fair agreement with those drawn from our earlier studies (1) on the behaviour of $T\delta(\Delta S_N^0)$ or ($\equiv T({}_s\Delta S^0 - {}_w\Delta S^0)$), i.e. T times the relative entropy of autoionization of water, as well as of $\Delta S_t^0(H_2O)$ derived therefrom, and also that from various other studies referred to therein for all these cosolvent systems. Notably, however, the structural changes reflected from the observed downward trends of $\Delta S_t^0(H_2O)$ around 4–14 mol% of DME referred to in the previous paper are not reflected in the behaviour of ΔY(HX) values. Seemingly, the behaviour of $\Delta S_t^0(H_2O)$ values, if free from uncertainties, is more informative than that of $T\Delta S_t^0$(HX) or ΔY values which, after all, contain the Born-type electrostatic contributions (25). Nevertheless, the present results are indicative of the fact that, at initial compositions, the THF molecule because of the larger hydrophobicity of its 4 (—CH_2—) groups, compared to the hydrophilicity of its one ethereal O-group, shifts the $(water)_{bulk} \leftrightarrow (water)_{dense}$ equilibrium towards the left. But the D molecule, because of its larger hydrophilicity of two ethereal O-centres over the two structure-promoting hydrophobic (—CH_2—CH_2—) groups, and the DME molecule, with its two CH_3-induced strongly negative and flexible O-centres, being more hydrophilic, shift the said equilibrium towards the right. Thus, the present results substantiate the observation of Ahluwalia and co-workers (26) that the initial structuring or destructuring ability of a cosolvent depends upon the ratio of hydrophobic to hydrophilic effects of the cosolvents. Increase in hydrophobic groups in the cosolvent increases the stabilization while increase in the hydrophilicity of H-bonding sites decreases the stabilization of the 3D structure of water.

The reaction of tetrasulphur tetranitride with bis(fluorosulphuryl) peroxide: the electronic structure of the tetrathiazyl dication

RAJENDRA D. SHARMA, FRIEDHELM AUBKE, AND NORMAN L. PADDOCK

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received May 1, 1981

RAJENDRA D. SHARMA, FRIEDHELM AUBKE, and NORMAN L. PADDOCK. Can. J. Chem. **59**, 3157 (1981).

Tetrasulphur tetranitride is oxidized quantitatively at room temperature to tetrathiazyl di(fluorosulphate) $S_4N_4(SO_4F)_2$. Conductance measurements in HSO_3F show this compound to dissociate into ions. The vibrational spectra of the cation are uniquely consistent with a flexible planar structure of D_{4h} symmetry, and the anion bands are characteristic of ionic SO_3F^-. CNDO and EHMO calculations indicate that the planar form of the cation is stable but easily deformable.

RAJENDRA D. SHARMA, FRIEDHELM AUBKE et NORMAN L. PADDOCK. Can. J. Chem. **59**, 3157 (1981).

On a oxydé quantitativement le tétranitrure de tétrasulfure à la température ambiante en di(fluorosulphate) de tétrathiazyle $S_4N_4(SO_4F)_2$. Les mesures de conductivité dans le HSO_3F montrent que ce composé se dissocie en deux ions. Les spectres de vibration du cation sont en accord avec une structure plane flexible de symétrie D_{4h} et les bandes de l'anion sont caractéristiques de l'espèce ionique SO_3F^-. Les calculs CNDO et EHMO indiquent que la forme plane du cation est stable mais se déforme facilement.

Introduction

Tetrasulphur tetranitride S_4N_4 occupies a central position in sulphur–nitrogen chemistry; very many derivatives can be made from it by reaction at sulphur or nitrogen. The length of the bonds between opposing sulphur atoms (2.60 Å) (1) (Fig. 1) is significantly greater than the length of the bonds in S_8 (2.06 Å) (2), and at least one of these bonds is usually broken on reaction. If the cross bonds are appreciably weaker than single bonds, as the structural evidence suggests, homolytic bond cleavage and reaction with radicals can be expected to take place easily. Some reactions of this type have been reported. S_4N_4 reacts with an excess of the radical $(CF_3)_2NO$ to give $N_4S_4[ON(CF_3)_2]_4$ (3), the $(CF_3)_2NO$ group being linked through oxygen to sulphur (4). The reaction of S_4N_4 with molecular chlorine, under carefully controlled conditions, gives first $N_4S_4Cl_2$ (5), and may be of the same type, but the dissociation energy of Cl_2 is high (239 kJ/mol), and it is possible that the first step in the reaction is the electrophilic attack of the chlorine molecule on sulphur. Bis(fluorosulphuryl) peroxide is a more likely source of radicals, since it is extensively dissociated at 100°C; even at −25°C, it abstracts hydrogen from dichloromethane, a reaction typical of free radicals (6). Its dissociation energy (91.3–97.6 kJ/mol) (7) is much less than that of chlorine, so that the mechanistic ambiguity, though still present, is less significant. In the experiments described here, $S_2O_6F_2$ was found to react smoothly and completely with S_4N_4 at room temperature to give $S_4N_4(SO_3F)_2$ (**1**). Since the electron affinity of the fluorosulphate radical is high (it has been estimated as 1060 kJ/mol (8) and 1110 kJ/mol (9)), the product is ionic, $S_4N_4^{2+}(SO_3F^-)_2$. The overall reaction is an an oxidation, the cation being the same as that produced in the oxidation of S_4N_4 by SbF_5 or $SbCl_5$ (10).

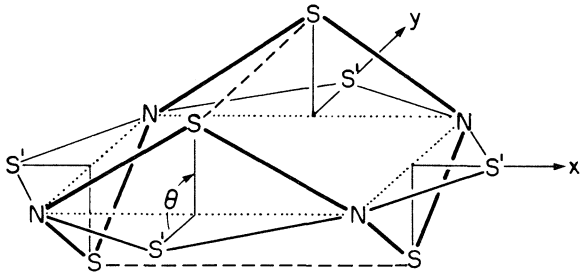

FIG. 1. Relation of normal conformation of S_4N_4 (D_{2d}, heavy lines) to planar $S_4'N_4^{2+}$ (D_{4h}). The cross bonds in S_4N_4 are shown by dashed lines. The rings are interconverted by local rotations ± θ about successive NN vectors.

Experimental

Tetrasulphur tetranitride was prepared by the ammonolysis of sulphur dichloride (11) and sublimed twice *in vacuo*. Bis(fluorosulphuryl) peroxide, prepared by the fluorination of SO_3 with AgF_2 as a catalyst (12), was stirred over a large quantity of anhydrous KF for 48 h and distilled *in vacuo*. Fluorosulphuric acid (Allied Chemicals) was doubly distilled (13). All manipulation was carried out in a dry atmosphere; the reaction vessels were fitted with greaseless Kontes Teflon stem valves. Infrared spectra were recorded from thin films on AgCl, AgBr, or KRS-5 windows on a Perkin–Elmer 457 grating spectrophotometer, and Raman spectra on a Spex Ramalog 5 spectrometer equipped with an argon ion laser (514.5 nm). The esr spectra were recorded on a Varian Associates E-3 spectrometer, electronic spectra on a Cary 17 spectrophotometer, and ^{19}F nmr spectra on an EM360 instrument. Electrical conductance measurements were carried out with a Wayne–Kerr Universal Bridge, Type B221. The measuring temperature of 25.00 ± 0.01°C was maintained in an oil bath equipped with a Sargent Thermonitor

Model ST temperature control unit. The conductivity cell, similar to that described by Barr *et al.* (13), was scaled down to allow measurements on small volumes (~ 50 mL).

Tetrathiazyl Di(fluorosulphate)

A large excess (~12 g) of $S_2O_6F_2$ was distilled on to S_4N_4 (0.020 g, 5 mmol) at −196°C. The reactor was warmed first to −78°C, and then very slowly to room temperature, when the orange colour of S_4N_4 changed to black (radical, 5 line esr spectrum) in about ten minutes, then to brown and finally to bright yellow in approximately 48 h. The excess of $S_2O_6F_2$ was distilled off *in vacuo*, leaving **1** as a very hygroscopic pale yellow powder (1.914 g, 100%); dec. 110°C. *Anal.* calcd. for $F_2N_4O_6S_6$: F 10.1, N 14.7, S 50.0; found: F 9.9, N 14.3, S 50.3. A solution of **1** in fluorosulphuric acid (from which the solute can be recovered) showed a single ^{19}F nmr signal characteristic of solvent in equilibrium with the fluorosulphate anion. A plot (Fig. 2) of the electrical conductance of **1** in HSO_3F as a function of concentration is slightly steeper than that for $Ba(SO_3F)_2$ (13), indicating higher conductance at the same concentration. Ionic association is presumably reduced by the larger size of the $S_4N_4^{2+}$ ion. The vibrational spectra of **1** are summarized in Tables 1 and 2. The electronic spectrum of the cation is shown in Fig. 3.

Results and Discussion

The synthesis of **1** described above is straightforward and quantitative. The oxidative addition reaction

[1] $S_4N_4 + S_2O_6F_2 \rightarrow S_4N_4(SO_3F)_2$

when performed with the peroxide in excess, requires no solvent, and the easy isolation of very pure **1** is ensured by the high volatility of $S_2O_6F_2$

and the absence of by-products. In addition, solutions of **1** in HSO_3F are stable, and the solute may be recovered quantitatively by removing the solvent *in vacuo*.

The vibrational frequencies of the anion are all comparable to those in the ionic $NOSO_3F$ (14), and the weakness of ionic polarization in **1** is attested not only by the small splitting of the E modes (e.g. by 27 cm^{-1} for $\nu_{as}(SO_3)$) but also by the particularly low value of ν(SF), characteristic of an isolated SO_3F^- ion. To a good approximation, the spectra of $S_4N_4^{2+}$ are those of an isolated cation, only slightly perturbed by the anion. Molecular symmetries C_{4h}, C_{4v}, and D_{2d} are ruled out, since they require both a larger number of bands and 4, 7, and 7 coincidences respectively between the Raman and infrared frequencies, and there are none. Symmetry D_{4h} requires two polarised Raman bands (A_{1g}) and five depolarized bands ($2B_{1g} + 2B_{2g} + E_g$) and four infrared bands ($A_u + 3E_u$), in agreement

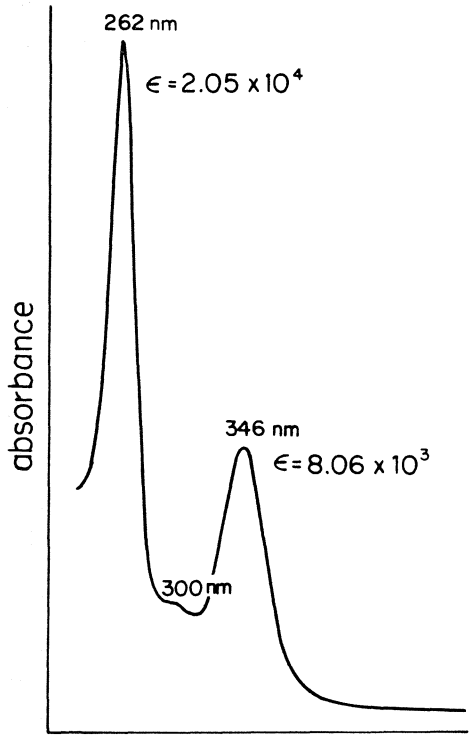

FIG. 3. The electronic spectrum of $S_4N_4^{2+}$ in HSO_3F.

with experiment, if the pair of infrared bands at 434/440 cm^{-1} is taken to be a partly resolved degenerate band. The Raman spectrum of the cation in solution shows no splitting of the degenerate band; the splitting found in the infrared spectrum of the solid may be a result of a low site symmetry or weak ionic polarization. We conclude that in solution, at least, $S_4N_4^{2+}$ is planar, with equal bond lengths, though the molecule appears to be flexible, and may be deformed in the crystal; the high symmetry may be attained statistically. The high value of ν(SN) (1205 cm^{-1}; cf. 1160 cm^{-1} in $S_4N_3^+$ (15)) shows that the SN bond is strong. The electronic spectrum of $S_4N_4^{2+}$ (Fig. 3) is quite different from that of S_4N_4 in organic solvents (16). Tetrasulphur tetranitride is oxidized by sulphuric acid (17), but the spectrum of the unidentified cation so produced varies with time, and shows fine structure near 400 nm; the product is evidently not $S_4N_4^{2+}$, because neither feature is found in the spectrum of $S_4N_4^{2+}$ in HSO_3F.

It is not possible to write a single canonical form for $S_4N_4^{2+}$ which reflects its high symmetry. The electronic structure of S_4N_4 itself has received considerable attention; an extensive list of references is given in ref. 18, which illuminates many of the features of S—N bonding through extensive *ab*

initio studies. We have found simpler methods helpful in considering the conformational effects of the ionization of S_4N_4.

The relation between the planar ring of $S_4N_4^{2+}$ and the saddle shape of S_4N_4 is shown in Fig. 1. All conformations with $\theta \neq 0$ have symmetry D_{2d}, but for convenience we reserve this symbol for the experimental conformation of S_4N_4 (1), for which $\theta = 93°$. If the interactions are restricted to pπ-orbitals at each atom, the energy of the highest antibonding level (a_{2u}) drops sharply as θ increases, eventually acquiring significant S—S bonding character through the interactions of opposing sulphur atoms (19). More detailed treatments of S_4N_4 (20) show that the energy of this orbital (b_2 in D_{2d}) is comparable to those of the highest occupied a_1, a_2, and b_1 combinations, which correspond to nonbonding S, N, N combinations in D_{4h}. The calculated energy range of the four orbitals is about 1 eV. The energies of the highest two occupied orbitals, at least, cannot be distinguished by photoelectron spectroscopy, which places them at −9.5 eV (20*c*) or −9.36 eV (20*e*), but the b_2 orbital is still formally antibonding with respect to the SN bonds, and ionization of electrons from it should strengthen the molecule, in agreement with the high value of ν(SN) in $S_4N_4^{2+}$.

The changes in the bond parameters, as a consequence of ionization, have been estimated by a population analysis of the EH molecular orbitals (Table 3).[1] We draw the following conclusions. (1) Ionization of S_4N_4 in either conformation increases the S—N bond population, consistent with the release of electrons from an orbital with partial antibonding character. (2) In the $D_{4h} \rightarrow D_{2d}$ transformation, the S—S bonds are made partly at the expense of the S—N bonds, but, for S_4N_4, there is a large net increase in total bond population (0.34) (3). In the same transformation of $S_4N_4^{2+}$, the S—S bonds are formed almost wholly at the expense of the S—N bonds.

More nearly quantitative results have been obtained through CNDO calculations on both S_4N_4 and $S_4N_4^{2+}$ over the whole conformation range, using the program of ref. 21. The energies and approximate descriptions of the molecular orbitals are given for the D_{4h} limit of $S_4N_4^{2+}$ in Table 4. They are shown in Fig. 4 as a function of θ; the levels of neutral S_4N_4 at the limiting conformations are also shown. Ionization stabilizes all the levels of either conformation, and, to a first approximation, to the same extent, without altering their order. The matching, to within an additive constant, is good for all orbitals except the HOMO, which is (relatively) destabilized in the ion, presumably because it is shielded better by the more contracted inner electrons. The LUMO (b_2) is strongly destabilized in the D_{2d} conformation, so that it is no longer competitive with the a_1, a_2 orbitals. An appreciable part of the S—S bonding is thereby lost, again in agreement with the EH results, and confirming that ionization is effectively from the $4b_2$ level.

Figure 4 shows, principally, the important influence of conformation on the energy levels. As the planar molecule approaches the cluster conformation, most of the bonding levels are lowered, not only those ($2a$, $3a$, $3b_2$, $4a_1$) with an appreciable b(SS) component. This is presumably a general result of improved overlap in the more compact molecule; its effect on the total electronic energy is partly offset by the π-bonding in the planar molecule, though this is weaker for 3pπ than for 2pπ-orbitals. Nuclear repulsion destabilizes the D_{2d} relative to the D_{4h} conformation, so that as the planar molecule is deformed, the total energy (CNDO) increases until the shorter range valence forces supervene near $\theta = 60°$, when the energy decreases again. At their face value, the CNDO

[1] We are grateful to Professor L. S. Bartell for the EHMO program, and to Dr. J. D. Head for the Mulliken analysis program.

For personal use only.

calculations on $S_4N_4^{2+}$ predict stability of the D_{2d} relative to the D_{4h} conformation. This result is not reliable, because the CNDO method is known to overestimate bonding contributions; the energy minimum found for S_4N_4 itself corresponds to much too short an S—S bond (22). The EH method frequently gives better results on conformational problems. In this case it, too, shows an energy maximum, but the planar form has the highest stability. The energy varies very slowly near $\theta = 0°$, and the ion can be expected to be flexible. Crystal structure determinations (R. J. Gillespie, personal communication), improving on the preliminary work (10), show that $S_4N_4^{2+}$ is frequently, but not always, quite planar in the crystal. More refined calculations, like those by X_α (20*b*) or *ab initio* methods (20*e*) are required both for a full discussion of the electronic spectrum of $S_4N_4^{2+}$, and for a more reliable assessment of conformational stability.

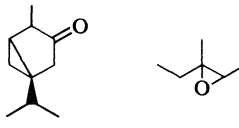
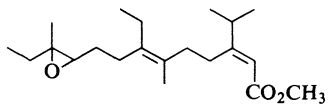
Introduction

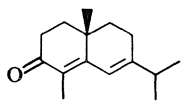
Previous communication from these laboratories described the uses of thujone **1**, readily available from Western Red Cedar leaf oil, in the preparation of acyclic juvenoid analogs (e.g. **2**) (1, 2) and of bicyclic natural products (e.g. (+)-β-cyperone **3**)



1



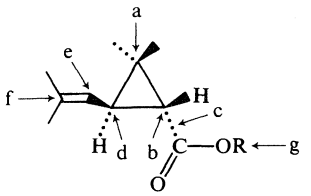
2



3

(3). In those experiments the propensity for opening of the cyclopropane ring was utilized to generate required functionality. In the synthesis of **3**, the optical purity of thujone enabled the preparation of (+)-β-cyperone with an optical purity > 98.8%. Here we report the preparation of several analogs of the biologically active pyrethrins in which the cyclopropane function of thujone has been retained (and, accordingly, the optical activity), or a new cyclopropane ring generated.

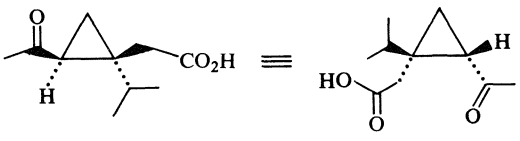
Pyrethroid insecticides, with general structure **4**, have pioneered a vast new area of insect control methods and in this light we set out to prepare *analogs*, readily derived from thujone **1**. Using α-thujaketonic acid (**5**) (obtained from **1** by permanganate cleavage) and its open chain derivatives, the following modifications (cf. **4**) in the



4

pyrethroid skeleton were envisaged: (*a*) optional *gem*-dimethyl substitution on the cyclopropane ring; (*b*) incorporation of an isopropyl group on the ring; (*c*) introduction of a methylene unit between the ring and the carboxyl group; (*d*) use of both *cis* and *trans* orientation of substituents on the cyclopropane ring; (*e*) alkyl substitution at the α-carbon of the side chain; (*f*) variation in the nature of the unsaturated side chain; (*g*) variation in the nature of the ester function, R.

The utility of α-thujaketonic acid (**5**), as an intermediate in pyrethroid synthesis, can be seen from the simple transformations indicated in the following schemes. In our initial studies (Scheme 1), Wittig reaction of the sodium salt of **5** with methyltriphenylphosphorane in dimethylsulphoxide (DMSO) gave the vinyl cyclopropane **6** in very



5

high yield. Subsequent reaction of the sodium salt of **6** with oxalyl chloride provided the labile acid chloride **7** which, on treatment with (±)*m*-phenoxybenzaldehyde cyanohydrin, gave the required analog **8**. Elliott *et al.* (4) have discussed the use of

[1]For part III, see ref. 3.

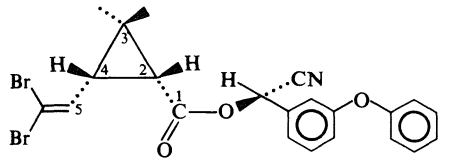
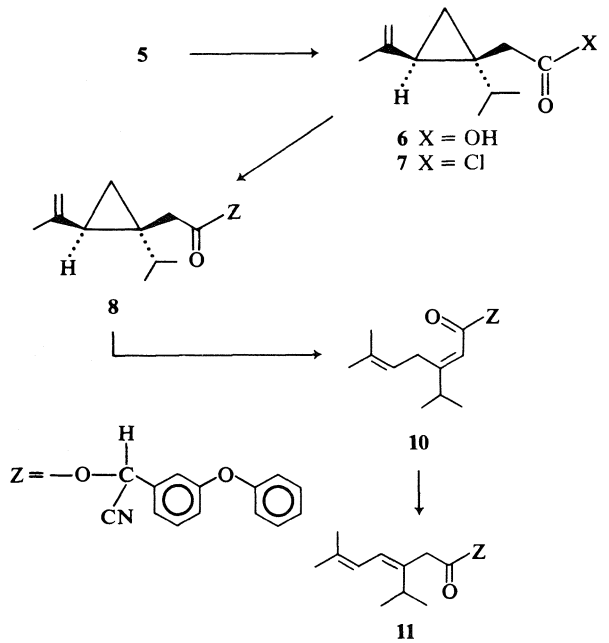
m-phenoxybenzaldehyde cyanohydrin as ester function in the preparation of pyrethrin insecticides with a "new order of activity"; e.g. NRDC 161, (**9**).



9

Pyrolysis of **8** at 130–140°C (e.g. under distillation) allowed facile conversion to the diene **10** which could also be obtained during the preparation of **8** over prolonged reaction periods. Treatment of **10** in petroleum ether with neutral alumina gave a low yield (ca. 25%) of the conjugated diene **11**. Elliott *et al.* (5) have also discussed the crucial 2*R* configuration for active pyrethroids, e.g. NRDC 161, (**9**), as well as the usefulness of both *cis* and *trans* orientation of groups about the cyclopropane ring. Analog **8**, although lacking in the required configuration at C-2, was nevertheless deemed a useful inclusion in our biological screening program.

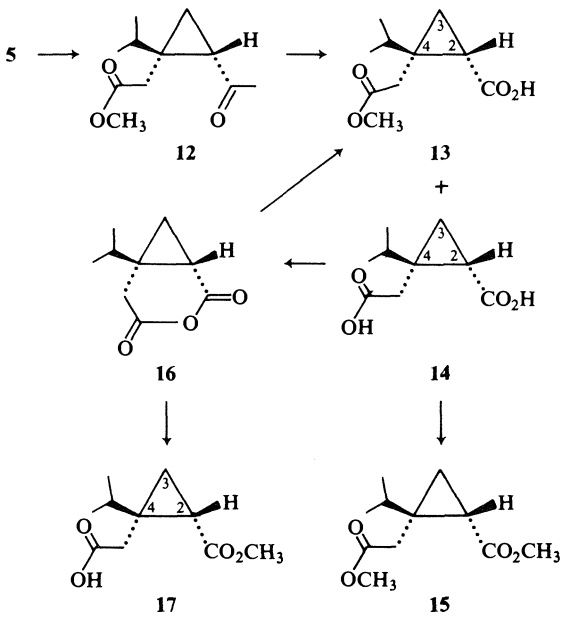
Scheme 2 illustrates the derivation of cyclopropane carboxylic acids and esters with the appropriate configuration at C-2. Here the acetyl cyclopropane function of α-thujaketonic acid methyl ester (**12**) was oxidized with NaOBr to give a mixture of the acid ester **13** (13%) and the diacid **14** (77%).



SCHEME 1

Esterification of **14** (CH_2N_2) gave the diester **15**, while reaction with Ac_2O provided the cyclic anhydride **16** in 89% yield. Treatment of **16** with pyridine in dry methanol solution gave a mixture of acid esters **17** and **13** in the ratio 6:4, not readily separated by standard chromatographic methods.

Thermolysis of **5** in boiling water gave the known (*E*)β-thujaketonic acid (**18**) in high yield (1). Wittig reaction of methyltriphenylphosphorane and the sodium salt of **18** gave the terminal olefin **19** which



SCHEME 2

on subsequent esterification with CH_2N_2 provided **20** in almost quantitative yield. Cyclopropanation using methyl diazoacetate, in the presence of copper sulphate catalyst, gave the racemic cyclopropane derivatives **21** and **22** in approximately equal amounts. Analogous treatment with ethyl diazoacetate provided **23** and **24** (Scheme 3).

The ^1H nmr spectra of **21**–**24** (Table 1) enable tentative assignment of *cis* (**22** and **24**) and *trans* (**21** and **23**) stereochemistry to the appropriate isomers. The significant downfield shifts (0.2–0.3 ppm) of three of the four methylene protons on C-5, C-6 in **22** and **24**, due to the influence of the proximate C-1 carboxyl group, was possible only in a *cis* orientation. The cyclopropane ring protons showed the usual 5 Hz *geminal* and *trans* coupling and 7 Hz *cis* relationships.

The preparation of cyclopropane derivatives carrying a *gem*-dimethyl function is described in Scheme 4. Here thermolysis of the acid **6** gave **25**

[a]Chemical shift values are given in δ ppm. Values in parentheses represent signal multiplicity and coupling constants in Hz.

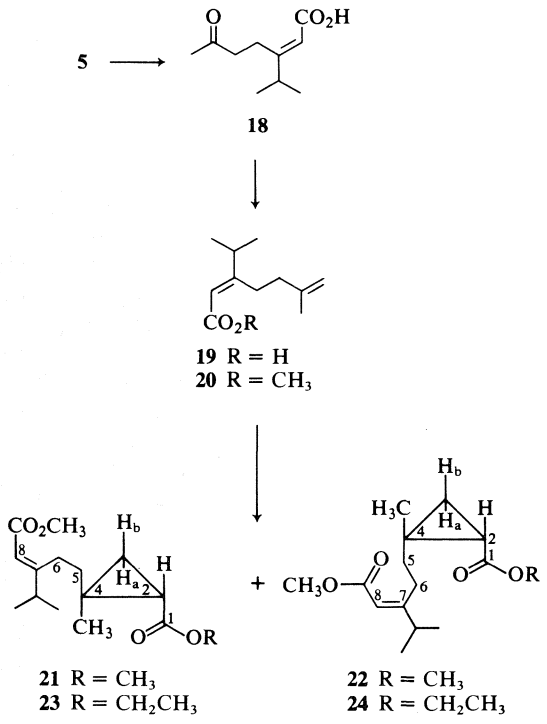
and subsequent esterification provided **26** in high yield. Cyclopropanation of **26** provided a *cis*/*trans* mixture of esters **27** which after ozonolysis gave the ketones **28** and **29**, separable by chromatography on silica gel.

The ^{1}H nmr spectra of **28** and **29** again provided sufficient information for assignment of stereochemistry. Here the *cis* isomer **28** was characterized by a coupling of 9 Hz between H-2 (δ 1.58, d) and H-4 (δ 1.46, dt, J = 6, 6, 9) while in **29**, H-2 (δ 1.25, d) was coupled to H-4 (δ 1.67, dt, J = 6, 6, 8) with J = 6 Hz. Again the methylene protons on C-5 in the *cis* isomer were shifted downfield by ca. 0.2–0.4 ppm relative to the *trans* isomer **29**. The relatively high field absorbance of H-2 in **29** is attributed to its relationship to the shielding zone of the C-6 carbonyl group.

Reduction of **28** with $NaBH_4$ gave the alcohol **30**. The derived tosylate **31** readily eliminated TsOH to give **32**. A similar sequence from **29** (viz. **29** → **33** → **34** → **35**) provided the *trans* isomer **35**.

These final racemic products, **32** and **35**, represent the closest analogs to the pyrethrins, generalized as **4**.

The synthetic sequences described in Schemes 1–4 form the basis of preparation of a wide variety of pyrethrin analogs from the relatively inexpensive versatile starting material thujone (**1**). Biological evaluation of these compounds is presently underway.



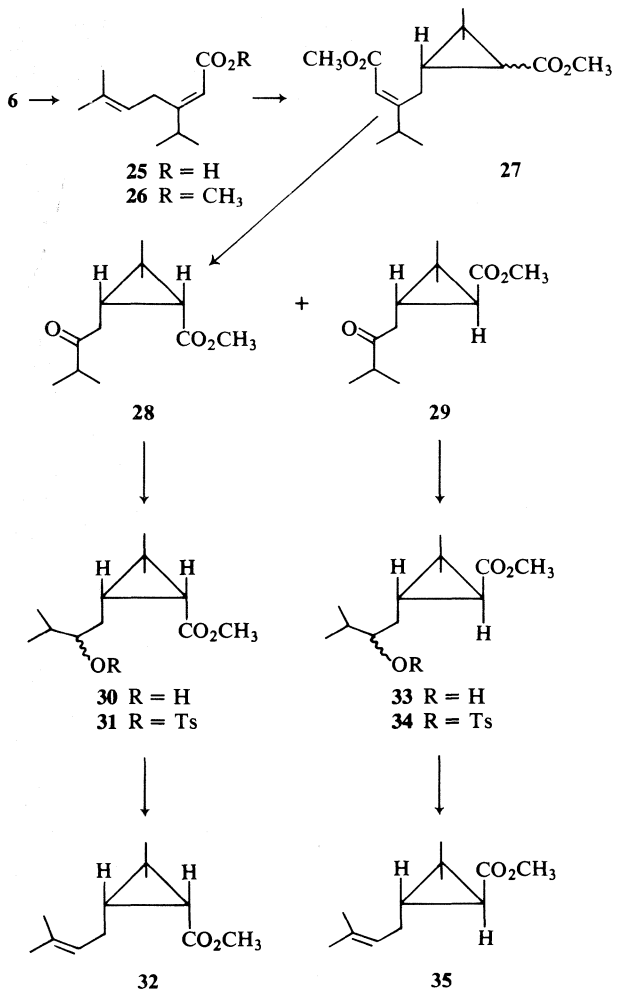
SCHEME 3

Experimental

Ultraviolet spectra were recorded on a Cary 15 spectrophotometer using methanol as the solvent. Infrared spectra were recorded on a Perkin–Elmer 457 spectrophotometer with samples as neat films. The ^{1}H nmr spectra were recorded on a Varian HA- or XL-100 or Nicolet Oxford H-270 or a 400 MHz instrument. The ^{13}C nmr spectra were recorded on a Varian CFT-20 instrument. Deuterochloroform was used as the solvent with TMS as internal standard. Mass spectra were recorded using an Atlas CH-4B or AEI MS-902 instrument. Microanalyses were carried out by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia. Column chromatography utilized Merck silica gel GF_{254} or Woelm neutral alumina grade I. Petroleum ether refers to the fraction with boiling range 30–60°C.

Isopropenyl Derivative ***6*** *(1)*

A solution of methyltriphenylphosphonium bromide (75 g) in dimethylsulphoxide (DMSO, 400 mL) was added to NaH (7.5 g) in DMSO (100 mL) at ambient temperature under nitrogen. The mixture was stirred for 15 min, cooled to 10°C and treated with



SCHEME 4

the sodium salt of α-thujaketonic acid (**5**) (14 g), and the solution stirred 20 h at ambient temperature. The solution was cooled, diluted with cold water (500 mL), and washed with dichloromethane (1 L). The aqueous layer was acidified with 10% H_2SO_4 and extracted with petroleum ether (2 L). This extract was washed with water (1 L), dried ($MgSO_4$), and concentrated *in vacuo* to give **6** (11.6 g, 94%); bp 249–250°C; ir ν_{max}: 1706, 1646; ^{1}H nmr δ: 4.93 (1H, bs), 4.63 (1H, bs), 2.27 (2H, ABq, J = 16), 1.78 (3H, s), 0.98 (3H, d, J = 7), 0.91 (3H, d, J = 7); ms *m/e*: 182 (M^+), 139, 93, 69 (100%).

Ester 8 via 7

Oxalyl chloride (1.5 mL) was added, slowly, to a stirred suspension of the sodium salt of **6** (221 mg) in benzene (8 mL) and pyridine (0.03 mL) at ca. 5°C under nitrogen. The mixture was stirred 2 h at 5°C, filtered, and concentrated *in vacuo* to give the crude acid chloride **7** (159 mg, 73%); ir ν_{max}: 1801. A solution of *m*-phenoxybenzaldehyde cyanohydrin (463 mg) and pyridine (0.096 mL) in benzene (8 mL) was added to **7** in benzene (3 mL) and the mixture refluxed under nitrogen for 45 min. The solvent was removed *in vacuo* and the residue partitioned between water and ether. The ether extract was washed, dried ($MgSO_4$), and concentrated. The oily residue was chromatographed on silica gel to give the ester **8** (115 mg, 37%); ir ν_{max}: 1749, 1643; ^{1}H nmr δ: 7.0–7.5 (9H, envelope), 6.39 (1H, s), 4.90 (1H, bs), 4.60 (1H, bs), 2.30 (2H, ABq, J = 16), 1.76 (3H, s), 0.89 (3H, d, J = 7), 0.87 (3H, d, J = 7); ms *m/e*: 389.1996 (M^+, $C_{25}H_{27}NO_3$ requires 389.1991). *Anal.* calcd. for $C_{25}H_{27}NO_3$: C 77.12, H 6.94, N 3.59; found: C 76.90, H 6.87, N 3.66.

Refluxing in toluene instead of benzene gave a mixture of **8** and **10** (see below) in approximately equal amounts.

Ester 10

The ester **8** (2.7 g) was heated at 130–140°C for 3 h under vacuum (ca. 0.04 Torr), cooled, and filtered (as solution in petroleum ether) through a short column of silica gel to give **10** (2.43 g, 90%); ir ν_{max}: 1723; ^{1}H nmr δ: 7.0–7.5 (9H, envelope), 6.46 (1H, s), 5.73 (1H, s), 5.06 (1H, t, J = 7), 3.43 (2H, d, J = 7), 2.45 (1H, septet, J = 7), 1.69 (6H, s), 1.07 (6H, d, J = 7); ms *m/e*: 389.1998 (M^+, $C_{25}H_{27}NO_3$ requires: 389.1991). *Anal.* calcd. for $C_{25}H_{27}NO_3$: C 77.12, H 6.94, N 3.59; found: C 77.19, H 6.87, N 3.70.

Ester 11

A mixture of the ester **10** (66.5 mg) and Woelm neutral alumina, grade I (3.3 g) was stirred in petroleum ether (30 mL) for 5 min, filtered, and concentrated *in vacuo*. The residue was chromatographed on silica gel to give starting material **10** (27 mg) and **11** (17 mg, 26%); uv λ_{max}: 234 nm (28 000); ir ν_{max}: 1748; ^{1}H nmr δ: 6.95–7.55 (9H, envelope), 6.40 (1H, s), 6.05 (2H, s), 3.1 (2H, s), 3.03 (1H, septet, J = 7), 1.80 (3H, s), 1.70 (3H, s), 0.95 (6H, d, J = 7); ms *m/e*: 389.1992 (M^+, $C_{25}H_{27}NO_3$ requires: 389.1991). *Anal.* calcd. for $C_{25}H_{27}NO_3$: C 77.12, H 6.94, N 3.59; found: C 77.43, H 7.23, N 3.46.

Acid Ester 13 and Diacid 14

Bromine (24 g) was added to a solution of NaOH (15 g) in water (200 mL) at −5°C. A solution of the ketoester **12** (9.7 g) in dioxane (100 mL) was added and the mixture stirred 1 h at −5°C. Saturated Na_2SO_3 solution (50 mL) was added and the mixture acidified with dilute HCl and extracted with dichloromethane. The organic layer was dried and concentrated *in vacuo* to give a viscous oil. Chromatography on silica gel gave the diacid **14** (7.2 g, 77%); mp 135–136°C (dichloromethane); ir ν_{max}: 3400–2400, 1715, 1690; ^{1}H nmr (acetone-d_6) δ: 2.68 and 2.57 (2H, ABq, J = 18), 1.63 (1H, dd, J = 8, 6), 1.41 (1H, septet, J = 7), 1.02–1.10 (2H, m), 0.96 (3H, d, J = 7), 0.95 (3H, d, J = 7); ^{13}C nmr (acetone-d_6) δ: 174.6, 174.2, 36.1, 32.5, 31.3, 24.4, 20.3, 19.5; ms *m/e*: 97, 96, 81, 69 (100), 68, 55, 41. *Anal.* calcd. for $C_9H_{14}O_4$: C 58.06, H 7.53; found: C 58.08, H 7.55.

Also obtained was the acid ester **13** (1.1 g, 13%); bp 150°C (0.1 Torr); ir ν_{max}: 3500–2400, 1735, 1695; ^{1}H nmr δ: 9.30 (1H, bs), 3.65 (3H, s), 2.74 and 2.59 (2H, ABq, J = 16.5), 1.64 (1H, dd, J = 8, 6), 1.26 (2H, m), 1.07 (1H, dd, J = 8, 4), 0.94 (3H, d, J = 7), 0.92 (3H, d, J = 7); ^{13}C nmr δ: 179.3, 173.0, 51.3, 36.2, 33.7, 32.4, 24.7, 21.0, 19.2; ms *m/e*: 200 (M^+), 126, 96, 81, 55 (100), 41. *Anal.* calcd. for $C_{10}H_{16}O_4$: C 60.00, H 8.00; found: C 59.80, H 8.06.

Diester 15

Esterification of **14** (2.1 g) with excess CH_2N_2 in ether gave the diester **15** (2.0 g, 80%); bp 140°C (0.1 Torr); ir ν_{max}: 1725; ^{1}H nmr δ: 3.69 (3H, s), 3.63 (3H, s), 2.72 and 2.56 (2H, ABq, J = 16), 1.67 (1H, dd, J = 8, 6), 1.26 (1H, septet, J = 7), 1.17 (1H, t, J = 5), 0.98 (1H, m), 0.94 (3H, d, J = 7), 0.92 (3H, d, J =7); ^{13}C nmr δ: 173.3, 172.9, 51.6, 51.3, 36.0, 32.3, 24.6, 20.1, 19.3, 19.1; ms *m/e*: 182, 154, 122, 96, 95, 69 (100), 68, 55, 41. *Anal.* calcd. for $C_{11}H_{18}O_4$: C 61.58, H 8.41; found: C 61.50, H 8.58.

Anhydride 16

A solution of the diacid **14** (1.7 g) in acetic anhydride (50 mL) was heated at 110°C for 24 h. The solvent was removed by distillation and the residue distilled *in vacuo* to give **16** (1.4 g,

89%); bp 120°C (0.1 Torr); mp (petroleum ether) 42–43°C; ir ν_{max}: 1800, 1760; ^{1}H nmr δ: 2.98 and 2.84 (2H, ABq, J = 16.5), 1.98 (1H, dd, J = 9, 4), 1.38 (2H, m), 1.17 (1H, t, J = 4), 1.04 (6H, d, J = 7); ^{13}C nmr δ: 167.9, 165.3, 33.9, 31.4, 28.7, 22.9, 20.8, 18.8; ms *m/e*: 168 (M^+), 126, 96, 71, 55 (100), 41. *Anal.* calcd. for $C_9H_{12}O_3$: C 64.28, H 7.14; found: C 63.99, H 7.29.

Conversion of ***16*** *to* ***13*** *and* ***17***

The anhydride **16** (5.0 g) was stirred in pyridine (1 mL) and methanol (50 mL) for 16 h at ambient temperature. The reaction mixture was poured into ice water (200 mL) and extracted with dichloromethane. The extract was dried and evaporated to give a mixture (5.2 g, 86%) of **13** (identical with that obtained above) and **17** (ratio 2:3); ^{1}H nmr δ: 9.1 (1H, bs), 3.67 (3H, s), 2.75 and 2.61 (2H, ABq, J = 16.5), 1.67 (1H, dd, J = 8, 6), 0.95 (3H, d, J = 7), 0.94 (3H, d, J = 7).

Acid ***19***

A mixture of sodium hydride (4.5 g) and dry DMSO (150 mL) was stirred at 70°C for 1 h under N_2. Methyltriphenylphosphonium bromide (68 g) in DMSO (150 mL) was added at room temperature and the solution stirred for 30 min. The sodium salt of (*E*)β-thujaketonic acid (**18**) (9.13 g) was added and the mixture stirred at 65°C for 20 h, diluted with ice-cold water (1.2 L), and washed with ether. The aqueous layer was acidified (5°C) with 6 *N* HCl and extracted with petroleum ether. The extract was dried (Na_2SO_4) and concentrated. Distillation *in vacuo* gave **19** (8.69 g, 98%); bp. 80–90°C (0.03 Torr); mp 46–48°C; ^{1}H nmr δ: 5.74 (1H, bs), 4.76 (2H, bs), 2.45 (1H, septet, J = 7), 1.80 (3H, bs), 1.12 (6H, d, J = 7); ms *m/e*: 182 (M^+). *Anal.* calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.95; found: C 72.34, H 9.69.

Ester ***20***

Esterification of **19** with CH_2N_2 gave **20** (quantitative); uv λ_{max}: 215 (log ε 3.89); ^{1}H nmr δ: 5.71 (1H, s), 4.7 (2H, bs), 3.71 (3H, s), 2.40 (1H, septet, J = 7), 1.86 (3H, bs), 1.10 (6H, d, J = 7); ms *m/e*: 196 (M^+). *Anal.* calcd. for $C_{12}H_{20}O_2$: C 73.43, H 10.27; found: C 73.43, H 10.15.

Cyclopropanes ***21*** *and* ***22***

Methyl diazoacetate (15 g) was added slowly (10 h) to a mixture of **20** (8.15 g) and anhydrous copper sulphate (0.8 g) at 0–5°C. The mixture was stirred until the evolution of gases ceased, then heated to 100°C. Additional methyl diazoacetate (5 g) was added at this temperature during 1 h. The mixture was cooled to room temperature, diluted with dichloromethane and filtered. The filtrate was evaporated and the residue extracted into petroleum ether. The extract was concentrated *in vacuo* and filtered through a short plug of silica gel. The eluate was then chromatographed (preparative hplc, Waters Associates LC-500) on silica gel to give **21** (3.54 g); uv λ_{max}: 217 (log ε 3.2); ir ν_{max}: 3065, 1710–1732, 1635, 1015, 870; ^{1}H nmr, see Table 1; ms *m/e*: 268 (M^+), 209, 208, 150. *Anal.* calcd. for $C_{15}H_{24}O_4$: C 67.14, H 9.01; found: C 67.60, H 9.20; and **22** (2.68 g); uv λ_{max}: 218 (log ε 3.2); ir ν_{max}: 3068, 1710–1735, 1638, 1025, 870; ^{1}H nmr, see Table 1; ms *m/e*: 268 (M^+), 209, 208, 150. *Anal.* calcd. for $C_{15}H_{24}O_4$: C 67.14, H 9.01; found: C 67.33, H 9.18.

Esters ***23*** *and* ***24***

Similarly, reaction of **20** with ethyl diazoacetate gave **23**; ir ν_{max}: 3035, 1720, 1640; ^{1}H nmr, see Table 1; ms *m/e*: 282 (M^+). *Anal.* calcd. for $C_{16}H_{26}O_4$: C 68.08, H 9.22; found: C 67.99, H 9.38; and **24**; ir ν_{max}: 3040, 1725, 1645, 790; ^{1}H nmr, see Table 1; ms *m/e*: 282 (M^+). *Anal.* calcd. for $C_{16}H_{26}O_4$: C 68.08, H 9.22; found: C 68.00, H 9.28.

Acid ***25***

The acid **6** (9.0 g) was heated, *in vacuo*, at 140°C for 6 h. The crude product was then chromatographed on silica gel to give **25** (6.65 g, 74%); mp 42–45°C; uv λ_{max}: 216 (log ε 4.07); ir ν_{max}: 3500–2600, 1690, 1635; ^{1}H nmr δ: 5.72 (1H, s), 5.18 (1H, bt, J = 7), 3.40 (2H, bd, J = 7), 2.42 (1H, septet, J = 7), 1.69 (6H, bs), 1.08 (6H, d, J = 7); ms *m/e*: 182 (M^+), 139, 41. *Anal.* calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.95; found: C 72.30, H 9.99.

Ester ***26***

Esterification of **25** with CH_2N_2 gave **26** (98%); uv λ_{max}: 218 (log ε 4.28); ir ν_{max}: 1720, 1630; ^{1}H nmr δ: 5.63 (1H, s), 5.04 (1H, bt, J = 7), 3.64 (3H, s), 3.39 (2H, bd, J = 7), 2.34 (1H, septet, J = 7), 1.63 (6H, bs), 1.00 (6H, d, J = 7); ms *m/e*: 196 (M^+), 165, 164, 154, 153, 149, 137, 121, 95, 93, 91, 81, 79, 77, 69, 67, 41. *Anal.* calcd. for $C_{12}H_{20}O_2$: C 73.43, H 10.27; found: C 73.23, H 10.21.

Cyclopropane Esters ***27***

Reaction of **26** (6.96 g) with methyldiazoacetate and copper sulphate, as described above, gave a *mixture* of the isomeric esters **27** (7.22 g, 76%); uv λ_{max}: 219 (log ε 3.99); ir ν_{max}: 1715, 1635, 1015, 870; ^{1}H nmr δ: 5.68 (2 × 1H, s), 3.66, 3.65, 3.62, 3.61 (4 × 3H, s), 3.03 (1H, dd, J = 14, 6), 2.90 (1H, dd, J = 13, 6), 2.85 (1H, dd, J = 13, 6), 2.80 (1H, dd, J = 14, 9), 2.48 (1H, septet, J = 7), 2.37 (1H, septet, J = 7), 1.51 (1H, dt, J = 9, 6, 6), 1.39 (1H, d, J = 6), plus overlapping methyl signals; ms *m/e*: 268 (M^+), 236, 193, 177, 154, 153, 135, 133, 107, 95, 67, 43, 41. *Anal.* calcd. for $C_{15}H_{24}O_4$: C 67.14, H 9.01; found: C 66.99, H 8.95.

Ozonolysis of ***27*** *to* ***28*** *and* ***29***

A solution of **27** (3 g) in dichloromethane (100 mL) was treated, at 0°C, with an excess of ozone for 30 min. The solution was washed with 5% Na_2SO_3 solution, dried (Na_2SO_4), and concentrated *in vacuo*. Chromatography on silica gel gave the isomeric ketones **28** (0.65 g); ir ν_{max}: 1720, 1000, 855; ^{1}H nmr δ: 3.64 (3H, s), 2.94 (1H, dd, J = 16, 6), 2.91 (1H, dd, J = 16, 6), 2.63 (1H, septet, J = 7), 1.58 (1H, d, J = 9), 1.46 (1H, dt, J = 6, 6, 9), 1.23 (3H, s), 1.16 (3H, s), 1.11 (3H, d, J = 7), 1.09 (3H, d, J = 7); ms *m/e*: 212 (M^+), 153, 152. *Anal.* calcd. for $C_{12}H_{20}O_3$: C 67.89, H 9.50; found: C 67.59, H 9.51; and **29** (0.84 g); ir ν_{max}: 1720, 1000, 875; ^{1}H nmr δ: 3.70 (3H, s), 2.65 (1H, septet, J = 7), 2.66 (1H, dd, J = 16, 6), 2.49 (1H, dd, J = 16, 8), 1.67 (1H, dt, J = 8, 6, 6), 1.28 (3H, s), 1.25 (1H, d, J = 6), 1.12 (3H, s), 1.11 (6H, d, J = 7); ms *m/e*: 212 (M^+), 153, 152. *Anal.* calcd. for $C_{12}H_{20}O_3$: C 67.89, H 9.50; found: C 67.75, H 9.44.

Alcohol ***30***

Reduction of **28** with $NaBH_4$ in methanol gave the alcohol **30** (88%); ir ν_{max}: 3440, 1725, 865; ^{1}H nmr δ: 3.64 (3H, s), 3.34 (1H, m), 1.92 (1H, m), 1.68 (2H, m), 1.62 (1H, bs, D_2O exchangeable), 1.20 (3H, s), 1.19 (3H, s), 0.91 (6H, d, J = 7); ms *m/e*: 196 (M − 18), 137, 136. *Anal.* calcd. for $C_{12}H_{22}O_3$: C 67.26, H 10.35; found: C 67.10, H 10.38.

Alcohol ***33***

Similarly, **29** gave **33**; ir ν_{max}: 3410, 1725, 865; ^{1}H nmr δ: 3.67 (3H, s), 3.44 (1H, m), 1.81 (1H, bs, D_2O exchangeable), 1.69 (1H, m), 1.60 (1H, m), 1.45 (2H, m), 1.24 (3H, s), 1.16 (3H, s), 0.92 (3H, d, J = 7), 0.91 (3H, d, J = 7), most signals were doubled due to the presence of two diastereomers; ms *m/e*: 214 (M^+), 196, 137, 136. *Anal.* calcd. for $C_{12}H_{22}O_3$: C 67.26, H 10.35; found: C 67.36, H 10.40.

The Olefin ***32*** *via* ***31***

Alcohol **30** (130 mg) and *p*-toluenesulphonyl chloride (140 mg) were heated in dry pyridine (1 mL) at 110°C for 6 h. The mixture was cooled, poured into ice-water, and extracted with ether. The extract was washed with $CuSO_4$ solution, dried (Na_2SO_4), and concentrated *in vacuo*. The residual oil was distilled *in vacuo* (0.2 Torr) at 50–60°C to yield **32** (94 mg, 79%); ir ν_{max}: 1725, 855; ^{1}H nmr δ: 5.05 (1H, bt, J = 8), 3.63 (3H, s), 2.33 (2H, bm), 1.99 (1H, bm), 1.69 (3H, bs), 1.62 (3H, bs), 1.24 (3H, s), 1.15 (3H, s); ms *m/e*: 196 (M^+), 137, 136. *Anal.* calcd. for $C_{12}H_{20}O_2$: C 73.43, H 10.27; found: C 73.23, H 10.19.

*The Olefin **35** via **34***

Similarly, **33** gave the olefin **35** (85%); ir ν_{max}: 1725, 820; ^{1}H nmr δ: 5.13 (1H, bt, $J = 8$), 3.68 (3H, s), 1.70 (3H, bs), 1.60 (3H, bs), 1.22 (3H, s), 1.17 (3H, s); ms *m/e*: 196 (M^+), 137, 136. *Anal.* calcd. for $C_{12}H_{20}O_2$: C 73.43, H 10.27; found: C 73.31, H 10.16.

The results of a uv–visible spectroscopic study of the interaction of 1,3-dinitrobenzene (DNB) with hydroxide ion in aqueous dimethylformamide (DMF) media are reported. Formation of several spectral species has been discerned, depending on factors such as the relative concentrations of the reactants, the time scale of the experiments, and the medium composition. The principal interaction is formation of the 1-hydroxy-2,4-dinitrocyclohexadienate anion. The molar absorptivities of this σ-complex, and the equilibrium constants (K_e) for its formation, have been determined as a function of medium composition. Values of K_e increase from 7.5 M^{-1} to 3×10^5 M^{-1} as the DMF content of the medium is changed from 57.4 to 95.8 mol% DMF. A solvent isotope effect, $K_e(D_2O)/K_e(H_2O)$, of ca. 0.4 has been observed. Structural and medium effects in this and related systems are evaluated. Correlations between log K_e and H_- are examined using the stoichiometric as well as the calculated free hydroxide ion concentrations. Attention is drawn to an important condition for equilibrium constant measurement in systems where one of the interacting species contributes significantly to the overall basicity, or to another property of the medium.

ERWIN BUNCEL et ALLEN W. ZABEL. Can. J. Chem. **59**, 3168 (1981).

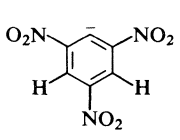
On rapporte les résultats de l'étude de la spectroscopie dans l'uv visible de l'interaction du dinitro-1,3 benzène (DNB) avec l'ion hydroxyde dans du diméthylformamide aqueux. On a décelé la formation de plusieurs expèces spectrales dépendant de facteurs tels les concentrations relatives des réactifs, la durée des expériences et la composition du milieu. La formation de l'anion hydroxy-1 dinitro-2,4 cyclohexadiénate est la réaction principale. On a déterminé, en fonction de la composition du milieu, les absorptions molaires de ce complexe σ et la constante d'équilibre (K_e) de sa formation. Les valeurs de K_e augmentent de 7,5 M^{-1} à $3 \times 10^5 M^{-1}$ lorsque la teneur en DMF du milieu passe de 57,4 à 95,8 mol% de DMF. On a observé un effet isotopique du solvant $K_e(D_2O)/K_e(H_2O)$ d'environ 0,4. On a évalué dans ce système et dans des systèmes apparentés, les effets de structure et les effets du milieu. On a examiné les corrélations entre log K_e et H_- en utilisant les concentrations stoechiométriques aussi bien que les concentrations calculées de l'ion hydroxyle libre. On a porté une attention particulière à une condition importante de la mesure de la constante d'équilibre dans les systèmes où l'une des espèces en interaction peut contribuer d'une façon importante soit à la basicité globale soit à une autre propriété du milieu.

[Traduit par le journal]

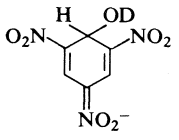
In the interaction of aromatic nitro compounds with bases such as alkoxides or amines, the predominant mode of interaction is Meisenheimer or σ-complex formation, although various other types of interaction have also been substantiated, viz. proton transfer, electron transfer processes, etc. (1–5). Our work in this area has attempted to delineate the conditions under which given interactions occur and to identify structurally the nature of the species that are formed. One aspect of this work has focussed on the effect of medium changes on these processes. Of particular interest have been the dipolar aprotic media dimethyl sulfoxide (DMSO) and dimethylformamide (DMF), and how these media affect the balance between hydrogen isotope exchange and σ-complex formation (6, 7).

For 1,3,5-trinitrobenzene (TNB) in DMF–D_2O media containing NaOD, we have found that deuterium exchange, occurring via carbanion **1** as the intermediate, was intimately related to formation of the σ-complex **2** (8, 9). The present work is concerned with a parallel approach to the case of 1,3-dinitrobenzene (DNB) in basic DMF media. We have shown in the accompanying paper that, with respect to deuterium exchange, the behaviour of DNB contrasts to that of TNB in a number of important aspects (10). The present paper describes the uv–vis spectroscopic results for DNB in alkaline DMF systems. The spectral behaviour is found to be much more complex than in the case of TNB (9).

The diversity of spectral behaviour found in the present system required a systematic variation of



1



2

parameters such as the medium composition, the relative concentrations of DNB and OH^-, etc. The principal species present has been identified, however, and the conditions for its formation are shown to parallel the accompanying study of deuterium exchange (10).

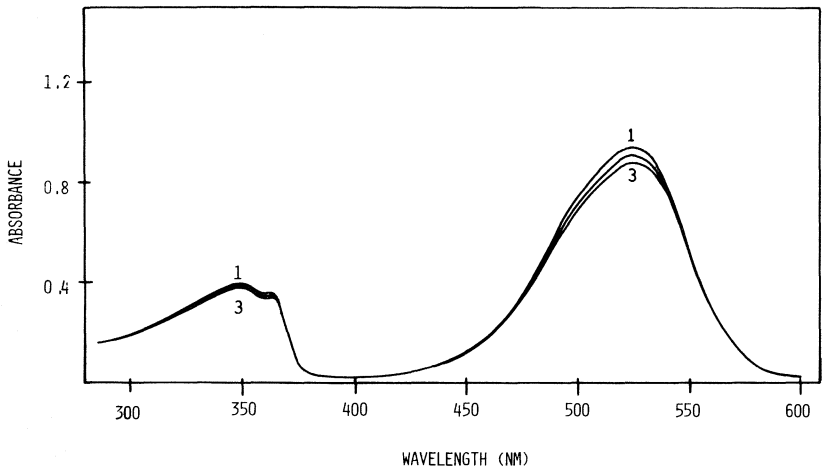

FIG. 1. Spectra of solution containing DNB (0.004 *M*) and Me_4NOH (0.004 *M*) in 91 mol% DMF taken at various times after preparation in 0.1 mm cuvette. (1) 1 min, (3) 20 min.

Results and Discussion

Characterization of Spectral Species

In Fig. 1 are shown the spectra of a solution of DNB (0.004 *M*) and tetramethylammonium hydroxide (0.004 *M*) in 91 mol% DMF taken at various intervals from the time of mixing. The spectra are characterized by a main absorption occurring at 526 nm and a minor absorption with maxima at 350 and 364 nm. It is seen that a uniform decrease in the absorptions, to the extent of 3%, has taken place over the entire spectral region over this period. This decrease continues thereafter at about the same rate until eventually there is no absorption in the visible region.

The decay in the absorptions as a function of time which is displayed in Fig. 1 can be ascribed to the removal of hydroxide ion from the equilibrium as a result of reaction with solvent DMF (11). The rate of decay of the spectral species is dependent on the free OH^- concentration and varies with solvent composition. In media of relatively low DMF content, where K_e is relatively small, the decay is relatively fast, while the converse holds for media of relatively high DMF content (e.g. Fig. 1).

The type of spectral behaviour shown in Fig. 1 was found to obtain in solvent compositions varying from ca. 96 mol% DMF, the upper limit studied, down to ca. 70 mol% DMF. However, in media of still lower DMF content another type of spectral behaviour was observed and this will be described subsequently. Increasing the concentrations of DNB and OH^- had no effect on the principal absorption at 526 nm under the condition that $[DNB] \geq [OH^-]$, but for $[DNB] < [OH^-]$ a different type of behaviour was observed (*vide infra*). At a relatively large DNB concentration and with the nitroaromatic in excess, the absorption maxima in the 350 nm region could not be seen, being swamped by the end absorption due to DNB. In the high DMF region, the rate of decay of the spectrum when DNB was in large excess over OH^- (0.5 *M* and 0.004 *M* respectively) was identical to that when the reagents were equimolar (0.004 *M*).

Addition of a slight excess (25%) of acid to a solution containing 0.004 *M* Me_4NOH and 0.1 *M* DNB led to instantaneous collapse of the entire visible spectrum. Addition to this solution, after an interval of 10 min, of an aliquot of base equivalent to the acid added earlier quantitatively restored the original spectrum. This type of behaviour is characteristic of Meisenheimer complex formation (1–5).

The stoichiometry of the colored species was investigated by means of a continuous variation (Job) plot (12) and the results for 81.8 mol% DMF are shown in Fig. 2. The two curves in this plot correspond to absorbances at 490 and 526 nm, which were chosen to determine whether changes in absorbance are dependent on the wavelength selected. In fact the curves in both cases are quite similar. Extrapolation in each case produces an apex corresponding to 0.47 mole fraction DNB, as opposed to 0.50 which would be expected for a 1:1 complex. However, careful scrutiny of the spectra upon which this plot is based reveals that more than one type of spectral behaviour is present. When $[DNB] \geq [OD^-]$, a single absorption at 526 nm occurs, which then slowly decreases with time. On

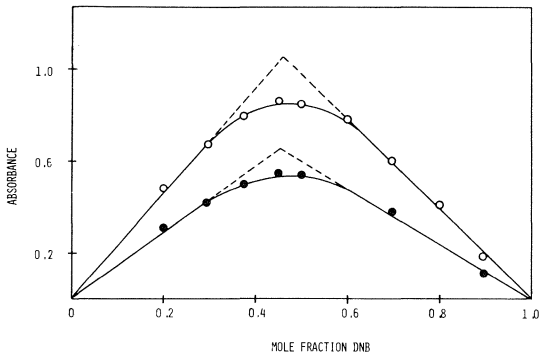

FIG. 2. Continuous variations plot for DNB + Me_4NOD system (total concentrations, 0.01 *M*) in 81.8 mol% DMF; absorbances in 0.1 mm cuvette at 526 nm (open circles) and 490 nm (closed circles).

the other hand, when [DNB] < [OD^-], the 526 nm absorption shifts with time to 533 nm, via an isosbestic point, and then slowly decreases. This suggests that another spectral species is formed when the base is in excess. The presence of this species, which could possibly result from addition of two hydroxide ion moieties to DNB, is presumably responsible for the lack of symmetry in the plots in Fig. 2. Since the isotopic exchange studies (10) were carried out under the conditions [DNB] ≫ [OD^-], the presence of only a 1:1 complex in those systems seems highly probable. It should be noted, however, that the Job method does not distinguish between a single 1:1 complex, and two (or more) 1:1 complexes coexisting in the same system.

Another, minor, spectral species could be discerned under some conditions in media containing <70 mol% DMF, and became somewhat more prominent as the DMF content was further decreased. A hint of this new species was first seen in the 68 mol% DMF medium, containing 2×10^{-4} *M* DNB and 1×10^{-2} *M* hydroxide ion, as a minor shoulder absorption at ca. 500 nm. This absorption remained following decay of the main absorption, λ_{max} 526 nm. The new species is visible more clearly in Fig. 3 which is applicable to 57.4 mol% DMF and [DNB] = [Me_4NOD] = 10^{-2} *M*. It is also seen that the spectra in this figure show an initial increase with time and upon reaching a maximum value begin to decay. This type of behaviour was found for all solutions containing <70 mol% DMF.

It was not possible to find conditions under which the 500 nm species predominated in the absence of the 526 nm species. As a result, the nature and stoichiometry of the former species could not be determined, though a possibility is σ-complex formation with the dimethylamine liberated in this system. This species should be unimportant under the typical conditions pertaining to the accompanying isotopic exchange study (10), namely in media of high DMF content and with DNB in large excess over the hydroxide (deuteroxide) ion concentration.

The increase in the 526 nm absorption in media containing <70 mol% DMF can be ascribed to a decrease in the forward rate constant for σ-complex formation as the aqueous component is increased. Such an effect was found in DMSO–methanol media where the rate of formation of the methoxide ion adduct of TNB and other nitroaromatics increased very greatly when the DMSO content was increased, but the rate of decomposition of the adduct was not appreciably affected

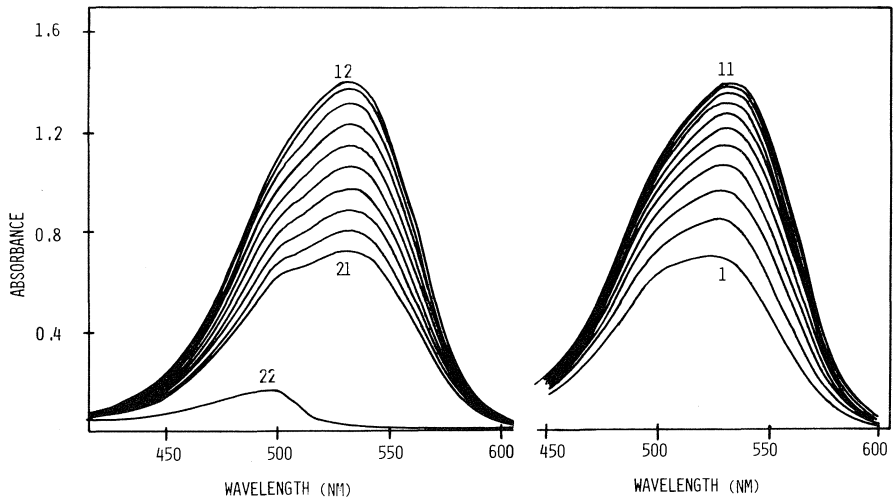

FIG. 3. Spectra of solution of DNB (0.01 *M*) and Me_4NOD (0.01 *M*) in 57.4 mol% DMF taken in 1 mm cuvette at various times after preparation: (1) 1 min, (11) 9 min, (12) 10 min, (21) 33 min, (22) 24 h.

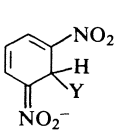
thereby (12, 13). This is consistent with the present results.

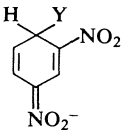
The 1-Hydroxy-2,4-dinitrocyclohexadienate Anion and Other Species in DNB–Base Systems

Our results show that in media of relatively high DMF content one species predominates. It is concluded that this species is the 1-hydroxy-2,4-dinitrocyclohexadienate anion, **4**, formed by the addition of OH^- (OD^-) to a carbon *para* to one of the NO_2 groups in DNB, for which the absorption maximum occurs at 526 nm (Fig. 1). The isomeric structure **3** could be formed only as a transient species. The evidence which points to this conclusion is as follows.



3

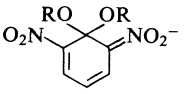
Y = OH or OD



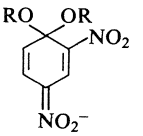
4

Unambiguous evidence concerning the structures of σ-complexes has been obtained by nmr spectroscopy for a variety of structural types (15–23). However, the nmr method has been found unworkable in the present system. This may be due in part to the generally low value of the equilibrium constant for formation of σ-complexes of DNB, simultaneously with its high affinity for electron transfer leading to the radical anion $DNB^{\cdot-}$ (24–28). Bellobono *et al.* (25) obtained evidence for the formation of $DNB^{\cdot-}$ by action of methanolic sodium methoxide on DNB, but only at very large MeONa concentrations (2.9–5 *M*). They reported a λ_{max} value of 500 nm for this species, which was also characterized by its esr spectrum. It was shown that $DNB^{\cdot-}$ was a reaction intermediate in the reduction of DNB to 3,3′-dinitroazoxybenzene, the final product. In contrast to the study of Bellobono *et al.* (25), under the conditions of the present study the spectral species with λ_{max} 348, 360, 526 nm was found to be formed reversibly, and DNB could be isolated in high yield on acidification (e.g. in the deuteration experiments). We can therefore exclude the formation of $DNB^{\cdot-}$ in the present system, except as a minor species.

Can one distinguish through uv–vis spectroscopy between the two σ-complexes **3** and **4**? Pollitt and Saunders (29) found that in σ-complex formation by 2,6- and 2,4-dinitroanisoles, the uv–vis spectra of adducts of type **5** were characteristically different from those of type **6** (for **5**, R = Me, λ_{max} 358, 586 nm; for **6**, R = Me, λ_{max} 348, 358, 503 nm), the longest wavelength absorption being the most intense in each case.

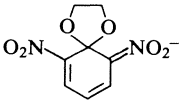


5

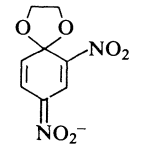


6

There was close similarity between the uv–vis spectra of **5** and **7**, and those of **6** and **8**. These structural assignments were confirmed in subsequent nmr studies on the σ-complexes **5**–**8** (28, 30).



7



8

The uv–vis spectrum that we have observed in the DNB–DMF–H_2O–OH^- system, as shown in Fig. 1, fits closely the characteristics given for **6** but not for **5**.

Following the discovery by Servis (31) that 2,4,6-trinitroanisole (TNA) reacts with MeO^- to yield the C-3 adduct in a kinetically preferred process and the C-1 adduct by thermodynamic control, a number of studies have confirmed this type of behaviour in related systems (2–5). It has been shown by Hasegawa and Abe (32) that this applies equally to the dinitrobenzene series, including DNB and 2,4-dinitroanisole. In these cases, uv–vis spectra taken by means of a rapid scan spectrophotometer showed that the initial spectrum taken ≤ 1 s after mixing had the characteristics ascribed above to species **3** (Y = OMe) and **5** (R = Me), while spectra taken at later times corresponded to **4** (Y = OMe) and **6** (R = Me), respectively. Since in our work initial spectra were taken ~ 1 min after mixing, only the σ-complex **4** would be detectable.

Equilibrium Parameters and Medium Effects

Preliminary experiments indicated that the equilibrium constants for formation of σ-complex **4** increase greatly with an increase in the DMF content of the medium. In Fig. 4 is shown a qualitative measure of this effect, as a plot of absorbance vs. [DNB] at constant [OD^-], for two different medium compositions. Both plots show an initial increasing portion when the reactant concentrations are in the order [DNB] < [OD^-], and a plateauing when [DNB] > [OD^-]. The sharpness of the transitional region in these plots is an indication of the magnitude of K_e. In 88.6 mol% DMF, the absorbance has reached virtually its maximum value when DNB is only in slight excess over OD^-, in accord with a very large value of K_e.

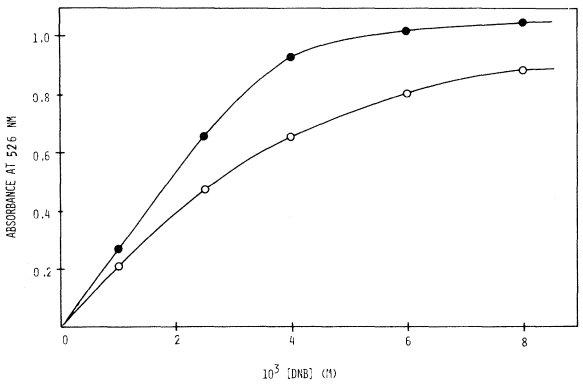

FIG. 4. Plot of absorbance vs. [DNB] at constant [Me_4NOD] (0.004 *M*) in 0.1 mm cuvette, for 81.8 mol% DMF (open circles) and 88.6 mol% DMF (closed circles).

Therefore, when K_e is large, that is in media of high DMF content, the molar absorptivity should readily be determined by the overload procedure, using a large excess of DNB over OH^- (or OD^-). Accordingly, typical measurements (Table 1) were performed using [Me_4NOD] = 0.004 *M* and [DNB] = 0.5 *M*, that is for [DNB]/[Me_4NOD] = 125:1. For the media with >70 mol% DMF, absorbance values at 526 nm were extrapolated with reasonable accuracy back to zero time, in order to correct for the decay of the spectra as a result of the reaction of OH^- with DMF. As noted earlier, in the 68.1 and 57.4 mol% DMF systems there was an initial increase in the absorbance prior to the slow decrease (Fig. 3). Since in these systems the absorbance passed through a maximum, this presented difficulty in determining the value to be used in subsequent calculations of K_e. An iterative method was adopted for this purpose (33) and gave results for the two solvent compositions which were consistent with expected trends (e.g. variation of K_e with solvent composition).

In Table 1 and Fig. 5 is shown the variation of the absorbance at 526 nm due to the σ-complex with the solvent composition, as determined in the above manner. It is seen that the absorbance rises steeply at first, reaching a near plateau at ca. 75 mol% DMF, and thereafter increases only very slightly as the DMF content is increased still further. The levelling off in absorbance indicates that beyond ca. 75 mol% DMF virtually all of the base has been complexed, the slight increase in absorbance in media richer in DMF being the result of a solvent effect on the extinction coefficient (9). The molar absorptivity (ε) at the absorption maximum in ≥75 mol% DMF is thus readily calculated from the relationship $A = \varepsilon cl$, where l is the cell path length and c is the hydroxide ion concentration which (as the species in deficit) will be equal to the stoichiometric concentration of σ-complex. For media containing ≥75 mol% DMF, A is the measured (limiting) absorbance value corresponding to the linear portion of the plot in Fig. 5. In media more aqueous than 75 mol% DMF, an extrapolated value from the linear plot was used, shown as the dotted line in Fig. 5. Because of the possibility of error in this procedure, it was only employed for media with >50 mol% DMF.

TABLE 1. Medium dependence of absorbance and molar absorptivities at 526 nm in DMF–D_2O system at 25°C (0.476 *M* DNB, 0.0038 *M* Me_4NOD)

Mol% DMF	A^a	ε M^{-1} cm^{-1}
57.4	0.286	26 600[b]
68.1	0.853	26 800[b]
73.3	0.993	27 000[c]
75.8	1.020	27 100[c]
81.8	1.033	27 200[c]
91.1	1.049	27 500[c]
95.8	1.050	27 700[c]

[a] Average values of absorbance, using 0.1 mm cuvette, extrapolated to zero time (see text).
[b] Extrapolated values based on dashed line in Fig. 5.
[c] Data from linear portion in Fig. 5.

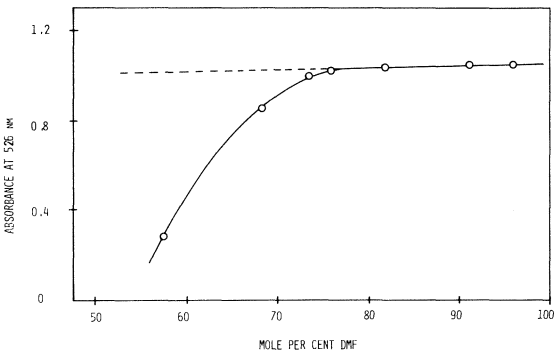

FIG. 5. Determination of molar absorptivity as function of medium composition by overload method for DNB = 0.5 *M*, Me_4NOD = 0.0038 *M*. Absorbances at 526 nm given relative to 0.1 mm cuvette.

The molar absorptivity values of **4** determined by the above procedure are given in Table 1 for a range of DMF–water solvent compositions. Another series of measurements was performed using H_2O as the aqueous component. The corresponding values were found to be identical within the error limits of these measurements (±2%).

With the molar absorptivity at λ_{max} for the σ-complex **4** in the various solvent compositions having been determined, the equilibrium constant for σ-complex formation could then be evaluated as a function of solvent composition. For this pur-

pose, the absorbance of a series of solutions containing equimolar concentrations of DNB and Me_4NOD was determined as a function of DMF composition, at 25°C. The concentration of **4** in these solutions can be obtained from the relationship $A = \varepsilon[\mathbf{4}]l$. The expression [1] for K_e containing the equilibrium species concentrations

$$[1] \quad K_e = \frac{[\mathbf{4}]}{[DNB]_e[OH^-]_e}$$

is then transformed into eq. [2] by substituting $[DNB]_e = [DNB]_0 - [\mathbf{4}]$ and $[OH^-]_e = [OH^-]_0 - [\mathbf{4}]$.

$$[2] \quad K_e = \frac{[\mathbf{4}]}{([DNB]_0 - [\mathbf{4}])([OH^-]_0 - [\mathbf{4}])}$$

The resulting K_e values are presented in Table 2. The uncertainty limits in these K_e values are considerable when K_e is large. For example in the 95.8 mol% DMF system (K_e ca. 10^5) a change of 1% in the absorbance value leads to a change of ca. 100% in K_e. However, in 75.8 mol% DMF an uncertainty of ±5% in the absorbance leads to uncertainty limits of ±10% in K_e. A noteworthy point is that in the several instances where a range of equimolar concentrations of the reagents was used, there was only moderate effect on the equilibrium constant. This suggests that the orders of magnitude of the K_e values might be generally applicable to other concentration values (10).

TABLE 2. Dependence of equilibrium constant for σ-complex formation on medium composition in DMF–D_2O system at 25°C[a]

Mol% DMF	$10^3[DNB]_0$ ($10^3[OD^-]_0$) M	$10^3[\mathbf{4}]$[b] M	K_e[c] M^{-1}

95.8	4.0	3.88	3.1×10^5

[a]Results given are mean values of several measurements (see text for error limits).
[b]Concentration of σ-complex, calculated from expression $A = \varepsilon[\mathbf{4}]l$ where $l = 0.01$ cm, using values of A extrapolated to zero time (see text).
[c]Calculated via eq. [2].
[d]Values obtained by iteration procedure (see text). Uncorrected K_e values based on maximum absorbances reached are $5.9\,M^{-1}$ for 57.4 mol% DMF and $41\,M^{-1}$ for 68.1 mol% DMF.

A second series of experiments was performed for the DMF–H_2O–Me_4NOH system as a function of solvent composition, using equimolar DNB and base solutions ($0.004\,M$), which yielded K_e values for the undeuterated media. The results are summarized in Table 3, which also gives the corresponding K_e values for the deuterated media, as well as the equilibrium constant ratio, that is the solvent isotope effect. The results for the 68.1 and 75.8 mol% solvent compositions are subject to error owing to the facility of the reaction of OH^- with DMF when K_e is relatively small, while in 95.8 mol% DMF the very large K_e value magnifies the error inherent in the experimental method. These considerations lead to a $K_e(D_2O)/K_e(H_2O)$ ratio in the region of 0.35–0.40 for this process.

Previous work has yielded solvent isotope effects for σ-complex formation processes varying between 0.38 and 0.54 (34–36). Use of Bunton and Shiner's model (37) led to a theoretical solvent isotope effect of 0.47 for the formation of **6** (R = Me), in close agreement with the experimental value of 0.38 (35).

Structural, Medium, and Basicity Correlations in Complexation

Table 2 shows that the medium effect on K_e is very large, that is K_e increasing from $7.5\,M^{-1}$ to $3.1 \times 10^5\,M^{-1}$ as the DMF content is increased from 57.4 to 95.8 mol%. In our previous work with TNB it was found that K_e increased from $5\,M^{-1}$ to $2 \times 10^4\,M^{-1}$ on increasing the DMF content of the medium from 1 to 33.8 mol% (9). In order to compare the data for the two systems more directly, one can extrapolate the log K_e vs. H_- plot (Fig. 6) for DNB to the H_- value for 33.8 mol% DMF (i.e. $H_- = 14.8$), yielding $K_e = 0.2\,M^{-1}$. This leads to an equilibrium constant ratio, $K_e(TNB)/K_e(DNB)$, of 10^5. The greater stability of σ-complexes derived from trinitroaromatic substrates, compared with corresponding dinitroaromatics has been noted in previous work (35, 38).

TABLE 3. Solvent isotope effect data on equilibrium constant for σ-complex formation[a]

Mol% DMF	$K_e(H_2O)$ M^{-1}	$K_e(D_2O)$ M^{-1}	$K_e(D_2O)/K_e(H_2O)$
68.1	33	55	0.60
75.8	1.2×10^2	1.5×10^2	0.80
81.8	3.5×10^2	8.9×10^2	0.39
88.6	3.5×10^3	9.9×10^2	0.35
91.1	1.2×10^4	3.6×10^4	0.33
95.8	9.5×10^4	3.1×10^5	0.31

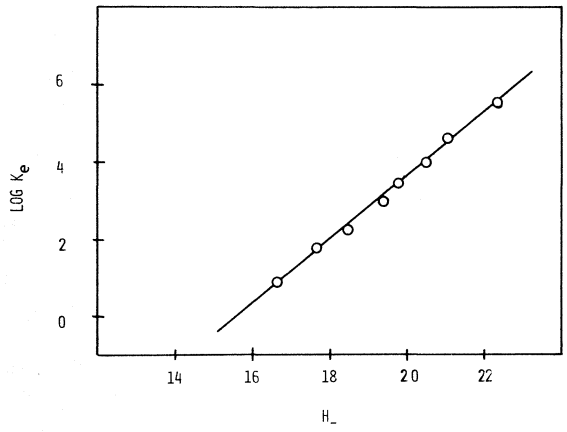

FIG. 6. Plot of log K_e for σ-complex formation vs. H_- acidity function in aqueous DMF system.

An estimate of the medium effect on K_e for the DNB·OH^- σ-complex can be extended to the entire DMF–water solvent system. Extrapolating the plot in Fig. 6 to more aqueous media, using the known H_- values applicable to this system (39), yields an estimated K_e in purely aqueous medium of $4 \times 10^{-4}\ M^{-1}$. One hence obtains for the increase in K_e on going from aqueous to 96 mol% DMF, a factor of ca. 10^9. Using an extrapolation procedure, Crampton estimated that formation of the TNB·OMe^- σ-complex is subject to an enhancement of 10^8 on going from methanol to DMSO medium (40). The generally held explanation of these very large medium effects considers desolvation of charge localized anions such as OH^- or OMe^- in dipolar aprotic media as the main factor, being supplemented in part by increased solvation of the σ-complex, with charge delocalized over the aromatic system (6, 41).

It appears from Fig. 6 that there is a reasonably satisfactory correlation between log K_e and H_-, as a measure of medium basicity (slope of plot, 0.83). However, H_- is referenced with respect to proton abstraction by hydroxide ion, whereas the present process is concerned with hydroxide ion addition. On the other hand, the J_- function has been proposed as a measure of the addition of base to an aromatic system (42). Only scant measurements of this function have been reported so far (42, 43) and no data are available for the aqueous DMF system. It would be desirable to extend the measurement of various solvent parameters (44) to DMF and its mixtures with hydroxylic solvents.

An unusual aspect of the present system is that in the series of measurements designed to evaluate the effect of medium changes on K_e, as depicted in Tables 1 and 2, the increased extent of σ-complex formation results in continuously decreasing concentration of free (uncomplexed) hydroxide ion. On the other hand, the medium basicity, as measured by the conventional H_- function, refers to constant hydroxide ion concentration (0.01 *M*). It is possible to take into account the variation in [OH^-], using the known K_e values in the various media (Table 2), and thereby calculate values of a new function, H_- (equil), as given in Table 4. These data allow one to construct the corresponding log K_e vs. H_- (equil) plot, which is also found to show fair linearity, slope 1.30. In this way account is taken of the changing OH^- concentration as well as the changing hydroxide ion activity as the medium is changed, whereas the conventional treatment reflects only the changes in the latter. However, a drawback of this approach is its limited applicability, since H_- (equil) will vary from one system to another depending on the values of K_e. On the other hand a plot, for example, of log K_e vs. mol% DMF would afford little insight since one can conceive that the decreasing base concentration could more than compensate for the increased base activity. In that case K_e could diminish with increasing DMF content, which would be puzzling indeed unless the change in free OH^- were noted.

An interesting possibility which should be considered is that the σ-complex itself would contribute to the basicity of the medium in these systems. Thus as K_e increases in magnitude and the free [OH^-] becomes very small, the contribution to medium basicity from the σ-complex would become increasingly significant relative to that of OH^-. This would tend to stabilize the medium basicity, since at very large K_e values the concentration of the σ-complex changes only slightly (Table 2). This reasoning would also serve to justify the use of the conventional H_- function in

TABLE 4. Variation of H_- function in aqueous DMF systems: (a) using constant [OH^-]; (b) under conditions where σ-complex formation occurs to significant extent

Mol% DMF	H_-[a]	H_- (equil)[b]
57.4	16.65	16.00
68.1	17.65	16.22
73.3	18.20	16.56
75.8	18.50	16.65
81.8	19.40	16.80
91.1	21.05	16.90
95.8	22.35	17.19

[a]Calculated from data in ref. 39 by means of correction factor for change in [Me_4NOH] from 0.019 *M* to 0.0038 *M* applicable to present system. Data for 91.1 and 95.8 mol% DMF are estimated values.

[b]Calculated H_- values based on the free (uncomplexed) hydroxide ion concentration in DNB–OH^- – DMF–H_2O systems where a significant proportion of OH^- is tied up as the DNB·OH^- σ-complex. The uncomplexed [OH^-] is calculated using K_e values in Table 2(3) for media containing $[DNB]_0 = [OH^-]_0 = 0.004$ *M*.

correlations with reaction parameters (e.g. Fig. 6), rather than H_- values based on free hydroxide ion concentrations in systems where extensive complexation has occurred.

Finally, our discussion is also pertinent with respect to the two widely used methods for evaluating complexation constants, namely the Benesi–Hildebrand method (45) and the presently used method based on absorbance measurements of equimolar solutions of the interacting species (12*b*). A unique difficulty arises in the application of these methods to systems where one of the species partaking in the equilibrium contributes significantly to the overall basicity (or another property) of the medium. It is apparent that K_e determined by such methods should be dependent on the actual concentration values of the species (e.g. OH^-) which are employed. A moderate effect of $[OH^-]$ on K_e values in the present work has already been noted (Table 2). Previous work has also demonstrated the dependence of K_e for σ-complex formation on [NaOMe] for various nitroaromatics (35, 46), but such results have generally been ascribed to salt effects or ion pairing effects (47).

Experimental

Tetramethylammonium hydroxide (Matheson, Coleman & Bell), purchased as a 25% solution, was diluted to 2 *M* and titrated with standard acid. A solution of Me_4NOD was prepared by evaporating the 25% Me_4NOH solution *in vacuo* until syrupy, followed by two treatments with D_2O (99.5%) and its removal *in vacuo* at 25°C, before the final dilution with D_2O to 1.9 *M*. DNB (Fisher Certified Reagent) was recrystallized twice from ethanol, mp 89.0–89.5°C (uncorrected), λ(ε) 234 nm (17 800 M^{-1} cm^{-1}). DMF (Fisher Certified Reagent) was distilled from P_2O_5 under vacuum.

In preparation of the reaction solutions for spectrophotometric measurement, stock solutions of $DMF/Me_4NOH/H_2O$ were not used in order to minimize the basic hydrolysis of DMF. The following procedure was hence adopted. DNB was weighed into a 25 mL volumetric flask, which was placed in a thermostated bath at 25°C, an appropriate volume of H_2O (D_2O) was added and made up to mark with DMF, weighing after each addition. The Me_4NOH (Me_4NOD) solution was added by means of a 50 μL syringe fitted with a Chaney adaptor and, after shaking to mix, an aliquot was transferred to a cuvette (0.01 to 1 cm) for spectrophotometric measurement. A Unicam SP800B spectrophotometer equipped with a thermostated cell holder was used. Spectral scans were run over the 300–600 nm region at regular intervals in those cases where the spectra exhibited a decrease (increase) as a function of time.

Hydrogen exchange studies. XIV.[1] Kinetics and mechanism of base-catalyzed hydrogen exchange in 1,3-dinitrobenzene in aqueous dimethylformamide and relationship with σ-complex formation[2]

ERWIN BUNCEL AND ALLEN W. ZABEL
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received April 30, 1981

ERWIN BUNCEL and ALLEN W. ZABEL. Can. J. Chem. **59**, 3177 (1981).

Kinetic data have been evaluated for hydrogen exchange in 1,3-dinitrobenzene (DNB), occurring at the 2-position, in dimethylformamide (DMF) – D_2O mixtures containing deuteroxide ion. The pseudo first order rate constants for exchange, k_{obs}, show inverse dependence on the initial DNB concentration, which can be quantitatively related to the extent of σ-complex formation in these systems. The profile for k_{obs} as function of medium composition exhibits a maximum at ca. 70 mol% DMF, and ε_{app} for σ-complex formation reaches a plateau at about the same medium composition. The equilibrium constants for σ-complex formation, K_e, are used to calculate the free, or uncomplexed, deuteroxide ion concentrations, which then allow one to calculate k_2, the second order rate constants for exchange. The k_2 values show a uniformly increasing tendency with increased DMF content. Correlations with medium basicity are examined, and the nature of the log k_2 and log K_e vs. H_- plots afford insight into the origin of the medium dependence of proton exchange. The results of the present study are consistent with the σ-complex being an unreactive form of the substrate towards exchange, which occurs via uncomplexed DNB present in small concentration. The study also rules out the possibility that the colored species present in these systems is the carbanion formed on deprotonation of DNB.

ERWIN BUNCEL et ALLEN W. ZABEL. Can. J. Chem. **59**, 3177 (1981).

On a évalué les données cinétiques de l'échange d'hydrogène se produisant en position 2 du dinitro-1,3 benzène (DNB) dans des mélanges de diméthylformamide (DMF) – D_2O contenant l'ion deutéroxyde. La constante de vitesse de pseudo ordre un de l'échange k_{obs}, révèle un effet inverse de la concentration initiale de DNB qui peut être relié quantitativement aux taux de formation du complexe σ dans ces systèmes. Le profil de k_{obs} en fonction de la composition du milieu montre un maximum pour environ 70 mol% de DMF et le ε_{app} de la formation du complexe σ atteint un plateau pour environ la même composition du milieu. On a utilisé la constante d'équilibre de la formation du complexe σ K_e, pour calculer les concentrations de l'ion deutéroxyde libre, ou non complexé qui permettent de calculer k_2 la constante de vitesse d'ordre deux de l'échange. Les valeurs de k_2 montrent une tendance d'augmentation uniforme avec la teneur en DMF. On a examiné les corrélations avec la basicité du milieu; la nature des courbes de log k_2 et log K_e en fonction de H_- fournit des renseignements sur l'origine de l'effet du milieu lors de l'échange de proton. Les résultats de la présente étude sont en accord avec un complexe σ qui ne donnerait pas de réaction d'échange celui-ci se produisant par l'intermédiaire du DNB non complexé présent à une concentration faible. L'étude écarte également la possibilité que l'espèce colorée présente dans ces systèmes soit le carbanion formé par la protonation du DNB.

[Traduit par le journal]

The capability of aromatic nitro compounds to interact with bases by a number of mechanisms has led to controversy regarding the occurrence and importance of nuclear hydrogen exchange (1–6). In the case of 1,3-dinitrobenzene (DNB), the species that have been postulated to be formed at different times through action of a base Y: are a charge transfer complex **1**, a radical anion **2**, covalent adducts (also known as Meisenheimer or σ-complexes) **3** and **4**, as well as the carbanions **5** and **6** which are the presumed intermediates in proton exchange.

6

The characteristic appearance of color on addition of base to DNB does not immediately serve to distinguish between these species; there is evidence that most of these species are colored. For example, the appearance of a new band characteristic of the charge-transfer type of interaction has been well documented (7–9). Similarly, radical anions of nitroaromatics formed via electron transfer processes have also been spectrally characterized (10–12). A variety of σ-complexes which are

closely analogous to **3** and **4** have been characterized by nmr as well as uv–vis spectroscopy (1–6, 13–22). However, there is as yet no unambiguous uv–vis or nmr evidence for the carbanions **5** and **6**.

In one of the original studies of deuterium exchange in DNB, as catalyzed by deuteroxide ion in dimethylformamide (DMF) – D_2O medium, the solution color was in fact ascribed to species **5** and/or **6** (23).[3] However, in a subsequent study but using methanolic dimethyl sulfoxide (DMSO) solutions, Crampton and Gold (24) disagreed with the earlier interpretation (*vide infra*).

In a preliminary communication we have described some initial results on hydrogen–deuterium exchange in DNB in a number of basic systems (25). Subsequently we carried out a detailed kinetic study of deuterium exchange in 1,3,5-trinitrobenzene (TNB) in the DMF–D_2O–OD^- system (26). An unusual kinetic behaviour was observed and discussed on the basis of σ-complex formation (27) competing with proton exchange. We now report a complementary study for the case of DNB. In the accompanying paper we describe pertinent results on σ-complex formation in this system (28).

Results and Discussion

Proton Exchange vs. σ-Complex Formation

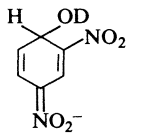
We have found that the deuteroxide ion catalyzed proton exchange in DNB in DMF–D_2O mixtures occurs readily, under mild conditions. For example, in 68 mol% DMF, a solution of 0.5 *M* DNB containing 0.004 *M* NaOD, at 25°C, undergoes virtually complete exchange in ~ 20 min. Only the proton in the 2-position was found to exchange, as shown by nmr on the recovered substrate following acidification of the reaction solution; there was no detectable exchange at the 4(6)-positions. This is in agreement with the earlier report by Pollitt and Saunders (23) for exchange in DNB in DMF–D_2O–NaOD. However, in a recent study (29) of tritium exchange in DNB we found, through tritium nmr spectroscopy, that whereas under mild conditions (CH_3ONa–HTO–dioxan) exchange was confined to the 2-position, under more strongly basic conditions (CH_3ONa–HTO–HMPT) exchange occurred also at the equivalent 4(6)-positions (30). We then showed that the reactivity of the C-2 proton was ca. 2000 times greater than that of the C-4(6) protons, which would explain the lack of observation of C-4 proton exchange in the present work, as monitored by the relatively insensitive nmr method.

[3]Though exchange occurs largely from the 2-position of DNB, Pollitt and Saunders (23) considered that the uv–vis spectrum was more readily explained in terms of proton loss from the 4-position.

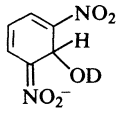
The reaction solutions undergoing exchange were found to be strongly colored, varying from pink to dark ruby red depending on the DMF composition and NaOD concentration. This brings into question the nature of the colored species and its role in the exchange process.

In the accompanying paper (28) we have reported on a uv–vis spectroscopic study of σ-complex formation between DNB and hydroxide or deuteroxide ion in DMF media containing H_2O or D_2O. Evidence was presented that the major covalent interaction is formation of σ-complex **7**, through addition of OD^- (OH^-) at C-4. Minor processes yielding **8** and other complexes may occur under some conditions. However, these interactions are not considered important under typical exchange conditions and will hence be disregarded in our subsequent discussions.

What will be the effect of σ-complex formation on proton exchange? The question of the interrelationship between these two processes will be central to most of the considerations in this paper.



7



8

Apparent Reaction Orders in Deuteroxide and Dinitrobenzene

The effect of varying the deuteroxide ion and DNB concentrations on the exchange rate was first examined at constant medium composition. The solvent composition of 68.1 mol% DMF was chosen since with a DNB concentration of 0.50 *M*, which was its maximum value throughout the study, the exchangeable D/H ratio in the system would be 20:1 on the basis of one labile hydrogen in the substrate. This would then allow exchange to reach 95% completion ignoring any possible equilibrium isotope effects.

Two series of exchange runs were performed, at 25°C, in which the initial sodium deuteroxide concentration, $[NaOD]_0$, was varied at two given DNB concentrations, namely at $[DNB]_0 = 0.50\,M$ and 0.25 *M*. The pseudo first order rate constants, k_{obs}, are given in Table 1. A typical kinetic plot is displayed in Fig. 1 and shows fairly good linear behaviour in the pseudo first order plot up to ca. 75% exchange.

A plot of $\log k_{obs}$ vs. $\log [NaOD]_0$ is shown in Fig. 2, corresponding to the results for 0.5 *M* DNB. The slope of the line drawn is 1.0. The data for 0.25 *M* DNB yield a plot with slope 1.2. It appears that the order with respect to OD^- is close to unity,

although the meaning of these plots will be reexamined subsequently.

Inspection of the data in Table 1 shows that k_{obs} is not independent of the initial, stoichiometric DNB concentration as might have been expected for a pseudo first order process. In fact, at constant $[NaOD]_0$, the rate approximately doubles when $[DNB]_0$ is halved. These results are reminiscent of the situation encountered previously with TNB (26) and suggest the following analogous explanation.

We consider that isotopic exchange occurs only through interaction between the uncomplexed, or free DNB and OD^- entities. With the concurrent equilibrium yielding the σ-complex (7) established, i.e. DNB + $OD^- \rightleftarrows$ DNB.OD^-, one has to evaluate the free, or uncomplexed concentrations, $[DNB]_e$ and $[OD^-]_e$, as a function of $[DNB]_0$ and $[NaOD]_0$. The details of the method of calculation are given in the Appendix. The results, summarized in Table 2, indicate an approximately inverse relationship between $[DNB]_0$ and $[OD^-]_e$, which is in accord with the observation of approximately inverse dependence between k_{obs} and $[DNB]_0$ at constant $[NaOD]_0$ (Table 1).

This treatment points also to a reinterpretation of the significance of the log k_{obs} vs. log $[NaOD]_0$ plot (Fig. 2). As seen in Table 2, the $[OD^-]_e$ values show approximately direct proportionality to $[NaOD]_0$

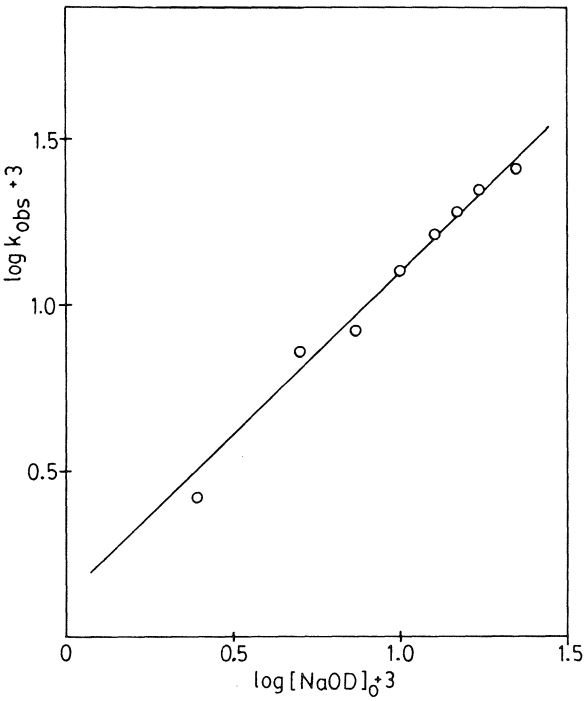

FIG. 2. Plot of log k_{obs} vs. log $[NaOD]_0$ for proton exchange in DNB in 68.1 mol per cent DMF at 25°C.

[a]See Appendix for method of calculation.

values, at constant $[DNB]_0$. Hence an increase in $[NaOD]_0$ will be reflected in proportional increase in k_{obs}.

Thus the results on the variation of k_{obs} with reactant concentrations (Table 1) are self-consistent and in accord with the σ-complex being an unreactive form of DNB as well as of OD^-. The observed rate behaviours as a function of initial reactant concentrations are a consequence of the relatively large value of the equilibrium constant for σ-complex formation, as well as the large excess of DNB over OD^-, thus resulting in the OD^- being essentially tied up in the form of the unreactive σ-complex.

Medium Dependence of Proton Exchange

Base catalyzed proton exchange processes are generally strongly accelerated in dipolar aprotic media such as DMSO or DMF, relative to typical hydroxylic solvents such as water or methanol (31, 32). The magnitude of such rate enhancement can, however, vary greatly depending on the system involved. Thus whereas a number of processes in which proton transfer from substrate to base is rate-determining exhibit rate enhancements of 10^{10} or more when the medium is changed from aqueous (or alcoholic) to ~ 99 mol% DMSO (33–38), exchange of D_2 in the DMSO–H_2O–OH^- system is accelerated only by ~ 10^4 when the medium is changed from purely aqueous to 99.5% DMSO (39, 40).

We have evaluated the effect of changing medium composition on the rate of proton exchange in DNB for the DMF–D_2O system. Thus a series of exchange reactions was performed in DMF–D_2O solvent mixtures ranging from 47.5 mol% DMF to 95.8 mol% DMF, keeping the DNB and OD^- concentrations constant, at 0.476 *M* and 0.0038 *M* respectively. In solvent compositions containing more than ~ 70 mol% DMF, the base employed was Me_4NOD due to the limited solubility of NaOD in DMF-rich media. The two bases gave identical exchange rates, within experimental error, in the 68.1 mol% DMF solvent system. The combined results are listed in Table 3 and shown graphically in Fig. 3 in the form of a plot of k_{obs} as a function of medium composition.

TABLE 3. Pseudo first order rate constants for proton exchange in DNB (0.48 *M*) as function of medium composition (DMF–D_2O), at constant NaOD concentration (0.0038 *M*), 25°C

95.8	0.752
95.8	0.782

It is seen from Fig. 3 that the rate of proton exchange, while increasing initially, passes through a maximum at ~ 70 mol% DMF and then decreases. This type of medium dependence of the rate of *base catalyzed* proton exchange is quite unusual and possibly unprecedented.

A qualitative explanation of the present results can, however, be given in terms of the two main factors bearing on this system. These are the medium effect on the exchange process itself, and the medium effect on the concurrent equilibrium

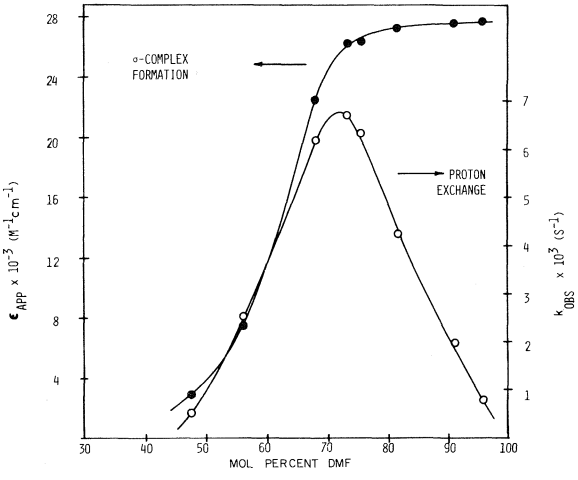

FIG. 3. Dependence of k_{obs} (exchange) and ε_{app} (σ-complex formation) on medium composition.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

σ-complex formation. We have already shown that K_e for σ-complex formation increases markedly with increasing DMF content (28). It follows that as the DMF content of the medium is increased, deuteroxide ion will become increasingly tied up in the form of the unreactive σ-complex towards proton exchange. Qualitatively, this could result in the type of behaviour which has been observed, since the decrease in the effective OD^- concentration as the DMF content is increased could eventually overcome the anticipated increase in exchange rate due to the effect of the dipolar aprotic component. However, the overall balance between these two opposing tendencies cannot be predicted *a priori*.

In Fig. 3 we have represented the σ-complex formation process by including the curve for the variation of ε_{app} with solvent composition, in addition to k_{obs}. ε_{app} is the apparent molar extinction coefficient at λ_{max} for the σ-complex **7** (28), and is a measure of the degree of complex formation in a given system. It is seen that the ε_{app} function shows initially increasing tendency but levels off at ca. 70 mol% DMF, and then remains practically constant. The latter portion corresponds to virtually complete tying up of OD^- in the form of the σ-complex with DNB, which is the component present in large excess. It is interesting to note that σ-complex formation attains ~99% of its maximum value about the same medium composition (~70 mol% DMF) that the maximum in k_{obs} is found (Fig. 3).

Further assessment of the importance of σ-complex formation as a factor pertinent to the exchange process requires that k_{obs} be dissected into its constituent terms. However, before proceeding with this treatment, we consider the possible implications of the concurrent basic hydrolysis of the solvent DMF.

Effect of Basic Hydrolysis of DMF on Proton Exchange

We had previously observed (41, 42) that DMF reacts readily with hydroxide ion, to give formate ion and dimethylamine, despite a statement in the literature suggesting the contrary.[4] In the present work a sharp odour characteristic of amine was evident in the "infinity" solutions following exchange. Thereafter, sodium formate was isolated and characterized following reaction of 0.1 *N* NaOH in 68 mol% DMF at room temperature for 24 h. The possible effect of the DMF hydrolysis reaction on the proton exchange process must be critically examined. However, as in the case of our study of proton exchange with TNB in the DMF–D_2O–OD^- system, it can readily be shown that the concurrent hydrolysis of DMF has little effect on proton exchange in the majority of cases.

In Table 4 are shown the half-lives for the DMF hydrolysis and for the proton exchange process in DNB. It is seen that except for the lowest DMF solvent composition, proton exchange is the faster of the two processes. The data for OD^-_e pertain to the uncomplexed deuteroxide ion under the exchange conditions and are estimated from the equilibrium constants for σ-complex formation. Thus, considering for example the 68.1 mol% DMF system, the loss in the overall OD^- concentration during one exchange half-life as a result of the reaction with DMF will be ~1%, assuming that only free base is consumed by reaction with DMF. The effect of this loss in OD^- on the exchange process should be small, as is evidenced by the linearity of the first order plot for exchange over >75% reaction. In media of lower DMF content, however, the effect of the competing DMF hydrolysis is greater and only initial rates can be determined in proton exchange. In all the exchange reactions the effect of the DMF hydrolysis was minimized in practice through addition of the $NaOD/D_2O$ solution as the final component to the reaction mixture.

Quantitative Evaluation of the Effect of σ-Complexing on Exchange Rates as Function of Medium Composition

The maximum in rate of exchange which is observed as the medium composition is varied, Fig. 3, represents quite unusual behaviour for base catalyzed proton exchange. The implication of σ-complex formation as influencing proton exchange has already been made apparent, but a quantitative relationship between the two processes still remains to be formulated. One approach is clearly to consider the rate law which should be applicable to this system of competing processes, in place of the phenomenologically evaluated k_{obs} which has been considered so far.

We have already drawn the conclusion on the basis of the available evidence that proton exchange occurs via reaction between the free, or uncomplexed, DNB and OD^- entities. The rate of exchange is hence given by the expression in eq. [1]

$$[1] \qquad \text{rate} = k_{obs}\,[\text{DNB}]_0 = k_2\,[\text{DNB}]_e\,[\text{OD}^-]_e$$

where $[DNB]_0$ is the initial, or stoichiometric, concentration of DNB, while $[DNB]_e$ and $[OD^-]_e$ are the concentrations under conditions where the σ-complexing equilibrium DNB + OD^- ⇄ DNB.OD^-

[d] $k_2 = k_{obs}/[OD^-]_e$.

is established. It is recalled that the results in Fig. 3 have been obtained using the reactant concentrations $[DNB]_0 = 0.48\,M$ and $[OD^-]_0 = 0.0038\,M$, i.e. $[DNB]_0 \gg [OD^-]_0$. Under these conditions, and with the equilibrium constant for σ-complex formation being typically large, one has $[DNB]_e \approx [DNB]_0$. Rewriting eq. [1] in the form [2], one then obtains eq. [3] for the second order rate coefficient for exchange.

$$[2] \quad k_{obs} = \frac{k_2[DNB]_e\,[OD^-]_e}{[DNB]_0}$$

$$[3] \quad k_2 \approx \frac{k_{obs}}{[OD^-]_e}$$

The variation of k_2 with DMF content should provide a more valid measure of the medium effect on exchange than is given by k_{obs} in Fig. 3. To this end, we have calculated the $[OD^-]_e$ values at the various DMF compositions listed in Table 3 by the method detailed in the Appendix, using measured K_e values (28) to calculate $[DNB.OD^-]$ and subtracting this from $[OD^-]_0$ to obtain $[OD^-]_e$. The appropriate data are given in Table 5 for the DMF–D_2O compositions corresponding to Fig. 3. It is seen that the k_2 values so derived exhibit a uniform increase with increasing DMF content of the medium. Thus correction for σ-complex formation leads to disappearance of the rate maximum which appeared in the k_{obs}–solvent composition profile in Fig. 3. The calculated k_2 values exhibit an increase of 4 powers of 10 as the DMF content is increased from 57 to 96 mol% DMF, which is entirely consistent with expectation from the known effect of dipolar aprotic media on OD^- catalyzed proton exchange in carbon acids (31–33).

