crude triflate **26c** was dissolved in a few mL of DMF and stirred (magnetic bar) with 40 mg of NaSPh for 14 h. Neutralization with HOAc and ether extraction afforded the crude thioether which was a mixture of several products from tlc analysis. Thick layer chromatography (EtOAc–hexanes, 1:5, development) gave a colorless liquid from the major band, ^{1}Hmr ($CDCl_3$) δ: 1.02(s) + 1.10(s) + 1.17(s) + 1.20(s) (total ~7H), 1.4–2.2 (m, CH_2s), 3.21 (3H, s, OCH_3), 3.95–4.38 (~3H, m, OCH), and 7.28 (~9H, s, Ph) ppm; ms *m/e* (25 eV): 312 ($M^+ + H - OCH_3$?).

Reformatsky Reaction with δ-Phenylvalerolactone (30)

(*a*) A solution of 377 mg of δ-phenylvalerolactone and 626 mg of ethyl α-bromoisobutyrate in 20 mL of benzene was added dropwise to a refluxing slurry of 210 mg of Zn dust and 10 mL of benzene under N_2. After 2 h the reaction was quenched by the addition of 4 mL of 25% aqueous H_2SO_4. Ether extraction afforded 447 mg (71%) of crude product. Thick layer chromatography in $CHCl_3$–MeOH (98:2) yielded pure liquid **ethyl 2,2-dimethyl-3-hydroxy-7-phenyl-7-oxoheptanoate 33**, uv (MeOH): 240 nm (8950); ir (neat): 3500 (OH), 1725 (ester C=O), and 1690 (PhC=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.18 (6H, s, *gem*-diMe), 1.26 (3H, t, $CH_3[CH_2O]$), 1.34–2.15 (4H, m, CH_2CH_2), 2.84 (1H, bm, OH), 3.02 (2H, t, J = 7 Hz, O=CCH_2), 3.68 (1H, dd (after D_2O), HC[OH]), 4.15 (2H, q, J = 7 Hz, $OCH_2[CH_3]$), 7.2–7.7 (3.65H, m, *m*- + *p*-H of PhC=O), and 7.9–8.1 (1.35H, m, *o*-H of PhC=O) ppm; ms *m/e* (25 eV): 292 (M^+), 274 ($M^+ - H_2O$), 247 (M^+ − OEt), 177 (base peak, $PhCOCH_2CH_2CH_2CHOH^+$), and 105 ($PhC{\equiv}O^+$). $M^+ - H_2O$ calcd. for $C_{17}H_{22}O_3$: 274.1569; found: 274.1567.[7]

(*b*) When the reaction of 0.88 g of lactone **30** and 1.95 g of ethyl α-bromoisobutyrate with 0.65 g of Zn dust in 50 mL of refluxing benzene was conducted for 5 h, the product was a mixture of four compounds. Column chromatography on silica gel with $CHCl_3$–MeOH (99:1) eluted the major, least polar product, **2,2-dimethyl-3-benzoyloxycyclohexanone 37** as a colorless liquid, uv (MeOH): 228 nm (14 850); ir (neat): 1700–1725 (b, ketone + ester C=O) cm^{-1}, no OH absorption; ^{1}Hmr ($CDCl_3$) δ: 1.20 (3H, s, Me), 1.27 (3H, s, Me), 1.65–2.65 (6H, m, $3CH_2$), 5.08 (1H, m, HCOBz), 7.17–7.47 (3H, m, *m*- and *p*-H of PhC=O), and 7.70–7.90 (2H, m, *o*-H of PhC=O) ppm; ms *m/e*: 246 (M^+), 124 ($M^+ - PhCO_2H$), and 105 (base peak, $PhC{\equiv}O^+$). M^+ calcd. for $C_{15}H_{18}O_3$: 246.1256; found: 246.1256.

(*c*) To a stirred (magnetic bar) mixture of 54 mg of Zn dust, 110 mg of lactone **30**, 2 mL of dry THF, and 1.25 mL of dry MeOH-free trimethyl borate (21) at room temperature under N_2 was added 122 mg of ethyl α-bromoisobutyrate. After 19 h when the Zn had apparently been consumed, the reaction was quenched by the addition of 0.65 mL of concentrated NH_4OH and 0.2 mL of glycerol. Dilution with water and extraction with ether gave 82 mg of essentially pure **methyl 5-hydroxy-5-phenylbutyrate**, ^{1}Hmr ($CDCl_3$) δ: 1.4–2.8 (7H, m, $3CH_2$ + OH), 3.53 (3H, s, OCH_3), 4.53 (1H, m, PhCH[OH]), and 7.05 (5H, s, Ph) ppm. M^+ calcd. for $C_{12}H_{16}O_3$: 208.1099; found: 208.1101.

[7]The molecular ion was too weak for exact mass determination.

Structure Proof of Rearrangement Product 37

(*a*) A 50-mg sample of **37** was dissolved in 20 mL of EtOH and treated with 0.1 g of $NaBH_4$ for 2.5 h at room temperature. Dilution with water and extraction with ether gave 32 mg of colorless oily *cis* **39**, uv (MeOH): 228 (16 400); ir ($CHCl_3$): 3615 and 3490 (OH), and 1710 (benzoate C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.07 (6H, s, *gem*-diMe), 1.1–2.0 (7H, m, 3 CH_2 + OH), 3.37 (1H, m, $w_{1/2}$ = 16 Hz, HC[OH]), 4.67 (1H, m, $w_{1/2}$ = 16 Hz, HCOBz), 7.10–7.47 (3H, m, *m*- and *p*-H of PhC=O), and 7.80–8.00 (2H, m, *o*-H of PhC=O) ppm.

(*b*) A 30-mg sample of the $NaBH_4$ product **39** was refluxed with NaOH–H_2O–THF for 24 h. Ether extraction gave 10 mg of crystalline **2,2-dimethyl-*cis*-1,3-cyclohexanediol**. Recrystallization from hexanes gave 4 mg of needles, mp 110–112°C (lit. (22) mp 110.5°C); ^{1}Hmr ($CDCl_3$) δ: 1.02 (s, *gem*-diMe) and 3.38 (m, 2HC[OH]) ppm; ms *m/e* (25 eV): 143 (M^+ − H) and 126 ($M^+ - H_2O$). $M^+ - H_2O$ calcd. for $C_8H_{14}O$: 126.1045; found: 126.1045. The melting point was not depressed on admixture with an authentic sample of the diol, mp 112–112.5°C, ^{1}Hmr ($CDCl_3$) δ: 1.02 (s, *gem*-diMe) and 3.37 (m, 2HC[OH]) ppm, prepared by $NaBH_4$ reduction of 2,2-dimethyl-1,3-cyclohexanedione obtained by the procedure of Stetter and Sandhagen (23).

Acidification of the basic aqueous saponification solution with aqueous HCl and extraction with ether gave 14 mg of benzoic acid, mp 120–121°C after recrystallization from hexanes, ir ($CHCl_3$) 2700–3400 (broad OH) and 1695 (aryl C=O) cm^{-1}. M^+ calcd. for $C_7H_6O_2$: 122.0368; found: 122.0368. The mixture melting point with an authentic specimen was 120–122°C.

Isomerization Experiments

(*a*) A solution of 80 mg of pure ketol **7** and 6 KOH pellets in 0.2 mL of water and 7 mL of *t*-BuOH was refluxed for 48 h under a N_2 atmosphere.[8] The reddish brown reaction mixture was diluted with water and extracted with ether to yield 70 mg of crude product. Thick layer chromatography gave a colorless liquid mixture of ketols **7** (70%, glpc ret. time 2.0 and 3.2 min)[9] and **8** (30%, glpc ret. time 2.7 min). Peak identities were checked by admixture of authentic **7** and **8**. The ^{1}Hmr spectrum ($CDCl_3$) contained the following characteristic signals: δ 0.92 *i*-Pr d of **8**, 1.08 *i*-Pr d of **7**, 4.68 PhCH[OH] m of 7, and the 7.88–8.04 *o*-benzoyl m of **8**.

(*b*) A 55-mg sample of pure ketol **8** was treated identically as in (*a*) to yield 28 mg of crude product; glpc showed the presence of both ketols **7** and **8** in about the same ratio as in (*a*).

(*c*) A solution of 63 mg of ketol ester **33**, 3 KOH pellets, and 0.2 mL of water in 8 mL of *t*-BuOH was refluxed for 66 h. Dilution with 10 mL of water and extraction with ether gave 42 mg (89%) of neutral material which proved to be an ~1:1 mixture of **35** and **36**; ^{1}Hmr ($CDCl_3$) δ: 0.91 (d, J = 7 Hz, Me_2[CHCHOH] of **36**), 1.07 (d, J = 7 Hz, Me_2[CHC=O] of **35**), 4.63 (m, PhCH[OH] of **35**), 7.17–7.56 (m, ArH of **35** and *m*- + *p*-ArH of **36**), and 7.80–8.00 (m, *o*-ArH of **36**) ppm, no $COOCH_2CH_3$ absorption.

[8]Both ketols **7** and **8** were stable in this reagent at room temperature.

[9]Ketol **7** always gave a characteristic double glpc peak, the origin of which must lie in the ketol ring-chain tautomerism. However, ketol **8** gave only a single peak.

Kinetics and mechanism of the oxidation of cyclohexanone by a nickel(III) macrocyclic ligand complex in CH_3CN

WILLIAM A. WELSH,[1] JOHN OTUTAKOWSKI,[2] AND PATRICK M. HENRY

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received September 7, 1979[3]

WILLIAM A. WELSH, JOHN OTUTAKOWSKI, and PATRICK M. HENRY. Can. J. Chem. **59**, 697 (1981).

The oxidation of cyclohexanone by the Ni(III) complex of the macrocyclic ligand, 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane(meso-[14]ane) in acetonitrile solution containing CF_3CO_2H obeyed the rate equation: $-d[Ni(III)]/dt = k[Ni(III)][cyclohexanone]/[CF_3CO_2H]$. Kinetic and spectral studies in the presence of CF_3CO_2Na indicate the inhibition term in CF_3CO_2H is not due to complexation of trifluoroacetate but is a real acid inhibition term. The isotope effect, k_H/k_D using 2,2,6,6-tetradeuterocyclohexanone as substrate, was 3.2. The main product found in greater than 100% yield based on Ni(III) was the non-oxidative product, 2(cyclohexen-1-yl)cyclohexanone, which must have been formed in a radical chain reaction. A mechanism involving deprotonation of one of the coordinated nitrogens followed by rearrangement to a Ni(II) ligand radical intermediate is proposed. The ligand radical extracts a hydrogen from cyclohexanone to give [Ni(II)meso-[14]ane] and a cyclohexanone radical which initiates a radical chain reaction to give the observed dimeric product. Support for the mechanism is provided by recent studies of the base catalyzed decomposition of Ni(III) complexes in aqueous and non-aqueous solvents.

In the presence of CF_3CO_2Na, the Ni(III) complex decomposes rapidly even in the absence of cyclohexanone. This is believed to occur via trifluoroacetoxy radicals, a mechanism which has analogy in other systems.

WILLIAM A. WELSH, JOHN OTUTAKOWSKI et PATRICK M. HENRY. Can. J. Chem. **59**, 697 (1981).

L'oxydation de la cyclohexanone par le complexe de Ni(III) du ligand macrocyclique hexaméthyl-5,5,7,12,12,14 tétraaza-1,4,8,11 cyclotétradécane (mesoane-[14]) dans une solution d'acétonitrile contenant du CF_3CO_2H obéit à l'équation de vitesse: $-d[Ni(III)]/dt = k[Ni(III)][cyclohexanone]/[CF_3CO_2H]$. Des études spectrales et cinétiques en présence de CF_3CO_2Na indiquent que le facteur d'inhibition dans le CF_3CO_2H n'est pas dû à la complexation du trifluoroacétate, mais qu'il est un facteur réel d'inhibition acide. L'effet isotopique k_H/k_D mesuré sur la tétradeutéro-2,2,6,6 cyclohexanone est de 3,2. Le produit principal obtenu avec un rendement supérieur à 100% si l'on se base sur le Ni(III) est un produit qui ne provient pas d'une oxydation, soit la (cyclohexène-1 yl)-2 cyclohexanone, qui a dû se former au cours d'une réaction radicalaire en chaîne. On propose un mécanisme qui fait intervenir la déprotonation d'un des atomes d'azote coordonnés suivie de la transposition en un intermédiaire ligand radicalaire du Ni(II). Le ligand radicalaire arrache un atome d'hydrogène de la cyclohexanone et conduit au [Ni(II)mésoane[14]] et au radical cyclohexanone qui initie la réaction radicalaire en chaîne conduisant aux produits dimères. Ce mécanisme est confirmé par des études récentes sur la décomposition catalysée par une base de complexes de Ni(III) dans des solvants aqueux et non aqueux.

En présence de CF_3CO_2Na, le complexe de Ni(III) se décompose rapidement même en l'absence de cyclohexanone. On pense que cette décomposition a lieu par l'intermédiaire de radicaux fluoroacétoxy, un mécanisme que l'on retrouve dans d'autres systèmes.

Introduction

Although transition metal salts catalyze a number of organic oxidation reactions (1–4) there have been few studies on the use of macrocyclic complexes of transition metals for this purpose. In one study the Fe(II), Co(II), and Ni(II) complexes of the saturated Curtius macrocyclic ligand, 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane(meso-[14]ane), were tested as catalysts for the air oxidation of cyclohexene in acetonitrile (5). The Fe(II) compound was the most active catalyst with the Co(II) compound next and the Ni(II) compound practically inactive. In another study the iron complex of T1M (2,3,9,10-tetramethyl-1,4,8,11-tetraazacyclotetradeca-1,3,8,10-tetraene) was found to catalyze the light promoted oxidation of methanol (6).

In our own studies of the oxidation of organic compounds by iron complexes containing nitrogen donor atoms the question has arisen as to the mode of electron transfer from the organic to the metal oxidant (7–10). With coordinately saturated complexes such as tris(1,10-phenanthroline)iron(III) the electron transfer must occur via an outer sphere mechanism (7, 8). However, with macrocyclic complexes of iron the axial positions are labile so electron transfer could occur after coordination of the organic to the metal center or by transfer of the electron from the organic without prior coordination (9, 10). One intriguing possibility for the latter route is electron transfer of the electron through the nitrogen attached to the Fe(III). An iron(II)–ligand radical intermediate which abstracts a hydrogen from the organic is a likely mechanism. Such an

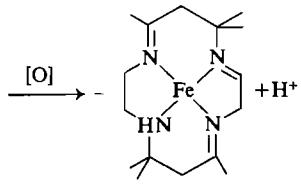
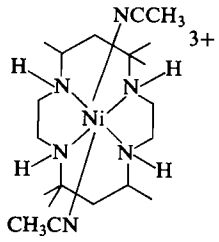
intermediate, **1**, has been suggested for the self-dehydrogenation of the iron(III) macrocyclic diene complex shown below in acetonitrile solution when water is added in the presence of molecular oxygen (11).

[1] 
1



In order to test the possibility of ligand radical intermediates such as **1**, it was decided to study the oxidation of organics by meso-[14]ane complex of Ni(III), **2**, in CH_3CN. **2** and other saturated macrocyclic ligand complexes have been shown to be true compounds of the Ni(III) oxidation state (12–14). Because of the high redox potential of the Ni(III)–Ni(II) couple (E_0 = ca. 1.0 vs. SHE in H_2O containing SO_4^{2-} (15)) this system should favour the ligand radical type intermediate in the oxidation of organics. This paper reports a study of the oxidation of cyclohexanone in acetonitrile by **2**.



2

After this work was begun Barefield and Mocella reported that the base catalyzed decomposition of the same complex proceeded via a Ni(II)–ligand radical (16). Later several Ni(III) macrocyclic complexes, including **2**, were generated by pulse radiolysis and their decomposition studied (17–20). Although there was some disagreement as to the actual identity of all species detected, an acid inhibition term in the decomposition of the Ni(III) complex was noted and attributed to the equilibrium given by [2], where N–H represents an amino group on the complex (17, 20).

[2] 
It was suggested (20)[4] that the deprotonated species rearranges to a ligand radical which decomposes by several routes including disproportionation

[3] 
to give the original complex and a complex with an additional imine group; abstraction of hydrogen from an H-donor; or ring fragmentation products.

Complexing in the axial positions with groups such as SO_4^{2-}, OH^-, and Br^- stabilized the Ni(III) complex (15, 17, 18). When Br^- is the ligating group decomposition occurs by formation of $Br^\cdot$ and the Ni(II) complex (17).

Experimental

General

Starting materials were of reagent or comparable grade. Freshly distilled cyclohexanone and CF_3CO_2H were used for the kinetic runs. The CH_3CN solvent was spectroquality and was dried over molecular sieves. The 2,2,6,6-tetradeuterocyclohexanone was prepared by equilibrating ordinary cyclohexanone with D_2O in the presence of a small amount of acid. The nmr spectra indicated that the 2,6 positions contained 95% deuterium. Air-sensitive reactions were carried out with oven-dried glassware using syringe techniques.

Proton nmr spectra were recorded on a Bruker WP-60. Infrared spectra were recorded on a Beckman IR5 while a Cary 118 was used for the visible–uv measurements. Gas chromatographic analyses were carried out with a Hewlett-Packard research chromatograph (model H.P. 5750B) using a 6 ft 20% carbowax 20M column on 60–80 mesh Chromosorb W. Temperature was 200°C and helium flow was 30 mL/min.

Syntheses

The $[Ni(meso\text{-}[14]ane)]^{2+}$ was prepared by reduction of the parent 4,11-diene complex using Raney nickel and base using the procedure described by Curtis (21). The rac and meso forms were then separated using sodium oxalate. The $[Ni(meso\text{-}[14]ane)(CH_3CN)_2](BF_4)_3$ was prepared by the procedure of Barefield and Mocella with the exception $NOBF_4$ was used in place of $NOClO_4$ (16).

Kinetic Runs

The rate of disappearance of the Ni(III) complex was followed by observing the disappearance of the band at 460 nm which is on the shoulder of a charge transfer band. This region of the spectrum is uncluttered by other reactant absorptions and the absorption due to the *d–d* transition of the Ni(II) complex at 460 nm was negligible. The only metal containing product found was the original $[Ni(meso\text{-}[14]ane)]^{2+}$ identified by its nmr spectrum (22). No attempt was made to detect free Ni(II) but the spectra of the final reaction solutions indicated the Ni(II) complex yield was essentially quantitative.

Runs were begun by adding cyclohexanone and/or

[4]Reference 20 proposes this step while ref. 16 does not consider the separate deprotonation equilibria given by [2]. Reference 17 does not consider the detailed pathways for decomposition of the deprotonated complex.

CF_3CO_2Na to a solution of the Ni(III) complex in CH_3CN thermostated at 25°C. If CF_3CO_2H is present it was added before the run was started. Good first order plots were obtained for at least two half-lines. Addition of $(CF_3CO)_2O$ to a run containing CF_3CO_2H in order to remove any water which might be present did not affect the rate.

Product Identification

In a typical run a mixture of 25 mL CH_3CN, 1 mL cyclohexanone, and 1.0 g of the Ni(III) complex were stirred for 45 min at which point the colour had changed from deep green to orange. The volume was reduced under vacuum at room temperature to ca. 10 mL. The solution was decanted from a pale green solid and 250 mL of ether was added. After standing in the refrigerator overnight the mixture was again filtered to remove more solid and the volume reduced at room temperature to 5 mL. Thin layer chromatography using CH_3CN as solvent on alumina indicated 3 or 4 minor products which moved with the solvent front and one major product which moved slowly. Gas chromatographic analysis gave only one large peak which had a retention time of about 30 min under the conditions used (see above). Several portions of the solution were injected and this peak was collected in melting point tubes. The nmr and infrared spectra were identical to those for an authentic sample of 2(cyclohexen-1-yl)cyclohexanone.

Control experiments were carried out by stirring 1 g of the Ni(II) complex, 25 mL CH_3CN, and 1 mL cyclohexanone overnight. After workup the concentrated reaction mixture was analysed by gc using the conditions described previously. No 2(cyclohexen-1-yl)cyclohexanone was detected.

Results

All kinetic and equilibrium studies were made at 25°C in dry acetonitrile solvent.

Kinetics

The kinetics were first determined in acid-free acetonitrile. The data are presented in Table 1. The fact that the value of k_2 calculated assuming the reaction is first order in each reactant is constant indicates the rate expression under these conditions is given by [4] with average value of 4.2×10^{-3} M^{-1} s^{-1} for k_2.

$$[4] \quad \text{Rate} = k_2[\mathbf{2}][\text{cyclohexanone}]$$

The average value of k_2 for the runs with 2,2,6,6-tetradeuterocyclohexanone is 1.3×10^{-3} M^{-1} s^{-1}. Thus the isotope effect k_H/k_D is 3.2.

Addition of trifluoroacetic or methanesulfonic acids caused a yellowing of the green solution and a lowering of the rate of cyclohexanone oxidation. The kinetics of the acid inhibition were studied using CF_3CO_2H. Results are listed in Table 2. A plot of k_2 vs. $1/[CF_3CO_2H]$ gives a linear plot with an intercept of zero and a slope of 1.24×10^{-5} s^{-1}. Thus the rate expression in the presence of CF_3CO_2H is given by [5] where k' is 1.24×10^{-5} s^{-1}.

$$[5] \quad \frac{-d[\mathbf{2}]}{dt} = \frac{k'[\mathbf{2}][\text{cyclohexanone}]}{[CF_3CO_2H]}$$

The effect of sodium trifluoroacetate on rates of oxidation of cyclohexanone was also studied. These systems did not give accurate results since the disappearance of the Ni(III) was only about 25% faster in the presence of cyclohexanone than it is in its absence. However, trifluoroacetic acid inhibited the rates of Ni(III) in both the presence and absence of cyclohexanone. Data are listed in Table 3.

Oxidation Products

Identification of oxidation products was not entirely successful. Thin layer chromatography indicated the presence of 3 or 4 minor products, none of which was 2-hydroxycyclohexanone, and one major product. The major product, present in greater than 100% yield based on Ni(III), was found to be 2(cyclohexen-1-yl)cyclohexanone but the minor products could not be separated and identified. The 2(cyclohexen-1-yl)cyclohexanone is not an actual oxidation product and could have been formed by an aldol condensation followed by

dehydration (23). However, control experiments with all reactants but the Ni(III) demonstrated that the aldol condensation does not occur under the reaction conditions.

Spectral Studies

In the absence of acid the Ni(III) macrocycle gave a spectra identical to that reported previously (12). The effect of CF_3CO_2H concentration on the spectra was studied in the range of $[CF_3CO_2H]$ used in the determination of acid dependence. Spectra are shown in Fig. 1. As the concentration of CF_3CO_2H increased the absorption in the 410 nm region decreased and the absorption in the 290 nm region increased giving an isosbestic point at 316 nm. The absorption due to CF_3CO_2H is observed at 210 nm. However the change in absorbancies is small and attempts to fit the data to reasonable equilibria using non-linear regression analysis gave no consistent sets of equilibrium constants.

The oxidation of cyclohexanone is also inhibited by methanesulfonic acid. However the changes in spectra upon addition of CH_3SO_3H were quite different from those obtained from the addition of CF_3CO_2H. The absorbance in both the 410 nm region and 325 nm region decreased with increase in absorbance at 280 nm and an isosbestic point at 299 nm.

The effect of added sodium trifluoroacetate on the spectra was also determined. Since the reduction of the Ni(III) was fast in the absence of CF_3CO_2H, some acid was also added. The spectra in the absence of acid, however, were qualitatively the same. Spectra are shown in Fig. 2.

Discussion

Before discussing possible mechanisms it is necessary to discuss the nature of the acid inhibition. It is possible that the acid itself is merely a source of trifluoroacetate ion which is coordinating to the Ni(III) and slowing the rate by lowering the redox potential (15, 17, 18). Thus the changes in spectra shown in Fig. 1 could result from ligation of trifluoroacetate although the changes could not be explained by any simple equilibria scheme. However, as shown in Fig. 2, addition of sodium trifluoroacetate changes the spectra considerably, suggesting that acid alone causes little complexing although the hump in spectra 5, in which there is only acid, suggests the possibility of some complexing. The fact that the spectra change little as the trifluoroacetate concentration increases indicates complexing is almost complete at the lowest $[CF_3CO_2Na]$.

The effect of sodium trifluoroacetate on rate is fairly definitive. The data are not very accurate because of the high rate of reduction of the Ni(III) complex in the absence of cyclohexanone. However the data in Table 3 indicate that both the trifluoroacetate and cyclohexanone induced re-

duction of Ni(III) are inhibited by acid. Thus the acid inhibition cannot be due to trifluoroacetate ligation since the acid inhibition would have disappeared if that were so.

In light of the recent work on the base catalysed decomposition of Ni(III) macrocycles (16–20) the results of the present work can best be explained by the following general mechanism.[5]

[6] $2 \underset{}{\overset{K_1}{\rightleftharpoons}}$  $+ H^+$

3

[7] $3 \overset{K_2}{\rightleftharpoons}$  $+ 2CH_3CN$

4

Organic products

Barefield and Mocella (16) proposed that one typical reaction of the radical, **4**, is hydrogen extraction from a H atom donor which in this case is cyclohexanone. The acid inhibition term in the rate expression indicates deprotonation of the ligand is a reversible process and the isotope effect with 2,2,6,6-tetradeuterocyclohexanone indicates [8] is the slow step. Thus radical formation ([7]) must also be an equilibrium process. This is the first evidence for the reversibility of ligand radical formation.

Although the general reaction scheme is consistent with the experimental results and previous work, the detailed pathways for some of the steps are not clearly defined. Thus the initial step of the organic reaction is written as H atom extraction to give the radical **5**. However another possibility involves electron transfer from the enol form of the ketone.

[9] 
7

Oxidation of cyclohexanone by one electron oxidants apparently usually proceeds the keto form although at least one such oxidant, tris(1,10-phenanthroline)iron(III) ($[Fe(III)phen_3]^{3+}$) which had been previously assumed to attack the keto form (24), has been shown to proceed via the enol tautomer (**7**). The probability of each path can be discussed in terms of the isotope effects.

There is little work on isotope effects in H extraction from C—H bonds by nitrogen radicals (25) but an isotope of k_H/k_D of 4 was reported for the extraction of benzylic hydrogens from toluene and

[5]The proton could also be lost from the nitrogen next to the carbon containing 2 methyl groups to give another isomer of **3**. Likewise the radical in **4** could, and very likely is, also on the other nitrogen. For simplicity only one isomer of **3** and **4** is shown.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

deuterated toluene by the dimethylamino radical (26) and a value, k_K/k_D, of 16 was found for extraction of H from cyclohexane and cyclohexane-d_8 by the 2,2,6,6-tetramethylpiperidyl radical (27). The latter value is probably high because of the hindered nature of the radical but the former falls in range (k_H/k_D = 2–7 for H extraction by carbon radicals (24, 25)). Thus the isotope effect of 3.2 found in the present study is in the expected range. It is even more difficult to predict the isotope effect on [9]. Since the reaction is first order in **2** the reaction of **2** with the enol would have to be rate determining and an equilibrium isotope effect for formation of the enol would be operative.[6] Since cleavage of O—H bonds has a higher isotope effect than cleavage of C—H bonds (28*a*), the isotope effect on k_{-1} would be greater than on k_1, and deuteration of the cyclohexanone would increase the content of enol and contribute to a negative isotope effect. Thus in the oxidation of cyclohexanone by $[Fe(III)phen_3]^{3+}$, a reaction known to proceed via the enol tautomer, a negative isotope effect, k_D/k_H of 2.7 was observed when the reaction was run in D_2O with non-deuterated cyclohexanone (7). The net isotope effect will depend on the value of k_H/k_D for k_2 which in turn will depend on whether the O—H bond is broken in the course of electron transfer of **4**. If it is broken the net isotope could easily be the 3.2. However if this bond is not broken a small or negative isotope effect would be expected. Previous work on the $[Fe(III)phen_3]^{3+}$ system mentioned above (7) suggested the O—H is not broken during electron transfer so the appreciable isotope effect of 3.2 would appear to favour [8].

[10] **6** + $Fe(III)(phen)_3$ + H_2O →  + $Fe(II)(phen)_3$ + H^+

The exact mode of oxidation of cyclohexanone is also not well defined. In the aqueous oxidation by $Fe(III)(phen)_3$ the only initial oxidation product is 2-hydroxycyclohexanone which must result from further oxidation of the initial radical by more $Fe(III)(phen)_3$ in the presence of water. In the present system the actual oxidation is overshadowed by a non-oxidative chain reaction to give 2-(cyclohexen-1-yl)cyclohexanone. One possible scheme is given below:

[11] **6** + 
Although radicals do not usually add to carbonyl compounds there are a few examples of addition (29–32), the closest analogy being the addition of cyclohexyl radicals to formaldehye to eventually give a product analogous to **7** (30).

The form of the acid inhibition in the rate expression deserves brief comment. If the acid base equilibrium in [5] is as written then a first order inhibition in $[CF_3CO_2H]$ would not be expected unless CF_3CO_2H is a strong acid in CH_3CN. If it is a weak acid the inhibition term would be a square root term since $[H^+] = \sqrt{CF_3CO_2H}\sqrt{K_a}$ where K_a is the acid dissociation constant of CF_3CO_2H in CH_3CN. Although the authors are aware of no determinations of the pK_a of CF_3CO_2H in CH_3CN, methanesulfonic acid, which is a stronger acid than CF_3CO_2H in water (28*b*), has a pK_a of 10 in CH_3CN (34). Thus CF_3CO_2H is almost certainly a weak acid in CH_3CN. The first order term means that the molecular acid rather than the free proton is causing the inhibition. This is not surprising for a non-hydroxylic solvent such as CH_3CN.

The rates in the presence of trifluoroacetate, shown in Table 3, are, as expected, lower than in the presence of acid alone because of change of redox potential by ligation (15, 17, 18). One curious result is the fact that at $[CF_3CO_2H] = 0.025\,M$ the values of blank and net k_{obs}'s increase little, if at all, with increase in $[CF_3CO_2Na]$ while at $[CF_3CO_2H] = 0.1\,M$, both increase almost linearly. However, detailed speculation in such a complicated system does not seem warranted.

The CF_3CO_2Na induced reduction of the Ni(III) complex probably involves electron transfer from a coordinated $CF_3CO_2^-$ to give a trifluoroacetate

[6]Of course if the reaction were run in a hydroxyl solvent such as water an equilibrium isotope effect would not be observed since the deuteriums would rapidly exchange with the protons of the solvent to produce non-deuterated cyclohexanone. However with CH_3CN as solvent no exchange can occur.

radical by a mechanism similar to that previously proposed for coordinated bromide (17).

The trifluoroacetate radical likely decomposes by decarboxylation to give the $CF_3\cdot$ radical, a reaction the acetoxy radical undergoes (35). The $CF_3\cdot$ can then extract hydrogen from solvent, cyclohexanone, or Ni(III) complex to give a variety of products.

[12] 
8

[13] 
Assuming that K_1 in [6] is small the rate expression for cyclohexanone oxidation is given by [14].

$$[14]\quad \text{Rate} = \frac{kK_1K_2[\mathbf{2}][\text{cyclohexanone}]}{[CF_3CO_2H](1 + K_2)}$$

The value of pK_1 in water has been estimated to be above 11 (17) and must be above 9 to explain the kinetic data (20). The value of pK_1 should be considerably higher in CH_3CN. Using the value of 10^{-11} for K_1 and the value of 1.24×10^{-5} for k' in [5] a value of $kK_2/(1 + K_2) \simeq 10^6$ can be calculated. There is little precedent on which to base an estimate of K_2 but for purposes of comparison it can be arbitrarily assigned a value of one. This gives a value of k in [8] of about 10^6. Dialkyl amino radicals have been reported to be poor H abstractors (26, 27, 33, 36, 37). However they undergo competitive decomposition reactions such as disproportionation very rapidly ($k \simeq 10^9\ M^{-1}\ s^{-1}$) so abstraction is masked. One case where the hydrogen abstraction rates have been measured is with the sterically hindered 2,2,6,6-tetramethylpiperidyl radical (27). With cyclohexane the second order rate constant for abstraction is $0.08\ M^{-1}\ s^{-1}$. Thus even taking into account the fact that this radical is hindered and cyclohexanone is probably more reactive than cyclohexane the value of $10^6\ M^{-1}\ s^{-1}$, which must be considered a minimum value, seems high. However **4** is likely to have very different reactivity from neutral organic nitrogen radicals. Thus it is possible it coordinates the organic substrate prior to electron transfer, thus making the reaction more facile. A study of the organic oxidation in aqueous solution using fast reaction techniques would probably provide further information on the detailed steps of the oxidation.

In spite of the uncertainties regarding detailed pathways this work does demonstrate that ligand radicals can be an important pathway in oxidation of organic compounds by macrocyclic ligand complexes.

^{13}C shieldings in *syn* and *anti* aldimines and ketimines

ROBERT R. FRASER, JACQUES BANVILLE, FUMINORI AKIYAMA, AND NOEMI CHUAQUI-OFFERMANNS
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received August 19, 1980

ROBERT R. FRASER, JACQUES BANVILLE, FUMINORI AKIYAMA, and NOEMI CHUAQUI-OFFERMANNS. Can. J. Chem. **59**, 705 (1981).

The ^{13}C chemical shifts in a variety of aldimines and in both acyclic and cyclic ketimines have been examined. A comparison of the shieldings at the α carbons in *syn* versus *anti* stereoisomers shows a consistent upfield shift of 8–11 ppm in the *syn* isomer. The greater magnitude found in imines vs. oximes or hydrazones is a clear indication of a steric origin for the differential shieldings. The shifts in the imines of cyclohexanones exhibited stereochemically dependent effects of methyl substitution, very similar to those in analogous oxime and hydrazone derivatives. Chemical shift differences in the *syn* isomers of the α-phenethylimines of chiral aldimines and ketimines allow a facile measurement of diastereomer ratios for such compounds.

ROBERT R. FRASER, JACQUES BANVILLE, FUMINORI AKIYAMA et NOEMI CHUAQUI-OFFERMANNS. Can. J. Chem. **59**, 705 (1981).

On a examiné les déplacements chimiques du ^{13}C de diverses aldimines et des cétimines acycliques et cycliques. En comparant le blindage au niveau des carbones en positions α des stéréoisomères *syn* et *anti*, on constante un déplacement vers les champs forts de 8–11 ppm en faveur de l'isomère *syn*. La valeur plus forte observée pour les imines par rapport à celle des oximes ou des hydrazones est une nette indication de l'origine stérique des blindages différentiels. Les déplacements observés dans les imines de cyclohexanones ont des effets qui dépendent stéréochimiquement de la substitution par les méthyles et qui sont très semblables à ceux des dérivés analogues d'oximes et d'hydrazones. Les différences de déplacement chimique des isomères *syn* des α-phénéthylimines d'aldimines et de cétimines chirales permettent de mesurer facilement les rapports de diastéréoisomères dans de tels composés.
[Traduit par le journal]

The ^{13}C spectral characteristics of aldehydes and ketones have been thoroughly studied (1, 2) and more recently many of their carbonyl derivatives including oximes (3–5), hydrazones (5, 6), and oxime ethers (6) have received considerable attention. Another class of nitrogen-containing carbonyl derivatives which has not been studied to any significant extent is the imines, data on only a few aryl (7) and a few *anti* aldimine derivatives (8) having been reported. During the course of our studies on the alkylation of ketimines (9, 10) and aldimines (11, 12) we have had the opportunity to record a large number of spectra of both the *syn* and *anti* isomers. In this paper we wish to describe the spectral characteristics of a number of representative examples in order to demonstrate the capability of ^{13}C nmr to reveal both configurational and conformational information for this class of compounds. In addition, the comparison of configurational effects with those previously observed in other species provides clear evidence for the dominance of steric factors in causing the large differential *syn–anti* shifts.

Experimental

The imines described herein have all been synthesized either from the parent ketone or aldehyde and amine or by alkylation of the lithiated intermediate. A typical procedure, the preparation of imine **34** and its *syn* alkylation product, **35**, follows.

A solution of 20 mmol of 4-*tert*-butylcyclohexanone in 15 mL of dry ether containing 8 g of 4A molecular sieves was treated with 30 mmol of isopropylamine. After stirring for 5 h the solution was filtered, the sieves washed with three 3-mL portions of ether, and the combined ether solutions concentrated. Bulb-to-bulb distillation of the residue gave an 82% yield of imine, **34**, bp 65–70°C (0.1 Torr). A solution of lithium diisopropylamide was prepared in a serum-capped flask under an atmosphere of nitrogen by the addition of 12.6 mmol of butyllithium (2 *M* in hexane, Alfa Inorganics) to 12.6 mmol of diisopropyl amine in 20 mL of dry tetrahydrofuran (THF) at −20°C. After stirring for 10 min 12 mmol of imine, **34**, was added. The resultant solution was stirred for 1 h at 25°C, cooled to −78°C, and then 12.6 mmol of methyl iodide was added. After stirring for 1 h the solvent was removed under reduced pressure at −20°C. The residue was extracted with ether and the ether extracts were washed with sodium carbonate (5%) and sodium chloride (5%) solutions, then dried. The residue after removal of solvent was dissolved in $CDCl_3$ (−20°C) and examined immediately by ^{13}C nmr at −20°C. The spectrum showed the product to consist of a 90:7:3 ratio of **35**:**36**:**37**. Hydrolysis of this mixture in 5 mL THF and 15 mL of 1 *M* oxalic acid for 1 h at 25°C gave, after extraction, drying, and distillation, a mixture of *cis* and *trans* 4-*tert*-butyl-2-methylcyclohexanone (13) in a ratio of 1:3. The yield was 81%.

Compounds **30** (14) and **31** (15) have been prepared previously. Compounds **32** and **33** were prepared by the method used to prepare **30** (14). Their proofs of structure rest with the method of preparation and their ^1H and ^{13}C nmr spectral properties.

The proof of structure for all the intermediate *syn* methylation products rests on (*a*) ^1H and ^{13}C spectra, (*b*) observed isomerization to the *anti* form which was synthesized independently, when possible, and (*c*) cleavage of the *anti* imine to the corresponding aldehyde or ketone of known structure as confirmed by ^1H nmr, ir, and vpc.

The chemical shifts in the ^{13}C spectra are reported in δ units (ppm from TMS) as measured on a Varian FT-80 nmr spectrometer (sweep width 4000 Hz, 8000 data points, acquisition time 1 s, pulse width 25°) operating at either 27°C or, for the purpose of observing the somewhat transient *syn* intermediate, at −20 to −40°C. The solvent used was normally $CDCl_3$ con-

taining 5 to 15% of residual THF. It was shown independently that the effect of adding 15% of THF to a chloroform solution of an imine resulted in less than 0.2 ppm change in any of the signals. The shift data are therefore reliable to better than 0.2 ppm. The assignments of signals were made on the basis of off-resonance decoupling experiments, known substituent effects, and, for the cyclohexanones reported in Table 4, in analogy with the closely related derivatives studied previously (6). Signals for carbons having the same multiplicity and differing by less than two ppm may therefore be of reverse assignment.

Results and Discussion

A. Acyclic Aldimines and Ketimines

Table 1 presents the chemical shift data for eleven aldimines and twelve ketimines. One important feature in the chemical shift data is particularly noteworthy. As previously observed (3–6) in oximes, oxime ethers, and hydrazones, there is a very pronounced upfield shift for a carbon *syn* to the *N*-substituent in comparison with the shift for the same carbon when *anti* (hereafter referred to as Δ_{sa}). Previously, upfield shifts have been attributed in the main to steric interactions although the possibility that the field effect of a polar N—OR or N—NR_2 group contributed to the shielding difference has frequently been proposed. In an interesting study of cyclic ketoximes, Geneste *et al.* (4) demonstrated a remarkable dependence of Δ_{sa} on

the dihedral angle between the αCH bond and the N—O bond. In assessing the role of the electric field effect these authors concluded that it makes a significant contribution along with steric factors. The magnitude of Δ_{sa} values which we have listed in Table 2 does not seem to be explicable on the basis of an electric field effect since the polarity of the N—C bond in all imines is the reverse of an NO bond, yet the Δ_{sa} values are invariably larger in the imines than in analogous oximes (3) or other derivatives (5, 6). Furthermore, there appears to be at least a trend for the larger Δ_{sa} values to appear in the sterically more congested cases, e.g. ketimines > aldimines and *N*-isopropyl > *N*-benzyl. In addition the well-documented 5 to 8 ppm high yield shift in *Z* versus *E* alkenes (16) cannot result from field effects.

B. Cyclic Ketimines

As already noted for the acyclic compounds, the data in Table 3 show much larger Δ_{sa} values for ketimines than for ketoximes (4) of the same ring size. For example, the respective Δ_{sa} values for the

TABLE 3. ^{13}C shifts in cyclic ketimines

[a] Not assigned.
[b] Not observed.

cyclopentanone derivatives are 8.6 vs. 3.5 and for the cyclohexanones 11.4 vs. 6.5. It is also interesting to note a parallel behavior for the shift of the methine carbon attached to nitrogen in that it shows a pronounced high field shift in **25** and **26** relative to **24**. This is also consistent with a reciprocal steric shielding effect on that carbon. Methyl substitution effects in the five-membered ring are consistent with those observed in cyclopentanone itself (2). The data for the endocyclic systems **30–33** appear unexceptional, resembling qualitatively those in cyclopentene, cyclohexene, and cycloheptene (1).

C. Cyclohexanone Imines, 34–44

The *N*-isopropyl imines of 4-*tert*-butylcyclohexanone and cyclohexanone and their monomethyl and dimethyl derivatives have been synthesized by a method which provides both the *syn* and *anti*-stereoisomers (8). Their ^{13}C chemical shifts have been measured and are presented in Table 4. We have previously described the ^{13}C shifts of methylation products for the oxime ethers and hydrazones of the same ketones (6) as well as of the structurally related *N*-nitrosopiperidines and 4-phenyl-*N*-nitrosopiperidines (17). The most notable feature of the data in Table 4 is that they reveal almost identical effects of methyl substitution in compounds **34** to **44** as those observed earlier for the oxime ethers and hydrazones of the same parent ketones, reflecting the same conformational properties for all three classes of carbonyl derivatives.

Thus the conformation of the potentially mobile *syn*-2-methylation compound **41** can be concluded to have the 2-methyl substituent axial (from the value of the shielding at C-4). The same conclusion applies to *cis*-2,6-dimethylcyclohexanone-*N*-isopropyl imine (i.e. only a diaxial arrangement of the two methyl groups can account for the shielding at C-4). By comparison, *anti*-2-methylcyclohexanone *N*-isopropyl imine appears to be an approximately equal blend of axial and equatorial conformers, while the *trans*-2,6-dimethyl derivative exists in the conformation having the *syn*-methyl axial and the *anti*-methyl equatorial. The steric factors responsible for these conformational properties are presumably the same as those discussed in detail in our two previous papers on the oxime ethers, hydrazones, and nitrosamines (6, 17).

D. Differential Shieldings on Diastereomeric α-Phenethyl Imines

In Table 1, entries for 5, 9, and 11 show how readily ^{13}C can detect the presence of two diastereomers in these *syn*-aldimines. The differences in chemical shifts for the two diastereomers are usually observable at those carbons closest to the site of steric compression. Thus the *anti*-isomers of the same aldimines showed either reduced or unobservable shielding differences. The same ability to observe separate signals in *syn*-2-substituted cyclohexanone-*N*-α-phenethyl imines is illustrated by entries **45**, **46**, and **47**, the assignment of stereochemistry for the two isomers being that earlier elucidated by the studies by Yamada and coworkers (18).

42[a]	42.1	35.3	23.6	27.8	26.9		17.6
43	30.3	31.5	15.2	31.9	40.3	18.9	20.7
44	30.8	33.1	20.0	36.5	35.9	16.7	17.4

[a]For **36**, **37**, and **42**, C-2 represents the carbon bearing the methyl group which is *anti* to the imine's alkyl group. In all other compounds C-2 is *syn*. The shifts for C-1 all fall in the range 170 to 175 while the *tert*-butyl signals appear at 32.2 ± 0.2 and 27.5 ± 0.3. *N*-isopropyl signals appear in the range 48.1–49.1 and 23.5 to 24.4.

The fact that the two diastereomers exhibit resolvable shift differences for those carbons close to or on the *N*-alkyl substituent makes ^{13}C a very convenient method of determining the ratio of diastereomers, which in turn will reflect the degree of asymmetric induction in the alkylation reaction (12). This use of ^{13}C for quantitative measurements assumes equal relaxation times for each pair of diastereomer signals.[1] To be sure that this is so, we have measured the peak height ratios using repetition rates of 1 and 10 s for three different diastereomeric mixtures and could detect less than a 5% difference in intensity ratios in every case. We can therefore be sure that the intensity ratio for a pair of signals representing the two diastereomers will have its accuracy determined by the S/N ratio unless this exceeds 20:1.

Differential capacity against electrode potential data are presented for the mercury/methanol interface for a variety of salts at 25°C and for $NaClO_4$ solutions as a function of temperature. Ionic specific adsorption from solutions of KF, $NaClO_4$, and $LiBF_4$ was shown to be absent on the basis of the usual criteria. The dielectric properties of the inner layer are discussed on the basis of the three-state model for solvent structure from which it is deduced that the majority of solvent molecules are adsorbed at mercury with their dipole vectors parallel to the interface. The deep minimum in inner layer differential capacity, which occurs at the same electrode charge density independent of the nature of the salt (-0.05 C m^{-2}), corresponds to conditions for which the surface concentrations of the minority components, dipoles oriented with the field or against it, are equal. The experimental temperature coefficient of the inner layer capacity is a maximum at this charge density in agreement with the predictions of the three-state model.

On présente des données de capacité différentielle versus potentiel d'électrode à l'interface mercure/méthanol pour divers sels à 25°C et pour des solutions de $NaClO_4$ à diverses températures. L'adsorption ionique spécifique à partir de solutions de KF, de $NaClO_4$ et de $LiBF_4$ est inexistante si on se base sur les critères usuels. On discute des propriétés diélectriques de la couche interne en s'appuyant sur un modèle de structure du solvant à trois états à partir duquel on déduit que la plupart des molécules du solvant sont adsorbées sur le mercure avec leurs dipoles orientés parallèlement à l'interface. La profondeur minimale de la capacité différentielle de la couche interne, qui se produit pour la même densité de charge à l'électrode indépendamment de la nature du sel ($-0{,}05$ C m^{-2}), correspond aux conditions pour lesquelles les concentrations de surface des composants secondaires (orientation des dipoles avec ou contre le champ) sont égales. Le coefficient expérimental de température de la capacité de la couche interne atteint son maximum pour cette densité de charge en accord avec les prévisions de la modèle de trois états.

Introduction

The differential capacity of the Hg/methanolic (MeOH) solution interface was studied by Grahame (1) who showed that capacity data obtained in the presence of KF could be analyzed on the basis of the dual capacitor model of the double layer with no evidence of ionic specific adsorption. Inner layer capacity curves in systems where specific adsorption is negligible all display a deep minimum at small negative charge densities, no other extrema being visible in the polarizable range even at lower temperatures (for a review, see ref. 2).

It was recently shown that the inner layer capacity against charge density curve for the Hg/MeOH interface can be successfully described on the basis of a three-state model which assumes that solvent molecules are not significantly associated at the surface (3). This model predicts that when the inner layer capacity curves exhibit a minimum, one should also observe maxima if the electrode can be polarized sufficiently far in the positive and negative directions from the minimum. Capacity maxima at positive charge densities have been observed for several aprotic solvents such as dimethylformamide (4), acetone (5), dimethylsulphoxide (6), and nitromethane (7); however, it is not clear whether these are due to solvent reorientation, anionic adsorption, or a combination of both phenomena (8).

The purpose of the present study was to obtain capacity data with a variety of electrolytes, the ions of which were anticipated to not adsorb strongly at mercury. The intention was also to extend the measurements as far as possible in the positive range to see whether a capacity maximum could indeed be observed. Finally, it was desirable to obtain inner layer capacity data as a function of temperature and to examine these data within the context of the three-state model (3).

Experimental

The differential capacity against electrode potential curves were measured at a frequency of 335 Hz on the ac bridge described previously (9) which was modified with operational amplifiers to provide potentiostatic control of the dropping mercury electrode (10). The potential of zero charge (pzc) was determined for each solution using a streaming mercury electrode in the absence of oxygen. All potentials were measured against a saturated KCl calomel refereńce electrode in methanol on a null voltameter of high input impedance with a precision of ± 0.1 mV. The reference electrode compartment was separated from the main body of the cell, the liquid junction being established in a solution wetted stopcock. The counter electrode was a cylinder of Pt (~3 cm^2 area) surrounding the dropping mercury elec-

trode. The whole cell was surrounded by an outer jacket through which methanol at a fixed temperature was pumped; the temperature of the methanol was established in Brinkman thermostat with a precision of ±0.2°.

Spectroscopic grade methanol was dried over 3 Å molecular sieves and distilled twice under a nitrogen atmosphere. The water content determined by Karl Fischer titration was ~0.01%. All salts were twice recrystallized, $NaClO_4$ from methanol, KF from triply distilled water, and $LiBF_4$ from acetone. The KF was dried in a Pt dish at very high temperatures. The other salts were dried at 100°C over P_2O_5 under vacuum. All measurements and solution preparation were carried out in a controlled atmosphere chamber under purified N_2. The solutions were deaerated with purified N_2 which had been presaturated with the vapour of the solution under study.

Results and Discussion

$NaClO_4$ as Electrolyte

Curves of differential capacity C against electrode potential E measured for $NaClO_4$ solutions in MeOH in the concentration range 0.01 to 0.2 mol dm^{-3} at 25°C are presented in Fig. 1. An inflection on the capacity curves is visible at the most positive potentials and a diffuse layer minimum, at the lower concentrations. The dependence of the pzc on salt concentration (Table 1) is rather small and within the limits expected because of the change in liquid junction potential between the main cell and reference electrode compartments. This result suggests that ionic specific adsorption is negligible at the pzc.

The presence of ionic specific adsorption was tested on the basis of plots of the reciprocal of the experimental capacity $1/C$ against the reciprocal of the diffuse layer capacity $1/C_d$ as estimated by the Gouy–Chapman model for constant electrode charge density σ and varying electrolyte concentration (11). These plots are linear with unit slope in the range $-0.04 \leq \sigma \leq 0.04$ C m^{-2}, suggesting that specific adsorption is absent. An adaptation of this plot at the pzc (12) involves plotting $1/C$ against the reciprocal of the square root of the electrolyte concentration $1/c^{1/2}$, the slope being $(RT/2F^2\varepsilon\varepsilon_0)^{1/2}$ according to the Gouy–Chapman model, where ε is the dielectric constant of the solvent, ε_0, the permittivity of free space, and the other symbols have their usual meaning. In the present case, when the electrolyte concentration is expressed in mol m^{-3}, the resulting straight line has a slope of 22.2 $mol^{1/2}$ $m^{1/2}$ F^{-1} corresponding to a solvent dielectric constant equal to 30.5. This value is somewhat smaller than that quoted for pure methanol (32.7) and may indicate some degree of dielectric saturation due to the electrolyte (13).

Esin and Markov plots were also constructed using the present data and values of activity coefficients reported elsewhere (14). Although this method of testing for ionic specific adsorption is not as sensitive as that discussed above, the plots have the appearance expected of a system without specific adsorption in the range $-0.15 \leq \sigma \leq 0.04$ C m^{-2} (Fig. 2). A similar conclusion was reached by Taraszewska (15) who attributed it to good solvation of the constituent ions in $NaClO_4$ by MeOH.

The Influence of the Counter Ion on the Inner Layer Capacity

In order to assess the influence of counter ion nature on the shape of the capacity against potential curves, measurements were also made with 0.1 M solutions of KF and $LiBF_4$ as electrolytes. The

present data for the KF system agree well with those obtained earlier by Grahame (1) who concluded that ionic specific adsorption was absent for this system in MeOH. On the basis of the results obtained (Fig. 3), it seems reasonable to assume that ionic specific adsorption is also not important for the $LiBF_4$ system. It is interesting to note that the minimum capacity (0.087 F m^{-2}) which occurs at negative potentials is independent of the nature of the electrolyte.

At more negative potentials, the capacity increases in the order

$$C(Li^+) < C(Na^+) < C(K^+)$$

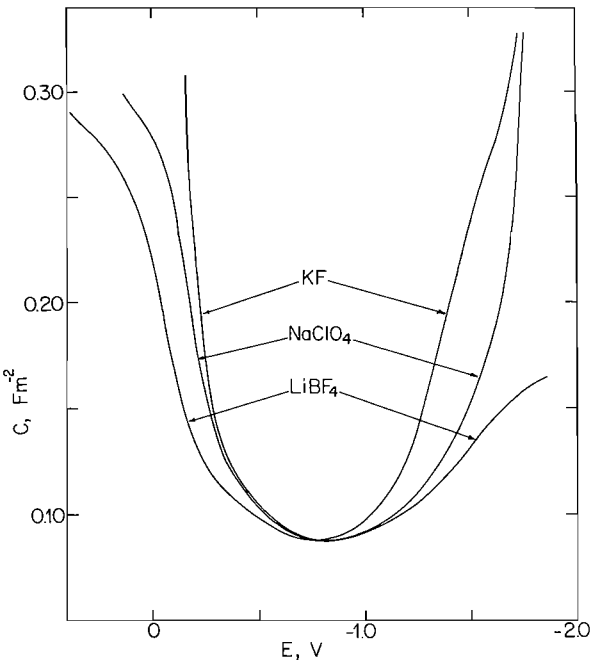

FIG. 3. Differential capacity C against electrode potential E for the Hg/methanol interface with 0.1 M solutions of KF, $NaClO_4$, and $LiBF_4$ as indicated.

Similar observations were made earlier for the alkali metal chlorides in methanol (16) and water (17) and for the alkali metal perchlorates in ethylene carbonate (9). This effect has been attributed to a corresponding decrease in the average thickness of the inner layer due to the generally recognized decrease in alkali metal cation solvation in the order (18)

$$Li^+ > Na^+ > K^+$$

On the other hand, it has also been explained by weak cation specific adsorption which cannot be detected on the basis of the usual criteria (19). A third explanation is that the dielectric constant of the inner layer is affected by the nature of the cation at the outer Helmholtz plane (oHp). This explanation is discussed in more detail below.

A marked dependence of the interfacial capacity on the nature of the anion is apparent at more positive potentials (Fig. 3). Comparison of inner layer capacity against charge density curves for KF, $NaClO_4$, $LiBF_4$, and KPF_6, calculated assuming that ionic specific adsorption is absent, reveals that C_i increases in the order

$$C_i(PF_6^-) < C_i(BF_4^-) < C_i(ClO_4^-) < C_i(F^-)$$

for positive values of σ. MeOH is one of the few non-aqueous solvents in which fluoride salts are soluble. The fact that the inner layer capacity is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

highest in the presence of this anion suggests that it may be weakly specifically adsorbed from methanol. The solvation of small non-polarizable anions like F^- depends greatly on hydrogen bonding which is much weaker in MeOH than in H_2O. The ordering of differential capacity observed for the other anions is similar to that observed in other solvents including dimethylsulphoxide (6), propylene carbonate (21), ethylene carbonate (9), acetone (5), and nitromethane (7). To the extent that these anions are not specifically adsorbed, the ordering of capacities can be attributed to variation in ionic size and the effects of the anions on dipole–dipole interactions in the solvent monolayer solvating the electrode.

The Temperature Dependence of the Inner Layer Capacity

The differential capacity of the Hg/MeOH interface was determined with 0.1 *M* $NaClO_4$ as electrolyte in the temperature range 0 to 54°C. Inner layer capacity against charge density curves estimated using the Gouy–Chapman model for the diffuse layer are shown in Fig. 4. The curves are characterized by a minimum whose position is independent of temperature at -0.05 C m^{-2}. The value of the capacity at the minimum increases with temperature, the temperature coefficient dC_i/dT being 1.5×10^{-4} F m^{-2} °C^{-1}. This result is similar to that obtained by Payne for NH_4NO_3 solutions in MeOH (2). At charge densities more negative than -0.1 C m^{-2}, C_i is approximately independent of temperature whereas at sufficiently positive values of σ, dC_i/dT becomes negative. At 0°C, a maximum is clearly visible on the inner layer capacity curve at 0.05 C m^{-2}, the position of the maximum shifting to higher charge densities with increase in temperature. Finally, at sufficiently far positive charge densities, the temperature coefficient of C_i falls to very low values. The variation in inner layer capacity with temperature is illustrated in Fig. 5 where the coefficient $d(1/C_i)/dT$ is plotted against electrode charge density. In assessing the data obtained here, it should be kept in mind that the observed temperature variation is considerably less than that obtained for the Hg/aqueous solution interface (22).

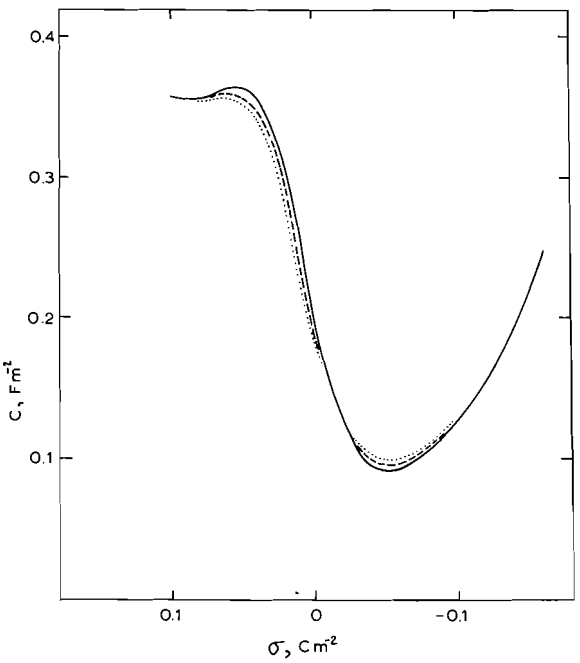

FIG. 4. Differential capacity of the inner layer C_i against electrode charge density σ for the Hg/methanol interface in the presence of $NaClO_4$ at three temperatures: (—) 0°C, (---) 25°C, and (· · ·) 54°C.

Molecular Models for the Dielectric Properties of the Inner Layer

A variety of models for the dielectric properties of the solvent in the inner layer have been developed in which the solvent is represented as a monolayer of dipolar spheres (23). Parsons (24) derived a four-state model for protic solvents in which molecular clusters are an important component of the monolayer. The four states considered are solvent monomers and clusters, each of which may occupy two positions with the dipole vector pointing towards ("up") or away from the metal electrode ("down"). When this model was used to describe the inner layer capacity data for the Hg/MeOH interface in the presence of KF (1), a good fit was obtained in the region of the minimum over a range of approximately 0.1 C m^{-2} but at more extreme positive and negative charge densities, the calculated curve lay above the experi-

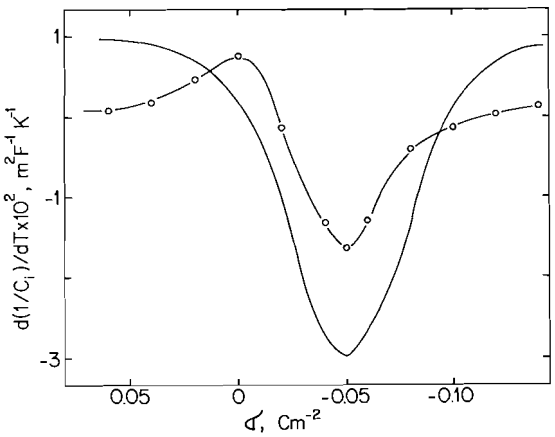

FIG. 5. The temperature coefficient $d(1/C_i)/dT$ against electrode charge density σ for the Hg/methanol interface in the presence of $NaClO_4$ (○) and according to the three-state model on the basis of the parameters for Na^+ (Table 3) (—).

mental points (25). Alternatively, a three-state model with solvent monomers having their dipole vectors in the "up" and "down" directions, and in a third direction with the vector "parallel" to the interface has been proposed for unassociated or weakly associated solvents in which molecular clusters are not an important component at the surface (3). This model is able to describe the same data over a wider range of electrode charge densities (~ 0.2 C m^{-2}); however, the calculated curve falls below the experimental points at positive charge densities (3, 23). In its simplest form, that is, when anisotropy of the polarizability is ignored, the three-state model predicts that the capacity curve is symmetrical with respect to the minimum value and that the minimum corresponds to the charge density where the surface concentrations of dipoles in the "up" and "down" orientations are equal.

Inner layer capacity curves for the three salts KF, $NaClO_4$, and $LiBF_4$ from which ionic specific adsorption was found to be either absent or negligible are presented in Fig. 6. It is readily apparent that one set of parameters is not able to describe any of the curves due to their lack of symmetry. Consideration of these data together with those

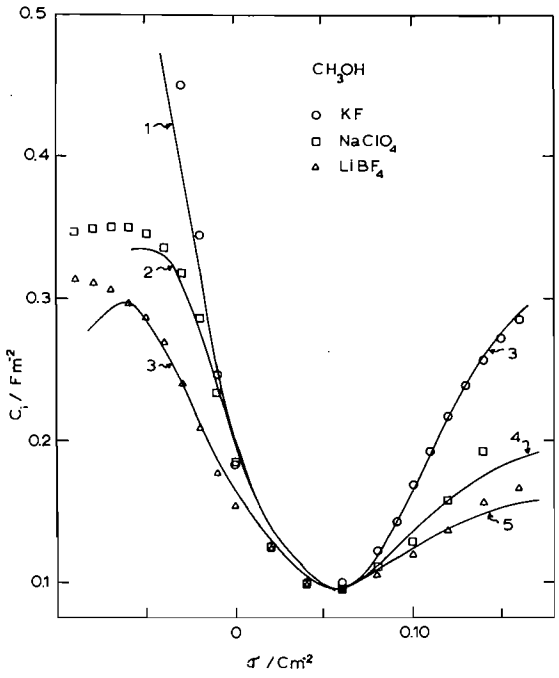

FIG. 6. Inner layer capacity C_i against electrode charge density σ for the Hg/methanol interface with KF (○), $NaClO_4$ (□), and $LiBF_4$ (△) as electrolytes. The curves *1–5* were calculated from the three-state model using the parameters summarized in Table 3. The curves are shown at charge densities positive or negative of the minimum on the curve, a point at which C_i is independent of the nature of the salt.

obtained in other solvents (2, 23, 26) suggests that one or more of the parameters characterizing the solvent molecules in the inner layer may depend on the nature of the counter ion at the oHp. One of these parameters is the effective thickness of the inner layer, d. Although the diameter of the solvent molecule represented as a sphere is a constant, the effective thickness depends on the size of the counter ion and the degree to which it retains its solvation sheath in the direction of the electrode/solution interface. Secondly, the effective coordination number c_e, which is very important in estimating the magnitude of the dipole–dipole interaction energy, may depend on the counter ion nature; since c_e is a reflection of the effectiveness of dipole imaging in the metal phase and the double layer beyond the initial monolayer which solvates the electrode, its value should depend on the "local" dielectric constant of the double layer which itself depends on the nature and concentration of ions at the oHp (27). Finally, it is interesting to note that the minimum value of C_i occurs at the same charge density for the three salts and that it is independent of the nature of the salt within experimental error.

Theoretical curves which best describe the experimental ones in regions positive and negative of the capacity minimum were constructed on the basis of the three-state model by varying d and c_e, the values of the dipole moment p (1.66 D) and polarizability (3.26×10^{-3} nm^3) being the experimental values reported in the literature (23). The equations defining the fractions of the surface covered by "up", "down", and "parallel" dipoles in the monolayer are (3)

$$[1] \quad f_1 + f_2 + f_3 = 1$$

$$[2] \quad kT \ln (f_1/f_2) = U_{20} - U_{10} - 2p(E + X)$$

and

$$[3] \quad kT \ln (f_1/f_3) = U_{30} - U_{10} - p(E + X)$$

f_1, f_2, and f_3 are the fractions of molecules in the "up", "down", and "parallel" orientations, respectively; U_{10}, U_{20}, and U_{30} are the corresponding residual energies; E is the field due to the charge on the electrode; and X is the reaction field at an average dipole due to surrounding dipoles. The reaction field is given by

$$[4] \quad X = c_e[p(f_1 - f_2) - \alpha E]/(d^3 + c_e\alpha)$$

Having assumed values for d and c_e these equations are solved for the fractions f_1, f_2, and f_3 and the potential drop across the monolayer $\Delta\phi$ is calculated:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

[5] $\Delta\phi = 4\pi\sigma d + (4\pi N_T d^3/c_e)X$

On differentiating eqs. [1]–[3] with respect to surface charge density, one obtains

[6] $x_1 + x_2 + x_3 = 0$

[7] $$kT\frac{x_1}{f_1} - kT\frac{x_2}{f_2} = -2p\left(4\pi + \frac{dX}{d\sigma}\right)$$

and

[8] $$kT\frac{x_1}{f_1} - kT\frac{x_3}{f_3} = -p\left(4\pi + \frac{dX}{d\sigma}\right)$$

where x_1, x_2, and x_3 are the derivatives $df_1/d\sigma$, $df_2/d\sigma$, and $df_3/d\sigma$, respectively, and

[9] $$\frac{dX}{d\sigma} = \frac{c_e}{(d^3 + c_e\alpha)}[p(x_1 - x_2) - 4\pi\alpha]$$

Having solved eqs. [6]–[8] for x_1, x_2, and x_3 the differential capacity of the inner layer is calculated according to the relationship

[10] $$\frac{1}{C_i} = \frac{d\Delta\phi}{d\sigma} = 4\pi d + \frac{4\pi N_T d^3}{c_e}\frac{dX}{d\sigma}$$

After choosing the parameters d and c_e, the residual energy differences, $U_{20} - U_{10}$ and $U_{30} - U_{10}$ were calculated from the experimental values of the charge density and inner layer capacity at the minimum on the capacity against charge density curve (3).

The theoretical curves generated for the negative segments of the inner layer capacity curves with Li^+, Na^+, and K^+ as counter ions, and for the positive segments with BF_4^-, F^-, and ClO_4^- as counter ions are shown in Fig. 6. The parameters chosen for each of these curves are summarized in Table 3. It is interesting to note that the assumed diameter of the methanol molecule represented as a sphere is constant for all of the curves except that with ClO_4^- as counter ion. The value chosen (0.335 nm) is reasonable on the basis of the Courtauld model for the molecule (23). As the effective coordination number c_e increases, the rate of increase of C_i from its minimum value decreases. If it is assumed that the distance of closest approach of the alkali metal cations is determined by their unsolvated radii, then the smallest cation, Li^+, would have the greatest influence on dipole orientation in the solvent monolayer. This is apparently reflected in the present model by an increase in the effective number of nearest neighbours for each dipole in the monolayer. The influence of anions is more difficult to assess since anion solvation reflects both ion–dipole interaction and hydrogen bonding in the case of methanol (20). In any case, the above analysis suggests that a more detailed model for the solvent monolayer should reflect the asymmetry in the capacity curves due to the influence of the counter ion at the oHp. Because of the variation in c_e and d with counter ion nature, the residual energy differences $U_{20} - U_{10}$ and $U_{30} - U_{10}$ also vary. The average value for $U_{20} - U_{10}$ is -17.4 kJ mol^{-1}; this reflects the fact that dipoles with their negative ends towards the metal are more stable than dipoles with positive orientation at the pzc. The average value for $U_{30} - U_{10}$ is -17.7 kJ mol^{-1}. Thus dipoles in the parallel orientation are the most stable at an uncharged surface and predominate in the monolayer over most of the polarizable range of the electrode (23). The average value of the surface potential ($\Delta\phi_0$ at the pzc) is -0.42 V. The assumption that minimum orientation in the monolayer occurs at negative charge densities which leads to the negative value of $\Delta\phi_0$ is supported by the observation that the maximum adsorption of aliphatic organic compounds occurs at a negatively charged Hg surface (28). It is also interesting to note that the surface potential at the methanol/air interface is negative (~ -0.2 V) (29).

TABLE 3. Parameters used in the three-state model to calculate inner layer capacity curves at the mercury/methanol interface in the presence of various counter ions

Curve*	Counter ion	Molecular diameter d (nm)	Effective coordination number, c_e
1	F^-	0.335	13.2
2	ClO_4^-	0.365	13.2
3	BF_4^-	0.335	13.95
	K^+		
4	Na^+	0.335	14.9
5	Li^+	0.335	15.5

*The integers in the table refer to the curves illustrated in Fig. 6. In all cases, the dipole moment of methanol was assumed to be 1.66 D (5.54×10^{-30} C m) and the polarizability, 3.26×10^{-3} nm^3.

According to the three-state model, the potential drop across the monolayer at the principal extremum is independent of temperature (4). If this feature of the theory is correct, one may estimate the temperature coefficient of the surface potential from the present data. Defining a rational potential scale with respect to the pzc, ϕ^m, the potential drop across the inner layer may be written as

[11] $\phi^m - \phi^d = \Delta\phi - \Delta\phi_0$

where ϕ^d is the potential drop across the diffuse layer and $\Delta\phi_0$, the potential drop across the solvent monolayer at the pzc. At the principal extremum, $d\Delta\phi_m/dT = 0$, and therefore

[12] $$\frac{d(\phi^m - \phi^d)_m}{dT} = -\frac{d\Delta\phi_0}{dT}$$

where the subscript m signifies the principal extremum. On the basis of the data obtained for the $NaClO_4$ system in MeOH, the value of $d\Delta\phi_0/dT$ is -0.2 mV K^{-1}. This value agrees well with those estimated on the basis of the temperature dependence of the potential of the pzc (14). The average value of $d\Delta\phi_0/dT$ estimated according to the three-state model on the basis of the parameters used to generate the curves in Fig. 6 is -0.12 mV K^{-1}. The sign of the temperature coefficient of the surface potential is easily explained on the basis of the three-state model. At the pzc, dipoles in the parallel orientation are the major component of the monolayer with the concentration of negatively oriented dipoles greater than that of positively oriented ones (3, 23). As the temperature increases, the number of dipoles in the parallel orientation decreases with a corresponding increase in the number of "down" (negatively oriented) dipoles.

It is also interesting to examine the predictions of the three-state model with respect to the temperature dependence of the inner-layer capacity. The variation in $d(1/C_i)/dT$ with electrode charge density on the basis of the parameters for Na^+ ion (Table 3) is illustrated in Fig. 5. The most striking feature of this curve is that a minimum in $d(1/C_i)/dT$ occurs at the same charge density where it is observed experimentally. The magnitude of the calculated coefficient is considerably greater than the experimental value at this extremum; however, the temperature dependence itself is small in comparison with the magnitude of the capacity. A maximum is observed on the experimental curve just positive of the principal extremum; on the other hand, the maximum on the calculated curve is much less pronounced and occurs at more positive charge densities. Because of the asymmetric character of the experimental capacity curves, it is clear that the simple three-state model cannot describe the temperature dependence of C_i in all its details. However, the fact that a minimum in $d(1/C_i)/dT$ is observed experimentally at the charge density where it is predicted to be according to the theory is striking.

The variation in the temperature coefficients of the inner layer capacity, potential drop, and free energy with temperature according to the three-state model is illustrated in Fig. 7 on the basis of the parameters for the Na^+ ion (Table 3). As pointed out above $d\Delta\phi/dT$ is zero at the principal extremum; it is also zero at charge densities corresponding to maxima on the calculated capacity curve. The potential drop $\Delta\phi$ cannot be measured experimentally. However, the temperature coefficient $d\Delta\phi/dT$ could be estimated on the basis

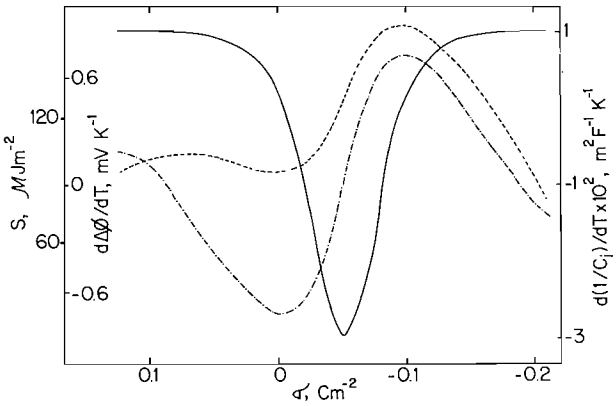

FIG. 7. Entropy of the solvent monolayer, S (---), and the temperature coefficients $d\Delta\phi/dT$ (- · · · -) and $d(1/C_i)/dT$ (—) as a function of electrode charge density σ according to the three-state model assuming $d = 0.335$ nm, $c_e = 14.9$, $p = 1.66$ D, and $\alpha = 3.26 \times 10^{-3}$ nm. The corresponding inner layer capacity is illustrated by curve *3* in Fig. 6.

of the temperature dependence of the potential drop across the inner layer, $\phi^m - \phi^d$, and the experimental estimate of $d\Delta\phi/dT$ at the pzc. The entropy of the monolayer obtained from the dependence of the free energy on temperature possesses a sharp maximum at charge densities negative of the principal extremum. The asymmetric nature of this curve is due to the fact that both the configurational entropy and dipole–dipole interaction energy are complex functions of the electrode field. This feature of the theory could be tested by studying the temperature dependence of the interfacial tension at the Hg/MeOH interface. Experiments to study this aspect of the Hg/non-aqueous solution interface are currently in progress.

In conclusion, the three-state model provides an acceptable description of the dielectric properties of the Hg/MeOH interface on the basis of available data. This model could be refined if some account is made of the effect of specific ions in the double layer on the thickness of the inner layer and on the magnitude of dipole–dipole interactions between solvent molecules which solvate the electrode. On the other hand, weak ionic specific adsorption is difficult to detect experimentally, and therefore, could account for part of the observed effect of specific ions. It is clear that an improved experimental technique for assessing ionic adsorption is required before the effect of ions on interfacial solvent structure can be asssessed further. It should be noted that in the three-state model it is not necessary to consider dipole–dipole interactions and the reaction field parallel to the electrode's field. Parsons has pointed out (30) that considerable ordering of dipole vectors parallel to the electrode is ex-

pected. In the case of methanol, hydrogen bonding would be expected to play a role in this ordering since in the "parallel" orientation the —OH bond is approximately parallel to the interface.

Kinetics of the oxidation of dimethyl sulfoxide with aqueous hydrogen peroxide catalyzed by sodium tungstate[1]

YOSHIRO OGATA[2] AND KAZUSHIGE TANAKA

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya, Japan

Received July 2, 1980

YOSHIRO OGATA and KAZUSHIGE TANAKA. Can. J. Chem. **59**, 718 (1981).

The oxidation of dimethyl sulfoxide (DMSO) by hydrogen peroxide in the presence of a catalytic amount of sodium tungstate (Na_2WO_4) has been studied kinetically by means of iodometry of hydrogen peroxide. The reaction is first-order with respect to the substrate and the catalyst, but independent of the concentration of hydrogen peroxide which is present in excess of the catalyst. The polarographic study implies that in solutions two main kinds of peroxytungstic acids (H_2WO_5 and H_2WO_8) are formed which contain active oxygen in ratios (active oxygen):(Na_2WO_4) of 1:1 and 4:1, respectively. The effect of acidity on the oxidation rate and a probable mechanism involving a rate-determining attack of peroxytungstic acids are discussed.

YOSHIRO OGATA et KAZUSHIGE TANAKA. Can. J. Chem. **59**, 718 (1981).

Faisant appel à l'iodométrie du peroxyde d'hydrogène, on a étudié l'oxydation du diméthylsulfoxyde (DMSO) par le peroxyde d'hydrogène, en présence d'une quantité catalytique de tungstate de sodium (Na_2WO_4). La réaction est du premier ordre par rapport au substrat et au catalyseur, mais elle est indépendante de la concentration du peroxyde d'hydrogène qui est en excès par rapport au catalyseur. Les études polarographiques indiquent qu'il se forme en solution deux types principaux d'acides peroxytungstiques (H_2WO_5 et H_2WO_8) qui contiennent respectivement des rapports d'oxygène actif (oxygène actif) (Na_2WO_4) de 1:1 et 4:1. On discute de l'effet de l'acidité sur la vitesse d'oxydation ainsi que d'une mécanisme probable faisant intervenir l'attaque des acides peroxytungstiques dans l'étape déterminante.

[Traduit par le journal]

Introduction

It is well known that molybdic and tungstic acids are converted to peroxy acids on treatment with aqueous hydrogen peroxide. Kinetic studies on the tungstic acid-catalyzed epoxidation of allyl alcohol (1) and fumaric acid (2) with H_2O_2 have been reported. However, details of the structure and behavior of peroxytungstic acid remain equivocal. The present paper describes the rate data, the effect of acidity, and a probable mechanism of the Na_2WO_4-catalyzed oxidation of DMSO by hydrogen peroxide in aqueous buffers.

Results and Discussion

Polarography

Before carrying out the kinetic studies, we intended to clarify the constituents of a mixture of sodium tungstate and hydrogen peroxide in an acetate buffer (pH 4.0) by the polarographic method (3). Firstly, the dependence of the kinetic current[3] of peroxytungstates upon reaction time was studied with an equimolar (each 2×10^{-3} *M*) mixture of Na_2WO_4 and H_2O_2 in the acetate buffer at 25°C. Although the decomposition of H_2O_2 in the presence of Na_2WO_4 at pH over 4.0 was appreciable in the kinetics as shown later, this effect is negligible in the polarography, since H_2O_2 decomposition is slow at pH 4.0–5.1 and H_2O_2 concentrations in the polarography are smaller than those in the kinetic study. The result is shown in Fig. 1. The observed kinetic current is a measure for the concentration of peroxytungstates (probably Na_2WO_5 and Na_2WO_8). The kinetic current at pH 4.0 increases with time and after ca. 3 h it reaches a constant value, 2.98 μA/m*M*.

[1] $\mathrm{ST} \overset{H_2O_2}{\rightleftharpoons} \mathrm{PeT}$

[2] $\mathrm{PT} \underset{a}{\overset{H_2O_2}{\rightleftharpoons}} \mathrm{PePT} \xrightarrow[b]{} \mathrm{PeT}$

This phenomenon suggests that depolymerization of peroxypolytungstates (PePT) is slow (step *b* in reaction [2]). Even if concentration of H_2O_2 is increased to four times that of Na_2WO_4, the kinetic current at pH 4.0 reaches a constant value, 8.87 μA/m*M*, only after ca. 2.5 h. But at pH 5.1, the

[1]Contribution No. 273.

[2]To whom all correspondence should be addressed.

[3]The kinetic current is the current produced by the reduction of peroxy compound which is continuously reformed at the surface of the cathode. For simplification, we considered only WO_4^{2-} and WO_5^{2-} as shown in the following reactions.

$$WO_4^{2-} + H_2O_2 \rightarrow WO_5^{2-} + H_2O$$
$$WO_5^{2-} + 2H^+ + 2e \rightarrow WO_4^{2-} + H_2O$$

Since the kinetic current is proportional to the concentration of peroxy compound, the concentration of H_2O_2 which reacted with the tungstate can be measured from the ratio of $[H_2O_2]_0/[Na_2WO_4]_0$ at inflection, thus the structure of the peroxide can be deduced.

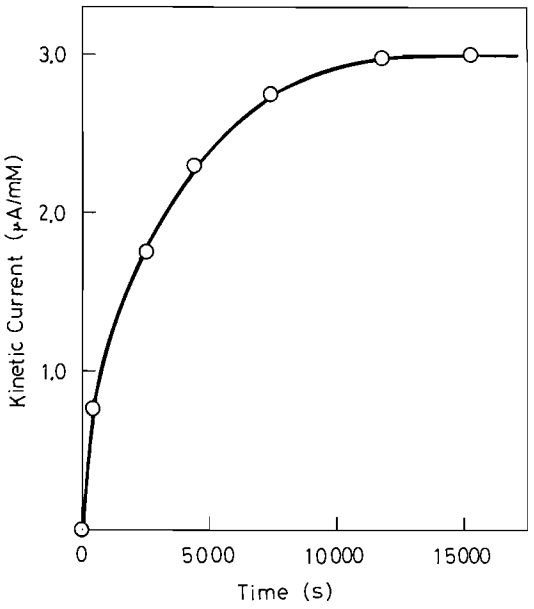

FIG. 1. The kinetic current of peroxytungstates in an acetate buffer (pH 4.0) at 25°C as a function of time. $[Na_2WO_4]_0 = [H_2O_2] = 2 \times 10^{-3}$ *M*.

kinetic current of a Na_2WO_4–H_2O_2 equimolar mixture (each 2×10^{-3} *M*) reaches a value of 3.63 μA/m*M* immediately and does not increase with time, which is ascribed to the absence of polytungstates (PT). Simple tungstate (ST) is totally converted immediately to peroxytungstates (PeT) (eq. [1]). Tungstate (WO_4^{2-}) has a tendency to polymerize to $[HW_6O_{21}]^{5-}$ and $[(HW_6O_{20})_n]^{3n-}$ with decreasing pH at 5.5–3.5 (4) and PT reacts rapidly with H_2O_2 (step *a* in reaction [2]) in view of our kinetic study as shown later, so that the above phenomena suggest that step *b* in reaction [2] is slower than reaction [1] at pH 4.0–3.5. Accordingly, reactions [1] and [2] occur simultaneously at pH 4.0, while only reaction [1] occurs at pH 5.1. Thus the rate of formation of PeT from PePT at pH 4.0 was rather slow; hence most of the kinetic current measurements by means of polarography were made after standing at 25°C for 4 h.

Some workers (1, 2, 5) have reported on the structures of peroxytungstic acids, but their structures are still ambiguous. Hence, the dependence of the kinetic current of PeT at various ratios of $[H_2O_2]_0/[Na_2WO_4]_0$ was studied (Fig. 2). The current is proportional to concentrations of PeT, e.g., 2.94 μA/m*M* with an equimolar (each 2×10^{-3} *M*) mixture. As seen in Fig. 2, the kinetic current increases with the ratio $[H_2O_2]_0/[Na_2WO_4]_0$ until the ratio reaches 4:1 and there is also an inflection at the ratio of 1:1. These results suggest that there are two

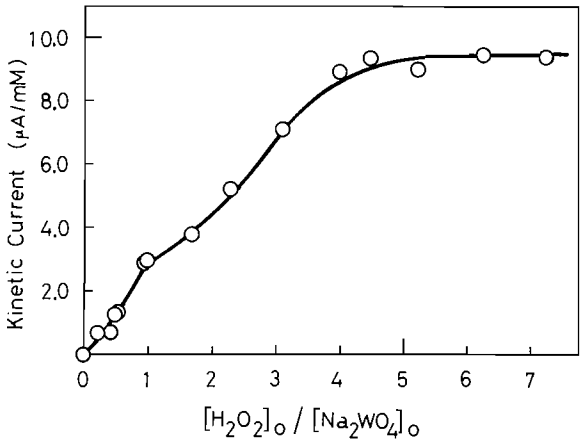

FIG. 2. The kinetic current of peroxytungstates in an acetate buffer (pH 4.0) at 25°C as a function of $[H_2O_2]_0/[Na_2WO_4]_0$.

principal PeT, presumably Na_2WO_5 and Na_2WO_8, whereas little Na_2WO_6 and Na_2WO_7 exist, if any, since there are no inflections at the ratio $[H_2O_2]_0/[Na_2WO_4]_0$ of 2:1 and 3:1. Though Richardson (5) postulated that an H_2O_2–H_2WO_4 mixture in the molar ratio of 4:1 contains polymeric acid $H_2W_2O_{15}$ besides H_2WO_8, $H_2W_2O_{15}$ does not seem to exist, because the second-order rate constant does not decrease with increasing concentration of tungstate as shown in our kinetics.

Kinetics

The kinetics of the oxidation of DMSO in a mixture of Na_2WO_4 and H_2O_2 were measured iodometrically in aqueous buffers of various pH values. Since the decomposition of H_2O_2 in the presence of Na_2WO_4 at pH over 4.0 was appreciable, the rate of oxidation of DMSO was calculated by subtracting the rate of the decomposition of H_2O_2 from the measured rate. The decomposition rate was faster than the oxidation rate at pH values greater than 7, thus the kinetics at these pH values were not reliable.

The rate thus corrected is first-order with respect to DMSO and the catalyst, but independent of the concentration of hydrogen peroxide which is present in excess of the catalyst (Table 1). Accordingly, the rate equation is expressed as:

$$v = k_2 w[\text{DMSO}]$$

Here w is the initial stoichiometric concentration of sodium tungstate and k_2 the second-order rate constant. Also, the rate calculated by the decrease of [DMSO] using nmr gave the same expression and analogous rate constant, e.g., 3.24×10^{-2} M^{-1} s^{-1} with 1×10^{-3} *M* Na_2WO_4 and 3.0×10^{-2} *M*

TABLE 1. Rate data[a] for the Na_2WO_4-catalyzed oxidation of DMSO with aqueous H_2O_2 at pH 4.0 (AcOH–AcONa) at 25°C

Initial concentration × 10^3 M			
$[Na_2WO_4]_0$	$[H_2O_2]_0$	$[DMSO]_0$	$k_2 \times 10^2$ M^{-1} s^{-1}
2.0	35.6	15.0	2.84
2.0	34.9	20.0	2.55
2.0	36.6	25.0	2.71
2.0	36.0	30.0	2.62
2.0	35.2	35.0	2.87
2.0	50.4	25.0	2.57
2.0	39.2	25.0	2.68
2.0	19.2	25.0	2.58
2.0	10.9	25.0	2.86
1.6	44.2	25.0	2.85
1.0	47.3	25.0	2.74
1.0	32.0	25.0	2.67
1.0	19.7	25.0	2.35

[a] $v = k_2[Na_2WO_4]_0[DMSO]$; rates were derived by subtracting the rate of the decomposition of H_2O_2 from the measured rate. The reaction was started by addition of DMSO to a Na_2WO_4–H_2O_2 mixture which was kept standing for 4 h.

H_2O_2 at pH 4.0, although the constancy of k_2 is rather poor.