Further insight into the origin of these phenomena can be gained by considering the dependence of the second order rate constant on some property measuring more directly the basicity of the medium than is represented by the per cent DMF composition. Also this will allow us to draw more valid comparisons with other systems. A measure of medium basicity which is generally used is that given by the H_- acidity function (43–46). We have previously evaluated an H_- scale for the DMF–H_2O–OH^- system, based on the deprotonation of very weak acid indicators (47), and in Table 5 we have listed the appropriate H_- values corresponding to the given solvent compositions. Using these data we have constructed the plots for the variation of log k_2 and log K_e with medium basicity, i.e. with H_-, as shown in Fig. 4. It is seen that the log k_2 vs. H_- plot exhibits an initial linear portion followed by a downward curving plot. However, the plot of log K_e vs. H_- remains linear over the entire range of

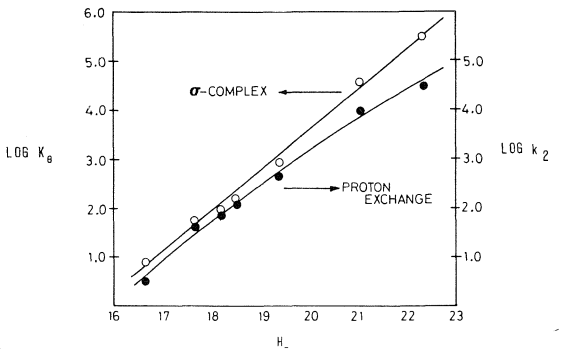

FIG. 4. Dependence of log k_2 (exchange) and log K_e (σ-complex formation) on H_- function.

medium composition. It is this steeper dependence of σ-complex formation on medium basicity, compared to proton exchange, which is thus the underlying cause for the decreasing exchange rate in media of high DMF content.[5]

Comparison with Other Systems

We first draw comparison between the results obtained in the present study and our previously reported work for TNB (26) which is also applicable to the DMF–D_2O–OD^- system. Interestingly, it was found (26) that k_{obs} *decreased* with increasing DMF content over the entire solvent composition range studied (25–80 mol% DMF), which contrasts with the results obtained in the DNB system (Fig. 3).

The principles governing the DNB and TNB systems should, however, be analogous, and the apparent differences in behaviour will arise at the quantitative level, from the different degrees of complexation in the two systems and as a function of medium basicity. That is, in the TNB case, predominant (say 99%) σ-complex formation has set in at a much lower DMF composition (~ 20 mol% DMF). Therefore if one were to extrapolate the plot for exchange in TNB to lower DMF composition, one would expect to observe an initial rise in k_{obs}, as in the DNB system. Hence, even though the experimental method used (26) did not allow measurement of exchange rates in < 25 mol% DMF , due to limited solubility of TNB, it can be predicted that use of an appropriate method (such as tritium exchange), which would be sensitive at low TNB concentrations, would reveal analogous behaviour in the k_{obs} vs. mol% DMF profile for the two substrates. This prediction of behaviour for TNB, which follows from the present results for DNB, will be tested in future work.

Comparison is also drawn between the present study and that reported by Crampton and Gold (24) for DNB in DMSO–MeONa–MeOT mixtures. In that work [MeONa], as well as [DNB], was kept constant and the DMSO content was varied in order to change the basicity of the medium. The plot of log k_{obs} vs. H_- showed an initial linear portion (slope 0.73) but then levelled off at an H_- value corresponding to practically complete (~ 99%) conversion to colored species. The plot of log ε_{app} vs. H_- was also linear initially (slope 1.22) and then levelled off as conversion of DNB to the σ-complex became virtually complete. The levelling off in rate was consistent with the σ-complex representing an unreactive form of the substrate and that exchange occurred via uncomplexed DNB present in very small concentrations. Although a maximum in the log k_{obs} vs. H_- plot was not observed, Crampton and Gold showed that such would be expected under either of the following assumptions: (*i*) the σ-complex is as effective as methoxide ion in catalyzing exchange; (*ii*) the σ-complex is totally ineffective as a catalyst. The authors allowed that an intermediate situation could obtain.

The suggestion by Crampton and Gold (24) that the σ-complex could act as a catalyst in exchange is pertinent also to our study. It would then follow that the σ-complex could also contribute to the basicity of the medium, which would serve to justify our current use of the H_- function in its normally accepted sense (43–46). Thus whereas H_- values are taken to refer to constant hydroxide (deuteroxide)[6] ion concentration (0.01 *M*), in the present system the free OD^- concentration is continually diminishing as a result of σ-complex formation. One could then envisage that as the free, or uncomplexed, deuteroxide ion concentration becomes very small, the contribution by the σ-complex to medium basicity could become significant. Since the concentration of the σ-complex remains essentially constant in media of high DMF content, the basicity of these media would also remain effectively constant. It is also possible that some other acidity function might represent better the medium basicity in the present case than H_-, as

[5]Closer examination of the plots in Fig. 4 suggests that in the initial region of low H_- values the points representing log K_e lie on a line whose slope is smaller than that of the log k_2 plot over the same H_- region, whereas in the region of high H_- values the opposite relationship holds. If this apparent relationship could be confirmed, it would likewise have the effect of favoring proton exchange relative to σ-complex formation in media of low DMF content, and vice versa in media of high DMF content, as is observed.

[6]The H_- function in D_2O/OD^- systems is expected to be larger by ca. 0.5 unit than in the H_2O/OH^- system (48); this, however, will not have an appreciable effect on the present discussion.

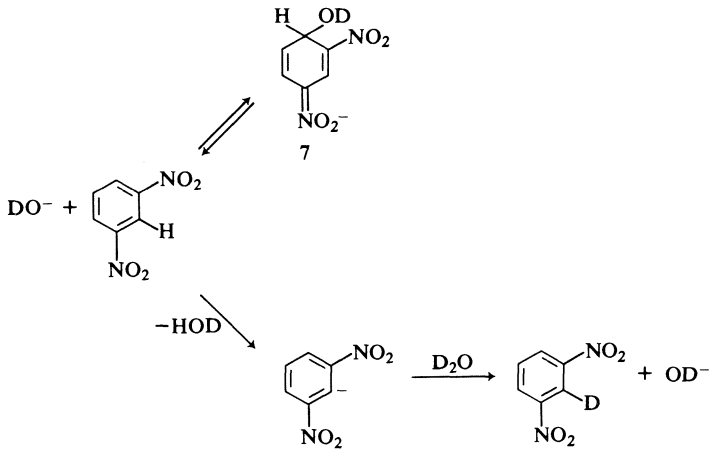

SCHEME 1

for example the J_- function (49, 50). However, such a function has so far not been determined for the system under study and our recourse has been to use the known H_- function but to point out the limitations in its applicability to the present system.

Mechanism of Exchange

The overall conclusion of our work is that the dominant interaction in the DNB–DMF–D_2O–OD^- system is equilibrium formation of σ-complex **7**, and that exchange occurs by proton abstraction from uncomplexed DNB via carbanion **6**, according to Scheme 1.

The possibility that the solution color could be due to the anion **6** (or **5** (23)) can be discounted, as shown by the relationship between k_{obs} and ε_{app} as a function of medium composition, Fig. 3, and discussed earlier. Direct evidence on this point was obtained by quenching with D_2SO_4–D_2O a solution of DNB in DMF–H_2O–OH^- under conditions where substantial conversion to colored species occurred. The DNB which was isolated from the reaction mixture was not detectably labelled with deuterium, thus eliminating the possibility that the carbanion **6** (or **5**) was present in appreciable concentration.

As to the detailed mechanism of exchange it should be pointed out that Scheme 1 is only an approximate representation and that the intimate mechanism must be discussed in terms of eqs. [4]–[6] (51):

$$[4] \quad ArH + OD^- \underset{k_{-a}}{\overset{k_a}{\rightleftarrows}} Ar^- \ldots HOD$$

$$[5] \quad Ar^- \ldots HOD + DOD \underset{k_{-b}}{\overset{k_b}{\rightleftarrows}} Ar^- \ldots DOD + HOD$$

$$[6] \quad Ar^- \ldots DOD \underset{k'_a}{\overset{k'_{-a}}{\rightleftarrows}} ArD + OD^-$$

However, we have no evidence as to the importance of these hydrogen-bonded species, and which of the various steps is rate determining. There has been some discussion whether log k–H_- plots can be informative in this regard, views for and against this notion being expressed (52–54). Recent work (55–57) suggests that kinetic isotope effects might shed light on this question, and we hope to undertake such studies in future work.

Experimental

Reagents

1,3-Dinitrobenzene (Fisher Certified Reagent) was recrystallized twice from ethanol, mp 89.0– 89.5°C (uncorrected), λ(ε) 234 nm (17 800 M^{-1} cm^{-1}). DMF (Fisher Certified Reagent) was distilled under vacuum from P_2O_5. The middle fraction, bp 40°C/7 Torr, was stored in the dark under N_2. A solution of NaOD (1 *M*) was prepared by adding freshly cut sodium metal to 99.5–99.8% D_2O (Diaprep or Stohler) under N_2. The HOD content was checked periodically by monitoring the O–H stretching band at 3400–3500 cm^{-1} in the ir spectrum. A solution of Me_4NOD was prepared by evaporating a solution of Me_4NOH under vacuum at 25°C until syrupy, followed by two treatments with D_2O and its removal under vacuum, before the final dilution with D_2O to 1.9 *M*.

Site of Isotopic Exchange in DNB

The nmr spectrum of normal DNB and of the material recovered following exchange in DMF– D_2O–NaOD are shown in Figs. 5A and 5B respectively. It is seen that the signal appearing in Fig. 5A at δ 8.75 (t), ascribable to H-2 in DNB, is greatly diminished in the spectrum shown in Fig. 5B (maximum exchange under the conditions was 94%). The ratios of the integral heights corresponding to H-4(6) (δ 8.45) and H-5 (δ 7.75) remain constant at 2:1 in Figs. 5A and 5B, indicating that these hydrogens do not undergo exchange. This deduction follows also from our observation that under the more strongly basic conditions of the tritium exchange experiment (29), H-4(6) but not H-5 was found to exchange.

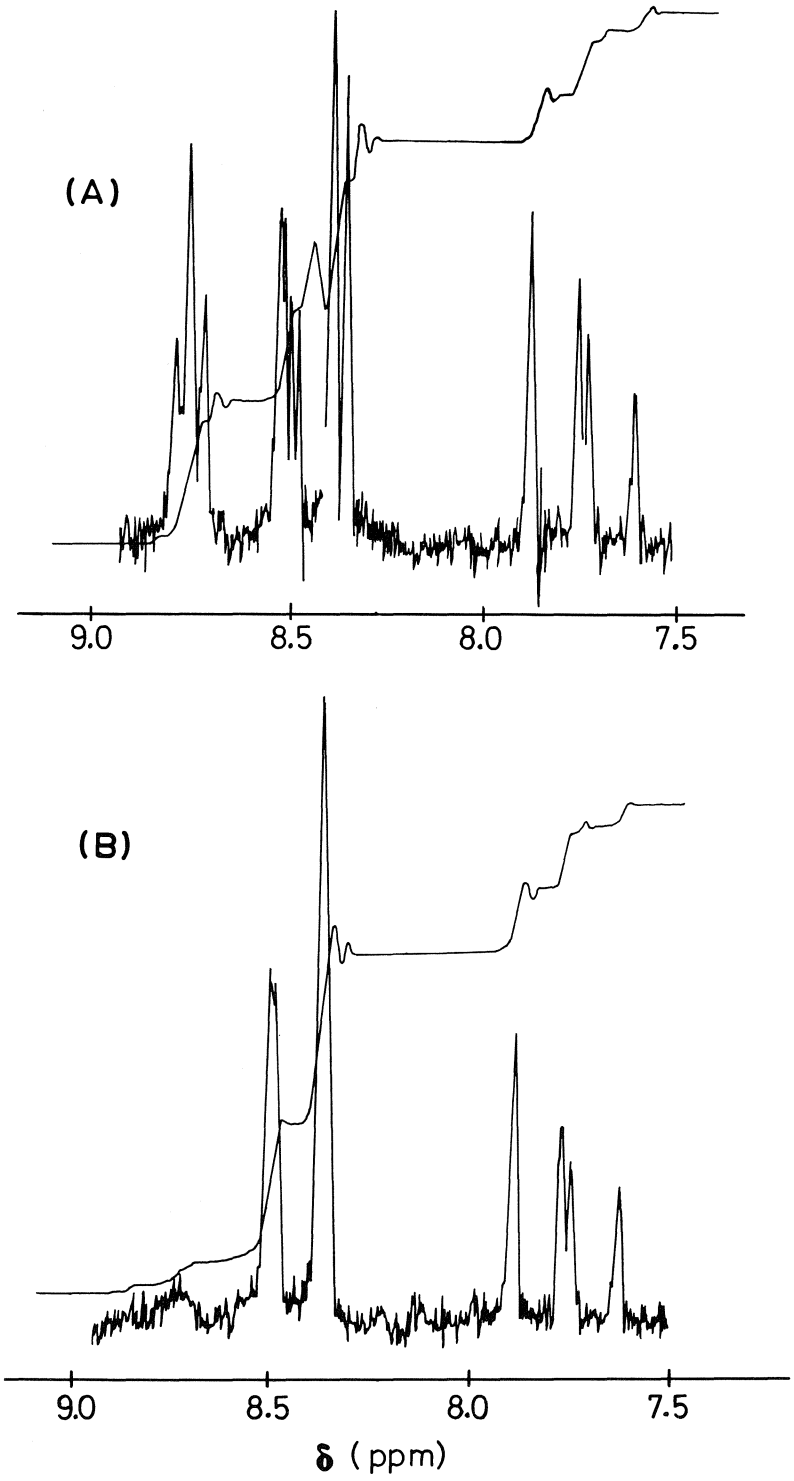

FIG. 5. The nmr spectra of normal DNB (A) and of material following exchange in DMF–NaOD–D_2O system (B).

Kinetic Method

Proton exchange was monitored by ir by following the development in the reaction solution of the O–H stretching band in HOD at 3480 ± 50 cm^{-1}, depending on the DMF–D_2O composition. Measurements were made in a thermostatted CaF_2 cell (0.1 or 0.2 mm pathlength), the temperature being measured by means of a thermocouple, with air in the reference beam to eliminate the possibility of adventitious introduction of moisture in a reference cell. A calibration curve was first prepared using standard solutions of HOD in DMF–D_2O, which yielded a linear Beer's law plot up to 0.5 *M* HOD. The measurements were taken on a Perkin Elmer 21 infrared spectrometer.

In a typical kinetic run, DNB was weighed into a 25 mL volumetric flask, an appropriate volume of D_2O was added and then made up to mark with DMF, weighing after each addition. Ten milliliters of this solution in a glass stopped flask were placed in a constant temperature bath and after equilibration the NaOD(Me_4NOD)–D_2O solution (1–2 *M*) was added by means of a syringe. After vigorous shaking of the reaction solution an aliquot was transferred by syringe to the thermostatted, carefully dried ir cell. The increase in the HOD band was followed until completion of reaction (10 half-lives). The concentration of HOD, obtained from the transmittance value via the calibration curve, yielded the extent of reaction, from which the pseudo first order plot (e.g. Fig. 1) was constructed. The C_0 used in these plots was generally the initial, stoichiometric concentration of DNB. However, use of this C_0 value leads to curvature in the first order plot since the initial effectively infinite deuterium pool becomes diluted by the exchanged hydrogen from the DNB as the reaction proceeds, leading to a back reaction. Alternatively, a C_0 value based on the labile deuterium to hydrogen ratio was chosen and a correction factor applied to k_{obs} using the method of Streitwieser *et al.* (58). This procedure led to first order plots which were linear for longer periods of time and was preferred for the solvent systems where relatively small labile deuterium to hydrogen ratio was present.

Appendix

Calculation of Uncomplexed (Free) Deuteroxide Ion Concentrations under Exchange Conditions in DNB–DMF–D_2O–NaOD Systems

Let the reaction between DNB and OD^- yielding the DNB.OD^- σ-complex (eq. [7]) be associated with an equilibrium constant K_e as given in eq. [8]:

[7] $$DNB + OD^- \rightleftarrows DNB.OD^-$$

[8] $$K_e = \frac{[DNB.OD^-]}{[DNB]_e[OD^-]_e}$$

The quantities $[DNB]_e$ and $[OD^-]_e$ are the concentrations when equilibrium is established, while $[DNB]_0$ and $[OD^-]_0$ are the initial, stoichiometric concentration values. Then eq. [8] can be rewritten as eq. [9]

[9] $$K_e = \frac{[DNB.OD^-]}{([DNB]_0 - [DNB.OD^-])([OD^-]_0 - [DNB.OD^-])}$$

which can be recast into quadratic form,

[10] $$px^2 + qx + r = 0$$

The concentration of σ-complex, [DNB.OD^-], is given by x, while the coefficients p, q, and r are given by known quantities as follows:

$$p = K_e$$

$$q = -K_e[DNB]_0 + K_e[OD^-]_0 + 1$$

$$r = K_e[DNB]_0[OD^-]_0$$

Thus [DNB.OD^-] can be evaluated via solution of the quadratic eq. [10]. One then obtains $[OD^-]_e$ by subtraction of [DNB.OD^-] from $[OD^-]_0$.

In Table 2 are given the calculated $[OD^-]_e$ data corresponding to two sets of values of $[DNB]_0$ and $[OD^-]_0$, and using K_e = 55 L mol^{-1} which is applicable to 68.1 mol% DMF. These results pertain to the discussion of the apparent order in deuteroxide and DNB, and lead to the following conclusions.

1. At constant $[DNB]_0$ of 0.50 *M*, doubling $[OD^-]_0$ from 0.004 to 0.008 *M* increases $[OD^-]_e$ by a factor of 2.02.
2. At constant $[DNB]_0$ of 0.25 *M*, doubling $[OD^-]_0$ from 0.004 to 0.008 *M* increases $[OD^-]_e$ by 2.03.
3. At constant $[OD^-]_0$ of 0.004 *M*, halving $[DNB]_0$ from 0.50 to 0.25 *M* increases $[OD^-]_e$ by 1.95.
4. At constant $[OD^-]_0$ of 0.008 *M*, halving $[DNB]_0$ from 0.50 to 0.25 *M* increases $[OD^-]_e$ by a factor of 1.96.

These conclusions are completely in accord with the observed effect of varying $[DNB]_0$ and $[OD^-]_0$ on k_{obs} (data in Table 1).

Ozonolysis of substituted 1,2-dichloroethylenes in methanol: products and reaction course

TAE-SEONG HUH,[1] JOACHIM NEUMEISTER, AND KARL GRIESBAUM[2]

Engler-Bunte-Institut, Bereich Petrochemie, Universität Karlsruhe (TH), D-7500 Karlsruhe, West Germany

Received June 12, 1981

TAE-SEONG HUH, JOACHIM NEUMEISTER, and KARL GRIESBAUM. Can. J. Chem. **59**, 3188 (1981).

Ozonolysis of *trans*-2,3-dichloro-2-butene (**5***a*), of *trans*-3,4-dichloro-3-hexene (**5***b*), and of 1,2-dichlorocyclohexene in methanol and in solutions of sodium methoxide in methanol have been examined. They afforded in high yields the corresponding ester fragments methyl acetate (**6***a*), methyl propionate (**6***b*), and dimethyl adipate (**8**), respectively. By trapping with phenylacetylene and formation of 1,1-dichloro-2,2-dimethoxy-2-phenylethane, the presence of methyl hypochlorite in the ozonolysis products was established. A reaction course has been proposed which is in accord with these results.

TAE-SEONG HUH, JOACHIM NEUMEISTER et KARL GRIESBAUM. Can. J. Chem. **59**, 3188 (1981).

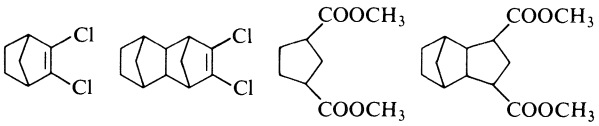
On a étudié l'ozonolyse du dichloro-2,3 butène-2 *trans* (**5***a*), du dichloro-3,4 hexène-3 *trans* (**5***b*) et du dichloro-1,2 cyclohexène dans le méthanol et dans des solutions de méthanolate de sodium dans le méthanol. Ils conduisent avec d'excellents rendements aux esters correspondants aux diverses fragmentations soit l'acétate de méthyle (**6***a*), le propionate de méthyle (**6***b*) et l'adipate de diméthyle (**8**). Le piégeage avec le phénylacétylène et la formation de dichloro-1,1 diméthoxy-2,2 phényl-2 éthane ont permis d'établir la présence de l'hypochlorite de méthyle parmi les produits de l'ozonolyse. On propose un schéma réactionnel qui s'accorde avec ces résultats.

[Traduit par le journal]

Introduction

The course and the products of the ozone cleavage of olefins containing monochloro-substituted double bonds in methanol have been described recently (1). By contrast, ozone cleavage of olefins having symmetrically dichloro-substituted double bonds in alcoholic media has been only reported at substrates having specific structures. Thus, ozonolysis of the cyclodiene insecticide-like compounds **1** and **2** in methanol has been found to afford the dimethylesters **3** and **4**, respectively, in virtually quantitative yields (2).

For the course of these reactions, we have advanced a proposal which at that time could not be substantiated by experimental evidence (2). The present paper describes the ozonolysis of the simple substrates **5***a*, **5***b*, and **7** in methanol, as well as experimental evidence for the previously proposed reaction course.



1 **2** **3** **4**

Organic Reaction Products

The ozonolysis reactions were carried out at ca. 1.3 *M* solutions of the substrates in methanol. The acyclic substrates **5***a* and **5***b* were ozonized at −40°C, the cyclic substrate **7** at ambient temperatures. In each case the reactions were slow and required an excess of ozone. After completion of the double bond cleavage and removal of dissolved ozone, the peroxidic solutions were stirred at ambient temperatures until the peroxide content had disappeared. Then, the crude mixtures were analyzed by nmr spectroscopy with the help of 1,1,1-trichloroethane as a standard. By this method, the ester fragments **6***a* and **6***b* have been identified in the crude reaction mixtures in yields of 90% and 92%, respectively. The dimethyl ester **8** has been isolated in a yield of 84%. These results are in agreement with those obtained in the ozonolysis of the bicyclic and tetracyclic substrates **1** and **2**, respectively, and they may well indicate a general mode of reaction for the ozonolysis of olefins having such structural moieties.

Reaction Course

Considerable evidence has been accrued in recent years for a Criegee-type cleavage pattern during the ozonolysis of substituted 1,2-dichloroethylenes in nonparticipating solvents (3–5). In a preliminary rationalization we have, therefore, also proposed a Criegee-type reaction mode for the

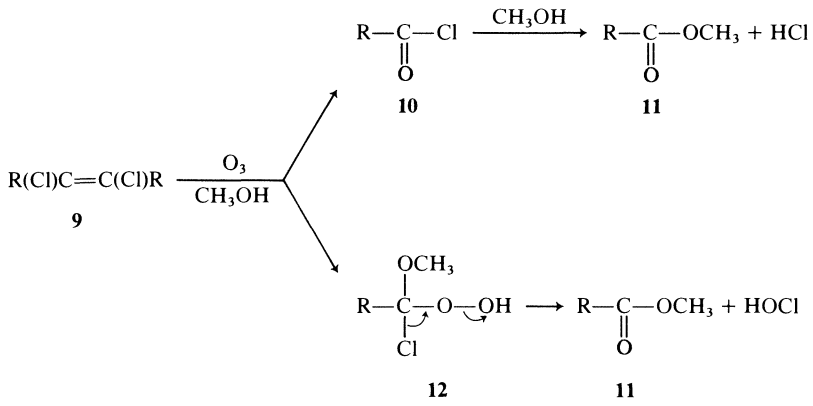
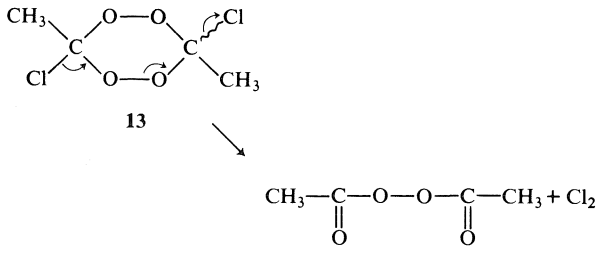


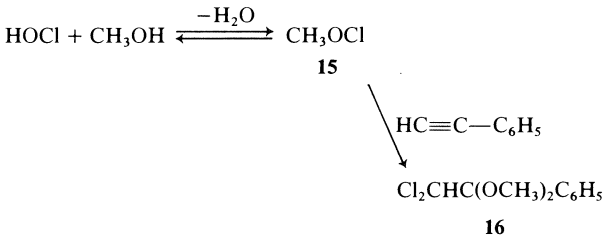
SCHEME 1

ozonolysis of dichloro olefins of structure **9** in methanol as depicted in Scheme 1 (2). In the double bond cleavage step, acyl chloride (**10**) and α-chloro-α-methoxyalkylhydroperoxide (**12**) were postulated as the primary reaction products. Obviously, the acyl chloride (**10**) undergoes rapid solvolysis with methanol to afford methyl ester **11** and hydrogen chloride. Although to our knowledge compounds of type **12** and their chemistry are largely unknown, it is reasonable to assume that they may be rather labile. We have proposed that they decompose in the way indicated in Scheme 1, viz. by loss of hypochlorous acid and formation of a second molecule of methyl ester (**11**). This proposal was based on a similar, albeit slower reaction of the α-chloro peroxide **13** to form diacetyl peroxide (**14**) and chlorine (3).



All our attempts at detecting **12** have been unsuccessful. Therefore we have tried to prove the formation of its postulated decomposition product, hypochlorous acid. It is known that hypochlorous acid and methanol react to form methyl hypochlorite (**15**), and it is furthermore established that the latter undergoes facile addition to phenylacetylene to yield the stable adduct **16** (6).

Consequently, addition of phenylacetylene to the ozonolysis reaction products of substituted 1,2-dichloroethylenes in methanol should be a suitable test for the formation of hypochlorous acid. Indeed, addition of excess phenylacetylene to the crude reaction mixtures from the ozonolysis of **5***a*, of **5***b*, and of **7** afforded in each case adduct **16**, which was identified by glc and by nmr analysis with the help of an authentic sample. However, adduct **16** was also formed, albeit in smaller yield,



when the crude product from the ozonolysis of 1-chlorocyclohexene (**17**) was treated with phenylacetylene, although this reaction was not expected to co-produce hypochlorous acid but has been shown to proceed via the sequence **17** → **18** → **19** by co-production of hydrogen chloride (1).

This apparent discrepancy showed that there is obviously an alternate source for methyl hypochlorite (**15**) than the postulated intermediate of structure **12**, and that under the prevailing conditions the formation of adduct **16** could not be taken as an unequivocal proof for the transient existence

of **12**. Based on some observations in other ozonolysis experiments, we had reason to assume that the alternate source for methyl hypochlorite originated from the ozone-initiated oxidation of methanol and from subsequent oxidation of hydrogen chloride by the peroxidic oxidation product to form chlorine. The latter, in turn, could react with methanol to form **15**. The above assumption could be verified by control experiments. Ozone treatment of a 0.35 *M* solution of anhydrous hydrogen chloride in methanol gave a peroxidic reaction mixture. When phenylacetylene was added, adduct **16** was formed, as evidenced by glc and by nmr analysis.

This alternate mode of formation of methyl hypochlorite (**15**) can be effectively prevented if the ozonolysis of chloro olefins is carried out in the presence of sodium methoxide. In its presence, hydrogen chloride is immediately neutralized and the sodium chloride, which is largely precipitated, appears to be resistant towards oxidation. Indeed, under these conditions ozonolysis of 1-chlorocyclohexene and subsequent treatment with phenylacetylene did not afford any detectable amounts of adduct **16**. By contrast, ozonolysis of **5***a*, **5***b*, and **7** and subsequent treatment with phenylacetylene afforded **16** in isolated yields of 92%, 66%, and 95%, respectively. It is felt that these results are good support for the reaction course proposed in Scheme 1 for the ozonolysis of dichloro olefins of type **9**.

Materials and Methods

Materials

The substrates **5***a* (3), **5***b* (7), and **7** (8) were prepared by known procedures. Methanol was of analytical grade. Stock solutions of hydrochloric acid in methanol were prepared by introducing gaseous anhydrous hydrogen chloride into methanol at 0°C and titration of the solutions with aqueous sodium hydroxide using phenolphthalein as indicator. Stock solutions of sodium methoxide were prepared by adding the appropriate amount of sodium to anhydrous methanol.

Analytical Methods

Gas–liquid chromatographic analyses were carried out on a Shimadzu GC-6A unit with flame ionization detector; glass columns: 0.3 × 100 cm, 2.5% Nitrilesiliconoil on Chromosorb G. Conditions: 60°C to 160°C at 4°C per min. Nuclear magnetic resonance spectra were recorded on a Bruker WP 60 spectrometer.

Ozonolysis Reactions in Methanol

trans-*2,3-Dichloro-2-butene* (*5*a)

A mixture of 5.00 g (0.04 mol) of **5***a* in 30 mL of methanol was ozonized at −40°C. Ozone uptake was slow and incomplete and 0.14 moles of ozone were applied over a period of 3 h until the substrate had disappeared. The solution was purged with nitrogen, kept stirring at ambient temperatures for 40 h, and admixed with 5.3 g (0.04 mol) of 1,1,1-trichloroethane as a standard. Nuclear magnetic resonance analysis showed the presence of methyl acetate (**6***a*; δ = 3.70, CH_3CO) in ca. 90% yield.

Phenylacetylene was added to a sample of the freshly ozonized solution and the mixture was stirred for 48 h. In the solution, adduct **16** was identified by co-injection and by comparison of the nmr data with those of an authentic sample (see below).

trans-*3,4-Dichloro-3-hexene* (*5*b)

A mixture of 6.24 g (0.041 mol) of **5***b* in 30 mL of methanol was treated with a total of 0.14 moles of ozone at −40°C within 3 h and then worked up as described above. Methyl propionate (**6***b*; δ = 1.13, t, 3H) was detected in 92% yield by nmr analysis. In a sample treated with phenylacetylene as described above, glc and nmr analysis revealed again the presence of adduct **16**.

1,2-Dichlorocyclohexene (*7*)

A mixture of 7.30 g (0.084 mol) of **7** in 30 mL of methanol was treated with a total of 0.23 moles of ozone within 5 h at ambient temperatures and purged with nitrogen. A small sample of the solution was treated with phenylacetylene as described above and analyzed by glc to afford the peak of adduct **16**. The major part of the ozonized solution was stirred at ambient temperatures for 48 h. Then methanol was removed at 15 Torr and 25°C and the residue was distilled from a micro distillation apparatus to yield 1.02 g (84%) of dimethyl adipate (**8**); bp 114°C/17 Torr. Identification occurred by glc co-injection and by nmr analysis.

1-Chlorocyclohexene (*17*)

A solution containing 1.16 g (0.01 mol) of **17** in 30 mL of methanol was ozonized to completion at ambient temperatures, then purged with nitrogen and stirred for 48 h at ambient temperatures. A sample of the solution was treated with phenylacetylene as described above; glc and nmr analysis showed the presence of adduct **16**.

Anhydrous HCl in Methanol

A solution of 0.25 g (0.007 mol) of hydrogen chloride in 20 mL of methanol was treated with a total of 0.046 moles of ozone within 1 h at ambient temperatures. Then 1.0 g (0.01 mol) of phenylacetylene was added and the mixture was kept stirring for 48 h. Adduct **16** was detected in approximately 18% in the mixture by co-injection with an authentic sample.

Ozonolysis Reactions in Methanol in the Presence of Sodium Methoxide

1-Chlorocyclohexene (*17*)

A solution of 1.16 g (0.01 mol) of **17** and 0.01 mol of sodium methoxide in 30 mL of methanol was ozonized to completion at ambient temperatures within 1 h. The mixture was purged with nitrogen, the precipitated sodium chloride was filtered off, the filtrate was cooled to 0°C, and 1.0 g (0.01 mol) of phenylacetylene was added. Then the solution was acidified to a pH of approximately 3 with a 13 *N* solution of anhydrous HCl in methanol and kept stirring at ambient temperatures for 48 h. The solution was neutralized with solid sodium bicarbonate, filtered, and distilled at 40°C and 15 Torr to remove the methanol. The distillation residue was dissolved in 30 mL of ether, washed with 15 mL of water, dried over sodium sulfate, and then distilled at ambient temperatures and 15 Torr to remove the ether. The residue (1.83 g) was analyzed by nmr spectroscopy. It showed the signals of dimethyl adipate (**19**) as the major component, along with some minor signals of unidentified assignment, however, not the signals of the adduct **16**. The residue was purified by column chromatography (silica gel; 200 mL of *n*-pentane/CH_2Cl_2 = 5:1; 200 mL of *n*-pentane/CH_2Cl_2 = 2:1; 400 mL of ether) to give 1.60 g (92%) of dimethyladipate (**19**) from the ether fraction.

trans-*2,3-Dichloro-2-butene* (*5*a)

A solution of 1.24 g (0.01 mol) of **5***a* and 0.1 mol of sodium

methoxide in 30 mL of methanol was ozonized to completion at ambient temperatures within 4 h and treated further as described above. After neutralization with sodium bicarbonate and filtration, the methanol was distilled off at 40°C and 15 Torr. From the residue 1.38 g of a solid precipitated at ambient temperatures within 30 h. It was recrystallized from methanol to give 1.08 g (92%) of 1,1-dichloro-2,2-dimethoxy-2-phenylethane (**16**); mp 62°C (lit. (6) mp 62°C); nmr (CCl_4, TMS), δ: 3.37 (s, 6H), 6.00 (s, 1H), 7.50 (mc, 5H).

trans-*3,4-Dichloro-3-hexene (5*b*)*

A solution of 1.52 g (0.01 mol) **5***b* and 0.1 mol of sodium methoxide in 30 mL methanol was ozonized to completion at ambient temperatures within 4 h and treated further as described above for **5***a*. After recrystallization from methanol 0.76 g (66%; mp 62°C) of **16** was obtained.

1,2-Dichlorocyclohexene (7)

A solution of 1.50 g (0.01 mol) of **7** and 0.1 mol of sodium methylate in 30 mL of methanol was ozonized to completion at ambient temperatures within 9 h and treated further as described for **5***a* above. After neutralization with sodium bicarbonate and removal of the methanol, the residue was dissolved in 30 mL of ether, washed with water, dried, and the ether distilled off at 40°C and 15 Torr. The viscous liquid residue was analyzed by glc and nmr. It contained 46% of dimethyl adipate (**19**) and 37% of 1,1-dichloro-2,2-dimethoxy-2-phenylethane (**16**).

Conformational effects on the enthalpy of formation of straight and branched-chain alkanes

JOHN T. EDWARD
Department of Chemistry, McGill University, 801 Sherbrooke St. West, Montreal, P.Q., Canada H3A 2K6

Received May 11, 1981

JOHN T. EDWARD. Can. J. Chem. **59**, 3192 (1981).

Benson's scheme for calculating the enthalpy of formation of straight and branched-chain alkanes by addition of increments for methyl, methylene, methine, and quaternary carbon groups, and by correction (where necessary) for steric effects, has been modified by a more detailed consideration of the effect of *gauche* interactions.

JOHN T. EDWARD. Can. J. Chem. **59**, 3192 (1981).

Le schéma développé par Benson pour calculer l'enthalpie de formation des alcanes linéaires et ramifiés qui fait appel à l'addition d'incréments pour les groupes méthyle, méthylène, méthine et carbone quaternaire et qui introduit des corrections (quand c'est nécessaire) pour les effets stériques a été modifié en faisant intervenir une considération plus détaillée des effets des interactions gauche.

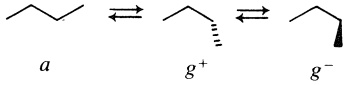
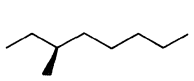
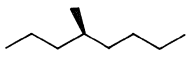
Benson (1) has developed an additive scheme for calculating the enthalpy of formation ΔH_f^0 of straight and branched-chain alkanes under standard conditions. His group values I and steric correction terms S are listed in Table 1. (Benson uses a different symbolism.) Benson takes account of the effect of *gauche* interactions, but only for branched-chain alkanes: in effect, he considers *n*-alkanes such as *n*-butane (C_4) only in their extended or all *anti* (*a*) conformations. In fact, at 25°C a 0.18 mole fraction of all *n*-butane molecules exist in the g^+, and a 0.18 mole fraction in the g^- conformation, so that the mole fraction Z_g of *gauche* conformations is 0.36. This has the effect of raising the enthalpy of *n*-butane by 0.36 × 700 cal/mol[1] over what it would be if it were completely in the *anti* conformation. This need not be serious in an additive scheme restricted to *n*-alkanes: Z_g increases regularly by 0.29 (corresponding to 0.20 kcal/mol) for each additional CH_2 group (4), and hence the effect of *gauche* interactions can be absorbed into the I value of this group. (Compare I values for CH_2 of Benson and of Edward in Table 1.) However, the limitations of such an approach become more apparent when isomeric branched alkanes are considered. Thus, according to Benson, $Z_g = 2.00$ for both 3-methyloctane (3-MeC_8) and 4-methyloctane (4-MeC_8). In fact, when contributions from the various folded conformations present at 25°C are also taken into account, $Z_g = 3.08$ for 3-MeC_8 and $Z_g = 2.92$ for 4-MeC_8 (4).





3-MeC_8



4-MeC_8

These and other steric factors are considered in the values of ΔH_f^0 calculated by the equation

$$[1] \quad \Delta H_f^0 = \sum_1^m n^k I^k + \sum_1^n m^l S^l$$

and recorded in Table 2. Values of I and S are given in Table 1. Z_g (which in [1] becomes m^1) was calculated by reported procedures (3, 4) when it was not already available in the literature (3, 4). In this calculation we have followed Mann (3) in neglecting any conformations containing a g^+g^- or g^-g^+ segment[2] where they could be avoided. However, in some compounds (e.g., 2,2,4-Me_3C_5: Fig. 1) such a segment is unavoidable if the staggered arrangement of the molecule is to be preserved. The value of S^2 reported in Table 1 for such g^+g^- or g^-g^+ arrangements has been adopted on empirical grounds, and agrees with other esti-

[1]More recent work would indicate a ΔH of about 900 cal/mol for the $a \rightarrow g$ conversion of *n*-butane in the gas phase (2). We have, however, retained the value of 700 cal/mol (S^1 in Table 1) used by Mann (3) because of the convenience of using the large number of Z_g values calculated by him, which depend on this value.

[2]Two conformations **A** and **B**, in which **B** has a g^+g^- segment but is otherwise similar to **A**, will be present in the ratio **A**/**B** of 28:1 (assuming the value of S^2 in Table 1). The enthalpy of the compound made up of the two conformations **A** and **B** will be 0.07 kcal/mol higher than if it were made up of **A** alone.

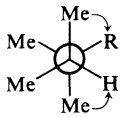
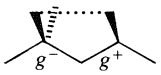
mates in the literature (3) (if not with Benson's (1)). The same is true for the S^3 and S^4 correction terms, taking into account the additional strain introduced by a *gem*-dialkyl group[3] vicinal to one or two alkyl groups. The S^2, S^3, and S^4 correction terms are based on a very limited amount of experimental

[3] The mutual repulsions of *gauche* methyl groups in the C_2 form of 2,3-dimethylbutane (**1**; R = H) are relieved by movement in the direction indicated by the arrows, slight increases in torsional and angle strain relieving a large strain energy due to non-bonded repulsions (8). Such relief is not possible for the top methyl group when the distant carbon atom is geminally disubstituted, as in 2,2,3-trimethylbutane (**1**; R = Me).



1



2,2,4-Me_3C_5

FIG. 1. The 2- and 4-methyl groups in a g^-g^+ relationship would be 2.54 Å apart (dotted line) in an undistorted staggered molecule, as compared with a 4.0 Å separation required by their van der Waals radii (7).

data, and may require revision in future. The occasions when they were used in calculating ΔH_f^0 are indicated in Table 2.

The values of ΔH_f^0 thus calculated generally agree with experimental values within the limits of experimental error.[4] For compounds with slight steric congestion (2,2-Me_2C_4 or $EtCMe_3$, 3,3-Me_2C_5 or Et_2CMe_2, 3-Et-3-MeC_5 or Et_3CMe, 2,2,4-Me_3C_5) agreement is better than that found in most other additive schemes (9). For compounds with severe steric congestion, agreement is poorer, but for these compounds other schemes fail completely (10, 11). However, the chief virtue of the present scheme lies in its simplicity and its concreteness. Some other additive schemes are mind-boggling in their complexity (10). Even the relatively simple Allen–Skinner scheme (11) has five steric terms for 2,2,3-trimethylpentane, in comparison with our two (m^1S^1 and m^3S^3). The schemes of Scott (5) and of Somolayajulu and Zwolinski (6) incorporate the steric terms S^1, S^2, S^3, and S^4 (in our terminology) and several more but, like all other schemes up to now, assume the molecule to have a fully extended conformation of the longest chain. Somolayajulu and Zwolinski recognize the limitations of this assumption, and the present paper shows how a realistic assessment of the conformational composition (Z_g) of a hydrocarbon leads to a simple and feasible scheme for calculating ΔH_f^0.

[4]A referee has written that it is doubtful if any ΔH_f^0 for an alkane is known to be better than ± 0.1 kcal mol^{-1} per C atom in absolute or relative terms, and that the uncertainties quoted in Table 2 are experimental precisions, which tend to be unrelated to accuracies.

Substituent effects upon cation–pseudobase equilibration for isoquinolinium and phthalazinium cations

JOHN W. BUNTING, VIVIAN S.-F. CHEW, AND SHINTA SINDHUATMADJA

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received June 4, 1981

JOHN W. BUNTING, VIVIAN S.-F. CHEW, and SHINTA SINDHUATMADJA. Can. J. Chem. **59**, 3195 (1981).

pK_{R+} values have been measured for cation–pseudobase equilibration by 4-X-2-methylisoquinolinium cations (**1**) (X = Br, $CONH_2$, COC_6H_5, CN, NO_2) at 25°C, ionic strength 0.1. These pK_{R+} values are well correlated by Hammett equations using either σ or σ^- *para* substituent constants. The best correlation gives: $pK_{R+} = -8.8\ (\pm 0.3)\sigma_p^- + 16.5\ (\pm 0.2)$ ($r = 0.998$). The value $pK_{R+} = 16.29$ measured by Cook *et al.* (Tetrahedron, **32**, 1773 (1976)) for the 2-methylisoquinolinium cation in dimethyl sulfoxide – water solutions is in reasonable agreement with this correlation equation. For the 2-methyl-5-nitrophthalazinium cation, $pK_{R+} = 7.87$, and $pK_{RO-} = 12.10$ for alkoxide ion formation by the pseudobase of this cation.

The pH dependence of the pseudo first-order rate constants (k_{obs}) for cation–pseudobase equilibration has been measured for **1**:X = $CONH_2$, COC_6H_5, CN and for the 2-methylphthalazinium cation (**3**) and its 5-NO_2 derivative (**4**). For each of these cations, $k_f = k_{OH}[^-OH] + k_{H_2O}$ and $k_d = k_1[H^+] + k_2$ and the parameters k_{OH} k_{H_2O}, k_1, and k_2 have been evaluated. For **1**:X = $CONH_2$ and CN and **3**, k_{OH} is consistent with a correlation line between log k_{OH} and pK_{R+} established for other isoquinolinium cations (J. Am. Chem. Soc. **99**, 1189 (1977)). For **1**:X = COC_6H_5, k_{OH} is seven-fold smaller, and for **4**, k_{OH} is five-fold greater than predicted by this correlation line.

JOHN W. BUNTING, VIVIAN S.-F. CHEW et SHINTA SINDHUATMADJA. Can. J. Chem. **59**, 3195 (1981).

On a mesuré les valeurs de pK_{R+} de l'équilibre pseudobase/cation provoquée par les cations X-4 méthyl-2 isoquinolénium (**1**) (X = Br, $CONH_2$, COC_6H_5, CN, NO_2) à 25°C et à une force ionique de 0,1. L'équation de Hammett permet d'établir une bonne corrélation entre ces valeurs de pK_{R+} et les valeurs σ et σ^- des substituants en *para*. La meilleure corrélation donne: $pK_{R+} = -8.8\ (\pm 0.3)\sigma_p^- + 16.5\ (\pm 0.2)$ ($r = 0.998$). La valeur de $pK_{R+} = 16{,}29$ mesurée par Cook *et al.* (Tetrahedron, **32**, 1773 (1976)) pour le cation méthyl-2 isoquinolinium dans des solutions de diméthylsulfoxyde–eau est raisonnablement en accord avec cette corrélation. Dans le cas du cation méthyl-2 nitro-5 phtalazinium, le $pK_{R+} = 7{,}87$ alors que le $pK_{RO-} = 12{,}10$ pour la formation de l'ion alcoolate par la pseudobase de ce cation. Pour le composé **1** où X = $CONH_2$, COC_6H_5, CN, ainsi que pour le cation méthyl-2 phtalazinium (**3**) et son dérivé nitré en position 5 (**4**), on a mesuré l'effet du pH sur la constante de vitesse de pseudo ordre un (k_{obs}) de l'équilibre cation/pseudobase. Pour chacun de ces cations, on a évalué $k_f = k_{OH}[OH^-] + k_{H_2O}$ et $k_d = k_1[H^+] + k_2$ et les paramètres k_{OH}, k_{H_2O}, k_1 et k_2. Pour le composé **1** où X = $CONH_2$ et CN et pour le composé **3**, k_{OH} est en accord avec la corrélation linéaire entre le log k_{OH} et pK_{R+} qu'on a établie pour d'autres cations isoquinoliniums (J. Am. Chem. Soc. **99**, 1189 (1977)). Pour les composés **4** et **1** où X = COC_6H_5, les valeurs de k_{OH} sont respectivement cinq et sept fois les valeurs prévues par cette ligne de corrélation.

[Traduit par le journal]

The phenomenon of pseudobase formation by heteroaromatic cations has been recognized for over 80 years (1–3). However, it is only during the past fifteen years that systematic quantitative studies of the equilibria and kinetics of cation–pseudobase equilibration have been attempted (4). In the present work, we report substituent effects upon equilibrium constants for cation–pseudobase equilibration for 2-methylisoquinolinium cations (**1**) bearing a variety of substituents at C-4, and also the pH dependence of the rates of equilibration in this system for those **1** which display cation–pseudobase equilibration rates that are sufficiently slow to allow measurement by the stopped-flow technique. We also report rates of cation–pseudobase equilibration for the 2-methylphthalazinium cation (**3**) and its 5-nitro derivative (**4**). These data allow the first comparison of rates of this phenomenon for the closely related isoquinolinium and phthalazinium cations.

5: X = H
6: X = NO_2

Experimental

Isoquinoline, 4-bromoisoquinoline, and phthalazine were purchased from Aldrich Chemical Co. 4-Cyanoisoquinoline was prepared by treatment of 4-bromoisoquinoline with cuprous cyanide as described by Tyson (5). 5-Nitrophthalazine was prepared by nitration of phthalazine by the method of Kanahara (6).

4-Isoquinolinecarboxamide

4-Cyanoisoquinoline (2.0 g) and Amberlite IRA-400 OH ion exchange resin (2.0 g) were refluxed for two hours in water

(15 mL) containing acetonitrile (1 mL). The resin was removed from the hot solution by filtration and the solvent evaporated on the steam bath to give 4-isoquinolinecarboxamide (1.7 g), mp 170–171°C (lit. (7) mp 168–172°C).

4-Benzoyl-2-methylisoquinolinium Perchlorate

2-Methylisoquinolinium bromide in basic aqueous acetone was treated with benzoyl chloride as described by Chen and Bradsher (8). The red oily product was stirred with aqueous perchloric acid (30%) to give a pale yellow solid which was filtered off, dried, and stirred with ether. Several recrystallizations of the solid product from ethanol after treatment with decolourizing charcoal gave white crystals of the desired perchlorate salt. *Anal.* calcd. for $C_{17}H_{14}NO_5Cl$: C 58.71, H 4.06, N 4.03; found: C 58.71, H 4.21, N 4.11.

Methylation of Isoquinolines

An acetone solution of the substituted isoquinoline was stirred with excess methyl bromide in a pressure bottle overnight. The white solid was filtered off and recrystallized several times from ethanol.

4-Aminocarbonyl-2-methylisoquinolinium Bromide

Anal. calcd. for $C_{11}H_{11}N_2OBr$: C 49.45, H 4.15, N 10.49; found: C 49.58, H 4.21, N 10.49.

4-Cyano-2-methylisoquinolinium Bromide

Anal. calcd. for $C_{11}H_9N_2Br$: C 53.04, H 3.64, N 11.12; found: C 52.91, H 3.72, N 11.21.

2-Methyl-5-nitrophthalazinium Iodide

This compound was prepared by methylation of 5-nitrophthalazine with methyl iodide and fractional crystallization to separate the 5-nitro and 8-nitro isomers as described by Kanahara (6).

Determination of pK_{R+} Values

All pK_{R+} values were determined spectrophotometrically at a suitable wavelength by the general method of Albert and Serjeant (9) in aqueous buffers of ionic strength 0.1 at 25°C. Reported pK_{R+} values are averages of the values calculated from at least eight different pH solutions in the range $pK_{R+} \pm 1$.

Kinetic Studies

All kinetic studies were made on a Durrum–Gibson stopped-flow spectrophotometer by mixing solutions of the heterocyclic cation (or pseudobase) with suitable aqueous buffers (ionic strength 0.1 after mixing) at 25°C. Absorbance vs. time curves at an appropriate wavelength were digitized (118 data points), and the data were collected and fitted to first-order rate equations in a Tektronix 4051 Minicomputer. The observed first-order rate constants (k_{obs}) for cation–pseudobase equilibration were separated into the individual rate constants for pseudobase formation (k_f) and pseudobase decomposition (k_d) back to the cation by the relationships (10):

$$k_f = k_{obs}/(1 + [H^+]/K_{R+})$$
$$k_d = k_{obs}/(1 + K_{R+}/[H^+])$$

Results and Discussion

pK_{R+} for Isoquinolinium Cations (1)

Each of the 2-methylisoquinolinium cations **1**:X = Br, $CONH_2$, COC_6H_5, CN display pH-dependent electronic absorption spectra in basic aqueous solutions. These spectra display clean isosbestic points and are readily reversible upon acidification of the solutions. Evaluation of pK_{R+} for each cation from the pH dependence of the absorbance at an appropriate wavelength gave the values collected in Table 1. Also included in Table 1 are a previously measured pK_{R+} for **1**:X = NO_2 and estimated and experimental values for **1**:X = H. This latter cation undergoes irreversible spectral changes in the concentrated basic solutions required to generate its pseudobase (11). An earlier estimate (11) of $pK_{R+} = 15.3$ for **1**:X = H was based upon substituent effects upon pK_{R+} values in the 4-bromo and 5-bromo-2-cyanoisoquinolinium cations and relatively uncertain pK_{R+} values for the corresponding 2-methylisoquinolinium cations. Our current estimate in Table 1 for **1**:X = H is based upon the current accurate pK_{R+} for **1**:X = Br and $\Delta pK_{R+} = -1.7$ for a 4-bromo substituent in the 2-cyanoisoquinolinium cation (12). This estimate remains somewhat lower than $pK_{R+} = 16.29$ measured for **1**:X = H by Cook *et al.* in dimethyl sulfoxide – water mixtures (13, 14).

TABLE 1. pK_{R+} for pseudobase formation by **1**[a]

X	pK_{R+}
H	15.5,[b] 16.29[c]
Br	13.81±0.02[d]
$CONH_2$	11.49±0.05
COC_6H_5	9.34±0.07
CN	7.80±0.05
NO_2	5.11[e]

[a] At 25°C, ionic strength 0.1.
[b] Estimated as described in text.
[c] Measured (13, 14) in dimethyl sulfoxide – water mixtures.
[d] Ionic strength 1.0.
[e] From ref. 10.

The X-dependence of the pK_{R+} values in Table 1 is consistent with a Hammett equation based upon either σ values for *para* substituents (σ_p) derived from benzoic acid ionization constants or σ^- values for *para* substituents (σ_p^-) derived from anilinium cation acidity constants (15).

$$[1] \quad pK_{R+} = -13.4\,(\pm 1.1)\sigma_p + 16.1\,(\pm 0.5) \qquad (r = 0.987)$$

$$[1a] \quad pK_{R+} = -14.2\,(\pm 0.9)\sigma_p + 16.5\,(\pm 0.4) \qquad (r = 0.992)$$

$$[1b] \quad pK_{R+} = -14.8\,(\pm 1.4)\sigma_p + 16.9\,(\pm 0.8) \qquad (r = 0.987)$$

$$[2] \quad pK_{R+} = -8.3\,(\pm 0.4)\sigma_p^- + 16.0\,(\pm 0.3) \qquad (r = 0.994)$$

$$[2a] \quad pK_{R+} = -8.8\,(\pm 0.3)\sigma_p^- + 16.5\,(\pm 0.2) \qquad (r = 0.998)$$

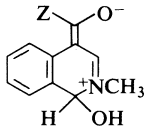
$$[2b] \quad pK_{R+} = -9.0\,(\pm 0.4)\sigma_p^- + 16.7\,(\pm 0.3) \qquad (r = 0.997)$$

Equations [1] and [2] are obtained using $pK_{R+} =$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

15.5 for **1**:X = H, while eqs. [1*a*] and [2*a*] result from using $pK_{R+} = 16.29$ for this cation as reported by Cook *et al.* (13, 14). Equations [1*a*] and [2*a*] produce better fits to the experimental data than eqs. [1] and [2] respectively on the basis of the correlation coefficients obtained. Equations [1*b*] and [2*b*] result when the data point for X = H is excluded. All the above correlation equations predict pK_{R+} for **1**:X = H to be somewhat greater than the estimates extrapolated from substituent effects with the 2-cyanoisoquinolinium cation, and we conclude that the value obtained by Cook *et al.* (13, 14) is most consistent with the data obtained for the other substituents in the current study.

Attempted correlations of pK_{R+} data using any form of *meta* substituent constants give much poorer correlations than those reported above, with the bromine substituent in particular showing a large deviation in any correlation line based upon *meta* substituent constants. The somewhat better correlations with σ_p^- (eqs. [2]–[2*b*]) than with σ_p (eqs. [1]–[1*b*]) are readily reconciled in terms of the importance of resonance contributors such as **7** to



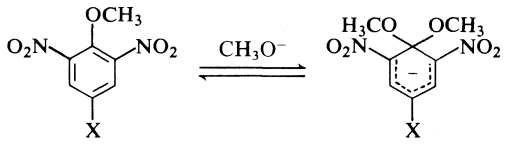
7

the electronic structure of the pseudobase species (**2**). Such resonance interaction of the X substituent with the ring nitrogen atom is not possible in the isoquinolinium cation (**1**). This resonance interaction of a substituent with the neutral nitrogen atom in the pseudobase but not in the heteroaromatic cation is analogous to the situation in the equilibration of neutral anilines and anilinium cations from which the σ_p^- values used in the present correlations have been derived. In fact, eq. [2*a*] for pK_{R+} for **1** can be combined with $pK_a = -2.89\,\sigma_p^- + 4.58$ for anilinium cation acidities (16) in the form of eq. [3].

[3] $\quad pK_{R+} = 3.0\,pK_a + 2.6$

Equation [3] can then be used to directly predict pK_{R+} values for all 4-X-2-methylisoquinolinium cations from the pK_a values for the corresponding 4-X-anilinium cations.

We note that the data of Terrier *et al.* (17) for substituent effects upon the equilibrium constants for Meisenheimer complex (**9**) formation from 4-X-2,6-dinitroanisoles (**8**) can also be correlated with σ_p or σ_p^-. Such observations provide quantitative support for the analogy between Meisenheimer complex formation from electron-deficient

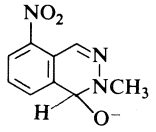


8 **9**

aromatic molecules and pseudobase formation from heteroaromatic cations (4).

pK_{R+} for the 2-Methyl-5-nitrophthalazinium Cation (4)

From the pH dependence of the electronic absorption spectrum of this cation we have calculated $pK_{R+} = 7.87 \pm 0.03$. In more basic aqueous solutions the spectrum of the pseudobase undergoes pH-dependent changes that are consistent with a further acid–base equilibration. We have calculated $pK_{RO-} = 12.10 \pm 0.03$ for this equilibration which we assign to alkoxide ion (**10**) formation



10

by the pseudobase **6**. Analogous pH-dependent spectral changes have been observed previously for the 2-methylphthalazinium cation **3** with $pK_{R+} = 11.0$ and $pK_{RO-} = 13.0$ having been reported (11). The influence of the 5-nitro group on each of these ionizations is qualitatively consistent with expectation. The $\Delta pK_{R+} = 3.13$ for the 5-nitro substituent effect in these phthalazinium cations is somewhat smaller than $\Delta pK_{R+} = 16.29 - 11.7 = 4.59$ calculated for a 5-nitro substituent in the 2-methylisoquinolinium cation ($pK_{R+} = 11.7$ for the 2-methyl-5-nitroisoquinolinium cation (18)).

Kinetics of Cation–Pseudobase Equilibration

Pseudo first-order rate constants (k_{obs}) for cation–pseudobase equilibration were evaluated at intervals of approximately 0.5 pH units for each cation over the pH range in which equilibration rates were sufficiently slow to allow measurement on the stopped-flow spectrophotometer. For **1**:X = Br equilibration was too rapid to allow rate measurements at any pH. Significant pH ranges were accessible for **1**:X = $CONH_2$, COC_6H_5, and CN and also **3** and **4**, and the experimentally derived pH dependences of k_{obs} for each of these cations are displayed in Figs. 1 and 2. In all cases k_{obs} vs. pH passes through a minimum as observed in previous studies (10, 19). Figures 1 and 2 dramatically indicate the influence of pK_{R+} on the overall shape of the k_{obs} vs. pH profiles. High pK_{R+} values lead to a relatively broad plateau region bounded by first-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

order dependence on $[H^+]$ and $[^-OH]$ in low and high pH regions respectively. For low pK_{R+} values, the plateau region is essentially eliminated.

As discussed previously (10), k_{obs} may be converted into separate rate constants for pseudobase formation (k_f) from the cation and pseudobase decomposition (k_d) to the cation. For each cation, k_f and k_d display individual pH dependences exemplified by that for **1**:X = COC_6H_5 in Fig. 3. These pH dependences can be described by equations of the form:

$$[4] \quad k_f = k_{OH}[^-OH] + k_{H_2O}$$

$$[5] \quad k_d = k_1[H^+] + k_2$$

Values of the parameters k_{OH}, k_{H_2O}, k_1, and k_2 were evaluated for each cation and are collected in Table 2. For **1**:X = $CONH_2$ and **3** (i.e. cations of high pK_{R+}) values of k_{H_2O} and k_1 are not accessible within the pH range for which rate data are available. The k_{OH}/k_{H_2O} ratios for **1**:X = COC_6H_5 and CN and **4** are within experimental error of $10^7\ M^{-1}$ as observed for many other quinolinium and isoquinolinium cations (19).

Substituent effects upon k_{OH} and k_{H_2O} indicate that these rate constants increase with the substituent electron-withdrawing effect in both the isoquinolinium and phthalazinium cations. A linear correlation (eq. [6]) between log k_{OH} and pK_{R+} has previously been established (19) for pseudobase formation from a variety of substituted isoquinolium cations. Comparison of experimental and calculated (from eq. [6]) log k_{OH} values gives satisfactory agreement for **1**:X = $CONH_2$ (4.45 (exptl), 4.70 (calcd.)) and **1**:X = CN (5.90 (exptl.), 6.03 (calcd.)). However, for **1**:X = COC_6H_5, $k_{OH} = 4.1 \times 10^4\ M^{-1}\ s^{-1}$ is almost an order of magnitude smaller than the value of $3 \times 10^5\ M^{-1}\ s^{-1}$ derived from eq. [6]. Inspection of k_1 and k_2 values in Table 2 also indicates that these rate constants are smaller for X = COC_6H_5 than expected on the basis of k_1 and k_2 values for other **1** and the X-dependence of pK_{R+}. Since the pK_{R+} value for **1**:X = COC_6H_5 is well correlated with pK_{R+} for other X substituents in **1**, these rate constant anomalies for X = COC_6H_5 appear to reflect a transition state phenomenon of some type.

$$[6] \quad \log k_{OH} = -0.36\ pK_{R+} + 8.84$$

The experimental value of $k_{OH} = 6.0 \times 10^4\ M^{-1}\ s^{-1}$ for **3** is within experimental error of $k_{OH} = 7.6 \times 10^4\ M^{-1}\ s^{-1}$ predicted for this cation on the assumption that eq. [6] is also applicable to phthalazinium cations. However, eq. [6] underestimates ($1.0 \times 10^6\ M^{-1}\ s^{-1}$) k_{OH} for **4** by a factor of five. It has been established (19) that quinolinium and isoquinolinium cations require quite different log k_{OH} vs. pK_{R+} correlation lines. Thus it is possible that the close

prediction for **3** above is fortuitous and that in general isoquinolinium and phthalazinium cations cannot be included on the same correlation line. Further data for phthalazinium cations will be required for a further exploration of this point. However, it should be noted that k_{OH} for **4** is sixfold larger than for **1**:X = CN even though these two cations have very similar pK_{R+} values.

Geometries of the ground and first excited triplet states of thioformaldehyde[1]

JOHN D. GODDARD

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received June 3, 1981

JOHN D. GODDARD. Can. J. Chem. **59**, 3200 (1981).

The geometries of the S_0 and T_1 states of thioformaldehyde are determined by *ab initio* SCF calculations with Gaussian basis sets ranging from minimal to double ζ plus both diffuse and polarization functions. The ground state geometries are all in reasonable agreement with experiment but for the $n \rightarrow \pi^*$ triplet state split valence or double ζ basis sets yield unreasonably long CS bond distances.

JOHN D. GODDARD. Can. J. Chem. **59**, 3200 (1981).

On a déterminé les géométries des états S_0 et T_1 de la thioformaldehyde en utilisant les calculs *ab initio* SCF avec des ensembles de base de Gauss allant du minimum à double ζ auxquels on ajoute les fonctions de diffusion et de polarisation. Les géométries de l'état fondamental sont raisonnablement en accord avec l'expérience mais dans le cas de l'état triplet $n \rightarrow \pi^*$, les ensembles de base impliquant le dédoublement de la valence ou le double ζ conduisent à de liaison CS qui sont anormalement longues.

Introduction

Considerable experimental interest exists in the electronic spectrum of thioformaldehyde (1, 2). Although an accurate microwave structure for the ground state of H_2CS has been available for some time (3), only very recently has an analysis of the $\tilde{a}^3A_2 \leftarrow \tilde{X}^1A_1$ absorption band yielded an r_0 structure for the lowest triplet state (2). A number of *ab initio* theoretical studies of the geometries of both the ground and lowest triplet states of thioformaldehyde have appeared (4–6) and very high level calculations on the ground state are also available (7). In the studies which considered the lowest triplet state geometry, only an approximate SCF calculation with a STO-2G + S $3d_\pi$ basis set (4) gave a CS bond length (1.675 Å) in very good agreement with the experimental result of 1.683 Å (2). An STO-3G CS bond length of 1.8075 Å has been reported for the lowest triplet state of thioformaldehyde (6). The CS bond lengths for the $^3n \rightarrow \pi^*$ state using double ζ (DZ) basis sets were 1.783 Å (SCF) and >1.783 Å (CI) (5) and thus at least 0.1 Å greater than experiment. These studies did predict geometries for the ground state in good agreement (e.g. CS bond length within 0.04 Å of the experimental value) with the microwave result.

For molecules containing only H, C, N, and O, it is known that SCF geometry predictions with split-valence or double ζ basis sets usually yield bond lengths within ~0.02 Å and bond angles within ~2° of experiment (18). However, for molecules containing heavier atoms such as S, the picture regarding the effects of the basis set on SCF structural predictions is not so clear (8, 9). It might be anticipated that at the SCF level, but possibly with more extensive basis sets, a similar agreement between experiment and theory could be recovered for a molecule such as thioformaldehyde. In this work, both the ground and lowest triplet state geometries of thioformaldehyde have been determined at the SCF level with basis sets ranging from minimal to double ζ plus diffuse and polarization functions. It is shown that medium sized basis sets without polarization functions such as 3-21G, 4-31G or double ζ yield CS bond lengths in the lowest triplet state of thioformaldehyde which are in very poor agreement with experiment.

Theoretical Methods

References for the Gaussian basis sets used are: STO-3G (S, ref. 10(*a*); C, H, ref. 10(*b*)), STO-3G* (8), 3-21G (S, ref. 12(*a*); C, H, ref. 12(*b*)), 4-31G (S, ref. 11(*a*); C, H, ref. 11(*b*)), and DZ (13). In adding diffuse functions on S, the orbital exponents were chosen to be $\alpha(4s) = 0.023$, $\alpha(4p) = 0.020$, and $\alpha(3d) = 0.015$ (13). The values chosen for the polarization function exponents were $\alpha(d)C = 0.75$, $\alpha(d)S = 0.55$ (7), and $\alpha(p)H = 1.0$. Except for the STO-3G* calculations the sixth *s*-type combination of the Cartesian *d*-type Gaussians was retained in the basis set. All geometries were fully optimized employing energy gradient methods (14, 15). The triplet state was calculated within the Unrestricted Hartree Fock approximation and satisfactory values of the $\hat{S}^2$ operator were obtained (footnote *f*, Table 2). Most calculations were carried out with MONSTERGAUSS 80 (16) which is an extensively modified version of GAUSSIAN 76 (17).

[e] r_0 structure (2).
[f] Expectation values of $\hat{S}^2$ were: 2.0083, 2.0242, 2.0123, 2.0132, 2.0138, 2.0148, 2.0216, 2.0221; and differ from the ideal value of 2.000 by ~ 1%.

the ground and lowest triplet excited state are collected in Tables 1 and 2. The experimental results of refs. 2 and 3 are included for comparison although for the triplet state the r_0, θ_0 structure (averaged over zero-point vibrational motion), of ref. 2 is *not* strictly comparable to the calculated r_e, θ_e (actual potential minimum) values (18). In addition, the invariance of the geometrical structure on isotopic substitution (CD_2S) was assumed in calculating the r_0 structure of $^3A_2$ thioformaldehyde from the observed rotational constants of the O_0^0 band (2).

For ground state thioformaldehyde all the Gaussian basis sets used predict r_e (CH) within 0.02 Å of the experimental value. STO-3G and STO-3G* predict HCH angles of 112.0° and 111.7° which are 4.9° and 5.1° smaller than experiment. All other basis sets predicted angles within 1.1° of the measured value. The CS bond lengths from the STO-3G and STO-3G* SCF calculations are shorter than experiment by ~ 0.04 Å and ~ 0.06 Å while the split valence (3-21G, 4-31G) or double ζ basis sets give CS bonds ~ 0.02 Å too long. The addition of diffuse functions on S (DZ to DZ + DIFFUSE) has very little effect on geometry with a change in the HCH angle of 0.2°. The extension of the basis set to include polarization functions on C, S, and H has a dramatic effect on the CS bond length decreasing it by nearly 0.04 Å to a value of 1.601 Å. For the S_0 state the STO-3G result of this work agrees (within small differences due to different geometry optimization criteria) with results previously reported (6). The split-valence, double ζ, and double ζ plus polarization geometries for H_2CS ($^1A_1$) are comparable to calculations with similar types of basis sets (5, 7, 19). It appears that with the possible exception of the STO-3G and STO-3G* results for the CS bond lengths, very reasonable SCF level geometries for ground state H_2CS are predicted.

Properties other than geometry will not be discussed in detail in this article although brief mention will be made of (*1*), the Koopmans theorem ionization potentials for removal of an electron from the sulfur lone pair and (*2*), the Mulliken net atomic charges on C and S. The experimental result

for the n_S ionization potential of thioformaldehyde is 9.38 eV (20). STO-3G and STO-3G* basis sets give Koopmans theorem values of 6.59 and 6.39 eV for this quantity and thus differ very markedly (by 2.79 and 2.99 eV) from experiment. All the other Gaussian basis sets considered in this work predict Koopmans theorem ionization potentials for n_S greater than but within 0.4 eV of experiment (3-21G: 9.66 eV, 4-31G: 9.41 eV, DZ + DIFFUSE: 9.75 eV, DZ**: 9.47 eV, DZ** + DIFFUSE: 9.55 eV).

The Mulliken net atomic charges are consistent with the greater electronegativity of C as compared to S as the C is always more negatively charged. The split valence or double ζ basis sets overemphasize charge separation (3-21G: C −0.703, S +0.168, Δq = 0.871; 4-31G: C −0.518, S +0.082, Δq = 0.600). Polarization functions provide a mechanism for charge transfer from C to S and thus reduce the bond polarity (DZ**: C −0.268, S −0.043, Δq = 0.225). The dramatic reduction of the polarity of the CS bond with the inclusion of polarization functions has been noted (7). Interestingly, STO-3G and STO-3G* basis set also yield smaller charge separations (STO-3G: C −0.236, S +0.007, Δq = 0.355; STO-3G*: C −0.107, S +0.007, Δq = 0.114) particularly for the basis set including *d* functions on S.

The geometries for the lowest triplet state of thioformaldehyde (Table 2) are unexpected as the STO-3G geometry is very different from that reported in ref. 6 where due to UHF-SCF convergence difficulties it appears that a $^3(\pi \rightarrow \pi^*)$ state was actually optimized rather than the lowest triplet ($n \rightarrow \pi^*$) state. The split valence (3-21G, 4-31G) and double ζ basis sets yield CS bond lengths at least 0.1 Å greater than experiment for triplet thioformaldehyde. A double ζ type basis also yielded a CS bond length for triplet H_2CS which was far too long in ref. 5. The addition of polarization functions very significantly reduces the CS bond length (by ~0.05 Å) to a value of 1.732 Å (DZ**) which is in reasonable agreement with the experimental result of 1.683(5) Å. It is noteworthy that the small STO-3G and STO-3G* basis sets yield values for *r*(CS) in the triplet state equally as good as the most extensive SCF calculations in this work. The STO-3G* result of 1.699 Å is clearly reminiscent of the good agreement reported with an STO-2G + $3d_\pi$ basis set (4) and suggests that *d* orbitals on S are effective in bringing the CS bond length into reasonable agreement with experiment. The STO-3G and STO-3G* results for the HCH angles are less satisfactory being 3.8° and 3.1° less than experiment. The largest basis set calculations (DZ** and DZ** + DIFFUSE) predict θ_e(HCH) within 0.1° of the experimental value. All basis sets yielded reasonable values for r_e(CH) which were usually slightly too short. The out-of-plane angle (α_e(oop)) is the most poorly defined quantity experimentally due to the very small barrier to pyramidal inversion at carbon (see below) and thus the extreme "floppiness" of nuclear motion in this coordinate. The STO-3G*, 3-21G, DZ, DZ**, and DZ** + DIFFUSE basis sets predict values for α_e in reasonable agreement with experiment (2) (i.e. within 2° of the limits of 13.1 to 18.9° given by the error bars). The STO-3G result is too pyramidal by 11.0° and the 4-31G too planar by 11.4°. The diffuse functions added on S which would normally be expected to cause small effects on the geometry change α_e by 3.3° (DZ to DZ + DIFFUSE) suggesting the weakness of the inversion potential and its extreme sensitivity to basis set effects.

The Mulliken net atomic charges for the T_1 state indicate greater polarization than in S_0 reflecting the charge transfer from a n-type orbital largely localized on S to a π^* orbital with significant C AO character. For example for the DZ** basis set in the T_1 state the net charges are C −0.391 and S +0.057 while for S_0 the same basis predicts C −0.268 and S −0.043. The split valence basis sets predict a very polar CS bond in the T_1 state (e.g. 3-21G: C −0.728, S +0.215). Polarization functions again provide a mechanism for reducing the large charge separation.

The relaxed planar transition states for the pyramidal inversion at C of T_1 thioformaldehyde were calculated for the STO-3G and DZ** + DIFFUSE basis sets. The calculated inversion barriers are STO-3G: 174 cm^{-1} and DZ** + DIFFUSE: 48 cm^{-1} which may be compared with the value of 13 cm^{-1} extracted from experimental data (2). A CI calculation but without full geometry optimization has reported a barrier of 108 cm^{-1} (5). The transition state geometrical parameters undergo small changes relative to the equilibrium results. For both the STO-3G and DZ** + DIFFUSE basis sets the CS bonds contract by 0.003 Å in the transition state. The HCH angles open up at the planar geometry from 115.8° to 118.6° (STO-3G) or 119.6° to 121.4° (DZ** + DIFFUSE) and the CH bond shorten slightly (1.082 Å to 1.079 Å, STO-3G; 1.075 Å to 1.074 Å (DZ** + DIFFUSE)).

This study further emphasizes that the split valence or double ζ basis sets which have proven so useful for molecules containing only first row atoms (C, N, O, H) have a much more limited value when the molecular species contains the second row atom sulfur.

The three conformations of 3,5-dichloro-2-hydroxythiophenol in solution

TED SCHAEFER, RICHARD P. VEREGIN, AND DAVID M. MCKINNON
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 4, 1981

TED SCHAEFER, RICHARD P. VEREGIN, and DAVID M. MCKINNON. Can. J. Chem. **59**, 3204 (1981).

The long-range spin–spin coupling constants for the sidechain protons in 3,5-dichloro-2-hydroxythiophenol show that the compound exists as a mixture of three conformers in CCl_4 solution at 305 K. The conformer, in which the S—H bond is held roughly perpendicular to the ring plane by an OH···3*p* hydrogen bond, is 13% abundant. The other two conformers, of roughly equal proportions, contain an OH···Cl hydrogen bond. One of these has the S—H bond *cis* to the OH group, the other has it *trans*. The chemical shifts of the SH proton and of H-6 are in agreement with these conclusions. The free energy preference of the OH···Cl over the OH···S bond is 1140 ± 100 cal/mol at 305 K. The five-bond coupling between the sidechain protons is negative and very likely involves proximate interactions via lone pairs on oxygen and/or sulfur.

TED SCHAEFER, RICHARD P. VEREGIN et DAVID M. MCKINNON. Can. J. Chem. **59**, 3204 (1981).

Les constantes de couplage à longue distance des protons de la chaîne latérale du dichloro-3,5 hydroxy-2 thiophénol révèlent que ce composé, en solution dans le CCl_4, à 305 K, est un mélange de trois conformères. Le conformère, dans lequel la liaison S—H est à peu près perpendiculaire au plan du cycle par une liaison hydrogène OH···3*p*, a une abondance de 13%. Les deux autres conformères en proportions à peu près égales contiennent une liaison hydrogène OH···Cl. Dans un des conformères, la liaison S—H est en position *cis* par rapport au groupement OH, l'autre conformère est son isomère *trans*. Les déplacements chimiques du proton SH et du proton en position 6 s'accordent avec ces conclusions. A 305 K, la liaison OH···Cl est favorisée par une énergie libre de 1140 ± 100 cal/mol par rapport à la liaison OH···S. Le couplage à travers cinq liaisons entre les protons de la chaîne latérale est négatif et implique vraisemblablement des interactions de proximité approchées par l'intermédiaire du doublet libre de l'oxygène ou du soufre ou des deux à la fois.

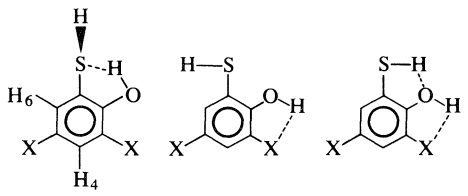
[Traduit par le journal]

Introduction

The novel perpendicular conformation of 2-hydroxythiophenol, **1** (X = H), deduced from spin–spin couplings, *J*, in CCl_4 at 305 K, can be rationalized with *ab initio* MO calculations (1). A qualitative explanation recognizes that the mainly 3*s* lone pair on sulfur is diffuse but the directional 3*p* lone pair is twisted into the benzene plane by electrostatic fields from the polar O—H bond. Hence the S—H bond now occupies the plane preferred by the 3*p* lone pair in thiophenol itself.

The strength of the OH···S bond could not be measured. The free energy advantage of **1** (X = H) over the three likely planar forms was at least 2 kcal/mol (1 kcal ≡ 4.184 kJ), in semiquantitative agreement with STO 3G results and with Schroeder–Lippencott potential functions (2).

Stereospecific coupling constants in phenol derivatives (3–5) allow the ordering of *ortho* substituents as to their attraction for the O—H dipole. In this work, such couplings for the SH and OH protons in 3,5-dichloro-2-hydroxythiophenol (DDHT) show that conformers **1** to **3** (X = Cl) occur in CCl_4 solution at 305 K. Their relative abundance is related only indirectly to the relative strengths of OH···Cl and OH···S hydrogen bonds. A negative $^5J^{OH,SH}$ is compared with theoretical predictions.



1 **2** **3**

Experimental

DDHT was prepared from the corresponding sulfonyl chloride (Aldrich) by reduction with zinc and hydrochloric acid. It gave the correct mass spectrum. A 2.0 mol% solution in CCl_4, containing 4 mol% tetramethylsilane (TMS), was degassed by the freeze–pump–thaw technique in a 5 mm od nmr tube. The tube was flame-sealed and intermolecular proton exchange was retarded in the usual way (4). There was no doubt that, as for 2-hydroxythiophenol (1), exchange was too slow to contribute to the peak widths. The latter were ≤ 0.10 Hz at half height and were determined by magnetic field inhomogeneity. The ^1H nmr spectrum was calibrated at 305 K on an HA100 spectrometer in the manner recently described in detail (6). Partial decoupling (7) and tickling (8) experiments determined the signs of the coupling constants. A similar solution in C_6D_6 was also examined. It displayed chemical shift degeneracy for the ring protons.

Solutions of 2,6-dichloro-, 2,6-dichloro-4-chloromethyl-, and 2,6-dichloro-4-mercaptophenol in CCl_4 were also examined.

INDO and CNDO/2 MO FPT (9) computations were made on an Amdahl 470/V7 system.

Results and Discussion

Spectral Analysis

(10, 11), the analysis gave the spectral parameters in Table 1. Figure 1 illustrates the spectral quality and one of the many double irradiation experiments. The analysis was highly precise because the linewidths were small and all of the calculated transitions were assigned.

The Conformational Equilibrium

$^5J_m^{OH,H_6}$ is 0.550 ± 0.012 and $^5J_m^{OH,H_4}$ is 0.084 ± 0.012 Hz (errors given as three times the standard deviations in Table 1, presumably at the 99% confidence level (6, 12)). The sum of the two couplings is 0.634 ± 0.024 Hz, a number expected on the basis of those observed for trihalophenol derivatives (3).

With reference to previous discussions (3–5, 13), one may write $\Delta G = -RT \ln 0.55_0/0.08_4 = -1140 \pm 100$ cal/mol for the free energy favoring **2** + **3** over **1**. The quoted error assumes an uncertainty of 0.012 Hz in each of the couplings. In previous competition experiments of this kind for 2,4,6-trisubstituted phenols (3–5), the free energy preferences were found as Cl ~ Br > F > I > CF_3. Relative to iodine, they were −75 ± 20 for F, −460 ± 60 for Cl and Br, and +1230 ± 200 cal/mol for CF_3. Therefore SH appears to fall between I and CF_3 in this sequence.

Of course, the order of hydrogen bond strengths in these compounds need not be the same as in monosubstituted phenols. Solvent and dimerization perturbations are probably lower for the 2,4,6-trisubstituted compounds. Nevertheless, for 2-iodophenol (14) and 2-hydroxythiophenol (1), the couplings provide no evidence for other than an intramolecularly hydrogen bonded conformer in CCl_4 at 305 K, suggesting a free energy preference of not less than 1.9 kcal/mol. The present competition experiment would then imply a free energy preference of about 3 kcal/mol for the OH···Cl bond of 2-chlorophenol in CCl_4, but this number must be treated with circumspection. Our CNDO/2 calculations give dipole moments of 1.2 D for each of **2** and **3**, and 1.8 D for **1** (X = Cl). The electrostatic theory of solvent stabilization of polar conformers (15) then yields not more than 100 cal/mol for the increased stability of **1** relative to **2** or **3** in CCl_4 solution.

Note, however, that while both of the OH···Cl and OH···S bonds may well involve an OH···3*p* interaction, the OH···S bond is formed at the expense of 3*p*,π conjugation. The latter amounts to about 0.8 kcal/mol (16, 17). Therefore the intrinsic OH···S bond strength may be nearly as large as the OH···Cl interaction (relative to **2** + **3**, there is *not* an entropy of *R* ln 2 favoring **1**). This discussion

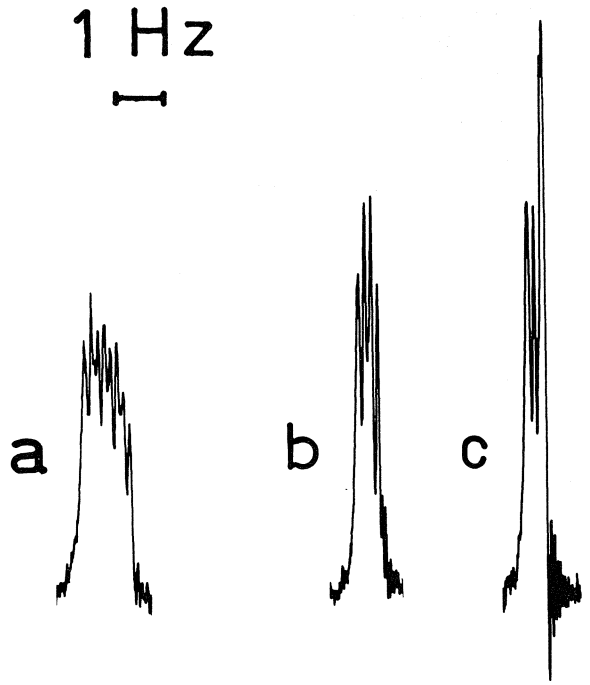

FIG. 1. In (a) the hydroxyl proton resonance at 305 K and 100.001_2 MHz is shown for a 2.0 mol% solution of 3,5-dichloro-2-hydroxythiophenol in CCl_4. The band spans 1 Hz and all 8 peaks expected from coupling to the other three protons are observed. In (b) the S—H proton resonance displays the four peaks expected when the hydroxyl protons are decoupled. In (c) an additional partial decoupling field is applied at 716.39 Hz in order to decouple H-6 from S—H for one spin state of H-4. The experiment shows that $^6J^{H,SH}/^4J_{46} < 0$. The smallest splitting in (b) and (c) is 0.12 Hz.

assumes that perpendicular **1** is indeed the conformer representing 13% of the population. Verification goes as follows.

Conformational Deductions about 1 to 3 (X = Cl)

Conformers **2** and **3** are analogous to those present in almost equal abundance in 2-methoxythiophenol (18). The exact *relative* abundance of **2** and **3** is not important in the following discussion, but it must be very nearly the same as the 43 and 57%, respectively, in 2-methoxythiophenol in order to reach the ensuing good agreement between calculated and observed parameters.

One has $P_1 = 0.13$ and $P_2 + P_3 = 0.87$. For a 1.9 mol% solution of 2-hydroxythiophenol in CCl_4, existing as **1** (X = H), $^6J_p^{H,SH}$ is -0.97_3 Hz (1) and is -0.13_6 Hz in 2-methoxythiophenol (18). Therefore $^6J_p^{H,SH}$ in DDHT should be $0.13 \times (-0.97) + 0.87 \times (-0.14)$ or -0.25 Hz. The observed value is -0.27 Hz. Similarly, $^4J_o^{H,SH}$ is calculated as -0.14 Hz and the observed number is -0.11_5 Hz.

In these calculations it is assumed that the chlorine substituents do not alter the reference values of $^6J_p^{H,SH}$ and $^4J_o^{H,SH}$, i.e., those observed in 2-hydroxythiophenol and in 2-methoxythiophenol. If these substituents, placed *meta* to the SH group, were to alter the rotational barrier about the C—S bond, the two couplings would also alter (17–19). Unfortunately, chemical shift degeneracy disallows the extraction of the couplings in 3,5-dichlorothiophenol (19). However, in 3,4-dichlorothiophenol, $^4J_o^{H,SH}$ is the same as in thiophenol (19), suggesting minor perturbations by chlorine substituents placed *meta* or *para* to SH. Yet, in 3,5-dichloro-4-hydroxythiophenol, $^4J_o^{H,SH}$ is -0.59_0 Hz in CCl_4 and is -0.64_9 Hz in *p*-methoxythiophenol (17). Here the perturbation by the chlorine substituents is roughly 0.59/0.65. If this reduction is applied in the calculation above, $^4J_o^{H,SH}$ becomes -0.12 Hz.

$^6J_p^{H,SH}$ is a $\sigma-\pi$ transmitted coupling. For another such coupling, $^6J_p^{H,CH}$ in toluene, no perturbation by *meta* substituents has been observed. Any perturbation of $^6J_p^{H,SH}$ should therefore be no larger than that observed for $^4J_o^{H,SH}$ (conformational changes) and then the calculated $^6J_p^{H,SH}$ becomes -0.23 Hz, still within cumulative experimental error of the observed value.

In view of a referee's remarks, it should be pointed out that **2** + **3** includes any contributions from nonplanar orientations of the S—H group *in* **2** + **3**, including an orientation in which the S—H group lies in a plane perpendicular to the molecular plane. This orientation is unfavorable energetically because the barrier to rotation about the C—S bond in **2** + **3** is substantial (18).

In 2-hydroxythiophenol, δ_{SH} is 2.82 (1) and is 3.66 ppm in 2-methoxythiophenol (18). Weighting these shifts according to the population distribution yields δ_{SH} as 3.55 ppm. The correction for the chlorine substituents is 0.18 ppm (δ_{SH} is 3.41 ppm for 3,5-dichlorothiophenol as a 1 mol% solution in CCl_4 at 305 K[1] and is 3.23 for thiophenol (20)). Dilution shifts are very small for thiophenol derivatives[1] and therefore the observed shift of 3.73 ppm agrees satisfactorily with the calculated shift of 3.73 ppm. The agreement is expected because the local environment of the SH proton is similar in **1**, **2**, and **3** and in the reference compounds (note that **2** and **3** are therefore implied to have the same relative populations as in 2-methoxythiophenol).

By way of contrast, the reference compounds for the hydroxyl proton shifts are not available. For example, δ_{OH} in 2,4-dichlorophenol is 5.40 ppm,[1] is 5.66 ppm in 2,6-dichlorophenol, and is 5.61 ppm in 2,4,6-trichlorophenol (all in CCl_4 at 305 K). In 2,4-dichlorophenol the OH·Cl conformer is at least 96% abundant in dilute solution (3) and the 4-chloro substituent causes only a small shift perturbation. Probably the best explanation for these observations invokes a small repulsion between lone pairs on oxygen and the lone pairs on the non-hydrogen-bonded, *ortho* chlorine substituent. If such repulsions are loosely labeled as steric crowding,[2] it then becomes apparent that δ_{OH} in **1** and **2** (X = Cl) should be larger than δ_{OH} in, respectively, **1** (X = H) and 2,4-dichlorophenol. The perturbation of δ_{OH} by SH in **3** is also quantitatively unknown.

If the δ_{OH} values of 6.03 ppm in **1** (X = H) and of 5.40 ppm in 2,4-dichlorophenol are weighted by 13 and 87%, respectively, then the calculated shift becomes 5.48 ppm for DDHT. The observed shift is 5.82 ppm. The excess shift of 0.34 ppm to low field is reasonably attributable to steric or other perturbations of the type exemplified above. This discussion is only meant to ensure that the observed δ_{OH} in DDHT is *not* taken as evidence against the conformational populations derived above.

The ring proton shifts in 3,5-dichlorothiophenol are[1] both 7.12 ppm. In DDHT, δ_6 is 7.15 ppm and is 7.14 ppm in 2-methoxythiophenol. Therefore H-6 does not display the substantial shift to low field of 7.36 ppm observed in 2-hydroxythiophenol. In the

[1]Unpublished measurement in this laboratory.

[2]Electric fields from the second *ortho* substituent cannot explain the increased shifts to low field. Replacement of Cl-6 by F or Br and I in 2,4,6-trichlorophenol causes high and low field shifts,[1] respectively, in opposite directions to the change in dipole moment of the C—X bond! Steric crowding by 6-X is also evident in the proximate $^4J^{OH,F}$ values for 2-F-4-diX-phenols, where X = Cl, Br, I (4).

latter the 3*p* orbital of sulfur lies approximately in the ring plane and may well turn out (21) to account for the large deshielding of H-6; its $n \rightarrow \pi^*$ excitation energy will be lower in this orientation. In DDHT conformer **1** is a minor constituent. The shifts of H-6 in these three compounds (Table 1) vary by only 0.03 ppm.

The Negative Coupling, $^5J_o^{OH,SH}$

In DDHT this coupling is −0.25 Hz and is −0.14 Hz in 2-hydroxythiophenol. Proton couplings over five bonds are usually positive. In DDHT it is likely that direct (22) or proximate interactions, probably involving lone pairs on sulfur and oxygen, are important, in a way similar to those observed and calculated for the hydroxyl proton and fluorine nuclei in the *cis* forms of 2-fluorophenol and 2-hydroxybenzotrifluoride (4, 23).

INDO MO FPT calculations tend to exaggerate the magnitudes of five-bond couplings in benzene derivatives (4). CNDO/2 calculations on the partially optimized geometries for the conformers of 2-hydroxythiophenol yield $^5J_o^{OH,SH}$ as −0.11, −0.11, and −1.38 Hz for **1**, **2**, and **3** (X = H) respectively. They are insensitive to the chlorine substituents, decreasing by less than 4% in their presence. If the C–S–H angle in **3** is increased by 5° (to 100.4°), $^5J^{OH,SH}$ changes to −0.84 Hz. The H···O distance changes by 0.1 Å. In other words, the coupling is very sensitive to the H···O distance in **3**, as anticipated for proximate interactions (4, 23).

Note that **1** has a calculated $^5J^{OH,SH}$ of −0.11 Hz, close to the observed value of 2-hydroxythiophenol. The present calculations cannot give the proportion of **2** and **3**, even though **3** has a large calculated magnitude for $^5J_o^{OH,SH}$ and **2** a small one. They do indicate that this coupling should be enhanced in magnitude relative to 2-hydroxythiophenol, as observed.

Heat capacity measurements of liquids with a Picker mixing flow microcalorimeter

MARC-ANDRÉ SIMARD AND JEAN-LUC FORTIER

Centre d'applications en calorimétrie et thermodynamique, Département de Chimie, Université de Sherbrooke, Sherbrooke (Que.), Canada J1K 2R1

Received March 31, 1981

MARC-ANDRÉ SIMARD and JEAN-LUC FORTIER. Can. J. Chem. **59**, 3208 (1981).

The Picker mixed flow microcalorimeter has been used without modification as a differential thermal balance to measure the volumetric heat capacity of liquids. The precision on volumetric heat capacity change is evaluated to be ±0.5% or better, and the limit of detection is $\pm 5 \times 10^{-5}$ J K^{-1} cm^{-3}. As a check, the apparent molar heat capacities of an aqueous solution of NaCl in the range 0.01 to 6 mol kg^{-1} were measured at 298.15 K. The performance of this instrument is compared with that of the Picker heat capacity flow microcalorimeter.

MARC-ANDRÉ SIMARD et JEAN-LUC FORTIER. Can. J. Chem. **59**, 3208 (1981).

Un microcalorimètre dynamique Picker pour chaleur de mélange a été utilisé, sans modification, comme balance thermique différentielle pour mesurer la capacité calorifique volumétrique de liquides. La précision sur un changement de capacité calorifique volumétrique est évaluée à ±0.5% ou mieux et la limite de détection est de $\pm 5 \times 10^{-5}$ J K^{-1} cm^{-3}. Pour vérifier la méthode, les capacités calorifiques molaires apparentes de solutions aqueuses de NaCl entre 0.01 et 6 mol kg^{-1} ont été mesurées à 298.15 K. L'utilisation de cet instrument pour mesurer la capacité calorifique est comparée à celle du microcalorimètre dynamique Picker "capacité calorifique".

Introduction

Heats of mixing and heat capacities are fundamental properties in the study of solute–solute and solute–solvent interactions in solution. Precise enthalpies have been measured for many years, but it is only recently, with the development of new microcalorimeters (1–3), that the heat capacity of solutions have received much attention. In the last decade, the literature shows an extraordinary expansion in this field. It is known that the temperature dependence of the excess enthalpy can be derived from the excess heat capacity. The possibility of measuring both the excess enthalpy and heat capacity of solutions with the same calorimeter is then a very interesting option. It is also known that C_p can be measured using a mixing microcalorimeter (4, 5), but a high precision on C_p is required (2) since an error of only 0.01% on specific heat capacities causes an uncertainty of about 40 J K^{-1} mol^{-1} on the apparent molal heat capacity (ϕ_C) of an aqueous solution at 0.01 mol kg^{-1}.

The purpose of this paper is to show that the sensitivity and stability of the commercial version of the Picker mixing flow microcalorimeter (1) is such that this instrument can be used, without modification, for the measurement of changes in the volumetric heat capacity of liquids (σ) with a sensitivity of $\pm 5 \times 10^{-5}$ J K^{-1} cm^{-3} and a precision of ±0.5% or better. To establish the performance of this technique, we carried out measurements on aqueous solutions of NaCl in the concentration range 0.01 to 6 mol kg^{-1} at 298.15 K. These values have been evaluated by many authors (2, 6–11) involving the use of different types of calorimeter.

Experimental

In this work, we used the commercial version[1] of the Picker mixing flow microcalorimeter. The principle of operation has been described in details elsewhere (1). Figure 1*A* shows schematically how it is used to measure the volumetric heat capacity of liquids. The calorimeter is differential, so the two cells are of identical construction. One inlet of both flow cells, marked X, was sealed-off. This calorimeter is fitted with mini-mixing device installed at the merging junction of the two inlets to ensure an efficient mixing of the liquids. With most of the aqueous solutions, this mixing device has negligible friction effect, but with viscous liquids it may be necessary to remove it for the present application. In the present work, measurements were made without these mixing devices. As with the Picker heat capacity flow microcalorimeter (1, 2), the two calorimetric cells are connected in series to ensure equal flow rates, and a delay loop is placed between these two cells. An identical heating power (W_0) is applied to heating elements of each cell to produce a temperature increase (ΔT) of about 2 K. The difference in temperature between the two cells is measured with a modulated thermal detector (1), which consists of a modulating flow device, feeding alternatively the heat exchanging fluid in the reference and observation branches, and the thermal detector at the common return of these branches. For the present application, the mixing calorimeter has to operate in adiabatic mode; this was achieved by the use of methanol as heat exchanging fluid with a total flow rate ($2f_E$) of 0.03 cm^3 s^{-1} and a liquid sample flow rate (f_s) of about 0.01 cm^3 s^{-1} in the calorimetric cells. With the heating power (W_0) applied on each cell, large thermal pulses are induced by the pulsation of the heat exchanging fluid, which may lead to saturation of the electronic detection; to avoid this problem the modulated thermal detection is set on a low sensitivity scale, the desired sensitivity is then obtained by increasing the recorder sensitivity.

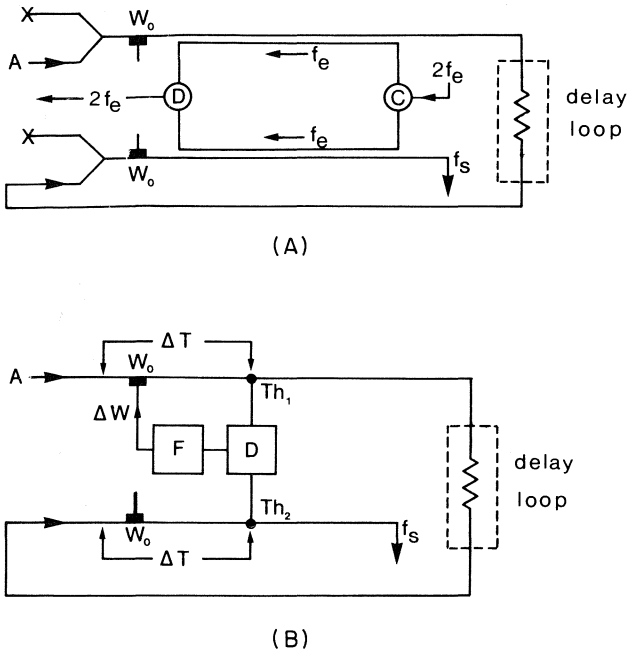

FIG. 1. Schematics. (*A*), The heat of mixing flow microcalorimeter used as a thermal balance for the measurement of the volumetric heat capacity of liquids; (*B*), the heat capacity flow microcalorimeter.

With this set-up the experimental procedure to measure the volumetric heat capacity of a liquid (σ) is similar to the one used with the Picker heat capacity flow microcalorimeter (2). First, a base line is recorded with a reference liquid of known volumetric heat capacity flowing through both cells, then the liquid to be measured is introduced. The difference in volumetric heat capacity ($\Delta\sigma = \sigma - \sigma_0$) between the reference and the sample liquid circulating in the two calorimetric cells is monitored by the difference in the temperature gradient ($\delta(\Delta)$) between these. Since there is no thermal feedback (2) to cancel this change of temperature, the measurement will depend on the flow of liquid. Therefore, this flow has to be kept constant during a run, but its value is not required in the calculations if a calibration is made in the same experimental conditions. With calibration made on the sample liquid, the change of power required to produce an identical $\delta(\Delta T)$ value will be equal to ΔW_s. If the calibration is made on the reference liquid, this change of power will then be different and identified as ΔW_R. The change of volumetric heat capacity between the sample and the reference liquid is evaluated using either eq. [1] or eq. [2] as appropriate.

$$[1] \quad \Delta\sigma/\sigma_0 = \Delta W_s/W_0$$

$$[2] \quad \Delta\sigma/\sigma_0 = \Delta W_R/(W_0 + \Delta W_R)$$

Densities of the solution were measured to within $\pm 3 \times 10^{-6}$ g cm^{-3} with a vibrating tube densimeter (12). All solutions were prepared by mass from distilled water and Fisher certified NaCl that had been dried in a vacuum oven at 150°C for 48 h.

Results and Discussion

If we compare the principle of measurement of the heat capacity flow microcalorimeter (Fig. 1*B*) with the one involved when we used the mixing flow microcalorimeter (Fig. 1*A*) as a thermal balance for the volumetric heat capacity measurement of liquids, we note two main differences. First, there is no heat exchanging device, the ΔT produced by the heating elements are monitored with two thermistors (Th_1, Th_0); second, instead of measuring $\delta(\Delta T)$, there is a thermal feedback circuit (F), connected to the heating elements of the working cell and controlled by the detection bridge (D), which changes the power supplied to the working cell by ΔW to keep the temperature gradient, ΔT_1, equal to the one in the reference cell, ΔT_0. With this thermal feedback and the series connection between the two calorimetric cells, the measurement is independent of the flow of liquids, assuming that there is no mixing effect in the delay loop which may produce an expansion or a contraction of the liquids. As already observed by Fortier *et al.* (13), this mixing effect may produce a significant error on the measured $\Delta\sigma$. This situation is not unique to the heat capacity flow microcalorimeter but it is also valid in the present technique.

For the limit of detection and the precision in the measurements, both techniques are equivalent, the values being respectively ± 5 J K^{-1} mol^{-1} and $\pm 0.5\%$. In the present technique, there is no thermal feedback to maintain a constant temperature gradient during a run, thus in a series of measurements, when the calibrations are made on the reference liquid, a shift of the mean temperature (δT_m) will be observed if the heating power (W_0), the flow rate (f), and the reference liquid are kept the same (single reference procedure). Under these conditions, the temperature gradient in the working cell (ΔT_1) will be directly proportional to the volumetric heat capacity of the measured liquids (σ) as shown in eq. [3], where the subscript 0 refers to the liquid in the reference cell.

$$[3] \quad \Delta T_1\sigma_1 = W_0/f = \Delta T_0\sigma_0$$

From this relation, the shift of the mean temperature can be expressed as

$$[4] \quad \delta T_m = \frac{\Delta T}{2}\left(\frac{\sigma_0}{\sigma} - 1\right)$$

With the aqueous solutions of NaCl, this shift is negligible since at $m = 5.320$, δT_m is only 0.062 K. For systems involving high values of $\Delta\sigma/\sigma_0$, this problem can be avoided by a proper flow adjustment between each run, or by making the calibration on the sample liquid.

The apparent molar heat capacities (ϕ_C) and

volumes (ϕ_V) of aqueous solutions were calculated using respectively eq. [5] and eq. [6].

$$[5]\quad \phi_C = Mc_p + 1000\,\frac{(c_p - c_{p0})}{m}$$

$$[6]\quad \phi_V = \frac{M}{d} - 1000\,\frac{(d - d_0)}{mdd_0}$$

in which M is the molecular weight of the solute, m is the molality of the solution (mol/kg solvent), d and d_0 are the densities of the solution and of the pure water ($d_0 = 0.997047$ g cm^{-3}), c_p and c_{p0} are the specific heat capacity of the solution and of pure water ($c_{p0} = 4.1793$ J K^{-1} g^{-1}). The apparent molar volumes and heat capacities results are given in Table 1 with the values of m, d, and $\Delta\sigma/\sigma_0$.

Our ϕ_C results were fitted using the following polynomial equation

$$[7]\quad \phi_C - 28.99(d_0m)^{1/2} = \phi_C^0 + Bm + Cm^2 + Dm^3 + Em^4$$

where the parameter 28.99 is the limiting slope of the Debye–Hückel theory for 1:1 electrolytes in water at 298.15 K (15). The other parameters were obtained with an unweighted least-squares fit, and the number of parameters was fixed by a statistical F-test (16). To represent the results at molalities up to 1 mol kg^{-1}, terms in m are sufficient ($\phi_C^0 = -85.6$, $B = 17.7_8$), but terms in m^4 are required to extend the fit up to 6 mol kg^{-1} ($\phi_C^0 = -86.0$, $B = 21.2_6$, $C = -4.09$, $D = 0.55_3$, $E = -0.034$). The interdependence of the parametric terms B, C, D, E, F explains the difference for the term in m and for the extrapolated value ϕ_C^0. This effect has been observed previously (8). In a residual plot ($\phi_C - \phi_C$ calculated with eq. [7]), the results agreed inside the experimental error which has been estimated to ± 0.5 J K^{-1} mol^{-1} for $m > 0.1$; at concentration below 0.1 m, this uncertainty increases significantly and reaches approximately ± 5 J K^{-1} mol^{-1} around 0.01 m.

In Fig. 2 we compare our experimental values with those from the literature. The graph represents the difference between our value calculated with eq. [7] and the values of different authors. Our experimental values are in good agreement with those from Olofsson (6) obtained with an LKB reaction solution calorimeter, Randall and Rossini (7), Tanner and Lamb (9), Perron *et al.* (10), and Fortier *et al.* (11) (corrected as mentioned by Desnoyers *et al.* (17)).

Sources of errors, such as heat losses, with the prototype and some early commercial versions of the Picker heat capacity flow microcalorimeter have been noted by some authors (6, 14, 17). It must be pointed out that with the Picker mixing flow microcalorimeter, heat losses proportional to the difference in temperature, if occurring, have no effect on the measured heat capacity values; since there is no thermal feedback, the heating power W_0 and calibration power ΔW_c are affected in the same way by these heat losses.

[a] In obtaining these tabulated quantities, we have used $\sigma_0 = 4.1670$ J K^{-1} cm^{-3} and $d_0 = 0.997047$ g cm^{-3}.

To pursue the application of using the mixing flow microcalorimeter as a thermal balance for the measurement of volumetric heat capacity of liquids, we have also verified that this instrument can be used as a differential flowmeter in the same way it has been done with the heat capacity flow microcalorimeter for the direct continuous measurements of the thermal expansion coefficients of liquids and solids (18). The experimental procedure is similar but the equations have to be modified to take into account the absence of the thermal feedback. In doing so, eq. [4] of ref. 8, becomes:

$$[8]\quad \alpha = \frac{f_0}{V}\,\frac{\Delta W}{W_0 + \Delta W}\left(\frac{dT}{dt}\right)^{-1} + \alpha_{cell} + \alpha_e$$

For the meaning of each term, the reader is referred to ref. 18.

Conclusion

As shown in the previous section, the Picker mixing flow microcalorimeter can be used as a

Experiment points: +, Olofsson (6), results with LKB calorimeter; ×, Randall and Rossini (7); □, Tanner and Lamb (9); △, Perron *et al.* (10); ○, Fortier *et al.* (11), corrected as mentioned by Desnoyers *et al.* (17).

differential thermal balance to measure the change in volumetric heat capacities of liquids with a sensitivity of $\pm 5 \times 10^{-5}$ J K^{-1} cm^{-3} and a precision of $\pm 0.5\%$. The results obtained are in good agreement with those measured with other types of calorimeter. Compared to the heat capacity flow microcalorimeter, the present technique is more time consuming, mainly due to the calibration which has to be done for each run; furthermore, the operation of the mixing flow microcalorimeter requires greater attention on the part of the user. But these little disadvantages are out-weighed by the possibility of measuring with the same instrument three of the most important thermodynamic properties in the study of solutions: heats, specific heats, and expansibilities.

J. William Lown and Hsiao-Hsiung Chen. Can. J. Chem. **59**, 3212 (1981).

The antitumor antibiotic daunorubicin, upon reduction in aqueous solution, gives a transient resolved epr spectrum of linewidth 17.0 G and g value of 2.0024. This is ascribed to the semiquinone previously tentatively assigned in the unresolved epr spectrum obtained by microsomal activation of the antibiotic. By reference to the epr spectrum of quinizarin semiquinone in aqueous solution the individual proton hyperfine splitting constants in both spectra were tentatively assigned by computer simulation. LCAO–MO calculations of one-electron wave function spin densities in both species gave good agreement between calculated and observed hfs for values of the parameters $\beta_{CO}/\beta_{CC} = 1.8$, $\delta\alpha = 1.4$, allowing definite assignment of the aromatic protons. By considering the angular dependence of the ring A benzylic proton hfs it was possible to discriminate between two alternative half-chair conformations of daunorubicin semiquinone. The preferred conformation of the intermediate is tentatively assigned as that which places both 7 and 9 oxygen functions equatorial and the C-9 acetyl group axial.

J. William Lown et Hsiao-Hsiung Chen. Can. J. Chem. **59**, 3212 (1981).

La réduction en solution aqueuse de la daunorubicine, un antibiotique antitumoral, permet d'observer un spectre de rpe d'un composé transitoire présentant une largeur de bandes de 17,0 G et avec une valeur de g de 2,0024. On attribue ceci à la semiquinone dont on avait supposé antérieurement l'existence en se basant sur un spectre de rpe non résolu obtenu par activation microsomique de l'antibiotique. En se référant au spectre de rpe de la semiquinone de la quinizarine en solution aqueuse et d'une simulation par ordinateur, on a attribué d'une façon préliminaire les constantes de couplage hyperfin. Les calculs LCAO–MO des densités de spin de la fonction d'onde d'un électron des deux espèces donnent une bonne corrélation entre les couplages hyperfins calculés et observés pour les valeurs des paramètres $\beta_{CO}/\beta_{CC} = 1.8$, $\delta\alpha = 1.4$ permettant ainsi une identification nette des protons aromatiques. En considérant la dépendance angulaire des couplages hyperfins du proton benzylique du cycle A, il est possible de distinguer entre les deux conformations demi-chaise possibles pour la semiquinone de la daunorubicine. On considère, sans l'avoir prouvé, que la conformation privilégiée de l'intermédiaire est celle dans laquelle les fonctions oxygénées 7 et 9 sont équatoriales et le groupe acétyle en C-9 est axial.

Introduction

The anthracycline antibiotics, especially daunorubicin (**1**) and adriamycin, are among the most promising clinically effective agents currently in use against a range of neoplasms (1, 2). Consequently considerable and widespread interest has been shown in their synthesis, biochemical pharmacology, and mechanism of action (1, 2). The antitumor properties in many cases correlate with the ability of the chromophore of the antibiotics to effect intercalative inhibition of DNA template functions (1–4). However, it is being recognized that other mechanisms, including the generation of free radical intermediates (5, 6) and possibly bioreductive covalent attachment to biomolecules, may also be significant (7). These agents suffer from two serious disadvantages: (*i*) a tendency to undergo reductive deglycosidation to produce the inactive 7-deoxyaglycones (1, 2), and (*ii*) a severe dose-related cardiotoxicity (8, 9). Evidence has accumulated to indicate that both effects require initial one-electron reduction of the chromophore and that in the second effect there is subsequent generation of reactive oxygen species including hydrogen peroxide, superoxide anion, and hydroxyl radicals (Fig. 1) (5, 6, 10–12). The susceptibility of cardiac tissue to lipid peroxidation by the latter species may be accounted for by the substantially lowered concentration of the cell protective enzymes superoxide dismutase, catalase, and glutathione peroxidase in the heart compared with other organs (10, 13, 14). A number of the species in the scheme (Fig. 1), which is central to the many in vivo reactions of the anthracyclines, have been

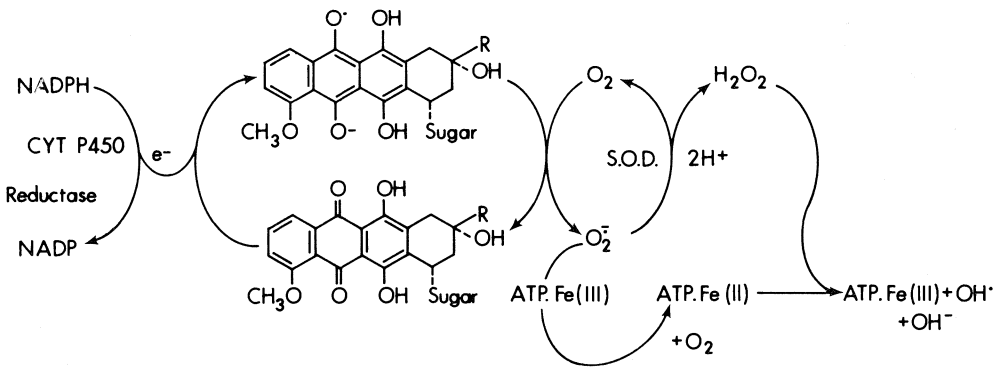

FIG. 1. Scheme for intracellular enzymatic reductive activation of the anthracycline chromophore and subsequent generation of superoxide anion, hydrogen peroxide and hydroxyl radicals.

identified. For example the intermediacy of $O_2^{\cdot-}$ and of H_2O_2 in the action of reductively activated anthracyclines on DNA is unambiguously established by their selective enzymatic removal by superoxide dismutase and by catalase, respectively (7). In addition the superoxide anion generated from daunorubicin in microsomal incubations has been spin-trapped (15). The hydroxyl radical generated from quinone antibiotics has also been spin-trapped in epr experiments (16). Moreover we recently provided evidence using kinetic criteria in conjunction with epr spectroscopy for the generation of free hydroxyl radicals from the anthracyclines as well as certain other antibiotics (17). The remaining species, the anthracycline semiquinone, is strongly implicated in the above processes. Hitherto characterization of this species in aqueous solution has been difficult owing to its transient nature (5, 18). While a steady-state electron paramagnetic resonance (epr) signal generated in vivo during the rat liver microsomal activation of daunorubicin has been tentatively attributed to the semiquinone, the poorly resolved spectrum obtained did not permit unambiguous identification (5, 18). An epr spectrum attributed to daunorubicin semiquinone (18, 19) and a somewhat different spectrum attributed to daunomycinone semiquinone (7) have been obtained in dimethyl sulfoxide solutions, which solvent in general has a stabilizing effect on organic radicals. Because of the profound effects of solvents on the conformation of daunorubicin (2, 20, 21) we have attempted to obtain the epr spectra in aqueous solution with a view to obtaining the unperturbed conformation of the radical. This necessitates some sacrifice in stability of the semiquinone species and some loss of resolution of the narrow splittings. The hyperfine splittings arising from the chromophore could be assigned by computer simulation and an LCAO–MO calculation and by comparison with quinizarin semiquinone as a model compound. By reference to the angular dependence of the hyperfine couplings arising from the protons of ring A a distinction was possible between two possible conformations of the semiquinone.

Experimental

Materials and Methods

Daunorubicin hydrochloride was a generous gift from Dr. F. Arcamone, Farmitalia, Milan. Peroxylamine disulfonate was purchased from Aldrich Chemical Co. Quinizarin was obtained from Aldrich Chemical Co. and was purified by recrystallization just before use.

Electron Paramagnetic Resonance Spectroscopy

The epr spectra were obtained on a Bruker ER-400 epr spectrometer fitted with a Varian V3601 12-inch magnet with VFR Hall effect controller. Hyperfine couplings were obtained by comparison with peroxylamine disulfonate (triplet, spacing 13.0 G) and g values were obtained by direct Fieldial measurements.

Generation and Detection of Daunorubicin and Quinizarin Semiquinones

Stock solutions containing 8×10^{-2} M of the quinones were prepared in triply distilled water. The reactions were performed at room temperature in a total volume of 500 μL in a quartz flat cell containing 4×10^{-3} M quinone, 4×10^{-3} M aqueous sodium borohydride in 50 mM potassium phosphate buffer, pH 7.4, with free access to atmospheric oxygen, and the epr spectra of the semiquinones rapidly recorded. While the spectrum of quinizarin semiquinone was stable, owing to the transient nature of daunorubicin semiquinone, several trials were necessary to obtain the resolved spectrum of the latter in aqueous solution.

Results and Discussion

Daunorubicin semiquinone gave an epr spectrum of spectral width ca. 17.0 G with g value estimated at 2.0024 (Fig. 2). This corresponds in field position to the broad unresolved single line signal obtained by rat liver microsomal activation of daunorubicin

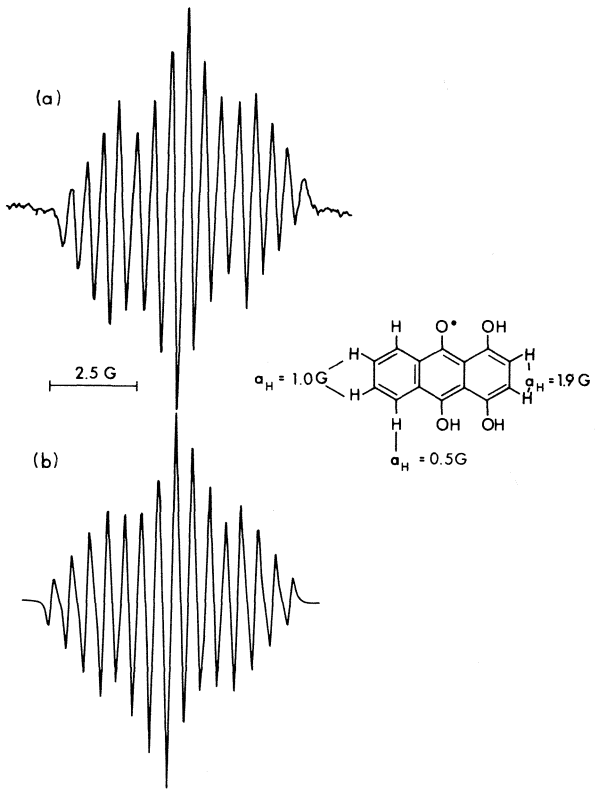

FIG. 3. The epr spectrum (microwave power 4 mW, modulation amplitude 0.06 G, scan time 1000 s) obtained from 1×10^{-4} *M* quinizarin in aqueous solution with reduction by 1×10^{-4} *M* sodium borohydride in 50 m*M* phosphate buffer, pH 7.4, in the presence of atmospheric oxygen. (a) Observed epr spectrum. (b) Computer simulation with Lorentzian line shapes and with line widths of 0.2 G and the hfs shown.

which was tentatively attributed to the antibiotic semiquinone (5, 18). The epr signal was quite short-lived under these conditions in accord with previous estimates of the upper limit of the average lifetime of this species of ca. 1 ms obtained electrochemically (22).

The multiplicity observed in the hyperfine coupling indicated that the unpaired spin density extended to the three benzylic protons of ring A and to the three aromatic protons of ring D of the chromophore. Owing to the lack of symmetry in the anthracycline chromophore, however, it was necessary to examine a model compound in order to assign the individual hyperfine splitting constants (hfs).

Quinizarin **2** has a similar substitution pattern to rings B and C of daunorubicin. Under similar reaction conditions quinizarin gave rise to a stable and well-resolved fifteen-line spectrum with an overall spacing of 7.8 G and a g value of 2.0026 (Fig. 3). Computer simulation gave an accurate match for hyperfine splitting by three pairs of equivalent protons with values for a_H of 0.5, 1.0, and 1.9 G respectively and assigned as shown in Fig. 3. The epr spectrum of quinizarin semiquinone has been obtained previously but under different reaction conditions (23). Although the two semiquinones have been depicted in Figs. 2 and 3 as the neutral species at pH 7, the pK_a values of the phenolic OH groups anticipated to be in the region of 3 to 4 (1, 2) may well result in the neutral species being in equilibrium with the radical anion forms under these conditions. However, since identical spectra were obtained in deuterium oxide solutions this indicates no additional coupling from the OH protons due to rapid exchange in aqueous solution, so the equilibrium level of protonation cannot be ascribed with certainty. In contrast, generation of the anthracycline semiquinone species in dimethyl sulfoxide solution (18, 19) may be expected to result in additional hyperfine splitting from the OH protons as a result of reduced rate of exchange.

On the basis of the tentative quinizarin hfs assignments (which indicate substantial unpaired spin density extending to ring B of the anthracy-

cline chromophore), the epr spectrum of daunorubicin semiquinone was analyzed as shown in Fig. 2. Computer simulation gives a match for hyperfine splittings the individual magnitudes of which are tentatively assigned as shown in Fig. 2.

Huckel Molecular Orbital Calculation of Unpaired Spin Densities Permitting Individual Hyperfine Splitting Constant Assignments

Theoretical studies have shown a direct proportionality between proton hyperfine splitting a_i and the calculated density of the unpaired electron ρ_i at the carbon adjacent to the proton (24–26)

[1] $a_i = Q\rho_i$

where Q is a constant. It has been pointed out by Vincow and Fraenkel (23) that although a molecular orbital theory calculation with neglect of configuration interaction cannot be expected to give reasonable results for radicals similar to odd-alternate hydrocarbons, however, the results for the even-alternate hydrocarbon radicals give fair agreement, sufficiently so to give one confidence in the accuracy of individual assignments.

One-electron LCAO – molecular orbital theory calculations were performed using the Huckel approximation for the BCD semiquinone aromatic ring system of the anthracycline as a 19 center pi (π) system, and on the quinizarin semiquinone as an 18 center π system. Molecular wave functions were calculated for a range of values of β_{CO}/β_{CC} from 1.55 to 2.0 and of $\delta\alpha = (\alpha_o - \alpha_C)/\alpha_{CC}$ and where α_C and β_{CC} are the Coulomb and resonance integrals for carbon, respectively. The unpaired spin densities computed as the squares of one-electron wave function coefficients for the carbons of interest in **1** and **2** are summarized in Table 1.[2] To obtain the predicted hfs a_H values from eq. [1], the widely accepted (23, 26, 27) value of $Q = 22.5$ was used for the aromatic protons in each case. For the benzylic protons in ring A of the anthracyclines it was then necessary to consider the angular dependence of axial or equatorial positions relative to the π orbitals at positions 6a and 10a in **2**. It has been argued that if the hyperfine coupling of C_β protons (β to the site of spin density) occurs by a hyperconjugative mechanism it should be proportional to $\cos^2\theta$, where θ is the angle between projections of the $2p_x$-orbital of C_α and the C_β—H bond on a plane perpendicular to the C_α—C_β bond (28). It has been found that, although the simple relationship between β-proton coupling and θ suggested above ($a_H \propto \cos^2\theta$) is fitted reasonably satisfactorily in some examples, closer agreement is obtained by modification of this relationship to form eq. [2]

[2] $a_H = \rho(B_0 + B\cos^2\theta)$

where B_0 is a constant between 3 and 4 G and B is in the range 45–50 (refs. 29–31). For alicyclic systems values of $B_0 = 3.5$ and $B = 45.6$ G have been found to be satisfactory (31, 32) and are therefore used here.

In eq. [2] due account is taken of spin-density values on C_α. Such spin-density transmission for the anthracycline semiquinone reflects the contribution of canonical forms of the type shown in Fig. 4, and which has been suggested to be involved in the enzymatic reductive deglycosidation of anthracyclines (34). The good agreement between calculated and observed a_H values for the aromatic protons of quinizarin and of the anthracycline chromophore given by the values $\beta_{CO}/\beta_{CC} = 1.8$ and $\delta\alpha = 1.4$ (Tables 1, 2)[2] gives one confidence that the unpaired spin densities are reasonably accurate. Therefore we felt justified in using the corresponding calculated spin densities for positions 7a and 10a in daunorubicin obtained by using $\beta_{CO}/\beta_{CC} = 1.8$ and $\delta\alpha = 1.4$ to make some deductions concerning the average conformation of ring A in daunorubicin semiquinone.

It has correctly been pointed out in a comparable conformational analysis of the parent antibiotic by proton magnetic resonance that the Karplus relationship should not be used to determine accurately dihedral angles from vicinal coupling constants (15). It should, however, be possible to use it (or the equivalent relationship in epr spectroscopy) to distinguish between alternative conformations. Two such conformations (Fig. 5, **a** and **b**) of the A ring need to be considered by analogy with daunorubicin itself. These correspond to two possible half-chair conformations of ring A of the antibiotic (2, 15, 20). The conformation **a** is favored for the anthracycline in solution in which the two oxygen functions are pseudo-equatorial (15). By contrast, conformation **b** is found in the crystal structure of

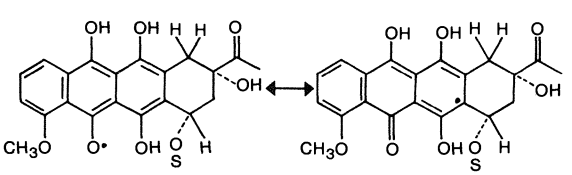

FIG. 4. Suggested transmission of unpaired spin density in daunorubicin semiquinone during enzymatic reductive deglycosidation (ref. 33).

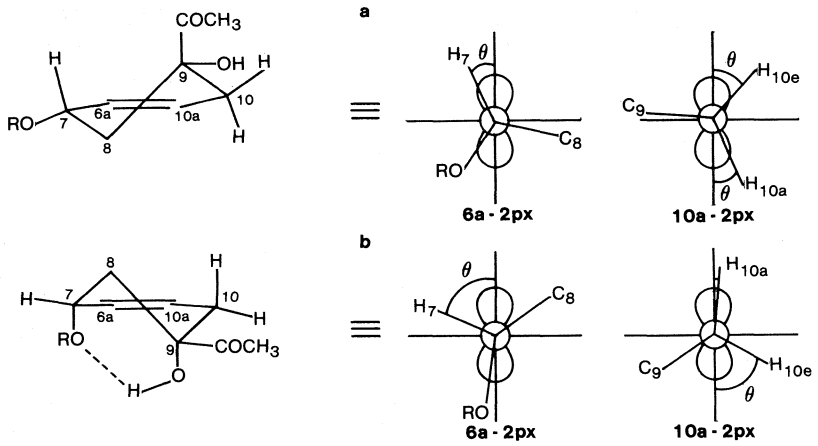

FIG. 5. Possible conformations of ring A in daunorubicin and the corresponding dihedral angles to the unpaired electron in $2p_x$ orbital at the carbons 6a and 10a of ring junction A/B.

the pyridine adduct of daunorubicin where strong hydrogen bonding is permitted between the two axial oxygen functions (35). Considerations of the geometries of the two corresponding conformations of the daunorubicin semiquinone permit certain predictions to be made concerning the relative magnitudes of the benzylic proton hyperfine couplings in ring A. As seen from Fig. 5, viewing along the C_7—C_{6a} bond and along the C_{10}—C_{10a} bond for conformation **a** predicts roughly comparable small values for θ for the respective axial protons at positions 7 and 10 and the equatorial proton at position 10. These values of θ are estimated to be in the 30–40° range. By contrast, the corresponding dihedral angles in conformation **b** are two large (ca. 75°) and one very small (~5°) in the hydrogen bonded structure **b**. In relating calculated hfs to observed it is recognized that initially at least the individual benzylic protons are assigned arbitrarily. The predicted unpaired spin densities at positions 6a and 10a are closely similar (see Table 1).[2] Moreover, since either conformation **a** or **b** predicts two axial and one equatorial or two equatorial and one axial, the two similar observed couplings (2.25 G) are assigned one to each of the 7 and 10 positions. By employing eq. [2] we can estimate the dihedral angles θ for the LCAO calculation with $\beta_{CO}/\beta_{CC} = 1.8$ and $\delta\alpha = 1.4$

$$a_{H_{10e}} = \rho_{10a}(B_0 + B\cos^2\theta)$$
$$2.85 = 0.08509\,(3.5 + 45.6\cos^2\theta)$$

which gives $\cos\theta = 0.81102$ or $\theta_{10e} \approx 36°$.

Similarly $a_{H_{10a}} = 2.25 = 0.08509\,(3.5 + 45.6\cos^2\theta)$, which gives $\cos\theta = 0.70931$ or $\theta_{10a} \approx 45°$. The corresponding dihedral angle for the proton at position 7 is derived from $a_{H_{7a}} = 2.25 = 0.08037\,(3.5 + 45.6\cos^2\theta)$, which gives $\cos\theta = 0.73292$ or $\theta_{7a} \approx 43°$. In contrast, conformation **b**, which requires dihedral angles of ca. 75° for the equatorial protons at positions 7 and 10 and of about 5° for H_{10a}, predicts hfs values of $a_{H_{7a}} = 0.53$, $a_{H_{10e}} = 0.56$, and $a_{H_{10a}} = 4.1$ G, respectively. Even allowing for some distortions in the rings these observations indicate that the conformation **a** depicted in Fig. 5 is in better agreement with the experimental data. It should be emphasized, however, that the epr spectra, owing mainly to the lack of resolution in aqueous media, may be subject to more than one analysis. For this reason the interpretation given must be regarded as tentative.

In view of its recognized role in the metabolism, cardiotoxicity, and possibly the molecular mechanisms of anticancer action of daunorubicin, this result may assist in the interpretation of the biochemical pharmacology of this important antibiotic. For example, the daunorubicin semiquinone has been described as a "site-specific" radical (5) and there is some evidence for its binding to DNA (7). A knowledge of the preferred conformation of this intermediate should be of assistance in delineating the geometry of the molecular recognition process in its interaction with DNA.

COMMUNICATION

Hydrogen–deuterium exchange and rearrangement of polycyclic aromatic hydrocarbons in dilute acid medium at elevated temperatures

NICK HENRY WERSTIUK AND GEORGE TIMMINS

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 8, 1981

NICK HENRY WERSTIUK and GEORGE TIMMINS. Can. J. Chem. **59**, 3218 (1981).

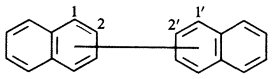
The high temperature – dilute acid (HTDA) method has been applied to the preparation of perdeuterated polycyclic aromatic hydrocarbons. Naphthalene (**1**), 1-methylnaphthalene (**2**), 2-methylnaphthalene (**3**), anthracene (**4**), phenanthrene (**5**), chrysene (**6**), pyrene (**7**), benz[*a*]anthracene (**8**), benzo[*a*]pyrene (**9**), 1,1′-binaphthyl (**10**), 1,2′-binaphthyl (**11**), and 2,2′-binaphthyl (**12**) have been perdeuterated in high yield in dilute DCl–D_2O solutions at elevated temperatures (240–280°C). **2**, **3**, **10**, **11**, and **12** also rearrange.

NICK HENRY WERSTIUK et GEORGE TIMMINS. Can. J. Chem. **59**, 3218 (1981).

On a préparé des hydrocarbures aromatiques polycycliques perdeutérés en opérant en milieu acide dilué et à haute température (ADHT). Utilisant des solutions diluées de DCl dans D_2O et opérant à des températures allant de 240 à 280°C, nous avons perdeutéré les hydrocarbures suivants avec d'excellents rendements: naphtalène (**1**) méthyl-1 naphtalène (**2**), méthyl-2 naphtalène (**3**), authracène (**4**), phénanthrène (**5**), chrysène (**6**), pyrène (**7**), benz [*a*] anthracène (**8**), benzo [*a*] pyrène (**9**), binaphtyl-1,1′ (**10**), binaphtyl-1,2 (**11**) et binaphtyl-2,2′ (**12**). Les composés **2**, **3**, **10**, **11** et **12** subissent aussi des transpositions.

[Traduit par le journal]

In continuing our study of the scope of the high temperature – dilute acid (HTDA) method of hydrogen isotope exchange (1–5) we examined the H–D exchange of naphthalene (**1**), 1-methylnaphthalene (**2**), 2-methylnaphthalene (**3**), anthracene (**4**), phenanthracene (**5**), chrysene (**6**), pyrene (**7**), benz[*a*]anthracene (**8**), benzo[*a*]pyrene (**9**), 1,1′-binaphthyl (**10**), 1,2′-binaphthyl (**11**), and 2,2′-binaphthyl (**12**). All substrates are perdeuterated in near-quantitative yield in a single reaction and **2**, **3**, **10**, **11**, and **12** rearrange. The results of our preliminary study are listed in Table 1.



10–12

Typically, substrate (0.030 g) was added to 5 mL of 2% w/v DCl–D_2O in a thick-walled glass tube, the solution was degassed via three freeze–pump–thaw cycles and sealed under vacuum. The tube was placed in a 600 mL Parr pressure apparatus which contained water to equalize pressure and heated for an appropriate period. Solid products were isolated by filtration and 1-methylnaphthalene was isolated by ether extraction. Deuterium content was determined mass spectrometrically at low ionizing voltage.

From Table 1 it can be seen that all compounds can be equilibrated with the deuterium pool and perlabelled in excellent yield in a single reaction at 250–280°C. Benzo[*a*]pyrene which chars substantially at 250°C in 2% w/v DCl–D_2O can be perdeuterated in 1% w/v DCl–D_2O at 240°C (entry 11). Exchange of **10**, **11**, and **12** occurs slowly in neutral D_2O at 280°C (for example entry 15). **1**, **5**, and **6** are also stable and undergo complete H–D exchange at 300°C in neutral D_2O (for example entry 2). With methylnaphthalenes **2** and **3**, the methyl groups also equilibrate with the deuterium pool under these conditions (entries 4 and 5). In a previous study of H–D exchange of toluene and xylenes at 250°C for shorter reaction times, little exchange of the methyl groups and no isomerization were observed (1, 3, 4). We expect that the methylnaphthalenes can similarly be selectively ring deuterated at lower temperatures.

Under HTDA conditions rearrangement of the methylnaphthalenes (entries 3–5) and binaphthyls (entries 12–17) also occurs. The rearrangements are subject to an isotope effect, rearrangement being faster in D_2O than in H_2O (entries 3 and 4 or

16	**11**	D, 250°C, 72h	92	1.2	92.8	6.1	98.1 (13.73)	98.2 (13.75)	98.1 (13.73)
17	**12**	D, 280°C, 50h	97	2.2	19.4	78.4	97.9 (13.71)	98.0 (13.72)	98.3 (13.76)

[a] Reactions were carried out in 2% w/v DCl–D_2O = D or 2% w/v HCl–H_2O = H solutions unless otherwise stated.
[b] Yields of crude product are reported.
[c] The values, average of at least three determinations, were obtained by glpc using electronic integrations.
[d] Deuterium content was determined mass spectrometrically (or, for mixtures, gc–ms) at low ionizing voltage (9 eV).
[e] **2** was isolated by ether extraction, the solution was dried and the ether removed under vacuum.
[f] Since the compounds could not be completely separated, the values quoted are averages of at least eight measurements of peak intensities as both compounds exited the gas chromatograph.

12 and 14). In our view, the binaphthyls rearrange via naphthalene naphthonium ions **13** and **14**. As far as we are aware, this is the first report of naphthyl shifts on aromatic rings via naphthonium ions although ethene naphthonium ions have been implicated as intermediates in the solvolysis of 1- and 2-naphthylethyl sulfonates (6–8).

PHILIP A. W. DEAN. Can. J. Chem. **59**, 3221 (1981).

$^{113}Cd(AsF_6)_2$ has been synthesized from ^{113}CdO by treatment in SO_2 with PF_5 then AsF_5. From the ^{113}Cd-enriched salt have been prepared $[Cd(EPR_3)_4]^{2+}$ (E = O, R = C_6H_{11}; E = S or Se, R = Ph), $[Cd(SP(C_6H_{11})_3)_x(SeP(C_6H_{11})_{n-x}]^{2+}$ (n = 4, x = 0–4; n = 3, x = 0–3), $[Cd(EP(o\text{-}C_6H_4Me)_3)_n]^{2+}$ (E = S, n = 4 or 2; E = Se, n = 3 or 2), $[Cd(Ph_2P(O)(CH_2)_nP(O)Ph_2)_3]^{2+}$ (n = 1 or 2), and $[Cd(Ph_2P(O)((CH_2)_2P(O)Ph_2)_2)_2]^{2+}$ in liquid SO_2. The reduced temperature slow exchange ^{31}P and ^{113}Cd nmr spectra have been measured and are discussed. The ^{31}P nmr are as expected from previous work on complexes containing ^{113}Cd at natural abundance except that several values of $^2J(^{113}Cd—O—^{31}P)$ have been measured. From the ^{113}Cd spectra the most important shielding sequences observed are $\delta_O \ll \delta_{Se} < \delta_S$ for $[Cd(EP(C_6H_{11})_3)_4]^{2+}$, $\delta_{2:1} < \delta_{3:1} < \delta_{4:1}$ for $[Cd(EPR_3)_n]^{2+}$ (E = S or Se, n = 1–4, constant R), and $\delta_{CdO_4} > \delta_{CdO_6}$ for the various phosphine oxide complexes studied.

The synthesis of SO_2-insoluble $Cd(SbF_6)_2 \cdot 3(OP(C_6H_{11})_3)$ is reported.

PHILIP A. W. DEAN. Can. J. Chem. **59**, 3221 (1981).

On a synthétisé le $^{113}Cd(AsF_6)_2$ en faisant réagir le ^{113}CdO dans le SO_2 avec du PF_5 puis avec du AsF_5. Utilisant des sels enrichis en ^{113}Cd et opérant dans le SO_2 liquide, on a préparé les composés suivants: $[Cd(EPR_3)_4]^{2+}$ (E = O, R = C_6H_{11}; E = S ou Se, R = Ph), $[Cd(SP(C_6H_{11})_3)_x(SeP(C_6H_{11})_{n-x}]^{2+}$ (n = 4, x = 0–4; n = 3, x = 0–3), $[Cd(EP(o\text{-}C_6H_4Me)_3)]_n^{2+}$ (E = S, n = 4 ou 2; E = Se, n = 3 ou 2), $[Cd(Ph_2P(O)(CH_2)_nP(O)Ph_2)_3]^{2+}$ (n = 1 ou 2), et $[Cd(Ph_2P(O)((CH_2)_2P(O)Ph_2)_2)_2]^{2+}$. On a mesuré et on discute des spectres rmn du ^{31}P et du ^{113}Cd dans lesquels des échanges lents sont observés à basse température. Les spectres rmn du ^{31}P correspondent à prévus par les travaux antérieurs sur les complexes contenant du ^{113}Cd en l'abondance naturelle, on a toutefois mesuré plusieurs valeurs de $^2J(^{113}Cd—O^{31}P)$. Les séquences de blindage les plus importantes observées dans les spectres du ^{113}Cd sont dans l'ordre suivant $\delta_O \ll \delta_{Se} < \delta_S$ pour le $[Cd(EP(C_6H_{11})_3)_4]^{2+}$, $\delta_{2:1} < \delta_{3:1} < \delta_{4:1}$ pour le $[Cd(EPR_3)_n]^{2+}$ (E = S ou Se, n = 1–4, R constant) et $\delta_{CdO_4} > \delta_{CdO_6}$ pour les différents complexes d'oxyde de phosphine étudiés. On rapporte la synthèse du composé $Cd(SbF_6)_2 \cdot 3(OP(C_6H_{11})_3)$ insoluble dans le SO_2.

[Traduit par le journal]

Introduction

Previously, we have used reduced temperature ^{31}P nmr to characterize, in SO_2 solution, a wide range of cadmium complexes with phosphine oxides, sulfides, or selenides, as well as some mixtures of these, as ligands (1, 2). Our intention was to establish a series of related complexes of Group VIA donor ligands in which the kernel could be varied methodically, so providing a basis for a ^{113}Cd nmr study in which the effect of systematic change about the cadmium could be investigated. There is general agreement on the need for more and better model compound studies to advance the application of ^{113}Cd nmr to less straightforward situations, but relatively few detailed studies of model series have appeared (e.g. refs. 3–15), and some of these (e.g. refs. 4, 9, 11) have been complicated by the necessity of working with mixtures undergoing rapid intermolecular exchange.

In this paper we present ^{113}Cd nmr results for selected members from among the cadmium complexes we characterized earlier (1, 2). Unambiguous slow exchange ^{113}Cd spectra have been observed, allowing us to assess the effect on the ^{113}Cd resonance of change of donor atom only, change in ligation number only, change of substituents on the phosphorus atom of the phosphine chalcogenides, and change in the number and size of chelate rings in six-coordinate complexes of chelating phosphine oxides.

Experimental

Materials

Isotopically-enriched CdO (96.3% ^{113}Cd), obtained from Oak Ridge National Laboratory, was dried by heating *in vacuo* prior to use, as were CdO (Mallinckrodt, Analytical Grade), HgO (Shawinigan, Reagent Grade), and ZnO (Fisher, Certified A.C.S. Grade). Arsenic pentafluoride (Ozark-Mahoning, Inc.) and phosphorus pentafluoride (Matheson) were used as received, while antimony pentafluoride (PCR, Inc.) was purified by double distillation in a nitrogen atmosphere. The literature routes (16) to $Cd(AsF_6)_2$ and $Cd(SbF_6)_2$ were used to prepare the salts containing ^{113}Cd in natural abundance, and the preparations of the ligands, except $OP(C_6H_{11})_3$, have been given earlier also (1, 2, 17). Tricyclohexylphosphine oxide was prepared from $S_2C \cdot P(C_6H_{11})_3$ (Strem Chemicals, Inc.) according to Issleib and Brack (18).

Sulfur dioxide (Matheson, Anhydrous Grade) was stored in

the gas phase over Linde 3A Molecular Sieves for at least 12 h before use.

General Manipulative Procedure

Glove box and vacuum line manipulations and preparations of sealed nmr samples were carried out as described in earlier publications from this laboratory (e.g. refs. 1 and 16).

Preparation of $Cd(AsF_6)_2$ from CdO

Isotopically-enriched cadmium was available only as the oxide, so an alternative to the previously reported route to $Cd(AsF_6)_2$ (16), which relies on anhydrous CdF_2 as a starting material, was necessary.

In a sealed glass H-apparatus of a type described earlier (19), CdO, suspended in SO_2, was treated with AsF_5 using AsF_5/CdO = 4. Within 15 min, the CdO dissolved to give a colourless solution.[3] Filtration, followed by removal of volatiles *in vacuo*, left colourless crude $Cd(AsF_6)_2$. *Anal.* calcd. for As_2CdF_{12}: As 30.56, Cd 22.93, F 46.51; found: As 29.79, Cd 22.42, F 45.28.

Samples of "$^{113}Cd(AsF_6)_2$" prepared by the preceding method gave ^{113}Cd, and with R_3PE (E = O, S, or Se), ^{31}P nmr spectra consistent with those reported earlier (1, 2, 16) for samples containing ^{113}Cd at natural abundance, and the cadmium salt prepared in this way were used in the earlier part of the present work. However, the nmr samples with R_3PE usually contained some insoluble material not present when authentic $Cd(AsF_6)_2$ was used.

The 193 K ^{19}F nmr spectra of SO_2 solutions in which AsF_5/CdO (or ZnO or HgO) = 4 show a broad ($\nu_{1/2} \sim 50$ Hz) line with $\delta_F \approx -48$ ppm and an AX_4 pattern ($\delta_A = -68.3$, $\delta_X = -37.5$ ppm, $J(F—F) = 130 \pm 2$ Hz). The latter spectrum can reasonably be attributed to a species with an AsF_5O kernel, with AsF_5O^- or $F_5AsOAsF_5^-$ (or their SO_2 solvates, O-sulfito complexes) being most likely. This oxygen-containing species may well be the contaminant in $Cd(AsF_6)_2$ prepared from CdO and AsF_5.

A better synthesis of $Cd(AsF_6)_2$ involves two stages. In the initial stage, CdO, suspended in SO_2, is treated with excess PF_5. Over a period of several days at room temperature, the colour of the CdO is blanched and POF_3, identified in the supernatant liquor by ^{19}F nmr, and white $CdF_2 \cdot nPF_5$ formed. From the $CdF_2 \cdot nPF_5$, CdF_2 can be obtained by removal of volatiles *in vacuo*. *Anal.* calcd. for CdF_2: Cd 74.73, F 25.27; found: Cd 74.45, F 25.56. (This proves a convenient route to anhydrous CdF_2 and other metal fluorides.) Normally the $CdF_2 \cdot nPF_5$ was not isolated, but, instead, treated with AsF_5 (AsF_5/Cd $\geq$ 2) in a second stage, causing its rapid (few min) dissolution. $Cd(AsF_6)_2$ was isolated from the colourless solution on removal of volatiles. *Anal.* calcd. for As_2CdF_{12}: see above; found: As 30.62, Cd 22.70, F 46.62. Samples of $Cd(AsF_6)_2$ prepared by this second route had properties identical with a sample prepared from CdF_2 and AsF_5, and this was the preferred synthesis of $^{113}Cd(AsF_6)_2$.

In brief attempts to prepare $M(SbF_6)_2$ (M = Zn, Cd, or Hg) we found that the appropriate metal oxides dissolve in SO_2 on treatment with SbF_5 (SbF_5/MO = 4). These solutions were shown by reduced temperature ^{19}F nmr to contain $Sb_2F_{11}^-$, $SbF_5 \cdot SO_2$ and a species with a *cis*-SbF_4O_2 kernel (A_2X_2 spectrum with $\delta_A = -115.5$, $\delta_X = -89.6$ ppm, $J(F—F) = 135 \pm 2$ Hz) (c.f. ref. 20). The complexity of this mixture deterred us from further efforts, but the desired salts could probably be prepared by a two stage synthesis with PF_5 then SbF_5, analogous to that used for $Cd(AsF_6)_2$ from CdO (see above).

[3]The reaction of metal oxides with MF_5 (M = P, As or Sb) does not seem to have been investigated previously, but a preliminary survey suggests that the reactions reported here may be quite general.

Preparation of $Cd(MF_6)_2 \cdot 3(OP(C_6H_{11})_3)$ (M = As or Sb)

In a sealed H-apparatus, an SO_2 solution of $Cd(MF_6)_2$ was added to a like solution of $OP(C_6H_{11})_3$, with $3 < L/M < 4$. The white *product* precipitated, and was filtered off, washed with several small portions of SO_2 and dried *in vacuo*. Both salts are similar; only the hexafluoroantimonate was analyzed. *Anal.* calcd. for $C_{54}H_{99}CdF_{12}O_3P_3Sb_2$: C 44.02, H 6.77, Cd 7.63, P 6.31; found: C 42.17, 41.97, H 6.70, 6.62, Cd 7.78, P 6.34.

Nuclear Magnetic Resonance Spectra

All nmr spectra were measured using a Varian XL-100-12 spectrometer system operating at 22.34 and 40.54 MHz in the FT mode for ^{113}Cd and ^{31}P, respectively, and 94.19 MHz in the CW mode for ^{19}F. Typically, for the ^{113}Cd spectra several thousand transients were accumulated with a spectral window of 12.5 kHz, tip angle of 30°, and a repetition rate of 14 min^{-1}. A 32 K Fourier transform was performed. Conditions for measurement of ^{31}P spectra have been given before (17).

In all cases shifts to higher frequency than the reference are taken as positive. For ^{19}F and ^{31}P nmr the 10 mm o.d. sample tube was fixed coaxially in a 12 mm o.d. nmr tube with the lock/reference mixture ($(CD_3)_2CO/CFCl_3$ for ^{19}F, $(CD_3)_2CO/OP(OMe)_3$ for ^{31}P) in the outer annulus. For ^{113}Cd nmr, external $(CD_3)_2CO$ was again used as a lock substance, but no external ^{113}Cd reference material, suitable for low temperature nmr, was available. Therefore the shifts in Table 2 are reported relative to the frequency of 4 *M* aqueous $Cd(NO_3)_2$ at ambient probe temperature. In none of the nmr was correction for susceptibility differences made.

Elemental Microanalyses

Carbon, hydrogen analyses were performed by Guelph Chemical Laboratories Ltd., all other analyses were performed by Analytische Laboratorien, Elbach, W. Germany.

Results and Discussion

Isotopically-enriched $^{113}Cd(AsF_6)_2$ was prepared from commercially available ^{113}CdO (96.3% ^{113}Cd) by treatment of the oxide in SO_2 firstly with PF_5 and secondly with AsF_5:

$$^{113}CdO + PF_5 \text{ (excess)} \xrightarrow[RT]{SO_2} {}^{113}CdF_2 \cdot xPF_5 + POF_3$$

$$^{113}CdF_2 \cdot xPF_5 + AsF_5 \text{ (excess)} \xrightarrow[RT]{SO_2} {}^{113}Cd(AsF_6)_2 + PF_5$$

Full details of this preparation, and other preparations attempted are given in the Experimental section (above).

The complexes for study by ^{113}Cd nmr were prepared as reported (1, 2), except that $^{113}Cd(AsF_6)_2$ was used as the source of cadmium. The contents of each solution were verified by reduced temperature ^{31}P nmr prior to the ^{113}Cd measurements. All of the complexes except $[Cd(OP(C_6H_{11})_3)_4]^{2+}$ had been characterized by ^{31}P nmr earlier (1, 2). The $OP(C_6H_{11})_3$ complex is new, although similar complexes of other trialkyl and related phosphine oxides are known (21). It is formed from $Cd(AsF_6)_2$ (or $Cd(SbF_6)_2$) and an excess[4] of the ligand in liquid

[4]When $3 \leq OP(C_6H_{11})_2/Cd \leq 4$, insoluble $Cd(MF_6)_2 \cdot 3(OP(C_6H_{11})_3)$ is formed (see Experimental section).

TABLE 1. Some values of $^2J(^{113}Cd—O—^{31}P)$ for phosphine oxide complexes of cadmium in SO_2 solution

Complex	T (K)	$^2J(^{113}Cd—O—^{31}P)$ (Hz)[a]
$[Cd(OP(C_6H_{11})_3)_4]^{2+}$	209	25.6[b]
	308	28.0[c]
$[Cd((OPPh_2)_2CH_2)_3]^{2+}$	220	2.4
$[Cd((OPPh_2)_2(CH_2)_2)_3]^{2+}$	205	14.2
$[Cd(triphos\ O_3)_2]^{2+}$[d]	205	~20[e]

[a] Estimated error ±0.5 Hz except where noted.
[b] $\delta_{OP(OMe)_3(ext)} = 62.6$ ppm. ($\delta_{OP(OMe)_3(ext)} = \delta_{H_3PO_4(ext)} - 1.7$ ppm.)
[c] $\delta_{OP(OMe)_3(ext)} = 62.4$ ppm; the free ligand resonance has $\delta_{OP(OMe)_3(ext)} = 55.5$ ppm.
[d] triphos O_3 = (tridentate) $(O)PPh(CH_2CH_2P(O)Ph_2)_2$.
[e] Using the notation of ref. 1, this is probably $^2J(^{113}Cd—P_C)$. $^2J(^{113}Cd—P_A)$ and $^2J(^{113}Cd—P_B)$ were not observed.

SO_2, and is characterized by the ^{31}P nmr spectral parameters included in Table 1. An interesting feature of the ^{31}P spectrum of this cation, even when made with isotopically normal cadmium, is the very clear $^{111}/^{113}Cd$ satellite spectrum, from two-bond Cd—O—P coupling, which is not completely collapsed even at 308 K. In our previous work (1), ^2J(Cd—O—P) could not be seen in the reduced temperature, slow-exchange ^{31}P spectra of complexes with $Ph_2P(O)(CH_2)P(O)Ph_2$, $Ph_2P(O)(CH_2)_2P(O)Ph_2$, or $PhP(O)((CH_2)_2P(O)Ph_2)_2$ as ligands. When $^{113}Cd(AsF_6)_2$ is used as a starting material, however, some of these couplings do become evident. They are given in Table 1, and represent the only new features found for all the phosphine oxide complexes restudied with ^{113}Cd-enrichment. As we have suggested (1), ^2J(Cd—O—P) is significantly smaller in magnitude than ^2J(Cd—E—P) (E = S or Se) for compounds of analogous ligands. The basis for the considerable variation in ^2J(Cd—O—P) shown by the data in Table 1 is not clear, and a more detailed investigation of this phenomenon might be instructive.

For comparison with the ^{113}Cd nmr of complexes with mixed chalcogenide ligands (ref. 2 and see below) we attempted to characterize the mixed ligand complexes $[Cd(OP(C_6H_{11})_3)_x(EP(C_6H_{11})_3)_{4-x}]^{2+}$ (E = S or Se), but both ^{31}P and ^{113}Cd nmr show that ligand distribution in these mixed systems is far from statistical: the parent complexes $[Cd(OP(C_6H_{11})_3)_4]^{2+}$ and $[Cd(EP(C_6H_{11})_3)_4]^{2+}$ were the predominant species at all $OP(C_6H_{11})_3/E(P(C_6H_{11})_3$ ratios when (total L)/Cd = 4. This appears to be an example of the "symbiotic" nature of ligands, i.e. the tendency of ligands of similar "hardness" or "softness" (22) ("class *a*" or "class *b*" behaviour (23)) to "flock" together, noted by Jørgensen (24).

Details of the ^{113}Cd nmr spectra of the various species studied are given in Tables 2–4. In all cases the low temperature spectra had the multiplicity expected on the basis of the known ^{31}P nmr spectra, confirming that slow exchange conditions prevailed. Unfortunately $[Cd(SeP(o\text{-}C_6H_4Me)_3)_4]^{2+}$ and $[Cd(SP(o\text{-}C_6H_4Me)_3)_3]^{2+}$ had solubilities too low to observe the expected ^{113}Cd multiplets: no signal for the former could be obtained in several

hours, though ^{31}P nmr (taken in ca. 30 min) showed the presence of the species, and only a weak (but reproducible) signal was seen in the region where the resonance of the latter (known from ^{31}P nmr to be present) was expected.

The data in Table 2 show that for the tetrahedral complexes $[Cd(EP(C_6H_{11})_3)_4]^{2+}$ (E = O, S, or Se), shielding is in the order O $\gg$ Se > S, and the data for $[Cd(EPPh_3)_4]^{2+}$ (E = S or Se) confirm the generality of the shielding pattern Se > S. The cyclohexyl complexes are the first series of analogous, discrete, tetrahedral complexes of first, second, and third row Group VIA donor atoms which have been scrutinized by ^{113}Cd nmr. However, in solid CdS and CdSe, in which the cadmium has a tetrahedral kernel, $\delta_{CdS} > \delta_{CdSe}$ (7). In addition, considerable evidence is available to show that replacement of an oxygen donor to cadmium by a sulfur donor frequently leads to extensive deshielding of the ^{113}Cd resonance (ref. 15 summarizes much of the previous data). Further, the sequence $\delta_{\text{2nd row donor}} > \delta_{\text{3rd row donor}}$ is the same one found for the tetrahalocadmates (11, 13, 14). In addition, $\delta_{\text{3rd row donor}} > \delta_{\text{4th row donor}}$ for CdX_4^{2-} (11, 13); the sequence $\delta_{\text{2nd row donor}} > \delta_{\text{3rd row donor}} > \delta_{\text{4th row donor}}$ has very recently been reported for $\delta_{^{199}Hg}$ of HgX_4^{2-} also (13), as has the sequence $\delta_{\text{2nd row donor}} > \delta_{\text{3rd row donor}}$ for $\delta_{^{199}Hg}$ of $Hg(SCN)_2(EPBu_3)_2$ (25).

The effect of varying the number of R_3PE ligands bound may be deduced by a consideration of results for the series $[Cd(EP(C_6H_{11})_3)_n]^{2+}$ (E = S or Se, n = 3 or 4) and $[Cd(EP(o\text{-}C_6H_4Me)_3)_n]^{2+}$ (E = S, n = 2, 3(?), or 4; E = Se, n = 2 or 3). With the reasonable assumption that, like the resonance of $[Cd(SP(o\text{-}C_6H_4Me)_3)_4]^{2+}$ compared with that of $[Cd(SPPh_3)_4]^{2+}$, the resonance of $[Cd(SeP(o\text{-}C_6H_4Me)_3)_4]^{2+}$ is deshielded from that of $[Cd(SePPh_3)_4]^{2+}$, then for the chalcogenide complexes the sequence $\delta_{4:1} > \delta_{3:1} > \delta_{2:1}$ is found. A similar sequence has been deduced for the series $CdCl_n(aq)^{(2-n)-}$ (9, 11) by an analysis of the variation of δ_{Cd} with Cl^-/Cd^{2+} in rapidly exchanging systems. (In ref. 11, δ_{Cd} for $CdCl_4^{2-}$ in the solid state has been used as a "benchmark".) Such analyses depend on a knowledge of the formation constants of all species present in the various mixtures and therefore it is hardly surprising that there is some doubt about the relative shifts of $CdBr_n(aq)^{(2-n)-}$ (9, 11). Because we have observed slow-exchange spectra here, there is no ambiguity in the shielding sequence found. One ambiguity we have been unable to resolve, however, is the extent to which the solvent and/or counterion are involved in the coordination sphere of $[Cd(EPR_3)_n]^{2+}$ ($n < 4$). We have previously suggested, from the variation of $^2J(^{111}/^{113}Cd—E—P)$ with the number of ligands coordinated, that solvent/anion involvement is slight (2). At the same time it must be recognized that $\delta_{Cd} \approx -230$ ppm for $Cd(AsF_6)_2$ or $Cd(SbF_6)_2$ in SO_2 (16), so replacement of EPR_3 (E = S or Se) by SO_2/AsF_6^- might well lead to extensive shielding of the cadmium resonance. A similar quandary exists with regard to the extent of solvation of the species $CdX_n(aq)^{(2-n)-}$ (X = Cl, Br, or I) (9, 11).

For the complexes $[Cd(EPR_3)_n]^{2+}$ (n = 4, E = S, R = C_6H_{11}, Ph, or $o\text{-}C_6H_4Me$; n = 4, E = Se, R = C_6H_{11} or Ph; n = 3, E = Se, R = C_6H_{11} or $o\text{-}C_6H_4Me$) there is a measurable dependence of δ_{Cd} on R (see Table 2). Surprisingly, the R-dependence of the sulfides and selenides is dissimilar. Within the rather limited series of data available, there is no overlap of chemical shifts for complexes having different E, n combinations, but for complexes of given n, the separation of the ranges for E = S and Se is comparable to the spread observed for constant n and E as R is varied, and it seems probable that for a wider range of R some overlap would occur, meaning that for the type of ligand studied here the cadmium chemical shift may not be interpretable unambiguously in terms of sulfur or selenium coordination. We see, for instance, that the chemical shifts observed for the mixed complexes $[Cd(SP(C_6H_{11})_3)_x(SeP(C_6H_{11})_3)_{4-x}]^{2+}$ (Table 3) fall, in some cases, very close to the range for n = 4, E = S or Se. Presumably overlap or near

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

overlap would also occur between the shifts of the mixed complexes $[Cd(SP(C_6H_{11})_3)_x(SeP(C_6H_{11})_3)_{3-x}]^{2+}$ (Table 4) and a wider range of data for $n = 3$, E = S or Se. The incremented shifts within the two series of mixed complexes (Tables 3 and 4) change monotonically but not linearly with x; for the four coordinate species the deviation from linearity at $x = 2$ is ca. 4 ppm, which is comparable to the 3 ppm found by McFarlane *et al.* (26) for the ^{119}Sn chemical shifts of the series $Sn(SMe)_x(SeMe)_{4-x}$. However, the total spread of δ_{Sn} found for the tin complexes (ca. 240 ppm) is much larger than the total spread of δ_{Cd} (68 ppm) for the tetrahedral mixed ligand complexes given in Table 3, and hence the deviation from first order chemical shift additivity is more pronounced for the CdS_xSe_{4-x} kernel studied here. The chemical shift data for both CdS_xSe_{4-x} and CdS_xSe_{3-x} kernels can be correlated empirically using the concept of pairwise additivity (27): the data for CdS_xSe_{4-x} (Table 3) can be reproduced using $\Delta\delta_{S-S} = 11.3$ ppm, $\Delta\delta_{S-Se} = 4.8$ ppm, while the corresponding parameters for CdS_xSe_{3-x} (Table 4) have values 17.4 and 8.0 ppm, respectively.

The cadmium chemical shift range covered by the six-coordinate complexes of chelating polyphosphine oxides is relatively small, 45 ppm at ca. 210 K (Table 1), and separate from the chemical shift of the only unambiguous tetrahedral phosphine oxide complex studied, $[Cd(OP(C_6H_{11})_3]_4^{2+}$. (A lack of fine structure renders structural assignment for $[Cd(Ph_2P(O)(CH_2)_2P(O)Ph_2)_2]^{2+}$ impossible.) Both decrease in chelate ring size (in the two tris(bidentate) complexes) and increase in the number of chelate rings ($[Cd(PH_2P(O)(CH_2)_2P(O)Ph_2)_3]^{2+}$ vs. $[Cd(PhP(O)((CH_2)_2P(O)Ph_2)_2)_2]^{2+}$) appear to cause slight deshielding of cadmium resonance, but the basicity of the donor site(s) must change from ligand to ligand too, and this creates an ambiguity which can only be resolved by further study. Also, more detailed study of a wider range of phosphine oxide complexes will be necessary to ascertain whether overlap of resonance ranges for octahedral and tetrahedral species can occur.

Reaction of hydrogen atoms with diethylsulfide

MBANEFO MBONU EKWENCHI, IMRE SAFARIK, AND OTTO PETER STRAUSZ
Department of Chemistry, University of Alberta, Edmonton, Alta, Canada T6G 2G2

Received March 2, 1981

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

MBANEFO MBONU EKWENCHI, IMRE SAFARIK, and OTTO PETER STRAUSZ. Can. J. Chem. **59**, 3226 (1981).

In the reactions of H atoms, generated by the $Hg(^3P_1)$-sensitized decomposition of H_2, with $C_2H_5SC_2H_5$ the primary reaction has been established to be $H + C_2H_5SC_2H_5 \xrightarrow{[1]} C_2H_5SH + C_2H_5$ with $k_1 = (4.7 \pm 0.9) \times 10^{13} \exp[-(3797 \pm 152)/RT]$ cm^3 mol^{-1} s^{-1} relative to the rate constant of the $H + C_2H_4 \rightarrow C_2H_5$ reaction. The mechanism postulated explains adequately all the experimental observations. The entropy of activation for the primary reaction, −22.1 eu is close to the value obtained for the $H + CH_3SCH_3$ reaction, suggesting a transition state with similar structure. H atoms do not abstract hydrogen from diethylsulfide, but the ethyl radicals from reaction [1] do with a rate coefficient of $k = (7.4 \pm 0.5) \times 10^{13} \exp[-(6860 \pm 98)/RT]$ cm^3 mol^{-1} s^{-1}.

MBANEFO MBONU EKWENCHI, IMRE SAFARIK et OTTO PETER STRAUSZ. Can. J. Chem. **59**, 3226 (1981).

Les atomes d'hydrogène produits par la décomposition du H_2 sensibilisée par le $Hg(^3P_1)$ réagissent avec le $C_2H_5SC_2H_5$; on a établi que la réaction primaire est la suivante $H + C_2H_5SC_2H_5 \xrightarrow{[1]} C_2H_5SH + C_2H_5$ avec $k_1 = (4{,}7 \pm 0{,}9) \times 10^{13} \exp[-(3797 \pm 152)/RT]$ cm^3 mol^{-1} s^{-1} par rapport à la constante de vitesse de la réaction $H + C_2H_4$. Le mécanisme proposé explique adéquatement tous les faits expérimentaux. La valeur de l'entropie d'activation de la réaction primaire, −22,1 ue, est près de celle obtenue pour la réaction de $H + CH_3SCH_3$; ceci suggère un état de transition ayant une structure similaire. Les atomes d'hydrogène n'enlèvent pas d'hydrogène du sulfure de diéthyle, mais les radicaux éthyles produits dans la réaction 1, enlèvent l'hydrogène avec un coefficient de vitesse $k = (7{,}4 \pm 0{,}5) \times 10^{13} \exp[-(6860 \pm 98)/RT]$ cm^3 mol^{-1} s^{-1}.

[Traduit par le journal]

In the course of our continuing studies on the gas phase reactions of hydrogen atoms with organosulfur compounds, the H + COS (1) and the H + thiirane (2) reactions have been first examined. The common feature that was found for these reactions is that the sulfur atom is abstracted by the hydrogen atom in a concerted single step attack on the substrate to yield SH. Further studies have revealed that in the reactions $H + CH_3SCH_3$ (3), $H + CH_3SSCH_3$ (4), and $H + C_2H_5SSC_2H_5$ (5) the hydrogen atom also attacks exclusively at the sulfur atom, forming the corresponding thiol in a metathetical displacement reaction. With thiols the occurrence of an analogous step, $H + RSH \rightarrow R + H_2S$, had been established earlier by Pryor and Olson (6) in the liquid phase and by Hori, Nishino, and Amano (7) in the gas phase. This step proceeds parallel and in competition with the hydrogen abstraction step $H + RSH \rightarrow H_2 + RS$.

In a continuation of our studies we have investigated the $H + C_2H_5SC_2H_5$ reaction in order to establish the primary processes and to determine whether the previously derived mechanism could be extended to this system. We wish to present here the results of this investigation.

Experimental

The apparatus, the general vacuum technique, the analytical technique, and the actinometric determinations were similar to those employed in the previous studies (4, 5). Hydrogen atoms were generated by the mercury-photosensitized decomposition of H_2; the mean value of the light intensity absorbed was 0.012 μeinstein min^{-1}.

Purification procedures for H_2 (Airco) and C_2H_4 (Matheson) were the same as before (4, 5). Diethylsulfide (Eastman) was purified by gc using a 10 ft 10% tricresylphosphate on Chromosorb W column operated between 60 and 65°C using helium as the carrier gas. The purity was always checked by gc prior to each experiment.

The major reaction products were identified by comparison of gc retention times and mass spectrometric analysis of the gc effluents with those of authentic samples.

In these experiments the fraction volatile at −160°C, consisting of C_2H_4 and C_2H_6, was analyzed on an 8 ft poropak N column at 59°C, while the fraction volatile at −130°C, consisting of C_4H_{10} and C_2H_5SH, on a 10 ft tricresylphosphate column at 25°C. The remaining condensable fraction at −130°C was analyzed by gc on the tricresylphosphate column by temperature programming (5° min^{-1}) to 120°C. In order to ascertain whether methane was formed in the reaction, the hydrogen fraction volatile at −210°C was passed through a 3 Å molecular sieve column kept at −196°C. After pumping off the hydrogen through the column, the column was heated to 100°C and the evolved gas was analyzed on a 10 ft 3 Å molecular sieve column.

Results

When hydrogen atoms are generated by the $Hg(^3P_1)$-sensitized decomposition of H_2 in the presence of $C_2H_5SC_2H_5$, the observed products are C_2H_5SH, C_2H_4, C_2H_6, C_4H_{10}, 4-methyl-3-thiahexane (MTH), 4,5-dimethyl-3,6-dithiaoctane (DMDTO), and some polymer at longer illumination times. The extent of quenching of the excited mercury atoms by $C_2H_5SC_2H_5$ was estimated to be

less than 5% in all cases. Control experiments in the range 25–188°C showed that $C_2H_5SC_2H_5$ was thermally stable.

In Table 1, the quantum yields of C_2H_5SH, C_2H_4, C_2H_6 and C_4H_{10} are presented as a function of $C_2H_5SC_2H_5$ pressure from 1 to 30 Torr. As seen, they all increase at low pressures with increasing substrate pressure but level off and become constant above 10 Torr $C_2H_5SC_2H_5$.

$\phi(C_2H_5SH)$ was determined at various time intervals at 25°C and at 20 Torr $C_2H_5SC_2H_5$, and was found to be independent of the time of illumination; therefore C_2H_5SH must be a primary product.

Next the effect of temperature on the product yields was investigated in the range 25 to 170°C and the results are given in Table 2. The yield of ethane increases with increasing temperature, while that of butane decreases; the ethylene yield, on the other hand, shows only moderate temperature dependence. $\phi(C_2H_5SH)$ first increases with increasing temperature but at 110°C reaches the value of 2.0 and from there on remains constant. The yield of MTH goes through a maximum at 110°C, but is negligibly small at 25 and 167°C.

Finally, in order to determine the rate parameters, temperature studies of the H + $C_2H_5SC_2H_5$ reaction have also been carried out with added ethylene, utilizing the addition reaction H + C_2H_4 → C_2H_5 as reference, for which reliable kinetic data are available. In the presence of ethylene no additional products were detected, but polymer formation was greatly reduced. The quantum yields of C_2H_5SH obtained in the presence of varying amounts of ethylene at different temperatures are listed in Table 3. As seen $\phi(C_2H_5SH)$ decreases with increasing ethylene pressure owing to the competitive scavenging of hydrogen atoms by the ethylene.

Discussion

The yield of C_2H_5SH is directly proportional to the exposure time, indicating that C_2H_5SH is a primary product. Therefore the initial step, by analogy to the H + CH_3SCH_3 reaction (3), is postulated to be

[1] $H + C_2H_5SC_2H_5 \rightarrow C_2H_5SH + C_2H_5$

followed by combination and disproportionation of the C_2H_5 radicals:

[2] $2C_2H_5 \rightarrow C_2H_6 + C_2H_4$

[3] $\rightarrow C_4H_{10}$

For C_2H_5 the accepted value for the k_d/k_c ratio is 0.14 (8). Assuming that C_2H_4 is formed exclusively in reaction [2] the data in Table 2 give k_2/k_3 = 0.24 at 25°C and 0.58 at 170°C. The room temperature value is rather high and the value at 170°C is at variance with the reported (9) very small temperature dependence of k_d/k_c for ethyl radicals.

$\phi(C_2H_6)$ is about an order of magnitude greater than $\phi(C_2H_4)$, indicating the existence of an efficient source of C_2H_6 in addition to reaction [2]. One of these additional C_2H_6-producing reactions

[a] $P(H_2) = 580$ Torr; $P(C_2H_5SC_2H_5) = 10.0$ Torr; I_a (μeinstein min^{-1}) × $10^2 = 1.06$; photolysis time = 45 min.

must be hydrogen abstraction from the substrate:

[4] $C_2H_5 + C_2H_5SC_2H_5 \rightarrow C_2H_6 + CH_3\dot{C}HSC_2H_5$

The site of the abstraction is most probably at the methylene moiety since the C—H bond here is weaker (~ 92 kcal mol^{-1}) than in the methyl group (98 kcal mol^{-1}), and moreover, MTH and DMDTO were identified among the products but the corresponding products from the expected reactions of the $CH_3CH_2SCH_2CH_2$ radical were not. The reaction sequence is completed by the combination and disproportionation reactions [5] to [9]:

[5] $C_2H_5 + CH_3\dot{C}HSC_2H_5 \rightarrow C_2H_6 + CH_2{=}CHSC_2H_5$

[6] $\rightarrow C_2H_4 + C_2H_5SC_2H_5$

[7] $\rightarrow C_2H_5\underset{\displaystyle CH_3}{\underset{|}{C}}HSC_2H_5$(MTH)

[8] $2CH_3\dot{C}HSC_2H_5 \rightarrow C_2H_5SCH(CH_3)CH(CH_3)SC_2H_5$(DMDTO)

[9] $\rightarrow CH_2{=}CHSC_2H_5 + C_2H_5SC_2H_5$

The formation of C_2H_4 in reaction [6] explains the high values obtained for k_2/k_3 from the uncorrected data in Table 2.

Ethylvinylthioether was not identified as a product, probably because reactions [5] and [9] are relatively slow. However, even if it were formed in small quantities, gc analysis for ethylvinylthioether in a mixture containing a large excess of $C_2H_5SC_2H_5$ would be difficult since the two compounds would probably have similar elution times.

From the above mechanism the following relationship for the product quantum yields can be derived:

[10] $\phi(C_2H_5SH) = \phi(C_2H_6) + \phi(C_2H_4) + 2\phi(C_4H_{10}) + \phi(MTH)$

The sums of the quantum yields on the right hand side at various temperatures are listed in Table 2, and are in very good agreement with $\phi(C_2H_5SH)$, providing further support for the postulated primary step, reaction [1].

Although H atoms are completely scavenged in the system at 10 Torr $C_2H_5SC_2H_5$ (Table 1), the data in Table 2 show that $\phi(C_2H_5SH)$ reaches its maximum value of 2.0 only at 110°C. Hence at room temperature the intervention of H-scavenging reactions in the mechanism must be considered.

A number of reactions may come to mind, of which the only relevant one in the present context is hydrogen abstraction from the substrate,

[11] $H + C_2H_5SC_2H_5 \rightarrow H_2 + CH_3\dot{C}HSC_2H_5$

To be important at 25°C but unoperative at 110°C, this should then have an activation energy considerably smaller than that of reaction [1], which is 3.6 kcal/mol (*vide infra*). In fact the activation energy of the abstraction reaction should have a negative value of ~ −9 kcal/mol which cannot be the case. This is in contrast to the $H + C_2H_5OC_2H_5$ reaction where hydrogen abstraction is the only major reaction.

Therefore it appears that at 25°C H atoms are lost in reactions such as

$$H + CH_3\dot{C}HSC_2H_5 \rightarrow C_2H_5SC_2H_5$$
$$H + C_2H_4 \rightarrow C_2H_5$$
$$H + CH_2{=}CHSC_2H_5 \rightarrow CH_3\dot{C}HSC_2H_5$$
$$H + C_2H_5SH \rightarrow C_2H_5S + H_2$$
$$H + C_2H_5SH \rightarrow C_2H_5 + H_2S, \text{ etc.}$$

which all have activation energies ≤3.6 kcal/mol. The combination reaction with ethyl radicals

$$H + C_2H_5 \rightarrow C_2H_6$$

however, is too slow to have any significance.

The Arrhenius parameters for the hydrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

abstraction of ethyl radicals [4] can be determined from the data on the basis of the above mechanism.

The total rate of ethane formation can be expressed as

[12] $R_{C_2H_6} = R_2 + R_4 + R_5$

Similarly, the total rate of ethylene formation is

[13] $R_{C_2H_4} = R_2 + R_6$

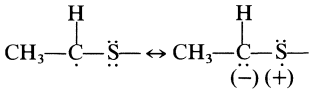
and assuming that $R_5 = R_6$

[14] $R_{C_2H_6} = R_{C_2H_4} + R_4$

Thus the values of R_4 can be calculated directly from the quantum yields of C_2H_6 and C_2H_4 listed in Table 2. The observed and derived values of R_3 and R_4 over the temperature range 25 to 170°C are listed in Table 4 together with the ratio $R_4/R_3^{1/2}$.

The Arrhenius plot of $R_4/R_3^{1/2}$, shown in Fig. 1, is linear. It is to be noted that the value at 25°C is a good fit to the straight line, lending support to the mechanism. From the slope and intercept, and taking $A_3 = 1.0 \times 10^{13}$ cm^3 mol^{-1} s^{-1} and $E_3 = 0$ kcal mol^{-1} (10), the value of k_4 is calculated to be $(7.4 \pm 0.5) \times 10^{13} \exp[-(6860 \pm 98)/RT]$ cm^3 mol^{-1} s^{-1}.

The value of E_4 seems reasonable when compared to those reported for other similar reactions, collected in Table 5. The somewhat lower activation energy for the diethylsulfide than for the ether reaction may be a consequence of the higher efficiency of sulfur to stabilize the incipient radical through electron-releasing conjugative effects (14):



Our measured value of E_4 for the $C_2H_5 + C_2H_5SC_2H_5$ reaction is twice as high as that derived by Knight and Smith (15) from the photolysis of ethylsulfide vapor at 253.7 nm:

[15] $C_2H_5SC_2H_5 \xrightarrow{h\nu} C_2H_5S + C_2H_5$

However, reaction [15] is exothermic by 41 kcal mol^{-1} at 253.7 nm and the ethyl radicals are formed with about 19 kcal excess energy. The low activation energy determined in this system is probably due to the involvement of "hot" ethyl radicals.

E_a for the abstraction reaction $C_2H_5S + C_2H_5SSC_2H_5$ is 3.6 kcal mol^{-1} and seems rather low in comparison to the other activation energies listed in Table 5. It was calculated (5) on the assumption that $k_d/k_c = 0.13$ for the C_2H_5S radical but this value is probably low and using a higher value would increase the activation energy correspondingly.

In the presence of ethylene, reaction [1] competes with reaction [16]:

[16] $H + C_2H_4 \rightarrow C_2H_5$

In regard to the fate of the ethyl radicals produced in [16] the addition of C_2H_5 radicals to ethylene

[17] $C_2H_5 + C_2H_4 \rightarrow C_4H_9$

is a relatively slow process ($\log k_{17} = 8.17 - 7560/2.303RT$) (17) compared to the other reactions involving C_2H_5; furthermore, butene, the disproportionation product of C_4H_9 radicals

[18] $2C_4H_9 \rightarrow C_4H_8 + C_4H_{10}$

was demonstrably absent. Also the polymerization reaction

[19] $C_4H_9 + nC_2H_4 \xrightarrow{CH_3\dot{C}HSC_2H_5}$ polymer

could not be important since polymer formation was greatly reduced in the presence of ethylene.

Simple steady-state treatment yields the following expression:

[20] $$\phi(C_2H_5SH)^{-1} = \tfrac{1}{2}\left(1 + \alpha + \frac{k_{16}[C_2H_4]}{k_1[C_2H_5SC_2H_5]}\right)$$

where $\alpha = R_{loss}/R_1$. Using the data from Table 3, eq. [20] is plotted at different temperatures in Fig.

$C_2H_5 + CH_3CH_2CH_2CH_2CH_2CH_3 \rightarrow C_2H_6 + CH_3\dot{C}H(CH_2)_3CH_3$	10.1	87–252	Photolysis	16
$C_2H_5S + C_2H_5SSC_2H_5 \rightarrow C_2H_5SH + CH_3\dot{C}HSSC_2H_5$	3.6	25–145	Hg* sensitization	5

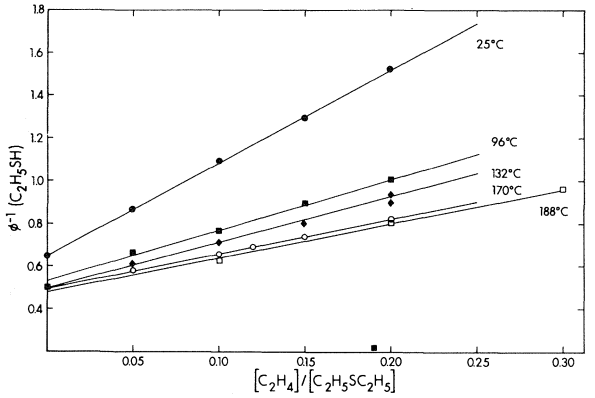

FIG. 2. $\phi(C_2H_5SH)^{-1}$ versus $[C_2H_4]/[C_2H_5SC_2H_5]$ at different temperatures.

2. The plots are all linear within the temperature range examined; the intercepts and slopes of the lines are listed in Table 6. The plots in Fig. 2 have an intercept of about 0.5 in the range 96 to 188°C indicating that for $T \geq 96$°C α is close to zero. At 25°C, on the other hand, the intercept is 0.654 which gives $\alpha = 0.3$, in agreement with the experimental value obtained at room temperature:

$$(2 - \phi(1))/\phi(1) = 0.47/1.53 = 0.31$$

The slopes of the straight lines in Fig. 2 are equal to $k_{16}/2k_1$ at the corresponding temperatures. When the k_{16}/k_1 ratios, listed in Table 6, are plotted in the Arrhenius form (Fig. 3) a good straight line is obtained from which

$$\log (k_{16}/k_1) = -(0.332 \pm 0.040) + (1731 \pm 69)/2.303RT$$

Using the value of Lee *et al.* (18) for the limiting high pressure rate constant of reaction [16],

$$k_{16} = (2.2 \pm 0.4) \times 10^{13} \exp[-(2066 \pm 83)/RT] \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

TABLE 6. Slopes and intercepts of the plots in Fig. 2[a]

T (°C)	Slope	Intercept	k_{16}/k_1
25	4.32±0.02	0.654±0.002	8.64±0.02
96	2.46±0.14	0.520±0.018	4.92±0.14
132	2.05±0.10	0.502±0.014	4.10±0.10
170	1.59±0.02	0.501±0.002	3.18±0.01
188	1.58±0.09	0.484±0.017	3.16±0.09

[a] The errors are standard deviations.

the absolute rate constant for reaction [1] is

$$k_1 = (4.7 \pm 0.9) \times 10^{13} \exp[-(3797 \pm 152)/RT] \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

The experimental entropy of activation calculated from the A factor is −22.1 eu for the standard state of 1 atm. This value is very close to $\Delta S^{\neq} = -24.1$ eu obtained for the $H + CH_3SCH_3$ reaction (3), suggesting that the transition states in the two reactions have a similar structure. Using Benson's method (19) the experimental activation entropy can indeed be reproduced by assuming a transition state similar to that proposed for the $H + CH_3SCH_3$ reaction (3):

$$H + C_2H_5SC_2H_5 \rightarrow [C_2H_5—\underset{\vdots}{\underset{H}{S}}\cdots C_2H_5]^{\neq} \rightarrow C_2H_5 + C_2H_5SH$$

which involves an initial interaction between the H atom and the non-bonding $3p$ orbital of the sulfur atom.

According to Benson's method (19)

$$\begin{aligned}\Delta S^{\neq} &= S_0{}^{\neq} - S_0(C_2H_5SC_2H_5) - S_0(H)\\ &= S_0(C_2H_5SC_2H_5) + R \ln 2 + x - S_0(C_2H_5SC_2H_5) - S_0(H)\\ &= R \ln 2 + x - S_0(H) = 1.4 + x - 27.4\\ &= -26 + x\end{aligned}$$

$$x = 26 - 22.1 = 3.9 \text{ eu}$$

The 3.9 eu could reasonably be attributed to

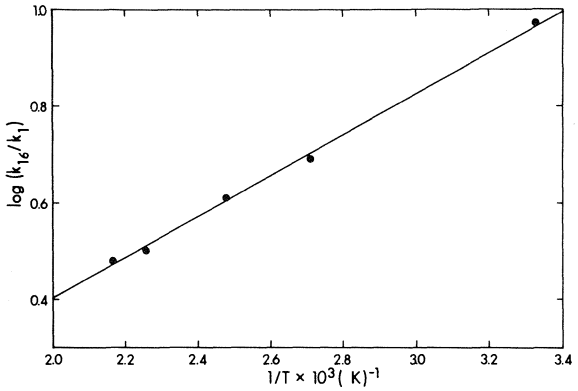

FIG. 3. Arrhenius plot of k_{16}/k_1 versus $1/T$.

contributions from the two new vibrational modes formed by the S···H bond in the activated complex.

The higher activation energy for reaction [1] is opposite to the trend in the C—S bond energy: $D(CH_3—SCH_3) = 77 \pm 1.5$ kcal mol^{-1} and $D(C_2H_5—SC_2H_5) = 74 \pm 2$ kcal mol^{-1} (20). This may be a consequence of the intramolecular H-bond formed between the non-bonding $3p$ orbital of the S atom and the H atoms of the alkyl groups in the molecule. A stronger H-bond in diethylsulfide as compared to dimethylsulfide could have a larger influence on the activation energy than the small difference in the C—S bond dissociation energies since the H-bonding would be weakened or broken in the activated complex.

It is interesting to note that although the methylene moieties in $C_2H_5SC_2H_5$ are expected to be rather amenable to hydrogen abstraction, no such reaction occurs. Instead, the attack takes place exclusively on the sulfur atom. This is in contrast to the reaction of hydrogen atoms with diethylether where the primary step is hydrogen abstraction (21):

[21] $H + C_2H_5OC_2H_5 \rightarrow H_2 + CH_3\dot{C}HOC_2H_5$

The rate coefficient reported (21) for reaction [21] is

$$k_{21} = (7.4 \pm 3.6) \times 10^{12} \exp[-(3240 \pm 100)/RT] \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

A similar value for the rate constant of the hydrogen abstraction reaction from $C_2H_5SC_2H_5$, reaction [11], would result in a strong competition with the primary substitution reaction at room temperature. The non-occurrence of [11] is due to the shadowing effect of the protruding non-bonding p orbital of the sulfur atom on the α hydrogens reducing the rate constant k_{11} to a value considerably lower than k_{21}.

Conformational aspects of L-histidine

R. RAMANI AND RUSSELL J. BOYD[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received June 15, 1981

R. RAMANI and RUSSELL J. BOYD. Can. J. Chem. **59**, 3232 (1981).

Ab initio molecular orbital (MO) calculations at the STO-3G level are reported for selected conformations of L-histidine. The minimum energy conformations are chosen on the basis of force-field calculations on the χ^1–$\chi^{2,1}$ plane of the side chain of histidine. The MO relative energies are observed to be substantially larger than the force-field values. With one exception both theoretical methods are consistent with the results of X-ray diffraction studies on L-histidine. The exception occurs in the case of the force-field calculations which suggest that the (60,80) conformation may be accessible contrary to the MO results and experiment. And finally the *ab initio* charge distribution is used to account for the fact that the $N^{\varepsilon 2}$ atom is always protonated in the crystal structures of L-histidine.

R. RAMANI et RUSSELL J. BOYD. Can. J. Chem. **59**, 3232 (1981).

On rapporte les calculs ab initio d'orbitales moléculaires du niveau STO-3G pour des conformations choisies de la L-histidine. On a choisi les conformations à énergie minimum en se basant sur les calculs du champ de force dans le plan χ^1–$\chi^{2,1}$ de la chaîne latérale de l'histidine. On a observé que les énergies relatives de l'O.M. sont substantiellement plus élevées que les valeurs du champ de force. À une exception, près les deux méthodes théoriques sont en accord avec les résultats des études de diffraction de rayons X sur la L-histidine. L'exception apparaît dans le cas des calculs du champ de force, ce qui suggère que la conformation (60,80) peut être accessible contrairement à l'expérience et aux résultats des OM. Finalement, on a utilisé la distribution de charge ab initio pour tenir compte du fait que l'atome $N^{\varepsilon 2}$ est toujours protoné dans les structures cristallines de la L-histidine.

[Traduit par le journal]

Introduction

Histidine, a functional amino acid, is well known as a proton donor, proton acceptor, and a nucleophilic reagent. The significance of histidine in protein chemistry is associated with the frequency with which it occurs at the active site of enzymes. It is known that histidine is directly involved in the proteolytic mechanisms of enzymes such as papain, subtilisin, chymotrypsin, and trypsin and in the coordination of zinc in zinc insulin (1). This is due to the facile transfer of protons to and from the nitrogen atoms in the imidazole ring of the side chain (Fig. 1).

In order to relate the conformation of histidine to its reactivity, several X-ray crystallographic studies have been reported (2). Some representative results are summarized in Table 1. In this paper we present an extensive conformational study of L-histidine. Force-field calculations are first used to determine the preferred conformations and then *ab initio* molecular orbital (MO) calculations are carried out for the minimum energy conformations. The MO relative energies are compared with the force-field values, and the theoretical conformations are compared with the results of X-ray diffraction studies on L-histidine. And finally the *ab initio* charge distribution is used to compute the electrostatic potential in the plane of the imidazole ring for the two tautomeric forms of histidine.

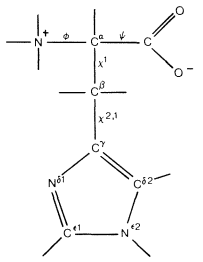

FIG. 1. Structural formula of histidine in the zwitterionic form.

Method

The requirements for computer time were reduced by use of force field calculations for the initial conformational analysis of L-histidine. The nonbonded interactions due to van der Waals forces were treated by use of the Lennard–Jones (6–12) potential function for which standard parameters were adopted (3). For the electrostatic interactions, partial charges were taken from the MO calculations. Torsional barriers to rotation about single bonds were modeled by assuming a threefold barrier for the χ^1 variation (see Fig. 1) while the barrier to variation of $\chi^{2,1}$ was assumed to be zero (3).

Standard single determinant *ab initio* MO theory, according to which closed shells are treated by the spin restricted Hartree–Fock (RHF) procedure (4), was used in this work. All calculations were carried out on a Control Data Cyber 170-720 system by use

of the Gaussian 76 program (5). The minimal STO-3G (6) basis set was used.

Results and Discussion

The structural formula of histidine in its zwitterionic form is shown in Fig. 1 and the assumed bond lengths and bond angles are listed in Table 2. The atoms and dihedral angles have been labelled in accord with the IUPAC-IUB Commission of Biochemical Nomenclature (7).

Before considering our calculations we would like to point out that analysis of the conformational properties of 18 examples of histidine from 12 crystal structures (Table 1) indicates that the dihedral angle ψ always assumes a small negative value and ranges from −1° to −41°, possibly due to steric hindrance between the oxygen atom of the carboxyl group and the C^β atom of the side chain. The values of χ^1 indicate three staggered conformations of the side chain about the C^α—C^β bond, while the $\chi^{2,1}$ values indicate that two distinct ranges (± 90°) are preferred by the imidazole ring about the C^β—C^γ bond. These comformations of the imidazole ring with respect to the backbone are such that the intramolecular constant distances between the C^α and $N^{\delta 1}$ atoms and the C^α and $C^{\delta 2}$ atoms are near or below the sum of the corresponding van der Waals radii (see Fig. 2), but above the respective normal limiting distances (3). In such a situation the nonbonded forces would stabilise a conformation for the imidazole ring with $\chi^{2,1} \approx \pm 90°$.

TABLE 2. Bond lengths (Å) and bond angles (degrees) adopted for calculations on histidine

Bond	Length	Bond	Angle
N—C^α	1.470	NC^αC′	110.8
C^α—C′	1.535	N$C^\alpha C^\beta$	109.8
C′—O	1.249	C^αC′O	117.5
C^α—C^β	1.537	OC′O	125.0
C^β—C^γ	1.499	$C^\alpha C^\beta C^\gamma$	112.7
C^γ—$N^{\delta 1}$	1.373	$C^\beta C^\gamma N^{\delta 1}$	124.2
$N^{\delta 1}$—$C^{\varepsilon 1}$	1.325	$C^\gamma N^{\delta 1} C^{\varepsilon 1}$	109.2
$C^{\varepsilon 1}$—$N^{\varepsilon 2}$	1.315	$N^{\delta 1} C^{\varepsilon 1} N^{\varepsilon 2}$	108.7
$N^{\varepsilon 2}$—$C^{\delta 2}$	1.370	$C^{\varepsilon 1} N^{\varepsilon 2} C^{\delta 2}$	108.7
$C^{\delta 2}$—C^γ	1.356	$N^{\varepsilon 2} C^{\delta 2} C^\gamma$	107.4
		$N^{\delta 1} C^\gamma C^{\delta 2}$	106.0

Throughout this work the bond lengths and bond angles were kept constant (8, 9) since a complete search for the optimum geometry is prohibitively expensive. The amino acid was assumed to be in the zwitterionic form, with the NH_3^+ group having a staggered conformation about the N—C^α bond. Several additional assumptions were made for the force-field calculations. The angle ϕ was not varied; while ψ was kept at −20°, which is the average of the observed range (see Table 1). The other two

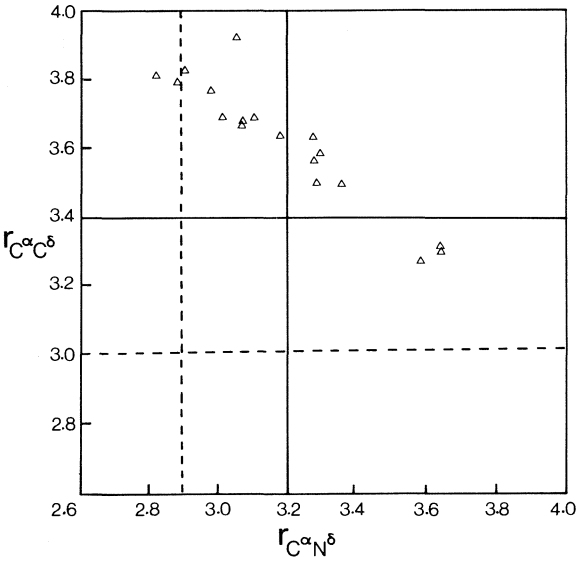

FIG. 2. Plot of observed contact distances between the C^α and $N^{\delta 1}$ atoms versus observed contact distances between the C^α and $C^{\delta 2}$ atoms. The sum of the van der Waals radii are indicated by the solid lines. The normal limiting distances are indicated by the dashed lines.

dihedral angles χ^1 and $\chi^{2,1}$ were varied stepwise and independently from 0° to 360°. No barrier to rotation about the C^β—C^γ bond was assumed, but a three-fold barrier of 3 kcal/mol was considered for rotation about the C^α—C^β bond. Here we should stress that we have taken the full imidazole ring into consideration, unlike an earlier calculation (10).

Table 3 lists the positions of minima and relative conformational energies for the two tautomeric forms of the imidazole ring as obtained from the force-field calculations and the MO calculations. A force-field conformation energy map on the χ^1–$\chi^{2,1}$ plane of the side chain is shown in Fig. 3 for the case where the $N^{\varepsilon 2}$ atom is protonated. The experimental observations from the crystal structures, summarized in Table 1, have been marked on the map. The general agreement between these observations and the theoretical calculations is evident. It is interesting to note, however, that no experimental observations lie in the region of the minimum at about $\chi^1 = 60°$ and $\chi^{2,1} = 80°$, whereas observations have been made in the regions of the other minima. This lack of experimental observations is corroborated by the MO calculations which place the (60,80) minimum above the other minima. Unfortunately a complete calculation of the MO conformational energy map is prohibitively expensive. Of the selected MO calculations we have carried out at the conformations corresponding to the force-field minima, the (60°,270°) conformation yields the lowest energy in agreement with the force-field prediction for the location of the global minimum. Similar agreement is observed for the protonation of $N^{\delta 1}$ (see Table 3). In both cases the MO calculations lead to larger energy differences for the selected conformations although we should stress that the minima have not been searched for by means of MO calculations and may therefore be over-estimated.

$H(N^{\delta 1})$	0.230	—
$H(N^{\varepsilon 2})$	—	0.228

charges of the $N^{\delta 1}$ and $N^{\varepsilon 2}$ atoms are observed to interchange. The difference is, however, only of the order of 0.06e. The classical electrostatic potential in the plane of the imidazole ring is shown in Figs. 4 and 5. In both of the tautomeric forms, a strong negative potential of the order of −200 to −250 kcal/mol is observed near the $N^{\varepsilon 2}$ atom, while the electrostatic potential near the $N^{\delta 1}$ atom remains at −85 kcal/mol. This calculation explains why in all the examples shown in Table 1 the $N^{\varepsilon 2}$ atom is always protonated. As an analogy, we point out the preference for the $N^{\varepsilon 2}$—H tautomer in aqueous solutions of histamine monocation (11). For a discussion of the reliability of electrostatic potentials for the determination of protonation sites we refer to the work of Andrews and Defina (27) and references therein.

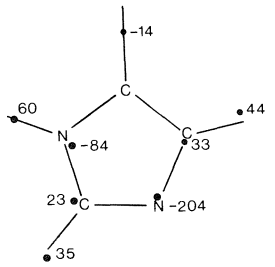

FIG. 4. Electrostatic potential (kcal/mol) in the plane of the imidazole ring for the case where the $N^{\delta 1}$ atom is protonated.

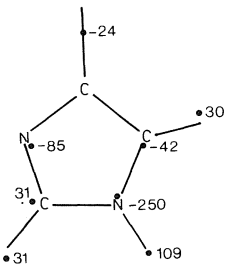

FIG. 5. Electrostatic potential (kcal/mol) in the plane of the imidazole ring for the case where the $N^{\varepsilon 2}$ atom is protonated.

In conclusion, this paper presents the first *ab initio* MO study on L-histidine. In an earlier MO study (28) of the protonation of simple amino acids, histidine was modelled by a methyl group attached to the imidiazole ring. Calculations for such a model lead to a difference of about 1.4 kcal/mol in the proton affinities for the two protonation sites. Our calculations on the complete molecule, however, yield a difference of only 0.1 kcal/mol (see Table 3). No doubt the use of model geometries in this and previous work (28) affects the computed proton affinities.

JOSEPH ARMAND, LINE BOULARES, KHALED CHEKIR, and CHRISTIAN BELLEC. Can. J. Chem. **59**, 3237 (1981).

The hydrogenation of 2,3-dimethylpyrazino[2,3-*b*]quinoxaline **1** and 2-phenylpyrazino[2,3-*b*]quinoxaline **2** leads to the corresponding 5,10-dihydroderivatives **3***b* and **4***b*. $LiAlH_4$ reduction of **2**, of 2,3-dimethyl-6,7-diphenylpyrazino[2,3-*b*]pyrazine **8** and 2,6,7-triphenylpyrazino[2,3-*b*]pyrazine **9** furnishes the corresponding 1,2,3,4-tetrahydroderivatives **7**, **10**, and **11**. $NaBH_4$ reduction of **2** leads to a mixture of **4***b* and **7**. In hydroorganic medium **1** and **2** are electrochemically reduced to **3***b* and **4***b* with which they form a redox system.

JOSEPH ARMAND, LINE BOULARES, KHALED CHEKIR et CHRISTIAN BELLEC. Can. J. Chem. **59**, 3237 (1981).

L'hydrogénation de la diméthyl-2,3 pyrazino[2,3-*b*] quinoxaline **1** et de la phényl-2 pyrazino[2,3-*b*] quinoxaline **2** conduit aux dérivés dihydro-5,10 correspondants **3***b* et **4***b*. La réduction par $LiAlH_4$ de **2**, de la diméthyl-2,3 diphényl-6,7 pyrazino[2,3-*b*] pyrazine **8** et de la triphényl-2,6,7 pyrazino[2,3-*b*] pyrazine **9** fournit les dérivés tetrahydro-1,2,3,4 correspondants **7**, **10** et **11**. La réduction de **2** par $NaBH_4$ donne un mélange de **4***b* et **7**. En milieu hydroorganique, **1** et **2** sont réduits électrochimiquement en **3***b* et **4***b* avec lesquels ils forment un système rédox.

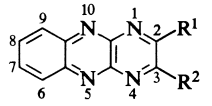
Although the synthesis of pyrazino[2,3-*b*]quinoxalines has been investigated (1) neither their chemical nor their electrochemical reduction has been studied.

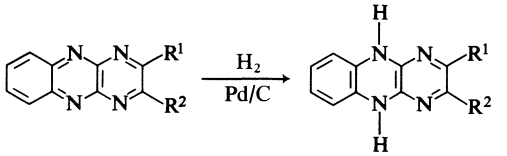


1 $R^1 = R^2 = CH_3$ **2** $R^1 = C_6H_5$, $R^2 = H$

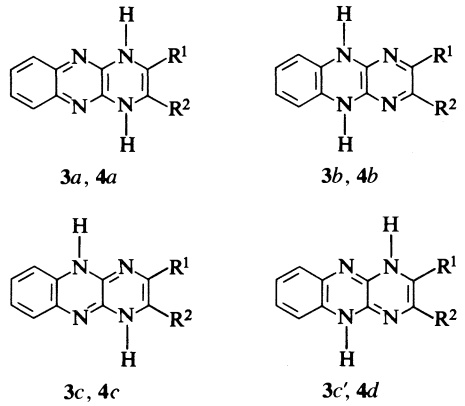
We report the hydrogenation, the reduction with $LiAlH_4$ and $NaBH_4$, and the electrochemical reduction of compounds **1** and **2**. Concerning the electrochemical reduction, the presence of two condensed pyrazine rings made possible two reaction paths, either a reduction into a 1,4- (or 5,10-) dihydro derivative as in the case of pyrazines, or a behaviour similar to that of flavines leading to a 1,5- (or 4,10-) dihydro compound.

Hydrogenation

In the presence of Pd/C, hydrogenation of **1** and **2** leads to the dihydro derivatives **3***b* and **4***b*, the structures of which were determined by nmr (Table 1). The reduction products of **1** and **2** have two amino protons which are readily exchanged by addition of D_2O so that the isomeric structures shown below have to be considered:



1 $R^1 = R^2 = CH_3$ **3***b* $R^1 = R^2 = CH_3$
2 $R^1 = C_6H_5$, $R^2 = H$ **4***b* $R^1 = C_6H_5$, $R^2 = H$



3*a*, **4***a* **3***b*, **4***b*

3*c*, **4***c* **3***c*′, **4***d*

A rapid equilibrium on the nmr time scale of the two tautomers **3***c* and **3***c*′ cannot be excluded on the grounds of the nmr spectrum. However, acetylation gives a diacetylated compound to which the nmr spectrum permits assigning the 1,4-diacetyl-1,4-dihydro structure or the 5,10-diacetyl-5,10-dihydro structure (see Experimental). Thus, the reduction product of **1** must have a plane of symmetry, which rules out structure **3***c*. Structures **3***a* and **3***b* can be discriminated by examination of the chemical shifts. The aromatic protons of 1,2,3,4-tetrahydrophenazine **5** give evidence of a multiplet

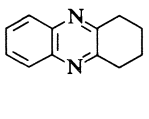
TABLE 1. Nuclear magnetic resonance data[a,b] for **3***b* and **4***b*

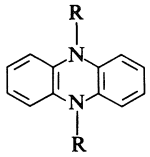
Compound		δ		
3*b*	2-CH_3 3-CH_3	1.93	s	6H
	6-H,7-H 8-H,9-H	6.28	AA'BB' pattern	4H
	5-H,10-H	8.54	s[c,d]	2H
4*b*	6-H,7-H 8-H,9-H	6.38	m	4H
	C_6H_5	7.32 7.70	m m	3H 2H
	3-H	7.40	s	1H
	5-H,10-H	8.88	s[c,d]	2H

[a] Solvent DMSO-d_6.
[b] δ values in ppm relative to internal TMS.
[c] Broad, exchanged with D_2O.
[d] Irradiation of these protons shows that there is no coupling with the methyl protons of **3***b* nor with the 3-H of **4***b*.

between 7.50 and 8.10 ppm (2) while those of 5,10-bis(*n*-propyl)-5,10-dihydrophenazine **6** appear as a multiplet between 6.06 and 6.70 ppm (3). In our case a multiplet is observed between 6.1 and 6.5 ppm. Structure **3***b* is the only one which can account for these results.



5



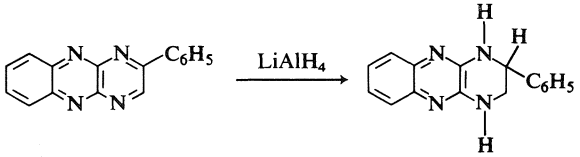
6 R = *n*-propyl

In the same way, the nmr spectrum of the reduction product of **2**, together with the results of an acetylation yielding a diacetylated compound with two nearly equivalent CO—CH_3 groups, permits assigning structure **4***b* to this compound.

This behaviour is different from that of pyrazines and quinoxalines. The hydrogenation of pyrazines (4, 5) gives 1,2-dihydro or 1,2,3,4-tetrahydro derivatives or piperazines; the hydrogenation of quinoxalines (6, 7) furnishes 1,2,3,4-tetrahydro derivatives.

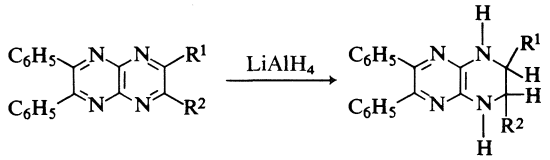
Reduction by $LiAlH_4$ and $NaBH_4$

The reaction of $LiAlH_4$ with **1** gives only gummy products while **2** gives in good yields the 1,2,3,4-tetrahydro compound **7**.



2 **7**

In view of this result, we reacted $LiAlH_4$ with pyrazino[2,3-*b*]pyrazines. The 2,3-dimethyl-6,7-diphenylpyrazino[2,3-*b*]pyrazine **8** as well as the 2,6,7-triphenylpyrazino[2,3-*b*]pyrazine **9** lead to the corresponding 1,2,3,4-tetrahydro derivative. Examination of the nmr spectrum of **10** shows that the two methyl groups have the *cis* configuration. Indeed, 2-H and 3-H give a multiplet at 3.48 ppm and Archer and Mosher (8) have shown that 2-H and 3-H are observed at 3.48 ppm in the case of *cis*-2,3-dimethyl-1,2,3,4-tetrahydroquinoxaline and at 2.98 ppm in the case of the *trans* derivative. The reduction of **8** is stereospecific as in the case of 2,3-dimethylquinoxaline (6).



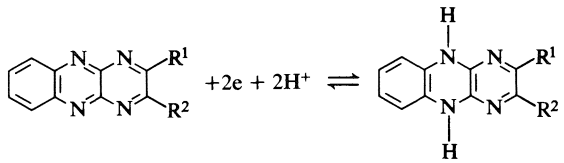
8 $R^1 = R^2 = CH_3$
9 $R^1 = C_6H_5$, $R^2 = H$

10 $R^1 = R^2 = CH_3$
11 $R^1 = C_6H_5$, $R^2 = H$

The reduction of **1** by $NaBH_4$ gives only a resinous product but **2** furnishes a 68:32 mixture of **4***b* and **7**.

Electrochemical Reduction

In hydroorganic medium (50% aqueous dimethylformamide) **1** and **2** are unstable at pH lower than 3. Between pH 3 and 12 they present a 2 F wave which corresponds to the reduction into 5,10-dihydro derivatives **3***b* and **4***b* as shown by preparative electrolysis. These last two compounds present a 2 F anodic wave, the half wave potential of which is very near that of the first cathodic waves of **1** and **2**. The half wave potentials are linearly dependent upon the pH: $E_{1/2}(V) = 0.19 - 0.060\,pH$ for **1** and $E_{1/2}(V) = 0.24 - 0.060\,pH$ for **2**. The reduction scheme is:



1 $R^1 = R^2 = CH_3$
2 $R^1 = C_6H_5$, $R^2 = H$

3*b*
4*b*

The first cathodic wave of **1** and **2** is followed by a second, ill-defined wave very near the background discharge (at pH 5, $E_{1/2} \sim -1.1$ V). The height of this wave decreases upon increasing the pH; it is close to 4 F in acidic medium and disappears at pH 10. This same wave is also observed on the polarograms of **3***b* and **4***b*; it must correspond to the reduction of these 5,10-dihydro compounds. However, preparative electrolysis of **3***b* and **4***b* gave only gummy products, thus preventing the possible establishment of a sound reaction scheme.

The observation of the redox couples **1**–**3***b* and **2**–**4***b* indicates that the electrochemical behaviour of pyrazino[2,3-*b*]quinoxalines is different from that of flavines, but similar to that of phenazine which forms a redox couple with the 5,10-dihydrophenazine (9). Besides, our results are in good agreement with the reduction scheme which we had proposed for the pyrazino[2,3-*b*]pyrazines (10). In this last case the dihydro derivatives were too oxidizable to be isolated; by analogy with what is observed in the case of quinoxalines we had assigned a 1,4- (or 5,8-) dihydro structure to these compounds and had excluded a 1,5- (or 4,8-) structure.

In aprotic medium (acetonitrile) the cyclic voltammogram of **2** shows two reversible monoelectronic peaks I_c and II_c at $E_{p_{c1}} = -0.72$ V and $E_{p_{c2}} = -1.37$ V.

As in the case of pyridopyrazines (11) this voltammogram corresponds to the following reduction scheme

$$2 \overset{e^-}{\rightleftarrows} 2^{\cdot -} \overset{e^-}{\rightleftarrows} 2^{2-}$$

Upon addition of phenol, the second couple progressively disappears while the first cathodic and anodic peaks increase in height up to a bielectronic behaviour while shifting to more positive potentials, e.g., for a 5×10^{-2} *M* concentration of phenol $E_{p_c} = -0.53$ V and $E_{p_a} = -0.43$ V. The cathodic peak corresponds to the reduction to **4***b*. Indeed a preparative electrolysis of **1** ($c = 2 \times 10^{-3}$ *M*); *c*(phenol) = 0.1 *M*, $E = -0.9$ V consumes 2 F per mol and gives **4***b* (75%).

A similar behaviour is evidenced in the case of **1** ($E_{p_c} = -0.92$ and -1.42 V in acetonitrile and $E_{p_c} = -0.78$ V in the presence of 5×10^{-2} *M* of phenol).

Experimental

Melting points are uncorrected. The ^{1}H nmr spectra were obtained on a Bruker WH 80 spectrometer using tetramethylsilane (TMS) as internal standard. The apparatus and techniques used for the electrochemical studies and pH measurements have been described previously (11); all the potentials are referred to the saturated calomel electrode; the temperature of the solutions was 20°C. The microanalyses were performed by M. E. Dorme (Service de Microanalyse, Université Pierre et Marie Curie). All the compounds described gave correct elemental analyses. The following abbreviations are used in reporting nmr results: s = singlet, d = doublet, t = triplet, q = quadruplet, m = multiplet.

Preparation of Pyrazino[2,3-b]quinoxalines and Pyrazino-[2,3-b]pyrazines

2,3-Dimethylpyrazino[2,3-b]quinoxaline **1** was prepared by condensation of 2,3-diaminoquinoxaline (12) with diacetyl according to ref. 1; mp > 190°C dec.; lit. (1) mp 193°C dec; nmr (DMSO-d_6): 2-CH_3 and 3-CH_3, s, 2.84 ppm (6H); 6-H, 7-H, 8-H, 9-H, AA'BB' pattern at 8.02 ppm, m (2H) and 8.30 ppm, m (2H).

2-Phenylpyrazino[2,3-b]quinoxaline **2**

Phenylglyoxal hydrate (1.5 g) was added to a suspension of 2,3-diaminoquinoxaline (1.6 g) in ethanol (40 mL). The mixture was stirred at room temperature for 5 h. The solid material was filtered, washed with ethanol, and dried to give 2.32 g (90%) of **2**; mp 215°C dec.; nmr (DMSO-d_6): 2-Ph, m, 7.68 ppm (3H) and 8.08 ppm (2H); 6-H, 7-H, 8-H, 9-H, m, 8.3–8.6 ppm (4H); 3-H, s, 10.06 ppm (1H).

2,3-Diamino-5,6-diphenylpyrazine

The experimental procedure of ref. 13 has been improved. A mixture of 2.5 g of 2,3-dibromo-5,6-diphenylpyrazine (14), 35 mL of methanol, and 35 mL of ammonium hydroxide solution in water ($d = 0.92$) and 100 mg of Cu powder was heated in a 125 mL steel bomb at 140°C for 24 h. The precipitate was filtered, washed with water, and dried to give 1.3 g (77%) of the diamine; mp > 270°C dec.; lit. (13) mp 275–282°C dec.

2,3-Dimethyl-6,7-diphenylpyrazino[2,3-b]pyrazine **8**

A mixture of 2,3-diamino-5,6-diphenylpyrazine (0.75 g) and diacetyl (5 g) in 15 mL ethanol was refluxed under nitrogen for half an hour. The solution was poured in 250 mL of water. The precipitate was filtered, washed with water, dried, and crystallized in ethanol to give 300 mg of **8** (34%); mp 230°C; lit. (15) mp 228–230°C; nmr ($CDCl_3$): 2-CH_3 and 3-CH_3, s, 2.81 ppm (6H); 6-Ph and 7-Ph, m, 7.2–7.7 ppm (10H).

2,6,7-Triphenylpyrazino[2,3-b]pyrazine **9**

A mixture of 2,3-diamino-5,6-diphenylpyrazine (0.87 g) and 1 g of phenylglyoxal hydrate in 60 mL ethanol was stirred at 0°C for 20 min. Stirring was continued for 3 h at room temperature. The solid material was filtered and crystallized in ethanol to give 0.74 g (62%) of **9**; mp 246°C; nmr ($CDCl_3$): 2-Ph + 6-Ph and 7-Ph, m, 7–8.5 ppm (15H); 3-H, s, 9.60 ppm (1H).

Hydrogenation of ***1*** *and* ***2****: Preparation of* ***3****b and* ***4****b*

A catalytic hydrogenation was carried out at room temperature with 350 mg of **1** in 100 mL dimethylformamide in the presence of 100 mg of 10% Pd/C. After 3 h of stirring and consumption of one mol of H_2 per mol of **1** the solution was filtered and poured in 300 mL of water. The precipitate was filtered, washed with water, and dried to give 295 mg of **3***b* (84%); mp 235°C dec.; nmr: see Table 1. With the same procedure 350 mg of **2** gave 310 mg (88%) of **4***b*: mp 225°C dec.; nmr: Table 1.

Acetylation of ***3****b and* ***4****b*

A solution of 200 mg of **3***b* in 4 mL of acetic anhydride was refluxed for 1 h, poured in water, and filtered to give the diacetyl derivative (180 mg; mp 160°C dec.); nmr (DMSO-d_6): 2-CH_3 + 3-CH_3 + 5-$COCH_3$ + 10-$COCH_3$, 2s, 2.42 and 2.50 ppm (6H + 6H); 6-H + 7-H + 8-H + 9-H, AA'BB' pattern between 7.18 and 7.83 ppm. With the same procedure **4***b* yielded a diacetyl derivative (165 mg; mp 170°C dec.); nmr (DMSO-d_6): 5-$COCH_3$ + 10-$COCH_3$, 2s, 2.48 and 2.53 ppm (6H); 3-H + 2-Ph + 6-H + 7-H + 8-H + 9-H, m, 7.1–8.3 ppm (10H).

Reduction with $LiAlH_4$ *of* ***2****,* ***8****, and* ***9****. Preparation of* ***7****,* ***10****, and* ***11***

$LiAlH_4$ (300 mg) was added slowly to a solution of **2** (516 mg) in freshly distilled tetrahydrofuran (75 mL). After 4 h of stirring at room temperature, the mixture was quenched with 5 mL of water and filtered. Tetrahydrofuran was evaporated and the solid which precipitated was filtered, washed with water, and dried. Compound **7**: 450 mg (86%); mp 215°C dec.; nmr (DMSO-d_6 + D_2O): 3-H, dd, 3.40 ppm ($J_{3-3'} = 12$ Hz; $J_{2-3} = 6$ Hz) (1H); 3'-H, dd, 3.72 ppm ($J_{2-3'} = 4$ Hz) (1H); 2-H, t, 4.82 ppm (1H); 2-Ph + 6-H, 7-H, 8-H, 9-H, m, 7.1–7.7 ppm (9H). In DMSO-d_6, the nmr spectrum presents a broad signal at 7.87 ppm (N*H*) and two multiplets centered at 4.82 and 3.40 ppm which simplify

after exchange of NH protons with D_2O; this result evidences a coupling between NH protons and 2-H, 3-H, and 3′-H.

With the same procedure 160 mg of **8** in 40 mL of tetrahydrofuran and 100 mg of $LiAlH_4$ gave 120 mg (74%) of **10**: mp 236°C dec.; nmr ($CDCl_3$ + D_2O): 2-CH_3 + 3-CH_3, d, 1.05 ppm (6H); 2-H + 3-H, m, 3.48 ppm (2H); 6-Ph + 7-Ph, m, 7.1–7.6 ppm (10H). In the same way, 160 mg of **9** in 40 mL of tetrahydrofuran and 100 mg of $LiAlH_4$ gave 104 mg (65%) of **11**; mp 192°C dec.; nmr (DMSO-d_6 + D_2O): 3-H + 3′-H, m, 3.40 ppm (2H); 2-H, m, 4.82 ppm (1H); 2-Ph + 6-Ph + 7-Ph, m, 6.6–7.6 ppm (15H).

Reduction with $NaBH_4$ of 2

$NaBH_4$ (300 mg) was added to a suspension of **2** (300 mg) in ethanol (30 mL). After 16 h of stirring at room temperature, the mixture was poured in 100 mL of water. Ethanol was evaporated and the solid which precipitated was filtered, washed with water, and dried to yield 240 mg of a solid which was shown by nmr to be a mixture of **4***b* (68%) and **7** (32%).