The above rate data suggest that H_2O_2 alone cannot oxidize DMSO directly under these conditions. Actually, H_2O_2 (2.95×10^{-2} M) and DMSO (2.50×10^{-2} M) do not react at 25°C in the absence of tungstate. Hence H_2O_2 should oxidize tungstic acid to peroxytungstic acids which react with DMSO in a rate-determining step. If the oxidation of tungstic acid to peroxytungstic acids determined the rate, then the rate of DMSO oxidation would be proportional to $w[H_2O_2]$ and independent of [DMSO]. Also the polyperoxytungstic acids (PPeT),[4] which has been postulated by Richardson, should exist only in small amounts, if any, under these conditions in view of the rate data, because the rate constants change little with changing concentration of Na_2WO_4 while holding the concentrations of DMSO and H_2O_2 constant; e.g., at 2.50×10^{-2} M DMSO, k_2 values were 2.35×10^{-2} M^{-1} s^{-1} with 1×10^{-3} M Na_2WO_4 and 1.97×10^{-2} M H_2O_2 and 2.58×10^{-2} M^{-1} s^{-1} with 2×10^{-3} M Na_2WO_4 and 1.92×10^{-2} M H_2O_2. PPeT should have less reactivity than simple PeT because of their lower content of active oxygen and their coiled structure.

The above kinetic results seem to be in conflict, since the reaction of Na_2WO_4 with H_2O_2 was rather slow at pH 4.0 on the basis of our polarographic studies. But this apparent slow formation of PeT at pH 4.0 may be due to the slow depolymerization of PePT. Tungstate reacts with H_2O_2 rapidly at pH 5.1, where PT and hence PePT hardly exist as is obvious in the polarography. Csányi (6) reported that no peroxypolymolybdate, but only monomeric dihydroperoxy-1-molybdate $MoO_2(OOH)(OO^-)$, was formed when H_2O_2 was added to polymolybdate. However, in the case of tungstate, PePT may be formed very rapidly from PT, since the oxidation rate constants for the reaction of DMSO with a Na_2WO_4–H_2O_2 mixture kept standing for only 2 min were similar (slightly smaller) to those for 4 h, e.g., k_2 values were 2.67×10^{-2} M^{-1} s^{-1} with a 4 h Na_2WO_4–H_2O_2 mixture and 2.46×10^{-2} M^{-1} s^{-1} with a 2 min Na_2WO_4–H_2O_2 mixture. These results imply that Na_2WO_5, Na_2WO_8, and PePT are formed immediately after mixing Na_2WO_4 with aqueous H_2O_2 in an acetate buffer (at pH 4.0) and PePT are gradually converted into Na_2WO_5 and Na_2WO_8. Furthermore, the oxidation rate of Na_2WO_8 may be slightly faster than that of Na_2WO_5 because of the higher electrophilicity of Na_2WO_8, while the oxidation rate per unit tungsten of PePT may be slightly lower than that of Na_2WO_5 because of the steric hindrance. But the difference between their rates seems to be small, since the rate constants for a Na_2WO_4–H_2O_2 mixture at 2 min are similar to those at 4 h.

Effect of Acidity

The effect of acidity of the solution on the second-order rate constant k_2 is shown in Fig. 3. The decrease of k_2 at high acidity (at $-H_0 > 1.5$) may be ascribed to the protonation of DMSO, forming $(CH_3)_2SOH^+$, in view of the observed partial protonation of DMSO in concentrated H_2SO_4

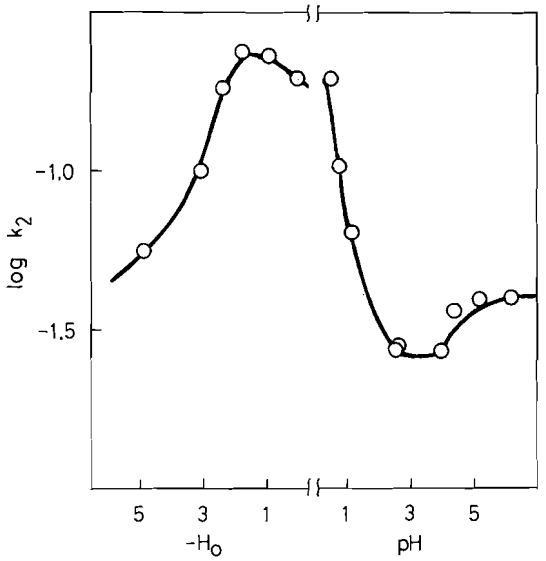

FIG. 3. Effect of acidity of solution on the second-order rate constant k_2 for the H_2O_2 oxidation of DMSO at 25°C. $[Na_2WO_4]_0 = 1 \times 10^{-3}$ M, $[H_2O_2]_0 = 3.0 \times 10^{-2}$ M, $[DMSO]_0 = 2.5 \times 10^{-2}$ M.

[4] PPeT are polymers of peroxytungstates, while PePT are peroxides of polytungstates.

(7). Since the oxidation by peracids involves an electrophilic attack, the reaction is inhibited by the protonation of substrate. The observed decrease of the rate constant with increasing pH at 0–2.5 suggests that the oxidation is retarded by increasing concentration of the anions (T—OO^-) of the peroxytungstic acids (T—OOH), since there are two distinct active species, i.e., T—OOH at pH < 0 and T—OO^- at pH > 2.5, where T—OOH means H_2WO_5 and H_2WO_8, etc. The curve is similar to that observed in Na_2MoO_4-catalyzed oxidation of DMSO by H_2O_2.[5] Both H_2WO_5 and H_2WO_8 may be main attacking species[6] for this oxidation. The free acids T—OOH should be more active than T—OO^-. The above reasoning assumes that the first ionization of peroxytungstic acids occurs at pH 0–2.5, because the second ionization constant for H_2WO_8 measured by Dedman by a direct and reliable way using pH and spectrophotometric measurements was 1.4×10^{-7} mol L^{-1} at 0.056 *M* H_2O_2 (8), and also the first ionization constant of peroxymolybdate H_2MoO_6, which gave a log k_2: pH curve analogous to that of peroxytungstic acids,[5] was reported to be 3×10^{-3} mol L^{-1} and its second ionization constant 7×10^{-10} mol L^{-1} (6). On the other hand, Raciszewski (1) assumed on the basis of his kinetics of allyl alcohol that the first ionization constant of H_2WO_5 was 4.5×10^{-7} mol L^{-1}, but his value, which was estimated by the acidity effect, is ambiguous as to whether it is the first or second ionization constant.

The observed minimum of log k_2 at pH ca. 4 may be explained by the polymerization of tungstate WO_4^{2-}, which has a tendency (4) to polymerize with decreasing pH at 5.5–3.0. This tendency toward polymerization is supported by our polarographic studies, in which the kinetic current of a Na_2WO_4–H_2O_2 mixture at pH 5.1 does not increase with time, while the current at pH 4.0 increases with time as stated above. These results suggest that PT may be present at pH 4.0. Since PePT seems to exist, as stated in the discussion of the kinetics, the stoichiometric initial concentration at pH 4.0 of tungstate is approximately expressed as:

$$w \cong [HWO_5^-] + [HWO_8^-] + [PT] + [PePT] + [HWO_4^-]$$

[PT] and $[HWO_4^-]$ can be neglected, assuming that PT and HWO_4^- react with H_2O_2 rapidly and completely to form their peroxides as described above; hence

$$[3] \quad w \cong [HWO_5^-] + [HWO_8^-] + [PePT]$$

Since [PePT] decreases with increasing pH at 5.5–3.5 because of the decrease of PT and thus the content of $[HWO_8^-]$ increases with pH, the rate increases with increasing pH.

Mechanism

These facts suggest the following mechanism for the oxidation at pH 3.5–5.0.

$$[4] \quad Na_2WO_4 \overset{\text{fast}}{\rightleftharpoons} 2Na^+ + WO_4^{2-}$$

$$[5] \quad WO_4^{2-} + H_2O \overset{\text{fast}}{\rightleftharpoons} HWO_4^- + OH^-$$

$$[6] \quad (a+b)HWO_4^- + (a+4b)H_2O_2 \overset{\text{fast}}{\rightleftharpoons} aHWO_5^- + bHWO_8^- + (a+4b)H_2O$$

$$[7] \quad HWO_5^- + (CH_3)_2SO \xrightarrow[k_1]{\text{slow}} (CH_3)_2SO_2 + HWO_4^-$$

$$[8] \quad HWO_8^- + (CH_3)_2SO \xrightarrow[k_2]{\text{slow}} (CH_3)_2SO_2 + HWO_7^-$$

$$[9] \quad HWO_7^- + H_2O_2 \overset{\text{fast}}{\rightleftharpoons} HWO_8^- + H_2O$$

In aqueous solution of pH 4.0, WO_4^{2-} is converted mostly into HWO_4^- (reaction [5]).[7] This acid anion reacts rapidly with H_2O_2 to give HWO_5^- and HWO_8^- (reaction [6]); PT also reacts with H_2O_2 to give PePT, which depolymerizes slowly in the presence of H_2O_2 to give HWO_5^- and HWO_8^-, as stated in the polarographic study. Since there is no polarographic evidence for the presence of HWO_7^- which contains active oxygen in a ratio (active oxygen):(Na_2WO_4) = 3:1, HWO_7^- may be unstable, changing rapidly to HWO_8^- by H_2O_2 (reaction [9]).

Thus the rate is expressed as

$$v = \{k_1[HWO_5^-] + k_2[HWO_8^-] + k_3[PePT]\}[DMSO]$$

Here k_1, k_2, and k_3 represent the rate constants of HWO_5^-, HWO_8^-, and PePT, respectively. Assuming $k_1 \cong k_2 \cong k_3$ as stated above

$$v \cong k_2\{[HWO_5^-] + [HWO_8^-] + [PePT]\}[DMSO]$$

or

$$v = k_2 w[DMSO]$$

This expression is consistent with the experimental results, and supports the mechanism.

Experimental

Materials

DMSO was purified by vacuum distillation (bp 86°C, 21 mm). Sodium tungstate was of commercial guaranteed reagent grade.

[5]This work was carried out in part by Mr. H. Shimizu, Nagoya University, 1979.

[6]PeT with the ratio of (active oxygen):$(Na_2WO_4)_t$ = 2:1 (i.e., H_2WO_6 or $H_2W_2O_{11}$) was reported to be formed in strong acid solutions (9), but PeT with ratio $[H_2O_2]_0$:$[Na_2WO_4]_0$ of 2:1 was not observed in our polarography at pH 4.0, hence they would be unstable, their concentrations being negligible.

[7]Dissociation constant for HWO_4^- (pK_2) is 6.9 (2).

Product

Oxidation of DMSO gave dimethyl sulfone ($DMSO_2$) in 91.5% isolated yield, when a mixture of DMSO (1×10^{-2} *M*), H_2O_2 (1×10^{-2} *M*), and Na_2WO_4 (1×10^{-3} *M*) was reacted at 25°C for 24 h in an acetate buffer (pH 4.0).

Polarography

The kinetic current was determined by the method described by Kolthoff (3), and measured with a Na_2WO_4–H_2O_2 system to obtain information on active species in the Na_2WO_4-catalyzed oxidation by H_2O_2. A mixture of Na_2WO_4 and H_2O_2 in an acetate buffer (pH 4.0) was kept standing at 25°C for 4 h, and then aliquots were taken out and analyzed on a Yanagimoto Model P8-D and P8-PT of direct polarography.

Kinetics

A mixture of Na_2WO_4 and H_2O_2 in an acetate buffer was kept standing at 25°C for 4 h (or 2 min in some cases), then the reaction was started by addition of DMSO. Aliquots (each 5 mL) were taken out at appropriate intervals of time, and their peroxide contents were determined iodometrically. The concentrations of DMSO were calculated from peroxide concentrations, since the oxidation product of DMSO was only dimethyl sulfone. At higher pH, where the marked decomposition of H_2O_2 was observed, the rate of oxidation of DMSO was corrected by subtracting the rate of the decomposition of H_2O_2 from the measured rate. In order to follow the rate of consumption of DMSO by nmr (δ 3.2) the oxidation was conducted at pH 4.0. The reaction was quenched by addition of aqueous $Na_2S_2O_3$ for nmr analysis.

The effect of acidity on the oxidation rate was studied in aqueous media using acetate – acetic acid buffers at pH 3.2–6.2, acetate – hydrochloric acid buffers at pH 0.8–3.2, and sulfuric acid at pH below 0.8.

Received June 23, 1980

ALEX D. BAIN, JACQUES BORNAIS, and SYDNEY BROWNSTEIN. Can. J. Chem. **59**, 723 (1981).

Analysis of the free induction decays from 90°–90° two-dimensional homonuclear pulse sequences gives complete spectral information from each transition in the f_2 dimension. Theoretical intensities and frequencies are illustrated for the common cases AX, A_2X, AMX, A_2X_2, AA'XX', and A_2X_3 along with experimental examples of each. An analysis of intensities is given. From these examples it should be possible to determine chemical shift and spin-coupling values even when many lines in the f_2 dimension are obscured by other spectral features.

ALEX D. BAIN, JACQUES BORNAIS et SYDNEY BROWNSTEIN. Can. J. Chem. **59**, 723 (1981).

L'analyse des désintégrations par induction libre obtenues à partir de séquences pulsées homonucléaires bi-dimensionnelles 90°–90° fournit une information spectrale complète de chaque état de transition dans la dimension f_2. On a illustré les intensités théoriques et les fréquences dans les cas usuels: AX, A_2X, AMX, AA', XX' et A_2X_3 de concert avec des exemples expérimentaux de chacun d'eux. On donne une analyse des intensités. A partir de ces exemples, il devrait être possible de déterminer les déplacements chimiques et les valeurs du couplage de spin même quand plusieurs pics de la dimension f_2 sont masqués par d'autres caractéristiques spectrales.

[Traduit par le journal]

Introduction

Two-dimensional homonuclear nmr spectroscopy is now well established as a technique for the nmr spectroscopist (1, 2). The basic principle is that we allow a spin system to evolve for some time t_1 before collecting the free induction decay (FID). Fourier transformation of the FID gives a spectrum whose frequency scale is conventionally called f_2. The experiment is repeated for a series of values of t_1, so that Fourier transformation of each point in the spectrum with respect to t_1 yields a second frequency dimension f_1. Our purpose here is to explore some of the details of chemical shift-correlated two-dimensional spin echo nmr spectroscopy (3, 4), which is closely related to the SECSY technique (5).

The most common pulse sequence used on homonuclear systems is the 90°–t_1/2–180°–t_1/2–FID sequence which spreads homonuclear couplings out in f_1 (1) while not affecting chemical shifts or heteronuclear couplings (6). This can help untangle complicated spectra with overlapped multiplets, but no new information is contained in such a spectrum.

By changing the second pulse in the sequence to a 90° pulse we can also discover the connectivity of the spin system. Any line in the 1D spectrum represents a transition of a particular nucleus. In the 90°–t_1/2–180°–t_1/2–FID sequence the f_1 spectrum of that transition shows only a single line (although the data are often "tilted" to collect members of a multiplet along one axis (7)). In the 90°–t_1/2–90°–t_1/2–FID experiment, the f_1 spectrum of a transition contains several lines. There are lines due not only to other members of the multiplet but also lines due to other nuclei that cause the spin–spin splitting. Therefore the f_1 spectrum corresponding to this transition is essentially a copy of the subspectrum to which the transition belongs. This allows us to obtain relative chemical shifts of nuclei which are coupled and hence the connectivity.

The price to be paid for this information is that the f_1 frequency range must be larger so that either more data must be collected or the digital resolution must be sacrificed. The original 90°–t_1–90°–FID (2) sequence produced a copy of the subspectrum in f_1 for each line in the 1D spectrum but required an f_1 sweep width equal to that in f_2. Changing the sequence to 90°–t_1/2–90°–t_1/2–FID produces two copies of the subspectrum in f_1 called the additive and subtractive spectrum (3) with the important feature that the subtractive spectrum is based at zero frequency in f_1. The additive spectrum is suppressed by the SECSY pulse sequence (5) so that the f_1 range needed is determined by the largest

chemical shift difference which can lead to substantial savings in digitization.

In this paper we apply the 90°–t_1/2–90°–t_1/2–FID sequence to most spin systems of common interest to the chemist. We analyse the positions and intensities of the lines in f_1 so that more complex spectra, beyond the reach of normal techniques, may be analysed using 2D nmr.

Line Intensities in Homonuclear 2D nmr

Unlike normal nmr, the relative line intensities in two-dimensional nmr are quite sensitive to experimental parameters; two major ones are the homogeneity of the static magnetic field and the flip angle of the second pulse. Field homogeneity is important because the experiment relies on the transfer of x–y magnetization at time t_1 after it has been created. Dephasing during t_1 decreases this magnetization and leads to broader and less intense lines in f_1, an effect which is only partly counteracted by the formation of a spin echo (8, 9). Since field inhomogeneities are not reproducible, no explicit formula can be given but, generally speaking, lines with higher f_1 frequencies will be most strongly affected. Furthermore, lines that are close together in f_1 are affected to a similar extent by this mechanism.

Within a multiplet, the intensity ratios familiar from 1D nmr are less frequently seen in 2D nmr. For a given transition of a particular nucleus, the f_1 spectrum contains two types of lines. The first type is lines that are due to the mixing of the given transition with other transitions of the same nucleus. For these lines in f_1 the intensities are "normal" when exact 90° pulses are used in the absolute value display, doublets have two equally intense lines, triplets are in the ratio 1:2:1, and quartets are in the ratio 1:3:3:1. The second type of line is that which arises from the mixing of the given transition with transitions of other nuclei, i.e. when coherence has been transferred between nuclei. In this case, for exact 90° pulses, the absolute value display gives doublets with two equally intense lines but triplets have their central lines missing and quartets appear in the ratio 1:1:1:1. These intensities are characteristic of coherence transfer (10, 11).

All these intensities are distorted if the second pulse is not exactly 90°, although these distortions can be suppressed by cycling the phase of pulses (12). By a generalization of the superspin description of 2D nmr (11, 13) we can derive an explicit formula for the flip angle dependence for the lines in the 2D spectrum of a weakly coupled system subjected to a 90°–t_1/2–α–t_1/2–FID experiment.

The magnetization corresponding to each line in the spectrum is represented by a vector in Liouville space which has the following form (14)

$$[1] \quad x = \mu\sqrt{n}|1^s_{+1}, 1) \sum_M f_{M,l}|M_0, l)$$

The notation used is as follows. The quantity μ^3 is the transition moment of the line (13) whose square is proportional to the normal intensity of the line. We assume that the transition belongs to a group of n equivalent spins, which are represented by the Liouville space ket $|1^s_{+1}, 1)$. The sum

$$\sum_M f_{M,l}|M_0, l)$$

characterizes the spins coupled to the group that we are observing. For instance, $n = 2$ for the components of the quartet part of the proton spectrum of an ethyl group, and

$$\sum_M f_{M,l}|M_0, l)$$

characterizes the spin combination of protons in the methyl group corresponding to each component. These coefficients, μ and $f_{M,l}$ are given in Tables 1 and 2 of ref. 14.

The transition defined by eq. [1] can mix, in either an additive or subtractive fashion, with itself, with another transition of the same nucleus, or with a transition of a different nucleus that is connected by scalar coupling to the nucleus we are considering. By the method in ref. 11 it can be shown that the intensity of the line in f_1, due to mixing of the transition in eq. [1] with another transition of the same nucleus (denoted by primes), is given by eq. [2a] and [2b]

$$[2a] \quad \text{subtractive intensity} = n\,\mu\mu'\,d^1_{1-1}(\alpha) \times \sum_M f_{Ml}\,f'_{Ml}\,d^M_{00}(\alpha)$$

$$[2b] \quad \text{additive intensity} = n\,\mu\mu'\,d^1_{11}(\alpha) \times \sum_M f_{Ml}\,f'_{Ml}\,d^M_{00}(\alpha)$$

where the $d^M_{mn}(\alpha)$ are Wigner matrix elements. In this case, they are simple; $d^1_{1-1}(\alpha) = (\sin^2\alpha/2)$, $d^1_{11}(\alpha) = (\cos^2\alpha/2)$ and $d^M_{00}(\alpha) = P_M(\cos\alpha)$, the Mth order Legendre polynomial, where α is the flip angle. Therefore for additive and subtractive mixing within the same multiplet, the dependence on flip angle is a sum of Legendre polynomials. For $\alpha = 90°$, all these formulae give "normal" intensities,

[3]The transition moment μ (13) is referred to in earlier work (14) as $-C_{1,1}$. Equations [7] and [8] in (14) are, respectively, missing factors of $\sqrt{m}$ and $\sqrt{n}$.

triplets have intensities in the ratio 1:2:1, etc. For larger flip angles, one peak becomes dominant (the only one that remains for $\alpha = 180°$) (3) and for small flip angles it is relatively less intense. Also, for $\alpha = 180°$, the additive spectrum disappears because $(\cos^2 \alpha/2) = 0$.

When the transition we are considering turns up in the f_1 spectrum of a line belonging to another nucleus, then coherence transfer (10, 11) has occurred. This happens via a particular part of the density matrix that is shared by the two nuclei (11) and gives "anomalous" intensities. The general formulae for the intensity in the subtractive and additive spectra are

$$[3a] \quad \text{subtractive intensity} = \mu\,\mu'\sqrt{n'}\sqrt{n}\, d^1_{10}(\alpha) \times d^1_{0-1}(\alpha)\, f_{1,1}\, f'_{1,1}$$

$$[3b] \quad \text{additive intensity} = \mu\,\mu'\sqrt{n'}\sqrt{n}\, d^1_{10}(\alpha) \times d^1_{01}(\alpha)\, f_{1,1}\, f'_{1,1}$$

In this case, $d^1_{10}(\alpha) = d^1_{0-1}(\alpha) = -d^1_{01}(\alpha) = -(\sin \alpha/\sqrt{2})$ and the coefficients $f_{1,1}$ are obtained from Table 2 of ref. 12. The flip angle dependence is simple; they are proportional to $(\sin^2 \alpha)/2$, which can be factored into $(\sin^2 \alpha/2)(1 + \cos \alpha) = (\sin^2 \alpha/2)(1 + P_1)$ or into $(\cos^2 \alpha/2)(1 - P_1)$. For $\alpha = 90°$, these formulae give the "anomalous" intensities: in the absolute value mode, doublets look normal, triplets have their central line missing, and quartets appear as four equally intense lines. This is illustrated in Fig. 1, where the subtractive part of the 2D ^{1}H nmr spectrum of an ethyl group subjected to a $90°$–$t_1/2$–$90°$–$t_1/2$–FID experiment is schematically illustrated. The symmetry of these intensities is a reflection of the symmetry of eqs. [2] and [3]. For instance, the two blocks in Fig. 1 which represent lines due to coherence transfer between nuclei are identical except in position. The central lines of the triplet are missing from the f_1 spectra of the quartet, and the f_1 spectrum of the central line of the triplet shows no quartet lines. These theoretical intensities are to be compared with the observed intensities in Fig. 2 where both the additive and subtractive lines are shown. Fig. 2*a* includes the slice along f_1 of the fourth column in Fig. 1, and 2*b* the fifth column. As the flip angle of the second pulse is increased, the intensity of the lines in f_1 due to coherence transfer decreases until it vanishes at 180°. Table 1 gives the explicit formulae for the full flip angle dependence in the AX system.

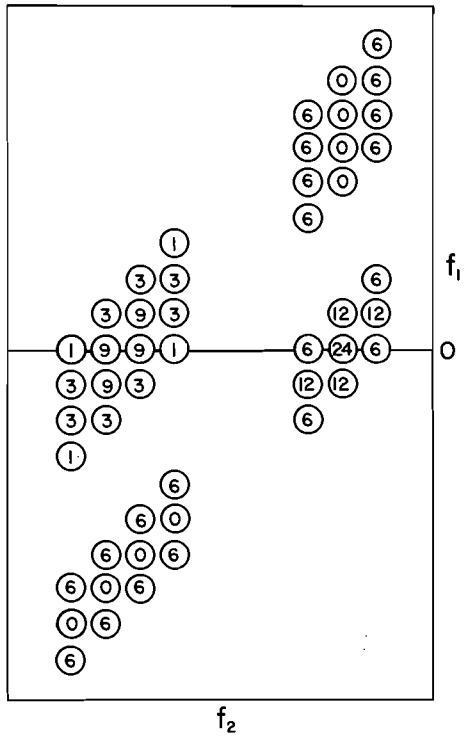

FIG. 1. Schematic plot of the subtractive part of a 2D nmr spectrum of an ethyl group subjected to the $90°$–$t_1/2$–$90°$–$t_1/2$–FID experiment. Circles represent line positions and the numbers represent intensities in the absolute value mode.

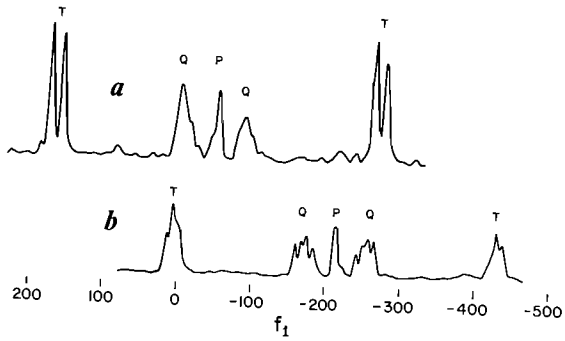

FIG. 2. Traces in f_1 space for the system ethylbromide. Lines Q arise from the quartet, lines T from the triplet, and lines P are phantom; (*a*) transition $\omega_A - 3J/2$; (*b*) transition $\omega_X + J$. The vertical scales in (*a*) and (*b*) are different.

Experimental

Samples were prepared by dissolving the compounds in deuterochloroform or dimethylsulfoxide without any precautions. Spin echo FID's were accumulated at room temperature for ^{1}H at 100.1 MHz on a Varian XL-100 spectrometer equipped with a Nicolet TT100 Fourier Transform System and a Nicolet 1180 computer. Peak positions in f_2 are relative to the carrier frequency and are not referenced to a chemical standard. A 90° pulse required 10 μs. The pulse sequence used was $90°$–$t_1/2$–$90°$–$t_1/2$–FID, with all timing under software control. Quadrature phase detection (QPD) was employed with the carrier in the center of the lines of interest in each case except vinyl acetate and the results of Fig. 2. For the vinyl acetate sample the carrier was placed to the low frequency side of the AMX system

[a]Where $P = \cos \alpha$.

to prevent folding into the spectral region of the signal from the methyl protons. For Fig. 2 it was important to ensure that the phase alteration scheme of our QPD software would not perturb line intensities. Spectral widths and the number of data points were varied for optimum presentation of the spectra within the limits imposed by the memory size of the magnetic disk system. When QPD was employed the spectral width would be slightly greater than the total spread of the lines in f_2. Without QPD it would be twice this value. The bandwidth of the receiver was adjusted by a filter to equal or slightly exceed the spectral width. The magnitudes of the increments in t_1 were chosen to give a sufficient spectral width in f_1 space to prevent folding of the signals in every case except vinyl acetate. Normally 256 increments were used, frequently followed by zero filling to improve the fineness of digitization. The FID data were collected and processed using Nicolet software. The fineness of digitization, Hz per data point, in the f_2 and f_1 dimensions respectively, are for the systems AX 0.31 and 0.20, for A_2X 0.23 and 0.25, for AMX 0.78 and 1.95, for A_2X_2 0.39 and 0.65, for AA'XX' 0.049 and 0.39, and for A_2X_3 0.49 and 1.95. The line widths are unlikely to be less than three times these numbers. Narrower lines could be obtained by finer digitization. All frequencies are in Hz.

Results

Calculated and observed peak positions in f_1 space, along with the expression for the calculation of peak positions, are presented for each transition in f_2 space in the tables. Frequencies in f_1, obtained directly from the traces, have been doubled to compare them with those calculated from f_2 values. Tables 2, 3, 4, 6, and 7 are deposited as unpublished data[4] and Table 5 is included herein as an example of the agreement between calculated and observed frequencies. It also indicates, by transition, the lines expected to have zero intensity for the A_2X_2 system. Table 2 is for the AX system of the aromatic protons of 3-bromo-4,5-dimethoxybenzoic acid dissolved in deuterodimethylsulfoxide. All 36 predicted signals are observed. The average deviation between observed and calculated frequencies is 0.24 Hz in a total spectral range of 35.97 Hz. For each of the four transitions the central signal is taken to be 0.00 Hz.

Table 3 has the results for the A_2X system of the aromatic protons of 2,6-dimethylaniline. Forty of the 47 signals with non-zero intensity are observed with an average deviation of 0.88 Hz in a range of 83.01 Hz. The lines in f_2 are perturbed from the ideal A_2X system since the ratio J/δ is rather large and also because of small couplings to the methyl protons. These effects are minor compared to the coarseness of digitization.

In Table 4, for the AMX system of the olefinic protons of vinyl acetate, 255 of a possible 300 signals are observed with an average deviation of 5.1 Hz in 1009.8 Hz. Similarly Table 5 for the A_2X_2 system of methoxyethylacetate lists 57 of 58 possible values with an average deviation of 0.6 Hz in a range of 149.8 Hz. Table 6 lists the theoretical and experimental values for the A_2X_3 system of ethyl bromide. Of the 89 possible lines 79 are observed with an average deviation of 0.7 Hz in a range of 394.9 Hz. There are 16 prominent lines in the nor-

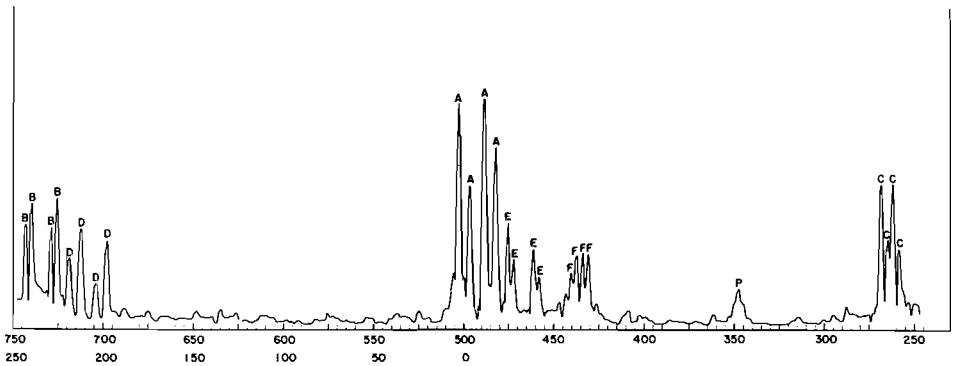

FIG. 3. The traces in f_1 space for the transition ($\omega_A - JA/2 - JX/2$) from the two dimensional proton spectrum of vinylacetate.

mal proton spectrum of *o*-dichlorobenzene, an AA'XX' system. This should give a total of 528 signals in the two-dimensional spectrum. The entire spectrum was recorded but only those lines corresponding to the 1st, 5th, and 11th lines, from the high frequency end, were analyzed. These were analyzed for the subtractive components to give 48 possible signals of which 34 were observed with an average deviation of 0.8 Hz in a range of 56.6 Hz. The results are listed in Table 7.

Discussion

In each of the six different types of nuclear spin systems investigated it is possible to explain all the observations by a relatively simple procedure (3). The frequency of each line in f_2 space is assigned as its separation from the carrier, due regard being taken of sign. For a given transition in f_2 space the line positions in f_1 space are given by the difference (subtractive) and sum (additive) of the frequency of that transition with the frequencies of all the other transitions in f_2 space. In addition there is one line (phantom) whose position in f_1 space is equal to the frequency of the transition in f_2 space. As a result a 1D spectrum containing N lines in a coupled spin system may yield up to $N(2N + 1)$ lines in the two-dimensional spectrum.

As an example of this analysis the trace in f_1 space for the transition ($\omega_A - JA/2 - JX/2$) is shown in Fig. 3. Since the lines for the three nuclear species A, M, and X are well separated compared to the coupling constants, groups of four closely spaced lines are observed for the subtraction or addition of the frequencies around that of A, M, or X. Two sets (additive and subtractive) for each of the three nuclei give six groups of four lines each. These groups are labelled A to F in the figure. In addition the phantom line, labelled P, is also observed. Groups C to F are folded and the frequency scale in Fig. 3 is also folded.

When the frequency of a line in f_1 space is greater than the spectral width used in that dimension there is folding back into the spectrum in the same manner as is found in one-dimensional Fourier Transform nmr. Although this folding can normally be identified it is preferable to avoid folding and therefore minimize the danger of overlap. At the same time it is desirable to use as small a spectral width as possible in f_1 space so that fine digitization may be employed without an excessive number of increments to t_1. The minimum spectral width in f_1 space is required when the carrier frequency is set in the center of the spectral region containing the signals of interest. This necessitates the use of QPD for the spectrometer. A consequence of obtaining the two-dimensional spectrum with quadrature phase detection and with the carrier in the center of the spectral region is a characteristic appearance for the spectrum. The lines to high frequency of the carrier in f_2 space will primarily also be to positive frequency in f_1 space. Under these conditions the phantom lines can be clearly distinguished about halfway between the subtractive and additive lines. This is illustrated in Fig. 4 for the proton resonance spectrum of ethyl bromide. Despite the absolute nature of the line positions when QPD is employed, no additional spectral information may be obtained. It has been shown that the lines in f_1 space from the additive spectra may be removed by the appropriate phase angle changes of the transmitter along with additive and subtractive accumulation of the FID's (5). There is some similarity between this sequence and that normally employed to remove instrumental imbalance during quadrature phase detection. It therefore follows that QPD is not necessarily "transparent" in two-dimensional nmr experiments. This is illustrated in Table 8 where the additive spectrum is more intense without QPD and with a smaller carrier offset. When employing QPD, additional weak lines are sometimes observed in f_1 space on both sides of zero at multiples of the offset frequency.

[a]For the methylene protons of 2-methoxyethyl acetate.
[b]These lines should have zero intensity.

In the first five spin systems illustrated it is possible to assign an explicit transition to each line observed in the one-dimensional spectrum. In these cases the theory is straightforward for calculation of the line positions in f_1 space (3). For the spin system AA′XX′ of *ortho*-dichlorobenzene it is not possible to describe all the lines explicitly (15). Nevertheless it is proven by this work that the approach of taking frequency differences between line positions in the one-dimensional spectrum, as dictated by theory, adequately predicts the line positions in f_1 space. Some lines in these cases may have zero intensity. It is to be noted that for this system only subtractive lines were observed.

The chief sources of error in obtaining line positions in f_1 space appears to be due to errors in timing and incrementing the t_1 intervals, and coarseness of digitization. The first error can be partially corrected by assigning a frequency of 0.0 to the zero position line and adjusting the values for

the other lines according to their deviation from the actual zero. This procedure was employed in the present investigation. It is not adequate when employed for folded lines.

It is clear from the present studies that all the information in the spectrum is contained in f_1 space for each transition in f_2 space as previously illustrated for an AX system (3). Although the intensities are often distorted, the causes of these distortions are understood.

Received July 10, 1980

HUSSEIN S. EL-KASHEF, REFAT ABDEL-HAMIDE, MOHAMED R. MAHMOUD, and MAHER M. HAMED. Can. J. Chem. **59**, 731 (1981).

The pK values of some 2-styryl-4-phenylthiazole ethiodide derivatives in different organic solvent – water mixtures were determined. It is observed that as the amount of the organic solvent in the medium increases the pK of the dimethylamino derivative is decreased while that of the hydroxy derivatives is increased. It is concluded that the major important effects responsible for this behaviour are the difference in the stabilization of the base by dispersion forces in case of the amino derivative and by donor hydrogen bonds from solvent molecules in the case of the hydroxy derivatives. The effect of the molecular structure of the compound on pK is also discussed.

HUSSEIN S. EL-KASHEF, REFAT ABDEL-HAMIDE, MOHAMED R. MAHMOUD et MAHER M. HAMED. Can. J. Chem. **59**, 731 (1981).

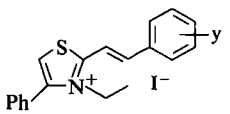
Opérant dans divers mélanges de solvants organiques et d'eau, on a déterminé les valeurs du pK de quelques dérivés de styril-2 phényl-4 thiazoles avec l'idoure d'éthyle. Lorsque la quantité de solvant organique du milieu augmente on observe d'une part que le pK du dérivé diméthylamine diminue alors que d'autre part le pK du dérivé hydroxylé augmente. On en conclut que les principaux facteurs responsables de ce comportement sont la différence de stabilisation de la base par des forces de dispersion dans le cas du dérivé aminé et par les donneurs de liaisons hydrogènes à partir des molécules de solvant dans le cas des dérivés hydroxylés. On discute également de l'effet de la structure moléculaire du composé sur la valeur du pK.

[Traduit par le journal]

Introduction

Recently we have reported the medium effect on the ionisation constants of some 2-styryl pyridine and quinoline ethiodide derivatives (1, 2). However, it is known that the styryl cyanine derivatives are quite interesting compounds because of their application as photosensitizers (3, 4) as well as in many biological aspects (5–8). Furthermore, 2-styryl-4-phenylthiazole ethiodide derivatives are recognized as useful indicators in many nonaqueous titrations of weak acids (9).

Since no work has been reported on the medium effect on the ionisation process of 2-styryl-4-phenylthiazole ethiodide derivatives, this paper reports the pK values of some 2-styryl-4-phenylthiazole ethiodide derivatives in water – organic solvent mixtures. The organic solvents used are methanol, ethanol, acetone, *N*,*N*-dimethylformamide, and dimethyl sulfoxide. The 2-styryl-4-phenylthiazole ethiodide derivatives used in this investigation are



I y = *p*-NMe_2
II y = *o*-OH
III y = *p*-OH
IV y = *m*-OMe, *p*-OH

Experimental

Materials and Methods

Compounds **I–IV** were prepared following the method of Mills and Smith (10); where equimolar amounts of 2-methyl-4-phenylthiazole ethiodide (11) and the appropriate aldehyde were refluxed in ethanol for 3 h in the presence of two drops of piperidine as a catalyst. The reaction mixture was concentrated and the solid product was recrystallized from ethanol. The results of analysis as well as the melting points of the compounds prepared are given in Table 1. All chemicals used in this investigation for preparation of the derivatives and the organic solvents used were of BDH (AR) grade. Stock solutions 10^{-3} M of the compounds were prepared by dissolving the solid in the organic solvent. More dilute solutions were prepared by accurate dilution.

pH control was achieved by using acetate buffer solutions and a modified universal buffer solution (12). The pH of the solutions was checked at 25°C using a WG PYE model 290 pH-meter, reading to ±0.005 pH units.

TABLE 1. Analytical and melting points data of the compounds **I–IV**

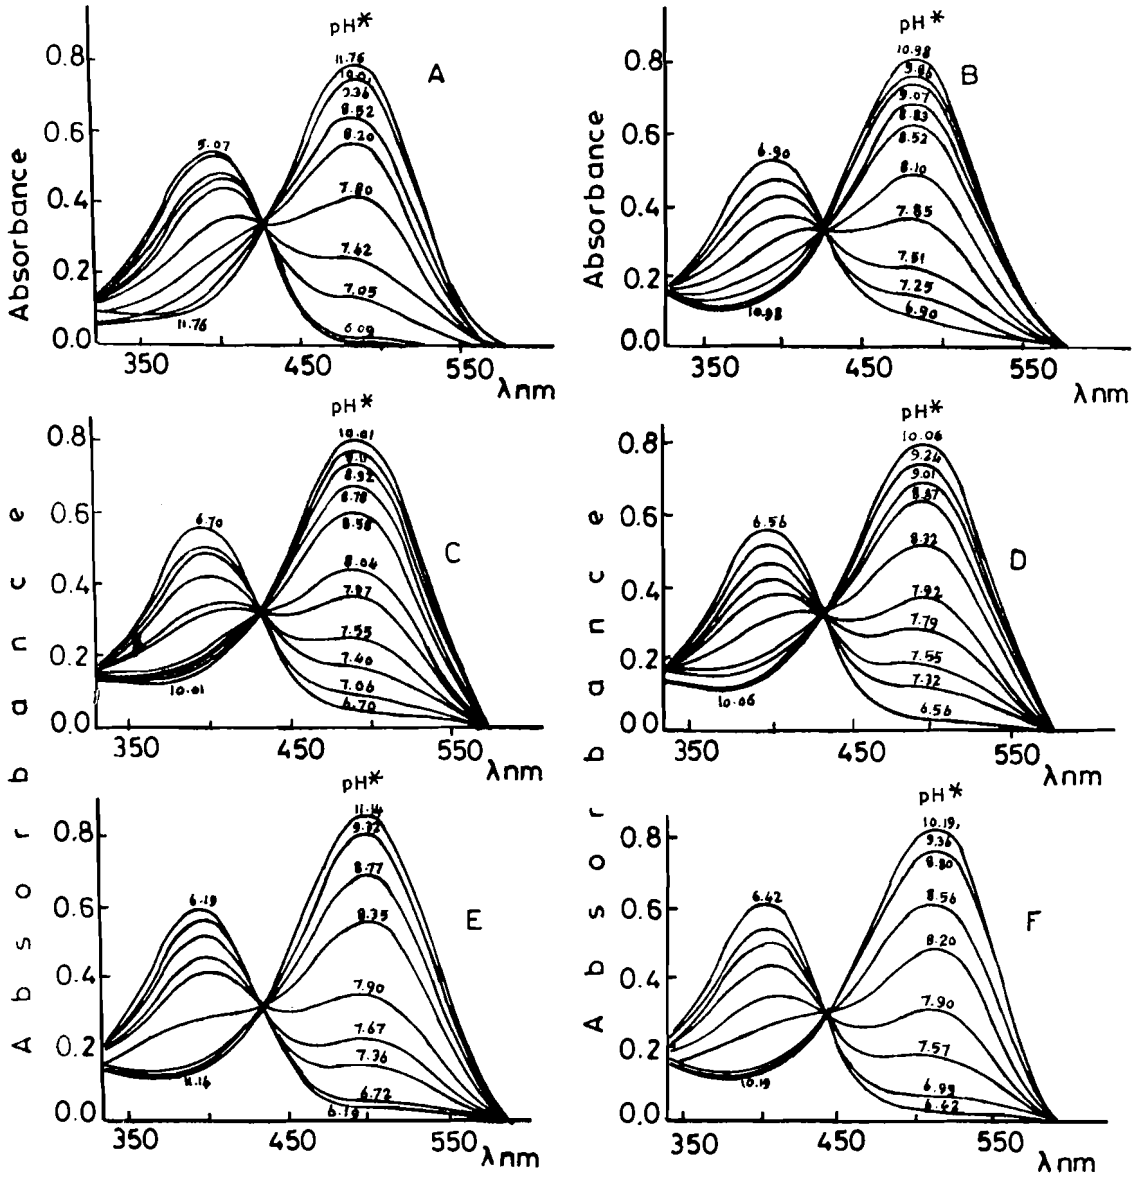

FIG. 1. Absorption spectra of 3×10^{-5} *M* of compound **IV** solution containing different percentages of methanol. By wt.% MeOH: *A*, 0.0; *B*, 8.08; *C*, 16.52; *D*, 25.35; *E*, 34.54; *F*, 44.18.

To account for the difference in properties for partially aqueous solutions relative to pure aqueous ones, the pH values of the former solutions were corrected making use of the procedure described by Douheret (13). If the pH-meter is standardized using aqueous buffers, the meter reading pH(R) obtained in a partially aqueous medium differs by an amount δ from the corrected reading pH* which refers to the standard state in the partially aqueous medium,

$$pH^* = pH(R) - \delta$$

The values of δ of the aqueous buffer solutions containing varying proportions of each of the organic solvents used were determined by Douheret (13, 14).

The absorption spectra were measured on a UNICAM SP 8000 spectrophotometer within the wavelength range 300–700 nm using 1 cm matched silica cells. All measurements were carried out at 25°C.

Results and Discussion

The visible absorption spectra of the compounds **I–IV** either in pure aqueous buffer solutions or in those containing different proportions of an organic solvent (methanol, ethanol, acetone, DMF, and DMSO) were recorded (Fig. 1). It is worth noting that acetate buffer solutions were used in the case of compound **I** due to the low p*K* value of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

this compound relative to the lower limit pH value of the universal buffer series. Generally, the spectra of solutions with low pH (< 2 in the case of compound **I** and <7 in the case of compounds **II–IV**) represent the absorption by the protonated or non-ionic species of compounds **I** and **II–IV** respectively, whereas those at higher pH of the medium are due to the non-protonated or ionic species. On increasing the pH of the medium, the absorbance of the band due to the protonated or non-ionic form decreases, whereas that of the non-protonated or ionic form increases.

The high red shift observed in the λ_{max} of the band in solutions of high pH's relative to that observed in solutions of low pH's is convincing evidence for the charge transfer nature of this band (1, 2).

The spectra of the compounds **I–IV** in all media studied are characterised by a clear isosbestic point denoting the existence of an acid–base equilibrium.

$H^+A^+ \rightleftharpoons A^+ + H^+$ Compound **I**
$HA^+ \rightleftharpoons A + H^+$ Compounds **II–IV**

The absorbance–pH* curves (Fig. 2) are of typical dissociation or association types, confirming the acid–base equilibrium.

The acid dissociation constant, pK_a, of the compounds was determined from the variation of the absorbance with pH* taking advantage of three different spectrophotometer methods, viz. the half-height (15), limiting absorbance (15), and Colleter methods (16). The results obtained are given in Tables 2 and 3.

The results listed in these tables reveal the fact that pK_a values of all compounds are largely dependent on both the proportion and the nature of the organic co-solvent used. The ionisation constant of the dimethylamino derivative (compound **I**) increases with increase in the amount of the organic solvent in the medium while that of the hydroxy derivatives (compounds **II–IV**) decreases in the same direction.

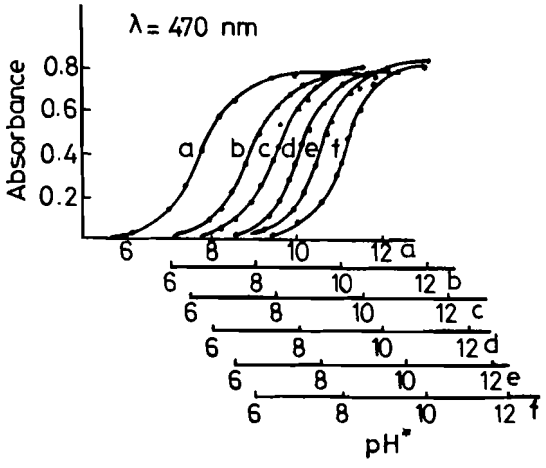

FIG. 2. Absorbance–pH* curves for compound **IV** in universal buffer solutions containing different percentages of methanol. By wt.% MeOH: *a*, 0.0; *b*, 8.08; *c*, 16.52; *d*, 25.35; *e*, 34.54; *f*, 44.18.

The acidity constant in aqueous medium (K_1) may be related to that in partially aqueous medium (K_2) by means of equations (17)

[1] $K_{(1)} = K_{(2)}\gamma_{H^+}\gamma_{A^+}/\gamma_{H^+A^+}$

[2] $K_{(1)} = K_{(2)}\gamma_{H^+}\gamma_{A}/\gamma_{HA^+}$

where γ is the activity coefficient of the subscripted species in a partially aqueous medium relative to that in a pure one. Since it is known that the electrostatic effects of solvents will operate only on the activity coefficients of any charged species (17), in the case of compound **I** the electrostatic effect on the activity coefficient of the proton (H^+), free base (A^+), and on that of the acid (H^+A^+) will cancel to a large extent. Consequently the electrostatic effect is expected to have a relatively small influence on the deprotonation constant of this compound. On the other hand, for the hydroxy derivatives the magnitude of this effect on the proton exceeds that on the acid (HA^+). Thus the ionisation constant of these compounds is expected to decrease with increase in the percentage of the organic solvent in the medium, which is in line with the results given in Tables 2 and 3.

Furthermore, it is recognized that effects such as hydrogen bonding, solvent basicity, dispersion forces, and proton–solvent interaction act as important factors influencing the ionisation constants of acids in the presence of organic solvent. Accordingly, the observed decrease in pK_a of compound **I** can be mainly ascribed to the high stabilization of the base of this compound by dispersion forces rather than by hydrogen bonding in partially aqueous media. This dispersion interaction is established between the delocalized oscillator dipole of the conjugated base and the localized oscillator dipole of the solvent. The high stabilization of the base by dispersion forces in partially aqueous media relative to those in pure aqueous media is due to the fact that the effective density of dispersion centers of any of the solvents under study is higher than that of water (18). Furthermore, the observed decrease in pK_a of the compound **I** as the amount of organic solvent in the medium is increased can be attributed also to the expected high stabilization of the proton by its interaction with organic solvent and water molecules in the mixture than that with water molecules alone (17).

42.34	73.80	1.43	348	484	8.24	386	495

Careful examination of the pK_a values of compound **I** in the different organic solvent – water media studied reveals the fact that in the presence of the same amount of the organic solvent in the medium, the pK_a values of this compound vary with the nature of the organic solvent used according to the following sequence

$$\text{DMSO} \leq \text{DMF} < \text{acetone} < \text{ethanol} < \text{methanol}$$

However, this is expected as a result of the decrease in the solvent polarizability on going from DMSO to methanol within the above sequence (18). This behaviour can be considered as convincing evidence for the fact that the high stabilization of the base by dispersion forces and of the proton by its interaction with solvent are the two important factors responsible for the decrease in pK_a of the compound **I** as the amount of the solvent in the medium is increased.

On the other hand, the increase in pK_a of each of compounds **II–IV** as the amount of the organic solvent in the medium is increased can be ascribed to the high stabilization of the ionic form by solvent donor hydrogen bonding in pure aqueous medium relative to that in partially aqueous medium. This is presumably due to the greater tendency of water molecules to donate hydrogen bonds as compared with the other solvent molecules (17).

The results given in Tables 1 and 2 for compounds **II–IV** indicate that the variation of pK_a value in the media containing the same percentage of alcohol or acetone appears to be in the order:

$$\text{methanol} < \text{ethanol} < \text{acetone}$$

This is presumably due to the decrease in tendency of the solvent molecules to donate hydrogen bonds to the ionic form on going from methanol to acetone (17, 19).

42.34	73.80	8.35	392	490	8.33	401	518

This behaviour can be considered as evidence for the fact that the difference in the stabilization of ionic forms by donor-hydrogen bond from solvent molecules is a major factor responsible for the increase in pK_a as the amount of the organic solvent in the medium is increased.

Careful examination of the results reveals that the pK_a value in the presence of the poorer hydrogen bond donors DMF or DMSO is less than the one obtained in the presence of the same amount of acetone or ethanol (Tables 2 and 3). This can be ascribed to the high basic character of the former solvents, reflecting itself in the construction of a strong acceptor hydrogen bond from the OH group of the non-ionised form and thus facilitating the ionisation process of the OH group (i.e. low pK_a).

The red shift observed in the λ_{max} of the band responsible for the absorption of the base of compound **I** and the ionic form of each compound **II–IV** as the amount of the solvent in the medium increases (Tables 2 and 3) can be interpreted as follows. In the case of compound **I**, as the concentration of the organic solvent in the medium increases the extent of dispersion forces between the base and the solvent molecules is expected to increase. This in turn will increase the proportion of the polarized structure of the base in solution and consequently an easy intramolecular charge transfer is expected to occur. On the other hand, in the case of compounds **II–IV** as the amount of the non-aqueous component in the medium increases, the free negative charge on the oxygen atom of the base is increased. This is due to the weak tendency of the molecules of the solvent to form donor hydrogen bonds with the oxygen atom relative to water molecules. This in turn will reflect itself in the increase of the intramolecular charge transfer from the oxygen atom to the delocalized molecular orbital of the

thiazolium cation and thus a lower excitation energy is required.

Effect of Molecular Structure on pK_a

It is evident that the pK_a value of each of the compounds under investigation in the presence of the same amount of organic solvent is lower than that of the corresponding derivative of 2-styryl pyridine or quinoline ethiodides (1, 2). This can be interpreted as follows. Since the thiazole ring belonging to the compounds under investigation contains two hetero atoms, one should expect that this ring is characterized by high electron-withdrawing character relative to the pyridine or quinoline rings. This leads to an increase in the intramolecular CT from the aryl moiety in case of the compounds under investigation, affording a lower negative charge density on the aromatic system. This in turn results in weaker bonding of the proton (low pK_a value).

CHOU KUO-CHEN and STURE FORSEN. Can. J. Chem. **59**, 737 (1981).

Four rules to deal with first-order or pseudo-first-order steady-state reaction systems are presented.

By means of Rule 1, we can immediately write down the apparent rate constants of consecutive reaction systems. This rule is actually the same as the "Rule of Thumb" proposed by Gilbert, but here its mathematical proof is given.

Rule 2 and Rule 3 may serve to derive the apparent rate constants of various complex reaction systems. In comparison with the general algebraic methods, these two rules can simplify laborious calculations that would otherwise be tedious and liable to errors.

Rule 4 presents a new schematic method to calculate the concentrations of the reactants. The new method, in simplifying the calculation of complex problems, is extraordinarily efficacious in comparison with the existing schematic methods. For complex mechanisms which are too complicated to be treated with the general manual calculation method, the practical calculations show that we can easily write down the desired results by means of Rule 4.

In addition, Rules 2, 3, and 4 include corresponding check formulae, by use of which we can avoid missing subgraphs to be counted. Their advantages will be manifested particularly in dealing with complex mechanisms.

The mathematical proofs of these rules are given in the Appendices.

CHOU KUO-CHEN et STURE FORSEN. Can. J. Chem. **59**, 737 (1981).

On présente quatre règles permettant de traiter des systèmes réactionnels où l'état stationnaire est du premier ordre et du pseudo premier ordre. A l'aide de la règle 1, on peut immédiatement décrire les constantes de vitesse apparentes pour des systèmes de réactions consécutives. Cette règle est de fait la même que l'approximation proposée par Gilbert mais on en fournit ici une preuve mathématique.

Les règles 2 et 3 peuvent servir à déduire les constantes de vitesse apparentes de plusieurs systèmes réactionnels complexes. Par comparaison avec les méthodes algébriques générales, ces deux règles permettent de simplifier les calculs laborieux qui seraient par ailleurs pénibles et susceptibles d'erreurs.

Dans la règle 4, on présente une nouvelle méthode schématique de calcul des concentrations des réactifs. La nouvelle méthode, en simplifiant la solution de problèmes complexes, est extraordinairement efficace par rapport aux méthodes schématiques existantes. Dans les cas des méchanismes complexes qui sont trop compliqués pour être traités par la méthode générale de calcul manuel, les calculs pratiques montrent que nous pouvons facilement aboutir aux résultats désirés à l'aide de la règle 4.

De plus les règles 2, 3 et 4 comprennent des formules de vérification qui permettent, lorsqu'elles sont utilisées, de s'assurer que tous les sous graphes sont comptés. Leurs avantages se manifestent particulièrement dans le traitement des méchanismes complexes.

On donne en Appendice les preuves mathématiques de ces règles.

[Traduit par le journal]

I. Introduction

In chemical kinetics, the following two categories of steady-state reaction systems are often encountered.

(*i*) It is assumed that in this category of reaction system the absolute rates of change of the concentrations of all intermediates are zero, and all individual rate constants can be treated as first-order or pseudo-first-order rate constants. For this kind of reaction system, it frequently becomes desirable or necessary to derive the apparent rate constant in terms of individual rate constants. Previous investigators (1–4) have accordingly suggested various algebraic methods for this purpose. However, as pointed out by Gilbert (5), this kind of derivation is laborious and error-prone for any but trivally simple mechanisms. Thus, he presented the "Rule of Thumb" (5), which is very effective for the consecutive reaction mechanisms whose common expression is as in [3]. However, Gilbert did not give the mathematical proof in his article (5). Besides, the "Rule of Thumb" cannot be used to deal with general mechanisms of the first category, such as mechanism [9] and mechanism [15]. For these mechanisms, the ordinary algebraic methods would involve more labour and be more error-prone. Hence, three schematic rules are presented here. Rule 1 is actually the same as the "Rule of Thumb", but the mathematical principle of this rule is given in Appendix 1 as a special case

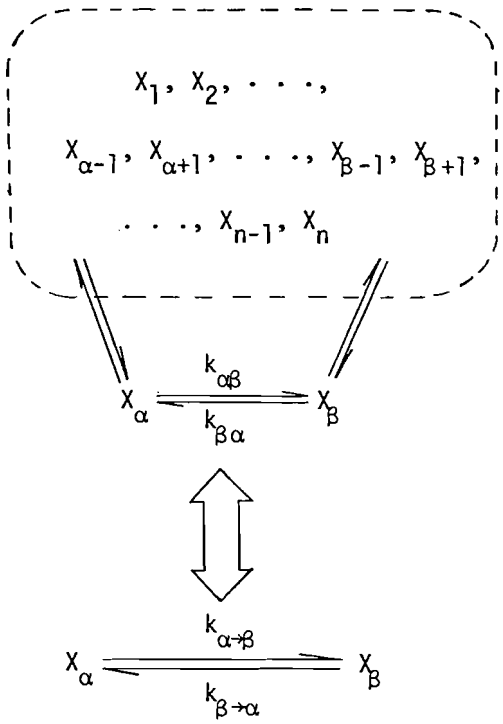
of the proof of Rule 2. Rule 2 and Rule 3 can be used to derive the apparent rate constants for general mechanisms of the first category.

(*ii*) Reaction systems of the second category are often encountered in enzyme kinetics. The fundamental assumption here is that the absolute rates of change of the concentrations of all enzyme species in the reaction system are zero, and the conversion rate constant between any two enzyme species can be treated as first-order or pseudo-first-order. Laidler (6) has given a thorough discussion of the validity of this assumption. In general, for this kind of reaction system, concentrations of various enzyme species are to be calculated. But such calculations are extremely tedious and liable to error for any but simple mechanisms of little interest if one uses the ordinary algebraic methods. King and Altman (7) thus first suggested the use of the schematic method. Their method has been widely welcomed and adopted due to its simplicity and appeal to intuition. Since then, several investigators (8–14) have successively developed and modified the King–Altman method. Nonetheless, the calculation procedure still becomes unwieldy with complex mechanisms (15). Thus, Indge and Childs (15) and Cornish-Bowden (16) suggested approaches suitable for implementation on a computer. From another viewpoint, in this paper we shall present a new schematic method (Rule 4). This method is very efficacious in simplifying the calculation of complex problems. Practical calculations show that for complex mechanisms which are too complicated to be treated with the existing manual calculation methods, we can easily write out the desired results by means of Rule 4.

II. The Graphical Rules Concerning the First Category of Steady-state Reaction Systems

This kind of reaction system can be illustrated as follows:

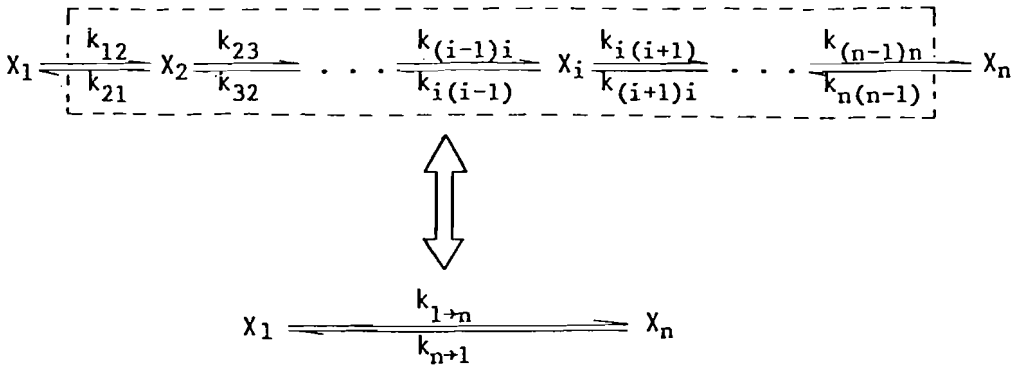


The symbols enclosed by the broken line denote the intermediates. According to the previous assumption, we have[2] $dx_\gamma/dt = 0$ ($\gamma \neq \alpha, \beta$). In order to be general as far as possible, we suppose that reversible reactions are possible between each pair of reactants in [1], and let the rate constant for $X_i \rightarrow X_j$ be k_{ij}, and that for $X_j \rightarrow X_i$ be k_{ji} ($i, j = 1, 2, ..., n$). Here, k_{ij} is the first-order or the pseudo-first-order rate constant. For the sake of simplicity in formulation, we may specify $k_{ii} = 0$ by definition of k_{ij}. Now, let us see how to express the apparent rate constants $k_{\alpha\rightarrow\beta}$ and $k_{\beta\rightarrow\alpha}$ in terms of the individual kinetic constants k_{ij}.

First of all, consider the following simple case:

[2] In this paper, the reactants are represented by capital letters and their concentrations by the corresponding lower-case letters.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.



[3]

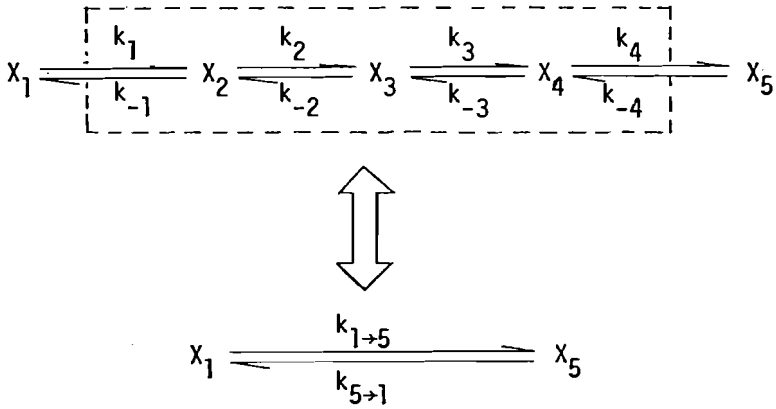
Obviously, [3] is a special case of [1] when $\alpha = 1$, $\beta = n$, and $k_{ij} = 0$ if $j \neq i \pm 1$. For this kind of consecutive reaction mechanisms, we have Rule 1 as follows.

Rule 1

(*a*) The numerator of $k_{1\to n}$ is equal to the product of all the individual rate constants in [3] whose arrows are towards the right, while the opposite is true for the numerator of $k_{n\to 1}$.

(*b*) The denominator of $k_{1\to n}$ and that of $k_{n\to 1}$ are the same, and both are equal to a sum of $n - 1$ items, in which the ith item can be obtained in the following way: cut the arrows between X_i and X_{i+1} ($i = 1, 2, \ldots, n - 1$) in [3], and then take the product of all rate constants whose arrows point in either direction away from the cut.

Example 1. Calculate the apparent rate constants of the following steady-state reaction system



By Rule 1, we immediately obtain

$$k_{1\to 5} = \frac{k_1k_2k_3k_4}{k_2k_3k_4 + k_{-1}k_3k_4 + k_{-1}k_{-2}k_4 + k_{-1}k_{-2}k_{-3}}$$

$$k_{5\to 1} = \frac{k_{-1}k_{-2}k_{-3}k_{-4}}{k_2k_3k_4 + k_{-1}k_3k_4 + k_{-1}k_{-2}k_4 + k_{-1}k_{-2}k_{-3}}$$

Although Rule 1 is very easy and intuitive, it cannot be used to derive the apparent rate constants of mechanisms like [9] and [15]. Therefore, more general rules are needed.

Rule 2

(*a*) Draw a directed graph $\mathscr{D}$ to express the reaction system [1]. The method is as follows: depict n points and label them with $X_1, X_2, \ldots, X_n$, respectively; if there is a directed reaction for $X_i \to X_j$, namely, $k_{ij} \neq 0$, then draw an arc from X_i to X_j (with an arrow towards X_j), and weight the arc with k_{ij}; if there is no directed reaction for $X_i \to X_j$, namely, $k_{ij} = 0$, then do not depict such an arc.

(*b*) The desired rate constants $k_{\alpha\to\beta}$ and $k_{\beta\to\alpha}$ can then be expressed as

$$[4]\quad \begin{aligned} k_{\alpha\to\beta} &= N_\beta/N_{\alpha,\beta} \\ k_{\beta\to\alpha} &= N_\alpha/N_{\alpha,\beta} \end{aligned}$$

Here, N_β can be obtained in the following way: find all subgraphs in $\mathscr{D}$, each of which possesses $n-1$ arcs (n is the number of points in $\mathscr{D}$), but contains no cycle, no two or more than two arcs coming out of one point, and no arc coming out of X_β (the point denotes the βth reactant). Then, for each of these subgraphs, take the product of all its weights. On taking a sum of these results, we immediately obtain N_β.

In a completely analogous way, we can get N_α.

$N_{\alpha,\beta}$ in eq. [4] can be obtained as follows: find all subgraphs in $\mathscr{D}$, each of which possesses $n-2$ arcs, but contains no cycle, no two or more than two arcs coming out of one point, and also no arc coming out of X_α and X_β (the points denote the αth and βth reactants, respectively). Then for each of these subgraphs, take the product of all its weights. The sum of these results will directly yield $N_{\alpha,\beta}$.

(*c*) In order to facilitate checking, and to avoid missing any subgraphs in the calculations, we can also calculate the numbers of subgraphs to be counted, beforehand. The method is as follows: construct a matrix $\mathbf{A}(\mathscr{D}) = [a_{ij}]$, where

$$[5]\quad a_{ij} = \begin{cases} 1 & \text{if there is a connecting line from } X_i \text{ to } X_j \text{ in } \mathscr{D} \\ 0 & \text{if there is no connecting line from } X_i \text{ to } X_j \text{ in } \mathscr{D} \end{cases}$$

Reconstruct a matrix $\mathbf{B}(\mathbf{A}) = [b_{ij}]$, where

$$[6]\quad b_{ij} = \begin{cases} \sum_{t=1}^{n} a_{it} & \text{if } i = j \\ -a_{ij} & \text{if } i \neq j \end{cases}$$

then we have

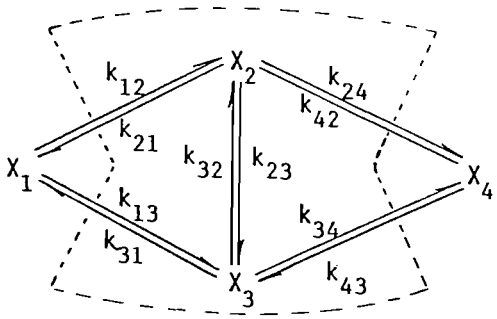
$$[7]\quad P_\alpha = \det \mathbf{B}_{\bar{\alpha},\bar{\alpha}},\quad P_\beta = \det \mathbf{B}_{\bar{\beta},\bar{\beta}}$$

$$[8]\quad P_{\alpha,\beta} = \det \mathbf{B}_{\bar{\alpha},\bar{\alpha};\bar{\beta},\bar{\beta}}$$

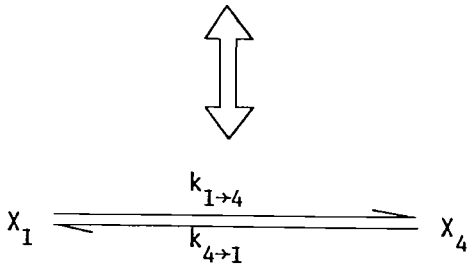
where P_α, P_β, and $P_{\alpha,\beta}$ are the numbers of subgraphs to be counted in the calculation of N_α, N_β, and $N_{\alpha,\beta}$, respectively; $\mathbf{B}_{\bar{\alpha},\bar{\alpha}}$ denotes the submatrix obtained by removing the αth row and αth column from $\mathbf{B}$; $\mathbf{B}_{\bar{\alpha},\bar{\alpha};\bar{\beta},\bar{\beta}}$ denotes the submatrix obtained by removing both the αth row, αth column and the βth row, βth column; and so on. The symbol det means taking the determinant value of the following matrix.

For the mathematical proof of Rule 2, refer to Appendix 1.

Example 2. Calculate the apparent rate constants $k_{1\to4}$ and $k_{4\to1}$ for the following mechanism



[9]



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

First of all, depict the corresponding directed graph as shown in Fig. 1. Then, following part *b* of Rule 2, we immediately obtain

[10] $N_4 =$ 
$$= k_{12}k_{24}k_{34} + k_{12}k_{32}k_{24} + k_{12}k_{23}k_{34} + k_{31}k_{12}k_{24} + k_{13}k_{34}k_{24} + k_{13}k_{23}k_{34} + k_{13}k_{32}k_{24} + k_{21}k_{13}k_{34}$$

[11] $$N_1 = k_{42}k_{21}k_{31} + k_{42}k_{32}k_{21} + k_{42}k_{23}k_{31} + k_{34}k_{42}k_{21} + k_{43}k_{31}k_{21} + k_{43}k_{23}k_{31} + k_{43}k_{32}k_{21} + k_{24}k_{43}k_{31}$$

[12] $N_{1,4} =$ 
$$= k_{24}k_{34} + k_{32}k_{24} + k_{23}k_{34} + k_{21}k_{31} + k_{23}k_{31} + k_{32}k_{21} + k_{21}k_{34} + k_{31}k_{24}$$

Substituting [10]–[12] into [4], we immediately obtain the desired results $k_{1\to4}$ and $k_{4\to1}$.

Check: From Fig. 1 and eqs. [5] and [6], we have

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & 1 & 0 \\ 1 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{bmatrix} \qquad \mathbf{B} = \begin{bmatrix} 2 & -1 & -1 & 0 \\ -1 & 3 & -1 & -1 \\ -1 & -1 & 3 & -1 \\ 0 & -1 & -1 & 2 \end{bmatrix}$$

Then from eqs. [7] and [8], we have[3]

[3]It can easily be proved that for a symmetric directed graph like Fig. 1 (i.e. the one in which whenever there is an arc from X_i to X_j there must exist an arc from X_j to X_i), the value of P_α is always the same no matter which number in 1, 2, ..., n is taken for α; and in such a case we also have $n^{\gamma\to\alpha} = n^{\alpha\to\gamma}$, $n^{\gamma\to m} = n^{m\to\gamma}$, and so on.

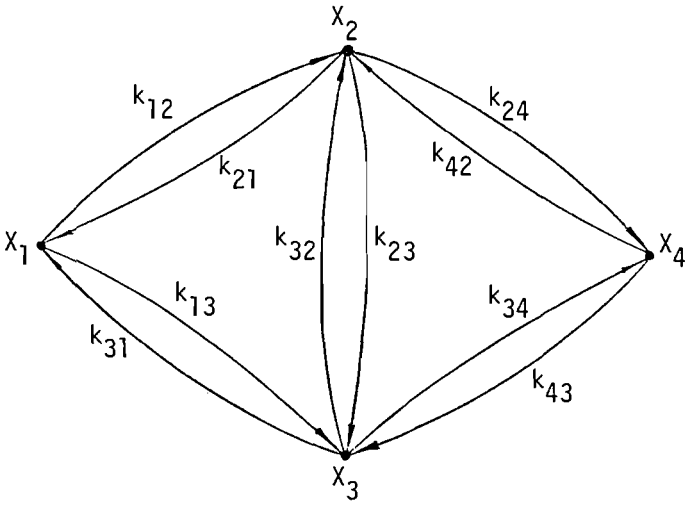


FIG. 1. The directed graph $\mathscr{D}$ of mechanism [9].

$$P_1 = \begin{vmatrix} 3 & -1 & -1 \\ -1 & 3 & -1 \\ -1 & -1 & 2 \end{vmatrix} = 8 \qquad P_4 = \begin{vmatrix} 2 & -1 & -1 \\ -1 & 3 & -1 \\ -1 & -1 & 3 \end{vmatrix} = 8 \qquad P_{1,4} = \begin{vmatrix} 3 & -1 \\ -1 & 3 \end{vmatrix} = 8$$

This means that no subgraph is omitted during the above calculations for N_1, N_4, and $N_{1,4}$.

This example tells us that the apparent rate constants for general mechanisms belonging to [1] can be easily derived by Rule 2. The calculational labor is much less than that by the general algebraic methods. However, when the mechanisms are more complex, the number of subgraphs to be counted will increase and confusion will ensue. In such a case, we suggest using Rule 3, as follows:

Rule 3

(*a*) Draw a directed graph $\mathscr{D}$ to express the reaction system [1].

(*b*) Add a loop with the weight $\sum_{i=1}^{n} k_{it}$ to each point X_i ($i = 1, 2, ..., n$), and alter the sign of the weight for each arc in $\mathscr{D}$, i.e., change k_{ij} to $-k_{ij}$ ($i \neq j$). The graph thus obtained is denoted by $\mathscr{D}^\dagger$. For instance, the $\mathscr{D}$ in Fig. 2 is in this way transformed to $\mathscr{D}^\dagger$ in Fig. 3.

(*c*) N_β in eq. [4] can then be obtained as follows: select any point in $\mathscr{D}^\dagger$, say X_γ, as a starting reference point.[4] Find all subgraphs in $\mathscr{D}^\dagger$, each of which possesses a path from X_γ to X_β, and all cycles that neither intersect with each other nor with the path. For each such subgraph, take the product of all of its weights and multiply by the sign of $(-1)^{n+c+1}$, where c is the number of cycles in the respective subgraph. On taking the sum of these results, we immediately obtain N_β.

N_α can be obtained in a completely analogous way.

(*d*) $N_{\alpha,\beta}$ in eq. [4] can be obtained in the following way: remove both the point X_α and the point X_β from $\mathscr{D}^\dagger$. (The arcs linked with the two points are of course also removed.) The graph thus obtained is denoted by $\mathscr{D}^\dagger_{\alpha,\beta}$. Find all subgraphs in $\mathscr{D}^\dagger_{\alpha,\beta}$, each of which possesses all those cycles that do not intersect with each other. Then, for each of these subgraphs, take the product of all its weights and multiply with a sign factor of $(-1)^{c_0}$, where c_0 is the number of cycles with arcs of even number in the respective subgraphs. Taking a sum of these results, we immediately obtain $N_{\alpha,\beta}$.

(*e*) In order to facilitate checking, we can also estimate the number of subgraphs to be counted. The method is as follows: if matrices $\mathbf{A}(\mathscr{D}^\dagger)$ and $\mathbf{A}(\mathscr{D}^\dagger_{\alpha,\beta})$ are constructed in accordance with eq. [5], then we have

$$[13] \quad n^{\gamma\to\alpha} = \text{per } [\mathbf{A}(\mathscr{D}^\dagger)]_{\bar{\alpha},\bar{\gamma}} \quad - n^{\gamma\to\beta} = \text{per } [\mathbf{A}(\mathscr{D}^\dagger)]_{\bar{\beta},\bar{\gamma}}$$

$$[14] \quad n_{\alpha,\beta} = \text{per } \mathbf{A}(\mathscr{D}^\dagger_{\alpha,\beta})$$

where $n^{\gamma\to\alpha}$ and $n^{\gamma\to\beta}$ are the numbers of subgraphs to be counted when X_γ is taken as the starting reference point to calculate N_α and N_β, respectively. $n_{\alpha,\beta}$ is the number of subgraphs when $N_{\alpha,\beta}$ is calculated; per

[4]The result is independent of the point that is selected as the starting reference point. However, we generally prefer to choose the reference point as far from the specified point as possible, so that fewer subgraphs will have to be counted.

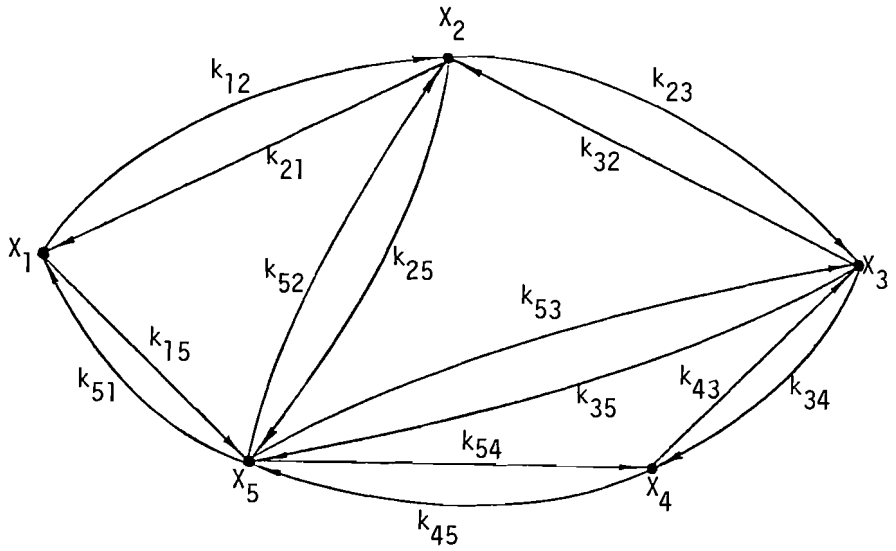

FIG. 2. The directed graph $\mathscr{D}$ of mechanism [15].

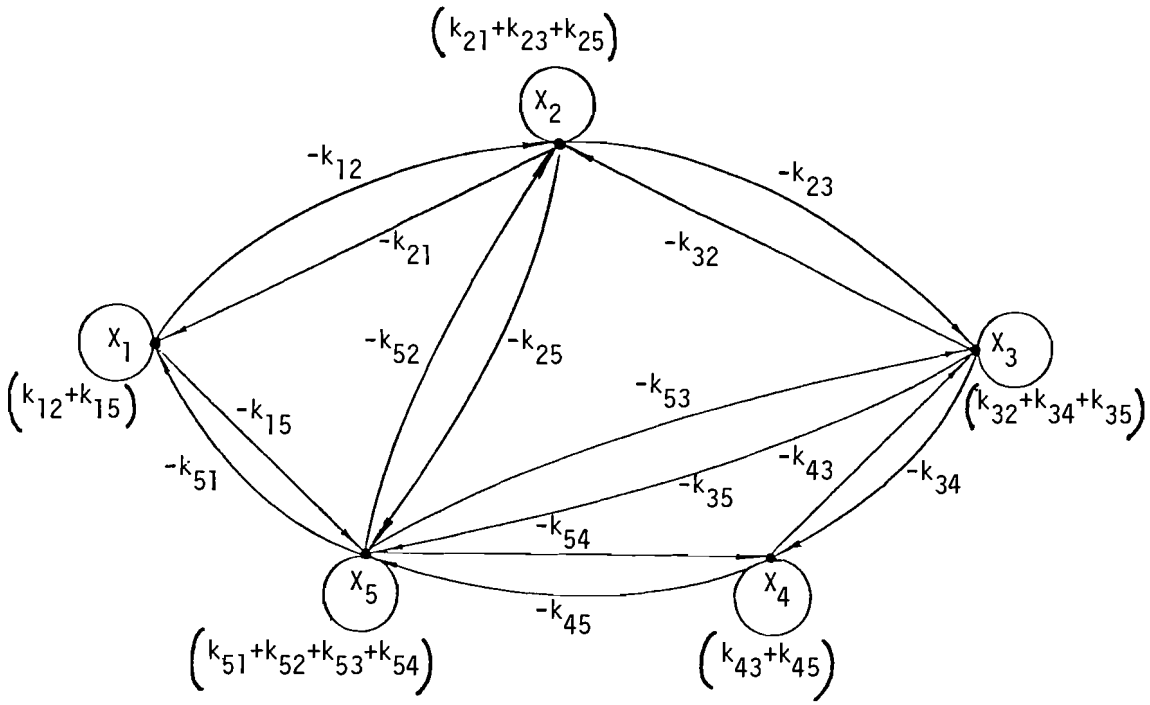

FIG. 3. The transformed graph $\mathscr{D}^{\dagger}$ obtained from Fig. 2 according to (*b*) of Rule 3.

denotes taking the permanent value of a matrix. *The so-called permanent of a matrix is a sum of all terms obtained by expanding the corresponding determinant but discarding the sign sgn σ which appears in each term of the determinant expansion.* Thus, it is very easy to calculate the permanent value of a matrix defined by [5] where the elements are either 1 or 0. For instance, we have

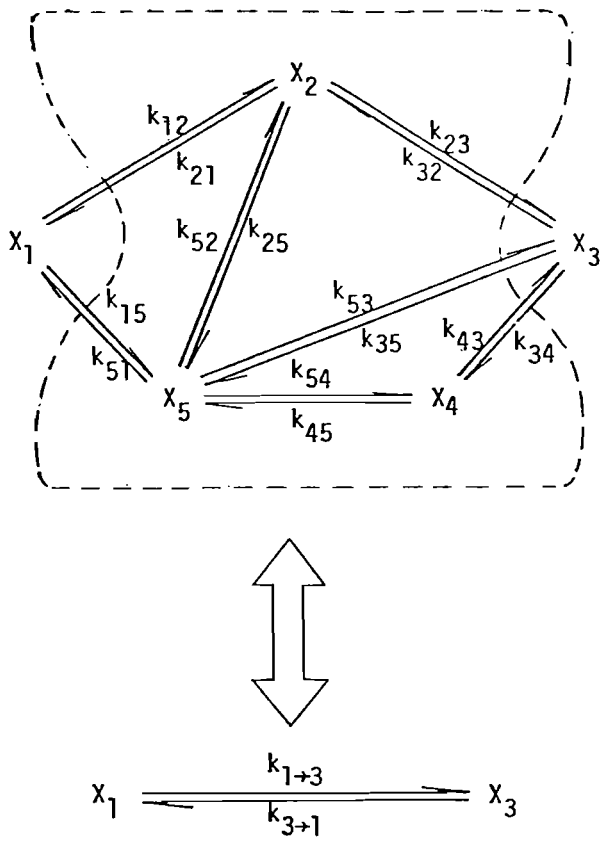
$$\text{per}\begin{bmatrix}1 & 1\\ 1 & 1\end{bmatrix} = 2 \qquad \text{per}\begin{bmatrix}1 & 1 & 0\\ 1 & 1 & 1\\ 1 & 1 & 1\end{bmatrix} = 4 \qquad \text{per}\begin{bmatrix}1 & 1 & 1\\ 1 & 1 & 1\\ 1 & 1 & 1\end{bmatrix} = 6$$

and so on. The permanent of a matrix is discussed in more detail in Appendix 2 and ref. 14.

The mathematical proof of Rule 3 is given in Appendix 3.

Example 3. Calculate the apparent rate constants $k_{1\to3}$ and $k_{3\to1}$ for the following mechanism

[15]



whose corresponding directed graph $\mathscr{D}$ is drawn in Fig. 2. For this mechanism, from [7] and [8] we have[3]

$$P_1 = P_3 = 21 \qquad P_{1,3} = 19$$

which indicates that if we use Rule 2 to calculate $k_{1\to3}$ (or $k_{3\to1}$), there are 21 and 19 subgraphs to be counted in deriving its numerator and denominator, respectively.

Now, let us use Rule 3. First, transform $\mathscr{D}$ of Fig. 2 into $\mathscr{D}^\dagger$ of Fig. 3 and $\mathscr{D}^\dagger_{1,3}$ of Fig. 4 according to part *b* and part *d*, respectively, of Rule 3. Then, from [13] and [14] we have

$$n^{1\to3} = \text{per}\,[\mathbf{A}(\mathscr{D}^\dagger)]_{\bar{3},\bar{1}} = \text{per}\begin{bmatrix}1&0&0&1\\1&1&0&1\\0&1&1&1\\1&1&1&1\end{bmatrix} = 7$$

$$n_{1,3} = \text{per}\,\mathbf{A}(\mathscr{D}^\dagger_{1,3}) = \text{per}\begin{bmatrix}1&0&1\\0&1&1\\1&1&1\end{bmatrix} = 3$$

which means that only 7 subgraphs are to be counted if we choose $\mathbf{X}_1$ as the starting reference point to calculate the numerator N_3, and only 3 subgraphs are enough for the denominator $N_{1,3}$. (Note that diagonal elements in the above matrices $\mathbf{A}(\mathscr{D}^\dagger)$ and $\mathbf{A}(\mathscr{D}^\dagger_{1,3})$ are 1's because each $\mathbf{X}_i$ is involved in an arc to itself.) Owing to the remarkable decrease in the numbers of counted subgraphs, we can directly write down the desired results according to part *c* and part *d* of Rule 3, respectively:

[16] $N_3 =$ 
$$= k_{12}k_{23}(k_{43}+k_{45})(k_{51}+k_{52}+k_{53}+k_{54}) - k_{12}k_{23}k_{45}k_{54} + k_{12}k_{25}k_{53}(k_{43}+k_{45}) + k_{12}k_{25}k_{54}k_{43} + k_{15}k_{52}k_{23}(k_{43}+k_{45}) + k_{15}k_{53}(k_{21}+k_{23}+k_{25})(k_{43}+k_{45}) + k_{15}k_{54}k_{43}(k_{21}+k_{23}+k_{25})$$

$$= k_{12}k_{23}k_{43}(k_{51}+k_{52}+k_{53}+k_{54}) + k_{12}k_{23}k_{45}(k_{51}+k_{52}+k_{53}) + k_{12}k_{25}k_{53}(k_{43}+k_{45}) + k_{12}k_{25}k_{54}k_{43} + k_{15}k_{52}k_{23}(k_{43}+k_{45}) + k_{15}k_{53}(k_{21}+k_{23}+k_{25})(k_{43}+k_{45}) + k_{15}k_{54}k_{43}(k_{21}+k_{23}+k_{25})$$

[17] $N_{1,3} =$ 
$$= (k_{21}+k_{23}+k_{25})(k_{43}+k_{45})(k_{51}+k_{52}+k_{53}+k_{54}) - k_{25}k_{52}(k_{43}+k_{45}) - k_{45}k_{54}(k_{21}+k_{23}+k_{25})$$

$$= (k_{21}+k_{23})k_{43}(k_{51}+k_{52}+k_{53}+k_{54}) + (k_{21}+k_{23})k_{45}(k_{51}+k_{52}+k_{53}) + k_{25}k_{43}(k_{51}+k_{53}+k_{54}) + k_{25}k_{45}(k_{51}+k_{53})$$

Substituting [16] and [17] into eq. [4], we immediately obtain $k_{1\to3}$. In a completely similar way, we can get $k_{3\to1}$.

From the above example we can see that for more complex mechanisms, it is more convenient to use Rule 3. But for simple mechanisms, Rule 2 is more intuitive, and furthermore it can naturally lead to Rule 1 (the "Rule of Thumb" (5)) when Rule 2 is applied to the consecutive reaction mechanisms whose common expression is illustrated by [3]. Of course, calculations with either rule will always lead to the same result.