Electrolysis of 1 and 2 in Hydroorganic Medium

Electrolysis was carried out according to the technique described previously (11) at pH = 6.5 and $E = -0.5$ V (sce). The cathodic compartment contained 210 mg of **1** in 100 mL of solution (dimethylformamide 50%). At the end of electrolysis (2.1 F per mol) the catholyte was poured in 200 mL of water and the precipitate was filtered, washed with water, and dried to give 165 mg (78%) of **3***b*.

With the same work-up, 258 mg of **2** led to 216 mg (83%) of **4***b*.

ANGEL GUZMAN, JOSEPH M. MUCHOWSKI, ARTHUR M. STROSBERG, and JOHN M. SIMS. Can. J. Chem. **59**, 3241 (1981).
A series of digitoxigenin analogues was prepared in which the butenolide moiety was replaced by other 5- or 6-membered cyclic Michael acceptor systems. Three compounds, **1***b*, **1***c*, and **1***d* showed weak to moderate cardiotonic activity.

ANGEL GUZMAN, JOSEPH M. MUCHOWSKI, ARTHUR M. STROSBERG et JOHN M. SIMS. Can. J. Chem. **59**, 3241 (1981).
On a préparé une série d'analogues de la digitoxigénine dans lesquelles on remplace le fragment buténolide par d'autres systèmes cycliques à 5 ou 6 chainons pouvant agir comme accepteurs dans des réactions de Michael. Les composés **1***b*, **1***c* et **1***d* présentent une activité cardiotonique varient de faible à modérée.

[Traduit par le journal]

In connection with our interest in steroid cardiac stimulants containing a modified butenolide ring (1) we wished to study the effect on the cardiotonic activity of the substitution of the butenolide moiety of digitoxigenin by other cyclic Michael acceptor systems. A similar strategy has been employed by Boutagy *et al.* (2) and others (3), whereby the replacement of the unsaturated latone ring with analogous open chain structures has led to compounds with substantial cardiotonic activity. This paper describes our efforts to synthesize the digitoxigenin analogues **1***b–g*, **1***j*, and **1***l–o* bearing 5- or 6-membered conjugated unsaturated systems at C-17. After this study was commenced (1975), several publications (5–7) describing the synthesis of certain lactam analogues of cardioactive steroids have appeared. Where overlap has occurred, the results described herein agree well with those already reported.

The point of departure for the synthetic studies described herein was the α-ketomethanesulfonate **2***b* which was prepared from the α-ketol **2***a*, a readily available (8) degradation product of digitoxigen acetate **1***a*.

The preparation of the aza analogue **1***b* of digitoxigenin acetate was accomplished using the method of Stork and Matthews (9). For this purpose, the azide **2***c*, derived from the methanesulfonate **2***b*, was catalytically reduced to the amine **2***d*, which was acylated with diethyl phosphonoacetic acid in the presence of dicyclohexylcarbodiimide. The phosphonate **2***e*, obtained in this way, underwent an internal Wadsworth–Emmons reaction to give the unsaturated lactam **1***b* in 50% yield. This compound was also recently synthesized by Guntert *et al.* (5) by a slightly different route. The *N*-methyl derivative **1***c* was prepared by alkylation of **1***b* with methyl iodide in dimethylformamide solution containing sodium hydride.

A reaction sequence, similar to that described above, was employed to prepare the thiolactone **1***d*. The α-mercaptoketone **2***f*, obtained from **2***b* and sodium hydrosulfide, was acylated with diethylphosphonoacetic acid, and the phosphonate **2***g* thus produced was converted in low (15%) yield into the unsaturated thiolactone **1***d*, with sodium hydroxide in aqueous tetrahydrofuran.

The 2,5-dihydrothiophene derivative **1***e*, a potential precursor of the sulfoxide **1***f* and the sulfone **1***g*, was generated according to the method of

McIntosh *et al.* (10), by an intramolecular Wittig reaction of the ylid derived from the putative phosphonium salt **2***h*. This salt, which was not characterized, was prepared by the reaction of **2***b* with the sodium salt of 2-mercaptoethyltriphenylphosphonium bromide, a substance which in turn was generated *in situ* from sodium hydrosulfide and vinyltriphenylphosphonium bromide. Selective oxidation of the dihydrothiophene derivative **1***e* with sodium metaperiodate gave a stereoisomeric mixture of sulfoxides **1***h* which was converted into the sulfone **1***i* with *m*-chloroperbenzoic acid. Various attempts to transform **1***h* and **1***i* into the conjugated isomers **1***f* and **1***g* under basic conditions failed. Mild conditions (sodium hydride/dimethoxyethane/0°C) resulted in recovery of the starting material or hydrolysis of the acetate moiety (sodium hydroxide/aqueous methanol/25°C), while more vigorous treatment (sodium hydride/dimethoxyethane/25°C) caused the formation of multiple products.

Several attempts to prepare the cyclopentenone analogue **1***j* of digitoxigenin acetate failed. For example, the reaction of the sulfonate **2***b*, or the corresponding iodide, with the dianion of dimethyl-2-oxopropylphosphonate (11) did not produce the cyclopentenone **1***j* or the diketophosphonate precursor **2***i* thereof. Furthermore, although ethyl acetoacetate was readily alkylated by **2***b*, or the related α-iodoketone, cyclization of the keto ester **2***j* so produced could not be affected under a variety of basic conditions (sodium hydride, DBN, sodium methoxide, etc.), nor could **2***j* be converted into the 1,4-diketone **2***k*. Finally, although it was expected that the desulfurization of the 1,4-diketosulfide **3***a* would provide **2***j*, this process could not be examined because the alkylation of the phenylthioketone **2***l*, with bromoacetone, gave complex mixtures of products in the presence of diverse bases.

The reaction of sodium-2-hydroxyethanethiolate with **2***b* gave the hydroxyethyl sulfide **2***m* which was transformed into the dihydro-1,4-oxathiin **1***k* when a dichloromethane solution of the sulfide, containing *p*-toluenesulfonic acid, was heated at reflux temperature. The cyclic vinylogous sulfinate **1***l* and sulfonate **1***m* were derived from the oxathiin by oxidative processes identical to those utilized for the synthesis of **1***h* and **1***i*.

In contrast to the difficulties encountered during the attempted synthesis of the cyclopentenone **1***j*, the sodium methoxide induced aldolization of the diketosulfide **2***n* to the 2,6-dihydrothiopyran-5-one derivative **1***n* occurred without incident, albeit in very modest yield.

The synthesis of the cyclohexenone derivative **1***o*, related to the thiopyrone **1***n*, was also effected by an intramolecular aldol condensation. Thus, brief (≤1 h) contact of the 1,5-diketone **2***p* with sodium methoxide in boiling methanol gave the expected cyclohexenone **1***o*. Longer reaction periods resulted in substantial isomerization of this compound to the 17α-epimer **3***b*. The two isomers were readily identified by their characteristic ^{13}C spectra which showed the anticipated upfield shifts for carbon 14 (85.50 ppm) and carbon 18 (15.71 ppm)

TABLE 1. Comparison of effects on myocardial contractility and inhibition of Na^+, K^+ – ATPase

Compound	Positive inotropic effect relative to digitoxigenin	Inhibition of Na^+, K^+ – ATPase potency relative to digitoxigenin
Digitoxigenin	1.0	1.0
1*b*	0.015	0.02
1*c*	0.015	0.15

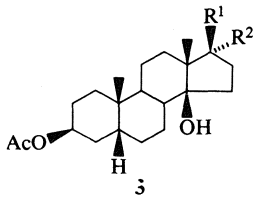
in the 17β-epimer **1***o* with respect to the absorptions for the corresponding carbon atoms (86.31, 18.66 ppm) in the 17α-compound **3***b*. Furthermore, as expected (12), C-20 in **1***o* was deshielded to the extent of 3 ppm, by the 14β-hydroxyl group, as compared to that observed for this carbon (166.61 ppm) in **3***b*. Analogous data have been reported (13) for digitoxigenin acetate and the 17α-isomer thereof.



3

a: R^1 = $COCH(SC_6H_5)CH_2COCH_3$; R^2 = H

b: R^1 = H; R^2 =

c: R^1 = $COCH(SO_2C_6H_5)CH_2CH_2COCH_3$; R^2 = H

The 1,5-diketonic precursor **2***p* of the cyclohexenone **1***o* was obtained by reductive desulfonylation (14) of **3***c* with zinc and acetic acid. This latter material was prepared by Michael addition of the α-ketosulfone **2***o* to methyl vinyl ketone.

The digitoxigenin analogues were examined for inotropic activity in driven left atria of guinea pigs (2*c*) and for their ability to inhibit bovine kidney Na^+, K^+ – ATPase.[5] The data in Table 1 indicate that of the ten compounds tested for inotropic effects, four showed a moderate to weak stimulatory action, four depressed the force of contraction, and two were inactive. The most active stimulants were the lactams **1***b* and **1***c* and the thiolactone **1***d*, whereas **1***n* and **1***o* showed no activity. Thus this datum is another illustration (3*c*) of a lack of parallelism between the myocardial contractility and the reactivity of the Michael acceptor (16). This statement also holds for the inhibition of the Na^+, K^+ – ATPase.

[5] Bovine kidney Na^+, K^+ – ATPase was used because it is readily available in substantial amounts, possesses high activity, and the heart and kidney enzyme activities are of the same order (15*a*). The assay method used was that of Barnett (15*b*).

Experimental

The melting points were determined in a Mel-Temp melting point apparatus and are not corrected. The infrared spectra were measured with a Perkin-Elmer Model 237 grating infrared spectrophotometer. The ultraviolet spectra were recorded on a Perkin-Elmer Model 402 ultraviolet visible spectrophotometer. The ^1H nmr spectra were measured with a Varian T-60 or a Varian HA-100 spectrometer and are expressed as parts per million (δ) from internal tetramethylsilane. The ^{13}C nmr spectra were recorded in chloroform solution with a Bruker WH-90 Pulse Fourier Transform spectrometer. The mass spectra were measured with an Atlas CH-4 spectrometer. All optical rotations were measured at ambient temperature.

Unless specified otherwise, the extracts of the reaction mixtures were dried over anhydrous sodium sulfate.

Synthesis of 3β-Acetoxy-14β-hydroxy-21-methanesulfonyloxy-5β-pregnan-20-one **2**b

Methanesulfonyl chloride (0.173 g) was added, in a dropwise manner at 0°C, to a stirred solution of 3β-acetoxy-14β,21-dihydroxy-5β-pregnan-20-one **2***a* (0.495 g) in anhydrous dichloromethane (10 mL) containing triethylamine (0.167 g). After 0.5 h at 0°C, the reaction was diluted with dichloromethane (40 mL); the solution was washed successively with saturated sodium bicarbonate solution and water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was crystallized from benzene to give the product (0.479 g, 80%) mp 149–150°C; $[\alpha]_D$ + 37.9° (c 0.303, $CHCl_3$) *Anal.* calcd. for $C_{24}H_{38}O_7S$: C 61.27, H 8.08, S 6.08; found: C 61.34, H 7.83, S 6.84.

Preparation of 3β-Acetoxy-14β-hydroxy-21-azido-5β-pregnan-20-one, **2**c

A solution of the methanesulfonate **2***b* (0.227 g) in anhydrous acetone (20 mL) containing sodium azide (0.650 g) was stirred at room temperature for 30 h. The mixture was poured into cold water, and extracted with ethyl acetate. The extract was washed with water, dried, and evaporated *in vacuo*. The residue was

subjected to thin layer chromatography (tlc) on silica gel using dichloromethane–hexane (3:2) as the developing solvent. After crystallization from dichloromethane–hexane, the azide (0.146 g, 70%) had mp 163–164°C dec.; $[\alpha]_D$ + 63° (c 0.500, $CHCl_3$) *Anal.* calcd for $C_{23}H_{35}N_3O_4$: C 66.18, H 8.39, N 10.07; found: C 66.01, H 8.38, N 10.07.

*Synthesis of 4-(3β-Acetoxy-14β-hydroxy-5β-androstan-17β-yl)-3-pyrrolin-2-one, 1*b

Palladium on charcoal (10%, 0.20 g), suspended in methanol (50 mL), was prehydrogenated at atmospheric pressure and the azido compound **2***c* (2.00 g) was added and hydrogenation was continued for 2 h. The catalyst was removed by filtration, the filtrate was mixed with a solution of hydrogen chloride (0.14 g) in methanol (5 mL) and the whole mixture was evaporated *in vacuo* to give the amine hydrochloride **2***d* which was immediately used in the next step.

The hydrochloride **2***d*, described above, was suspended in dry dichloromethane (50 mL) and dicyclohexylcarbodiimide (1.03 g) and a solution of diethyl phosphonoacetic acid (0.982 g) in dichloromethane (20 mL) were added in succession with stirring. Agitation was continued for 14 h, the mixture was poured into water, the organic phase was washed successively with a saturated sodium bicarbonate solution and water, dried, and evaporated. The residue was subjected to tlc on silica gel (ethyl acetate – hexane, 9:1) to give the phosphonate **2***e* (0.970 g, 70%) as a foam; $[\alpha]_D$ + 25° (c 0.206, $CHCl_3$); ir ($CHCl_3$) 3420, 1730, 1675 cm^{-1}; nmr ($CDCl_3$) δ 0.90 (s, 18 – CH_3), 0.94 (s, 19 – CH_3), 1.32 (t, J = 7.1 Hz, CH_3CH_2O of phosphonate), 2.01 (s, CH_3CO), 2.88 (d, J = 20 Hz, $COCH_2P$), 4.15 (m, 21 – CH_2 and CH_3CH_2O of phosphonate), 5.04 (m, H—3), 7.34 (m, W_H = 9 Hz, exchanged with D_2O); mass spectrum *m/e* 569 (M^+). This compound was homogeneous (by tlc) and was used without further purification or characterization in the next step.

To a suspension of sodium hydride (prepared from 50% sodium hydride (0.096 g) in mineral oil and washed free of the carrier with hexane) in dry dimethylformamide (3 mL) was added the phosphonate **2***e* (0.569 g) and the mixture was stirred for 1 h at room temperature. The mixture was poured into ice–water, and after acidification with 0.5 *N* hydrochloric acid the product was extracted into dichloromethane. The extract was washed with water, dried, and evaporated *in vacuo*. The residue was subjected to tlc on silica gel (ethyl acetate – acetone – dichloromethane, 8:2:1) to give the lactam **1***b* as a solid (0.300 g, 50%) which had mp 256–258°C (lit. (5) 253–257°C) $[\alpha]_D$ + 29° (c 0.135, $CHCl_3$); uv (MeOH) 216 nm (ε 9800); ir ($CHCl_3$) 3460, 1730, 1680 cm^{-1}; nmr ($CDCl_3$) δ 0.83 (s, 18—CH_3), 0.94 (s, 19—CH_3), 2.02 (s, CH_3CO), 2.66 (m, H—17), 4.03 (m, 21—CH_2), 5.02 (m, H—3), 5.86 (m, H—22), 6.36 (m, NH); mass spectrum *m/e* 416 (M^+) *Anal.* calcd. for $C_{25}H_{37}NO_4$: C 72.25, H 8.98, N 3.37; found: C 72.30, H 9.01, N 3.25.

*Synthesis of 1-Methyl-4-(3β-acetoxy-14β-hydroxy-5β-androstan-17β-yl)-3-pyrrolin-2-one, 1*c

A solution of the lactam **1***b* (0.208 g) in anhydrous dimethylformamide (30 mL) was added to a suspension of sodium hydride (derived from 50% sodium hydride (0.026 g) which had been washed with hexane) in dry dimethylformamide (20 mL). After 1 h, methyl iodide (1 mL) was added and the mixture was stirred for 24 h. The solution was poured into water, the product was extracted into dichloromethane, the extract was washed with water, dried, and evaporated *in vacuo*. The residue was subjected to tlc on silica gel to give the *N*-methylated lactam **1***c* (0.086 g, 40%) as a solid which had mp 193–194°C after crystallization from hexane–benzene; $[\alpha]_D$ + 31° (c 0.225, $CHCl_3$); uv (MeOH) 217 nm (ε 13 000); ir ($CHCl_3$) 3620, 3420, 1730, 1670 cm^{-1}; nmr ($CDCl_3$) δ 0.82 (s, 18—CH_3), 0.97 (s, 19—CH_3), 2.03 (s, CH_3CO), 2.69 (m, H—17), 2.95 (s, NCH_3), 3.95 (s, 21—CH_2), 5.00 (m, H—3), 5.78 (m, H—22); mass spectrum *m/e* 429 (MH^+) *Anal.* calcd. for $C_{26}H_{39}NO_4$: C 72.69, H 9.15, N 3.26; found: C 72.86, H 9.17, N 3.09.

*Synthesis of 2,5-Dihydro-4-[3β-acetoxy-14β-hydroxy-5β-androstan-17β-yl)-thiophen-2-one, 1*d

A solution of the methanesulfonate **2***b* (1.88 g) in dimethoxyethane (5 mL) was added at 0°C to a solution of sodium hydrosulfide (0.112 g) in methanol (50 mL). After 15 min the solution was diluted with dichloromethane, the solution was washed with water, dried over sodium sulfate, and evaporated *in vacuo* to give the crude mercapto compound **2***f* (0.980 g); ir ($CHCl_3$) 3400, 1721 cm^{-1}; nmr ($CDCl_3$) δ 1.00 (s, 18—CH_3, 19—CH_3), 2.09 (s, CH_3CO), 3.33 (s, 21—CH_2), 5.08 (m, H—3). This material was used without further purification in the next step.

A solution of the mercapto compound **2***f* in dichloromethane (25 mL) was added to a stirred solution of dicyclohexylcarbodiimide (1.648 g) in anhydrous dichloromethane (50 mL) containing diethyl phosphonoacetic acid (1.568 g). After stirring for 24 h the reaction mixture was poured into saturated sodium bicarbonate solution (50 mL) and the solid which separated was collected by filtration. The filtrate was separated into aqueous and organic phases and the aqueous phase was extracted with dichloromethane. The organic phases were combined, washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue, on subjection to tlc on silica gel, (ethyl acetate – hexane – acetone, 8:2:1) gave the crude phosphonate **2***g* (2.08 g); $[\alpha]_D$ + 45° (c 0.245, $CHCl_3$); ir ($CHCl_3$) 3440, 1730 cm^{-1}; nmr ($CDCl_3$) δ 0.94 (s, 18—CH_3, 19—CH_3), 1.32 (t, J = 7.1 Hz, CH_3CH_2O of phosphonate), 2.01 (s, CH_3CO), 3.64–4.29 (m, 21—CH_2 and CH_3CH_2O of phosphonate), 5.40 (m, H—3); mass spectrum *m/e* 390 [M^+ – $PO(OCH_2CH_3)_2$]. This compound was homogeneous by tlc and was used without further purification in the next step.

A sodium hydroxide solution (2.95 mL, 1 *N*) was added to a stirred and cooled (0°C) solution of the phosphonate **2***g* (1.70 g) in tetrahydrofuran (40 mL). The reaction was allowed to reach room temperature and after 30 min it was neutralized by the addition of acetic acid. The solution was diluted with dichloromethane, washed with water, dried, and evaporated *in vacuo*. The crude reaction mixture showed the presence of at least five spots, in addition to that corresponding to the desired compound, on examination by tlc. The desired product was isolated from this mixture by tlc (hexane – ethyl acetate, 7:3) and after crystallization from acetone–hexane a solid (0.192 g, 15%) mp 212–214°C was obtained; $[\alpha]_D$ + 10° (c 0.530, $CHCl_3$); uv (MeOH) 237 nm (ε 12 300); ir ($CHCl_3$) 3600, 3440, 1730, 1670 cm^{-1}; nmr ($CDCl_3$) δ 0.82 (s, 18—CH_3), 0.94 (s, 19—CH_3), 2.00 (s, CH_3CO), 2.77 (m, H—17), 4.08 (m, 21—CH_2), 5.00 (m, H—3), 6.09 (m, H—22); mass spectrum *m/e* 432 (M^+). *Anal.* calcd. for $C_{25}H_{36}O_4S$: C 69.44, H 8.33, S 7.40; found: C 69.54, H 8.47, S 7.30.

*Synthesis of 2,5-Dihydro-4-(3β-acetoxy-14β-hydroxy-5β-androstan-17β-yl)thiophene, 1*e

Vinyl triphenylphosphonium bromide (5.54 g) was added to a stirred solution of sodium hydrosulfide (0.70 g) in methanol (50 mL). After 10 min a solution of the methanesulfonate **2***b* (1.175 g) in tetrahydrofuran (30 mL) was added and when a further 1 h had elapsed the solvent was removed *in vacuo*. The residue was suspended in anhydrous tetrahydrofuran (40 mL) and sodium hydride (0.696 g, 50% in mineral oil) was added. The mixture was stirred for 3 h, and then poured into water. The product was extracted into ethyl acetate, the extract was dried and the solvent was evaporated. The residue was subjected to tlc on silica gel (hexane – ethyl acetate; 7:3) to give a solid (0.375 g, 40%) which was the 3-hydroxy compound corresponding to the desired product; mp 93–95°C, $[\alpha]_D$ + 11° (c 0.136,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

$CHCl_3$); ir ($CHCl_3$) 3450 cm^{-1}; nmr ($CDCl_3$) δ 0.88 (s, 18—CH_3), 0.93 (s, 19—CH_3), 3.69 (m, CH_2SCH_2), 5.54 (m, C=CH); mass spectrum *m/e* 358 ($M^+ - H_2O$). This material was not easily manipulated and it was therefore immediately acetylated with acetic anhydride in pyridine at room temperature. The desired acetate **1***e* was thus obtained in 36% overall yield. After crystallization from methanol, it had mp 183–185°C, $[\alpha]_D$ + 11.7° (c 0.367, $CHCl_3$); ir ($CHCl_3$) 3625, 3540, 1734 cm^{-1}; nmr ($CDCl_3$) δ 0.89 (s, 18—CH_3), 0.96 (s, 19—CH_3), 2.01 (s, CH_3CO), 2.57 (m, H—17), 3.69 (s, CH_2SCH_2), 5.01 (m, H—3), 5.52 (s, H—22); mass spectrum *m/e* 400 ($M^+ - H_2O$). *Anal.* calcd. for $C_{25}H_{38}O_3S$: C 71.77, H 9.09, S 7.65; found: C 71.99, H 9.17, S 7.71.

*Synthesis of 2,5-Dihydro-4-(3β-acetoxy-14β-hydroxy-5β-androstan-17β-yl)thiopene sulfoxide, 1*h

A solution of sodium metaperiodate (0.028 g) in water (0.25 mL) was added, with stirring, to the sulfide **1***e* (0.027 g) dissolved in methanol (2 mL). After 1 h the reaction mixture was poured into water and the product was extracted into dichloromethane. The extract was washed with water, dried, and evaporated *in vacuo*. The residue (0.0225 g, 80%), which was a mixture of stereoisomeric sulfoxides, on crystallization from hexane–benzene had mp 203°C; $[\alpha]_D$ + 30° (c 0.180, $CHCl_3$); ir ($CHCl_3$) 3400, 1730 cm^{-1}; nmr ($CDCl_3$) δ 0.80, 0.90 (singlets, 18—CH_3), 0.93 (s, 19—CH_3), 2.00 (s, CH_3CO), 3.60–3.80 (m, CH_2SOCH_2), 5.05 (m, H—3), 5.60 (m, C=CH); mass spectrum *m/e* 416 ($M^+ - H_2O$). *Anal.* calcd. for $C_{25}H_{38}O_4S$: C 69.09, H 8.81, S 7.36; found: C 69.37, H 8.70, S 7.23.

*Synthesis of 2,5-Dihydro-4-(3β-acetoxy-14β-hydroxy-5β-androstan-17β-yl)thiophene sulfone 1*i

m-Chloroperbenzoic acid (0.259 g) was added at 0°C to a stirred solution of the sulfoxide **1***h* (0.434 g) in anhydrous dichloromethane (30 mL). After 1 h at this temperature, dichloromethane (50 mL) was added and the solution was washed successively with a saturated sodium bicarbonate solution and water. The extract was then dried and evaporated *in vacuo* to give a solid (0.330 g, 73%) which, after crystallization from methanol, had mp 213–215°C; $[\alpha]_D$ + 18.6° (c 0.207, $CHCl_3$); ir ($CHCl_3$) 3540, 1730 cm^{-1}; nmr ($CDCl_3$) δ 0.84 (s, 18—CH_3), 0.92 (s, 19—CH_3), 2.00 (s, CH_3CO), 2.51 (m, H—17), 3.34–4.28 (m, $CH_2SO_2CH_2$), 5.05 (m, H—3), 5.67 (m, H—22); mass spectrum *m/e* 433 ($MH^+ - H_2O$). *Anal.* calcd. for $C_{25}H_{38}O_5 \cdot 0.25H_2O$: C 66.00, H 8.47, S 7.04; found: C 65.88, H 8.47, S 7.14.

*3β-Acetoxy-14β-hydroxy-21-hydroxethythio-5β-pregnan-20-one, 2*m

2-Mercaptoethanol (0.195 g) was added to a stirred solution of sodium methoxide (prepared from sodium (0.0575 g)) in methanol (5 mL) at 0°C. After 15 min the methanesulfonate **2***b* (0.235 g) in methanol (5 mL) was added and stirring at 0°C was continued for a further 30 min. The reaction mixture was diluted with dichloromethane, the solution thus obtained was washed with water, dried, and evaporated *in vacuo*. The residue was crystallized from hexane–dichloromethane to give the sulfide **2***m* (0.158 g, 70%), mp 97–98°C; $[\alpha]_D$ + 55° (c 0.233, $CHCl_3$); ir ($CHCl_3$) 3420, 1730, 1715 cm^{-1}; nmr ($CDCl_3$) δ 0.95 (s, 18—CH_3, 19—CH_3), 2.00 (s, CH_3CO), 2.63 (t, *J* = 5.9 Hz, SCH_2), 3.07 (m, H—17), 3.28 (s, CH_2CO), 3.70 (t, *J* = 5.9 Hz, CH_2O), 5.05 (m, H—3); mass spectrum *m/e* 434 ($M^+ - H_2O$). *Anal.* calcd. for $C_{25}H_{40}O_5S \cdot 1.5H_2O$: C 62.63, H 8.971, S 6.68; found: C 62.57, H 8.61, S 6.63.

*2,3-Dihydro-6-(3β-acetoxy-14β-hydroxy-5β-androstan-17β-yl)-1,4-oxathion 1*k

A solution of the sulfide **2***m* (1.00 g) in anhydrous dichloromethane (250 mL) containing *p*-toluenesulfonic acid monohydrate (0.010 g) was heated at reflux temperature for 2 h. The cooled solution was washed with water, dried, and evaporated. The residue was subjected to tlc on silica gel (hexane – ethyl acetate, 7:3) to give a solid (0.700 g, 72%) which, on crystallization from hexane–benzene, had mp 207–208°C; $[\alpha]_D$ + 75° (c 0.204, $CHCl_3$); uv (CH_3OH) 231 nm (ε 9200); ir ($CHCl_3$) 3500, 1730 cm^{-1}; nmr ($CDCl_3$) δ 0.91 (s, 18—CH_3), 0.95 (s, 19—CH_3), 2.00 (s, CH_3CO), 2.26 (m, H—17), 2.90 (t, *J* = 4.5 Hz, CH_2S), 4.32 (t, *J* = 4.5 Hz, CH_2O), 4.94 (s, (C=CH), 5.04 (m, H—3); mass spectrum *m/e* 434 (M^+). *Anal.* calcd. for $C_{25}H_{38}O_4S$: C 69.12, H 8.75, S 7.37; found: C 68.92, H 8.69, S 7.42.

*2,3-Dihydro-6-(3β-acetoxy-14β-hydroxy-5β-androstan-17β-yl)-1,4-oxathiin sulfoxide 1*l

A solution of sodium metaperiodate (0.690 g) in water (5 mL) was added to a stirred solution of the sulfide **1***k* (0.700 g) in a mixture (1:1) of methanol and tetrahydrofuran (20 mL). After 2 h the solution was diluted with water, the product was extracted into dichloromethane, the extract was washed with water, dried, and evaporated *in vacuo*. The residue was subjected to tlc on silica gel (acetone–methanol, 95:5) to give the sulfoxide **1***l* (0.400 g, 55%) as a mixture of epimers. After crystallization from ethyl acetate the product had mp 193°C; $[\alpha]_D$ + 61° (c, 0.258, $CHCl_3$); uv (MeOH) 231 nm (ε 9800); ir ($CHCl_3$) 3540, 1730 cm^{-1}; nmr ($CDCl_3$) δ 0.87, 0.96 (singlets, 18—CH_3), 0.96 (s, 19—CH_3), 2.01 (s, CH_3CO), 2.34 (m, H—17), 2.59–2.98 (m, CH_2SO), 4.49, 4.58 (multiplets, CH_2O), 5.06 (m, H—3), 5.75, 5.77 (singlets, C=CH); mass spectrum *m/e* 450 (M^+). *Anal.* calcd. for $C_{25}H_{38}O_5S$: C 66.66, H 8.44, S 7.11; found: C 66.46, H 8.56, S 6.82.

*2,3-Dihydro-6-(3β-acetoxy-14β-hydroxy-5β-androstan-17β-yl)-1,4-oxathiin sulfate, 1*m

m-Chloroperbenzoic acid (0.216 g) was added to a stirred solution of the sulfoxide **1***l* (0.255 g) in dichloromethane (25 mL). After 1 h the reaction was worked up as described for **1***i* and the crude product was subjected to tlc (hexane – ethyl acetate, 1:1) to give the sulfone **1***m* (0.140 g, 60%) as a solid which, after crystallization from methanol, had mp 209–210°C; $[\alpha]_D$ + 34° (c 0.177, $CHCl_3$); uv (MeOH) 222 nm (ε 9550); ir ($CHCl_3$) 3560, 1730, 1615 cm^{-1}; nmr ($CDCl_3$) δ 0.95 (s, 18—CH_3, 19—CH_3), 2.02 (s, CH_3CO), 3.25 (m, CH_2SO_2), 4.75 (m, CH_2O), 5.06 (m, H—3), 5.72 (s, C=CH); mass spectrum *m/e* 466 (M^+). *Anal.* calcd. for $C_{25}H_{38}O_6S$: C 64.37, H 8.15, S 6.86; found: C 64.32, H 8.28, S 6.77.

*3β-Acetoxy-14β-hydroxy-21-acetonylthio-5β-prenan-20-one, 2*n

Mercaptoacetone ((17), 0.270 g) was added, with stirring at 0°C, to a solution of sodium methoxide (prepared from sodium (0.058 g)) in methanol (15 mL). After 5 min a solution of the methanesulfonate **2***b* (0.235 g) in a mixture of methanol and tetrahydrofuran (1:1, 10 mL) was added. In 10 min the reaction was complete and the solution was poured into water, the product was extracted with dichloromethane, the extract was washed with water, dried, and evaporated. Crystallization of the residue from methanol gave the desired compound (0.163 g, 71%), mp 130–131°C; $[\alpha]_D$ + 47° (c 0.233, $CHCl_3$); ir ($CHCl_3$) 3440, 1725 cm^{-1}; nmr ($CDCl_3$) δ 0.96 (s, 18—CH_3, 19—CH_3), 2.05 (s, CH_3CO), 2.27 (s, CH_3CO), 3.27 (s, SCH_2), 3.37 (s, SCH_2), 5.08 (m, H—3); mass spectrum *m/e* 446 ($M^+ - H_2O$). *Anal.* calcd. for $C_{26}H_{40}O_5S$: C 67.24, H 8.62, S 6.89; found: C 67.26, H 8.60, S 7.01.

*5-(3β-Acetoxy-14β-hydroxy-5β-androstan-17β-yl)-thiopyran-4-en-3-one, 1*n

The sulfide **2***n* (0.093 g) was added to a solution of sodium methoxide (prepared from sodium (0.015 g)) in anhydrous methanol (6 mL) and the solution was heated at reflux tempera-

ture for 1 h. The solution was poured into 0.01 *N* hydrochloric acid (20 mL) and the product was extracted into dichloromethane. The extract was washed with water, dried, and evaporated *in vacuo*. The product (0.013 g, 15%) was obtained from the residue by tlc (hexane – ethyl acetate, 7:3). After crystallization from acetone it had mp 231–232°C; $[\alpha]_D$ + 15° (c 0.258, $CHCl_3$); uv (MeOH) 251 nm (ε 10 700); ir ($CHCl_3$) 3500, 1730, 1660 cm^{-1}; nmr ($CDCl_3$) δ 0.88 (s, 18—CH_3), 0.94 (s, 19—CH_3), 2.02 (s, CH_3CO), 2.49 (m, H—17), 3.24 (q, J = 16.8 Hz, SCH_2CO), 3.52 (q, J = 17.3 Hz, SCH_2), 5.06 (m, H—3), 5.93 (m, C=CH); mass spectrum *m/e* 428 ($M^+ - H_2O$) *Anal.* calcd. for $C_{26}H_{38}O_4S$: C 69.95, H 8.52, S 7.17; found: C 69.88, H 8.52, S 7.03.

3β-Acetoxy-14β-hydroxy-21-phenylthio-5β-pregnan-20-one, 2l

Thiophenol (1.155 g) was added to a solution of sodium methoxide (prepared from sodium (0.241 g)) in anhydrous methanol (10 mL). The solution was cooled to 0°C and the methanesulfonate **2***b* (1.00 g) dissolved in 1:1 methanol–tetrahydrofuran (10 mL) was added. The mixture was stirred for 0.5 h, poured into water, and the product was extracted into dichloromethane. The extract was washed with water, dried, and evaporated *in vacuo*. The residue was crystallized from methanol to give the product (0.880 g, 86%) mp 123–124°C; $[\alpha]_D$ + 26° (c 0.260, $CHCl_3$); ir ($CHCl_3$) 3440, 1730, 1690 cm^{-1}; nmr ($CDCl_3$) δ 0.90 (s, 18—CH_3), 0.96 (s, 19—CH_3), 2.03 (s, CH_3CO), 3.15 (m, H—17), 3.68 (s, CH_2S), 5.06 (m, H—3), 7.18–7.48 (m, C_6H_5); mass spectrum *m/e* 484 (M^+). *Anal.* calcd. for $C_{29}H_{40}O_4S$: C 71.90, H 8.26, S 6.61; found: C 71.78, H 8.26, S 6.66.

3β-Acetoxy-14β-hydroxy-21-phenylsulfonyl-5β-pregnan-20-one, 2o

m-Chloroperbenzoic acid (80%, 0.236 g) was added, with stirring at 0°C, to a solution of the thioether **2***h* (0.242 g) in dichloromethane (10 mL). The solution was left to come to room temperature and after 1 h it was diluted with dichloromethane, washed successively with saturated sodium bicarbonate solution and water, dried, and evaporated. The residue was subjected to tlc (dichloromethane – ethyl acetate, 95:5) to give the product (0.220 g, 86%) as a foam; $[\alpha]_D$ + 46° (c, 0.249, $CHCl_3$); ir ($CHCl_3$) 3460, 1730 cm^{-1}; nmr ($CDCl_3$) δ 0.89 (s, 18—CH_3), 0.93 (s, 19—CH_3), 2.01 (s, CH_3CO), 3.16 (m, H—17), 4.23 (q, J = 1.6 Hz, CH_2SO_2), 5.06 (m, H—3), 7.45–7.93 (m, C_6H_5). *Anal.* calcd. for $C_{29}H_{40}O_6S$: C 67.44, H 7.75; found: C 67.43, H 7.96.

3β-Acetoxy-14β-hydroxy-21-(3-oxobutyl)-5β-pregnan-20-one, 2p

A solution of the sulfone (0.258 g), in tetrahydrofuran (2.5 mL) containing methyl vinyl ketone (0.350 g) and tetramethylguanidine (0.115 g), was stirred for 4 h. It was then neutralized with acetic acid, diluted with dichloromethane, washed with water, dried, and evaporated. The residue was subjected to tlc (ether–hexane, 7:3) to give the Michael adduct **3***c* (0.146 g, 50%) as a foam; ir ($CHCl_3$) 3450, 1720, 1345 cm^{-1}; nmr ($CDCl_3$) δ 0.96 (s, 18—CH_3, 19—CH_3), 2.04, 2.06 (singlets, CH_3CO and 3—CH_3CO_2), 4.45 (t, J = 6.0 Hz, 21—CH), 5.08 (m, H—3), 7.50–7.90 (m, C_6H_5). The crude product was used immediately as described below.

To a solution of **3***c* (0.0586 g) in ethyl acetate (0.6 mL) containing ethanol (0.2 mL) and acetic acid (0.2 mL) was added zinc dust (0.059 g) and the mixture was heated at reflux temperature with stirring for 2 h. The mixture was diluted with ethyl acetate, washed successively with a sodium bicarbonate solution and water, dried, and evaporated. The residue was submitted to tlc (hexane – ethyl acetate, 7:3) to give the product (0.0178 g, 40%) which, after crystallization from ethyl acetate – hexane, had mp 117–119°C; $[\alpha]_D$ + 42.4° (c 0.205, $CHCl_3$); ir ($CHCl_3$) 3400, 1710 cm^{-1}; nmr ($CDCl_3$) δ 0.92 (s, 18—CH_3), 0.96 (s, 19—CH_3), 2.05 (s, CH_3CO), 2.13 (s, CH_3CO), 2.48 (t, J = 6.7 Hz, CH_2CO), 2.54 (t, J = 7.2 Hz, CH_2CO), 2.87 (m, H—17), 5.08 (m, H—3); mass spectrum *m/e* 446 (M^+). *Anal.* calcd. for $C_{27}H_{42}O_5$: C 72.64, H 9.41; found: C 72.61, H 9.66.

1-(3β-Acetoxy-14β-hydroxy-5β-androstan-17β-yl)-cyclohexen-3-one, 1o

The 1,5-diketone **2***p* (0.223 g) was added to a solution of sodium methoxide (prepared from sodium (0.223 g)) in anhydrous methanol (8 mL) and the solution was heated at reflux temperature for 1 h. Acetic acid (0.2 mL) was added followed by dichloromethane. The mixture was washed with water, dried over sodium sulfate, and the dichloromethane was removed *in vacuo*. The residue was acetylated with acetic anhydride in pyridine at room temperature (2 h) and after the usual workup and crystallization from ethyl acetate the desired product (0.064 g, 30%) was obtained, mp 235–237°C; $[\alpha]_D$ – 3° (c 0.227, $CHCl_3$); uv (MeOH) 245 nm (ε 16 600); ir ($CHCl_3$) 3625, 3480, 1733, 1660, 1612 cm^{-1}; nmr ($CDCl_3$) δ 0.87 (s, 18—CH_3), 0.97 (s, 19—CH_3), 2.03 (s, CH_3CO), 5.08 (s, H—3), 5.97 (s, C=CH); mass spectrum *m/e* 428 (M^+). *Anal.* calcd. for $C_{27}H_{40}O_4$: C 75.66, H 9.41; found: C 75.58, H 9.21.

If the reaction was extended to more than 1 h, isomerization of **1***o* to the 17α-isomer, 1-(3β-acetoxy-14β-hydroxy-5β-androstan-17α-yl)cyclohexen-3-one, **3***b*, became significant. At the end of 3 h the 17α-isomer became the principal product. After the usual workup and acetylation, this compound could be isolated by tlc (hexane–acetone, 7:3) in *ca.* 15% yield. After crystallization from ethyl acetate – hexane it had mp 210°C; $[\alpha]_D$ + 36.8° (c 0.242, $CHCl_3$); uv (MeOH) 247 nm (ε 17 400); ir ($CHCl_3$) 3580, 3450, 1725, 1660, 1612 cm^{-1}; nmr ($CDCl_3$) δ 0.98 (s, 18—CH_3), 1.04 (s, 19—CH_3), 2.04 (s, CH_3CO), 5.10 (H—3), 5.96 (s, C=CH); mass spectrum *m/e* 428 (M^+). *Anal.* calcd. for $C_{27}H_{40}O_4$: C 75.66, H 9.41; found: C 75.34, H 9.30.

Viscosity of ternary mixtures. IV. Urea – *tert*-butyl alcohol – water at 25°C

MARC PALMA AND JEAN-PIERRE MOREL

Laboratoire d'Etudes des Interactions Solutés–Solvants, Groupe de Chimie Physique, Université de Clermont II, Bât. 6 Chimie, B.P. 45, 63170 Aubière, France

Received April 16, 1981

MARC PALMA and JEAN-PIERRE MOREL. Can. J. Chem. **59**, 3248 (1981).

We have measured, at 25°C, the viscosities of urea and *tert*-butyl alcohol ternary aqueous solutions for total concentrations reaching about 4 *M* and various ratios of the solutes. We have also determined *B* coefficients of the Jones–Dole law for urea in water–*tert*-butyl alcohol mixtures and for *tert*-butyl alcohol in water–urea mixtures. The results can be fitted in the form:

$$\eta_r = 1 + B_1 m_1 + B_2 m_2 + D_{11} m_1^2 + D_{22} m_2^2 + D_{12} m_1 m_2 + \ldots.$$

where η_r is the viscosity relative to water and subscripts 1 and 2 characterise the two solutes. B_1 and B_2 are determined in water and the additional *D* parameters appear as pair-interaction contributions of the solutes to the viscosity of the system. Some relations are established and verified between the previous parameters and the *B* coefficients of *1* and *2* determined, respectively, in the aqueous mixtures of *2* and *1*.

MARC PALMA et JEAN-PIERRE MOREL. Can. J. Chem. **59**, 3248 (1981).

Nous avons mesuré, à 25°C, la viscosité des solutions aqueuses d'urée et d'alcool *tert*-butylique pour des concentrations totales allant jusqu'à environ 4 *M* et des proportions différentes de l'un et l'autre des deux solutés. D'autre part, nous avons déterminé les coefficients *B* de la loi de Jones–Dole de l'urée dans les mélanges eau – alcool *tert*-butylique et de l'alcool *tert*-butylique dans les mélanges eau–urée. Les résultats obtenus peuvent s'exprimer à l'aide d'une relation de la forme:

$$\eta_r = 1 + B_1 m_1 + B_2 m_2 + D_{11} m_1^2 + D_{22} m_2^2 + D_{12} m_1 m_2 + \ldots.$$

où η_r est la viscosité relative par rapport à l'eau et les indices 1 et 2 caractérisent les deux solutés. Les différents paramètres *D* qui figurent en plus des coefficients B_1 et B_2 déterminés dans l'eau apparaissent comme caractéristiques des contributions par paires des solutés à la viscosité du système. Des relations sont établies et vérifiées entre les paramètres précédents et les coefficients *B* de *1* et *2* déterminés, respectivement, dans les mélanges aqueux de *2* et *1*.

Introduction

It has been shown (1) that the viscosity of ternary mixtures water – electrolyte (E) – *tert*-butyl alcohol (N) in the water-rich region can be represented by

$$[1] \quad \eta_r = 1 + A_E m_E^{1/2} + B_E m_E + B_N m_N + D_{EE} m_E^2 + D_{NN} m_N^2 + D_{EN} m_E m_N + \ldots.$$

where η_r is the viscosity of the solution relative to water, m_E and m_N the molalities of the electrolyte and the nonelectrolyte, A_E, B_E, and B_N the coefficients of the classical Jones–Dole law (2), respectively, obtained from the viscosity studies of binary solutions of electrolyte and of nonelectrolyte. The *D* parameters are supplementary terms of significant weight at high concentrations. D_{EE} and D_{NN} are obtained from binary solutions of E and N in water, but D_{EN} is a supplementary term characteristic of ternary solutions. D_{EN} is additive for different ionic pairs and it can be correlated to the entropic coefficient of pair interaction (1); thus it seems to reflect some pair-interaction contribution to the excess viscosity of ternary mixtures.

There is no theory related to transport properties, like McMillan–Mayer theory for thermodynamics, which justifies relation [1]. Therefore, it appears interesting to verify the generality of this formalism and to see if it deserves theoretical speculations.

In our previous study (1), D_{EN} parameters were determined from the viscosities of ternary solutions of equal molality of electrolyte and nonelectrolyte, the best precision on D_{EN} being obtained when $m_E = m_N$. It is, of course, necessary to check the validity of relation [1] for various ratios m_E/m_N to state its generality.

The classical viscosity studies of electrolytes in binary water–co-solvent mixtures have described the variations of the *B* coefficient of the electrolyte with the concentration of co-solvent in water (3, 4). When this concentration becomes of the same magnitude as m_E, both N and E play symmetrical solute roles in water. The formalism of relation [1] which permits one to express the relative viscosity with respect to water is then more adequate. We shall show how the coefficients obtained through these two approaches are related.

We have chosen for this study the ternary system water – urea – *tert*-butyl alcohol. By using two nonelectrolytes we get rid of the A_E coefficient of Falkenhagen (5) that takes into account ionic interactions. The two selected nonelectrolytes urea and *tert*-butyl alcohol are of different natures: the first is hydrophilic and a water-structure breaker, the second is hydrophobic and considered a water-

structure promoter. On the other hand, the thermodynamic properties of the ternary solutions of these nonelectrolytes have been previously studied (6).

Experimental

Apparatus and Products

The general technique and instrumentation for the viscosity and density measurements have been described previously (3, 7).

Urea (Merck, analysis) was dried under vacuum at 50°C for 48 h. The purification of *tert*-butyl alcohol (Prolabo) has been described elsewhere (8). All solutions were prepared by weight with triply-distilled water and then filtered (glass porosity 4). All measurements were made at 25.000 ± 0.001°C.

Results

Binary Mixtures

In earlier work (1) the relative viscosities of *tert*-butyl alcohol solutions in water enabled us to write (up to m = 2.5 mol kg^{-1}).

$$[2] \quad \eta_r = 1 + 0.386m + 0.054m^2 - 0.0044m^3$$

By similar study of urea–water solutions, we have found here

$$[3] \quad \eta_r = 1 + 0.038m + 0.0015m^2$$

In the concentration range $0 < m < 3$, this expression fits all measurements within experimental error (see Tables 2 and 3).

Ternary Mixtures

Let us call m_1 and m_2 the molalities of urea and *tert*-butyl alcohol in water, respectively. We first carry out measurements of relative viscosities with respect to water of various solutions such that $m_1/m_2 = r$ = constant. In Table 1 are listed the molalities $m = m_2$ and the corresponding relative viscosities and densities for three different ratios r. On the other hand, we have reported in Table 2, for different molalities of water–urea system, the density, the relative viscosity, and the classical Jones–Dole B coefficients of *tert*-butyl alcohol in these systems. In Table 3 are listed the parallel values for water – *tert*-butyl alcohol mixtures and the B coefficients of urea in these mixtures (ρ in g cm^{-3} and m in mol kg^{-1}).

Discussion

Extended Jones–Dole Law Approach

By analogy with expression [1], we shall write the relative viscosity of the ternary systems studied here as follows

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

[4] $$\eta_r(m_1,m_2) = \eta(m_1,m_2)/\eta_0 = 1 + B_1m_1 + B_2m_2 + D_{11}m_1^2 + D_{22}m_2^2 + D_{12}m_1m_2 + E_{111}m_1^3 + E_{112}m_1^2m_2 + \ldots$$

where η_0 is the absolute viscosity of water, B_1, D_{11} and B_2, D_{22} are determined by expressing the extended Jones–Dole law equations for both water–urea and water – *tert*-butyl alcohol binary systems.

[5] $$\eta_r(m_1) = \eta(m_1)/\eta_0 = 1 + B_1m_1 + D_{11}m_1^2 + E_{111}m_1^3 + \ldots$$

[6] $$\eta_r(m_2) = \eta(m_2)/\eta_0 = 1 + B_2m_2 + D_{22}m_2^2 + E_{222}m_2^3 + \ldots$$

By setting $m_1/m_2 = r$ and $m_2 = m$, measurements of $\eta_r(m)$ in a well-defined concentration range allow us to determine the D_{12} value. This coefficient can be obtained from the intercept of

[7] $$G(m) = \{\eta_r - 1 - (rB_1 + B_2)m\}/m^2 = (D_{11}r^2 + D_{12}r + D_{22}) + (E_{111}r^3 + E_{112}r^2 + E_{122}r + E_{222})m$$

Since B_1, D_{11}, B_2, D_{22} may be deduced from the results of binary mixtures (relations [2], [3]), a least-squares treatment gives $D_{12} = -0.034$, -0.034, -0.035 respectively for $r = 0.299$, 3.32, and 1.00. We must point out that the same value is found for D_{12} whatever the ratio value r; we shall adopt in the present calculations $D_{12} = -0.035$, which is obtained in the best conditions. The range of concentration studied to determine the D coefficients is of primary importance and has been discussed elsewhere (1). In fact, the problem is that of the independent determination of the various coefficients; it has been resolved in the case of B coefficient (9), and we intend to apply an extended form of this method in further work.

The relative viscosities, η_r, calculated from eq. [4], reduced to the B and D coefficients are listed in Table 1 (columns *2*). Agreement with experimental values (columns *1*) is generally better than 2%. It would seem reasonable to expect a better agreement with the use of the E coefficients. The different values of r permit a rough estimation of these terms and we found: $E_{112} = 0.007$ and $E_{221} = -0.004$. Hence, the complete eq. [4] allows us to calculate again η_r (columns *3*). The agreement with experimental results is now about 0.1%. In other words, the expression of the relative viscosity $\eta_r(m_1, m_2)$ given by eq. [4] is valid whatever the relative concentrations of the mixture constituents. This result reinforces our assumption that D_{12} are pair-interaction terms and E triplet ones. Nevertheless, we ought to point out that a better knowledge of these coefficients needs a more appropriate method for their more correct determination.

Relation with Classical Approach

It is usual to measure the variations of the B coefficient of a solute in the mixture of water with a co-solvent. Such results are given in Tables 2 and 3 for our system. Let us show that a relation exists between these B coefficients and the parameters defined by our previous formalism.

Starting from the expressions [4], [5], [6] of the relative viscosities of binary and ternary solutions with respect to water, the B, D, and E coefficients are defined at infinite dilution in water. If we call ${}^{(w+1)}B_2$ the B coefficient of the solute *2* in a solution of the co-solvent *1* at molality m_1 in water, we can write, within the range of validity of the Jones–Dole law (dilute solution of *2*)

[8] $$\eta(m_1,m_2)/\eta(m_2) = 1 + {}^{(w+1)}B_2\,{}^{(w+1)}m_2$$

where ${}^{(w+1)}m_2$ is the molality of *2* in the aqueous mixture of *1*. This molality is related to the molality in water

[9] $${}^{(w+1)}m_2 = m_2/(1 + 10^{-3}M_1m_1)$$

where M_1 is the molecular weight of *1*. We can write

[10] $$\frac{\eta(m_1,m_2) - \eta(m_1)}{\eta_0} = \frac{\eta(m_1)}{\eta_0}\left[\frac{\eta(m_1,m_2)}{\eta(m_1)} - 1\right]$$

and relations [4], [5], [8] lead to

[11] $$B_2m_2 + D_{12}m_1m_2 + E_{112}m_1^2m_2 + \ldots = \eta_r(m_1)^{(w+1)}B_2\,{}^{(w+1)}m_2$$

because, for dilute solutions of *2*, expression [4] is limited to the terms which only contain one subscript 2. Hence, we can write, with [9],

[12] $${}^{(w+1)}B_2 = (B_2 + D_{12}m_1 + E_{112}m_1^2 + \ldots) \times (1 + 10^{-3}M_1m_1)/\eta_r(m_1)$$

and see that ${}^{(w+1)}B_2$ is obtained from B_2 (value in pure water), $\eta_r(m_1)$ the relative viscosity of the hydroorganic solvent and the various D_{12}, E_{112}, ... coefficients. We can also express the limiting slope, when $m_1 = 0$, of the tangent at the ${}^{(w+1)}B_2$ versus m_1 curve, as

[13] $$\frac{d^{(w+1)}B_2}{dm_1} = D_{12} + B_2(10^{-3}M_1 - B_1)$$

Now, we must note that symmetrical relations can be obtained by replacing subscript 1 by 2 and

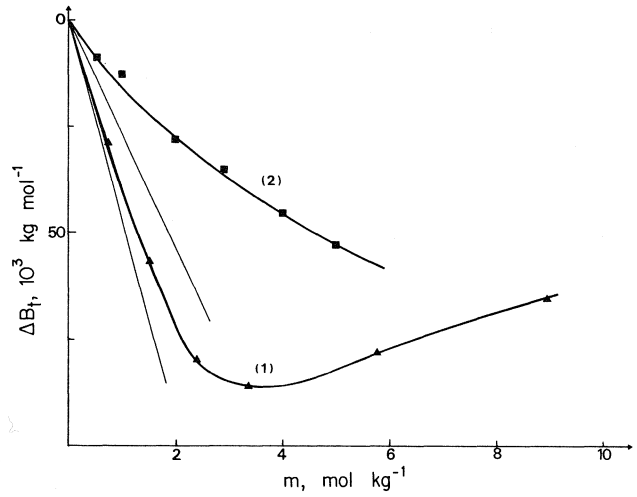

FIG. 1. Variation of B coefficients of urea (*1*) in water – *tert*-butyl alcohol (*2*) mixtures and of *tert*-butyl alcohol (*2*) in water–urea (*1*) mixtures. $\Delta B_{t_1} = {}^{(w+2)}B_1 - B_1$ versus m_2 (curve *1*); $\Delta B_{t_2} = {}^{(w+1)}B_2 - B_2$ versus m_1 (curve 2).

vice versa in eqs. [8] to [13]. In Fig. 1, we have drawn the variations of the B coefficient of urea in water – *tert*-butyl alcohol ($\Delta B_{t_1} = {}^{(w+2)}B_1 - B_1$ versus m_2) and of the B coefficient of *tert*-butyl alcohol in water–urea ($\Delta B_{t_2} = {}^{(w+1)}B_2 - B_2$ versus m_1). The slopes of the two straight lines are respectively −0.047 and −0.026, these values being calculated by relation [13]; it appears that the two straight lines may be taken as the tangents at the origin of the experimental curves. On the other hand, ${}^{(w+2)}B_1$ and ${}^{(w+1)}B_2$ values calculated with relation [12] are given in Tables 2 and 3 for comparison with experimental determinations. The agreement is very satisfying considering the low precision on our evaluation of E_{112} and E_{221}; the weight of these and higher terms is very important for solutions containing more than 3 m co-solvent leading, consequently, to a bad agreement.

Conclusion

The relation [4] which we have proposed for the relative viscosity of the solution of two nonelectrolytes in water is valid whatever the proportions of these two solutes. This strengthens our assumption considering D parameters as pair-interaction contributions to the excess viscosity of the solution. On the other hand, the different terms of relation [4] can be correlated to the classical B coefficient of one solute in a water mixture of the other solute. Here again, the good agreement with the experimental values shows the coherence of the proposed formalism.

Acid catalysed rearrangements of 8,8-dimethyl-2,3-homotropone

RONALD F. CHILDS[1] AND ARAVAMUTHAN VARADARAJAN

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 2, 1981

RONALD F. CHILDS and ARAVAMUTHAN VARADARAJAN. Can. J. Chem. **59**, 3252 (1981).

The Brønsted and Lewis acid catalysed rearrangements of 8,8-dimethyl-2,3-homotropone, **2**, have been examined. Four major products have been identified: 2-isopropyltropone, **6**; isobutyrophenone, **7**; 2-isobutenylphenol, **8**; and 8,8-dimethylbicyclo[3.2.1]-octa-3,6-dien-2-one, **5**. The relative amounts of these products differ very markedly as the acid medium changes. Mechanisms are proposed to account for these reactions.

RONALD F. CHILDS et ARAVAMUTHAN VARADARAJAN. Can. J. Chem. **59**, 3252 (1981).

On a examiné les transpositions catalysées par les acides de Brønsted et Lewis de la diméthyl-8,8 homo-2,3 tropone (**2**). On a identifié quatre produits majoritaires: l'isopropyl-2 tropone (**6**), l'isobutyrophénone (**7**), l'isobutényl-2 phénol (**8**) et la diméthyl-8,8 bicyclo[3.2.1] octadiène-3,6 one-2 (**5**). Les quantités relatives de ces produits varient largement avec les changements d'acidité du milieu. On propose des mécanismes pour expliquer ces réactions.

[Traduit par le journal]

Hydroxyhomotropylium cations undergo a variety of photochemical and thermal isomerizations (1–3). Thermally induced rearrangements include *exo–endo* interconversion of substituents on the bridging C(8) carbon by a ring flipping process (1, 4), isomerizations to protonated aromatic ketones (2–4), and circumambulatory rearrangements of the bridging carbon (2, 5). This latter process becomes facile when the bridging carbon bears charge stabilizing groups. An example of these circumambulatory rearrangements is shown in Scheme 1 for the 8,8-dimethyl substituted systems (2).

One feature of the reactions shown in Scheme 1 is that the ultimate product is the protonated bicyclo[3.2.1]octadienone, **5H**. Thus **1H**, **2H**, and **4H** all isomerize to **5H**.[2] At first glance the thermodynamic stability of **5H** is surprising inasmuch as this cation can formally be regarded as "antibishomoaromatic" (6), while **1H**, **2H**, **3H**, and **4H** are homoaromatic ions (2, 7). However, there is a considerable difference in strain energy expected between the two types of cation and this could override any difference in stability due to delocalization.

As part of a program designed to quantitatively probe the importance of strain and delocalization energies in these systems it was desirable to establish the relative stability of the ketones **2** and **5**. This could be achieved by establishing an equilibrium between the two ketones and measuring the equilibrium constant. To this end we examined the acid catalysed reactions of **2** and have uncovered a further series of isomerizations.

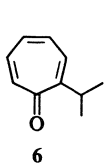
[a] Times given are approximately those required for complete reaction.
[b] Yields are based on ^1H nmr and glc analyses. Recovered yields are about 10% lower.
[c] Other minor products present.
[d] *p*-Toluenesulfonic acid. The acid was not completely soluble in CCl_4.
[e] 4,5-Benzo-2,2-dimethyldihydrofuran is also produced on further reaction of **8**. This is included with **8** in terms of product distribution.

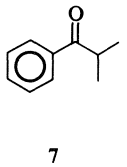
Results

8,8-Dimethyl-2,3-homotropone, **2**, (8) was reacted with a variety of Brønsted acids. The reactions were carried out on a small scale and monitored directly by ^1H nmr spectroscopy on the solutions. The acids and acid concentrations were chosen such that **2** was not completely protonated and converted to **2H**. It became apparent from these preliminary observations that **5** was not being formed but rather a series of other compounds, Table 1.

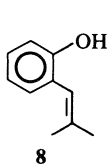
With 0.15 *M* CF_3COOH in CCl_4, **2** was found to isomerize cleanly to 2-isopropyltropone, **6**. The structure of **6** was established by comparison with an authentic sample prepared by the reaction of tropone with isopropylmagnesium iodide and subsequent oxidation of the resulting products (9). Solutions of HCl in $CDCl_3$ and CCl_3COOH in CCl_4 caused the clean isomerization of **2** to **6**.



6



7

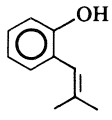


8

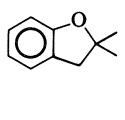
As the concentration of CF_3COOH in CCl_4 was increased beyond 0.15 *M*, an additional product was observed. This was identified as **7** on the basis of comparison of its spectroscopic properties and glc retention times with an authentic sample. When CF_3COOH itself was used as solvent, **7** was the major product present and only traces of **6** could be detected. Ketones **6** and **7** were not interconverted under the reaction conditions.

Yet another product was found when *p*-toluenesulfonic acid hydrate was used as the acid catalyst. Heating **2** in the presence of this acid led to the production of the phenol **8** with no detectable amounts of **6** or **7** being produced. Again the structure of **8** was established by comparison of its properties with an independently synthesized material (10).

Lewis acid catalysts were also examined. The same products were obtained with Lewis acids as with the Brønsted acids described above. One complicating feature was that the phenol **8** underwent a cyclization to give the benzodihydrofuran **9** with the stronger Lewis acids (11). (For the sake of simplicity the amounts of this further product have been combined with those of **8** in Table 1.)



8



9

With either catalytic amounts or a molar excess of BCl_3, the only products observed were phenol **8** or furan **9**. Similarly, catalytic amounts of BBr_3 or $TiCl_4$ again led to **8**/**9**. Catalytic amounts of BF_3 etherate, on the other hand, led to the formation of **5** and **7** in equal proportions, while an excess of BF_3 or $SbCl_5$ in $CDCl_3$ caused **2** to isomerize cleanly to **5**. With molar excesses of the Lewis acids, it would appear from ^1H nmr evidence that the ketone **2** is completely complexed. Control experiments showed that apart from the conversion of **8** → **9**, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

products did not interconvert in the presence of the Lewis acids.

Discussion

It is clear from the results presented above that it is not possible to measure an equilibrium constant between **2** and **5** using either weak protic acid or Lewis acid catalysts to equilibrate the two ketones. Instead we have uncovered a variety of isomerization pathways and a remarkable acid dependence on the relative energies of these paths. In FSO_3H, where the various ketones are fully protonated, **2H** isomerized essentially exclusively to **3H** and then to either **4H** or **5H** (2). None of the products found under the acid catalysed conditions used here was detected on rearrangement of **2H** in FSO_3H. This suggests that with the weaker protic acids and certain Lewis acids, the rearrangements of **2** to **6**, **7**, and **8** do not simply involve cationic intermediates but that various unobserved covalent intermediates are also formed. Thus although the aromatic ketone **7** could be formed by isomerization of **2H** to **1H** by a cyclopropyl walk followed by the known isomerization of the **1H** to protonated ketone **7H**, eq. [1] (2–4), the absence of such a reaction in FSO_3H makes it difficult to see why such a pathway should operate with the weaker acids.

[1] $2 \overset{H^+}{\rightleftharpoons} 2H \rightleftharpoons 1H \rightleftharpoons 7H \rightleftharpoons 7$

Instead we suggest that with a weaker acid it is likely that **1H** can lose a proton to give cyclooctatrienone **1**. It is known that **1** exists preferentially as its valence tautomer **10** (12) and that this on protonation irreversibly yields **7H**, eq. [2] (2).

[2] 
Likewise, formation of **6** could have been considered to arise by a hydride shift from C(1) to C(8) of **2H** or an ion closely related to **2H** involved in the circumambulatory rearrangements of these cations. It is known that there is considerable localization of positive charge on C(8) during this migration and Hehre has suggested that partial hydrogen bridging might occur in the "allowed" transition state for cyclopropyl circumambulation (13). However, as **6** (or **6H**) is only formed in the weaker acids it is suggested that a more appropriate mechanism might be as shown in eq. [3], in which nucleophilic capture at C(8) occurs to give **11**. This would be followed by ketonization of the intermediary enol. This is known to occur by protonation preferentially at C(2) as shown (14). This is followed by loss of X^-, a hydride shift and proton loss.

[3] 
From the data in Table 1 it can be seen that with trifluoroacetic acid both **6** and **7** are produced from **2**. The tropone **6** predominates when small amounts of the acid are used in a nonpolar medium (CCl_4) where ion pairing would be maximized and nucleophilic attack likely. As the amount of trifluoroacetic acid is increased the solvent polarity would be enhanced. Consequently less nucleophilic capture, to give **11** and an increase in the relative amount of **7**, might be expected.

An alternative course of reaction for **11** would be its reionization prior to ketonization. Sargent has shown that cycloheptatriene carbinyl systems ionize from their norcaradiene valence tautomers to yield styrene derivatives (15). As is shown in eq. [4], this would yield a potential route to the phenol **8**.

[4] 
Some measure of support for these suggestions comes from the Lewis acid catalysed reaction. With an excess of a strong Lewis acid such as BF_3 or $SbCl_5$, a situation similar to that occurring with FSO_3H pertains. With catalytic amounts of BF_3, however, decomplexation of **1**.BF_3 could occur. This would be expected to lead to **7** as is observed. BCl_3, BBr_3, and $TiCl_4$ all lead to the quantitative formation of **8**. This, we would suggest, occurs by the attack of halide at C(8) of the complexes of **2**. Certainly in the cases of BCl_3 and BBr_3 this is not unexpected and probably also occurs from the

bisketone complex of $TiCl_4$. With a Lewis acid such as BF_3, the -OBF_3^- or BF_4^- groups would not be expected to dissociate a fluoride which could then nucleophilically add to the complex. In the absence of a protic acid, ketonization of **11** could well be slower than reionization and formation of **8**.

In conclusion it is of interest to reconsider the reactions observed in FSO_3H, Scheme 1. In this acid **1H** thermally rearranged to **2H**, indicating that the latter cation is thermodynamically more stable than **1H**. At higher temperatures **2H** further rearranged to **4H** and **5H** via **3H**. The results obtained in this work suggest that the barrier for the isomerization of **2H** to **1H**, a reaction not observed in FSO_3H because of the equilibrium position between the two cations, is lower than that for the conversion of **2H** to **3H**. This suggests that the ground state energy difference between **1H** and **2H** can only be of the order of 1 kcal/mol.

Experimental

The ^1H nmr spectra were recorded on Varian EM-390 and Bruker WP-80 spectrometers. Infrared spectra were obtained with a Perkin–Elmer model 283 instrument. Varian A-90-P3 and 3700 gas chromatographs, respectively, were used for preparative and analytical glpc.

General Isomerization Procedure

8,8-Dimethyl-2,3-homotropone, **2** (5–20 mg), was dissolved in $CDCl_3$ or CCl_4 (0.7 mL) in an nmr tube, the solution cooled to −78°C, and the appropriate amount of acid added under an argon blanket. The mixture was warmed to the appropriate temperature and the reaction monitored by ^1H nmr spectroscopy. After reaction the mixture was poured into a saturated solution of $NaHCO_3$ and the organic materials extracted into CH_2Cl_2 (3 × 5 mL) and the combined extracts dried over $MgSO_4$. The solvent was removed *in vacuo* and the residue subjected to glpc and ^1H nmr analysis. The results are summarized in Table 1.

Product Characterizations

(a) Rearrangement Catalysed by Trifluoroacetic Acid

Ketone **2** (20 mg) in CCl_4 (1 mL) and trifluoroacetic acid (20 mg) were mixed and heated at 70°C for 16 h. The reaction mixture was neutralized with $NaHCO_3$, the product extracted into CH_2Cl_2 and dried as above. Removal of the solvent and bulb to bulb distillation (80°C/0.1 Torr) gave **6** (19 mg); ir (film): 2960, 1630, 1580, 1520, 780, 690 cm^{-1}; ^1H nmr (CCl_4, TMS) δ: 6.81 (vinyl H, 5H, m), 3.34 (methine H, m, J = 6 Hz), 1.14 (CH_3, d, J = 6 Hz). The ir and ^1H nmr spectra of **6** were identical to an authentic sample prepared by the method of Noyori *et al.* (9).

(b) Rearrangement Catalysed by p*-Toluenesulfonic Acid*

Ketone **2** (20 mg) in CCl_4 (1 mL) was treated with *p*-toluenesulfonic acid hydrate (2 mg). The reaction was heated at 75°C for 3 h and subsequently worked up as described above. Removal of the solvent gave the crude phenol **8** (10 mg). The phenol was purified by extraction into aqueous NaOH, acidification and reextraction into ether, drying ($MgSO_4$), and solvent removal. Infrared (CS_2): 3540, 2960, 750, 695 cm^{-1}; ^1H nmr ($CDCl_3$, TMS) δ: 7.0 (aromatic H, 4H, m), 6.2 (vinyl H, 1H, s), 5.17 (OH, 1H, s), 2.0 and 1.72 (CH_3, each 3H, s). The ^1H nmr and ir spectra and glpc retention times of **8** were identical to an independently prepared sample (10).

(c) Rearrangement Catalysed by BCl_3

BCl_3 (30 mg) was condensed into a frozen solution of **2** (13 mg) in $CDCl_3$ (1 mL) at −78°C. The mixture was warmed to 25°C. After 1 h at this temperature the reaction mixture was quenched and worked up as described above. Removal of the solvent and bulb to bulb distillation (150°C/15 Torr) gave 2,3-dihydro-2,2-dimethylbenzofuran. Infrared (film): 2920, 1595, 1455, 1260, 1205, 890, 745 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.17 and 6.83 (aromatic H, 4H, m), 3.03 (CH_2, 2H, s), 1.46 (CH_3, 6H, s). The ^1H nmr and ir spectra and glpc retention times were identical to those of an authentic sample prepared by the method of Martini *et al.* (11).

(d) Rearrangement Catalysed by BF_3/OEt_2

Ketone **2** (20 mg) in CCl_4 (mL) was treated with $BF_3.OEt_2$ (1 mg) and heated at 70°C for 3 h. Working up the reaction as described above gave a mixture of **5** and **7** (10 mg). These were separated by preparative glpc (15% SE30 on Chromosorb W; retention times: **5**, 5.8 m, and **7**, 6.6 m, at 130°C). The properties of **5** were identical to those previously described (2). Isobutyrophenone, **7**, ir (film): 2980, 1690, 1600, 1582, 1480, 1430, 1315, 1225, 1160, 970, 788, 696 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.86 and 7.43 (aromatic H, 5H, m), 3.45 (CH, 1H, h, J = 7 Hz), 1.15 (CH_3, 6H, d, J = 7 Hz). The properties of **7** were identical to a commercial sample.

W. RONALD FAWCETT and ANDRZEJ LASIA. Can. J. Chem. **59**, 3256 (1981).

The mechanism of electroreduction of aromatic aldehydes was investigated by cyclic voltammetry in dimethylformamide and acetonitrile in the presence of tetraethylammonium, potassium, and sodium perchlorates. It was found that the reaction products disappear in a dimerization reaction. Rate constants for the subsequent dimerization and association constants for ion pair intermediates were determined. The reactivity of the anion radicals initially formed decreases in the sequence: 9-anthraldehyde > benzaldehyde > 2-naphthaldehyde > 1-naphthaldehyde. The Hückel molecular orbital method was used to explain the reactivity sequence and the properties of the radical intermediates.

W. RONALD FAWCETT et ANDRZEJ LASIA. Can. J. Chem. **59**, 3256 (1981).

Faisant appel à la voltamétrie cyclique, on a étudié le mécanisme d'électoréduction des aldéhydes aromatiques dans le diméthylformamide et dans l'acétonitrile en présence des perchlorates de tétraéthylammonium, de potassium et de sodium. On a trouvé que le produit de la réaction disparaît dans une réaction de dimérisation. On a déterminé la constante de vitesse de la dimérisation et les constantes d'association de la paire d'ions intermédiaire. La réactivité des radicaux anions qui se forment initialement décroît dans l'ordre suivant: antraldéhyde-9 > benzaldéhyde > naphtaldéhyde-2 > naphtaldéhyde-1. On a utilisé la méthode d'orbitale moléculaire de Hückel pour expliquer l'ordre de réactivité et les propriétés des radicaux intermédiaires.

[Traduit par le journal]

Introduction

The reaction mechanism for the electroreduction of aromatic aldehydes, in particular, benzaldehyde, has been widely studied in protic solutions (see ref. 1 and references therein). It was found that electron transfer to benzaldehyde is a fast process with an apparent rate constant of the order 0.1 cm s^{-1} (2). The reduction mechanism involves protonation of the resulting anion radical and dimerization (3, 4). Nekrasov *et al.* (5) suggested that the products of dimerization are pinacols and other substances with a quinoid structure.

The reduction of aromatic aldehydes in aprotic solvents has been studied in less detail (6–17). Anthoine *et al.* (6) presented half-wave potentials of aldehydes in dimethylformamide (DMF) and found a linear relationship between the energy of the lowest empty molecular orbital and the half-wave potential, $E_{1/2}$. They also found that the first reduction step is reversible in cyclic voltammetric experiments carried out at high sweep rates (20 Hz). Most papers were concerned with the reduction of benzaldehyde (7–17). Large scale electrolysis in DMF at the potentials corresponding to the first polarographic wave gave pinacol as a main product (8, 9). Vykhodtseva and Nekrasov (15) suggested that in DMSO not only pinacols but also other dimers with a quinoid structure are formed.

The kinetics of dimerization of benzaldehyde was investigated by Armstrong *et al.* (13, 14) in sulfolane. In the presence of 0.1 tetrabutylammonium perchlorate the second order rate constant was equal to $2.4 \times 10^3 M^{-1}$ s^{-1}. The possibility of dimerization of two radical anions or of the radical anion with the parent molecule was discussed by Yeh (18) for *p*-cyanobenzaldehyde in DMSO.

Kalinowski (17) studied the reduction of benzaldehyde in DMF in the presence of alkali metal and alkaline earth metal perchlorates and found a linear relationship between the half-wave potential and the ionic potential (defined as the ratio of the charge on the cation to its radius). This result was attributed to ion pair formation between anion radicals and cations of the supporting electrolyte with subsequent dimerization of the ion pairs.

The purpose of the present study was to investigate the mechanism of electroreduction of simple aromatic aldehydes: benzaldehyde (BA), 1-naphthaldehyde (1NA), 2-naphthaldehyde (2NA), and 9-anthraldehyde (AA), and to assess the influence of ion association on that process.

Experimental

Chemicals

Spectroquality DMF (Matheson, Coleman, and Bell) was purified as described earlier (19). Spectroquality acetonitrile

(ACN) (Matheson, Coleman, and Bell) was dried with 3A molecular sieves and P_2O_5 and then distilled under a nitrogen atmosphere. All perchlorates were dried according to previous procedures (19). The aldehydes were distilled or sublimated under reduced pressure before use. The concentration of the supporting electrolyte was 0.1 *M* in all experiments. Peak potentials were measured against an aqueous saturated calomel electrode (SCE). All measurements were performed at 21 ± 1°C.

Apparatus

The apparatus for voltammetry consisted of a PAR Model 173 potentiostat, a PAR Model 175 waveform generator, and a PDP-11 minicomputer. Positive feedback iR compensation was used in the experiments with fast scan rate. In the kinetic measurements sweep rates varied from 1 to 100 V s^{-1}. The peak potentials were measured from the voltammetric curves recorded at a sweep rate of 0.04 V s^{-1} using an X–Y recorder.

Estimates of the anodic to cathodic current ratio were obtained by comparing the voltammetric curves observed for a given system with the curves for *p*-dicyanobenzene (20) obtained at the same scan rate and depolarizer concentration but with 0.1 *M* tetraethylammonium perchlorate (Et_4NClO_4) as a supporting electrolyte.

The working electrode was a platinum disk (diameter 0.1 cm) electrolytically covered by a thin layer of silver and amalgamated by dipping in mercury.

The cell for kinetic measurements contained a Luggin capillary with a W wire as a pseudo-reference electrode (21) and a Hg pool as an auxiliary electrode. The cell for potential measurements was described previously (22). Peak potentials were determined for at least six curves, standard deviations being less than or equal to 1 mV.

Data Analysis

Analysis of the kinetic data was performed using the theoretical results calculated by Olmstead *et al.* (23) for cyclic voltammetry in which the product of the electron transfer process undergoes subsequent dimerization:

[1] $O + ne \rightarrow R$

[2] $R + R \rightarrow Z$

The second order rate constant k_{eff} defined by the equation

[3] $-dc_R/dt = 2k_{eff}c_R^2$

was determined by studying the variation in the ratio of anodic peak current to cathodic peak current with τ, the time interval between the standard potential on the cathodic sweep and the potential at which the sweep is reversed (23, 24). The value of $k_{eff}c_O^0\tau$, and thus k_{eff} itself, can be determined from the current ratio (23, 24), c_O^0 being the bulk concentration of O.

TABLE 1. The dependence of the dimensionless peak potential ξ_p on the kinetic parameter λ for a subsequent dimerization reaction in linear potential sweep voltammetry

λ	$-\xi_p$
0.25	1.00
0.50	0.91
1.0	0.765
1.5	0.65
2.0	0.575
4.0	0.365

In order to separate the ion pairing effects from the effects of dimerization of the reaction products, one must be able to estimate the shift in the peak potential from the standard potential due to each effect. Olmstead *et al.* (23) presented a plot $\xi_p/f = n(E_p^k - E^0)$ against $\lambda = k_{eff}c_O^0/nfv$ where E_p^k is the peak potential in the presence of dimerization (no ion pairing), E^0, the standard potential, v, the voltage sweep rate and $f = F/RT$. Since data of sufficient precision cannot be obtained from the graph, values of ξ_p and λ were calculated by the finite difference method described in the literature (25) with the integrated kinetic term (26); the new values are recorded in Table 1. For $\lambda > 2$, ξ_p may also be estimated by the approximate relationship (23)

[4] $\xi_p = (\ln 2\lambda - 3.12)/3$

to a precision better than ±0.02.[1]

Having estimated the shift in peak potential due to dimerization, $\Delta E_p^k = E_p^k - E_p^0$ where E_p^0 is the peak potential in the absence of a subsequent reaction and ion pair formation, one may find the contribution due to ion pairing ΔE_p^{ip} from the total observed shift in peak potential, ΔE_p:

[5] $\Delta E_p = \Delta E_p^{ip} + \Delta E_p^k$

The ion pair association constants are calculated from the slope of plots of exp ($f\Delta E_p^{ip}$) against metal ion concentration, [M^+] (22). Error estimates in the derived association constants were obtained from least-squares regression analysis.

Results

The cyclic voltammetric measurements performed in DMF in the presence of 0.1 *M* Et_4NClO_4 at a sweep rate of 0.1 V s^{-1} show that BA and AA form unstable ion radicals which disappear in subsequent dimerization reactions. In acetonitrile in the presence of the same supporting electrolyte all aldehydes form unstable radicals. The dimerization rate constants determined by the cyclic voltammetric method are presented in Table 2.

In the presence of alkali metal perchlorates, a shift of the peak potential in the positive direction is observed and the subsequent dimerization reaction proceeds more rapidly. The results of kinetic measurements in DMF are shown in Table 3. In the last column the shift of the peak potential (defined as the difference between the peak potential in the presence of alkali metal perchlorates and in 0.1 *M* Et_4NClO_4) is presented.

The data in Table 3 indicate that the rate constants for dimerization increase with increase in alkali metal cation concentration because of the formation of reactive ion associates. To analyse the mechanism of dimerization it is assumed (22,

[1]It should be noted that in the paper of Olmstead *et al.* (23) eq. [3] was written without the factor 2 normally used in defining the rate constant for reaction [2], so that k_{eff} in that work is twice that defined here. Since the definitions of λ given here is the same, the values of ξ_p recorded in Table 1 do not correspond to those which may be read from the graph in ref. 23.

27–32) that the reaction proceeds in three parallel pathways:

$$\left.\begin{array}{ll} [6] & 2R^{\cdot -} \xrightarrow{k_1} \\ [7] & R^{\cdot -} \ldots M^+ + R^{\cdot -} \xrightarrow{k_2} \\ [8] & 2R^{\cdot -} \ldots M^+ \xrightarrow{k_3} \end{array}\right\} \text{products}$$

The observed rate constant k_{eff} can be described by the equation (27–32):

$$[9] \quad k_{eff} = \frac{k_1 + k_2 K_{ass}[M^+] + k_3 K_{ass}^2 [M^+]^2}{(1 + K_{ass}[M^+]^2}$$

In order to analyze the data in Table 3 on the basis of eq. [9], the value of the ion pairing association constant K_{ass} was determined from the peak potential measurements as described above. This calculation first involved estimating k_{eff}, and then the corresponding value ΔE_p^k by interpolation in the table of values of λ and ξ_p (Table 1). The association constants were estimated from values of ΔE_p^{ip} obtained by subtracting ΔE_p^k from the observed value of ΔE_p.

TABLE 4. Association constants and rate constants for the dimerization reaction (reactions [7] and [8]) of aromatic aldehydes in DMF

Aldehyde	Cation	K_{ass}/M^{-1}	$k_2/M^{-1}\,s^{-1}$	$k_3/M^{-1}\,s^{-1}$
1NA	K^+	0.95±0.2	4.0×10^5	—
	Na^+	9.5 ±0.6	1.7×10^4	1.0×10^6
2NA	K^+	10.9 ±0.5	8.9×10^4	1.0×10^6
BA	K^+	63 ±8		

The rate constants k_1, k_2, and k_3 were determined by fitting the function $k_{eff}(1 + K_{ass}[M^+])^2$ to a quadratic equation in $[M^+]$ using least squares. Because the slopes of plots of E_p against log $[M^+]$ were smaller than 59 mV, the existence of associates more complex than 1-to-1 can be excluded for the concentration range studied (22). In all cases k_1 was negligible, indicating that dimerization involving the unassociated anion radicals can be neglected. The values of k_2 and where measurable, k_3, are recorded in Table 4. The estimated error in the rate constants is at least 30%.

Discussion

The comparison of the kinetic results indicate that $k_1 < k_2 < k_3$. It follows that the reaction of two ion pairs is the fastest and two ion radicals the slowest one and that Coulomb interactions have a large influence on the kinetics of the dimerization reaction.

From the data presented in Tables 2–4, it follows that the reactivity of ion radicals and ion pairs increases in the order: 1NA < 2NA < BA < AA. In order to explain this result, HMO calculations were performed assuming $\beta_{C=O} = 1.55\beta$ and $\alpha_O = \alpha + 1.7\beta$ (11). The spin densities obtained using the McLachlan modification (33) of the HMO method (with $\lambda = 1.2$) are presented in Table 5. In the dimerization reaction, the spin density at the reaction site is the main factor which influences the rate of reaction. The spin densities on the carbonyl carbon atom increase in the order: AA < 1NA < 2NA < BA. Thus, only the AA radical is out of order in comparing spin densities with reaction rates. However, one should take into account the possibility that dimers other than pinacols are formed. The highest spin density in the AA anion radical is at position 10, and it is possible that dimerization proceeds between the carbonyl carbon atom 1a and carbon 10 or between two radicals in position 10. A similar reaction for 2NA in position 1 should be more difficult because of steric hindrances. In fact, it was found that 2-acetylnaph-

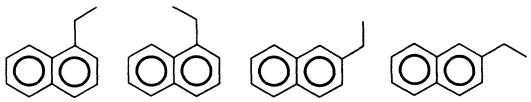
thalene during macroelectrolysis in aqueous solutions forms only pinacols (34) whereas 1-acetylnaphthalene forms more complicated dimers (35). Reactions of BA and 1NA radicals at position 4 cannot be excluded. The possibility of the formation of such dimers for benzaldehyde was proposed by Nekrasov and co-workers (5, 15). Calculating the maximum sums of the spin densities one obtains: 2NA (C(1a) + C(1a) 0.4334, C(1) + C(1) 0.7128), 1NA (C(4) + C(4) 0.5926), BA (C(1a) + C(1a) 0.7054), AA (C(10) + C(10) 0.7666). This order (excluding the possibility of the reaction of 2NA in position 1) is in agreement with the observations in acetonitrile. However, one should remember that the HMO calculations are rather approximate and do not take into account the change in the spin density distribution due to the formation of ion pairs and the influence of the solvent. In order to substantiate the proposed mechanisms, further investigations are planned.

The results shown in Table 4 indicate that the association constants of ketyl radicals with the potassium cation in DMF increase in the sequence 1NA < 2NA < BA. This phenomenon may be attributed to the difference in electron distribution in the radical anions. The HMO calculations (36, 37) indicate that in the ion pairs of the carbonyl radicals, the metal atom is located over the CO bond close to oxygen atom. However, more accurate *ab initio* (38) and SCF LHP (39) calculations show two minima: one over the carbonyl oxygen and a deeper one on the line of the C—O bond (in the plane). Using the HMO method and assuming sp^2 hybridization in the molecules and an O—Me^+ distance equal to 3 Å, association energies were calculated for the two above locations of the metal ion. For 1NA and 2NA two possible orientations of the carbonyl group were taken into account:



I II III IV

The calculated association energies are shown in Table 6. When the cation is located over the oxygen atom, the sequence of the change of association energies is in agreement with that observed experimentally. But, for the other location of the metal cation, the sequence of 1NA and 2NA is reversed. The simple HMO method does not take into account the influence of the solvent, and the calculated structure of the ion pair *in vacuo* may be different from the structure in the dipolar solvent. Miertus *et al.* (38) tried to account for the influence of the solvent but the simple physical model which they used seems to be insufficient because it does not consider specific donor–acceptor interactions. Thus, the model in which the metal ion is located over the oxygen atom is able to explain the experimental results more satisfactorily.

From the kinetic measurements it follows that in ACN all anion radicals are unstable and the subsequent reactions are faster in ACN than in DMF. This result may be rationalized on the basis of

TABLE 6. Association energies of free radicals with a monovalent cation, $r_{O—M^+} = 3$ Å

Radical	E_{ass}/β	
	Cation over oxygen	Cation on C—O line
BA	1.748	1.667
1NA(I)	1.689	1.605
1NA(II)	1.693	1.657
2NA(III)	1.716	1.632
2NA(IV)	1.712	1.614
AA	1.650	1.628

solute–solvent interactions. Considering the donor (DN) and acceptor (AN) numbers of DMF (DN = 26.6, AN = 16.0) and ACN (DN = 14.1, AN = 18.9) (40), it follows that ACN interacts somewhat more strongly with anions and DMF much more strongly with cations. These facts are also verified by the difference in free energies of solvation of Cl^- and K^+ in DMF and ACN ($\Delta\Delta G_{sv}(Cl^-) = 1.22$ kcal, $\Delta\Delta G_{sv}(K^+) = -3.6$ kcal) (41, 42). Thus, the reactivity of cations is greater in ACN than in DMF, and ion pairs are much more associated in ACN (40–42) and therefore, more reactive.

The results presented above indicate that the ion association process plays an important role in the electroreduction of aromatic aldehydes and that the simple HMO method may be helpful in explaining the properties and reactivity of the radical intermediates.

The chemical rate constants for the addition of the muonium atom (Mu) across the vinyl double bonds of acrylamide, acrylic acid, acrylonitrile, methylmethacrylate, and styrene were determined in aqueous solution; they are, respectively, $k_M = 1.9 \times 10^{10} M^{-1} s^{-1}$, $1.6 \times 10^{10} M^{-1} s^{-1}$, $1.1 \times 10^{10} M^{-1} s^{-1}$, $9.5 \times 10^{9} M^{-1} s^{-1}$, and $1.1 \times 10^{9} M^{-1} s^{-1}$. Since muonium can be considered a very light isotope of hydrogen, the kinetic isotope effects, k_M/k_H, for acrylamide (1.1) and acrylonitrile (2.8) were calculated. The muonium rate constants of these monomers are also compared to those of hydroxyl and methyl radical additions where available. The muonium substituted free radical formed by reaction with styrene is represented by two peaks in the Fourier Transform of the μSR spectrum at 500, 1500, and 2500 G with a hyperfine coupling constant of 213.5 MHz. This spectrum shows that Mu addition to styrene occurs at the vinyl bond only and not at the benzene ring.

J. M. STADLBAUER, B. W. NG, D. C. WALKER, Y. C. JEAN et Y. ITO. Can. J. Chem. **59**, 3261 (1981).

On a déterminé en solution aqueuse, les constantes de vitesse chimique de l'atome de muonium (Mu) à travers la double liaison vinylique de l'acrylamide, de l'acide acrylique, de l'acrytonitrile, du méthacrylate de méthyle et du styrène. Ces constantes sont respectivement de $K_M = 1{,}9 \times 10^{10} M^{-1} s^{-1}$, $1{,}6 \times 10^{10} M^{-1} s^{-1}$, $1{,}1 \times 10^{10} M^{-1} s^{-1}$, $9{,}5 \times 10^{9} M^{-1} s^{-1}$ et $1{,}1 \times 10^{9} M^{-1} s^{-1}$. Puisque le muonium peut être considéré comme un isotope très léger de l'hydrogène, on a calculé les effets isotopiques cinétiques k_M/k_H pour l'acrylamide (1,1) et l'acrylonitrile (2,8). On a également comparé les constantes de vitesse du muonium avec ces monomères à celles qui sont disponibles pour les additions radicalaires de l'hydroxyle et du méthyle. Le radical libre substitué du muonium formé par la réaction avec le styrène est représenté par deux pics dans la transformation de Fourier du spectre μSR à 500, 1500 et 2500 G avec une constante de couplage hyperfin de 213,5 MHz. Le spectre révèle que l'addition du Mu sur le styrène se produit seulement au niveau de la double liaison vinylique et non sur le noyau benzénique.

[Traduit par le journal]

Introduction

The muonium atom (Mu), one ninth the mass of ^1H but with the same Bohr radius and ionization potential, can be considered a very light radioactive isotope of hydrogen. It can, therefore, be used as a hydrogen-like probe to study addition, redox, abstraction, and spin conversion reactions. Muonium is formed when an energetic positive muon (μ^+) abstracts an electron from the stopping media and combines with it to form a bound state. The muon, a product of a pion decay, has a 2.2 μs lifetime which allows enough time to study the chemical reactions of muonium in many chemical systems (1–3).

Muonium Spin Rotation (MSR), the method used to observe the presence of the atom, monitors the muonium spin precession frequency under external magnetic fields. The Larmor frequency for the Mu precession under a transverse magnetic field is 1.39 MHz/G, while the precession frequency for the free muon is 13.6 kHz/G. The factor of 102 between the two frequencies distinguishes Mu from muons in other chemical states. Further descriptions of the MSR technique have been detailed elsewhere (2).

Mu atoms have been observed to form in pure liquids such as water (3), alcohols (4), and hydrocarbons (5). The relatively long lived (up to 4 μs in water) precession signals of Mu in these pure liquids indicate that spin depolarization reactions between Mu and the liquids are relatively unimportant. However, if these liquids are used as solvents for various solutes of interest, the chemical reactivity of Mu towards those solutes can be easily measured. As the free triplet Mu reacts with the solute its precession signal is damped and a muonium decay constant, λ, can be obtained. From these decay constants second order chemical rate constants can be calculated and then compared with the related hydrogen atom rate constant (when available) to determine kinetic isotope effects.

Experimental

(A) MSR: Muonium Spin Rotation Measurements

At the M20 channel at TRIUMF a beam of 4.1 MeV surface muons was made to strike the sample target, which consisted of approximately 80 mL of solution contained in a shallow Teflon

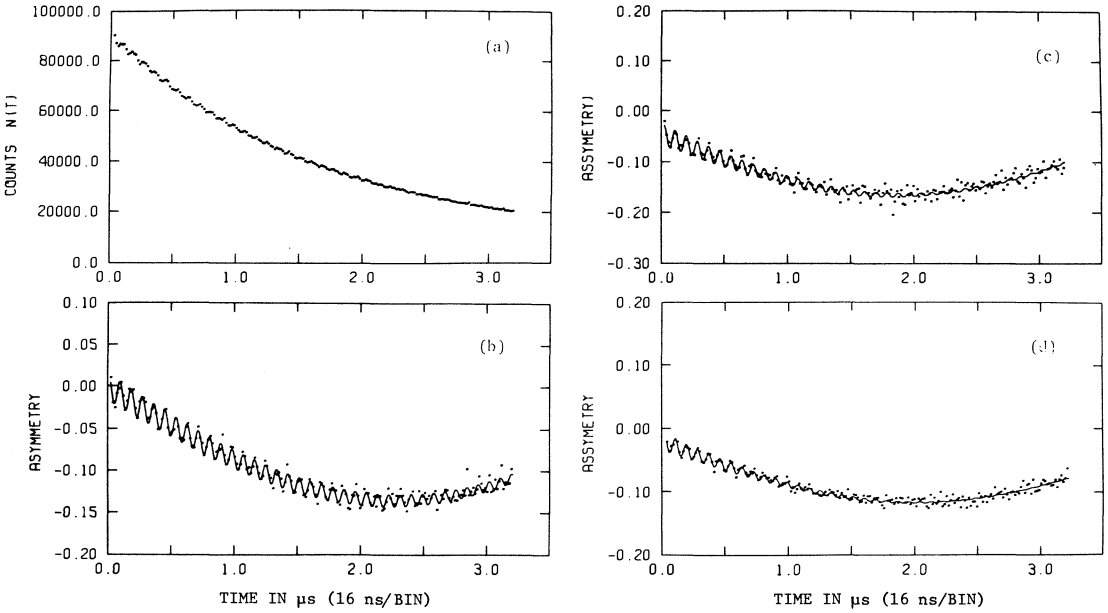

FIG. 1. (*a*) Raw data histogram for water at 8G before MINUIT fit; (*b*) the same data computer fitted to eq. [1]; (*c*) computer fitted histogram for 0.02 m*M* acrylamide; and (*d*) 0.05 m*M* acrylamide aqueous solution.

cell with 0.007 cm mylar as muon window. With a range of 150 mg cm^{-2} almost all of the incident muons came to rest in the target solution. Helmholtz coils provided transverse magnetic fields of 80 G for diamagnetic muon data and 8 G for paramagnetic muonium data.

The MSR experimental histograms were computer processed with a χ^2-minimization program (MINUIT) to fit an eight-parameter function. Equation [1] shows that function with the background and muon decay subtracted out.

$$[1]\quad A(t) = A_\mu \cos(\omega_\mu t + \phi_\mu) + A_M \exp(-\lambda t)\cos(\omega_M t - \phi_M)$$

where A_μ and A_M are the muon and muonium amplitudes, ω_μ and ω_M their frequencies, ϕ_μ and ϕ_M their initial phases, and λ the muonium spin polarization decay constant. Figure 1 shows typical histograms of both raw and fitted data. The bimolecular rate constant, k_M, for the reaction between muonium and the solute, of concentration [S], can be calculated from λ by eq. [2].

$$[2]\quad \lambda = \lambda_0 + k_M[S]$$

The decay constant for the pure water solvent, λ_0, has a value of about $(2.4 \pm 0.6) \times 10^5$ s^{-1} (4–6). The λ values for the separate left and right (or top and bottom, depending on field orientation) detectors are plotted against the solute concentration and the slope, k_M, of the best line determined.

(B) MRSR: Muonium Radical Spin Rotation

For an initial look at muonium radicals in pure styrene, high energy muons (24 MeV) were made to strike the samples sealed in glass cells held in transverse magnetic fields up to 2500 G. Dissolved oxygen was removed from the bulk monomer by the freeze–pump–thaw method before sealing. Resultant data were examined by a Fast Fourier Transform (FFT) computer program to obtain radical frequencies and the hyperfine coupling constant, as described elsewhere (7, 8). Similar radical studies in styrene were also performed using the surface muons in conjunction with the thin Teflon cells at fields up to 500 G.

(C) Chemicals

Acrylamide and acrylic acid were supplied by Eastman and were transferred directly from the reagent bottle. Acrylonitrile, methylmethacrylate, and styrene were purchased from Aldrich and purified before use. The acrylic acid contained 200 ppm *p*-methoxyphenol as an inhibitor. At the solute concentrations used, 5×10^{-5} *M* and 7.4×10^{-5} *M*, the inhibitor would be present only at $\sim 10^{-8}$ *M* so it could not contribute significantly to the decay of muonium because the reaction with acrylic acid turns out to be near the diffusion-controlled limit of 2×10^{10} M^{-1} s^{-1}.

All aqueous solutions were bubbled immediately before and during the experiment with high purity helium to remove dissolved oxygen. Because of the volatile nature of the acrylic and styrene monomers the gas was passed through a prebubbler containing a solution of the same concentration as the target sample.

Results

Table 1 shows the muonium rate constants, k_M, obtained in this study for the five monomers investigated. These values were obtained from the measurement of λ at two solute concentrations, prepared individually, and at each concentration there were two independent (left and right or top and bottom) histograms. Each value of k_M, therefore, arose from the averaging of four values of λ. Though the statistical error on each value of λ arising from the computer fits range, in these experiments, from 5% to 17%, the overall actual probable errors are taken to be about ±25%. As often transpires in MSR measurements there are unknown random irreproducibilities arising from

TABLE 1. Reaction rate data for Mu addition to vinyl monomers in aqueous solution

Monomer	[S]/M	$\lambda/10^6\ s^{-1}$	$k_M^*/10^{10}\ M^{-1}\ s^{-1}$
Acrylamide	2.0×10^{-5}	0.83	1.90±0.13
	5.0×10^{-5}	1.23	
Acrylic acid	5.0×10^{-5}	0.89	1.55±0.25
	7.4×10^{-5}	1.63	
Acrylonitrile	2.0×10^{-5}	0.45	1.14±0.20
	5.0×10^{-5}	0.88	
Methylmethacrylate	2.6×10^{-5}	0.58	0.95±0.19
	5.0×10^{-5}	0.80	
Styrene	5.0×10^{-5}	0.38	0.11±0.01
	8.0×10^{-5}	0.41	

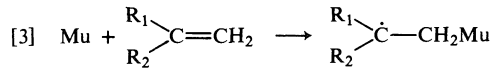
*Errors quoted are the computed statistical errors; but, as pointed out in the text, the actual reproducibilities may be ~±25 %.

the cell positioning, muon beam asymmetry, detector thresholds, background counts, sample contamination, and error in the evaluation of sample concentrations, which together seem to contribute some ±25% to the overall reliability of a k_M value (6). Within the broad context of rate constant data obtained by direct physical techniques or competitive rate methods, this level of reproducibility is quite good.

Figure 2 shows the FFT spectra of the styrene sample at 500, 1500, and 2500 G. At 1500 G the radical frequencies at 83.5 MHz and 130.1 MHz add to give the hyperfine coupling constant, A_μ = 213.6 MHz. The same coupling constant is obtained from the radical frequencies of 70.3 MHz and 143.2 MHz at 2500 G, and 92.3 MHz and 121.6 MHz at 500 G. Acrylonitrile and methylmethacrylate as pure liquids were examined briefly (~2 million events) and also showed muonium radicals. The FFT spectra indicated that the hyperfine coupling constants were 281 and 279 MHz respectively for acrylonitrile and methylmethacrylate.

Discussion

It can be seen that k_M ranges from $1\times10^{10}\ M^{-1}\ s^{-1}$ to $2\times10^{10}\ M^{-1}\ s^{-1}$ for the acrylic vinyl bonds and is $1\times10^{9}\ M^{-1}\ s^{-1}$ for styrene. The reaction type is undoubtedly that of addition to the vinyl bond. The net result of addition is likely to be the radical shown in [3],



where R_1 = H, R_2 = $CONH_2$ for acrylamide; R_1 = H, R_2 = CO_2H for acrylic acid; R_1 = H, R_2 = CN for acrylonitrile; R_1 = CH_3, R_2 = CO_2CH_3 for methylmethacrylate; and R_1 = H, R_2 = C_6H_5 for styrene. Roduner *et al.* (7) have shown that muonium radicals such as in reaction [3] produce a Fourier Transform spectrum containing three peaks. The most intense is the diamagnetic muon, the other two are due to the radical. The addition of the frequencies of these two radical peaks gives a value for the hyperfine coupling constant, a_μ, that is

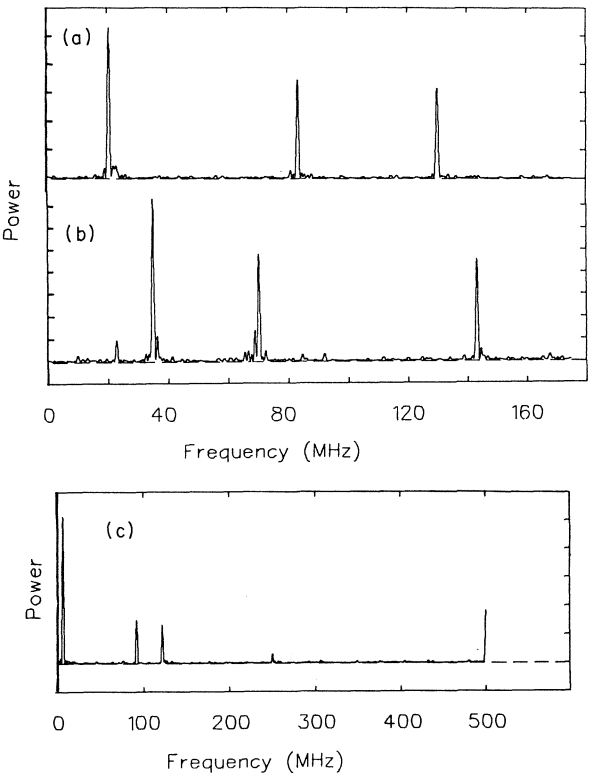


FIG. 2. Fast Fourier Transform spectra of styrene radical from muonium addition to vinyl bond; (*a*) at 1500G, (*b*) at 2500G, and (*c*) at 500G. The latter utilized surface (4.1 MeV) muons. (In the Fourier transform spectrum of (*c*) the peaks at 500 and 250 Hz should be ignored. They are spurious effects arising from the 1GHz clock as beat frequencies.)

†k_2 = methyl addition, k_1 = hydrogen abstraction by methyl radical. N.B. For muonium, this ratio is also $\sim10^3$, based on a comparison of maleic acid versus formate (6).

independent of the magnetic field. The styrene spectra presented in Fig. 2 clearly show that such a radical is produced in bulk styrene with a field independent coupling constant of $a_\mu = 213.5$ MHz. This observation strongly confirms (see later) that addition across the vinyl bond occurred. Furthermore, the evidence of Fig. 2(*c*) shows that only one radical is observed and that there is negligible production of cyclohexadienyl radicals which are expected to have hyperfine coupling constants of ~500 MHz (7). The radicals are observed in the μSR time-window of 10^{-7} to 10^{-5} s, so it is conceivable that they are not the primary radicals but result from rearrangements.

That "addition" rather than "abstraction" occurred is certainly indicated by these observed muonium radicals. This is also in accord with the kinetic data with regard to both the absolute rate constants and the kinetic isotope effect relative to H. Thus addition reactions typically have $k_M \sim 10^{10}\ M^{-1}$ s^{-1} whereas H-abstraction reactions have $k_M \sim 10^7$–$10^8\ M^{-1}$ s^{-1}; and additions have isotope effects close to unity whereas for abstraction of H-atoms k_M/k_H has been found to be of the order of 10^{-2} (2, 4, 6).

The k_M values obtained for the acrylic monomers ($1–2 \times 10^{10}\ M^{-1}$ s^{-1}) are similar to those determined by Percival *et al.* (4) for muonium addition to the vinyl bond in maleic and fumaric acids. The reaction with maleic acid has also been shown to have an activation energy of ~17 kJ mol^{-1}, corresponding to the activation for diffusion in water (6). We conclude, therefore, that the reaction with the acrylic compounds is within a factor of two or so of the diffusion-controlled limit. The question then arises, why do the various acrylic monomer rates differ slightly and what factors, such as electrophilicity and steric hindrance, reduce the rate constant slightly below the diffusion limited value? In the case of styrene the k_M value is more than one order of magnitude less than the diffusion limited value; but here π-delocalization may play a dominant role. A comparison of these initiation rates with those obtained previously for H, OH, and CH_3 radicals could also be of importance. These matters are discussed below.

From Table 1 the order of reactivity of the four acrylic monomers can be seen to be methylmethacrylate (MMA) ≤ acrylonitrile (AN) < acrylic acid (AA) < acrylamide (AM). MMA, the least reactive of the four, has the least accessible double bond due to the "blocking" effect of the methyl group on the α carbon. The other three are three-carbon straight-chain conjugated compounds with the vinyl bond equally open to attack. Of these, acrylamide and acrylic acid, having the carbonyl oxygen to withdraw electron shielding from the target carbons, would be expected to react slightly faster than acrylonitrile with muonium—a nucleophile. Between acrylamide and acrylic acid a difference lies in that unbuffered acrylic acid solution (pK_a =4.25) (9), is 64% dissociated at a solute concentration of $5.0 \times 10^{-5}\ M$. One would expect to see a somewhat slower reaction rate for the acid anion, compared to the undissociated acid, because the delocalized anionic charge could increase the carbon target shielding.

Styrene, with $k_M = 1.1 \times 10^9\ M^{-1}$ s^{-1}, is the least reactive of the five monomers studied. It also has the highest degree of conjugation and the largest π-delocalization of any of these monomers. Therefore, we must conclude that this delocalization stabilizes the molecule thereby reducing the efficiency of muonium addition.

From absorption band labelling, Swallow (10) inferred that for H atom addition reactions with styrene, the hydrogen possibly added to the ring 85% of the time and to the vinyl bond 15% of the time. This indicates that the conjugated π-electron cloud is delocalizing the H atom attack over the

For personal use only.

entire molecule. This, however, we believe to be incorrect. If H adds to the ring as well as to the vinyl bond of styrene then Mu should also. One would therefore expect two radicals to be formed with distinctive hyperfine coupling constants, one around 200 MHz for the vinyl radical and one around 500 MHz for the ring radical. Roduner *et al.* have shown that the cyclohexadienyl radicals from the Mu addition to benzene and the tetramethylethane radical from the Mu addition to tetramethylethylene have coupling constants of 514.6 MHz and 161.3 MHz, respectively (7, 8). We have calculated the coupling constants of the styrene, acrylonitrile, and methylmethacrylate radicals to be 213.6 MHz, 281 MHz, and 279 MHz, respectively. From the tetramethylethane and acrylic radical constants, almost half the magnitude of the cyclohexadienyl radical coupling constant, we conclude that Mu is adding to the vinyl double bond of styrene rather than to the molecule's benzene ring.

Table 2 lists some rate constants for hydrogen and hydroxyl additions, and methyl radical rate constant ratios, for these same monomers. The only H atom rate constants found were for acrylamide and acrylonitrile, $k_H = 1.8 \times 10^{10}\ M^{-1}\ s^{-1}$ (11) and $(4.0 \pm 0.5) \times 10^9\ M^{-1}\ s^{-1}$ (12), respectively. Using these we calculate kinetic isotope effects, k_M/k_H, of 1.1 ± 0.4 for acrylamide and 2.8 ± 1.0 for acrylonitrile. The first agrees nicely with the k_M/k_H of 1.4 calculated for maleic acid (4, 6) which indicate no mass effect on these addition reactions. At the diffusion-controlled limit, it is a matter of current interest as to whether the Stokes–Einstein relationship should apply to particles as small as H and Mu, or whether there should be an isotope effect of 3, as with acrylonitrile, because the mean velocity of Mu (with a mass 1/9 that of H) is three times that of H (6). However, there is no obvious reason for the k_M/k_H values for these two addition reactions to be different. Therefore, and because of the limited amount of H atom addition rate constant data, we reserve judgement on the matter of kinetic isotope effects at this time.

The hydroxyl radical data shows a trend that points toward OH being less nucleophilic than Mu. For OH the order of reactivity towards the monomers is reversed, with styrene having a rate constant $k_{OH} = 6 \times 10^9\ M^{-1}\ s^{-1}$ (13, 14) while acrylamide and acrylic acid have the smaller specific rates at $2 \times 10^9\ M^{-1}\ s^{-1}$ (15) and $1.4 \times 10^9\ M^{-1}\ s^{-1}$ (13, 16), respectively. This is also expected as the hydroxyl oxygen will decrease that radical's nucleophilicity compared to hydrogen or muonium atoms. The increased reactivity of styrene toward the more electrophilic hydroxyl radical compared to the acrylic monomers is further supported by the earlier cationic, anionic, and radical initiated polymerization studies (17). These data show that (*i*) styrene and the acrylics polymerize equally when radical initiated (50:50 mixtures of styrene and MMA produce a copolymer containing equal proportions of the two monomers), (*ii*) styrene prefers cationic polymerization (the same 50:50 mixture produces only polystyrene), and (*iii*) MMA prefers anionic polymerization (the polymer produced contains only MMA). The cationic propagation of styrene shows that it undergoes electrophilic attack, while the anionic data show that MMA, and presumably the other acrylic monomers, undergo nucleophilic attack. A comparison of our muonium data with the published hydroxyl (electrophilic) rate data therefore supports the conclusion that muonium acts as a nucleophilic reagent in its addition reactions.

In the case of the methyl radical additions, the rate constant for the addition, k_2, is given relative to the rate constant for the H-abstraction by the radical, k_1 (18, 19). The three monomer–methyl reaction constant ratios listed (see Table 2) for acrylonitrile, methylmethacrylate, and styrene show the same trend in reactivity as do the muonium specific rates. In fact the ratio of the muonium rate constants for acrylonitrile and methylmethacrylate (k_MAN/k_MMMA) and the ratio of their methyl addition constants (k_2AN/k_2MMA) are both 1.2. This ratio of the reactivities of these two monomers might be a useful indicator of the steric hindrance of the H vs. CH_3 substitution on the α carbon. Such a comparison between styrene and MMA, however, does not hold true. This is expected because the hydrogen addition band labelling studies (10) indicate that all accessible carbons in styrene are attacked and there is a higher probability for H atom abstraction from styrene by methyl radicals than from MMA. The latter factor would decrease the apparent reactivity gap between styrene and MMA for methyl additions (k_1 styrene > k_1MMA) but not for muonium additions.

Conclusion

Though the five muonium rate constants reported are rather similar, we believe the preceding arguments based on electrophilic and steric factors can explain their differences and their falling just short of the diffusion-controlled limit. Although we reserve judgement on the kinetic isotope effects in the Mu compared to H addition reactions, the only ones for which H atom data are available are close to the diffusion controlled limit. It would be interesting to know k_M/k_H for the styrene reaction

which, at least for Mu, occurs at more than an order of magnitude slower than the collision frequency due to the π-delocalization.

Since there is a scarcity of data on the initiation of polymerization of monomers by the simplest atom, the hydrogen atom, perhaps these muonium atom data will fill a real need. Once the kinetic isotope effect is fully understood, the MSR method could supercede the more tedius H-atom techniques in this and other areas.

Triphenylphosphine complexes of cadmium(II) perchlorate, nitrate, and trifluoroacetate preparation, characterization, and spectral studies

RAM G. GOEL AND NARENDRA K. JHA[1]

Guelph Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received May 11, 1981

RAM G. GOEL and NARENDRA K. JHA. Can. J. Chem. **59**, 3267 (1981).

1:2 complexes, $CdX_2(PPh_3)_2$, where X = ClO_4, NO_3, CF_3CO_2 and 1:1 complex, $Cd(CF_3CO_2)_2PPh_3$, have been isolated and characterized by elemental analysis and by vibrational and $^{31}P—\{^1H\}$ nmr spectral measurements. Conductance measurements show that the complexes behave as non-ionic species in dichloromethane. The vibrational spectra of the perchlorato complex are consistent with a six-coordinate structure in the solid state as well as in solution but it is difficult to deduce the structures of the nitrato and trifluoroacetato complexes from the spectral data. Assignments for the metal–ligand stretching frequencies for all the four complexes have been proposed. The $^{31}P—\{^1H\}$ nmr spectra of the four complexes have been discussed. Formation of the 1:3 and 1:4 complexes, $Cd(ClO_4)_2(PPh_3)_3$ and $Cd(ClO_4)_2(PPh_3)_4$, in solution, has also been established by $^{31}P—\{^1H\}$ nmr spectral measurements.

RAM G. GOEL et NARENDRA K. JHA. Can. J. Chem. **59**, 3267 (1981).

On a isolé les complexes 1:2 du type $CdX_2(PPh_3)_2$ où X = ClO_4, NO_3, CF_3CO_2 et le complexe 1:1 du type $Cd(CF_3CO_2)_2$ PPh_3 et on les a caractérisé par l'analyse élémentaire et par les mesures des spectres de vibration et de rmn du $^{31}P—\{^1H\}$. Des mesures de conductance montrent que les complexes se comportent dans le dichlorométhane comme des espèces non ioniques. Les spectres de vibration du complexe perchloré sont en accord avec une structure hexacoordonnée aussi bien à l'état solide qu'en solution, mais il est difficile de déduire la structure des complexes nitrés ou trifluoroacétyés à partir des données spectrales. On a identifié les fréquences d'élongation métal–ligand des quatres complexes. On discute des spectres de rmn du $^{31}P—\{^1H\}$ des quatres complexes. On a également mis en évidence la formation des complexes 1:3 et 1:4 du type $Cd(ClO_4)_2(PPh_3)_3$ et $Cd(ClO_4)_2(PPh_3)_4$ en solution en utilisant les données spectrales de la rmn du $^{31}P—\{^1H\}$.

Introduction

Tertiary phosphine complexes of cadmium(II) and mercury(II) halides were first reported (1) more than 40 years ago. In the intervening years phosphine complexes of several other mercury(II) derivatives such as pseudohalides (2–11), carboxylates (12–16), nitrate (2, 17–19), and perchlorate (2, 20, 21) have been prepared and investigated by spectroscopic as well as X-ray diffraction studies. Surprisingly, phosphine complexes of cadmium(II) derivatives other than the halides have remained virtually unexplored.

Cadmium(II) halides are known to form only 1:2 complexes with triphenyl phosphine (1, 22) as well as with *para*- and *meta*-substituted triarylphosphines (23). These complexes are indicated (22–24) to be molecular species with a pseudotetrahedral coordination around cadmium. Recent work in this laboratory showed that cadmium(II) thiocyanate, unlike cadmium(II) halides, forms only 1:1 complexes with triarylphosphines (25) as well as with trialkylphosphines such as tricyclohexylphosphine (25) and tri-*tert*-butylphosphine (26). The work reported herein was undertaken to seek information on triphenylphosphine complexes of cadmium(II) salts of oxy-anions such as perchlorate, nitrate, carboxylates, and to compare the properties of such complexes with the analogous mercury(II) complexes.

Results and Discussion

Cadmium(II) perchlorate as well as the nitrate, like the halides, gave only the 1:2 complexes upon treatment with triphenylphosphine. Attempts to isolate 1:1 complex of either salt gave the 1:2 complex and the unreacted cadmium(II) salt. The failure to isolate 1:1 complexes of cadmium(II) perchlorate and nitrate is thus in marked contrast with the behaviour of mercury(II) perchlorate and nitrate both of which form readily isolable 1:2 as well as 1:1 complexes (2) with triphenylphosphine. Cadmium(II) trifluoroacetate, like mercury(II) trifluoroacetate (14), readily gave 1:1 as well as 1:2 complexes. However, cadmium(II) acetate, in marked contrast with mercury(II) acetate (14), did not react with triphenylphosphine as shown by the infrared and $^{31}P—\{^1H\}$ nmr spectral measurements of the products obtained upon treating cadmium(II) acetate with varying amounts of the phosphine.

The analytical data, melting points, molar conductances, and the characteristic infrared frequencies due to the anionic groups for the four complexes isolated in the present study are given in Table 1. All four complexes are white crystalline solids. The

§Compound decomposed.

trifluoroacetato complexes are air-stable but the nitrato and perchlorato complexes are sensitive to atmospheric moisture. All the complexes are soluble in polar organic solvents like acetone and dichloromethane and insoluble in pentane or light petroleum ether. The complexes of cadmium(II) trifluoroacetate are also soluble in benzene. Molar conductance of 10^{-3} *M* solutions of the trifluoroacetato complexes, in dichloromethane, were less than 0.4 ohm^{-1} cm^2 mol^{-1} indicating no ionization of these complexes in solution. The Λ_M values for the nitrato and perchlorate complexes were 3 and 5 ohm^{-1} cm^2 mol^{-1}, respectively, showing slight ionization; the molar conductance for the 1:1 electrolyte NEt_4ClO_4, in dichloromethane, was found to be 40 $ohms^{-1}$ cm^2 mol^{-1}.

The infrared spectra of the complexes were examined in the 4000 to 50 cm^{-1} region, in the solid state. The infrared frequencies due to the anionic ligands for each complex were assigned with reasonable certainty by comparing the spectra with that of free phosphine. As shown by the data in Table 1, the infrared spectrum of the perchlorate complex showed strong bands at 1165, 1120 and 998, and 888 cm^{-1} and medium bands at 630, 618, 605, and 484 cm^{-1} due to the vibrations of the perchlorate groups. It is, therefore, evident that the perchlorate groups in this complex act as bidentate ligands (27*a*). The infrared spectrum of a dichloromethane solution of the complex in the 1200 to 800 cm^{-1} region showed bands similar to those observed in the solid state; the perchlorate bands were at 1160, 1125, 998, and 890 cm^{-1}. Thus, the observed reduction in the perchlorate symmetry cannot be attributed to the solid state effects and the complex is indicated to contain octahedrally coordinated cadmium in the solid state as well as in solution. The infrared spectrum of the nitrato complex showed strong or medium bands at 1465, 1266, 1017, 810, 736, and 685 cm^{-1} due to the internal vibrations of the nitrate groups (27*b*). Thus, the symmetry of the nitrate groups in the nitrato complex is also not higher than C_{2v}. Although it is difficult to distinguish between unidentate and bidentate nitrato groups on the basis of infrared data alone, the observed infrared frequencies due to the nitrate groups in $Cd(NO_3)_2(PPh_3)_2$ are similar to those reported for $Cu(NO_3)(PPh_3)_2$ (28) which contains bidentate nitrato group as shown by an X-ray crystallographic study (29). The infrared bands at 1465 and 1266 cm^{-1} observed for $Cd(NO_3)_2(PPh_3)_2$ in the solid state were also observed in the spectrum of its solution in dichloromethane. Thus, like the perchlorato complex, the nitrato complex is also indicated to maintain its solid state structure in solution.

The vibrational frequencies due to the internal vibrations of the trifluoroacetate group have been established and attempts have been made to correlate these frequencies with the mode of its bonding (30). Since the number of infrared or Raman bands observed for a trifluoroacetate group is independent of its environment, the antisymmetric and symmetric CO_2 stretching frequencies and their separation have been used to infer the mode of its bonding. As shown by the data in Table 1, the infrared spectra for both the 1:1 and 1:2 complexes of cadmium(II) trifluoroacetate showed bands at ca. 1650 and 1690 cm^{-1} which are attributable to the antisymmetric CO_2 stretching vibration of the coordinated trifluoroacetate groups. The relative intensities of these bands in the two complexes were, however, reversed. Unfortunately, the symmetric CO_2 stretching frequency could not be ascertained for either compound due to the presence of several phenyl bands in this region. It is, therefore, difficult to ascertain the mode of bonding of the trifluoroacetate groups in either complex. The antisymmetric CO_2 stretching frequencies for both the complexes were not significantly altered in

solution in dichloromethane. Thus, the structures of these complexes, like the perchlorate and the nitrato complexes, do not seem to be altered in going from solid state to solution. The ^{19}F nmr spectra of both the 1:1 and 1:2 complexes at 213 K were almost identical and showed a single resonance at ca. 74.15 ppm upfield of $CFCl_3$. Although some workers have claimed (31) that the ^{19}F chemical shift can be used to ascertain the mode of coordination of the trifluoroacetate group, the ^{19}F chemical shifts for trifluoroacetates of some twenty different metals are reported (30) to fall in the narrow range of −74 to −79 ppm. We, therefore, believe that the ^{19}F nmr data also do not seem to provide much useful structural information.

The observed infrared as well as Raman frequencies for the four complexes in the 400 to 50 cm^{-1} region, in the solid state, are listed in Table 2. Since neither the perchlorate nor the nitrate group is expected to give rise to any infrared or Raman frequency in this region, the observed frequencies for the perchlorato and the nitrato complexes are attributable either to the internal vibrations of the phosphine (32) or to the skeletal vibrations of the complex or to the lattice modes. The infrared and Raman frequencies due to the internal vibrations of triphenylphosphine are identified, with reasonable certainty, by comparison of the spectra of the complexes with those for free phosphine. Although little is known about skeletal vibrational frequencies for cadmium(II) complexes, the strong and broad infrared band at 190 cm^{-1} for the perchlorato complex and a similar band at 205 cm^{-1} for the nitrato complex are tentatively assigned to the vibrations involving stretching of the Cd—O bonds. The assignments are consistent with those for the Cd—N stretching frequencies for cadmium(II) thiocyanate (33) which has been shown to contain octahedrally coordinated cadmium(II) (34). A lower Cd—O stretching frequency for the perchlorato complex is consistent with a weaker coordinating ability of the perchlorate ligand. The Raman bands at 141 and 124 cm^{-1} are assigned to the symmetric Cd—P stretching frequency by comparison with the assignments for the cadmium(II) halide complexes, $CdX_2(PR_3)_2$ (23). The higher Cd—P stretching frequency for the perchlorato complex is consistent with its lower Cd—O stretching frequency. Assignments for the infrared bands at 154 and 90–70 cm^{-1} for the perchlorato complex and at 145 and 65 cm^{-1} for the nitrato complex are not so clear-cut.

The strong infrared band in the 270–280 cm^{-1} region in the spectra of the trifluoroacetato complexes is attributable to an internal mode of the CF_3CO_2 group (30). The strong infrared bands at

188 and 144 cm^{-1} for the 1:1 complex and similar bands at 168 and 147 cm^{-1} for the 1:2 complex are tentatively assigned to the stretching modes involving Cd—O bonds; assignments for the remaining infrared bands are uncertain. The Raman bands at 152 and 128 cm^{-1} are assigned to the Cd—P stretching frequency.

The ^{31}P—$\{^1H\}$ nmr spectra of the four complexes, like those for the cadmium(II) halide complexes, at ambient temperatures, consisted of a single resonance without any satellite showing that the complexes undergo fast ligand exchange on the nmr time scale. Well-resolved satellites due to the ^{113}Cd—^{31}P and ^{111}Cd—^{31}P spin–spin couplings were observed at 213 K for the perchlorato and the trifluoroacetato complexes but the nitrato complex had to be cooled to 183 K to observe the satellites. The observed ^{31}P nmr chemical shifts and the $^1J(^{113}Cd—^{31}P)$ and $^1J(^{111}Cd—^{31}P)$ values for the complexes are listed in Table 3. As can be seen from the data in Table 3, the ratio $^1J(^{113}Cd—^{31}P)/^1J(^{111}Cd—^{31}P)$ is in excellent agreement with the theoretical value of 1.046. The data also show that the magnitude of $^1J(Cd—P)$ decreases in the order: $ClO_4 > NO_3 > CF_3CO_2$. The effective nuclear charge at cadmium is also expected to decrease in this order. Thus, the magnitude of $^1J(Cd—P)$ for these complexes, like the cadmium(II) halide complexes (23), increases with an increase in the effective nuclear charge at the cadmium. Consistent with this trend, the magnitude of $^1J(^{111}Cd—^{31}P)$ for the 1:1 complex, $Cd(CF_3CO_2)_2PPh_3$, is markedly higher than that for the 1:2 complex.

Contrary to the views of other workers (15, 35), recent work in this laboratory (14, 23) has shown that there is no meaningful correlation between the coordination chemical shift, $\Delta\delta$ ($\delta_{complex} - \delta_{PPh_3}$), and the magnitude of metal phosphorus nuclear spin–spin coupling, $^1J(M—P)$. This is further supported by the data in Table 3 which show that although the magnitude of $^1J(Cd—P)$ for $Cd(CF_3CO_2)_2PPh_3$ is markedly higher than that for $Cd(CF_3CO_2)_2(PPh_3)_2$, the $\Delta\delta$ values for the two complexes are not significantly different.

Low temperature ^{31}P—$\{^1H\}$ nmr spectral measurements on solutions containing $Cd(ClO_4)_2(PPh_3)_2$ and varying amounts of PPh_3 provided evidence for the formation of 1:3 as well as 1:4 complexes. The spectral parameters for these complexes are included in Table 3. The ^{31}P—$\{^1H\}$ nmr spectrum of a solution containing $Cd(ClO_4)_2(PPh_3)_2$ and PPh_3, in 1:1 mole ratio, at 213 K, consisted of a main resonance (δ = 9.54 ppm) flanked by satellite doublets on each side due to ^{113}Cd—^{31}P and ^{111}Cd—^{31}P spin–spin coupling; the $^1J(^{113}Cd—^{31}P)$ and $^1J(^{111}Cd—^{31}P)$ values were 1574 and 1504 Hz respectively. From the marked decrease in the $^1J(Cd—P)$ values (as compared to those observed for the 1:2 complex) and the absence of any other ^{31}P resonance, it is evident that the 1:2 complex is completely converted into the 1:3 complex upon addition of one mole-equivalent of PPh_3. Addition of another mole-equivalent of PPh_3 to the solution gave a spectrum showing a main resonance (δ = 9.54 ppm) with two satellite doublets on each side, corresponding to $^1J(^{113}Cd—^{31}P)$ values of 1574 and 1129 Hz and $^1J(^{111}Cd—^{31}P)$ values of 1504 and 1078 Hz, respectively. Another resonance peak (δ = −7.84 ppm) with no satellite was also present in the spectrum. The latter resonance signal was about half as intense as the former and is undoubtedly due to free PPh_3. The observed $^1J(Cd—P)$ values are thus indicative of the presence of both $Cd(ClO_4)_2(PPh_3)_3$ and $Cd(ClO_4)_2(PPh_3)_4$. Relative intensities of the satellite signals due to the 1:3 and 1:4 complexes indicted that the 1:4 complex undergoes considerable dissociation as represented by the equation given below and that the equilibrium lies towards the left.

$$Cd(ClO_4)_2(PPh_3)_3 + PPh_3 \rightleftharpoons Cd(ClO_4)_2(PPh_3)_4$$

The ^{31}P—$\{^1H\}$ nmr spectrum of a solution containing $Cd(ClO_4)_2(PPh_3)_2$ and PPh_3 in 1:4 mole ratio showed resonances at 9.64 and −7.8 ppm with almost equal intensity. Two satellite doublets showing the presence of both the 1:3 and 1:4 complexes were still present on each side of the 9.64 ppm peak but the intensity of the satellite due to the 1:4

For personal use only.

complex was about twice that the satellites due to 1:3 complex. The $^1J(^{113}Cd—^{31}P)$ or $^1J(^{111}Cd—^{31}P)$ values for the $Cd(ClO_4)_2(PPh_3)_2$, $Cd(ClO_4)_2(PPh_3)_3$, and $Cd(ClO_4)_2(PPh_3)_4$ complexes are approximately in the 1:0.66:0.50 ratio. If one assumes that the Cd—P bonds in the 1:2 complex use *sp* hybrid cadmium orbitals, the Cd—P bonds in the 1:3 and 1:4 complexes are indicated to use sp^2 and sp^3 hybrid cadmium orbitals, respectively. Similar $\Delta\delta$ values for the three perchlorate complexes provide further support to our proposal that no meaningful correlation exists between $\Delta\delta$ and the magnitude of $^1J(M—P)$.

The $^{31}P—\{^1H\}$ nmr spectrum of a solution containing $Cd(NO_3)_2(PPh_3)_2$ and one mole-equivalent of PPh_3 showed a broad resonance which was accompanied by a broad and unresolved satellite peak on each side. Unfortunately, the spectrum could not be recorded at a lower temperature which caused precipitation of the complex. $^{31}P—\{^1H\}$ nmr spectrum of solutions containing $Cd(CF_3CO_2)_2(PPh_3)_2$ and PPh_3, in 1:1, 1:2, and 1:3 mole ratios, gave a broad resonance signal without any satellites due to $^{113}Cd—^{31}P$ or $^{111}Cd—^{31}P$ spin–spin coupling at 213 K or 183 K. At 178 K, the spectrum showed broad resonances due to the 1:2 complex and free phosphine indicating no reaction between the two components. Addition of a large excess of phosphine (1:8 mole ratio) gave a spectrum showing a broad single resonance.

Experimental

Materials and Solvents

Triphenylphosphine was recrystallized twice from ethanol and its purity was established by ^{31}P nmr measurement. Reagent grade cadmium(II) perchlorate hexahydrate, cadmium(II) nitrate tetrahydrate, silver trifluoroacetate, and triethylorthoformate were used as received. The solvents were purified by standard methods.

Preparations of the Complexes

Complexes of Cadmium(II) Perchlorate

$Cd(ClO_4)_2 \cdot 6H_2O$ (1 mmol) was dissolved in triethylorthoformate and the solution was allowed to stand for 2 h in an atmosphere of dry nitrogen. Triphenylphosphine (2 mmol) was added slowly, with stirring, to this solution to give a clear solution which after standing for an hour yielded white crystalline powder of $Cd(ClO_4)_2(PPh_3)_2$. The product was filtered, washed with pentane, and dried *in vacuo*. Attempts to prepare 1:1 or 1:3 complexes by a similar procedure also gave the 1:2 complex as shown by the infrared and $^{31}P—\{^1H\}$ nmr data.

Complexes of Cadmium(II) Nitrate

$Cd(NO_3)_2 \cdot 4H_2O$ (1 mmol) was dissolved in triethylorthoformate and the solution was left to stand for 2 h under dry nitrogen. A solution of triphenylphosphine (2 mmol) in ethanol was added slowly, with stirring to the above solution and the resulting mixture was cooled in an ice bath to give $Cd(NO_3)_2(PPh_3)_2$ as white crystalline powder which was filtered, washed with pentane, and dried *in vacuo*. Attempts to prepare the 1:1 complex following a similar procedure gave a white solid which gave correct C, H, and N analyses for $Cd(NO_3)_2PPh_3$ but the infrared and $^{31}P—\{^1H\}$ nmr spectra as well as the X-ray powder photograph of the product showed it to be a mixture of $Cd(NO_3)_2(PPh_3)_2$ and $Cd(NO_3)_2$.

Complexes of Cadmium(II) Trifluoroacetate

A solution of cadmium(II) trifluoroacetate (1 mmol) was prepared from the reaction of silver trifluoroacetate with cadmium(II) iodide in ethanol. Precipitated silver iodide was filtered off and a solution of triphenylphosphine (2 mmol) in ethanol was added dropwise to the filtrate with stirring. White precipitate of $Cd(CF_3CO_2)_2(PPh_3)_2$ was obtained upon concentrating the reaction mixture *in vacuo*. The product was washed with pentane and recrystallized from a mixture of dichloromethane and pentane.

To a solution of $Cd(CF_3CO_2)_2$ (1 mmol) in ethanol (prepared in the same way as above), a solution of triphenylphosphine (1 mmol) in ethanol was added dropwise, and the mixture was stirred for an hour to give a clear solution. Removal of the solvent gave a white solid which was recrystallized from a mixture of ethanol and petroleum ether to give pure $Cd(CF_3CO_2)_2PPh_3$.

Physical Measurements

Microanalyses were performed by Guelph Chemical Laboratories, Guelph. Melting points were determined with a Gallenkamp melting point apparatus. Conductance measurements were made at 25°C using a Yellow Springs conductivity bridge and a glass conductivity cell with platinized platinum electrodes. Infrared spectra were recorded in the 4000–50 cm^{-1} region using a Perkin-Elmer 180 spectrophotometer. Spectra, in the solid state, were measured on mulls in Nujol and halocarbon oil using KRS-5 windows or polyethylene discs. Solution spectra were recorded using 0.1 mm path length demountable liquid cells with AgBr windows. Raman spectra were measured in the solid state with a Jarrell Ash spectrophotometer using 5145A exciting line of an argon ion laser. The infrared and Raman frequencies are accurate within ± 2 cm^{-1}. $^{31}P—\{^1H\}$ and ^{19}F nmr spectra were measured in the Fourier-transform mode using Bruker WP-60 and Bruker HFX-90 spectrometers, respectively. All the measurements were carried out on solutions in dichloromethane containing 10% $CDCl_3$. External H_3PO_4 and $CFCl_3$ were used as references for the ^{31}P and ^{19}F nmr spectral measurements, respectively. The positive chemical shifts are downfield from the reference.

Nucleophilic substitution of 5,5-dimethyl-2-cyclopentenyl derivatives. Lack of S_N2' reaction[1]

KARL R. KOPECKY AND CYRIL LEVINE

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2E1

Received April 3, 1981

KARL R. KOPECKY and CYRIL LEVINE. Can. J. Chem. **59**, 3273 (1981).

Treatment of tetramethyl-1,3-cyclobutanedione with two equivalents of allyl oxide anion at 140°C yields 2,2-dimethyl-4-pentenoic acid which is cyclized via the acid chloride with aluminum chloride to 5,5-dimethyl-2-cyclopentenone, **4**. Reduction of **4** with aluminum hydride provides 5,5-dimethyl-2-cyclopentenol **1**-OH which is pyrolyzed to 5,5-dimethyl-1,3-cyclopentadiene in dimethylsulfoxide. Reduction of **4** with tri-*t*-butoxyaluminum hydride at −70°C gives 2,2-dimethylcyclopentanone.

The 2,6-dichlorobenzoate ester of **1**-OH failed to yield S_N2' products under a variety of conditions. The rate constants for solvolysis of the *p*-nitrobenzoate esters of **1**-OH, 2-cyclopentenol and *Z*-2-methyl-4-hexene-3-ol in 80% ethanol at 80°C are 20.2, 523, and 0.63×10^{-6} s^{-1}, respectively, and the main products of solvolysis are 5-ethoxy-3,3-dimethylcyclopentene, 3-ethoxycyclopentene, and *E*-2-ethoxy-5-methyl-3-hexene, respectively. There is steric hindrance to solvation during ionization of the *p*-nitrobenzoate of **1**-OH.

KARL R. KOPECKY et CYRIL LEVINE. Can. J. Chem. **59**, 3273 (1981).

La tétraméthylcyclobutanedione-1,3 réagit avec deux équivalents d'anion allyloxyde à 140° en donnant l'acide diméthyl-2,2 pentène-4 oique. Ce dernier réagit avec le chlorure d'aluminium en donnant le chlorure d'acide qui par cyclisation conduit à la diméthyl-5,5 cyclopentène-2 one (**4**). La réduction du composé **4** par l'hydrure d'aluminium permet d'obtenir le diméthyl-5,5 cyclopentene-2 ol (OH-**1**) que l'on pyrolyse en diméthyl-5,5 cyclopentadiène-1,3 dans le diméthylsulfoxyde. La réduction du composé **4** par l'hydrure de tri-*tert*-butoxyaluminium à 70°C donne la diméthyl-2,2 cyclopentanone.

Soumis à diverses conditions, l'ester dichloro-2,6 benzoate de OH-**1** n'a pas donné de produits de type S_N2'. Les constantes de vitesse des solvolyses des esters *p*-nitrobenzoates du OH-**1**, du cyclopentène-2 ol et du (*Z*)-méthyl-2 hexène-4 ol-3 à 80°C dans l'éthanol à 80% sont respectivement 20.2, 523 et 0.63×10^{-6} s^{-1} et les produits principaux de ce solvolyses sont respectivement l'éthoxy-5 diméthyl-3,3 cyclopentène, l'éthoxy-3 cyclopentène et le (*E*)-éthoxy-2 méthyl-5 hexène-3. Il y a un encombrement stérique à la solvatation lors de l'ionisation du *p*-nitrobenzoate de OH-**1**.

[Traduit par le journal]

The recent flurry of activity in the study of the S_N2' reaction (1) prompts the present report of the unsuccessful attempt to observe this reaction in the 5,5-dimethyl-2-cyclopenten-1-yl system **1**, reaction [1],

[1] 
1 **2**

using conditions under which the corresponding 6-alkyl-2-cyclohexen-1-yl derivatives produce S_N2' products (2). In the latter reactions there was a *syn* relationship between the entering and leaving groups. However, a possible *anti* reaction might have been hindered because of a possible unfavorable conformation of the cyclohexenyl system chosen (3). The present research was prompted by a desire to investigate the stereochemistry of the S_N2' reaction in a system much more rigid than the cyclohexenyl system and in which there would be no impediment to an *anti* reaction. Use of racemic **1** would have given no information about the stereochemistry of the reaction, but had an S_N2' reaction been observed for racemic **1** further studies with optically active **1** would have been carried out.

While the original objective of this study was not met an efficient synthesis for 2,2-dimethyl-4-pentenoic acid **3** was developed during the course of this work. This allows 2,2-dimethylcyclopentanone **5** and 5,5-dimethyl-1,3-cyclopentadiene **6** to be easily prepared on a large scale. The solvolysis of the *p*-nitrobenzoate ester **1**-OPNB and two analogues was also studied briefly.

Results

The preparation of 5,5-dimethyl-2-cyclopenten-1-ol **1**-OH, Scheme 1, proceeds via cyclization of the acid chloride of **3** with aluminum chloride. Large amounts of **3** can be prepared readily in a one-pot reaction with inexpensive materials by treatment of tetramethylcyclobutan-1,3-dione with two equivalents of allyl oxide anion at 140°C. This reaction probably represents the most convenient large scale synthesis of **3** (4) using inexpensive, readily available materials, and is based on the observation (5) that allyl 2,2,4-trimethyl-3-oxopentanoate is cleaved by methoxide ion to a

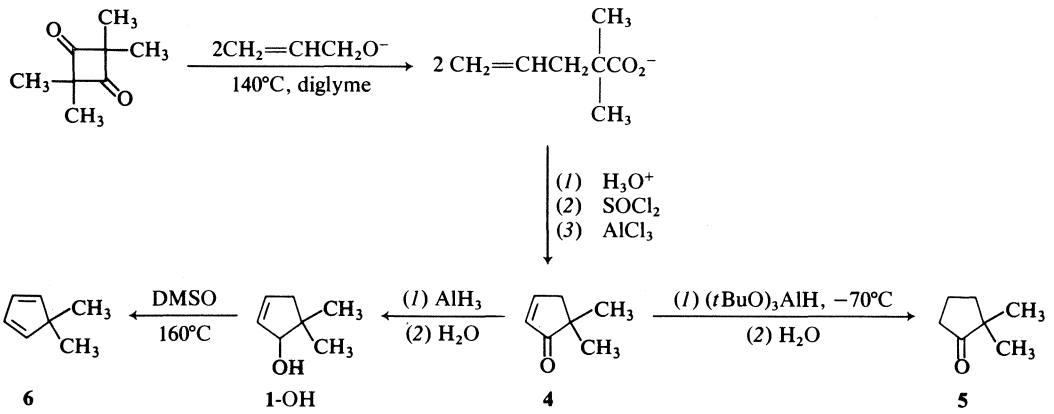
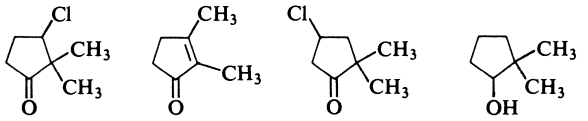


SCHEME 1

mixture of the anion of **3** and methyl 2-methylpropanoate.

In addition to 5,5-dimethyl-2-cyclopentenone **4** (52%), the cyclization of the acid chloride of **3** produced 3-chloro-2,2-dimethylcyclopentanone **7** (~25%) and 2,3-dimethyl-2-cyclopentenone **8** (~15%). Formation of products such as **7** in acylation reactions of this kind is well known (6). In the present work the cyclization reaction was carried out in a nitromethane – methylene chloride solvent mixture.

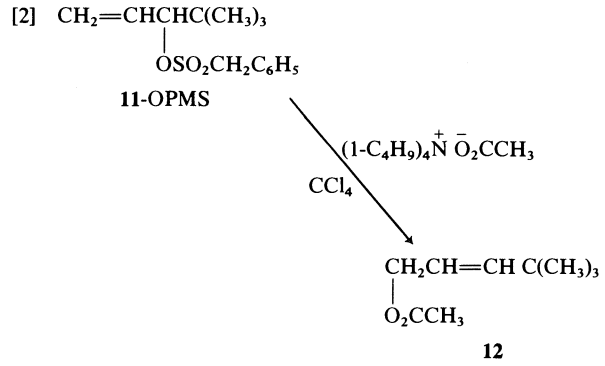


7 **8** **9** **10**

The isomeric chloroketone **9**, but neither **7** nor **8**, is reported to be formed when the reaction is carried out in carbon disulfide (7).

Considerable difficulty was experienced in finding a suitable method for the reduction of **4** to the allylic alcohol **1**-OH. The method of choice proved to be aluminum hydride in ether (8). The saturated ketone **5** or the saturated alcohol **10** were the exclusive products when **4** was treated with lithium tri-*t*-butoxyaluminum hydride at −70°C or with sodium borohydride, respectively. Pyrolysis of the alcohol **1**-OH in dimethylsulfoxide (9) forms **6**. Overall, the syntheses presented here appear to be the most efficient for the preparation of **4** (7, 10), **5** (10, 11), and **6** (12).

The 2,6-dichlorobenzoate of the cyclohexenyl system first studied (6) required rather drastic conditions for reaction so preparation of **1** containing a more reactive leaving group was attempted. Preliminary experiments with the more readily available acyclic model compound 4,4-dimethyl-1-penten-3-ol **11**-OH were first carried out. The phenylmethanesulfonate ester **11**-OPMS was prepared and treated with tetrabutylammonium acetate TBA in carbon tetrachloride, reaction [2].



After 5 h at 40–45°C, ~50% of **11**-OPMS had been converted to **12**, as judged from the nmr spectrum of the reaction mixture. A doublet at τ5.30, J = 8 Hz, due to the methine proton of **11**-OPMS, was decreased in intensity, while a new doublet J = 5.5 Hz, assigned to the methylene group of **12**, appeared at τ5.60. It appeared that the product was exclusively the rearranged acetate **12**.

Further identification was not made and after these preliminary results attempts were made to isolate the phenylmethanesulfonyl ester **1**-OPMS of the dimethylcyclopentenyl system. However, these were not successful. The ester apparently formed but rapidly decomposed, even at −30°C, in the reaction mixture to yield the diene **6** among other, unidentified, products.

The 2,6-dicholorobenzoate ester **1**-ODCB was then prepared and a series of qualitative experiments was carried out to determine conditions under which the S_N2' reaction would occur. No evidence for the S_N2' reaction was obtained. The ester was recovered unchanged after treatment

For personal use only.

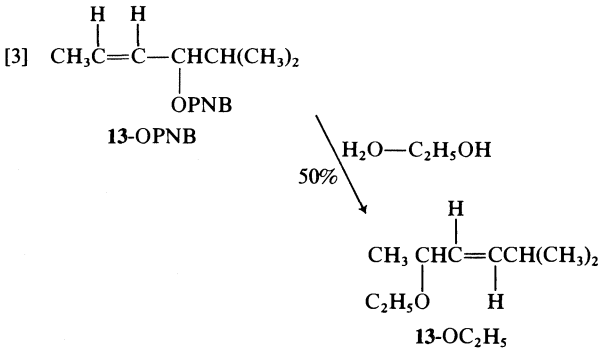
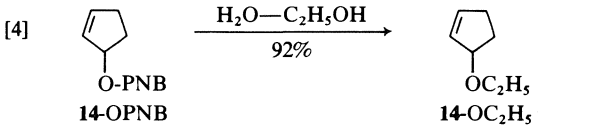
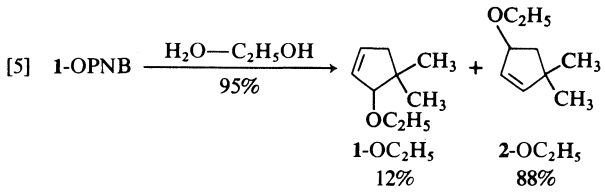
with TBA in carbon tetrachloride for 9 h at 90°C (TBA was destroyed), with thiourea in dimethylformamide for 40 h at 100°C, and with diethyl malonate anion in dimethylformamide for 36 h at 100°C. In piperidine solution at 130°C the ester was slowly destroyed and had disappeared after 90 h. The nmr spectrum of the reaction mixture showed no signals attributable to the desired product of rearrangement **2**, N=piperidyl. Mainly the diene **6** appeared to be formed when the ester was treated with cyanide or with thiocyanate ion in dimethylformamide at 150°C.

After this unsuccessful search for an S_N2' reaction, a brief study of the solvolysis of the *p*-nitrobenzoate ester **1**=OPNB was made to determine whether this system was unusually unreactive. For comparison the rates of solvolysis of *Z*-2-methyl-4-hexen-3-yl *p*-nitrobenzoate **13**-OPNB and 2-cyclopentenyl *p*-nitrobenzoate **14**-OPNB were also measured. The esters were allowed to solvolyze in 80% aqueous ethanol, Table 1. The reactions







were followed to at least 80% completion and obeyed first order kinetics throughout. There is internal return upon ionization of **1**-OPNB. After one half-life of reaction of **1**-OPNB ~25% of the *p*-nitrobenzoate ester that was recovered consisted of the rearranged compound **2**-OPNB. Since first-order kinetics were obeyed during solvolysis of **1**-OPNB for over three half-lives the rearranged ester must undergo solvolysis at a rate quite similar to that of **1**-OPNB. No rearranged ester could be detected after one half-life of solvolysis of **13**-OPNB.

The major products of solvolysis of the esters are the ethyl ethers, reactions [3]–[5], which from **1**- and **13**-OPNB are mainly the rearranged compounds. Several other products were detected by gc from solvolysis of **13**-OPNB, but these were not identified.

Discussion

The order of solvolytic reactivity, **14**-OPNB > **13**-OPNB, is consistent with previous work (13) in which it was found that 3-bromocyclopentene undergoes solvolysis 210 times as rapidly as 4-bromo-2-pentene in 80% ethanol at 0°C. The moderately slower rate of solvolysis of **1**-OPNB as compared with that of **14**-OPNB is likely due to steric inhibition of solvation (14) during ionization of **1**-OPNB. There is thus no remarkable lack of reactivity of **1**-OPNB under solvolytic conditions.

The failure to observe S_N2' substitution reactions with **1**-ODCB was not expected. Good yields of S_N2' reaction products were obtained under reaction conditions similar to those used here from the original cyclohexenyl systems studied (2). It may be that the *gem*-dimethyl groups in the rigid **1**-ODCB present enough of a steric barrier so as to make the S_N2' reaction considerably more sluggish than in the more flexible cyclohexenyl systems. Little work appears to have been done to evaluate steric effects in substitution reactions in cyclopentyl systems. Steric effects in pyrazoline decompositions are quite pronounced (15). Steric effects in 5-membered rings may be greater than in analogous acyclic or cyclohexyl compounds. A clearer assessment of the steric effects in S_N2' reactions of cyclopentenyl systems might be made from a study of the *cis*- and *trans*-4-methyl-2-cyclopenten-1-yl analogues.

Experimental

Melting points and boiling points are uncorrected. Refractive indices were measured on a Bausch and Lomb Abbe-3L refractometer. Infrared spectra were recorded on Perkin-Elmer Model 421 and 337 spectrophotometers, and only characteristic absorption bands are given. Nuclear magnetic resonance spectra were recorded on Varian analytical spectrometers, Models A-60, A-60A, and HR-100. Gas chromatography was carried out on a Perkin-Elmer Vapor Fractometer using a 5 ft × 1/4 in. column of 20% SE-30 on 60/80 chromosorb W.

Anhydrous ethanol was prepared by the method of Fieser (16). Eighty volumes of this at 25°C were mixed with 20 volumes of water, which had been distilled from potassium permanganate in all all-glass apparatus at 25.0°C to make the 80% ethanol.

Elemental analyses were performed in the microanalytical laboratories of the Chemistry Department under the supervision of Darlene Mahlow.

Solutions were dried with magnesium sulfate.

*2,2-Dimethyl-4-pentenoic acid, **3***

To a stirred suspension of 5.67 g (0.26 mol) of sodium hydride in 200 mL purified (17) diglyme was added 207 g (3.6 mol) of dry (molecular sieve) allyl alcohol over a 20 min period while keeping the temperature below 30°C. After hydrogen evolution ceased the clear, red solution was cooled to 10°C and 250 g (1.79 mol) of tetramethyl-1,3-cyclobutanedione was added in small portions at such a rate as to keep the temperature below 30°C. The resultant solution was stirred 1 h, transferred to a dropping funnel, and added to a stirred suspension of 90.7 g (3.69 mol) sodium hydride in 450 mL purified diglyme at 110°C. The rate of addition was such as to maintain the solution at 120–140°C without external heating. The mixture was stirred at 140°C for 1 h after the addition was complete, cooled and treated cautiously with water until the excess sodium hydride was destroyed. More water was added and the resulting solution was extracted with 3 × 200 mL ether. The aqueous layer was poured slowly into a mixture of ice and 450 mL concentrated hydrochloric acid. The resultant mixture was shaken with 500 mL pentane and the resulting aqeuous layer was shaken twice with 200 mL pentane. The combined pentane extracts were dried, concentrated through a Vigreux column, and the residual oil distilled through a 30 cm Vigreux column to give 60 g of forerun, bp 30–104°C/17 Torr and 299 g (65%) of **3** bp 104–109°C/17 Torr, n_D^{28} 1.4301 (lit bp 104–108°C/20 Torr (4*a*), n_D^{25} 1.4318 (18)).

*5,5-Dimethyl-2-cyclopentenone, **4***

Anhydrous aluminum chloride, 160 g (1.20 mol), was slowly added with stirring to 250 mL nitromethane and the resulting suspension was diluted with 900 mL methylene chloride. A solution of 181 g (1.23 mol) of the acid chloride of **3** in 1100 mL methylene chloride was added dropwise to the refluxing suspension over 10 h, and the resulting mixture was heated under reflux for 2 h more. The mixture was cooled and poured slowly into a stirred mixture of ice and concentrated hydrochloric acid. The aqueous layer was shaken with 2 × 400 mL methylene chloride and the combined organic layers were shaken with brine, aqueous sodium bicarbonate, brine, and dried. Solvent was removed through a Vigreux column and the residue was distilled through an annular Teflon spinning-band column to give, in addition to a forerun of nitromethane, 71 g (52%) of **4**, bp 150–152°C/700 Torr, n_D^{25} 1.4550 (lit bp 104–108°C/20 Torr (4*a*) n_D^{20} 1.4337 (4*b*)) and 55 g of a fraction, bp 186–188°C/700 Torr, that was shown by gc to consist of two major components in a ratio of about 1.7:1 and two minor components. The major components were identified as indicated below.

*3-Chloro-2,2-dimethylcyclopentanone **7***

The high boiling fraction from the preparation of **4** was stored at −10°C for several months and the supernatant liquid was decanted from the crystals that formed. The crystals were melted and refrozen. The decantation, melting, and freezing process was repeated twice more after which the product was distilled to give 5 g of a colorless oil, bp 95–97°C/30 Torr; mp 16.8–17.0°C; n_D^{29} 1.4661; ir (CCl_4): 1745, 1365, and 1385 cm^{-1}; ^{1}Hnmr (CCl_4): τ5.83 (m, 1H, —C*H*Cl—), 7.4–8.0 (broad m, 4H, —CH_2CH_2—); 8.92 (two s, 6H). *Anal.* calcd for $C_7H_{11}ClO$: C 57.35, H 7.59; found: C 57.41, H 7.80.

This compound possesses a pleasant camphor-like odor, and was unaffected after treatment with silver nitrate in ethanol at 77°C for 24 h, with silver nitrate in acetic acid at 110°C for 40 h, or with *N*,*N*-dimethylaniline at 190°C for 20 h. Heating this material with silver nitrate in boiling benzoic acid (235°C) for 8.5 h destroyed 50% of it to give a 25% yield of **4** and an unidentified compound. This lack of reactivity is more likely to be expected of **7** than of **9**.

The other major component of the high boiling fraction was isolated from the effluent of the gc using a 20 ft × 1/4 in. column of 20% ethylene glycol succinate on 60/80 chromosorb W at 150°C, and was identified as **8**, n_D^{29} 1.4774; ν_{max} (CCl_4): 1701 and 1655 cm^{-1}; uv (C_6H_{12}) λ_{max} 225 nm (6750); ^{1}Hnmr (CCl_4): τ7.4–8.1 (broad m, 4H), 8.04 (m, 3H), 8.40 (m, 3H). These spectroscopic properties are in good agreement with those reported (19).

*5,5-Dimethyl-2-cyclopentenol **1**-OH*

A solution of 27.7 g (0.25 mol) **4** in 500 mL ether was added over 1 h to a stirred mixture of aluminum hydride prepared (8) from 5.28 g (0.14 mol) lithium aluminum hydride and 6.0 g (0.05 mol) aluminum chloride in 500 mL ether. The resulting mixture was stirred overnight and then hydrolyzed by cautious addition of saturated ammonium chloride solution. The liquid was decanted and the salts were washed with ether. The combined ether solutions were dried, concentrated, and the residual oil was distilled to give 23 g (82%) of **1**-OH, bp 65.6–66.5°C/20 Torr; n_D^{25} 1.4598; ν_{max} (CCl_4) 3590, 3340, 1610 cm^{-1}; ^{1}Hnmr (CCl_4): τ4.30 (m, 2H), 5.95 (s, 1H, —C*H*—OH), 6.90 (s, 1H, O*H*), 7.88 (m, 2H), 8.95 (two close s, 6H). A satisfactory analysis was not obtained.

The *p*-nitrobenzoate was prepared, mp 66.3–67.0°C. *Anal.* calcd. for $C_{14}H_{15}NO_4$: C 64.36, H 5.79, N 5.36; found: C 64.13, H 5.74, N 5.36.

The 3,5-dinitrobenzoate was prepared, mp 71–72°C. *Anal.* calcd for $C_{14}H_{14}N_2O_6$: C 54.90, H 4.61, N 9.15; found: C 54.87, H 4.57, N 9.25.

*5,5-Dimethyl-2-cyclopentenyl 2,6-dichlorobenzoate, **1**-ODCB*

Treatment of **1**-OH with 2,6-dichlorobenzoyl chloride in pyridine solution (2) failed to produce any of the desired ester.

A solution of 4.36 g (0.039 mol) of **1**-OH in 10 mL tetrahydrofuran was added to a hot suspension of 4.8 g (0.2 mol) sodium hydride in 100 mL tetrahydrofuran at such a rate as to maintain gentle reflux. The resulting mixture was cooled to −11°C and a solution of 8.15 g (0.039 mol) 2,6-dichlorobenzoyl chloride (2) in 30 mL tetrahydrofuran was added over 25 min while keeping the temperature below −8°C. The cooling bath was removed, the reaction mixture stirred overnight and then filtered. The precipitate was triturated with tetrahydrofuran, the filtrates were combined, dried, and concentrated under 10 Torr. Hexane was added to the oily residue and 1.36 g of what appeared to be 2,6-dichlorobenzoic anhydride crystallized out. After three crystallizations from hexane this had mp 154–155°C, ν_{max} (CCl_4): 1820 and 1760 cm^{-1}; ^{1}Hnmr (CCl_4): τ2.60(s). The filtrate was concentrated to 25 mL and left at −10°C. The product was recrystallized from hexane to give 7.9 g (71%) of colorless crystals, mp 56–57°C; ν_{max} (CCl_4) 1735 cm^{-1}; ^{1}Hnmr (CCl_4): τ2.63 (s, 3H), 3.55–3.96 (m, 1H), 3.96–4.25 (m, 1H): 4.32 (m, 1H), 7.75 (m, 2H), 8.81 (two close s, 6H). *Anal.* calcd for $C_{14}H_{14}Cl_2O_2$: C 58.97, H 4.95, Cl 24.86; found: C 59.86, H 5.18, Cl 24.57.

*2,2-Dimethylcyclopentanone, **5***

A solution of 3.0 g (0.027 mol) of **4** in 35 mL tetrahydrofuran was added over a 1 h period to a stirred mixture of 13.8 g (0.055 mol) lithium tri-*t*-butoxyaluminum hydride and 45 mL tetrahydrofuran at −78°C. The resulting mixture was stirred 2 h at −78°C, and a further 16 h after removal of the cooling bath. A solution of Rochelle salt was added slowly with cooling. The upper of the two layers which formed was extracted into pentane. The pentane extract was dried, concentrated, and the

For personal use only.

residue was distilled to give 2.0 g (66%) of **5**, bp 65°C/70 Torr, n_D^{25} 1.4306 ((lit. 12*a*) bp 140–143/745 Torr; $n_D^{22.5}$ 1.4312).

*2,2-Dimethylcyclopentanol, **10***

A solution of 3.2 g (0.029 mol) of **4** in 30 mL 2-propanol was added to a boiling solution of 2.32 g (0.061 mol) sodium borohydride in 40 mL 2-propanol over a 40 min period and the resulting solution was heated under reflux for 4 h. Then 125 mL water was added and this solution was heated under reflux overnight, cooled, and shaken with 2 × 600 mL pentane. The pentane layers were combined, dried, concentrated, and the residue distilled to give 2.65 g (80%) of **10**, bp 70°C/27 Torr, n_D^{25} 1.4518 ((lit. 12*a*) bp 151–152°C/760 Torr, n_D^{20} 1.4532).

*4,4-Dimethyl-1-penten-3-yl phenylmethanesulfonate, **11**-OPMS*

Treatment of dimethylpropanal with vinylmagnesium chloride (20) followed by workup of the reaction mixture produced 4,4-dimethyl-1-penten-3-ol in 16% yield, bp 128–129°C/700 Torr, n_D^{25} 1.4286 (lit (21) bp 131°C/760 Torr, n_D^{25} 1.4282). Some reduction product, 2,2-dimethyl-1-propanol, was also formed (4.5%).

A solution of 0.414 g (4 mmol) triethylamine in 5 mL carbon tetrachloride was added over 10 min to a stirred mixture of 0.224 g (2 mmol) of the above allylic alcohol and 0.374 g (2 mmol) of phenylmethanesulfonyl chloride (22) in 10 mL carbon tetrachloride at 22°C. Stirring was continued for 1 h and the mixture filtered. The precipitate was triturated with carbon tetrachloride, the filtrates were combined and concentrated at 0°C to a red oil which solidified at −10°C and then remained solid at 22°C. This solid was treated with pentane which left a dark red oil. The pentane was decanted, cooled to −11°C, and the resultant white crystals were filtered at −5°C under dry nitrogen. Four recrystallizations from pentane gave 0.223 g (42%) of slightly yellow needles, mp 38.5–39.5°C; ^{1}Hnmr (CCl_4): τ2.59 (s, 5H), 3.95–4.85 (m, 3H), 5.30 (m, 1H), 5.77 (s, 2H), 9.10 (s, 9H). *Anal.* calcd. for $C_{14}H_{20}O_3S$: C 62.66, H 7.51; found: C 62.13, H 7.41.

This compound was very unstable, decomposing within 10 min at 22°C, but could be stored for months at −10°C. All apparatus involving its preparation and other operations was rinsed with isopropylamine before use.

2-Cyclopentenyl p-*Nitrobenzoate, **14**-OPNB*

This was prepared by treatment of 2-cyclopentenol (23) with *p*-nitrobenzoyl chloride in the presence of trimethylamine, mp 79.5–80.2°C; ^{1}Hnmr (CCl_4): τ1.75 (s, 4H), 3.65–4.20 (m, 3H), 7.35–8.15 (m, 4H). *Anal.* calcd. for $C_{12}H_{11}NO_4$: C 61.80, H 4.75, N 6.01; found: C 61.93, H 4.76, N 6.12.

Z-2-Methyl-4-hexen-3-yl p-*nitrobenzoate, **13**-OPNB*

Hydrogenation of 2-methyl-4-hexyn-3-ol (24) in pyridine solution over palladium on barium sulfate produced *Z*-2-methyl-4-hexen-3-ol which was converted directly without workup to **13**-OPNB, mp 64.1–65.0°C; ^{1}Hnmr ($CDCl_3$): τ1.75 (s, 4H), 4.05–4.65 (m, 3H), 8.25 (d, J = 5 Hz, 3H), 7.90–8.40 (m, 1H), 9.05 (d, J = 7 Hz, 64). *Anal.* calcd. for $C_{14}H_{17}NO_4$: C 63.86, H 6.51, N 5.32; found: C 63.77, H 6.50, N 5.45.

3-Ethoxy-4,4-dimethylcyclopentene

A solution of 18 g (0.11 mol) iodoethane in 30 mL dimethylformamide was added to a stirred suspension containing the anion of **1**-OH prepared from 5.73 g (0.05 mol) **1**-OH and 6.5 g (0.27 mol) sodium hydride in 100 mL dimethylformamide. The mixture was stirred overnight, water was cautiously added, and the resulting solution was extracted with 3 × 100 mL pentane. The pentane extracts were combined, shaken with 2 × 150 mL water, dried, concentrated, and the residual oil distilled to give 2.1 g (29%) of a colorless oil, bp 58.0–58.5°C/43 Torr; n_{25}^D 1.4295; ^{1}Hnmr (CCl_4): τ4.25 (m, 2H), 6.20 (m, 1H), 6.58 (m, 2H, —O—CH_2—), 7.9 (m, 2H), 8.75 (s, 3H), 8.95 (t, J = 7 Hz, 3H, overlapping with s, 3H): ms *m/e*: 140.1200 ($M^{+\cdot}$, calcd for $C_9H_{16}O$: 140.1201).

Z-4-Ethoxy-5-methyl-2-hexene

This was prepared using a procedure similar to that described for the above ether, except that the reaction was carried out in tetrahydrofuran. From 4.0 g *Z*-2-methyl-4-hexen-3-ol, obtained by saponification of **13**-OPNB, 2.67 g (54%) of the ether was obtained, bp 52–53°/35 Torr; n_D^{26} 1.4148; ^{1}Hnmr (CCl_4): τ4.10–5.00 (m, 2H), 6.20–7.00 (m, 3H), 8.35 (dd, J = 1.5 and 7Hz, 3H), 8.9–9.50 (m, 10H); ms *m/e*: 142.1358 ($M^{+\cdot}$, calcd. for $C_9H_{18}O$: 142.1358).

E-*5-Methyl-3-hexen-2-yl* p-*Nitrobenzoate*

The fraction boiling at 78–81°C/51 Torr, n_D^{24} 1.4293, 32 g (0.28 mol) of the product of reduction of 99 g *E*-5-methyl-3-hexen-2-one (24) with aluminum hydride (8) was treated with 57.5 g (0.28 mol) *p*-nitrobenzoyl chloride in 300 mL dry pyridine at 0°C and the mixture stirred overnight. The usual workup and several recrystallizations from hexane at −20°C gave 18.7 g (25%) product, mp 47.7–48°C; ^{1}Hnmr (CCl_4): τ1.80 (s, 4H) 3.90–4.60 (m, 3H), 7.50–7.90 (m, 1H): 8.52 (d, J = 7 Hz, 3H), 8.90 (d, J = 7 Hz, 6H). *Anal.* calcd. for $C_{14}H_{13}NO_4$: C 63.87, H 6.51, N 5.32; found: C 63.86, H 6.89, N 5.58.

E-*2-Ethoxy-5-methyl-3-hexene*

Saponification of *E*-5-methyl-3-hexen-2-yl *p*-nitrobenzoate gave *E*-5-methyl-3-hexen-2-ol, bp 86–88°C/74 Torr, n_D^{24} 1.4310, which was converted to the ethyl ether using the procedure described for the preparation of 3-ethoxy-4,4-dimethylcyclopentene. A pure sample was isolated by gc, bp 63°C/73 Torr; n_D^{25} 1.4168; ^{1}Hnmr (CCl_4): τ4.50–5.00 (m, $J_{3,4}$ = 15 Hz, 2H), 6.40–7.00 (m, 3H, —O—CH_2— and >C*H*O), 7.85 (m, 1H), 9.10 (m, 12H); ms *m/e*: 142.1358 ($M^{+\cdot}$, calcd. for $C_9H_{18}O$: 142.1358).

Rate Studies

Solutions (0.03 *M*) of the *p*-nitrobenzoate ester in 80% ethanol were charged into ampoules which were sealed and inserted into thermostatted heating baths. From time to time ampoules were removed, equilibrated to 25.0°C, and broken open. Aliquots, 5 mL, were removed with calibrated automatic pipettes, drained into 50 mL methanol, α-naphtholbenzein was added, and titration carried out with 0.03 *M* sodium hydroxide solution. The runs were all followed to more than 80% completion and at least seven points were taken. The values of the first order rate constants were calculated from the expression

$$k = \frac{2.303}{t} \log \frac{V_\infty - V_0}{V_\infty - V_t}$$

where V_0, V_t, and V_∞ are the volumes of titrant at time $t = 0$, t, and infinity, respectively. The first ampoule was removed from the heating bath after 4–5 min, this time taken as zero time and the volume of titrant taken as V_0. The instantaneous values of k within each run were averaged, the average deviation of each point from this average k_t was computed, and any point further than an arbitrarily chosen three times the average deviation from the mean was rejected from the computation. Refinement of the data was continued this way until a suitably precise result emerged. In no case were more than two points rejected. The activation parameters were then calculated (25). The results are presented in Table 1.

Products of solvolysis

(A) From 1-OPNB

A solution of 0.605 g **1**-OPNB in 75 mL 80% ethanol was heated at 100°C for one half-life of solvolysis and then the

TABLE 1. Rates of solvolysis of 0.03 *M* **1**-, **13**-, **14**-OPNB in 80% ethanol

Ester	Temperature (°C)	$10^6 k$, s^{-1}	Relative rate	E_a, (kcal/mol)	$\Delta S^{\neq}$ eu (80°C)
1-OPNB	80.1	20.2±0.9	32	26.7±1	7±3
	100.0	157±8			
13-OPNB	80.1	0.632±0.04	1	27.8±1.1	11±3
	100.0	5.24±0.16			
14-OPNB	50.1	23.5±0.7		23.3±0.6	10±2
	70.0	197±7			
	80	523[a]	828		

[a] Extrapolated rate constant.

solvent was thoroughly evaporated under reduced pressure. The residue 0.475 g (95.6%, based on 50% ester remaining and 50% *p*-nitrobenzoic acid produced) was analyzed by ^{1}Hnmr ($CDCl_3$). From the relative areas of the aromatic protons of **1**-OPNB and **2**-OPNB at τ1.75 and 1.83, respectively, and also of olefinic and methine protons it was estimated the recovered ester consisted of ~75% **1**-OPNB and ~25% **2**-OPNB.

A solution of 0.202 g **1**-OPNB in 25 mL 80% ethanol was heated at 100°C for 18 half-lives of solvolysis in a sealed ampoule. A weighed quantity of cumene was added to a 10 mL portion of the solution which was then analyzed by gc. Calibration was carried out with known mixtures of cumene and **1**-OC_2H_5. The remainder of the solvolysis mixture was poured into an equal volume of water and the resulting solution concentrated with 3 × 80 mL dichloromethane. The combined extract was shaken with potassium hydroxide and brine, and dried and carefully concentrated through a Vigreux column with a partial reflux head. Gas chromatographic analysis disclosed three peaks in a ~90:5:5 ratio. The major component was collected from the effluent of the gc and shown by nmr to be a mixture of **1**- and **2**-OC_2H_5, the composition of which was determined from the ratios of the areas of the peaks due to the methine protons. ^{1}Hnmr for **2**-OC_2H_5 (CCl_4): τ4.46 (s, 2H), 5.70 (dd, J = 7.0 and 5.0 Hz, 1H), 6.72 (q, J = 7.5 Hz, 2H), 8.30 (dd, J = 13.0 and 7.0 Hz, 1H), 8.52 (dd, J = 13.0 and 5.0 Hz, 1H); 8.99 (t, J = 7.5 Hz, 3H), 8.99 (s, 3H), 9.10 (s, 3H).

(B) From 13-OPNB

The procedure was operationally similar to that described above. Examination of the nmr spectrum of the ester isolated from the interrupted solvolysis disclosed that no rearranged *p*-nitrobenzoate had been formed. The major product of solvolysis was isolated from the effluent of the gc and shown by nmr to be *E*-2-ethoxy-5-methyl-3-hexene.

(C) From 14-OPNB

Using the methods described above the product of solvolysis was shown to be **14**-OC_2H_5 by comparison of the nmr spectrum with that of an authentic (26) sample.

Tetrabutylammonium Acetate TBA

A solution of 164 g TBA-hydrate (27), mp 14.7–14.9°C (lit. (27) mp 15.1°C) in 200 mL ethanol was allowed to stand 7 days over 200 g 3A molecular sieve, decanted, and then concentrated. The residue was heated overnight with rotation under 7 Torr at 45°C. The residue then crystallized on cooling with evolution of much heat, mp 45–48°C, and was shown by nmr to contain 3% water, corresponding to TBA·½ H_2O. Treatment with molecular sieve was repeated except that the final pumping out was done at 80°C. The resulting solid, mp 70–72°C, was extraordinarily hygroscopic and all operations were carried out under dry nitrogen. A water content corresponding to 10TBA·H_2O was deduced from integration of the nmr spectrum which showed the water peak at τ2.1 (CCl_4). This material was used in the S_N2' experiments.

Reaction between 11-OPMS and TBA

A carbon tetrachloride solution 0.4 *M* in **11**-OPMS and 0.45 *M* in TBA was placed in nmr tube and the nmr spectrum taken at various times. The results have been described in the text.

Attempted S_N2' Reactions of 1-ODCB

Solutions 0.4 *M* in 1-ODCB and 0.5 *M* in various nucleophiles or in piperidine in nmr tubes were heated as described in the text and analyzed from time to time by nmr. The results have been given in the text.

DAVID JOHN MITCHELL, SAUL WOLFE, and H. BERNHARD SCHLEGEL. Can. J. Chem. **59**, 3280 (1981).

Calculations have been performed at four basis set levels (STO-3G, STO-3G*, 4-31G, 4-31G*) on the model ylides methylenesulfurane (CH_2SH_2) and methylenephosphorane (CH_2PH_3), their stable tautomers (CH_3SH and CH_3PH_2), their dissociation products (SH_2, PH_3 and CH_2), and the protonated species $CH_3SH_2^+$ and $CH_3PH_3^+$. At each basis set level all geometries have been optimized fully, using the FORCE method. The conformational behaviour of the ylides as a function of C—X bond-stretching, C—X torsion, and CH_2 (or SH_2) bending has been examined in some detail. The experimental properties (i.e., geometries, relative stabilities, proton affinities, rotation–inversion behaviour) of sulfonium and phosphonium ylides are reproduced well by the model calculations with the 4-31G* basis set, which contains *d*-type functions on both carbon and sulfur (or phosphorus). All other basis sets are deficient in different ways and for different reasons, which are discussed in detail. The principal result of this work is the conclusion that *d*-type functions are essential for a proper description of the hypervalent species CH_2SH_2 and CH_2PH_3, but not for the normal-valent species SH_2, PH_3, CH_3SH, and CH_3PH_2. The conclusion concerning hypervalent species reverses our earlier views. The role of the *d*-type functions is to concentrate charge into the C—X region of the ylides, and thus to stabilize the system. Evidence for this effect has been obtained from quantitative perturbational molecular orbital (PMO) analyses of interactions associated with the carbon lone pair, as well as comparisons of electron density plots with and without the *d* AO's. A second conclusion is that the imposition of various geometrical constraints such as assumed C—X, C—H, or X—H bond lengths, and HCH or XH_n bond angles, as was necessary for computational reasons in all previous work on such systems, has major and previously unrecognized consequences. For example, the assumption that the CH_2 moiety is planar in CH_2SH_2 leads to very similar geometries with and without *d* AO's, although only in the latter case does such a geometry at carbon correspond to the true energy minimum; in the absence of *d* AO's the C—S bond length is maintained by a symmetry-enforced barrier to dissociation. These and other consequences of geometrical constraints at carbon, sulfur, or phosphorus are analyzed in detail.

DAVID JOHN MITCHELL, SAUL WOLFE et H. BERNHARD SCHLEGEL. Can. J. Chem. **59**, 3280 (1981).

Utilisant quatre ensembles de base (STO-3G, STO-3G*, 4-31G, 4-31G*), on a effectué des calculs sur des modèles d'ylures de méthylenesulfurane (CH_2SH_2) et de méthylenephophorane (CH_2PH_3), sur leurs tautomères stables (CH_3SH et CH_3PH_2), sur leurs produits de dissociation (SH_2, PH_3 et CH_2) et sur leurs espèces protonées CH_3SH_2, $CH_3PH_3^+$. Faisant appel à la méthode de FORCE, on a optimisé pleinement toutes les géométries pour tous les ensembles de base. On a examiné soigneusement le comportement conformationnel des ylures en fonction de l'élongation de la liaison C—X, de la torsion de cette liaison et de la déformation du CH_2 (ou du SH_2). On a reproduit convenablement les propriétés expérimentales (i.e. les géométries, les stabilités relatives, les affinités pour le proton, le comportement à la rotation–inversion) des ylures de sulfonium et de phosphonium en utilisant des calculs modèles de la base 4-31* qui contient les fonctions de type-*d* sur le carbone et le soufre (ou sur le phosphore). Tous les autres ensembles de base sont déficients de différentes façons et pour des raisons différentes que l'on discute en détail. Le résultat principal de ce travail permet de conclure que les fonctions-*d* sont essentielles pour une description adéquate des espèces hypervalentes CH_2SH_2 et CH_2PH_3 mais ne le sont pas dans le cas des espèces à valence normale SH_2, PH_3, CH_3SH et CH_3PH_2. La conclusion relative aux espèces hypervalentes renverse notre première idée. Les fonctions de type-*d* concentrent la charge dans la région de C—X des ylures et stabilisent alors le système. On a obtenu la preuve de cette action à partir des analyses quantitatives des pertubations d'orbitale moléculaires (POM) des interactions associées au doublet libre du carbone ainsi qu'à partir des comparaisons des courbes de densité électronique avec ou sans les OA *d*. On conclut également que l'imposition de contraintes géométriques variées telles qu'assumées par les longueurs de liaison C—X, C—H, ou X—H et par les angles HCH ou XH_n qui étaient nécessaires pour des raisons de calculs dans tous les travaux antérieurs portant sur de tels systèmes, ont des conséquences importantes et inconnues. Par exemple, l'hypothèse relative à la planéité de la portion CH_2 du CH_2SH_2 conduit à deux géométries très semblables avec ou sans les OA *d* bien que ce soit seulement dans le deuxième cas qu'une telle géométrie du carbone corresponde à l'énergie minimum réelle. En l'absence des OA *d*, la longueur de liaison C—S est maintenue par une barrière à la rotation induite par la symmétrie. On analyse en détail ces faits et d'autres conséquences relatives aux contraintes géométriques au niveau du carbone, du soufre ou du phosphore.

Introduction

The participation of low-lying virtual atomic *d*-orbitals ("outer" *d*-orbitals (1)) in molecular bonding has been studied extensively (2). Attention has focused, especially, upon hypervalent molecules (3), i.e., molecules having Lewis structures with more than eight valence electrons about a central atom (e.g., silicon, phosphorus, sulfur, chlorine) (4–12).

Included in the class of hypervalent molecules are the sulfonium and phosphonium ylides (13*a*), also known as methylenesulfuranes and methylenephosphoranes, which are isoelectronic with the corresponding sulfoxides (13*b*) and phosphine oxides. The importance of such ylides in organic synthesis (13*c*) has led to numerous theoretical investigations at both the semi-empirical (14) and *ab initio* levels (15, 16). All of the *ab initio* studies have employed either idealized geometries or have included a limited geometry optimization subject to some constraints.

One of the objectives of the present work is to reexamine the two model ylides methylenesulfurane (CH_2SH_2) and methylenephosphorane (CH_2PH_3) at the *ab initio* level, with complete geometry optimization. A second objective is to perform computations with and without *d*-atomic orbitals (*d* AO's) in the basis set, to evaluate the degree and manner of the participation of *d* AO's in the bonding in both ylides. Certain other points on the CSH_4 and CPH_5 hypersurfaces have also been examined, to assess the consequences of various geometrical constraints. The calculated relative energetics have been placed within the context of known experimental quantities by computation of the protonation energies and sulfur inversion barriers of selected species.

To facilitate the discussion, certain points will be highlighted using qualitative arguments based on the perturbational molecular orbital (PMO) method (17). As will be seen, the PMO treatment of these ylides is dominated by the presence of the lone pair on carbon.

Computational Details

The *ab initio* calculations were performed using either the GAUSSIAN 80 program system (18) or a modified version of GAUSSIAN 76 (19). All geometry optimizations were performed using the FORCE method (20), a gradient relaxation procedure now incorporated into GAUSSIAN 80. Setting the convergence on the RMS gradient at 0.0025 mdyne gave bond lengths accurate to 0.001 Å and bond angles accurate to 0.1°.

The basis sets used were the standard STO-3G (21), STO-3G* (10), 4-31G (22*a*), and 4-31G* (22*b*) basis sets of Pople. The 4-31G* basis set contains six second-order Gaussian functions (xx, yy, zz, xz, yz, xy) on all heavy atoms. The *d*-orbital exponents for sulfur and phosphorus were optimized variationally for the lowest energy conformations of CH_2SH_2 ($\alpha_d = 0.59$) and CH_2PH_3 ($\alpha_d = 0.51$), and were then used unchanged in subsequent calculations. The *d*-orbital set on carbon was not modified.

The program used to plot electron density difference maps was adapted from Jorgensen's PSI/77 (23). Energy surfaces were generated using the program 3DPLOT (20).

In those sections of the discussion which deal with a quantitative PMO analysis, the fragment orbital energies and the properties of these orbitals necessary for the computation of orbital interaction energies were obtained by the procedure described earlier (24). The two-orbital, four-electron interaction energies were calculated using eq. [1] where e_i^0 and e_j^0 are the energies of the fragment orbitals ϕ_i^0 and ϕ_j^0, and S_{ij} and Δ_{ij} are the overlap integral and the interaction matrix element between them, respectively. The two-orbital, two-electron interaction energies were calculated by direct solution of the appropriate secular determinant (eq. [2]).[2]

$$[1] \quad \Delta e_{ij} = 2S_{ij}[-2\Delta_{ij} + (e_i^0 + e_j^0)S_{ij}]/(1 - S_{ij}^2)$$

$$[2] \quad \begin{vmatrix} e_i^0 - e & \Delta_{ij} - S_{ij}e \\ \Delta_{ij} - S_{ij}e & e_j^0 - e \end{vmatrix} = 0$$

Results and Discussion

1. Ab initio *Calculations*

Thermodynamic Aspects of the CSH_4 and CPH_5 Hypersurfaces

Calculations with full geometry optimization were performed at the four different basis set levels for selected conformations of the two ylides CH_2SH_2 and CH_2PH_3, the staggered conformations of the stable tautomers CH_3SH and CH_3PH_2, and the dissociation products H_2S, PH_3, and CH_2. Calculations are also reported for the staggered conformations of the protonation products $CH_3SH_2^+$ and $CH_3PH_3^+$. The various geometries and total energies of the two heavy-atom sulfur and phosphorus

[2] The usual equation [3], which approximates the solution to [2],

$$[3] \quad \Delta e_{ij} = 2(\Delta_{ij} - e_i^0 S_{ij})^2/(e_i^0 - e_j^0)$$

could not be used because of the unusually large stabilizing interactions in these molecules.

[a] Bond lengths in Å, bond angles in degrees.
[b] In hartrees.

systems are collected in Tables 1 and 2, respectively. Results for the simple hydrides are reported in Table 3. The relative energies are summarized in Tables 4 and 5.

A number of points can be made concerning the CSH_4 and CPH_5 surfaces. The experimental energy difference for the equilibrium process of eq. [4] is reasonably well reproduced at both the 4-31G

[4] $CH_3XH_n \rightleftarrows {}^1A_1CH_2 + XH_{n+1}$

and 4-31G* levels. Thus, addition of *d* AO's to a split-valence basis set has only a modest effect upon this net proton transfer – dissociation process. An analogous result is obtained at the STO-3G and STO-3G* levels, but the energy is greatly overestimated by these minimal basis sets. The problem is caused by a lack of flexibility within such basis sets, and also by basis set superposition (29).

Since the *tautomerization* energy of CH_2SH_2 is *greater* than that of CH_2PH_3, and, at the same time, the *dissociation* energy of CH_2SH_2 is *less* than that

of CH_2PH_3, it follows that the sulfonium ylide is intrinsically the less stable species. This is in accord with experiment (30).

The most important finding is that inclusion of *d* AO's on the second row atoms has a large effect upon the stabilities of the ylides. With the split-valence basis set the stabilization is nearly 27 kcal/mol in both cases. Consequently, deletion of the *d* AO's forces the ylides to lie too close to their dissociation limits. Indeed, as seen in Table 4, the sulfonium ylide **1** is actually calculated to be less stable than the dissociation products, even without correction for basis set superposition.

On the other hand, the energy differences associated with the normal valent species of eq. [4] do not depend greatly upon the presence of *d* AO's, as already noted. This indicates that the concept of hypervalence may be of some value in defining those species that require *d* AO's for a proper description.

Table 6 compares the proton affinities calculated for the two ylides and their stable tautomers. The experimental proton affinities of methanethiol and methylphosphine are also included for comparison. It is clear that the 4-31G* basis set predicts this experimental quantity quite well (31). The very similar proton affinities of CH_2SH_2 and CH_2PH_3 with the *d*-orbital basis sets are noteworthy. Apparently, PH_3^+ and SH_2^+ substituents have almost the same effect upon the protonation of an adjacent carbanionic centre.

Structures of the Ylides

[a] Bond lengths in Å, bond angles in degrees.
[b] In hartrees.
[c] Results for these systems at the STO-3G, STO-3G*, and 4-31G levels may be found in ref. 10*a* (H_2S, PH_3) and in ref. 10*b* (CH_2).
[d] Complex orbitals were used.

ifically in the description of the hypervalent species methylenesulfurane (cf. 13*b*). Thus, the geometries of methanethiol **4** and methylsulfonium cation **5** show only minor dependence on the basis set; the principal trends are longer C—S bond lengths at the split-valence level, and the shortening of this bond upon addition of *d* AO's (10). In contrast, the geometries of the ylides depend greatly upon the choice of basis set.

Computations were performed initially on conformation **1**, in which the carbon centre is constrained to planarity and the HCH plane bisects the H_2S plane. These constraints result in somewhat similar structures with the different basis sets, and the C—S bond length varies in the manner already described for **4** and **5**.

Release of all constraints, to allow both pyramidalization at carbon and C—S torsion, illustrates the effect of the *d*AO's. When these functions are present, the carbon centre remains planar and no rotation occurs, so that **1** is the true minimum. In the absence of these functions, the carbon centre becomes strongly pyramidal, the C—S bond lengthens to values greater than 2 Å and the molecule rotates to the anti structure **2**. It is noteworthy that optimization of the *anti* conformation using the *d* AO-containing basis sets also reveals pyramidalization at carbon and C—S bond lengthening; however, **2** then becomes a rotational maximum. The *syn* conformation **3** was also examined. It is a rotational maximum with all basis sets.

Therefore, at the STO-3G* and 4-31G* levels, **1** is the only minimum on the conformational hypersurface. It lies in a deep well with respect to C—S torsion (see below). On the other hand, at the STO-3G and 4-31G levels, **2** is the most stable conformation, and is 5.0 and 3.7 kcal/mol, respectively, more stable than the *syn* conformation **3**, which remains the maximum on the rotational potential. No distinguishable minimum corresponding to a *gauche* conformation (e.g. **10**) exists at 4-31G, although a careful search did reveal an extremely shallow minimum 1.3 kcal/mol above **2** at STO-3G.

10

These results are of some importance in assessing the validity of a model proposed recently for the prediction of the relative acidities of diastereotopic protons in sulfonium salts (33). This model is derived from an examination of the C—S rotational potential of $CH_2S(CH_3)_2$ at the 4-31G level with the following major assumptions: (*i*) a pyramidal carbon; (*ii*) a 1.85 Å C—S bond length; (*iii*) 105° angles at sulfur; (*iv*) rigid rotation. With these various assumptions, the computations of Graham and Heathcock lead to a *gauche* minimum. It should be clear that this result is an artifact for two reasons, viz., the neglect of *d* AO's and the choice of geometry.

Figure 1 illustrates further the consequences of the imposition of geometrical constraints and the usefulness of a computational procedure which allows ready optimization of all parameters. The figure shows C—S torsion of **2** at the STO-3G level with rigid rotation of the fully optimized structure (r_{CS} = 2.06 Å) and of the structures having r_{CS} = 1.86 Å and 1.66 Å. It can be seen that a *gauche* minimum could be made to exist by the artificial choice of an appropriately short C—S bond length and, presumably, other arbitrary constraints.[3] There is a parallel between the artificial behaviour achieved in Fig. 1 and the experimental properties of nonhypervalent A_2X_4 systems. In hydrazines (r_{NN} ~ 1.45 Å) (34), the *gauche* conformation is adopted, while diphosphines (r_{PP} ~ 2.20 Å) and diarsines (r_{AsAs} > 2.4 Å) (35) prefer the *anti* conformation.

In view of the large effect of *d* AO's upon the energy of CH_2SH_2 it seems, at first glance, surprising that the geometries computed for **1** under C_s symmetry at STO-3G or 4-31G are close to the fully optimized values obtained at STO-3G* or 4-31G*.

[3] In fact, holding r_{CS} = 1.66 Å and optimizing all other parameters of **2** and **10** at the STO-3G level produces *gauche* minima lying 9.8 and 18.6 kcal/mol, respectively, *below* the *anti* structure.

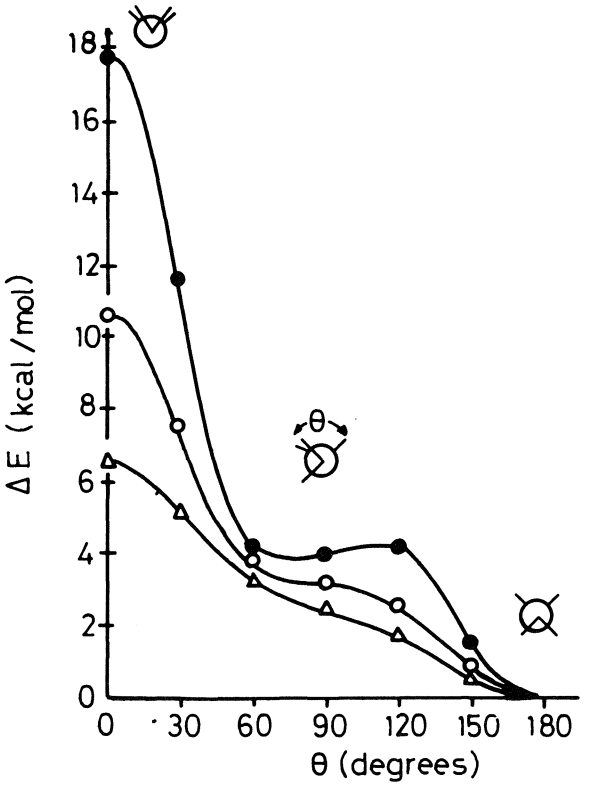

FIG. 1. Effect of geometrical constraint upon the C—S torsional potential of **2** at the STO-3G level. △, r_{C-S} = 2.06 Å (fully optimized); ○, r_{C-S} = 1.86 Å; ●, r_{C-S} = 1.66 Å.

The reason for this is that, when carbon is planar, dissociation of the ylide along only a C—S stretching coordinate would require the formation of CH_2 in the excited $^1\Delta$ state. This causes the CSH_4 energy surface along this stretching coordinate to rise steeply from **1**; therefore, at the STO-3G and 4-31G levels the ylide exists within the symmetry of **1** because of a large symmetry-enforced barrier to separation of the fragments. Such barriers have been recognized previously by Trinquier and Malrieu in their pseudopotential study of CH_2PH_3 (15*f*).

Pyramidalization at carbon provides a mechanism for dissociation which avoids the high-energy

ridge of the surface. Nevertheless, complete dissociation does not occur because the C—S bond stretching – carbon pyramidalization surface contains a minimum corresponding to **10**, which transforms to **2** when rotation is permitted to occur. The calculated topology of this surface in the absence of *d* AO's is shown in Fig. 2. In agreement with this assessment, the structures obtained for **2** have long C—S bonds and HSH and HCH planes nearly perpendicular to this bond axis. Therefore, **2** is best regarded as $^1A_1$ carbene solvated by hydrogen sulfide. Such behaviour is reminiscent of that exhibited by so-called oxonium ylides (15*g*, 36).

When *d* AO's are added to the basis set, **1** is no longer a saddle point on the conformational hypersurface but, as already seen, the minimum. Dissociation is now entirely endothermic, as can be seen in Fig. 3. The enantiomeric dissociation paths p and p′ are directly comparable to Fig. 2 of ref. 15*f*.

This analysis also accounts for the very modest effect of *d* AO's upon the P—O bond length of H_3PO observed by Wallmeier and Kutzelnigg in their study of hypervalent oxides (37). As pointed out by these workers, direct dissociation of H_3PO leads to an excited state of atomic oxygen. This corresponds to the effect seen here for the isoelectronic CH_2. However, in the case of H_3PO, no symmetry-breaking path exists and no dramatic bond lengthening occurs upon deletion of the *d* AO's.

Finally, Table 7 lists the STO-3G* and 4-31G* energies computed for pyramidal inversion at sulfur for $CH_3SH_2^+$ and CH_2SH_2. Comparison of the 4-31G* data with experimental results shows satisfactory agreement.

CH_2PH_3

The phosphorus analog of **1** is **6** (Table 2), in

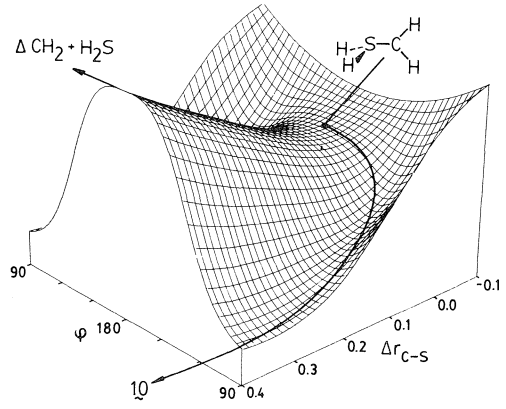

FIG. 2. Dissociation of CH_2SH_2 by a combination of C—S bond stretching and pyramidalization at carbon when *d* AO's are omitted.

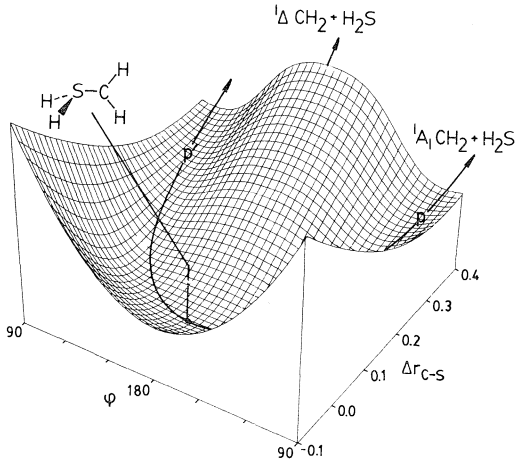

FIG. 3. Effect of *d* AO's upon the C—S bond stretching – carbon pyramidalization surface of CH_2SH_2.

which a P—H bond formally replaces a sulfur hybrid lone pair. As with the sulfonium ylide, addition of the *d* AO's causes a small decrease in the C—P bond length of **6** and the carbon centre is planar.

With all basis sets, **7** is the rotational minimum. The very nonplanar carbon geometry and C—P bond lengthening obtained at STO-3G is mainly a result of the effects already described for the sulfonium ylide. With all other basis sets, and in general agreement with Lischka (15*d*), Strich (15*e*), and Dixon and co-workers (15*g*), the carbon centre of **7** is nearly planar.

The 4-31G* C—P bond length in **7**, 1.652 Å, is in excellent agreement with previous theoretical (15) and experimental (38) determinations. An interesting feature of the geometries of **6** and **1** is the substantial deviation of the PH_3 moiety from local C_{3v} symmetry. The rotational barrier for CH_2PH_3 (**7** → **6**) is relatively small (0.7 kcal/mol at the STO-3G* level and 1.0 kcal/mol at the 4-31G* level), but larger than calculated previously (15) because the geometry at the PH_3 moiety has been taken into account. The reasons for this unusual geometry are discussed below in some detail.

The bond stretching – carbon inversion energy

TABLE 7. Pyramidal inversion barriers[a] at sulfur in methylsulfonium cation and methylenesulfurane

surface of Fig. 2 is also appropriate for methylenephosphorane at the STO-3G level although, even without *d* AO's, the saddle point **6** lies below $^1A_1$ CH_2 + PH_3. With all other basis sets, a surface analogous to that shown in Fig. 3 better describes the dissociation of **6**.

The ability of the 4-31G basis set to provide a reasonable description of the geometry of CH_2PH_3 (but not CH_2SH_2) illustrates the importance of obtaining accurate relative energies for the ylides and the dissociation products. The very poor energy for **1** relative to $^1A_1$ CH_2 + H_2S at the STO-3G and 4-31G levels renders these surfaces very unstable towards dissociation. This process is prevented because of the existence of a dative-bonded complex **2**. Since CH_2PH_3 is intrinsically more stable than CH_2SH_2, the dissociation limit lies well above the ylide even without *d* AO's, and much less bond lengthening occurs. Nevertheless, the *d* AO's are necessary for the description of the relative energetics of the phosphorus system; their absence simply has less of a geometrical consequence than in the sulfur system.

II. PMO Analyses

All of the *ab initio* results are consistent with the view that stabilization of the carbon lone pair of an ylide is a major factor affecting the energy differences between CH_2SH_2 and CH_2PH_3 and their more stable tautomers. This can be seen more clearly from a PMO analysis of the geometrical and basis set factors which influence the interaction of a CH_2 group with an adjacent H_nX system.

Bonding

The PMO analysis of the model ylide CH_2XH_n consists of the fragmentation $H_2C\cdots XH_n$ and evaluation of the energies associated with the allowed interactions between the two sets of group orbitals. Although many valence orbital interactions are present (e.g., twelve in the case of $H_2C\cdots SH_2$), attention will be focused upon only those interactions associated with n_C, the carbon lone pair. This choice follows from the dominant contribution of this orbital to the HOMO's of these ylides, and the dominant contribution of the two-electron and four-electron interactions associated with this lone pair to the total interaction energies (17*c*). Although the other interaction energies are not zero, they are overwhelmed by the effects of the carbon lone pair.

Figure 4 shows the interaction diagram for conformation **6** of CH_2PH_3. Interaction *a* is a four-electron destabilizing interaction between the carbon lone pair (n_C) and the bonding π-type orbital of the PH_3 group (π_y). Interaction *b* is a two-electron stabilizing interaction between n_C and the antibonding PH_3 orbital, π_y^*. This latter interaction is large because n_C is high-lying and π_y^* is low-lying. Figure 5 shows the interaction diagram which results from a 90° rigid rotation of the CH_2 group (i.e., **7**). For a PH_3 group having C_{3v} symmetry, interactions *a* and *b* of Fig. 5 are identical to interactions *a* and *b* of Fig. 4, because the π-type orbitals are doubly degenerate. Therefore, this qualitative argument suggests no conformational preference in CH_2PH_3. This idealized picture is in accord with the low barrier computed for this ylide, which may be attributed to small variations in the σ-system.

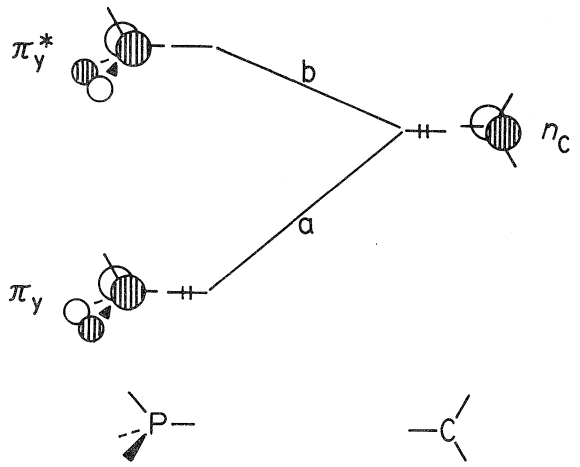

FIG. 4. Frontier orbital interactions in conformation **6** of CH_2PH_3.

The corresponding interaction diagrams for CH_2SH_2 are shown in Figs. 6 and 7. Figure 6, which refers to **1**, is entirely analogous to Fig. 4 for **6**; however, Fig. 7, which represents a 90° rigid

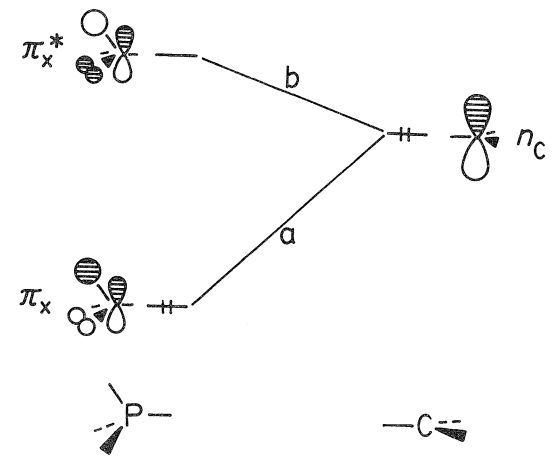

FIG. 5. Frontier orbital interactions in conformation **7** of CH_2PH_3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

rotation of **1** is very different from Fig. 5. Interaction *a* takes place between n_C and the sulfur lone pair, n_S, while interaction *b* takes place between n_C and the antibonding orbital σ_{SH_2}*. The n_C–n_S interaction is more destabilizing than n_C–π_y because n_S lies higher in energy than π_y; the n_C–σ_{SH_2}* interaction is much less stabilizing than n_C–π_y* because the overlap is smaller and σ_{SH_2}* lies higher than π_y*. The result is a strong preference for conformation **1**.

Rotation of **1** by 90° leads to an increase in the C—S bond length and pyramidalization at carbon since the strong n_C–π_y* interaction is lost and the destabilizing n_C–n_S interaction is reduced by such changes. Conformation **2** is the result.

The qualitative PMO analysis just presented has focused on the net effects of an XH_n fragment upon one common orbital, n_C, of an adjacent CH_2 moiety. If this treatment is reasonable, the relative magnitudes of the stabilization (or destabilization) by SH_2 and PH_3 should be related to the intrinsic stabilities of the two ylides, i.e., the tautomerization and dissociation energies. Table 8 reports the results of a quantitative PMO analysis on **1** and **6** with the different basis sets. This indicates that **6** is more stabilized than **1** in all cases. The same trend was seen in the tautomerization energies.

The function of the *d* AO's is to polarize or rehybridize the π-type antibonding acceptor orbitals of XH_n into the C—X region. As can be seen by comparison of the magnitudes of interaction *b* for **1** and **6** from Table 8, the *d* orbital polarization of the π* orbitals increases the overlap with n_C and greatly strengthens the stabilization.

That such a polarization exists can be demonstrated by examination of electron density plots.

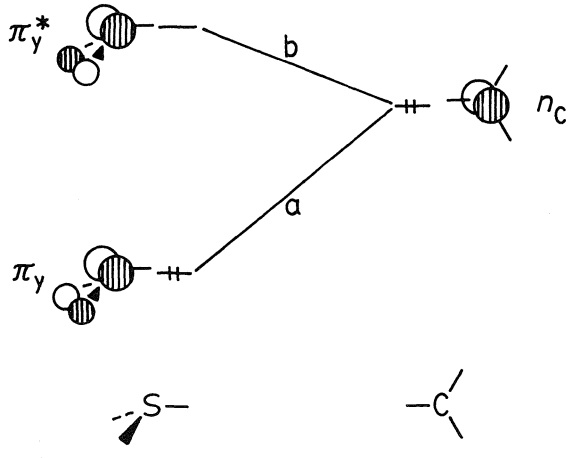

FIG. 6. Frontier orbital interactions in conformation **1** of CH_2SH_2.

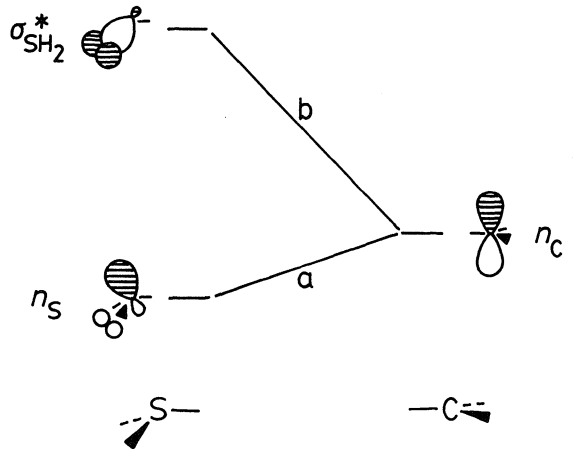

FIG. 7. Frontier orbital interactions in CH_2SH_2 following a 90° rotation of conformation **1**.

Figures 8 and 9 show the electron density in the HOMO (taken in the *yz* plane) of the sulfonium ylide **1** at the 4-31G and 4-31G* levels, respectively. Clearly the *d* AO's have not altered the nodal characteristics of this predominantly *p*-type lone pair on carbon. Their effect only becomes evident in the density difference plot. Figure 10 shows the electron density difference in the HOMO for **1** at the 4-31G* – 4-31G level; an identical result is observed for **6**. This figure now demonstrates that the effect of the *d* AO's is to concentrate charge into the C—S or C—P π-bonding region.

The form of this figure is dominated by the *d* AO's on sulfur; thus, in the 4-31G* HOMO of **1** the coefficients of the two contributing carbon *d* AO's are 0.002 and 0.023, while those of the corresponding sulfur *d* AO's are 0.060 and −0.136. In addition, deletion of the *d* AO's from carbon has no significant effect upon the sulfur *d* and carbon *p* coefficients computed at 4-31G*. The effect of the analysis presented here is to cast the role of *d* AO participation in a somewhat different language than is customary in the concept of p_π–d_π bonding, with its implication of conjugation with "free standing" *d* orbitals.

Geometric Consequences

The orbital interactions considered in Figs. 4–7 also provide insight into the origins of the geometric distortions in the XH_n fragments of these ylides. Each of these interactions will lead to distortion of XH_n to permit minimization of the four-electron destabilization or maximization of the two-electron stabilization. Such effects have been discussed recently for methyl groups by Radom and coworkers (41).

Figure 11 shows interactions *a* and *b* of **1**.

TABLE 8. Quantitative PMO analyses of CH_2SH_2 and CH_2PH_3

Basis set	Molecule	Interaction energy[a]			Difference[c]
		Interaction *a*	Interaction *b*	Total	
STO-3G[b]	**1**	31.7	−57.0	−25.3	−8.8
	6	26.7	−60.8	−34.1	
STO-3G*	**1**	28.2	−107.5	−79.3	−18.6
	6	18.7	−116.6	−97.9

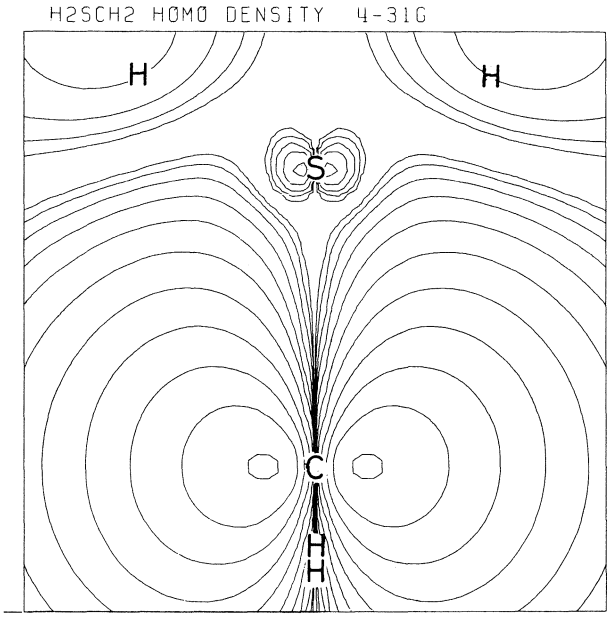

FIG. 8. Total electron density plot of the 4-31G HOMO of CH_2SH_2 in the plane perpendicular to the HCH plane with the C—S bond along the *z*-axis. Contour levels are at 0.0001, 0.00022, 0.00047, 0.001, 0.0022, 0.0047, 0.01, 0.022, 0.047, 0.1, 0.22e.

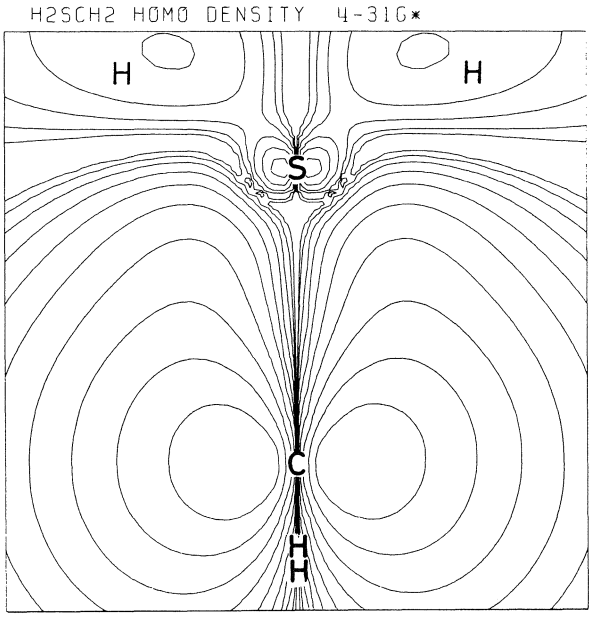

FIG. 9. As for Fig. 8 but at the 4-31G* level.

Secondary overlap is depicted by double-headed arrows. In *a* this secondary overlap will cause the HSH plane to tilt away from carbon, so as to decrease the unfavourable overlap associated with the destabilizing interaction. The tilt is in the same direction in *b*, so as to *increase* the overlap associated with the *stabilizing* interaction. The angular distortion resulting from these reinforcing effects leads to CSH angles in **1** which range from 109.2°–113.2° for the four basis sets. The corresponding angle in **4** is 95.1°–97.8° and in **5** it is 98.4°–102.4°.

An additional consequence of interaction *b* is lengthening of the S—H bonds of **1**, because charge is delocalized into an S—H antibonding region. Inspection of Table 1 reveals that this effect amounts to ca. 0.03 Å, the S—H bond of **1** being longer than those of **2**–**5**.

Figure 11 also describes interactions *a* and *b* of **6**. In this case, the distortion of PH_3 is greater than that of SH_2. Thus $\angle CPH_{4,5}$ of **6** ranges from 120.8°–122.1°, compared to a ∠CPH range in **8** of 95.7°–97.5°. This suggests that a PH_3 group is more readily deformed than an SH_2 group,[4] but interaction *b* is also stronger in **6** than in **1**. The disparity between the two different ∠CPH angles of **6**

[4] The calculated diagonal force constant for this rocking mode is k_{rock} = 1.05 mdyne Å/rad² for **6** and k_{rock} = 1.24 mdyne Å/rad² for **1**.

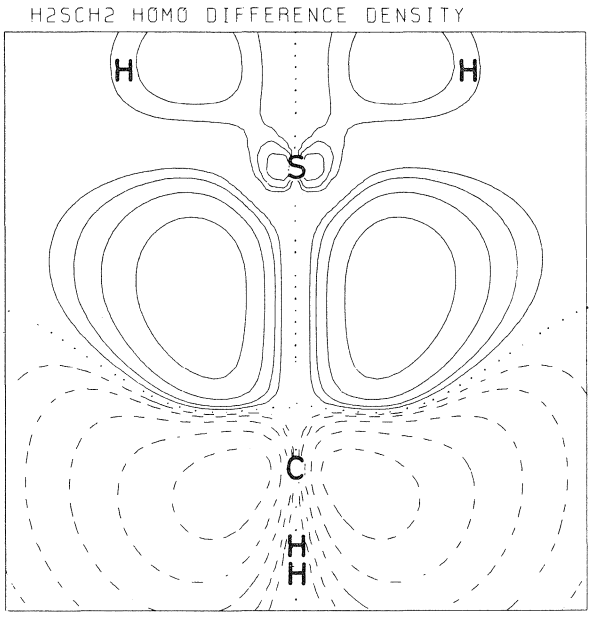

FIG. 10. Electron density difference plot (4-31G* − 4-31G) for the HOMO of CH_2SH_2 in the plane perpendicular to the HCH plane with the C—S bond along the z-axis. Solid contours refer to regions which gain electron density upon addition of d-orbitals; dashed contours represent regions which lose electron density. Dotted lines represent nodes. Contour levels are at ±0.001, ±0.0022, ±0.0047, ±0.01, ±0.022e.

corresponds to a tilt angle (the angle between the nominal C_3 axis of the PH_3 group and the C—P bond[5]) of +7.6° at the 4-31G* level. Interaction **6** also leads to selective weakening of the P—$H_{4,5}$ bonds compared to P—H_3, as can be seen in the 0.02 Å–0.03 Å difference recorded in Table 2 (cf. 24*b*).

As depicted in Fig. 12, a tilt of the PH_3 group is also expected in **7**, but in the opposite sense to that of **6**. In this case, an approximately *16° difference* between ∠CPH_3 and ∠CP$H_{4,5}$ is found, corresponding to a tilt angle of *−10.4°*. These results indicate that the assumption of local C_{3v} symmetry for the PH_3 group about the P—C axis is a much greater approximation than was previously supposed and would have significant effects upon calculated rotational barriers (15*a*, *d*, *f*, *g*) and the experimental structure refinement of $CH_2P(Me)_3$ (30). An additional feature of interaction *b* in **7** is the prediction that P—H_3 should be longer than P—$H_{4,5}$ (cf. 24*b*); this effect is seen in the data of Table 2.

Summary and Conclusions

The first *ab initio* molecular orbital calculations on sulfur-containing carbanions were reported in

[5]Calculated using 3 cos (α_1 + 2α) = 4 cos α_2 − cos α_1 where α = tilt angle, α_1 = ∠CPH_3, and α_2 = ∠CP$H_{4,5}$. See ref. 41.

1969 (42, 43). At that time it was necessary to employ minimal level basis sets and experimental or idealized bond lengths and bond angles. As a result of that work on alpha-sulfinyl and alpha-sulfonyl systems and subsequent, more detailed computations on alpha-thio and alpha-oxycarbanions (44), it was concluded that *"the asymmetry of alpha-sulfinyl and alpha-sulfonylcarbanions need not be related to a possible existence of 3*d*-orbital conjugation"* (43), but that *"small basis set calculations were ... necessary forerunners to the more extensive and elaborate calculations that now have to be done"* (42).

The present work provides some indication of the type of study that will be needed and is now feasible. The experimental properties (geometries, relative stabilities, proton affinities, rotation–inversion behaviour) of sulfonium and phosphonium ylides are reproduced well by the model calculations with the 4-31G* basis set, which contains *d*-type functions on carbon, sulfur, and phosphorus. All other basis sets are deficient, in different ways, and for different reasons. The necessity of *d* AO's to *stabilize* these hypervalent molecules, and the mechanism of this stabilization, have become clear. At the same time, it has been found that a proper manifestation of the *d*-orbital effects upon the *stereochemical properties* of these systems depends upon the initial choice of geometry. If the C—X bond length is incorrect, incorrect carbon valence angles or torsional angles about the C—X bond are predicted, whether *d* AO's are present or not. On the other hand, the assumption of planarity at carbon leads to very similar bond lengths and torsional angles with and without *d* AO's, although only in the latter case does such a geometry at carbon correspond to the true energy minimum. In the absence of *d* AO's, this assumption leads to an acceptable C—X bond length because of a symmetry-enforced barrier to dissociation. The existence of such a barrier then obscures the effects of the *d* AO's.

Consequently, a reinvestigation of the geometrical properties of alpha-sulfinyl and alpha-sulfonylcarbanions, and the effects of *d* AO's upon these properties, will require full geometry optimization of all structures at several basis set levels. Depending on the adequacy of the earlier geometrical assumptions (42, 43), the 1969 rotation–inversion behaviour may yet prove to be reliable. However, the conclusions concerning the role of the *d* AO's will probably have to be revised.

Palladium compounds of pyrimidine and pyridine derivatives – proposed structure assignment changes

PI-CHANG KONG AND F. D. ROCHON

Département de chimie, Université du Québec à Montréal, C.P. 8888, Montréal (Qué.), Canada H3C 3P8

Received May 8, 1981

PI-CHANG KONG and F. D. ROCHON. Can. J. Chem. **59**, 3293 (1981).

The complexes $[PdL_2X_2]$ where L = cytosine, 1-methylcytosine, cytidine, 2-amino-4-methylpyrimidine, 2-hydroxy-4-methylpyrimidine, 4-methylpyrimidine, 2-hydroxypyrimidine, 2,4-diethoxy-5-methylpyrimidine, 2-hydroxypyridine, and methyl-4-picolinate, and X = Cl and Br, were prepared from the reaction of K_2PdCl_4 and L in aqueous solution. When L = cytosine, the *cis*-isomer was obtained. *trans*-Compounds were obtained with all other ligands. The *trans*-isomer of cytosine was prepared from the *cis*-isomer. The configuration of the reported compounds of cytidine and methyl-4-picolinate has been reassigned.

PI-CHANG KONG et F. D. ROCHON. Can. J. Chem. **59**, 3293 (1981).