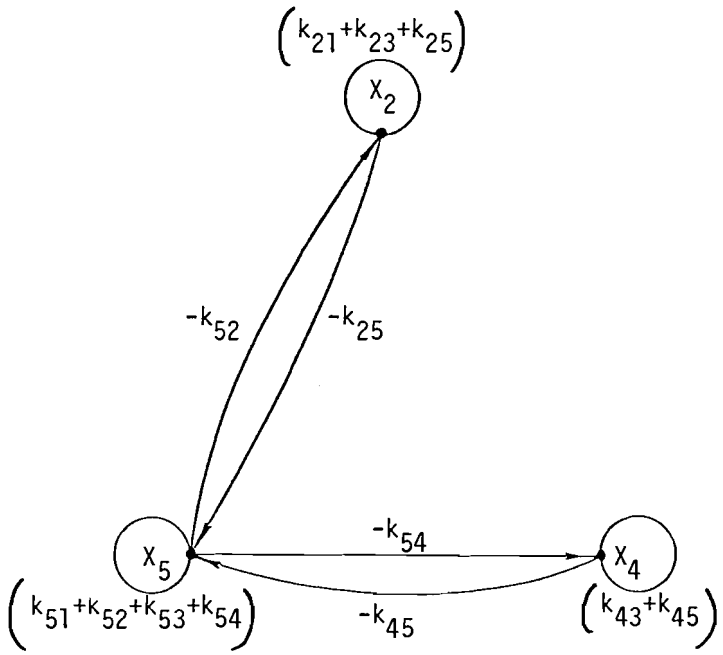

FIG. 4. The transformed graph $\mathscr{D}^{\dagger}_{1,3}$ obtained from Fig. 3 according to (*d*) of Rule 3.

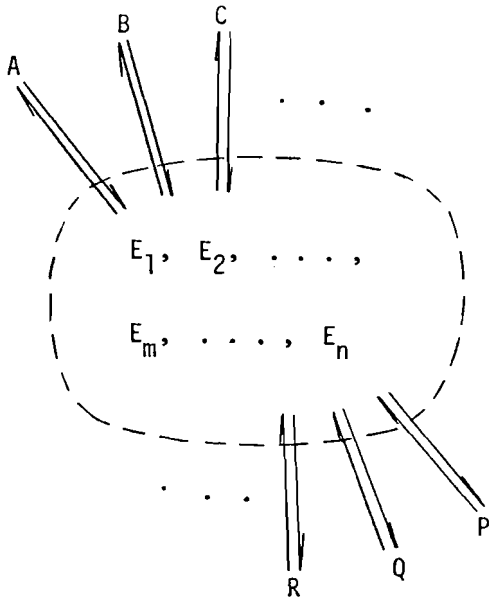
III. The Graphical Rules Concerning the Second Category of Steady-state Reaction Systems

This kind of reaction system can be summarily illustrated as follows:

[18]



E_m ($m = 1, 2, \ldots, n$) enclosed by the dotted line represents various enzyme species; A, B, C, ... and P, Q, R, ... represent substrates and products, respectively. Likewise, let the rate constant for $E_i \rightarrow E_j$ be k_{ij}, and that for $E_j \rightarrow E_i$ be k_{ji}. Here, k_{ij} and k_{ji} are first-order or pseudo-first-order rate constants. For reaction systems of this category, the steady-state assumption requires $de_m/dt = 0$.[2] Below, we shall present a new graphical rule to derive e_m, the concentration of the mth enzyme species.

Rule 4

(*a*) Draw a directed graph $\mathscr{D}$ to express mechanism [18]. As a special example, let us consider the following

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

three-state single substrate, single product reaction

$$[19]\quad E + A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} EA \qquad EA \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} EP \qquad EP \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} E + P$$

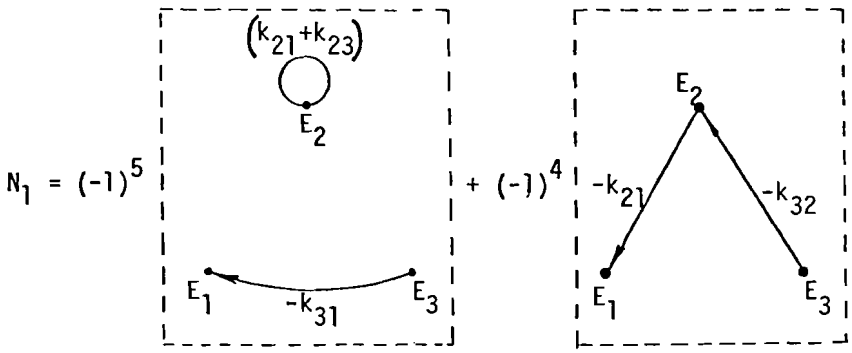
which was employed by King and Altman (7) as a model, and obviously belongs to the category of [18]. If we suppose $E_1 = E$, $E_2 = EA$, $E_3 = EP$, and $k_{12} = k_1 a$, $k_{21} = k_{-1}$, $k_{23} = k_2$, $k_{32} = k_{-2}$, $k_{31} = k_3$, $k_{13} = k_{-3}p$, then the directed graph $\mathscr{D}$ of mechanism [19] is as shown in Fig. 5.

(*b*) Add a loop with weight $\sum_{t=1}^{n} k_{it}$ to each point E_i ($i = 1, 2, \ldots, n$), and alter the sign of the weight for each arc in $\mathscr{D}$. The new graph thus obtained is denoted by $\mathscr{D}^\dagger$. For instance, the $\mathscr{D}$ in Fig. 5 is accordingly transformed to $\mathscr{D}^\dagger$ in Fig. 6.

(*c*) Then we have

$$[20]\quad e_m = \frac{N_m}{\sum_{i=1}^{n} N_i} e_0$$

where e_0 is the total enzyme concentration. N_m can be obtained in a completely analogous way as given in part *c* of Rule 3 for calculating N_β. (X and β in Rule 3 are replaced by E and *m*, respectively.) For instance, following this procedure, for $\mathscr{D}^\dagger$ of Fig. 6, we at once have:



$$= k_{31}(k_{21}+k_{23}) + k_{32}k_{21}$$

$$N_2 = k_{32}(k_{12}+k_{13}) + k_{31}k_{12}$$

$$N_3 = k_{13}(k_{21}+k_{23}) + k_{12}k_{23}$$

Substituting N_1, N_2, N_3 into [20], we immediately obtain the concentrations of the enzyme species in mechanism [19].

(*d*) Likewise, we have the check formula

$$[21]\quad n^{\gamma \to m} = \text{per } \mathbf{A}(\mathscr{D}^\dagger)_{\bar{m},\bar{\gamma}}$$

to estimate the number of subgraphs being counted when E_γ in $\mathscr{D}^\dagger$ is taken as the reference point to derive N_m. For instance, for Fig. 6 we have

$$\mathbf{A}(\mathscr{D}^\dagger) = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix}$$

and

$$n^{3\to 1} = \text{per}\begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix} = 2$$

which indicate that no subgraph was lost in the above calculation of N_1.

For personal use only.

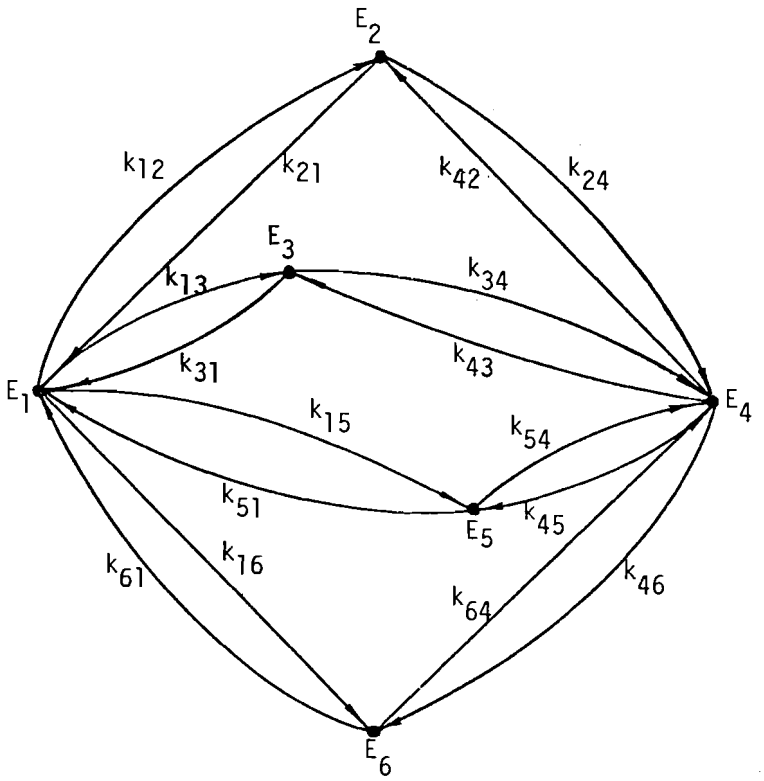

FIG. 7. The directed graph $\mathscr{D}$ of mechanism [22].

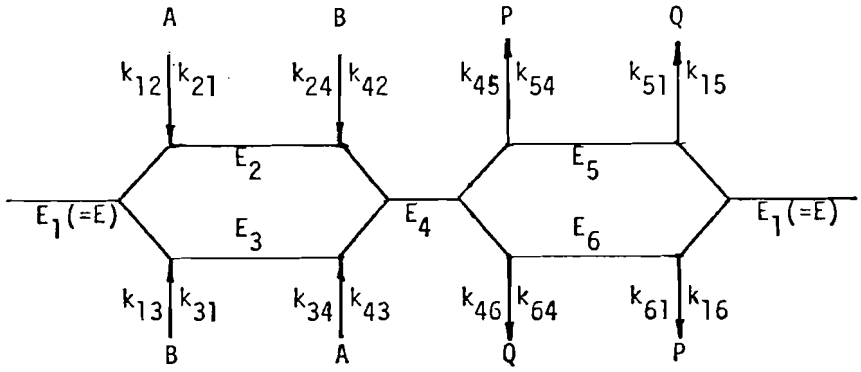
The mathematical principle of Rule 4 is given in Appendix 4.

Example 4. Consider the following Bi Bi random mechanism (17)

[22]



The corresponding directed graph $\mathscr{D}$ is drawn in Fig. 7. For such a mechanism, if the King–Altman method is used, 32 subgraphs (18)[5] must be counted to calculate each N_m ($m = 1, 2, ..., 6$). It is too laborious to be practical, as the probability of committing errors is great. It is also very difficult (18) to use the existing manual calculation methods to obtain the desired results. Now, let us use Rule 4. First, transform $\mathscr{D}$ of

[5]The number of subgraphs to be counted for the King–Altman method can be easily estimated with a rule presented by Chou *et al.* in ref. 14.

Fig. 7 into $\mathscr{D}^{\dagger}$ of Fig. 8 according to (*b*) of Rule 4. By [21] we then have

$$n^{4\to 1} = \text{per}\begin{bmatrix}1&1&0&0&0\\1&0&1&0&0\\0&1&1&1&1\\1&0&0&1&0\\1&0&0&0&1\end{bmatrix} = \text{per}\begin{bmatrix}0&1&0&0\\1&1&1&1\\0&0&1&0\\0&0&0&1\end{bmatrix} + \text{per}\begin{bmatrix}1&1&0&0\\0&1&1&1\\1&0&1&0\\1&0&0&1\end{bmatrix}$$

$$= \text{per}\begin{bmatrix}1&1&1\\0&1&0\\0&0&1\end{bmatrix} + \text{per}\begin{bmatrix}1&1&1\\0&1&0\\0&0&1\end{bmatrix} + \text{per}\begin{bmatrix}0&1&1\\1&1&0\\1&0&1\end{bmatrix}$$

$$= 1 + 1 + 2 = 4$$

$$n^{1\to 4} = n^{4\to 1} = 4 \text{ (see footnote 3)}$$

$$n^{1\to 2} = n^{1\to 3} = n^{1\to 5} = n^{1\to 6} = 7$$

The above results tell us that only 4 subgraphs need to be counted in calculating N_1 (taking E_4 as the reference point) and N_4 (taking E_1 as the reference point), and only 7 subgraphs need to be counted in calculating N_2, N_3, N_5, N_6 (all taking E_1 as the reference point). Due to the evident decrease in the number of subgraphs, it is very easy by following part *c* of Rule 4 to obtain the desired result:

[23] $N_1 = (-1)^{10}$ 
$+(-1)^{10}$ 
$+(-1)^{10}$ 
$+ (-1)^{10}$ 
$$= k_{42}k_{21}(k_{31}+k_{34})(k_{51}+k_{54})(k_{61}+k_{64}) + k_{43}k_{31}(k_{21}+k_{24})(k_{51}+k_{54})(k_{61}+k_{64}) + k_{46}k_{61}(k_{21}+k_{24})(k_{31}+k_{34})(k_{51}+k_{54} + k_{45}k_{51}(k_{21}+k_{24})(k_{31}+k_{34})(k_{61}+k_{64})$$

From the symmetry concerning E_1 and E_4 in Fig. 8, we readily see

N_4 = The result obtained from eq. [23] through exchanging subscripts 1 and 4

In a similar way, we can also get the expressions for N_2, N_3, N_5, and N_6. In fact, however, when this method becomes familiar, it is quite unnecessary to depict the decomposed subgraphs one by one as done above; very often we can directly write down the desired results according to the graph $\mathscr{D}^{\dagger}$ or even $\mathscr{D}$, as follows:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

[24] $$N_2 = k_{12}(k_{31}+k_{34})(k_{42}+k_{43}+k_{45}+k_{46})(k_{51}+k_{54})(k_{61}+k_{64}) - k_{12}k_{34}k_{43}(k_{51}+k_{54})(k_{61}+k_{64}) - k_{12}k_{45}k_{54}(k_{31}+k_{34})(k_{61}+k_{64}) - k_{12}k_{46}k_{64}(k_{31}+k_{34})(k_{51}+k_{54}) + k_{13}k_{34}k_{42}(k_{51}+k_{54})(k_{61}+k_{64}) + k_{15}k_{54}k_{42}(k_{31}+k_{34})(k_{61}+k_{64}) + k_{16}k_{64}k_{42}(k_{31}+k_{34})(k_{51}+k_{54})$$

$$= k_{12}k_{31}k_{51}k_{61}(k_{42}+k_{43}+k_{45}+k_{46}) + k_{12}k_{31}k_{51}k_{64}(k_{42}+k_{43}+k_{45}) + k_{12}k_{31}k_{54}k_{61}(k_{42}+k_{43}+k_{46}) + k_{12}k_{31}k_{54}k_{64}(k_{42}+k_{43}) + k_{12}k_{34}k_{51}k_{61}(k_{42}+k_{45}+k_{46}) + k_{12}k_{34}k_{51}k_{64}(k_{42}+k_{45}) + k_{12}k_{34}k_{54}k_{61}(k_{42}+k_{46}) + k_{12}k_{34}k_{54}k_{64}k_{42} + k_{13}k_{34}k_{42}(k_{51}+k_{54})(k_{61}+k_{64}) + k_{15}k_{54}k_{42}(k_{31}+k_{34})(k_{61}+k_{64}) + k_{16}k_{64}k_{42}(k_{31}+k_{34})(k_{51}+k_{54})$$

Likewise, with the help of the symmetry in Fig. 8 between E_2 and E_3, E_2 and E_5, and E_2 and E_6, we at once have

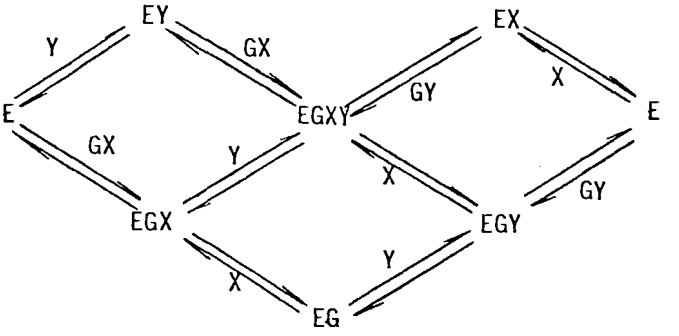
N_3 = The result obtained from eq. [24] through exchanging the subscripts 2 and 3

N_5 = The result obtained from eq. [24] through exchanging the subscripts 2 and 5

N_6 = The result obtained from eq. [24] through exchanging the subscripts 2 and 6

Substituting the above results into eq. [20], we immediately obtain e_m ($m = 1, 2, ..., 6$), the concentrations of all enzyme species in mechanism [22].

In addition, Rule 4 has been successfully used to deal with a Bi Uni Uni Bi Ping Pong Mechanism (19*a*, 20), and we obtained the result that the concentration of each enzyme species contains 64 terms in the numerator and 512 terms in the denominator (21). Such a complicated result could hardly be derived if the ordinary manual calculation methods are employed. Rule 4 has also been used to derive the concentrations of the enzyme species of a mechanism with branched catalytic cycles such as



Ainsworth (19*b*) pointed out that the derivation of the rate equation of this mechanism is a formidable task if a computer would not be employed because there are 672 terms in the denominator for the concentration of each enzyme species, and 96 terms in the corresponding numerator. However, by means of Rule 4, we could easily write down the rather involved result (22), which is exactly the same as that obtained by Kinderlerer and Ainsworth (23) with a computer.

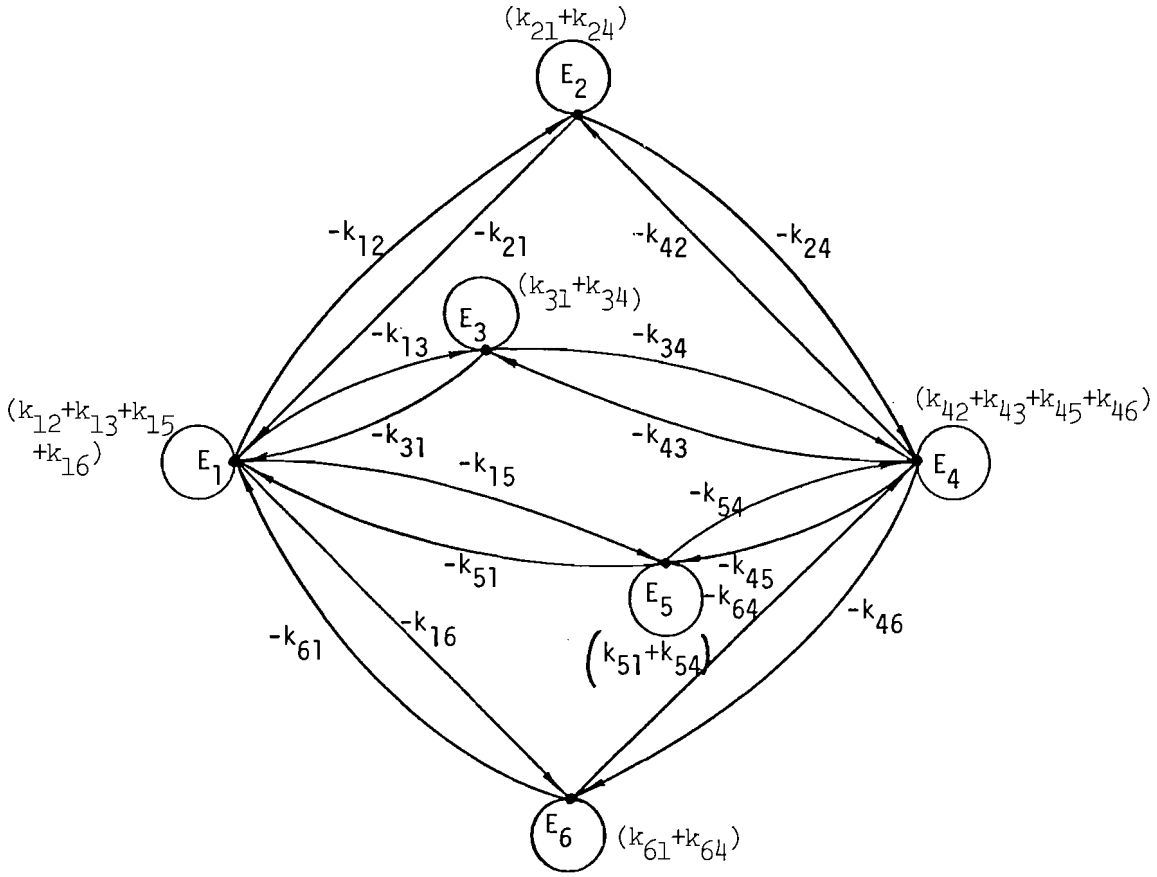


FIG. 8. The transformed graph $\mathscr{D}^{\dagger}$ obtained from Fig. 7 according to (*b*) of Rule 4.

Appendix 1. The Mathematical Principles of Rule 1 and Rule 2

Let us first prove Rule 2. Since Rule 1 is a special case of Rule 2, if the latter is proved, the former will automatically be valid. For the general mechanism [1] of the first category of steady-state reaction systems, without lossing generality, we may prescribe $\alpha = 1$, and $\beta = n$. Now, in order to derive the apparent rate constant $k_{1\to n}$, according to the steady-state assumption, we have the following system of equations:

$$[A.1]\quad \begin{cases} -\dfrac{dx_1}{dt} = \displaystyle\sum_{i=1}^{n} k_{1i}x_1 - k_{21}x_2 - \cdots - k_{(n-1)1}x_{n-1} = v \\ -\dfrac{dx_2}{dt} = -k_{12}x_1 + \displaystyle\sum_{i=1}^{n} k_{2i}x_2 - \cdots - k_{(n-1)2}x_{n-1} = 0 \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ -\dfrac{dx_{n-1}}{dt} = -k_{1(n-1)}x_1 - k_{2(n-1)}x_2 - \cdots + \displaystyle\sum_{i=1}^{n} k_{(n-1)i}x_{n-1} = 0 \\ -\dfrac{dx_n}{dt} = -k_{1n}x_1 - k_{2n}x_2 \cdots - k_{(n-1)n}x_{n-1} = -v \end{cases}$$

where x_i ($i = 1, 2, \ldots, n$) is the concentration of the reactant X_i, v is the steady-state reaction rate, and k_{ij} is the conversion rate constant for $X_i \to X_j$. For simplification, we can prescribe $k_{ii} = 0$ by the definition of k_{ij}. In the above n equations, the negative sum of the preceding $n - 1$ equations will yield the nth equation, hence these n equations are linearly dependent. Discarding the nth equation, we have (in accordance with Cramer's rule):

$$[A.2]\quad x_1 = \frac{\det \mathbf{K}_{\bar{1},\bar{1},\bar{n},\bar{n}}}{\det \mathbf{K}_{\bar{n},\bar{n}}} v$$

where $\mathbf{K}_{\bar{n},\bar{n}}$ is the $n - 1$ order matrix obtained by removing the nth row and nth column from the matrix

$$[A.3]\quad \mathbf{K} = \begin{bmatrix} \displaystyle\sum_{i=1}^{n} k_{1i} & -k_{12} & \cdots & -k_{1n} \\ -k_{21} & \displaystyle\sum_{i=1}^{n} k_{2i} & \cdots & -k_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ -k_{n1} & -k_{n2} & \cdots & \displaystyle\sum_{i=1}^{n} k_{ni} \end{bmatrix}$$

and $\mathbf{K}_{\bar{1},\bar{1},\bar{n},\bar{n}}$ is the $n - 2$ order matrix obtained by removing both the 1st row, 1st column, and the nth row, nth column from K. It is obvious that det $\mathbf{K}_{\bar{n},\bar{n}}$ is just the same as N_n in refs. 14 and 18, so it is profitable to let

$$[A.4]\quad \begin{cases} N_n = \det \mathbf{K}_{\bar{n},\bar{n}} \\ N_{1,n} = \det \mathbf{K}_{\bar{1},\bar{1},\bar{n},\bar{n}} \end{cases}$$

On the other hand, by definition of the apparent rate constant, we have

$$[A.5]\quad v = dx_n/dt = k_{1\to n}x_1$$

Substituting [A.4] and [A.5] into [A.2], we obtain

$$[A.6]\quad k_{1\to n} = N_n/N_{1,n}$$

It has been proved in ref. 14 that the numerator N_n in eq. [A.6] can be calculated with the schematic method as described in Rule 2. Moreover, according to Tutte's theorem (24), it is readily seen that the number of subgraphs involved in such a way can be calculated by eq. [7].

As for the denominator $N_{1,n}$ in [A.6], following the analysis given by Cornish-Bowden (18), we learn that the expansion of the determinant $N_{1,n} = \det \mathbf{K}_{\bar{1},\bar{1};\bar{n},\bar{n}}$ will be a sum of products of $n - 2$ rate constants, in each of which: 1 and n do not occur as first subscript, while 2, ..., $n - 1$ occur once only as first subscript; no cycles of subscripts (such as $k_{23}k_{34}k_{42}$...) occur; each product has a positive sign; all allowed products occur. If the above conclusions are expressed in the schematic terminology, we get at once the calculation method for $N_{1,n}$ as given in Rule 2. Furthermore, in terms of Tutte's theorem, it is also evident that the number of subgraphs thus involved can be calculated by eq. [8].

Likewise, the corresponding conclusions can be obtained for $k_{n\to 1}$.

This completes the proof of Rule 2. Obviously, it will naturally lead to Rule 1 if Rule 2 is applied to the reaction mechanisms whose common expression is written as [3].

Appendix 2. The Permanent of a Matrix and Its Principal Properties

By the definition given in Rule 3 for a permanent, the following fundamental properties are obvious.

Property 1. A matrix **C** has the same permanent value as its transposed matrix; i.e.

$$\text{per } \mathbf{C} = \text{per } \mathbf{C}^{\mathrm{T}}$$

Property 2. The permanent value remains the same on exchanging any two rows (or columns) of a matrix.

Property 3. The permanent of a matrix can be expanded along any of its rows (or columns), e.g.,

$$\text{per}\begin{bmatrix} c_{11} & c_{12} & \cdots & c_{1n} \\ c_{21} & c_{22} & \cdots & c_{2n} \\ \cdot & & & \cdot \\ \cdot & & & \cdot \\ \cdot & & & \cdot \\ c_{n1} & c_{n2} & \cdots & c_{nn} \end{bmatrix} = c_{11}\,\text{per}\begin{bmatrix} c_{22} & \cdots & c_{2n} \\ \cdot & & \\ \cdot & & \\ \cdot & & \\ c_{n2} & \cdots & c_{nn} \end{bmatrix} + c_{12}\,\text{per}\begin{bmatrix} c_{21} & c_{23} & \cdots & c_{2n} \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ c_{n1} & c_{n2} & \cdots & c_{nn} \end{bmatrix}$$

$$+ \cdots + c_{1n}\,\text{per}\begin{bmatrix} c_{21} & \cdots & c_{2(n-1)} \\ \cdot & & \cdot \\ \cdot & & \cdot \\ \cdot & & \cdot \\ c_{n1} & \cdots & c_{n(n-1)} \end{bmatrix}$$

By means of this property, for a matrix whose elements are either 1 or 0 as defined by eq. [5], the permanent can be easily calculated.

Corollary 1. If **J** is an $n \times n$ matrix with all of its elements equal to 1, we then have

$$\text{per } \mathbf{J} = n!$$

Corollary 2. If $\mathbf{J}_n^{(m)}$ is an $n \times n$ matrix in which there are m independent zero elements (i.e., any two of these zero elements are in different rows and columns) and all the other elements are equal to 1, then we have

$$\text{per } \mathbf{J}_n^{(m)} = n! - (n-1)!C_m^{\,1} + (n-2)!C_m^{\,2} + \ldots + (-1)^m(n-m)!C_m^{\,m}$$

Corollary 3. The permanent of a matrix with any zero row (or column) is equal to zero.

Remark. Owing to Property 2, which reflects an essential difference between permanent and determinant, it is usually forbidden during the operation of taking the permanent to add a multiple of one row (or column) to another as done in the calculation of a determinant.

Appendix 3. The Mathematical Principles of Rule 3

In fact, Rule 3 is another schematic method for calculating N_α, N_β, and $N_{\alpha,\beta}$. As in Appendix 1, we may assume $\alpha = 1$ and $\beta = n$ without losing generality.

We know that an $n \times n$ matrix $\mathbf{C} = [c_{ij}]$ can be expressed by a weighted directed graph with n points $(C_1, C_2, \ldots, C_n)$. The method is as follows: If $c_{ij} \neq 0$, draw an arc from point C_i to point C_j, and label it

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

with weight c_{ij}; if $c_{ij} = 0$, do not depict an arc from C_i to C_j. In this way, a one-to-one correspondence between the matrix and the directed graph is established.

Now, it is obvious that the matrix corresponding to the directed graph $\mathscr{D}^{\dagger}_{1,n}$ obtained through steps (*a*), (*b*), and (*d*) is exactly $\mathbf{K}_{\bar{1},\bar{1};\bar{n},\bar{n}}$. Consequently, we can use the graphical method as given in part *d* of Rule 3 and the check formula [14] to calculate $N_{1,n} = \det \mathbf{K}_{\bar{1},\bar{1};\bar{n},\bar{n}}$ of eq. [A.6]. Proof concerning the last step involves more terminology of graph theory and hence is omitted. The interested reader can find the details of the proof in ref. 14.

As for N_1 and N_n, let us consider the following hypothetical equations:

$$\text{[A.7]} \quad \begin{cases} \sum_{i=1}^{n} k_{1i}x_1 - k_{21}x_2 - \cdots - k_{n1}x_n = 0 \\ -k_{12}x_1 + \sum_{i=1}^{n} k_{2i}x_2 - \cdots - k_{n2}x_n = 0 \\ \quad\vdots \qquad\quad \vdots \qquad\qquad\quad \vdots \\ -k_{1n}x_1 - k_{2n}x_2 - \cdots \sum_{i=1}^{n} k_{ni}x_n = 0 \end{cases}$$

$$\text{[A.8]} \quad x_1 + x_2 + \cdots + x_n = 1$$

The n equations in [A.7] are linearly dependent since their sum is always equal to zero (note that $k_{ii} = 0$ according to the previous prescription). In order to get the definite solutions, we can replace any one of [A.7] with eq. [A.8].

If we use eq. [A.8] to replace the nth equation in [A.7], then from Cramer's rule and the properties of determinants, we can obtain

$$\text{[A.9]} \quad x_n = N_n \Big/ \sum_{i=1}^{n} N_i$$

where

$$\text{[A.10]} \quad N_i = \det \mathbf{K}_{\bar{i},\bar{i}} \quad (i = 1, 2, \ldots, n)$$

Therefore, N_n in [A.9] is just the same as that given in [A.4].

On the other hand, if we use [A.8] to replace the γth ($\gamma \neq n$) equation in [A.7], the result of x_n thus derived should remain the same, and can also be written as [A.9]. But for these n equations, according to ref. 25, N_n, the numerator of the root x_n, can also be calculated with the schematic method as given in part *c* of Rule 3 and with eq. [13] as a check formula. Obviously, such a conclusion can be extended to cover any of N_i ($i = 1, 2, \ldots, n$).

This completes the proof of Rule 3.

Appendix 4. The Mathematical Principles of Rule 4

Actually, the equations describing the second-category steady-state reaction system, whose common expression is given in [18], can be directly obtained from the hypothetical eqs. [A.7] and [A.8] by replacing $x_1, x_2, \ldots, x_n, 1$ with $e_1, e_2, \ldots, e_n, e_0$, respectively.

Likewise, according to Cramer's rule and the properties of determinants, we have

$$e_m = \left(N_m \Big/ \sum_{i=1}^{n} N_i\right) e_0 \quad (m = 1, 2, \ldots, n)$$

where the N_i are exactly the same as those in [A.10]. Therefore, the proof given in Appendix 3 has already covered the remaining part of the mathematical principles of Rule 4.

Spin trapping chemistry of 3,3,5,5-tetramethylpyrroline-*N*-oxide: an improved cyclic spin trap

EDWARD G. JANZEN, RAGHAV V. SHETTY, AND SUSAN M. KUNANEC

Department of Chemistry, Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received November 17, 1980

EDWARD G. JANZEN, RAGHAV V. SHETTY, and SUSAN M. KUNANEC. Can. J. Chem. **59**, 756 (1981).

The use of 3,3,5,5-tetramethylpyrroline-*N*-oxide as a spin trap has been investigated. Spin adducts are found to be more persistent than for 5,5-dimethylpyrroline-*N*-oxide (DMPO) although the esr spectra are quite similar.

EDWARD G. JANZEN, RAGHAV V. SHETTY et SUSAN M. KUNANEC. Can. J. Chem. **59**, 756 (1981).

On a étudié la possibilité d'utiliser le *N*-oxyde de la tétraméthyl-3,3,5,5 pyrroline comme capteur de spin. On a trouvé que les adduits de spin qui en découlent sont plus persistants que ceux qui proviennent du *N*-oxyde de diméthyl-5,5 pyrroline (ODMP); ceci en dépit du fait que les spectres rpe sont tout à fait semblables dans les deux cas.

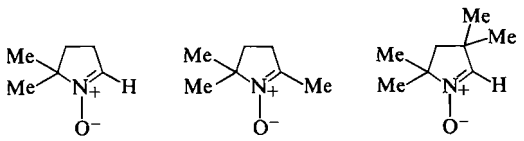
[Traduit par le journal]

Introduction

Many applications of the use of 5,5-dimethylpyrroline-*N*-oxide, **1**, (DMPO) as a spin trap have been published since the first esr study appeared in the literature (1–3). The β-hydrogen hyperfine splitting constants (β-H hfsc's) of the spin adducts vary markedly with the nature of the radical trapped, and the rate constant of spin trapping is very fast (4–7). DMPO has been particularly useful in trapping hydroxyl radicals in the presence of hydrogen peroxide or superoxide because the spectra of the spin adducts of the hydroxy and hydroperoxy/peroxy anion are easily distinguishable (8, 9). Both adducts appear to be reasonably persistent in a number of solvents (10–12).

However, other DMPO adducts have relatively short lifetimes and sometimes cannot be detected under normal spin trapping conditions, e.g. alkyl, aryl, benzoyloxy adducts. Since disproportionation of cyclic nitrones with β-methine hydrogens is probably relatively fast (13) it seems reasonable to expect that steric hindrance could slow down this reaction and thus make the spin adducts more persistent. The nitrone desired would be 3,3,5,5-tetramethylpyrroline-*N*-oxide (**3**).[1] This compound was synthesized by a literature procedure (14) and the spin trapping chemistry investigated. Preliminary results are reported here.

Since the acronym TMPO has already been used for **2** (2, 11) we suggest 3,3,5,5-M_4PO for **3** (or M_4PO) and hence 5,5-M_2PO for **1** and 2,5,5-M_3PO for **2**.



1 5,5-M_2PO

2 2,5,5-M_3PO

3 3,3,5,5-M_4PO

Results

The spin adduct spectra of M_4PO consist of doublets of triplets or triplets of doublets depending on the radical trapped (see Table 1). As was found for DMPO adducts, nonpolar substituents give spectra with relatively large β-H hfsc's, e.g. alkyl or aryl. The β-H must be in a pseudo-axial position if $a_\beta^H \simeq 26$–30 G. However, for electron-withdrawing polar groups the β-H hfsc is much smaller, indicating that the polar substituent prefers the pseudo-axial position regardless of bulk. For DMPO only the hydroxy and azidyl adducts have $a_N = a_\beta^H$ (8, 16). In the M_4PO adducts $a_N \neq a_\beta^H$ for the hydroxy adduct but $a_N = a_\beta^H$ for azidyl and acyl adducts. This coincidence of hfsc's seems fortuitous. It should be noted that no γ-H hfs is

[1]Compound **3** is a colorless, crystalline solid at room temperature (mp 33–35°C) and easier to handle than DMPO. Compound **3** is purified by recrystallization from pentane and is soluble in a wide range of polar and nonpolar solvents.

[e] Commercial potassium phosphate monobasic – sodium hydroxide buffer containing formalin as inhibitor.
[f] Commercial potassium chloride – hydrochloric acid buffer containing formalin as inhibitor.
[g] Additional lines due to other spin adducts and nitroxyl radicals; see ref. 15.
[h] a_β^N = 2.98 G; see ref. 16.
[i] 0.1 *M* Dicyclohexyl-18-crown-6 ether.

found for M_4PO adducts, indicating that in DMPO adducts this splitting comes from the 3-position.

Of interest is the observation that spin adducts of M_4PO are much more persistent than those of DMPO. Thus the phenyl and benzoyloxy adducts of M_4PO still give strong esr spectra even after 2 or 3 days, whereas with DMPO the former is very weak after one hour, while the latter cannot be detected at all using phenylazotriphenylmethane and benzoyl peroxide in benzene at room temperature, respectively. In competition experiments using 0.05 *M* of both phenyl *tert*-butyl nitrone (PBN) and M_4PO in the same solution and 0.003 *M* di-*tert*-butylperoxalate as a *tert*-butoxyl radical source the ratio of the initial slopes of the intensities of the spin adduct spectra is 16:5 for M_4PO:PBN, i.e. the rate constant for spin trapping *tert*-butoxyl radicals is about 3× faster for M_4PO than for PBN. Based on earlier data (4) it can be estimated that the rate constant for trapping *tert*-butoxyl radicals is only 3× slower for M_4PO than for DMPO. It thus appears that by introducing two methyl groups in the 3-position of a 5-membered ring nitrone the usefulness as a spin trap can be greatly enhanced because the relatively small loss in rate of the spin trapping reaction due to steric hindrance is more than made up for by the large gain in spin adduct persistence.

Constantes d'ionisation de dérivés de la pyrazolidine-3,5-dione dans l'éthanol. Relation avec l'électroactivité

CLAIRE GUEUTIN-PELINARD, ELISABETH NIVAUD, PATRICK BOUCLY ET MICHEL GUERNET

Laboratoire de Chimie Analytique, Centre d'Etudes Pharmaceutiques, Rue J. B. Clement, 92290 Chatenay Malabry, France

Reçu le 21 mars 1980[1]

CLAIRE GUEUTIN-PELINARD, ELISABETH NIVAUD, PATRICK BOUCLY et MICHEL GUERNET. Can. J. Chem. **59**, 759 (1981).

Les constantes d'ionisation de dérivés pharmacologiquement actifs de la pyrazolidine-3,5-dione ont été déterminées dans l'éthanol par potentiométrie et spectrophotométrie. L'électroactivité de ces composés est sous la dépendance de l'équilibre entre les formes énolique et dicétonique existant dans ce solvant.

CLAIRE GUEUTIN-PELINARD, ELISABETH NIVAUD, PATRICK BOUCLY, and MICHEL GUERNET. Can. J. Chem. **59**, 759 (1981).

Ionisation constants of some pyrazolidine-3,5-dione derivatives were measured in ethanol by potentiometric and spectrophotometric methods. The electroactivity of these compounds is in relation to the enolic and diketonic equilibrium in this medium.

Introduction

La réduction électrochimique dans l'éthanol de quelques dérivés de la pyrazolidine-3,5-dione a été précédemment étudiée (1). En voltampérométrie linéaire à une électrode de mercure, la phénylbutazone, l'oxyphenbutazone, la cétophénylbutazone, la prénazone et la sulfinpyrazone, se réduisent à des potentiels de demi-vague très voisins. Cependant, les intensités limites pour des concentrations et des conditions expérimentales identiques varient considérablement de l'un à l'autre de ces composés.

La présente étude a pour but de préciser les réactions mises en jeu lors des réductions électrochimiques et d'expliquer les variations de courant observées. Les déterminations potentiométrique et spectrale des pK_a apparents des différents dérivés et l'étude de leur électroactivité en fonction de l'acidité du milieu permettent de proposer une relation entre l'électroactivité et les équilibres entre les différentes formes tautomères présentes en solution.

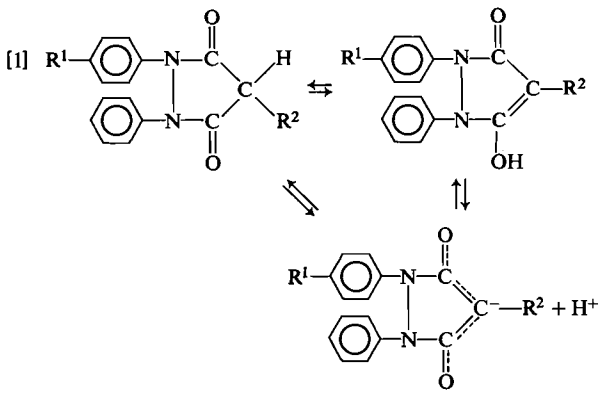
Résultats

Les composés étudiés existent sous deux formes moléculaires tautomères, énolique et dicétonique, et sous une forme anionique, énolate; les constantes d'acidité apparentes globales mesurées correspondent à l'ensemble des équilibres en solution (éq. [1]).

L'expression des constantes d'acidité apparentes K_a peut s'écrire:

$$K_a = \frac{[\text{énolate}][H^+]}{[\text{moléculaire}]}$$

[1]



Composé	R^1	R^2
Phénylbutazone	H	C_4H_9
Oxyphenbutazone	OH	C_4H_9
Cétophénylbutazone	H	$CH_2-CH_2-C(=O)-CH_3$
Sulfinpyrazone	H	$CH_2-CH_2-S(=O)-C_6H_5$
Prénazone	H	$CH_2-CH=C(CH_3)_2$

La forme moléculaire est constituée de la forme énol et de la forme dicétone, il en résulte que l'égalité suivante est toujours vérifiée: [moléculaire] = [dicétone] + [énol].

La méthode de détermination spectrophotométrique de ces constantes K_a met à profit le fait qu'en milieu très acide ces dérivés existent uni-

quement sous forme moléculaire dicétonique (2) et absorbent dans l'ultra-violet; en milieu basique la forme ionisée (énolate) qui prédomine absorbe également mais la longueur d'onde du maximum d'absorption est différente de celle de la forme moléculaire dicétonique. Les valeurs des différents paramètres spectraux déterminés en milieu neutre, perchlorique (1 *M*) et en présence d'éthylate de sodium (1 *M*) sont reportés dans le tableau 1.

Les pK_a sont déterminés selon la méthode décrite par Albert et Serjeant (3); les variations d'absorbance *A* en fonction du pH tamponné de la solution éthanolique, déterminées au maximum d'absorption de la forme énolate permettent d'atteindre les constantes d'acidité apparentes en utilisant la relation:

$$pK_a = pH_i + \log \frac{(A\ pH_b - A\ pH_i)}{(A\ pH_i - A\ pH_a)}$$

ou pH_i = pH du tampon utilisé, $A\ pH_i$ = absorbance de la solution tamponnée, $A\ pH_b$ = absorbance en milieu éthylate de sodium 0,1 *N* et $A\ pH_a$ = absorbance en milieu perchlorique 0,1 *N*.

Les tampons sont choisis de telle manière que le pH soit proche du pK_a apparent à déterminer; le couple acide dichloroacétique/dichloroacétate de sodium, pK_a = 6,89 (4) est employé pour la cétophénylbutazone et la sulfinpyrazone; le couple acide monochloracétique/monochloracétate de sodium, pK_a = 8,51 (4) est utilisé pour la phénylbutazone, l'oxyphenbutazone et la prénazone. Les valeurs obtenues et leurs limites de confiance, calculées pour un risque d'erreur à 5% sont reportées dans le tableau 2.

Dans le double but de confirmer ces valeurs et d'étudier l'influence de la concentration sur l'équilibre dicétoénolique, une détermination de ces mêmes constantes a été effectuée par potentiométrie avec une électrode à hydrogène. Le domaine de concentration utilisable pour ces déterminations est alors trois cents fois supérieur à celui des déterminations spectrales. En effet il n'était pas exclu que la dilution ait une influence sur cet équilibre, entraînant une variation du pK_a apparent.

Les pK_a sont déterminés par mesure du pH d'une solution éthanolique de concentration équimoléculaire (10^{-2} *M*) en forme moléculaire et en base conjuguée. Le pH est mesuré à l'aide d'une électrode à hydrogène préalablement étalonnée. L'expression du pH de la solution est donnée par la relation (5):

$$pH_x = pH_s + \frac{(E_x - E_s)F}{2{,}303\ RT}$$

ou pH_x = pH à déterminer, pH_s = pH du tampon standard utilisé, E_x = potentiel de la solution de la substance à étudier, E_s = potentiel de la solution tampon standard, F = 96 487 C mol^{-1}, R = 8,3143 J K^{-1} mol^{-1} et T = température en degré K.

Les valeurs des pK_a obtenus sont résumées dans le tableau 2. Une étude statistique de comparaison des moyennes obtenues pour chaque composé par l'une ou l'autre méthode montre que celles-ci ne sont pas significativement différentes pour un risque d'erreur inférieur à 5% à l'exception de l'oxyphenbutazone pour lequel l'écart entre les deux méthodes atteint 0,18 unité pH.

Une bonne concordance est donc observée entre les déterminations spectrophotométriques et potentiométriques.

Les potentiels de demi-vague ($E_{\frac{1}{2}}$) mesurés par rapport à celui du système ferrocène–ferrocinium et les intensités limites (I_l) observées en solution éthanolique en milieu neutre en présence de perchlorate de lithium sont reportés dans le tableau 2. Les voltampérogrammes réalisés dans l'éthanol en milieu acide ($HClO_4$ $2 \cdot 10^{-3}$ *M*) et basique (EtONa $2 \cdot 10^{-3}$ *M*) ne présentent pas de vague de réduction correspondant au composé étudié. Dans le dichlorométhane en présence de perchlorate de tétrabutylammonium, les composés étudiés ne sont pas électroréductibles.

Discussion

La valeur du courant limite I_l est reliée à la concentration de la forme électroactive C_s selon la loi de Fick $I_l = -n \cdot d \cdot C_s$ (*n* étant le nombre d'électrons échangés, *d* le coefficient de proportionalité). L'électrolyse à potentiel imposé (1) montre que ces composés se réduisent tous selon un processus monoélectronique; en admettant que pour ces dérivés de structure voisine, les coefficients de diffusion sont très peu différents, les intensités observées I_l, sont directement fonction de la concentration de la forme électroactive présente en solution. Il apparaît à l'exception de la sulfinpyrazone qui se réduit en deux étapes en raison de la présence d'un groupement sulfoxyde et qui de ce fait doit être considérée à part, que plus le pK_a est petit, plus le courant limite est important. Les mesures voltampérométriques étant effectuées en milieu non tamponné, il est exclu que les valeurs de courant observées soient imputables à l'autodissociation (acide/base conjuguée) en solution; en effet, compte tenu des valeurs des pK_a, le pourcentage infime de ces composés sous forme énolate dans les conditions de la voltampérométrie est indécelable. Les différences de courant observées ne peuvent s'expliquer que par la possibilité pour ces dérivés d'exister sous plusieurs formes dont une seule serait électroactive.

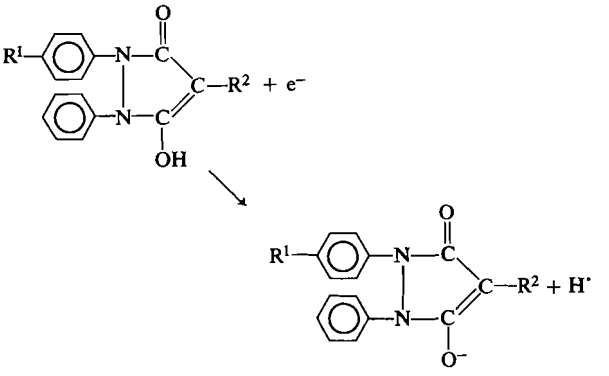
La forme énolique étant plus acide que la forme dicétonique, l'augmentation du rapport [énol]/[cétone] entraîne une diminution du pK_a apparent. Comme l'acidité apparente des composés évolue dans le même sens que les intensités limites de diffusion, il apparaît vraisemblable que seule la forme énolique est électroréductible. Notons que les constantes d'ionisation apparentes ne sont pas liées uniquement à l'équilibre cétoénolique mais aussi à la nature des différents substituants R^1 et R^2; la constante d'ionisation globale ne permet pas de déterminer la part qui revient à chacun des facteurs.

Cependant, l'hypothèse de la corrélation entre le pK_a, l'équilibre dicétoénolique et le courant limite de diffusion est confirmée par l'étude de l'électroactivité en fonction du pH dans l'éthanol. En effet, l'étude voltampérométrique montre que l'électroactivité disparaît lors de l'addition de protons: celle-ci entraîne une prédominance de la forme dicétonique par déplacement de l'équilibre [1]. De même, dans un milieu alcalinisé par l'éthylate de sodium il n'existe pas de vague de diffusion correspondant à la réduction du composé; l'énolate n'est donc pas électroactif.

Dans le dichlorométhane, solvant dans lequel seule la forme dicétonique est présente (2), aucune réduction électrochimique n'a été mise en évidence.

La forme énolique peut donc seule être responsable de l'électroactivité de ces molécules; ceci est confirmé par le fait que les dérivés de la pyrazolidine-3,5-dione disubstitués en 4 qui ne peuvent exister sous forme énol ne sont pas réductibles dans les conditions décrites (1).

La réaction électrochimique peut être schématisée:



Conclusions

Les formes énoliques de la phénylbutazone, de la prénazone, de la cétophénylbutazone et de l'oxyphenbutazone sont responsables de l'électroactivité de ces molécules. Les intensités limites correspondant aux vagues de réduction observées en voltampérométrie linéaire augmentent lorsque la constante d'ionisation augmente; l'exploitation des courbes intensité–potentiel apporte des renseignements précieux sur la structure des composés en solution.

Partie expérimentale

Réactifs

Ethanol Merck deshydraté par la méthode de Lund et Bjerrum (6). La teneur en eau déterminée par la méthode de Karl Fischer est inférieure à 0,025%. Acide glycolique cristallisé dans

Phénylbutazone, oxyphenbutazone, cétophénylbutazone, prénazone et sulfinpyrazone: leur pureté est vérifiée par ccm sur plaque de silicagel fluorescent en utilisant comme solvant, soit cyclohexane/méthylisobutylcétone/acide acétique glacial (80:35:5) (phénylbutazone R_f 0,77, oxyphenbutazone R_f 0,40, cétophénylbutazone R_f 0,25); soit cyclohexane/chloroforme/méthanol/acide acétique glacial (60:30:5:5) (sulfinpyrazone R_f 0,34, prénazone R_f 0,50). La migration est effectuée sous atmosphère d'azote, à l'abri de la lumière. La teneur en eau déterminée par la méthode de Karl Fischer est inférieure à 0,2%.

Matériel et technique

Les pK_a sont déterminés par spectrophotométrie (3) en solution $3 \cdot 10^{-5}$ M au maximum d'absorption de la forme anionique (spectrophotomètre Varian type 635) à 25° ± 0,1°C. Pour chaque produit 7 déterminations sont effectuées à l'aide de 7 tampons de pH correspondant à $pK_a \pm 0{,}6$, $pK_a \pm 0{,}4$, $pK_a \pm 0{,}2$ et pK_a (valeur approximative déterminée lors d'un essai préliminaire).

Les déterminations potentiométriques sont réalisées en solution éthanolique 10^{-2} M neutralisées à 50% par addition d'éthanolate de sodium, à l'aide de la cellule: Pt/H_2 (1 atmosphère) solution tampon//LiCl (0,1 M) AgCl/Ag. L'électrode à hydrogène est à plaque de platine platiné Tacussel type Pt151. L'électrode de référence est une électrode Ag/AgCl. Quatre mesures indépendantes sont réalisées pour chaque composé. L'étalonnage est réalisé à l'aide de 2 solutions tampons (5), acide salicylique 10^{-2} M/salicylate de Li 10^{-2} M et acide diéthylbarbiturique 10^{-2} M/diéthylbarbiturate de Na 10^{-2} M. Les mesures de potentiel sont effectuées à 25°C ± 0,1° sur un millivoltmètre Tacussel S70AS/N.

Les mesures voltampérométriques sont réalisées en solution éthanolique $2 \cdot 10^{-3}$ M en présence de perchlorate de lithium 0,2 M (Merck pour analyse). Les potentiels sont imposés à l'aide d'un potentiostat Tacussel type PRG 5. Les électrodes utilisées sont les suivantes. Electrode de travail: électrode à goutte de mercure à temps de goutte imposé Tacussel type MPO; électrode de référence: électrode au calomel aqueux; électrode auxiliaire: électrode de platine poli.

DANIEL T. W. CHU, STUART N. HUCKIN, EDITH BERNSTEIN, DAVID L. GARMAISE, RICHARD S. EGAN, and RUTH S. STANASZEK. Can. J. Chem. **59**, 763 (1981).

The nature of the products obtained from the reaction of chelocardin (**1**) and the model compound 2-acetyldimedone (**5**) with a variety of amines was investigated. It was observed that amines react with β-triketones having an exocyclic carbonyl side-chain to give exclusively β,β′-diketoenamines with substitution at the side-chain carbonyl.

DANIEL T. W. CHU, STUART N. HUCKIN, EDITH BERNSTEIN, DAVID L. GARMAISE, RICHARD S. EGAN et RUTH S. STANASZEK. Can. J. Chem. **59**, 763 (1981).

On a étudié la nature des produits provenant de la réaction de la chélocardine (**1**) et du composé type l'acétyl-2 dimédone (**5**) avec différentes amines. On a observé que les amines réagissent avec les β tricétones ayant sur la chaîne latérale un groupe carbonyle exocyclique pour conduire exclusivement aux β,β′-dicétoénamines portant le substituant au niveau du carbonyle de la chaîne latérale.

[Traduit par le journal]

Chelocardin, a broad spectrum antibiotic that was first described in 1962 (1) and subsequently shown to be **1** (2), possesses a β-triketone system in ring A. During the course of our chemical investigation on the modifications of chelocardin, it was found that the ring A β-triketone is the most reactive center in the molecule and is highly susceptible to chemical modification.

We have reported that chelocardin hydrochloride (**1**) reacted with a variety of amino compounds (amines, hydrazines, hydrazides, and aromatic amines) to yield 2a-substituted derivatives (**2**)[6] having antibacterial spectra similar to the parent antibiotic (3) as illustrated in Scheme 1.

The same reaction course was observed with *N*-carbobenzoxychelocardin (**3**) (4). Condensation of **3** with amino compounds also yielded 2a-substituted derivatives **4**. This exclusive substitution reaction represents a preferential attack of the side chain carbonyl to provide a novel β,β′-diketoenamine structure. An analogous condensation of the exocyclic carbonyl in the β-tricarbonyl system of usnic acid has recently been reported (5). However, the spectroscopic data were not sufficient to establish the substitution at the exocyclic carbonyl instead of the other two carbonyl groups. The correctness of the structural assignments was only established by X-ray analysis.

This article presents our results on further chemical studies with model β-triketones designed to provide spectroscopic evidence to firmly establish the position of amino substitution.

The nmr spectra of chelocardin and its derivatives (other than a few 4-*N*-acyl derivatives) are poorly resolved. Hence, their nmr spectra offer little clue as to which carbonyl in ring A has undergone substitution. However, the ^{13}C nmr spectrum shows one resonance for each carbon in the molecule, and the structural assignments of these derivatives were based on extensive analyses of the ^{13}C nmr data.

The three carbonyl carbons of the A-ring β-triketone system and the C(12) carbonyl make up the four most downfield resonances of chelocardin hydrochloride and its derivatives in the ^{13}C nmr spectra. These resonances are all generally found between 170 ppm and 210 ppm. Comparison of the chemical shifts of 2-acetyldimedone (**5**) with ring A resonances of chelocardin hydrochloride (1) and *N*-carbobenzoxychelocardin (**3**) permits assignments of the corresponding carbons (Table 1).

5 **1** **3**

Assignments	5	1	3
C(1)	196.3	190.6	190.6
C(3)	196.3	191.1	196.0
C(2)	112.0	110.7	111.2
C(2a)	201.6	200.0	200.5
C(2a)CH_3	28	26.5	26.3
C(12)	—	199.6	200.8

[a]Chemical shift data are given in ppm downfield from internal Me_4Si and spectra taken in Me_2SO.

The specific C(1) and C(3) assignments were made on the basis of relative insensitivity of C(1) to changes in the substituent at C(4). Differentiation between C(2a) and C(12) in *N*-carbobenzoxychelocardin (**3**) was made on the basis of long range couplings visible in coupled spectra; the 200.5 ppm resonance is clearly split into a quartet as a consequence of coupling with the methyl protons. Excellent agreement for C(2), C(2a), and C(2a)-methyl resonances was also observed. Hence a positive correlation with known derivatives of 2-acetyldimedone with respect to their ^{13}C nmr chemical shifts would firmly establish the position of substitution by the amino reagents.

2-Acetyl-5,5-dimethyl-3-*N*-pyrrolidylcyclohex-2-en-1-one (**8**) was prepared according to the method of Alt and Speziale (6) as shown in Scheme 2. Its structure was shown by nmr analysis to have no vinyl proton, and to possess two sets of nonequivalent methylene protons at δ 2.07 and δ 2.56 ppm.

Reaction of acetyldimedone (**5**) with pyrrolidine under similar experimental conditions as those for the preparation of aminochelocardin derivatives gave the pyrrolidylacetyldimedone (**9**). This compound is different from compound **8**, having a different R_f value in the thin-layer chromatographic analysis. Its nmr spectrum shows the presence of a singlet at δ 2.12 corresponding to four methylene protons. On the basis of symmetry considerations, the presence of the pyrrolidyl group at the side chain was fully established. This represents the first time a complete structure proof for the product of condensation of amines with a β-triketone sys-

[b]Substantial changes occurred with substitution.

tem having an exocyclic carbonyl side chain was obtained by spectroscopic methods.

Aminoacetyldimedone (**10**) prepared by treatment of acetyldimedone (**5**) and hexamethyldisilazane or ammonium acetate (7) shows the presence of a singlet at δ 2.54 ppm corresponding to four methylene protons in its nmr spectrum. Its structure was established based on symmetry and off-resonance single frequency decoupling (ORSFD) considerations.

The nmr chemical shift data of 2-acetyldimedone (**5**) as well as the amino substituted 2-acetyldimedone derivatives **8**, **9**, and **10** are given in Fig. 1. No significant change in chemical shift for the 2a-methyl group is observed. Their comparative ^{13}C nmr chemical shift data are shown in Table 2. The ^{13}C nmr chemical shifts of the three carbonyl carbons of the β-triketone system and also the 2a-methyl of the 2-acetyldimedone (**5**) are profoundly affected by substitutions of amino functions on the 2a carbonyl as well as the 1 or 3 carbonyl as illustrated in Table 2.

FIG. 1. Comparative nmr chemical shift data (given in ppm with spectra taken in DMSO-d_6) of 2-acetyldimedone (**5**) and substituted 2-acetyldimedones.

When the substitution of the amino group is on the 2a carbonyl (e.g. **9** and **10**), the C(2a) and C(2a)-methyl carbon resonances undergo substantial *upfield* shifts. On the other hand, when the substitution of the amino group is on the 1 or 3 carbonyl, the C(2a)-methyl carbon resonance undergoes substantial *downfield* shift. This observation in chemical shifts in ^{13}C nmr is extremely useful in the determination of the location of the substitution of amino reagents to chelocardin (**1**) or its *N*-protected derivatives.

All the amino-chelocardin derivatives obtained according to the route described (3) show an additional absorption at approximately 307–312 nm in their uv spectra, indicating the formation of a vinylogous imide system (6). Their mass spectra show the presence of several fragments normally found in the mass spectrum of chelocardin; the most important and prominent ion can be assigned to structure B shown in Fig. 2 (*m/e* 270, $C_{16}H_{14}O_6$) (2). This suggests that substitution of the amino group is not located in the B, C, and D rings.

In order to establish the position of the substitution, an analysis of the ^{13}C nmr spectra of the amino-chelocardin derivatives and also those of 2-acetyldimedone and its amino analogues was studied. The comparative ring A ^{13}C nmr chemical shift data of chelocardin hydrochloride (**1**), *N*-carbobenzoxychelocardin (**3**), and their amino derivatives **11**, **12**, **13**, **14**, **15**, and **16** are shown in Table 3. An excellent correlation was observed when their

[b]Substantial upfield shift observed.

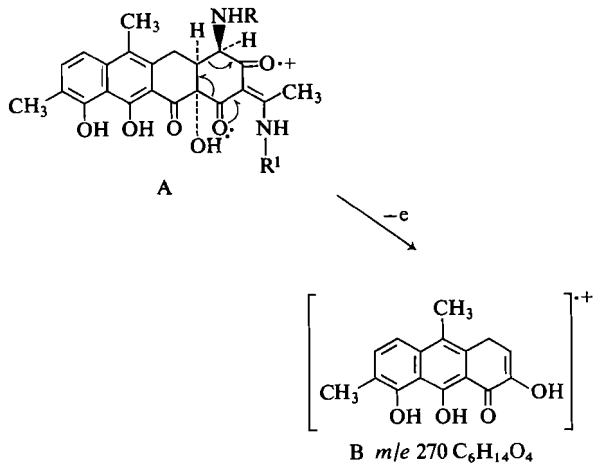

FIG. 2. Major fragmentation of chelocardin and analogues.

^{13}C nmr chemical shift values were compared with those of aminoacetyldimedones. (**13** vs. **10** and **14** vs. **9**). All the derivatives show substantial *upfield* shifts for their corresponding C(2a) and C(2a)-methyl carbon resonances. Using the previous observations with 2-acetyldimedone (**5**) and its amino analogues, all the amino-chelocardin analogues would have their amino substitutions at the 2a-carbonyl group. This confirms our previous finding that reaction of chelocardin hydrochloride (**1**) or *N*-carbobenzoxychelocardin (**3**) with amino reagents always gives rise to 2a-amino substituted chelocardin derivatives **2** or **4**.

In summary, we have provided a confirmation of the structures of the chemical reaction products obtained with the highly functionalized and reactive chelocardin and various amines. It further establishes a general reaction that a β-triketone having an exocyclic carbonyl function reacts with amines to give β,β′-diketoenamines having substitution exclusively on the exocyclic carbonyl.

Experimental

Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. The infrared spectra were recorded on a Beckman Model IR8 infrared spectrophotometer. The nmr spectra were recorded on Varian Associates EM-360 and HA-100 spectrometers in deuterated solvents; resonance positions are given on the δ scale (ppm) relative to internal tetramethylsilane. The mass spectra were recorded on an AEI MS-902 double-focussing mass spectrometer. The uv spectra were recorded on a Unican SP-800A spectrometer in 0.1 *N* methanolic hydrogen chloride solution. The ^{13}C nmr spectra were recorded on a Varian Associates XL-100-15/TT-100 spectrometer system in Me_2SO; resonance positions are given in ppm relative to internal tetramethylsilane. Parameters used were pulse width (30°) 3.5/μs, pulse delay 0.5–1.0, 6K sweep width, and 8K data table.

Preparation of Amino Derivatives of Chelocardin

2a-Amino-substituted analogues of chelocardin were prepared according to the procedure reported previously (3, 4). The general procedure for the preparation of these analogues was to add a slight excess of 1 mole equivalent of the corresponding hydrazine, hydrazide, or aniline to a solution of chelocardin hydrochloride (**1**) or its free base or *N*-carbobenzoxychelocardin (**3**) in 98% aqueous tetrahydrofuran or methanol. (In the case of anilines, one to two mole equivalents of acetic acid was also added.) The reaction mixture was allowed to stand for at least 1 h at room temperature (a few compounds required a longer reaction time). The product was isolated by precipitation, filtration, and recrystallization.

Amino Derivatives of 2-Acetyldimedone

The 2-acetyl-5,5-dimethyl-3-*N*-pyrrolidylcyclohex-2-en-1-one (**8**) was prepared according to the method of Alt and Speziale (6). The preparation of 2-aminoacetyldimedone (**10**) was reported recently (7).

Pyrrolidylacetyldimedone (9)

Pyrrolidylacetyldimedone was prepared as follows. Pyrrolidine (71 mg, 1 mmol) was added to a solution of 2-acetyldimedone (182 mg, 1 mmol) in benzene (25 mL). After it was refluxed with removal of water for 8 h, the benzene was removed to give a yellow solid. Column chromatography on silica gel using chloroform/methanol (9:1) as eluent yielded 210 mg pure product **9** (90% yield). The nmr and ^{13}C nmr data are given in the text. *Anal.* calcd. for $C_{14}H_{21}NO_2$: C 71.45, H 8.99, N 5.95; found: C 71.15, H 9.10, N 5.91.

Solubility of water in vinyl chloride

E. COLIN CLARKE, DAVID N. GLEW, AND DENIS J. MAISONNEUVE

Corporate Research and Development, Dow Chemical of Canada, Limited, Sarnia, Ont., Canada N7T 7K7

Received August 12, 1980

E. COLIN CLARKE, DAVID N. GLEW, and DENIS J. MAISONNEUVE. Can. J. Chem. **59**, 768 (1981).

The solubility of water in liquid vinyl chloride has been measured over the temperature range −17° to 60°C by a classical water absorption method. Solubility equations for water in vinyl chloride have been derived and the standard thermodynamic function changes for water transfer have been evaluated.

E. COLIN CLARKE, DAVID N. GLEW et DENIS J. MAISONNEUVE. Can. J. Chem. **59**, 768 (1981).

Utilisant la méthode classique d'absorption d'eau, on a mesuré la solubilité de l'eau dans le chlorure de vinyle liquide dans un intervalle de température allant de −17° à 60°C. On a déduit les équations de solubilité de l'eau dans le chlorure de vinyle et on a évalué les variations de la fonction thermodynamique standard du transfert de l'eau.

[Traduit par le journal]

Introduction

Although the solubility of vinyl chloride in water has been measured recently (2) there are apparently no measurements reported in the literature for the solubility of water in liquid vinyl chloride. This work describes such solubility measurements which define the vinyl chloride – water system between −17° and 60°C.

The solubility of water in liquid vinyl chloride is determined by a classical weighing method. Water and vinyl chloride liquid are equilibrated at constant temperature. Part of the water-saturated vinyl chloride phase is vaporized completely and passed through a preweighed drying tower. The increase in weight of the drying tower is attributed to the water in the vinyl chloride.

Experimental

A 500 cm^3 stainless steel cylinder, fitted with short dip-tube and Nupro stainless steel bellows valve, was evacuated, plugged, and weighed. All weights were corrected for the buoyancy of air. About three grams of water, injected by syringe into a 200 cm^3 roundbottomed flask, were vacuum distilled into the cylinder cooled by a Dry Ice – acetone mixture. The cylinder was plugged, brought to ambient temperature, and reweighed. About 350 g of vinyl chloride were charged by gravity into the recooled cylinder from a sample cylinder. The cylinder was plugged, warmed to ambient temperature, and reweighed.

The cylinder was inverted carefully to avoid getting water into the dip-tube and was fitted, as shown in Fig. 1, with capped exit tube a, with aluminum ring bearing b, and with aluminum drive collar c. The cylinder was immersed with its axis 35° from the vertical in a large thermostat bath and located by gripping collar c in the chuck of a slow-drive electric motor with ring b bearing on a stationary Teflon® seat. The thermostat temperature was maintained within 0.01°C and measured by platinum resistance thermometer and Müller bridge. The vinyl chloride liquid was saturated with water by rotating the cylinder once per second for a period of 20 h; equilibration for 72 h proved that full saturation was attained within 20 h. After rotation was stopped, the cylinder was left for one hour to permit settling of dispersed water, if any.

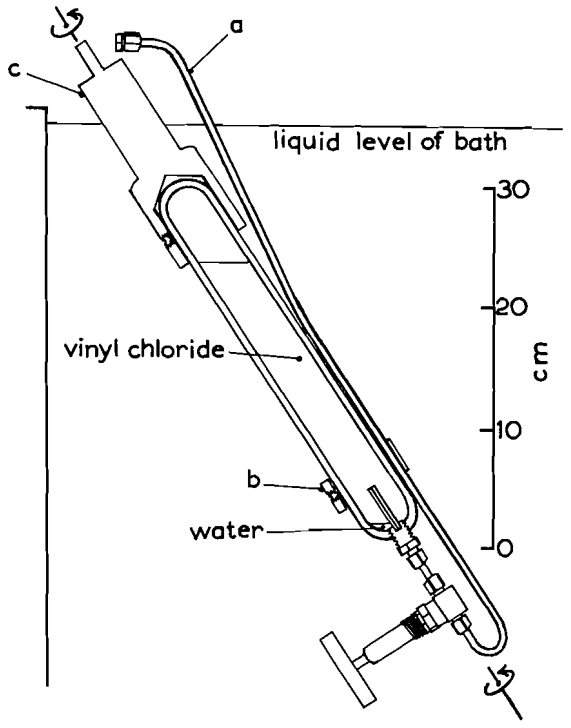

FIG. 1. Assembly for cylinder rotation.

A dry nitrogen stream of 700 cm^3/min was passed for five minutes through a needle control valve, the drying tower, and a Gilmont No. 2 flowmeter connected in series. The nitrogen flow was stopped and the pressure dropped to atmospheric, the Teflon® stopcocks on the tower were closed, the tower was disconnected and weighed full of nitrogen. The tower weight was corrected for the weight of nitrogen and the buoyancy of air.

The needle valve, drying tower, and flowmeter were reconnected and the closed needle valve was attached to the freshly uncapped exit tube a from the cylinder. A miniature thermocouple was taped to the underside of tube a 5 cm from the needle valve and two infrared lamps were positioned to heat the airborne section of tube a. The cylinder valve below the thermostat liquid was opened and the infrared lamps switched on to

maintain tube a about 15°C above thermostat temperature. Vinyl chloride liquid saturated with water was vaporized completely in heated tube a and the vapour controlled by the needle valve to give a flow of 370 cm^3/min through the drying tower. The flow was continued for 3–4 h until 120–180 g vinyl chloride had passed through the drying tower, after which the cylinder valve was closed. Residual vinyl chloride liquid in tube a was allowed to evaporate after which the needle valve was closed and tube a was disconnected and capped. A nitrogen flow of 700 cm^3/min was passed for five minutes through the drying tower to displace vinyl chloride vapour, and the drying tower full of nitrogen was weighed as before. The final weight of the drying tower minus its initial weight gave the weight of water removed from the vaporized vinyl chloride.

The cylinder still contained 170–230 g vinyl chloride which was sufficient to cover the dip-tube and ensure that only liquid vinyl chloride had left the cylinder. The cylinder assembly, shown in Fig. 1, was removed from the thermostat, fittings b and c removed, the cylinder and valve washed with acetone and dried, tube a was disconnected from the valve, and the valve plugged. To remove thermostat liquor from within the valve bonnet, the stem, handle, and bonnet were disassembled from the body-bellows, all were washed with acetone and dried, and the valve was reassembled. The cylinder was reweighed. The cylinder weight minus its initial weight full of vinyl chloride gave the weight of vinyl chloride saturated with water that passed into the drying tower. The small weight of vinyl chloride vapour at atmospheric pressure remaining in tube a that did not pass into the drying tower was neglected.

The drying tower containing a cylindrical bed of solid desiccant 4.5 cm diameter and 5 cm deep weighed about 600 g. Many experiments were carried out to find suitable drying agents for vinyl chloride. Molecular sieves and activated alumina were unsuitable because of strong vinyl chloride adsorption and possible polymerization. Potassium hydroxide (5 mm pellets) and calcium oxide (5 mm lumps) were insufficiently fine to remove all water from the vinyl chloride. The desiccant finally chosen for use in the drying tower was a 5 cm bed of 2 mm barium oxide granules having equilibrium water pressure about 10^{-19} atm.

All experiments were conducted with the drying tower backed-up in series by a second and similar drying tower which was weighed and invariably confirmed that no significant water escaped with the vinyl chloride from the first tower.

Because of the known long-term toxic effects of vinyl chloride, care was taken to ensure that none was released into the laboratory workspace and that all was vented via an efficient fume-hood system directly into the atmosphere where degradation was fast.

Results and Discussion

Results for the solubility S (mg H_2O/kg solution) of water in liquid vinyl chloride between −17° and 60°C are presented in Table 1. The solubility between 0° and 60°C in equilibrium with liquid water is best represented by the equation

$$[1] \quad \log_{10} S = 7.1666 - 1246.7/T$$

which was evaluated by a weighted least-squares method (1) with $T(K) = 273.15 + t(°C)$. The weights were assessed on the basis that the errors derived entirely from the two weighings of the drying tower. The standard error shown in Table 1 is the experimental uncertainty of the solubility determination.

Table 2 presents calculated S values together with their standard errors as derived from [1] and the error matrix for temperatures between 0°C and 80°C.

Liquid Water – Liquid Vinyl Chloride – Gas System

The liquid water (l_1) – liquid vinyl chloride (l_2) – gas (g) three-phase system attains equilibrium at constant temperature according to the equation

$$[2] \quad \underset{\substack{x_1^{l_1} \\ x_2^{l_1}}}{H_2O\,(l_1)} + \underset{\substack{x_1^{l_2} \\ x_2^{l_2}}}{C_2H_3Cl\,(l_2)} \rightleftharpoons \underset{p_1}{H_2O\,(g)} + \underset{p_2}{C_2H_3Cl\,(g)}$$

in which $x_1^{l_1}$ and $x_1^{l_2}$ are the mole fractions of component 1, water, in phases l_1 and l_2; $x_2^{l_1}$ and $x_2^{l_2}$ are the mole fractions of component 2, vinyl chloride, in l_1 and l_2; and p_1 and p_2 are the water and vinyl chloride saturation partial pressures for equilibrium.

Table 3 presents values of the equilibrium phase compositions for the water – vinyl chloride system between −17°C and 60°C. The second column gives our solubility results expressed as mole fractions. The third column gives $x_2^{l_1}$ values calculated from

$\Delta S_1^0(l_1 \rightarrow l_2) = 32.44 \pm 0.67$ J K^{-1} mol^{-1}
$R = 8.31434$ J K^{-1} mol^{-1} (6)

the solubility measurements of Hayduk and Laudie (2), together with the vapour pressure of vinyl chloride (3). The water partial pressure, p_1, is given in the fourth column of Table 3. Above 0°C p_1 is evaluated from the vapour pressure of water (4) using Raoult's Law. Below 0°C p_1 is the vapour pressure of ice (4).

Consider the equilibrium of water between phases l_1 and l_2 represented by the equation

$$[3] \quad \underset{x_1^{l_1}}{H_2O\,(l_1)} \rightleftharpoons \underset{x_1^{l_2}}{H_2O\,(l_2)}$$

with equilibrium constant K_1 defined by

$$[4] \quad K_1 = x_1^{l_2}/x_1^{l_1}$$

In order to include our solubilities in equilibrium with ice we use an equivalent definition of K_1 given by

$$[5] \quad K_1 = x_1^{l_2}/a_1$$

where a_1 is the water activity, evaluated as the vapour pressure of ice divided by that of supercooled water (4).

Over the temperature range of our measurements K_1 is well represented by

$$[6] \quad \log_{10} K_1 = 1.6943 - 1243.0/T$$

which was determined by a weighted least-squares method (1). The weight assigned to the $\log_{10} K_1$ value for each solubility measurement was proportional to the square of the mass of water absorbed in the drying tower. From the fit of the measurements by [6], the standard error on a single solubility was equivalent to 3.3 mg H_2O on the two weighings of the drying tower.

The least-squares analysis gives the calculated values and associated standard errors at 25°C, $K_1 = 3.352 \pm 0.026 \times 10^{-3}$, ΔG_1^0 ($l_1 \rightarrow l_2$) = 14 126 ± 19 J mol^{-1}, ΔH_1^0 ($l_1 \rightarrow l_2$) = 23 796 ± 213 J mol^{-1}, ΔS_1^0 ($l_1 \rightarrow l_2$) = 32.44 ± 0.67 J K^{-1} mol^{-1}. These standard thermodynamic function changes refer to eq. [3] for the molar transfer of water at unit mole fraction from a liquid water phase into a liquid vinyl chloride phase. The water transfer into vinyl chloride is seen to be limited by the high enthalpy change but promoted by the positive entropy change; this corresponds with hydrogen bonded water at low enthalpy and orientationally constrained in the liquid water phase, giving weakly bonded water with more orientational freedom in the liquid vinyl chloride phase.

Table 4 presents calculated values and standard errors for the equilibrium constant and standard thermodynamic function changes for water transfer into vinyl chloride between −20° and 80°C.

Consider the equilibrium of water between phases l_2 and g represented by the equation

$$[7] \quad \underset{x_1^{l_2}}{H_2O\,(l_2)} \rightleftharpoons \underset{p_1}{H_2O\,(g)}$$

with equilibrium Henry Law constant H_1 defined by

$$[8] \quad H_1 = p_1/x_1^{l_2}$$

Between −17° and 60°C H_1 is well represented by

$$[9] \quad \log_{10} H_1 = 25.8846 - 2016.1/T - 7.335 \log_{10} T$$

which was determined by least squares (1) using the same weights as before. From the fit of the measurements by [9] the standard error on a single

ΔCp_1^0 ($l_2 \rightarrow g$) = −60.99 ± 23.94 J K^{-1} mol^{-1}
R = 8.31434 J K^{-1} mol^{-1} (6)

solubility measurement was again found to be equivalent to 3.3 mg H_2O for the two drying-tower weighings. Student's t-test shows that the coefficient of $\log_{10} T$ in [9] is significant at the 2.9% level (5).

The above analysis gives calculated values and their standard errors at 25°C, H_1 = 9.388 ± 0.102 atm, ΔG_1^0 ($l_2 \rightarrow g$) = −5551 ± 27 J mol^{-1}, ΔH_1^0 ($l_2 \rightarrow g$) = 20 414 ± 278 J mol^{-1}, ΔS_1^0 ($l_2 \rightarrow g$) = 87.09 ± 0.94 J K^{-1} mol^{-1}, ΔCp_1^0 ($l_2 \rightarrow g$) = −61.0 ± 23.9 J K^{-1} mol^{-1}. These standard thermodynamic function changes refer to [7] for the molar transfer of water from a liquid vinyl chloride phase at unit water mole fraction into an ideal gas phase at one atmosphere pressure. These values show that in its vaporization from liquid vinyl chloride water behaves like a normal nonassociated liquid with a standard vaporization entropy of 87 J K^{-1} mol^{-1}, near to the characteristic Trouton value 88. Our results indicate a heat capacity for water dissolved in vinyl chloride of 95 ± 24 J K^{-1} mol^{-1}.

Table 5 presents calculated values and standard errors for the Henry Law constant and standard thermodynamic function changes for water transfer from liquid vinyl chloride into the gas phase between −20° and 80°C.

Solution of the strong-collision master equation for unimolecular reaction

S. R. VATSYA[1] AND H. O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received September 10, 1980

S. R. VATSYA and H. O. PRITCHARD. Can. J. Chem. **59**, 772 (1981).

A complete solution of the strong-collision master equation for unimolecular reaction is derived, for any number of distinct reaction products. This solution provides exact results for any chemical activation process under the strong-collision assumption.

S. R. VATSYA et H. O. PRITCHARD. Can. J. Chem. **59**, 772 (1981).

On a trouvé une solution complète, quelque soit le nombre de réactifs impliqués, de l'équation fondamentale dérivant des réactions unimoléculaires impliquant des collisions fortes. Cette solution fournit des résultats exacts pour tout processus d'activation chimique pour lequel on fait l'hypothèse d'une collision forte.

Introduction

The purpose of this paper is to provide a complete solution of the strong-collision unimolecular reaction problem using the master-equation formulation; systems considered include thermal reaction to give a single product or to give any number of distinct products, and also the complementary chemical activation problems, but all in the absence of electromagnetic radiation. We summarise briefly here the key results of this dissertation. (*i*) An extremely accurate approximation for the shape of the unimolecular fall-off in strong-collision systems is given by eq. [23], and rarely will a practising kineticist want to go beyond this approximation; if however, it is necessary to do so, the exact rate constant can be found by using eq. [11]. (*ii*) Equation [25] gives an equally accurate representation of the different fall-off shapes when there are two (or more) distinct reaction products; again, an exact solution is available through the use of eq. [22]. (*iii*) Equation [17], together with eq. [15], gives the population evolution as a function of time, and this, via eq. [26], yields a complete solution to the chemical activation problem within this approximation.

In establishing these conclusions, the complete eigenvalue spectrum for the strong-collision case is required for all pressures, and many of these results will be used later in a treatment of the weak-collision problem.

The Master Equation for Unimolecular Reaction

We divide the energy-level spectrum of the reactant molecule into n grains having fractional populations $\tilde{n}_i$ at thermal equilibrium. Transitions between the grains are induced by collision with the heat bath molecules M, with rate constants q_{ij} for transition from grain i to grain j. In the absence of any reaction, the thermal relaxation of the reactant molecule is described by the set of equations

$$[1] \qquad \mathrm{d}\boldsymbol{n}(t)/\mathrm{d}t = \mathbf{A}\boldsymbol{n}(t)$$

where $\boldsymbol{n}(t)$ is the population vector and $\mathbf{A}$ is a matrix whose elements are

$$a_{ij} = q_{ji}[\mathrm{M}], \quad a_{ii} = -\sum_{j \neq i} a_{ji}$$

The matrix $\mathbf{A}$ is symmetrised by the transformation

$$[2] \qquad \mathbf{B} = -\mathbf{E}^{-1/2}\mathbf{A}\mathbf{E}^{1/2}$$

with $e_{ij} = \delta_{ij}\tilde{n}_i$; $\mathbf{B}$ has one eigenvalue which is zero, with corresponding eigenvector $\mathbf{S}_0$ having elements $S_{0j} = \tilde{n}_j{}^{1/2}$, $j = 0, 1, \ldots, n-1$, and the remainder of the eigenvalues are positive and, in general, distinct.

We may choose a special form of $\mathbf{A}$, viz.

$$[3] \qquad a_{ij} = \mu\{(1 - \delta_{ij})\tilde{n}_i - \delta_{ij}(1 - \tilde{n}_i)\}$$

which has a single eigenvalue equal to zero, and an $(n-1)$-fold degenerate eigenvalue of numerical magnitude μ, the relaxation rate (1). The matrix $\mathbf{A}$ corresponds to the strong-collision assumption usually made in the description of unimolecular reactions, except that it is somewhat more general (2, 3) — in the sense that μ does not have to be equated to the collision rate, but can take any appropriate value, viz. $\mu = -\lambda[\mathrm{M}]Z$ in the usual terminology (1); many properties of this relaxation matrix have already been given (1, 3).

When unimolecular decay of the molecule from within certain grains is allowed, the evolution of the population vector now becomes (in the absence of any back-reaction)

$$[4] \qquad \mathrm{d}\boldsymbol{\eta}(t)/\mathrm{d}t = (\mathbf{A} - \mathbf{D})\boldsymbol{\eta}(t)$$

where $\eta_i(t)$ is the fraction of the original population remaining in grain i at time t, and $\mathbf{D}$ is a diagonal matrix whose elements $d_{ij} = \delta_{ij}d_i$ are the specific rate constants for decay from the grain i to products. Usually, in the reactive region, d_i will differ from grain to grain, but in the non-reactive region, there will be many grains having $d_i = 0$; in what follows, we will treat the general case where the multiplicity of any d_i is arbitrary.

The matrix $(\mathbf{A} - \mathbf{D})$ in [4] may be symmetrised in the same way as [2] to give $(\mathbf{B} + \mathbf{D})$, and we now derive the complete eigenvalue spectrum of this matrix, together with the corresponding eigenvectors. The following definitions will be useful: (,) represents the scalar product of two vectors, and $p_0 = \mathbf{S}_0(\mathbf{S}_0,)$ is the eigenprojection corresponding to the zero eigenvalue of the matrix $\mathbf{B}$.

The Eigenvalues of $(\boldsymbol{B} + \boldsymbol{D})$

Let the distinct diagonal elements of $\mathbf{D}$ be d_j, each with multiplicity m_j, $j = 0, 1, 2, ..., M$. We order the set $\{d_j\}$ in an increasing manner. Also, let the eigenvalues γ_{ji} of $(\mathbf{B} + \mathbf{D}) = [\mu(1 - p_0) + \mathbf{D}]$ be organised in $(M + 1)$ groups, the jth group defined by $(\mu + d_{j-1}) < \gamma_{ji} \leq (\mu + d_j)$, $i = 0, 1, ...$; and we arbitrarily set $d_{-1} = -\infty$. Since $0 \leq [\mu(1 - p_0) + \mathbf{D}] \leq (\mu + \mathbf{D})$, all of the eigenvalues are covered by this definition. We shall also assume that the distinct eigenvalues $\{\gamma_{ji}\}$ of the jth group are ordered in an increasing manner with i.

The eigenvalue equation for a particular (ji) takes the following form

$$[5] \qquad (\mu - \gamma_{ji} + \mathbf{D})\rho_{ji} = \mu p_0 \rho_{ji}$$

If $\gamma_{ji} \neq \mu + d_j$, then

$$[6] \qquad \rho_{ji} = \mu(\mu - \gamma_{ji} + \mathbf{D})^{-1} p_0 \rho_{ji}$$

From [6] it follows that the range of ρ_{ji} is spanned by the single vector $(\mu - \gamma_{ji} + \mathbf{D})^{-1}\mathbf{S}_0$ and hence the multiplicity of γ_{ji} is one, i.e. γ_{ji} is a simple eigenvalue. Equation [6] now yields that γ_{ji} is a solution of

$$[7] \qquad 1 = \mu(\mathbf{S}_0,(\mu - \gamma + \mathbf{D})^{-1}\mathbf{S}_0) = \mu \sum_{k=0}^{M} \frac{\tilde{n}^k}{(\mu - \gamma + d_k)}$$

where

$$\tilde{n}^k = \sum_{l=1}^{m_k} \tilde{n}_{v(k,l)}$$

and $v(k,l)$ is defined by $(\mathbf{D})_{vv} = d_k$, $l = 1, 2, ..., m_k$; note that whenever the degeneracy m_k of d_k is 1, $\tilde{n}^k$ becomes $\tilde{n}_k$, the fractional equilibrium population for the grain k. Each of the solutions of [7] is easily seen to be some eigenvalue γ_{ji} with an eigenvector being equal to $(\mu - \gamma_{ji} + \mathbf{D})^{-1}\mathbf{S}_0$.