Les complexes $[PdL_2X_2]$ où L = cytosine, méthyl-1 cytosine, cytidine, amino-2 methyl-4 pyrimidine, hydroxy-2 méthyl-4 pyrimidine, méthyl-4 pyrimidine, hydroxy-2 pyrimidine, diéthoxy-2,4 méthyl-5 pyrimidine, hydroxy-2 pyridine et picolinate-4 de méthyle et X = Cl et Br, ont été préparés par la réaction de K_2PtCl_4 et L en solution aqueuse. Lorsque L = cytosine, l'isomère *cis* a été obtenu. Les complexes *trans* ont été obtenus avec tous les autres ligands. Le composé *trans* de la cytosine a été préparé à partir de l'isomère *cis*. La configuration des deux composés rapportés dans la littérature, avec cytidine et picolinate-4 de méthyle, a été réattribuée.

Introduction

Since the discovery of the antitumour properties of some platinum amine complexes $[Pt(am)_2Cl_2]$, a great number of platinum compounds have been tested for antitumour activity. The screening results have shown that the active compounds have the *cis*-configuration while the *trans*-isomers have no activity. Several authors have been looking for many years for other active metal complexes. Recently, Kirschner *et al.* reported some palladium complexes which seemed to be active (1). Previous studies on the chemistry of palladium complexes have shown that *cis*-$[Pd(am)_2Cl_2]$ isomerizes easily to the *trans*-isomer (2–4). It is therefore important that these isomerization reactions be well understood before drawing any conclusion from the antitumour activity results, especially when some of these tests are performed in non-aqueous solvents like DMF. Recently we have been interested in the isomerization reactions of platinum pyrimidine complexes (5). We now want to report a study of palladium complexes with pyrimidine and pyridine derivatives and reassign the configuration of two complexes which have already been reported.

Experimental

$PdCl_2$ was bought from Strem Chemical Inc. 2-Aminopyrimidine was obtained from Eastman and purified as previously described (5). Other pyrimidine derivatives were purchased from Aldrich or Biochemical and used without purification. The infrared spectra were measured in Nujol with cesium iodide plates on a Perkin-Elmer 621.

Solution of K_2PdX_4, X = Cl or Br

$PdCl_2$ and potassium halide were mixed together in 1:4 molar ratio. After 24 h, all $PdCl_2$ was digested. The solution was filtered and the filtrate was ready for use. The concentration of K_2PdX_4 was made approximately 0.1 *M*.

$[PdL_2X_2]$

Ligand (2 mmol) was added to 10 mL of the K_2PdX_4 solution (1 mm Pd). After stirring 3–5 h, the precipitate was filtered off, washed with water, air-dried, then washed with ether and dried.

The ligands used in this method are cytosine (cyto), cytidine (cyti), 1-methylcytosine (1Mcyto), 2-amino-4-methylpyrimidine (2A4Mpm), 2-hydroxy-4-methylpyrimidine (2H4Mpm), 4-methylpyrimidine (4Mpm), 2,4-diethoxy-5-methylpyrimidine (2,4E5Mpm), 2-hydroxypyrimidine (2Hpm), 2-hydroxypyridine (2Hpy), and methyl-4-picolinate (4Mpy).

trans-*$[Pd(cyto)_2Cl_2]$*

cis-$[Pd(cyto)_2Cl_2]$ was refluxed in water with cytosine in 1:2 molar ratio until the suspension became a yellow solution. After cooling to room temperature, the solution was filtered. Concentrated hydrochloric acid was added dropwise to the filtrate until the concentration of HCl was about 0.5 *M*. The mixture was stirred for 30 min. The yellow precipitate was filtered off, washed with 0.5 *M* HCl solution, and air-dried.

trans-*$[Pd(cyto)_2Br_2]$*

K_2PdBr_4 solution (10 mL, 1 mmol) was slowly added dropwise to a 75 mL solution of cytosine (4 mmol) at 75°C. A yellow solution was first formed, and then a precipitate appeared. The mixture was stirred for 30 min and then cooled to room temperature. The product was collected by filtration and washed with water. Yield 52%. The filtrate was acidified with a dilute HCl solution and a yellow precipitate was obtained. The product was isolated by filtration and washed with water. Yield 30%. Infrared spectroscopy showed that the two products were the same.

Ethanolic Solution of Li_2PdCl_4

An aqueous solutions of Li_2PdCl_4 was first prepared by the

method described to prepare K_2PdCl_4. The solution was then evaporated to dryness and dissolved in ethanol.

Attempt to Prepare cis-*[Pd(4Mpm)$_2$Cl$_2$]*

The ethanolic solution of Li_2PdCl_4 and 4-methylpyrimidine dissolved in ethanol were separately cooled in a dry ice – acetone bath. The pyrimidine solution was then added dropwise to the solution of Li_2PdCl_4 and a yellow precipitate appeared immediately. The product was isolated by filtration and washed with cooled ethanol and ether. The infrared spectrum of this compound was the same as that of *trans*-[Pd(4Mpm)$_2$Cl$_2$] isolated from water.

Results and Discussion

Infrared spectroscopy is a very effective method for distinguishing the *cis* from the *trans*-isomers of palladium complexes because there are marked differences in their spectra especially in the region of the skeleton vibrations of the complexes (3, 6). Recently, the structure of a pyrimidine complex, dichloro-bis(1-methylcytosine)palladium(II), was determined by X-ray diffraction (7). It was found to be the *trans*-isomer. We have prepared this compound and measured its infrared spectrum. The Pd—Cl stretching vibrations showed a single sharp band. This is consistent with a *trans*-configuration. N(3) is the binding site. The infrared spectrum of this *trans*-compound was used as reference to assign the configuration of other palladium compounds, which were prepared by a method similar to that of 1-methylcytosine, i.e. by the reaction of K_2PdCl_4 and the ligands in water.

All the ligands used in this study, except cytosine, gave compounds whose infrared spectrum showed a single Pd—Cl stretching band. They were therefore assigned to the *trans*-configuration (see Fig. 1 and Table 1). Kukushkin *et al.* (8) investigated several palladium complexes with various nitrogen bases (L). They reached the conclusion that the *cis*-isomer, PtL_2Cl_2, formed for the reaction of K_2PdCl_4 and L in water, isomerized rapidly, because of the higher stability of the *trans*-isomer. *cis*-[Pd(NH$_3$)$_2$Cl$_2$] (9) and *cis*-[Pd(py)$_2$Cl$_2$] (3) were isolated at low temperature but isomerized to the *trans*-compounds even in the solid state (2, 3). This would explain why the *cis*-isomers of palladium are quite rare. We attempted to prepare a *cis*-compound with 4-methylpyrimidine, by the reaction to Li_2PdCl_4 and the ligand in an ethanolic solution at low temperature. We had no success, since the *trans*-isomer was obtained.

The infrared spectrum of the cytosine compound showed two Pd—Cl stretching bands at 348 and 330 cm^{-1}. This is characteristic of *cis*-compounds. *trans*-Platinum pyridine complexes can usually be prepared by the following reactions (10):

[1] *cis*-[Pt(py)$_2$Cl$_2$] $\xrightarrow{py}$ [Pt(py)$_4$]Cl$_2$ $\xrightarrow{HCl}$ *trans*-[Pt(py)$_2$Cl$_2$]

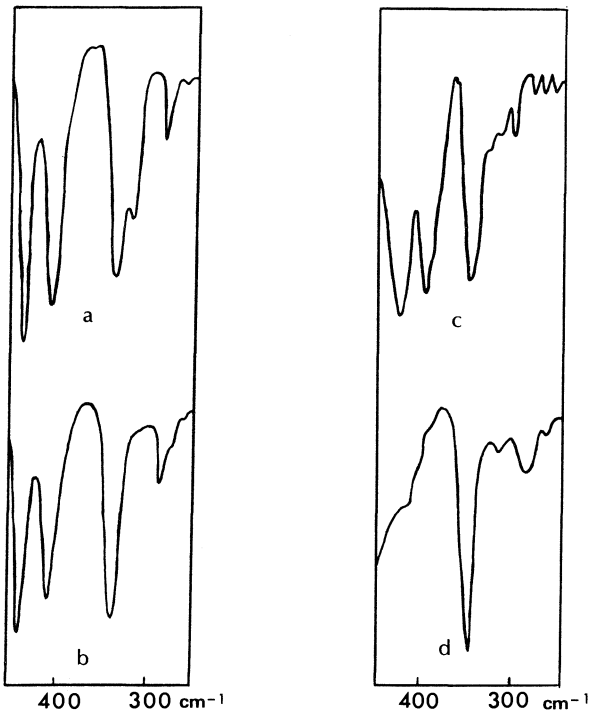

FIG. 1. Infrared spectra of (*a*) *cis*-[Pd(cyto)$_2$Cl$_2$], (*b*) *trans*-[Pd(cyto)$_2$Cl$_2$], (*c*) *trans*-[Pd(1Mcyto)$_2$Cl$_2$], and (*d*) *trans*-[Pd(cyti)$_2$Cl$_2$].

In order to obtain additional evidence on the *cis*-configuration of the cytosine compound, we attempted to prepare the *trans*-isomer by the above reactions. *trans*-[Pd(cyto)$_2$Cl$_2$] was obtained and its infrared spectrum showed just one single sharp Pd—Cl stretching band at 349 cm^{-1} (Fig. 1). A few *cis*-compounds, *cis*-[PdL$_2$X$_2$] where L = imidazole and X = Cl, Br (4) and L = benzimidazole, X = Br (8) have been reported. All these compounds showed two Pd—X stretching bands in their infrared spectra. The infrared spectra of both isomers of [Pd(cyto)$_2$X$_2$] are also different in the fingerprint region. Both isomers of the chloro compounds are yellow while the bromo isomers can be easily distinguished visually. The *cis*-compound is orange while the *trans*-isomer is yellow. *cis*-[Pd(cyto)$_2$Br$_2$] also differs from the *trans*-compound in its reaction with potassium iodide and perchloric acid. In dimethylformamide (DMF) solution, *cis*-[Pd(cyto)$_2$Br$_2$] reacts with KI to give a black colour within 1 h, while the *trans*-isomer has no apparent change after 2½ h (0.01 g of compound dissolved in 5 mL DMF + 0.15 g KI dissolved in 5 mL DMF). *cis*-[Pd(cyto)$_2$Br$_2$] in $HClO_4$ solution decomposes within 5 min while the *trans*-isomer starts to decompose 45 min later (0.02 g of compound in 5 mL of 0.6 *M* $HClO_4$).

*Calculated value of element analysis in first row.

A few years ago, $[Pd(4Mpy)_2Cl_2]$ (4Mpy = 4-$CH_3OC(O)C_5H_4N$), was reported (11*a*). Its infrared spectrum showed two stretching Pd—Cl bonds at 365 and 337 cm^{-1}. Therefore the compound was assigned as the *cis*-isomer by the authors. However, its bromo analogue has an infrared band at 340 cm^{-1}, which may be assigned as a bending mode of CH_3—O—C (12). We might conclude then, that the band at 337 cm^{-1} observed for the chloro compound is not caused by a Pd—Cl stretching but by the bending of CH_3—O—C. Therefore, there would be only one Pd—Cl stretching band, characteristic of the *trans*-configuration. The compound with 4-picolinic acid which has no ester group, *trans*-$[Pd(4\text{-}OHC(O)C_5H_4N)_2Cl_2]$, has only one Pd—Cl band at 369 cm^{-1} (11*a*). Furthermore the chloro compound was refluxed in the presence of the free pyridine ligand, and it was found to be unchanged. Because of reaction [1], this behaviour is not consistent with other *cis*-compounds. Complexes of the type $[ML_2X_2]$ (where M = Pd or Pt, L = nitrogen base, and X = halide) undergo *cis*-to-*trans* isomerization when heated (13), catalysed by an impurity (14) or by the free ligand (15, 16). There is no known case of isomerization in the opposite direction, *trans*-to-*cis*. It may therefore be assumed that the reactions are as follows:

$$[MX_4]^{2-} \xrightarrow{L} \textit{cis}\text{-}[ML_2X_2] \rightarrow \textit{trans}\text{-}[ML_2X_2]$$

When M = Pd, the *cis*-intermediate is often unstable and can be rarely isolated. We can therefore conclude that the compound $[Pd(4\text{-}CH_3OC(O)C_5H_4N)_2Cl_2]$ is the *trans*-isomer.

The synthesis of $[Pd(cyti)_2Cl_2]$ was reported (17). It was assigned as the *cis*-isomer without any comment. No infrared spectrum was reported. We have prepared this compound and its infrared spectrum was similar to other *trans*-complexes. One single band was observed in the Pd—Cl stretching region (Fig. 1*d*). Therefore it should be assigned as the *trans*-isomer.

Palladium and platinum coordinate to 1-methylcytosine and cytidine through N(3) (7, 18, 19). Cytosine coordinates to copper through N(3) (7). When N(1) is not deprotonated, usually N(3), which is a pyridine-type nitrogen, is the preferred coordination site. Therefore cytosine should also coordinates to palladium through N(3). N(1) of 4-methylpyrimidine, 2-amino-4-methylpyrimidine,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

2-hydroxy-4-methylpyrimidine, and 2,4-diethoxy-5-methylpyrimidine has less steric hindrance and should be the binding site (5).

The infrared spectrum of the palladium complex of 2-hydroxypyridine showed a strong ν_{O-H} stretching band at a frequency of 3420 cm^{-1} with a shoulder at 3480 cm^{-1}. Two strong bands at 1602 and 1580 cm^{-1} may be assigned as the stretching vibrations of the aromatic ring (11*b*). No other band appears higher than 1602 cm^{-1}, indicating that the ligand is not in the ketone form. A strong band at 262 cm^{-1} might tentatively be assigned as Pd—N stretching. All pyrimidine complexes have an absorption band in the 250–300 cm^{-1} region. This band is weak except for the 2-amino-4-methylpyrimidine and 2-hydroxy-4-methylpyrimidine complexes where the absorption band is medium. We cannot at the moment assign it unambiguously as a Pd—N stretching.

Both *cis*- and *trans*-$[Pd(cyto)_2Cl_2]$ react with thiourea (tu) to give $[Pd(tu)_4]Cl_2$, i.e. they do not respond to Kurnakov's test:

$$cis\text{-}[ML_2Cl_2] \xrightarrow{tu} [M(tu)_4]Cl_2 + 2L$$

$$trans\text{-}[ML_2Cl_2] \xrightarrow{tu} trans\text{-}[ML_2(tu)_2]Cl_2$$

Kurnakov's test should be used with extreme care because many isomers like *cis*- and *trans*-$[Pd(cyto)_2Cl_2]$ do not respond to the test, or at least the appropriate conditions for the reactions have not been found (16). The well known *trans*-compound of pyridine *trans*-$[Pd(py)_2Cl_2]$ liberates pyridine immediately in water, at room temperature, when mixed with thiourea. Correct information on the configuration of a compound therefore cannot be obtained by just testing one isomer which would give $[M(tu)_4]Cl_2$ (20). Infrared spectroscopy is probably a more reliable method.

High resolution nuclear magnetic resonance studies of platinum(II) – guanosine-5′-monophosphate interactions in aqueous solutions

MOSCHOS POLISSIOU,[1] MINH TAN PHAN VIET, MAURICE ST-JACQUES,[2] AND THEOPHILE THEOPHANIDES[2]

Université de Montréal, Département de Chimie, Montréal, (Qué.), Canada H3C 3V1

Received June 23, 1981

MOSCHOS POLISSIOU, MINH TAN PHAN VIET, MAURICE ST-JACQUES, and THEOPHILE THEOPHANIDES. Can. J. Chem. **59**, 3297 (1981).

A detailed 400 MHz ^{1}H nmr study was carried out on platinum complexation products of GMP by K_2PtCl_4. Coupling constant values show that platination on N7 induces a conformational change on the ribose moiety: the ^3E form of the ring and the gt conformer about the C(4′)—C(5′) bond are favoured upon complexation. The results are compared to the conformational changes induced by N7 protonation and methylation.

MOSCHOS POLISSIOU, MINH TAN PHAN VIET, MAURICE ST-JACQUES et THEOPHILE THEOPHANIDES. Can. J. Chem. **59**, 3297 (1981).

Faisant appel à la spectroscopie de rmn à 400 MHz, on a étudié les produits provenant de la complexation du MPG par le K_2PtCl_4. Les valeurs des constantes de couplage montrent que l'introduction du platine sur l'azote en position 7 provoque des changements de conformation sur le fragment ribose; la complexation favorise la forme ^3E du cycle et le conformère gt autour de la liaison C(4′)—C(5′). On a comparé ces résultats aux changements de conformation provoqués par la protonation et la méthylation de l'azote en position 7.

[Traduit par le journal]

Introduction

Platinum complexes and their interactions with purine and pyrimidine nuclosides and nucleotides as well as with nucleic acids have been the subject of extensive investigations in recent years (1). Interest in such interactions stems from the discovery that platinum compounds (e.g. *cis*-$Pt(NH_3)_2Cl_2$, *cis*-dichlorodiammineplatinum) show antitumor activity (2) and are being used in cancer treatment (3).

Most of the quantitative structural data on platinum–nucleotide interactions have been derived from X-ray diffraction and spectroscopic studies in the solid state (4, 5). These solid state studies reveal several interesting structural and conformational features of the nucleotides, such as sugar-ring pucker, rotation of the exocyclic methylene group and the phosphate group, as well as the orientation of these groups with respect to the platinum square plane. Reported X-ray results, mainly on 1:2 complexes of platinum with guanine nucleotides, such as *cis*-$[Pt(ammine)_2(nucleotide)_2]^{2+}$ have shown that the platinum atom is coordinated to N7 of guanine (6, 7).

Guanosine-5′-monophosphate (G^5′p), was chosen in this nmr study because of the recognized affinity of the guanosine base for platinum salts (8). Potassium tetrachloroplatinate(II) (K_2PtCl_4) was selected as complexing agent with G^5′p because it is one of the simplest ionic platinum salts available from which fundamental information about the effects of complexation could be derived by ^{1}H nmr measurements.

In the present work we report high resolution 400 MHz ^{1}H nmr spectra of D_2O solutions of K_2PtCl_4 and G^5′p for various metal/nucleotide concentrations. The chemical shifts of the H(8) proton of guanine provide information on the site of platinum binding to guanine while the chemical shifts of the sugar protons together with spin-coupling constants suggest that complexation perturbs the conformational equilibrium of the ribose ring significantly and causes the phosphate group to rotate with respect to the sugar ring.

Experimental

Guanosine-5′-monophosphate disodium salt was purchased from Sigma Chemical Company. K_2PtCl_4 was obtained from Johnson Matthey and Mallory Ltd. and the D_2O(99.996%) was supplied by Kor Isotopes.

The ^{1}H nmr spectra were obtained with a Bruker High Resolution WH-400 Spectrometer located at the Laboratoire régional de RMN à haut champ at Université de Montréal. Typically, a total of 200–500 transients were acquired in 32K of memory using a pulse width of 5 μs (corresponding to a flip angle of 60–70°). For coupling constant measurements, the 3000 Hz spectral width used results in an acquisition time of 5.472 s and in a digital resolution no better than 0.18 Hz. Probe temperature was about 20°C. The chemical shifts are referenced relative to the internal standard, sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS). The pD of the solutions was measured both before and after recording the nmr spectra with a Fisher Accumet 630 pH meter. The samples of G^5′p in D_2O were lyophilized

twice to reduce the HDO concentration. A partial exchange of H(8) was observed after lyophilization.

Samples of $[(PtCl_3)G^5'p]^-$ and $(PtCl_2)(G^5'p)_2$ (abbreviated: $Pt^7G^5'p$ and $Pt^7(G^5'p)_2$, respectively) were prepared using different ratios, $r = [Pt]/[G^5'p]$. The reaction of K_2PtCl_4 and $G^5'p$ in D_2O was slowed down by the addition of NaCl in order to follow the spectral changes of the new species formed. A typical nmr solution was prepared by mixing a solution of (5 or 10 m*M*) K_2PtCl_4 in D_2O in the presence of NaCl (20 m*M*) with a solution of $G^5'p$ (20 m*M*) in D_2O and the reaction was followed by ^1H nmr spectroscopy with time.

Excess of $G^5'p$ was used to avoid the formation of small quantities of paramagnetic polymeric blue complexes which broaden the nmr resonances (9). The blue complexes are predominant at high platinum-to-$G^5'p$ ratios, high reaction temperatures, and at pH above 9. The addition of 20 m*M* of NaCl in the solutions was necessary to slow down the substitution reaction by the base in the first coordination sphere of the platinum atom. The substitution of the second chloride in the *cis*-position was slower. Furthermore, aquation studies (9) of $[PtCl_4]^{2-}$ show that for concentrations of the order of 10^{-2} to 10^{-3} *M* the most predominant aquated species in solution is $[PtCl_3(H_2O)]^-$, the diaquated species, $PtCl_2(H_2O)_2$, exists in smaller quantities and is further suppressed by the presence of the chloride ions in solution. Aquation of the monosubstituted complex $[PtCl_3(G^5'p)]^-$ to form $[PtCl_2(H_2O)(G^5'p)]$ is also assumed to be very slow and comparable to diaquation of $[PtCl_4]^{2-}$. In fact, with a ratio of 4:1, $G^5'p$ to K_2PtCl_4 the monosubstituted complex is present in significant amount after 24 h at room temperature, whereas the disubstituted forms slowly and is dominant after about one week. Finally, the reaction of K_2PtCl_4 with $G^5'p$ can still be slowed down by lowering the pH (pD = 1) of the solutions and therefore have the platinum competing with the proton for the N7 site.

Results and Discussion

High resolution 400 MHz ^1H nmr spectra of samples of $G^5'p$ and of $G^5'p$–K_2PtCl_4 mixtures in D_2O were studied. The spectrum reported in Fig. 1 was taken 24 h after mixing and it reveals signals compatible with a mixture of two species, the major one being free $G^5'p$ and the minor one being the reaction complex $[PtCl_3(G^5'p)]^-$. The signal assignments shown are the same as that reported by Davies and Danyluk (10). Phosphorus decoupling simplifies the signals of H(4′) and H(5′,5″) as also shown in Fig. 1. The various chemical shift values are summarized in Table 1 while the coupling constants are collected in Table 2, where the data reported for the disubstituted species were obtained 160 h after mixing.

The high field spectra were analyzed by the first order method, which for $G^5'p$ gave parameters, are identical to those obtained from computer fits of spectra recorded at lower field (10, 11). In the case of $[PtCl_3(G^5'p)]^-$ and $[PtCl_2(G^5'p)_2]$, however, the signal of H(3′) appears as a triplet instead of a quartet. In such a situation, the two coupling constants involved ($^3J_{2',3'}$ and $^3J_{3',4'}$) are not necessarily equal and their individual values cannot be determined accurately by first order analysis. In

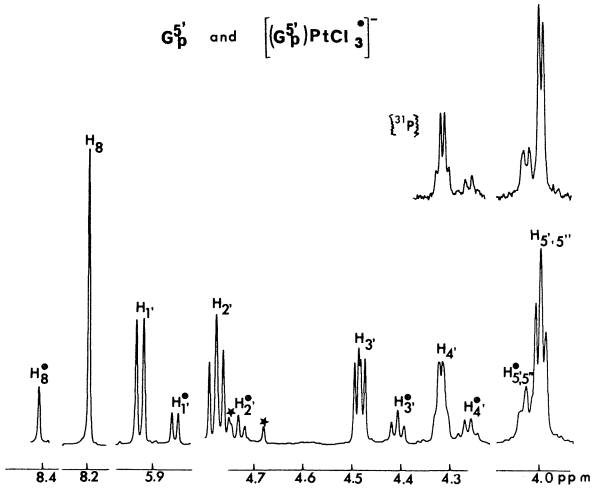

FIG. 1. 400 MHz ^1H nmr spectrum of a mixture of $G^5'p$ and $[PtCl_3(G^5'p)]^-$ (signals marked with a dot) in D_2O at 20°C. The inset shows the effect of ^{31}P irradiation. The * identifies spinning side bands of the residual HOD signal.

fact such "approximate" triplets yield only the sum of the two coupling constants involved. Homonuclear and ^{31}P decoupling experiments were used to simplify the analysis and the coupling constants obtained are given in Table 2. Among these a few are mean values.

The experimental results (Fig. 1 and Table 1) clearly show that H(8) and H(5′,5″) are displaced downfield whereas the sugar-ring protons H(1′), H(2′), H(3′), and H(4′) are all shifted upfield upon reaction and complexation with K_2PtCl_4. Chemical shifts for the disubstituted platinum complex $[PtCl_2(G^5'p)_2]$ recorded 160 h after mixing follow the same trend as observed for $[PtCl_3(G^5'p)]^-$. In fact, the upfield shift of the sugar-ring protons is even more pronounced.

The downfield shift of H(8) for $[PtCl_3(G^5'p)]^-$ appears to be a direct consequence of platinum binding at N7 which produces a polarizing effect of the C—H(8) bond towards the imidazole ring causing it to become electron deficient (11, 12), hence the use of the abbreviation $Pt^7G^5'p$. The downfield shift of 0.202 ppm observed for $Pt^7G^5'p$ is somewhat less than the value of 0.858 ppm determined for protonation of $G^5'p$ at N7 (Table 1) but is nevertheless compatible with a certain degree of positive character on the imidazole ring.

Support for the above conclusion is provided by the crystal structures of several metal–purine reaction complexes which reveal that binding of Pt occurs preferentially at N7 of the imidazole ring. For example, Kong and Theophanides have shown by ^1H nmr that the complexes $[Pt(Guo)_2(en)_2]^{2+}$

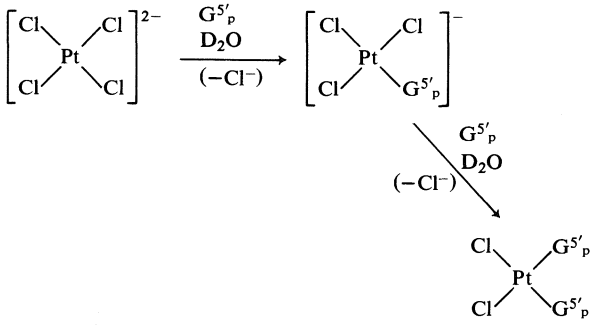
		Δδ	+0.831	+0.177	−0.049[b]	−0.001	+0.101	+0.354	+0.239
$m^7G^{5'}p$	7.0[c]	Δδ	—	+0.131	−0.156	−0.002	+0.048	+0.139	0.031

[a] The chemical shifts were determined relative to DSS.
[b] The values reported here for $H^7G^{5'}p$ are very similar to those reported in ref. 16 except for H(2′). However, the spectra shown in the paper suggest that our value is correct and that a typographical error exist in Table 1 or ref. 16.
[c] The values for $m^7G^{5'}p$ are all taken from ref. 11.

and $[Pt(Guo)_2(NH_3)_2]^{2+}$ are characterized by Pt binding to N7 of the guanine base in solution (8). These structures have been confirmed later by X-ray diffraction analysis (6, 7).

The crystal structure of the monosubstitution complex $Pt^7G^{5'}p$ is not known, although it has been observed that guanosine (G) reacts with K_2PtCl_4 to form 1:1 and 2:1 complexes (9). Mononucleoside platinum complexes have been shown to form in solution (8), and in some cases they have been isolated in the solid state (13). In the former study (9) K_2PtCl_4 has been found to give polynuclear paramagnetic blue or green substances at high temperatures, high pH values, and high $Pt/G^{5'}p$ ratios. For this reason the reaction conditions employed here were mild in order to avoid the formation of any polymeric species in solution which might perturb the proton resonances.

Initially the reaction of tetrachloroplatinate$^{(2-)}$ ion with $G^{5'}p$ yields predominantly $[PtCl_3(G^{5'}p)]^-$ in aqueous solution. With time the monosubstituted complex is transformed into the disubstituted derivative most likely according to the following reactions:



The above reaction is well known to proceed in two steps, firstly aquation and then substitution of the water molecule by $G^{5'}p$. The substitution process could in principle continue until all four chlorine atoms have been substituted by $G^{5'}p$ molecules (9). However, with excess chloride ions (NaCl) in solution the reaction rate is controlled and the above two steps are slowed down sufficiently to follow the evolution of each species by ^{1}H nmr spectroscopy. It is deduced that the second molecule of $G^{5'}p$ is complexed in the *cis*-geometry because the *trans* effect of chlorine atoms is higher than the —N= of the pyrole ring.

The disposition of the two $G^{5'}p$ units in the disubstituted complex can be determined from the chemical shift data. Only in the *cis*-form can the purine base be close enough to each other so that they may experience mutual shielding created by the ring currents in the purine moiety (14). Consequently such an effect is expected to lead to the additional upfield shift of H(8), H(1′), H(2′) of the disubstituted complex for which the two $G^{5'}p$ are *cis*.

Table 2 reveals that the coupling constants change significantly upon coordination of the platinum atom to N7 of $G^{5'}p$. Only the value of $J_{1',2'}$ decreases; all others ($J_{2',3'}$, $J_{3',4'}$, $J_{4',5'}$, and $J_{5',P}$) increase. It is now well known that the behavior of these parameters provides insight on the conformation of the sugar ring (15). Furthermore, results for protonation (16) and methylation (11) on N7 of $G^{5'}p$ ($H^7G^{5'}p$ and $m^7G^{5'}p$ respectively) provide useful references to which the effect of platination can be compared. Table 2 shows that $J_{1',2'}$ decreases from 6.1 for $G^{5'}p$ to 4.9 Hz for $Pt^7G^{5'}p$ whereas it has been reported that for $H^7G^{5'}p$ and $m^7G^{5'}p$ the values are 3.4 and 3.6 Hz respectively. The reduction of 1.2 Hz for $Pt^7G^{5'}p$ instead of ~2.5 Hz determined for the two model compounds is compatible with a reduced electronegativity of the guanine base owing to the fact that complexation with $PtCl_3^-$ is less electron demanding from N7 and the imidazole ring than is protonation or methylation.

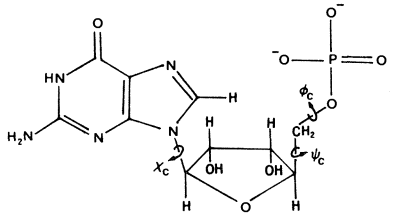
$^{3}E \equiv$ C3′endo $\quad$ $^{2}E \equiv$ C2′endo

Conformational populations for different segments of G^{5}′p were determined by methods explained below and are summarized in Table 3. Lee *et al.* (17) and Ezra *et al.* (11) have proposed a method to estimate the population of each of the C(2′)–endo (^{2}E) and C(3′)–endo (^{3}E) conformers of the ribose ring from the sum of $J_{1',2'}$ and $J_{3',4'}$. The value of 10.1 Hz determined for $Pt^{7}G^{5}$′p differs from the standard value of 9.5 Hz and can be ascribed to charge perturbations in the imidazole ring brought about by complexation. Because $J_{3',4'}$ is not expected to be affected significantly by electronegativity changes of the base, the $^{3}E/^{2}E$ ratios were determined using values of $J_{3',4'}$ and the standard sum of 9.5 Hz for $J_{1',2'} + J_{3',4'}$ (11).

The results given in Table 3 show that platination on N7 causes a change in the $^{2}E \rightleftharpoons {}^{3}E$ equilibrium whereby the proportion of the ^{3}E conformer increases from ~36% to ~51% for $Pt^{7}G^{5}$′p. This 15% increase is comparable to the 18% change observed for $m^{7}G^{5}$′p. Similar conformation changes were estimated for $H^{7}G^{5}$′p (16). Thus it appears that, notwithstanding differences in charge distribution in these three compounds, the ribose ring is shown to undergo a similar conformational change in favor of the ^{3}E form.

On the other hand Table 2 reveals that some differences do exist between the coupling constants of $Pt^{7}G^{5}$′p and $m^{7}G^{5}$′p. The mean value, $(J_{4',5'} + J_{4',5''})/2$, increases upon platination from 3.7 to 5.1 Hz while for $m^{7}G^{5}$′p a decrease from 3.6 to 2.1 Hz was reported (11). This difference is indeed very striking. In addition, the respective coupling constants of H(5′,5″) with ^{31}P could also be different; $^{3}J_{4',5'}$ and $^{3}J_{4',5''}$ are known with greater precision from the ^{31}P-decoupled ^{1}H nmr spectrum and their interpretation should be most significant.



3

Structure 3 illustrates the symbols employed to describe the various conformational features of G^{5}′p; χ_c describes the rotation of the glycosidic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

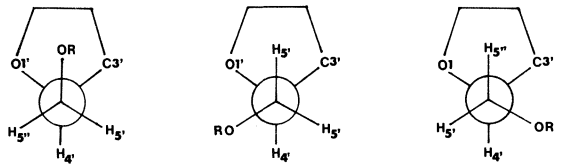
bond, ψ_c the rotation of the C(4′)—C(5′) bond, and ϕ_c the rotation of the C(5′)—O(5′) bond.



gg gt tg

The population of the gg, gt, and tg conformers about the C(4′)—C(5′) bond can be computed from $\sum = (J_{4',5'} + J_{4',5''})$ using the expression suggested by Lee and Sarma (18). Similarly the three rotameric populations about the C(5′)—O(5′) bond can be estimated from $\sum' = (J_{5'P} + J_{5''P})$.

The data in Table 3 show that the population change about the C(5′)—O(5′) bond is relatively small and because of the larger error in determining $\sum'$ for $Pt^7G^5'p$, the difference is not significant and will not be discussed further.

The conformational change about the C(4′)—C(5′) bond is, on the other hand, very significant. It is seen that the proportion of the gg form decreases from 65% for $G^5'p$ to 36% for $Pt^7G^5'p$. This change is to be contrasted with the increase to 97% of gg for $m^7G^5'p$ and 87% for $H^7G^5'p$. Thus N7 platination and methylation (or protonation) of $G^5'p$ produce opposite conformational changes. The conformational change determined for $m^7G^5'p$ was explained in terms of an electrostatic attraction involving the positively charge imidazole ring and the phosphate group (11). The opposite conformational change determined for $Pt^7G^5'p$ (from gg → gt (or tg)) can adequately be rationalized in terms of an electrostatic repulsion between the phosphate group and the platinum halide moiety. A similar interaction would exist with the $PtCl_2(G^5'p)$ moiety in $Pt^7(G^5'p)_2$ because here too the population of gg has decreased.

It is therefore quite interesting to note that while the $^2E \rightarrow {}^3E$ ribose conformation change is found to be very similar for platination and methylation on N7, the conformational change about the C(4′)—C(5′) bond is opposite and found to favour gg for $m^7G^5'p$ vs. gt (or tg) for $Pt^7G^5'p$. It would therefore appear that conformational interdependence between the ribose ring and the C(4′)—C(5′) bond, if it exists as suggested by Hruska (19), breaks down for nucleotides with a charged imidazole ring.

Alternatively, this result could provide support for the suggestion that a correlation exists only between the ribose ring conformation and the glycosidic bond orientation (χ_c). Of the various conformational features of nucleotides, rotation of the glycosidic bond (base orientation) has been most difficult to characterize quantitatively in solution although useful information was obtained in the crystalline state (4, 15).

Table 1 illustrates the effect of protonation, platination, and methylation of $G^5'p$ on ^1H chemical shifts. While protonation and methylation produce similar chemical shift changes relative to $G^5'p$ for the ribose ring proton, platination leads to striking differences. If compared to $H^7G^5'p$ and $m^7G^5'p$, H(3′) of $Pt^7G^5'p$ is more shifted upfield (about 0.076 ppm) and H(1′) and H(4′) show a sign reversal on platination compared to protonation and methylation.

There is no doubt that chemical shift differences can arise in part from a perturbation of the ribose ring conformation, rotation of the C(4′)—C(5′) conformation, and base reorientation. In spite of this complexity many attempts have focused on using the chemical shifts of H(1′) and H(2′) as probes for χ_c variations. The method used is based on semi-empirical calculations of shielding constants (20) in terms of several contributions such as ring current effects, diamagnetic and paramagnetic parts of atomic anisotropy of the bases as well as of the sugar phosphate backbone, polarization of bonds by molecular charge distribution, etc ... This approach has been applied with some success to non-complexed nucleic acid derivatives (20). For $m^7G^5'p$, it led to the conclusion that a small *syn* → *anti* shift of the conformational equilibrium takes place on methylation.

Unfortunately results for $Pt^7G^5'p$ show that H(1′) moves in opposite direction on platination (upfield) compared to methylation and protonation (downfield). Nevertheless, the upfield shift of the H(2′) signal for all three species as shown in Table 1 could suggest that changes in base orientation are similar for all three complexes as was found to be the case for the conformational change ($^2E \rightarrow {}^3E$) of the ribose ring provided the anisotropy effect of the $PtCl_3^-$ moiety is not dominant. It is therefore tempting to suggest that the differences observed for the chemical shifts of H(1′), H(3′), and H(4′) do not reflect significant differences in base reorientation.

Furthermore, it appears reasonable to expect that the gg → gt (or tg) change about the C(4′)—C(5′) bond will most affect the chemical shifts of H(3′) and H(4′) which are nearest to the rotated bond. This conformational change is therefore believed to be responsible in large part for the upfield shift of H(3′) and H(4′) relative to $m^7G^5'p$ and $H^7G^5'p$.

The upfield shift of H(1′) is more difficult to rationalize since complexation at N7 is expected to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

increase the electronegativity of the imidazole ring and thereby produce a downfield shift, although this effect is expected to be smaller than for protonation and methylation as is indicated from the behavior of H(8). This observation could argue against the validity of the hypothesis of a small anisotropy effect for the $PtCl_3^-$ moiety. On the other hand, a smaller H(1′) downfield shift on platination coupled to an upfield shift caused by the gg → gt change of the C(4′)—C(5′) bond could account for the observed chemical shift change of H(1′).

It must, however, be stressed that qualitative interpretation of small chemical shift differences in terms of specific conformational changes in metal-complexed nucleotides is not straightforward and may lead to erroneous conclusions whereas conformational changes deduced from variations in coupling constants are usually more reliable.

It therefore appears reasonable to conclude that platination of G5′p produces a small $^2E \rightarrow {}^3E$ ribose ring conformational change and a small perturbation of the purine base orientation similar to those produced by protonation and methylation on N7 but that different conformational changes are noted at the C(4′)—C(5′) bond. Platination therefore produces a gg → gt (or tg) rotation whereas protonation and methylation produce an opposite rotation gt (or tg) → gg.

Thermally induced crossed aldol condensations

JOHN A. FINDLAY, DIXIT N. DESAI, AND JOHN B. MACAULAY
Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received August 4, 1981

JOHN A. FINDLAY, DIXIT N. DESAI, and JOHN B. MACAULAY. Can. J. Chem. **59**, 3303 (1981).

A relatively efficient, noncatalytic method for effecting crossed aldol condensations between cyclic ketones and aldehydes and between cyclic 1,3-diones and methyl vinyl ketone is reported.

JOHN A. FINDLAY, DIXIT N. DESAI et JOHN B. MACAULAY. Can. J. Chem. **59**, 3303 (1981).

On rapporte une méthode, non catalytique, relativement efficace qui permet d'effectuer des condensations aldoliques croisées entre des cétones cycliques et des aldéhydes et également entre des diones cyclique-1,3 et la méthylvinylcétone.

[Traduit par le journal]

In the course of studies successfully directed at the total synthesis of the phytoalexin phytuberin we noted (1) the thermally induced C2 epimerization of 2-hydroxy methyl-2-methyl-5-isopropenylcyclohexanone **1***a* to **3***a* by heating at 185°C for 15 min in a sealed Pyrex tube (2), providing a 5:4 mixture of the diastereomers. We have now established that prolongation of the reaction time to 3 h provides dihydrocarvone **2** (3) plus the diastereomeric mixture **1***b*, **3***b* at the expense of the **1***a*/**3***a* yield. Pyrolysis of dihydrocarvone and paraformaldehyde under the same conditions gives a similar mixture (see Table 1). Performing these reactions in Pyrex vessels pretreated with trimethylsilylchloride does not alter the rate of reaction and thus it appears that the operative mechanism is the dealdolization–aldolization depicted in Scheme 1 in which the enol form of the cyclohexanone ring is the key intermediate.

Similar crossed condensations have now been

TABLE 1. Thermally induced crossed aldol condensations

Reactants	Temperature (°C)	Time (h)	Products[a]	Yield (%)

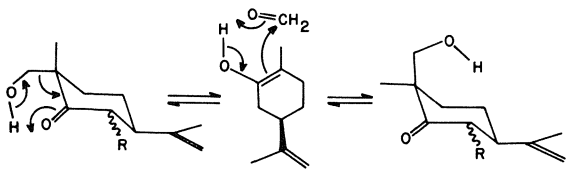

SCHEME 1. Dealdolization–aldolization mechanism.

effected by us between cyclohexanone and a number of aldehydes and between 2-methyl-1,3-cyclohexanedione and methyl vinyl ketone to provide an improved synthesis of the known (4) 3,4,8,8a-tetrahydro-8a-methyl-1,6(1*H*,7*H*)-naphthalenedione **7**.

We have not observed any competing crossed or self-condensation products in the examples studied and starting compounds constituted the bulk of the balance of recovered materials in all cases. Attempted isolation of compounds **5** and **6** using silica gel chromatography led exclusively to their corresponding dehydration products while compound **7** was recovered directly from the reaction mixture.

Attempts to condense acetone or acetophenone with aldehydes under the conditions described were unsuccessful and this is consistent with the belief that the thermally induced aldolization proceeds via a six-membered ring transition state employing the enol form of the ketone (see Scheme 1) since the enol form of cyclic ketones is known (5) to be more prevalent than that of acyclic carbonyl systems. It is also possible that the failure in some cases may be due to unfavourable equilibria between aldol product and starting materials.

Mixtures of methyl isobutyl ketone with three butanols at various temperatures

ROQUE RIGGIO, JUAN F. RAMOS, MARIANA HERNANDEZ UBEDA, AND JOSÉ A. ESPINDOLA

Departamento de Ciencias Exactas, Universidad Nacional de Salta, Salta, Argentina

Received August 15, 1980[1]

ROQUE RIGGIO, JUAN F. RAMOS, MARIANA HERNANDEZ UBEDA, and JOSÉ A. ESPINDOLA. Can. J. Chem. **59**, 3305 (1981).

The viscosities, densities, and refractive indices at 20, 25, 30, and 35°C were determined for the systems: methyl isobutyl ketone – *n*-butanol (MIK–B_1), methyl isobutyl ketone – *sec*-butanol (MIK–B_2), and methyl isobutyl ketone – isobutanol (MIK–B_3). From the experimental results the excess volume, excess viscosity, and excess molar free energy of activation of flow were calculated. The deviations from ideality for the excess thermodynamic function are more important for the system (MIK – B_2) than for the systems (MIK–B_3) and (MIK–B_1). This fact is explained by the existence of hydrogen bonds in the alcohols, stronger in the primary alcohols than in *sec*-butanol.

ROQUE RIGGIO, JUAN F. RAMOS, MARIANA HERNANDEZ UBEDA et JOSÉ A. ESPINDOLA. Can. J. Chem. **59**, 3305 (1981).

Les valeurs de la viscosité, densité et indice de réfraction ont été determinées à 20, 25, 30 et 35°C pour les sytèmes: methyle isobutyle cétone – *n*-butanol (MIK – B_1), méthyle isobutyle cétone – butanol secondaire (MIK – B_2) et méthyle isobutyle cétone – isobutanol (MIK – B_3). Les fonctions de l'écoulement ont été calculées à partir des données expérimentales. Les déviations de l'idéalité pour les fonctions thermodynamiques d'excès sont plus importantes pour le systeme (MIK – B_2) que pour les systèmes (MIK –B_3) et (MIK – B_1). Ce fait est expliqué par l'existence de ponts hydrogene moins forte dans les alcools primaires que ceux dans le butanol secondaire.

Introduction

Viscosities of binary liquid–nonelectrolyte mixtures have been studied to obtain information about the type and degree of interaction between molecules of the components of some binary systems. Positive deviations from ideal behavior mean strong interaction between unlike molecules, but if negative deviations are present, dispersion forces are dominant (1).

The following systems: methyl isobutyl ketone + *n*-butanol (MIK–B_1), methyl isobutyl ketone + *sec*-butanol (MIK–B_2), and methyl isobutyl ketone + isobutanol (MIK–B_3) were chosen because the alcohols show hydrogen bonding and the methyl isobutyl ketone has polar characteristics.

Densities, viscosities, and refractive indices for the three systems at different molar fractions were measured at 20, 25, 30, and 35°C. Some data for these three physical constants of the pure compounds are tabulated in the literature.

From the experimental results the following thermodynamic functions have been calculated: ΔV^E (excess molar volume), $\Delta\eta^E$ (excess of viscosity), and ΔG^{*E} (excess molar free energy of activation of flow).

Experimental

Density

Densities were determined with a Robertson specific gravity bottle (2). The total pycnometer volume was about 20 mL and was calibrated with doubly distilled water at various temperatures. All weighing operations were made on a Mettler balance H-311 with an accuracy of ± 0.0001 g, and corrected to vacuum.

Viscosity

Viscosities of pure liquids and mixtures have been determined with a Cannon Feske viscosimeter calibrated with doubly distilled water, benzene, and sucrose solutions (3).

Refractive Index

The refractive indices for the sodium D line of the pure components and mixtures were measured with a Jena refractometer with an accuracy of ± 0.00002. In the three cases a thermostatically controlled bath, constant to ± 0.01°C, was used.

Materials and Solutions

Methyl isobutyl ketone, *n*-butanol, *sec*-butanol, and isobutanol, all Merck Darmstadt p.a., were twice distilled over dried K_2CO_3 under a nitrogen atmosphere with a Vigreux column, and only the middle half of each distillation was recovered and used in the experiments.

The physical properties of the components are compared with those reported in the literature (Table 1).

Results

The experimental molar fraction, densities, viscosities, and refractive indices[2] for all the systems at 20, 25, 30, and 35°C were used to calculate the excess thermodynamic functions with the following equations (4):

$$\Delta\eta^E = \eta - (x_1\eta_1 + x_2\eta_2)$$

$$\Delta V^E = V - (x_1V_1 + x_2V_2)$$

$$\Delta G^{*E} = RT\ln\eta V - (x_1\ln\eta_1 V_1 + x_2\ln\eta_2 V_2)$$

where η, η_1, and η_2 are the viscosity of the mixture and of the pure components; V, V_1, and V_2 are the molar volume of the mixture and of the pure

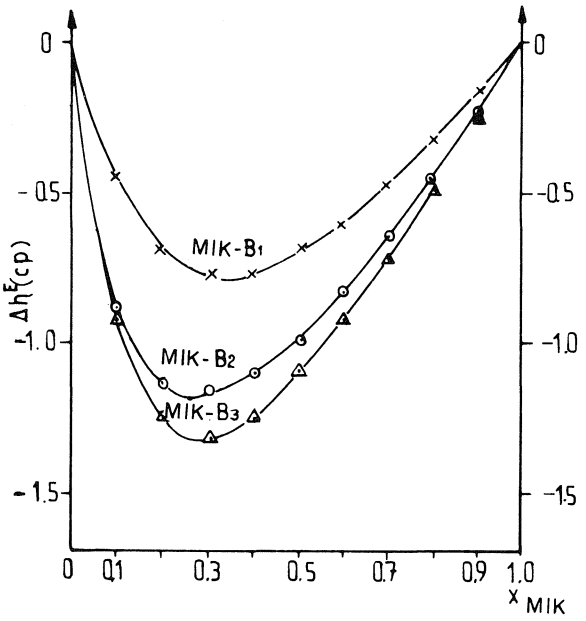

FIG. 1. $\Delta\eta^E$ vs. X_{MIK} at 25°C.

the standard error of the estimate defined by

$$\sigma x = \left[\sum (x_{obs} - x)^2/(n_{obs} - n)\right]^{1/2}$$

was determined (where n_{obs} is the number of measurements.) The optimum number of coefficients was ascertained from an examination of the variation of the standard error of the estimate with n.

The values adopted for the coefficients a_j and the standard error of the estimate are summarized in Table 2. These values are in good agreement with previous results for the (MIK–B_1) system (5, 6).

Only $\Delta\eta^E$, ΔV^E, and ΔG^{*E} at 25°C are shown in Fig. 1, 2, and 3; for the other temperatures the curves are similar.

In order to determine the minimum values of $\Delta\eta^E$ the Newton–Raphson method (7) was applied to eq. [1]. The values obtained were 0.268 for the (MIK–B_2) system, 0.284 for (MIK–B_3), and 0.340 for (MIK–B_1).

Discussion

The experimental values of viscosities show a relatively high decrease after the initial addition of

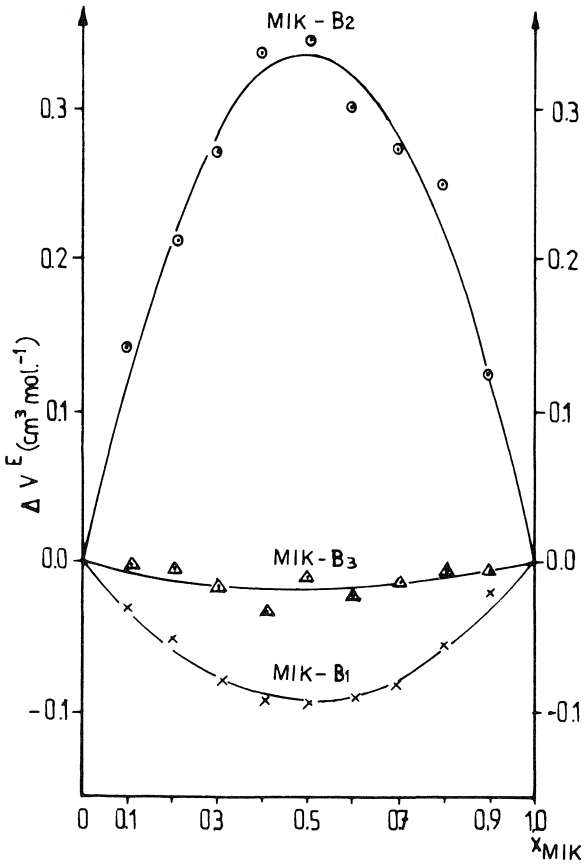

FIG. 2. ΔV^E vs. X_{MIK} at 25°C.

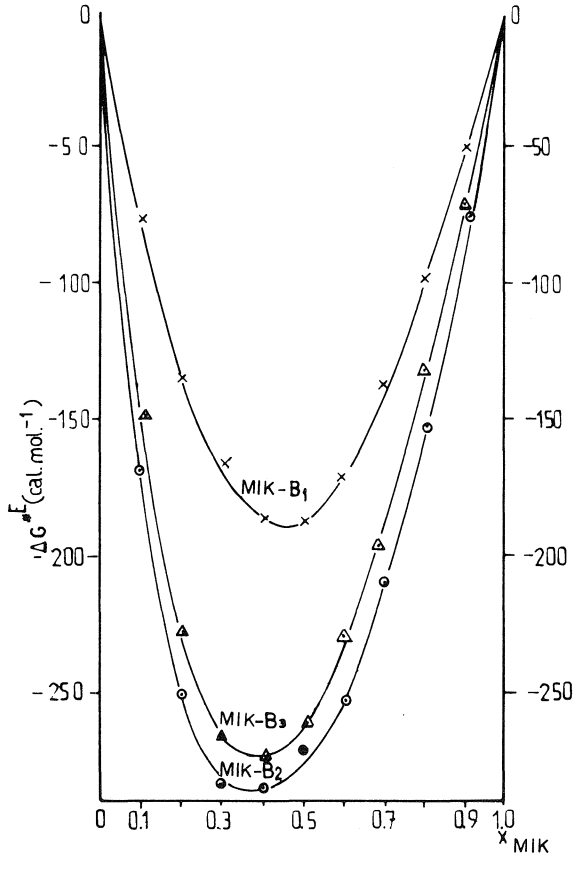

FIG. 3. ΔG^{*E} vs. x_{MIK} at 25°C.

the alcohols. This behavior is characteristic of systems in which at least one of the components exhibits hydrogen bonding.

On account of the very important values of the MIK concentration in the initial mixtures, this component has a predominant effect and causes the hydrogen bonding of the alcohols to break.

This behavior suggests that the hydrogen bonding between the *sec*-butanol molecules is the most labile of all, in good agreement with the literature on secondary alcohols (12). Isobutanol shows more negative values of $\Delta\eta^E$ than *n*-butanol owing to the fact that isobutanol has a methyl group at the α-carbon. These conclusions are strengthened by the values obtained for $\Delta\eta^E$ in these systems.

One expects (Fig. 2) breaking of hydrogen bonding in the alcohols to result in curves of ΔV^E with positive deviations for the systems (MIK–B_1) and (MIK–B_3). The negative values obtained for such systems show that there is an apreciable association between the different molecules.

For the (MIK–B_2) system we do observe a positive deviation. This behavior can be attributed to a neat rupture of association complexes between the alcohol molecules and the small possibility of forming other types of complexes between the MIK and B_2 owing to the position of OH^- group in the alcohol molecule.

On the basis of Fig. 3, we observe increasingly negative deviations in the order (MIK–B_2) > (MIK–B_3) > (MIK–B_1). This behavior is in good agreement with the discussion of the preceding paragraph.

The almost linear variation of the refractive indices for the three systems in terms of the composition is in agreement with the conclusion of Loiselier (13) for a large number of ideal and nonideal systems.

Neither the polar characteristic of the MIK nor the existence of hydrogen bonding in alcohols seem to have any important effect on the linear dependence of this property with concentration.

Isotopic exchanges in the treatment of cyclopentane or cyclohexane with some deuterated or tritiated acids

CHOI CHUCK LEE AND ERIC C. F. KO

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received May 26, 1981

CHOI CHUCK LEE and ERIC C. F. KO. Can. J. Chem. **59**, 3309 (1981).

The exchange between the H atoms of cyclopentane (**3**) or cyclohexane (**4**) and the labeled acid protons of CF_3SO_3D (**2**-*d*), $[^3H]CF_3SO_3H$ (**2**-*t*), $[^3H]H_2SO_4$ (**1**-*t*), or $ZnCl_2$–$[^3H]HCl$ (**5**-*t*) has been investigated. Results from the treatment of **3** or **4** with **2**-*d* at 0° or 20°C, respectively, gave rise to polydeuterated cycloalkanes, indicating that all H atoms of **3** or **4** could be involved in the exchange. The rates of incorporation of the T-label into the hydrocarbon layer from the tritiated acids were found to be directly related to acid strength. After treatment of **3** or **4** with **2**-*t*, quenching of the acid layer and analysis by isotope dilution showed the presence of cyclopentanol or cyclohexanol. A carbocationic chain mechanism for the exchange, as well as the mechanism for the formation of the cycloalkyl cation from the cycloalkane, are discussed.

CHOI CHUCK LEE et ERIC C. F. KO. Can. J. Chem. **59**, 3309 (1981).

On a étudié la réaction d'échange entre les atomes d'hydrogène du cyclopentane (**3**) ou du cyclohexane (**4**) et les protons acides marqués des composés suivants: CF_3SO_3D (*d*-**2**), $[^3H]CF_3SO_3H$ (*t*-**2**), $[^3H]H_2SO_4$ (*t*-**1**) ou $ZnCl_2$–$[^3H]HCl$ (*t*-**5**). Les produits issus de la réaction des composés **3** ou **4** avec le composé *d*-**2** à 0° ou 20°C respectivement sont des cycloalcanes polydeutérés, indiquant par là que tous les atomes d'hydrogène des composés **3** ou **4** peuvent être impliqués dans l'échange. On a trouvé que les vitesses d'incorporation des marqueurs au tritium dans la phase hydrocarbonée à partir des acides tritiés sont reliés directement à la force de l'acide. Le piégeage de la phase d'acide, après la réaction des composés **3** ou **4** avec le composé *t*-**2**, suivi d'une analyse par dilution isotopique révèle la présence de cyclopentanol et de cyclohexanol. On discute d'un mécanisme en chaine de type carbocationique pour l'échange, ainsi que d'un mécanisme de formation du cation cycloalkyle à partir du cycloalcane.

[Traduit par le journal]

The treatment of cyclopropane with D_2SO_4 (**1**-*d*) (1) or $[^3H]H_2SO_4$ (**1**-*t*) (2) led to the formation of 1-propyl products with the isotopic label distributed over all three carbon positions, and these results were attributed to the involvement of equilibrating protonated cyclopropane intermediates (3, 4). The treatment of cyclobutane with **1**-*t*, CF_3SO_3D (**2**-*d*), or $[^3H]CF_3SO_3H$ (**2**-*t*) failed to give any significant amount of open chain butyl product, but a facile incorporation of the T-label from **2**-*t* into the hydrocarbon layer was observed (5). This exchange was recently shown to involve a carbocationic chain mechanism and quenching with H_2O led to the detection of cyclobutanol, cyclopropylcarbinol, and allylcarbinol, indicating the formation of the bicyclobutonium ion (6). The results from cyclobutane thus resemble closely the earlier finding of Otvos *et al.* (7), reported in 1951, that the treatment of isobutane with **1**-*d* gave rise to the *tert*-butyl cation, and that exchange occurred with all 9 α-hydrogens. It is of interest to ascertain what would take place when cycloalkanes other than the small ring hydrocarbons are treated with acids under similar conditions. Hence in the present work, studies were made on the exchange reactions between cyclopentane (**3**) or cyclohexane (**4**) with some deuterated or tritiated acids.

The treatment of **3** or **4** with **2**-*d* followed by mass spectral analysis showed the presence of polydeuterated species in the region of the molecular ions, and the results are summarized in Tables 1 and 2. In measuring the relative composition of the various deuterated species given in these tables, while the errors in some cases could be as high as ± 5–10% of the recorded values, all of the observed peaks were definitely present. Although the relative composition of the d_{10} species from **3** was only $0.2 \pm 0.02\%$ and that of the d_{12} species from **4** was $0.1 \pm 0.01\%$, their presence was real. The results in Tables 1 and 2 thus indicate that all of the H atoms of **3** or **4** could be involved in the H–D exchange, a behavior that was also observed in similar studies with cyclobutane and **2**-*d* (6).

Upon treatment of **3** or **4** with **2**-*t*, incorporation of the T-label into the hydrocarbon through H–T exchange also took place, again as was observed in the treatment of cyclobutane with **2**-*t* (6). Since all of the H atoms of the cycloalkane could be involved in the exchange as was demonstrated in studies with **2**-*d*, at infinite time, a complete mixing of all H isotopes could be assumed and the specific activity of the recovered **3** or **4** after complete exchange, x_∞, could then be calculated (6). At different reaction times, the specific activities of the recovered cycloalkane were determined and the ratio, x/x_∞, would give a measure of the extent of exchange. Such results from the reaction of **2**-*t* with **3** and with **4**, at 20° and 40°C, respectively, are summarized in

[a] From mass spectral analysis of 0.20 mL aliquots of the hydrocarbon layer withdrawn periodically from an initial mixture of 3.00 mL of **4** and 6.00 mL of **2**-*d* mechanically shaken at 20°C, the d_0 species being at *m/e* 84 for C_6H_{12}.
[b] There was an induction period and no D incorporation into the hydrocarbon was observed at reaction times of up to 1.5 h.
[c] Corrected for $p + 1$ and $p + 2$ due to ^{13}C.

Tables 3 and 4. From plots of ln $[1 - (x/x_\infty)]$ vs. reaction time, straight lines were obtained, the negative slopes of which gave the first order rate constants, k, for the appearance of T in the recovered **3** or **4** (6, 7). The k values obtained were 2.6×10^{-5} s^{-1} and 1.5×10^{-5} s^{-1}, respectively, for the incorporation of T into **3** at 20°C and into **4** at 40°C (Tables 3 and 4). When **3** or **4** was treated with **2**-*t* for 24 h at 20° or 40°C, respectively, the nmr spectrum of the hydrocarbon layer showed the presence of only **3** or **4**. After quenching the acid layer with H_2O, analysis by isotopic dilution showed the presence of only cyclopentanol or cyclohexanol, indicating the formation of the cyclopentyl or cyclohexyl cation from **3** or **4**, respectively, and no methylcyclopentyl cation from **4** was detected.

On treating **3** or **4** with **1**-*t* at 85°C in sealed tubes, H–T exchange was also found to have taken place, but the incorporation of T into the cycloalkane was much slower than in the reactions with **2**-*t*. The results are given in Tables 5 and 6, the k values for the appearance of T in **3** or **4** on treatment with **1**-*t* at 85°C being 4.9×10^{-7} s^{-1} and 1.5×10^{-7} s^{-1}, respectively. Attempts were also made to ascertain whether exchange would occur between **3** or **4** and tritiated Lucas reagent (ZnCl–[^{3}H]HCl, **5**-*t*). When mixtures of **3** or **4** and **5**-*t* in sealed tubes were heated at 85°C as in the experiments with **1**-*t*, there was a high tendency for the tubes to break. Consequently, only two experiments were carried out with **3** at reflux temperature. When a stirred mixture of 3.0 mL of **3** and 9.0 mL of tritiated Lucas reagent was heated under reflux in a water bath at

TABLE 3. Incorporation of T into the hydrocarbon layer in the treatment of cyclopentane (**3**) with [^{3}H]CF_3SO_3H (**2**-*t*) at 20°C[a]

[a] Samples each containing 1.00 mL of **3** and 2.00 mL of **1**-*t* with specific activity of 2.82×10^6 dpm/mmol were shaken in sealed tubes at 85°C. The calculated x_∞ was 6.01×10^6 dpm/mmol C_5H_{10}.
[b] To allow for the induction period, each sample was shaken for 1.5 h before being regarded as having reached its zero time.

50°C for 2 or 4 days, the recovered **3** showed x/x_∞ values of 1.2×10^{-4} and 2.2×10^{-4}, respectively, indicating that only a very small amount of exchange has taken place.

From the results described above, it is clear that cyclopentane (**3**) or cyclohexane (**4**), when treated with the various deuterated or tritiated acids, showed behaviors quite similar to those observed for cyclobutane (6), and these results may be interpreted by a carbocationic chain mechanism as originally suggested by Otvos *et al.* (7). The chain initiation is the formation of a carbocation, the cyclopentyl or cyclohexyl cation from **3** or **4**. A slow formation of such a cation in the initiation step may thus account for the observation, in the present and previous studies (6, 7), of a variable induction period. The carbocationic chains are

TABLE 6. Incorporation of T into the hydrocarbon layer in the treatment of cyclohexane (**4**) with [^{3}H]H_2SO_4 (**1**-*t*) at 85°C[a]

Reaction time (h)	Specific activity x (10^{-5} dpm/mmol)	x/x_∞

[a] Samples each containing 0.50 mL of **4** and 1.00 mL of **1**-*t* with specific activity of 2.82×10^6 dpm/mmol were shaken in sealed tubes at 85°C. The calculated x_∞ was 7.03×10^6 dpm/mmol C_6H_{12}.
[b] To allow for the induction period, each sample was shaken for 1.5 h before being regarded as having reached its zero time.

then propagated through intermolecular transfers of hydride ions between the cation and the cycloalkane ($R^+ + RH \rightleftarrows RH + R^+$). During the lifetime of the carbocation, H–D or H–T exchange may occur, presumably at the carbons α to the positive charge, since in the studies with isobutane and **1**-*d* (7) the 9 α-H atoms, but not the tertiary H atom, were found to undergo H–D exchange. The involvement of all H atoms of **3** or **4** in the exchange observed in the present work may be explained by the occurrence of 1,2-hydride shifts around the ring in the cyclopentyl or cyclohexyl cation, thus allowing the H atoms at all carbon positions to become α to the positive charge and to undergo exchange.

It is of interest to note that Olah and Lukas (8) have found that protonation of **3** in FSO_3H–SbF_5 or HF–SbF_5 solution at above −10°C yielded, via cleavage and rearrangement, the *tert*-amyl cation. At temperatures below −10°C and in solution diluted with SO_2ClF, the cyclopentyl cation was obtained from **3** and the ^{1}H nmr spectrum of this cation showed only one singlet, indicating rapid 1,2-hydride shifts around the ring, thus rendering all H atoms equivalent. The treatment of **4** with FSO_3H–SbF_5 (8) at room temperature was found to give rise to a 9:1 mixture of the methylcyclopentyl and 2,3-dimethyl-2-butyl cations resulting from rearrangement and cleavage of the incipient cyclohexyl cation. The present work has shown that by the use of ordinary acids such as CF_3SO_3H or H_2SO_4, instead of the super-acids employed by Olah and Lukas, and at ordinary temperatures, the cyclopentyl or cyclohexyl cation could be generated from **3** or **4**. Under these conditions, proton exchanges could occur but there was little cleavage to give acyclic products. The present results also would suggest that if a nonspecifically labeled cycloalkane were to be prepared, a treatment with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

a deuterate or tritiated acid such as **2**-*d* or **2**-*t* under quite mild conditions would be an easy route to produce such a labeled cycloalkane.

The formation of a carbocation from the corresponding hydrocarbon would, of course, involve an overall oxidation or hydride abstraction (6–8). In the present work, it was found that the treatment of **3** with tritiated Lucas reagent did give rise to a very small, but detectable, amount of exchange. Since Lucas reagent could not act as an oxidizing agent, this finding would suggest the possibility that a direct chemical oxidation may not be the mechanism responsible for the carbocation formation. The rates of incorporation of T through exchange between the acid proton and the cycloalkyl cation have clearly been shown to be $CF_3SO_3H > H_2SO_4 > ZnCl_2$–HCl, and these findings could be considered as being consistent with Olah's proposal (9) of an electrophilic protolysis of a C—H bond to give a pentacoordinated carbonium ion as a key step in the eventual formation of the tricoordinated carbocation.

Experimental

Materials

[^{3}H]H_2SO_4 (**1**-*t*), [^{3}H]CF_3SO_3H (**2**-*t*), and CF_3SO_3D (**2**-*d*) were prepared as described previously (6). The tritiated Lucas reagent, **5**-*t*, was made up by combining equimolar amounts of $ZnCl_2$ and concentrated HCl containing [^{3}H]HCl. Cyclopentane (**3**) and cyclohexane (**4**) were of spectroquality and were washed with cold concentrated H_2SO_4 and redistilled or purified by preparative vpc.

Treatment of ***3*** *or* ***4*** *with* ***2***-d

A mixture of 3.00 mL of **3** and 6.00 mL of **2**-*d* was shaken mechanically in a stoppered glass tube kept at 0°C in an ice–water bath. Periodically, 0.20 mL aliquots of the hydrocarbon layer were withdrawn and analyzed by mass spectrometry to give the results recorded in Table 1. Similarly, from a mixture of 3.00 mL of **4** and 6.00 mL of **2**-*d* shaken at 20°C, analysis of 0.20 mL aliquots of the organic layer withdrawn periodically gave the results summarized in Table 2.

Treatment of ***3*** *or* ***4*** *with* ***2***-t

A mixture of 5.00 mL (3.75 g, 53.5 mmol) of **3** and 10.00 mL (17.15 g, 114.3 mmol) of **2**-*t*, with a specific activity of 2.10×10^7 dpm/mmol, was shaken mechanically in a stoppered glass tube kept in a water bath maintained at 20°C. After the induction period had passed, 0.20 mL and 0.40 mL aliquots, respectively, of the hydrocarbon and acid layers were withdrawn at different times. Each hydrocarbon aliquot was redistilled and its activity determined. In this way, the relative amounts of hydrocarbon to acid, and hence the theoretical specific activity in the hydrocarbon layer at complete exchange, x_∞, would remain constant throughout the experiment.

In this experiment, the total amount of activity involved was $114.3 \times 2.70 \times 10^7 = 2.40 \times 10^9$ dpm, and the total amount of H involved was $(53.5 \times 10) + 114.3 = 649.3$ mg atoms.

At complete exchange, the specific activity, x_∞, would be $(2.40 \times 10^9)/649.3 = 3.70 \times 10^6$ dpm/mg atom H or 3.70×10^7 dpm/mmol C_5H_{10}.

Using the specific activity x determined for the hydrocarbon aliquots at different times, x/x_∞ values were calculated. The results are given in Table 3.

In a similar manner, treatment of 5.00 mL (3.90 g, 46.3 mmol) of **4** with 10.00 mL (17.15 g, 114.3 mmol) of **2**-*t* at 40°C gave the results summarized in Table 4.

After a mixture of **3** or **4** and **2**-*t* under the conditions described above was shaken at 20° or 40°C, respectively, for 24 h, the nmr and mass spectra of the recovered hydrocarbon showed it to be unchanged **3** or **4**, with singlet nmr absorption at 1.43 or 1.40 ppm and molecular ion at *m/e* 70 or 84 for **3** or **4**, respectively. Quenching of 1.00 mL aliquots of the acid layer with 10.0 mL of H_2O containing 1.0 mL of cyclopentanol or cyclohexanol as carrier, followed by vpc purification of the recovered alcohol and its conversion to the α-naphthylurethane in a manner as described previously (6), showed that the urethane derivative was radioactive, the mean specific activity of the α-naphthylurethane of the cyclopentanol or cyclohexanol obtained under these conditions being 1.60×10^3 or 8.90×10^3 dpm/mmol, respectively.

Treatment of ***3*** *or* ***4*** *with* ***1***-t

The treatment was carried out at 85°C in individual sealed tubes each containing 1.00 mL (751 mg, 10.7 mmol) of **3** and 2.00 mL (3.88 g, 39.6 mmol) of **1**-*t* or 0.50 mL (390 mg, 4.63 mmol) of **4** and 1.00 mL (1.44 g, 19.8 mmol) of **1**-*t*. The reaction mixtures were shaken at 85°C for 1.5 h before being considered as having reached zero time. At different times after this arbitrarily chosen induction period, the incorporations of T into the hydrocarbon layer were measured to give the results summarized in Tables 5 and 6.

Treatment of ***3*** *with* ***5***-t

A mixture of 3.00 mL (2.25 g, 32.1 mmol) of **3** and 9.00 mL (30.3 mmol HCl) of tritiated Lucas reagent (**5**-*t*) with a specific activity of 3.25×10^6 dpm/mmol was heated with stirring and under reflux in a water bath at 50°C for 2 or 4 days. The recovered hydrocarbon was washed with a 5% NaOH solution, dried with $MgSO_4$, and redistilled. Its activity was found to be 334 and 607 dpm/mmol, respectively, for the samples recovered after 2 and 4 days. Under these conditions, the calculated x_∞ was 2.80×10^6 dpm/mmol, hence x/x_∞ values for the recovered **3** after reaction times of 2 and 4 days were 1.2×10^{-4} and 2.2×10^{-4}, respectively.

N-(2′-Deoxy-β-D-*erythro*pentofuranosyl) formamide is an ionizing radiation-induced degradation product of 2′-deoxythymidine. This work describes a facile chemical synthesis of this molecule, and discusses the results of an ^1H and ^{13}C nmr study. The rotational barrier to *cis–trans* isomerization about the amide linkage is calculated, and details of the molecular conformation of the *cis* and *trans* isomers in aqueous solution are presented.

La dégradation de la déoxy-2′ thymédine induite par une radiation ionisante conduit au *N*-(déoxy-2′β-D-*erythro* pentofuranosyl) formamide. Ce travail décrit une synthèse chimique facile de cette molécule; on discute aussi des résultats obtenus lors de son étude par la rmn du ^1H et du ^{13}C. On a calculé la barrière à la rotation de l'isomérisation *cis–trans* autour du lien amide et on fournit des détails relatifs à la conformation des isomères *cis* et *trans* en solution aqueuse.

[Traduit par le journal]

Introduction

Exposure of nucleic acids to ionizing radiation leads to a modification of their constituents and to local functional and conformational alterations in polynucleotides (1). *N*-(2′-deoxy-β-D-*erythro*-pentofuranosyl) formamide (dF, Fig. 1) and its derivatives appear to be the main, stable products of ionizing irradiation of dT (2), 5′dTMP (3), d(TpT) (4), and the thymine moieties of DNA (5) in aerated, aqueous solution.[2] The formation of dF probably involves α-hydroxy peroxide cleavage (6), followed by hydrolytic cleavage, of the hydroxy-hydroperoxy intermediates which were initially formed through attack on dT by the hydroxyl radicals generated from radiolytic decomposition of water (7).

From the viewpoint of nucleoside stereochemistry, the formamide product poses an interesting problem since the restricted rotation of the amide bond leads to separate nmr spectra for the *cis* and *trans* isomers. Here we discuss a facile chemical synthesis of dF, and the data of a ^1H and ^{13}C nmr study, including nuclear Overhauser effect (NOE) and ^1H relaxation time (T_1) measurements. Spectral assignments are made, and the *cis–trans* isomer ratio and the energy barrier to amide bond rotation are determined. Comparison of the data with those of 2′-deoxyuridine provides information

about the relation between sugar conformation and nature of the aglycone. This study should also provide insight into the stereochemical properties of similar amide *ribo*nucleotide derivatives which are intermediates in purine biosynthesis (8).

Experimental

Materials

dT was purchased from Merck (Darmstadt, F.R.G.). dF was synthesized by a modification of the earlier procedure of Cadet and Teoule (9). Bromine (600 μL) was added dropwise to a well-stirred solution of dT (2 g) in water (30 mL, 0°C). Then pyridine (30 mL) was added and the mixture warmed for 1 h 30 min at 60°C. After evaporation to dryness under reduced pressure the resulting oily residue was dissolved in a solution of sodium metaperiodate (10 g) in water (50 mL). The mixture was shaken overnight at room temperature and then evaporated to dryness. A fraction of the salts was precipitated by addition of methanol (2 × 10 mL) and removed by filtration. The filtrate was evaporated under reduced pressure and the resulting oil dissolved in 20 mL of water. The solution was rendered neutral by the addition of sodium acetate leading to a further precipitation of salts. The filtrate was concentrated to 20 mL and then analyzed (2 × 10 mL) by preparative high-performance liquid chromatography on a ^{18}C-reverse phase column using a LC 500 Prep. chromatograph (Waters Ass., Milford, MA,) equipped with a refractive index detector. The main peak ($k' = 1.0$) was collected and combined (2 × 200 mL). Evaporation to dryness afforded 596 mg (yield 45%) of homogeneous dF as a syrup.

Nuclear Magnetic Resonance Experiments

Continuous wave ^{1}H nmr spectra were obtained on a 250 MHz CAMECA TSN Spectrometer at a probe temperature of 30°C. D_2O or DMSO-d_6 (containing respectively 3-(trimethylsilyl) propionate-2,2,3,3-d_4 (TSP) or tetramethylsilane (TMS) as the internal standard) were used as the solvent and provided the internal deuterium lock.

Nuclear magnetic resonance measurements in the Fourier transform mode were made with a Varian XL-100-15 NMR spectrometer equipped with a deuterium lock for field stabilization. Carbon and proton resonances were observed at 25.1 and 100.1 MHz respectively.

The ^{1}H spin–lattice relaxation time measurements were made on the Varian XL-100-15 spectrometer with a 32 K Informatek 620 L-100 computer as complementary equipment. The proton T_1 values were determined using the inversion recovery pulse sequence (180°–t–90°–T_∞). The delay between pulses (T_∞) was in all cases at least $5T_1$. The relative uncertainty in the ^{1}H T_1 values was about ±5%.

The NOE enhancements were measured with the electronic integrator of the spectrometer since changes in the peak height could not be used due to the occurrence of a small scalar coupling between the formyl and anomeric protons. The optimal H_2 intensity level was determined by ensuring complete decoupling of the $H_{2'}$ and $H_{2''}$ patterns when $H_{1'}$ was irradiated. The NOE is expressed as the percentage change in the peak intensity when the formyl proton was saturated and when the double resonance field was applied off resonance, c.a. 10 ppm down field of the formyl proton resonance. About 20 measurements were made in each case. The temperature was regulated by the Varian temperature accessory and was checked before and after each experiment with a copper–constantan thermocouple. The potential difference was measured with a Philips PM 2435 millivoltmeter. For the NOE and T_1 measurements the nucleoside was lyophilized three times from 99.8% D_2O (Commissariat Energie Atomique, France), then dissolved in 99.95% D_2O to a concentration of 0.2 M and the resulting solution carefully degassed.

Table 1 lists, for the major and minor isomers, the ^{1}H and ^{13}C chemical shifts (δ) and the ^{1}H–^{1}H coupling constants. The ^{1}H data were obtained by spectral analysis using iterative LAOCOON (10).

Results and Discussion

Assignment of the ^{1}H and ^{13}C nmr Spectra

Figure 2 shows the 250 MHz spectrum of the isomer mixture in D_2O (30°C) accompanied by a computer-simulated spectrum. The isomer ratio (major:minor = 3:2) was determined by integration of the well-separated formyl proton (H_2) resonances at lowest field (major: 8.12 ppm; minor: 8.22 ppm from TSP, Table 1). The assignments of the 2′-deoxyribose protons, to the major and minor components, were based on line intensity considerations and extensive spin-decoupling experiments, and are in line with published data for a large number of 2′-deoxyribosides (11). For example, irradiation of the major H_2 band confirmed the location of the major $H_{1'}$ band (5.89 ppm) and the presence of a $^4J_{21'}$ coupling (0.9 Hz). Irradiation of this $H_{1'}$ band then led to location of the $H_{2'}$ and $H_{2''}$ bands, and so on. The distinction between the $H_{2'}$ and $H_{2''}$ bands for the same isomer was based on coupling constant arguments (12, 13), while the $H_{5'}$ and $H_{5''}$ assignments followed from arguments by Remin and Shugar (14) and the selective deuteration studies of Ritchie and Perlin (15).

The 25.1 MHz ^{13}C nmr spectrum of dF exhibited distinct pairs of signals for the C_2, $C_{1'}$, and $C_{2'}$ carbons, whereas single signals were observed for $C_{3'}$, $C_{4'}$, and $C_{5'}$ carbons distant from the formamide group. The assignments were made by "off-resonance" and selective heteronuclear (^{1}H) decoupling experiments.

Isomer Assignment

Several criteria (16) were used to assign the major and minor components to the *trans* and *cis* rotamers of dF, respectively (Fig. 1), the most reliable being the nuclear Overhauser effect (NOE) method (17–19). In NOE measurements at 12°C (Table 2), in which the minor $H_{1'}$ proton was irradiated, a 17% increase in the integrated intensity of the minor H_2 band was observed; no increase in intensity in the major H_2 band was detected. However, irradiation of the major $H_{1'}$ band had no effect on the integrated intensities of either H_2 band. Given the r^{-6} dependence of the enhancements, the results are in line with a close approach of $H_{1'}$ and H_2 (minor), possible only in the dF(*cis*) isomer in its *anti* conformation about the *N*-glycosyl link (see below). The minor form must therefore be dF(*cis*).

31	2.5	5.2	4.7	10.9	7.6

[a] In D_2O. See Experimental section for details.

Support for this assignment is provided as follows.

(*a*) The shorter longitudinal relaxation times (T_1) of the $H_{1'}$ and H_2 protons of the minor form, relative to the corresponding proton of the major form (Table 3), are consistent with the close approach of these protons in the dF(*cis*) form in its *anti* conformation.

(*b*) With slow exchange in DMSO-d_6 solution, the amide proton (H_1) resonances can be observed at 7.99 ppm (major) and 8.11 ppm (minor) from TMS, with a 3:2 relative, total intensity. Double resonance experiments confirmed that the splittings of 11.2 Hz in the minor H_1 and H_2 bands, and of 1.2 Hz in the major H_1 and H_2 bands, were due to vicinal $^3J_{12}$ interactions. The couplings are in line with the *trans* H_1, H_2 orientation in dF(*cis*) (minor) and their *cis* orientation in dF(*trans*) (major) (16, 20, 22). No crossover of the major and minor H_2 bands occurs in D_2O, so the isomer assignment must be the same as in DMSO-d_6.

(*c*) Support also comes from the four-bond coupling interactions between the anomeric $H_{1'}$ and formyl H_2 protons ($^4J_{1'2}$:0.9 Hz, major; 0.2 Hz, minor, Table 1). Their relative magnitudes conform with the stereochemical trends defined by ^4J interactions seen in *N*-methyl and *N*,*N*-dimethyl formamides (16).

In general, the *trans* form is favored in *N*-alkyl formamides when the alkyl substituent is small (e.g. methyl); the amount of the *cis* form increases with increasing substituent size due to steric inter-

For personal use only.

actions with the carbonyl oxygen atom (16). In spite of its size, the 2′-deoxyribose sugar does not lead to a preference for the *cis* form. This we suggest points to a preference for the *anti* conformation about the *N*-glycosyl link which minimizes interactions between the sugar and formamide (see below). It would be interesting to study the ribose analog of dF and determine the influence of the 2′-hydroxyl on the isomer ratio.

In NOE experiments at 31°C irradiation of *either* the minor or the major $H_{1'}$ band led to an enhancement (6%–9%) of the intensities of *both* the minor and major H_2 bands (Table 2). This absence of selectivity in the NOE at this higher temperature can be rationalized in terms of saturation transfer since the T_1 values of the $H_{1'}$ and H_2 protons in each rotamer (2.5–9 s) are similar to the rotamer lifetimes (8 s; Table 3). Thus, on the chemical shift difference time scale, the rotamer lifetimes (τ) must be long (since separate rotamer spectra are observed), but must be of intermediate magnitude on the ^1H relaxation time scale ($\tau \approx T_1$, see below). A similar situation, leading to magnetization transfer, has been observed for a variety of amides (22).

Barrier to Amide Bond Rotation

Estimates of the energy barrier to *cis–trans* interconversion should provide insight into the stereochemistry of purine biosynthesis which involves amides analogous to dF (8). To evaluate the free energy of activation ($\Delta G^{\ddagger}$) for rotation about the amide bond, coalescence temperatures were measured for the formyl proton (H_2) in D_2O (T_c = 369 K) and for the formyl carbon (C_2) in DMSO (T_c = 378 K). The barrier was calculated from the Eyring equation (23)

$$[1] \quad \Delta G^{\ddagger}\,(\text{kcal mol}^{-1}) = 4.57\, T_c \left(9.67 + \log \frac{T_c}{\Delta\nu}\right)$$

where T_c is in degrees K and $\Delta\nu$ is the chemical shift difference (Hz) for a given nucleus in the two isomers when the exchange is slow. Thus, from the H_2 data (T_c = 369 K; $\Delta\nu$ = 24.0 Hz) $\Delta G^{\ddagger}$ = 18.3 kcal mol^{-1} in D_2O; from the C_2 data (T_c = 378 K; $\Delta\nu$ = 94.2 Hz), $\Delta G^{\ddagger}$ = 17.7 kcal mol^{-1}. Thus a small solvent effect on $\Delta G^{\ddagger}$ is apparent. Also, the barrier is considerably smaller than that measured for dimethylformamide (21 kcal mol^{-1}; average for several solvents (16)). The reason for this difference is not immediately apparent to us.

Conformation about $C_{1'}$—N_1

As in normal nucleosides, two broad *anti* and *syn* ranges of conformational angles about $C_{1'}$—N_1, defining the relative orientation of the formamide and sugar moieties, should be accessible to dF(*cis*) and dF(*trans*) (Fig. 1). Our data point to a preference for the *anti* form in both the *cis* and *trans* isomers. The preference for *anti* in dF(*trans*) is suggested by the upfield shift (0.24 ppm) of $H_{2'}$ relative to $H_{2'}$ of dU. If the conformation were predominantly *syn*, $H_{2'}$ should experience a large downfield shift (≃ 0.5 ppm) due to the juxtaposed carbonyl oxygen (24–26). The effects of *cis–trans* isomerization on the sugar proton and carbon chemical shifts also point to a dominant *anti* conformer for both dF(*cis*) and dF(*trans*). Thus, the $H_{1'}$ chemical shifts are sensitive to the isomerization (*cis–trans* difference: 0.266 ppm; Table 1). The shifts of the remaining sugar protons (in particular, $H_{2'}$) are relatively insensitive to isomerization (largest *cis–trans* difference: 0.037 ppm). Likewise, the $C_{2'}$, $C_{3'}$, $C_{4'}$, and $C_{5'}$ shifts are relatively insensitive (largest *cis–trans* difference: 0.3 ppm). Now note (*a*) the large increase in separation between $H_{1'}$ and the keto oxygen upon isomerization of *anti* dF(*trans*) to *anti* dF(*cis*) and (*b*) the presence of H_1 over the sugar ring (in proximity with $H_{2'}$, etc.) in the two *anti* forms (Fig. 1).

The *anti* conformation in dF(*cis*) is also suggested by the NOE and T_1 measurements which reveal that $H_{1'}$ and H_2 are near. No NOE enhancement of the $H_{3'}$, $H_{4'}$, $H_{5'}$, and $H_{5''}$ signals was noted upon irradiation of H_2 in dF(*cis*), in line with the *anti* conformation. The vicinal $H_{1'}$—$C_{1'}$—N_1—H_1 couplings which can be measured in DMSO solution (9.0 Hz in dF (*trans*); 9.6 Hz in dF(*cis*)) point to a similarity in the *N*-glycosyl angle distribution for the two isomers, but are not easily treated in terms of conformer distributions.

Sugar Pucker

Comparison of the sugar ^1H–^1H coupling constants of our molecules (with fragmented bases) and those of dU (taken from ref. 27) provides insight into the influence of the aglycone on the sugar pucker. For dF(*cis*) and dF(*trans*), the corresponding *cis* couplings ($J_{1'2''}$, $J_{2'3'}$) and *trans* couplings ($J_{2''3'}$, $J_{3'4'}$) are identical to within 0.2 Hz while the *trans* $J_{1'2'}$ couplings differ by 0.5 Hz (Table 1). Thus, the sugar conformations are not very sensitive to the amide bond orientation. Relative to dU, the $J_{1'2'}$ couplings of the dF isomers are larger by 0.7–1.2 Hz whereas $J_{2''3'}$ and $J_{3'4'}$ are smaller by 0.3–0.7 Hz. These trends indicate a small shift towards the *S*-pucker (28). (Following Remin *et al.* (29) we estimate from $J_{3'4'}$ 70% *S* for dU and 80% *S* for the dF isomers.) Also relative to dU, the *cis* couplings, $J_{1'2''}$ and $J_{2'3'}$, of the dF isomers are smaller by 0.6–0.7 Hz. This means that on a time-averaged basis the torsion angles about the $C_{1'}$—$C_{2'}$ (τ_1) and $C_{2'}$—$C_{3'}$ (τ_2) bonds are larger

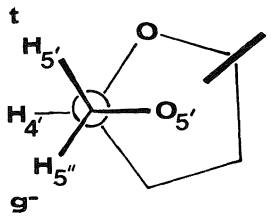

FIG. 3. Newman projection viewed along the C5′—C4′ bond. The g^+ conformer is shown. t and g^- give location of $O_{5'}$ in the t and g^- conformers, respectively.

in dF (28). These increases could be a result of changes in the pseudorotational parameters (P_N, P_S) and/or in the degrees of pucker ($\tau_m(N)$, $\tau_m(S)$), but disentanglement of the contributions is difficult (28).

Recently Gerlt and Youngblood (30) studied a series of furanosides which are not substituted at $C_{1'}$ with a heterocyclic base, namely methyl-β-D-ribofuranoside, its 5′-phosphate, and the corresponding 2′-deoxyribose derivatives.[3] In these molecules unusually small coupling constants between the $C_{1'}$ and $C_{2'}$ protons were noted, due, perhaps largely, to the electronegativity of the O-atom of the methoxy substituent at $C_{1'}$. Comparison of these couplings with our corresponding data is hazardous. However, the $J_{3'4'}$ data can safely be compared in conformational terms since electronegativity effects should be small here. Thus, $J_{3'4'}$ is 5.5 Hz and 6.1 Hz in uridine and methyl-β-D-ribofuranoside, respectively (30), suggesting a slight shift towards an *N*-type pucker in the latter. $J_{3'4'}$ is 4.0 Hz in dU and in methyl-β-D-2′-deoxyribofuranoside, indicating that the sugar conformations are identical, at least insofar as the $C_{3'}$—$C_{4'}$ bond is concerned. Thus, it seems that a uracil base, in a preferred *anti* conformation, does not have any profound influence on the pucker of a ribose or 2′-deoxyribose ring when compared with the smaller formamide and methoxyl groups.

Conformation about the $C_{4'}$—$C_{5'}$ Bond

We have used the Haasnoot *et al.* parameterization (31) to determine the conformer distribution (Fig. 3) for dU, dF(*cis* and *trans*) and methyl-β-D-2′-deoxyribofuranoside (Table 4). The data reveal that the g^+ conformer dominates in dU (50%) while g^- is least occupied. In dF(*cis* and *trans*) a reduction (to ~ 40%) occurs. This stabilizing influence of the uracil base, relative to the formamide group, is probably a consequence of an attraction between the electron deficient 6-carbon (32) and the 5′-hydroxyl. For methyl-β-D-2′-deoxyribofuranoside,

[3]To facilitate comparison of the formamides and the (deoxy)-nucleosides, we have used "primed" numbers for the atoms of the Gerlt-Youngblood molecules.

TABLE 4. Calculated rotamer populations (%) for $C_{4'}$—$C_{5'}$ bond[a]

	Population		
Compound	g^+	t	g^-
dU	50	38	22
dF(*cis*)	40	39	21
dF(*trans*)	41	38	21
dM[b]	22	56	22

[a]Calculated from the *J* data in Table 1 following Haasnoot *et al.* (31).
[b]Methyl-β-D-2-deoxyribofuranoside. Data taken from Gerlt and Youngblood (30).

the large decrease in the g^+ population (to 22%), and the concomitant increase in t population (to 56%) could be due to repulsion between the oxygen atoms of the 5′-hydroxyl and methoxy groups.

Conclusion

In the present work we have studied the formamide derivative obtained by radiation-induced degradation of dT. Hindered rotation about the amide bond (energy barrier $\Delta G^* \simeq 18$ kcal mol^{-1}) is revealed by separate ^{1}H and ^{13}C spectra for the *cis* (minor) and *trans* (major) isomers at room temperature. Fragmentation of the pyrimidine base leads to an enhancement of the *S* (2′ *endo*) pucker and a destabilization of the g^+ ($C_{4'}$—$C_{5'}$) conformation.

(Ref.: Can. J. Chem. **59**, 957 (1981))
Received September 21, 1981

On page 962 the sentence beginning "It can be readily shown that hydroxide ion catalysis becomes manifest ...", and the following sentence, should read "It can be readily shown that hydroxide ion catalysis becomes manifest when $pH = pK_{H_2O} - \log dpf$; at this pH the dominant path changes from one in which water is the base to one in which hydroxide ion is the base. Furthermore, when $pH = pK_{ZH^+} + \log paf$ the dominant path changes from one in which ZH^+ is the substrate to one in which Z is the substrate".

In the second sentence from the end of the same paragraph $pH_{(a)}$ should be $pH_{(b)}$, and vice versa.

Formation and characterization of transitory platinum–ammonia complex ions using pulse radiolysis

The reactions of tetraammineplatinum(II) complex ion with the hydrated electron and hydrogen atom have been investigated in aqueous media using the technique of pulse radiolysis coupled with absorption and conductivity detection. Analysis has also been carried on pulse-irradiated solutions for the formation of free ammonia and for changes in concentration of Pt(II). The hydrated electron and hydrogen atom react with the complex at near diffusion-controlled rates, with the respective rate constant being $1.9 \pm 0.1 \times 10^{10}\ M^{-1}\ s^{-1}$ and $2.8 \pm 0.3 \times 10^{10}\ M^{-1}\ s^{-1}$. The nascent products of these reactions are shown to be different transitory species. For the electron reaction, the initial product is $Pt(NH_3)_4^+$ in which the metal center is formally Pt(I). In acidic media, there is a subsequent and rapid release of two ammonia ligands, with only the second step being measurable ($k = 4.2 \pm 1.7 \times 10^4\ s^{-1}$). In the reaction of H atom, the results support the occurrence of an addition process, giving rise to a hydrido type product. This species undergoes a first-order reaction ($k = 2.2 \pm 0.6 \times 10^4\ s^{-1}$); however the process is not associated with a change in conductivity, and thus it is not one involving loss of ammonia. Subsequent to this process, the loss of one ammonia ligand is observed, with $k = 2.0 \pm 0.6 \times 10^3\ s^{-1}$. The natures of these transients and the long term behavior of these systems are discussed.

HASAN M. KHAN, WILLIAM L. WALTZ, ROBERT J. WOODS et JOCHEN LILIE. Can. J. Chem. **59**, 3319 (1981).

Faisant appel à la technique de radiolyse par impulsion couplée avec la détection par absorption et par conductivité, on a étudié les réactions de l'ion complexe platine(II) tétrammine avec l'électron hydraté et l'atome d'hydrogène. On a également analysé des solutions irradiées par impulsion afin d'évaluer la formation d'ammoniac libre et les changements de concentration en Pt(II). L'électron hydraté et l'atome d'hydrogène réagissent avec le complexe au voisinage des vitesses contrôlées par la diffusion avec des constantes de vitesse respectives de $1{,}9 \pm 0{,}1 \times 10^{10}\ M^{-1}\ s^{-1}$ et de $2{,}8 \pm 0{,}3 \times 10^{-10}\ M^{-1}\ s^{-1}$. On montre que les produits naissants de ces réactions sont des espèces transitoires différentes. Dans le cas de la réaction de l'électron, le produit initial est l'ion $Pt(NH_3)_4^+$ dans lequel le Pt est formellement le métal central. En milieu acide, il se produit une rapide libération additionnelle de deux ligands d'ammoniac, dont seulement la vitesse de la deuxième étape peut être mesurée ($k = 4{,}2 \pm 1{,}7 \times 10^4\ s^{-1}$). Lors de la réaction des atomes d'hydrogène, les résultats confirment l'existence d'une réaction d'addition donnant lieu à un produit de type hybride. Cette espèce réagit selon une cinétique d'ordre un ($k = 2{,}2 \pm 0{,}6 \times 10^4\ s^{-1}$); cependant on n'associe pas la réaction à un changement de conductivité et dans ces conditions elle ne libère pas d'ammoniac. A la suite de cette réaction, on observe la perte d'un ligand d'ammoniac, avec $k = 2{,}0 \pm 0{,}6 \times 10^3\ s^{-1}$. On discute de la nature de ces intermédiaires et de leur comportement à long terme.

Introduction

Both the hydrated electron, e_{aq}^-, and hydrogen atom represent two of the most elementary reagents available for investigating the oxidation–reduction mechanisms of transition-metal coordination compounds. These radical species are formed as primary products along with hydroxyl radical when aqueous solutions are exposed to ionizing radiation such as high energy electrons (2–20 MeV in this work)

[1] $H_2O \xrightarrow{e^-} e_{aq}^-,\ H,\ OH,\ H^+$

The hydrated electron and hydrogen atom are also interrelated in the manner of a conjugate acid – base pair,

[2] $H \rightleftharpoons H^+ + e_{aq}^-$

with pK_a of 9.7 (1). Through the use of the fast reaction technique of pulse radiolysis, a number of studies have been carried out on the electron reactions with metal complexes, generally processes leading to the reduction of the metal center (2–4). In some instances, this has afforded the unique opportunity to investigate transitory products in which the metal is formally in an unusual oxidation state, for example platinum(I), a feature of this study.

By way of contrast, relatively few reports exist concerning the reactions of H atom with metal complexes; however, the results do indicate that the processes can involve not only single electron reduction as for e_{aq}^- but also ones of addition and atom transfer (3, 5). The potential differences as well as similarities in reaction mechanisms between e_{aq}^- and H atom are exemplified in their

reactions with square-planar platinum(II) complex ions. Pulse radiolysis studies using uv–visible absorption detection have shown that a common product arises from their reactions with $Pt(Cl)_4^{2-}$ (6, 7). With complexes containing bi- and tridentate amines or glycine as ligands and that of $Pt(CN)_4^{2-}$, the nascent products are different, implying a difference in mechanism (7–10).[2] These studies and one on the reaction of e_{aq}^- with *cis*-$Pt(NH_3)_2(Cl)_2$ (11) indicate that the initial products are capable of undergoing further and rapid reactions involving, for example, ligand substitution. The final products from these reactions have generally not been characterized, due in part to the very low concentrations formed in pulse radiolysis experiments; however, based upon some of the kinetic results and the detection of metallic platinum, dismutation processes have been proposed. Additional interest in the occurrence and properties of Pt(I) species has been engendered by the role of platinum compounds in radiation sensitization of cellular materials where the sensitizing action may be in part derived from the reactions of Pt(I) with organic substrates and/or the release of toxic ligands such as ammonia (11, 12).

The present study was undertaken to compare the reactions of e_{aq}^- and H atom with $Pt(NH_3)_4^{2+}$ and to characterize the reaction products and their subsequent chemical behavior. In so doing, we have endeavored to enlarge the scope of such investigations in part through the use of conductivity as well as absorption detection techniques. The former has been particularly useful in elucidating the nature and reaction properties of the intermediates, for which the platinum center is formally in an unusual oxidation state. The kinetic studies have been supplemented by product analysis on pulse-irradiated solutions for the formation of free ammonia and for changes in total Pt(II) concentrations.

Experimental Section

Materials and Solutions

Tetraammineplatinum(II) perchlorate was prepared from the chloride salt, obtained commercially (Platinum Chemicals, Alfa Division of Ventron Corp., K and K Labs of ICN Pharmaceuticals, Inc.) (13), and the compound was characterized by comparison of its uv absorption spectrum with that reported (14) and by elemental analysis (15). All solutions used for pulse radiolysis experiments, carried out at about 23°C, were prepared just prior to use with triply distilled water or water purified by a Millipore Super-Q system. The solutions were deaerated by procedures which are described elsewhere (16) and which employed argon, helium, or nitrous oxide gases. The pH of the solutions was adjusted by addition of reagent grade perchloric acid or sodium hydroxide, and was measured by pH-meter, calibrated with certified buffer solutions. All other materials were of reagent grade.

Product Analysis

Pulse-irradiated solutions were analyzed for uncoordinated ammonia and for changes in total Pt(II) content by the following spectrophotometric methods. The determination of free ammonia was based upon its reaction with hypochlorite and phenol to give indophenol, the absorption of which was measured at 625 nm in basic media at 25°C (15, 17). Analysis for changes in total Pt(II) concentration upon irradiation made use of the oxidation of Pt(II) to Pt(IV) in 0.2 *M* HCl and 0.2 *M* NaCl solutions at 25°C by $K_2[Ir(Cl)_6]$ (15, 18). The decrease in the intense absorption peak of the oxidant, $Ir(Cl)_6^{2-}$, at 487 nm, a wavelength where other species present do not absorb significantly, was used to measure the concentration of Pt(II). While some colloidal platinum metal was formed upon irradiation, its presence under our conditions did not appear to interfere with the analysis: removal by filtration of the suspension prior to analysis did not alter the results. Our findings for solutions containing $Pt(NH_3)_4^{2+}$ (50–250 μM) or *cis*-$Pt(NH_3)_2(H_2O)_2^{2+}$ (123 μM) and that of others on related Pt(II) complex ions (18, 19) would indicate that this analytical test provides a valid measure of the total concentration of Pt(II).[3]

Pulse Radiolysis Apparatus and Dosimetry

The apparatus employing conductivity and optical detection methods and the associated dosimetry have been described previously (16). Of note is that the transient signals represent differences between those of the unirradiated and the pulsed solutions. Such differences were calibrated against one of the following dosimetry solutions: ferrocyanide, thiocyanate, or tetranitromethane. The absorption spectra were recorded on a point-to-point basis, generally at 10 nm intervals, using an optical cell of 3.93 cm light path. Contributions to the absorption changes owing to the absorption of $Pt(NH_3)_4^{2+}$ were minor as this complex ion absorbs only weakly over the wavelength range investigated, and thus the spectra have not been corrected for this (or for minor contributions by alcohol radicals below 300 nm (20)). The *G*-values (number of a given species formed or lost per 100 eV of energy absorbed) used were $G_{e^-} = G_{H^+} = 2.66$ and $G_H = 0.55$ (21). In the study of the reaction of H atom and $Pt(NH_3)_4^{2+}$, conditions were maintained so that e_{aq}^- reacted predominantly with the proton, and thus the effective *G*-value for H atom was now the sum of G_{e^-} and G_H. The equivalent ionic conductivity values for H^+, OH^-, and NH_4^+ were taken as 350, 198, and 74 Ω^{-1} cm^2 equiv^{-1} respectively, and those for the platinum complex ions were anticipated to be about 50 Ω^{-1} cm^2 equiv^{-1} (22, 23).

Results

Reactions Associated with e_{aq}^- and $Pt(NH_3)_4^{2+}$

The reaction of the hydrated electron with $Pt(NH_3)_4^{2+}$ was followed by monitoring the decrease in the electron absorption at 578 nm in solutions at a natural pH of about 5.6 and containing 0.1 *M* isopropanol. This alcohol is a facile

[2]Results of a recent low temperature, esr study on $Pt(CN)_4^{2-}$ indicate that *in methanol* the electron product, $Pt(CN)_4^{3-}$, undergoes proton addition to yield the same complex, H—$Pt(CN)_4^{2-}$, as formed by H atom reaction in aqueous sulfuric acid matrices (10).

[3]Owing to the low concentrations of other Pt(II) complex ions which might be formed under pulsed-irradiation conditions, it was not feasible to identify their specific compositions although such possible products are likely to be aquated species such as *trans*- and *cis*-$Pt(NH_3)_2(H_2O)_2^{2+}$ (11).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

scavenger of both hydrogen atom and hydroxyl radical (5, 24). Under the condition where the concentration of complex ion (15–174 μ*M*) was considerably in excess of that for e_{aq}^-, the optical decay obeyed a pseudo first-order rate law. A plot of the observed rate constant versus complex concentration was linear, and from the slope of the plot, the second-order rate constant was calculated to be $1.9 \pm 0.1 \times 10^{10} M^{-1} s^{-1}$. The products derived from this reaction exhibited optical absorption at shorter wavelengths as shown in Fig. 1. The studies of these products were carried out over a pH range of 4.1 to 11.4 on solutions containing 0.1–0.2 *M* isopropanol or 0.2 *M* *tert*-butyl alcohol. The concentration of $Pt(NH_3)_4^{2+}$ used was now in general higher (100–524 μ*M*) than that employed to study the disappearance of e_{aq}^- so as to minimize any possible interference by the electron reaction to subsequent events.

For these conditions, a prompt increase in absorption occurred following the irradiation pulse (Fig. 1 at 1 μs). Following this, there transpired a decrease in absorption at wavelengths below 350 nm and a concomitant increase at longer wavelengths. Addition of N_2O, used as a scavenger of e_{aq}^- (4), eliminated these changes except for small levels of residual absorption at shorter wavelengths, having the properties characteristic of the alcohol radicals that are formed by the reactions of OH and H with the alcohols (5, 20, 24). This observation confirms that the species observed in Fig. 1 are ones derived from the electron reaction. Furthermore, it implies that the alcohol radicals are unreactive towards $Pt(NH_3)_4^{2+}$, a feature that has also been noted for other Pt(II) complex ions (6–9). Below pH 7, the absorption changes obeyed a first-order rate law with a rate constant of $4.9 \pm 1.7 \times 10^4 s^{-1}$. This value was found to be independent of dose (10-fold), concentration of complex (5-fold), the nature and concentration of the alcohol although the values were somewhat higher (ca. 50%) in the region of 300–340 nm. On the same time scale as the optical change, there was a decrease in conductivity to $-190\,\Omega^{-1}\,cm^2\,equiv^{-1}$ as shown in Fig. 2*a*. This change exhibited first-order kinetics with a rate constant of $3.6 \pm 0.1 \times 10^4 s^{-1}$, which is within experimental error the same as that for the absorption change. At longer times (0.1 s scale), relatively minor alterations in absorption and conductivity took place. This situation may, however, be more apparent than real because both here and in the case of the H atom reaction with $Pt(NH_3)_4^{2+}$, suspensions of metallic platinum were observed after irradiation.

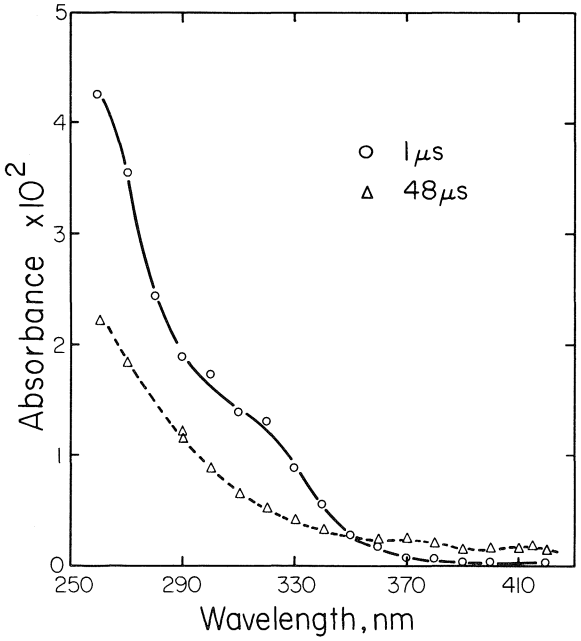

FIG. 1. Absorption spectra arising from reaction of e_{aq}^- and $Pt(NH_3)_4^{2+}$. (○) at 1 μs; (△) at 48 μs for 408 μ*M* $Pt(NH_3)_4^{2+}$, ca. 2.8 μ*M* e_{aq}^-, 2.0 *M* isopropanol at natural pH of ca. 5.6.