Consider a solution $\bar{\gamma}$ of [7]. Since $(\mu - \bar{\gamma} + \mathbf{D})^{-1}$ exists, we have

$$(\mu - \bar{\gamma})(\mu - \bar{\gamma} + \mathbf{D})^{-1} = 1 - (\mu - \bar{\gamma} + \mathbf{D})^{-1}\mathbf{D}$$

and hence $\bar{\gamma}$ is a solution of

$$[8] \qquad \gamma = \mu(\mathbf{S}_0,(\mu - \gamma + \mathbf{D})^{-1}\mathbf{D}\,\mathbf{S}_0) = \mu \sum_{k=0}^{M} \frac{\tilde{n}^k d_k}{(\mu - \gamma + d_k)}$$

Conversely, a solution $\bar{\gamma} \neq \mu$ of [8] is a solution of [7], by the same argument. Thus [8] may have a spurious solution equal to μ, which will happen if and only if $d_0 \neq 0$, which follows from the following: if $d_0 \neq 0$, $\mathbf{D}^{-1}$ exists and hence μ is clearly a solution of [8]; if $d_0 = 0$, then the right side of [8] is easily seen to be less than μ for each $\gamma \leq \mu$. It is clear that [7] cannot have μ as a solution for all μ; thus, if $d_0 = 0$, then [7] and [8] are equivalent. Further, it is clear that an eigenvalue in the jth group which is not a solution of [7] is equal to $(\mu + d_j)$. With the appropriate transcription of symbols, [8] is the same as eq. [20] derived by Nordholm in ref. 2. The solutions of [7] are easily seen to be the zeros of a polynomial, as expected. The degree of the polynomial is $(M + 1)$ and therefore it has $(M + 1)$ zeros. All of these zeros will be distinct, otherwise there will be at least one simple eigenvalue having multiplicity greater than one. Further

$$\delta(x) = \mathrm{d}/\mathrm{d}x[(\mathbf{S}_0,(\mu - x + \mathbf{D})^{-1}\mathbf{S}_0)] = (\mathbf{S}_0,(\mu - x + \mathbf{D})^{-2}\mathbf{S}_0) \geq 0$$

and

$$\delta(x) \neq 0$$

for that would imply that $\mathbf{S}_0 = 0$. Thus, $(\mathbf{S}_0,(\mu - x + \mathbf{D})^{-1}\mathbf{S}_0)$ is a strictly increasing function for

$$(\mu + d_{j-1}) < x < (\mu + d_j)$$

and each j; and

$$\lim_{x \to \mu + d_{j-1}, \mu + d_j} (\mathbf{S}_0,(\mu - x + \mathbf{D})^{-1}\,\mathbf{S}_0) = -\infty, +\infty \qquad j = 1, 2, ..., M$$

For $j = 0$, $(\mathbf{S}_0,(\mu - x + \mathbf{D})^{-1}\mathbf{S}_0)$ is a positive increasing function on $(-\infty,\mu + d_0)$ and while it approaches infinity at $(\mu + d_0)$, at $-\infty$ it is zero. Consequently, there is at least one solution of [7] in each of the $(M + 1)$ groups.

Now consider a typical degenerate eigenvalue, i.e. $(\mu + d_j)$ for some j. The eigenvalue equation reads as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

[9] $(\mathbf{D} - d_j)\rho_j' = \mu p_0 \rho_j'$

where we denote by ρ_j' the eigenprojection corresponding to the eigenvalue $(\mu + d_j)$. For an arbitrary vector ϕ we have that $(\mathbf{S}_0,\rho_j'\phi)\tilde{n}_k^{1/2} = 0$ for each $k = \nu(j,l)$, $l = 1, 2, ..., m_j$; and hence $(\mathbf{S}_0,\rho_j'\phi) = 0$ for each ϕ. This, together with [9], implies that $(\rho_j'\phi)_k = 0$ for $k \neq \nu(j,l)$. The range of ρ_j' is, therefore, the set of vectors ϕ such that $(\mathbf{S}_0,\phi) = 0$ with $\phi_k = 0$ for $k \neq \nu(j,l)$, which is clearly $(m_j - 1)$ dimensional. Thus, the multiplicity of the degenerate eigenvalue of the jth group is $(m_j - 1)$.

It is clear now that in the jth group there are two distinct eigenvalues, one $(\mu + d_j)$ with multiplicity $(m_j - 1)$ and one strictly less than $(\mu + d_j)$ with multiplicity one. If $m_j = 1$, then the matrix has no eigenvalue equal to $(\mu + d_j)$ which is implied by the fact that the multiplicity of $(\mu + d_j)$ is zero; if $m_j = 2$, $(\mu + d_j)$ is a simple eigenvalue. However, for the present, we reserve the term simple for the solutions of [7] and degenerate for the others; the eigenprojection corresponding to the degenerate eigenvalues is already determined. In the following, we obtain approximations to the simple eigenvalues; the corresponding eigenvectors are clearly determined by [6]. For a further convenience of writing, the simple eigenvalue of the jth group will now be denoted by γ_j.

Let

[10] $\gamma_j = \mu + d_j - \gamma_j'$

and rearrange [7] to read

[10a] $\gamma_j' = \dfrac{\mu\tilde{n}^j}{1 - \mu\beta(\gamma_j')} = \chi(\gamma_j')$

where

$$\beta(x) = \sum_{j \neq k=0}^{M} \tilde{n}^k/(x + d_k - d_j)$$

The correction γ_j', thus, is the unique fixed point of $\chi(x)$ in $(0,d_j - d_{j-1})$. Since $\gamma_j' + d_k - d_j \neq 0$ for all j and $k \neq j$, we have

$$\lim_{\mu \to 0} \gamma_j'/\mu = \tilde{n}^j$$

i.e.

$$\gamma_j \simeq d_j + \mu(1 - \tilde{n}^j)$$

for small μ; this is consistent with the pattern of behaviour observed numerically, i.e. eqs. [15] and [16] of ref. 3.

If $d_0 = 0$, then

$$\gamma_0 \simeq \mu \sum_i{}' \tilde{n}_i$$

where the summation is over all *reactive* states, denoted by $\sum'$. In two other recent articles we have shown that (4) the approximation

$$\gamma_{ap} \simeq \mu \sum_i{}' \tilde{n}_i \Big/ \left(1 - \sum_i{}' \tilde{n}_i\right)$$

and that (5) $\gamma_{ap} \geq \gamma_0$; in both these treatments we had assumed that $\gamma_0 < \mu$, which is true for all μ if and only if $d_0 = 0$. This we show in the following.

The *if* part is already established from the fact that $\gamma_0 < \mu + d_0$. For the *only if* part we notice that γ_0 is the smallest eigenvalue of $[\mu(1 - p_0) + \mathbf{D}]$ and $\mu(1 - p_0) \geq 0$; therefore $\gamma_0 \geq d_0$. If $\gamma_0 < \mu$ and $d_0 \neq 0$, then for small enough μ we shall have $\gamma_0 < d_0$.

It should be remarked here that for moderate values of μ, γ_0 does not have to be greater than μ even if $d_0 \neq 0$. In fact for large enough μ, $\gamma_0 < \mu$ for any value of d_0 as we shall see shortly.

For $j \geq 1$ we have that

$$\lim_{\mu \to \infty} \gamma_j'/\mu = 0$$

for $0 < \gamma_j' < (d_j - d_{j-1})$. Now the trace of

$$[\mu(1 - p_0) + \mathbf{D}] = (n - 1)\mu + \sum_{j=0}^{M} m_j d_j$$

must be equal to the sum of its eigenvalues which is

$$n\mu + \sum_{j=0}^{M} (m_j d_j - \gamma_j')$$

Hence

[10b] $\sum_{j=0}^{M} \gamma_j' = \mu$

Therefore

$$\lim_{\mu \to \infty} \gamma_0'/\mu = 1$$

i.e.

$$\lim_{\mu \to \infty} \gamma_0/\mu = 0$$

Re-writing eq. [8] for γ_0, we get

[11] $\gamma_0 = \mu \sum_{k=0}^{M} \dfrac{\tilde{n}^k d_k}{(\mu - \gamma_0 + d_k)} = \bar{\phi}(\gamma_0)$

It follows that

$$\lim_{\mu\to\infty}\gamma_0 = \lim_{\mu\to\infty}\sum_{k=0}^{M}\tilde{n}^k d_k \Big/ \left(1 - \frac{\gamma_0}{\mu} + \frac{d_k}{\mu}\right)$$

$$= \sum_{k=0}^{M}\tilde{n}^k d_k$$

$$= \lim_{\mu\to\infty}\gamma_{ap} \quad (4)$$

In order to obtain

$$\gamma_j'(\infty) = \lim_{\mu\to\infty}\gamma_j'$$

for $j \geq 1$, we notice that

$$\lim_{\mu\to\infty}(1 - \mu\beta(\gamma_j')) > 0$$

otherwise $\gamma_j' < 0$ or ∞ for some μ. Also

$$\lim_{\mu\to\infty}(1 - \mu\beta(\gamma_j')) = \infty$$

otherwise

$$\lim_{\mu\to\infty}\gamma_j' = \infty$$

and

$$\gamma_j' < d_j - d_{j-1}$$

Thus

$$\mu\beta(\gamma_j') \xrightarrow[\mu\to\infty]{} -\infty$$

and hence

$$[12]\quad \gamma_j'(\infty) = -\frac{\tilde{n}^j}{\beta(\gamma_j'(\infty))}$$

$$= \frac{\tilde{n}^j}{\sum_{j\neq k=0}^{M}\tilde{n}^k/(d_j - d_k - \gamma_j'(\infty))} = \bar{\chi}(\gamma_j'(\infty))$$

Equation [12] does not appear to have any simple solution even though

$$[12a]\quad \sum_{j=1}^{M}\gamma_j'(\infty) = \lim_{\mu\to\infty}(\mu - \gamma_0') = \sum_{i=0}^{M}\tilde{n}^i d_i - d_0$$

is a rather simple relation. Rather, therefore, than obtaining approximations to $\gamma_j'(\infty)$, $j \geq 1$, separately, we will obtain approximations to $\gamma_j'(\mu)$ for all μ. In fact the properties of $\chi(x)$ and $\bar{\chi}(x)$ are similar; therefore, treating [10*a*] and [12] separately is unnecessary.

For each μ there must be an interval U_j containing γ_j' such that $1 - \mu\beta(x) > 0$ for x in U_j; otherwise since $\beta(x)$ is continuous $\mu\beta(\gamma_j') \geq 1$ and hence $\gamma_j' < 0$ or ∞. The function $\beta(x)$ is a decreasing function of x in $(0, d_j - d_{j-1})$ taking a maximum (finite) value at zero, the minimum being $-\infty$ at $d_j - d_{j-1}$. If the set $\{d_k,\tilde{n}_k\}$ is such that $\beta(0) \leq 0$ then clearly U_j may be taken to be $[0,d_j - d_{j-1}]$ for all μ. However, if $\beta(0) > 0$, which certainly can happen for some choices of $\{d_k,\tilde{n}_k\}$, then there is a maximum value of μ up to which $[0,d_j - d_{j-1}]$ may be taken for U_j and above which U_j is properly contained in $[0,d_j - d_{j-1}]$.

Let x_0 be in U_j and $x_{m+1} = \chi(x_m)$, $m = 0, 1, 2, \ldots$. We now consider the convergence properties of $\{x_m\}$. First, we have that

$$\chi(x) > 0; \quad \lim_{x\to d_j - d_{j-1}}\chi(x) = 0$$

and

$$\frac{d\chi(x)}{dx} = -\frac{\mu^2\tilde{n}^j\delta(x)}{(1 - \mu\beta(x))^2} \leq 0, \quad x \text{ in } U_j$$

where

$$\delta(x) = \sum_{j\neq k=0}^{M}\tilde{n}^k/(x + d_k - d_j)^2$$

In fact, $d\chi(x)/dx < 0$, for the equality would imply that $\delta(x) = 0$. Thus, $\chi(x)$ is a strictly decreasing function of x in U_j. These remarks apply also to $\bar{\chi}(x)$ of [12] with obvious modifications. Following the argument of Theorem 1, ref. 5, it is now easy to establish the following result.

Let x_0 be in U_j and $\chi(\chi(x_0)) \geq x_0$; then $x_{2m+1} \downarrow y_1 \geq \gamma_j'$ and $x_{2m} \uparrow y_2 \leq \gamma_j'$. If the inequality in the assumption is reversed, the bound property and the inequalities in the result are also reversed. If $x_0 = 0$ is in U_j and $\chi(x_0) < d_j - d_{j-1}$, $\chi(\chi(x_0)) > 0$ and hence the condition is satisfied.

It is well known that if $|d\chi(x)/dx| < 1$ for all x in U_j, and $\{x_m\}$ as defined above are in U_j, then $x_{m\xrightarrow{m\to\infty}}\gamma_j'$. It is easy to check that this will be true for small μ, but for arbitrary choice of $\{d_k,\tilde{n}_k\}$ and μ, this condition may not be satisfied even at γ_j'. (If the condition is satisfied at γ_j', then it is clearly satisfied in some interval about γ_j' which may be smaller than U_j.) However, for a large class of $\{d_k,\tilde{n}_k\}$ we expect that $|d\chi(x)/dx| < 1$ for all μ; in fact, the leading term in $-d\chi(x)/dx$ is easily seen to be $\tilde{n}^j/\tilde{n}^{j-1}$ which is usually less than one in most unimolecular applications.[2] An approximation to γ_j' is given by $\chi(x_0)$ for some x_0 in U_j: in that case, an

[2]We refrain from reproducing the derivation here: it is available upon request, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

error bound is given by

$$[13]\quad \chi(x_0) - \chi(\gamma_j') = \frac{\mu^2 \tilde{n}^j(\beta(x_0) - \beta(\gamma_j'))}{(1 - \mu\beta(x_0))(1 - \mu\beta(\gamma_j'))}$$

$$= \frac{\mu\gamma_j'(\gamma_j' - x_0)}{(1 - \mu\beta(x_0))} \times \sum_{j\neq k=0}^{M} \tilde{n}^k/[(x_0 + d_k - d_j)(\gamma_j + d_k - d_j)]$$

It is clear that if μ is small, the error is small; the error may also be small if $|d_k - d_j|$ are large and γ_j', x_0 are small in comparison with $d_j - d_{j-1}$. All of these results remain valid for $\gamma_j'(\infty)$ if the limiting value is taken as μ becomes large.

The Convergence of Approximations to γ_0

In the following, we produce an alternative scheme to approximate γ_0 under the assumption that $d_0 = 0$, which is always true in the unimolecular reaction problem. We recall in this case that γ_0 is the unique fixed point of $\bar{\phi}(x)$ in $(0,\mu)$.

We observe that $\bar{\phi}(x) > 0$ for x in $(-\infty, \mu + d_1)$, $\bar{\phi}(-\infty) = 0$, $\bar{\phi}(\mu + d_1) = \infty$, and all of the fixed points of $\bar{\phi}(x)$ are simple eigenvalues. Thus, there must be precisely two fixed points of $\bar{\phi}(x)$ in $(0,\mu + d_1)$, one of them being $\gamma_0 < \mu$, and the other being $\gamma_1 > \mu$. Let $\bar{x}_0 \leq \gamma_0$ and $\bar{x}_{m+1} = \bar{\phi}(\bar{x}_m)$, $m = 0, 1, 2, \ldots$; then $\bar{x}_m \uparrow \gamma_0$ from the following argument: Since $\bar{x}_0 \leq \gamma_0$, we have that $\bar{x}_1 = \bar{\phi}(\bar{x}_0) \geq \bar{x}_0$. Further, if $\bar{x}_{m+1} \geq \bar{x}_m$, then $\bar{x}_{m+2} = \bar{\phi}(\bar{x}_{m+1}) \geq \bar{\phi}(\bar{x}_m) = \bar{x}_{m+1}$, and therefore, by induction, $\{\bar{x}_m\}$ is a non-decreasing sequence. Now, since

$$\gamma_0 - \bar{x}_{m+1} = \int_{\bar{x}_m}^{\gamma_0} \frac{d\bar{\phi}(x)}{dx}\, dx$$

$\bar{x}_m \leq \gamma_0$ implies that $\bar{x}_{m+1} \leq \gamma_0$. This together with the fact that $\bar{x}_0 \leq \gamma_0$ implies that $\{\bar{x}_m\}$ is bounded by γ_0 and hence must converge from below to $y_0 \leq \gamma_0 < \mu$. It is trivial to check that y_0 is a fixed point of $\bar{\phi}(x)$ and in view of the uniqueness of the fixed point in $(0,\mu)$, $y_0 = \gamma_0$. It is obvious that x_0 may be taken to be zero.

A similar argument shows that if $\bar{x}_0$ is such that $\gamma_1 > \bar{x}_0 \geq \gamma_0$ then $\bar{x}_m \downarrow \gamma_0$. Thus it is possible to produce lower and upper bounds to γ_0 using the present procedure, provided that $d_0 = 0$. However, if $\bar{x}_0 > \gamma_1$, the above argument may be modified to show that $\{\bar{x}_m\}$ will exhibit rather uncontrollable behaviour; this could arise in practice if the original reaction matrix contains some rather small values $d_1, d_2, \ldots$, whence γ_1 will lie rather close to γ_0 in the region of low pressure, and could account for some of the convergence difficulties noted by Nordholm (2).

It is pertinent to remark here that in ref. 5 a function $\phi(x)$ was obtained with the properties that $\phi(\gamma_0) = \gamma_0$ and if $\bar{x}_m \lessgtr \gamma_0$, then $x_m = \phi(\bar{x}_m) \lessgtr \gamma_0$. The present bound $\bar{x}_m$ may therefore be used to produce an opposite bound x_{m+1}. Further, all of the above results remain valid for $d_0 \neq 0$ for μ not too small so that $\gamma_0 < \mu$ if γ_1 in the discussion is replaced by μ and d_1, by d_0.

Calculation of Population Distribution $\boldsymbol{\eta}$(t)

The evolution of the system is described by

$$[14]\quad \boldsymbol{\eta}(t) = \mathbf{E}^{1/2} \exp\{-[\mu(1 - p_0) + \mathbf{D}]t\}\mathbf{E}^{-1/2}\boldsymbol{\eta}(0)$$

$$= \mathbf{E}^{1/2}\Big\{\sum_{j=0}^{M} \rho_j \exp(-\gamma_j t) + \sum_{j=0}^{M} \rho_j' \exp[-(\mu + d_j)t]\Big\}\mathbf{E}^{-1/2}\boldsymbol{\eta}(0)$$

where γ_j, ρ_j are the simple eigenvalues and the corresponding eigenprojections, and ρ_j' is the eigenprojection corresponding to $(\mu + d_j)$ which could have multiplicity $(m_j - 1) \geq 0$; in the case that $(\mu + d_j)$ has multiplicity zero, $\rho_j' = 0$. Let ψ_j be the normalised eigenvector corresponding to γ_j, i.e.

$$[15]\quad \psi_j = \frac{(\mu - \gamma_j + \mathbf{D})^{-1}\mathbf{S}_0}{||(\mu - \gamma_j + \mathbf{D})^{-1}\mathbf{S}_0||} = \frac{(\mu - \gamma_j + \mathbf{D})^{-1}\mathbf{S}_0}{\left[\sum_{i=0}^{n-1} (\mu - \gamma_j + (\mathbf{D})_{ii})^{-2}\tilde{n}_i\right]^{1/2}}$$

We have $\rho_j = \psi_j(\psi_j,)$. Let I_j be the projection defined by $\mathbf{D}I_j = d_j I_j$; the projection ρ_j' is given by

$$[16]\quad \rho_j' = I_j - \frac{I_j\mathbf{S}_0(I_j\mathbf{S}_0, \quad)}{(\mathbf{S}_0, I_j\mathbf{S}_0)} = I_j - \frac{I_j\mathbf{S}_0(I_j\mathbf{S}_0, \quad)}{\sum_{i=1}^{m_j} \tilde{n}_{\nu(j,i)}}$$

The ith component $\eta_i(t)$ of the vector $\boldsymbol{\eta}(t)$ is now given by

$$[17]\quad \eta_i(t) = \tilde{n}_i^{1/2} \sum_{j=0}^{M} (\psi_j)_i \exp(-\gamma_j t) \sum_{k=0}^{n-1} (\psi_j)_k \tilde{n}_k^{1/2}\eta_k(0) + \tilde{n}_i^{1/2} \sum_{j=0}^{M} \exp[-(\mu + d_j)t] \sum_{k=1}^{m_j} \delta_{i\nu(j,k)} \times \left[\tilde{n}^{-1/2}{}_{\nu(j,k)}\eta_{\nu(j,k)}(0) - \tilde{n}^{1/2}{}_{\nu(j,k)} \frac{\sum_{l=1}^{m_j} \eta_{\nu(j,l)}(0)}{\sum_{l=1}^{m_j} \tilde{n}_{\nu(j,l)}}\right]$$

The first term in [17] is similar to the expression

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

usually given for the evolution of the population (1); the second term allows for the contribution to the relaxation from any groups of degenerate eigenvalues, whose existence was not fully appreciated previously.

Reaction to Two or More Products

Many unimolecular reactions give two or more distinguishable products and, in general, the fall-off behaviour for the formation of each product will be different (6–8). Let d_i^1 and d_i^2 be the respective rate constants for formation of products 1 and 2 from grain i, and assume that these two processes do not interfere with each other except in so far as the occurrence of each depletes the population of the grain itself, and of the neighbouring grains: thus $d_i^1 + d_i^2 = d_i$. Now

$$[18] \quad \gamma_0 = -\lim_{t\to\infty} \frac{1}{N(t)} \frac{dN(t)}{dt}$$

where

$$[19] \quad N(t) = \sum_{i=0}^{n-1} \eta_i(t) \sim [\exp(-\gamma_0 t)] \times (\mathbf{S}_0,\psi_0)(\psi_0,\mathbf{E}^{-1/2}\boldsymbol{\eta}(0)) \text{ for large } t$$

Further

$$[20] \quad \frac{dN(t)}{dt} = -\sum_{i=0}^{n-1} d_i\eta_i(t) \sim [\exp(-\gamma_0 t)] \times (\mathbf{S}_0,\mathbf{D}\psi_0)(\psi_0,\mathbf{E}^{-1/2}\boldsymbol{\eta}(0))$$

and thus $\gamma_0 = (\mathbf{S}_0,\mathbf{D}\psi_0)/(\mathbf{S}_0,\psi_0)$ as expected. The decomposition we need is

$$\gamma_0 = \gamma_0^1 + \gamma_0^2$$

where

$$[21] \quad \gamma_0^{1,2} = \lim_{t\to\infty} \sum_{i=0}^{n-1} d_i^{1,2}\eta_i(t) \Big/ \sum_{i=0}^{n-1} \eta_i(t) = (\mathbf{S}_0,\mathbf{D}^{1,2}\psi_0)/(\mathbf{S}_0,\psi_0)$$

$$[22] \quad = \mu(\mathbf{S}_0,(\mu - \gamma_0 + \mathbf{D})^{-1}\mathbf{D}^{1,2}\mathbf{S}_0)$$

This solution is exact provided that $t \gg \mu^{-1}$.

Approximate values for $\gamma_0^{1,2}$ can be obtained by substituting approximate values for γ_0. Suppose one substitutes $x_m \simeq \gamma_0$ for γ_0 in [22]: it is clear that the approximate values $\bar{\gamma}_0^{1,2}$ of $\gamma_0^{1,2}$ satisfy the relation

$$\bar{\gamma}_0^1 + \bar{\gamma}_0^2 = \bar{\Phi}(x_m) = x_{m+1} \simeq \gamma_0$$

Approximate expressions for $\gamma_0^{1,2}$ may also be obtained by using [21] directly, which is valid for an arbitrary eigenvector ψ_0 rather than the normalised one. Approximate expressions γ_{ap} and ψ_{ap} for γ_0 and ψ_0 respectively were obtained in ref. 4 which satisfy

$$\gamma_{ap} \geq \gamma_0$$

$$(\mathbf{S}_0, \psi_{ap}) = 1$$

and

$$(\mathbf{S}_0,\mathbf{D}\psi_{ap}) = \gamma_{ap}$$

These expressions are

$$[23] \quad \gamma_{ap} = (\mathbf{D}^{1/2}\mathbf{S}_0,[1 + \mu^{-1}\mathbf{D}^{1/2}(1 - p_0)\mathbf{D}^{1/2}]^{-1} \times \mathbf{D}^{1/2}\mathbf{S}_0) = (\mathbf{J}\mathbf{S}_0,(1 - \mu^{-1}\mathbf{J}p_0\mathbf{J})^{-1}\mathbf{J}\mathbf{S}_0) = \frac{\mu \sum_{i=0}^{n-1} \tilde{n}_i d_i(\mu + d_i)^{-1}}{\left[1 - \sum_{i=0}^{n-1} \tilde{n}_i d_i(\mu + d_i)^{-1}\right]}$$

where

$$\mathbf{J} = (1 + \mu^{-1}\mathbf{D})^{-1/2}\mathbf{D}^{1/2}$$

Also, for ψ_{ap}, we have

$$[24] \quad \psi_{ap} = \mathbf{S}_0 - \mu^{-1}(1 - p_0)\mathbf{D}^{1/2} \times [1 + \mu^{-1}\mathbf{D}^{1/2}(1 - p_0)\mathbf{D}^{1/2}]^{-1}\mathbf{D}^{1/2}\mathbf{S}_0 = \mathbf{S}_0 - \mu^{-1}(1 - p_0)\mathbf{J}^2 \times \mathbf{S}_0/[1 - \mu^{-1}(\mathbf{S}_0, \mathbf{J}^2\mathbf{S}_0)] = (1 + \mu^{-1}\mathbf{D})^{-1}\mathbf{S}_0/[1 - \mu^{-1}(\mathbf{S}_0, \mathbf{J}^2\mathbf{S}_0)]$$

An approximation to $\gamma_0^{1,2}$ is now clearly given by

$$[25] \quad \gamma_0^{1,2} \simeq \bar{\gamma}_0^{1,2} = \frac{\mu \sum_{i=0}^{n-1} \tilde{n}_i d_i^{1,2}(\mu + d_i)^{-1}}{1 - \sum_{i=0}^{n-1} \tilde{n}_i d_i(\mu + d_i)^{-1}}$$

which satisfies the relation $\bar{\gamma}_0^1 + \bar{\gamma}_0^2 = \gamma_{ap}$ as expected. The extension to more than two product channels is obvious.

Discussion

For a simple unimolecular reaction yielding only one product, a good approximation to the strong-collision rate constant is given by eq. [23], as we have shown previously (4). If there are two products, equivalent approximations to the partial rates are given by eq. [25], and so on.

However, if we wish to know the evolution of the population distribution or, alternatively, wish to treat a chemical activation problem which implicitly requires this information, then we need to know all the eigenvalues and eigenvectors of the reaction matrix. Moreover, since there is a strong tendency for inconsistencies between the reaction matrix, its eigenvalues, and its eigenvectors to become magnified

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

in such calculations, it is necessary to know these quantities with reasonable precision.

From our examination of the properties of the reaction matrix and its eigenvalues, we come to the following conclusions. The general topology of the eigenvalues is as we have already described it (1, 3–5, 9). However, if there are m_j entries in the reaction matrix having identical values of the decay rate constant d_j, then there is an eigenvalue of exactly $(\mu + d_j)$ with degeneracy $(m_j - 1)$. Only one member of each such group is shifted in value to $\gamma_j = \mu + d_j - \gamma_j'$, eq. [10]. If the quantity d_j appears only once, then the eigenvalue γ_j is also given by this same expression, [10]. Now, provided that the graining can be achieved in such a way that $\tilde{n}^j > \tilde{n}^{j-1}$, the iterative scheme [10*a*] should converge extremely quickly to give the small correction γ_j', thus yielding γ_j itself very easily. This scheme is also valid for γ_0, and it will be perfectly satisfactory at low pressures. However, at high pressures, since $\gamma_0'(\mu) \to \mu$, it will be preferable to use the alternative scheme based on eq. [11], which is in fact that used by Nordholm (2). We note that, assuming $d_0 = 0$, a sure way to achieve convergence is to start with a point x_0 in $[0,\mu]$ in the iteration procedure. If $x_0 \geq \gamma_0$, a non-increasing sequence will result while $x_0 \leq \gamma_0$ will yield a non-decreasing sequence, both converging from above and below respectively. Zero or γ_{ap} (if $\gamma_{ap} \leq \mu$) are of course acceptable starting points, which will clearly yield lower and upper bounds respectively. These remarks apply to $\gamma_0^{1,2}$ in [22] as well.

Note that in the low pressure limit

$$\gamma_{ap} = \mu\sum'\tilde{n}_i/(1 - \sum'\tilde{n}_i)$$

whereas the *exact* solution is

$$\gamma_0 = \mu\sum'\tilde{n}_i$$

on the other hand, $\gamma_{ap} \to \gamma_0$ as $\mu \to \infty$, the high pressure limit.

Having obtained all the eigenvalues to the required accuracy, the non-degenerate eigenvectors are given by [15]; for the degenerate eigenvalues, the eigenvectors are not unique and are best handled through the corresponding eigenprojection [16] as in the general expression [17] for the population evolution.

Complete solution of the chemical activation problem follows once the evolution of the populations is known. We start with an initial population vector $\boldsymbol{\eta}(0)$ representing the distribution formed from reactants in the initial act. The rate of formation of the rth dissociation product is simply

$$[26] \quad \int_0^\infty \sum' d_i^r \eta_i(t) \mathrm{d}t$$

where $\sum'$ denotes summation over only reactive states, and r runs over all open reaction channels, *including* redissociation to reactants. The extent of stabilisation is obtainable either by difference, or by calculation of the total non-reactive populations at long time. Notice that it is necessary to use the full expression [17] for $\eta_i(t)$ in [26] (rather than some long-time approximation such as we used in [19] or [20]), since it is only through the contributions from the second term in [17] for which $d_i = 0$ that significant non-linearity of the stabilisation to dissociation ratios at low pressures, i.e. the so-called "low pressure turn-up" (10), will arise.

The preparation of porphyrin S-411 (dehydrocoproporphyrin) and harderoporphyrin from protoporphyrin IX

DAVID DOLPHIN AND RAMANI SIVASOTHY

Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received August 22, 1980

DAVID DOLPHIN and RAMANI SIVASOTHY. Can. J. Chem. **59**, 779 (1981).

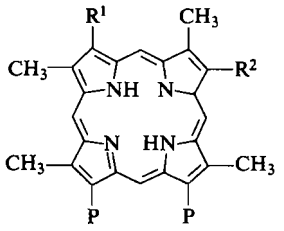
Protoporphyrin IX dimethyl ester has been converted into the two 2,4-positional isomers bearing hydroxyethyl and methoxycarbonylvinyl side chains. The 4-(2-hydroxyethyl) group was extended to a methoxycarbonylethyl group to give the tetramethyl ester of porphyrin S-411 (2-methoxycarbonylvinyl-4-methoxycarbonylethyldeuteroporphyrin dimethyl ester). On the other hand reduction of the 4-methoxycarbonylvinyl to the corresponding methoxycarbonylethyl group and dehydration of the 2-(2-hydroxyethyl) to a vinyl side chain gave the trimethyl ester of harderoporphyrin (2-vinyl-4-methoxycarbonylethyldeuteroporphyrin dimethyl ester).

DAVID DOLPHIN et RAMANI SIVASOTHY. Can. J. Chem. **59**, 779 (1981).

On a transformé l'ester diméthylique de la protoporphyrine IX en ses isomères de positions en 2 et 4 ayant des chaînes latérales hydroxyéthyle et méthoxycarbonylvinyle. On a allongé le groupe (hydroxy-2 éthyl)-4 de façon à obtenir l'ester tétraméthylique de la porphyrine S-411 (ester diméthylique de la méthoxycarbonylvinyl-2 méthoxycarbonyléthyl-4 deutéroporphyrine). D'autre part, la réduction du groupe méthoxycarbonylvinyl-4 en groupe méthoxycarbonyléthyle correspondant et la déshydratation subséquente du groupe (hydroxy-2 éthyl)-2 en une chaîne latérale vinylique conduisent à l'ester triméthylique de la hardéroporphyrine (ester diméthylique de la vinyl-2 méthoxycarbonyléthyl-4 deutéroporphyrine).

[Traduit par le journal]

During studies on porphyrin biosynthesis and metabolism two previously unknown porphyrins have been recently identified. Harderoporphyrin **1** (R^1 = —CH=CH_2, R^2 = —$CH_2CH_2CO_2H$), an intermediate between the copro and proto ring systems, was first isolated from the Harderian gland of rodents (1) and its structure confirmed by synthesis (1–6). Meconium is accumulated in the bowel during human fetal development; it is discharged shortly after birth and has been found to be rich in bile pigments and porphyrins (7). Investigation, by counter current distribution techniques, of ether soluble porphyrins obtained from meconium detected a porphyrin having a Soret absorption band at 410–411 nm in 5% w/v hydrochloric acid. This porphyrin was called porphyrin S-411 (8); it is also known as dehydrocoproporphyrin. Its structure was assigned (9) as **1** (with R^1 and R^2 as —CH=$CHCO_2H$ and $CH_2CH_2CO_2H$), and this was confirmed by synthesis of both isomers via *b*-oxobilanes (10). Porphyrin S-411 is also found in normal bone marrow and feces (11). Finally *Spirographis* porphyrin **1** (R^1 = CHO, R^2 = —CH=CH_2), also known as chlorocruoroporphyrin, has been isolated from various polychete worms (12) where it functions as an oxygen carrying pigment.



1

Syntheses of harderoporphyrin (1–6), porphyrin S-411 (5, 10), and *Spirographis* porphyrin (3) have been reported. We report here the preparation of these porphyrins, as their methyl esters, from protoporphyrin IX dimethyl ester. Protoporphyrin IX has two peripheral vinyl groups at the 2- and 4-positions. Although it has been reported (13) that the 2-vinyl group is more reactive than the 4-vinyl, subsequent studies (3, 14–16) have not substantiated the initial claim. Consequently partial derivatization of the vinyl groups results in a mixture of the 2,4-isomeric porphyrins. Therefore, if such intermediates are to be synthetically attractive, an efficient method for their separation is essential. Reports on the partial syntheses from protoporphyrin IX of *Spirographis* porphyrin (3, 15–18), and harderoporphyrins (3) have appeared. The most novel of these is from Inhoffen *et al.* (18), where the mono-derivatization of protoporphyrin was effected via the photoprotoporphyrins **4**, and we chose this as our starting point. Exposure of protoporphyrin IX to oxygen and light gives the isomeric (2 and 4) photoprotoporphyrins (**4**) in a yield of 75%. The reaction involves the 1,4-addition of singlet oxygen, whose formation is photosensitized by porphyrin, to either of the vinyl substituted pyrrolenine rings (A or B) followed by de-

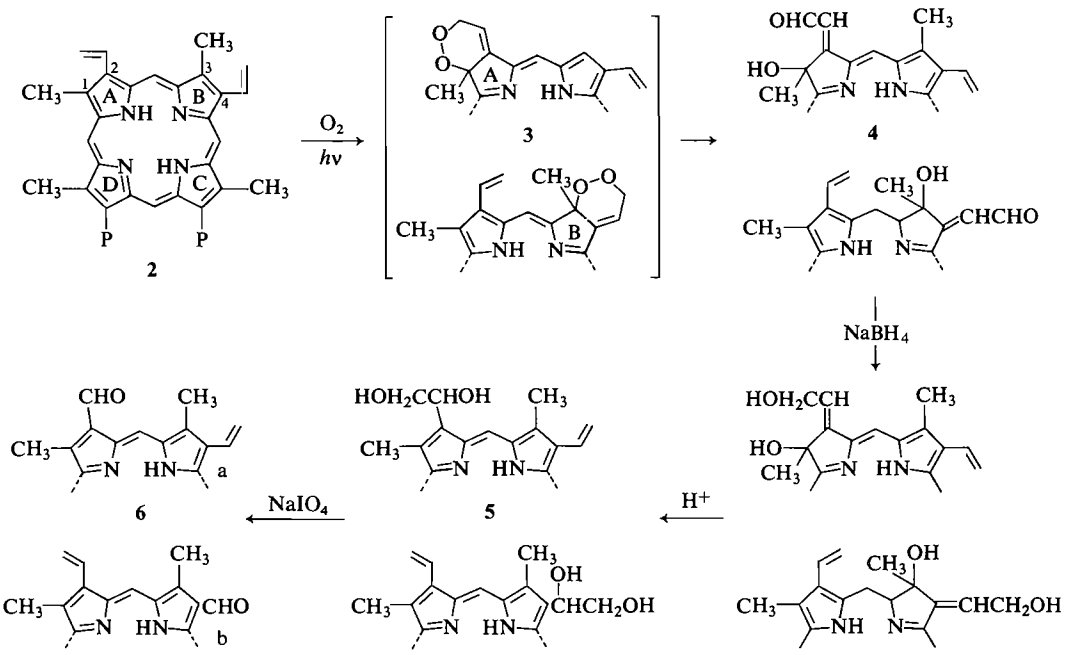
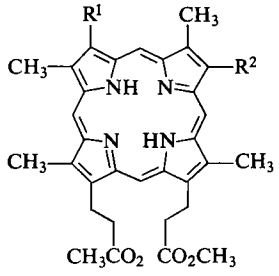


SCHEME 1

composition of the peroxide (**3**) (18) (Scheme 1). Mono-derivatization is achieved through the inhibitory electron-withdrawing effect of the formylethylidene group (**4**) towards an additional Diels–Alder reaction. This procedure, after chromatography of the isomeric photoprotoporphyrins, gave a 35% yield of each isomer. Isomeric porphyrins are, in general, difficult to separate chromatographically since the small differences in mobility exerted by the different disposition of the peripheral groups are overwhelmed by the flat porphyrin. This is not the case with the nonplanar "chlorins", such as the photoprotoporphyrins, and their chromatographic behaviours are usually sufficiently different to make separation routine. This proved to be the case where the compound of higher mobility (silica gel/dichloromethane) was identified as 4-photoprotoporphyrin (ring B). Borohydride reduction of the photoprotoporphyrins followed by rearrangement and cleavage of the resulting glycols (**5**) gave the corresponding formyl-vinyl derivative **6** (*Spirographis* porphyrins) in an 80% yield. The high yields reported by Inhoffen *et al.* (18) for the synthesis of the isomeric formyl-vinyl porphyrins **6** could not be reproduced using the cited reaction conditions (19, 20). Clezy and Fookes (19) obtained a yield of 25% from the photoprotoporphryin dimethyl ester by changing the solvent from dichloromethane–benzene to dioxane. A 60% yield was reported by Hamilton (21), who used a modification of Clezy's method. In the present study, a procedure similar to that of Hamilton's was employed to give a 75% yield.

While chromatographic separation of the photoprotoporphyrin isomers (**4**) is routine it is nevertheless tedious. Thus the mixed isomers were used to develop the chemistry described below, after which the pure isomers were used to synthesize the final products.

The condensation of the formylvinyldeuteroporphyrins **6** with malonic acid was achieved in pyridine using piperidine as the base catalyst to give the acrylic side chain of **7**.



7

a $R^1 = -CH{=}CHCO_2H$, $R^2 = -CH{=}CH_2$

b $R^1 = -CH{=}CH_2$, $R^2 = -CH{=}CHCO_2H$

Conversion of the vinyl group of **7** into a propionate side chain would provide porphyrin S-411. A sequence of reactions to effect this conversion is outlined in Scheme 2. The scheme relies on a preferential oxidation of the vinyl over the acrylate group and if the photooxidation is a Diels–Alder

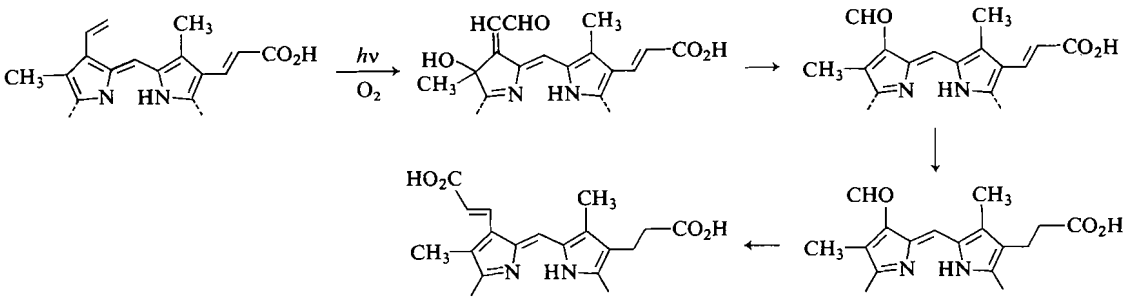
For personal use only.

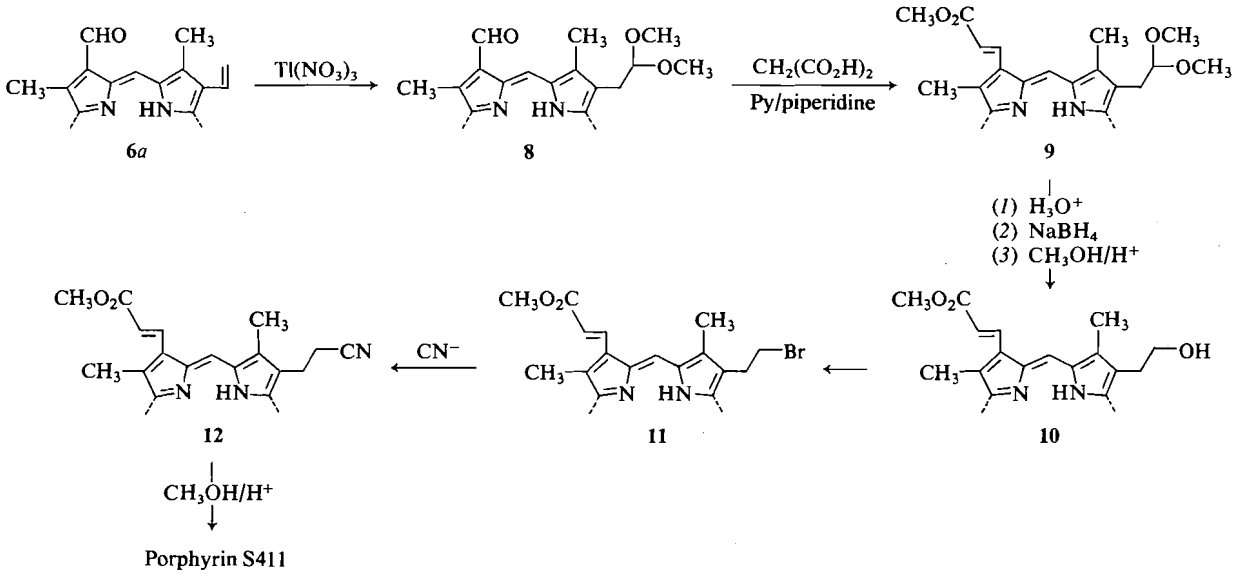


SCHEME 2

type of reaction, as has been suggested, the acrylic acid diene component should be deactivated by the electronegative carboxylic acid. Consequently, a preferential oxidation of the vinyl group was anticipated. When the mono-acrylic acid mono-vinyl-deuteroporphyrin **7** in dichloromethane containing 10% pyridine was exposed to direct sunlight a color change from red to green was observed over a period of three days. Thin-layer chromatography of the green solution revealed four (two pairs) and not, as expected, only one pair of products. Clearly the acrylic acid and the vinyl-containing dienes can both participate in the photooxidation. Since separation of these components proved impractical, as did prior reduction of the acrylate double bond in the presence of the vinyl group, this route was abandoned.

Kenner *et al.* (22) converted the two vinyl groups of protoporphyrin IX to propionic acid groups to give coproporphyrin III. Using a similar approach, as outlined in Scheme 3, conversion of the vinyl group of **6** to a propionic acid group gave porphyrin S-411. Treatment of **6** with two equivalents of thallium(III) nitrate (TTN) in methanol gave the 2,2-dimethyoxyethyl derivative **8** (3, 22). Strict adherence to the literature procedure (3) resulted in a 70% yield, whereas a modified procedure consistently gave a yield of 90%. Condensation of **8** with malonic acid as described above gave **9**. Hydrolysis of the acetal in THF followed by sodium borohydride reduction and re-esterification gave the 2-hydroxyethyl derivative **10**. Conversion of **10** to **11** may be effected with either thionyl bromide in dichloromethane–DMF (22) or carbon tetrabromide–triphenylphosphine (3). The former method was found unsatisfactory in the presence of alkenes whereas the latter method proved satisfactory in our hands. Treatment of **11** with cyanide in 1-methylpyrrolidone gave the nitrile **12** which upon methanolysis gave the porphyrin S-411 which was identical to an authentic sample with respect to melting point, mixture melting point, spectral properties (nmr, ir, uv–vis, ms), and tlc mobility.

The conversion of a 2-hydroxyethyl to a vinyl



SCHEME 3

13

side chain is well established in porphyrin chemistry where the need arises for a vinyl precursor which is stable to the conditions employed for the condensations of pyrroles to porphyrins. Thus conversion of the 2-hydroxy to the 2-chloroethyl derivative and dehydrohalogenation of the porphyrin zinc complex with potassium *tert*-butoxide generates the vinyl group (23). More recently Clezy *et al.* (24) have generated the vinyl group from either the 2-chloroethyl or methanesulfonate derivative using sodium hydroxide in aqueous pyridine. These reactions suggest how the other photoprotoporphyrin isomer (**4***b*) which was not used in the synthesis of S-411 would provide an intermediate suitable for the synthesis of harderoporphyrin (**1**; $R^1 = —CH=CH_2$, $R^2 = —CH_2CH_2CO_2H$).

Indeed conversion of **4***b* (as outlined in Schemes 1 and 3) to the corresponding 2,4-positional isomer of **10** gave 2-(hydroxyethyl)-4-methoxycarbonylvinyldeuteroporphyrin dimethyl ester (**7**; $R^1 = —CH_2CH_2OH$, $R^2 = —CH{:}CHCO_2CH_3$) via the corresponding 2-(2,2-dimethoxyethyl)-4-formyl (**7**; $R^1 = (CH_3O)_2CHCH_2—$, $R^2 = —CHO$), 2-(2,2-dimethoxyethyl) - 4 - methoxycarbonylvinyldeuteroporphyrin dimethyl ester (**7**; $R^1 = (CH_3O)_2CHCH_2—$, $R^2 = —CH{:}CHCO_2CH_3$). Acetylation of **7** ($R^1 = —CH_2CH_2OH$, $R^2 = —CH{:}CHCO_2CH_3$) gave 2-(2-acetoxyethyl)-4-methoxycarbonylvinyldeuteroporphyrin dimethyl ester (**7**; $R^1 = —CH_2CH_2OCOCH_3$, $R^2 = —CH{:}CHCO_2CH_3$) and catalytic reduction of the acrylate side chain gave the corresponding propionate side chain of 2-(2-acetoxyethyl-4-methoxycarbonylethyldeuteroporphyrin dimethyl ester (**13**). Compound **20** was a key intermediate in the total synthesis of harderoporphyrin (**10**), and its conversion by the same route gave, in our hands, harderoporphyrin which was identical to an authentic sample.

Experimental

Visible spectra were obtained on a Cary 17 spectrophotometer using Spectro grade dichloromethane unless otherwise specified. The ^1H nmr were obtained in the FT mode at either 100 or 270 MHz with a Varian XL-100 or Nicolet Model MC-80 spectrometer using $CDCl_3$. Mass spectra (ms) were recorded using Atlas CH-4 and A.E.I. MS-902 spectrometers. Column chromatography was performed using silica gel (Woelm-activity IV). Thin layer chromatography was carried out on Silica Gel GF precoated plates (Analtech-Uniplate 250 μ).

*Photoprotoporphyrin Dimethyl Esters (4*a, b)

Photoprotoporphyrins were prepared from protoporphyrin IX dimethyl ester according to the method of DiNello and Dolphin (25) in a combined yield of 72%. The average yield of each pure crystalline isomer after chromatography was 22%.

*Isomer I (4*a)

An analytical sample was recrystallized from dichloromethane–methanol mp 220–222°C (lit. (18) mp 222–223°C); λ_{max}(nm): 388, 436, 568, 613, 671; ^1H nmr: 1.26 (s, 3H, aliphatic CH_3), 3.26 (m, 4H, propionate, βCH_2), 3.36, 3.42, 3.62 (s, each 3H, ring methyls), 3.71 (d, 6H, methyl ester CH_3), 4.28 (m, 4H, propionate αCH_2), 6.14 (m, 2H, vinyl CH_2), 6.54 (d, 1H, olefinic CH), 7.60 (m, 1H, vinyl CH), 7.60, 8.42, 9.66, 9.76 (s, each 1H, *meso*-H), 9.97 (s, 1H, aldehyde H); ms: 622 (100), 579 (48), 549 (19).

*Isomer II (4*a)

An analytical sample was recrystallized from dichloromethane–methanol mp 241–243°C (lit. (18) mp 244°C); λ_{max}(nm): 393, 422, 566, 610, 668; ^1H nmr: 1.38 (s, 3H, aliphatic CH_3), 2.72, 3.27, 3.39 (s, each 3H, ring methyls), 3.27 (m, 4H, propionate βCH_2), 3.73 (s, 6H, methyl ester CH_3), 4.24 (m, 4H, propionate αCH_2), 5.91 (d, 1H, olefinic CH), 6.17 (m, 2H, vinyl CH_2), 7.93 (m, 1H, vinyl CH), 7.49, 8.19, 9.59, 9.62 (s, each 1H, *meso*-H), 10.06 (s, 1H, aldehyde H); ms: 622 (100), 579 (44), 549 (15).

*2-(4)-Formyl-(2)-vinyldeuteroporphyrin Dimethyl Esters (6*a, b)

The procedure used is a modification of Hamilton's method (21). To a solution of **4***a* or **4***b* (250 mg) in dry dichloromethane (125 mL) was added sodium borohydride (250 mg) in dry methanol (10 mL). The reaction mixture was stirred at room temperature for one hour. Thin-layer chromatography at the end of this reaction period, methyl acetate – heptane 1:1 v/v, R_f starting material 0.46, product 0.25, indicated the completion of the reaction. Excess sodium borohydride was destroyed by the dropwise addition of acetic acid. The reaction mixture was washed with water (200 mL × 2), dried over sodium sulfate, filtered, and the solvent removed *in vacuo*.

The dark brown residue was dissolved in dioxane (125 mL) and sodium periodate (400 mg) in boiling water (0.75 mL) was added, followed by concentrated sulfuric acid (0.5 mL). The reaction was monitored by tlc, methyl acetate – heptane 1:1 v/v, R_f starting material 0.25, product 0.75. The reaction was complete in one hour. The purple solution was diluted with water (600 mL) and extracted with dichloromethane (100 mL). The organic phase was washed with 5% $NaHCO_3$ and water, dried over sodium sulfate, filtered, and evaporated to dryness. The solid was dissolved in a minimum volume of chloroform and chromatographed on silica gel (methanol–chloroform 1:20 v/v). The first fraction was the desired product.

*Isomer I (6*a)

An analytical sample was recrystallized from dichloromethane – petroleum ether (30–60°C), mp 275–278°C (lit. (18) mp 278–279°C); λ_{max}(nm): 418, 518, 558, 583, 642; ^1H nmr 3.26 (t, 4H, propionate βCH_2), 3.52, 3.58, 3.70, 3.76 (s, 12H, ring methyls), 3.66 (s, 6H, methyl ester CH_3), 4.35 (m, 4H, propionate αCH_2), 6.32 (m, 2H, vinyl CH_2), 8.21 (dd, 1H, vinyl CH), 9.78, 9.86, 9.92, 10.66 (s, each 1H, *meso*-H), 11.32 (s, 1H, aldehyde H); ms: 592 (100), 519 (81), 446 (18).

Isomer II (6b)

An analytical sample was recrystallized from dichloromethane – petroleum ether (30–60°C); mp 223°C (lit. (18) mp 225°C); λ_{max}(nm): 420, 518, 558, 583, 642; ^{1}H nmr: 3.20 (m, 4H, propionate βCH_2), 3.30, 3.42, 3.48, 3.58 (s, each 3H, ring methyls), 3.69 (d, 6H, methyl ester CH_3), 4.26 (m, 4H, propionate αCH_2), 6.12 (dd, 2H, vinyl CH_2), 7.84 (q, 1H, vinyl CH), 9.19, 9.52, 9.60, 10.28 (s, each 1H, *meso*-H), 11.06 (s, 1H, aldehyde H); ms: 592 (100), 519 (57), 446 (18).

2-(4)-Acrylic Acid-4-(2)-vinyldeuteroporphyrin Dimethyl Esters (7a, b)

A solution of the mixed isomers **6***a* and **6***b* (100 mg) was dissolved in pyridine (50 mL), and malonic acid (2 g) in pyridine (10 mL) was added. The mixture was heated to 50°C, with stirring, and piperidine (0.75 mL) was added. The temperature of the reaction mixture was then raised to 80°C and maintained there for five hours.

After cooling the reaction mixture to room temperature it was poured into dilute hydrochloric acid (100 mL, 5% v/v). The porphyrin was extracted into chloroform and the organic layer washed with water, dried over sodium sulfate, filtered, and the solvent removed *in vacuo*. The residue was chromatographed on a silica gel preparative layer plate with chloroform–methanol 20:1 v/v as eluent. The slow moving band was removed from the silica gel with a chloroform–methanol solution and the solvent removed *in vacuo*. The residue was crystallized from dichloromethane–methanol in a yield of 72%; λ_{max}(nm): 418, 512, 552, 581, 637; ^{1}H nmr: 3.26 (m, 4H, propionate βCH_2), 3.52–3.66 (m, 18H, ring methyls, methyl ester CH_3), 4.38 (m, 4H, propionate αCH_2), 6.24 (m, 2H, vinyl CH_2), 6.88 (m, 1H, acrylic acid βCH), 8.16 (m, 1H, vinyl CH), 9.18 (m, 1H, acrylic acid αCH), 9.84 (s, 4H, *meso*-H).

Photooxidation of 7

A solution of 7*a*, *b* (20 mg) in dichloromethane containing 10% pyridine in a 100 mL measuring cylinder was exposed to direct sunlight. A colour change from red to green was observed after a day. The reaction was monitored by tlc using dichloromethane–ether 20:1 v/v. The completion of the reaction was gauged by the disappearance of the starting material on tlc. The reaction mixture was successively washed with 1 *N* hydrochloric acid, 5% sodium bicarbonate solution, and finally with water. The organic phase was dried over sodium sulfate and the solvent removed *in vacuo*.

The thin-layer chromatogram of the reaction mixture revealed two pairs of bands which could not be separated by tlc.

2-(4)-Formyl-4-(2)-(2,2-dimethoxyethyl)deuteroporphyrins

To a solution of **6***a* (or **6***b*) (100 mg) in dichloromethane (30 mL) and methanol (5 mL), was added thallium(III) nitrate trihydrate (300 mg, 3.2 mmol) in methanol (10 mL). The solution was stirred at room temperature for 45 min. Concentrated HCl (0.5 mL) was added and SO_2 was passed through the solution for 10 min. The mixture was extracted with dichloromethane (100 mL). The organic phase was washed with water, dried over sodium sulfate, filtered, and taken down to dryness *in vacuo*. The residue was dissolved in a minimum volume of dichloromethane and chromatographed on silica gel (dichloromethane–ether 20:1 v/v). The main fraction was taken down to dryness and the residue crystallized from dichloromethane – petroleum ether to give 96 mg (90%) of deep red needles.

2-Formyl-4-(2,2-dimethoxyethyl)deuteroporphyrin Dimethyl Ester (8)

An analytical sample was recrystallized from dichloromethane – petroleum ether (30–60°C), mp 167–169°C; λ_{max}(nm) (ε mM): 413 (251), 515 (10.9), 555 (19.1), 578 (11.7), 640 (2.00); ^{1}H nmr: 3.24 (t, 4H, propionate βCH_2), 3.42 (s, 6H, acetal CH_3), 3.48, 3.53, 3.56, 3.59 (s, each 3H, ring methyls), 3.66 (d, 6H, methyl ester CH_3), 4.24 (m, 4H, propionate αCH_2), 4.38 (d, 2H, acetal CH_2), 5.05 (t, 1H, acetal CH), 9.62, 9.85, 10.59 (s, 4H, *meso*-H), 11.22 (s, 1H, aldehyde H); ms: 654 (44), 622 (100), 549 (44). *Anal.* calcd. for $C_{37}H_{42}N_4O_7$: C 67.87, H 6.47, N 8.56; found: C 67.76, H 6.27, N 8.34.

2-(2,2-Dimethoxyethyl)-4-formyldeuteroporphyrin Dimethyl Ester (7; $R^1 = (CH_3O)_2CHCH_2$—, $R^2 = CHO$)

An analytical sample was recrystallized from dichloromethane – petroleum ether (30–60°C), mp 174–176°C; λ_{max}(nm) (ε mM): 413 (186.2), 515 (8.5), 555 (13.8), 578 (6.03), 639 (1.41); ^{1}H nmr: 3.22 (t, 4H, propionate βCH_2), 3.36 (s, 6H, acetal CH_3), 3.48, 3.52, 3.58, 3.61 (s, each 3H, ring methyls), 3.64, 3.68 (s, each 3H, methyl ester CH_3), 4.06 (d, 2H, acetal CH_2), 4.24, 4.32 (two t, each 2H, propionate αCH_2), 4.9 (t, 1H, acetal CH), 9.60 (s, 1H), 9.74 (s, 2H), 10.6 (s, 1H, *meso*-H), 11.24 (s, 1H, aldehyde H); ms: 654 (15), 622 (100), 549 (44). *Anal.* calcd. for $C_{37}H_{42}N_4O_7$: C 67.87, H 6.47, N 8.56; found: C 68.17, H 6.00, N 8.14.

2-Methoxycarbonylvinyl-4-(2,2-dimethoxyethyl)deuteroporphyrin Dimethyl Ester (9)

A solution of **8** (100 mg) and malonic acid (3 g) in pyridine (100 mL) was heated to 50°C. To this solution piperidine (0.2 mL) was added and the temperature raised to 80°C. The progress of the reaction was monitored by tlc using dichloromethane–methanol 20:1 v/v, R_f starting material 0.88, product 0.12. After five hours the reaction mixture was cooled and poured into 1 *N* hydrochloric acid (400 mL) and extracted into chloroform (200 mL). The chloroform layer was washed with 5% sodium bicarbonate solution and repeatedly with water. The organic phase was dried over sodium sulfate, filtered, and the solvent evaporated under reduced pressure.

The porphyrin residue was treated with 5% sulfuric acid in methanol (100 mL) overnight in the cold (refrigerator). The porphyrin ester was extracted into chloroform and the organic phase washed first with 5% sodium bicarbonate solution and then with water; it was dried over sodium sulfate, filtered, and the solvent removed *in vacuo*.

The residue was chromatographed on 100 g silica gel using chloroform–acetone 30:1 v/v as eluent. The desired porphyrin was eluted as the second fraction. The eluate was evaporated and the residue crystallized from dichloromethane – petroleum ether (30–60°C) in a yield of 78 mg (72%). An analytical sample was recrystallized from dichloromethane – petroleum ether (30–60°C), mp 192–194°C; λ_{max}(nm) (ε mM): 412 (218.8), 509 (14.5), 549 (20.9), 574 (12.3), 635 (3.55); ^{1}H nmr: 3.26 (t, 4H, propionate βCH_2), 3.43 (s, 6H, acetal CH_3), 3.56 (s, 6H, methyl ester CH_3), 3.56, 3.63, 3.68 (s, 12H, ring methyls), 4.08 (s, 3H, acrylic ester CH_3), 4.34 (m, 6H, propionate αCH_2, acetal αCH), 5.06 (t, 1H, acetal βCH), 6.99 (d, 1H, acrylic acid βCH), 9.22 (d, 1H, acrylic acid αCH), 9.87, 9.94, 9.98 (s, 4H, *meso*-H); ms: 710 (44), 678 (100), 605 (44). *Anal.* calcd. for $C_{40}H_{46}N_4O_4$: C 67.69, H 6.52, N 7.88; found: C 67.26, H 6.25, N 7.75.

2-Methoxycarbonylvinyl-4-(2-hydroxyethyl)deuteroporphyrin Dimethyl Ester (10)

A solution of **9** (53 mg) in tetrahydrofuran (30 mL) containing water (0.6 mL) was refluxed with concentrated hydrochloric acid (0.2 mL) for five minutes. The reaction mixture was cooled and the porphyrin extracted into dichloromethane (30 mL) containing pyridine (10 mL). The organic phase was washed with water, dried over sodium sulfate, and the solvent removed *in vacuo*. The residue in dichloromethane (30 mL) at 0°C was treated with a cold (0°C) solution of borohydride (250 mg) in methanol (10 mL). While stirring, the reaction mixture was allowed to attain room temperature. The excess sodium borohy-

For personal use only.

dride was then destroyed by the dropwise addition of acetic acid. The organic phase was washed with water, dried over sodium sulphate, filtered, and the solvent evaporated under reduced pressure. The residue was re-esterified with 5% sulphuric acid in methanol and chromatographed using dichloromethane–ether 20:1 (v/v) as eluent. The major band was collected, the solvent evaporated, and the residue crystallized from dichloromethane–methanol to give 30 mg (70%). An analytical sample was recrystallized from dichloromethane–methanol; λ_{max}(nm) (ε mM): 412 (275), 508 (20.0), 548 (26.3), 574 (16.6), 636 (5.0); ^{1}H nmr: 3.28 (m, 4H, propionate βCH_2), 3.50, 3.95, 4.06 (m, 18H, ring methyls, propionate ester CH_3), 4.08 (s, 3H, acrylic ester CH_3), 4.42 (m, 6H, propionate αCH_2, hydroxyethyl αCH_2), 7.07 (d, 1H, acrylic βCH), 9.35 (d, 1H, acrylic αCH), 10.04 (s, 2H), 10.10 (s, 1H), 10.14 (s, 1H, *meso*-H); ms: 666 (100), 635 (26), 607 (10), 593 (21). *Anal.* calcd. for $C_{38}H_{42}N_4O_7$: C 68.45, H 6.35, N 8.40; found: C 68.08, H 6.72, N 8.16.

2-Methoxycarbonylvinyl-4-(2-bromoethyl)deuteroporphyrin Dimethyl Ester (11)

Method 1

Compound **11** was prepared from **10** according to the method of Kenner *et al.* (22). The reaction was carried out at room temperature to give a 55% yield.

Method 2

A solution of carbon tetrabromide (100 mg) and triphenyl phosphine (80 mg) in dry dichloromethane (2 mL) was added to a stirred solution of **10** (30 mg) in dry dichloromethane (10 mL) and refluxed for 20 min. The cooled reaction mixture was diluted with dichloromethane (20 mL) and washed with water. The organic phase was dried over sodium sulfate, filtered, and the solvent removed *in vacuo*. The residue was chromatographed using dichloromethane–ether 20:1 v/v. The major band which eluted first was collected and taken to dryness. The residue was crystallized from dichloromethane – petroleum ether to give compound **11** in a yield of 72%.

An analytical sample was recrystallized from dichloromethane – petroleum ether (30–60°C), mp 196–200°C; λ_{max}(nm) (ε mM): 413 (467), 508 (33.1), 548 (41.7), 576 (25.1), 635 (9.1); ^{1}H nmr: 3.24 (m, 4H, propionate βCH_2), 3.50 (m, 12H, ring methyls), 3.64 (s, 3H, 3.66 and s, 3H, propionate ester CH_3), 4.08 (m, 5H, acrylic ester CH_3, bromoethyl βCH_2), 4.34 (m, 6H, propionate αCH_2, bromoethyl αCH_2), 6.93 (d, 1H, acrylic βCH), 9.12 (d, 1H, acrylic αCH), 9.74 (s, 2H), 9.80 (s, 1H), 9.92 (s, 1H, *meso*-H); ms: 730 (100), 728 (100), 657 (21), 655 (21), 648 (46). *Anal.* calcd. for $C_{38}N_{41}N_4O_6Br$: C 62.55, H 5.66, N 7.68, Br 10.95; found: C 62.50, H 5.54, N 7.44, Br 10.68.

2-Methoxycarbonylvinyl-4-(2-cyanoethyl)deuteroporphyrin Dimethyl Ester 12

To a solution of **11** (10 mg) in *N*-methylpyrrolidone (10 mL) was added, with stirring, a solution of sodium cyanide (10 mg) in *N*-methylpyrrolidone (5 mL). The reaction mixture was stirred at room temperature and the progress of the reaction was monitored by tlc using dichloromethane–ether 20:1 v/v; R_f starting material 0.58, product 0.29. On completion of the reaction, the reaction mixture was diluted with dichloromethane. The organic phase was repeatedly washed with water, dried over sodium sulfate, filtered, and taken to dryness. The residue was chromatographed on silica gel using dichloromethane–ether 20:1 v/v as eluent. The major band was collected, the solvent evaporated, and the residue crystallized from dichloromethane – petroleum ether in a yield of 70%. An analytical sample was recrystallized from dichloromethane – petroleum ether, mp 242–244°C; λ_{max}(nm) (ε mM): 412 (389), 507 (33.1), 547 (37.2), 576 (240), 634 (9.33); ^{1}H nmr: 3.26 (m, 6H, propionate βCH_2, cyanoethyl βCH_2), 3.60 (s, 9H), 3.67 (s, 9H, ring methyls, propionate ester CH_3), 4.09 (s, 3H, acrylic ester CH_3), 4.36 (m, 6H, propionate αCH_2), 7.04 (d, 1H, acrylic acid βCH), 9.28 (d, 1H, acrylic ester αCH), 9.81 (s, 1H), 9.98 (s, 1H), 10.02 (s, 2H, *meso*-H); ms: 675 (100), 602 (30), 635 (50).

Porphyrin S-411 Tetramethyl Ester

(1; R^1 = —CH=CHCO$_2$CH$_3$, R^2 = —CH$_2$CH$_2$CO$_2$CH$_3$)

Compound **12** (10 mg) was dissolved in methanol (10 mL) saturated with hydrogen chloride and left overnight in the refrigerator. The porphyrin was extracted into dichloromethane and the organic layer washed with 5% sodium bicarbonate solution and water. After the solvent was removed *in vacuo* the residue was chromatographed with dichloromethane–ether 20:1 v/v as eluent. The first eluted compound was collected, the solvent removed *in vacuo*, and the residue crystallized from dichloromethane – petroleum ether, in almost quantitative yield to give a product, mp 237–239°C (lit. (10) mp 236–238°C), which was identical to an authentic sample of porphyrin S-411; λ_{max}(nm): 413, 509, 549, 576, 635; ^{1}H nmr: 3.26 (m, 6H, propionate βCH_2), 3.48 (s, 9H), 3.60 (s, 3H), 3.64 (s, 3H), 3.68 (s, 6H), 4.08 (s, 3H, ring methyls, acrylic ester CH_3, and propionate ester CH_3), 4.38 (m, 6H, propionate αCH_2), 7.04 (d, 1H, acrylic βCH), 9.30 (d, 1H, acrylic αCH), 9.96 (s, 1H), 10.00 (s, 2H), 10.04 (s, 1H, *meso*-H); ms: 708 (100), 677 (7), 649 (14), 635 (34).

2-(2-Hydroxyethyl)-4-methoxycarbonylvinyldeuteroporphyrin Dimethyl Ester (7; R^1 = —CH$_2$CH$_2$OH, R^2 = —CH:CHCO$_2$CH$_3$)

2-(2,2-Dimethoxyethyl)-4-methoxycarbonylvinyldeuteroporphyrin dimethyl ester (**7**; R^1 = $(CH_3O)_2CHCH_2$—, R^2 = $—CH_2CHCO_2CH_3$) (prepared from **7**; R^1 = $(CH_3O)_2CHCH_2$—, R^2 = CHO as described above for the isomer **9**) was reacted in a manner identical to that described above for the preparation of **10** to give the product in 70% yield. An analytical sample was recrystallized from dichloromethane–methanol; λ_{max}(nm) (ε mM): 410 (274), 507 (16.2), 548 (26.7), 573 (15.2), 635 (6.6). *Anal.* calcd. for $C_{38}H_{42}N_4O_7 \cdot 1/2H_2O$: C 67.53, H 6.42, N 8.29; found: C 67.66, H 6.83, N 7.79.

2-(2-Acetoxyethyl)-4-methoxycarbonylvinyldeuteroporphyrin Dimethyl Ester (7; R^1 = —CH$_2$CH$_2$OCOCH$_3$, R^2 = —CH:CHCO$_2$CH$_3$)

2-(2-Hydroxyethyl)-4-methoxycarbonylvinyldeuteroporphyrin dimethyl ester was dissolved in pyridine (10 mL) containing acetic anhydride (1 mL) and allowed to stand overnight. The reaction mixture was poured into 1% hydrochloric acid (50 mL) and the porphyrin extracted into ether. The organic layer was washed with 5% sodium bicarbonate solution followed by water. After drying over sodium sulfate the solvent was removed *in vacuo*. The residue was purified by chromatography using dichloromethane–ether 20:1 v/v. The major band was collected, the solvent removed, and the residue crystallized from dichloromethane – petroleum ether in a yield of 72%; λ_{max}(nm): 411, 508, 548, 575, 635; ^{1}H nmr: 2.10 (s, 3H, acetoxyethyl CH_3), 3.16 (m, 4H, propionate βCH_2), 3.56, 3.62, 3.64 (all s, 18H, ring methyls, propionate CH_3), 4.90 (m, 2H, acetoxyethyl βCH_2), 4.02 (s, 3H, acrylic ester CH_3), 4.34 (m, 6H, propionate αCH_2, acetoxyethyl αCH_2), 7.02 (d, 1H, acrylic βCH), 9.34 (d, 1H, acrylic αCH), 10.12 (s, 2H), 10.20 (s, 1H), 10.24 (s, 1H, *meso*-H).

2-(2-Acetoxyethyl)-4-methoxycarbonylethyldeuteroporphyrin (13)

2-(2-Acetoxyethyl)-4-methoxycarbonylvinyldeuteroporphyrin dimethyl ester (5 mg) in tetrahydrofuran (5 mL) was hydrogenated over 10% palladium–charcoal at room temperature until the solution turned colourless. The catalyst was filtered off and the solution was stirred while air was bubbled through until the visible spectrum indicated the complete oxidation of the porphyrinogen. The solvent was removed *in vacuo* and the

residue chromatographed using dichloromethane–ether 20:1 v/v as eluent. The major band was collected, the solvent evaporated under reduced pressure, and the residue crystallized from dichloromethane – petroleum ether to give **13** (3.3 mg, 65%), mp 155–157°C (lit. (10) mp 155–156°C), which had identical spectral properties to those previously reported (10); λ_{max}(nm): 399, 500, 531, 567, 621; ^{1}H nmr: 2.08 (s, 3H, acetoxyethyl CH_3), 3.20 (m, 6H, propionate βCH_2), 3.67, 3.69 (d, 21H, ring methyls, methyl ester CH_3), 4.24 (m, 8H, propionate αCH_2, acetoxyethyl αCH_2), 4.88 (t, 2H, acetoxyethyl βCH_2), 10.10 (s, 2H), 10.12 (s, 2H, *meso*-H).

Harderoporphyrin Trimethyl Ester (1; R^1 = —CH=CH_2, R^2 = —$CH_2CH_2CO_2CH_3$)

2-(2-Acetoxyethyl)-4-methoxycarbonylethyldeuteroporphyrin (**13**) (5 mg) was converted to harderoporphyrin trimethyl ester in the manner reported by Couch *et al.* (10) via the intermediacy of 2-(2-hydroxyethyl)- and 2-(2-chloroethyl)-4-methoxyethylcarbonyldeuteroporphyrins to give 2 mg (35%) of a product identical to an authentic sample of harderoporphyrin trimethyl ester, mp 201–202°C (lit. (10) mp 203–204°C); a mixture melting point showed no depression with an authentic sample.

Acknowledgements

We wish to thank Professors A. H. Jackson and K. M. Smith for generous gifts of porphyrin S-411 and harderoporphyrin. This work was supported by the Natural Sciences and Engineering Research Council of Canada and the United States National Institutes of Health (AM 17989). D.D. wishes to express his thanks to the Harvard Chemistry Department for its assistance in the preparation of this manuscript during his stay as a Visiting Professor, fall 1980.

Received July 31, 1980

BOGUMIL BRZEZINSKI and GEORG ZUNDEL. Can. J. Chem. **59**, 786 (1981).

$HClO_4$ salts of *N,N'*-tetramethylalkanes (compounds **1–6**) and of *N,N'*-tetraalkyl-*o*-xylildiamines (compounds **7–11**) and $HAuCl_4$ salts of *N,N'*-tetramethyl-*o*-xylildiamine-di-*N*-oxide (compound **12**) and of *o*-xylildipiperidyl-di-*N*-oxides (compounds **13–14**) were studied by nmr and ir spectroscopy. It is shown that in the compounds **3**, **4**, **5**, and **7–11**, long intramolecular $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ hydrogen bonds with large proton polarizability and in compounds **12–14**, short intramolecular $O^+H\cdots O \rightleftharpoons O\cdots H^+O$ hydrogen bonds with large proton polarizability are formed. The study of the compounds **1–6** shows that the most favorable conditions for the formation of the intramolecular easily polarizable hydrogen bonds occur with compound **4**, i.e., if these hydrogen bonds are present in the 7-membered rings. In the case of compounds **7–14** it is shown that the continua usually observed with easily polarizable hydrogen bonds vanish when these bonds become screened from their solvent environments. Then, instead of continua only bands of the fundamental transitions are observed, with the long $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ bonds in the region 2800–1800 cm^{-1} and with the short $O^+H\cdots O \rightleftharpoons O\cdots H^+O$ bonds in the region 1200–850 cm^{-1}. This result demonstrates that for the occurrence of the ir continua, the interaction of the easily polarizable hydrogen bonds with their solvent environments is absolutely necessary. Furthermore, it is shown with the long as well as the short hydrogen bonds that the intensity of the continua decreases strongly with deuteration, demonstrating that in both cases the deuteron polarizabilities are much smaller than the proton polarizabilities of the hydrogen or deuterium bonds, respectively. From this observation it is concluded that the proton potentials of these structurally symmetrical hydrogen bonds are considerably deformed by their molecular surroundings.

BOGUMIL BRZEZINSKI et GEORG ZUNDEL. Can. J. Chem. **59**, 786 (1981).

On a étudié, par spectroscopie ir et nmr, les perchlorate de *N,N'*-tétraméthylalcanes (composés **1** à **6**) et de *N,N'*-tétraalkyl *o*-xylildiamines (composés **7** à **11**) et les sels de $HAuCl_4$ du di-*N*-oxyde de la *N,N'*-tétraméthyl *o*-xylildiamine (composé **12**) et des di-*N*-oxydes de *o*-xylildipipéridyle (composés **13**, **14**). Dans le cas des composés **3**, **4**, **5** et **7–11** on montre qu'il se forme de longues liaisons hydrogène intramoléculaires $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ avec polarisabilité forte alors que dans les composés **12** à **14**, il se forme de courtes liaisons hydrogène intramoléculaires $O^+H\cdots O \rightleftharpoons O\cdots H^+O$ avec polarisabilité forte. L'étude des composés **1** à **6** révèle que les conditions les plus favorables à la formation de liaisons hydrogène intramoléculaires facilement polarisables sont réalisées dans le composé **4**, i.e. si ces liaisons hydrogène se retrouvent dans des cycles à 7 chaînons. On montre, dans le cas des composés **7** à **14**, que les continus habituellement observés avec les liaisons hydrogènes facilement polarisables, disparaissent quand ces liaisons deviennent blindées de l'environnement du solvant. On n'observe alors que des bandes des transitions fondamentales, au lieu des continus avec les longues liaisons $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ dans la région de 2800–1800 et avec les courtes liaisons $O^+H\cdots O \rightleftharpoons O\cdots H^+O$ dans la région de 1200–850 cm^{-1}. Ce résultat démontre que l'interaction des liaisons hydrogène facilement polarisables avec l'environnement de leur solvant est absolument nécessaire à l'existence des continus en ir. De plus on montre qu'avec les longues, aussi bien qu'avec les courtes liaisons hydrogène, l'intensité des continus diminue fortement avec la deutériation, démontrant que dans les deux cas les polarisabilités du deutéron sont respectivement beaucoup plus faibles que celles du proton ou du deutérium des liaisons hydrogène. A partir de ces observations, on a conclu que les potentiels du proton de ces liaisons hydrogène structurallement symétriques sont considérablement déformés par leur environnement moléculaire.

[Traduit par le journal]

Introduction

The proton polarizabilities of hydrogen bonds with double minimum proton potential or with a broad flat proton potential well, i.e., hydrogen bonds in which the protons may fluctuate, are extremely large (1–4*a*). Intramolecular hydrogen bonds show some advantages for studies of hydrogen bonded systems, for instance, they form, usually quantitatively, if the steric conditions are appropriate. Various types of intramolecular hydrogen bonds with large proton polarizabilities of the type $B^+H\cdots B \rightleftharpoons B\cdots H^+B$ (5, 6), of the type $B_1{}^+H\cdots B_2 \rightleftharpoons B_1\cdots H^+B_2$ (7) and of the type $B_1H\cdots B_2 \rightleftharpoons B_1{}^-\cdots H^+B_2$ (8–10) have already been studied from this point of view. In this paper, various properties of such bonds are investigated systematically with long and short, positively charged, structurally symmetrical hydrogen bonds.

Due to their large proton polarizabilities and dipole moments, these hydrogen bonds usually interact strongly with their environments (4*a*). Firstly, the local electrical fields in solutions polarize these hydrogen bonds (induced dipole interaction). Secondly, due to the large proton polarizability, transitions in the hydrogen bonds couple with transitions in their environments, whereby the coupling with

low wave number vibrations is probably of particular significance. Both interaction effects are important for the occurrence of ir continua in systems with easily polarizable hydrogen bonds. Thus, these continua should vanish if these hydrogen bonds are screened from their solvent environments (4*a*). This effect of screening has already been demonstrated with the $HClO_4$ salts of *N*,*N*′-dipiperidylalkanes (5).

Easily polarizable hydrogen bonds of medium length cause continua extending from about 3200 cm^{-1} toward smaller wave numbers over the whole ir region. Easily polarizable hydrogen bonds which are relatively long cause continua which are particularly intense in the region 2800–1800 cm^{-1} and extend with less intensity toward smaller wave numbers, whereas easily polarizable hydrogen bonds which are relatively short absorb preferentially in the region 1600–600 cm^{-1}. This relation between bond length and wave number distribution has already been studied with various systems (4, 11) and was confirmed theoretically (3, 13). If these easily polarizable bonds are considered isolated, the proton polarizability is greatest with the long hydrogen bonds and decreases with the bond length (2–4*a*). In this paper, examples of long and short structurally symmetrical, easily polarizable hydrogen bonds will be discussed.

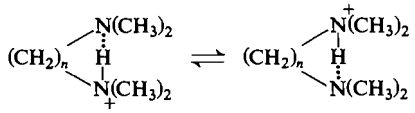
From a theoretical study (12) it is known that when the hydrogen or deuterium bonds have a symmetrical double minimum potential, the deuteron polarizabilities are much larger than the proton polarizabilities, whereas with asymmetrical double minimum potentials the deuteron polarizabilities are smaller than the proton polarizabilities.

Results and Discussion

Structurally symmetrical intramolecular hydrogen bonds are investigated with respect to the following parameters: *1*, the influence of stereochemical condition on the formation of these intramolecular bonds; *2*, the influence of screening; and *3*, the influence of deuteration on the infrared absorbance.

1. Stereochemistry and Formation of Hydrogen Bonds

The $HClO_4$ salts of *N*,*N*′-tetramethylalkanes were studied. The structural formulas are as follows:



1–6: $n = 1–6$

The formation of the intramolecular hydrogen bonds was studied in solutions as a function of *n*, i.e., the number of CH_2 groups in the molecules. The nmr data are given in Tables 1 and 2. The chemical shift of the NH^+ protons in the case of the $HClO_4$ salts of compounds **3**, **4**, and **5**, and especially the comparison of this chemical shift with the value of the 1:2 complexes (1 *M* base: 2 *M* $HClO_4$) shows that the NH^+ groups in the $HClO_4$ salts of these compounds form hydrogen bonds. This is in contrast to the finding with the $HClO_4$ salts of compounds **1**, **2**, and **6**. With the $HClO_4$ salts of the compounds **3**, **4**, and **5**, these chemical shifts of the NH^+ protons are completely independent of concentration (Table 1), and excess of base has no influence on the NH^+ proton signal with compounds **4** and **5** and only a very weak influence with compound **3** (Table 2). All these results taken together demonstrate that the hydrogen bonds formed are intramolecular.

In the case of the $HClO_4$ salt of compound **3**, the chemical shift of the NH^+ proton is smaller than with the compounds **4** and **5** (Table 1), and only a very weak shift is observed when an excess of base is added (Table 2). This finding can be explained by incomplete formation of the hydrogen bonds as well as by the fact that the hydrogen bonds formed are weaker intramolecular hydrogen bonds. The ir results presented later show that both effects together are responsible for the smaller chemical shift.

With the $HClO_4$ salts of compounds **1** and **2** and especially with that of compound **6**, small shifts of the NH^+ proton signals towards lower fields are observed (Table 1). Furthermore, additional base also shifts these signals a little toward lower fields (Table 2). These findings can be explained by the formation of a small number of intermolecular hydrogen bonds.

Figure 1 shows the ir spectra of the $HClO_4$ salt solutions of compounds **2–6** and, for comparison, the spectra of the free bases. The spectrum of the $HClO_4$ salt of compound **1** is very similar to that of compound **2**. In the cases of the $HClO_4$ salts of compounds **3**, **4**, and **5** (Fig. 1 *b*, *c*, and *d*), intense continua are observed. These continua are much more intense in the region 2800–1800 cm^{-1}, showing a band-like structure with one maximum, and extend with less intensity toward smaller wave numbers over the whole region studied. This spectral feature is characteristic for long, easily polarizable hydrogen bonds (13). Thus, the intramolecular $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ bonds are relatively long hydrogen bonds with large proton polarizability.

This result is confirmed by nmr data. Table 1 shows that the CH_3 proton signal is a doublet for the $HClO_4$ salts of compounds **1**, **2**, and **6**, as well as for all 1:2 complexes (1 *M* base: 2 *M* $HClO_4$). This splitting is caused by the spin–spin coupling of the CH_3 protons with the NH^+ proton. In contrast to this finding, for the $HClO_4$ salts of compounds **3**, **4**, and **5** only a singlet CH_3 proton signal is observed. This result demonstrates that the NH^+ proton is delocalized in the $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ bonds, as expected, in light of the ir results.

In the case of the $HClO_4$ salt of compound **3**, the continuum is a little less intense, and the broad maximum is shifted considerably toward higher wave numbers. The nmr data have already suggested that the intramolecular hydrogen bonds are not formed quantitatively with the $HClO_4$ salt of compound **3**. This result is confirmed by the broad shoulder of the stretching vibration of non-hydrogen bonded NH^+ groups at about 3100 cm^{-1}. In the $HClO_4$ salts forming no intramolecular hydrogen bond, this vibration is observed as an intense band with maximum at 3100 cm^{-1}. Thus, the finding that the continuum is less intense with compound **3** is explained by incomplete formation of the intramolecular hydrogen bonds. The broad band-like structure of the continuum is mainly caused by the fundamental transitions. Thus, the shift of the

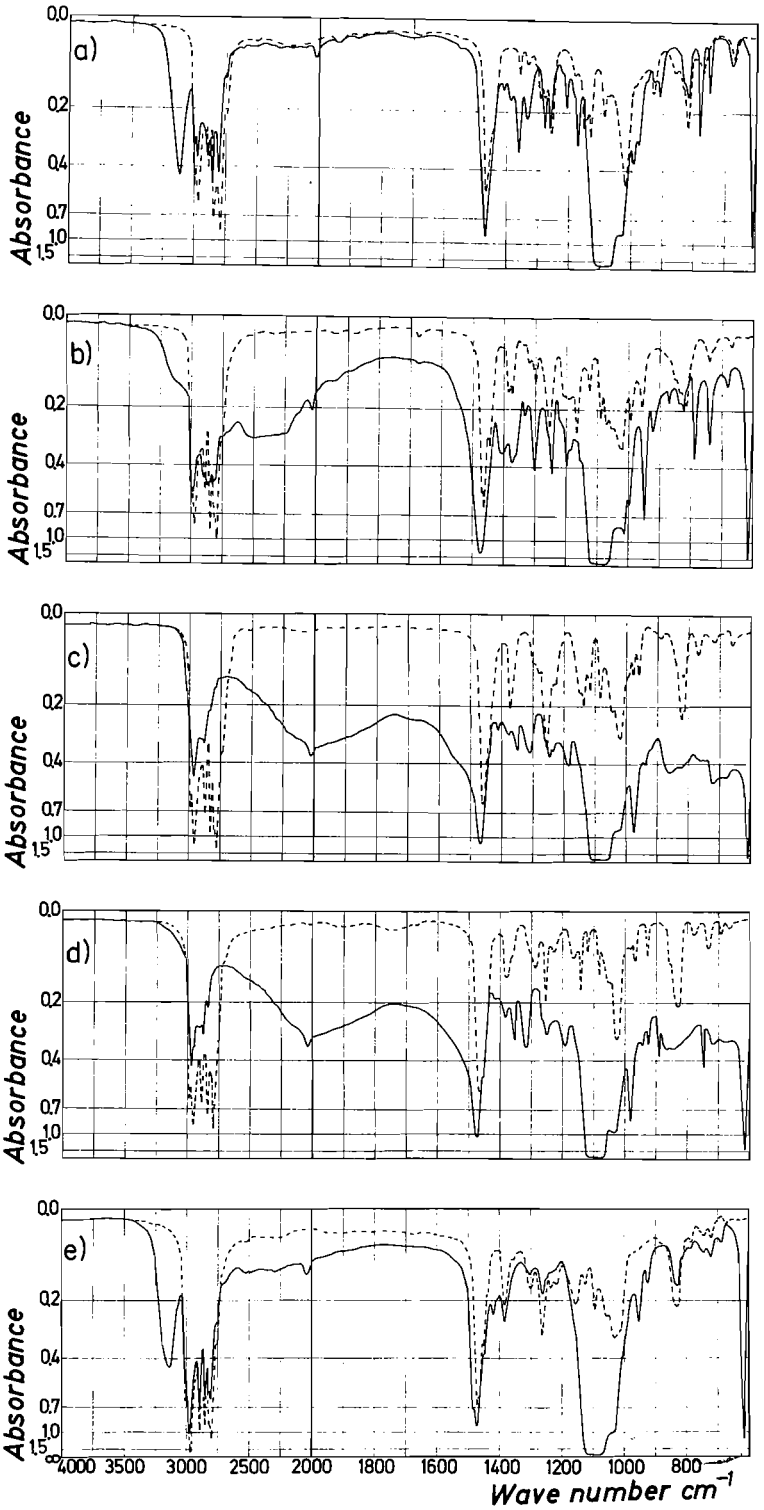

FIG. 1. Infrared spectra of bases (---) and of their $HClO_4$ salts (—) of compounds **2–6**.

maximum of the continuum toward larger wave numbers, observed with the $HClO_4$ salt of compound **3**, demonstrates that the intramolecular bonds are weaker. This result is in good agreement with the non-complete formation of these hydrogen bonds with this compound.

The very weak continuum observed with compound **6** may be caused by an intermolecular $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ bond. The presence of a few such bonds was suggested by nmr data.

In summary we can state that in contrast to the results with the $HClO_4$ salts of compounds **1**, **2**, and **6**, with the $HClO_4$ salts of compounds **3**, **4**, and **5** intramolecular easily polarizable $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ hydrogen bonds are formed. With the $HClO_4$ salt of compound **3**, these hydrogen bonds are a little weaker and not formed quantitatively. With the $HClO_4$ salt of compound **5**, these hydrogen bonds are a little weaker than with the $HClO_4$ salt of compound **4**, but the hydrogen bonds are also formed quantitatively.

All these results can be understood by considering the steric conditions. Molecular models show that with the $HClO_4$ salts of compounds **1** and **2**, the formation of an intramolecular hydrogen bond is impossible due to sterical constraint and the formation of intermolecular hydrogen bonds is hindered by the bulky CH_3 groupings and the rest of the molecule. With the $HClO_4$ salt of compound **3**, the steric constraint is smaller, therefore, a bent intramolecular hydrogen bond can be formed which is weaker than that in the $HClO_4$ salt of compound **4**. In the case of this $HClO_4$ salt, the steric conditions for the formation of the intramolecular $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ bonds are most favorable, and decrease a little in the case of the $HClO_4$ salt of compound **5**. In the $HClO_4$ salt of compound **6**, the steric constraint is again so great that no intramolecular hydrogen bonds can be formed.

2. *Screening of the Hydrogen Bonds from their Environments*

The influence of screening against their solvent environment was studied with long, structurally symmetrical intramolecular $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ bonds in $HClO_4$ salts of *N,N'*-tetraalkyl-*o*-xylildiamines (compounds **7–11**), and with short structural symmetrical intramolecular $O^+H\cdots O \rightleftharpoons O\cdots H^+O$ bonds in $HAuCl_4$ salts of *N,N'*-tetramethyl-*o*-xylildiamine-di-*N*-oxide (compound **12**) and *o*-xylildipiperidyl-di-*N*-oxides (compounds **13–14**). These compounds were chosen for these studies because the sterical conditions are very favorable for the formation of intramolecular hydrogen bonds. With the compounds **12–14** the salts were formed with $HAuCl_4$ instead of $HClO_4$, since with these compounds the formation of short intramolecular hydrogen bonds is expected (14, 15). Such hydrogen bonds cause continua which are most intense at smaller wave numbers (4*a*, 13, 16). Studies of $HClO_4$ salts in this region are strongly hindered by the very intense stretching vibration of the ClO_4^- ions masking the spectrum between 1000 and 1150 cm^{-1}.

12, R = $(CH_3)_2$

13, R =

14, R =

The chemical shift of the NH^+ protons (compounds **7–11**) and that of the OH^+ protons (compounds **12–14**), and especially the comparison of these chemical shifts with the value of the 1:2 complexes (1 *M* base: 2 *M* $HClO_4$) in Table 1, shows that these NH^+ or OH^+ groups in their respective salts form hydrogen bonds. These signals are completely independent of the concentration and of the presence of excess base (Table 2), if their solubility allows these compounds to be studied with excess base.

These results together demonstrate that the hydrogen bonds are intramolecular and formed quantitatively.

The position of the NH^+ proton signals is almost the same with compounds **7–11**, demonstrating that the intramolecular $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ bonds are of comparable strength in all these compounds. The position of the OH^+ proton signal differs a little with compound **11**, where R = $(CH_3)_2$, and with compounds **12** and **13**. This difference of the shifts is, however, so small that these hydrogen bonds are also of comparable strength.

In view of the fact that all these hydrogen bonds are structurally symmetrical, the proton potentials must also be symmetrical if these hydrogen bonds are considered isolated from their environment. Hydrogen bonds with such proton potentials are

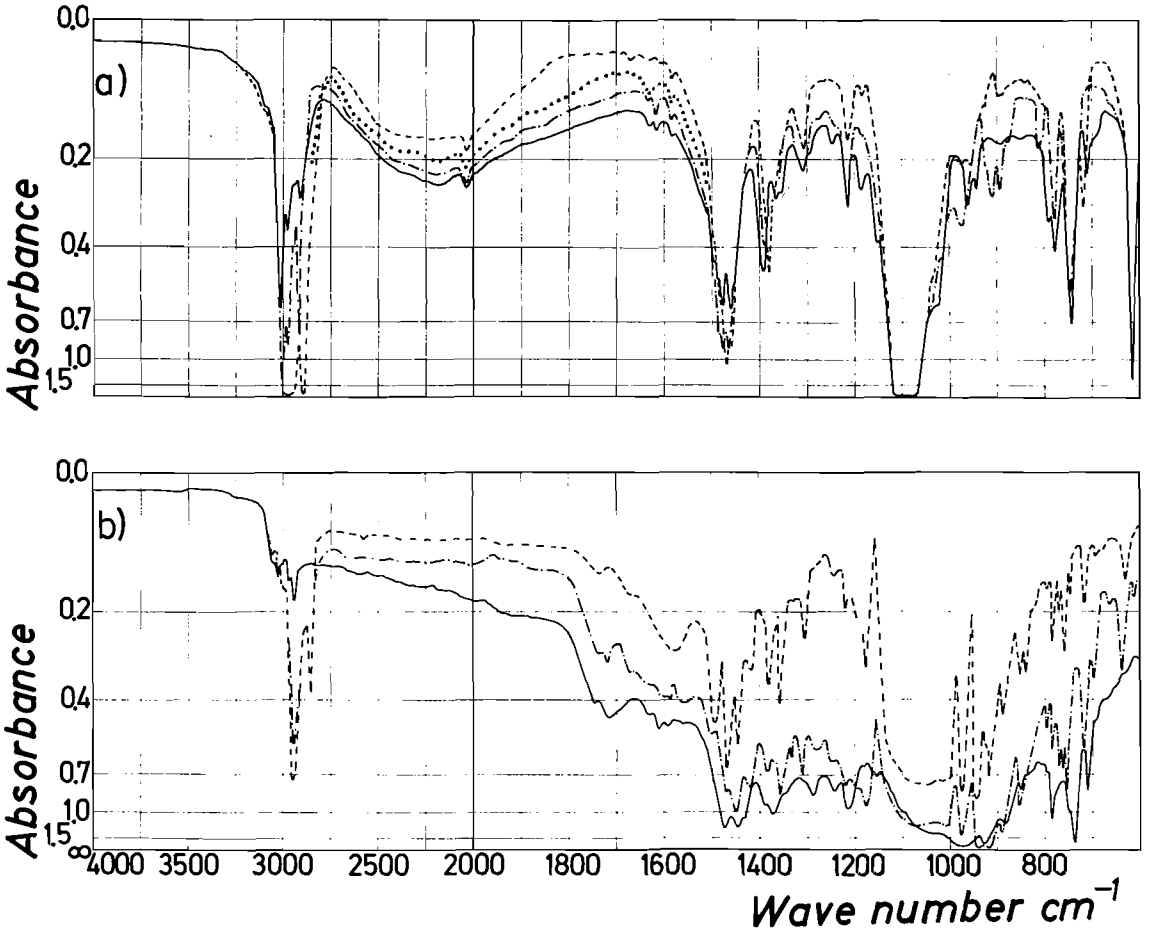

FIG. 2. Infrared spectra of *N*,*N*′-tetra-R-*o*-xylildiamine $HClO_4$ salts. (*a*) — R = C_2H_5 (**7**); ----- R = C_3H_7 (**8**); ··· R = C_4H_9 (**9**); --- R = C_6H_{13} (**11**). (*b*) $HAuCl_4$ salts of compounds **12**–**14**: —, **12**; -----, **13**; ---, **14**.

usually easily polarizable (1–4*a*). The proton within easily polarizable hydrogen bonds is delocalized. This result is confirmed by the nmr data in Table 1. The CH_2 proton signals of the 1:2 complexes (1 *M* base: 2 *M* acid), if they can be studied (solubility), are doublets, indicating spin–spin coupling of the CH_2 proton. When hydrogen bonds are formed, the CH_2 signals are singlets in all cases, indicating that such coupling no longer occurs, because the protons in these intramolecular hydrogen bonds are delocalized.

The ir spectra of these compounds are shown in Fig. 2, in Fig. 2*a* are shown compounds with $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ bonds and in Fig. 2*b* those with $O^+H\cdots O \rightleftharpoons O\cdots H^+O$ bonds. Let us first consider compound **7** (solid line in Fig. 2*a*) and compound **12** (solid line in Fig. 2*b*). With these compounds, the substituents are relatively small, and, therefore, the intramolecular hydrogen bonds may interact with their environments. With compound **7**, a continuum is observed. It shows an intense band-like structure in the region 2800–1800 cm^{-1}, with maximum at about 2100 cm^{-1}, and extends with less intensity towards smaller wave numbers over the whole region. This spectral feature is characteristic of long hydrogen bonds with large proton polarizability (4*b*, 11, 13). With compound **12**, a continuum is found which is most intense in the region 1800–700 cm^{-1}. This spectral feature is characteristic of short hydrogen bonds with large proton polarizability (4*a*, 13). Thus the intramolecular $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ bonds are relatively long and the intramolecular $O^+H\cdots O \rightleftharpoons O\cdots H^+O$ bonds relatively short, easily polarizable hydrogen bonds.

In the series of compounds **7**–**11**, the substituents become increasingly bulky and thus, the intramolecular $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ bonds increasingly screened from their solvent environments. The same is true in the series of compounds **12**–**14**

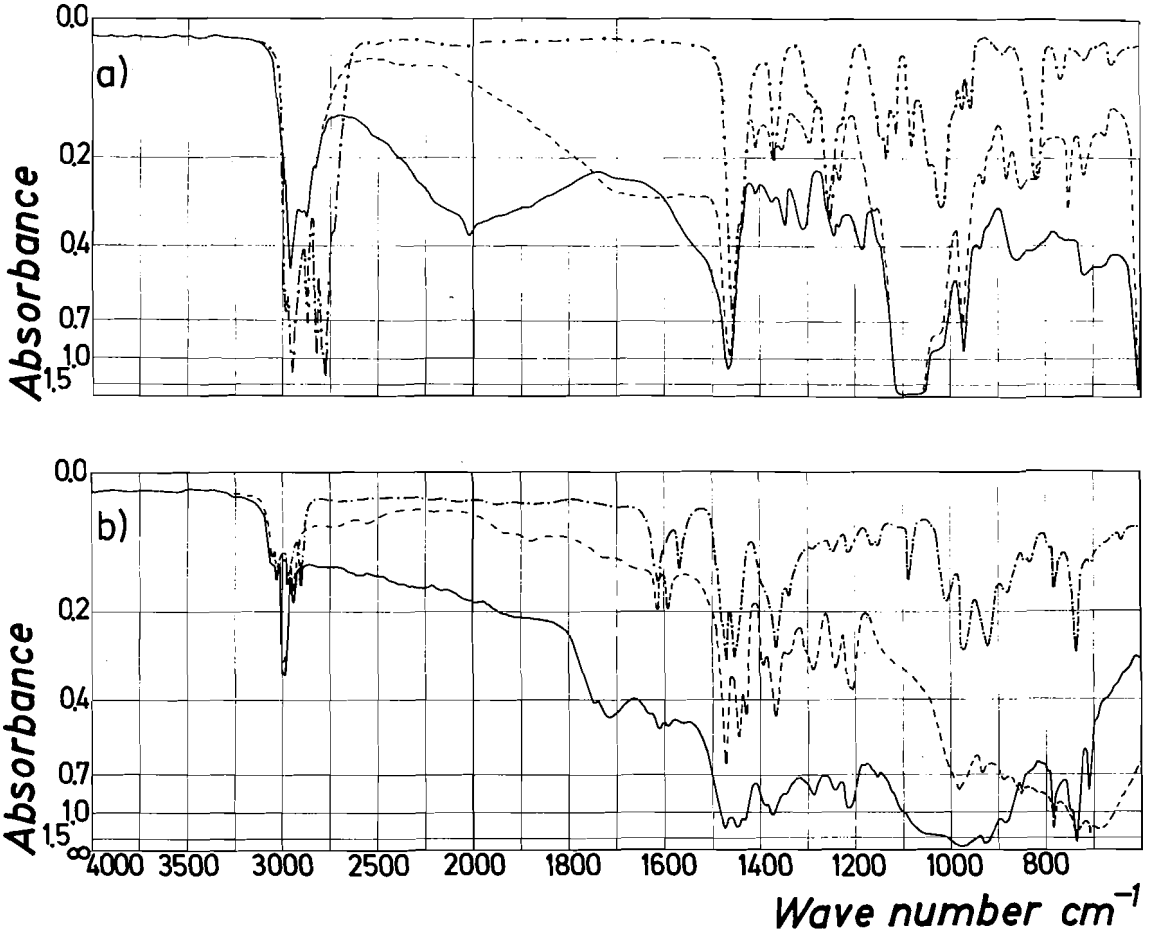

FIG. 3. Infrared spectra of (*a*) compound **3**: —, $HClO_4$ salt; ---, $DClO_4$ salt; -·-·-, free base; (*b*) compound **12**: —, $HAuCl_4$ salt; ---, $DAuCl_4$ salt; -·-·-, free base.

with the intramolecular $O^+H\cdots O \rightleftharpoons O\cdots H^+O$ bonds.

With increasing screening of the $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ bonds (Fig. 2*a*), the continuum vanishes almost completely and a band remains. This band is found in the same position (region 2800–1800 cm^{-1}) where the continuum has shown its band-like structure, which was mainly caused by the fundamental transition of the hydrogen bonds.

With increasing screening of the $O^+H\cdots O \rightleftharpoons O\cdots H^+O$ bonds, as can be seen in Fig. 2*b*, the continuum vanishes and an intense broad band remains in the region 1200–850 cm^{-1}, and a much less intense band is found in the region 1700–1400 cm^{-1}. In analogy to the assignment in ref. 15, the intense band at smaller wave numbers is assigned to the fundamental transition of the hydrogen bonds and the relatively weak band at higher wave numbers to the bending vibration. When with increasing screening the continuum draws back to the band in the region 1200–850 cm^{-1}, various pronounced Evans holes (17–19) arise within this band at 1157, 990, 954, and 930 cm^{-1}.

In summary we can state that with increasing screening of the easily polarizable hydrogen bonds against their solvent environment the ir continua vanish and bands of the usual fundamental transitions of the hydrogen bonds are observed. Thus, for the occurrence of the continua the interaction of the easily polarizable hydrogen bonds with their solvent environments is absolutely necessary. This confirms the theory that the continuity of energy level differences observed as ir continua arises due to the interaction of the easily polarizable hydrogen bonds with local fields in their environment, and due to coupling of transitions in the easily polarizable hydrogen bond with vibrations in their solvent environment.

3. *Change of the Polarizability with Deuteration*

Figure 3 shows spectra of the $HClO_4$ salts and their deuterated analogues, and for comparison the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

spectra of the free bases. As an example of long hydrogen bonds, spectra of compound **3** are shown, and as an example of short hydrogen bonds, spectra of compound **12**.

These figures show that with long hydrogen bonds the continuum decreases strongly with deuteration. The band-like structure caused by the fundamental transitions of the deuterium bonds is found with maximum at 1650 cm^{-1}. With short hydrogen bonds the continuum also decreases strongly with deuteration and a band of the fundamental transition of the deuterium bond appears with maximum at about 710 cm^{-1}.[1] These results demonstrate that with these long and short intramolecular hydrogen bonds, the deuteron polarizabilities are much less than the proton polarizabilities of the respective hydrogen bonds. This shows (see Introduction) that the potentials in these structurally symmetrical hydrogen or deuterium bonds, respectively, are already so strongly deformed that the deuteron is largely localized at one side of the bonds, whereas this is not the case with the protons, since the levels of the proton have a little higher energy than those of the deuteron. Thus the protons may have much larger fluctuation amplitudes within the potential well than the deuterons.

These results together demonstrate that the potentials, of easily polarizable hydrogen bonds, even structurally symmetrical ones are strongly deformed by interaction with the solvent.

Conclusions

It is shown that the most favorable conditions for the formation of intramolecular, easily polarizable $NH^+\cdots N \rightleftharpoons N\cdots H^+N$ bonds in the $HClO_4$ salts of compounds **1–6** occur when these hydrogen bonds are present within the 7-membered rings.

When easily polarizable hydrogen bonds are screened from their solvent environments the continua, usually observed when easily polarizable hydrogen bonds are present in amorphous media, vanish. Then, with the long $N^+H\cdots N \rightleftharpoons N\cdots H^+N$ bonds, the band of the fundamental transitions is found in the region 2800–1800 cm^{-1}, whereas with the short $O^+H\cdots O \rightleftharpoons O\cdots H^+O$ bonds, this band is observed in the region 1200–850 cm^{-1}. Thus, for the occurrence of the continua, interaction of the easily polarizable hydrogen bonds with their solvent environments is absolutely necessary. This confirms that the continuity of energy level differences, observed as ir continuum, arises only due to the interaction of the easily polarizable hydrogen bonds with local electrical fields in their environments, and due to coupling of transitions in the easily polarizable hydrogen bonds with vibrations in their environments.

With long as well as with short, structurally symmetrical hydrogen bonds, the continuum decreases strongly with deuteration, demonstrating that the deuteron polarizabilities are much less than the proton polarizabilities. This becomes understandable, if one also assumes that with the structurally symmetrical hydrogen bonds, the potentials are strongly deformed due to interaction effects with their solvent environment.

The reason for this great deformation of the proton potentials due to their molecular surroundings is the large proton polarizability these hydrogen bonds have if isolated from their environment.

The result that the proton potentials of easily polarizable hydrogen bonds are strongly deformed by interaction with their solvent environments is in good agreement with other theoretical as well as experimental findings. In ref. 21, the interaction of a structurally symmetrical hydrogen bond with a polar environment was treated theoretically with the result that if the proton is in the ground state, the proton potentials usually become more and more asymmetrical due to polar environments. The intensity of the Rayleigh scattering in the Raman spectra near the excitation line is a direct measure of the anisotropy of the proton or deuteron polarizabilities and thus, since these polarizabilities occur only in bond direction, of the polarizabilities. It was shown (22) that this scattering is much more intense with easily polarizable hydrogen bonds than with deuterium bonds.

Materials and Methods

The preparation of the substances as well as the analytical data are given in ref. 23. The substances were deuterated by triple recrystallisation from methanol-d_1. All handling of these substances must be done in a very carefully dried glove box.

All spectra were recorded in 0.5 *M* CD_3CN solutions. CD_3CN was stored over 3 Å molecular sieve. The nmr spectra were recorded with a Varian HA 100 spectrometer. All these spectra were calibrated against TMS as internal standard. To record the ir spectra a cell with NaCl windows was used (layer thickness 0.1 mm). The bands of acetonitrile-d_3 were compensated by a cell with pure acetonitrile-d_3 in the reference beam. All ir spectra were obtained with a spectrophotometer 325 (Bodenseewerk Perkin-Elmer, Überlingen) (program 6.5, time response 2).

N-Picrylethylenediamine – methoxide ion interactions: *N*-deprotonation and σ-complex formation reactions

ERWIN BUNCEL,[1] MASASHI HAMAGUCHI,[2] AND ALBERT R. NORRIS[1]

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received August 18, 1980

ERWIN BUNCEL, MASASHI HAMAGUCHI, and ALBERT R. NORRIS. Can. J. Chem. **59**, 795 (1981).

The interactions of *N*-picrylethylenediamine as the HCl salt (PED) with methoxide ion in dimethyl sulfoxide – methanol (DMSO/MeOH) media and with 1,4-diazabicyclooctane in dimethyl sulfoxide have been investigated spectrophotometrically at 25.0°C. Evidence is presented to show that, in solvent mixtures rich in dimethyl sulfoxide (e.g. 95/5, V/V, DMSO/MeOH), deprotonation reactions at the nitrogen centres on the ethylenediamine occur in preference to reactions in which σ-complexes are formed via addition of CH_3O^- to one or more ring carbon atoms. The initial 1:1 interaction of CH_3O^- and PED results in the rapid, reversible deprotonation of the NH centre while the 2:1 interaction is associated with rapid, reversible abstraction of H^+ from the NH_3^+ centre. At mole ratios of CH_3O^- to PED > 3 a σ-complex is formed as a result of the addition of CH_3O^- ion to a C-3 ring carbon atom of the di-deprotonated PED. The uv–visible absorption properties of these various species are reported and compared to the properties of corresponding species formed in related systems.

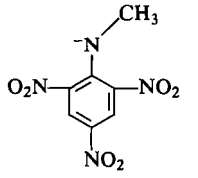
ERWIN BUNCEL, MASASHI HAMAGUCHI et ALBERT R. NORRIS. Can. J. Chem. **59**, 795 (1981).

On a étudié, par spectrophotométrie à 25°C, les interactions du chlorhydrate de *N*-picryléthylènediamine (PED) avec l'ion méthylate dans un mélange de diméthylsulfoxide – méthanol (DMSO/MeOH) et avec le diaza-1,4 bicyclooctane dans le diméthylsulfoxyde. On prouve que dans des mélanges de solvant riches en diméthylsulfoxyde (i.e. 95/5, V/V, DMSO/MeOH) les réactions de déprotonation ont lieu au niveau de l'azote central de l'éthylènediamine de préférence aux réactions dans lesquelles les complexes σ se forment via l'addition de CH_3O^- à l'un ou plusieurs des atomes de carbone du cycle. L'interaction initiale 1:1 du CH_3O^- et du PED conduit à une déprotonation rapide, réversible du NH central tandis que l'interaction 2:1 est associée à une élimination rapide, réversible de H^+ à partir du NH_3^+ central. Pour des rapports molaires de CH_3O^- à PED > 3 il se forme un complexe σ par suite de l'addition de CH_3O^- au carbone en position 3 du cycle de PED bidéprotoné. On rapporte les spectres d'absorption dans le visible et l'uv de ces différentes espèces et on les compare à celles des espèces correspondantes formées dans les système apparentées.

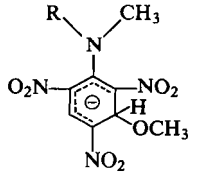
[Traduit par le journal]

Introduction

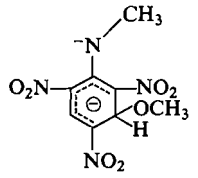
We have reported previously (1, 2) that, in dimethyl sulfoxide – methanol (DMSO/MeOH) solvent mixtures, the interaction of methoxide ion (CH_3O^-) with *N*-methylpicramide (NMP) leads to the formation of species **1**, **2** (R = H), and **3**, while *N*,*N*-dimethylpicramide (DMP) gives rise to species **2** (R = CH_3) and **4**.



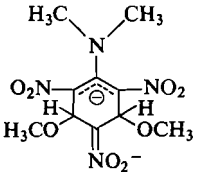
1



2



3



4

A particularly important observation which emerged from these studies was that DMSO stabilizes the conjugate base of NMP, **1**, with respect to the σ-complex **2** (R = H). As a result, DMSO/MeOH solutions rich in DMSO, e.g. 95 volume % DMSO, in which the mole ratio of CH_3O^- to NMP was < 1, contained **1** as the major product of the interaction of CH_3O^- and NMP. This fact enabled us to obtain, for the first time, good uv–visible absorption data for species **1** and **3**.

As part of a continuing study of the reactions of *N*-substituted picramides with CH_3O^-, we now report on the species formed in the reactions of the HCl salt of *N*-picrylethylenediamine, **5**, with methoxide ion in DMSO/MeOH media and with 1,4-diazabicyclooctane (DABCO) in dimethyl sulfoxide.

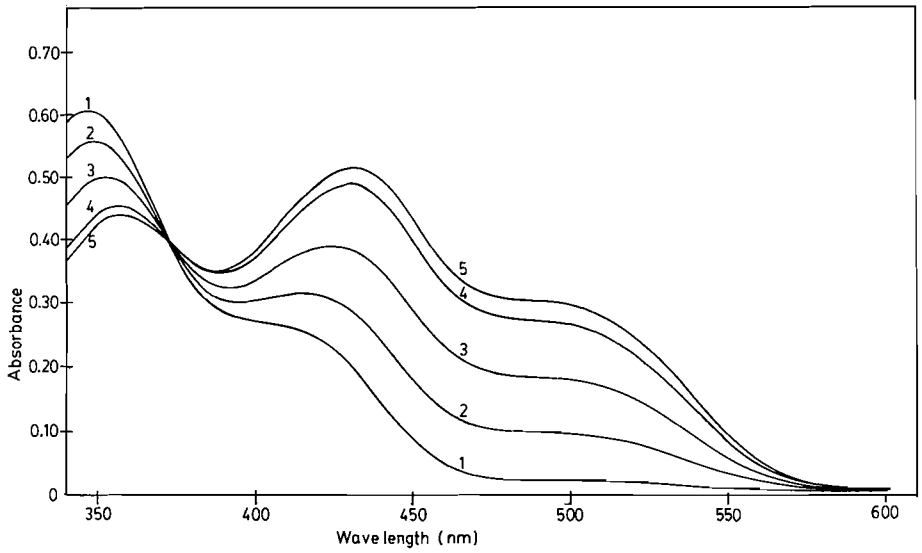

FIG. 1. Initial absorption spectra of the HCl salt of *N*-picrylethylenediamine (4.26×10^{-4} *M*) in dimethyl sulfoxide – methanol (95/5, V/V) containing various concentrations of sodium methoxide ($NaOCH_3$). $[CH_3O^-]$ (*M*): *1*, 0; *2*, 1.04×10^{-4}; *3*, 2.21×10^{-4}; *4*, 3.29×10^{-4} *M*; *5*, 4.08×10^{-4}; 0.10 cm cell; 25.0°C.

amine as the HCl salt (**5**) shows, in dimethyl sulfoxide – methanol (95/5, V/V) as solvent, an absorption maximum at 347 nm ($\varepsilon = 1.44 \times 10^4\ M^{-1}\ cm^{-1}$) and a broad shoulder with midpoint at 405 nm ($\varepsilon = 0.64 \times 10^4\ M^{-1}\ cm^{-1}$).

The addition of progressively larger amounts of sodium methoxide ($NaOCH_3$) to a solution of **5** in dimethyl sulfoxide – methanol (95/5, V/V) results in the simultaneous disappearance of the absorption band due to **5** and the appearance of a new band characterized by an absorption maximum at 430 nm and a broad shoulder whose mid-point occurs at 490 nm (Fig. 1). Conversion of starting material to this new absorbing species, **M**, is essentially complete upon the addition of 1 mol-equiv. of base to the solution containing **5**. The equilibrium constant (K_1) associated with the formation of **M** according to the reaction

[1] $\mathbf{5} + CH_3O^- \rightleftharpoons \mathbf{M}$

is accordingly estimated to be $\geq 5 \times 10^5\ M^{-1}$ at 25.0°C. Solutions containing only **5** and **M** exhibit an isosbestic point at 374 nm (Fig. 1). Both the conversion of **5** to **M** and the conversion of **M** to **5**, via the addition of trifluoroacetic acid (TFA), occur within the time required to mix the reagents and record the spectrum of the resulting solution (< 20 s). Assuming complete conversion of **5** to **M** as the result of the addition of 1 mol-equiv. of $NaOCH_3$ to **5**, we calculate molar absorptivity (ε) values of 1.38×10^4 and $0.81 \times 10^4\ M^{-1}\ cm^{-1}$ at 430 and 490 nm, respectively, for species **M** (Table 1).

The addition of progressively increasing amounts of $NaOCH_3$ to a solution containing species **M** leads to the replacement of the absorption band due to **M** by a new absorption band possessing an absorption maximum at 443 nm and a shoulder with mid-point at 490 nm (Fig. 2). Conversion of **M** to this new absorbing species, **N**, is essentially complete upon the addition of a further 1 mol-equiv. of base to the solution containing **M** (2 mol-equiv. of $NaOCH_3$, in total, added to **5**). The equilibrium constant (K_2) characterizing the formation of **N** from **M** and $NaOCH_3$ is once again estimated to be $\geq 5 \times 10^5\ M^{-1}$ at 25.0°C. The spectra of solutions containing only **M** and **N** are characterized by an isosbestic point at 391 nm (Fig. 2). The addition of TFA rapidly and quantitatively converts **N** to **M** and, with the addition of excess acid, **N** to **5**. Assuming complete conversion of **M** to **N** as the result of the addition of 2 mol of $NaOCH_3$ per mol of **5** originally present in solution, we calculate ε values of $1.72 \times 10^4\ M^{-1}\ cm^{-1}$ and $1.29 \times$

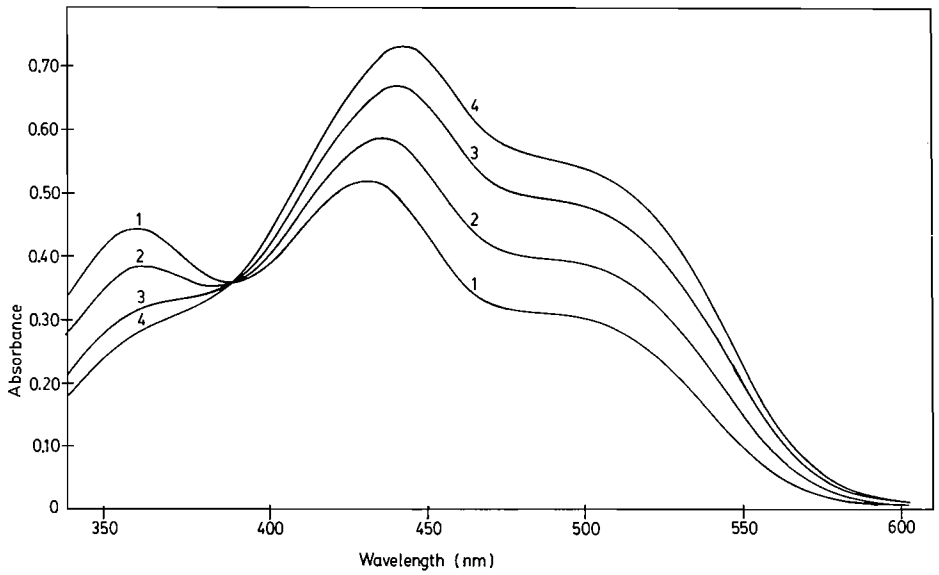

FIG. 2. Initial absorption spectra of the HCl salt of *N*-picrylethylenediamine (4.26×10^{-4} *M*) in dimethyl sulfoxide – methanol (95/5, V/V) containing various concentrations of sodium methoxide ($NaOCH_3$). $[CH_3O^-]$ (*M*): *1*, 4.26×10^{-4}; *2*, 5.56×10^{-4}; *3*, 7.02×10^{-4}; *4*, 8.41×10^{-4}; 0.10 cm cell; 25.0°C.

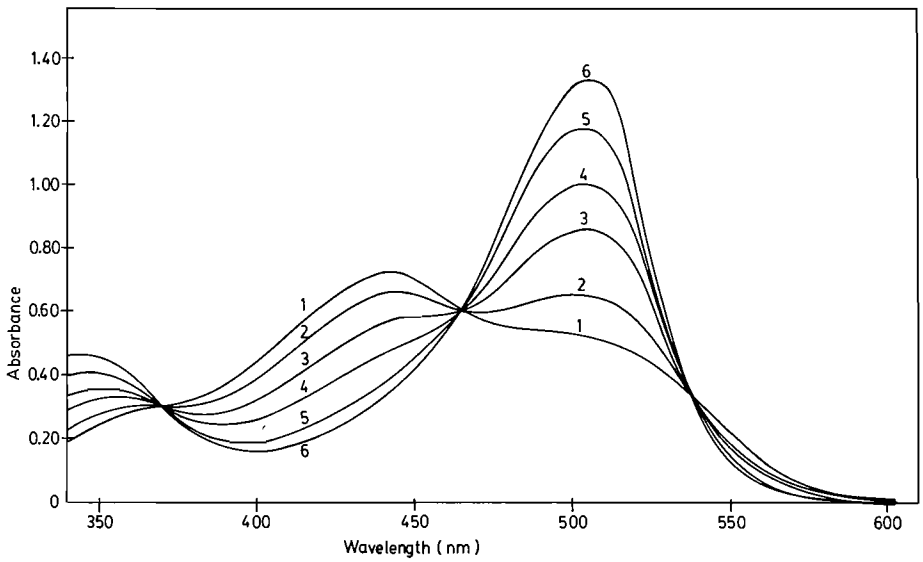

FIG. 3. Initial absorption spectra of the HCl salt of *N*-picrylethylenediamine (4.38×10^{-4} *M*) in dimethyl sulfoxide – methanol (95/5, V/V) containing various concentrations of sodium methoxide ($NaOCH_3$). $[CH_3O^-]$ (*M*): *1*, 8.76×10^{-4}; *2*, 11.3×10^{-4}; *3*, 14.4×10^{-4}; *4*, 16.9×10^{-4}; *5*, 29.3×10^{-4}; *6*, 42.8×10^{-4}; 0.10 cm cell; 25.0°C.

10^4 M^{-1} cm^{-1} at 443 and 490 nm, respectively, for species **N**.

The addition of sodium methoxide to a solution containing species **N** results in the simultaneous disappearance of the absorption band due to **N** and the appearance of a new absorption band with maxima at 344 and 506 nm (Fig. 3). The new maxima are attributed to the production of a single new absorbing species, **O**, in solution. Solutions containing only the absorbing species **N** and **O** are characterized by isosbestic points at 370, 466, and 538 nm (Fig. 3). The conversion of **N** to **O** is rapid and is quantitatively reversed by the addition of TFA; TFA in excess of total base added to the original solution regenerates **5** from **O**. Utilizing the limiting absorbance values obtained at high concentrations of $NaOCH_3$ and, assuming complete conversion of **5** to **O** under these conditions, we

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

calculate ε values of 1.16×10^4 and 3.37×10^4 M^{-1} cm^{-1} at 344 and 506 nm, respectively, for species **O**. The value of the equilibrium constant (K_3) associated with the reaction

[2] $N + CH_3O^- \rightleftharpoons O$

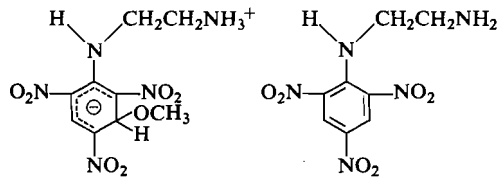
is calculated to be $1.8 \pm 0.1 \times 10^3$ M^{-1} at 25.0°C.

The rapid ($t_{1/2} < 1$ s) conversion of **N** to **O** described above is followed by a much slower process ($t_{1/2} \sim 30$ min) as a result of which the absorption maximum in the visible region shifts from 506 to 503 nm and the value of the absorbance at the absorption maximum increases very slightly (<5%). During this time the peak at 345 remains constant in position and the value of the absorbance at 345 nm remains unchanged. An isosbestic point at 464 nm is associated with the spectra of the solution throughout the course of this slow conversion of **O** to the new absorbing species. The addition of TFA, in excess of total base, to a solution containing the species absorbing at 503 and 345 nm rapidly regenerates the original reactant **5**.

Discussion

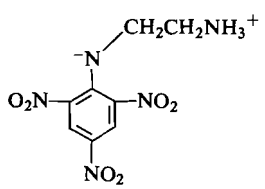
It has been shown that the reaction of **5** with CH_3O^- in dimethyl sulfoxide – methanol (95/5, V/V) leads to the rapid, reversible formation of at least three and possibly four new absorbing species in solution. What are the composition and structure of each of these species?

Species **M** is generated as a result of a 1:1 interaction of **5** and CH_3O^-. This interaction may involve either proton abstraction by CH_3O^- or the addition of CH_3O^- to a ring carbon atom to form a σ-complex. If the reaction is one of proton abstraction, at what point in the molecule is the proton being abstracted? Based on the results obtained in earlier studies (1–4), reasonable formulations of **M** would include the following:



6

7



8

The addition reaction to form σ-complex **6** may be ruled out by noting that, by analogy with the spectra observed for other related σ-complexes (4), e.g. **4**, one might expect **6** to show two distinct absorption maxima in the visible region with an ε value at the lower wavelength maximum of $\sim 3 \times 10^4$ M^{-1} cm^{-1}. Species **M** clearly does not display these absorption characteristics (Fig. 1) and formulation of **M** as the σ-complex **6** may be tentatively ruled out on this basis. A much stronger argument ruling against the formulation of **M** as **6** is the observation that in dry dimethyl sulfoxide, 1,4-diazabicyclooctane (DABCO), which cannot form a σ-complex (5) but can deprotonate the N-centres, also reacts with **5** to generate a species whose absorption characteristics are identical (λ_{max} and ε) to those of **M**.

Given that the initial interaction of **5** and CH_3O^- involves deprotonation and not σ-complex formation, which N-centre is being deprotonated? It would seem that **7** should possess absorption characteristics little different from those of the related compounds picramide and *N*-methylpicramide, the uv–visible absorption characteristics of which are very similar to those of the starting compound **5**. Thus, in that case, conversion of **5** to species **7** should be accompanied by only minor spectral changes. However, as noted in Fig. 1, there is a marked change in spectral features accompanying the conversion of **5** to **M** and, for this reason, we believe that **M** is not likely to be correctly formulated as species **7**.

This leaves us with **8** as the remaining plausible formulation for **M**. The absorption properties (λ_{max} and ε) for species **M** are not inconsistent with this suggestion; values of λ_{max} and ε at λ_{max} for species closely related to **8** are listed in Table 2. We note that the ε for species **M** at its absorption maximum (1.38×10^4 M^{-1} cm^{-1}) is somewhat lower than the ε values quoted for the related species **1**, **9**, and **10** (6,

TABLE 2. Values of absorption maxima and molar absorptivities (ε) at the absorption maxima for some selected anions and σ-complexes

1 9 10

7). This may possibly be the result of one of the *ortho* nitro groups in **8** being somewhat out of the plane of the ring as a consequence of strong H-bonding between a hydrogen on the NH_3^+ group and an oxygen atom of the *ortho* nitro group (8).

A possible alternative explanation of the lower than expected value of ε at 430 nm is that species **M** consists of an equilibrium mixture of **7** and **8**. Rapid equilibration of **7** and **8** (reaction [3]) characterized

[3] $7 \rightleftharpoons 8$

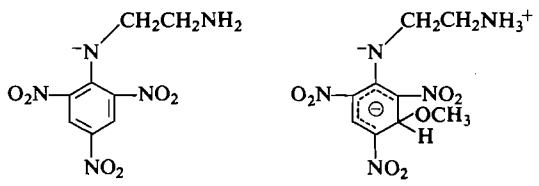
by an equilibrium constant K' would then yield a weighted average value of ε_{430} given by eq. [4] (9).

[4] $$\varepsilon_{430} = \left(\frac{1}{K' + 1}\right)\varepsilon_8 + \left(\frac{K'}{K' + 1}\right)\varepsilon_7$$

In this case, an $\varepsilon_7 = 0$ and an $\varepsilon_8 = 1.42 \times 10^4\ M^{-1}\ cm^{-1}$ at 430 nm yield a K' of 34, i.e. the predominant reaction product is species **8**. However, the position of equilibrium in the interconversion of **7** and **8**, and as a result ε_{430}, would be expected to be strongly solvent dependent. Since the same value of ε_{430} for species **M** is obtained in experiments involving the reaction of DABCO with **5** in dry DMSO and in the reaction of CH_3O^- with **5** in DMSO/MeOH (95/5, V/V), it seems unlikely that the somewhat lower value of ε_{430} for **8** can be explained in this way.

The equilibrium constant of $\geq 5 \times 10^5\ M^{-1}$ associated with the formation of **8** from **5** and CH_3O^- seems reasonable when compared to the equilibrium constant of $2 \pm 1 \times 10^5\ M^{-1}$ associated with the formation of **1** via reaction of *N*-methylpicramide and CH_3O^- under comparable reaction conditions (1).

Given that **M** is correctly formulated as **8**, the reaction of **M** with a further molecule of CH_3O^- to form **N** could conceivably result in either **11** or **12** being formed.



11 12

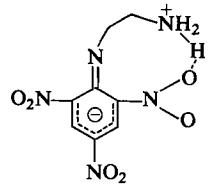
The differences in the spectral properties of **N** and related σ-complex **3** conclusively rules against formulating **N** as **12**. In accord with this conclusion is the observation that, in dry dimethyl sulfoxide, the addition of excess DABCO to a solution of **5** results in a species whose spectral properties are identical to those of **N**. Further, the spectral properties of **N** and **1** are almost identical in terms of λ_{max} values and values of ε at λ_{max} (Table 2). Species **N** is therefore formulated as **11**.

We note that in the closely related species **9**, **1**, and **10** the more electronegative the atom bearing the formal negative charge, the higher the energy required to bring about the lowest energy electronic transition. The promotion of an electron in **8** must be rendered somewhat more difficult than in **11** (or **1**) by virtue of the positive charge on the NH_3^+ group in **8**. In agreement with this, the absorption maximum of **8** is at 430 nm, while the absorption maxima of **1** and **11** are at 442 and 443 nm, respectively.

We conclude, therefore, that in dimethyl sulfoxide – methanol (95/5, V/V) the addition of 2 mol of CH_3O^- per mol of **5** results in successive reversible deprotonation reactions according to the sequence:

[5] $5 \rightleftarrows 8\,(M) \rightleftharpoons 11\,(N)$

This order must reflect, on the one hand, higher solvation energies associated with **8** as compared to **7** and, on the other, a higher solvation energy for the deprotonated species **8** and **11** as compared to the anionic σ-complexes **6** and **12**. The preferential solvation of **8** over **7** is perhaps somewhat unexpected (10, 11). It could conceivably result from the possibility in **8** of delocalizing negative charge from the N centre over the ring and the ability of the NH_3^+ function to H-bond to the partially negatively charged oxygen of an *ortho* nitro group as depicted in **13**. Alternatively, both the negatively charged



13

trinitrocyclohexadienate portion of the molecule and the NH_3^+ group may each be strongly solvated by hydrogen bonding to DMSO. The preferential formation of deprotonated species **1** over σ-complex **2** (R = H) in solvents rich in dimethyl sulfoxide (e.g. 95/5, V/V) has been observed previously (1) in the reactions of *N*-methylpicramide and

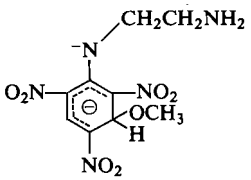
CH_3O^- in mixed dimethyl sulfoxide – methanol solutions.

Further reaction of N with CH_3O^- is postulated to result in the formation of **14** (species **O**).

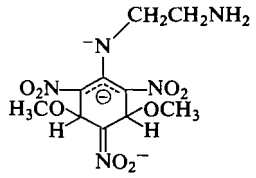


14

The similarities in the absorption properties of species **O** and compound **3** (Table 1) offers excellent support for the formulation of species **O** as **14**. Also in agreement with this conclusion is the observation that the addition of a large excess of DABCO to dry dimethyl sulfoxide solutions containing species **N** does not result in any further spectral change, i.e. there is no evidence for the formation of species **O** under these reaction conditions.

The equilibrium constant of $1.8 \pm 0.1 \times 10^3\ M^{-1}$ characterizing the conversion of **N** to **O**, i.e. **8** to **14**, is very similar to the equilibrium constant characterizing the conversion of **1** to **3** ($1.5 \pm 0.2 \times 10^3\ M^{-1}$) under comparable reaction conditions (1). This observation lends further support to our conclusions regarding asssignment of the structures of **8** and **14**.

The rather slow conversion of species **O** to species **P** remains to be considered. It is possible that species such as **15** and **16** are formed via the

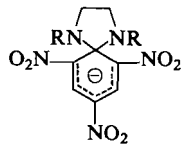


15

16

reaction of **14** (**O**) with CH_3O^-. However, the very slight changes in absorption noted in going from **O** to **P** together with the observation that species of general structure **15** and **16** possess markedly different spectra (3, 4, 10) than does a species such as **14** argues against formulating species **P** as **15** or **16**. In view of the similarities in their spectra, it seems more likely that **O** and **P** differ but slightly in their structures. One possibility is that **14** exists in two isomeric forms in which the $CH_2CH_2NH_2$ group attached to N-1 is either *syn*- or *anti*- to the CH_3O group attached at C-3 (4, 12, 13). If one isomeric form is kinetically preferred in the reaction of **11** with CH_3O^- but is thermodynamically unstable with respect to the second, more slowly generated isomer, the slow conversion of **O** to **P** might then be associated with the establishment of the equilibrium mixture of isomers in solution.

It is of interest that at no time was there evidence for the formation of the spiro species **17** (R = H) or **18** (R = H). These species would be isomeric with **11** and **14**, respectively.



17

18

The corresponding methyl substituted species, **17** (R = CH_3), is readily formed in the reaction of *N*,*N*′-dimethyl-*N*-picrylethylenediamine with CH_3O^- under comparable reaction conditions (14, 15) and its spectrum is characteristically different from the spectra of the species observed in the present study.

One reason that **17** (R = H) is not observed is clearly that deprotonation of **7** to form **11** is kinetically more favorable than formation of **17** (R = H) by reaction of **7** and CH_3O^-. Steric factors (relief of strain in formation of **17** (R = CH_3) from its precursor) might also be important in determining the stability of **17** (R = CH_3) as compared to **17** (R = H).

Experimental

N-Picrylethylenediamine hydrochloride (**5**) was prepared by a modification of the procedure given by Bernasconi and Gehriger (14). A solution of picryl chloride (2.50 g, 0.010 mol) in benzene (50 mL) was added dropwise during 20 min to a stirred mixture of ethylenediamine (1.21 g, 0.020 mol) in benzene (15 mL) and 2 *N* KOH solution (15 mL). After 1 h the benzene layer was separated and the residue acidified with dilute HCl until 1 *N*. The aqueous solution after heating with activated carbon, filtering, and cooling yielded 1.2 g (40%) of crude product. This was twice recrystallized from 1 *N* HCl to yield white crystals mp 250°C (decomposed). *Anal.* calcd. for $C_8H_{10}O_6N_5Cl$: C 31.23, H 3.28, N 22.76; found: C 31.26, H 3.39, N 22.35. Use of the two-phase system, as described above, minimizes the formation of dipicrated ethylenediamine which leads to the rather low yields obtained when C_2H_5OH is used as a reaction medium. Dimethyl sulfoxide, methanol, and 1,4-diazabicyclooctane were purified as described previously (1, 2).

The procedures used in preparing stock solutions of the above reagents and in carrying out the spectrophotometric measurements were as described previously (1, 2).

Acylation du (cyclopropylméthyl)triméthylsilane. Une nouvelle voie d'accès aux énones non conjuguées

M. GRIGNON-DUBOIS, J. DUNOGUÈS ET R. CALAS

Laboratoire de Chimie Organique et Laboratoire de Chimie des Composés Organiques du Silicium et de l'Etain associé au C.N.R.S. (No 35), Université de Bordeaux I, 351, Cours de la Libération 33405 Talence, France

Reçu le 24 juillet 1980

M. GRIGNON-DUBOIS, J. DUNOGUÈS et R. CALAS. Can. J. Chem. **59**, 802 (1981).

L'acylation du (cyclopropylméthyl)triméthylsilane par $RCOCl/AlCl_3$ (R: groupe hydrocarboné saturé) constitue une voie douce d'accès aux cétones β,γ-éthyléniques exemptes d'isomères conjugués. Avec les chlorures d'acides α,β-éthyléniques, on observe une compétition entre la scission C—H et C—Si en position allylique alors que le chlorure de chloracétyle conduit essentiellement à la cétone γ,δ-éthylénique. Une interprétation de l'ensemble de ces résultats est proposée: elle met en jeu le rôle catalytique d'HCl dans la formation des cétones β,γ-éthyléniques et des chlorocétones.

M. GRIGNON-DUBOIS, J. DUNOGUÈS, and R. CALAS. Can. J. Chem. **59**, 802 (1981).

Acylation of (cyclopropylmethyl)trimethylsilane using $RCOCl/AlCl_3$ (R: saturated hydrocarbon group) constitutes a mild, convenient route to β,γ-unsaturated ketones free from the conjugated isomers. With α,β-unsaturated acyl chlorides a competitive reaction between the C—H and C—Si allylic cleavage is observed whereas chloroacetyl chloride affords the γ,δ-ethylenic corresponding ketone. A mechanism involving the catalytic role of HCl in the formation of β,γ-unsaturated and chloroketones is proposed.

Introduction

Au cours de travaux antérieurs, nous avons montré que le (cyclopropylméthyl)triméthylsilane **1**, facilement obtenu par cyclopropanation de l'allyltriméthylsilane (rdt: 70%) (1), réagissait avec les électrophiles par ouverture du cycle conduisant à des butènes fonctionnels. Ainsi, avec le chlorosulfonate de triméthylsilyle (1), la réaction est univoque et l'on isole l'ester sulfonique γ,δ-éthylénique $CH_2{=}CH{-}(CH_2)_2SO_3SiMe_3$ résultant de la scission de la liaison $C{-}SiMe_3$ et avec le brome, électrophile plus faible, la réaction conduit au mélange de dibromo-1,2 et tribromo-1,2,4 butanes, résultant de l'addition de Br_2 respectivement au butène-1 et au bromo-1 butène-3 formés dans un premier stade (2). Nous avions alors invoqué, pour interpréter ces resultats, une compétition entre l'élimination du groupe $SiMe_3$ et celle d'un proton.

La mise en évidence d'une telle compétition, alors qu'habituellement c'est la liaison C—Si allylique qui est scindée, nous a encouragés à approfondir notre étude dans ce domaine. De plus, les cétones β,γ- et γ,δ-éthyléniques étant des composés recherchés et souvent difficiles à obtenir à l'état pur, nous avons entrepris d'étudier l'acylation du (cyclopropylméthyl)triméthylsilane catalysée par $AlCl_3$. Nous avons analysé la composition du mélange réactionnel en fonction de la nature du chlorure d'acide utilisé.

Résultats

Le composé **1** a été mis à réagir avec une série de chlorures d'acides en présence d'une quantité stœchiométrique de chlorure d'aluminium. Selon les cas, nous avons obtenu, après hydrolyse, des cétones γ,δ- ou β,γ-éthyléniques parfois accompagnées de dérivés chlorés. Ces résultats sont résumés dans le tableau 1.

Notons qu'avec le chlorure de chloracétyle (exemple *h*) la réaction conduit essentiellement à la cétone γ,δ-éthylénique, alors qu'avec le chlorure d'isobutyryle ou de pivaloyle, électrophiles plus faibles, on isole la cétone β,γ-éthylénique exempte de son isomère γ,δ-insaturé. Les chlorures d'acides α,β-insaturés occupent une position intermédiaire puisque, moins réactifs que le chlorure d'acétyle par exemple, ils permettent néanmoins d'isoler les dérivés à double liaison terminale.

D'un point de vue synthétique, cette réaction constitue une nouvelle méthode de préparation des cétones β,γ-éthyléniques exemptes d'isomères conjugués, ce qui confère à notre méthode une valeur synthétique réelle. En outre, les composés **4, 5, 6, 11, 14** et **16** n'avaient jamais été décrits à notre connaissance.

Discussion

L'obtention de cétones γ,δ-éthyléniques s'interprète aisément par un mécanisme comparable à

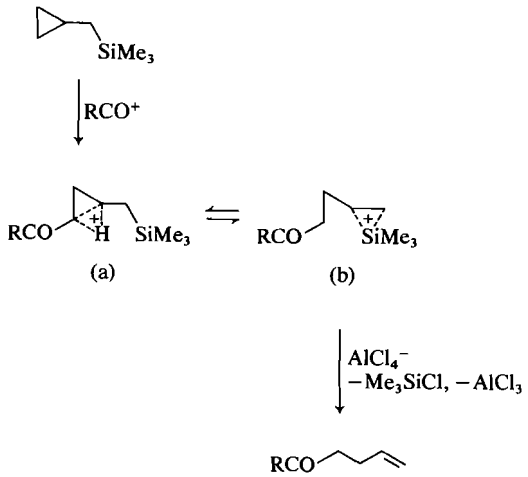
f	$CH_3CH{=}CH$—	**10**	17	**11**	50	**12**	33	60
g	$CH_3{-}C(CH_3){=}CH$—	**13**	60	**14**	25	**15**	15	50
h	$ClCH_2$—	**16**	30	**17**	5	**18**	5	35

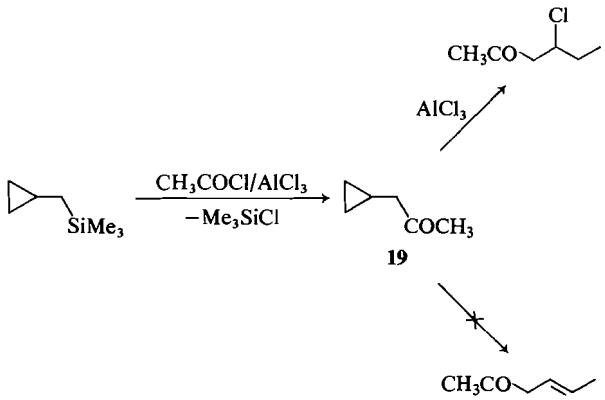
celui précédemment proposé dans le cas de la sulfonation (1).

Notons que la forme protonée (a) a souvent été invoquée en série cyclopropanique (3). Cependant, il a été montré par le calcul, que le silicium pouvait également donner lieu à un "pontage" (forme b) (4) et de telles espèces ont été depuis fréquemment invoquées (5).



Par contre, la formation de cétones β,γ-éthyléniques et de chlorocétones ne peut s'interpréter directement à partir du substrat. Nous avons vérifié que ces composés ne provenaient pas d'une altération de la cétone γ,δ-éthylénique. Cette dernière est parfaitement stable dans les conditions où l'on opère et même en présence de deux équivalents d'$AlCl_3$.

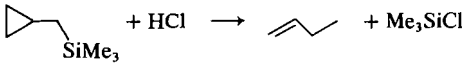
Par ailleurs, nous avons synthétisé la cyclopropylacétone **19**. En effet on peut supposer que **19** pourrait se former par scission de la liaison C—Si selon:



En présence d'$AlCl_3$ ce composé se transforme partiellement en chlorocétone. Toutefois, nous n'avons pas retenu un tel mécanisme, puisqu'il ne rend pas compte de l'obtention de la cétone β,γ-éthylénique.

Enfin, une éventuelle isomérisation de **1** en triméthylsilyl-4 butène-1 est également à rejeter. En effet, Sakurai *et al.* (6) ont montré que l'acétylation de ce composé conduisait essentiellement à **19**.

A partir de ces résultats, nous pensons que la formation de cétones β,γ-éthyléniques et de chlorocétones est due à la présence d'HCl. Il se formerait en cours de réaction et entraînerait la scission de **1** avec libération de butène-1, dont l'acylation permet de rendre compte de nos résultats. Effectivement **1** réagit avec HCl gazeux selon:



L'acétylation du butène-1 à −15°C, conduit à un mélange de **2** et **3** (proportions en poids **2:3** = 70:30). Cette réaction, relativement lente en l'ab-

SCHÉMA 1. Interprétation proposée pour l'acylation du (cyclopropylméthyl)triméthylsilane.

sence de catalyseur, est très rapide en présence d'$AlCl_3$. De plus, l'acétylation de **1** réalisée en présence d'un équivalent de *N*-chlorosuccinimide (NCS)[1] conduit à un mélange complexe ne contenant pas de produit d'acétylation, mais dans lequel nous avons décelé (spectrométrie de masse) la présence de dérivés chlorés. En opérant en présence de triéthylamine, on favorise l'apparition de cétone γ,δ-éthylénique.[2]

La formation d'HCl au sein du milieu réactionnel semble donc bien réelle et est à rapprocher des résultats obtenus lors de la bromuration de **1** (2). Ces observations nous amènent à proposer le schéma réactionnel ci-après (Schéma 1).

En fonction de la nature du réactif, il interviendrait une compétition entre la scission de la liaison C—Si conduisant à un dérivé à double liaison terminale et celle d'une liaison C—H. En effet, on peut penser que l'espèce intermédiaire A évoluera différemment en fonction de l'importance de sa charge positive: plus cette charge sera grande et plus le silicium aura tendance à la stabiliser conduisant ainsi à l'intermédiaire B qui évoluera ensuite vers la cétone γ,δ-éthylénique. C'est effectivement ce que l'on observe avec le chlorure de chloracétyle qui est un électrophile puissant. Par contre, si cette charge est faible, le caractère cyclopropanique restera marqué dans l'état de transition qui évoluera plutôt vers la forme C, susceptible de se stabiliser par perte d'un proton, conduisant ainsi à une cétone éthylénique siliciée et à HCl. Ce dernier, en présence d'$AlCl_3$, réagit instantanément avec **1** pour donner du butène-1 beaucoup plus réactif que **1** en acylation électrophile. Celle-ci va donc venir concurrencer la réaction étudiée et conduira à la cétone β,γ-éthylénique et à la chlorocétone. C'est ce qui intervient par exemple avec les chlorures d'acétyle ou de pivaloyle qui sont des électrophiles relativement faibles.

Notons que la formation de cétone β,γ-éthylénique s'accompagne de la libération d'HCl qui est ainsi régénéré. Il suffit donc d'une trace d'acide (et par conséquent de cétone siliciée)[3] pour que la réaction puisse évoluer totalement vers la formation de butène-1.

Le cas des chlorures d'acides α,β-éthyléniques est apparemment en contradiction avec les autres résultats puisqu'ils conduisent à la formation de

[1]Le NCS réagit avec HCl avec formation de succinimide et libération de chlore (7).

[2]L'adjonction de quantités croissantes d'Et_3N abaisse considérablement les rendements et les cétones γ,δ-éthyléniques n'ont pu être obtenues exemptes des isomères β,γ- par cette méthode.

[3]Ceci explique que nous n'ayons pas trouvé trace de ce composé qui doit, de plus, être très instable dans le milieu réactionnel.

cétones γ,δ-éthyléniques. En fait nous avons ici des composés peu réactifs et si l'on peut admettre que la forme C est défavorisée lorsque l'électrophilie du complexe $RCOCl/AlCl_3$ diminue, il faut aussi considérer que la facilité d'acylation du butène diminue et donc que le mécanisme faisant appel à HCl pourrait être défavorisé. La compétition serait alors favorable à la formation de la cétone γ,δ-éthylénique.

Avec PhCOCl, électrophile beaucoup plus faible, on peut admettre que B serait trop défavorisé par rapport à C et qu'en dépit d'une faible réactivité de PhCOCl vis-à-vis du butène, la formation de la cétone β,γ-éthylénique et de la chlorocétone serait favorisée. Cette observation est corroborée par les faibles rendements observés.

Rappelons que nous avons déjà signalé une telle compétition en fonction du réactif lors de l'acétylation de sila-3 cyclopentènes-1 (7), et en fonction de la structure du substrat lors de la sulfonation des sila-3 cyclopentènes-1 et silabicyclo[3.1.0] hexanes (8), ainsi que lors de l'acétylation de ces derniers.

Remarque

L'acétylation de **1** par $CH_3CO^+BF_4^-$ a conduit à la cétone β,γ-éthylénique alors que cet électrophile réputé puissant aurait dû conduire à l'isomère γ,δ-éthylénique. Ceci n'est pas en contradiction avec notre interprétation puisque le cycle catalytique fait alors intervenir HF, beaucoup plus réactif que HCl vis-à-vis de **1**.

Conclusion

De même que la sulfonation et la bromuration, l'acylation électrophile du (cyclopropylméthyl)-triméthylsilane s'effectue avec ouverture du cycle à 3 chaînons. L'attaque du noyau cyclopropanique conduit au développement d'une charge positive qui, en fonction du réactif, évolue par perte d'un proton ou du groupe $SiMe_3$.

Cette compétition entre la scission d'une liaison C—H et celle d'une liaison C—Si en β d'une charge positive, non pas au stade de l'attaque mais à celui de l'élimination, n'avait pas été signalée sur ces substrats. Ces résultats constituent un nouvel exemple de la réactivité de ces liaisons C—H que nous avions mise par ailleurs en évidence (8, 9) et viennent confirmer l'interprétation que nous avions alors donnée.

Sur le plan synthétique, nous proposons une nouvelle méthode de préparation de cétones β,γ-éthyléniques particulièrement intéressante dans le cas où R = *i*Pr ou *t*Bu, puisque les produits correspondants, qui n'étaient pas connus, sont obtenus avec de bons rendements.

Partie expérimentale

Préparation du (cyclopropylméthyl)triméthylsilane

Nous l'avons obtenu par cyclopropanation de l'allyltriméthylsilane. Nous avons utilisé la méthode de Simmons-Smith modifiée selon Rawson et Harrison (10) en utilisant une durée de chauffage de 24 h. Le composé **1** est ainsi obtenu avec 70% de rendement, pé = 113°C/760 Torr; rmn (CCl_4, $HCCl_3$ à 7,27 ppm comme réf. int.) δ (s: singulet, d: doublet, m: massif ou multiplet): 0,3 (s, 9H, $SiMe_3$), 0,3 à 0,7 (m, $3CH_2$ et 1 CH) ppm.

Réactions d'acylation

Elles sont effectuées à la rampe à vide sous atmosphère d'argon. Le chlorure d'aluminium est préalablement dégazé à la pompe à palettes.[4] Les chlorures d'acides sont distillés sur magnésium puis conservés sous argon.

Dans un ballon à tubulure latérale, on place 0,02 mol d'$AlCl_3$ que l'on recouvre par 20 cm^3 de CH_2Cl_2. L'ensemble étant refroidi à 0°C, on additionne 0,02 mol de chlorure d'acide. Au bout d'une heure à 0°C la solution de complexe est rapidement dégazée. Le (cyclopropylméthyl)triméthylsilane (0,019 mol), en solution dans 10 cm^3 de CH_2Cl_2, est alors additionné à −90°C. Cette température est maintenue pendant 15 min puis on la laisse remonter jusqu'à −15°C (durée 2 h); CH_2Cl_2 et Me_3SiCl formé sont alors en partie éliminés sous pression réduite (trompe à eau). La solution résiduelle est ensuite versée sur un mélange eau glacée/NaCl/pentane (100 cm^3 d'eau pour 50 cm^3 de pentane environ) vigoureusement agité. Cette technique permet d'opérer à −10°C et de soustraire les cétones formées à la solution aqueuse fortement acide. Celle-ci est ensuite extraite au pentane et l'ensemble des phases organiques est lavé avec une solution saturée de $NaHCO_3$, puis à l'eau et enfin séché.

Le mélange réactionnel obtenu après élimination du solvant est filtré sur une petite colonne de SiO_2 (Silice 60 Merck, 70–230 mesh). Par élution au pentane, on sépare l'hexaméthyldisiloxane et le substrat n'ayant pas réagi, des dérivés carbonylés. Ces derniers sont analysés en cpg et purifiés par chromatographie liquide–solide ou par cpg préparative.

Description des produits obtenus

Les spectres de rmn (^1H) ont été enregistrés sur un appareil fonctionnant à 60 MHz (Perkin-Elmer R 24) (δ ppm, solvant CCl_4, réf. int. TMS à 0,0).

Tous les produits nouveaux ont des microanalyses C, H, O en accord avec les formules proposées (voir le tableau 2).

Cétones β,γ-éthyléniques

A l'exception de **8, 11** et **14**, elles présentent toutes en ir (film NaCl) une bande ν(C=O) vers 1715 cm^{-1}.

Le composé **2**, rmn: 1,6 (massif large, CH_3), 2,0 (s, CH_3CO), 3,0 (pseudo t, CH_2), 5,5 (m, 2H, CH=CH).

Le composé **4**, rmn: 0,9 (t, CH_3), 1,7 (massif large, 3H, CH_3—C=), 2,5 (q, 2H, CH_2—CH_3), 3,1 (pseudo t, CH_2CO), 5,5 (m, 2H, CH=CH).

Le composé **5**, rmn: 1,1 (d, 6H, $2CH_3$), 1,8 (massif large, 3H, CH_3—C=), 2,3 (sept, CH), 3,1 (pseudo t, CH_2CO), 5,4 (m, 2H, CH=CH).

Le composé **6**, rmn: 1,3 à 2 (massif, 10H, 5 CH_2 du cycle), 2 à 2,3 (massif 1H, CH—CO), 3,1 (pseudo t, CH_2CO), 5,4 (m, 2H, CH=CH).

Le composé **8**, ir: ν: 1680 (C=O), 1600 et 1580 (C=C, aromatiques) cm^{-1}; rmn: 1,7 (d élargi, 3H, CH_3), 3,5 (pseudo t, CH_2CO), 5,5 (m, 2H, CH=CH), 7,1 à 7,5 (m, 3H aromatiques), 7,8 à 8,1 (m, 2H aromatiques).

Le composé **11**, rmn: 1,6 (d élargi, 3H, CH_3CH—), 1,8 (d élargi, 3H, CH_3CH=), 3,05 (pseudo t, CH_2CO), 5,3 (m, 2H,

[4]L'utilisation d'$AlCl_3$ fraîchement sublimé ne modifie pas les résultats obtenus.

TABLEAU 2. Résultats de microanalyse des composés nouveaux

	Analyse (%)					
	calc.			trouvée

CH=CH), 5,7 et 6,0 (2 m, 1H, =C*H*—CH_3), 6,2 à 6,8 (2q, J = 6,5 Hz, 1H, =CH—CH_3).

Le composé **14**, rmn: 1,8 (d élargi, 3H, CH_3C=), 2,1 (d, 6H, $(CH_3)_2C$=), 3,0 (pseudo t, CH_2CO), 5,5 (m, 2H, CH=CH), 6,0 (signal large, 1H, =CH—CO).

Cétones γ,δ-éthyléniques

Elles sont caractérisées en ir par la fréquence de vibration ν(C=C) vers 1650 cm^{-1} et ν(C=O) vers 1720 cm^{-1}. En rmn les protons éthyléniques donnent un spectre ABC (X_2) caractéristique.

Le composé **10**, ir: ν: 1680 (C=O), 1650 (C=C) cm^{-1}; rmn: 1,7 (d élargi, 3H, CH_3—C=), 2 à 2,5 (m, 4H, CH_2CH_2), 4,8, 4,9 et 4,95 (3m, 2H, CH_2=CH), 5,2 à 5,7 (m, 1H, C*H*=CH_2), 5,8 et 6 (2m, 1H, =CH—CO), 6,5 à 7 (m, 1H, CH_3*C*H=).

Le composé **13**, rmn: 1,8 (s, 3H, CH_3), 2,0 (s, 3H, CH_3), 2,2 (signal large 2H, CH_2—C=), 3,0 (massif, 2H, CH_2CO), 4,85, 5,0 et 5,1 (3m, 2H, CH_2=CH), 5,3 à 6 (m, 1H, C*H*=CH_2), 6 (signal large, 1H, =CH—CO).

Le composé **16**, ir: ν: 1710 (C=O), 1620 (C=C) cm^{-1}; rmn: 1,5 à 3 (m, 4H, CH_2—CH_2), 4,0 (s, 2H, CH_2CO), 4,8, 4,9 et 5,1 (3m, 2H, CH_2=CH), 5,3 à 6 (m, 1H, C*H*=CH_2).

Cétones β-chlorées

En rmn (^{1}H), ces cétones se caractérisent notamment par un multiplet (^{1}H) centré vers 4 ppm attribuable au proton de —CHCl— et un spectre AB dédoublé (2H) (—CO—CH_2—) où n'apparaissent nettement que les 4 raies principales. Signalons que ces cétones sont instables même à température ambiante (perte de HCl).

Acétylation du butène-1

Dans 20 cm^3 de CH_2Cl_2 refroidi à −15°C, on dissout 5 g de butène-1 (0,09 mol) puis on additionne 0,02 équivalent du complexe $CH_3COCl/AlCl_3$ préparé comme précédemment. Les réactifs sont laissés en contact pendant 1 h à cette température puis après hydrolyse, extraction à l'éther, séchage et filtration sur silice, on récupère 1 g d'un mélange **2** + **3** dans les proportions ~70:30.

Obtention de 19

Le butène-3 ol-1 (0,4 mol) et Me_6Si_2NH (0,2 mol) sont chauffés 2 h au reflux après addition de quelques gouttes de Me_3SiCl. Le produit ainsi obtenu est alors soumis à la cyclopropanation (mode opératoire précédemment décrit pour **1**, rdt: 60%). La fonction OH est ensuite restituée par méthanolyse en présence de quelques gouttes d'HCl puis oxydée par le réactif de Corey et Suggs (11). On isole ainsi la cyclopropylacétone **19** avec un rendement global de 48%; ir: ν(C=O) à 1716 cm^{-1}; rmn: 0,15 (m, 2H, cyclopropyl), 0,6 (m, 2H, cyclopropyl), 1,04 (m, 1H, cyclopropyl), 2,2 (s, 3H, CH_3CO), 2,3 (d, 2H, CH_2—CO).

Some comments on Linnett Double Quartet theory

WILLIAM B. JENSEN

Department of Chemistry, University of Wisconsin, Madison, WI 53706, U.S.A.

Received July 22, 1980

WILLIAM B. JENSEN. Can. J. Chem. **59**, 807 (1981).

The recent critical evaluation of Linnett Double Quartet theory by Langler, Trenholm, and Wasson is critically examined and found to be based on misrepresentations of the theory's basic postulates and its use in predicting chemical reactivity. Various ways in which Linnett's original work can be profitably extended are suggested and briefly discussed.

WILLIAM B. JENSEN. Can. J. Chem. **59**, 807 (1981).

Un examen approfondi révèle que la critique récente de la théorie du double quartet de Linnet faite par Langler, Trenholm et Wasson est le reflet d'une mauvaise interprétation des postulats de base de la théorie et de leur utilisation dans la prévision de la réactivité chimique. On suggère différents moyens d'utiliser avec profit le travail original de Linnet et on en discute brièvement.

[Traduit par le journal]

The April 15, 1980, issue of this journal carried an article by Langler, Trenholm, and Wasson (1) which purports to be a critical reexamination and evaluation of the application of Linnett Double Quartet (LDQ) theory to problems of structure, reactivity, and resonance in organic chemistry. This article presents an interpretation of LDQ theory which is, in the present writer's opinion, incorrect and potentially misleading for those readers who are only superficially acquainted with Linnett's work. Consequently, it is felt that some comments on this interpretation are in order. On the other hand, the article does call attention to a number of situations which, though far from invalidating LDQ theory as the authors contend, do point to a need for a more explicit consideration of nuclear–nuclear repulsions in certain qualitative applications of the theory. Such a treatment is made in the present paper and is shown both to resolve the problems raised by Langler *et al.* and to point to a new area of application for Firestone's theory of Linnett or L strain (2, 3).

The Role of the Nuclei in LDQ Theory

The major source of difficulty with the authors' interpretation of LDQ theory stems from their misconceptions about its primary postulates. After first describing the concept of two tetrahedral spin sets, the authors summarize the theory as follows: "Molecular structures are elaborated by maximizing electronic separations and minimizing electronic repulsions. Priority, it is assumed, must be given to maximizing the separation of electrons having the same spin." This is correct as far as it goes, but appended to this statement is a footnote which reads, "The role of the nuclei is ignored." In other words, the authors claim that LDQ theory is based on the premise that electron correlation is the *sole* determinant of both molecular structure and reactivity. This is simply not true. Thus, for example, Dale (4) in his summary of LDQ theory lists, in addition to the postulates dealing with electronic charge and spin correlation, the following two additional postulates. (*1*) "The attraction between electrons and atomic nuclei tends to draw a maximum number of electrons to regions between atoms." (*2*) "Two electrons of opposite spin may occur together as a pair (coincidence) when more electrons can thereby be concentrated between two atoms to form a bond." Likewise, Lawless and Smith (5) state the underlying principles of LDQ theory to be that "electrons are electrostatically attracted by the nuclei, are mutually repelled by other electrons, and have a tendency to achieve a fairly uniform charge distribution in a given chemical species, as limited by the effect of the spin wave function and relative electronegativities of the atoms involved."

In both statements the nuclei are assigned a key role. Structures are a result of the dynamic interplay between the desire of the electrons, on the one hand, to reduce their mutual repulsions by maintaining their spin sets and as much anticoincidence between the sets as possible, and the desire of the nuclei, on the other hand, to increase their electron attractions and reduce nuclear–nuclear repulsions by concentrating as many electrons as possible along the internuclear axes. Indeed, the role of the nuclei is assumed to be so apparent from traditional bonding concepts that the two standard books on LDQ theory by Luder (6) and Linnett (7) do not even explicitly state postulates dealing with these effects, the authors concentrating instead on the novelty which the postulate of spin correlation introduces into the treatment of the electron repulsions. Nevertheless, a reading of these books quickly shows that the nuclei play the roles outlined by Dale, and by Lawless and Smith.

Linnett himself originally presented LDQ theory as a simple modification of Lewis' original bonding concepts (8). Like both the two-dimensional topological Lewis structures themselves, and their three-dimensional extensions in terms of the tangent sphere model (9–14) and the VSEPR rules (15), LDQ theory makes use of such concepts as the octet rule (for period 2 elements), the electroneutrality principle (in terms of favorable formal charge distributions), and the isoelectronic principle, as well as assorted electrostatic arguments common to all such localized bonding models. Its sole innovation is its use of the postulate of the two tetrahedral spin sets to account for the effects of the Pauli principle and its attempt to maximize their degree of correlation within the bounds set by the other electrostatic energy components. The practical consequences of this are the appearance of valence electrons which are not close-paired and the possibility of one, three, and five electron bonds in addition to the close-paired two, four, and six electron bonds of the conventional Lewis – tangent sphere – VSEPR model. As Serratosa has succinctly put it, "All fundamental principles of chemical bonding are preserved in Linnett's theory, except the 'idolatry' for the Lewis *doublet*" (16).

It is true, however, that writers on LDQ theory, while always emphasizing the role of the nuclei in forcing the spin sets into coincidence, have often had little or nothing to say about the relative efficiency of various electron configurations in reducing nuclear–nuclear repulsions or about the relative efficiency of various kernels, as expressed by their charges and sizes (i.e., electronegativities), in forcing the electrons into coincidence and in distorting the spin sets due to inequalities in their relative attractions for the electrons. This emphasis (or lack thereof) is in fact consistent with the origins of LDQ theory as, like the Lewis – tangent sphere – VSEPR model, it assumes that electronic repulsions and electron–nuclear attractions are the two major determinants of molecular structure in the case of primarily covalent species. However, in so doing, LDQ theory does not deny the existence of nuclear–nuclear repulsions nor that they play a role in determining the finer details of structure and reactivity (or, indeed, a major role in the case of ionic species). Bent, for example, has made a number of specific applications of nuclear–nuclear repulsions within the context of LDQ theory in order to rationalize certain trends in bond angles and bond lengths (9–14), and Firestone has called attention to a number of situations in which it is not possible to arrive at a satisfactory disposition of the tetrahedral spin sets without simultaneously moving bonding electrons away from the regions of the nuclear–nuclear axes (2, 3). This frequently occurs in the case of transition state species and the resulting destabilization, due to the increase in nuclear–nuclear repulsions and the decrease in electron–nuclear attractions, has been termed Linnett or L strain by Firestone and has been used by him to analyze the origin of activation energies in the case of E2, S_H2, and S_N2 reactions (17). A similar explicit treatment of nuclear–nuclear repulsions quickly resolves a number of the problems discussed by Langler *et al.*

A case in point is the authors' treatment of the excited states of oxygen. The Linnett structures of the ground state ($^3\Sigma_g^-$) and first two excited states ($^1\Delta_g$) and ($^1\Sigma_g^+$) are given by structures **1–3**. The authors point out that the ground state **1** and the first excited state **2** differ very little in the degree of electron close-pairing and yet have an energy separation of 22.6 kcal/mol, whereas the first excited state **2** and second excited state **3** differ a great deal in the amount of electron repulsion, all six electron pairs having become close-paired in the $^1\Sigma_g^+$ state, and yet differ in energy by only 15.1 kcal/mol. They conclude that while an "analysis of apparent electronic separations is qualitatively helpful ... (it) ... can be somewhat misleading quantitatively." However, an examination of structures **1** and **2** shows that while both exhibit similar degrees of electron correlation and both place four electrons in the bond region, structure **1** concentrates at least one of these electrons directly on the nuclear–nuclear axis, whereas structure **2** does not. The resulting difference in the efficiency of screening the nuclear–nuclear repulsions, as well as the greater electron–nuclear attraction for the electron so placed, should account for most of the 22.6 kcal/mol separation. Structures **2** and **3**, on the other hand, do not differ significantly in the degree to which they concentrate electrons on the nuclear–nuclear axis and their somewhat lower energy separation of 15.1 kcal/mol should be largely due to differences in electron repulsion energy resulting from the increased close-pairing in structure **3**.

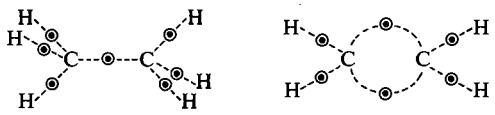
A similar analysis resolves the anomalies in the average bond energies per CC bonding pair discussed by the authors later in the paper (where we are again reminded in a footnote that the nuclei are neglected). Using Linnett structures **4–6** for



4

5

6

ethane, ethene, and ethyne, the authors argue that LDQ theory would predict a similar average energy per CC bond pair in ethane and ethene, as both contain close pairs, but a much higher energy per pair in ethyne where the pairs have achieved a degree of anticoincidence. They then point out that the observed energies per pair are exactly the opposite, being 83.1 kcal/mol for ethane, 73.5 kcal/mol for ethene, and 64.6 kcal/mol for ethyne. Again, as with the simplest possible electrostatic model, LDQ theory would not predict a double bond to be twice as strong as a single bond. The close pairs in ethene are not localized directly on the nuclear–nuclear axis like the pair in ethane and the resulting increase in nuclear–nuclear repulsion (and decrease in electron–nuclear attraction) should lead to a lower average energy per bond pair in ethene. In ethyne the nuclear–nuclear repulsions would be even greater as the spin set polyhedra now share common faces rather than common edges, drawing the nuclei even closer together without at the same time increasing the degree to which the electron density is directly concentrated on the nuclear–nuclear axis. However, the decrease in electron repulsion in ethyne should partly offset this increase and, if anything, the drop in energy per CC pair on going from ethene to ethyne should be somewhat less than the drop on going from ethane to ethene, as is in fact observed.

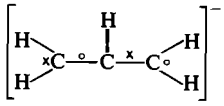
Molecular Structure

Given the authors' premise that LDQ theory denies the role of the nuclei in structure formation, it is difficult to imagine how they account for the electrons ever forming close pairs; indeed, in the case of simple hydrides they assume that the electrons don't. Any attempt to invoke close-pairing of the electrons due to electron–nuclear attractions is labeled as inconsistent. Instead the authors postulate that the central atoms in CH_4, NH_3, and H_2O maintain the completely correlated spin sets of Ne and they place the protons on lines connecting electrons of opposite spin with no electron density whatsoever directly between the proton and central kernel. The completely correlated electrons of Ne lie at the corners of a cube formed by the interpenetration of the two tetrahedral spin sets, electrons of like spin being separated by the face diagonals of the cube and electrons of opposite spin by the cube edges. Needless to say, given 12 edges and only four to two protons, several alternatives are equally likely, leading to the authors' claim that LDQ theory "may be ambiguous" in predicting molecular geometry. In the case of CH_4, for example, they conclude that, on the basis of electronic correlation alone, square planar and tetrahedral methane are equally likely, but by invoking proton–proton repulsions arrive at the tetrahedral structure. A similar procedure in the case of NH_3, however, leads to the incorrect conclusion that it is trigonal planar.

Surely, given the proton's size, no nucleus or kernel could be expected to be more effective in inducing close pair formation. Only such small highly-charged kernels as F^{7+} and O^{6+} would be capable of combating this tendency, as is postulated in the case of hydrogen-bonded species such as HF_2^-. These are the only cases in which Linnett appears to propose structures for stable long-lived species in which the electrons bonded to H are not close paired and even here at least one electron per bond is placed directly between the proton and the other kernel. Though the authors' treatment of hydride geometries may be viewed as an unsuccessful attempt on their part to try new variations of Linnett's postulates in which electron repulsions and nuclear–nuclear repulsions are considered as the major determinants of structure, rather than electron repulsions and electron–nuclear attractions, this treatment does not correspond to that of standard LDQ theory, which correctly predicts that NH_3 is pyramidal (6, 7).

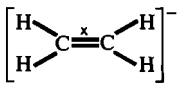
However, the authors do call attention to a number of interesting problems relating to the structures of hydrocarbon anions. They point out, for example, that it is impossible to write a LDQ structure for the allyl anion in which one has both resonance stabilized CC bonds (i.e., two non-close-paired, three-electron CC bonds rather than one close-paired double and one close-paired single bond) and close-paired CH bonds at the same time. Using Linnett's more condensed symbolism, in which a thin line represents an anticoincident pair and a thick line a coincident or close pair, the struc-

ture for the allyl anion (which is isoelectronic with O_3) may be written as



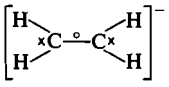
7

The authors also propose a LDQ structure for the ethene anion which suffers from the even graver problem of simultaneously forcing three electrons into spatial coincidence, two of which have the same spin



8

and they imply that this result casts severe doubts on the validity of standard LDQ theory. However, this proposed structure is incorrect on several counts. Not only does it violate the octet rule for carbon, it incorrectly predicts a bond order of $2\frac{1}{2}$ for the CC bond. Addition of an electron to the π^* LUMO of ethene should in fact reduce the CC bond order to $1\frac{1}{2}$. The proper Linnett structure for $C_2H_4^-$ (which is isoelectronic with O_2^-) should be:



9

Unlike structure **8**, this structure does not require the spatial coincidence of three electrons and gives the proper CC bond order. However, like the structure for the allyl anion, it leads to a lack of close-pairing in the CH bonds.[1]

What both the allyl and ethene anion structures appear to represent is, in fact, a previously unrecognized example of the application of Firestone's concept of Linnett or L strain (2, 3). Because it is not possible to reduce the electron repulsions in the CC bonds without simultaneously increasing the nuclear–nuclear repulsions in the CH bonds, these species suffer, like the transition states discussed by Firestone, from L strain. Consequently, LDQ theory would predict that they should be highly reactive, particularly with respect to oxidation, as is indeed the case.

Reactivity

The authors' treatment of the application of LDQ theory to reactivity is even more misleading. An analysis of this treatment is simplified by first defining some vocabulary. By *kind* of bond we will mean the kind of nuclei involved in the bond (e.g., H—H vs. O—H); by bond *multiplicity* we will mean the total number of valence electrons in the bond, and by bond *electron correlation*, the arrangement of these electrons. This latter factor is unique to LDQ theory and affects the bond energy both through changes in electron repulsion energies and changes in the relative screening of the nuclear–nuclear repulsions.

All of these factors affect the energy of a species and hence the energy of a reaction. Only in the case of a reaction in which the number, kind, and multiplicities of the bonds in the products and reactants are identical can one expect a correlation between ΔH of the reaction and the change in electron correlation. In cases in which one or more of the other factors also change, we can also expect a correlation if we compare two reactions such that the changes in all the factors, save the electron correlation, are the same for both reactions. In this case the correlation will involve the sign of the relative ΔH values (i.e., $\Delta\Delta H$) and the relative changes in the correlation energies for the two reactions; that is, it will tell us which of the two reactions is the more endothermic, but will tell us nothing about the absolute values or signs of the individual ΔH changes of each reaction.

A third situation in which LDQ theory may be applied is in predicting whether the experimental ΔH of a reaction will be more exothermic or more endothermic than the theoretical value calculated be means of simple Lewis structures and tabulated bond energies. This requires that LDQ theory predict the structure of either a single reactant or product to differ significantly from that given by its close-paired Lewis structure. This difference may involve both bond multiplicities and electron correlation. The situation is exactly similar to that used to evaluate resonance energies, the classic example being the difference between the experimental ΔH for the hydrogenation of benzene and that calculated for a single Kekulé structure. This analogy is more than formal as both resonance in VB theory and configuration interaction in MO theory are attempts, like the double-quartet hy-

[1]It should be noted that the authors themselves also suggest a resolution of the ethene and allyl anion structures which involves separation of the electrons in the σ bonds. However, they introduce a new symbolism into their formulas at this point and never explain what it means. That is, from their proposed formulas, one cannot tell whether they are postulating an angular splitting or a radial splitting of the σ bonds. If their proposed structures are identical with LDQ structures **7** and **9**, then it is difficult to understand why they bring up structure **8** in the first place and why they fail to cite Firestone's work for a proper interpretation of the result within the context of standard LDQ theory.

pothesis, to account for electron correlation effects.

On the other hand, Langler *et al.*, consistent with their denial of the role of the nuclei, put forward the claim that LDQ theory pretends to be able to predict the sign of the enthalpy change for a reaction by simply evaluating the change in electron correlation, irrespective of the number, kind, and multiplicities of the bonds made or broken in the reaction. The procedure they adopt is to evaluate the change in the number of close pairs on going from reactants to products. If this change is positive (loss of correlation), ΔH is assumed to be positive; if it is negative (gain of correlation), ΔH is assumed to be negative. This procedure is then applied to ten reactions and shown to give an incorrect result for virtually all of them, allowing the authors to conclude that LDQ theory "does not provide a guide to chemical reactivity, in contrast to claims made for it." An examination of these reactions shows that eight of them involve the making and breaking of different kinds of bonds (mostly H—H bonds converted into O—H, N—H, and C—H bonds or vice versa) and that the remaining two involve changes in bond multiplicities. In short, none of them conform to the circumstances under which LDQ theory (in contrast to the authors) would postulate a correlation between ΔH and change in electron correlation.

It is instructive in this regard to examine the three reactions (not included in the table of ten just mentioned) which the authors quote[2] from Linnett's original paper (8) and book (7) in order to justify their procedure:

[1] $2(CH_3)_2CO \rightarrow C(CH_3)_4 + CO_2$ $\Delta H < 0$

[2] $3(^1\Sigma_g^+O_2) \rightarrow 2O_3$ $\Delta H < 0$

[3] $2NO \rightarrow ONNO$ $\Delta H > 0$

Again making use of Linnett's condensed symbolism,[3] the first of these reactions may be written as

[4] 
[2]See ref. 7, pp. 45–46 and ref. 8, p. 2647 and footnote 14 on the same page.