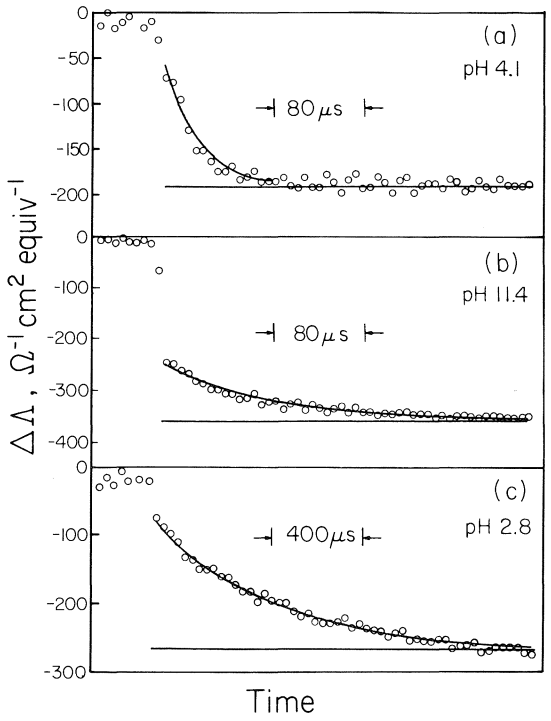

FIG. 2. Equivalent conductivity changes with time: (*a*) and (*b*), reaction of e_{aq}^- and $Pt(NH_3)_4^{2+}$: 495 μ*M* $Pt(NH_3)_4^{2+}$, 2.0 *M* isopropanol, pH 4.1 and 11.4 respectively; (*c*) reaction of H atom and $Pt(NH_3)_4^{2+}$: 96 μ*M* $Pt(NH_3)_4^{2+}$, 0.10 *M* *tert*-butyl alcohol, pH 2.8.

The foregoing absorption results show that the nascent product of the electron reaction, which is expected to be $Pt(NH_3)_4^+$ (2, 3), undergoes subsequent reactions. The observed decrease in conductivity at short time scales demonstrates that more than one ammonia ligand is released from $Pt(NH_3)_4^+$, even though only one kinetic step could be discerned. If only one NH_3 had been lost from this Pt(I) species, then the rapid reaction of the NH_3 with the proton formed via the irradiation process, reaction [1], would have resulted in essentially no net change in conductivity in contrast to the observed decrease. Support for the presence of free ammonia is also provided by its detection in substantial amounts as a final product. For product analysis, solutions containing 60–260 μM $Pt(NH_3)_4^{2+}$ and 0.1–2.0 M isopropanol at a pH of ca. 5.6 were pulse-irradiated (1–11 successive pulses) to an extent of about 15 to 75% reaction, based upon the amount of the electron reacted. For three separate measurements, the concentration ratio of free ammonia formed to that of the cumulative amount of e_{aq}^- was (3.7 ± 0.6)/1, and the corresponding ratio for loss in Pt(II) relative to that of the electron was (1.1 ± 0.1)/1.

In alkaline media (pH 11.4 and 2.0 M isopropanol), the absorption features were essentially the same as those at lower pH (Fig. 1). There was however an immediate decrease in conductivity to about $-240\,\Omega^{-1}\,cm^2\,equiv^{-1}$ at the end of the irradiation pulse, followed by a further decrease of $-110\,\Omega^{-1}\,cm^2\,equiv^{-1}$ (Fig. 2*b*). (No subsequent changes occurred at times up to 1 s.) For the latter process, both the absorption and conductivity signals obeyed first-order rate laws with a rate constant of 1.2 ± 0.3 × $10^4\,s^{-1}$, a value smaller by three-fold than that obtained at pH 4.1. At pH 11.4, free NH_3 will not undergo protonation as the pK_a of NH_4^+ is 9.24 (25), nor will there be extensive ionization of isopropanol radical with a pK_a of 12.2 (20). While it was not feasible to carry out investigations at higher pH, this secondary decrease in conductivity suggests that the platinum transient(s) has acidic properties. The prompt decrease of $-240\,\Omega^{-1}\,cm^2\,equiv^{-1}$ is accounted for by the rapid neutralization of the proton formed during the irradiation pulse, and by the reaction of e_{aq}^- with $Pt(NH_3)_4^{2+}$.

Reactions Associated with H Atom and $Pt(NH_3)_4^{2+}$

These investigations were carried out at pH's between 1.1 and 2.9 and at low enough levels of $Pt(NH_3)_4^{2+}$ to insure that the predominant electron reaction was with proton to give hydrogen atom (4).

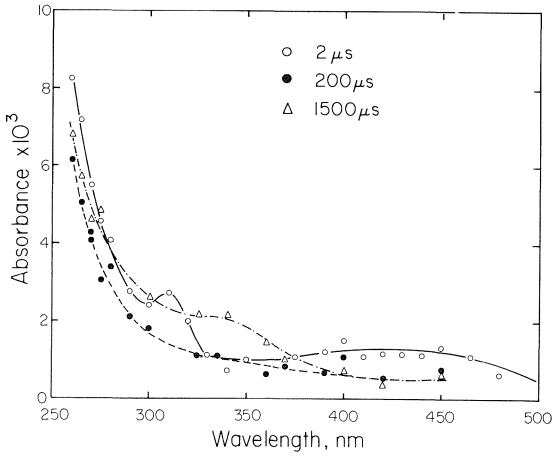

FIG. 3. Absorption spectra arising from the reaction of H atom and $Pt(NH_3)_4^{2+}$. (○) at 2 μs; (●) at 200 μs; (△) at 1500 μs for 112 μM $Pt(NH_3)_4^{2+}$, ca. 3.1 μM H atom, 0.21 M *tert*-butyl alcohol at pH 2.3.

Sufficient *tert*-butyl alcohol (0.1–0.2 M) was present to scavenge OH but not to react unduly with H atom (5, 24). The concentrations of the platinum complex ranged between 15 and 245 μM. The results described below were found to be independent of the concentration of alcohol, pH, and dose (5-fold). As shown in Fig. 3, irradiation led to the formation of absorption spectra in the region of 260 to 500 nm. Addition of 2.1 M isopropanol, a scavenger of H atom, eliminated the absorption in this region aside from minor amounts at short wavelengths, which are attributable in the main to the alcohol radicals (20). The rates of the initial growth in absorption were measured at 260–300, 420, and 425 nm. Under the condition where the complex concentration (15–100 μM) was considerably in excess of that for H atom, the growth in absorption followed a pseudo first-order rate law. The values of the associated rate constant increased linearly with the concentration of complex, and from this behavior, the second-order rate constant was determined to be 2.8 ± 0.3 × $10^{10}\,M^{-1}\,s^{-1}$ for the reaction of H and $Pt(NH_3)_4^{2+}$.

The initial absorption spectrum (Fig. 3 at 2 μs) is considerably different in its features (peaks at about 310 and 430 nm) and in its level of absorption (ca. 4-fold less on a normalized basis at 260 nm) from that of the electron case (Fig. 1). The differences between the two cases also extended to the kinetic aspects. For the hydrogen atom situation, two intervening absorption changes were observed (Fig. 3), with both obeying first-order rate laws: a general decrease in absorption at intermediate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

times ($k = 2.2 \pm 0.6 \times 10^4\ s^{-1}$),[4] followed by a slower growth in absorption at wavelengths below 400 nm ($k = 1.9 \pm 0.6 \times 10^3\ s^{-1}$). In contrast to the two absorption changes, only one conductivity step was found as shown in Fig. 2*c* ($\Delta\Lambda_{final} = -260\ \Omega^{-1}\ cm^2\ equiv^{-1}$), and this process conformed to a first-order rate law with $k = 2.1 \pm 0.2 \times 10^3\ s^{-1}$. Of note is that the conductivity step correlates with the *second* absorption change (growth).

At longer times, there was a general decrease in the absorption spectrum, the kinetics of which were not describable by simple rate law expressions. The conductivity was now constant up to 0.1 s. As with the electron reaction, this situation may be complicated by the development of the observed platinum suspensions. Pulse-irradiation (6–11 successive pulses) of 200 μM $Pt(NH_3)_4^{2+}$ solutions to an extent of about 25 to 80% reaction of the complex also gave rise to free ammonia as a final product. The ratio of ammonia concentration to that of H atom formed was (1.6 ± 0.4)/1 (3 trials). Relatively small losses in Pt(II) concentration occurred, and the results of two trials suggest that the ratio of Pt(II) loss to that of H atom formed probably does not exceed 0.3/1.

Discussion

The foregoing kinetic results and product analyses indicate that the reactions of e_{aq}^- and H atom with $Pt(NH_3)_4^{2+}$ give rise to situations that are different from each other, both from the perspective of the short- and long-term processes involved. For the electron reaction, the nascent product is expected to be the platinum(I) species, $Pt(NH_3)_4^+$ (2–4). The events associated with its occurrence show that at fast time scales, this species undergoes ligand substitution. In particular, the conductivity results indicate the release of two ammonia ligands occurs sequentially

[3] $Pt(NH_3)_4^+ + H_2O \rightarrow Pt(NH_3)_3(H_2O)^+ + NH_3$

[4] $Pt(NH_3)_3(H_2O)^+ + H_2O \rightarrow Pt(NH_3)_2(H_2O)_2^+ + NH_3$

The first step, represented by reaction [3], is presumed to be fast based upon the following observations. At high concentrations of $Pt(NH_3)_4^{2+}$ where the rate of electron reaction with the complex is very rapid (half-life < 0.1 μs), only one kinetic step was discernible subsequent to the prompt development of absorption in the near-uv region (Fig. 1). In addition at pH 4.1, no net conductivity change was observed immediately after the irradiation pulse. This latter feature is consistent with the rapid release of one ammonia whose reaction with an amount of proton equivalent to that formed by irradiation (reaction [1]) forestalls a noticeable change in conductivity. (In the absence of such a neutralization process, a substantial increase in conductivity, due primarily to the radiolytically generated proton, would have been recorded.) Within this context, the initial absorption spectrum of Fig. 1 should be representative in the main of that for $Pt(NH_3)_3(H_2O)^+$. The substitution of an ammonia ligand in this species is associated with the observed changes in conductivity and absorption, having an average first-order rate constant of $4.2 \pm 1.7 \times 10^4\ s^{-1}$. Protonation of the released ammonia is anticipated to lead to an overall decrease in conductivity of about $-250\ \Omega^{-1}\ cm^2\ equiv^{-1}$, in reasonable agreement with that found, Fig. 2*a*.

This two-step sequence parallels that observed in the case of the reaction of e_{aq}^- and *cis*-$Pt(NH_3)_2(Cl)_2$ although in this instance the steps pertain to chloride substitution (11). The loss of the first chloride ligand was prompt, and was followed by release of a second chloride ion ($k = 4.9 \times 10^3\ s^{-1}$). In both studies, the resulting diamino Pt(I) species appear to be relatively stable within the time domain of pulse radiolysis. With reference to their compositions, we have portrayed them above as being four coordinate, on the basis that other d^9 metal complexes such as those of Ag(II) exhibit this (or a higher) coordination number (26, 27), and that our results found in basic media suggest the presence of coordinated water.

In this latter circumstance (pH 11.4), protonation of free NH_3 will be minimal (25). The level of the prompt decrease in conductivity ($-240\ \Omega^{-1}\ cm^2\ equiv^{-1}$) shown in Fig. 2*b* is near that expected ($-250\ \Omega^{-1}\ cm^2\ equiv^{-1}$) owing to the electron reaction and the neutralization of radiolytically produced proton, under the assumption that extensive ionization of $Pt(NH_3)_3(H_2O)^+$ did not occur. The subsequent absorption and conductivity changes, which proceeded at a somewhat slower rate (ca. 3-fold) than that in acidic media, suggest two additional facets, namely that reaction [3] may now reflect a rapid approach towards equilibrium and that $Pt(NH_3)_2(H_2O)_2^+$ undergoes ionization to yield a base form such as $Pt(NH_3)_2(H_2O)(OH)$. Rapid formation of this base form would give rise to the observed decrease in conductivity. The magnitude of this change ($-110\ \Omega^{-1}\ cm^2\ equiv^{-1}$) would imply a pK_a of the order of 11, which might reasonably be

[4]Between 290–310 nm, the rate constants were higher by a factor of three than that cited here for higher and lower wavelengths, and this may indicate the presence of an additional transient.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

anticipated from the pK_a values (4–8) encountered for the analogous platinum(II) complexes of $Pt(NH_3)_2(H_2O)_2^{2+}$ (28).

Both the hydrated electron and hydrogen atom can function as strong, single-electron reducing agents although for the latter other modes are also possible (2–5). For their reactions with $Pt(Cl)_4^{2-}$, a common initial product was observed optically (6, 7) whereas with platinum(II) complexes containing organic amines, glycine or cyano ligand systems, the products arising from the electron and H atom reactions exhibited different optical and kinetic properties (7–10). Our conductivity and absorption results concerning the corresponding reactions of $Pt(NH_3)_4^{2+}$ place this system in the second category. If the reaction of H atom with this complex was to involve a charge transfer mechanism (in analogy to the electron reaction), then the proton so generated would cause in acidic media a prompt and large increase in conductivity, in contrast to our observation of essentially no net, initial change. While the absence of such a change might be masked in a kinetic sense by a rapid release and protonation of NH_3, in a process analogous to reaction [3], the observed product should be $Pt(NH_3)_3(H_2O)^+$. If so, then common spectral and kinetic features (as well as final products) should now prevail between the two situations. This expectation is not in accord with our findings.

A mechanism that encompasses the findings, in particular the occurrence of no initial conductivity change and the discernment of two subsequent absorption steps with the slower one coinciding with a process involving a conductivity decrease, is

[5] $H + Pt(NH_3)_4^{2+} \rightarrow H—Pt(NH_3)_4^{2+}$

[6] $H—Pt(NH_3)_4^{2+} \rightarrow [H—Pt(NH_3)_4]^{2+}$ (rearrangement)

[7] $[H—Pt(NH_3)_4]^{2+} + H_2O \rightarrow H—Pt(NH_3)_3(H_2O)^{2+} + NH_3$

The near diffusion-controlled rate constant associated with reaction [5] is compatible with this step being one of hydrogen atom addition to the metal center. (Such addition reactions are frequently faster than those pertaining to abstraction and charge transfer processes (5).) The resulting five coordinate product, $H—Pt(NH_3)_4^{2+}$, may undergo structural rearrangement such as a transformation from a square-pyramidal form to one of a trigonal-bipyramidal type. Such a process would be in keeping with the observed, first absorption change not being accompanied by an alteration in conductivity. The products of reactions [5] and [6] formally contain a hydrido ligand, a species well known for its *trans* activating capacity in ligand substitution reactions. Its presence in a complex of trigonal-bipyramidal form would be expected to promote labilization of the ammonia ligand in the *trans* position to it, and so give rise to reaction [7], followed by rapid protonation of the released ammonia (pH 2). The latter reaction would yield a conductivity decrease of about $-270\,\Omega^{-1}\,cm^2\,equiv^{-1}$, in good agreement with the experimental value of $-260\,\Omega^{-1}cm^2\,equiv^{-1}$.

For both the electron and hydrogen atom cases, the subsequent processes leading to the disappearance of the intermediates are less readily characterized, in large measure because only minor changes in absorption and conductivity occurred during the longer time periods (upwards of 1 s). Clearly changes did eventually occur as evidenced by the development of colloidal platinum metal (an indication of further reduction) and by the detection of amounts of free ammonia in excess of those that can be accounted for by the intervening processes of reactions [3], [4], and [7]. Pulse radiolysis results concerning the behavior of related platinum complexes have intimated that Pt(I) species decay by disproportionation to yield equal amounts of Pt(0) and Pt(II) (6–9, 11). Within this context, the expected ratio for loss in Pt(II) relative to each e_{aq}^- reacting to produce Pt(I) would be 0.5/1. Our observed ratio of 1.1 ± 0.1 for the electron reaction is substantially higher, and as such implicates for the case of $Pt(NH_3)_4^{2+}$ the occurrence of either processes in addition to disproportionation or a different mechanistic sequence. One possible sequence could involve the oxidation of water (or ammonia) and concomitant reduction of Pt(I) to metallic platinum (Pt(I) is isoelectronic with Ag(II), a strong oxidant (26)). This scheme would be representative of a noncomplementary redox situation. A likely consequence would be the occurrence of several reaction steps, the rates of which may be slow and thus not necessarily observable on our time scales. By way of contrast to the electron case, the overall loss in Pt(II) and formation of free ammonia associated with the hydrogen atom reaction were substantially less. These differences not only underscore the dissimilarity between the two situations but also suggest that decay of the hydrido species leads in part to regeneration of Pt(II), perhaps in association with the formation of molecular hydrogen.

Single drop square wave polarography

LOUIS RAMALEY[1] AND WEE TEE TAN

Trace Analysis Research Centre, Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received March 12, 1981

LOUIS RAMALEY and WEE TEE TAN. Can. J. Chem. **59**, 3326 (1981).

The theory of square wave voltammetry for reversible electrode reactions is expanded to include average currents and currents flowing to a growing drop (single drop square wave polarography) using an expanding plane model. Excellent agreement between theory and experiment was found for the reduction of Fe(III), good agreement for the reduction of Cd(II). The expanding plane model proved superior, but not greatly superior to the simpler theory. For the case of average current the effect on the polarogram of the times at which integration is started and stopped is discussed. Integration decreases sensitivity but increases signal-to-noise ratio. The conditions for maximum analytical usefulness are presented.

LOUIS RAMALEY et WEE TEE TAN. Can. J. Chem. **59**, 3326 (1981).

En utilisant un modèle plan élargi, on a développé la théorie de la voltamétrie en signaux carrés pour des réactions reversibles d'électrode dans le but d'inclure les courants moyens et les courants circulants dans une goutte en formation (polarographie en signaux carrés d'une goutte unique). L'accord est excellent entre la théorie et l'expérience dans le cas de la réduction de Fe(III) et il est bon dans le cas de la réduction de Cd(II). Le modèle plan élargi se révèle supérieur, mais il ne surpasse pas la théorie la plus simple. On discute de l'effet, du temps de départ et d'arrêt de l'intégration, sur le polarogramme dans le cas du courant moyen. L'intégration diminue la sensibilité mais augmente le rapport signal/bruit. On propose des conditions qui confèrent à ce modèle une grande utilité du point de vue analytique.

[Traduit par le journal]

Introduction

Traditionally, pulse and square wave polarography have been techniques in which the current is sampled at only one potential on each mercury drop. Construction of the entire polarogram thus requires several hundred drops. Even with very short drop times, such analyses are quite lengthy. Superimposition of a square wave on a potential sweep and application of the result to a stationary electrode has been used to reduce analysis time considerably (1, 2). More recently (3–6), entire polarograms have been recorded on a single drop at the dropping mercury electrode (dme). The use of the dme reduces the effect of electrode surface contamination but requires faster sweep rates. Commercial instruments have been modified (7, 8) and circuits designed (9) to provide such fast sweep rates. A flow detector based on single drop square wave polarography (SDSWP) has been described (10) and an alternate drop technique which provides a flatter baseline in SDSWP has been proposed (11). Drake *et al.* (12) have indicated that cyclic square wave voltammetric methods might be very useful in the study of electrode processes as well as in chemical analysis.

At this time, it would be appropriate to examine more closely the theory of square wave polarography at an expanding mercury drop and compare the theory to experiment. Commercial instruments and many laboratory-constructed polarographs (4, 13) use gated integration to improve the experimental signal-to-noise ratio, yet no theoretical treatment has been presented for average currents. In addition, no treatment exists for currents at an expanding electrode. These problems are treated in this paper.

Theory

Ramaley and Krause (1) solved the diffusion equations using the Laplace transform and the superposition principle to provide equations for both the instantaneous and differential current in square wave voltammetry at a stationary, plane electrode. Christie *et al.* (5) expanded the treatment to include non-symmetrical pulse trains (differential pulse voltammetry). They applied their model to a dropping electrode by multiplying the current calculated for a plane, stationary electrode by a factor proportional to the change in area of the growing drop. Rifkin and Evans (14) showed that these treatments could be completely generalized for any type of pulse sequence and could be obtained by employing the Heaviside unit function rather than the superposition principle.

In the following, reference is made only to square wave polarography. The potential applied to the test electrode is the sum of a true square wave of amplitude ΔE and half period τ and a staircase ramp with a

For personal use only.

step amplitude of E_s and period 2τ. The resulting nomenclature is simpler and, in practice, there is little or no advantage to using unsymmetrical waveforms, especially in chemical analysis. The electrode reaction

[1] $O + n\,e \leftrightarrows R$

will be assumed to be reversible and diffusion will be considered semi-infinite. The initial concentration of R will be set to zero, the usual case in square wave polarography. The more generalized treatments (5, 14) can be used to include non-symmetrical waveforms or different initial conditions.

The average current flowing between times t_a and t_b is obtained from the law of the mean.

$$[2] \quad i_{av} = \frac{1}{t_b - t_a}\int_{t_b}^{t_a} i\,dt$$

Applying this law to eq. [3] of ref. 1 gives the average current flowing during the jth half-period of the applied square wave at a stationary, plane electrode.

$$[3] \quad (i_{av})_j = \frac{2nFAD_0{}^{1/2}C^*}{\pi^{1/2}(\beta_b - \beta_a)\tau^{1/2}}\sum_{k=1}^{j}[(j - k + \beta_b)^{1/2} - (j - k + \beta_a)^{1/2}](Q_{k-1} - Q_k)$$

with

$$[4] \quad Q_j = \frac{\exp[(E_j - E_{1/2})nF/RT]}{1 + \exp[(E_j - E_{1/2})nF/RT]}$$

and

$$[5] \quad E_{1/2} = E^0 + \frac{RT}{2nF}\ln(D_r/D_0)$$

In the above, A is the electrode area, D_0 and D_r the respective diffusion coefficients, C^* the bulk concentration of the oxidized species, E_j the applied potential during the jth half-period of the square wave, β_a the fraction of τ at which integration begins, and β_b the fraction of τ at which integration ends,

$$[6] \quad 0 \leq \beta_a < \beta_b \leq 1$$

The remaining terms have their usual meaning and Q_0 equals unity. By comparison (1), the instantaneous current is given by

$$[7] \quad i_j = \frac{nFAD_0{}^{1/2}C^*}{\pi^{1/2}\tau^{1/2}}\sum_{k=1}^{j}\frac{(Q_{k-1} - Q_k)}{(j - k + \beta)^{1/2}}$$

where β is the fraction of τ at which the current is measured,

$$[8] \quad 0 \leq \beta \leq 1$$

Equations [3] and [7] can be applied to dropping electrodes when the diffusion layer thickness is small compared to the radius of curvature so that planarity is a reasonable approximation, and when the electrode does not expand appreciably during the period of integration. The growth of the electrode can be taken into account by substituting for A the area of the mercury drop.

$$[9] \quad A = 4.836\,(mt/\rho)^{2/3}$$

where m is the mass flow rate and ρ the density of mercury. Assuming that the drop area remains constant during a single half-period of the square wave

$$[10] \quad A = 4.836\,(m/\rho)^{2/3}(t_d + j\tau)^{2/3}$$

where t_d is the time between the beginning of drop life and the start of the experiment. Thus [3] and [7] become respectively

$$[11] \quad (i_{av})_j = \frac{5.457nF(m/\rho)^{2/3}(t_d + j\tau)^{2/3}D_0{}^{1/2}C^*}{(\beta_b - \beta_a)\tau^{1/2}}\sum_{k=1}^{j}[(j - k + \beta_b)^{1/2} - (j - k + \beta_a)^{1/2}](Q_{k-1} - Q_k)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

and

$$[12]\quad i_j = \frac{2.728nF(m/\rho)^{2/3}(t_d + j\tau)^{2/3}D_0{}^{1/2}C^*}{\tau^{1/2}} \sum_{k=1}^{j} \frac{(Q_{k-1} - Q_k)}{(j + k - \beta)^{1/2}}$$

A more accurate treatment of the cell current that flows at a dme can be provided by using the expanding plane model (15, 16) originally used in the derivation of the Ilkovic equation. In this model, the electrode is allowed to expand; however, the curvature of the electrode surface is ignored. In dc polarography this assumption results in inaccuracies very early in drop life when the radius of curvature of the dme is very small and for very long drop times when the thickness of the diffusion layer approaches the radius of curvature of the dme. In SDSWP the sweep is delayed well into drop life avoiding the first difficulty and the sweep is usually carried out in a very short time so that the diffusion layer never becomes very thick, avoiding the second difficulty even for very long drop times. The results of the use of this model, derived in the appendix, are

$$[13]\quad (i_{av})_j = \frac{3.572nF(m/\rho)^{2/3}D_0{}^{1/2}C^*}{(\beta_b - \beta_a)\tau} \sum_{k=1}^{j} \{([t_d + (j - 1 + \beta_b)\tau]^{7/3} - [t_d + (k - 1)\tau]^{7/3})^{1/2} - ([t_d + (j - 1 + \beta_a)\tau]^{7/3} - [t_d + (k - 1)\tau]^{7/3})^{1/2}\}(Q_{k-1} - Q_k)$$

and

$$[14]\quad i_j = 4.168nF(m/\rho)^{2/3}[t_d + (j - 1 + \beta)\tau]^{4/3}D_0{}^{1/2}C^* \times \sum_{k=1}^{j} \frac{(Q_{k-1} - Q_k)}{([t_d + (j - 1 + \beta)\tau]^{7/3} - [t_d + (k - 1)\tau]^{7/3})^{1/2}}$$

The above equations give the actual cell current whereas the differential cell current is usually what is desired, especially in chemical analysis. One method for calculating the differential current is as follows:

$$[15]\quad i_{dif} = i_{j-1} - i_j \qquad j = 2, 4, 6 \text{ etc.}$$

and by convention i_{dif} will be positive if the even half-periods are the more anodic.

Experimental

Apparatus

A block diagram of the instrument is shown in Fig. 1. It is a conventional operational amplifier potentiostat provided with digital control and interfaced to a dedicated minicomputer. The computer interface, staircase generator, control logic, and differential autoranging amplifier, A, are similar to modules described elsewhere (17–20). The output of A, which is proportional to cell current, is integrated by I to provide the average current for acquisition by the computer. The control logic divides each square wave half-period into eight equal segments (19). Integration can start at any of these segments and continue for as many segments as desired until the half-period ends. The staircase generator provides a wide variety of sweep rates and step sizes. In this study, sweep rates varied from 1.563 to 0.04883 V/s and step sizes of 2.00 and 4.00 mV were used. The computer system consisted of a Hewlett-Packard 2114B minicomputer with paper tape and magnetic tape peripherals and a point plotter. All control programs were written in assembly language.

Unthermostated borosilicate glass cells of 10 mL capacity were employed. A conventional saturated calomel electrode (sce) was connected to the cell through a side arm filled with supporting electrolyte. The dme consisted of a 10 second capillary sealed above a 6 mm soft glass tube which was drawn to a fine tip. Electrical contact was made below the capillary. This arrangement avoids the shielding and capillary resistance of the normal dme. No drop dislodging device was employed; the breaking of a light beam by the free-falling drop signalled the beginning of a new drop and was used to synchronize the start of a sweep. A variable delay between drop fall and sweep origin was provided, the usual delay time being 5.00 s. Measurements were carried out between 23 and 25°C.

Specific details of the instrument, the computer system, and the programming can be obtained from the authors by request.

Reagents

All chemicals were reagent grade and were used without further purification except KCl, which was crystallized once from distilled water. Cadmium(II) in 1.00 *M* KCl medium was employed as an example of an amalgam forming species and Fe(III) in 0.500 *M* $K_2C_2O_4$ at pH 5.00 served as an example in which both halves of the redox couple are soluble in solution. Stock Fe(III) solutions were prepared by oxidation of the Fe(II) in $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$ taken as a primary standard; stock Cd(II) solutions were prepared from $Cd(NO_3)_2 \cdot 4H_2O$ and were standardized by EDTA titration. Laboratory distilled water was run through activated charcoal and distilled once more from an all-glass still before use.

Results and Discussion

The general shape of square wave polarograms and the effects of C^*, ΔE and E_s, and n on those polarograms have already been well-covered (1, 2, 5, 6, 14, 21) for the case of instantaneous current measurements. No changes occur in these effects when integration is used to provide average current. Figure 2 shows the agreement between theory and experiment for the average differential current in the reduction of Fe(III). A diffusion coefficient of 6.31×10^{-6} cm^2 s^{-1} (22) for Fe(III) was used in the theoretical calculation. Simple theory, [11], and the expanding plane theory, [14], give results which are almost indistinguishable and which agree very well with experiment. Figure 3 demonstrates the agreement when the actual cell current is displayed. The upper curve is the current flowing on the more cathodic half-cycles; the lower is that flowing on the more anodic half-cycles. Agreement is still good, but differences are evident, especially on the cathodic tail of the wave. The expanding plane theory gives

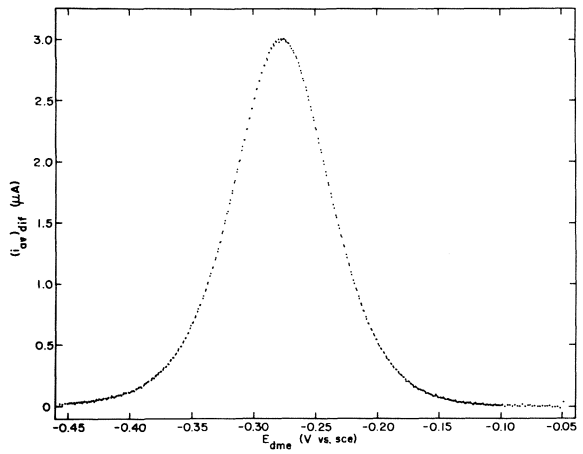

FIG. 2. Theoretical and experimental differential square wave polarograms of the reduction of 2.00×10^{-4} *M* Fe(III) in 0.50 *M* $K_2C_2O_4$ at a pH of 5.01; $\Delta E = 10$ mV, $E_s = 2$ mV, sweep rate = 0.0488 V s^{-1}, $\tau = 20.48$ ms, $\beta_a = 0.125$, $\beta_b = 0.250$, $m = 1.35$ mg s^{-1}, $t_d = 4$ s.

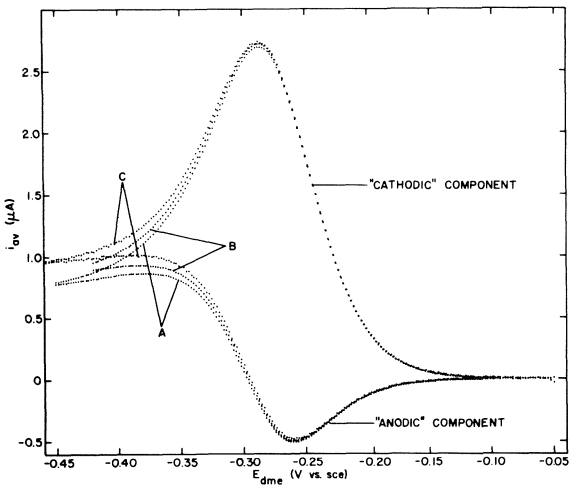

FIG. 3. Theoretical and experimental square wave polarograms. Conditions as in Fig. 2. *A* = corrected stationary electrode model, *B* = expanding plane model, *C* = experiment.

closer agreement as expected; however, the differences between the simple and more complex theories are not as great as might be expected. These differences decrease as τ decreases, again as expected since the drop better approximates a stationary electrode as sweep times become shorter. All calculations were carried out on the laboratory computer and required the use of extended precision arithmetic (48 bit) and a period about ten times as long for the calculation of the expanding plane data as compared to the data for the simple theory which could be satisfactorily computed with 32 bit arithmetic. Considering the increased complexity of calculations using the expanding plane theory, use of the simple theory is advisable except where very subtle differences are being investigated.

The data for Cd(II) reduction are similar to those for Fe(III) except that a diffusion coefficient of 9.8×10^{-6} cm^2 s^{-1} was required to provide an adequate fit between theory and experiment. The accepted experimental value is 7.91×10^{-6} cm^2 s^{-1} (5). A wider difference between theory and experiment is observed near the cathodic tail of the peak than in the case of Fe(III). The cause of this discrepancy was not uncovered by the data taken in this study. Further experimentation may provide an explanation of this effect.

Simple theory predicts that, since τ does not appear in the summations of [11] and [12], the peak differential current, i_p, should be proportional to $\tau^{-1/2}$ provided that β or β_a and β_b are constant and provided that t_d is adjusted so that $(t_d + j\tau)$ at the peak is constant. Although it is not obvious from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

the forms of [13] and [14], the expanding plane theory produces the same result. In practice, instantaneous current measurements should be made or integration started as soon as the double layer charging current has decayed to a suitable level. Thus β or β_a will increase as τ decreases. In this case, theory predicts that a plot of i_p vs. $\tau^{-1/2}$ should deviate negatively from linearity. This was borne out by experiments using both Cd(II) and Fe(III). At the highest sweep rates used, 0.781 and 1.56 V s^{-1}, the experimental currents were slightly higher than those calculated from theory. No obvious explanation is proposed for this behaviour; instrument response may be the cause of the discrepancy between theory and experiment.

The effect of β on the square wave polarogram is more complicated when integration is considered. It was first pointed out by Ramaley and Krause (1) and later confirmed by Christie *et al.* (5) that for instantaneous current measurement greater sensitivity is achieved by making β as small as possible and lengthening τ rather than making τ as small as possible while setting β to unity. When integration is introduced, the effect of integration time must be considered. Defining sensitivity as the ratio of peak current to concentration, sensitivity decreases as integration time increases (β_b increases) holding β_a and τ constant. Furthermore, integration always produces a lower sensitivity than measurement of instantaneous current, provided β_a equals β. If integration time is held constant, increasing τ while beginning integration as soon as possible leads to increased sensitivity as in the case of instantaneous current measurement. However, the above statements do not take into account the effect of integration on noise reduction. In chemical analysis, signal-to-noise ratio (S/N) is the parameter of importance since it determines detection limits and the ability to make accurate estimates of quantity.

Although integration decreases sensitivity, it also decreases noise and thus may increase S/N. With our apparatus, this is exactly what is observed as demonstrated in Fig. 4 for solutions of 1.00×10^{-5} M Cd(II) where τ equals 2.56 ms, β_a equals 0.125 and integration times of 0.32, 0.96, 1.60, and 2.24 ms were used. The sensitivities decrease with increasing integration time from 0.216 to 0.114 AL mol^{-1}, but S/N increases from 104 to 288 for the data of Fig. 4. The noise was determined by calculating the standard deviations of two sets of fifty data points along the baseline on either side of the peak and averaging these two values. If integration is begun as soon as possible after decay of the charging current and continued until the end of the half-period, sensitivity falls as τ increases. As above, however, S/N increases. Allowing 0.64 ms between the beginning of a new

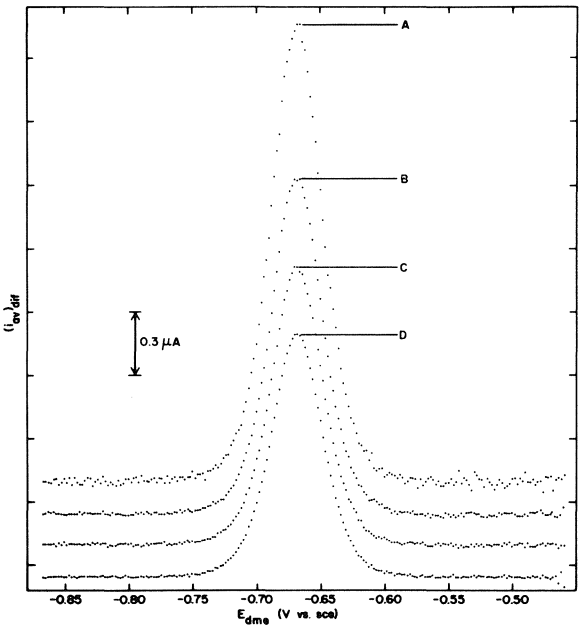

FIG. 4. Experimental differential square wave polarograms of the reduction of 1.00×10^{-5} M Cd(II) in 1.0 M KCl; ΔE = 10 mV, E_s = 2 mV, sweep rate = 0.391 V s^{-1}, τ = 2.56 ms, β_a = 0.125, m = 1.35 mg s^{-1}, t_d = 8 s. Integration period: A = 0.32 ms, B = 0.96 ms, C = 1.60 ms, D = 2.24 ms.

half-period and the start of integration, the sensitivity decreases from 0.0923 to 0.0594 AL mol^{-1} as τ increases from 1.28 to 5.12 ms, but S/N increases from 275 to 697. Although the actual value of S/N will depend on the instrument used, the above indicates that maximum S/N, and thus best detection limits, will be obtained by making β_a as small as possible, β_b equal unity, and τ as large as possible. An increase in τ alone results in a proportional decrease in sweep rate and can only be carried out until sweep time becomes an appreciable percentage of drop time. τ can be increased with no change in sweep rate by increasing E_s, which causes a decrease in resolution. Thus, a compromise must be established between maximum S/N, resolution, and drop time.

It has been proposed that square wave polarography be employed in investigations of electrode mechanisms (12). The similarity of the current–voltage profiles of ac and square wave polarography suggest a comparison. Square wave polarography is more sensitive and might find use in a few cases where concentrations could not be made high enough to use ac polarography. However, exact mathematical treatment is more difficult for the square wave case and much less has been done in this regard than for ac polarography. In addition to the differential current, the individual components

For personal use only.

of the current, the "cathodic" and "anodic" components as shown in Fig. 3, are available in square wave polarography and could also be used in electrochemical investigations. Unfortunately, the distinctive features of these components, peak position and height, vary considerably as a function of β and integration time for a simple reversible reaction as shown in Figs. 5 and 6. In general, as β_a goes to zero and β_b approaches β_a, the peak potentials both approach $E_{1/2}$ and the peak heights become equal but opposite in sign. The "anodic" features are the most sensitive to various parameter changes. These features are also functions of ΔE and E_s and the peak heights depend directly on $\tau^{-1/2}$, but the positions are independent of τ. This complexity may make the application of square wave polarography less useful as a diagnostic tool in electrochemical investigations; the final answer must await the development of theory for cases other than a simple reversible reaction. An excellent beginning in this regard has recently been made by O'Dea *et al.* (23).

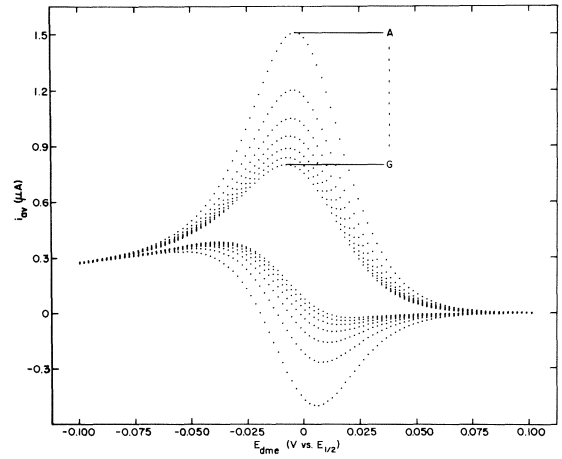

FIG. 5. Theoretical square wave polarograms; $n = 2$, $C^* = 1 \times 10^{-5}$ M, $D_0 = 1 \times 10^{-5}$ cm^2 s^{-1}, $m = 1.5$ mg s^{-1}, $t_d = 5$ s, $\Delta E = 10$ mV, $E_s = 2$ mV, sweep rate $= 0.5$ V s^{-1}, $\tau = 2$ ms, integration time $= 0.25$ ms. β_a increases from 0.125 to 0.875 in steps of 0.125 from A to G.

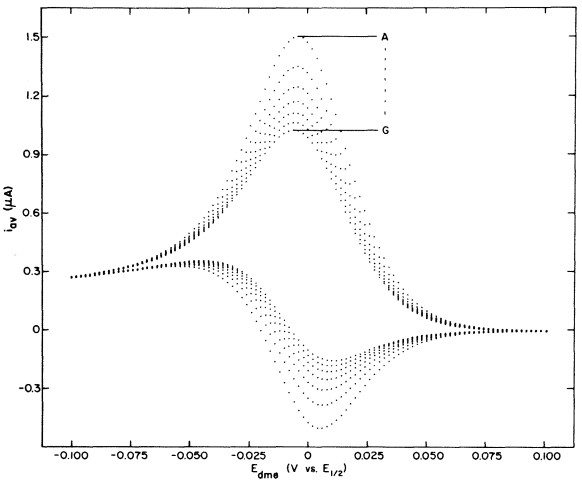

FIG. 6. Theoretical square wave polarograms; conditions as in Fig. 5 except $\beta_a = 0.125$. Integration time increases from 0.25 to 1.75 ms in 0.25 ms steps from A to G.

Appendix

For electrode reaction [1] Fick's second law of diffusion for an expanding plane can be written (15, 16)

[16] $\partial C_0/\partial t = D_0(\partial^2 C_0/\partial x^2) + (2x/3t)(\partial C_0/\partial x)$

where x is the distance from the electrode surface into the solution. The initial and boundary conditions that prevail are as follows:

[17] $C_0 = C^*$, $C_r = 0$ for $0 \leq t \leq t_d$ and $0 \leq x \leq \infty$

[18] $C_0 \rightarrow C^*$, $C_r \rightarrow 0$ as $x \rightarrow \infty$ for $t > t_d$

[19] at $x = 0$, $C_0 = C_1$ for $t_d < t < t_1$

$C_0 = C_2$ for $t_1 < t < t_2$

. .

. .

. .

$C_0 = C_{j-1}$ for $t_{j-2} < t < t_{j-1}$

$C_0 = C_j$ for $t_{j-1} < t$

Conditions [17] and [19] can be written

at $x = 0$, $C_0 = I_0 C^*$ where $I_0 = 1$ for $0 \leq t < t_d$, zero otherwise

.

.

.

$C_0 = I_j C_j$ where $I_j = 1$ for $t > t_{j-1}$, zero otherwise

or

[20] at $x = 0$, $C_0 = \sum_{k=0}^{j} I_k C_k$ where $C_0 = C^*$

Using the substitutions

[21] $z = xt^{2/3}$

[22] $g = (3D_0/7)t^{7/3}$

Equations [16], [18], and [20] become respectively

[23] $\partial C_0/\partial g = \partial^2 C_0/\partial z^2$

[24] $C_0 \rightarrow C^*$ as $z \rightarrow \infty$ for $g > g_d$

[25] at $z = 0$, $C_0 = \sum_{k=0}^{j} I_k C_k$ where $I_0 = 1$ for $0 \leq g \leq g_d$ etc.

Solution is achieved by transforming [23] to [25] into Laplace space where [23] becomes a simple differential equation. The following transforms using the unit finite impulse function (24) or Heaviside unit function are useful in transforming [25] and back transforming the result.

[26] $F(t) = 1$ for $0 < t < k$ $\quad f(s) = \dfrac{1 - \exp(-ks)}{s}$

$= 0$ for $t > k$

[27] $F(t) = 1$ for $k_1 < t < k_2$ $\quad f(s) = \dfrac{\exp(-k_1 s) - \exp(-k_2 s)}{s}$

$= 0$ otherwise

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

[28] $F(t) = 1 \text{ for } t > k \qquad f(s) = \dfrac{\exp(-ks)}{s}$

$= 0 \text{ for } 0 \leq t < k$

where s is the Laplace variable and $f(s)$ is the Laplace transform of $F(t)$. The final solution in Laplace space is

[29] $$\bar{C}_0 = \frac{C^*}{s} + \exp(-s^{1/2}z)\left(\frac{C^* \exp(-g_0 s)}{s} + \frac{1}{s}\sum_{k=1}^{j-1} C_k[\exp(-g_{k-1}s) - \exp(-g_k s)] + \frac{C_j \exp(-g_{j-1}s)}{s}\right)$$

Upon reverse transformation and back substitution of [21] and [22] the result is

[30] $$C_0 = C_j + \sum_{k=1}^{j} (C_{k-1} - C_k) \operatorname{erf} \frac{(7/3)^{1/2} x t^{2/3}}{2D_0{}^{1/2}(t^{7/3} - t_{k-1}{}^{7/3})^{1/2}}$$

[31] $$i = nFAD_0(\partial C_0/\partial x)_{x=0}$$

Applying [31] to [30], substituting [9] for A and using [4] as follows

[32] $$C_k = C^* Q_k$$

which is valid for a reversible reaction, yields

[33] $$i_j = 4.168nF(m/\rho)^{2/3} t^{4/3} D_0{}^{1/2} C^* \sum_{k=1}^{j} \frac{(Q_{k-1} - Q_k)}{(t^{7/3} - t_{k-1}{}^{7/3})^{1/2}}$$

Average current is obtained by integrating [33] according to [2] which produces

[34] $$(i_{av})_j = \frac{3.572nF(m/\rho)^{2/3} D_0{}^{1/2} C^*}{t_b - t_a} \sum_{k=1}^{j} ([t_b{}^{7/3} - t_{k-1}{}^{7/3}]^{1/2} - [t_a{}^{7/3} - t_{k-1}{}^{7/3}]^{1/2})(Q_{k-1} - Q_k)$$

Equations [33] and [34] are completely general in that any potential or time sequence may be applied — symmetry with regard to potential changes or time periods is not required — and they may be used for linear or cyclic sweeps with symmetric or asymmetric pulse trains. When a symmetric pulse train is used (square wave polarography), the following equations apply:

[35] $t = t_d + (j - 1 + \beta)\tau$ for instantaneous current

[36] $t_a = t_d + (j - 1 + \beta_a)\tau$ for average current

[37] $t_b = t_d + (j - 1 + \beta_b)\tau$ for average current

[38] $t_{k-1} = t_d + (k - 1)\tau$ for all cases

When these equations are appropriately substituted into [33] and [34] eqs. [14] and [13] result.

The potential program applied to the electrode can be written in several ways. The program used in this work is given by

[39] $$E_j = E_i + \{(j - 1)/2\}E_s + (-1)^j \Delta E/2$$

where E_i is the potential applied when $0 < t < t_d$ and the term $\{(j - 1)/2\}$ represents the greatest integer not exceeding $(j - 1)/2$.

Adsorption enhancement in square wave polarography

LOUIS RAMALEY,[1] JOHN A. DALZIEL,[2] AND WEE TEE TAN
Trace Analysis Research Centre, Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received June 25, 1981

LOUIS RAMALEY, JOHN A. DALZIEL, and WEE TEE TAN. Can. J. Chem. **59**, 3334 (1981).

Reduction peaks in single drop square wave polarography (SDSWP) for metal ions such as Cd(II) and Pb(II) in the presence of picolinic acid gave peak currents that can be an order of magnitude or more greater than diffusion-limited peaks. Various studies using techniques such as controlled-potential electrolysis, tast polarography, staircase voltammetry, and SDSWP demonstrated that this enhancement effect was due to the adsorption of metal–picolinate complexes on the electrode surface. Since it provides a detection limit of about 0.2 ppb with ions such as Cd(II), adsorption enhancement appears to be of use in trace analysis under certain circumstances. Linearity is observed only up to 1×10^{-5} *M* and any substance capable of adsorption is a potential interferent.

LOUIS RAMALEY, JOHN A. DALZIEL et WEE TEE TAN. Can. J. Chem. **59**, 3334 (1981).

Les pics de réduction dans la polarographie à onde carrée sur goutte pendante (POCGP) d'ions métalliques tels le Cd(II) et le Pb(II) en présence de l'acide picolinique donnent des courants de pointe qui peuvent plus grands que les pics limites par la diffusion par un ordre de grandeur ou plus. Plusieurs études utilisant des techniques comme l'électrolyse à potentiel controlé, la polarographie échantillonnée, la voltamérie à impulsions surimposés d'amplitudes croissantes et la POCGP ont démontré que cet effet d'augmentation est due à l'adsorption des complexes picolinate-métal à la surface de l'électrode. Puisqu'elle fournit une limite de détection de 0,2 ppb avec des ions comme le Cd(II), l'augmentation de l'adsorption apparaît utile dans l'analyse des traces dans certaines circonstances. On observe une linéarité seulement jusqu'à 1×10^{-5} *M* et toute substance capable d'adsorber pourrait éventuellement interférer.

[Traduit par le journal]

Introduction

Complexing reagents are often used to selectively shift the reduction potentials of metal ions. In a study of this effect using single drop square wave polarography (SDSWP) it was observed that addition of common complexing reagents such as citric acid or ethylene diamine to solutions containing Cd(II) with chloride or sulfate salts as supporting electrolyte caused cathodic shifts in the peak reduction potential and no change or a decrease in the peak current. This is the expected behaviour. However, the addition of picolinic acid (pyridine-2-carboxylic acid) caused not only the predicted cathodic potential shift but also an increase in current by a factor of six to ten. One explanation for this behaviour could be the involvement of Cd(II) in a catalytic or kinetic reduction of picolinic acid. It has been reported that picolinic acid is reduced to the aldehyde under conditions similar to those used in this study (1, 2). However, no experimental evidence was found to support a kinetic or catalytic mechanism as the cause of the current enhancement.

Adsorption of electroactive species on the electrode also leads to increased faradaic currents in some electrochemical techniques. In dc polarography adsorption can cause shifts in wave position (3) but little or no enhancement in measured current. However, techniques that use rapid potential sweep rates such as cyclic voltammetry (4) or oscillopolarography (5), or techniques which employ pulse waveforms such as normal (6, 7) or differential pulse polarography (DPP) (8), produce both wave shifts and enhanced currents. In general, the faster the sweep rate or the shorter the measurement time after application of the pulse, the greater the enhancement. Qualitatively the enhancement is caused by the presence of excess electroactive species right at the electrode surface which can oxidize or reduce without a time consuming diffusion step.

Adsorption current enhancement has been observed in several chemical systems. The inorganic complexes formed by Cd(II) in iodide solution (8) or Pb(II) in bromide solution (6) produce this effect. In systems involving an organic ligand either the metal, as in the case of the nickel–dimethylglyoxime complex (9), or the ligand, for the Al(III) or Be(II) complexes of diazo compounds (10, 11), may be the electroactive species. Mixed systems involving metal ions with both inorganic and organic ligands have also been investigated (5). Uncomplexed species, usually uncharged organics, behave in the same manner (3, 4).

The experimental conditions employed in SDSWP should make it well suited for observation and analytical use of adsorption effects. Turner *et al.* (12) have observed enhancements using SDSWP

while working with Cd(II) in iodide medium. Similar techniques such as classical square wave polarography (6) and DPP (8, 9, 13) also provide large, potentially analytically useful current enhancements.

Exact theoretical treatment of adsorption requires the inclusion of an adsorption isotherm (which may not correspond to reality) and some form of potential dependence of adsorption coefficient in the mathematics. Wopschall and Shain have presented a treatment for certain types of adsorption in linear and cyclic voltammetry (4). Laviron has derived equations for the cyclic voltammetry of both reversible and irreversible electrochemical reactions involving adsorption of reactant and product at a dropping mercury electrode (dme) (3). Barker and Bolzan present results for normal pulse polarography and an approximate expression for classical square wave polarography which predicts an increase of four in sensitivity caused by adsorption (6). Anson and co-workers have both solved the boundary value problem mathematically and applied digital simulation in investigating adsorption in normal pulse polarography (7), DPP (8, 13), and the behaviour of reagents confined to the electrode surface (14), a situation similar to strong adsorption of product and reactant. Usually in these treatments one or, at most, several different adsorption isotherms were assumed and the adsorption coefficient was considered independent of potential.

Even though to the authors' knowledge no specific theoretical treatment has been published for adsorption behaviour in SDSWP, certain predictions can be made from the treatments of other, similar techniques. Adsorption requires inclusion of an extra capacitance term (pseudocapacitance) in the faradaic impedance. It might thus seem unusual that a technique such as SDSWP, which is relatively insensitive to capacitive effects, should produce large adsorption enhancements. This phenomenon was first explained by Barker and Bolzan (6) in their treatment of adsorption in normal pulse polarography. For a reversible electrode process in which only the oxidized (or reduced) species is adsorbed, the oxidant can be reduced as rapidly as charge can be supplied to the electrode since oxidant need not diffuse to the surface. However, reductant must diffuse away from the surface. Since the ratio of concentrations at the surface is fixed by the Nernst equation, the rate at which oxidant can be reduced is limited by the rate at which reductant diffuses from the surface, allowing the observation of an enhanced current in SDSWP. In the case where oxidized and reduced species are both about equally strongly adsorbed, the behaviour should be capacitive (14) and the type of enhancement described above should not be observed.

In SDSWP the dme is held at a constant potential, E_i, for a period of time, t_d, before applying a potential scan consisting of a staircase waveform superimposed on a square wave. If reactant is adsorbed at E_i, the surface concentration of reactant, Γ_0 (assuming the reactant to be the oxidized species), is given by the Koryta equation (15).

$$[1] \quad \Gamma_0 = 0.739 D_0^{1/2} C^* t^{1/2}$$

where C^* is the bulk concentration of oxidant, D_0 its diffusion coefficient, and t the time from the beginning of drop life. Equation [1] applies under conditions where all reactant molecules or ions arriving at the surface are adsorbed (strong adsorption); thus the bulk concentration must be below that at which the surface saturates at the time in question. Under these conditions reactant continuously diffuses to the electrode from the beginning of drop life. The solution concentration of reactant near the electrode is very low, while the surface concentration continues to increase, the drop acting as a preconcentration site. When the sweep is applied and reduction occurs, virtually all current is supplied by adsorbed oxidant with little contribution from diffusion. Increasing the bulk concentration increases the contribution of adsorption while that of diffusion remains small until surface saturation is approached. At this point concentration of reactant near the surface is no longer negligible and diffusion begins to contribute to the reduction current. For any further increase in bulk concentration the contribution of adsorption remains fixed while that of diffusion now increases until the reaction appears to be totally controlled by diffusion.

The fractional surface coverage is given by

$$[2] \quad \theta = A_m N \Gamma_0$$

in which A_m is the area occupied by a molecule of adsorbate and N is Avogadro's number. On substitution of [1] this becomes

$$[3] \quad \theta = 0.739 A_m N D_0^{1/2} C^* t^{1/2}$$

which applies under the same conditions as [1]. Substituting typical values for A_m (100 Å^2), D_0 (1×10^{-5} cm^2 s^{-1}) and t (5 s) and setting θ equal to unity produces a value for C^* of 3.2×10^{-5} M, the bulk concentration at which surface saturation occurs. Since the boundary at which diffusion begins to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

play a part will be diffuse rather than sharp, especially if the adsorption is not particularly strong, one would expect diffusion effects to begin to be observed at concentrations somewhat less than 3×10^{-5} *M*.

For a reversible, diffusion controlled SDSWP experiment (16) with all parameters except electrode area held constant

$$[4] \quad i_p = K_1 A_p = K_2 t_p^{2/3}$$

and with all parameters except square wave half-period, τ, held constant

$$[5] \quad i_p = K_3 \tau^{-1/2} = K_4 \nu^{1/2}$$

In these expressions i_p is the peak differential current, ν is the sweep rate, and A_p and t_p are the electrode area and time during drop life at which i_p is measured. The "*K*'s" are proportionality constants.

For a system in which the reactant is adsorbed and provides the major contribution to reduction current, assuming that peak current is proportional both to electrode area and to surface concentration,

$$[6] \quad i_p = K_5 A_p \Gamma_0 = K_6 (t_p^{2/3})(t_p^{1/2}) = K_6 t_p^{7/6}$$

As in the case of other electrochemical techniques involving adsorption (4), one would expect that peak current would approach a first power dependence on sweep rate as opposed to the half power dependence observed for diffusion control.

Experimental

Apparatus

The computer-controlled potentiostat and cell system used have been previously described (16). All potentials were measured versus the saturated calomel reference electrode and experiments were carried out between 23 and 25°C. Delay times, t_d, were normally 5 s, mercury flow rate was 1.5 mg s^{-1}, staircase step height was 2 mV, and square wave amplitude was 10 mV.

Reagents

All chemicals were reagent grade and were used without further purification except KCl, which was crystallized once from distilled water. Stock Cd(II) and Pb(II) solutions were prepared from $Cd(NO_3)_2 \cdot 4H_2O$ and $Pb(NO_3)_2$. Picolinic acid (J. T. Baker or Aldrich Chem. Co.) was purified by crystallization and by sublimation. There was little difference in behaviour between purified and unpurified picolinic acid and the majority of experiments were performed with the unpurified acid. Laboratory distilled water was passed through activated charcoal and distilled once more from an all-glass still before use.

Results and Discussion

Initial studies were carried out using controlled potential electrolysis with a conventional laboratory-built potentiostat in conjunction with spectral methods of analysis to determine what species were being reduced under the conditions that produced a current enhancement in SDSWP. Electrolyses were performed on 0.0010 *M* Cd(II) solutions in 1.0 *M* KCl electrolyte in the absence and in the presence of 0.010 *M* picolinic acid. The mercury pool potential was set at −0.90 V, a value well negative to the reduction peak in both cases. The charge passed in both cases was identical and was equivalent to two faradays per mole of Cd(II). Ultraviolet spectra were obtained on the solutions which contained picolinic acid before and after electrolysis at wavelengths where the acid and picolinaldehyde could be readily identified. Electrolysis produced no change in the spectra and no evidence was obtained for the presence of any picolinaldehyde after electrolysis. Finally the electrolyzed solutions were subjected to atomic absorption analysis for Cd(II). The results indicated that over 97% of the Cd(II) had been removed by electrolysis. It was therefore concluded that Cd(II) was the only species undergoing reduction.

A qualitative experiment involving Triton X100, a strong surfactant, was performed to determine what effect adsorption was having on the observed current enhancement. No enhancement was observed for tast polarograms of 1.0×10^{-5} *M* Cd(II) with 0.010 *M* picolinic acid. Addition of up to 0.0025% Triton X100 produced no changes in the tast polarography of Cd(II) with or without added picolinic acid or in the SDSWP of Cd(II) solutions without picolinic acid. However, for the SDSWP of 1.0×10^{-5} *M* Cd(II) with 0.010 *M* picolinic acid, addition of 0.0005% surfactant caused the sixfold current enhancement to decrease by 20%, and addition of 0.001% surfactant caused a 50% decrease. Since adsorption does not cause current enhancement in dc polarography, these observations are consistent with a mechanism in which adsorption is responsible for the enhancement in SDSWP.

The effect of pH on enhancement was studied in 1.0 *M* KCl electrolyte. No enhancement occurred at pH values less than about 3.0. Enhancement increased rapidly to a pH of 5.0 and continued a more gradual increase up to pH 9.0. All experiments described below were carried out between pH 5 and 6 using picolinic acid itself to buffer the solutions, since its pK_a is 5.23 (17). Table 1 presents the effect of supporting electrolyte on the enhancement. Of the electrolytes studied, KCl gave the smallest enhancement and the smallest peak current (in the presence of picolinic acid) while NaF provided the largest of both. Ammonium sulfate produced an almost equal enhancement and the second largest peak current. For this

TABLE 1. Effect of supporting electrolyte on enhancement of peak current for 1.0×10^{-5} *M* Cd(II) in 1.0×10^{-2} *M* picolinic acid (PA) at pH of 6.0

	i_p (μA)		E_p (V)		
Electrolyte	No PA	PA	No PA	PA	Enhancement
1.0 *M* KCl	1.77	8.86	−0.641	−0.747	5.0
1.0 *M* KNO_3	1.62	10.44	−0.588	−0.739	6.4
0.50 *M* $(NH_4)_2SO_4$	1.40	12.60	−0.606	−0.740	9.0
1.0 *M* $(NH_4)ClO_4$	1.17	11.00	−0.590	−0.731	9.4
0.50 *M* NaF	1.64	15.60	−0.602	−0.754	9.5

reason, and because it is a more benign material than NaF, it was used in a majority of the enhancement studies. Potassium chloride was also used in some studies because Cd(II) showed the most ideal behaviour in this medium in the absence of picolinic acid.

Figure 1 depicts the effect of varying the concentration of Cd(II) on peak current at constant picolinic acid concentration. Linearity is observed below 1.0×10^{-5} *M*, while the expected change from adsorption to diffusion control is noted above this concentration. Figure 2 demonstrates the behaviour when picolinic acid concentration varies and that of Cd(II) is held constant. Maximum enhancement occurs at a picolinic acid concentration of 5×10^{-3} *M*.

The variation in drop time during a set of tast polarograms run at various concentrations of picolinic acid is shown in Fig. 3. As the acid concentration is raised, drop time, and thus surface tension, is decreased at more positive potentials. However, at potentials on the diffusion plateau, all drop times are the same, indicating that the surfactant causing the lowering of surface tension has been removed.

If all experimental parameters are held constant except delay time, a plot of ln (i_p) vs. ln (t_p) should have a slope of 0.67 for diffusion control and 1.17

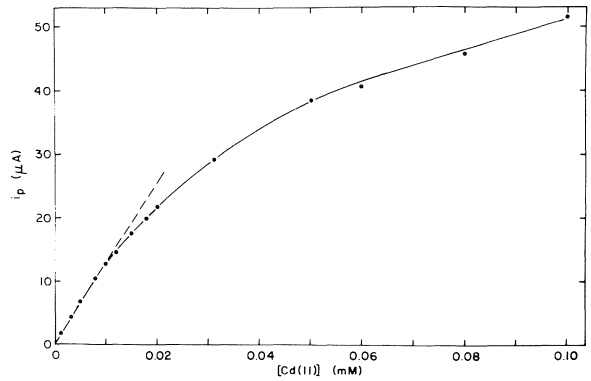

FIG. 1. Variation of peak current in SDSWP with Cd(II) concentration; 1.0×10^{-2} *M* PA, 0.50 *M* $(NH_4)_2SO_4$, pH 6.0, sweep rate 0.781 V s^{-1}.

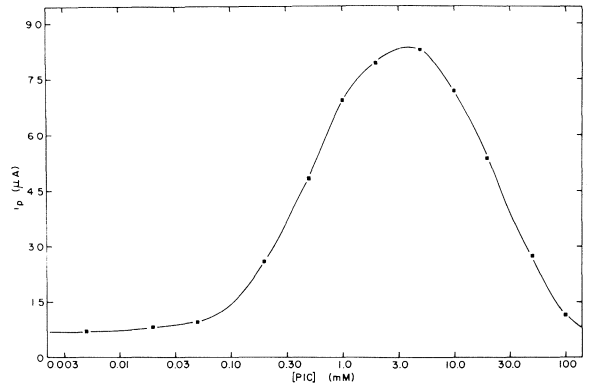

FIG. 2. Variation of peak current in SDSWP with picolinic acid concentration; 1.0×10^{-5} *M* Cd(II), 0.50 *M* $(NH_4)_2SO_4$, pH 6.0, sweep rate 0.781 V s^{-1}.

for adsorption control (from [4] and [6] above). Diffusion conditions produced a good straight line of slope 0.74, while adsorption conditions resulted in a line with slight negative curvature and a least-squares slope of 1.01. The slope for diffusion control is greater than expected, possibly because at larger delay times the drop is less spherical and the shielded area is a smaller fraction of the total area, both effects causing the electrode area to increase more rapidly than expected. The slope for

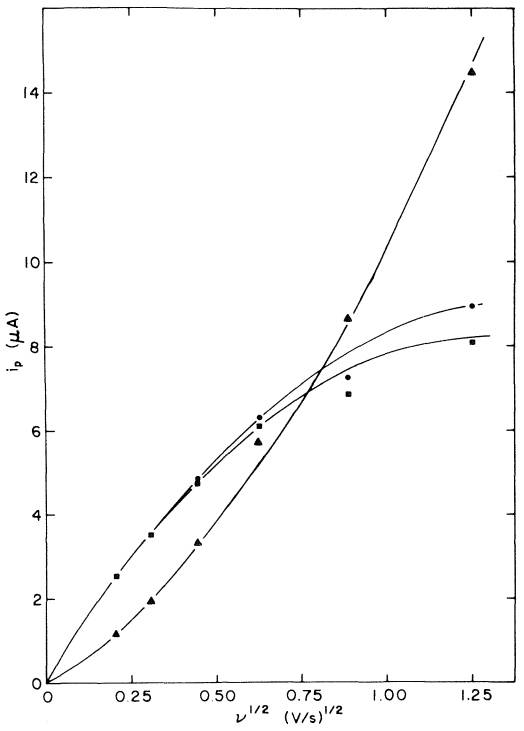

FIG. 4. Dependence of peak current in SDSWP with sweep rate; 0.50 M $(NH_4)_2SO_4$; ●, theory for 1.0×10^{-4} M Cd(II); ■, experimental data for 1.0×10^{-4} M Cd(II); ▲, 1.0×10^{-5} M Cd(II) with 0.010 M PA.

adsorption control is considerably larger than that for diffusion, as expected, but is less than that predicted from [6]. This may be due to the adsorption not being strong enough for the Koryta equation to be rigorously applied.

The effect of variation in sweep rate is demonstrated in Fig. 4. Diffusion control should produce a linear plot, provided that all experimental parameters are held constant, including peak time, t_p, and the portions of the square wave half-period over which the current is integrated. Unfortunately, our instrument cannot hold these two parameters constant over a wide range in sweep rate, the result being a non-linear graph. Theoretical calculations agree well with the experimental data for diffusion control except that they are consistently high at higher sweep rates. For adsorption control, peak current is related to sweep rate by a power greater than one-half, as expected, but somewhat less than the predicted value of one.

All of the above data point to specific adsorption of a complex of Cd(II) with picolinic acid (PA) as the cause of enhanced currents in SDSWP. The most likely complex would be the neutral $Cd(PA)_2$ complex in which the ligands assume a square planar configuration around the metal ion. Loss of a ligand (perhaps water) from one of the two remaining coordination sites would allow both aromatic rings to lie flat against the electrode surface when adsorbed. Some evidence for this can be inferred from Fig. 2. Calculations using the appropriate stability constants (17, 18) predict that $[Cd(PA)_2]$ will be maximum in 0.50 M $(NH_4)_2SO_4$ at a ligand concentration of 0.004 M; Fig. 2 indicates a maximum at 0.005 M. That the adsorption is not particularly strong is indicated by the less than first power dependence of i_p on ν and the less than 7/6 power dependence of i_p on t_p. The data in Table 1 indicate that the effect depends on double layer structure and the ability of the supporting electrolyte to compete with picolinic acid as a ligand. As the electrolyte anion competes less and/or specifically adsorbs less, the magnitude of the enhancement effect increases. This also indicates that the adsorption of complex is not particularly strong.

Further evidence for adsorption is provided by cyclic staircase voltammetry as shown in Fig. 5. In the absence of picolinic acid, the voltammogram is normal. When ligand is added, the cathodic peak is greatly enhanced, is more symmetrical and closer in potential to the anodic peak which still has the shape of a diffusion peak. For comparison the individual current components in SDSWP are shown in Fig. 6. Without picolinic acid the curve is normal and agrees with theory. In the presence of the acid the anodic or reverse component remains truly anodic for almost the entire peak, indicating a large amount of metal which can be reoxidized into solution on the anodic or reverse half-cycle. Without added ligand the currents stay cathodic well

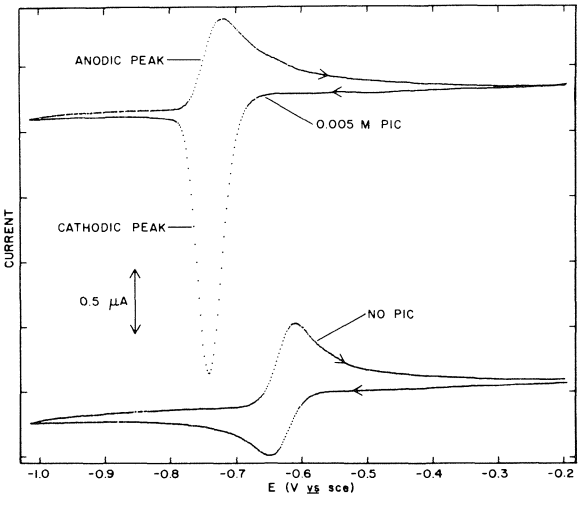

FIG. 5. Staircase cyclic voltammograms of 1.0×10^{-5} M Cd(II) in 0.50 M $(NH_4)_2SO_4$; sweep rate, 0.781 V s^{-1}.

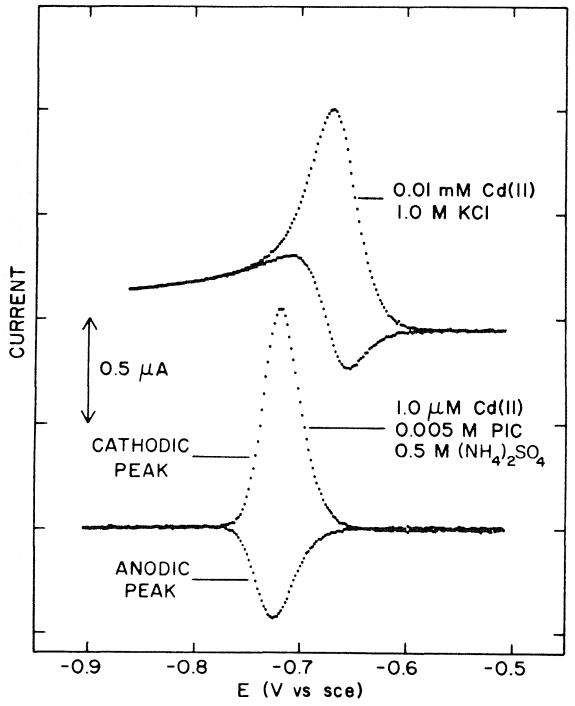

FIG. 6. Individual current components in SDSWP of Cd(II).

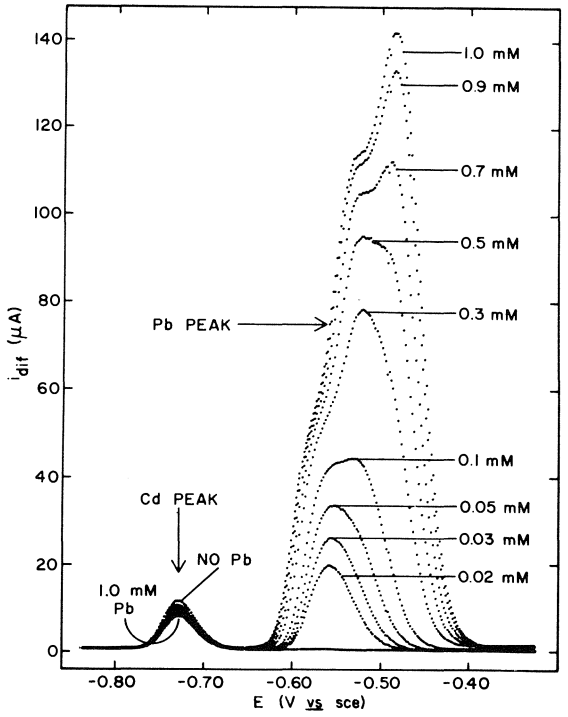

FIG. 7. SDSWP of 1.0×10^{-5} *M* Cd(II) with added Pb(II) in 1.0 *M* KNO_3 and 0.010 *M* PA; sweep rate 0.781 V s^{-1}.

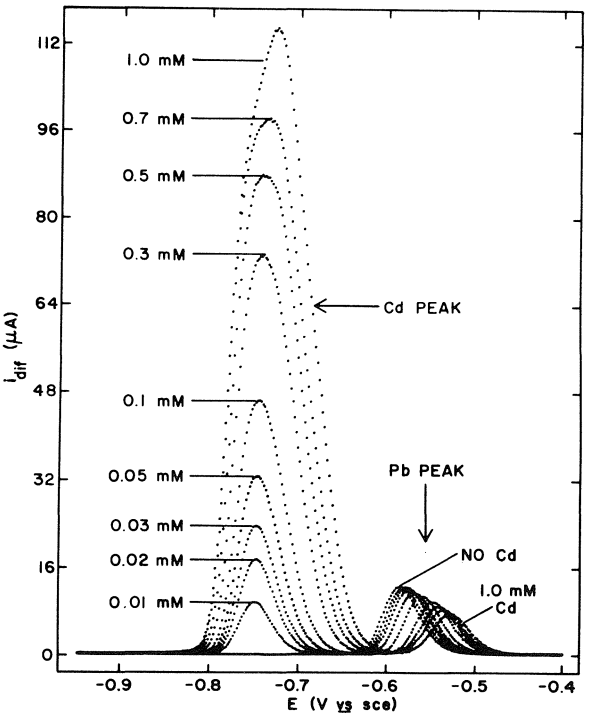

FIG. 8. SDSWP of 1.0×10^{-5} *M* Pb(II) with added Cd(II) in 1.0 *M* KNO_3 and 0.010 *M* PA; sweep rate 0.781 V s^{-1}.

after the peak due to continued diffusion of metal ion to the electrode; with ligand the currents return almost to zero after the peak since the diffusion layer is much thicker, having existed since the beginning of drop life rather than since the beginning of the peak. This effect may also be partially responsible for the reverse component of current staying anodic for the entire peak. Interestingly, the peak for the anodic component is more cathodic than that for the cathodic component.

During the course of this study it became obvious that metal ions other than Cd(II) exhibit an enhancement with picolinic acid, Pb(II) being a good example. A high concentration of one adsorbable ion should interfere with the enhancement of a second such ion. This interference is demonstrated in Figs. 7 and 8, in which [Cd(II)] is held constant while [Pb(II)] is varied and vice versa. In the absence of picolinic acid no interference between ions is observed. With picolinic acid addition of one ion suppresses the peak for the other, and in the case of the addition of Cd(II) to a solution containing fixed Pb(II), the potential of the Pb(II) peak also shifts to more anodic values. This occurs because Cd(II) competes with Pb(II) for the ligand and for the electrode surface sites, both effects tending to cause a shift in peak potential. The reason that a similar shift is not observed in the case where Pb(II) is added to a Cd(II) solution is explained by noting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

that since Cd(II) is reduced after Pb(II), when Cd(II) undergoes reduction there is no Pb(II) remaining on or near the electrode surface to compete for ligand or surface sites. Depression of peak current is still observed because the surface concentration of Cd(II) is lowered by Pb(II) which is present during drop growth up to a fraction of a second before Cd(II) reduction. This effect cannot be explained by differences in the formation constants of lead and cadmium picolinates since they are almost identical (17).

The magnitude of the enhancement raises the question of its usefulness as an aid to trace metal analysis. SDSWP is a very sensitive method in its own right and can be made a factor of ten more sensitive using the adsorpion enhancement effect of picolinic acid. Figure 9 demonstrates the sensitivity attainable. All supporting electrolytes used contained enough Pb(II) and Cd(II) impurities to be easily detectable. Standard additions of sufficient Cd(II) stock solution to cause changes in solution concentration of 2.0×10^{-9} *M* produced the curves shown in Fig. 9. From these data the detection limit for Cd(II) was determined to be 2×10^{-9} *M* or 0.2 ppb (signal twice the standard deviation of the background noise) and the concentration of Cd(II) in the supporting electrolyte was found to be 9×10^{-9} *M*. With such high sensitivity, the technique has obvious merit. However, caution should be exercised since linearity is observed only up to 1×10^{-5} *M* and the presence of any other substance capable of adsorption will interfere. Such substances include other adsorbable metal ions or neutral organics at concentrations above 1×10^{-5} *M*. Thus the ability to increase sensitivity through addition of picolinic acid or other such reagents will be highly matrix dependent. On the other hand adsorption of electroactive species may be more common in some practical samples than suspected and can lead to errors in quantitation when using trace techniques such as DPP or SDSWP if not recognized. In addition to any analytical applications, the use of reagents like picolinic acid coupled with pulse techniques such as SDSWP may provide a simple and sensitive method to obtain electrochemical information on adsorption as indicated by the data of Table 1 and Figs. 7 and 8.

Studies are continuing to determine which other metal ions exhibit adsorption enhancement with picolinic acid and similar ligands.

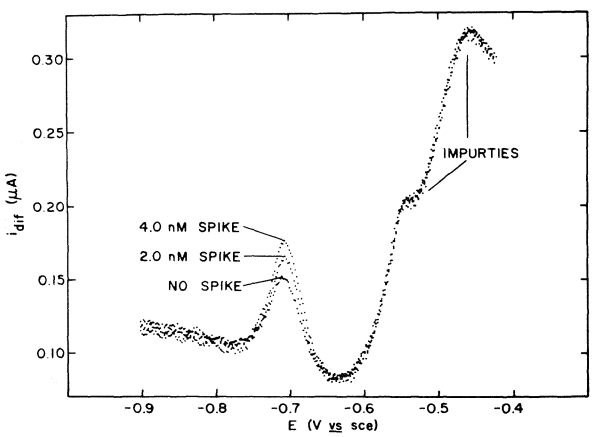

FIG. 9. SDSWP of Cd(II) in 0.50 *M* $(NH_4)_2SO_4$ and 0.0050 *M* PA; t_d 8 s; square wave amplitude 50 mV; sweep rate 0.195 V s^{-1}, 20 runs averaged.

Introduction

A la suite de nos travaux sur les spectres de vibration du triazole-1,2,4 et de quelques uns de ses dérivés (1–5), nous nous sommes proposés de définir un champ de force susceptible de rendre compte des données expérimentales relatives à la molécule de chlorotriazole[3] et de ses trois dérivés deutériés.

Mel'nikov *et al.* avaient déjà effectué un tel calcul en utilisant une géométrie ClTA[1H] (6) analogue à celle du triazole-1,2,4 (7).

Les récentes études cristallographiques entreprises sur cette molécule ont montré que la structure du ClTA correspond à une configuration [4H] (2), aussi le champ de force proposé par Mel'nikov est-il contestable. L'objet de notre travail consistera donc, à partir des nouvelles attributions des spectres infrarouges et de la structure du cristal précédemment publiées, de proposer une fonction potentielle pour le ClTA et ses trois homologues deutériés.

Conditions de calcul

Pour le calcul des modes normaux de vibration de la molécule de ClTA et de ses homologues deutériés sélectivement sur l'azote ClTA[D]-4, sur le carbone ClTA[D]-5 dideutérié sur l'azote et le carbone ClTA[D]$_2$-4,5, nous avons utilisé la méthode de Wilson *et al.* (8) dans l'hypothèse d'un champ de force de valence. Le programme employé est celui écrit par Schachtschneider (9) modifié par Forel.[4]

La géométrie introduite est celle déterminée par rayons X et la molécule est supposée isolée dans le réseau cristallin. Cette approximation fait implicitement entrer dans le champ de force des paramètres liés à la force des interactions intermoléculaires et en particulier aux liaisons hydrogènes.

Nous avons décrit la matrice **F** de l'énergie potentielle dans la même approximation que la matrice **G** de l'énergie cinétique, c'est à dire en posant nulles les constantes de force d'interaction entre vibrateurs sans atome commun.

Choix des coordonnées

La notation des coordonnées internes est indiquée sur la figure 1.

L'analyse vibrationnelle ayant été faite dans l'approximation des vibrations de groupe, nous avons choisi pour les vibrations de déformation autour des atomes C_3, N_4 et C_5 les coordonnées suivantes:

$$\theta_i = \frac{1}{\sqrt{6}}(2\alpha_i - \phi_i - \phi_i') = \text{déformation des angles } i \text{ du cycle}$$

$$\beta_i = \frac{1}{\sqrt{2}}(\phi_i - \phi_i') = \text{déformation } \delta\text{NH, } \delta\text{CH ou } \delta\text{CCl}$$

$$\rho_i = \frac{1}{\sqrt{3}}(\alpha_i + \phi_i + \phi_i') = 0 \text{ coordonnée redondante}$$

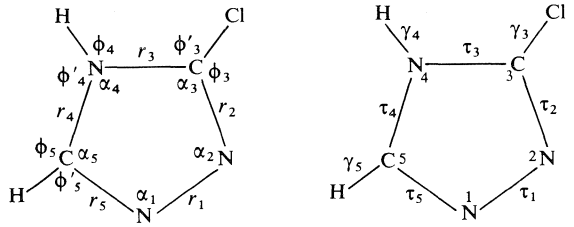

FIG. 1. Coordonnées internes du ClTA.

Les torsions τ ont été définies en considérant pour chaque lien valenciel tous les angles dièdres mis en jeu.

Champ de force

La fonction potentielle initiale a été définie à partir des constantes de force proposées pour le triazole-1,2,4 (10). Pour le vibrateur C—Cl, nous avons transféré les paramètres publiés pour le chloro-2 thiazole (11). L'amélioration du champ de force ainsi initialisé s'est révélée difficile; en effet, comme l'avait suggérée l'analyse des spectres, les modes normaux mettent presque tous en jeu plusieurs vibrations de groupe.

La comparaison des spectres calculés avec les spectres expérimentaux ainsi que l'examen des termes de la matrice **G**, nous ont amenés à introduire des constantes de force d'interaction supplémentaires, puis à modifier les valeurs de ces constantes de force à partir d'un processus itératif stoppé lorsque nous avons jugé satisfaisant l'accord obtenu pour les quatre composés.

Présentation et discussion des résultats

Le champ de force final que nous avons obtenu pour le ClTA comparé à celui du triazole-1,2,4 (10) est donné dans le tableau 1. Seize constantes de force principales et dix huit constantes d'interaction ont été nécessaires pour rendre compte des 69 fréquences expérimentales.

Nous avons reporté dans les tableaux 2 à 5 les fréquences calculées et observées, les distributions d'énergie potentielle (DEP) par rapport aux constantes de force principales ainsi que les attributions que nous avons proposées pour les quatre molécules de ClTA.

Analyse du champ de force

Le champ de force final est constitué de 23 constantes de force qui ont permis de rendre compte de 52 fréquences A′ et de 11 relatives aux 17 modes A″ observés.

Ces constantes de force restent relativement proches de celles du triazole-1,2,4 (tableau 1). Rappelons cependant que le calcul se rapporte pour le triazole à la forme [1H] (10) et pour le ClTA à la forme [4H]. En outre, la substitution de l'atome d'hydrogène en position 3 par un atome de chlore est de nature à modifier la structure électronique du cycle. Nous avons donc été amenés à introduire, en plus des constantes de force de valence et de déformation de la liaison C—Cl, de nouvelles constantes d'interaction et à différencier certaines constantes de forces principales relatives au squelette triazolique.

C'est ainsi que nous avons donné une valeur plus élevée pour $F(\theta_3)$ que pour les autres $F(\theta_i)$. Cette modification se justifie, en particulier, par la présence du chlore en position 3 du cycle. En plus, nous avons fait intervenir des constantes de force d'interaction entre liaison du cycle triazolique et angle de déformation du cycle avec un atome commun; les constantes de force ont une valeur assez élevée et sont négatives.

Nous avons dû également tenir compte d'une interaction entre les modes γCH et γNH que l'on peut rapprocher de celle qui existe entre γNH et rCH_2 dans le δ valérolactame (12) ainsi que d'une interaction entre les modes γCH et τ avec un atome commun.

Les valeurs des constantes de force F(νCCl), F(δCCl) et F(γCCl) sont comparables à celles reportées dans le cas du chloro-2 thiazole (11). Les constantes d'interaction $f|(r_2, \delta CCl), (r_3, \delta CCl)|$ et $f|(\tau_2, \gamma CCl), (\tau_3, \gamma CCl)|$ ont été introduites par analogie avec celles mettant en jeu les vibrations de déformation dans et hors du plan des groupements NH et CH.

En outre, il a été nécessaire de faire intervenir des interactions entre νCCl et θ_3 et entre δNH et δCCl. L'introduction de cette dernière constante de force se justifie par le voisinage sur le cycle des deux vibrateurs NH et CCl et par la masse relativement importante du chlore qui peut entraîner le NH dans son déplacement.

Attribution et répartition d'énergie potentielle

Les distributions d'énergie potentielle reportées sur les tableaux 2 à 5 confirment en la nuançant l'interprétation que nous avons proposée précédemment.

Comme nous l'avons signalé, les fréquences situées entre 1550 et 1050 cm^{-1} correspondent à des

mouvements mettant en jeu le cycle triazolique et de façon plus ou moins importante les vibrateurs CH (ou CD) et NH (ou ND). On observe bien pour le ClTA[D]-4, le couplage entre une vibration de noyau R_5 et δCH. Pour le ClTA, l'interaction est plus complexe et met également en jeu le mode situé à 1185 cm^{-1}. Les vibrations δCD par contre semblent relativement pures. Il en est de même des vibrations νCCl et δCCl.

Comme nous l'avions suggéré précédemment (2), les fréquences calculées à 707, 731, 564 et 541 cm^{-1} pour les ClTA, ClTA[D]-4, ClTA[D]-5 et ClTA$[D]_2$-4,5 respectivement, correspondent à des modes normaux relativement semblables. Cependant, il ne nous a pas été possible de traduire par le calcul le caractère γCH (ou γCD) que la comparaison des spectres nous avait conduit à envisager.

Enfin, nous n'avons pas réussi à situer correctement la vibration de plus basse fréquence.

Ces divergences entre calcul et expérience, qui se manifestent surtout dans le cas des vibrations A″, doivent être liées vraisemblablement à l'autoassociation importante du ClTA, à la forte anharmonicité qui en résulte pour les vibrations γNH et γND et aux couplages intermoléculaires qui doivent se manifester pour ces modes, mais que nous n'avons pas pu observer à cause de leur intensité nulle sur nos spectres Raman.

Coulometric determination of several water-insoluble aromatic nitro compounds with electrogenerated chromium(II)

I. M. AL-DAHER[1] AND B. KRATOCHVIL

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2

Received January 31, 1981[2]

I. M. AL-DAHER and B. KRATOCHVIL. Can. J. Chem. **59**, 3346 (1981).

The electrochemical reduction of a series of water-insoluble aromatic nitro compounds with coulometrically generated chromium(II) has been investigated. Samples ranging from 0.2 to 0.5 μmol could be determined for several substances with a precision and accuracy of about 1%. The number of electrons involved in the reductions corresponded in most cases to the formation of hydroxylamines or amines, but in some instances to dihydrazo products.

I. M. AL-DAHER et B. KRATOCHVIL. Can. J. Chem. **59**, 3346 (1981).

On a étudié la réduction électrochimique d'une série de composés aromatiques nitrés insolubles dans l'eau par le chrome(II) produit par coulométrie. Dans des échantillons dont la concentration varie de 0,2 à 0,5 μmol, on peut déterminer plusieurs substances avec une précision d'environ 1%. Le nombre d'électrons impliqués dans les réductions correspond, dans la plupart des cas, à la formation des hydroxylamines ou des amines; dans certains cas, il correspond à des produits dihydrazo.

Electrochemically generated chromium(II) at a mercury cathode has been applied to the determination of a number of aromatic nitro compounds in our laboratory (1). We became interested in determining whether this method could be applied to other water-insoluble nitro compounds, both to extend the analytical applicability of the system and to study the effect of various functional groups on the ease of reduction of the nitro group. The same procedure has also been used successfully for the determination of some herbicides and insecticides containing the nitro function (2).

An important feature of the method is the use of constant current potentiometry for end-point detection, since conventional potentiometry does not respond adequately to the organic species being titrated, and the titration solution is too intensely colored by the chromium(III) bromide from which the chromium(II) is generated for indicators to be employed.

Experimental

Chemicals

Chromium(III) bromide (K & K Laboratories) was washed twice with ethyl ether, the excess ether removed by suction, and the solid dried under vacuum at room temperature. This material yields the rapidly reducible $CrBr(H_2O)_5^{2+}$ species at a mercury cathode (3). A solution 0.1 *M* in $CrBr(H_2O)_5^{2+}$ and 1.5 *M* in HCl was used as the catholyte in the coulometric cell (1). *p*-Nitroethylbenzene (K & K Laboratories), nitrobenzene (Fisher), and *o*-nitrophenetole (Aldrich Chemical Co.) were distilled under vacuum and the middle portions of the distillates used. *o*- and *m*-Nitrobenzaldehyde (Aldrich Chemical Co.) were used as received. The following compounds were recrystallized from ethanol until melting points within ±1°C of reported values were obtained: *o*- and *m*-nitrocinnamic acid, *p*-nitrosotoluene, 2-nitronaphthalene, *p*-nitroanisole, and 2-methyl-1-nitronaphthalene (Aldrich Chemical Co.); *p*-nitrophenetole, 2,4-dinitrophenetole, and 2,6-dinitrothymol (Eastman). 1,8-Dinitronaphthalene (K & K Laboratories) was recrystallized from chloroform. Cacotheline (Fluka AG) was used as received as was chloromycin obtained from L. Chatten, Faculty of Pharmacy, University of Alberta. Acetonitrile (Matheson, Coleman and Bell) was purified by distillation from calcium hydride; only the middle fraction was retained.

Apparatus

The coulometer, titration cell, and catholyte composition were as previously described (1). A 20-mA coulometric current, found to be satisfactory in earlier work, was employed (1), as was the constant current potentiometric system for end point detection, a pair of electrodes with a 10 μA current passing between them.

Titration Procedure

Into the anode compartment of the coulometry cell place 50 mL of 0.01 *M* HCl – 1.0 *M* KCl solution. Into the cathode compartment place 70 mL of a solution 0.1 *M* in $CrBr(H_2O)_5^{2+}$ and 1.5 *M* in HCl. Deaerate both solutions for 15 min with oxygen-free nitrogen. Then direct the nitrogen over the surface of the catholyte and introduce the mercury pool cathode. Run a blank by generating chromium(II) at the mercury cathode at a current level of about 20 mA, continuously at first and then in increments of 5 to 10 s near the end point, until the potential between the polarized pair of platinum microelectrodes begins to decrease. Record the potential and time readings for several points just before and beyond the potential decrease. Then inject about 1 g of approximately millimolar sample solution by hypodermic syringe and generate chromium(II), recording the time and potential readings as for the blank. Weigh the syringe before and after sample injection to determine the amount of sample delivered. Plot the readings against time of current generation and locate the end point by linear extrapolation (1). The amount of chromium(II) to be generated beyond the end point depends on the compound being determined. With sharp

For personal use only.

end points only about a 2% excess is needed; for more sluggish reactions about a 25% excess may be necessary.

When products of the first titration do not interfere, inject a second weighed portion of sample solution and repeat the titration, calculating the time of current generation from the previous end-point value.

Results and Discussion

Results of the titrations studied are summarized in Table 1. With some compounds four or five samples can be titrated in the same catholyte before it must be replaced, but with other compounds it is possible to analyse one sample only. The first sample run in the fresh catholyte solution sometimes must serve as a blank to establish an initial end point, and in these instances should not be used in the calculations. The total time required for titration of individual samples after injection into the cell ranged from 6 to 25 min. Sample solutions were always titrated within a few hours of preparation. Acetonitrile was used as solvent for all the compounds in Table 1 except cacotheline, for which water was used.

Rates of reaction varied widely with the compound; *p*-nitrophenetole, *p*-nitroethylbenzene, and 1,8-dinitronaphthalene were the most rapid. Where the reactions are rapid, the end points are usually sharp, and the error small. An exception was *o*-nitrosotoluene, which gave results about 5% high for a 2-electron reduction even though the end point was excellent. The error may be due to the presence of nitrotoluene formed by aerial oxidation during the recrystallization from hot ethanol, since the melting point after recrystallization, 70°C, is somewhat lower than the reported value of 72–75°C. Oxidation after recrystallization is also a possible contributing factor.

Cacotheline, nitrobenzene, and chloromycin react too slowly to be determinable; all give sloping end points with drifting potentials. The stoichiometry of 2,6-dinitrothymol and 2,4-dinitrophenetole suggests that one of the nitro groups undergoes a 6-electron reduction to the amine and the other a 5-electron reduction to a coupled hydrazo species. A 5-electron reduction was observed previously for 5-nitro-1-naphthylamine (1). 1,8-Dinitronaphthalene is involved in an overall 10-electron reduction. If the nitro group in the 1 position undergoes a 6-electron reduction as in 1-nitronaphthalene (1), then the nitro group in the 8 position may be reduced to the hydroxylamine for a total of ten electrons per molecule.

On the basis of previous (1, 2) and present results on the reduction of aromatic nitro compounds, all under the same conditions, we can summarize the relation between the molecular structure of a given aromatic nitro compound and reduction by chromium(II) as follows. Those compounds which contain methoxy or ethoxy groups on the benzene ring are easily reduced to the corresponding hydroxylamines or amines. The end points are sharp, and the potential difference between the indicator electrodes after the end point is stable. For *o*-nitroanisole reduction takes place with 4 electrons to the hydroxylamine, which may be stabilized by formation of a hydrogen bond to the oxygen of the anisole. The related compounds *p*-nitroanisole and *p*-nitrophenetole undergo 6-electron reduction to the corresponding amines. Although *o*-nitrophenetole reacts cleanly and sharply, the results of 12 determinations (rel. std. dev. 0.2%) were 8.7% higher than expected for a 4-electron reduction, and did not change when an additional distillation from a spinning band column at reduced pressure was performed on the material before titration. Further, a mass spectrum of the purified material showed only a parent peak and fragments corresponding to dissociation of the parent.

Methyl groups on the aromatic ring have an effect on the reduction of nitro groups similar to that of the methoxy group. *o*-Nitrotoluene, *m*-nitrotoluene, and 2-methyl-1-nitronaphthalene all undergo reduction only to the hydroxylamine with sharp end points. Potentials between the polarized platinum electrodes are stable at the end point for these compounds, especially if the methyl group is located *ortho* to the nitro group. The ease of reduction decreases if the nitro group is in the para position, as in *p*-nitrotoluene. However, the reduction of *p*-nitroethylbenzene, though rapid, requires only 5 electrons.

1-Nitronaphthalene undergoes rapid and stoichiometric reduction to the amine, but reduction of 2-nitronaphthalene is slow and nonstoichiometric, despite a well-defined end point. On the other hand, 1,8-dinitronaphthalene undergoes a rapid 10-electron reduction with a clean, sharp end point.

Dinitro compounds possessing a hydroxyl and methyl or butyl group on the aromatic ring undergo 12-electron reduction to the corresponding diamines; 4,6-dinitro-*o*-cresol and the herbicide dinoseb (2-(1-methylpropyl)-4,6-dinitrophenol) fall into this class (2). On the other hand, a ketone group in the *ortho*, *meta*, or *para* position decreases the ease of reduction of nitro groups. Thus *o*-, *m*-, and *p*-nitrobenzoic acid, *o*- and *m*-benzaldehyde, and 4-nitrophthalic acid all undergo 4-electron reduction, but with slow, poor end points that are unsatisfactory for analytical use. The introduction

of a side chain containing a carboxylic group and a carbon–carbon double bond results in a reduction of between 4 and 5 electrons. This was observed with both *o*- and *m*-nitrocinnamic acid. *o*-Nitrophenol behaves in a similar way. A hydroxyl group in the *meta* or *para* position, however, yields reduction to the corresponding amines, as with *m*- and *p*-nitrophenol.

A study related to the biological detoxification of Kraft pulp mill effluent is presented. Several fungal and bacterial preparations were evaluated for their action on isopimaric acid (IPA), one of the effluent constituents toxic to fish. *Mortierella isabellina* was the organism selected for the biodegradation of IPA and subsequent chemical studies established the structures of three diterpenoid substances with very much lower acute toxicity.

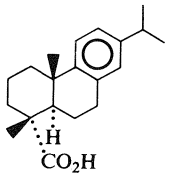
On présente une étude sur la désintoxication biologique des résidus provenant des moulins à papier. On a évalué l'action de plusieurs préparation bactériennes et fongiques sur l'acide isopimarique (AIP), un des constituants du résidu toxique pour les poissons. On a choisi l'organisme *Mortierella isabellina* pour dégrader l'AIP et des études chimiques qui ont suivi ont permis d'établir les structures de trois substances diterpéniques ayant une toxicité beaucoup plus faible.

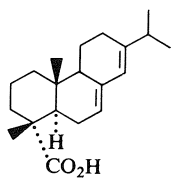
[Traduit par le journal]

Introduction

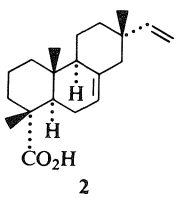
Of the major toxicants in Kraft pulp mill effluent (KME), dehydroabietic acid (DHA; **1**) has been shown to be efficiently transformed into non-toxic compounds by the fungus *Mortierella isabellina* (1). In this earlier work, specific biotransformation products from **1** were identified and quantified and a major pathway of DHA transformation was elucidated. *M. isabellina* proved to be a stable and readily produced organism potentially useful as a supplement to existing biobasins for the detoxification of DHA. Preliminary tests indicated that the metabolites produced had no significant toxicity to sockeye salmon fry or to juvenile *Daphnia pulex*.



1



3



2

A second major toxicant of KME is isopimaric acid (IPA; **2**) (2, 3). IPA is a highly toxic resin acid with a 96-h LC_{50} for rainbow trout of 0.4 mg/L[3]. It also appears to be more resistant to biodegradation than other resin acids. For example, in studies of the biodegradation of the sodium salts of resin acids (4), the IPA salt was most recalcitrant to breakdown by the natural, mixed micro-flora of an activated sewage sludge and of the waters of two rivers.

In the present study, several bacteria and fungi were screened for their abilities to degrade IPA. As in the case of DHA, *M. isabellina* was most effective.

Methods, results, and discussion

Culture growth

In preliminary screening experiments, *M. isabellina* was the only organism among five fungi and six bacteria (Table 1) to degrade IPA. Shake flask, batch cultures of *M. isabellina* were used to further examine IPA degradation. When grown in dextrose–yeast extract broth (Fig. 1), there was a 12 h lag followed by rapid growth resulting in a maximum dry weight of 3.7 mg/mL after 24 h incuba-

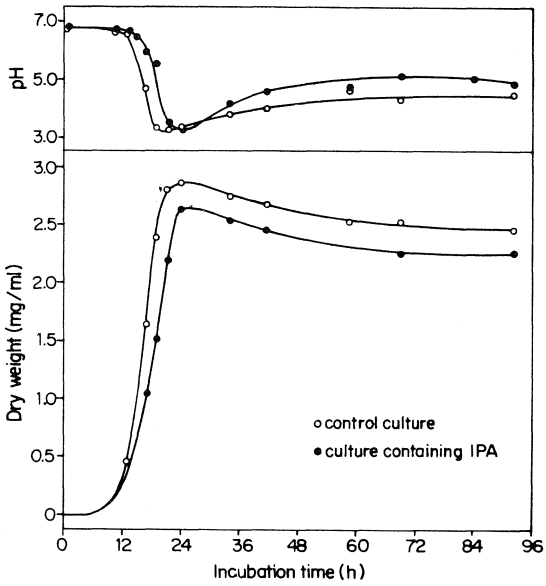

FIG. 1. Growth of *M. isabellina* in DYE and DYE plus IPA (80 mg/L) at 35°C.

tion. Inclusion of IPA at 80 mg/L caused a slight extension of the lag phase and a small reduction in the final biomass yield. A further extension of the lag phase occurred if the inoculum was not preconditioned to IPA. The cultures experienced a growth-associated decrease in pH.

Quantitative analysis

It was thought that a specific analytical technique that simultaneously evaluates the concentrations of several toxic resin acids would be useful in applications to the natural environment (e.g. KME). Therefore, a method was developed for the simultaneous measurement of DHA, IPA, abietic acid (ABA; **3**), and the metabolites derived from these compounds. Since IPA, unlike DHA and abietic acid, lacks an ultraviolet chromophore to facilitate simple detection (1), the acid was converted to its relatively stable imidazolide **4** by reaction with 1,1′-carbonyldiimidazole. The imidazolides of all three resin acids were sufficiently stable to be analysed in aqueous methanol without detectable decomposition. The actual analyses were performed by quantitative hplc on reverse phase C-8 columns, with methanol/water mixtures. Standard curves for the analysis of the three resin acids **1**, **2**, and **3** as their imidazolides are given in Fig. 2.

Optimization of the separation of the imidazolides of **1**, **2**, and **3** (see Experimental) gave k' values of 15.8, 21.5, and 23.5, respectively. The imidazolides of **2** and **3** were resolved to $R \simeq 1$, using methanol/water (77:23) on a Waters Associates C-8 radial pak at 2 mL/min, with detection at 280 nm. For the purposes of the present study, the IPA imidazolide standard curve shown in Fig. 2 was used for monitoring the disappearance of IPA and the appearance of its metabolites in cultures.

The imidazolides of the metabolites of IPA were assumed to have the same response factors as those of **2** since no new chromophores were introduced during biotransformation (see Experimental). Collectively, the standard curves in Fig. 2 will allow similar monitoring of **1**, **2**, and **3** during the detoxification of KME.

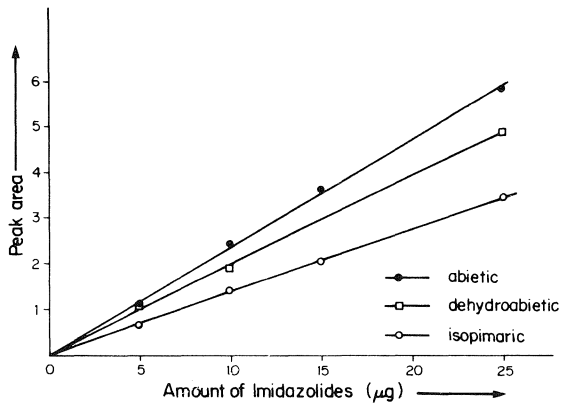

FIG. 2. Hplc quantitation of abietic, dehydroabietic, and isopimaric acids as their imidazolides: column: C8-reverse phase (radial pak A); solvent: CH_3OH/H_2O (77:23); flow rate: 2 mL/min; detector: Waters model 440 uv, (280 nm).

Biotransformation of IPA by M. isabellina

IPA (80 mg/L) was fed to cultures of *M. isabellina* in dextrose–yeast extract broth and the biotransformation of IPA over 96 h was followed using hplc analysis (Fig. 3). Most of the IPA was converted during the first 24 h of incubation. Three major metabolites were present in approximately equal concentrations at about 17 h, however, only one metabolite reached a plateau and remained in the culture until the end of the sampling period (Fig. 4).

Identification and isolation of the IPA metabolites

A large-scale incubation of *M. isabellina* containing approximately 480 mg of IPA was allowed to proceed for 17 h, at which time the cultures were harvested. The presence of the three major metabolites was confirmed by hplc analysis and each was separated from the crude mixture by preparative layer chromatography. On the assumption that the carboxylic acid function was not altered by *M. isabellina*, the metabolites (**5**, **9**, and **12**) were converted to their methyl esters (**6**, **10**, and **13**, respectively) for purification and identification.

The methyl ester **6** had molecular formula $C_{21}H_{32}O_3$ indicating the introduction of one additional oxygen to the IPA skeleton. The ir spectrum indicated hydroxyl stretching at 3700–3400 cm^{-1}. The ^{1}Hmr spectrum revealed a nine line, one proton absorbance at δ 3.9 for a ring proton geminal to a hydroxyl group. The splitting pattern (tt., J_{aa} = 12 Hz, J_{ae} = 4.0 Hz) was consistent with an axial proton split by two adjacent methylenes. These data indicated that a hydroxyl group was introduced at the $C_{2\alpha}$ position. To obtain further proof of this structure, the lactone, **7**, was formed by treatment of **5** with *p*-toluene sulphonic acid in refluxing benzene. Infrared absorption at 1770 cm^{-1} confirmed the γ-lactone function. Furthermore, oxidation of **6** with pyridinium chlorochromate gave **8** which exhibited an ir stretching band at 1708 cm^{-1} in addition to a saturated ester stretching at 1722 cm^{-1}. From these results, the possibility of an α,β-unsaturated ketone arising from oxidation of a C_6-hydroxyl group, which could also have formed a γ-lactone, was eliminated. Therefore, the first-formed major metabolite had structure **5**.

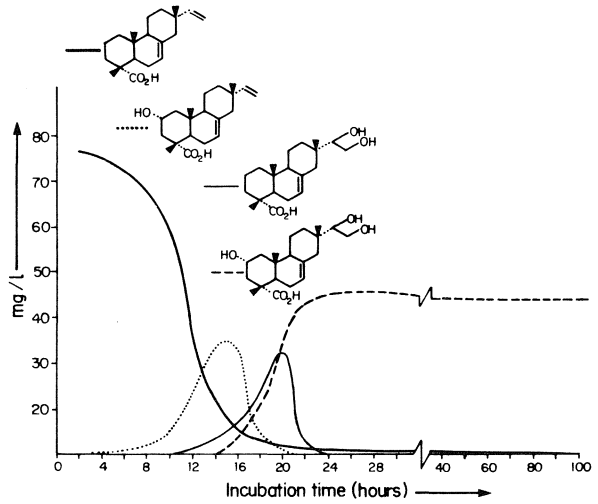

FIG. 3. Isopimaric acid biodegradation sequence by *M. isabellina*: column: C8-reverse phase (radial pak A); solvent: CH_3OH/H_2O (77:23); flow rate: 2 mL/min; detector: Waters model 440 uv, (280 nm).

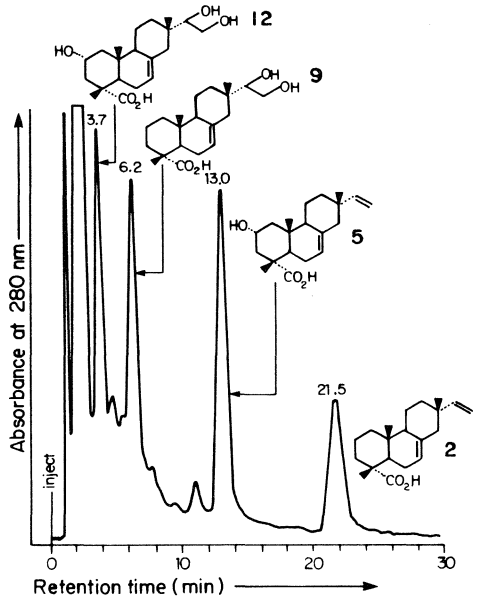

FIG. 4. Plot of absorbance at 280 nm of **2**, **5**, **9**, **12** versus retention time: column: C8-reverse phase (radial pak A); solvent: CH_3OH/H_2O (77:23); flow rate: 2 mL/min; detector: Waters model 440 uv, (280 nm).

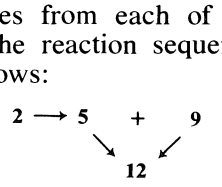
The methyl ester **10** of the second product of the biotransformation of IPA was a dihydroxy compound with molecular formula $C_{21}H_{34}O_4$, indicating the addition of two hydroxyl groups to the parent IPA skeleton. This may have occurred by dihydroxylation at one of the double bonds or by the addition of a molecule of water across a double bond plus monohydroxylation elsewhere. The latter possibility was excluded by analysis of the ^{1}Hmr spectrum which included only one vinyl proton multiplet at δ 5.35 and a three proton multiplet at δ 3.35–3.77, suggesting the side chain double bond had undergone dihydroxylation. This was supported by the fact that **10** gave an acetonide (**11**) on refluxing with acetone in the presence of anhydrous copper sulphate. Furthermore, the ^{1}Hmr spectrum of **11** is identical with that of a synthetic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

sample made by selective hydroxylation of the side chain double bond of IPA by osmium tetroxide. The second metabolite, therefore, had structure **9**.