[3]Here we have positioned the lines for nonbonding pairs in a manner similar to conventional Lewis structures in order to avoid the appearance of dangling bonds conveyed by Linnett's original formulas.

As can be seen, the number, kind, and multiplicities of the bonds are the same on both sides. The correlation of the CC and CH bonds is also the same, only that of the CO bonds changing. In other words, unlike the ten reactions tested by the authors, this reaction conforms to the conditions under which there should be a correlation between ΔH and change in electron correlation. Interestingly, Linnett's purpose in quoting this reaction was not to explicitly predict the sign of its enthalpy change but to use its known ΔH value to estimate the energy involved per electron pair in close pairing.

The second reaction may be formulated as

[5] 
It fails to conform to the necessary conditions as there is a change in both bond multiplicity and electron correlation. However, Linnett does not pretend to predict the sign of ΔH for this reaction as the authors claim, but rather the sign of $\Delta\Delta H$ relative to the same reaction using the $^3\Sigma_g^-$ ground state of O_2

[6] 
The change in bond multiplicity is the same for both reactions so $\Delta\Delta H$ must reflect the relative changes in the electron correlation energies for the two reactions. In keeping with the predictions of LDQ theory, reaction [5] is in fact found to be more exothermic than [6] by 57 kcal/mol. The fact that the ΔH of reaction [5] happens to be exothermic and that of [6] endothermic is an accident of the example used, and Linnett's correlation deals only with the sign of $\Delta\Delta H$ and not the signs of the individual ΔH values.

Finally, we have the third example, which involves changes in bond multiplicities, electron correlation, and kind of bond.

[7] 
Here again Linnett is not predicting the sign of ΔH as the authors claim, but rather that it must be more endothermic than would have been predicted by the classically formulated version given by simple Lewis structures:

[8] 
In other words, it is an example of the third situation discussed earlier.[4] Reaction [8] must be inherently exothermic as, like all simple radical dimeri-

[4]A comparison of this type is also given for O_3 in ref. 7, pp. 61–62.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

zations, it merely involves the formation of a new bond without any old bonds being broken in the process. In contrast, the Linnett structure in eq. [7] predicts that the N—N bond can only be formed at the expense of the multiplicity of the NO bonds and with loss of the electron correlation in the monomer. In other words, LDQ theory predicts that the experimental ΔH should be more endothermic than that predicted by eq. [8]. Linnett does not quantitatively test this prediction by comparing the experimental and calculated ΔH values, but instead remains content with the fact that NO doesn't dimerize to any great extent under ambient conditions, indicating that the endothermic shift ($\Delta\Delta H$) relative to the necessarily exothermic ΔH predicted by [8] is so large as to either make the real reaction inherently endothermic or the exothermic value so small that is is unable to offset the unfavorable entropy change expected for dimerization reactions in general.

Curiously, in their discussion of reactivity, the authors let pass without comment one of the few explicit attempts to apply LDQ theory to problems of reactivity, namely Firestone's (2, 3, 17) analysis of E2, S_H2, and S_N2 transition states in terms of Linnett or L-strain, even though they reference his papers on the subject. Finally, the authors' bibliography of the literature dealing with LDQ theory is far from complete, a number of major references being conspicuously absent (4, 5, 9–14, 18–39).

In conclusion, the paper by Langler *et al.* is anything but a critical evaluation of the application of LDQ theory to problems of structure and reactivity in organic chemistry. By denying the role of the nuclei and applying only the postulates dealing with electron repulsion, they produce a misleading picture of LDQ theory and then proceed to demonstrate that it leads to unsatisfactory results in predicting structure and reactivity. Indirectly, however, the Langler article points to the need for a greater development and refinement of Linnett's original work. One area of refinement, briefly touched on here, is a comparison of the relative efficiency of the electrons in bonds of the same kind and multiplicity, but differing correlation, in screening kernel–kernel repulsions.

A second area of refinement would be in assessing the relative efficiency of various nuclei or kernels in inducing close pairing. Other things being equal, one would expect this ability to increase with increasing kernel charge and decreasing kernel size. When kernels of identical charge but differing size act as central atoms in isoelectronic species, there will also be a tendency to resist ligand-induced close-pairing as the central kernel increases in size. This is because the same number of valence electrons must screen a proportionately larger surface area in the case of a large kernel, or, conversely, close pairing for a large kernel will be more strongly resisted because it results in the descreening of a proportionately larger amount of surface area. Likewise, distortions of the shared spin sets due to differences in the electronegativities of the kernels, or even due to differences in the relative attraction of a kernel for the bonding versus the nonbonding electrons in a given spin set, can lead to a decrease in electron repulsion because of the resulting *radial* electron correlation, thereby supplementing the *angular* correlation which LDQ theory currently emphasizes.[5]

Considerations of this kind could easily provide a qualitative rationale for the discontinuity in structures and bonding properties shown on passing from period 2 species to their heavier group analogs (e.g., H_2O vs. H_2S, H_2Se, H_2Te; NH_3 vs. PH_3, AsH_3, SbH_3, etc.), accounting for the differences in bond angles, the inert pair effect, the reluctance of these elements to form multiple bonds among themselves, etc. Another area of application would be in assessing the relative amounts of L-strain to be expected in a series of S_N2 displacement reactions in which the donor species and acceptor atom are kept constant but the substituents on the acceptor atom are varied.

Ab initio molecular orbital calculations for SF_4, SOF_2, and SO_2F_2 [1]

N. COLIN BAIRD AND KATHLEEN F. TAYLOR

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received September 9, 1980

N. COLIN BAIRD and KATHLEEN F. TAYLOR. Can. J. Chem. **59**, 814 (1981).

Ab initio molecular orbital calculations are reported for SF_4 (both C_{2v} and C_{4v} symmetries), SOF_2, and SO_2F_2. Geometry searches were conducted using the STO-3G* basis set; the energies were recalculated at the predicted equilibrium structures also using STO-3G and 44-31G, and the latter basis set with the addition of five real *d* Gaussian orbitals on the sulfur atom. The predicted geometries agree well with experiment, although S=O bonds are consistently predicted too long by ~0.03 Å, and the variation in S—F bond lengths among different environments is underestimated. The energy stabilization associated with the addition of *d* orbitals is generally consistent with our previous calculations, i.e. it is a constant amount per bond in hypervalent sulfur compounds in extended basis calculations. Replacement of F by OH is predicted to be more exothermic in SO_2F_2 than in SOF_2, and the relevance of this prediction to estimated heats of formation for SOF_2 and $SO(OH)_2$ is discussed.

N. COLIN BAIRD et KATHLEEN F. TAYLOR. Can. J. Chem. **59**, 814 (1981).

On rapporte des calculs *ab initio* des orbitales moléculaires du SF_4 (symétries C_{2v} ainsi que C_{4v}) du SOF_2 et du SO_2F_2. On a étudié la géométrie en utilisant la base STO-3G*; faisant appel à des bases STO-3G et 44-31G, on a calculé de nouveau les énergies au niveau d'équilibre prédit pour les structures; on a aussi effectué des calculs utilisant la base 44-31G à laquelle on a ajouté 5 orbitales de Gauss réelles sur l'atome de soufre. Les géométries prévues sont en accord avec les résultats expérimentaux en dépit du fait que les liaisons S=O soient surestimées d'environ 0,03 Å et les variations des longueurs de liaison S—F dans des environnements différents soient sous-évaluées. L'énergie de stabilisation associée à l'addition des orbitales *d* est généralement en accord avec nos calculs antérieurs, c'est à dire qu'elle correspond à une quantité constante par liaison dans les composés de soufre hypervalents lors de calculs sur des bases larges. On prédit que le remplacement de F par OH doit être plus exothermique dans SO_2F_2 que dans SOF_2 et on discute de l'importance de cette prévision dans l'évaluation des chaleurs de formation du SOF_2 et du $SO(OH)_2$.

[Traduit par le journal]

Introduction

Recently we reported *ab initio* MO calculations for a series of oxides, oxyacids, and oxyanions of sulfur in its +4 and +6 oxidation states (1). The predicted geometries, obtained using the STO-3G* basis set (i.e. with five real 3*d* Gaussian orbitals on the sulfur atom) agreed fairly well with experiment, consistent with the experience of Collins *et al.* for hypervalent systems (2). The energy lowering associated with the addition of sulfur 3*d* orbitals to the basis set was found to be approximately constant per bond for S(IV) and S(VI). We extended the 44-31G basis set for sulfur also to include *d* orbitals, and established that while the effect of the *d* orbital addition was less, the gain per bond varies little from an average of 28 kcal mol^{-1}.

In this report, these calculations are extended to some interesting molecules containing sulfur–fluorine bonds, namely the tetrafluoride SF_4 and the oxyfluorides SOF_2 and SO_2F_2. Our main interest was to establish whether the STO-3G* basis would predict accurate geometries for these systems, and whether the energetic stabilization upon *d* orbital addition to the STO-3G and to the 44-31G basis sets held to the constant values established previously for S—O and S—O—H systems. The tetrafluoride is of particular interest, given the calculations reported for it by Radom and Schaefer (3). They found that whereas the 44-31G basis set correctly predicts a C_{2v} structure for the molecule, the STO-3G basis incorrectly predicts that the C_{4v} (square pyramid) geometry is much more stable.

Method of Calculation

All computations reported herein were obtained using the "Gaussian 76" program (4) on a CDC Cyber 73 computer. Details concerning the STO-3G, STO-3G*, and 44-31G basis sets are discussed in papers by Pople and co-workers (2). The 44-31G* basis set corresponds to the addition of five real 3*d* Gaussian orbitals, each of exponent 0.60, to sulfur. (This value is the average of optimized exponents for SO_2 and SO_3, as established previously (1).) Bond lengths and angles were consecutively varied and reoptimized until the variations were less than 0.01 Å and 0.5°, respectively. In each case, the initial geometry chosen was close to that reported experimentally (except of course for the C_{4v} structure of SF_4).

Once the optimum structure for each molecule had been obtained at the STO-3G* level, its energy was recalculated using the STO-3G, 44-31G, and 44-31G* basis sets. The total energies obtained

TABLE 1. Calculated energies of sulfur–fluorine molecules

Name and formula	Total energy (au)		Energy improvement (kcal mol^{-1}) by addition of d orbitals	
	STO-3G*	44-31G*	STO-3G*	44-31G*
Sulfur tetrafluoride C_{2v} SF_4	−785.4374	−794.2550	266.2	110.3
C_{4v}	−785.4311	−794.2366	249.4	103.3
Thionyl fluoride SOF_2	−663.2037	−670.4227	225.4	110.3
Sulfuryl fluoride SO_2F_2	−737.0526	−745.1542	357.2	179.7

using the bases with d orbitals, and their differences compared to the STO-3G and 44-31G bases, are reported in Table 1. The optimized STO-3G* structures are shown in Fig. 1; experimental values are given in parentheses.

Results and Discussion

The geometries computed for thionyl fluoride and for sulfuryl fluoride both agree fairly well with the modern electron-diffraction results (see Fig. 1). The O=S=O angle in SO_2F_2 is correctly predicted to be significantly larger than tetrahedral, although the effect is exaggerated slightly. (The same value for this angle was predicted for sulfuric acid.) The O=S—F and F—S—F angles in both SOF_2 and SO_2F_2 agree well with experiment. The sulfur–oxygen bond lengths in these molecules are overestimated by 0.03 Å and 0.04 Å respectively, an effect previously established from our study of sulfur–oxygen systems.

The sulfur–fluorine bond lengths predicted for SOF_2, SO_2F_2, and SF_4 (C_{2v} structure) agree well with the experimental results, the average deviation being 0.026 Å. This latter value is somewhat misleading, however, since the differences are not consistently positive or negative; the net spread in the calculated S—F distances (1.56 to 1.61 Å) is rather less than for the experimental values (1.530 to 1.646 Å). Although the "in-plane" bonds in sulfur tetrafluoride are predicted correctly to be shorter than those out of plane, the differential is only half that observed. In their study of the isoelectronic molecule ClF_3 also using the STO-3G* basis set, Collins *et al.* also established that the differential between the equatorial and the axial bonds was underestimated (0.012 Å calculated versus 0.100 Å experimental). They found that the difference was reproduced accurately using the 44-31G basis set, although the Cl—F bond lengths were seriously overestimated. The same holds true for

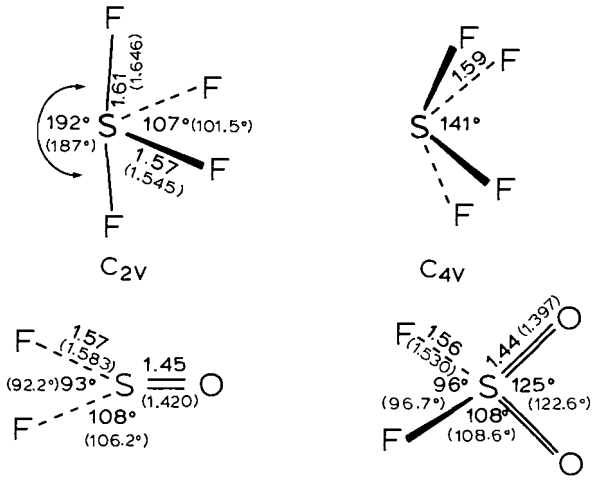

FIG. 1. Calculated STO-3G* geometries for SF_4 (C_{2v} and C_{4v}), SOF_2, and SO_2F_2. All distances are in Å. Experimental values (in parentheses) for SF_4 are from Tolles and Gwinn (8), for SOF_2 are from Hargittai and Mijlhoff (9), and for SO_2F_2 are from Hagen *et al.* (10).

SF_4, since the S—F length differential was well predicted (0.092 Å versus 0.101 Å experimental), but the absolute values were too large (by ~0.09 Å), in the 44-31G calculations reported by Radom and Schaefer (3). The conclusion that d orbitals are required to obtain realistic geometry predictions is consistent with the work of several authors (1, 5, 6) who found that the lengths of S=O bonds are not predicted even semiquantitatively without the addition of such functions to sulfur.

For SF_4, the STO-3G* basis set predicts the C_{2v} structure to be that of lowest energy, in agreement with the experimental geometry (see Table 1 and Fig. 1). Both the F_{axial}—S—F_{axial} and the $F_{equatorial}$—S—$F_{equatorial}$ angles are somewhat greater than observed (Fig. 1). The optimum C_{4v} structure lies only 3.9 kcal mol^{-1} above the C_{2v} form at the STO-3G* level; we have not investigated

whether any barrier exists to prevent the collapse of the C_{4v} form to the C_{2v} form. The energetic advantage of the C_{2v} form over the C_{4v} form rises to 11.5 kcal mol^{-1} at the 44-31G* level, compared to 4.5 kcal with the extended basis set minus the *d* functions on sulfur. With the STO-3G* basis, the C_{4v} structure is preferred, by 12.8 kcal mol^{-1}, compared to the 22.4 kcal preference found by Radom and Schaefer; the difference presumably is due to the use of experimental bond angles for the C_{2v} structure in the earlier calculations. We conclude that the incorrect C_{4v} structure for sulfur tetrafluoride is obtained only with the minimal basis set, and that improvement of the wavefunction either by addition of *d* orbitals to the sulfur (as in the present calculations) or by use of an extended basis set (as in the present calculations and also in the 44-31G geometry optimization by Radom and Schaefer) leads to the correct prediction that the C_{2v} geometry is optimum.

The calculated improvements in the total energies upon addition of sulfur *d* orbitals (see Table 1) for the three fluorine-containing molecules are similar to those found for the S(IV) and S(VI) oxides and oxyacids, when comparisons are made on a per bond basis (1). The stabilization energies with the extended basis for SF_4 (C_{2v} structure) and SOF_2 both are 27.6 $kcal^{-1}$, close to the average established previously. The corresponding improvement in SO_2F_2 is 30.0 kcal mol^{-1} per bond for a total of 179.7 kcal, slightly above the range in the oxides and oxyacids. In contrast, the *d* orbital stabilization for the C_{4v} structure of sulfur tetrafluoride of 25.8 kcal mol^{-1} per bond falls at the low end of the scale. The energy improvements calculated upon addition of *d* orbitals to sulfur at the minimal basis set level, as expected, are larger than with the extended basis; however only the value for SF_4 (C_{2v}) falls outside (slightly above) the rather wide ranges found in the sulfur–oxygen systems.

A comparison of the total energies reported previously for $SO_2(OH)_2$ and $SO(OH)_2$ with those for the isoelectronic molecules SO_2F_2 and SOF_2 reveals that the replacement of fluorine by hydroxyl is predicted to be more favourable by 6.1 kcal mol^{-1} at the 44-31G* level (and 7.5 at STO-3G*) for SO_2F_2 than it is for SOF_2. If valid, this implies that Benson's predicted heat of formation ΔH_f (7) of -127 ± 3 kcal mol^{-1} for $SO(OH)_2$ is about 7 kcal mol^{-1} too negative, or that the experimental ΔH_f of -130 ± 5 kcal mol^{-1} for SOF_2 is 7 kcal too positive, or some combination of the two effects. The lesser stabilization of fluorine replacement by hydroxyl in SOF_2 than in SO_2F_2 is consistent with Benson's rule (7) that such replacements become increasingly favourable as the electronegativity of the central atom or group increases, since presumably the $\diagdown\!\!\diagup SO_2$ group is more electronegative than is the $\diagdown\!\!\diagup SO$ unit.

STEFANIA TANIEWSKA-OSIŃSKA, LEOKADIA KAMIŃSKA-BARTEL, HENRYK PIEKARSKI, and TADEUSZ M. KRYGOWSKI. Can. J. Chem. **59**, 817 (1981).

The enthalpies of solution of benzamide in several aliphatic alcohols and of benzoic acid in *n*-hexanol have been measured. A linear correlation has been found between standard enthalpies of solution of benzamide and benzoic acid and Hancock steric constants.

STEFANIA TANIEWSKA-OSIŃSKA, LEOKADIA KAMIŃSKA-BARTEL, HENRYK PIEKARSKI et TADEUSZ M. KRYGOWSKI. Can. J. Chem. **59**, 817 (1981).

Les enthalpies de solution du benzamide dans divers alcools aliphatiques et de l'acide benzoique dans le *n*-hexanol ont été mesurés. On a démontré qu'il existe une corrélation linéaire entre les enthalpies standards de solution et les constantes stériques de Hancock pour le benzamide et l'acide benzoique.

[Traduit par le journal]

Introduction

Calorimetric and spectrometric investigations of benzoic acid solutions in aliphatic alcohols (1, 2) suggested that this compound forms mixed associates in alcohol solutions, probably of the type AB_2 (A = acid, B = alcohol).

In the earlier work (3) calorimetric measurements of benzamide solutions in methanol, 1-propanol, and 2-propanol were carried out. These results also led to the conclusion that benzamide occurs in alcohols at infinite dilution in the form of mixed associates.

The present work is concerned with the effect of the size and the shape of alcohol molecules on the thermochemical properties of benzamide solutions in alcohols.

We have also attempted here to correlate standard enthalpies of solution of benzamide with Hancock steric constants.

Experimental

Benzamide (by POCh-Gliwice, reagent grade) was crystallized twice from twice distilled water and dried in a vacuum dryer at 70°C. Benzoic acid was sublimed and dried under vacuum at 56°C. Alcohols: ethanol, isobutanol, *n*-pentanol, *n*-hexanol, *t*-butanol, and *t*-pentanol, were initially dried by means of molecular sieve (type 4A, Fluka AG) and then distilled (4). Alcohols purified in this way were again stored over the molecular sieves and redistilled directly before use.

Water content in the investigated alcohols, determined by spectroscopic methods, did not exceed 0.05%. To observe the influence of water present in the solvent on the investigated effects we measured the heat of solution of benzamide in the solvent with additional small amount of water. The results did not change within the experimental error limits.

The solution enthalpy measurements were performed by an "Isoperibol" calorimeter described in the literature (5).

The measurements of heat of solution of benzamide in *t*-butanol were performed at 299.15 K (mp 298.85 K), for other alcohols at 298.15 K.

Results and Discussion

The experimental values of integral enthalpies of solution, ΔH_m, of benzamide in the investigated alcohols and of benzoic acid in *n*-hexanol are summarized in Table 1.

The integral enthalpy of solution is, within the limits of experimental error, a linear function of concentration in all investigated solutions. The ΔH^0 values were determined by calculating the parameters of a straight line

$$\Delta H_m = \Delta H^0 + Am$$

by the method of least squares and extrapolation to $m = 0$.

Standard enthalpies of solution $\Delta H^0(BzNH_2)$ of benzamide are given in Table 2. The values of standard enthalpies of solution of benzoic acid ΔH^0(HBz) taken from earlier works (1, 2, 6, 7) are also included in Table 2.

In order to compare the enthalpies of solvation of benzoic acid and benzamide in alcohols one must know the enthalpies of sublimation of both compounds. According to Davies and Jones (8) the enthalpy of sublimation of benzoic acid is

21 850 cal/mol. We did not find in the literature the value of the sublimation enthalpy of benzamide. Then we calculated this quantity by means of approximate methods (9–11). The evaluated sublimation enthalpy of benzamide was 20.00 kcal/mol.

From the comparison of the enthalpies of solvation of benzamide $\Delta H_{sol}(BzNH_2)$ and benzoic acid $\Delta H_{sol}(HBz)$, which in the case of methanol solutions are: −16.02 kcal/mol and −18.87 kcal/mol, respectively, it can be noted that the effect of the solvation of benzamide in alcohols is less negative than in the case of benzoic acid. The observation can probably be explained by the difference of the energy of the bonds O—H···O and N—H···O both in the crystalline state and in solution (3).

The more endothermic effect of the dissolution of benzamide in alcohols may also be explained by the non-planar structure of the benzamide molecules (12, 13) which makes their penetration into the structure of the alcohol more difficult than in the case of the planar molecules of benzoic acid. The increase of ΔH^0 with the growth of both the length of the alkyl chain of the alcohol and its branching seems to be caused by non-specific interactions (1, 3).

We tried to correlate the obtained standard enthalpies of solution of benzamide in alcohols with Taft steric constants E_s.

The solution enthalpies of benzamide $\Delta H^0(BzNH_2)$ as well as of benzoic acid $\Delta H^0(HBz)$ in nine aliphatic alcohols (Table 2) are described according to the relation given by Taft (14) by means of the equations:

$$\Delta H^0(BzNH_2) = -1.40E_s + 4.36, \quad r = 0.937$$

and

$$\Delta H^0(HBz) = -1.20E_s + 3.09, \quad r = 0.937$$

However, in the case of benzoic acid it was found that the steric constants calculated according to Palm, taking hyperconjugation into consideration, correlate standard enthalpies of benzoic acid solutions much better (15). In this work we applied Hancock steric constants E_s^* (16) calculated from the equation

$$E_s^* = E_s + 0.36(n - 3)$$

in which n is the number of C—H bonds. For the same set of $\Delta H^0(BzNH_2)$ values in nine alcohols we found a linear regression of the type

[1] $$\Delta H^0(BzNH_2) = -1.12E_s^* + 4.12$$

with regression coefficient $r = 0.983$. In the case of benzoic acid solutions we obtained the equation

[2] $$\Delta H^0(HBz) = -0.95E_s^* + 2.89$$

for which the linear regression coefficient was $r = 0.989$. The improvement of linear regression caused by the change of Taft constants from E_s to Hancock constants E_s^* is significant at C.L. = 0.95.

The functions calculated according to equations

with Hancock's steric constants (solid lines) and the experimental points are presented in Fig. 1.

It follows from Fig. 1, both in the case of benzamide and benzoic acid, that there are two alcohol solutions, *t*-butanol and *t*-pentanol, which do not satisfy the linear correlation. The magnitudes of these deviations, endothermic in nature, are as follows: 0.89 kcal/mol and 1.76 kcal/mol for benzoic acid and 2.12 kcal/mol and 2.45 kcal/mol respectively for benzamide solutions. For two systems not obeying the linear correlation the most probable explanation is that the solvation mechanism from the other systems under investigation becomes different. In this case, because of the branched alkyl groups of *t*-butanol and *t*-pentanol probably a lower number of alcohol molecules takes part in the solvation. This results in a more endothermic shift of the heat of solution in comparison to the heats for the alcohols obeying relations [1]and [2].

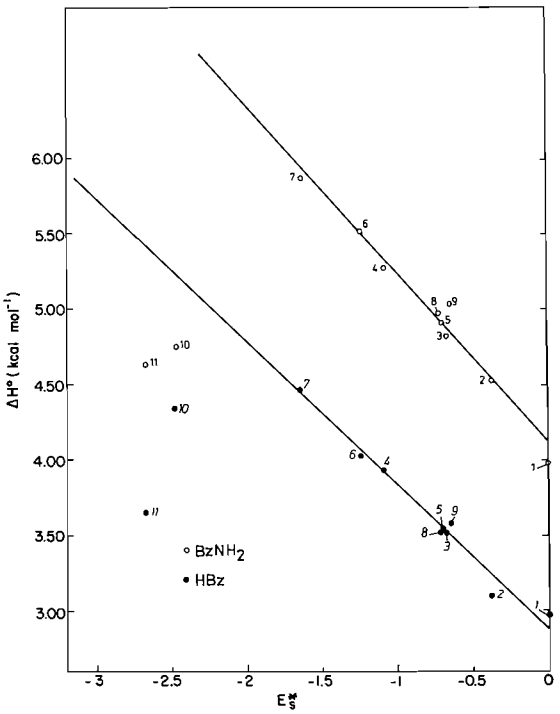

FIG. 1. Correlation of standard enthalpies of solution and Hancock's steric constants.

Linear dependence of standard enthalpies of solution of benzamide and benzoic acid on steric effects, and thus on size and shape of alkyl radicals of alcohols, seems to confirm the conclusion that nonspecific interactions are responsible for the differences among the heats of solution in particular alcohols.

It is well known that steric constants refer usually to changes of free enthalpy of some process. In our case they are linear functions of the solution enthalpy of solvation processes. Thus it can be supposed that in the investigated systems the entropy of solution, ΔS^0, is a linear function of the enthalpy, ΔH^0, or is constant within the limits of the experimental errors.

Confirmation of this suggestion would demand further investigations of changes of free enthalpy of benzamide and benzoic acid solutions in alcohols.

Spectroscopic and electrochemical properties of intramolecularly hydrogen-bonded compounds. *Ortho*-hydroxyazobenzenes

SALVATORE MILLEFIORI AND ARCANGELO MILLEFIORI

Istituto Dipartimentale di Chimica e Chimica Industriale, Università di Catania, viale A. Doria 8, 95125 Catania, Italy

Received April 18, 1980

SALVATORE MILLEFIORI and ARCANGELO MILLEFIORI. Can. J. Chem. **59**, 821 (1981).

The gas-phase uv photoelectron spectra and the half-wave polarographic reduction potentials in acetonitrile solutions of a series of 2-hydroxy-5-methylazobenzene have been determined. The first three IP's and the $E_{1/2}$ values were linearly correlated with σ^+ and σ constants, respectively. $E_{1/2}$ can also be linearly related to the energy of the lowest unoccupied molecular orbital. Effects of the intramolecular hydrogen bonding on the pe spectra and on the polarographic reduction of the title compounds were evaluated by comparing the experimental findings in 2-hydroxy-5-methylazobenzene, 2-methoxy-5-methylazobenzene, and *p*-hydroxyazobenzene. On H-bond formation, the antibonding combination of the two nitrogen lone-pairs, n_-, and the oxygen lone-pair is ionized at a slightly higher energy and at a lower energy, respectively, than in the non H-bonded compound. The first π-ionization band is slightly lowered in energy in the non H-bonded structure, probably owing to a normal substituent effect. These features are not maintained in the 4′-nitro derivative, where the band encompassing the n_- ionization remains at the same potential in both structures, while the first π band in the non H-bonded compound moves toward higher IP. Spectral differences between the bonded and nonbonded structures are the result of a balance of substituent effects, and of both hydrogen bond and orbital interactions. The solution electron affinity of the studied compounds increases on H-bond formation by an amount comparable with the experimental strength of the H-bonding. INDO/S-CI calculations are in qualitative agreement with the experimental results.

SALVATORE MILLEFIORI et ARCANGELO MILLEFIORI. Can. J. Chem. **59**, 821 (1981).

On a déterminé les spectres photoélectroniques uv en phase gazeuse et la demi-onde des potentiels de réduction polarographique, dans des solutions d'acétonitriles, d'une série d'hydroxy-2 méthyl-5 azobenzènes. Les trois premières valeurs des PI et la valeur $E_{1/2}$ sont respectivement reliées d'une façon linéraire aux constantes σ^+ et σ. La valeur $E_{1/2}$ peut également être reliée d'une façon linéaire à l'énergie de la plus basse orbitale moléculaire vacante. On a évalué les effets de la liaison hydrogène intramoléculaire sur les spectres pe et sur la réduction polarographique des composés mentionnés dans le titre, en comparant les résultats expérimentaux obtenus pour l'hydroxy-2 méthyl-5 azobenzène, le méthoxy-2 méthyl-5 azobenzène et le *p*-hydroxyazobenzène. Lors de la formation de la liaison hydrogène, la combinaison anti-liante du doublet électronique libre de l'azote, n_-, et le doublet électronique libre de l'oxygène est ionisé respectivement à une énergie légèrement supérieure et à une plus faible énergie que dans le cas des composés n'ayant pas de liaison hydrogène. La première bande d'ionisation π a une énergie légèrement plus faible dans la structure ne comportant pas de liaison hydrogène à cause d'un effect normal de substituant. Ces caractéristiques ne se maintiennent pas dans le dérivé nitré en position 4′, où la bande englobant l'ionisation n_- reste au même potentiel dans les deux structures, alors que la première bande π dans le composé sans liaison hydrogène, se déplace vers des valeurs de PI plus élevées. Les différences spectrales entre les deux structures liée et non liée sont le résultat d'un équilibre des effets de substituant, et des interactions de liaison hydrogène et d'orbitale. L'affinité électronique de la solution des composés étudiés augmente lors de la formation d'une liaison hydrogène, d'une quantité comparable à la force expérimentale de la liaison hydrogène. Les calculs INDO/S-CI s'accordent qualitativement avec les résultats expérimentaux.

[Traduit par le journal]

Introduction

Hydrogen bonds induce physically and chemically significant electronic perturbations within a molecule. Ultraviolet and X-ray photoelectron (pe) spectroscopy have proved that on H-bond formation the molecular orbital (MO) localized on the proton-acceptor atom is stabilized, while the MO localized on the proton-donor atom moves in the opposite direction (1). These results are supported by theoretical calculations (2). The effects of the H-bonding on the electron affinity (EA) of the molecule are less known. The H-bonding effects can mix with those arising from orbital interactions. In spite of the fact that the available experimental data, to our knowledge, are all in line with the above findings, a different behaviour cannot a priori be excluded. In fact *ab initio* calculations on β-hydroxyacrolein have shown (2*b*) that the *n* orbital energy of the H-bonded C_{2v} form is raised by 0.14 eV relative to the non H-bonded C_s (*trans*) form. CNDO/2 calculations on the intramolecular H-bonding in *ortho*-hydroxyazobenzenes (3) have also predicted a destabilization, following H-bonding, of both the MO's localized on the proton-acceptor center (the azo group) and on the lowest unoccupied MO (LUMO), together with a lowering of the energy of the highest π MO (HO-π-MO). The present work is undertaken to study the effects of the intramolecular H-bonding on the electronic structure of *ortho*-hydroxyazobenzenes by means of gas-phase uv pe spectroscopy and polarographic experiments. In addition some INDO/S-CI calcu-

lations were carried out. This theoretical approach has proved to be valuable in studying spectroscopic properties of azo compounds (4).

Experimental

Ultraviolet pe spectra were recorded on a Perkin-Elmer PS 18 spectrophotometer with He(I) and He(II) excitations. Xe and Ar have been used for calibration. Polarographic half-wave reduction potentials were obtained using a three-electrode Amel polarograph model 563. Spectrograde acetonitrile was used as solvent. It was dried over neutral alumina and distilled at constant boiling point. Polarographic-grade tetrabutylammonium iodide (TBAI) was used as supporting electrolyte. It was dried under reduced pressure at 90°C before use. The depolarizer's concentration was about 5×10^{-4} *M*. The concentration of TBAI was 0.1 *M* throughout the experiments. Solutions were deoxygenated by H_2. The potentials, uncorrected for IR drop, are referred to a saturated calomel electrode. Polarograms were recorded at 25 ± 0.5°C. 2-Methoxy-5-methylazobenzene **1**, not previously reported in the literature, was obtained from 2-hydroxy-5-methylazobenzene **2** by methylation with $(CH_3)_2SO_4$ in sodium ethoxide solution: red oil bp 180°C at 10 Torr. Its identity was checked by means of nmr spectroscopy. In particular, no trace of a hydroxyl proton peak was detected. 2-Hydroxy-5-methylazobenzene and derivatives were synthesized by means of the familar diazo-coupling reactions, following standard procedures, from *p*-cresol and the appropriate amine. The presence of the CH_3 group in the *p*-position with respect to the OH group allows us to obtain exclusively the *ortho*-hydroxy azo derivative. INDO/S-CI calculations have been carried out using the parameterization reported in ref. 5.

Results and Discussion

Photoelectron Spectroscopy

In the 7.5–10.5 eV spectral region of azobenzene derivatives five ionization events are expected. They should correspond to those observed in azobenzene (6), which arise (*1*) from the $a_u(\pi_1)$ MO delocalized on the whole molecule; (*2*) from the $a_g(n_-)$ MO (the antibonding combination of the two nitrogen lone-pairs) localized in the azo group; (*3*, *4*) from two degenerate MO's (π_2 and π_3) which have nodes in 1–4 positions; and (*5*) from the $b_g(\pi_4)$ MO delocalized on the whole molecule. It was shown that electron-donor substituents make the $a_u(\pi_1)$ MO shift above the $a_g(n_-)$ MO (7). Actually the pe spectrum of 2-methoxy-5-methylazobenzene shows, in the low-energy spectral region, three bands (Fig. 1). However, their relative intensities are roughly in the ratio 1:2:2. On the basis of previous work (7), the first band at 7.87 eV can be attributed to a π ionization (corresponding to the a_u ionization in the C_{2h} point group). The second band should encompass the n_- and π_2 ionizations, and the third band the π_3 and π_4 ionizations. The spectrum of 2-hydroxy-5-methylazobenzene (Fig. 1) shows the same three band system in the 7–10 eV range, the higher-energy band now being split. The spectra of 4'-derivatives of **2** are similar; they are exemplified by

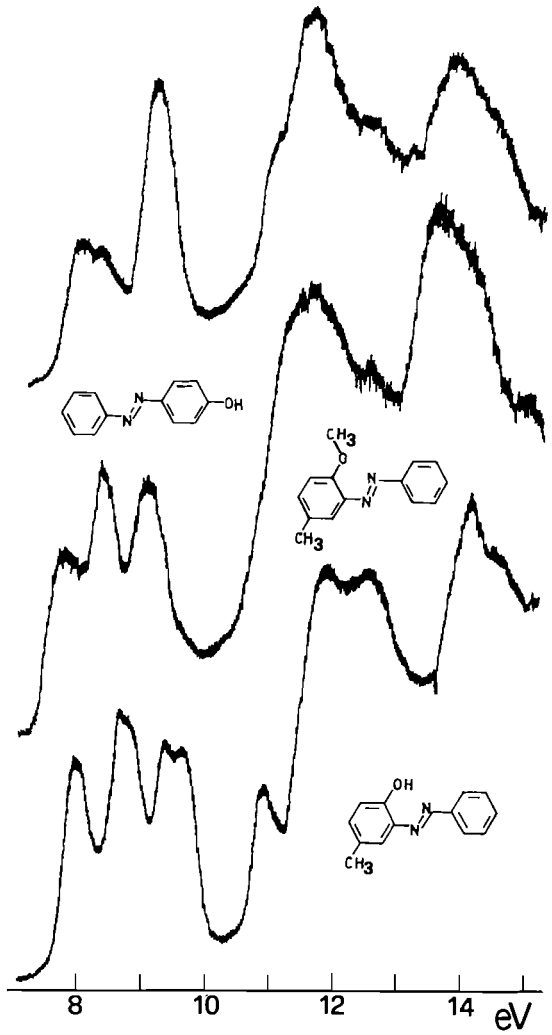

FIG. 1. He(I) photoelectron spectra of 2-hydroxy-5-methylazobenzene (**2**), 2-methoxy-5-methylazobenzene (**1**), and 4-hydroxyazobenzene.

the spectrum of 2-hydroxy-5-methyl-4'-chloroazobenzene (Fig. 2). This compound is also chosen to illustrate the effect of the energy radiation on the band intensity. It is evident that under He(II) radiation (Fig. 2) the intensity of the second band increases slightly relative to the first and third bands. Moreover the intensity of the band centered at 11.52 eV is weaker in the He(II) spectrum. This band very probably includes the Cl_{3p} ionization.

The above results support the tentative inference that the second band includes the n_- ionization, given that the proposed cross-section order of 2*p* orbitals at He(II) radiation is C < N (8).

The pe spectra of 3' derivatives of **2** are exemplified by the spectrum of 2-hydroxy-5-methyl-3'-chloroazobenzene, Fig. 2. Now the relative in-

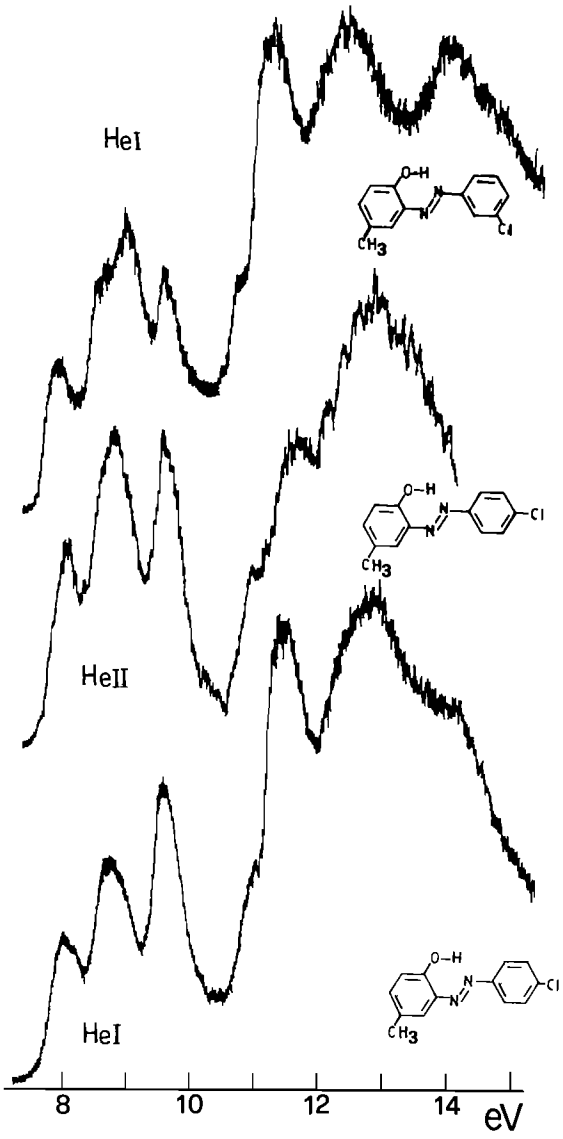

FIG. 2. Photoelectron spectra of 2-hydroxy-5-methyl-4'-chloroazobenzene, He(I); 2-hydroxy-5-methyl-4'-chloroazobenzene, He(II); and 2-hydroxy-5-methyl-3'-chloroazobenzene, He(I).

tensity within the three-band system is roughly 1:3:1. The second band is split and it very likely includes, besides the n_- and π_2 ionizations, the π_3 ionization, which is shifted towards a lower IP relative to **2**, owing to its marked sensitivity to the *meta* substitution. INDO/S-CI calculations, in fact, predict that the π_3 MO is entirely localized on the *ortho* and *meta* positions of the non H-bonded ring.

The measured IP's of the studied compounds are reported in Table 1, together with the proposed assignment. This is supported by the INDO/S-CI calculations, whose predicted ionization energies are also included in Table 1.

Polarographic Reduction

The pertinent polarographic data for the present azo compounds are summarized in Table 2. In acetonitrile solution all compounds are reduced in two one-electron steps. The first wave of the two non H-bonded compounds is reversible. It is slightly less reversible for the H-bonded compounds as can be deduced from the potential index $E_{1/4} - E_{3/4}$, which is somewhat higher than the theoretical value of 56 mV (9). The second wave is irreversible. This behaviour is typical of the electroreduction of azocompounds in aprotic media (10–13).

Correlation of Substituent Effects

The evolution of the first three ionization bands in the present series is followed by means of a σ^+ type (14) correlation, to have data comparable with previous ones (4, 7). However, the use of the Hammett σ constant (15) gives comparable results. The regression lines are:

$$IP_1 = 7.94 \pm 0.02 + (0.24 \pm 0.04)\sigma^+$$

$$IP_2 = 8.65 \pm 0.02 + (0.32 \pm 0.04)\sigma^+$$

$$IP_3 = 9.53 \pm 0.02 + (0.51 \pm 0.05)\sigma^+$$

There is no cross-over between equivalent bands, thus the nature of the band can be considered the same along the series. As found previously (4, 7, 16, 17) the n_- ionization (IP_2) is markedly dependent on substituent. The slope of the plot is equal to that found (0.33 eV) in a corresponding series of disubstituted non H-bonded azo compounds (*p*-methoxyazobenzenes) (4). Therefore the H-bonding (which involves the nitrogen lone-pairs) does not apparently affect the sensitivity of the n_- ionization towards the substituent.

A linear relationship is also obtained between the first reduction potential of the azocompound and the Hammett σ constant (15)

$$E_{1/2} = -1.12 \pm 0.003 + (0.27 \pm 0.01)\sigma$$

The use of the σ^+ constant in electrode reduction processes is not well defined and limited to a few particular cases (18). We are not aware of recent applications of σ^+ type correlation in polarographic experiments. The $E_{1/2}$ vs. σ correlation ensures that the electrode reduction mechanism relative to the first electron transfer is the same through the series, so that correlations between $E_{1/2}$ and structural indexes are meaningful. The *p*-NO_2 derivative is very far off the general trend. The use of σ^- (1.04–1.27) (18) for this compound much improves

its position on the correlation and gives indication of considerable participation of mesomeric interactions. $E_{1/2}$ can also be related to the energy of the LUMO (Fig. 3), thus indicating that it can be taken as a measure of the solution EA of the azocompound. The regression line is

$$E_{1/2} = -2.15 \pm 0.07 + (0.56 \pm 0.04)\mathrm{EA}$$

Effects of Hydrogen Bond

The electronic perturbations induced by the intramolecular H-bonding can be evaluated by comparing the pe spectra of **1**, **2**, and 4-hydroxyazobenzene, Fig. 1. Although band shifts are relatively small, on passing from **1** to **2** we may note (*a*) a small shift (ca. 0.1 eV) towards a higher IP of the first band, which can probably be associated with the substitution of H for CH_3, (*b*) a shift of ca. 0.2 eV towards a higher IP of the second band encompassing the n_- ionization, (*c*) the appearance at 10.95 eV of a band, not evident in the spectrum of **1**,

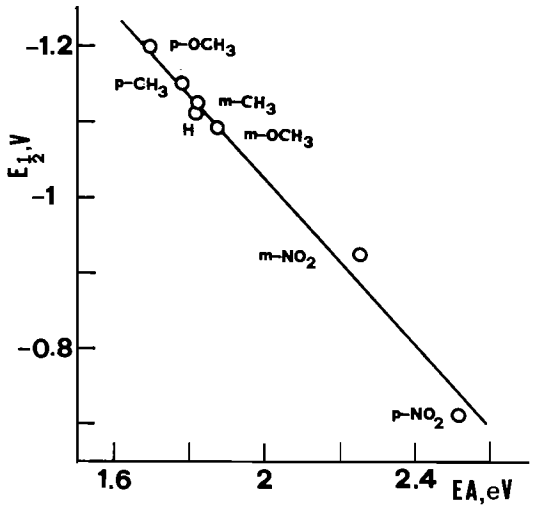

FIG. 3. Plot of the first half-wave reduction potential of 2-hydroxy-5-methylazobenzenes vs. the calculated INDO/S-CI electron affinity.

probably because it is hidden under the intense band centered at about 12.1 eV. This ionization is absent in the pe spectrum of azobenzene, but it appears at ca. 11.2 eV in 4-hydroxyazobenzene. It can reasonably be assigned to the O_{2p} ionization. In fact the corresponding event is observed at ca. 11.5 eV in the phenol (19), at 11.1 eV in 2-methoxy-*N*-benzylidenemethylamine (20) and at 10.79 eV in *p*-methoxyazobenzene (4).

These results seem to point out a slight stabilization of the n_- MO on H-bond formation, and the expected destabilization (ca. 0.3 eV) of the MO localized on the proton-donor atom.

The INDO/S-CI calculations, while rightly predicting a slightly higher ionization energy of the n_- MO, do not, however, show a MO clearly localized on O_{2p} atomic basis owing to heavy mixing, so that the inferred destabilization of the O_{2p} MO cannot be settled by the calculations.

The observed stabilization of the n_- orbital in **2** with respect to **1** is less than that obtained in other intramolecularly H-bonded systems (1). In particular it is much less than that observed (0.6 eV) in 2-hydroxy-*N*-benzylidenemethylamine (20), where an intramolecular H-bonding of comparable energy is present (21, 22). This can very probably be traced back to the correlation diagram of Fig. 4. In the non H-bonded conformation the two N lone-pairs are nearly degenerate and the n_- level is raised by **a** above the N_1 level because of n–n interactions. In the H-bonded conformation the N_2 lone-pair is stabilized owing to the H-bonding. Consequently (23) the destabilization of the n_- orbital is **b** < **a**. Experimentally we observe, on H-bonding formation, a decrease in the n_- MO energy by an amount

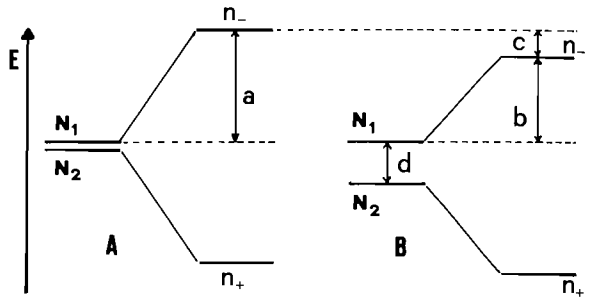

FIG. 4. Correlation diagram for the two nitrogen lone-pairs interaction; (A) non H-bonded structure, (B) H-bonded structure.

c, which is likely to be less than **d**. In addition, through-space interactions (23) between n_- and the O_{2p} lone-pair, which would contribute in raising the energy of the n_- level, may be operative. In fact, INDO/S-CI calculations show that the n_- orbital mixes with the O_{2p} σ-MO in an antibonding way, while contributions to this orbital from the O_{2p} lone-pair are vanishing in the nonbonded structure. Through-bond interactions (23) can also operate in both structures and they are expected to lower the IP_{n_-}. Notice that orbital interactions are conformation-dependent (24) and cannot be quantitatively assessed without a precise knowledge of the molecular geometry.

The sum of substituent, H-bonding, and MO interactions lead in the 4′-nitro derivatives to the situation illustrated in Fig. 5. Now the first two bands in the nonbonded compound are poorly resolved owing to the shift of the first band to a higher IP, while the second band, encompassing the n_- ionization, appears to rest at the same potential in both compounds. Thus in this case we note a different behaviour than in the parent compounds **1** and **2**. These results indicate that the electronic structure of the present azo-compounds, as inferred from their pe spectra, results from a delicate balance among substituent, H-bonding, and orbital interaction effects. Therefore they point out the difficulty in relating electronic effects to the presence of intramolecular H-bonding when many perturbation factors are operative, even if the observed trends are in the expected direction. No attempt has been made to extend the above analysis to the other members of the series.

The effects of the intramolecular H-bonding on the solution EA of the title compounds were evaluated by comparing the effects of the OH and OCH_3 groups on $E_{1/2}$.

The first reduction potential of **1** $E^1_{1/2}$ (**1**) (−1.1445 V) is 0.039 V more negative than $E^1_{1/2}$ of 5-methylazobenzene (−1.406 V) (11), obtained under the same experimental conditions. This is a

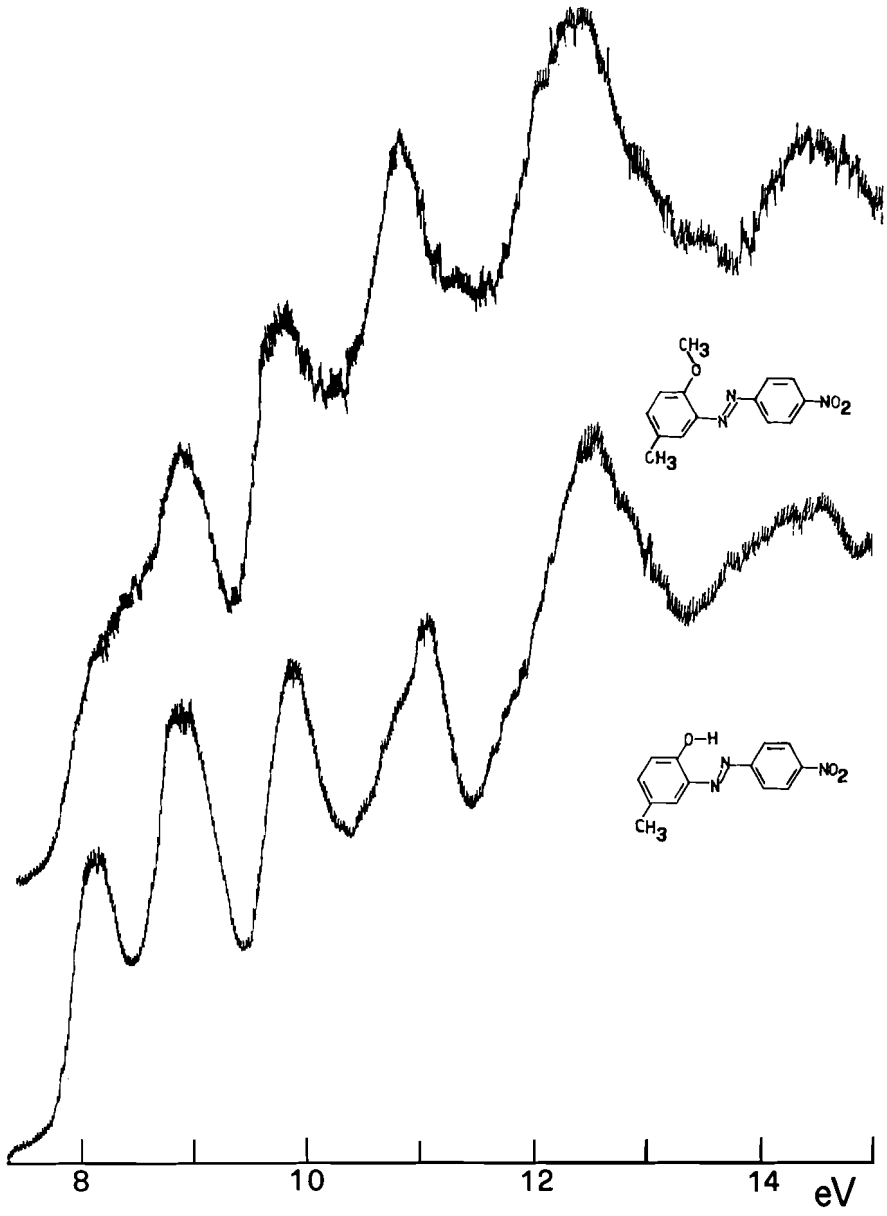

FIG. 5. He(I) photoelectron spectra of 2-hydroxy-5-methyl-4′-nitroazobenzene and 2-methoxy-5-methyl-4′-nitroazobenzene.

normal effect of the OCH_3 group on $E_{1/2}$, since electron-donor groups make the electrode reduction more difficult. In the absence of specific interactions, a similar effect is expected on replacing the OCH_3 with the OH group. Actually $E^1_{1/2}$ (**2**) (−1.112 V) is more positive than that of 5-methylazobenzene. Therefore, under the reasonable assumption that OH and OCH_3 groups display the same "normal" substituent effect on $E_{1/2}$, the energy difference $E^1_{1/2}$ (**2**) − $E^1_{1/2}$(**1**) of 0.333 V is very likely to be the consequence of the H-bonding on EA. The corresponding figure in 4′-nitro derivatives of **1** and **2** is 0.315 V. Orbital interactions between the LUMO and occupied MO's should operate in the opposite direction, i.e. they should decrease the EA value. On the basis of INDO/S-CI calculations it is probable that they do not contribute to the difference between the π^* levels of **1** and **2**, given the same MO composition in both compounds. The calculated INDO/S-CI EA values (within the Koopmans' approximation) for **1** and **2** are 1.52 and 1.83 eV respectively, i.e. EA(**2**) − EA(**1**) = 0.31 eV, in excellent agreement with the experimental results. The polarographic half-wave

reduction potentials may reveal themselves useful for investigating electronic perturbations arising from H-bonding interactions. Accordingly $E_{1/2}$ values may be used for a relative evaluation of the H-bonding energy (3, 25). In the present case $E_{1/2}$ values compared well with the experimental H-bonding strength of 2-hydroxy-5-methylazobenzene (0.38 eV) and 2-hydroxy-5-methyl-4′-nitroazobenzene (0.37 eV), obtained by means of ^{1}H nmr measurements (21).

The biosynthesis of cyclopropane fatty acids. I. Feeding experiments with oleic acid-9,10-d_2, oleic acid-8,8,11,11-d_4, and L-methionine-methyl-d_3

PETER H. BUIST AND DAVID B. MACLEAN
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received September 8, 1980

PETER H. BUIST and DAVID B. MACLEAN. Can. J. Chem. **59**, 828 (1981).

cis-9-Octadecenoic acid-9,10-d_2 and *cis*-9-octadecenoic acid-8,8,11,11-d_4 and L-methionine-methyl-d_3 were administered to cultures of *Lactobacillus plantarum* and converted by the organism to the corresponding cyclopropyl compounds. The first experiment showed that no scrambling or loss of label occurred when a methylene unit was added across the double bond of the labelled substrate. In the second experiment, again, no loss or scrambling of label occurred, a result which ruled out any mechanism for biological cyclopropanation involving allylic activation of the double bond. The third experiment yielded a biosynthetic cyclopropane fatty acid containing deuterium located exclusively at the methylene group of the cyclopropane ring. Up to 17% of a d_1-species accompanied the major dideuterated compound. The lone deuterium in the d_1-cyclopropane fatty acid occupies both positions of the methylene group to the same extent. It has been shown that the extent to which d_1-cyclopropane fatty acid is produced increases with cell growth. The extent of exchange was similar in the cyclopropanation of both the 9,10- and 11,12-isomers of *cis*-octadecenoic acid.

PETER H. BUIST ET DAVID B. MACLEAN. Can. J. Chem. **59**, 828 (1981).

Les acides octadécen-9 *cis* oique 9,10-d_2 et octadécèn-9 *cis* oique 8,8,11,11-d_4 ainsi que la L-méthionine-méthyl-d_3 injectés dans des cultures de *Lactobacillus plantarum* sont transformées en composés cyclopropaniques correspondants. La première expérience a montré qu'il n'y a pas de mélange ou de perte du marqueur lorsqu'on ajoute un méthylène à travers la double liaison du substrat marqué. Une deuxième expérience confirme la première; ces résultats écartent tout mécanisme de cyclopropanation biologique impliquant une activation allylique de la double liaison. La troisième expérience a provoqué la biosynthèse d'un acide gras contenant un cyclopropane portant un deutérium exclusivement sur le méthylène du cyclopropane. Dans le composé principal bideutéré, on trouve jusqu'à 17% d'unités monodeutérés. Le deutérium de l'acide gras comportant un cyclopropane monodeutéré est réparti également entre les deux positions du méthylène. On a montré que le taux de production d'acide gras marqué comportant un cyclopropane-d_1 augmente avec la croissance de la cellule. Les taux d'échange sont très voisins lors de la cyclopropanation des deux isomères 9,10 et 11,12 de l'acide octadécènoique *cis*.

[Traduit par le journal]

Cyclopropane fatty acids such as lactobacillic acid, **1**, and dihydrosterculic acid, **2**, occur as phospholipid esters in many bacterial cell membranes (1). From the biosynthetic studies of Hofmann, O'Leary, and Law, it was determined that the cyclopropane ring in these compounds was formed by the addition of a C_1 unit, derived from methionine, across the double bond of the corresponding olefinic fatty acid. Thus, the alkylation of *cis*-vaccenic acid, **3**, yielded lactobacillic acid, **1**, and the alkylation of oleic acid, **4**, gave rise to dihydrosterculic acid, **2** (2). Later, using partially purified enzyme preparations, Law and co-workers established, by in vitro studies, that the cyclopropanation reaction involved *S*-adenosyl-L-methionine (SAM) as the alkylating agent, and olefinic fatty acid phospholipids, in the correct micellar state, as the substrate (2), Fig. 1. The precise mechanistic details of this unique biochemical reaction have not been elucidated, primarily because of difficulties in purifying the enzyme(s) responsible for this transformation. Only very recently has any substantial progress been made in this direction (3).

4

The crucial mechanistic point to be clarified is whether proton abstraction to form the methylene unit occurs before or after carbon–carbon bond

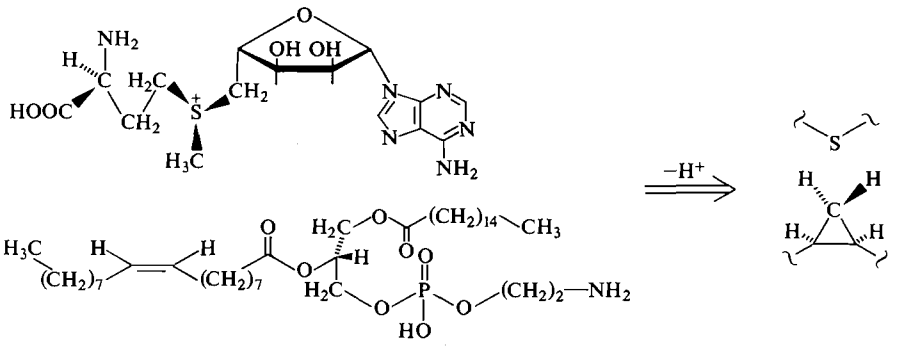

FIG. 1.

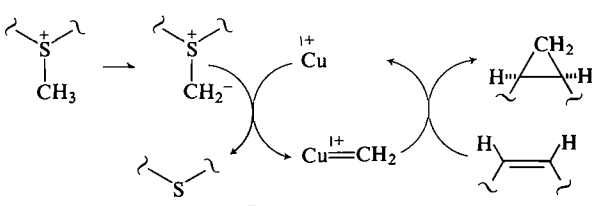
formation. Reasonable chemical mechanisms can be written for both alternatives.

Cohen *et al.* have proposed that the cyclopropanation reaction may proceed via a sulfur ylid which donates its methylene unit to a metal such as copper (4). Methylenation of a double bond by this metal–carbenoid species would lead to cyclopropane ring formation (Scheme 1).

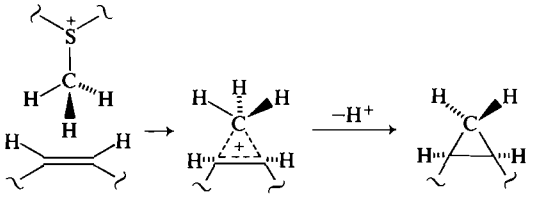
Lederer, in his review of *C*-alkylation reactions (5), proposed that the cyclopropane ring might be formed by direct methylation of a double bond by SAM, followed by a 1,3-elimination of a proton. He linked cyclopropane ring formation with biological exomethylene group formation. Compounds containing the latter group are considered to be derived from the same intermediate carbonium ion, which then undergoes a 1,2-hydride shift followed by 1,2-elimination of a proton (Scheme 2).

In previous studies the involvement of allylic protons in the cyclopropanation reaction was not investigated. In order to test for any reaction at the allylic positions, such as that shown in a general way in Scheme 3, allylically deuterated oleic acid was prepared and administered in lieu of biotin to *Lactobacillus plantarum*. The use of this microorganism in these studies was convenient since *L. plantarum* will grow in the absence of biotin (a vitamin required for fatty acid biosynthesis) if olefinic fatty acids, such as oleic acid, are supplied in the medium. Under these conditions, very high (ca. 100%) incorporation of labelled oleic acid into dihydrosterculic acid can be achieved (6).

Vinylically deuterated oleic acid was also pre-



SCHEME 1



SCHEME 2

pared and administered to the same organism. Although this experiment had already been reported by Polacheck *et al.* (6), its repetition at this time was appropriate for two reasons. Firstly, we were able to prepare oleic acid-9,10-d_2 of better isotopic and stereochemical purity than the previous workers, and secondly, we were able to locate the label unambiguously both in the precursor and in the biosynthetic product through ^2H, ^1H, and ^{13}C nmr spectroscopy. In fact, nmr methods, along with ms, were used routinely throughout this work to locate and to quantitate the label, respectively.

Methyl oleate-9,10-d_2 was prepared by catalytic reduction of the corresponding alkyne using D_2 and Lindlar's catalyst (7) (Scheme 4). Only traces of the *trans* isomer were formed when hexane was used as solvent (up to 8% was formed when ethyl acetate or ethanol-O-*d* was used as solvent). This method also gave methyl oleate-9,10-d_2 with very high deuterium content (>95% d_2) in contrast with other procedures in the literature (e.g. ref. 8). Examination of the ^1H, ^2H, and ^{13}C nmr spectra of the product showed that essentially all the label was at the vinylic positions.

Methyl oleate-8,8,11,11-d_4 was prepared by the route outlined in Scheme 5. The 9,10-diketone, obtained by permanganate oxidation of oleic acid (9), was treated with a mixture of D_2O, DCl, and acetic acid-O-*d*. Catalytic reduction of the exchanged diketone gave predominantly the *erythro* diol which could be freed from the *threo* isomer by recrystallization from ethyl acetate. The *erythro* diol was treated with methyl orthoformate and the

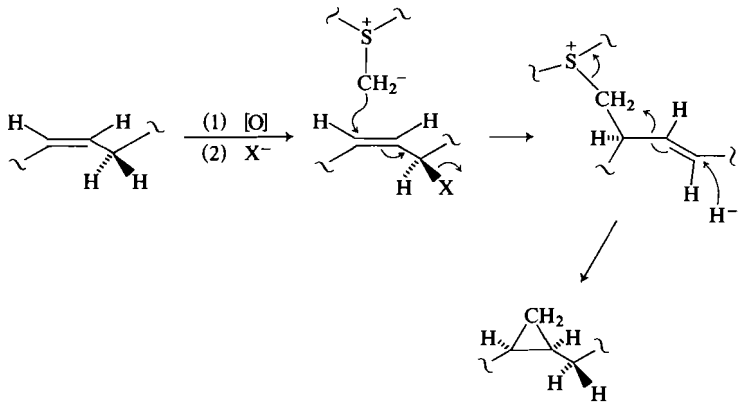
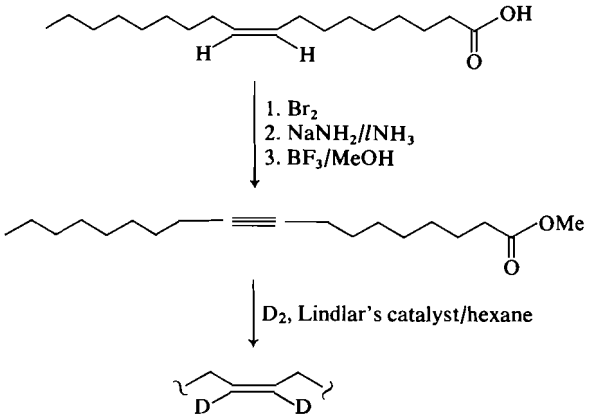


SCHEME 3



SCHEME 4

resulting 1,3-dioxalan was heated to yield a mixture of methyl oleate and oleic acid, by elimination of CO_2 and methanol. No *trans* olefin was detected in the product. The crude mixture was treated with diazomethane to convert all of the fatty acid to its methyl ester.

L-Methionine-methyl-d_3 was obtained commercially.

The two deuterated fatty acids were fed to the microorganism at a concentration of 0.07 m*M* on a 10 L scale. Approximately 5 mg of cyclopropane fatty acid were isolated in each experiment (representing a 2.5% conversion). For comparison purposes, the Simmons–Smith reaction (10) was employed to prepare deuterated cyclopropanes from the corresponding deuterated olefins. Examination of the synthetic and biosynthetic samples by ms indicated that label was not lost in either feeding experiment (Table 1). The presence of small amounts (2–3%) of unlabelled cyclopropane fatty acid in the biosynthetic products was probably caused by residual olefin fatty acid biosynthesis.

The label in the biosynthetic product from both feeding experiments was located by nmr methods. The cyclopropyl protons in the ^{1}H nmr of methyl dihydrosterculate appear as multiplets at δ 0.66 (3H) and at δ −0.26 (1H). These resonances have been assigned by Longone and Miller (11). The *cis* protons at C-9 and C-10 and the methylene proton *trans* to the two alkyl substituents resonate together at ca. δ 0.6 while the methylene proton *cis* to the 2 alkyl substituents is observed at ca. δ −0.3. Specific deuterium labelling at the methylene would be necessary in order to check these assignments. In the ^{1}H nmr spectrum of the biosynthetic cyclopropane derived from oleic acid-9,10-d_2, a pair of doublets (J_{gem} = ca. 4 Hz) at δ 0.55 (1H) and δ −0.36 (1H) was observed as expected. The ^{2}H nmr spectrum of the above compound featured one signal at δ 0.93. (Errors of ± δ 0.5 are not uncommon when an external reference is used.) Comparison of the ^{13}C nmr spectrum of the nonlabelled and biosynthetic cyclopropane (compounds 1 and 2, Table 2) showed that the spectrum of the latter compound lacked a signal at 16.2 ppm (previously assigned by Batchelor *et al.* (12) to C-9 and C-10). Also, β isotope shifts were observed for the signals of the adjacent methylenes at C-8 and C-12 (0.2 ppm) and of the bridging carbon atom at C-19 (0.2 ppm). On the basis of the above evidence, it was concluded that scrambling or loss of deuterium had not occurred on biological cyclopropanation of oleic acid-9,10-d_2.

That no scrambling of label had occurred in the oleic acid-8,8,11,11-d_4 feeding was clear from the following spectroscopic data. The ^{1}H nmr spectrum of the biosynthetic cyclopropane revealed that the signals of the cyclopropyl protons were not reduced in intensity and further that the multiplet at δ 0.66 was sharpened because of the absence of hydrogen at C-8 and C-11. The ^{2}H nmr spectrum showed one peak at δ 1.3, as might be expected for deuterons located at C-8 and C-11. The ^{13}C nmr

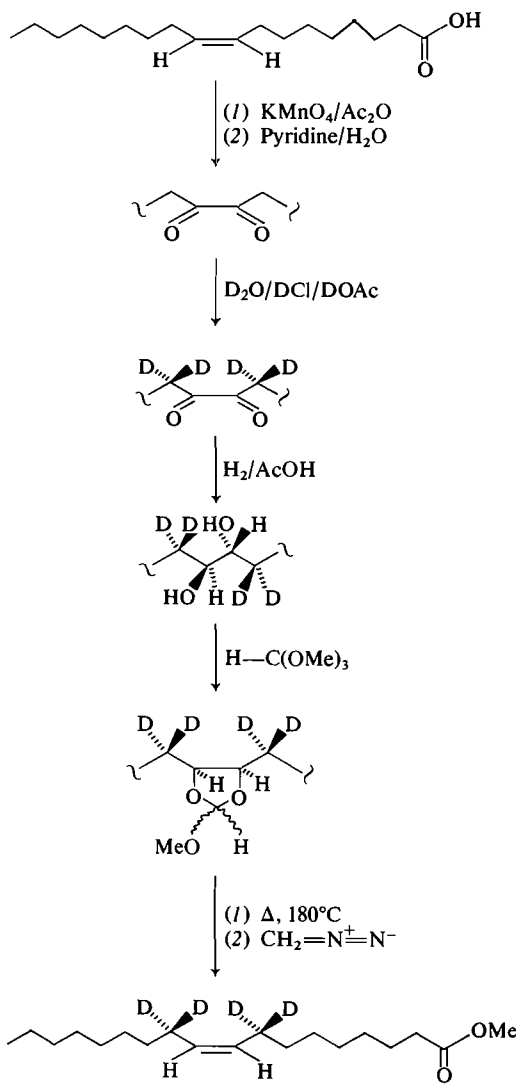
spectrum of the biosynthetic sample was identical with that of a synthetic sample prepared by a Simmons–Smith reaction on methyl oleate-8,8,11,11-d_4 (compounds 3 and 4, Table 2).



SCHEME 5

The results with allylically deuterated methyl oleate rule out any mechanism for biological cyclopropanation involving allylic protons and the results of the oleic acid-9,10-d_2 feeding confirm those obtained by Polacheck *et al.* (6). One may also conclude that if the carbonium ion mechanism (Scheme 2) is correct, then the intermediate from which a proton is abstracted might be considered to be an edge-protonated cyclopropane. The fact that scrambling and loss of label did not occur in the oleic acid-9,10-d_2 feeding, suggests that no equili-

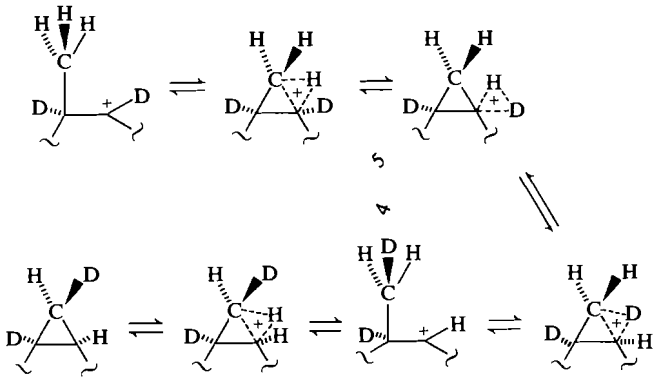

SCHEME 6

bration of edge and various corner-protonated cyclopropyl species had occurred (13) (Scheme 6).

We also carried out feeding experiments with methionine-methyl-d_3, in which the label in the biosynthetic cyclopropyl product was again located and measured by nmr and ms methods, respectively. Earlier workers showed that a cyclopropane fatty acid derived from methionine-methyl-d_3 contained two deuterium atoms; however, it was not stated whether any d_1 species was present, nor was the label in the biosynthetic product located (14).

In this study, methionine-methyl-d_3 (d_3, 95.8%; d_2, 1.4%; d_1; 0.9%; d_0, 1.9%) was administered to *L. plantarum* under a variety of culture conditions. The results of the mass spectral examination of the biosynthetic cyclopropyl product obtained in each experiment are shown in Table 3. It can be seen that a significant amount of d_1-cyclopropyl fatty acid accompanies the d_2-species in each case. The reasons for the variation in d_1-content will be discussed (see below). To check the reliability of the ms analysis, methyl dihydrosterculate-19-d_2 was prepared by treating methyl oleate with CD_2I_2 in a Simmons–Smith reaction; its deuterium content was shown to be identical with that found for the CD_2I_2 from which it was prepared.

Various nmr methods were used to locate the deuterium label in the biosynthetic product. The ^1H nmr spectrum of the cyclopropyl product obtained in Experiment 1 (see Table 3) showed that the signal at δ −0.3, assigned to the methylene proton *syn* to the two alkyl substituents in the nonlabelled material (11) had disappeared. The signal at δ 0.6, assigned to H-9, H-10, and the methylene proton *anti* to the two alkyl substituents was two-thirds as intense as the signal in the nondeuterated analogue. The ^2H nmr spectrum of the biosynthetic cyclopropyl fatty acid from Experiment 5 (Table 3) had two peaks of equal intensity at δ 0.42 and δ −0.5.

TABLE 3. Deuterium content of biosynthetic cyclopropane fatty acids derived from methionine-methyl-d_3

Experiment*	Deuterium content (%) d_0	d_1	d_2	$d_1/d_1 + d_2$
1. (Biotin) 36 h	3.9	9.7	86.4	9.7
2. (Oleic acid)	0.8	7.3	91.9	7.4
3. (*a*) (Biotin)	1.5	13.8	84.7	14.1
(*b*) (Biotin) 64 h	1.9	13.8	84.3	14.1
4. (*a*) (Biotin)	4.1	16.0	79.9	16.7
(*b*) (Oleic acid)	3.3	5.6	91.1	5.8
(*c*) (Vaccenic acid)	5.6	7.2	87.2	7.6
5. (Biotin) 48 h	15.7†	12.2	72.0	14.5

*Either biotin (10 μg/L) or the fatty acid (0.07 m*M*) indicated was added to the basal medium of Henderson and Snell (26) along with methionine-methyl-d_3 (0.67 m*M*). Unless otherwise stated cells were harvested after 24 h. Experiment 5 was carried out under anaerobic conditions but otherwise conditions were similar to 3(*a*). Deuterium contents were determined by ms (see Experimental).

†The high d_0 content was due to d_0-methionine in the methionine-methyl-d_3 used for this feeding.

Curve fitting and integration showed the peak intensities to be in the ratio of 49.4 ± 2 to 50.5 ± 2, indicating that the monodeuterated species contributing 14.5% of the total signal intensity was equally labelled at both methylene positions. Inspection of the ^{13}C nmr spectrum of the dihydrosterculic acid obtained in Experiment 2 (Table 3) showed that deuterium label had not shifted to C-9 or C-10, since the signal attributed to these carbon atoms, although showing a β isotope shift of 0.2 ppm, was not reduced in intensity. The signal assigned by Batchelor *et al.* (12) to the methylene carbon atom in the undeuterated compound was absent. From the above data, it can be seen that the deuterium label from methionine-methyl-d_3 was located at the two methylene positions of the cyclopropane.

Support for this conclusion was obtained by closer mass spectrometric examination of the

*The numbers in the table represent the ratio, $(M + 1)^+/M^+$ for methyl lactobacillate-d_2.

biosynthetic cyclopropyl fatty acid from Experiment 4(a), in order to determine if any d_3 species were present. The $(M + 1)^+/M^+$ ratio for synthetic methyl lactobacillate-19-d_2 was compared with that of the methyl lactobacillate derived from methioninemethyl-d_3. The results of these gc–ms runs are shown in Table 4. A d_3-species might have arisen by the mechanism shown in Scheme 7. The fact that such a species was not found is consistent with the nmr results (see above) and the observation that scrambling or loss of deuterium label was not detected in the oleic acid-9,10-d_2 feeding experiment.

The formation of d_1-cyclopropane fatty acid in the methionine-methyl-d_3 feedings (Table 3) indicates that exchange of a d_3-methyl species had occurred at some stage in the biosynthetic pathway. Examination of Table 3 (Experiments 2, 4 (b), (c)) shows that the extent to which this exchange process occurs is independent of the nature of the fatty acid administered to the organism. *cis*-Vaccenic and oleic acids, when added in lieu of biotin to the medium, gave products that had similar d_1-contents. It is also apparent that the acids reduced the extent of d_1-species formation markedly. Since growth on the fatty acid medium was rather poor, it was thought that the extent of exchange increased with cell growth. Comparison of the d_1 content obtained in Experiment 1, where for some undetermined reason the cells did not grow out properly, and the d_1 content obtained in Experiments 3 and 5, where growth was normal, further substantiated this hypothesis. A feeding experiment, using methionine-methyl-d_3 was performed in which the cells were isolated at early exponential phase (13 h) and late exponential phase (24 h) and the d_1 content of the biosynthetic cyclopropane fatty acid determined by ms. The results are shown in Table 5. As anticipated, the ratio $\% d_1/(\% d_1 + \% d_2)$ of the cyclopropane fatty acid isolated at 13 h was substantially (50%) lower than that isolated at 24 h. One factor which might control the extent of exchange is the pH of the medium, which drops at a rate proportional to cell growth. If the exchange is occurring at the active site of cyclopropane synthetase, then it might be expected that the rate of exchange would be sensitive to pH, since it is thought that the cyclopropanation reaction takes place on the cell membrane phospholipids, in close proximity to the external medium (15).

The observation of exchange in cyclopropane fatty acid biosynthesis is important because it establishes a possible mechanistic link between biological cyclopropyl and exomethylene group formation. In 1965, Jauréguiberry *et al.* (16) showed that significant quantities of d_1-tuberculostearic acid (11%) and d_1-ergosterol (16%) accompanied the d_2 species in feeding experiments using methionine-methyl-d_3 (Scheme 8). (The $\% d_1$ val-

ues quoted in this discussion have been recalculated as $\% d_1/(\% d_1 + \% d_2)$ values in order to allow better comparison of the data.) Because the exomethylene intermediates leading to the above two compounds had not been examined for d_1-content, some confusion existed as to the stage at which the exchange had occurred (5). That the methyl group of methionine had not exchanged prior to the alkylation step was shown by the isolation of aurantiogliocladin and ergosterol from the same methionine-methyl-d_3 feeding experiment; the former compound was shown to contain d_3-methyl groups without any appreciable exchanged species, while the ergosterol contained 17% of a d_1-species (5). More recently, Mercer and Russell (17) have determined the deuterium contents of three intermediate 24-exomethylene sterols as well as that of ergosterol, isolated from a methionine-methyl-d_3 feeding experiment. When the d_1-contents of these compounds are expressed as $\% d_1/(\% d_1 + \% d_2)$, it is clear that both the exomethylene intermediates and ergosterol contain the same amount of monodeuterated species (20–24%). One possible interpretation of these data is that exchange is taking place at the initial carbonium ion stage in the formation of the exomethylene group. In view of our findings, the mechanism for this exchange might be explained by reversible cyclopropane group formation, prior to the 1,2-hydride shift, as originally suggested by de Mayo (as quoted in ref. 5) (Scheme 9). Exchange in cyclopropane group biosynthesis might thus be occurring by a similarly reversible 1,3-proton elimination process. This explanation for the exchange process assumes that the cyclopropanation reaction is, in fact, proceeding by a carbonium ion mechanism similar to that proposed for exomethylene group formation. Support for this assumption comes from the enzymological studies of Law and co-workers (2, 18). Both processes require SAM as the alkylating agent. The olefinic substrate must be present as a phospholipid in an appropriate micellar state (the precise structure of the required micelle is not known). Both reactions occur at the 9,10-position of a *cis*-monounsaturated C_{18} fatty acid, although C_{16} substrates are also alkylated. Sulfhydryl reagents such as *p*-hydroxymercuribenzoate inhibit both enzymes, indicating that thiol groups may be important in catalysis (19, 20). Both enzymes are water soluble and thus not membrane bound. As in the case of cyclopropane fatty acid biosynthesis, tuberculostearic acid production increases as the cells enter the stationary growth phase. These observations indicate that the two processes, cyclopropanation and exomethylene group formation, have much in common and suggest that the enzymes in both cases operate on phospholipids present in the cell membrane.

The above arguments do not, however, rule out

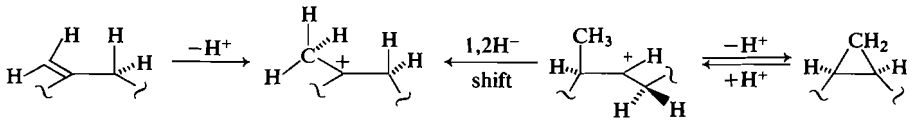

SCHEME 9

Cohen's carbenoid mechanism for the biological cyclopropanation reaction. Reversible sulfur ylid formation (Scheme 1) prior to methylene transfer would also account for the exchange process. However, it has never been proved that cyclopropane synthetase is a metalloenzyme. In order to do this, extensive purification of the enzyme would be required and only recently has any progress been made in this direction (3). Early studies with crude enzyme preparations showed that cyclopropane synthetase was not inhibited by cyanide ion, a reagent known to inhibit metalloenzymes (19, 21). This fact tends to militate against the carbenoid mechanism.

It has been assumed that the exchange process is, in fact, intimately connected with the mechanism of the cyclopropanation reaction. Yet it is possible that exchange of the methyl group is occurring via a process totally unrelated to the alkylation reaction. Mercer and Russell, for example, have suggested that degradation and resynthesis of methionine could, at least partially, account for the observed d_1 content in biosynthetic 24-exomethylene sterols isolated from a methionine-methyl-d_3 feeding (17). In a future paper, experiments will be described which test this explanation for the exchange observed in the biosynthesis of cyclopropane fatty acids.

Experimental

Apparatus, Methods, and Materials

Melting points were determined on a Kofler micro hot stage apparatus and are uncorrected. Infrared spectra were obtained on a Perkin Elmer 238 spectrophotometer. The ^{1}H nmr spectra were run at 90 MHz on a Varian EM 390 spectrometer or on a Bruker WH 90 FT spectrometer. The ^{13}C nmr and ^{2}H nmr spectra were obtained on the latter instrument. The ^{13}C nmr spectra were recorded at 22.62 MHz, at a probe temperature of 30°C. Samples were 0.3 *M* in C_6D_6 using the solvent resonance at 128.05 ppm as reference. A microprobe was used for small samples (≤ 10 mg). The ^{2}H nmr was performed at 13.8 MHz at a probe temperature of 35°C. Samples were 0.02 *M* in CCl_4 using acetone-d_6 as external reference or C_6D_6 as internal reference. All chemical shifts are reported with reference to TMS and are quoted in δ (ppm) values.

Methionine-methyl-d_3 and methylene iodide-d_2 were purchased from Merck, Sharp and Dohme Canada, Limited, Isotope Division, Pointe Claire–Dorval, P.Q.

Silica gel 60F-254 (Merck) was used for tlc and open column chromatography. A Waters A.L.C. 100 liquid chromatograph, equipped with a refractive index detector, was used for the hplc of fatty acid methyl esters. A reverse phase column (Partisil-ODS-2 Magnum 9, 50 cm × 9.4 mm id) was used in both the preparative and analytical mode. The mobile phase was acetonitrile – ethyl acetate 70:30 at a flow rate of 1.6 mL/min. Gas–liquid chromatography of the fatty acid methyl esters was performed, using a Pye Unicam Series 104 gas chromatograph, equipped with a flame ionization detector. A stainless steel column (20 ft × ⅛ in. id), packed with 15% OV-275 on Chromosorb P, A.W. DCMS (100/120) was used with helium as the mobile phase at a flow rate of 7 mL/min and at a temperature of 220°C.

The microorganism used in this study was *Lactobacillus plantarum*, ATCC 8014, obtained from the American Type Culture Collection, Rockville, MD, U.S.A. The organism was grown at 37°C in a Precision Thelco hot air incubator and maintained as a stab culture at 4°C in a nutrient agar medium prepared by adding 2% agar to Lactobacilli M.R.S. broth (Difco). The biochemical and morphological characteristics of the organism were checked at the outset of this study and were found to be in accord with those described in the literature. Cells were isolated by centrifugation either at 3500 rpm on an International Clinical desk-top centrifuge for small scale experiments or at 5000 rpm on a Beckman Model J-21 centrifuge equipped with a JA10 or JA20 centrifuge head. Cells were dried in a New Brunswick Sci. Co. Freezer dryer.

Deuterium contents of the fatty acid methyl esters were determined by ms using either a CEC No. 21-110B mass spectrometer at 70 eV and a source temperature of 100–150°C and a direct introduction probe or a VG Micromass 7070F instrument, at a source temperature of 190°C, coupled to a Varian model 3700 gas chromatograph. When the CEC instrument was used, approximately 0.5 mg of sample was needed to allow scanning of the M^+ and $(M-32)^+$ ions. (The $M-32$ ion resulted from the loss of methanol from the fatty acid methyl esters.) The distribution of deuterium was calculated from both sets of data; good agreement between the two calculated results was always observed to within experimental error. The ion intensities were arrived at by taking the average of 5–10 measurements. The standard deviation was ±1 for each ion intensity. The precision of the calculated deuterium content was ±1% for each isotopic species expressed as a percentage. In the gc–ms method, the entire gc peak was scanned repetitively, once per second, and the intensities integrated. This procedure eliminated errors caused by isotopic fractionation on the gc column. An independent check on the validity of this method was made by running the same compound on the CEC and VG mass spectrometers. The calculated deuterium content was as follows; on the CEC: d_2, 79.9%; d_1, 16.0%; d_0, 4.1%; on the VG: d_2, 79.9%; d_1, 15.9%; d_0, 4.2%.

Methyl cis*-9-Octadecenoate-9,10-*d_2

9-Octadecynoic acid was prepared from oleic acid by the method of Khan *et al.* (22). The corresponding methyl ester was used to prepare the title compound by a modification of a literature procedure (7).

Lindlar's catalyst was prepared in the following manner. Calcium carbonate (1.25 g) was placed in a two-necked 50 mL round bottomed flask, followed by D_2O (10 mL, 99.95% deuterated), and the flask attached to a hydrogenation apparatus via a reflux condenser. The apparatus was flushed with argon. Palladium dichloride (105 mg) was dissolved in D_2O (1.1 mL) containing DCl (0.1 mL) and the red solution added via syringe to the calcium carbonate suspension. The mixture was stirred for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

5 min at room temperature and 10 min at 80°C, whereupon the apparatus was evacuated and filled with deuterium gas (D_2). The flushing procedure was repeated twice, after which the solution was stirred and the absorption of D_2 at atmospheric pressure was monitored. When D_2 absorption had stopped (20 mL), the now grey suspension was filtered and resuspended in D_2O (12.5 mL) and a solution of lead diacetate (125 mg) in D_2O (2.0 mL) was added under argon. The mixture was stirred at room temperature for 10 min and at 100°C for 40 min. The catalyst was then filtered, washed with D_2O, and dried over P_2O_5 *in vacuo*.

The reduction of methyl 9-octadecynoate (0.5 mmol) was performed using deuterium gas at room temperature, over Lindlar's catalyst (12 mg) at atmospheric pressure, in hexane (5 mL). After 15 min, the theoretical amount of D_2 had been absorbed. The distribution of deuterium was determined by ms to be: d_2, 96%; d_1, 3%; d_0, 1%. ^1H nuclear magnetic resonance of the product showed that the vinyl proton absorption at δ 5.3 in the unlabelled analogue had disappeared. Also in the ^{13}C nmr spectrum, the signals at 130 ppm attributed to the vinyl carbon atoms of the d_0-material were absent. The ^2H nmr of the product showed only traces of deuterium at carbon atoms other than the vinylic (δ 5.3).

9,10-Dioxooctadecanoic Acid-8,8,11,11-d_4

Acetic anhydride, distilled through glass helices (102 g), was placed in a three-necked, 500 mL, round bottomed flask fitted with a reflux condenser and an addition funnel. Deuterium oxide (99.7% D, 40.0 g) was added and the reaction mixture stirred and heated until an exothermic reaction set in, at which point heating was halted. When the hydrolysis was complete, the flask was cooled in ice and acetyl chloride (19.6 g) was added slowly. The final mixture contained acetic acid-O-*d* (2.25 mol), D_2O (0.75 mol), DCl (0.25 mol). 9,10-Dioxooctadecanoic acid (7.8 g), prepared by the method of Jensen and Sharpless (9), was added and the mixture heated to 65°C for 0.5 h. The solvent was removed *in vacuo* and the exchange repeated once more with fresh medium. After work-up, ^1H nmr showed that the intensity of the signal at 2.7 ppm had been greatly reduced. The sample (7.8 g) was dried *in vacuo* to remove traces of DCl and D_2O, and used directly in the next step.

9,10-Dihydroxyoctadecanoic Acid

Platinum oxide (500 mg), suspended in acetic acid (10 mL) in a 250 mL round bottomed flask, was prehydrogenated, after which the tetradeutero diketone (7.8 g) prepared above was added in acetic acid (50 mL) and the hydrogenation allowed to proceed over 22 h; 1090 mL of hydrogen was absorbed (97% of theoretical). The white solid which had precipitated out of solution was dissolved by adding acetone and the solution was filtered from the catalyst. The solvents were removed *in vacuo* and an aliquot of the residue (mp 115°C) was methylated with diazomethane and analyzed via boric acid impregnated silica gel tlc (mobile phase 60:40 ether – petroleum ether; the tlc plates were prepared by spraying Merck silica gel plates with a saturated methanolic boric acid solution). Comparison with an authentic sample prepared by $KMnO_4$ oxidation of oleic acid showed that the major product was the *erythro* diol. Two recrystallizations from ethyl acetate yielded pure *erythro* diol, 5 g, mp 126–128°C (lit. 23 mp 132°C).

Methyl cis-*9-Octadecenoate-8,8,11,11-*d_4

Erythro-9,10-dihydroxyoctadecanoic acid-8,8,11,11-d_4 (5 g) was heated with methyl orthoformate (6 mL) under argon at 90°C for 0.5 h. Excess methyl orthoformate was evaporated and the resulting 1,3-dioxalan heated at 160°C for 4.75 h, at which time the evolution of carbon dioxide had ceased. The product was shown by tlc to be mainly oleic acid accompanied by some methyl oleate. The product was treated with diazomethane to convert the acid to its methyl ester which was isolated by dissolving the crude product in chilled hexane and centrifuging to remove a large amount of gelatinous precipitate. Removal of the solvent gave a residue of 3.9 g. Open column chromatography using Merck T.L.C. silica gel (100 g) and elution with ether–hexane (2:23) yielded the pure title compound; glc analysis showed the product to be the stereochemically pure *cis*-olefin. Analysis of the ^1H, ^2H, and ^{13}C nmr spectra showed that the label was exclusively at the allylic positions. In the ^1H nmr spectrum, the signal at δ 2.0, present in the unlabelled compound, was absent. The signal assigned to the allylic carbon atoms at 27.4 ppm in the unlabelled compound had disappeared in the ^{13}C nmr spectrum of the labelled material. Only 1 peak at δ 1.8 was present in the ^2H nmr spectrum, as expected. Analysis of the product by ms showed that it had the following deuterium content: d_4, 79.1%; d_3, 15.1%; d_2, 4.0%; d_1, 1.4%; d_0, 0.4%.

Preparation of Methyl cis-*9,10-Methyleneoctadecanoate-9,10-*d_2(10)

Zinc dust (400 mg, AnalaR B.D.H.) was suspended in boiling acetic acid in a 10 mL round bottomed flask. The mixture was stirred for 1 min, cupric diacetate (80 mg) in boiling acetic acid (2 mL) was added, and stirring continued for ca. 3 min until the blue solution had been completely decolorized. The red-brown zinc–copper couple was washed with acetic acid (5 × 3 mL) and ether (5 × 3 mL). Ether (1 mL) was then added, followed by diiodomethane (2.5 g) and methyl *cis*-9-octadecenoate-9,10-d_2 (100 mg) in ether (4 mL). A reflux condenser was fitted to the flask and the system flushed with argon. The ether solution was warmed to initiate the reaction and after an initial exothermic reaction had subsided, the solution was heated under reflux for 24 h, under argon, at an oil bath temperature of 55°C. (After 12 h, ether (2 mL) was added to replace that lost by evaporation.) Pyridine and ether were added to the cooled reaction mixture until a white precipitate ceased to form. The mixture was filtered and the solids washed with ether. The yellow residue, obtained by evaporation of the ether, was placed under high vacuum (0.01 Torr) and excess pyridine and diiodomethane removed. The residual oil was taken up in hexane and filtered through glass wool to remove an orange solid. Reverse phase hplc analysis (acetonitrile – ethyl acetate, 75:25) showed essentially one peak assigned to the cyclopropane compound. Preparative separation of an aliquot of the crude product gave a sample which was subjected to ms analysis.

Preparation of Methyl cis-*9,10-Methyleneoctadecanoate-8,8,11,11-*d_4

Methyl oleate-8,8,11,11-d_4 was converted to the title compound by a method identical with that used for the preparation of methyl *cis*-9,10-methyleneoctadecanoate-9,10-d_2.

Feeding Experiments with cis-*9-Octadecenoic Acid-9,10-*d_2 *and* cis-*9-Octadecenoic Acid-8,8,11,11-*d_4

The same protocol was used for both feeding experiments.

The labelled fatty acids (200 mg) in 95% ethanol (1 mL) were added to an autoclaved basal medium (10 L) containing Tween 40 (10 g). The basal medium (1 L) contained Bacto-Biotin Assay medium (Difco) (37.5 g) and a vitamin free casein hydrolysate solution (50.0 mL). Two culture tubes containing the complete medium (10 mL) were inoculated with a saline cell suspension[1] (0.05 mL), and the cultures allowed to grow for 24 h. The result-

[1]A freshly grown inoculum was used. A culture tube containing M.R.S. Broth (Difco, 10 mL) was inoculated from a stock stab culture. After 24 h of growth, the cells were harvested, washed with 0.85% saline several times, and resuspended in saline (10 mL).

For personal use only.

ing culture (4 mL) was used to inoculate 3 × 500 mL Erlenmeyer flasks containing identical media (150 mL). After 24 h of growth, each culture was used to inoculate identical media (3.25 L), each contained in 3 × 5 L culture flasks. Growth was allowed to continue for 36 h, after which the cells were harvested and the fatty acids extracted according to the method of Hofmann *et al.* (24). The methyl esters were separated by preparative hplc (see Apparatus, Methods, and Materials). The total amount of fatty acids obtained in the oleic acid-9,10-d_2 feeding was 18 mg. The relative proportions of the three major fatty acids were: oleic acid (C_{18}), 8%; palmitic acid (C_{16}), 58%; dihydrosterculic acid (C_{19}), 34%. The total fatty acids amounted to 10 mg in the oleic acid-8,8,11,11-d_4 feeding. The relative proportions of the three fatty acids were: C_{18}, 12%; C_{16}, 43%; C_{19}, 45%.

Methionine-methyl-d_3 *and Biotin Feeding (Experiment 1, Table 3)*

A filter sterilized solution of methionine-methyl-d_3 was added along with biotin to autoclaved basal medium to make a final concentration of 100 mg/L (methionine) and 10 μg/L (biotin). The complete medium (10 mL) was inoculated from a stab culture. After 24 h of growth, aliquots of this culture (0.1 mL) were used to inoculate the same medium (5 × 10 mL). After 24 h of growth, each culture was used to inoculate identical media in 5 × 500 mL Erlenmeyer flasks (200 mL each). After 36 h, only 2 flasks had grown out properly. The reason for this was not determined. The cells from all flasks were harvested and the fatty acids extracted by the procedure of Hofmann *et al.* (24). The total fatty acids amounted to 5.0 mg. The relative proportions of each fatty acid were *cis*-vaccenic (C_{18}), 11%; palmitic (C_{16}), 48%; lactobacillic (C_{19}), 41%.

Methionine-methyl-d_3 *and Oleic Acid Feeding (Experiment 2, Table 3)*

Methionine-methyl-d_3 (120 mg, filter sterilized) was added to autoclaved basal medium (1.26 L) containing oleic acid (24 mg and Tween 40 (2.2 g)). The complete medium (16 × 10 mL) was inoculated with a saline cell suspension (0.05 mL). After 24 h, these cultures (2 × 10 mL) were used to inoculate each of 8 × 500 mL Erlenmeyer flasks containing identical media (125 mL each). The cells were harvested after 24 h of growth and the fatty acids extracted.

The total fatty acid content of the cells was 20 mg. The relative proportion of each fatty acid was: C_{18}, 17%; C_{16}, 54%; C_{19}, 39%.

Methionine-methyl-d_3 *and Biotin Feeding (Experiment 3*(a),(b), *Table 3)*

Methionine-methyl-d_3 (100 mg) was added to basal medium (1015 mL) along with biotin (10 μg). After filter sterilization, the complete medium (14 × 10 mL) was inoculated with a saline cell suspension (0.05 mL) and allowed to grow for 24 h. The resulting cultures (2 × 10 mL) were used to inoculate 7 × 250 mL Erlenmeyer flasks containing identical media (125 mL). Twenty-four hours later, 3 flasks were harvested and after 64 h, the remaining flasks were harvested and the fatty acids extracted. The cells from the 24 h culture contained 5.3 mg of total fatty acid. The relative proportion of each fatty acid was C_{18}, 8%; C_{16}, 38%; C_{19}, 54%. The cells from the 64 h culture contained 9.6 mg of total fatty acid. The relative proportion of each fatty acid was: C_{18}, 7%; C_{16}, 36%; C_{19}, 57%.

Feeding Experiments Using Methionine-methyl-d_3 *and Either Biotin, Oleic Acid, or* cis-*Vaccenic Acid (Experiment 4* (a),(b),(c), *Table 3)*

Basal medium (2 L) was prepared and to 1600 mL was added Tween 40 (1.6 g) (Medium A) and to the remaining 400 mL was added biotin (4.0 mg) (Medium B). Medium A was distributed among 160 culture tubes and Medium B among 40 culture tubes. The media were then autoclaved. *cis*-Vaccenic acid (16 mg) in 95% ethanol (1 mL) was added in equal portions to 80 culture tubes containing Medium A. The same procedure was carried out using oleic acid. L-Methionine-methyl-d_3 (120 mg in 21 mL of water) was filter sterilized separately and 0.1 mL aliquots were added aseptically to each of the 200 culture tubes. Each culture tube was then inoculated with a saline cell suspension (0.05 mL, a Klett reading of 360 was recorded for this inoculum). After 24 h, good growth was obtained in the biotin-containing medium, but only poor growth resulted in both fatty acid-containing media. The cells were harvested and the fatty acids extracted. The total amount of fatty acids obtained from the cells grown in biotin was 9.7 mg (C_{18}, 40%; C_{16}, 37%; C_{19}, 23%); from the cells grown on oleic acid, 5.0 mg (C_{18}, 21%; C_{16}, 53%; C_{19}, 26%); from the cells grown on vaccenic acid, 10.3 mg (C_{18}, 35%; C_{16}, 53%; C_{19}, 12%).

Methionine-methyl-d_3 *Feeding (Isolation of Cells at 13.5 and 24 h)*

Methionine-methyl-d_3 (145 mg) and biotin (14.5 μg) were added to basal medium (1.45 L). After filter sterilization, the medium was distributed in 145 mL portions among 15 250 mL Erlenmeyer flasks. The flasks were inoculated with a saline cell suspension (1 mL, Klett reading of 490). At 13.5 h, 6 flasks were harvested, after measuring pH and turbidity. The cells were dried and weighed (598 mg) and the fatty acids extracted (by the procedure of Ohlrogge *et al.* (25)). The total fatty acid content was 4.7 mg (C_{18}, 51%; C_{16}, 37%; C_{19}, 21%). At 24 h, the same procedure was carried out with another 4 flasks. The total fatty acid content was 20.7 mg from 721 mg of cells (C_{18}, 27%; C_{16}, 41%; C_{19}, 32%).

Methyl Dihydrosterculate-19-d_2

Methyl oleate was converted to the title compound using CD_2I_2 by the methods described for the preparation of methyl *cis*-9,10-methyleneoctadecanoate-9,10-d_2.

Acknowledgements

We thank the Natural Sciences and Engineering Research Council of Canada for financial support. One of us (P.H.B.) gratefully acknowledges the award of an N.S.E.R.C. postgraduate scholarship.

We also wish to thank Dr. J. J. Miller for the use of his laboratory facilities for growing and harvesting the microbial cultures and Dr. J. B. Stothers for running the ^2H nmr spectrum of methyl oleate-9,10-d_2.

PETER DAVID GOLDING, SETHU REDDY, JOHN MARSHALL WILLIAM SCOTT, VALERIE ANN WHITE, and JUNE GERTRUDE WINTER. Can. J. Chem. **59**, 839 (1981).

The rates of rearrangement of *N*-bromo-4-chloroacetanilide to 2-bromo-4-chloroacetanilide catalyzed by trifluoroacetic acid and trifluoroacetic acid-*d* have been measured as a function of acid concentration in chlorobenzene at $T = 323$ K. Similar experiments have been carried out with *N*-bromoacetanilide and *N*-bromo-4-chloro-2,6-dideuterioacetanilide. A comprehensive analysis of the observed rates for each substrate as a function of acid concentration reveals that the rearrangements involve at least three mechanistic steps when trifluoroacetic acid is the catalyst. In contrast, the rate of rearrangement of *N*-bromoacetanilide catalyzed by trichloroacetic acid at $T = 288$ K appears to follow a limiting form of the same rate law. Earlier observations are assessed in the light of the proposed mechanism, and it is concluded that both present and past work can be satisfactorily rationalized in terms of an intramolecular migration of bromine.

PETER DAVID GOLDING, SETHU REDDY, JOHN MARSHALL WILLIAM SCOTT, VALERIE ANN WHITE et JUNE GERTRUDE WINTER. Can. J. Chem. **59**, 839 (1981).

On a mesuré les vitesses de transposition de la *N*-bromochloro-4 acétanilide en bromo-2 chloro-4 acétanilide catalysée par les acides trifluoroacétiques normaux et deutérés, en fonction de la concentration de l'acide dans le chlorobenzène à 323 K. On a réalisé des expériences identiques avec la *N*-bromoacétanilide et la *N*-bromo chloro-4 dideutéro-2,6 acétanilide. Une analyse complète des vitesses observées, pour chaque substrat en fonction de la concentration de l'acide, révèle que les transpositions font intervenir au moins trois étapes mécanistiques quand le catalyseur est l'acide trifluoroacétique. A l'opposé, la vitesse de transposition de la *N*-bromoacétanilide catalysée par l'acide trichloroacétique à 288 K semble suivre une forme limite de la même loi de vitesse. A la lumière du mécanisme proposé, on a évalué les observations antérieures et on a conclu que le présent travail ainsi que le précédent peuvent être rationalisés en fonction d'une migration intramoléculaire du brome.

[Traduit par le journal]

Introduction

The rearrangement of *N*-halogenoanilides to their corresponding ring halogenated isomers has attracted much attention since the early days of a more physical approach to the behaviour of organic molecules (2). The details of the rearrangement in aqueous systems with hydrohalic acids as catalysts are well established, but mechanistic descriptions of the rearrangement in aprotic solvents catalyzed by carboxylic acids and phenols present a less satisfactory picture. In the most recent review of the rearrangement, Shine (3) states that the role of the acid catalyst in aprotic media is not yet understood.

The study of proton transfer reactions, of which the Orton rearrangement is an example, constitutes an important and significant part of modern chemical theory (4–6). Catalyses by acids and bases have been extensively examined in hydroxylic or protic solvents, whereas the same phenomena in aprotic solvents have received less comment (4, 7). Indeed, the current situation with respect to acid–base catalysis in aprotic media is virtually identical to an account offered by Bell (7) over thirty years ago. The reluctance of chemists to examine acid–base catalysis in aprotic media may be associated with the view that ionogenic or nominally ionogenic reactions in aprotic media tend to be complex (cf. ref. 8). There is no real difference in principle, however, between protic and aprotic solvents with respect to the fundamental problem, namely, the specification of the catalytic species and their relative reactivities. In the present communication we attempt to solve this problem for the rearrangements of *N*-bromo-4-chloroacetanilide (NBCA) to 2-bromo-4-chloroacetanilide and *N*-bromoacetanilide (NBA) to 4-bromoacetanilide catalyzed by trifluoroacetic acid (TFA) in chlorobenzene. The kinetics of the rearrangements of NBCA and *N*-bromo-4-chloro-2,6-dideuterioacetanilide (NBCA-2,6-d_2) in chlorobenzene with TFA-*d* and TFA as the respective catalysts have also been investigated.

The variation of these rates of rearrangement as a function of acid concentration shows interesting and marked differences from those of the NBA/trichloroacetic acid (TCA) system reported by Bell (9). We regard these differences to be of considerable mechanistic significance when related to earlier observations (1, 10–14) and the details of these matters form the substance of the present contribution.

Experimental

Materials

The preparation and purification of NBA and NBCA, and the purification of commercial chlorobenzene were accomplished by methods described previously (11). The hydrogen atoms attached to the 2,6-carbons of *p*-chloroaniline were exchanged for deuterium under acidic conditions, and the resulting 4-chloro-2,6-dideuterioaniline was acylated and *N*-brominated in the usual way (11) to produce NBCA-2,6-d_2.The reaction of deuterium oxide with a slight excess of trifluoroacetic anhydride was used to prepare TFA-*d* which was then purified by distillation. The physical and analytical properties of the above compounds were in satisfactory agreement with literature values. The concentrations of acids and substrates in chlorobenzene were determined by titration, and all materials and solutions were stored in the absence of light over anhydrous Drierite.

Kinetic Measurements

Kinetic measurements were carried out using conventional methods (9, 11) at $T = (323.15 \pm 0.02)$ K with a single concentration (ca. 0.01 *M*) of substrate (NBCA, NBCA-2,6-d_2, or NBA) and several acid concentrations (TFA or TFA-*d*). In all cases the stoichiometric concentration of acid (c_a) was never less than three times that of the substrate. Pseudo-first order rate constants were obtained via a linear least-squares treatment of the concentration–time data, and these observed rate constants (k_{obs}) were at worst reproducible to 5%. The results of these measurements are summarized in Tables 1 to 3, and Table 4 provides similar quantities related to the NBA/TCA system measured by Bell (ref. 9, see Table II, p. 384). The tables also include the quantity $k_{obs}/c_a = \alpha$, which represents the apparent second order rate constants (see ref. 9, p. 387).[4]

The data for the NBCA/TFA system are a combination of the results of two different investigators[5] working in periods separated by a year. The two separate studies employed different, freshly prepared samples of all substances. That the results of the two studies were in excellent agreement strongly supports the observation of the unusual acid dependence of the pseudo-first order rate constants (see below).

Results and Discussion

A Comparison with Earlier Work

The most extensive investigation prior to the present study was Bell's (9) in which the rate of rearrangement of NBA was examined as a function of temperature, solvent, and the strength and concentration of phenolic and carboxylic acid

[4]The meaning of α here should not be confused with the more common usage as a Brönsted exponent. The continued use of α in the present text is prompted only by our fidelity to Bell's original notation.

[5]S.R. and V.A.W.

TABLE 1. The rates of rearrangement for NBCA (and NBCA-2,6-d_2)[a] catalyzed by TFA in chlorobenzene at $T = (323.15 \pm 0.02)$ K

$c_a \times 10^2$, mol·L^{-1}	$k_{obs} \times 10^5$, s^{-1} (runs)[b]	$\alpha \times 10^4$, L·mol^{-1}·s^{-1}
2.01	2.11 ± 0.06 (4)	10.5 ± 0.3
3.92	5.02 ± 0.31 (3)	12.8 ± 0.8
5.45	7.93 ± 0.24 (4)	14.6 ± 0.4

31.4	54.7 ± 1.4 (4)	17.4 ± 0.5

[a]At 323 K and the same TFA concentration, the rates of rearrangement for NBCA-2,6-d_2 and NBCA are not appreciably different. For example, at a TFA concentration of 0.246 mol·L^{-1} the rate for NBCA-2,6-d_2 is $(44.1 \pm 0.56) \times 10^{-5}$ s^{-1}.
[b]The rates here and in Tables 2 and 3 are mean values (± standard deviation) weighted with respect to the reciprocal variance of each of the kinetic runs at the various acid concentrations.

catalysts. In chlorobenzene the pseudo-first order rate constants (k_{obs}) for various acid concentrations (c_a), when reduced to unit acid concentration (α) and subsequently plotted against c_a, gave shallow curves with negative slopes which are concave in shape from $c_a = 0$ (cf. Fig. 1). Under favorable circumstances these curves could be extrapolated graphically to yield k_{obs}/c_a at infinite dilution (α_0), the value of which was considered to be a measure of the catalytic power of the *monomeric* acid. Values of α_0 estimated in this way for various phenols and carboxylic acids provided an excellent Brönsted linear free energy relationship (ref. 9, p. 389).

Bell explained the form of the α versus c_a curves in the following manner. It was assumed (9) that the carboxylic acid catalysts (RCOOH) were present in monomeric (M) and dimeric (D) forms, the result of the dimerization

$$[1] \quad 2\text{RCOOH} \overset{K_d}{\rightleftharpoons} (\text{RCOOH})_2$$

where K_d is the dimerization constant, and that the respective rate constants k_M and k_D were related to the observed rate by

$$[2] \quad k_{obs} = k_M[M] + k_D[D]$$

Bell also tacitly assumed that the rate was first order with respect to both the monomeric and dimeric forms of the acid catalyst, i.e., k_M and k_D were second order rate constants. The concentration–rate data, however, were not analyzed in such a way so as to confirm this crucial, yet perhaps unwarranted, assumption. Indeed, Bell apparently relegated the observed rates to be entirely functions of monomeric acid catalysis inasmuch as the abscissa of his Brönsted linear free energy relationship is the pK_a of the aqueous monomeric acid.

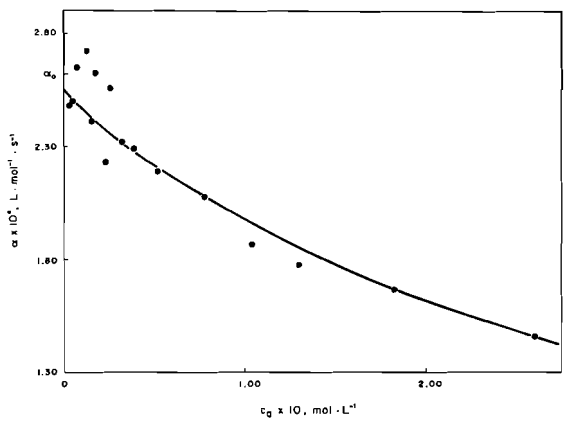

FIG. 1. The α versus c_a profile for the rearrangement of NBA catalyzed by TCA in chlorobenzene at $T = 288$ K. The value of k_{obs}/c_a at infinite dilution reported by Bell (9) is shown as α_0.

Nevertheless, if we develop Bell's original hypothesis from the equilibrium given by eq. [1]

$$[3] \quad K_d = [D]/[M]^2$$

Mass balance requires that the stoichiometric concentration of the catalyst be related to the concentrations of M and D such that

$$[4] \quad c_a = [M] + 2[D]$$

which, in conjunction with eq. [3], gives

$$[5] \quad c_a = [M] + 2K_d[M]^2$$

Combining eqs. [2], [3], and [5] yields

$$[6] \quad k_{obs} = k_M c_a - K_d(2k_M - k_D)[M]^2$$

and division by c_a leads to

$$[7] \quad \frac{k_{obs}}{c_a} = k_M - \frac{K_d(2k_M - k_D)[M]}{1 + 2K_d[M]}$$

As $c_a \rightarrow 0$, $[M] \rightarrow 0$; thus the negative term on the right hand side of eq. [7] is well behaved mathematically at infinite dilution, and the intercept of the α versus c_a curve may be correctly identified with the second order rate constant appropriate to the monomeric catalyst.[6] Within the framework of the major portion of Bell's experimental findings the above analysis is satisfactory, but in some solvents (e.g., benzene) the steep rise of the curve precluded extrapolation to α_0.

Nevertheless, Bell's treatment does not satisfactorily accommodate our observations. Firstly, since α depends on c_a for all the systems investigated (see also refs. 9, 11), none of the reactions are of unit order with respect to the catalysts. Further confirmation of this is provided by plots of $\log_{10} k_{obs}$ versus $\log_{10} c_a$ which give slopes considerably in excess of unity. This observation implies that the isotope effect for NBCA rearrangement cannot be calculated from the ratio of the respective rate constants, $k_{obs}(H)/k_{obs}(D)$, at identical concentrations of TFA and TFA-*d*.

Secondly, and more fundamental, the behaviour of the α versus c_a correlations for NBCA/TFA, NBCA/TFA-*d*, and NBA/TFA differs from that observed by Bell (9) for NBA/TCA (see Figs. 1 and 2). For all the phenolic and carboxylic acid catalysts employed by this author, α is assumed to extrapolate to a finite, positive, limiting value (α_0) as $c_a \rightarrow 0$ (cf. Fig. 1). In the present work, how-

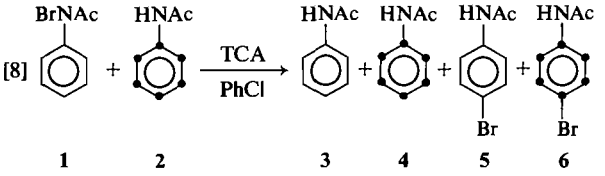
[6]It should be noted that since c_a, not [M], is the independent variable in the α versus c_a correlation, the graphical extrapolation procedure employed by Bell to estimate α_0 corresponds to the limiting form of eq. [7] at infinite dilution. Ultimately, no confirmation of eq. [2] was offered since Bell did not develop eq. [7] to evaluate the magnitude of k_D.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

ever, the α versus c_a curves for the NBA/TFA, NBCA/TFA, and NBCA/TFA-*d* systems have *positive* slopes and are *convex* in shape from $c_a = 0$, and the curves also appear to extrapolate to the *origin* of the α, c_a coordinate system rather than to a positive, upper limiting value (see Fig. 2). Furthermore, there is a strong indication in the present work that the α's may go through maxima at various c_a values, although these maxima are not sharply defined,[7] but eq. [7], which embodies the formalities of Bell's treatment, will not support a concentration dependent maximum in the α,c_a coordinate system. In consequence, the validity of Bell's extrapolation procedure (9) of α to α_0 at infinite dilution must now be considered suspect, since it is certainly inappropriate in the case of our own observations (see Fig. 2); moreover, any evaluation of the isotope effect for NBCA rearrangement from $\alpha_0(H)/\alpha_0(D)$ is precluded. In an effort to resolve these differences we first find it necessary to reinterpret some results of another study which also have a contradictory bearing on Bell's original assumptions.

Evidence for Two Intermediates in the Rearrangement

Some years ago Dewar and Couzens (13) conducted a series of experiments designed to distinguish between an intermolecular or an intramolecular mechanism for the rearrangement. The first of these experiments involved the "rearrangement" of NBA in the presence of acetanilide uniformly labelled with ^{14}C.



Dewar and Couzens reasonably assumed that products **3** and **6** would be absent if the rearrangement is intramolecular. While the presence of all four products indicated the mechanism to be complex, in the present context the more important fact is that **3** and **6** arose from an acid catalyzed, bromine "scrambling" reaction between **1** and **2** *which was faster than the loss of "active" bromine from nitrogen to the ring*. Dewar and Couzens also demonstrated that bromine exchange between nitrogens did not involve the intermediate production of trichloroacetyl hypobromite (CCl_3COOBr).

[7]There is a hint of a similar maximum in the plot of α versus c_a for the NBA/TCA data (see Table 4 and Fig. 1), but this maximum was ignored in the original presentation and perhaps considered the result of experimental error.

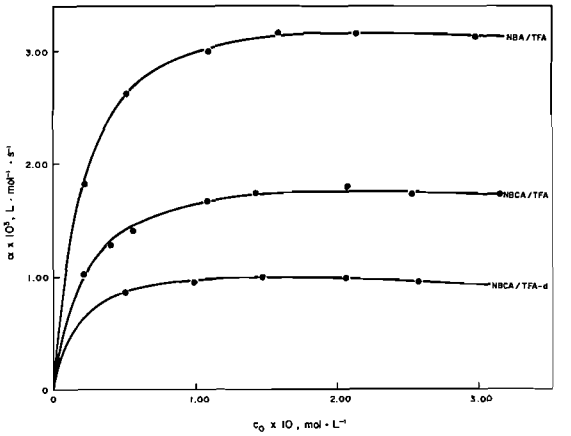


FIG. 2. The α versus c_a profiles for the rearrangement of NBA catalyzed by TFA and the rearrangement of NBCA catalyzed by TFA and by TFA-*d* in chlorobenzene at $T = 323.15$ K.

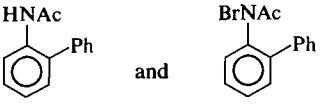
The reality of the bromine scrambling reaction was elegantly confirmed by examining the rate of loss of active bromine from (*a*) **1** in the presence of an equimolar amount of **7**, and (*b*) **3** in the presence of an equimolar amount of **8**, where **7** and **8** are



7 8

It was observed that in both (*a*) and (*b*) the mixtures gave *identical* rates of loss of active bromine despite the fact that separately the rate of loss of active bromine from **1** is ca. *a factor of ten faster* than that from **8**. An acid catalyzed scrambling reaction of bromine between the species provides a satisfactory explanation of these observations, i.e., whether one starts with **1** and **7** or with **3** and **8**, equimolar amounts of **1**, **7**, **3**, and **8** are rapidly produced via the scrambling reaction.

Mechanistic discussions of the Orton rearrangement in aprotic solvents have invariably assumed that the slow step in the rearrangement is proton transfer to nitrogen (or oxygen) and that the migration of bromine to its terminal location subsequent to protonation is rapid and irreversible (cf. ref. 15). This mechanistic description, however, must be revised since it fails to accommodate both our own results and those of the Dewar, Couzens investigation. Clearly, the rate of proton attack on nitrogen (or oxygen) must be faster than the observed rate for rearrangement, since the rate of proton transfer exceeds the overall rate of bromine scrambling, which in turn is faster than the observed rate for rearrangement. Thus, proton transfer to the acetanilides cannot be entirely rate determining.

Initially, proton attack by carboxylic acid

For personal use only.

catalysts in aprotic media undoubtedly will take the form of hydrogen bonding, a process known to be both rapid and reversible between oxygen and nitrogen (cf. ref. 16). Consequently, while hydrogen bonding between the acetanilides and acid catalysts is unlikely to be rate determining, it is followed by the slower, formal transfer of a proton to the substrate. The resulting pre-equilibrium mechanism then requires that both the hydrogen bonded and the protonated *N*-bromo compounds be considered as intermediates. Thus, the simplest mechanistic description for rearrangement is

$$[9] \quad S + \Sigma A_n \overset{K_1}{\rightleftharpoons} \Sigma SA_n \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \Sigma I_n \xrightarrow{k_3} \text{products}$$

where S represents the substrate (*N*-bromo compound), A_n are the various catalytic species (monomeric and higher polymeric forms of the acid catalyst), SA_n are the associated hydrogen bonded intermediates and I_n are the corresponding protonated *N*-bromo intermediates. How many of the acid species (A_n) contribute to k_{obs}? Does the acid catalyst participate in reaction steps subsequent to the protonation of substrate? What is the simplest rate law which accommodates the differences between the variations of α with c_a reported by Bell and those observed in the present work? The answers to these important questions and an explanation for our observations in which TFA and TFA-*d* are catalysts are contingent upon an interpretation of other significant observations related to rearrangement in anisole and chlorobenzene.

Evidence for a Third Intermediate

The mechanism for the rearrangements of *N*-bromo- and *N*-chloroacetanilides[8] catalyzed by phenols and carboxylic acids has consistently resisted several probing investigations into the nature of its details (see particularly ref. 13). These rearrangements are typified by

[10] 
and

[11] 
where R = H, Ph, CH_3, Cl, Br, NO_2, etc. and X = Cl, Br. While all of the data examined above suggest that reversible protonation is the first step in the advance towards product, the nature of the intermediate arising from protonation has not been specified. The intermediate is perhaps best considered as a tight ammonium ion pair, and its fate under various conditions is an important mechanistic step for which two alternate paths have been proposed.

Soper and co-workers (14) examined the reaction of *N*-bromoacetanilide with acetic acid in anisole/chloroform mixtures and found 4-bromoanisole to be the major product. They also observed that the rate of disappearance of bromine bonded to nitrogen was independent of the anisole concentration. To explain these observations they postulated that the protonated substrate gave acetyl hypobromite in a slow step

[12] 
followed by the rapid bromination of anisole

[13] 
to give 4-bromoanisole and acetic acid, the catalyst. The postulated intermediacy of the hypobromite is superfluous, however, in the sense that bromine transfer to anisole could take place directly from nitrogen. Hence, the production of hypobromite may be an unwarranted hypothesis both for the rearrangement itself and for halogen migration to a more reactive aromatic system. The latter forms the gist of Dewar's criticism (15) of the Soper mechanism. The alternative proposed by Dewar was that halogen migration is intramolecular and proceeds via a π-complex subsequent to proto-

[8]The only iodo compound about which there is information is *N*-iodoformanilide. The rearrangement of this compound in anisole appears to occur in the same fashion as the rearrangements of *N*-bromo- and *N*-chloroacylanilides in chlorobenzene. This is unusual inasmuch as the *N*-bromo and *N*-chloro compounds halogenate anisole under similar conditions (1, 12–14, 17).

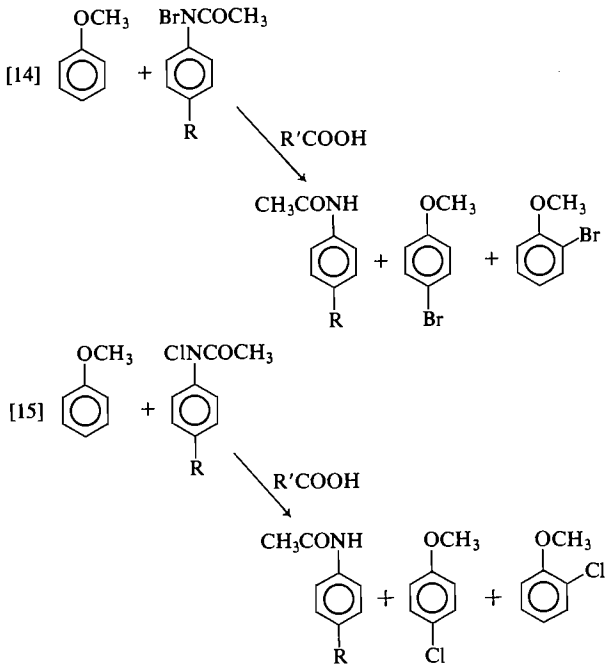
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

nation, and that all steps following protonation are rapid and irreversible.

In 1957 Dewar and Scott (10) reported that *N*-bromo-2-nitroacetanilide failed to rearrange when treated with TCA in chlorobenzene (see reaction [11]; R = NO_2, X = Br), and that the products from this particular process were 4-bromochlorobenzene and 2-nitroacetanilide. Other 2-substituents with electron attracting properties inferior to that of the 2-nitro group, namely, R = CH_3, F, Cl, Br, and Ph, gave the normal rearrangement products in chlorobenzene. In carbon tetrachloride, however, *N*-bromo-2-nitroacetanilide rearranged in the presence of TCA to give 4-bromo-2-nitroacetanilide, the expected product. Scott (11) subsequently demonstrated that a series of similar 4-substituted *N*-bromo compounds in reaction [10] behaved like those in reaction [11], i.e., a nitro group in the 4-position also led to the production of 4-bromochlorobenzene. A kinetic investigation of the reactions summarized by eq. [10] was consistent with bromine migration in the 4-nitro compound occurring subsequent to protonation. Dewar and Scott (10) and Scott (11) speculated that the exceptional behaviour of the 2-nitro and 4-nitro substrates was a consequence of the increased electrophilic character of the bromine at some stage along the reaction coordinate, and this was attributed to the strong electron withdrawing properties of the nitro group relative to the other substituents investigated.

In 1957 Dewar (13) reconsidered his earlier proposals with respect to the mechanism of the rearrangement on the basis of his work with Couzens (see eq. [8] and related discussion). We may usefully add that the scrambling reaction discovered by these workers exceeds the rate of rearrangement only when the carboxylic acid catalyst is strong. This suggests that the electrophilic character of the bromine in the exchange between nitrogens also depends on the ease or extent of proton transfer. Although acid hypobromites were specifically excluded in Dewar's explanation for the nitrogen to nitrogen migration of bromine, these were retained as "complexed" rather than "kinetically free" intermediates. Further comment as to their role in the rearrangement itself, however, was apparently left in abeyance.

A further study by Scott and Martin (12) of the reaction investigated by Soper and co-workers (see reactions [12] and [13] above) and the related reaction involving *N*-chloroacylanilides (1) revealed that the reactions afforded both the 2-halogeno- and 4-halogenoanisoles. The scope of these experiments is summarized in the following equations.



The observed *ortho*/*para* product ratios related to each *N*-bromoacylanilide/carboxylic acid system (eq. [14]; 16 ratios) and each *N*-chloroacylanilide/carboxylic acid system (eq. [15]; 12 ratios) are pertinent to the present discussion.

Firstly, we wish to draw attention to the fact that the ratios from the bromination reactions are a function of both the bromine source and the acid catalyst. As noted earlier, this observation is inconsistent with the intermediate production of kinetically free hypobromites (12). Secondly, we also note that the reactivity of the bromine, as measured by the selectivity of the bromination, increases with the basic strength of the amine related to the *N*-bromoacylanilide and the acidic strength of the catalyst. Alternatively, it may be stated that the electrophilic character of the bromine is increased by factors in the reactants which facilitate proton transfer. The same factors appear to be operative in the case of the *N*-chloroacylanilides, although the ratios are less sensitive to structural alterations in the chlorine source. This reduction in sensitivity is due to the replacement of bromine by the more electronegative chlorine, a case analogous to that shown by *N*-bromo-4-nitroacetanilide where the basicity of the *N*-halogenoacylanilide is reduced as a consequence of the electron withdrawing properties of the 4-substituent.

As we noted earlier, bromine migration to solvent is not confined to anisole but also occurs in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

chlorobenzene with *N*-bromo-2-nitroacetanilide and *N*-bromo-4-nitroacetanilide. In contrast to the anisole brominations, however, the less strongly electron withdrawing substituents, i.e., F, Cl, Br, CH_3, and Ph, give the anticipated rearranged products in chlorobenzene. Clearly, two possibilities exist for the bromination of chlorobenzene and anisole. Either bromine migration occurs at the same position along the reaction coordinate for both solvents or the migrations of bromine to each solvent involve different intermediates. All the evidence presented above is consistent only with the *direct transfer of bromine from nitrogen to solvent* in the anisole brominations. If the same situation existed in chlorobenzene, then since the nitro group produces the *least reactive* bromine in anisole, i.e., the *most selective* anisole brominations, the other substituents, namely, F, Cl, Br, CH_3, and Ph, should also induce bromination of the chlorobenzene. This is *not* what is observed. We can only conclude that the bromination of chlorobenzene by the 2-nitro and 4-nitro substrates takes place by a different mechanism, one involving a further distinct intermediate, namely, the π-complex. Thus, the bifurcation of products which occurs in chlorobenzene is a consequence of the differing reactivity of bromine at the π-complex stage where the reactivity of the incipient bromine cation is enhanced by electron withdrawing substituents and diminished by electron donating substituents. In anisole, on the other hand, the extent or ease of proton transfer to form the protonated substrates will be increased by electron donating substituents and decreased by electron withdrawing substituents. Hence, the effect of the substituents is entirely in the *opposite sense* in anisole and depends solely on how efficiently the substituents facilitate proton transfer.

While the intervention of acyl hypobromites in the chlorobenzene reactions would lead to the same results, we exclude this possibility because the products obtained by Dewar and Couzens (13) in reaction [8] cannot be accounted for by the invocation of kinetically free hypobromite intermediates. We take these latter results to mean that bromine scrambling occurs from the protonated substrate, while rearrangement proceeds via a π-complex.

Finally, we wish to draw attention to one further interesting fact concerning the Orton rearrangement which has thus far been neglected. Bell and Brown (17) reported some time ago that *N*-iodoformanilide rearranges in anisole when treated with carboxylic acids and phenols. The 4-position in anilides is approximately a factor of 10 *less* reactive towards electrophiles than the same position in anisole (18), and hence, if rearrangement occurred via a kinetically free hypoiodite, substitution would not favour the anilide. Indeed, since the molar concentration of anisole is ca. 10 $mol \cdot L^{-1}$ while the concentration of *N*-iodoformanilide in the anisole varied from about 0.01 to 0.1 $mol \cdot L^{-1}$, the effective competition factor, which is a function of both concentration and reactivity, will favour the anisole by at least three orders of magnitude. In spite of this large "reactivity gradient", *N*-iodoformanilide *rearranges* in the presence of anisole. This, together with all the evidence presented above, is strongly indicative of an intramolecular rearrangement for the acid catalyzed component of the reaction in which the halogenating species never becomes kinetically free.

The Role of the Carboxylic Acid Catalysts

The association of carboxylic acids in nonaqueous solvents is well documented (cf. refs. 19, 20), but recent studies (21, 22) of these hydrogen bonding phenomena and the polymeric aggregates which result reveal that monomeric association is not limited to cyclic dimers for acid concentrations above 10^{-3} $mol \cdot L^{-1}$. In general, however, the trend of increasing association with decreasing acid strength is evident (19–21), and the contention that TFA in chlorobenzene at 323 K is likely to be present predominately as monomer in equilibrium with a small amount of dimer, even for acid concentrations exceeding 10^{-3} $mol \cdot L^{-1}$, is supported by Stevens (19) in his study of the self-association of TFA in nonaqueous solvents.

With reference to Fig. 2, the variation of α with c_a at lower TFA concentrations requires that at least a term in $[M]^2$ be present in the expression for the observed rates since the shape of the curves cannot be accommodated solely by a term in [M]. Furthermore, since the concentration–rate data for the TFA systems are not amenable to treatment according to Bell's rate law (see eq. [2]), in which terms in both [M] and $[M]^2$ are present, we can only surmise that the substrate is not catalyzed to product by a single monomeric species. The kinetic meaning of a term in $[M]^2$ in the rate expression is equivocal; such a term can be interpreted as the attack of dimer on substrate, a termolecular reaction between substrate and two monomers, or the sequential attack of two monomers, first on substrate and then on an intermediate. A further examination of k_{obs} as a function of c_a, however, shows that the observed rates cannot be interpreted simply as a function of $[M]^2$ at lower TFA concentrations. This observation leads to the conclusion that the successive attack of two monomeric

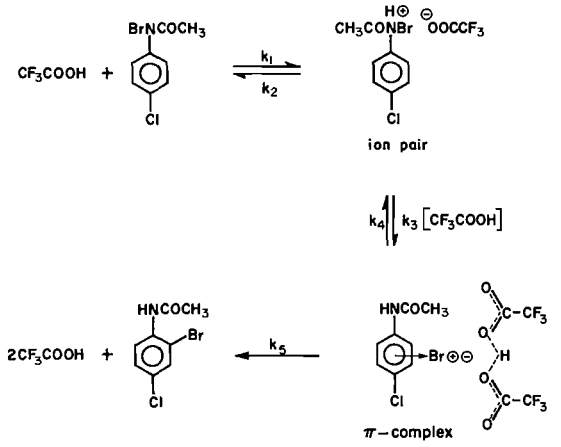


FIG. 3. A simplified mechanistic description for the rearrangement of NBCA catalyzed by TFA in chlorobenzene.

species on the substrate must account for the major portion of catalytic activity in the TFA systems.

In the light of the foregoing, we propose a general mechanism like that shown in Fig. 3 for monomeric TFA catalysis of NBCA to rearranged product. This mechanism is summarized by

$$[16]\quad S + M \underset{k_2}{\overset{k_1}{\rightleftharpoons}} I_1 \underset{k_4}{\overset{k_3[M]}{\rightleftharpoons}} I_2 \xrightarrow{k_5} \text{products}$$

In view of the previous observations related to both intermolecular bromine scrambling between substrate nitrogens (13) and bromine transfer reactions from substrate to solvent (1, 10–12, 15), we envisage I_1 as a tight ammonium ion pair. The k_1 step then initially involves a hydrogen bonding preequilibrium between monomeric acid and substrate followed by the slower, formal transfer of a proton to the substrate. While it is generally accepted that hydrogen bonding between oxygen and oxygen or nitrogen is rapid and reversible, and that proton transfer subsequent to hydrogen bonding is relatively slower, such a description may be oversimplified (cf. ref. 23). To avoid such complexity at this stage and any conjecture regarding the initial site of hydrogen bonding in the substrate (oxygen or nitrogen), we prefer to simply consider the hydrogen bonding and proton transfer processes as a single reaction step.

While the solvation, separation, and reaction of the ions in aqueous protonated substrate is likely to be rapid, a similar demise of the ion pair in chlorobenzene is not apt to occur since the solvent is unlikely to separate and support the resulting solvated, free ions. Clearly the necessary reorganization of charge for further reaction must occur within the species in some other manner. We view the attack of a second acid monomer on I_1 as electrophilic catalysis, wherein the acid monomer hydrogen bonds to the anionic moiety of the tight ammonium ion pair. In concert with this wider distribution of negative charge over the resulting "dimeric anion", the positive charge of the tight ion pair migrates to bromine, formally producing a brominium ion which may participate in a scrambling reaction, transfer to solvent, or, by intramolecular migration, form the π-complex I_2.[9] Reaction from I_2 to products is represented for convenience as a single reaction step, but this advance presumably occurs via the usual series of aromatic substitution equilibria and intermediates, namely, from the $Br^{(+)}$ π-complex to the σ-complex to the $H^{(+)}$ π-complex, from which a final, irreversible proton transfer to the dimeric anion occurs, thus rendering the rearranged product.

To test the fidelity of the foregoing description, application of the steady state theorem to eq. [16] leads to a rate law given by

$$[17]\quad k_{obs} = \frac{k_1 k_3 k_5 [M]^2}{k_2(k_4 + k_5) + k_3 k_5 [M]} = \frac{k_1 [M]^2}{k_2(k_4 + k_5)/k_3 k_5 + [M]}$$

Our data for the NBA/TFA, NBCA/TFA, NBCA/TFA-*d* systems and those for the NBA/TCA system reported by Bell (9) have been regressed in compliance with eq. [17] using the method suggested by Wentworth (24) for nonlinear regression. The regression results, quoted in Table 5 and illustrated in linear form ($[M]^2/k_{obs}$ vs. [M]) in Figs. 4 and 5, satisfactorily accommodate both our own results and those of Bell for the NBA/TCA system.

The magnitude and reproducibility of the K_d values quoted in Table 5 should reflect primarily on the validity of the data treatment and ultimately on the justification for the assumption which constrains catalytic reactivity to the monomeric species in the simple monomer–dimer acid equilibrium. While thermodynamic data apparently are unavailable for the self-association of TCA or TFA in chlorobenzene, some comparisons can be made. Bulmer and Shurvell (21) have summarized some K_d values reported for TCA/C_6H_6 based on a monomer–dimer model, 1.1 L·mol^{-1} at 293 K (25), 6.7 and 5 L·mol^{-1} at 298 K (26, 27), which are in reasonable agreement with K_d (TCA/PhCl/288 K)

[9]We have described the k_3 step here as a concerted process more for the sake of brevity than to deny the existence of a second ion pair intermediate between I_1 and the π-complex. The existence of such an intermediate will not significantly alter the present mechanistic argument.

TABLE 5. Carboxylic acid dimerization constants and rate constants for some acid catalyzed rearrangements of NBA and NBCA in chlorobenzene[a]

Substrate/acid	K_d, L·mol^{-1}	$k_1 \times 10^4$, L·mol^{-1}·s^{-1}	$[k_2(k_4+k_5)/k_3k_5] \times 10^4$, L·mol^{-1}
NBA/TFA	0.387 ± 0.104	42.0 ± 1. 7	246 ± 18
NBCA/TFA	0.362 ± 0.053	22.5 ± 0.5	230 ± 10
NBCA/TFA-*d*	0.749 ± 0.206	14.4 ± 0.9	235 ± 17
NBA/TCA[b]	3.57 ± 0.31	2.86 ± 0.06	4.27 ± 1.19

[a] These results are obtained by treating the entire concentration–rate data sets using the weighted, nonlinear regression technique suggested by Wentworth (24).

[b] These data are computed from Bell's work (9) at 288 K, a temperature different from T = 323 K for the other substrate/acid systems reported here.

= 3.57 L·mol^{-1} found here. There are also favourable comparisons between the values of K_d(TFA/PhCl) = 0.387 and 0.362 L·mol^{-1} quoted in Table 5 and K_d(TFA/C_6H_6) < 1 L·mol^{-1} and K_d(TFA/$ClCH_2CH_2Cl$) ≃ 0.6 L·mol^{-1} calculated for 323 K from data estimated by Stevens (19). In view of these comparisons, the K_d values determined here appear to be of the correct order of magnitude.

The internal consistency of the data treatment is also good, inasmuch as K_d(TFA/PhCl) is reproducible from the kinetic results of two different systems, NBA/TFA and NBCA/TFA (see Table 5). Indeed, the two K_d values are much closer than might be reasonably expected since they represent the indirect determination of a parameter which is entirely dependent on the precision of a different primary observable, i.e., the kinetics of the systems. Hence, both the magnitude and reproducibility of the K_d values lend some credence to the approximations implicit in the rate law of eq. [17] when taken in conjunction with the monomer–dimer self-association model of eq. [1]. The large standard errors associated with the K_d values reported in Table 5 perhaps reflect the fact that carboxylic acid self-association is not confined to cyclic dimerization but that higher, "linear" polymers are also present (cf. refs. 21, 22). Nevertheless, while the concentrations of such species are apt to be appreciable for weaker carboxylic acids in chlorobenzene, concentrations of these linear polymers are likely to be much lower at comparable acid concentrations of stronger carboxylic acids, e.g., TFA and TCA (19, 21). Another consideration which might adversely influence the constancy of the K_d values is the association of catalytic acid with product. This effect, however, is likely to be

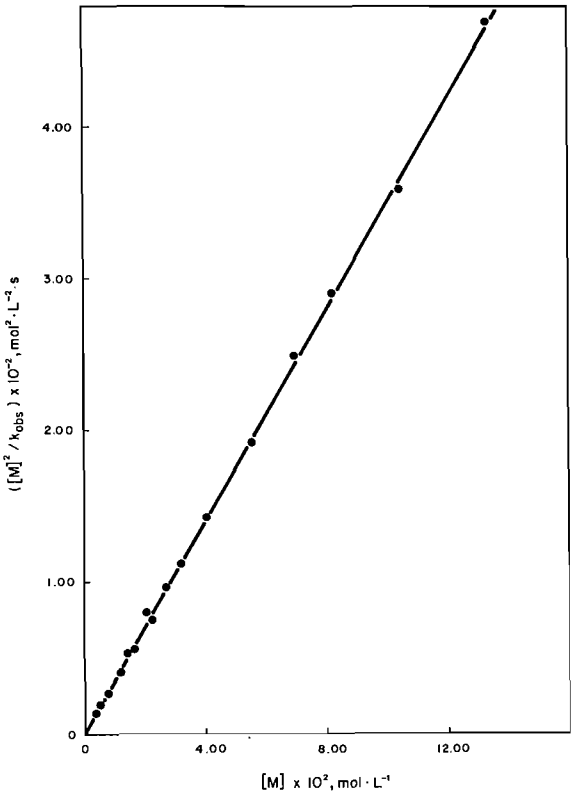

FIG. 4. The linear correlation of $[M]^2/k_{obs}$ versus [M] for the rearrangement of NBA catalyzed by TCA in chlorobenzene at T = 288 K.

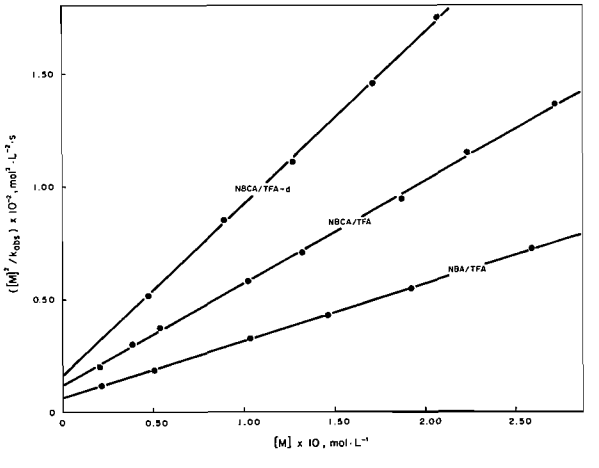

FIG. 5. The linear correlations of $[M]^2/k_{obs}$ versus [M] for the rearrangement of NBA catalyzed by TFA and the rearrangement of NBCA catalyzed by TFA and by TFA-*d* in chlorobenzene at 323.15 K.

minimized since the reactions were carried out under pseudo-first order conditions.

The standard errors associated with the rate constants quoted in Table 5 are much lower than those for the K_d values, indicating the values of k_1 and $k_2(k_4 + k_5)/k_3k_5$ are less sensitive to the acid self-association model. The k_1 values support the hypothesis that the first overall reaction step involves proton transfer in that k_1(NBA/TFA/323 K) > k_1(NBA/TCA/288 K) and k_1(NBCA/TFA/323 K) > k_1(NBCA/TFA-*d*/323 K), i.e., the rate of proton transfer diminishes with decreasing aqueous acid strength. Further, from a simple inductive consideration NBA is likely to be a better proton acceptor than NBCA. If the initial mechanistic step is proton transfer, this should and does result in k_1(NBA) > k_1(NBCA) for TFA/PhCl at the same temperature.

Within their standard errors, the rate constant ratios $k_2(k_4 + k_5)/k_3k_5$ are the same for the NBA/TFA, NBCA/TFA, and NBCA/TFA-*d* systems. This implies that these ratios are not very sensitive to substrate structure, with one inference being that participation of the second acid monomer is largely independent of substrate, a feature expected for our proposed mechanism. In view of this result it also seems plausible to assume that $k_5 \gg k_4$ in our mechanistic scheme, such that $k_2(k_4 + k_5)/k_3k_5 \simeq k_2/k_3$. This simplification seems to be in accord with the notion that a second acid monomer hydrogen bonds to the anionic moiety of the ion pair in the electrophilic catalysis of the species to π-complex. Since association via hydrogen bonding is apparently more favourable for weaker than for stronger carboxylic acids, the k_2/k_3 ratio might be expected to diminish with the increases in k_3 which accompany decreasing strength in the acid catalyst. This is apparently the case, viz. k_2/k_3(NBA/TFA/323 K) > k_2/k_3(NBA/TCA/288 K), where TCA, the weaker acid at a lower temperature, is likely to associate with the ion pair more readily than TFA in the k_3 reaction step.

In the present study the deviation of the order of reaction from unity with respect to TFA concentration clearly centers on the magnitude of $k_2(k_4 + k_5)/k_3k_5$. If, however, k_3 increases more rapidly than k_2 as the strength of the catalytic acid decreases and $k_5 >> k_4$, such that $k_2/k_3 << [M]$, the rate law will take the limiting form

$$[18] \quad k_{obs} = k_1[M]$$

for weaker carboxylic acid catalysts. Some support for these limiting simplifications in the rate law is forthcoming from an examination of the results for NBA/TCA/PhCl/288 K in Table 5 wherein $k_2(k_4 + k_5)/k_3k_5$ is small compared to the lowest [M]. The concentration–rate data for this system then should be amenable to treatment according to eq. [18] and this is indeed the case, with $K_d = 3.57$ and $k_1 = 2.86 \times 10^{-4}$ L·mol^{-1}·s^{-1}. The observation that the empirical rate law for catalysis by weaker carboxylic acids will take the limiting form of eq. [18] puts Bell's (9) contention that proton transfer is rate determining in the rearrangement into perspective. Since Bell's work centered mainly on the catalysis of NBA rearrangement by several carboxylic acids which are considerably weaker than TFA, the bulk of his results would be more or less empirically consistent with eq. [18]. Despite the fact that Bell's work suggests the participation of only a single acid monomer in the rearrangement and that proton transfer is entirely rate determining, we emphasize here that such a proposal is not consistent with our results for catalysis by TFA. Moreover, the simplest mechanism which will accommodate our observations is one which requires the successive participation of two monomeric acid species.

A further point with respect to the influence of $k_2(k_4 + k_5)/k_3k_5$ and K_d on the α,c_a profiles may be usefully added. Division of eq. [17] by eq. [5] gives

$$[19] \quad \alpha = \frac{k_1k_3k_5[M]}{\{k_2(k_4 + k_5) + k_3k_5[M]\}\{1 + 2K_d[M]\}}$$

Differentiation of eq. [19] with respect to c_a leads to the conclusion that the rate law given by eq. [17], when taken in conjunction with the concentration expression of eq. [5], will yield a maximum in the α,c_a coordinate system. The differentiation itself is lengthy, and for brevity we omit its entire description save to quote the result, namely,

$$[20] \quad c_{a\,max} = (2K_d)^{-\frac{1}{2}}(r)^{\frac{1}{2}} + r$$

where $r = k_2(k_4 + k_5)/k_3k_5$, the ratio of rate constants in the denominator of the rate law. In view of this result, eq. [17] is clearly the simplest rate law which can accommodate concentration dependent maxima in the α versus c_a plots for the NBCA/TFA, NBCA/TFA-*d*, and NBA/TFA systems (see Fig. 2). We reiterate that the same procedure, when applied to a simpler, single intermediate mechanism (see eq. [18]) or to Bell's rate law (see eq. [2]), will not yield a concentration dependent maximum in the α,c_a coordinate system. In consequence, these mechanistic schemes cannot accommodate our data for the stronger catalytic acids if the shallow maxima observed in the α,c_a plots for these acids are indeed real.

For a weaker carboxylic acid K_d will be larger than for a stronger one, and $c_{a\,max}$, the concentration at which the maximum occurs in the α,c_a coor-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

dinate system, will tend to be lower for a weaker acid, with the maximum lying closer to the α-axis. This effect is further enhanced since $k_2(k_4 + k_5)/k_3k_5 \simeq k_2/k_3$ is smaller for a weaker acid (see above). This point allows the resolution of a question outstanding in the previous discussion as to whether or not the apparent maximum in the α,c_a profile for the NBA/TCA system is real or spurious (see Fig. 1). From the data in Table 5, eq. [20] predicts a maximum at $c_{a\,max} = 1.56 \times 10^{-3}$ mol·L^{-1}, a concentration below the TCA concentration range examined by Bell (see Table 4). On this basis we can only conclude that the apparent maximum at $c_a = 1.3 \times 10^{-2}$ mol·L^{-1} in the α,c_a curve is indeed spurious. Even though a real maximum was not observed for this system at 288 K, maxima are evident for several substrates catalyzed by TCA at 318 K in chlorobenzene (11). Since only three acid concentrations were examined for these substrates, however, analysis of these data is limited to qualitative comment.

Isotope Effects

The fact that NBCA-2,6-d_2/TFA demonstrated no measurable isotope effect when compared with NBCA/TFA (see Table 1) would seem to support our contention that k_5 is large compared to the other rate constants (e.g., $k_5 >> k_4$, see above) and that the reaction steps from the first π-complex to product are relatively rapid. This observation, however, does not necessarily confirm (nor invalidate) the mechanistic considerations related to the final stages of the rearrangement, i.e., whether proton (or deuteron) loss with strong carboxylic acids may or may not become part of the rate determining step of the rearrangement.[10] Wolfsberg and co-workers (28–30) have argued on numerous occasions that the observation of isotope effects is a consequence of force constant changes between the ground and transition states. This is a necessary but not a sufficient condition for isotope effects to be observed since, as Streitweiser *et al.* (31) have pointed out, if there is no net change in the frequency sums of the vibrations between the two states, the isotope effect arising from other "non-zero point" sources is likely to be small. They specifically consider the problem of aromatically bonded hydrogen/deuterium and the behaviour of such systems in aromatic substitution. They explain the small isotope effects (31) by a cancellation in the frequency sums between reactants and transition states.

The small, normal isotope effect associated with proton/deuteron transfer for NBCA/TFA and NBCA/TFA-*d*, $k_1(H)/k_1(D) = 1.6$, is consistent with other observations for these processes between oxygen and nitrogen. The large, inverse isotope effect $K_d(H)/K_d(D) = 0.48$ for the association of TFA versus TFA-*d* is puzzling, however, since the gas phase dimerization does not appear to show any appreciable isotope effect (ref. 20, p. 367). Nevertheless, one might generally anticipate deuterated acids to display more association in solution than the related hydrogen acids since the deuterated acids are weaker.[11] By way of qualitative rationalization we again offer the Streitwieser zero point energy treatment which considers only the vibrations of the protium compound. The dimerization of an "*n* atom" carboxylic acid must give rise to six new vibrations since the reactants are characterized by $2(3n - 6)$ vibrations whereas the product is characterized by $6n - 6$ vibrations. The new vibrations generated in the dimerization involve hydrogen in an important way since the new links are through hydrogen. The frequency sum related to the six new motions may increase even if some of the force constants are reduced relative to the monomeric acid.[12] Such an increase would lead to an inverse effect.

Final Comments

The rates of rearrangement of the *N*-bromoacylanilides demonstrate a further complexity, namely, that in some cases the pseudo-first order rates at a fixed acid concentration are functions of the substrate concentration. This is well established for NBA/TCA in chlorobenzene (33), but the phenomenon is absent in the case of *N*-bromo-2-methylacetanilide/TCA in the same solvent (10). While the origins of these observations remain obscure, the rationalization of their behaviour proposed by Bell and Levinge (33) may be valid. Rearrangements of the *N*-chloro and *N*-iodo analogues are kinetically complex, and in some instances show drastic departures from pseudo-first order kinetics. This is in marked contrast to the *N*-bromoacylanilides, which are invariably well behaved in this respect (see, however, the *N*-bromobenzanilide/TCA system (34)). The erratic

[10]It should be noted that at any given acid concentration the simple ratio of the observed rate constants for NBCA/TFA and NBCA-2,6-d_2/TFA, $k_{obs}(H)/k_{obs}(D)$, does not provide $k_5(H)/k_5(D)$, the ratio required to establish the isotope effect for this final step.

[11]This is evident, for instance, in the case of D_2O and H_2O wherein D_2O is the more associated (32) and is also the weaker acid.

[12]Since the force constants are related to the motions of all of the atoms, force constants in the dimer cannot be compared rigorously with those originally present in the monomer. The qualitative nature of this argument is appreciated.

behaviour of the *N*-chloro and *N*-iodo compounds has been attributed to side reactions between substrate and product, and also to a reaction involving two substrate molecules. Unfortunately, these complexities prohibit clarification of the acid catalyzed mechanism since it is doubtful whether the carboxylic acid catalyzed component of the rearrangement can be quantitatively isolated from the other processes which contribute to the diminution of substrate.

The present communication strongly suggests that the Orton rearrangement in aprotic solvents is intramolecular and that the mechanistically significant steps in the advance to product are protonation of the substrate, heterolytic fission of the nitrogen–halogen bond, and rearrangement of the resulting ion pair to π-complex.

Received September 3, 1980

KARL R. KOPECKY, PETER A. LOCKWOOD, RODRIGO RICO GOMEZ, and JAN-YIH DING. Can. J. Chem. **59**, 851 (1981).

The title compounds have been isolated in crystalline form by cyclization of the corresponding bromo- or iodohydroperoxides. The activation parameters for thermolysis are, respectively (E_a, kcal/mol, ΔS^*, eu): 25.6 ± 0.6, 4 ± 2; 29.8 ± 0.4, 4 ± 2; 26.3 ± 0.5, 1 ± 2. The singlet $^1\phi$ and triplet $^3\phi$ excited state product yields produced on thermolysis of these compounds are, respectively: 0.011, 0.10; 0.0019, 0.18; 0.0013, 0.11. These yields are relative to a value of 0.31 for $^3\phi$ of tetramethyl-1,2-dioxetane. The cyclic 1,5-diones from thermolysis of the last two title compounds cyclized before isolation to give the bicyclic hydroxyketones.

KARL R. KOPECKY, PETER A. LOCKWOOD, RODRIGO RICO GOMEZ et JAN-YIH DING. Can. J. Chem. **59**, 851 (1981).

La cyclisation des bromo- ou iodo-hydroperoxydes correspondants permet d'isoler les composés mentionnés dans le titre, sous forme cristallisée. Les paramètres d'activation de thermolyse sont respectivement: (E_a kcal/mol, ΔS^*, u.e.): 25,6 ± 0,6, 4 ± 2; 29,8 ± 0,4, 4 ± 2; 26,3 ± 0,5, 1 ± 2. Les rendements en produits de l'état singulet $^1\phi$ et triplet $^3\phi$ excité, obtenus lors de la thermolyse de ces composés, sont respectivement de 0,011, 0,10; 0,0019, 0,18; 0,0013, 0,11. Ces rendements sont exprimés en fonction d'une valeur de 0,31 pour le $^3\phi$ du tétraméthyl-dioxétane-1,2. Les diones-1,5 cycliques provenant de la thermolyse des deux derniers composés mentionnés dans le titre se cyclisent avant d'être isolées en donnant les hydroxycétones bicycliques.

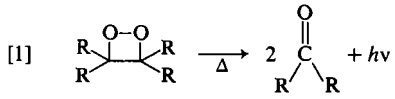
Thermolysis of 1,2-dioxetanes results in the formation of carbonyl cleavage products in quantitative yield and in light emission (1), eq. [1]. Both



singlet and triplet excited states are formed directly in the primary step of the reaction and the triplet almost always predominates by a large factor in the examples studied to date; for reviews see ref. 2. The factors which affect the yield of excited states and the triplet–singlet ratio are the subject of considerable investigation (3). The tricyclic dioxetane 3,4:3,4-dibutano-1,2-dioxetane **1**, prepared in order to study the effect of the rigidity of its structure on the rate of its thermolysis and the yield of excited states produced, was found to produce much smaller amounts of excited state products than were formed from the mono- and bicyclic dioxetanes trimethyl-, **2**, tetramethyl-, **3**, and *cis*-3,4-butano-3,4-dimethyl-1,2-dioxetane, **4** (4).

The present paper reports the preparation and thermolysis of three other tricyclic dioxetanes, 3,4:3,4-dipropano-1,2-dioxetane **5**, 3,4-butano-3,4-propano-1,2-dioxetane **6**, and 3,4-pentano-3,4-propano-1,2-dioxetane **7** in a test to determine whether the behaviour of **1** is general for dioxetanes of this structural type.

5 **6** **7**

Results

The preparation and chemical characterization of **5**, **6**, and **7** are shown in Schemes 1, 2, and 3, respectively. The route shown appears to be more convenient than previous methods (5) for the preparation of the alkene **8** on a large scale. The silver ion assisted cyclization (1*f*) of the corresponding β-halohydroperoxides was used to prepare the 1,2-dioxetanes. These products were characterized chemically by low temperature reduction with lithium aluminum hydride to the corresponding diols and by thermolysis to the diketones. The diketones **9** and **11** from **6** and **7** could not be isolated. They cyclized spontaneously to the corresponding ketols **10** and **12** (6). These were the only products that could be detected from ozonolysis of the corresponding alkenes and from the manganese dioxide oxidation of the corresponding diols. All three 1,2-

dioxetanes were crystallized from 2-methylbutane at −78°C to give yellow crystals. Solutions of **5** were stable, but crystalline material, freed of solvent, 92% active oxygen, always decomposed rapidly and completely, even at 0°C. Crystalline **7**, 99% active oxygen, was quite stable and **6**, 98% active oxygen, melted below room temperature to give a relatively stable yellow oil.

The rates of thermolysis, Table 1, of the 1,2-dioxetanes were measured by following the decay of luminescence of their aerated benzene or toluene solutions containing added 9,10-dibromoanthracene DBA (1*e*, 4). First order kinetics were obeyed for at least three half-lives of decomposition. Activation parameters were calculated (7) from the rate constants. Yields of excited singlet $^1\phi$ and triplet $^3\phi$ products formed on thermolysis of the 1,2-dioxetanes, Table 2, were determined from

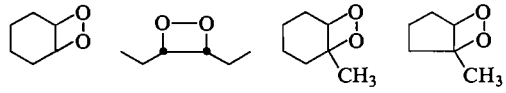
plots of the reciprocal of the light intensity vs. the reciprocal of the 9,10-diphenylanthracene, DPA, and 9,10-dibromoanthracene, DBA, concentrations, respectively (1*e*, 6). The spectrofluorimeter was calibrated using DBA solutions of **3** as a light standard. A value of 0.31 was used for the yield of excited triplet acetone formed from thermolysis of **3** (6).[4]

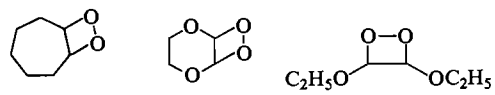
Discussion

Kinetics

The four tricyclic 1,2-dioxetanes **1**, **5**, **6**, and **7** undergo thermolysis with energies of activation that span a range of 7 kcal/mol. The rapid thermolysis of **1** is not at all general for tricyclic 1,2-dioxetanes. Neither is a somewhat decreased stability restricted to **1**, for two other 1,2-dioxetanes with 3,4-butano substituents are less stable than expected: **13**, E_a = 22.5 kcal/mol, is less stable than **14**, E_a = 24.5 kcal/mol (11); and **15**, E_a = 23.7 kcal/mol, is less stable than **16**, E_a = 25.2 kcal/mol, or **17**, E_a = 25.9 kcal/mol (12). However, the 1,2-dioxetanes **4** and **6**, which also have 3,4-dibutano substituents, have stabilities similar to that of **3** and are more stable than **1**, **13**, and **15**. Also, the 1,2-dioxetane **18** is as stable as **19** (3*a*), so that rather subtle effects appear to be involved in these thermolyses.



13 **14** **15** **16**



17 **18** **19**

The energies of activation for thermolysis of these bi- and tricyclic 1,2-dioxetanes could be calculated in principle with the assumption that the rate determining step is cleavage of the O—O bond to form a diradical, eq. [2] (13). The fusion of a

[2] 
1,2-dioxetane ring to a mono- or bicyclic ring system most likely will introduce a strain in addition to the sum of the strain energies of the component rings. There are no experimental values for the

[4] This value is based on the luminol light standard (8). The use of the luminol standard should yield apparent excited state yields that are smaller by a factor of ~2.5 (9) than those determined on the basis of the radioactive light standard (10) which is often used (1*e*, 2*a*). The value of 0.31 obtained for the yield of excited triplet acetone formed from **3** (4) compares well with the value of 0.3 which was based on the radioactive light standard (3*a*). A fortuitous combination of errors in our determination of this value (4) must have accumulated in order to make it equal to that obtained by using the radioactive standard. The excited state yields determined by us previously (4) and in the present paper of all the other dioxetanes can be compared directly relative to **3** even without regard to the correctness of the absolute values.

For personal use only.

heats of formation of bi- or tricyclic hydrocarbon molecules analogous to any of the above 1,2-dioxetanes from which one could estimate the magnitude of the extra strain energies. The extra strain energies probably vary from structure to structure since all the tricyclic 1,2-dioxetanes are calculated to have the same energies of activation for thermolysis if it is assumed that there is no extra strain energy or if all have the same extra strain energy.

Although a quantitative calculation of the energetics of the thermolysis of the various 1,2-dioxetanes cannot be made yet, some of the structural effects can be accounted for in a qualitative way. The cyclohexane ring in *cis*-bicyclo[4.2.0]octane is flattened at the side of the bridge and twisted at the other side (14). The distortion in the 1,2-dioxetane analogue should be similar. If the O—O stretching is accompanied by a twisting motion during decomposition (11), eq. [3],

[3] 
20 21

the extra strain energy will decrease as the diradical is formed. This might account for the lesser stability of **13** as compared with **14** and of **1** as compared with the other tricyclic 1,2-dioxetanes. The other tricyclic 1,2-dioxetanes all contain at least one five-membered ring. In cyclopentane the dihedral angle between the adjacent *cis*-bonds is smaller than in cyclohexane and the fusion of a 1,2-dioxetane ring to the corresponding bicyclic hydrocarbon ring systems to produce **5**, **6**, and **7** may not introduce as much extra strain energy as is present in **1**, **13**, and **15**. This would result in a higher energy of activation for decomposition of **5**, **6**, and **7**. There will be little, if any, twisting motion on opening of the 1,2-dioxetane ring in **5**, **6**, and **7** to the corresponding diradicals. Since **5** and **6** have stabilities similar to that of **3**, the twisting motion is not a required one for 1,2-dioxetane decomposition.

The 1,2-dioxetane **7** is extremely stable. Inspection of molecular models indicates that the "inside" hydrogen atoms on the carbon atoms adjacent to the bridgehead carbon atoms of the seven membered ring of **7** are forced closer together as the O—O bond is stretched. No such transannular interaction occurs when the O—O bonds of **1**, **5**, or **6** are stretched, and this may account, at least in part, for the much greater stability of **7**. A twisting motion can accompany the O—O stretch in decomposition of the bicyclic dioxetane **17** and the transannular H—H interaction can be much less than in **7**.

In comparing **4** (**20**, $R^1 = R^2 = CH_3$) with **15** (**20**, $R^1 = H$, $R^2 = CH_3$) there is relief of CH_3—CH_3 interaction by the twisting motion but an increase in this interaction as the O—O bond stretches in **4**. As well, the axial CH_3 interaction with CH_2 is increased as the twisting motion occurs. None of these interactions occurs in **15**, but it is not clear that the balance of these interactions should cause **4** to decompose with the higher energy of activation.

The 1,4-dioxane and cyclohexane rings have nearly the same shape (15) so that the extra strain energy in **18** and in **13** might be about the same. The diradical corresponding to **21** which is derived from **18** will be destabilized relative to that derived from **13** because of the anomeric effect (16) of an axial oxygen atom. However, the magnitude (17) of this effect is not large enough to account for all the greater stability of **18** over that of **13**, $\Delta E_a = 1.9$ kcal/mol (3*a*).[5]

Excited State Yields

The unusually low yield of excited state product found (4) to be produced on thermolysis of **1** is not general for tricyclic 1,2-dioxetanes. The yields of excited states formed from **5**, **6**, and **7** are greater than those from **1** by a factor of 10 to 20, although they are somewhat smaller than those, $^3\phi = \sim 0.25$ to ~ 0.5, from monocyclic 1,2-dioxetanes containing four alkyl substituents (3*b*). As has been found for mono- and bicyclic 1,2-dioxetanes, the yield of triplet products is much greater than that of excited singlet state products on thermolysis of all the tricyclic 1,2-dioxetanes. There is a large variation in yield of excited singlet state formed from the tricyclic 1,2-dioxetanes. These yields from **1** and **5** vary by a factor of about 2000. The rate of thermolysis of **5** in the presence of 10^{-2} *M* DPA was

[5] A referee has pointed out that an empirical correlation results by assuming that the ring strain correction for bicyclic dioxetanes can be obtained from the differences in ring strain between the cycloalkane and the cycloalkene. As shown below, the correlation places the energy of activation for decomposition of **13** and **17** within experimental error of that for the model **14** and places those for **15** and **16** within experimental error of each other:

Compound	E_a (exp.)[a]	Ring strain correction[a,b]	Corrected E_a[a]
14	24.5	0	24.5
13	22.5	1.4	23.9
17	25.9	−1.0	24.9
15	23.7	1.4	25.1
16	25.2	−0.4	24.8

[a] In kcal/mol.
[b] Cycloalkane–cycloalkene ring strain.

For personal use only.

within experimental error the same as that in the presence of 10^{-2} *M* DBA. This makes it unlikely that luminescence initiated by an electron transfer (18) from DPA to **5** contributes to the light emitted from solutions of **5** containing DPA. Thus, the yield of excited singlet state given in Table 2 for **5** is likely the true yield. The varying yields of excited singlet state formed to not appear to correlate with any structural factor.

In order to assess whether the low excitation yields from **1** were due to a lack of sufficient energy from the decomposition, the energies available for excitation of the carbonyl products from the tricyclic 1,2-dioxetanes were calculated, Table 3. The values of ΔH_r for reaction of **1**, **5**, **6**, and **7** will be maximum values, and therefore the values of the energy available for excitation, $E_a - \Delta H_r$, will be minimum values, as the calculations were made with the assumption that there is no extra strain energy in these molecules. These values of ΔH_r were obtained by adding the individual hydrocarbon ring strains (13*a*) to ΔH_r for **3**. In fact, as indicated above, there is likely to be extra strain energy in these molecules and its magnitude will vary from structure to structure. Another assumption that was made is that there is no strain energy in the product diketones (implying that they are born in their most stable conformation). This is likely to be so. The strain energies of cyclooctanone, cyclononanone, and cyclodecanone are 1.5, 4.6, and 3.6 kcal/mol, respectively (13*c*, 19). These strain energies are much smaller than those of the corresponding cycloalkanes. Molecular mechanics calculations show that introduction of a second carbonyl group into cyclodecanone reduces the strain energy by another 3 kcal/mole (20) so that the cyclic diones derived from **1**, **5**, and **7** must be nearly strain-free and that from **6** will have little more than 2 kcal/mol of strain energy at most.

The low yields of excited states produced from **1** are not caused by insufficient exothermicity, as the energy available, at least 93 kcal/mol, is sufficient to populate even the singlet, ~85–87 kcal/mol, as well as the triplet, ~77 kcal/mol, excited states. If **1** contains some extra strain energy, then there will be as much or more energy available from it as from **3**, which produces 30 times as much triplet excited state as does **1**. Thus it appears that the total energy available from thermolysis is not a factor in the amounts of excited states that are formed. Even **7**, from which there is at least 17 kcal/mol more energy available than from **3**, produces less excited triplet state product than does **3**.

It has been noted (3*c*) that there is a correlation between excited state yield and the energy of activation for a considerable number of 1,2-dioxetanes. This trend is obeyed by the tricyclic 1,2-dioxetanes studied here, with the compounds having the lowest and highest energies of activation for thermolysis producing respectively the lowest and highest yields of excited states.

TABLE 3. Calculated energies available for excitation

Dioxetane	$\Delta H_r^{a,b}$	$E_a - \Delta H_r^a$
1	−69	92
3	−69[c]	95
5	−83	108
6	−76	102
7	−83	113

[a] In kcal/mol.
[b] $\Delta H_r = \Delta H_f^\circ$ (carbonyl products) − ΔH_f° (dioxetane).
[c] A value of ~65 has been obtained experimentally (13*b*).

Mono- and bicyclic 1,2-dioxetanes have available to them a twisting motion that may accompany the opening of the ring to form the diradical. Any such motion must be quite restricted in the tricyclic 1,2-dioxetanes **5**, **6**, and **7**, yet this has little effect on excited state yields. The results show that a twisting motion is not necessary for the efficient production of excited states.

Experimental

Melting points and boiling points are uncorrected. Nuclear magnetic resonance spectra were recorded with Varian analytical spectrometers models HA-100, A-60, and A-56/60 (^{1}H spectra) using tetramethyl silane as internal standard and with a Brucker HFX 10 spectrometer (^{13}C spectra). Gas chromatography analyses were carried out on Aerograph 202 and A-90-P3 gas chromatographs. Infrared spectra were recorded on Perkin-Elmer Model 421 and Model 337 spectrophotometers. Refractive indexes were measured with a Bausch and Lomb Abbe-3L refractometer.

Anhydrous magnesium sulfate was used as drying agent and solvents were removed with a rotary evaporator unless otherwise noted. Iodometric analyses were carried out using the method of Organic Synthesis (21).

1(5)-Bicyclo[3.3.0]octene **8**

Hydroboration–oxidation of 1,5-cyclooctadiene produced 1,5-cyclooctanediol (22) which was oxidized (23) to 1,5-cyclooctanedione which was in turn cyclized with zinc amalgam in hydrochloric acid (5*e*, 24) to give *cis*-1,5-bicyclo[3.3.0]octanediol in 93% yield, mp 64.5–65.5°C (lit. (24*a*) mp 61.5–62°C). A mixture of 10.3 g (0.07 mol) of this diol and 10 g (0.07 mol) of triethyl orthoformate was placed in a bath at 130°C (25). Ethanol began to distill (through a short path distillation apparatus) after 10 min. This distillation was complete after 30 min, a small chip of sodium metal was added, and the residue was distilled to give 12.0 g (85%) of a clear oil, bp 74–76°C/3 Torr, n_D^{20} 1.4590. This reaction was very sluggish, even with added acetic acid, unless the diol had been recrystallized from carbon tetrachloride.

The mixed ortho ester was placed in a short path distillation apparatus, a few crystals of benzoic acid were added, and the mixture was heated to 180°C. After 5 h distillation was complete,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

the distillate was washed with water, dried ($CaCl_2$), and chromatographed through silica gel using pentane as the eluent to produce 5.6 g (86%) of **8**, a clear oil, bp 141–142°C/707 Torr, n_D^{20} 1.4836 (lit. (5*e*) bp 141°C/760 Torr, n_D^{20} 1.4832).

1(7)-Bicyclo[5.3.0]decene

A mixture of 1(2)- and 1(6)-bicyclo[4.4.0]decene obtained by reduction of tetralin with lithium in ethyl- and dimethylamine (26) was treated with performic acid (27) and from the reaction mixture *trans*-1,6-bicyclo[4.4.0]decanediol was isolated. The crude diol was converted with lead tetraacetate (27) to 1,6-cyclodecanedione which was in turn heated with hot aqueous sodium bicarbonate to give 1(7)-bicyclo[5.3.0]decen-2-one (28). This material decomposed on standing so unless it was used immediately it was reduced to the corresponding allylic alcohol with sodium borohydride (28).

A solution of 10 g (0.067 mol) of the ketone in 100 mL ether was added very slowly to a slurry made up from 30.6 g (0.29 mol) of aluminum chloride and 4.4 g (0.116 mol) lithium aluminum hydride and which had been stirred at 10°C for 15 min (29). After the addition was complete the reaction mixture was heated under reflux for one hour, then cooled and diluted with 200 mL ether. Sodium sulfate was added in small portions until gas evolution ceased. The pure white precipitate was filtered, washed with ether, and the combined filtrates were shaken with water and then dried. Solvent was removed and the residual yellow oil was distilled in a Kugelrohr apparatus to give a colorless oil. This was chromatographed on alumina using pentane as an eluent. Pentane was removed and the residue distilled to give 5.2 g (57%) of an oil, bp 193°C/700 Torr, n_D^{20} 1.4937 (lit. (30) bp 95°C/27 Torr, n_D^{20} 1.4935); ^{13}C nmr ($CDCl_3$): 137.16, 40.03, 30.75, 30.16, 27.76, and 22.39 ppm. *Anal.* calcd. for $C_{10}H_{16}$: C 88.16, H 11.84; found: C 88.41, H 11.71.

Either the ketone or the allylic alcohol could be used in this reduction. Attempts to convert the allylic alcohol to **9** using sodium in liquid ammonia, a procedure found to be useful for reduction of other allylic alcohols (31), always resulted in recovered starting material.

1(6)-Bicyclo[4.3.0]nonene

A mixture of 13 g indane, 9.0 g of lithium metal, and 350 mL of 1-propylamine was stirred under argon for 4.8 h (32). Ammonium chloride was then added until the reaction mixture remained colorless after which 200 mL ether and 200 mL water were added. The aqueous layer was extracted with ether and the combined ether layers were dried and concentrated. The residual oil was distilled (bad foaming) through a 10 cm Vigreux column to give 7.8 g (63%) of colorless oil, bp 165°C/710 Torr (lit. (33) bp 168–169°C/760 Torr).

3,4:3,4-Dipropano-1,2-dioxetane 5

To 4 mL ether at −40°C was added very slowly 1.7 g 98% hydrogen peroxide, then 1.0 g (9.2 mmol) **8**, and then in small portions over 1.5 h 1.75 g (4.6 mmol) 1,3-diiodo-5,5-dimethylhydantoin. The dark mixture was then stirred 15 min at −40°C, allowed to warm to −25°C over 20 min, and then poured into a mixture of 30 mL ice-water and 20 mL ether. The organic layer was washed quickly with cold water (2 × 20 mL), with small portions of cold 5% sodium thiosulfate solution until the iodine color was just discharged, with cold water, and dried at −20°C. It was then concentrated at 0°C to one-fourth its volume and 30 mL cold dichloromethane was added. The concentration and addition of dichloromethane was repeated twice more. The final solution was added to a stirred slurry of 5.5 g silver acetate in 30 mL dichloromethane. The resulting mixture was stirred at 0°C for 15 min, filtered through Celite, and the filtrate was washed with water, aqueous sodium bicarbonate, water, and then dried. Solvent was removed at 0°C to give a light yellow oil which was allowed to warm to 20°C under 0.01 Torr. The volatile material was trapped at −70°C to give a bright yellow oil which was stored at −70°C. The combined products of five such preparations were chromatographed at −40°C. The product was eluted as a yellow band with 95:5 pentane–ether. Solvent was removed at 0°C and the resulting bright yellow oil was recrystallized three times from 2-methylbutane at −70°C to give 0.27 g (4%) of pale yellow crystals of **5**, 92% active oxygen, which melted below room temperature.

Use of the bromohydroperoxide gave poorer yields of product. Neither the bromo- nor the iodohydroperoxide of **8** could be purified by chromatography or low temperature crystallization.

Solutions of **5** could be stored in aerated 2-methylbutane or benzene solution for many weeks but decomposed within a few seconds at room temperature when freed of solvent.

1-Bromo-6-hydroperoxybicyclo[4.3.0]nonane

Addition of 3.7 g (12.9 mmol) of 1,3-dibromo-5,5-dimethylhydantoin to a mixture of 3.0 g (25 mmol) of 1(6)-bicyclo[4.3.0]nonene and 3.75 mL (110 mmol) of 98% hydrogen peroxide in 25 mL ether at −5°C was carried out and the resulting reaction mixture worked up in the usual way (1*f*). After drying ($CaCl_2$) most of the solvent was removed at −10°C and the residual liquid was kept at −78°C overnight. Solvent was decanted from the crystals which formed. These were washed with cold ether and solvent was removed under 0.5 Torr at −10°C to give 2.8 g (47%) of crystals that decomposed within 60 s at room temperature, mp 43–46°C (dec., preheated bath). A satisfactory analysis was not obtained. This material was used directly for the preparation of the 1,2-dioxetane.

3:4-Butano-3:4-propano-1,2-dioxetane 6

A solution of 2.8 g (12 mmol) of the above product in 20 mL dichloromethane was added quickly to a suspension of 18 g (110 mmol) of silver acetate in 160 mL dichloromethane at 0°C. The reaction mixture became red during the addition and then rapidly turned pale yellow. It was stirred a further 20 min and filtered through Celite. The filtrate was shaken with water and with bicarbonate solution, dried, and concentrated at 0°C to give 1.9 g yellow liquid. This was applied to a 4 × 20 cm column of silica gel at −30°C and the column was eluted with 95:5 pentane–ether. The fractions (20 mL) were monitored by tlc and those containing only **6** were pooled and concentrated at 0°C to give 0.19 g (11%) of yellow oil which was taken up in 2 mL isopentane. Beautiful yellow crystals of **6** were deposited at −78°C which melted below 20°C after removal of solvent at −78°C to give a yellow liquid, 98.4% active oxygen. The stability of pure **6** at 20°C is much greater than that of **5**.

Later fractions of the chromatography contained a single compound which was tentatively identified from its infrared and nmr spectra as an allylic hydroperoxide, 0.8 g (47%).

3:4-Pentano-3:4-propano-1,2-dioxetane 7

This 1,2-dioxetane was prepared from the iodohydroperoxide using the procedure described above for the preparation of **5**, except that the crude product obtained from the silver acetate reaction was not subjected to low pressure distillation. From 2.0 g of 1(7)bicyclo[5.3.0]decene there was obtained 2 g yellow oil which was adsorbed in four portions on a 1 × 20 cm column of silica gel at −40°C. The column was eluted with 4:1 pentane–ether. The fractions containing the yellow bands from the four chromatographies were combined and rechromatographed as before. The product was recrystallized four times from 2-methylbutane at −78°C to give 0.65 g (26%) of yellow needles, mp 57–59°C, 99.5% active oxygen, which appeared to be quite stable at 20°C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

Characterization of 5

Solvent was removed at 0°C from a sample of **5** in pentane. After about 30 s at 20°C the residual yellow liquid had turned into white crystals (50 mg) which consisted (tlc) of a major and a minor component. Column chromatography on silica gel using ether as eluent gave 42 mg (84%) of 1,5-cyclooctanedione, mp and mixture mp 71–72°C.

A solution of 46 mg **5** in 5 mL pentane was added to a stirred slurry of 90 mg lithium aluminum hydride in 20 mL ether at −78°C. Sodium sulfate decahydrate was then added to the reaction mixture until no more hydrogen was evolved. The precipitate was filtered, washed with ether, and the combined filtrates dried and concentrated to an oil which was taken up in 10 mL benzene. The benzene was evaporated. The evaporation with benzene was repeated once more and left 41 mg (87%) of white crystals, mp and mixture mp with authentic *cis*-1,5-bicyclo[3.3.0]octanediol 64–65.5°C.

cis-*1,6-Bicyclo[4.3.0]nonanediol*

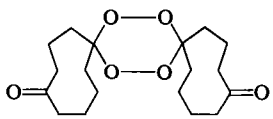
A mixture of 0.55 g (3.5 mmol) of 1(6)-bicyclo[4.3.0]nonene and 1.0 g (3.9 mmol) of osmium tetroxide in 25 mL ether was stirred at 20°C for 24 h. The reaction mixture was filtered and the precipitate was boiled with a solution of 5 g sodium bisulfite in 25 mL ethanol and 100 mL water for 14 h. The reaction mixture was filtered, the filtrate was concentrated to half its volume and extracted with methylene chloride. The organic layer was dried, and concentrated to yield 0.35 g (61%) of white crystals, mp 64–66°C (lit. (33) mp 67–67.5°C).

6-Hydroxybicyclo[4.3.0]nonan-2-one

A mixture of 0.12 g of the above diol and 1.1 g of manganese dioxide (34) in 5 mL methylene chloride was stirred at 22°C for 3 h and then filtered. Removal of the solvent left a viscous oil, homogeneous on tlc with a different R_f from starting material, which showed strong absorption in the infrared spectrum at 3500 and 1700 cm^{-1}. This was presumably 6-hydroxybicyclo[4.3.0]nonan-2-one. Yellow crystals were initially deposited on preparation of the 2,4-dinitrophenylhydrazone. These quickly turned red when the reaction mixture was warmed. The product was recrystallized from methanol–chloroform to give red needles, mp 248–250°C (lit. (35) mp 250°C for the 2,4-dinitrophenylhydrazone of 1(6)-bicyclo[4.3.0]nonen-2-one).

Ozonolysis of 1(6)-Bicyclo[4.3.0]nonene

Ozone was passed through a solution of 2 g of the alkene in 50 mL methylene chloride at −78°C (until the blue color persisted). A solution of dimethyl sulfide in methylene chloride was added. The reaction mixture was allowed to warm to 22°C and washed several times with water. The solvent was removed to give a white solid which was recrystallized from ether to give 0.3 g of a white powder, mp 180°C (lit. (33) mp 180°C for



A mixture of 170 mg of this material and 50 mg platinum dioxide in 30 mL dioxane was stirred under hydrogen for 18 h. Removal of catalyst and solvent left an oily solid which gave 50 mg white powder on crystallization from ether, mp 190°C; ms(CH_5^+) *m/e*: 341.1976 ($M^+ + 1$, $C_{18}H_{24}O_6 + H^+$ required 341.1964). *Anal.* calcd. for $C_{18}H_{24}O_6$: C 63.51, H 8.23; found: C 63.33, H 8.43. It has not been possible yet to isolate 1,5-cyclononanedione (33, 35, 36).

Characterization of 6

Reduction of 9 mg of **6** with lithium aluminum hydride as described for **5** gave a trace of an oil which was homogeneous on tlc and had the same R_f value as that of *cis*-1,6-bicyclo[4.3.0]nonanediol.

A solution of toluene containing 2 mg of **6** was heated at 80°C for 4 h; tlc of resulting solution revealed one product with R_f the same as that of 6-hydroxybicyclo[4.3.0]nonan-2-one.

cis-*1,7-Bicyclo[5.3.0]decanediol*

A mixture of 0.53 g (3.9 mmol) of 1(7)-bicyclo[5.3.0]decane and 1.0 g (3.9 mmol) of osmium tetroxide in 40 mL ether was allowed to react and the mixture worked up as described for the preparation of *cis*-1,6-bicyclo[4.3.0]nonanediol to give a yellow oil. This was chromatographed on silica gel using ether as eluent. The product was colorless oil, 0.45 g (68%), ir ν_{max} (neat): 3460; ^{13}C nmr ($CDCl_3$): 82.21, 43.43, 39.27, 30.53, 22.82, and 21.01 ppm. *Anal.* calcd. for $C_{10}H_{18}O_2$: C 70.55, H 10.66; found: C 70.56, H 10.62.

1(6)-Bicyclo[4.4.0]decen-2-one

Ozone in an argon stream (37) was passed through a solution of 0.25 g 1(7)-bicyclo[5.3.0]decene in 40 mL ethyl acetate at −78°C until a blue color just persisted. The resulting solution was allowed to warm to 0°C while passing through a stream of argon. Platinum black, 200 mg, was then added and the mixture was stirred under an atmosphere of hydrogen for several hours. Removal of the catalyst and solvent gave 0.29 g (94%) of a colorless oil which showed strong absorption at 3480 as well as at 1705 in the infrared spectrum and was presumably the cyclized ketol *cis*-6-hydroxybicyclo[4.4.0]decan-2-one **12** (6). The oil was warmed a few minutes with 25 mL methanolic 1% potassium hydroxide. Work-up and removal of solvent gave 0.24 g (92%) of a light yellow oil, n_D^{20} 1.500, semicarbazone mp 243–245°C, oxime mp 147–148°C (lit. (38) for 1(6)-bicyclo[4.4.0]decen-2-one, n_D^{20} 1.4931, semicarbazone mp, 246–247°C, oxime 148–149°C).

Attempts to isolate the diketone **11** from oxidation of *cis*-1,7-bicyclo[5.3.0[decanediol with active manganese dioxide (37) were also unsuccessful. Only the oily cyclic ketol **12** was obtained.

Characterization of 7

Reduction of 50 mg of **7** with lithium aluminum hydride as described for **5** gave 46 mg (91%) of an oil which was identical (tlc and infrared) with the *cis*-1,7- bicyclo[5.3.0]decanediol prepared as described above.

A 100 mg sample of **7** in 5 mL benzene was heated at 100°C for 15 h in a sealed tube. Removal of benzene gave 100 mg of an oil whose infrared spectrum was very similar to that of the ketol **12** prepared as described above.

Kinetic Studies

The rates of decay of luminescence of solutions of the 1,2-dioxetanes containing DBA or DPA were measured using the apparatus previously described (1*f*). The results are presented in Table 1.

Excited State Yields

The apparatus and methods used have been described (4). Plots of the reciprocal of the light intensity vs. the reciprocal of the fluorescer concentration for solutions of the dioxetanes were made and light intensities at infinite fluorescer concentration (DBA for triplet yields, DPA for singlet yields) determined from the intercepts of the plots. The apparatus was calibrated with a toluene solution of **3** containing DBA (4) at 44.8°C. The yield of triplet acetone formed from **3** was taken to be 31% and the efficiency of energy transfer from the triplet excited ketones to give singlet excited DBA was taken as 0.2 (2*a*). The fluorescence efficiency of DPA was taken to be 1 at all temperatures

studied and the fluorescence efficiences of DBA at 25, 45, and 69°C were calculated to be 0.093, 0.065, and 0.036, respectively (3*a*).

Interactions gauches et chemins réactionnels. Etudes conformationnelles d'hydroxyalkyl-4 cyclohexènes contraints

JEANINE BOUTEILLER-PRATI, JEAN-CLAUDE BOUTEILLER ET JEAN-PIERRE AYCARD[1]

Laboratoire de Chimie Organique Structurale, Université de Provence, 13, Rue Henri Poincaré, 13397 Marseille, Cedex 13, France

Reçu le 11 février 1980[2]

JEANINE BOUTEILLER-PRATI, JEAN-CLAUDE BOUTEILLER et JEAN-PIERRE AYCARD. Can. J. Chem. **59**, 859 (1981).

L'étude par rmn des alcools obtenus par addition de CH_3Li ou $AlLiH_4$ au carbonyle exocyclique des alkyl-3 méthoxycarbonyl-4 (acétyl-4) cyclohexènes *cis* et *trans* (alkyl = H, CH_3 ou $C(CH_3)_3$), permet d'accéder aux paramètres J et δ. A partir des valeurs des constantes de couplage expérimentales, on détermine les enthalpies libres conformationnelles (ΔG^0_X) des substituants méthylcarbinol et diméthylcarbinol (−0,62 et 2,08 kcal mol^{-1} respectivement) ainsi que les équilibres conformationnels des différents alcools. Pour R = *tert*-butyle, la nette prépondérance du conformère diaxial des isomères *trans* permet d'envisager une addition à partir des conformères de plus haute énergie.

JEANINE BOUTEILLER-PRATI, JEAN-CLAUDE BOUTEILLER, and JEAN-PIERRE AYCARD. Can. J. Chem. **59**, 859 (1981).

From J and δ values determined by the nmr study of alcohols obtained by addition of CH_3Li and $LiAlH_4$ to the exocyclic carbonyl of *cis* and *trans* 3-alkyl 4-carbomethoxy (or acetyl) cyclohexenes (alkyl = H, CH_3, $C(CH_3)_3$), we have deduced the conformational free energy values (ΔG^0_X) of the $CH(CH_3)OH$ and $C(CH_3)_2OH$ substituents (0.62 and 2.08 kcal mol^{-1} respectively) as well as the values for some related conformational equilibria. For *trans tert*-butyl derivatives the stability of the diaxial conformer agrees with a reaction path involving high energy conformers.

Introduction

S'il est bien connu que la proportion et la nature des produits de réaction ne dépend que de la différence d'énergie libre des états de transition (1), pour des structures présentant un équilibre conformationnel, il existe peu d'exemples dans la littérature d'intervention préférentielle des conformères de haute énergie (2, 3).

Ayant mis en évidence un tel comportement dans des dérivés substitués en position 4 du *tert*-butyl-3 cyclohexène (3) nous avons essayé dans le présent travail de relier l'intervention de ces conformères "peu stables" au développement des contraintes stériques dans l'état de transition.

Pour ce, nous avons entrepris une étude structurale et conformationnelle par rmn d'alcools résultants d'une addition nucléophile sur la fonction carbonyle exocyclique d'alkyl-3 acétyl-4 ou méthoxycarbonyl-4 cyclohexènes (alkyl = H, méthyl, *tert*-butyl). En effet, pour ce type de réaction, nous pouvons envisager que dans l'état de transition, l'accroissement des contraintes stériques entre les substituants vicinaux, provenant du passage d'un carbone hybridé sp^2 à un carbone de type sp^3, va se traduire par d'importantes modifications conformationnelles et qu'il sera possible de favoriser des chemins impliquant des conformères de haute énergie qui seront moins contraints dans l'état de transition.

Résultats expérimentaux

Les différents alcools (cf. Schéma 1) sont obtenus (cf. Partie expérimentale) par addition de CH_3Li ou des hydrures $LiAlH_4$ et Sélectride sur la fonction carbonyle d'alkyl-3 acétyl-4 ou méthoxycarbonyl-4 cyclohexènes (alkyl = H, CH_3, $(CH_3)_3C$). D'une manière générale et malgré l'utilisation de molécules deutériées en position allylique (4), les spectres de rmn relatifs au protons H_1, H_2 et H_3 (cf. Schéma 1) sont de type ABC partiellement masqués par les signaux des groupements alkyles.

SCHÉMA 1. Numérotation des composés*

	R		
X	H	CH_3	$C(CH_3)_3$
$CHCH_3OH$	**10**		**30***t*
$C(CH_3)_2OH$	**11**	**21***c*	**31***t*
		21*t*	
CH_2OH	**12**	**22***c*	**32***c*
		22*t*	**32***t*

*L'indice *c* ou *t* est relatif α la position respectivement *cis* ou *trans* des substituants. Pour faciliter les comparaisons nous avons utilisé la même numérotation que dans les réferences 4 et 10, les protons exocycliques sont numérotés H_6 et H_7.

*Solvant: CCl_4, T = 303 K, δ en ppm par rapport au TMS, *J* en Hz.

Afin de pouvoir les analyser nous avons utilisé un réactif de déplacement l'Eu(FOD)$_3$-D-27; les paramètres ainsi déterminés sont regroupés dans le Tableau 1.

Analyse des spectres de rmn

Lors de l'attaque d'un ion hydrure sur les alkyl-3 acétyl-4 cyclohexènes, il peut se former *a priori* deux diastéréoisomères suivant l'entrée du réactif par l'une ou l'autre des faces du carbonyle.

Dans ce cas, les spectres rmn des produits se compliquent par la superposition des signaux des deux isomères *thréo* et *érythro*, et seuls les paramètres du diastéréoisomère majoritaire de **10** et **30*t*** obtenu par action du Sélectride ont pu être déterminé. L'utilisation de cet hydrure encombré permet en effet d'augmenter la diastéréosélectivité de la réaction qui passe de 50% à 90%. Cependant, malgré cette préférence (5) et contrairement aux résultats observés en série cyclique (6), l'existence dans nos composés de trois conformères acycliques (7) pour chacune des deux conformations cycliques possibles (4) empêche toute prévision suivant l'un des modèles de Cram et Abd Elhafez (8) ou de Felkin et coll. (9); il est donc impossible d'attribuer à ce diastéréoisomère la stéréochimie *thréo* ou *érythro*.

Le spectre du composé **10** présente à δ = 5,10 et δ = 2,92 ppm deux singulets correspondant respectivement aux protons éthyléniques et au proton du groupement hydroxyle; à δ = 1,24 ppm on observe un doublet (*J* = 6,7 Hz) attribué aux protons du groupement méthyle. Le reste du spectre se compose d'un multiplet à 3,46 ppm facilement identifiable au proton H_6 du groupement méthylcarbinol, de quatre raies attribuables au signal du proton H_2, ainsi qu'à δ = 1,48 ppm d'un système complexe qui peut être attribué au signal du proton H_1 couplé par trois autres protons. Le signal du proton H_3 en partie recouvert par celui du groupement méthyle apparait sous la forme de quatre raies centrées à δ = 1,28 ppm dont l'attribution est confirmée par l'existence de deux grandes constantes de couplage (−13 et 9,4 Hz).

Sans réactif de déplacement, le diastéréoisomère majoritaire (90%) **30*t***, obtenu par réduction à l'aide du Sélectride du *trans tert*-butyl-3 trideutérioacétyl-4 cyclohexène D_3-3,6,6, présente essentiellement un spectre de type AB centré à 5,75 ppm correspondant au signal des protons éthyléniques et un doublet à δ = 3,50 ppm identifiable au proton exocyclique H_6. Les autres protons et le signal du *tert*-butyle compris entre 0,80 et 1,80 ppm ne peuvent être résolus. Après addition d'Eu(FOD)$_3$-D-27, tous les protons du cycle sont différenciés: à δ = 2,58 ppm, on observe un massif composé de cinq raies attribuable au proton H_1 couplé à trois autres protons; centrés à 2,0 et 2,15 ppm apparaissent deux massifs composés de quatre raies présentant une grande constante de couplage (*J* = 14,5 Hz) correspondant vraisemblablement à la constante *gem* et deux petites constantes (*J* = 4,2 et 3,4 Hz respectivement) qui indiquent malgré l'ambiguité d'attribution une position préférentiellement axiale du substituant méthylcarbinol.

TABLEAU 2. Equilibres conformationnels des alcools

Composé	$\langle {}^3J_{13} \rangle$	x_e*	$\Delta G^0 = G_e - G_a$ kcal mol^{-1}
10	9,4	0,74	$-0,62 \pm 0,02$
30*t*	4,2	0,22	$+0,77 \pm 0,06$
	3,4	0,14	$+1,10 \pm 0,07$
11	11,7	0,97	$-2,08 \pm 0,02$
21*t*	8,4	0,64	$-0,34 \pm 0,03$
31*t*	5,8	0,38	$+0,29 \pm 0,04$
12			$-0,9$ (7)
22*t*		0,92	$-1,5$ (6)
22*c*	10,4		$-0,9$ (6)
32*c*	5,5	0,35	$+0,37 \pm 0,04$
32*t*	3,8	0,18	$+0,92 \pm 0,06$
	2,9	0,09	$+1,40 \pm 0,08$

*x_e = Fraction molaire du conformère à substituant équatorial en position 4 sur le cyclohexène calculée à partir des paramètres J_{ee} = 2 Hz et J_{aa} = 12 Hz.

En présence de réactif de déplacement, le spectre du composé **11** présente à $\delta = 5,70$ ppm un singulet correspondant aux protons éthyléniques et trois massifs distincts entre 1 et 3 ppm. Le proton H_3 est facilement attribuable au triplet centré à 1,67 ppm, l'observation de deux grandes constantes de couplage (J = 12 Hz et J = 11,7 Hz) indiquant une position équatoriale préférentielle du groupement diméthylcarbinol. Les protons H_1 et H_2 se présentent sous forme de deux massifs de quatre raies chacun, centrés respectivement à 2,45 ppm et 2,27 ppm. L'attribution de ces protons a été effectuée en considérant leurs constantes de couplage avec H_3 et en prenant ${}^2J_{23} = -12$ Hz.

Le spectre du composé **21***t* obtenu en présence de sel de lanthanide présente pour les protons du cycle un système de type ABX, partiellement recouvert par les signaux des deux groupements méthyles du carbinol, et dont les massifs de quatre raies centrés à δ = 4,00, 3,00 et 3,11 ppm sont facilement attribuables respectivement aux protons H_1, H_3 et H_2. Les protons éthyléniques apparaissent sous forme d'un système AB.

Pour le composé **21***c*, l'addition d'Eu(FOD)$_3$-D-27 conduit à un déplacement simultané des signaux des protons du cycle et des groupements méthyles sans qu'il soit possible d'en éliminer la superposition et seule la partie du spectre correspondant aux protons éthyléniques ($\delta_4 = 5,56$ ppm, $\delta_5 = 5,48$ ppm, $J_{45} = -10,4$ Hz) peut être exploitée.

L'analyse du spectre de **31***t*, analogue à celui de **21***t* ne présente pas de difficulté. L'existence des deux petites constantes de couplage entre les protons H_1H_2 et H_1H_3 semble indiquer, dans l'hypothèse d'une conformation demi-chaise, une préférence axiale du substituant diméthylcarbinol.

Pour le composé **31***c* comme pour **21***c* l'utilisation d'Europium ne permet pas d'exploiter le spectre de rmn car les signaux de groupements méthyles du diméthyl carbinol se déplacent en même temps que ceux des protons du cycle.

Dans le cas des composés **32***c* et **32***t* l'ensemble des paramètres de rmn (cf. Tableau 1) sont obtenus à partir des modifications isotopiques D_3 et D_5 provenant de la réduction des *tert*-butyl-3 méthoxycarbonyl-4 cyclohexènes D_3-3,6,6 *cis* et *trans* par $LiAlH_4$ et $LiAlD_4$ respectivement. En présence de réactif de déplacement les spectres de type AMX et ABX ne présentent pas de difficultés particulières. Au niveau du substituant exocyclique le spectre de **32***c* se compose d'un doublet correspondant aux deux protons H_6 et H_7 couplés à H_1 avec une constante de 7,4 Hz. Pour **32***t*, on observe un spectre de type ABX composé d'un triplet à δ = 3,47 ppm (J = 10,2 Hz) et de quatre raies centrées à δ = 3,78 ppm correspondant à des couplages de 10,2 et 4,2 Hz.

Conformation cyclique (cf. Tableau 2)

A partir des constantes expérimentales $\langle {}^3J_{13} \rangle$[3] entre les protons *trans* portés par les carbones C-4 et C-5 et les constantes spécifiques estimées dans un travail précédent (10), $2 < J_{ee} < 5$ Hz et J_{aa} = 12 Hz, il est possible de déterminer les populations des différents conformères en équilibre, ainsi que les différences d'énthalpie libre qui leur sont associées. Ces valeurs sont regroupées dans le Tableau 2, nous y avons joint celles obtenues par Mackay (11) sur l'hydroxyméthyl-4 cyclohexène **12**, ainsi que celles relatives aux méthyl-3 hydroxyméthyl-4 cyclohexènes **22***c* et **22***t* (10).

Pour les dérivés monosubstitués **10** et **11** les valeurs obtenues correspondant aux enthalpies libres conformationnelles des substituants en position 4 sur le cyclohexène, $\Delta G^0_{CHCH_3OH} = -0,62 \pm 0,02$ kcal mol^{-1}; $\Delta G^0_{C(CH_3)_2OH} = -2,08 \pm 0,02$ kcal mol^{-1} ($-2,18$ kcal mol^{-1}) (11).

Ces résultats confirment la préférence équatoriale des substituants en position 4 sur le cyclohexène. Il faut noter toutefois la préférence équatoriale très marquée du groupement diméthylcarbinol homomorphe d'un groupement *tert*-butyle.

Pour le composé **32***c*, la faible valeur de J (5,5 Hz, cf. Tableau 1) implique une préférence axiale du substituant en position 4, analogue à celle observée pour le *tert*-butyl-3 méthoxycarbonyl-4 cyclohexène (ΔG^0 = 0,3 kcal mol^{-1}) (4*a*).

[3]Nous avons montré dans un travail cristallographique récent (cf. réf. 13*b*) que pour ce type de dérivés la valeur de l'angle dièdre ϕ_{45} était peu soumise à variation (cf. Table 1, réf. 13*b*). Cette variation maximum $\Delta\phi \simeq 4°$ correspondrait à un $\Delta J \simeq$ 0,7 Hz trop faible pour influencer notablement la valeur de ΔG^0.

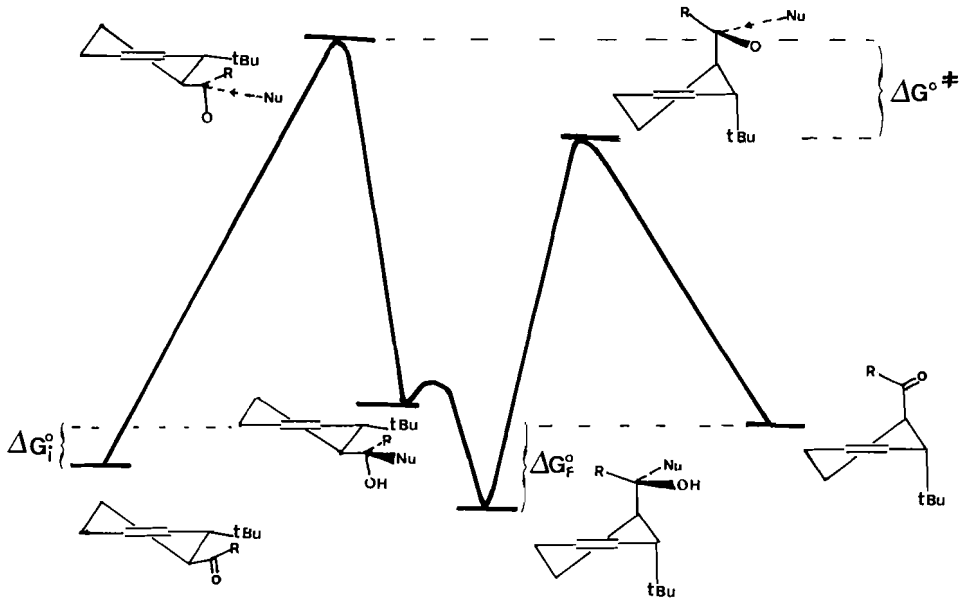

SCHÉMA 2

Dans le cas des alcools tertiaires **11**, **21***t*, **31***t* on observe une augmentation de la valeur du ΔG^0 avec la taille du substituant R (de $\Delta G^0 = -2{,}1$ kcal mol^{-1} pour R = H à $\Delta G^0 = +0{,}29$ kcal mol^{-1} pour R = *tert*-butyle). Ce résultat illustre bien la déstabilisation des conformères diéquatoriaux sous l'effet d'une interaction diéquatoriale entre un groupement encombrant $C(CH_3)_2OH$ homomorphe d'un *tert*-butyle et un groupement R vicinal.

La dernière remarque que nous pouvons faire est relative à l'ensemble des dérivés *tert*-butylés **30***t*, **31***t*, **32***t*. Pour ces dérivés analogues aux di-*tert*-butyl-3,4 cyclohexènes *trans*, nous obtenons de petites constantes de couplage J_{13} (4,2 ou 3,4, 5,8 et 3,8 ou 2,9 Hz), qui dans l'hypothèse d'une conformation demi-chaise ou sofa (12), indiquent une nette préférence pour des conformères à groupement *tert*-butyle pseudo-axial.[4] Cette valeur élevée des populations de conformères diaxiaux (≥ 60%) supérieure à celle observée pour les homologues *tert*-butyl-3 cyano-4 ou méthoxycarbonyl-4 cyclohexènes (4) est vraisemblablement due à l'augmentation de l'encombrement stérique du substituant exocyclique,[5] qui dans nos composés, est équivalent à un groupement méthyle ou *tert*-butyle.

Interactions gauches et chemins réactionnels

A partir des résultats obtenus dans le paragraphe précédent, nous pouvons envisager une hypothèse quant à la nature du conformère impliqué dans l'attaque du nucléophile. En effet, conformément au principe de Hamond (1), celle-ci aura lieu sur le conformère conduisant à l'état de transition de plus basse énergie, c'est-à-dire sur celui dans lequel les contraintes stériques seront minimales.

Si pour les dérivés monosubstitués, l'approche du réactif se traduit par une augmentation de l'encombrement stérique qui n'affecte pas la plus grande stabilité des conformères équatoriaux (cf. Tableau 2, composés **10**, **11**, **12**). Pour les dérivés disubstitués en 3,4, et particulièrement pour les isomères *trans*, le passage du carbone sp^2 du carbonyle à une hybridation sp^3 conduit à une déstabilisation importante des conformères diéquatoriaux.[6]

Dans ces conditions, nous pouvons envisager

[4]Pour ces composés, l'évolution de la valeur ΔG^0 qui conduit à une diminution de la fraction molaire des conformères diaxiaux en passant de **30***t* à **32***t* peut s'expliquer par l'existence de deux phénomènes antagonistes: d'une part, la déstabilisation du conformère diéquatorial sous l'effet de l'interaction entre les substituants *tert*-butyle et CR_2OH, et d'autre part une stabilisation de celui-ci due à la préference conformationnelle du substituant CR_2OH.

[5]Dans un travail récent (13) il a été montré que l'une des causes possibles de l'existence d'une hétérogénéité conformationnelle dans cette série, était la courte distance existant entre le carbone central du substituant en position 4 et les carbones du groupement *tert*-butyle.

[6]Alors que pour les *t*-Bu-3 méthoxycarbonyl-4 ou acétyl-4 cyclohexènes *trans* (4) la fraction molaire de l'isomère diéquatorial est de l'ordre de 0,75 pour les composés **30***t*, **31***t* et **32***t* elle est inférieure à 0,40.

pour ces dérivés (cf. Schéma 2) un chemin réactionnel issu du conformère de haute énergie à substituants diaxiaux, énergétiquement favorisé dans l'état de transition.

Conclusion

Ce travail nous a permis de déterminer les équilibres conformationnels d'une série de carbinol, méthylcarbinol et diméthylcarbinol-4- cyclohexènes diversement substitués en position 3. Les résultats obtenus pour les stéréoisomères *trans tert* -butylés en 3 permettent d'envisager une addition sur le conformère diaxial.

Partie expérimentale

Toutes les synthèses ont été effectuées sur des stéréoisomères purs préalablement séparés par chromatographie en phase vapeur préparative. La synthèse des cétones et des esters utilisés a déjà été décrite (4).

Les alcools primaires et secondaires ont été préparés suivant la méthode générale indiquée ci-dessous.

Dans un ballon équipé d'un réfrigérant muni d'un piège à chlorure de calcium, d'une ampoule à verser et d'une agitation magnétique, on introduit $LiAlH_4$ en suspension dans de l'éther anhydre. On verse ensuite goutte à goutte la cétone ou l'ester en solution éthérée ($LiAlH_4$ est en excès). Lorsque l'addition est terminée, on porte à reflux pendant une heure tout en maintenant l'agitation. On effectue ensuite une hydrolyse basique du mélange réactionnel (14). L'alumine formée est filtrée sur verre fritté. On lave ensuite le mélange réactionnel avec une solution saturée en chlorure de sodium, puis on sèche sur $MgSO_4$ anhydre. Le mélange réactionnel est analysé par chromatographie en phase vapeur (cpv) dans les conditions suivantes: Chromatographe Girdel Série 3000 équipé d'un détecteur à ionisation de flamme; gaz vecteur: azote, débit $\simeq$ 10 cm³/min; température injecteur 200°C; température détecteur: 215°C; colonne en acier inoxydable de 1/8 po de diamètre et de 3 m de long, remplie de Chromosorb W(NAW) 60/80 mesh, imprégné de polyéthylèneglycol 4000 à 20% en poids.

tert-*Butyl-3 méthylcarbinol-4 cyclohexène* trans ***30***t

On fait réagir 0.25 g ($1.4 \cdot 10^{-3}$ mol) de *tert*-butyl-3 acétyl-4 cyclohexène *trans* (*4b*) et 0.014 g ($3.5 \cdot 10^{-3}$ mol) de $AlLiH_4$. Le rendement est de 98%; cpv: température 140°C; tr: 50,0 min; ir (CCl_4) ν_{max}: 3630 et 3450 (—OH), 3030 (=C—H), 1650 (C=C) cm^{-1}.

On synthétise de la même manière le *tert*-butyl-3 méthylcarbinol-4 cyclohexène (D_3-3,6,6) *trans* et le *tert*-butyl-3 [méthyl (D_3) carbinol]-4 cyclohexène (D_3-3,6,6) *trans* à partir des cétones correspondantes.

tert-*Butyl-3 carbinol-4 cyclohexène* cis ***32***c

On l'obtient par action de 0.5 g ($1.3 \cdot 10^{-2}$ mol) de $AlLiH_4$ sur 0.5 g ($2.4 \cdot 10^{-3}$ mol) de *tert*-butyl-3 méthoxycarbonyl-4 cyclohexène *cis* (*4a*). Le rendement est de 98%; pé: 98°C/2 Torr; cpv: température 170°C; tr: 39,5 min; ir (CCl_4) ν_{max}: 3630 et 3400 (—OH), 3020 (=C—H) cm^{-1}.

tert-*Butyl-3 carbinol-4 cyclohexène* trans ***32***t

On opère comme précédemment; pf: 67–70°C; cpv: température 170°C; tr: 48.1 min; ir (CCl_4) ν_{max}: 3630 et 3410 (—OH), 3020 (=C—H), 1650 (C=C) cm^{-1}.

On a préparé de la même manière les *tert*-butyl-3 carbinol-4 cyclohexènes (D_3-3,6,6) *cis* et *trans* à partir des esters correspondants. Par action de $AlLiD_4$ sur ces esters, nous avons obtenu les *tert*-butyl-3 [carbinol (D_2)]-4 cyclohexène (D_3-3,6,6) *cis* et *trans*.

Méthylcarbinol-4 cyclohexène (D₄-3,3,6,6) ***10***

On utilise 0.65 g d'acétyl-4 cyclohexène (D_4-3,3,6,6) et 0.05 g de $AlLiH_4$; cpv: température 120°C; tr: 36 min; ir (CCl_4) ν_{max}: 3620 et 3510 (—OH), 3030 (=C—H), 1650 (C=C) cm^{-1}.

Réduction par le Li-Sélectride (5)

Dans un ballon muni d'un réfrigérant surmonté d'un piège à chlorure de calcium, d'une ampoule à verser, d'une arrivée d'azote et d'une agitation magnétique, on effectue un balayage d'azote durant une heure tout en refroidissant à −78°C. On verse ensuite 3.75 cm³ ($3.75 \cdot 10^{-3}$ mol) d'une solution commerciale 1 *M* de tri-(*sec* butyl) borohydrure de lithium (Li-Sélectride) (Aldrich) et 20 cm³ de THF anhydre. Puis on ajoute goutte à goutte $1.5 \cdot 10^{-3}$ mol de cétone en solution dans du THF anhydre. Lorsque l'addition est terminée, on laisse revenir le mélange reactionnel à température ambiante. L'excès d'hydrure est détruit par quelques cm³ d'eau que l'on ajoute tout en maintenant le ballon à 0°C. Après avoir alcalinisé avec 1.5 cm³ de solution de soude 3 *N* et chauffé à 35°C quelques instants, on ajoute 2.5 cm³ de H_2O_2 (110 volumes) tout en refroidissant le ballon à l'aide d'un mélange eau/glace. On verse ensuite le mélange réactionnel sur de la glace, on ajoute une petite quantité de chlorure de sodium solide et on extrait au pentane. Rendement 88%.

tert-*Butyl-3 [méthyl(D_3) carbinol]-4 cyclohexène (D_3-3,6,6)* trans ***30***t D_6

On l'obtient par action du Li-Sélectride sur le *tert*-butyl-3 trideutérioacétyl-4 cyclohexène (D_3-3,6,6) *trans*; ir (CCl_4) ν_{max}: 3630 et 3450 (—OH), 3030 (=C—H), 2100 à 2220 (C—D), 1650 (C=C) cm^{-1}.

Les alcools tertiaires sont obtenus par l'addition du méthyl lithium en solution dans l'éther (solution commerciale 2 *M*, Aldrich) sur les cétones ou esters correspondants, selon le mode opératoire suivant.

Dans un ballon refroidi par un bain de glace, on fait réagir le méthyl lithium sur l'ester ou la cétone en solution dans l'éther anhydre, tout en maintenant le mélange réactionnel sous atmosphère d'azote. Lorsque l'addition est terminée on porte à reflux pendant une dizaine de minutes, puis on hydrolyse à froid avec une solution saturée en NH_4Cl. La phase aqueuse est extraite à l'éther puis cette solution éthérée est séchée sur sulfate de magnésium anhydre. Après évaporation du solvant, on obtient l'alcool tertiaire.

Les conditions d'analyse en chromatographie en phase vapeur sont les mêmes que précédemment.

Diméthylcarbinol-4 cyclohexène (D₄-3,3,6,6) ***11***

On additionne à 0.6 g d'acétyl-4 cyclohexène (D_4-3,3,6,6), 4 cm³ de la solution de méthyl lithium. Le rendement est de 98%; cpv: température 120°C; tr: 33.2 min; ir (CCl_4) ν_{max}: 3620 et 3500 (—OH), 2100 à 2200 (C—D) cm^{-1}.

Méthyl-3 diméthylcarbinol-4 cyclohexène cis ***21***c

Chromatographie en phase vapeur: température 130°C; tr: 24.5 min; ir (CCl_4) ν_{max}: 3620 et 3500 (—OH), 3020 (=C—H) cm^{-1}.

Méthyl-3 diméthylcarbinol-4 cyclohexène trans ***21***t

Chromatographic en phase vapeur: température 130°C; tr: 19.9 min; ir (CCl_4) ν_{max}: 3620 et 3500 (—OH), 3020 (=C—H) cm^{-1}.

*tert-Butyl-3 diméthylcarbinol-4 cyclohexène (D_3-3,3,6,6) 31*t

On fait réagir 0.50 g de *tert*-butyl-3 acétyl-4 cyclohexène (D_3-3,3,6,6) avec 3 cm³ de la solution de méthyl lithium. Rendement de 99%; cpv: température 140°C; tr: 51 min; ir (CCl_4) ν_{max}: 3610 et 3480 (—OH), 3030 (=C—H), 2100 à 2200 (C—D) cm^{-1}.

Spectres de rmn

Les spectres de rmn ont été enregistrés sur un appareil Varian XL 100 équipé d'un découpleur hétéronucléaire du deutérium, en utilisant des solution d'alcool (10% dans CCl_4 sec) préalablement dégazées. L'Eu(FOD)$_3$-D-27 est ajouté par fractions de 10 mg environ jusqu'à l'obtention de spectres simples. Les spectres sont simulés sur un ordinateur HP 2100 à l'aide du programme LAOCON III (15). Les paramètres affinés par itérations successives du même programme sont regroupés dans le Tableau 1.

Catalytic oxidation of *n*-propane and methyl alcohol over nickel(II) oxide

I. M. HOODLESS, R. A. ROSS, AND R. SWAMINATHAN

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received July 28, 1980

I. M. HOODLESS, R. A. ROSS, and R. SWAMINATHAN. Can. J. Chem. **59**, 865 (1981).

The catalytic oxidation of propane over nickel(II) oxide has been studied in the temperature range 280 to 490°C. Complete oxidation to carbon dioxide and water occurred. Fractional rate order dependencies were obtained for propane and oxygen and the reaction was inhibited by water vapour but not by carbon dioxide. It is suggested that the interaction of the adsorbed hydrocarbon with the adsorbed oxygen species, O^-, is the rate-limiting step in the reaction at the lower temperature.

Preliminary measurements of the oxidation of propane–methanol mixtures indicated that the alcohol supressed carbon dioxide formation. Conductivity studies have shown that, in these mixtures, methanol strongly interacts with the catalyst resulting in surface reduction.

I. M. HOODLESS, R. A. ROSS et R. SWAMINATHAN. Can. J. Chem. **59**, 865 (1981).

On a étudié l'oxydation catalytique du propane par l'oxyde de Ni(II) dans l'intervalle de température allant de 280 à 490°C. On a observé une oxydation complète en dioxyde de carbone et en eau. On a déterminé pour le propane et l'eau, les facteurs qui influencent l'ordre de vitesse fractionnaire et on a trouvé que la réaction est inhibée par la vapeur d'eau mais non par le bioxyde de carbone. On suggère que l'interaction entre l'hydrocarbure adsorbé et les espèces adsorbées d'oxygène, O^-, est l'étape déterminante de la réaction aux températures les plus basses.

Des mesures préliminaires sur l'oxydation de mélanges propane/méthanol indiquent que l'alcool élimine la formation de CO_2. Des mesures de conductivité ont montré que dans ces mélanges le méthanol interagit fortement avec le catalyseur formé par réduction de la surface.

[Traduit par le journal]

Introduction

Transition metal oxides are widely used as oxidation catalysts. The variation in their catalytic activity for redox reactions has been correlated with properties such as metal–oxygen bond strengths and oxygen lability (1–3). In determining the oxide activity, one standard reaction employed is the complete oxidation of methane (4, 5). Considering the importance of the catalytic oxidation of hydrocarbons it is surprising that relatively few studies of this type have been made on higher alkanes. Moro-Oka *et al.* (6) measured the catalytic activity of various oxides for the oxidation of isobutene, acetylene, ethylene, and propane and found a correlation of the activity with the heat of formation of the oxide. Yu Yao *et al.* (7, 8) have also carried out a detailed study of the oxidation of hydrocarbons on NiO and Cr_2O_3 microcrystals while Anshits *et al.* (9, 10) investigated the relative reactivity in oxidation of C_1 to C_8 alkanes on copper oxide catalysts.

One feature of the previous work is that the reactions were carried out in an excess of oxygen and complete oxidation occurred. The present paper reports on a kinetics study of propane oxidation on a NiO catalyst and, in this case, the hydrocarbon is present in excess. Some preliminary studies of the oxidation of propane–methanol mixtures are also reported.

Experimental Section

Apparatus and Method

The design and operation of the flow system has been described (11). High-purity helium was used as the carrier gas at atmospheric pressure in the flow system and in the Beckman GC-5 gas chromatograph which was operated as previously described (11). The catalyst reactor was used in a differential mode and constructed from stainless steel, 30 cm × 3.14 cm id. Temperature was maintained to within ± 0.5°C by a "Thermoelectric 400" proportional controller. "Blank" runs with reacting gas mixtures showed no measurable catalysis on the reactor walls until >430°C; at 480°C this accounted for 5% reaction using the standard propane/oxygen mixture.

All reaction rate measurements were recorded after steady catalytic activity was achieved, for example, after 3 h at 280°C. The standard inlet reacting gas mixture contained *n*-propane and oxygen at respective partial pressures of 45.6 and 15.2 Torr (6.08 and 2.03 kPa). The experiments were conducted up to 490°C where a maximum conversion level of 15% was recorded. Details of experiments with other gas mixtures are included in the Results section.

The conductivity cell, constructed in Pyrex, was of the flow-through type. The NiO compact, 1.3 cm diameter and 0.2 cm in thickness, was clamped under slight pressure between platinum electrodes. The temperature of the sample was determined by an iron–constantan thermocouple in contact with the lower electrode. The compact was maintained in a constant flow of helium (26 mL min^{-1}) and reactant gases were introduced at a flow rate of 3–4 mL min^{-1}. The conductivity was measured on a Wayne-Kerr B641 universal bridge operating at 1592 Hz.

Surface areas were determined by low-temperature krypton adsorption (BET; −196°C; $\sigma = 21.5$ Å^2). The NiO had a surface area of 2.5 $m^2\ g^{-1}$ and in the catalysis experiments a 1 g sample was used.

Materials

Nickel(II) oxide was prepared from nickel carbonate as noted earlier (12). No changes in color or in the X-ray powder diffraction patterns were detected in samples before and after catalysis.

n-Propane (I.G.; 99.5% minimum), carbon dioxide (Coleman; 99.99%), carbon monoxide (C.P.; 99.5% minimum), oxygen

(super-pure; 99.99%), helium (high purity; 99.995%), and A.C.S. reagent grade methanol were used as supplied.

Results

Kinetics of Propane Oxidation

The reaction rate was determined from 280 to 490°C. Kinetics measurements were made in the region of less than 15% total reaction and under these conditions the rate of reaction was essentially independent of the flow rate, Fig. 1. A standard flow rate of 250 mL min^{-1} (N.T.P.) was employed in subsequent studies. In all cases the only products of catalysis detected were carbon dioxide and water.

The reaction orders were investigated from 280 to 320°C and from 450 to 490°C by varying the partial pressures of propane (15.5–60.2 Torr) and oxygen (3.04–15.2 Torr), Fig. 2. The orders of reaction for propane and oxygen were 0.50 ± 0.06 and 0.25 ± 0.07 respectively from 280 to 320°C and 0.37 ± 0.02 and 0.43 ± 0.06 respectively from 450 to 490°C. As noted in the Experimental section, the results at the higher temperatures are slightly complicated by the fact that a small amount of oxidation occurs in the absence of the catalysts. The effect of additions of the products on the reaction rate is shown in Fig. 3; carbon dioxide has no effect on the rate, while water appears to inhibit the reaction. The reaction order for water in both temperature ranges was -0.35 ± 0.04.

Conductivity Studies

The effects of individual reactants and mixtures of reactants on the conductivity of an NiO compact were investigated in the reaction temperature range (345 to 350°C). Some of the results are shown in Fig. 4. Oxygen and mixtures of oxygen and propane always increase the catalyst conductivity while methanol and mixtures of methanol, propane, and oxygen always decrease the conductivity. The influence of propane on the catalyst conductivity is more variable; admission of propane to the catalyst, pre-treated in oxygen, reduces its conductivity while if the catalyst is pre-reduced in methanol the effect of propane is to produce a limited increase in the conductivity.

Competitive Oxidation Studies

A number of preliminary studies have been made of the oxidation of propane in the presence of methanol, Fig. 5(*a*). The only products detected in gas chromatographic analysis were carbon dioxide, water, and formaldehyde although trace quantities of ethylene were detected by mass spectrographic analysis. The rates of disappearance of methanol

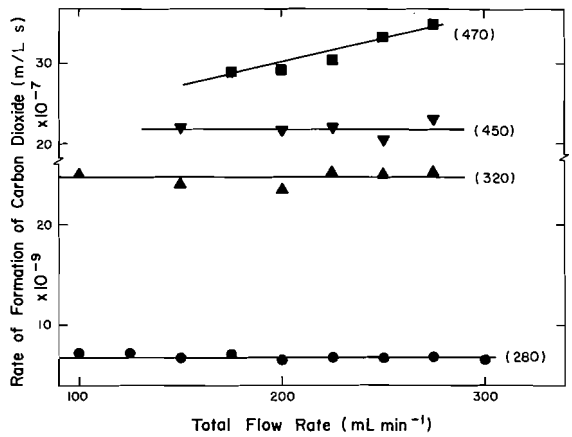

FIG. 1. Effect of flow rate on the rate of formation of carbon dioxide; partial pressure of propane 45.2 Torr, oxygen partial pressure 15.2 Torr. Reaction temperatures (°C) are in parentheses.

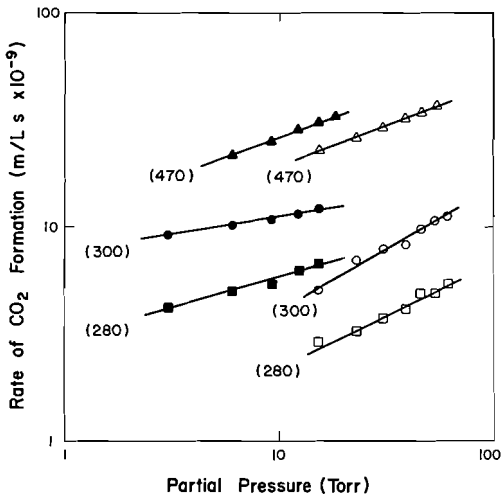

FIG. 2. Rate of formation of carbon dioxide as a function of partial pressures of reactants. ■, ●, ▲, varying partial pressure of oxygen with constant partial pressure of propane (45.6 Torr); □, ○, △, varying partial pressure of propane with constant partial pressure of oxygen (15.2 Torr). Rates at 470°C have been divided by 100. Reaction temperature (°C) are in parentheses.

and propane exceeded the amounts of carbon dioxide and formaldehyde formed but there was no evidence for the formation of significant amounts of carbon monoxide or C_1 to C_4 hydrocarbons to account for this discrepancy.

In the oxidation of mixtures of propane and carbon monoxide, the latter is rapidly oxidised to carbon dioxide, Fig. 5(*b*). At partial pressures above 20 Torr carbon monoxide, the rate of propane oxidation also increases while at lower pressures it appears likely that the carbon monoxide has either

For personal use only.

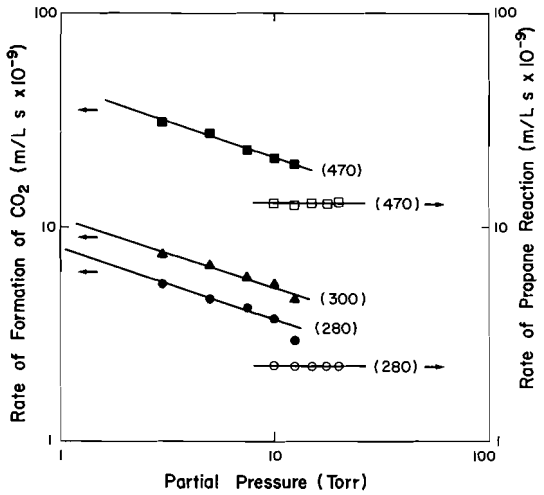

FIG. 3. Rate of oxidation of propane as a function of partial pressures of products. ●, ▲, ■, varying partial pressure of water with constant partial pressures of propane (45.6 Torr) and oxygen (15.2 Torr); ○, □, varying partial pressure of carbon dioxide with partial pressures of propane and oxygen as above. Rates at 470°C have been divided by 100. Reaction temperatures (°C) are in parentheses.

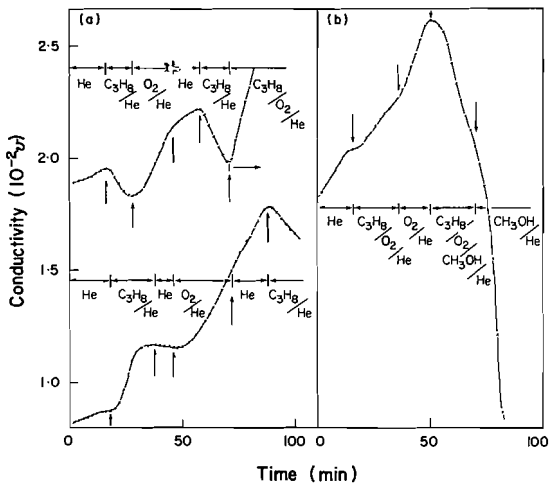

FIG. 4. Effect of reactants and mixtures of reactants on the conductivity of NiO at reaction temperature of 348 ± 2°C. (*a*) Upper curve: NiO compact pre-treated in oxygen, lower curve: NiO compact pre-treated in methanol, (*b*) NiO compact pre-treated in oxygen.

no effect or suppresses the rate of propane oxidation. The results indicate that carbon monoxide oxidation, if it is an intermediate step in the oxidation of propane, is not rate limiting.

Discussion

The rate of carbon dioxide formation, r, as a function of the partial pressures, p, can be described by an empirical expression of the form:

$$[1] \quad r = k \frac{P_{O_2}{}^m P_{C_3H_8}{}^n P_{CO_2}{}^o}{P_{H_2O}{}^l}$$

The temperature dependence of the rate of formation of carbon dioxide is shown in Fig. 6, from which an apparent activation energy of 106.9 kJ mol^{-1} has been determined. Moro-Oka *et al.* (6) and

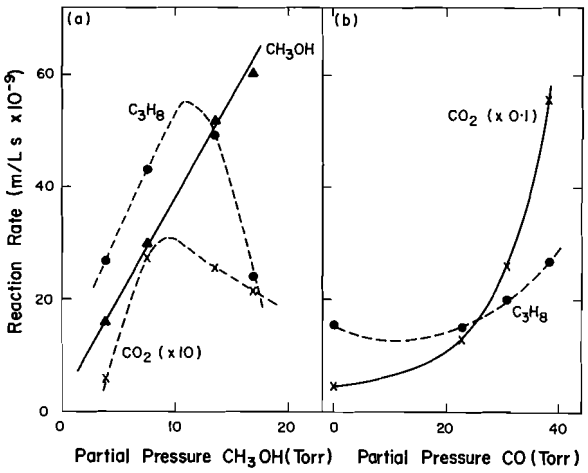

FIG. 5. (*a*) The effect of varying methanol partial pressures on the rate of formation of carbon dioxide and the rate of disappearance of the reactants at 320°C ($P_{C_3H_8}$ = 28.4 Torr, P_{O_2} = 14.3 Torr). (*b*) The effect of varying partial pressures of carbon monoxide on the rate of formation of carbon dioxide and the rate of reaction of propane at 320°C ($P_{C_3H_8}$ = 45.6 Torr, P_{O_2} = 15.2 Torr).

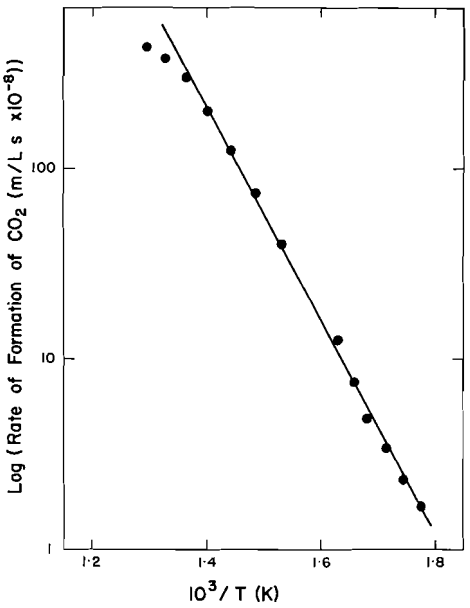

FIG. 6. Temperature dependence of the rate of formation of carbon dioxide ($P_{C_3H_8}$ = 45.6 Torr, P_{O_2} = 15.2 Torr).

TABLE 1. Kinetic orders and activation energy for propane oxidation, $r = kP_{O_2}{}^m P_{C_3H_8}{}^n P_{CO_2}{}^o / P_{H_2O}{}^l$

Reference	Temperature range (°C)	l	m	n	Activation energy (kJ mol^{-1})
Moro-Oka *et al.* (6)	350–416		0.40	0.89	109.5
Yao and Kummer (7)	230–400	0.26	0.29	0.53	87.8
Present work	280–320	0.35	0.25	0.50	106.9
	450–490	0.35	0.43	0.37	

Yu Yao and Kummer (7) have also investigated the oxidation of hydrocarbons on a number of metal oxides. Their results for the oxidation of propane on NiO are compared with the present work in Table 1.

Since the reaction orders for propane and oxygen are less than unity a Langmuir–Hinshelwood type mechanism may be inferred with competition between the hydrocarbon and oxygen for adsorption sites. Both adsorption of oxygen and of propane (on a reduced surface) led to increase in the conductivity of the sample indicating electron transfer from the catalyst to the adsorbate. It is evident that the oxygen was the more abundant species on the surface since only complete oxidation of the hydrocarbon was detected.

A number of mechanisms have been proposed for the catalytic oxidation of alkanes. On the basis of their studies on a Cu_2O catalyst, Anshits *et al.* (10) suggested that, at lower temperatures, complete oxidation occurred by an associative mechanism, i.e., the interaction of molecular oxygen with the adsorbed form of the hydrocarbon. In terms of the present work on NiO, the observed reaction orders appear to be inconsistent with this mechanism and, in addition, the conductivity results show that oxygen is readily absorbed on the catalyst in an anionic form. A second mechanism proposed (10) for the reaction at higher temperatures was that the rate-limiting step involved the reaction of the hydrocarbon with the catalysts with the formation of carboxylate and formate-type groups at the surface. Additionally kinetic isotope effect measurements (6) indicate that fission of a C—H bond is involved in the rate-determining step. This reaction of the hydrocarbon with the surface could involve either lattice oxygen or adsorbed oxygen. In the present work on NiO there is some evidence that the adsorbed oxygen species plays a direct role in the reaction rather than acting as a reservoir for the reduction–oxidation cycle of the catalyst. When propane alone is admitted to the catalyst no oxidation products are detected. Additionally the opposite changes in conductivity when propane is introduced to an oxygen-covered and a reduced surface, Fig. 4, would suggest that the propane is undergoing reaction with the adsorbed oxygen.

The experimental rate order in oxygen partial pressure increased from 0.25 between 280 and 320°C to 0.43 between 450 and 490°C. This phenomenon is probably related to the nature, lability, and amount of adsorbed oxygen on the catalyst surface. The rate order in the higher temperature range would be close to that expected from a simple dissociative reaction where catalytically active $O^-(a)$ species are formed on oxygen adsorption:

$$[2] \quad \tfrac{1}{2}O_2(g) + Ni^{2+}(c) \rightleftharpoons Ni^{2+\oplus}(c) + O^-(a)$$

$Ni^{2+\oplus}$ is a positive hole which can be equated to $O^-(a)$ at the steady state if the intrinsic positive hole concentration is negligible.

Numerous studies of oxygen chemisorption on oxides have indicated that the anionic adsorbed species may be O_2^- or O^{2-} as well as O^- (13–15). Adsorbed O^- has been suggested as the reactive species for a number of oxidation reactions on NiO (16, 17) including previous investigations of alkane oxidations at 279°C on NiO/Al_2O_3 catalysts (18). It is, however, surprising that only products of complete oxidation, CO_2 and H_2O, were observed in the present work.

While the surface will be predominantly covered by adsorbed oxygen, as shown by the effect of propane–oxygen mixtures on the conductivity (Fig. 4), it might be expected that in the decomposition of the carboxylate-type compounds, formed by the interaction of the hydrocarbon, some C_2 products would be produced. Either the C_2 fragments must be rapidly readsorbed and undergo oxidation or, possibly, the hydrocarbon initially adsorbs "planar" to the catalysts surface so that interaction with adsorbed oxygen and fission of C—H bonds on more than one carbon atom occurs without the necessity for readsorption. The inhibiting effect of water can be ascribed to its competing with oxygen and the hydrocarbon for the reactive adsorption sites on the surface.

The oxidation of mixtures of propane and methanol has not yet been studied in such detail. The initial results indicate that the presence of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

methanol supresses the rate of carbon dioxide formation but the rate of propane disappearance is increased. Additionally both the rate of carbon dioxide production and the rate of propane disappearance go through a maximum with increase in the partial pressure of methanol, Fig. 5. Additional experiments have shown that the position of the maximum is a function of the propane and oxygen partial pressures. The major product detected in the reaction is formaldehyde and one obvious route for its formation is through the dehydrogenation of methanol. Previously O^-(a) has been sugggested as the active species in alcohol dehydrogenation on oxides (19). The appearance of a maximum in the hydrocarbon curve is consistent with competition between propane and methanol for O^-(a) sites. However, the disappearance of propane is greatly in excess of the appearance of carbon dioxide and possibly some polymerization may occur on the surface under these conditions. The conductivity measurements (Fig. 4) show that in mixtures of propane, methanol, and oxygen, it is methanol which has the dominent influence on the surface and the rapid decrease in conductivity in the presence of methanol alone indicates that it can also react with lattice oxygen causing reduction at the surface.

Total synthesis of (+)-thromboxane B_2 from D-glucose. A detailed account[1]

STEPHEN HANESSIAN AND PIERRE LAVALLEE[2]
Department of Chemistry, University of Montreal, Montreal, P.Q., Canada H3C 3V1
Received August 13, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

STEPHEN HANESSIAN and PIERRE LAVALLEE. Can. J. Chem. **59**, 870 (1981).

The total synthesis of thromboxane B_2 from D-glucose is described, based on the recognition of hidden carbohydrate-type symmetry in the molecule. Methyl 2-deoxy-α-D-*ribo*-hexopyranoside was prepared from D-glucose and manipulated in such a way as to introduce C-branching at C-4 in a stereocontrolled manner. This crucial intermediate was then transformed into the target compound by adaptations of established methodology in the field.

STEPHEN HANESSIAN et PIERRE LAVALLEE. Can. J. Chem. **59**, 870 (1981).

La synthèse totale du thromboxane B_2 à partir du D-glucose est décrite. La stratégie est basée sur la reconnaissance d'une symétrie type carbohydrate dans le squelette carboné de la molécule. Le méthyl 2-deoxy-α-D-*ribo*-hexopyrannoside préparé à partir du D-glucose a été manipulé afin d'introduire les substituants requis de façon régio- et stéréocontrôllée. Un intermédiaire crucial a été ainsi obtenu, qui, après modifications systématiques a donné accès au produit désiré.

The field of prostaglandin biosynthesis has been recently crowned by two landmark events, namely, the discovery of the thromboxanes (TXA_2 and TXB_2), and prostacyclin (PGI_2) (1). Pioneering studies have shown that PGI_2, the predominant product formed from endoperoxides in blood vessel linings, is capable of preventing the blood clotting process, while the same endoperoxides in platelets can be converted into TXA_2 which causes platelets to clump and aggregate. Thus, a common biosynthetic intermediate appears to be leading to two unique substances. A critical balance in the production of PGI_2 and TXA_2 appears to be a vital biological condition, and further knowledge gained from research on these naturally-occurring and structurally related bioregulatory agents will undoubtedly expand our understanding of the factors responsible for atherosclerosis and related disease states. Samuelsson and co-workers (2) have shown that TXA_2 is transformed rather rapidly into TXB_2, which unlike its precursor, is biologically inert as a platelet aggregating agent. Nevertheless, it is a valuable substrate for the study of a variety of biochemical processes.

The first syntheses of TXB_2 were reported by the Upjohn group (3) where $PGF_{2\alpha}$ and two of its synthetic intermediates were individually utilized as starting materials. Shortly thereafter, we announced our synthesis of TXB_2 from D-glucose (4), which was followed by a direct total synthesis of the racemic material (5) and other syntheses (6) leading to optically active intermediates of TXB_2.

In this paper, we disclose the details of our original stereocontrolled synthesis of (+)-TXB_2 which is also adaptable to the preparation of analogs. Examination of the structure of TXB_2 shows the presence of a 6-membered lactol which can be related to a 2,4,6-trideoxy-D-*ribo*-hexopyranose (Scheme 1). Viewed in this perspective (7) it becomes apparent that the major synthetic challenge in attaining the intended objective is the regio- and stereocontrolled introduction of chain-branching at C-4 utilizing an appropriate carbohydrate precursor. The judicious choice of protecting groups compatible with otherwise well known operations in prostaglandin chemistry (8) becomes an important parameter in finalizing the general synthetic blueprint for such a structure.

Methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*ribo*-hexopyranose **2**, which is readily available in high yield from α-D-glucose (9), was an ideal starting material since it already contains a deoxy function as required in the tetrahydropyran portion of the target (Scheme 2). The corresponding crystalline benzoate **3** was subjected to hydrogenolysis and the resulting crystalline diol **4** was transformed into the highly crystalline *tert*-butyldiphenylsilyl ether **5** by treatment with *tert*-butyldiphenylsilyl chloride (10). The choice of protecting group for the primary

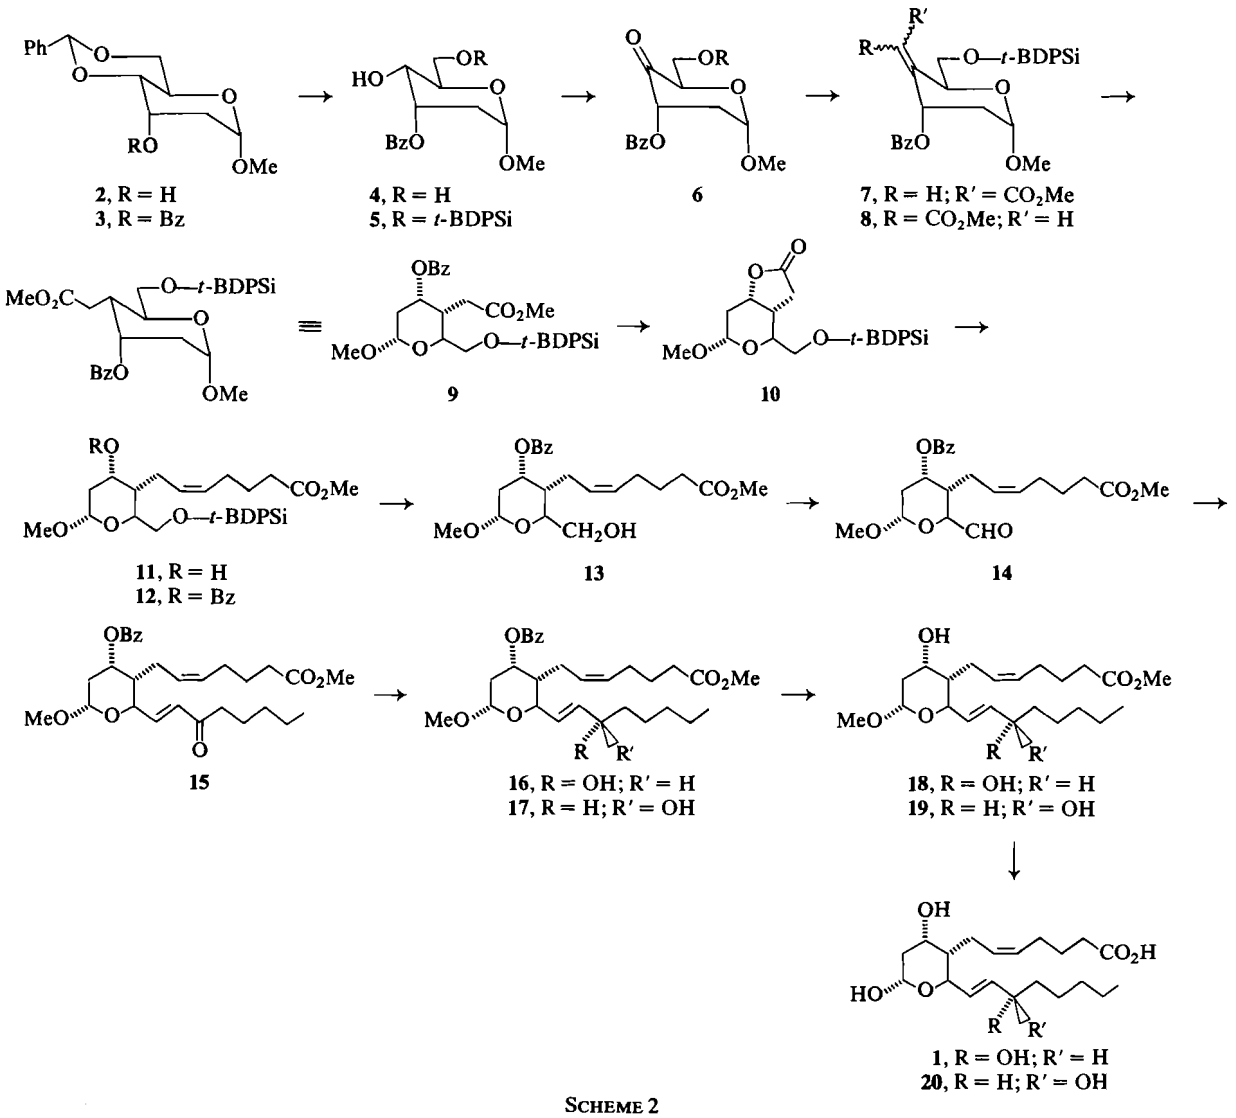

SCHEME 2

hydroxyl function was critical, since alternative options such as the commonly used trityl and *tert*-butyldimethylsilyl group (11) would not have been compatible with subsequent transformations envisaged in our synthetic scheme. Oxidation of the C-4 hydroxyl group in **5** could be effected with a variety of oxidants including DMSO – acetic anhydride. This led to the expected ketone **6** in 80% yield but contamination of the mother liquors with the methylthiomethyl ether derivative of **5** rendered the recovery of additional product somewhat lengthy. Oxidation of **5** in DMSO in the presence of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (12) and pyridinium trifluoroacetate led to the crystalline ketone derivative **6** in 94% yield without resorting to chromatography. That no epimerization at C-3 had taken place was evident from ^{1}Hmr data and from the chemistry that was to follow. Although this carbodiimide is better known as a reagent for peptide coupling (12), we have found it to be an excellent substitute for dicyclohexylcarbodiimide in Pfitzner–Moffatt oxidations (13), particularly in that the hydrochloride salt of the corresponding urea derivative is water soluble. Our initial attempts at chain-branching by treatment of **6** with (ethoxycarbonyl)methylenetriphenylphosphorane were unsuccessful and the ketone was recovered unchanged, even when the reaction was attempted in refluxing THF. With the more reactive tributylphosphine analog, a complex

mixture of products was obtained which was difficult to resolve by chromatography. Application of the phosphonate modification of the Wittig reaction proved much more practical, although the choice of base and solvent was critical. Thus, treatment of **6** with dimethyl(methoxycarbonyl)-methylphosphonate in the presence of sodium hydride in 1,2-dimethoxyethane, THF, or toluene, and at different temperatures, gave in all cases the expected exocyclic olefinic product (as a mixture of *E* and *Z* isomers), contaminated with another unknown olefinic product. However, adopting a published procedure (14) in which the carbanion was generated with potassium *tert*-butoxide in anhydrous toluene proved highly efficient in our case and led to the formation of a 1:1 mixture of the olefins **7** and **8** as the sole products in a combined yield of 90% after chromatographic purification. Based on spectroscopic data and literature precedents (9), the two products thus obtained were assigned as *E* and *Z* isomers respectively. In the *E* isomer, H-3 is found at δ 6.16 ppm ($J_{3,2a}$ = 10 Hz), downfield from the same signal in the parent ketone **6** by only 0.29 ppm, while in the *Z* isomer **8** H-3 is strongly deshielded, Δδ 0.98, due to the effect of the carbomethoxy group. By the same reasoning the deshielding patterns of H-5 in the respective isomers are reversed. The olefins **7** and **8** were individually oxidized with ozone and each was converted into the starting ketone **6** in high yield, thus providing chemical proof for their structures. The presence of an axial group at C-3 and the original choice of an α-glycoside were considered to be dominant factors in controlling the outcome of the catalytic hydrogenation of the exocyclic olefinic linkage. Not too surprisingly, however, there were substantial differences in the hydrogenation rates, although the product was the expected branched-chain derivative **9** in either case. Thus, whereas the *Z* isomer **8** was converted into **9** in the presence of 10% palladium-on-charcoal within 8 h, the *E* isomer **7** required 20% palladium hydroxide-on-charcoal and a 24 h exposure. The reasons for this are not immediately apparent, although inspection of molecular models reveals that in the *E* isomer, an interaction could exist between the methoxycarbonyl and the bulky *tert*-butydiphenylsilyl group, thus rendering the β-side somewhat less readily accessible to a weaker catalyst. Definitive proof for the orientation of the acetic acid side-chain was secured from spectroscopic data and chemical transformations. Having thus introduced the crucial branch-point at C-4, attention was next turned to the elaboration of the carboxyl-containing side chain of TXB_2. Treatment of the ester **9** with 1.4 equivalents of DIBAH in toluene at −78°C led to a mixture of the desired aldehyde and starting material. Using a large excess of reagent led to a mixture of several products. A practical recourse was to generate a lactone intermediate such as **10**. Thus, treatment of **9** with 0.3 equivalents of sodium methoxide in methanol led, after 4 days, to the crystalline lactone **10** in 76% yield. A more efficient procedure was to subject the ester **9** to methanolysis in the presence of anhydrous potassium carbonate, which led to the lactone **10** in higher yield (85%). Alkoxide mediated alcoholysis of diesters of the type **9** is expected to produce the corresponding hydroxy ester; however, using quasi-stoichiometric quantities of alkoxide the intramolecularly formed *cis*-lactone is apparently the thermodynamically more stable entity compared to the corresponding *cis*-hydroxy ester from which it is derived. Treatment of the lactone **10** with DIBAH following known methodology gave the corresponding lactol which was treated with the Wittig reagent generated from (4-carboxybutyl)-triphenylphosphonium bromide in the presence of lithium hexamethyldisilazane in HMPT (15). This led to the expected *cis*-olefin **11** in good yield after esterification. The prostaglandin literature (8) is replete with syntheses in which the *cis*-olefinic linkage of the carboxyl side chain has been introduced using the above mentioned phosphonium salt and dimsylsodium in DMSO as solvent. Until recently, however, few experimental details were available in the literature for this method (16). In our hands, we have found the Rosen procedure (15) to be convenient and highly reproducible from run to run and have used it in this as well as other instances, particularly when small quantities of materials were available for the Wittig reaction.

At this juncture, we deemed it necessary to secure chemical evidence concerning the correct orientation of substituents at C-3 and C-4, since epimerization at C-3 in **6** and a subsequent reduction of the products **7** and **8** from the α-side could have conceivably led to a *cis*-lactone with the opposite stereochemistry relative to **10**. Accordingly, **11** was oxidized with 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride in DMSO to the corresponding 3-keto derivative **21** (Scheme 3) in 86% yield. This was treated in methanol with

potassium carbonate during 5 h after which chromatographic examination revealed the presence of the original ketone and a small quantity of a product arising from elimination. The ketone **21** was subsequently isolated from such a mixture (72.5%) and was found to be identical to the original material. Had the olefinic side-chain been in the axial orientation, it would have undergone base-catalyzed epimerization to the equatorial isomer. Reduction of **21** with sodium borohydride in methanol at 0°C led to **11** in 74% yield. From the experiments, it was clear that the stereochemical integrity at C-3 had been maintained during the oxidation and subsequent phosphonate condensation reaction, and that the reduction of the olefins **7** and **8** led, as expected, to the acetate side-chain with an α-orientation (D-*ribo* configuration as in **9**). The ^{13}Cmr spectral parameters for compounds **4–10** are listed in Table 1 and the assignments are based on correlations with known compounds and from literature data (17). Pursuing our synthetic scheme towards TXB_2, the hydroxyl group in **11** was protected by benzoylation to give **12** as a syrup, which was desilylated with fluoride ion (11) to the alcohol **13** and the latter was oxidized to the aldehyde **14** with the Collins reagent according to its adaptation to carbohydrates (18). The yields of these individual steps were high and the products were characterized by spectroscopic data. Chain extension of the aldehyde **14** was effected with *n*-tributylphosphoranylidene-2-heptanone (19) in the usual manner to give the α,β-unsaturated ketone derivative **15** in 79% yield after chromatography. In view of their modes of formation and genesis, all the intermediates to this point in the synthesis are optically pure. Reduction of **10** was effected with zinc borohydride in a mixture of 1,2-dimethoxyethane and ether, whereby two epimeric alcohols were formed in high yield and separated by thick layer chromatography. A slight preponderance (40%) of the "15-*S*" epimer **16** (later to be related to the natural product) was observed over the 15-*R* epimer **17** (33%). These compounds were individually transformed into TXB_2 and its "15-*R*" isomer by carefully executed deprotection techniques. Debenzoylation of **16** in the presence of potassium carbonate in methanol under a nitrogen atmosphere afforded the corresponding alcohol **18** as a syrup in 80% yield. The corresponding *O*-trimethylsilyl derivative showed a mass spectrum that was in complete accord with the expected structure and with the results published by Samuelsson and co-workers (2). The ester **18** was hydrolyzed with dilute alkali and the resulting sodium salt was treated with excess Dowex-50 (H^+) giving first the methyl glycoside derivative of TXB_2, which on longer contact with the acidic resin was hydrolyzed to TXB_2. The material crystallized from a mixture of ethyl acetate, ether, and petroleum ether to give beautiful plates, identical with an authentic sample. Similar treatment of the epimeric **17** gave the ester **19** and finally "15-epi" TXB_2, **20**, a syrup. The ^{13}Cmr data for compounds **11–18** in the natural series are listed in Table 2 and the assignments have been made based on literature precedents in the PG area. Since the Wittig reagent that provides the C-15 side-chain is available in optically pure form from malic acid (20), the sequence **14** → **16** can provide material with the natural "15-*S*" configuration directly, or indirectly by inversion of configuration of **17** as in the PG series (21). Thus, the entire synthesis of (+)-TXB_2 can be considered to be stereospecific. An X-ray crystallographic study of TXB_2 has shown that the unit

cell consists of α,β-anomers in the ratio of 35:65 (22).

Experimental

Melting points are uncorrected. Optical rotations were measured on a Perkin-Elmer automatic spectropolarimeter, model 141. The ^{1}Hmr spectra were recorded on a Jeol instrument at 60 MHz unless otherwise stated, with tetramethylsilane as internal standard, in deuterochloroform as solvent. The ^{13}C nmr spectra were recorded on a Bruker WH-90 instrument at 22.6 MHz. Mass spectra were recorded on an AEI-902 mass spectrometer at low resolution. Column chromatography was done using silica gel G254, with application of moderate suction. Solvents for tlc are as follows; solvent A: benzene–EtOAc, 10:1; solvent B: benzene–EtOAc, 10:3; solvent C: benzene–EtOAc, 10:6; solvent D: benzene–EtOAc, 1:1; solvent E: ethyl acetate – acetic acid, 99:1; solvent F: $CHCl_3$–MeOH, 10:1.

*Methyl 3-*O*-Benzoyl-4,6-*O*-benzylidene-2-deoxy-*α*-*D*-ribo-hexopyranoside (3)*

A solution containing 8 g (30 mmol) of **2** (9) in 60 mL of dry pyridine was treated with 4.2 mL (36 mmol) of benzoyl chloride at 0°C. The solution was stirred overnight at room temperature, then it was poured in a mixture of water, ice, and ether. Processing the organic layer in the usual way gave a syrup that crystallized from ether – petroleum ether to give the title compound in three crops (10.34 g, 93%). Recrystallization gave a pure sample, mp 100–101°C; $[\alpha]_D^{25}$ +182.9° (*c* 1.18, $CHCl_3$); λ_{max}(KBr): 1715 cm^{-1}; nmr data, δ (ppm): 2.08 (H_{2a}, $J_{2a,2e}$ = 15.7 Hz, $J_{2a,1}$ = 4 Hz, $J_{2a,3}$ = 3.5 Hz), 2.39 (H_{2e}, $J_{2e,2a}$ = 15.7 Hz; $J_{2e,3}$ = 3 Hz; $J_{2e,1}$ = 0.75 Hz), 3.37 (s, OCH_3), 4.75 (H_1, dd, $J_{1,2a}$ = 4 Hz, $J_{1,2e}$ = 0.75 Hz), etc. *Anal.* calcd. for $C_{21}H_{22}O_6$: C 68.10, H 5.99; found: C 68.58, H 6.15.

*Methyl 3-*O*-Benzoyl-2-deoxy-α-*D*-ribo-hexopyranoside (4)*

A solution of **3** (11 g, 30.5 mmol) in a mixture of ethyl acetate (150 mL) and methanol (75 mL) was hydrogenated in the presence of 20% palladium hydroxide on charcoal (1.5 g) (23). After 18 h, the catalyst was filtered and the filtrate was evaporated to dryness. The residue was crystallized from a mixture of dichloromethane, ether, and petroleum ether to give the title compound (7.93 g, 94%). An analytical sample was obtained, after two recrystallizations, from a mixture of hexanes and pentane, mp 112–114°C; $[\alpha]_D$ +158° (*c* 1.06, $CHCl_3$); R_f 0.57 (solvent F); λ_{max}(KBr): 3340 (OH), 1720 (C=O) cm^{-1}. *Anal.* calcd. for $C_{14}H_{18}O_6$: C 59.56, H 6.43; found: C 59.60, H 6.78.

*Methyl 3-*O*-Benzoyl-6-*O*-(tert-butyldiphenylsilyl)-2-deoxy-α-*D*-ribo-hexopyranoside (5)*

A solution containing **4** (7.48 g, 26.5 mmol) and imidazole (4.1 g, 59 mmol) in 53 mL of dry DMF was treated at 0°C with a 0.5 *M* solution of *tert*-butyldiphenylsilyl chloride (10) (58 mL, 29 mmol) in the same solvent. After stirring at room temperature for 20 h, the solution was diluted with water and ether. Processing the organic layer gave a crystalline residue that was recrystallized from ether – petroleum ether to give the title compound, mp 114–116°C (11.7 g, 85%). An analytical sample showed mp 116–118°C (hexanes); $[\alpha]_D$ +90.2° (*c* 1.1, $CHCl_3$); R_f 0.41 (solvent A); ms *m/e*: 489 (M^+ – Me_3C), etc. *Anal.* calcd. for $C_{30}H_{36}O_6Si$: C 69.20, H 6.97; found: C 69.05, H 6.76.

*Methyl 3-*O*-Benzoyl-6-*O*-(tert-butyldiphenylsilyl)-2-deoxy-α-*D*-erythro-hexopyranosid-4-ulose (6)*

To a cooled solution containing **5** (20.8 g, 40 mmol) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDAC·HCl) (4, 12) (23.04 g, 120 mmol) in 300 mL of dry DMSO was added successively 4.9 mL (60 mmol) of pyridine and 3.6 mL (50 mmol) of trifluoracetic acid and the solution was diluted with ether and ice-water; the organic layer was pro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

cessed as usual to give a viscous syrup which crystallized from a mixture of ether – petroleum ether to give compound **6** (19.94 g, 94%). Two recrystallizations gave an analytical sample, mp 86–88°C; $[\alpha]_D$ +148° (*c* 1.22, $CHCl_3$); R_f 0.68 (solvent A); λ_{max}(KBr): 1760 (C=O) cm^{-1}; ms *m/e*: 461 ($M^+ - Me_3C$), 429 ($M^+ - Me_4C - MeOH$), etc; *Anal.* calcd. for $C_{30}H_{34}O_6$ Si: C 69.47, H 6.61; found: C 69.97, H 7.07.

*Synthesis of Methyl 3-O-Benzoyl-6-O-(*tert*-butyldiphenylsilyl)-2,4-dideoxy-4-C-[E-(methoxycarbonyl)methylene]-*α*-D-erythro-hexopyranoside 7, and the Z Isomer, 8*

To a cooled suspension of potassium *tert*-butoxide (0.8 g, 7.2 mmol) in 100 mL of toluene was added dimethyl (methoxycarbonyl)methylphosphonate dropwise and with stirring. After 1 h, ketone **6** (3.1 g, 6.0 mmol) was added in one portion and the solution was stirred at room temperature for 8 h. The solution was diluted with ether, then treated with 10% dihydrogen sodium phosphate. Processing the organic layer gave a mixture of the *E* and *Z* isomers (3.26 g, 94%). Chromatographic separation (solvent A) gave the *Z* isomer **8** (1.68 g, 48.6%) and the *E* isomer **7** (1.46 g, 42.8%) in that order of elution. For **7**, $[\alpha]_D$ +199.3° (*c* 1.16, $CHCl_3$); nmr data, at 100 MHz, δ (ppm): 1.70 (m, H_{2a}, $J_{2a,2e}$ = 14 Hz, $J_{2a,3}$ = 10 Hz, $J_{2a,1}$ = 3.75 Hz), 2.90 (dd, H_{2e}, $J_{2e,2a}$ = 14 Hz, $J_{2e,1}$ = 7.0 Hz), 3.40 (s, OMe), 3.63 (s, CO_2Me), 5.0 (dd, H_1, $J_{1,2e}$ = 7.0 Hz, $J_{1,2a}$ = 3.75 Hz), 6.0 (s, C=CH), 6.15 (d, H_3, $J_{3,2a}$ = 10 Hz), etc; M^+ 574, ms *m/e*: 543 ($M^+ - MeO$), etc; for **8**, $[\alpha]_D$ +162.5° (*c* 1.0, $CHCl_3$); nmr data at 100 MHz, δ(ppm): 2.25 (m, H_{2a}, H_{2e}), 3.3 (s, OMe), 3.75 (s, CO_2Me), 6.0 (s, C=CH), 6.85 (m, H_3), etc; M^+ 543; ms *m/e*: 517 ($M^+ - Me_3C$), etc.

Ozonolysis of 7 and 8

A solution containing **7** (50 mg, 0.87 mmol) in 10 mL of methanol was treated with a stream of ozone (0.12 mmol/min) at −78°C. After 5 min of stirring (0.88 mmol ozone uptake; ~1 equivalent), nitrogen gas was passed through the solution, then 4 drops of dimethylsulfide were added. After standing at room temperature overnight, the solution was evaporated to dryness and the residue was purified by preparative tlc (solvent A, R_f 0.68) to give 36 mg (80%) of **6** as a homogeneous syrup. Crystallization was effected from petroleum ether to give 17 mg of **6**, mp and mixture mp 86–88°C; $[\alpha]_D$ +147.3°. Ozone treatment of the other isomer **8** gave essentially the same results.

*Methyl 3-O-Benzoyl-6-O-(*tert*-butyldiphenylsilyl)-2,4-dideoxy-4-C-[(methoxycarbonyl)methyl]-*α*-D-ribo-hexopyranoside, (9)*

From **7**: A solution containing 1.46 g (2.54 mmol) of **7** in a mixture of ethyl acetate and methanol (120:50 mL) was hydrogenated in the presence of 20% palladium hydroxide on charcoal (23) (0.5 g). After 24 h, the catalyst was filtered and the filtrate was processed as usual to give a syrup. Chromatography (solvent A, R_f 0.48) gave 1.11 g (70%) of the title compound as a viscous syrup, $[\alpha]_D$ +100.4° (*c* 1.17, $CHCl_3$); λ_{max}(film): 1737 (CO_2Me) cm^{-1}; nmr data, δ(ppm): 3.3 (s, OMe), 3.55 (s, CO_2Me), 4.85 (m, H_1), 5.4 (m, H_3), etc; ms *m/e*: 545 ($M^+ - MeO$), 519 ($M^+ - Me_3C$), etc. From **8**: hydrogenation of this isomer for 8 h gave the title compound (92%) having the physical constants described above.

*Methyl 6-O-(*tert*-Butyldiphenylsilyl)-4-C-(carboxymethyl)-2,4-dideoxy-*α*-D-ribo-hexopyranoside,γ-Lactone, (10)*