The methyl ester **13** of the third metabolite had molecular formula $C_{21}H_{34}O_5$, indicating addition of three hydroxyls to the parent IPA skeleton. The ir spectrum showed hydroxyl stretching at 3700–3400 cm^{-1}, while the ^{1}Hmr spectrum again indicated a $C_{2\alpha}$-hydroxylation. In addition, the hydroxy acid **12** gave the lactone **16** when heated in benzene containing *p*-toluene sulphonic acid and acetone. A three proton multiplet at δ 3.55–3.77 and a single proton multiplet at δ 5.35 suggested C_{15}–C_{16} double bond dihydroxylation. Further confirmation of this feature was obtained from additional chemical transformations. When the methyl ester **13** was heated under reflux in the presence of anhydrous copper sulphate the acetonide **14** was formed which upon pyridinium chlorochromate oxidation furnished the ketoacetonide **15**. These latter compounds were characterized by their various spectral data. Considering the foregoing information, **12** was determined to be the structure of the third biotransformation product.

The experiments outlined above clearly indicate the tendency for *M. isabellina* to oxygenate IPA at $C_{2\alpha}$, C_{15}, and C_{16} positions. Introduction of the $C_{2\alpha}$ hydroxyl group is initiated first, followed by attack at the C_{15} and C_{16} positions. The two processes appear to proceed independently in that **5** is not a precursor of **9**, or vice versa. The trihydroxylated IPA (**12**) arises from each of the first-formed metabolites. the reaction sequence may be described as follows:

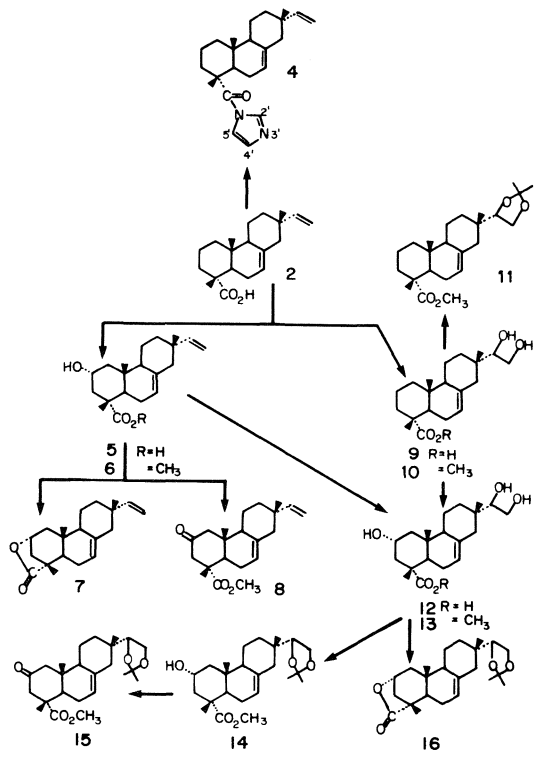


The last formed compound (12) resists further biotransformation by *M. isabellina* up to 96 h under the culture conditions described above.

Preliminary toxicity measurements (using juvenile *Daphnia pulex*) of the crude degradation mixture indicate very efficient detoxification of IPA by *M. isabellina*. Quantitative evaluation is presently underway, as are studies into the detoxification of abietic acid.

Experimental

Ultraviolet spectra were recorded on a Cary 15 spectrophotometer. Low resolution mass spectra were recorded on either an Atlas CH-4B or an AEI MS-902 spectrometer. High resolution mass data were measured on an AEI MS-902 instrument. The ^{1}Hmr spectra were recorded on Varian XL-100 and Nicolet Oxford H-270 instruments. Chemical shifts are reported as ppm from tetramethylsilane, used as internal standard. Microanalyses were performed by P. Borda, Microanalytical Laboratory, University of British Columbia. Melting points are uncorrected.



Screening of microorganisms for the ability to degrade IPA

Liquid media containing IPA at 50 mg/L (50 mL of medium per 250 mL Erlenmeyer flask) were inoculated with 1 mL of cell suspensions prepared by washing the surface of six-day old slant cultures with 5 mL of sterile Aerosol OT solution (Fisher Scientific: 450 μL per L distilled water). Cultures were incubated at room temperature (21 to 25°C) and 200 rpm on a rotary shaker. Bacterial cultures were harvested after 48 h and fungal cultures after 96 h. The presence of IPA was determined after derivatization, using hplc. Fungi were maintained as slant cultures on potato–dextrose agar (Difco) and were tested against IPA in dextrose–yeast extract broth (DYE) (5.0 g D-glucose, 0.5 g yeast extract (Difco), 1.0 g KH_2PO_4, 1.0 g $(NH_4)_2HPO_4$, 1.0 g NaCl, and 0.5 g $MgSO_4.7H_2O$ per L distilled water). Bacteria were kept as slant cultures on nutrient agar (Difco) and were tested against IPA in nutrient broth (Difco).

Biotransformation of IPA by M. isabellina

Cultures to be used as inocula were grown on 100 mL of potato–dextrose agar supplemented with 10 mg/L IPA in Roux bottles at 25°C. Inocula were prepared by washing the surface of a confluent mature culture (older than 10 days but younger than two months) with 50 mL of sterile Aerosol OT solution. The resulting suspension containing approximately 10^6 spores per mL (as determined using a Howard mold counting chamber) was inoculated into DYE at a volumetric ratio of 1:50. Controls contained no IPA, while cultures used to follow IPA degradation contained IPA at 80 mg/L which was added as a filter sterilized solution made slightly alkaline with NaOH. All cultures were 100 mL in 250 mL Erlenmeyer flasks. The cultures were incubated at 35°C and 200 rpm on a rotary shaker. To obtain a sample, a whole culture was harvested. Culture dry weights

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

were measured using membrane filtered (0.45 μm cellulose acetate filters, Millipore Corp.), freeze-dried cells.

Quantitative analysis for DHA, IPA, and ABA

Stock solutions (1.0 mg/mL) of DHA, IPA, and ABA were prepared in anhydrous acetonitrile (distilled from P_2O_5). Aliquots were taken to make up the following standards.

Acid (mg/3 mL)	Sample #1	2	3	4	5
DHA	2.5	1.0	0.5	0.0	0.0
IPA	0.5	1.0	0.0	2.5	1.5
ABA	0.0	1.0	2.5	0.5	1.5

A solution (0.5 mL) of 1,1′-carbonyldiimidazole (32 mg/mL) in anhydrous acetonitrile was added to each and the vials sealed and kept at room temperature for 1 h. The resin acid imidazolides were then analysed by analytical hplc (Waters Associates Data Module, System Controller and WISP Automatic injector coupled to a Radial Compression Module carrying a C_8 reverse phase column, and with a Model 440 UV detector operating at 280 nm and at 254 nm). Optimum resolution was obtained using the solvent system methanol/water (77:23) at 2 mL/min. The k' values, retention times, and response ratios were as follows:

		Relative response ratio	
Acid imidazolide	k'	280 nm	254 nm
DHA imidazolide	15.8 (16 min)	1.00	1.00
IPA imidazolide	21.5 (21.8 min)	0.82	0.90
ABA imidazolide	23.5 (23.8 min)	0.58	4.30

Peak areas, calculated electronically, were used to derive the standard curves shown in Fig. 2.

Analysis of cultures

Harvested cultures (50 mL each) were acidified to pH 2 and extracted with ethyl acetate (3 × 25 mL). The combined extracts were washed with water (10 mL), dried ($MgSO_4$), and concentrated *in vacuo*. The dried residues were dissolved in a solution (3.5 mL) of 1,1′-carbonyldiimidazole (16 mg) in dry acetonitrile, kept at room temperature for 1 h, and analysed by hplc. The polar products from IPA were eluted before the acid (**2**) (Fig. 3), and had k' values of 13.16 (**5**), 6.23 (**9**), and 3.75 (**12**).

*Isopimaric acid imidazolide (**4**)*

IPA (**2**) (30 mg) was reacted with 1,1′-carbonyldiimidazole (50 mg) in dry dichloromethane (2 mL). The excess reagent and imidazole was removed by washing with 1% $NaHCO_3$ solution. The organic layer was dried (Na_2SO_4) and concentrated *in vacuo*. The unstable imidazolide (**4**) was isolated (90%) as a viscous oil; uv (MeOH) λ_{max} 248 (1400); ir (film) ν_{max} 1720, 1650, 1480, 930, 745 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 0.98 (3H, s, C20—methyl), 1.00 (3H, s, C19—methyl), 1.50 (3H, s, C17—methyl), 4.9–5.1 (2H, m, C16—vinyl), 5.30 (1H, m, C7—H), 5.85 (1H, m, C15—H), 7.10 (1H, d, J = 1 Hz, C4′—H), 7.66 (1H, d, J = 1 Hz, C5′—H), 8.40 (1H, s, C2′—H); ms *m/e* 352 (M^+), 337, 316, 257, 119, 121, 88, 84.

*Methyl 2α-hydroxyisopimarate (**6**)*

The title compound was obtained as a white solid; mp 103–107°C (ether – petroleum ether); ir ($CHCl_3$) ν_{max} 3700–3300, 1722 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 0.8 (3H, s, C20—methyl), 0.96 (3H, s, C19—methyl), 1.32 (3H, s, C17—methyl), 3.68 (3H, s, CO_2CH_3), 3.92 (1H, tt, J = 12, 4 Hz, C2β—H), 4.82–5.12 (2H, m, C16—vinyl), 5.3–5.4 (1H, m, C7—H), 5.68–6.04 (1H, m, C15—H); ms *m/e* 332 (M^+), 314, 299, 255, 239, 201. *Anal.* calcd. for $C_{21}H_{32}O_3$: C 75.90; H 9.63; found: C 75.43, H 9.36. High resolution molecular weight determination, calcd. 332.2343, found 332.2353.

*Methyl 15,16-dihydro-15,16-dihydroxyisopimarate (**10**)*

The ester **10** was obtained as a white solid; mp 68–72°C (ether – petroleum ether); ir ($CHCl_3$) ν_{max} 3700–3300, 1725 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 0.77 (3H, s, C20—methyl), 0.9 (3H, s, C19—methyl), 1.27 (3H, s, C17—methyl), 3.35–3.77 (3H, m, C15—H and C16—H_2), 3.65 (3H, s, CO_2CH_3), 5.25–5.35 (1H, m, C7—H); ms *m/e* 350 (M^+), 299, 290, 289, 288, 257, 229. *Anal.* calcd. for $C_{21}H_{34}O_4$: C 72.0, H 9.71; found: C 71.83, H 9.49. High resolution molecular weight determination, calcd. 350.2448; found 350.2460.

*Methyl 15,16-dihydro-2α, 15,16-trihydroxyisopimarate (**13**)*

The ester **13** was obtained as a white solid; mp 135–140°C (ether); ir ($CHCl_3$) ν_{max} 3700–3300, 1725 cm^{-1}, ^{1}Hmr ($CDCl_3$) δ 0.77 (3H, s, C20—methyl) 0.92 (3H, s, C19—methyl), 1.3 (3H, s, C17—methyl), 3.33–3.75 (4H, m, C2β—H, C15—H and C16—H_2), 3.67 (3H, s, CO_2CH_3), 5.25–5.45 (1H, m, C7—H); ms *m/e* 366 (M^+), 305, 287, 255, 227, 185, 159, 157, 145, 131, 128. *Anal.* calcd. for $C_{21}H_{34}O_5$: C 68.85, H 9.28; found C 68.27, H 9.06. High resolution molecular weight determination, calcd. 366.2397, found 366.2416.

*2α-Isopimaric acid lactone (**7**)*

p-Toluene sulphonic acid (5 mg) was added to a refluxing solution of the hydroxy acid (**5**) (14 mg) in dry benzene (25 mL). The solution was refluxed for 30 min, cooled, washed with water, dried ($MgSO_4$), and concentrated *in vacuo*. Chromatography on silica gel gave lactone (**7**) (8 mg, 59%); ir ($CHCl_3$) ν_{max} 1770 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 0.80 (3H, s, C20—methyl), 1.15 (3H, s, C19—methyl), 1.32 (3H, s, C17—methyl), 4.5–4.7 (1H, m, $W/2$ = 13 Hz, C2β—H), 4.0–4.5 (3H, m, C15—H, C16—H_2), 5.3–5.45 (1H, m, C7—H); ms *m/e* 300 (M^+), 285, 271, 256, 241. High resolution molecular weight determination, calcd. 300.2082, found 300.2081.

*Methyl 2-oxoisopimarate (**8**)*

A solution of **6** (15 mg) in dichloromethane (1.5 mL) was added to a suspension of pyridinium chlorochromate (25 mg) in dichloromethane (2 mL) at room temperature and the mixture stirred for 1.5 h, diluted with ether (25 mL), filtered, and concentrated *in vacuo*. Chromatography on silica gel gave the ketone (**8**) (10.4 mg, 69%): ir ($CHCl_3$) ν_{max} 1725, 1710 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 0.76 (3H, s, C20—methyl), 0.92 (3H, s, C19—methyl), 1.26 (3H, s, C17—methyl), 3.70 (3H, s, CO_2CH_3), 4.80–5.10 (2H, m, C16—H_2), 5.25–5.45 (1H, m, C7—H), 5.60–6.00 (1H, m, C15—H); ms *m/e* 330 (M^+), 315, 271, 255, 213, 187. High resolution molecular weight determination: calcd. 330.2187, found 330.2196.

*Acetonide (**11**)*

Anhydrous $CuSO_4$ (500 mg) and the dihydroxy ester (**10**) (22 mg) were stirred in dry acetone (5 mL) at room temperature for 16 h. The mixture was filtered and the filtrate concentrated *in vacuo*. Chromatography on silica gel gave **11** (18.5 mg, 75%); ir ($CHCl_3$) ν_{max} 1722 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 0.75 (3H, s, C20—methyl), 0.87 (3H, s, C19—methyl), 1.25 (3H, s, —CH_3), 1.32 (3H, s, C17—methyl), 1.37 (3H, s, —CH_3), 3.62 (3H, s, CO_2CH_3), 3.65–3.85 (3H, m, C15—H, C16—H_2), 5.20–5.40 (1H, m, C7—H); ms *m/e* 390 (M^+), 375, 332, 317, 314, 255. *Anal.* calcd. for $C_{24}H_{38}O_4$: C 73.84, H 9.74; found C 73.49, H 9.67. High resolution molecular weight determination, calcd. 390.276, found 390.2771.

*The acetonide lactone (**16**)*

The trihydroxy acid (**12**) (35 mg), *p*-toluene sulphonic acid (10 mg) and anhydrous $CaCl_2$ (20 mg) were heated in refluxing, dry acetone (20 mL) for 20 min. The mixture was cooled, and evaporated. Benzene (15 mL) was added to the residue and the mixture refluxed for 20 min, cooled, filtered, washed with water, dried ($MgSO_4$), and concentrated *in vacuo*. Chromatography on

silica gel gave **16** (26 mg, 70%) mp 164–167°C (ether – petroleum ether); ir ($CHCl_3$) ν_{max} 1770 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 0.76 (3H, s, C20—methyl), 1.14 (3H, s, C19—methyl), 1.18 (3H, s, —CH_3), 1.34 (3H, s, C17—methyl), 1.40 (3H, s, —CH_3), 3.60–3.90 (3H, m, C15—H, C16—H_2), 4.60–4.80 (1H, m, $W/2$ = 13 Hz, C2β—H), 5.25–5.50 (1H, m, C7—H); ms *m/e* 374 (M^+), 316, 298, 272. *Anal*. calcd. for $C_{23}H_{34}O_4$: C 73.79, H 9.09; found: C 73.81, H 8.98. High resolution molecular weight determination, calcd. 374.2448; found 374.2442.

*The acetonide (**14**)*

Acetonide (**14**) was obtained in 86% yield by stirring a mixture of the ester **13** (37 mg), and anhydrous $CuSO_4$ (500 mg) in acetone (20 mL) for 12 h at room temperature as above; ir ($CHCl_3$) ν_{max} 3700–3300, 1722 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 0.75 (3H, s, C20—methyl), 0.92 (3H, s, C19—methyl), 1.30 (3H, s, —CH_3), 1.40 (3H, s, C17—methyl), 1.45 (3H, s, —CH_3), 3.67 (3H, s, CO_2CH_3), 3.56–4.00 (4H, m, C2β—H, C15—H, C16—H_2), 5.25–5.50 (1H, m, C7—H); ms *m/e* 406 (M^+), 391, 348, 330, 315, 286, 272, 253. *Anal*. calcd. for $C_{24}H_{38}O_5$: C 70.93, H 9.35; found C 70.74, H 9.16. High resolution molecular weight determination, calcd. 406.2709, found 406.2716.

*The acetonide (**15**)*

The hydroxyacetonide **14** was oxidised using pyridinium chlorochromate, as described above, to give **15** in 84% yield; ir ($CHCl_3$) ν_{max} 1722, 1708 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ 0.76 (3H, s, C20—methyl), 0.92 (3H, s, C19—methyl), 1.26 (3H, s, —CH_3), 1.36 (3H, s, C17—methyl), 1.40 (3H, s, —CH_3), 3.70–3.95 (3H, m, C15—H, C16—H_2), 3.72 (3H, s, CO_2CH_3), 5.30–5.50 (1H, m, C7—H); ms *m/e* 404 (M^+), 389, 346, 331, 328, 302, 287, 269, 243. *Anal*. calcd. for $C_{24}H_{36}O_5$: C 71.28, H 8.91; found: C 71.19, H 8.63. High resolution molecular weight determination: calcd. 404.2553; found 404.2561.

Nucleic acid related compounds. 35. Synthesis of 5-bromo- and 5-deuterio-3-deazauridine[1]

MORRIS J. ROBINS, CHISATO KANEKO,[2] AND MASAKATSU KANEKO[3]
Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 20, 1981

MORRIS J. ROBINS, CHISATO KANEKO, and MASAKATSU KANEKO. Can. J. Chem. **59**, 3356 (1981).

Bromination of 3-deazauracil (4-hydroxy-2-pyridinone) (**1**) gave the 3,5-dibromo compound (**2**). Selective debromination of **2** gave 5-bromo-4-hydroxy-2-pyridinone (**3**). Trimethylsilylation of **3** and condensation of the product (**4**) *in situ* with tetra-*O*-acetyl-β-D-ribofuranose (**5**) using tin(IV) chloride as catalyst gave 1-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)-5-bromo-4-hydroxy-2-pyridinone (**7**). Deprotection of **7** gave 5-bromo-3-deazauridine (**6**). Catalytic hydrogenolysis of **7** gave 3-deazauridine triacetate (**8***a*) and deuteriolysis gave the 5-deuterio product (**8***b*). Deprotection of **8***b* gave the isotope-labeled anticancer agent, 5-deuterio-3-deazauridine (**9**). Biochemical and clinical implications are discussed.

MORRIS J. ROBINS, CHISATO KANEKO et MASAKATSU KANEKO. Can. J. Chem. **59**, 3356 (1981).

La bromation du déaza-3 uracile (hydroxy-4 pyridinone-2) (**1**) conduit au composé dibromé en positions 3 et 5 (**2**). Une débromation sélective du composé **2** donne la bromo-5 hydroxy-4 pyridinone-2 (**3**). La triméthylsylilation du composé **3** suivie de la condensation *in situ* du composé **4** obtenu sur le tétra-*O*-acétyl β-D-ribofurannose (**5**) en utilisant le chlorure d'étain(IV) comme catalyseur permet d'obtenir la (tri-*O*-acétyl-2,3,5 β-D-ribofurannosyl)-1 bromo-5 hydroxy-4 pyridinone-2 (**7**). La déprotection du composé **7** conduit à la bromo-5 déaza-3 uridine (**6**). Par hydrogénolyse catalysée, le composé **7** conduit au triacétate de la deaza-3 uridine (**8***a*) et par deutérolyse, on obtient le produit deutéré en position 5 (**8***b*). La déprotection de ce dernier donne l'agent anticancérigène marqué isotopiquement: la deutéro-5 déaza-3 uridine (**9**). On discute des implications biochimiques et cliniques.
[Traduit par le journal]

The synthesis of 3-deazauridine (4-hydroxy-1-β-D-ribofuranosyl-2-pyridinone) was described by us several years ago (2). This nucleoside analogue was found to possess significant antileukemia activity in cell culture and also in infected experimental animals (3). A remarkable collateral sensitivity to 3-deazauridine was observed in a leukemia cell line that had developed resistance to the widely used clinical drug araC (1-β-D-arabinofuranosylcytosine) (4). It was found that 3-deazauridine is phosphorylated rapidly by cellular enzymes. Its 5′-triphosphate product functions as a potent inhibitor of cytidine triphosphate (CTP) synthetase, the enzyme that effects the sole *de novo* pathway into cytosine nucleotide metabolism (5). It has been observed very recently that significantly elevated levels of CTP synthetase occur in certain tumors (6). Cytidine and deoxycytidylate dearminases were found to be inhibited by 3-deazauridine and its 5′-monophosphate, respectively (7). These combined effects of blockage of *de novo* CTP production and depression of deamination of cytosine-type nucleosides and nucleotides provide a strong rationale for combination chemotherapy employing 3-deazauridine plus araC (8, 9) or 5-azacytidines (10, 11).

Successful pharmacological evaluation in animals led to introduction of 3-deazauridine into human clinical trials (9, 12). A very recent report notes a term clinical remission in a leukemia patient whose disease had become resistant to standard araC therapy (9).

Incorporation of 5-bromouracil into nucleic acids results in enhanced mutation frequencies (13). No incorporation of 3-deazauridine into cellular RNA or DNA was detected previously (14). However, 5-bromo-3-deazauridine had not been synthesized and the level of radioactivity achieved previously in labeled 3-deazauridine was insufficient for certain biochemical and metabolic studies. Therefore, we sought routes to make these compounds available.

Bromination of protected 3-deazauridine occurs readily at C-3 (15). However, attempted 3,5-dibromination resulted in decomposition of the protected nucleoside. Rapid hydrogen exchange with protic solvents occurs at C-3 (2), which precludes this position for labeling. We have employed the Vorbrüggen silyl ether coupling procedure (16) with 5-bromo-3-deazauracil and acetylated ribofurnanose to provide the needed product nucleosides.

Bromination of 3-deazauracil (4-hydroxy-2-pyridinone) (**1**) gave 3,5-dibromo-4-hydroxy-2-pyridinone (**2**) in 71% yield as described by den Hertog (17). Compound **2** was selectively debrominated at C-3 with aniline in aqueous hydrobromic acid to give 5-bromo-4-hydroxy-2-pyridinone (**3**) in 82% yield as described (18). The ^{1}H nmr and elemental

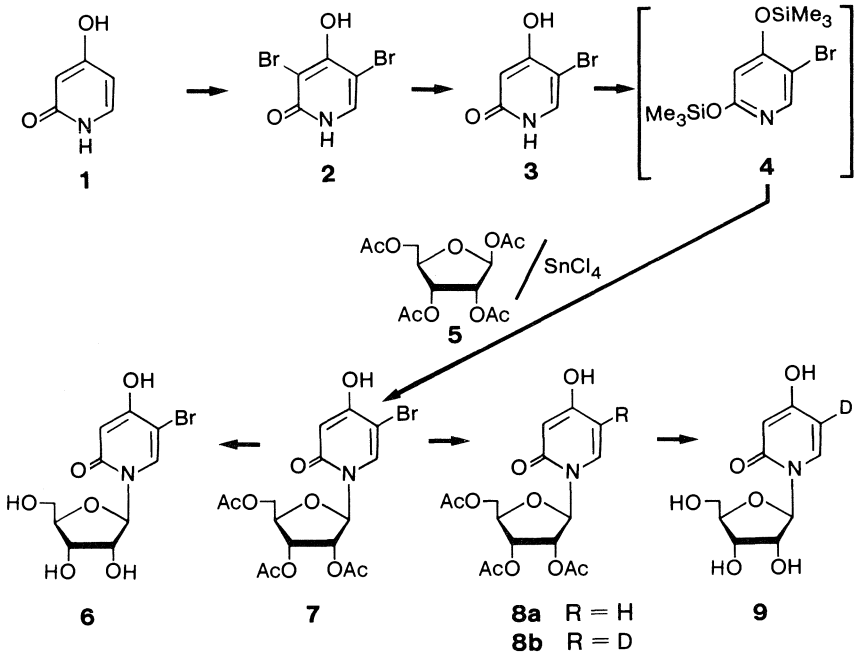
Reaction Scheme



analysis data confirmed the structures of **2** and **3**, whose melting point behavior was divergent from reported values.

Treatment of **3** with a catalytic amount of chlorotrimethylsilane in hexamethyldisilazane gave an oily product (presumed **4**) that was condensed with 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose (**5**) in the presence of tin(IV) chloride (16). A 97% yield (78% recrystallized) of 1-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)-5-bromo-4-hydroxy-2-pyridinone (**7**) was obtained. Deprotection of **7** with methanolic ammonia gave 5-bromo-3-deazauridine (**6**) as a crystalline monoacetamide complex in 51% yield. Removal of the acetamide was effected by chromatography on Dowex 1-X2 (OH^-). However, the free **6** resisted crystallization under a variety of conditions. A solid sample of **6** was obtained by lyophilization of a solution in benzene. Addition of one equivalent of acetamide to a solution of the free nucleoside again resulted in crystallization of a **6**·monoacetamide complex.

Catalytic hydrogenolysis of **7** gave 3-deazauridine triacetate (**8*a***) in 80% yield. This product was identical to a sample prepared from 3-deazauridine, which confirmed the N-1 attachment site and β configuration of **6–8**. Identical treatment of **7** in monodeuterioacetic acid (DOAc) with deuterium gas gave **8*b*** cleanly in 88% yield. Deuteriolysis of **7** in glacial acetic acid resulted in partial incorporation of protium at C-5. Deprotection of **8*b*** with methanolic ammonia gave 5-deuterio-3-deazauridine (**9**) in 83% yield. The H-6 and H-3 protons gave rise to clean singlets in the nmr spectrum of **9**.

The present work has provided the previously unknown 5-bromo-3-deazauridine[4] (**6**) and makes readily available a convenient precursor for labeling 3-deazauridine with hydrogen isotopes at a chemically stable site (C-5). Such a tritium-labeled product with high specific activity[5] was urgently needed for biomedical studies.

Experimental

General

Melting points were obtained on a Reichert microstage block and are uncorrected. Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer. The ^1H nmr spectra were determined on a Varian 100-MHz spectrometer with Me_4Si as internal reference. Mass spectra (ms) were measured at 70 eV with an AEI MS-50 instrument with coupled computer analysis using direct probe sample introduction at 150–250°C by the mass

[4]Evaluation of compound **6** in a murine leukemia L1210 cell culture indicated no inhibitory activity at a concentration of 100 μ*M*.

spectral laboratory of this department. Elemental analyses were determined by the microanalytical laboratory of this department. Evaporations were effected with a Buchler rotary evaporator equipped with a Dewar "Dry-Ice" condenser at mechanical oil pump (*in vacuo*) or water aspirator vacuum.

The 4-hydroxy-2-pyridinone (2,4-dihydorxypyridine, 3-deazauracil) was purchased from Aldrich Chemical Co. and the 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose from Raylo Chemicals Ltd., Edmonton, Alberta.

*3,5-Dibromo-4-hydroxy-2-pyridinone (**2**)*

A 1.1 g (9.9 mmol) sample of 4-hydroxy-2-pyridinone (**1**) was brominated with 1.1 mL (20 mmol) of Br_2 essentially as described (17) to give 1.88 g (71%) of **2**. Recrystallization from 98% EtOH gave colorless needles of **2**, mp 259–262°C (after becoming dark colored from 235–245°C) (lit. (17) mp ~ 245°C (dec.), mp (19) 225–240°C (dec.)); nmr (Me_2SO-d_6) δ: 7.67 (s, 1, H-6). *Anal.* calcd. for $C_5H_3Br_2NO_2$: C 22.34, H 1.12, N 5.21; found: C 22.28, H 1.14, N 5.27.

*5-Bromo-4-hydroxy-2-pyridinone (**3**)*

A 0.54 g (2 mmol) sample of **2** was heated with 0.19 g (2 mmol) of aniline in 5 mL of 47% HBr/H_2O at 100°C for 4 h in a sealed tube. Processing as described previously (18) and recrystallization from 95% EtOH gave 0.31 g (82%) of white needles of **3**, mp 250–251°C (lit. (20) mp 226.5–227.5°C); nmr (Me_2SO-d_6) δ: 5.72 (s, 1, H-3), 7.56 (s, 1, H-6). *Anal.* calcd. for $C_5H_4BrNO_2$: C 31.61, H 2.12, N 7.37; found: C 31.71, H 2.21, N 7.44.

*1-(2,3,5-Tri-O-acetyl-β-D-ribofuranosyl)-5-bromo-4-hydroxy-2-pyridinone (**7**)*

A 1.71 g (9 mmol) sample of **3** was suspended in 7 mL of hexamethyldisilazane and 3 drops of chlorotrimethylsilane was added. The mixture was heated at reflux with exclusion of moisture for 3 h. A clear solution was obtained and solid NH_4Cl was deposited in the reflux condenser. The volatile materials were evaporated *in vacuo* at 40°C to give the presumed bis-trimethylsilyloxypyridine derivative (**4**) as a colorless viscous oil.

A solution of the oily **4** in 5 mL of 1,2-dichloroethane was added to a solution of 2.75 g (8.6 mmol) of 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose (**5**) in 50 mL of dichloroethane. The vigorously stirred mixture was cooled in an ice-bath and then 0.75 mL (6.5 mmol) of redistilled $SnCl_4$ was added. The pale yellow solution was allowed to stand at room temperature for 18 h while protected from moisture. The solution was diluted with 20 mL of 1,2-dichloroethane and then was shaken with 40 mL of saturated $NaHCO_3/H_2O$. The resulting emulsion was filtered using a layer of Celite. The Celite cake was washed with 10 mL of $CHCl_3$. Dilute HBr/H_2O was added to the combined filtrate to pH ~ 4 (indicator paper). NaCl was added to saturate the aqueous layer and the mixture was extracted with 3 × 40 mL of $CHCl_3$. The combined organic phase was washed with saturated $NaCl/H_2O$, dried over Na_2SO_4, filtered, and evaporated. The resulting amorphous residue was purified by chromatography on silica using 3% $MeOH/CHCl_3$ for elution to give 3.75 g (97%) of **7** as an amorphous colorless solid. Crystallization from absolute EtOH gave 3.02 g (78%) of white needles of **7**, mp 195–196°C; uv (0.1 *N* HCl): max 295 nm (ε 3900), min 262 nm (ε 1100); (H_2O): max 268, 286 (sh) nm (ε 4900, 4000), min 248 nm (ε 3700); nmr (Me_2SO-d_6) δ: 2.05 (s, 3, OAc), 2.07 (s, 6, two OAc's), 4.28 (m, 3, H-4′, 5′, 5″), 5.28–5.50 (m, 2, H-2′, 3′), 5.74 (s, 1, H-3), 6.02 (d, $J_{1'-2'}$ = 4.0 Hz, 1, H-1′), 7.95 (s, 1, H-6); ms *m/z*: 449.0127 (5.1%, M^+ [^{81}Br] = 449.0144), 447.0160 (4.6%, M^+ [^{79}Br] = 447.0165). *Anal.* calcd. for $C_{16}H_{18}BrNO_9$: C 42.88, H 4.05, N 3.13; found: C 42.74, H 4.03, N 3.00.

*5-Bromo-4-hydroxy-1-β-D-ribofuranosyl-2-pyridinone (5-Bromo-3-deazauridine) (**6**)*

To 30 mL of MeOH saturated with NH_3 at 0°C was added 868 mg (1.94 mmol) of **7**. The mixture was allowed to stand for 18 h in a refrigerator at 4°C and then was evaporated to give a white solid foam. This residue was crystallized from isopropanol to give 379 mg (51%) of white needles of a **6**·monoacetamide complex, mp 180–181°C; uv (0.1 *N* HCl): max 293 nm (ε 4000), min 261 nm (ε 1300); (H_2O): max 284, 270 nm (ε 4000, 4200), min 278, 249 nm (ε 3900, 3500); (0.1 *N* NaOH): max 264, 270 (sh), 286 (sh) nm (ε 7400, 7200, 4200), min 244 nm (ε 5000); nmr (Me_2SO-d_6) δ: 1.78 (s, 3, acetamide methyl), 3.66 (m, 2, H-5′, 5″), 3.96 (m, 3, H-2′, 3′, 4′), 4.98, 5.20, 5.34 (br singlets, three OH's), 5.75 (s, 1, H-3), 5.94 (d, $J_{1'-2'}$ = 3.8 Hz, 1, H-1′), 6.63 and 7.25 (br, 1 & 1, acetamide NH's), 8.30 (s, 1, H-6); ms *m/z*: 322.9835 (3.3%, M^+ [^{81}Br] = 322.9829), 320.9847 (3.1%, M^+ [^{79}Br] = 320.9848). *Anal.* calcd. for $C_{10}H_{12}BrNO_6 \cdot C_2H_5NO$: C 37.82, H 4.50, N 7.35; found: C 37.83, H 4.52, N 7.27.

An aqueous solution of 500 mg (1.31 mmol) of **6**·monoacetamide complex was applied to a column of 20 mL of Dowex 1-X2 (OH^-) resin. The column was washed with water to remove the acetamide and then was eluted with 1% $HOAc/H_2O$. Fractions containing **6** were pooled and evaporated *in vacuo*. The residue failed to crystallize under a variety of conditions. It was dissolved in a minimum amount of methanol, diluted with dry benzene, and lyophilized to give 395 mg (89%) of **6** as an amorphous white solid containing ~ 0.2 equivalents of benzene solvate; uv (0.1 *N* HCl): max 294 nm (ε 4100), min 262 nm (ε 1300); (H_2O): max 287, 273 nm (ε 4000, 3900), min 278, 252 nm (ε 3800, 3300); (0.1 *N* NaOH): max 265, 285 (sh) nm (ε 7300, 4200), min 245 nm (ε 4800); the nmr (Me_2SO-d_6) spectrum was identical to that of the above **6**·monoacetamide complex except for the absence of peaks for acetamide and the presence of ~ 1.2 H from residual benzene; ms *m/z*: 322.9840 (6.3%, M^+ [^{81}Br] = 322.9829), 320.9853 (6.0%, M^+ [^{79}Br] = 320.9848). *Anal.* calcd. for $C_{10}H_{12}BrNO_6 \cdot 0.2\ C_6H_6$: C 39.83, H 3.94, N 4.15; found: C 39.85, H 4.12, N 3.91.

*1-(2,3,5-Tri-O-acetyl-β-D-ribofuranosyl)-5-deuterio-4-hydroxy-2-pyridinone (**8**b)*

A suspension of 500 mg of 5% Pd·C catalyst in 8 mL of acetic acid-d_1 (DOAc) was stirred vigorously for 20 min in a deuterium atmosphere with intermittent bubbling of D_2 through the mixture. A 500 mg (1.12 mmol) sample of **7** was added and the mixture was stirred vigorously for 5 h at room temperature under 1 atm pressure of D_2. The mixture was filtered, 410 mg (5 mmol) of NaOAc was added to the filtrate, and this solution was evaporated *in vacuo*. The residue was treated with 10 mL of $CHCl_3$ and 5 mL of H_2O and the organic layer was separated. The aqueous phase was extracted with 2 × 10 mL of $CHCl_3$. The combined organic phase was washed with 10 mL of H_2O, dried over Na_2SO_4, filtered, and evaporated. The resulting pale violet residue (365 mg, 88%) was dissolved in dry benzene and lyophilized to give a powder. The powder was crystallized from dry benzene to give violet tinted needles of **8***b*, mp 155–155.5°C; uv (0.1 *N* HCl): max 282, 228 (sh) nm (ε 4500, 3200), min 252 nm (ε 1500); (H_2O): max 282 nm (ε 4800), min 250 nm (ε 1800); nmr ($CDCl_3$) δ: 2.09 (s, 6, two OAc's), 2.14 (s, 3, OAc), 4.38 (br, 3, H-4′, 5′, 5″), 5.33 (br, 2, H-2′, 3′), 5.96 (s, 1, H-3), 6.28 (d, $J_{1'-2'}$ = 3.8 Hz, 1, H-1′), 7.45 (s, 1, H-6); ms *m/z*: 370.1117 (8.0%, M^+ = 370.1123). *Anal.* calcd. for $C_{16}H_{18}DNO_9$ (by H_2O/HDO gas volume analysis): C 51.90, H 5.17, N 3.78; found: C 51.95, H 5.13, N 3.65.

*1-(2,3,5-Tri-O-acetyl-β-D-ribofuranosyl)-4-hydroxy-2-pyridinone (**8**a)*

A 100 mg (0.223 mmol) sample of **7** was subjected to the identical procedure for the above conversion of **7** → **8***b* (but employing ^{1}H isotope in place of deuterium) to give 66 mg (80%) of amorphous **8***a*. This product was crystallized from absolute EtOH to give colorless prisms of **8***a*, mp 153–155°C; uv (same as for **8***b*); nmr ($CDCl_3$) (sugar protons same as for **8***b*) δ: 5.96 (d,

J_{3-5} = 2.0 Hz, 1, H-3), 6.10 (d of d, J_{5-3} = 2.0 Hz, J_{5-6} = 7.0 Hz, 1, H-5), 7.47 (d, J_{6-5} = 7.0 Hz, 1, H-6); ms *m/z*: 369.1052 (6.4%, M^+ = 369.1060). *Anal.* calcd. for $C_{16}H_{19}NO_9$: C 52.04, H 5.19, N 3.79; found: C 52.03, H 5.13, N 3.70.

This compond was identical to a sample prepared from 3-deazauridine (M. Kaneko, to be published) by mp, ir, ^{1}H nmr, and mass spectral comparisons.

5-Deuterio-4-hydroxy-1-β-D-ribofuranosyl-2-pyridinone (5-Deuterio-3-deazauridine) (9)

To 30 mL of MeOH saturated with NH_3 at 0°C was added 365 mg (0.986 mmol) of **8***b*. The mixture was allowed to stand for 18 h in a refrigerator at 4°C and then was evaporated. The residual pale yellow foam was dissolved in H_2O and applied to a column of 10 mL of Dowex 1-X2 (OH^-) resin. The column was washed with 500 mL of H_2O, 1000 mL of 30% MeOH/H_2O, and then was eluted with 500 mL of 0.5% HOAc/H_2O. Appropriate fractions were pooled and evaporated *in vacuo*. The residue was dissolved in a minimum volume of MeOH, diluted with dry benzene, and lyophilized to give 200 mg (83%) of **9** as a pale yellow powder. This material was crystallized from MeOH to give off-white prisms of **9**, mp 248–249°C; uv (0.1 *N* HCl): max 280, 272 (sh), 230 nm (ε 5000, 4800, 4900), min 250, 223 nm (ε 2300, 4500); (H_2O): max 281 nm (ε 6300), min 250 nm (ε 2200); (0.1 *N* NaOH): max 255, 270 (sh) nm (ε 10 000, 7300), min 232 nm (ε 4800); nmr (Me_2SO-d_6) δ: 3.63 (br, 2, H-5′, 5″), 3.96 (m, 3, H-2′, 3′, 4′), 5.00 (br, 2, two OH's), 5.27 (br, 1, OH), 5.57 (s, 1, H-3), 5.98 (d, $J_{1'-2'}$ = 3.8 Hz, 1, H-1′), 7.80 (s, 1, H-6), 13.0 (br, 1, pyridine-4-OH); ms *m/z*: 244.0812 (1.3%, M^+ = 244.0805). *Anal.* calcd. for $C_{10}H_{12}DNO_6$ (by H_2O/HDO gas volume analysis): C 49.19, H 5.37, N 5.74; found: C 49.07, H 5.33, N 5.64.

MORRIS J. ROBINS, FRITZ HANSSKE, and SALWA E. BERNIER. Can. J. Chem. **59**, 3360 (1981).

A modified trimethylsilylation of guanosine (**1**) followed by *in situ* replacement of the 6-trimethylsilyloxy group with ammonia at 150°C gave 2,6-diamino-9-β-D-ribofuranosylpurine (**2**) in 92% yield. Treatment of **2** with diazomethane in the presence of tin(II) chloride dihydrate gave the 2′-*O*-methyl (**3**) and 3′-*O*-methyl (**4**) ethers of **2** in 98% combined yield. The ratios of **3**/**4** could be varied from 51:47 to 34:64 by changing the amount of catalyst used. Treatment of **3** and **4** with adenosine deaminase resulted in clean conversion of these 2-aminoadenosine ethers to 2′-*O*-methylguanosine (**5**) and 3′-*O*-methylguanosine (**6**), respectively, in optimized yields of 40% and 54% overall from **1**. The ^{13}C nmr data for six ribonucleosides and their isomeric methyl ether derivatives have been correlated to provide a convenient method of identification.

MORRIS J. ROBINS, FRITZ HANSSKE et SALWA E. BERNIER. Can. J. Chem. **59**, 3360 (1981).

Une triméthylsilylation de guanosine (**1**) suivie d'une réaction *in situ* avec l'ammoniac à 150°C conduit, par déplacement du groupe triméthylsilyloxy-6, à la diamino-2,6 β-D-ribofurannosyl-9 purine (**2**) avec un rendement de 92%. Le composé **2** réagit avec le diazométhane en présence du dihydrate du chlorure d'étain(II) pour en donner les éthers *O*-méthyl-2′ (**3**) et -3′ (**4**) avec un rendement combiné de 98%. On peut faire varier le rapport **3**/**4** de 51:47 à 34:64 en changeant la quantité de catalyseur utilisé. En faisant réagir les composés **3** et **4** avec la désaminase de l'adénosine, on transforme ces éthers de l'amino-2 adénosine en *O*-méthyl-2′ guanosine (**5**) et *O*-méthyl-3′ guanosine (**6**) avec des rendements globaux respectifs optimisées de 40 et de 54%. On a établi une corrélation entre les données de la rmn du ^{13}C de six ribonucléosides et de leurs éthers méthyliques isomères de façon à obtenir une méthode convenable d'identification.

[Traduit par le journal]

The 2′-*O*-methyl ethers of the four major ribonucleosides occur as ubiquitous "minor components" in all types of ribonucleic acids (RNA's) (2). Recently, an extreme thermophile, *Thermus thermophilus* HB27, was found to have markedly enhanced levels of 2′-*O*-methylguanosine in its tRNA when grown at 80°C. It was inferred that the enzyme activity of a specific methyl transferase in the bacterium was higher at the elevated temperature (3). The 5′-triphosphate of synthetic 3′-*O*-methylguanosine was shown to effect termination of biosynthesis of RNA catalyzed by a RNA polymerase. This termination technique has been applied to sequencing studies of RNA and DNA (4).

Convenient and high yield methods have been devised for synthesis of the 2′-*O*- and 3′-*O*-methyl ethers of adenosine, cytidine, and uridine (see the discussion and references quoted in ref. 5). However, guanosine has presented significant difficulties. Khwaja and Robins (6) treated 2-amino-6-chloro-9-β-D-ribofuranosylpurine with diazomethane followed by sodium hydrogen sulfide to give 2′-*O*-methyl-6-thioguanosine. This product was converted to 2′-*O*-methylguanosine in ~14% yield overall from guanosine. Goodman and co-workers first prepared 3′-*O*-methylguanosine by a multistep carbohydrate synthesis and base–sugar coupling (7). We had obtained the 2′-*O*- and 3′-*O*-methylguanosines in ~15% yield, each, by careful treatment of guanosine with diazomethane and stannous chloride as catalyst. However, tedious chromatographic separation and isolation were involved (5). Kusmierek and Shugar (8) converted guanosine to its 6-ethoxy analogue. Treatment of this product with diazomethane/tin(II) chloride followed by separation of isomers and hydrolysis gave low overall yields of 2′-*O*- (7%) and 3′-*O*-methylguanosine (5%). Ekborg and Garegg very recently have reported overall yields of the 2′-*O*- (13%) and 3′-*O*-methyl (28%) isomers by treatment of 5′-*O*-*tert*-butyldiphenylsilylguanosine with diazomethane/stannous chloride followed by chromatography and fractional crystallization (9). We now report a convenient procedure that allows complete separation of isomers on the Dekker column (10) (Dowex 1-X2 (OH^-) resin) and gives good overall yields of 2′-*O*- (40%) and 3′-*O*-methylguanosine (54%) from guanosine.

The acidic cyclic amide function of guanosine

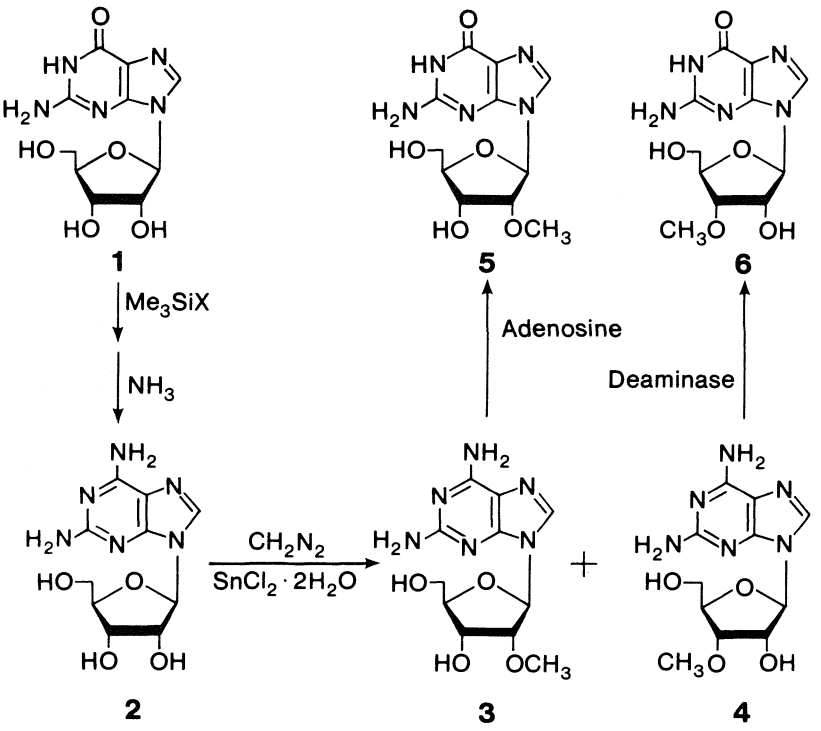
Reaction Scheme



($pK_a = 9.16$) was converted to a weakly basic cyclic amidine by modification of the procedure of Vorbrüggen and Krolikiewicz (11). Guanosine (**1**) was exhaustively trimethylsilylated and treated *in situ* with anhydrous ammonia in toluene at 150°C to give 2,6-diamino-9-β-D-ribofuranosylpurine (2-aminoadenosine) (**2**) in 92% yield. Methylation of **2** with diazomethane/stannous chloride dihydrate (5) in warm *N*,*N*-dimethylformamide (DMF) proceeded to completion. The 2′-*O*- (**3**) and 3′-*O*-methyl-2-aminoadenosine (**4**) products were resolved cleanly on the Dekker column in a combined yield of 98% after crystallization. The ratio of **3**/**4** could be varied from 51:47 to 34:64 by altering the quantity of catalyst. Attempts to alter the product ratio using other inorganic catalysts (12) were not productive.

Conversion of **3** and **4** to the corresponding guanine nucleosides **5** and **6** was effected smoothly using adenosine deaminase, as demonstrated previously with the parent nucleosides **2** → **1** (13). In parallel with rates of the enzymatic deamination of 2′-*O*- and 3′-*O*-methyladenosine,[4] the conversion of **3** → **5** proceeded more rapidly than **4** → **6**. The overall conversion of **1** → **5** was effected in 40% yield and **1** → **6** in 54% with catalyst optimization for each isomer.

The ^1H nmr and mass spectral properties of these *O*′-methyl isomers are in harmony with previously noted trends (5). The 2′-identifying mass spectral ion at B + 44 (2′-OH) or B + 58 (2′-OCH_3) is distinctive. Minor proton shifts (~0.15 ppm) are characteristic as noted by Reese and co-workers (14). However, the small magnitudes of these shifts would make assignment extremely tenuous unless both methylated isomers were available.

The ^{13}C nmr shifts in the *O*′-methyl nucleosides provide a clear means of identification even if only one isomer and the parent nucleoside are available. Table 1 contains ^{13}C nmr data for the four major naturally occurring ribonucleosides plus 2-aminoadenosine (**2**) and 6-thioinosine. Table 2 lists ^{13}C data for the six 2′-*O*-methyl compounds and Table 3 that for their 3′-*O*-methyl isomers. Resonance assignments for the parent nucleosides are in harmony with those of Grant and co-workers (15) with the positions for C-2′ and C-3′ reversed (16) as corrected by Mantsch and Smith (17).

No major effects on the ^{13}C resonances of the base carbons occur upon methylation of the sugar hydroxyl groups. Methylation of O-2′ results in a

[4]F. Hansske, unpublished observation.

3′-*O*Me-6-TI	176.02	144.97	143.67	140.79	135.32	87.65	83.12	79.22	73.18	60.93	57.43
3′-*O*MeCyd	141.48	155.37	165.68	—	93.80	89.99	82.18	79.00	72.86	60.98	57.46
3′-*O*MeUrd	140.42	150.63	163.00	—	101.61	87.86	82.39	78.92	72.53	60.73	57.48

marked downfield shift of the signal for C-2′ relative to that of the parent nucleoside (average $\Delta\delta$ −9.04 ppm with a range of −8.85 to −9.29 ppm for the six compounds). Upfield shifts for C-1′ (average $\Delta\delta$ 1.37, range 0.55 to 1.82 ppm) and C-3′ (average $\Delta\delta$ 1.62, range 1.06 to 1.84 ppm) occur consistently. Methylation of O-3′ results in the pronounced downfield shift of the signal for C-3′ (average $\Delta\delta$ −9.37, range −9.01 to −9.76 ppm) and upfield shifts for C-2′ (average $\Delta\delta$ 0.84, range 0.39 to 1.15 ppm) and C-4′ (average $\Delta\delta$ 2.40, range 1.96 to 2.68 ppm).

A small upfield shift for C-5′ was observed with all the 2′-*O*-methyl isomers and all but two of the 3′-*O*-methyl compounds. Shifts for C-4′ in the 2′-*O*-methyl and C-1′ in the 3′-*O*-methyl series were small generally, and were not consistent in direction.

This study has provided a convenient route to 2′-*O*-methylguanosine (**5**) and its 3′-*O*-methyl isomer (**6**). The overall yields from guanosine (**1**) are three times greater for **5** and double for **6** those obtained by prior methods. Clean resolution of isomers **3** and **4** was effected on the Dekker column. The ^{13}C nmr shifts provide rapid identification of the methylated isomers. A pronounced downfield shift of ~−9 ppm for C-2′ and upfield shifts of ~1.4 ppm for C-1′ and ~1.6 ppm for C-3′ are diagnostic for the 2′-*O*-methyl compounds. A marked downfield shift of ~−9.4 ppm for C-3′ and upfield shifts of ~0.8 ppm for C-2′ and ~2.4 ppm for C-4′ are observed with the 3′-*O*-methyl isomers, which causes a "cross-over" for the C-2′ and C-3′ resonances in this series relative to the parent and 2′-*O*-methylnucleosides.

Experimental

General

Most general procedures and instrumentation used are given in ref. 1. All nmr spectra were determined in Me_2SO-d_6 with Me_4Si as internal standard. The ^{13}C nmr spectra were obtained at ~22.6, ~50.3, or ~100.6 MHz with broad band ^1H decoupling on Bruker HFX-90, WH-200, or WH-400 spectrometers by the high field nmr laboratory of this department. All uv spectra were measured at pH 7.0 in an aqueous phosphate buffer. Samples for analysis were dried over P_2O_5 at 100°C for three days *in vacuo*. Thin-layer electrophoresis (tle) was performed on 0.1 mm cellulose 300 UV_{254} plates from Macherey & Nagel with a 0.1 *M* aqueous sodium borate buffer (pH 10.0) using a Desaga tle

double chamber apparatus at 800–1000 V for 1–1.5 h. The tle mobilities are given relative to the migration of guanosine (R_{Guo} = 1.0), which migrated toward the positive (+) electrode.

2,6-Diamino-9-β-D-ribofuranosylpurine (2-Aminoadenosine) (2)

A mixture of 45 g (0.16 mol) of dried guanosine (**1**), 600 mL of hexamethyldisilazane, and 20 mL of chlorotrimethylsilane was stirred at reflux for 16 h while protected from moisture under dry nitrogen. Volatile materials were distilled at atmospheric pressure and the silylation procedure was repeated on the residual syrup. The second solution was evaporated *in vacuo* and the yellow syrup was dissolved in 250 mL of anhydrous toluene. This solution was transferred quickly into a dried Parr pressure bomb under dry nitrogen, sealed, and cooled to −40°C in a "Dry-Ice"/acetone bath. The bomb was opened under dry nitrogen and 40 mL of hexamethyldisilazane, 3.75 g of trimethylsilyl trifluoromethanesulfonate ($CF_3SO_3SiMe_3$), and 22 mL of anhydrous liquid ammonia were added. The bomb was sealed quickly, heated at 150°C for 3 days, and cooled. The ammonia was vented and 500 mL of MeOH/H_2O (1:1) was added. The mixture was stirred at reflux for 4 h and the MeOH removed by evaporation. Water (300 mL) was added and the hot mixture decolorized with charcoal. The filtrate was chilled to give 37.4 g (83%) of colorless crystals of **2**. This filtrate was concentrated and applied to a column (2.5 × 30 cm) of Dowex 1-X2 (OH^-) resin. The column was washed with H_2O. Elution with MeOH/H_2O (6:4) gave an additional 3.7 g of crystallized product for a total yield of 41.1 g (92%) of **2**, mp 250–252°C (lit. (11) mp 242–244°C); tle R_{Guo} = 0.34 (+); uv max: 280, 256, 216 nm (ε 10 900, 10 000, 25 600); ^{1}H nmr δ: 3.57 (m, 2, H-5′,5″), 3.90 (m, $J_{4'-3'}$ = 3 Hz, $J_{4'-5',5''}$ ~7 Hz, 1, H-4′), 4.09 (m, $J_{3'-3'OH}$ = 4.5 Hz, $J_{3'-2'}$ = 5 Hz, 1, H-3′), 4.50 (m, $J_{2'-2'OH}$ = 6 Hz, $J_{2'-1'}$ = 6 Hz, 1, H-2′), 5.06 (d, 1, 3′-OH), 5.32 (d, 1, 2′-OH), 5.43 (t, $J_{5'OH-5',5''}$ = 6 Hz, 1, 5′-OH), 5.67 (br s, 2, 2-NH_2), 5.69 (d, 1, H-1′), 6.72 (br s, 2, 6-NH_2), 7.87 (s, 1, H-8); ms *m/z*: 282.1075 (8.8%, M^+ = 282.1077), 193.0837 (9.7%, B + 43 = 193.0838), 150.0655 (100%, B = 150.0654). *Anal.* calcd. for $C_{10}H_{14}N_6O_4$: C 42.55, H 5.00, N 29.78; found: C 42.32, H 4.99, N 29.83.

2,6-Diamino-9-(2-O-methyl-β-D-ribofuranosyl)purine (3) and 2,6-Diamino-9-(3-O-methyl-β-D-ribofuranosyl)purine (4)

To a stirred solution of 2.26 g (8 mmol) of **2** in 150 mL of hot DMF was added 324 mg (1.44 mmol) of $SnCl_2 \cdot 2H_2O$. The mixture was stirred at 50–55°C (to maintain solubility of **2**) and 120 mL of ~0.2 *M* CH_2N_2 in 1,2-dimethoxyethane was added dropwise over 3–4 h. The resulting yellow solution became cloudy, and stirring at 50°C was continued overnight. Complete disappearance of **2** with formation of two products was observed by tle. The mixture was evaporated, the residue dissolved in water, and the solution applied to a column (3 × 34 cm) of Dowex 1-X2 (OH^-). The column was washed with water and then **3** (1.21 g, 51%) was eluted with MeOH/H_2O (1:9). Elution with MeOH/H_2O (3:7) gave 1.11 g (47%) of **4**. These pure samples (recrystallized once each from MeOH) were recovered in a combined yield of 98% and had for **3**, mp 122–123°C; tle R_{Guo} = 0.68 (−); uv max: 280, 256, 216 nm (ε 11 000, 10 500, 26 500); ^{1}H nmr δ: 3.28 (s, 3, 2′-OCH_3), 3.58 (m, 2, H-5′,5″), 3.93 (m, 1, H-4′), 4.26 (m, 2, H-2′,3′), 5.14 (d, $J_{3'OH-3'}$ = 4.5 Hz, 1, 3′-OH), 5.43 (t, $J_{5'OH-5',5''}$ = 6 Hz, 1, 5′-OH), 5.71 (br s, 2, 2-NH_2), 5.83 (d, $J_{1'-2'}$ = 6 Hz, 1, H-1′), 6.74 (br s, 2, 6-NH_2), 7.92 (s, 1, H-8); ms *m/z*: 296.1239 (13%, M^+ = 296.1233), 207.0998 (29%, B + 58 = 207.0994), 150.0651 (100%, B + H = 150.0654). *Anal.* calcd. for $C_{11}H_{16}N_6O_4$: C 44.59, H 5.44, N 28.36; found: C 44.71, H 5.51, N 28.54.

Isomer **4** had mp 234–235°C; tle R_{Guo} = 0.50 (−); uv max: 280, 255, 216 nm (ε 10 500, 10 000, 25 600); ^{1}H nmr δ: 3.40 (s, 3, 3′-OCH_3), 3.57 (m, 2, H-5′,5″), 3.80 (m, $J_{4'-3'}$ = 3 Hz, $J_{4'-5',5''}$ ~ 4.5 Hz, 1, H-4′), 3.99 (m, $J_{3'-2'}$ = 6 Hz, 1, H-3′), 4.64 (m, $J_{2'-2'OH}$ = 6 Hz, $J_{2'-1'}$ = 6 Hz, 1, H-2′), 5.36 (d, 1, 2′-OH), 5.44 (dd, $J_{5'OH-5'}$ = 5,5 Hz, $J_{5'OH-5''}$ = 6.5 Hz, 1, 5′-OH), 5.69 (br s, 2, 2-NH_2), 5.69 (d, 1, H-1′), 6.74 (br s, 2, 6-NH_2), 7.89 (s, 1, H-8); ms *m/z*: 296.1244 (20%, M^+ = 296.1233), 193.0846 (13%, B + 44 = 193.0839), 150.0656 (100%, B + H = 150.0654). *Anal.* calcd. for $C_{11}H_{16}N_6O_4$: C 44.59, H 5.44, N 28.36; found: C 44.25, H 5.43, N 28.43.

Repetition of the above methylation of **2** using 216 mg (0.96 mmol) of $SnCl_2 \cdot 2H_2O$ gave 1.0 g (42%) of **3** and 1.33 g (56%) of **4**. A run using 108 mg (0.48 mmol) of $SnCl_2 \cdot 2H_2O$ gave 0.81 g (34%) of **3** and 1.52 g (64%) of **4**.

2′-O-Methylguanosine (5)

A mixture of 888 mg (3 mmol) of **3** dissolved in 30 mL of Me_2SO, 75 mL of 0.1 *M* aqueous sodium phosphate buffer (pH 7.4), and 20 mg of adenosine deaminase (Sigma Chemical Co., crude, type II) was stirred at ambient temperature for 3 days. Progress of the deamination reaction was monitored by tle. The solution was applied to a column (2.5 × 20 cm) of Dowex 1-X2 (OH^-) and the column was washed well with H_2O. Elution of **5** was effected using 0.03 *M* aqueous triethylammonium bicarbonate buffer (pH 7.5). Fractions containing **5** were pooled, evaporated, and the buffer salt volatilized by repeated addition and coevaporation of H_2O. The resulting solid was recrystallized from H_2O and then from MeOH to give 767 mg (86%) of **5**, mp 235–237°C (lit. mp (for **5**·MeOH) (5) 234–236°C, (9) 229–232°C); tle R_{Guo} = 0.25 (−); uv max: 253, 270 (sh) nm (ε 13 900, 9800); ^{1}H nmr data were in accord with literature values (5); ms *m/z*: 297.1078 (8.5%, M^+ = 297.1073), 208.0871 (20%, B + 58 = 208.0835), 151.0493 (100%, B + H = 151.0494). *Anal.* calcd. for $C_{11}H_{15}N_5O_5$: C 44.44, H 5.09, N 23.56; found: C 44.20, H 5.04, N 23.85.

3′-O-Methylguanosine (6)

A 888 mg (3 mmol) sample of **4** was treated identically to the above conversion of **3** → **5** to give 820 mg (92%) of recrystallized **6**, mp > 265°C (dec.) (lit. (5) mp > 258°C (dec.), (7) 263–300°C (dec.)); tle R_{Guo} = 0.18 (−); uv max 253, 270 (sh) nm (ε 14 000, 9900); ^{1}H nmr data were in accord with literature values (5); ms *m/z*: 297.1087 (5.5%, M^+ = 297.1073), 194.0677 (5.4%, B + 44 = 194.0678), 151.0496 (100%, B + H = 151.0494). *Anal.* calcd. for $C_{11}H_{15}N_5O_5$: C 44.44, H 5.09, N 23.56; found: C 44.21, H 5.04, N 23.85.

The synthesis of 2,3,5,6-*endo,endo,endo,endo*-tetrakis-substituted bicyclo[2.2.1]heptanes

DOUGLAS N. BUTLER AND TIMOTHY J. MUNSHAW
Chemistry Department, York University, Downsview, Ont., Canada M3J 1P3

Received June 22, 1981

DOUGLAS N. BUTLER and TIMOTHY J. MUNSHAW. Can. J. Chem. **59**, 3365 (1981).

Oxidation of the readily available diketone **2** affords high yields of the symmetrical dilactone **5**, from which the *all-endo*-tetrakis(hydroxymethyl)norbornane **10** can be made. A related tetrol **22** is also described. These tetrols are dehydrated to polycyclic di-ethers **12**, **13**, and **23** which constrain their oxygen atoms in rigid proximity within their structures.

DOUGLAS N. BUTLER et TIMOTHY J. MUNSHAW. Can. J. Chem. **59**, 3365 (1981).

L'oxydation de dicétone **2**, que l'on peut obtenir facilement conduit avec d'excellents rendements à la dilactone symétrique **5** à partir de laquelle on peut préparer le tétrakis (hydroxyméthyl) norbonanes (**10**) complètement *endo*. On décrit également le tétrol apparenté (**22**). La déshydratation de tétrols conduit aux diéthers polycycliques **12**, **13** et **23** dans lesquels les atomes d'oxygène sont maintenus dans un voisinage rigide à l'intérieur de leurs structures.

The anticipated congestion of the *endo* face requires that any scheme directed toward the preparation of a 2,3,5,6-*all-endo*-tetrasubstituted norbornane must mark the prevention of epimerization of one (or more) of the substituents of any of the intermediates of the synthesis into the more stable *exo* stereochemistry. The caveat is successfully countered by using the readily available photo-cage **1** (1) from the cyclopentadiene/benzoquinone Diels–Alder adduct as the starting point of the synthesis only if the necessary carbon–carbon disconnections within **1** can be effected by processes which exclude any possibility of such an isomerization, preferably intramolecular events which maintain the *all-endo* stereochemistries until nonepimerizable functionalities are in place.

A 2,3,5,6-tetrakis(hydroxymethyl) derivative of norbornane has been described (2), the origins of which suggest 2,3-*endo,endo*-5,6-*exo,exo* as the likely stereochemistry. The objective of this work was to prepare the *all-endo* isomer in order to study the chemical and physical consequences of the congestion imposed on the functionalities by this geometry. The dissolving-metal reduction (3) of the cage dione **1** required refluxing conditions (4) in our hands in order to produce **2**. Curiously, very little chemistry has been described for this diketone, although it is easily prepared and ideal for the purpose at hand. Initially, we envisioned functionalizing the two methylene carbons α to the carbonyls as a logical strategy; however, selenium dioxide oxidation to the anticipated tetraketone **3** failed. A stereospecific bromination proceeded very efficiently to give a dibromide to which we ascribe the structure **4** from steric and spectroscopic rationalizations. The acetate and hydroxide anionic nucleophiles did not change **4** under the conditions tried and a stronger base (methoxide) slowly produce a rearranged monobromoketo-ester of unknown structure (presumably via a Favorskii mechanism).

Although unreactive to *m*-chloroperbenzoic acid, **2** reacted cleanly with trifluoroperacetic acid at room temperature to produce a mixture of dilactones. Fortunately, this mixture was predominantly one isomer (> 95%) whose structure was unambiguously assigned as **5** from spectroscopic evidence. The other symmetrical dilactone **6** was isolated from the mother liquors in low yield. The major dilactone **5**, whilst only slightly soluble in cold water, can be easily recrystallized from hot water. Remarkably, it is freely soluble in cold dilute aqueous alkali to give solutions which show different ^{1}H and ^{13}C nmr signals from those of hot aqueous solutions of **5**. Since acidification reprecipitates the dilactone immediately, we propose **7** as the alkaline hydrolysis product and we are currently studying the kinetics of this most facile hydrolysis.

The success of the Baeyer–Villiger reaction on **2** led us to attempt similar oxidations of **1** and **4**. The cage diketone **1** gave a mixture of dilactones, again with one symmetrical isomer predominating and for which we favour structure **8** over **9** (5).

Once again an extremely rapid hydrolysis is observed for this compound. We could not find any literature precedent for the peracid oxidation of an α-bromoketone; however, in the event, we did not observe any reaction of **4** with trifluoroperacetic acid either at room temperature or at reflux in methylene chloride.

The excellent overall yields of dilactones **5** and **8** from such readily available precursors render these compounds highly accessible synthons for *all-*

endo-2,3,5,6-tetrasubstituted bicyclo[2.2.1]heptanes (see also ref. 5). It might also be noted that more than 20 photo-cage isomers of various diene/quinone adducts are reported in the literature (1, 6) although apparently only two of these have been reduced to their dihydro derivatives (3, 4). Thus, a considerable scope of synthetic utility is predictable for this sequence.

The reduction by lithium aluminum hydride of the dilactone **5** and the isolation of the *all-endo* tetrol **10** presented several difficulties. Partial reduction readily occurred but complete reduction was slow, requiring 48 h at reflux in 1,2-dimethoxyethane. The course of the reduction was followed by hydrolysing aliquots of the reaction mixture, acetylating, and subjecting these to gas chromatographic/mass spectrometric (gc–ms) analysis. The isolation of the tetrol from the hydrolysed reaction mixture was complicated by the presence of aluminium salts in the aqueous extracts; however, with care, a 63% yield of the tetrol **10** was realized. The protons on the oxygen-bearing carbons showed temperature variable line shapes arising from restricted rotation and/or hydrogen bonding; however, the four line ^{13}C nmr spectrum confirmed the molecular symmetry and ruled out any possible epimerization during reaction.

Whilst from **10** the tetra(trimethylsilyl) ether and the tetra-acetate formed readily, thionyl chloride produced an ether dichloride, **11***a*, as the major product along with minor amounts of both the diethers **12** and **13** and an elimination product **14**

(*vide infra*). The identity of **11***a* as a six-ring ether was established by its seven line ^{13}C nmr spectrum. Both diethers **12** and **13** can also be formed from **10**, either by heating in dimethyl sulfoxide (7) or by treatment with carbon tetrachloride/triphenyl phosphine (8). The identity of **12** and **13** as the bis-five- and bis-six-ring ethers respectively was inferred from consideration of the shapes of the A_2B_2 patterns of the methylene hydrogens attached to the oxygen-bearing carbon atoms. Thus in all the compounds having a six-ring ether partial structure (e.g. **11***a*, **11***b*, **13**, **18**, and **20***b*) this A_2B_2 was a clean first-order pattern with $J_{AB} \approx 12$ Hz, whereas in the five-ring ether examples (e.g. **12** and **17**) the corresponding pattern was more complex (see Fig. 1). Inspection of molecular models supports this assignment in terms of the dihedral angles of the vicinal protons involved. These isomers have only been isolated by preparative gas chromatography. An attempt at tetratosylate formation resulted likewise in the formation of an ether ditosylate **11***b*.

Several base-promoted eliminations were carried out on **11***a* and **11***b*. Thus heating **11***a* with potassium *tert*-butoxide in dimethyl sulfoxide produced a complex mixture of products which was separated by preparative gas chromatography into the known tetraene **15** (2), a methylated tetraene **16** (presumably by methylene transfer[1] from dimsyl anion), and the two ether dienes **17** and **18**. These two dienes were also formed from the ether ditosylate **11***b* using the same elimination reagent (9). Again these diene structural assignments followed from the seven line ^{13}C nmr spectrum of the major elimination product (from both precursors) namely **18**.

The identity of the minor elimination product **14** mentioned above, arising from the treatment of the tetrol **10** with thionyl chloride, was secured when it was found that it was converted by KO^{t}Bu/DMSO into the two dienes **17** and **18** in about the same ratio (8:2) as in the double elimination of **11***a* under the same conditions. Thus **14** is the logical precursor to both dienes with the new allylic hydrogen being abstracted by the base to initiate the elimination-rearrangement to provide **17** as shown on structure **14**.

In an attempt to prepare the *all-endo*-tetramethyl hydrocarbon **19**, the dichloride **11***a* was slowly reduced by lithium aluminium hydride in hot monoglyme to the dimethyl ether **20***b* via the monochloride **20***a*. A variety of reagents including trimethylsilyl iodide (10) were tried in an effort to cleave the ether of **20***b* but they all were ineffective under normal conditions or destroyed the compound under forcing conditions. Other routes to **19** are currently being studied.

A second series of *all-endo*-tetrasubstituted bi-

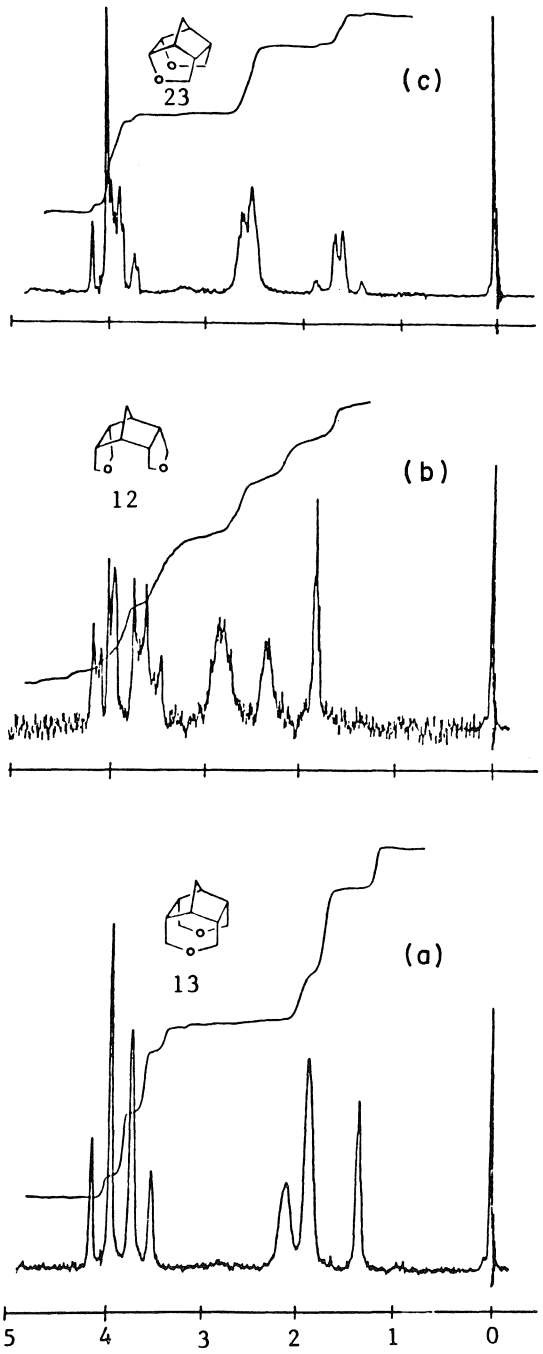

FIG. 1. The 60 MHz ^1H nmr spectra of (a) **13**, (b) **12**, and (c) **23** in $CDCl_3$.

[1]From the ^1H nmr data we assign the structure of **16** as shown. We have observed similar methylations in bis-tosylate eliminations using KO^{t}Bu in DMSO.

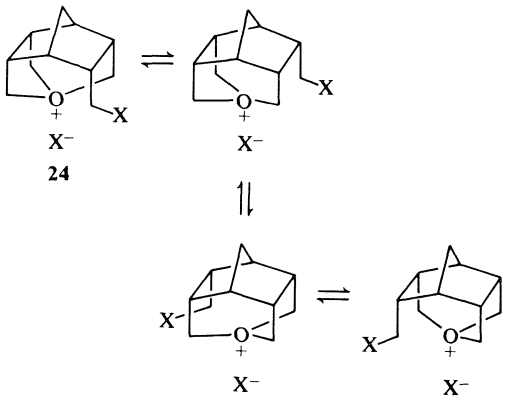
cyclo[2.2.1]heptanes was prepared from the known dilactone **21**. Several synthetic methods for this dilactone are reported (11); however, in our hands none of these gave reliable yields of large quantities and we have modified one of these procedures (**11***b*) (see Experimental).

Reduction of **21** with lithium aluminium hydride afforded good yields of the tetrol **22** which formed a tetra-acetate and a tetra(trimethylsilyl) derivative and which was dehydrated by heating in dimethyl sulfoxide (7) or by thionyl chloride into the di-ether **23** (see Fig. 1).

The special spatial characteristics of the two oxygen atoms in each of the three di-ethers **12**, **13**, and **23** provoke questions relating to their ability to complex electrophilic species e.g. H^+, CH_3^+, or metal ions. Of the three, **23** is the most rigid with the two oxygen atoms about 2.3 Å apart (from Drieding models). From the models, **12** appears to be the most sterically congested and because it is formed in minor amount and has only been purified by preparative gas chromatography it has not yet been further studied. Both **13** and **23** appear to be protonated in 6 *M* sulfuric acid as judged by the appearance of their respective ^1H nmr spectra as the acidity was increased by dropwise addition of sulfuric acid to D_2O solutions or, in reverse, as D_2O was added to concentrated sulfuric acid solutions of these two di-ethers. Thus **13** and **23** appear to be more basic than even tetrahydrofuran (12) and it is tempting to propose a shared proton between both ether oxygens somewhat reminiscent of "proton sponge" (13). Further studies are underway relating to the ability of these di-ethers to complex electrophiles and to nonbonding electron interactions as revealed by photo-electron spectroscopy. Interestingly, all three di-ethers are soluble in water and organic solvents and bind strongly to silica as compared to comparable mono-ethers.

Finally there remains the intriguing possibility of positional scrambling within the oxonium salt **24** derived from the ether dichloride **11***a* as shown in Scheme 1. Early results are inconclusive and we are continuing a study of this possibility.



SCHEME 1

Experimental

All melting points are uncorrected. The ir spectra were taken on a Unicam SP1000 instrument as liquid films or Nujol mulls. The ^1H nmr and ^{13}C nmr spectra were recorded on Varian EM360 and CFT20 instruments respectively. The uv spectra were recorded on a Unicam SP800A spectrophotometer. Mass spectra were taken at 70 eV using a Hitachi–Perkin–Elmer RMU-6E mass spectrometer. Both the analytical and the preparative gas chromatography were carried out on a Varian Aerograph Series 1700 instrument on a 6 ft. × 1/4 in. od glass column packed with 2.5% SE30 + 3.5% QF1 on Chromosorb W (acid washed), 60–80 mesh (HMDS treated).

Tetracyclo[6.3.0.0^{4,11}.0^{5,9}]undeca-2,7-dione **2**

The photo-dione **1** (1) (20 g) was dissolved in glacial acetic acid (1 L) in a 2-*L* three-necked flask equipped with an overhead stirrer, reflux condenser, and stopper. Freshly activated zinc dust (50 g) (prepared by suspending the zinc in aqueous 2% hydrochloric acid for 1 min, filtering, washing under nitrogen with degassed, distilled water until neutral, washing with ethanol and ether, and drying under vacuum) was then added with stirring and the mixture brought to and then held at reflux for 5 h. The zinc was then removed by filtration on the water pump, washed with methylene chloride (2 × 50 mL), and the bulk of the solvents removed on a rotary evaporator at water-pump pressure. The residue was mixed with an equal volume of water and extracted with methylene chloride (4 × 100 mL). The combined organic phase was washed with dilute (10%) aqueous sodium hydroxide solution until the water phase remained alkaline and then the organic phase was separated, dried (Na_2SO_4), and filtered through a 2.5 cm filter containing a 5 cm column of silica. Evaporation of the solvent left light-brown crystals which were sublimed under vacuum to afford **2** (16 g; 80%), mp 255–257°C; ir: 1725, 1755 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.92 (s, 2H), 2.26 (s, 4H), 2.7–2.8 (s + sh, 6H); ^{13}C nmr ($CDCl_3$) δ: 34.2 (t, J = 133.6 Hz), 38.2 (d, J = 141.6 Hz), 39.7 (t, J = 133.6 Hz), 47.4 (d, J = 149.3 Hz), 58.0 (d, J = 154.0 Hz), and 217.3 (s); mass spectrum: m/e = 176 (M^+).

Dibromide **4**

The diketone **2** (9.0 g) was dissolved in methylene chloride (100 mL) in a flask equipped for magnetic stirring and reflux. A 15% solution of bromine in carbon tetrachloride (100 mL) was added slowly with stirring through the open end of the reflux condenser together with 5 drops of concentrated aqueous hydrobromic acid (48%). The mixture evolved HBr gas with vigorous refluxing over a 1/2 h period, then it was transferred to a rotary evaporator and the solvent and excess bromine removed to leave the crude product. This was recrystallized from chloroform to yield the pure dibromide **4** (14 g; 85%) as a fine white solid, mp 217–218°C; ir: 1730, 1760 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.05 (s, 2H), 3.03 (s, 4H), 3.45 (s, 2H), and 4.36 (s, 2H); ^{13}C nmr ($CDCl_3$) δ: 34.0 (t, J = 134.3 Hz), 46.2 (d, J = 150.1 Hz), 47.1 (d, J = 158.0 Hz), 50.4 (d, J = 150.1 Hz), 57.9 (d, J = 142.2 Hz), and 200.8 (s); mass spectrum: m/e = 332, 334, 336 (M^+).

*5,6-*endo,endo-*Bis(hydroxymethyl)bicyclo[2.2.1]heptane-2,3-*endo,endo-*dicarboxylic Acid Dilactone* **5**

To the diketone **2** (7 g) dissolved in methylene chloride (200 mL) was added with stirring a solution of trifluoroperacetic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

acid (prepared by adding trifluoroacetic anhydride (13 mL) to a well-stirred, ice-cold mixture of 90% H_2O_2 and methylene chloride (50 mL) – *careful: vigorous reaction with foaming*) and the mixture allowed to stand overnight. The pale yellow oil remaining after the solvent had been removed (under vacuum) was rubbed with pentane (200 mL) with cooling in an ice-bath until the crop of light-brown granular crystals had formed. The pentane was decanted, carbon tetrachloride (150 mL) was then added followed by absolute ethanol (5 mL) to give the product as a white precipitate. After thorough chilling this was filtered off, washed with cold carbon tetrachloride, dried, and recrystallized from methanol/acetone (1:1) to afford fine crystals of the pure dilactone **5** (6 g; 75%) mp > 350°C; ir: 1730 cm^{-1}; ^1H nmr (hot $CDCl_3$) δ: 1.8 (AB pattern, 2H), 2.5 (bd s, 2H), 2.8 (bd s, 2H), 3.2 (bd s, 2H), and 4.6 (bd s, 4H); ^{13}C nmr (hot D_2O (70°C) referenced to sodium 2,2-dimethyl-2-silapentane-5-sulfonate = −1.1 ppm) δ: 34.8, 39.4, 40.5, 46.4, 71.7, C=O not observed; mass spectrum: *m/e* = 208 (M^+). *Anal.* calcd. for $C_{11}H_{12}O_4$: C 63.45, H 5.81%; found: C 63.61, H 5.78%.

The filtrates from three of the above preparations were combined and evaporated to give a thick amber oil (5 g) which was fractionally crystallized using methanol/methylene chloride. After the separation of several small crops of impure **5**, the filtrates were evaporated to a white solid (0.2 g, mp 287–295°C) which (by its ^1H nmr spectrum) was mainly the isomeric dilactone **6** still contaminated with **5**. A pure sample of **6** was not obtained; ir: 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.8 (AB pattern, 2H), 2.3 (s, 2H), 2.75 (bd s, 2H), 2.9 (s, 4H), and 4.53 (s, 2H).

2,3,5,6-endo,endo,endo,endo-*Tetrakis(hydroxymethyl)-bicyclo[2.2.1]heptane* ***10***

The finely ground dilactone **5** (10 g) was suspended in dry monoglyme (100 mL) and added slowly to lithium aluminium hydride (8 g) in ice-cold monoglyme (150 mL) with stirring. This mixture was subjected to reflux for 48 h under anhydrous conditions. After cooling in ice, the reaction mixture was quenched by the careful addition of aqueous 2 *N* sodium hydroxide solution (100 mL) and the resultant slurry washed by decantation with hot methanol (4 × 100 mL) with vigorous stirring during each of the wash steps. The combined aqueous and methanol extracts were evaporated to dryness under vacuum, the resulting solid dissolved in a minimum of hot methanol, and dry ether added until the solution became cloudy with a fine precipitate of alumina. Solid Dry Ice (20 g) was added, allowed to evaporate, and the resulting slurry filtered (or centrifuged) to remove the inorganic material. Evaporation of the filtrate to dryness left a gummy solid upon which the above treatment was repeated several times until the evaporated extracts became a clear amber-coloured syrup. This was dissolved again in a minimum volume of hot methanol and dry ether added until a faint cloudiness appeared. This mixture was then set aside in a refrigerator until the product crystallized. Three repetitions of this recrystallization afforded **10** (6.5 g; 63%) as small colorless plates, mp 127.5–128.5°C; ir (Nujol mull): 2600–3500, 1090, 1005 cm^{-1}; ^1H nmr (D_2O referenced to HOD = 4.72 ppm) δ: 1.45 (s, 2H), 2.30–2.38 (s, sh, 6H), and 3.30–3.95 (m, 8H); ^{13}C nmr (D_2O internally referenced to dioxane = 67.4 ppm) δ: 42.2 (t, J = 118.7 Hz), 44.3 (d, J = 116.6 Hz), 44.7 (d, J = 111.3 Hz), and 67.40 (t, J = 111.3 Hz). *Anal.* calcd. for $C_{11}H_{20}O_4$: C 61.09, H 9.32%; found: C 60.85, H 9.18%.

Tetra-acetate: colorless plates from dry ether, mp 96–97°C. Tetrakis(trimethylsilyl)ether: white solid, mp 123–125°C; mass spectrum: *m/e* = 504 (M^+).

6,10-endo,endo-*Bis(chloromethyl)-3-oxatricyclo[5.2.1.0^{5,9}]-decane* ***11***a

The tetrol **10** (2 g) was added portionwise to thionyl chloride (40 mL) and this mixture subjected to reflux under anhydrous conditions for 6 h. The excess thionyl chloride was then removed under vacuum to afford an orange syrup, gc–ms analysis of which revealed it to be a mixture of **14** (13.5%), **12** (9%), **13** (12%), and **11***a* (65.5%) which separated by vacuum distillation into a forerun boiling up to 84°C/0.02 Torr and the main fraction bp 84–95°C/0.02 Torr. Sufficient of the forerun was separated by preparative gas chromatography to allow spectroscopic characterization of the three minor components **14**, **13**, and **12** (in order of elution); **14**, an amber liquid, ir(film): 3040, 2900, 1660, 1460, 1270, 1150, 1095, 1040, 880, and 730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.52 (s, 2H), 1.90 (s, 1H), 2.3 (m, 3H), 2.95 (s, 1H), 3.2–4.1 (overlapping multiplets, 6H), 4.91 (s, 1H), and 5.08 (narrow m, 1H); mass spectrum: *m/e* = 198, 200 (M^+). For **13** and **12**, see details below. The main fraction solidified on cooling and scratching and was recrystallized from pentane to give **11***a* (1.2 g; 55%) as clear plates, mp 44–45°C; ir (Nujol mull): 1300, 1270, 1140 med shp, 1090, 1080, 1015 str br; ^1H nmr ($CDCl_3$) δ: 1.42 (s, 2H), 1.88 (bd s, 1H), 2.32 (bd s, 2H), 2.54 (bd s, 2H), and 3.2–4.25 (overlapping multiplets, 8H); ^{13}C nmr ($CDCl_3$) δ: 34.1 (d, J = 139.7 Hz), 39.6 (t, J = 127.0 Hz), 41.0 (d, J = 133.5 Hz), 44.4 (t, J = 152.4 Hz), 45.6 (d, J = 140.0 Hz), 46.3 (d, J = 133.5 Hz), and 65.7 (t, J = 133.0 Hz); mass spectrum: *m/e* = 234, 236, 238 (M^+).

endo, endo-*3,8-Dioxatetracyclo[8.3.0.0^{5,13}.0^{6,11}]tridecane* ***13*** *and* endo, endo-*4,10-Dioxatetracyclo[5.5.1.0^{2,6}.0^{8,12}]-tridecane* ***12***

DMSO Method

The tetrol **10** (0.50 g) was heated in dimethyl sulfoxide (4 mL) at 170°C for 15 h under a reflux condenser fitted with a drying tube. The bulk of the solvent was removed from the black reaction mixture under vacuum (0.02 Torr) to leave a black residue which was shown by gas chromatography to be a mixture of the two di-ethers **13** and **12** in a 82:18 ratio. Passage of this dark mixture in ether through a short silica column allowed the black impurities to pass through whilst retaining the two di-ethers. These in turn were eluted with methanol and were obtained by evaporation under vacuum as a gummy residue (0.36 g; 86%). Sufficient of this mixture was subjected to preparative gas chromatography to allow spectroscopic characterization. Compound **13**, mp 120–135°C; ir(Nujol mull): 1165, 1080, and 1003 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.41 (s, 2H), 1.90 (bd s, 4H), 2.19 (bd s, 2H), 3.65 (d, J = 12 Hz), and 4.00 (d, J = 12 Hz) (see Fig. 1); ^{13}C nmr ($CDCl_3$) δ: 36.4 (d, J = 131.7 Hz), 37.6 (t, J = 131.7 Hz), 41.9 (d, J = 137.5 Hz), and 63.5 (t, J = 143.8 Hz); mass spectrum: *m/e* = 180 (M^+), 79 (base peak). Compound **12**, mp 135–138°C; ir (Nujol mull): 1083, 1010, and 955 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.80 (s, 2H), 2.32 (bd s, 2H), 3.62 (m, 4H), and 4.07 (m, 4H) (see Fig. 1); ^{13}C nmr ($CDCl_3$) δ: 43.6, 48.0, 51.1, and 67.6; mass spectrum: *m/e* = 180 (M^+), 79 (base peak).

Triphenylphosphine/Carbon Tetrachloride Method

The tetrol **10** (0.2 g) and triphenylphosphine (0.5 g) were dissolved in carbon tetrachloride (30 mL) and dry tetrahydrofuran (5 mL) and this mixture subjected to reflux under anhydrous conditions for 24 h. The solvents were evaporated off under vacuum and the residue extracted with pentane (200 mL). The precipitated triphenylphosphine oxide was filtered off and the filtrate evaporated to a clear oil which was shown by gas chromatographic analysis to be a 3:2 mixture of **13** and **12**.

6,10-endo, endo-*Bis(hydroxymethyl)-3-oxatricyclo[5.2.1.0^{5,9}]-decane Di*-p-*toluene Sulfonate* ***11***b

The tetrol **10** (0.25 g) and *p*-toluene sulfonyl chloride (0.9 g) were taken up in pyridine (10 mL) and kept for 5 days in the refrigerator. Water (70 mL) was then added and the mixture stirred magnetically for 3 h after which time it was extracted with methylene chloride (3 × 25 mL). The combined organic

For personal use only.

phases were back-extracted with 1 *N* aqueous hydrochloric acid until the aqueous phase remained acid, dried, and evaporated under vacuum to a gummy residue which was taken up in a minimum volume of warm methanol and water added until just cloudy. This was set aside in the refrigerator until the product precipitated. The collected solid was recrystallized from methanol to give **11***b* (0.34 g; 54%), mp 121–123°C; ir (Nujol mull): 1180, 1100, 950, and 840 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.45 (s, 2H), 1.8–2.0 (m, 4H), 2.45 (s, 6H), 3.35 (A_2 of A_2B_2 pattern, 2H), 3.80 (B_2 of A_2B_2 pattern, 2H), 4.31 (m, 4H), 7.4 (d, 4H), and 7.8 (d, 4H).

Elimination Reactions

*From Ether Dichloride 11*a

The dichloride **11***a* (0.53 g) was dissolved in DMSO (10 mL) and freshly prepared potassium *tert*-butoxide (1.1 g) was added. This mixture was heated to reflux for 5 min, cooled, water (5 mL) added, and extracted with pentane (3 × 5 mL). Analysis of this extract revealed the presence of four products and these were individually collected by preparative gas chromatography with the column temperature set at 150°C. In order of elution these were **15** (2) (6%); ^1H nmr ($CDCl_3$) δ: 1.65 (s, 2H), 3.40 (s, 2H), 4.95 (s, 4H) and 5.21 (s, 4H); mass spectrum: *m/e* = 144 (M^+); **16** (9%); uv (hexane): λ_{max} 246, sh 261 nm; ^1H nmr ($CDCl_3$) δ: 1.70 (s, 2H), 1.87 (d, *J* = 8 Hz, 3H), 3.49 (bd s, 1H), 4.72 (bd s, 1H), 5.0 (m, 4H), 5.2 (d, *J* = 1.6 Hz, 2H), and 5.81 (q, *J* = 8 Hz, 1H); mass spectrum: *m/e* = 158; **18**, clear liquid (63%); uv (hexane): λ_{max} = 244 nm; ir (film): 3090, 2860, 1720, 1660, 1160, and 1090 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.55 (s, 2H), 2.14 (s, 3H), 3.25 (s, 1H), 3.60 (A_2 of A_2B_2 pattern, 2H), 4.00 (B_2 of A_2B_2 pattern, 2H), 4.87 (s, 2H), and 5.08 (d, *J* = 2 Hz, 2H); ^{13}C nmr ($CDCl_3$) δ: 39.1, 39.9, 40.5, 56.0, 68.3, 103.4, and 156.4; and **17**, clear liquid (22%); uv (hexane): λ_{max} = 251 nm; ir (film): 3020, 2900, 1625, 1075, 1020, 980, and 860 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.60 (s, 2H), 2.78 (bd s, 4H), 3.45 (A_2 of A_2B_2 pattern, 2H), 3.70 (B_2 of A_2B_2 pattern, 2H), 4.79 (s, 2H), and 5.30 (s, 2H).

*From Ether Ditosylate 11*b

The ether ditosylate **11***b* (0.124 g) was dissolved in DMSO (5 mL) and potassium *tert*-butoxide (0.5 g) added; the mixture was stirred at room temperature for 24 h, then added to water (40 mL) and extracted with pentane (3 × 10 mL). The pentane extract was dried and evaporated to a low volume (≈ 0.25 mL) and this was separated by preparative gas chromatography at 150°C into **13** (14.6 mg; 36.6%) and **12** (9.7 mg; 24.3%).

6,10-endo, endo-*Dimethyl-3-oxatricyclo[5.2.1.0^{5,9}]decane* ***20***b

A solution of the dichloride **11***a* (0.20 g) in dry monoglyme (3 mL) was added to lithium aluminium hydride (0.1 g) in the same solvent (10 mL) and this mixture stirred under reflux for 72 h. The reduction was monitored by hydrolysing small aliquots approximately every 12 h, extracting with a small volume of pentane, and analysing this using gc–ms. The sequence **11***a* → **20***a* → **20***b* was readily followed and when complete the reaction was worked up by the addition of aqueous 2 *N* sodium hydroxide (0.5 mL) and the white suspension extracted with pentane (3 × 10 mL). The combined extracts were passed through a short Florisil column and eluted with ether. Evaporation under vacuum afforded **20***b* as a white solid, mp 38–40°C (0.088 g; 62%); ir (film): 2900, 1450, 1370, 1260, 1230, 1165, 1090, 1035, 1000, 970, 900, 840, and 720 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.18 (s, 2H), 1.20 (s, 6H), 1.62 (s, 1H), 1.8–2.2 (m, 5H), 3.48 (A_2 of A_2B_2 pattern, 2H), and 3.90 (B_2 of A_2B_2 pattern, 2H); ^{13}C nmr ($CDCl_3$) δ: 13.6, 35.4, 37.8, 40.3, 41.0, 49.0, and 66.4.

endo,endo-*5,6-Dihydroxybicyclo[2.2.1]heptane*-endo,endo-*2,3-dicarboxylic Acid Dilactone* ***21*** *(12)*

exo,exo-5,6-Dibromobicyclo[2.2.1]heptane-*endo,endo*-2,3-dicarboxylic anhydride (40 g) (14) was added to a solution of sodium carbonate decahydrate (36 g) in water (350 mL) and this mixture was subjected to reflux for 3 h during which time the pH was maintained at approximately 10 by the addition of more sodium carbonate (if required). This clear solution was acidified with aqueous 2 *N* hydrochloric acid to pH 2 and then evaporated under vacuum to dryness to leave a white solid which was gently heated at 0.02 Torr with a free flame until dehydration was complete. The white residue was freed from inorganic salts by washing with cold water (50 mL) on the filter pump, resuspended in cold ethanol (50 mL), filtered, and washed with cold dry ether to leave the pure dilactone **21** (20.5 g; 92%), mp 266–268°C; ^1H nmr ($CDCl_3$–$C_6H_5NO_2$ 4:1) δ: 2.05 (s, 2H), 3.15 (s, 2H), 3.50 (s, 2H), and 4.86 (s, 2H); mass spectrum: *m/e* = 180 (M^+).

endo,endo-*2,3-Bis(hydroxymethyl)*-endo,endo-*5,6-dihydroxybicyclo[2.2.1]heptane* ***22***

The dilactone **21** (19.4 g) suspended in dry monoglyme (80 mL) was slowly added to excess lithium aluminium hydride (16 g) with stirring and this mixture refluxed for 72 h under anhydrous conditions. After cooling in an ice-bath, aqueous 2 *N* sodium hydroxide (50 mL) was carefully added with vigorous stirring and the whole reaction mixture diluted to a total volume of 1.5 L with methanol and then centrifuged in 4 × 375 mL portions. The combined supernatant liquid was evaporated to a white slurry under vacuum, dissolved in a minimum volume of hot methanol, and ether added until cloudy. Then solid Dry Ice (5 g) was added and the mixture recentrifuged. This process was repeated until the supernatant liquid evaporated to a clear viscous liquid (≈ 8 times), which was subjected to vacuum (0.02 Torr) at 80°C for 2 h to remove any water as this interfered with crystallization. The clear residue was taken up in a minimum of hot methanol, dry ether added until just cloudy, and stored in the refrigerator for 16 h. The product crystallized as small prisms and was collected by filtration. Further dilution of the mother liquors with dry ether produced two further crops, total yield 17.4 g. This was recrystallized using methanol/dry ether to give the pure tetrol **22** (14.4 g; 71%), mp 209–212°C; ir (Nujol mull): 3310, 3140, 1150, 1115, 1090, 1020, and 990 cm^{-1}; ^1H nmr (D_2O referenced to HOD = 4.72 ppm) δ: 1.35 (s, 2H), 2.45–2.55 (s + sh, 4H), and 4.15 (m, 6H); ^{13}C nmr (D_2O referenced to internal dioxane = 67.4 ppm) δ: 32.9 (t, *J* = 136.7 Hz), 43.4 (d, *J* = 126.0 Hz), 46.2 (d, *J* = 149.9 Hz), 62.0 (t, *J* = 143.9 Hz), and 70.8 (d, *J* = 145.2); mass spectrum: *m/e* = 188 (M^+).

Tetra-acetate, mp 85–86°C (dry ether).

2,6-Dioxatetracyclo[6.3.0.0^{1,10}.0^{7,8}]undecane ***23***

DMSO Method

The tetrol **22** (0.90 g) was heated in DMSO (10 mL) at 150°C for 15 h under anhydrous conditions. The bulk of the solvent was then removed from the black reaction mixture by vacuum (0.02 Torr) transfer and the residue directly subjected to preparative gas chromatography at 170°C. The product so collected was sublimed at 115°C and 20 Torr to give the diether **23** (0.23 g; 32%), mp 120–125°C; ir (film): 1350, 1290, 1240, 1070, 1010, 900 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.55 (AB q, *J* = 13 Hz, 2H), 2.45–2.60 (2 bd s, 4H), 3.80 (A_2 of A_2B_2 pattern, 2H), 3.98 (s, 2H), and 4.01 (B_2 of A_2B_2 pattern, 2H); ^{13}C nmr ($CDCl_3$) δ: 24.6 (t, *J* = 132.5 Hz), 41.2 (d, *J* = 145.1 Hz), 44.9 (d, *J* = 145.2 Hz), 69.1 (t, *J* = 145.0 Hz), and 77.9 (d, *J* = 151.4 Hz); mass spectrum: *m/e* = 152 (M^+).

Thionyl Chloride Method

The tetrol **22** (0.25 g) was heated to reflux for 2 h with thionyl chloride (5 mL) and the mixture evaporated under vacuum to an orange gum. This was dissolved in dry ether and applied to a silica column (0.5 × 8 cm) packed in ether. After eluting with ether to remove any by-products, the column was washed with methanol and this eluate evaporated to leave behind the crude

product which was purified by sublimation as before to give clear, granular crystals of the di-ether **23** (0.082 g; 41%), mp 120–123°C.

Dilactone 8 (or 9) from Photo-dione 1

The photo-dione **1** (1) (5 g) was dissolved in methylene chloride (50 mL) and trifluoroperacetic acid, prepared by carefully adding trifluoroacetic anhydride (8.5 mL) to 90% hydrogen peroxide (1.4 mL) in methylene chloride (25 mL), was added and the mixture kept at room temperature for 15 h. This was reduced to a volume of 5 mL under vacuum and the clear amber oil so obtained taken up in carbon tetrachloride (100 mL) and then absolute ethanol (20 mL) was added with shaking and ice-cooling. The fine, white precipitate was collected and washed with dry ether to leave the crude product (4.7 g; 79%) which was recrystallized from methylene chloride to give **8** (or **9**) as needles, mp 250–255°C; ir (Nujol mull): 1755, 1725, 1250, 1180, 1080, 945, and 850 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.8 (s, 2H), 2.95 (bd s, 4H), 3.30 (s, 2H), and 5.20 (m, 2H); ^{13}C nmr ($CDCl_3$) δ: 36.2 (d, J = 157.1 Hz), 39.4 (t, J = 135.1 Hz), 39.7 (d, J = 144.5 Hz), 45.1 (d, J = 150.8 Hz), 73.9 (d, J = 163.4 Hz), and 169.7 (s); mass spectrum: m/e = 206 (M^+).

A. Bruce McKague, Steven J. Rettig, James Trotter, and George R. Douglas. Can. J. Chem. **59**, 3372 (1981).

Several compounds suspected to be mutagenic have been isolated by large scale fractionation of chlorination-stage effluent from a bleached kraft pulp mill. When reacted with diazomethane, one of these compounds yields a crystalline material, **1**. Crystals of **1** are triclinic, $a = 7.8814(7)$, $b = 8.3988(8)$, $c = 10.309(1)$ Å, $\alpha = 71.529(8)$, $\beta = 80.002(7)$, $\gamma = 62.587(9)°$, $Z = 2$, space group $P\bar{1}$. The structure was solved by Patterson and Fourier techniques and was refined by full-matrix least-squares procedures to $R = 0.030$ and $R_w = 0.036$ for 1795 reflections with $I \geq 3\sigma(I)$. The structure analysis has unambiguously identified compound **1** as 1,6-dioxa-4,4,10-trichlorodispiro[2.1.4.3]dodec-10-en-12-one, implying that the material originally present was 1-oxa-6,10,10-trichlorospiro[4.5]dec-6-en-8,9-dione.

A. Bruce McKague, Steven J. Rettig, James Trotter et George R. Douglas. Can. J. Chem. **59**, 3372 (1981).

Certains composés mutagéniques ont été isolés par fractionnement à grande echelle des effluents de l'étage de chloruration d'une usine de blanchiment de pâte à papier (bleached Kraft). Par réaction avec le diazomethane, l'un de ces composés donne un produit cristallin **1**. Les cristaux de **1** sont tricliniques, $a = 7.8814(7)$, $b = 8.3988(8)$, $c = 10.309(1)$ Å, $\alpha = 71.529(8)$, $\beta = 80.002(7)$, $\gamma = 62.587(9)°$, $Z = 2$, group d'espace $P\bar{1}$. On a déterminé la structure par les méthodes de Patterson et de Fourier et on l'a précisée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0.030$ et $R_w = 0.036$ pour 1795 réflexions avec $I \geq 3\sigma(I)$. Cette analyse nous a permis d'identifier sans l'ambiguité le composé 1 comme étant dioxa-1,6 trichlor-4,4,10 dispiro [2.1.4.3]dodec-10-en-12-one, ce qui suppose que le produit primitif était l'oxa-1 trichloro-6,10,10 spiro[4.5]dec-6-en-8,9-dione.
[Traduit par le journal]

Introduction

Since chlorination-stage effluents from bleached kraft pulp mills were first reported to be mutagenic (1), interest in their chemical composition has increased. During the past two years several publications have appeared describing the identification and testing of mutagenic compounds found in this effluent (2–7). As a result of a large scale fractionation of chlorination-stage effluent from an interior B.C. mill we have obtained a number of compounds possibly associated with the mutagenicity. One of these compounds gave a crystalline product when reacted with diazomethane. The structure of the product has been determined by X-ray crystallography as the trichlorocyclohexenone **1**, suggesting the corresponding cyclohexenedione **2** was originally present.

2

Experimental

Concentration of the Chlorination-stage Effluent

Three-litre columns of XAD-2 resin were prepared by washing with methanol (2 L), ether (6 L), methanol (4 L), and water (30 L). A sample of chlorination-stage effluent (105 L) was passed through three columns, 35 L/column at a rate of 3 L/h. Each column was eluted with ether (10 L) to recover the adsorbed material. The solvent was removed under reduced pressure on a rotary evaporator with use of a bath temperature below 50°C. the evaporated ether eluate was dissolved in ether (500 mL), dried ($MgSO_4$), and re-evaporated.

Fractionation of the Ether Eluate on Silica Gel

A portion of the ether eluate from the chlorination-stage sample equivalent to 25 L effluent (4.5 g) was separated into 5 fractions by chromatography on silica gel (300 g, 60/200 mesh). The column was eluted successively with hexane (1.5 L), hexane:ether 9:1 (1.5 L), hexane:ether 1:1 (1.5 L), ether (2 L), and methanol (1.5 L). Solvents were evaporated under reduced pressure as previously described. Material eluted by hexane:ether 1:1 was further fractionated in three successive chromatographic steps on silica gel, in each instance using a 1:90 weight ratio of material:silica gel and a fraction volume equal to the weight of silica gel. In the first step the column was eluted with hexane:ether 9:1 (5 fractions), hexane:ether 4:1 (5 fractions) and hexane:ether 2:1 (5 fractions). Fractions 7–11 were combined for the second step where the column was eluted with hexane:ether 9:1 (22 fractions) and hexane:ether 4:1 (8 fractions). Fractions 22–27 were combined and in the final step the column was eluted with hexane:ether 7:1 to provide an orange

oil which was one spot by tlc (silica gel, benzene:ethyl acetate 9:1, uv or 2,4-DNP visualization). The compound had ms (chemical ionization, corrected for ionizing gas) *m/e* (% relative intensity); 272(13) $M^+ + 4$, 270(28) $M^+ + 2$, 268(29) M^+, 204(100); ir (cm^{-1}); 3400, 1710; uv (nm): 238.

Trichlorocyclohexenone, 1

Diazomethane, generated from *N*-nitrosomethylurea, was bubbled through a solution of the material obtained above (40 mg) in ether (2 mL) for 1 h. After standing another hour the ether was evaporated with a stream of N_2 and the residue fractionated by preparative thin layer chromatography on silica gel (benzene:ethyl acetate 95:5). The major uv absorbing band ($R_f \sim 0.8$) was recovered, triturated with hexane, and crystallized from ether–hexane giving colourless needles, mp 87–89°C; ms (electron impact) *m/e* (% relative intensity): 284(6) $M^+ + 2$, 282(6) M^+, 136(100); ir (cm^{-1}): 1700; uv(nm): 242.

X-ray Crystallographic Analysis of the Trichlorocyclohexenone, 1

A crystal ca. 0.40 × 0.30 × 0.12 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Mo Kα radiation (λ = 0.71073 Å). Crystal data at 22°C are:

$C_{10}H_9Cl_3O_3$ f.w. = 283.54

Triclinic, $a = 7.8814(7)$, $b = 8.3988(8)$, $c = 10.309(1)$ Å, $\alpha = 71.529(8)$, $\beta = 80.002(7)$, $\gamma = 62.587(9)°$, $V = 574.2(1)$ Å^3, $Z = 2$, $\rho_c = 1.640$ g cm^{-3}, $F(000) = 288$, μ(Mo Kα) = 18.4 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (C_i^1,No. 2, lattice constants refer to reduced cell) from structure analysis.

Intensities were measured with graphite-monochromated Mo Kα radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.26–10.06° min^{-1} over a range of (0.60 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 4%. After data reduction, an absorption correction was applied using the Gaussian integration method (8, 9). Transmission factors ranged from 0.598 to 0.811 for 188 sampling points. Of the 2617 independent reflections measured, 1795 (68.6%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.03(S - B))^2$ with S = scan count and B = background count.

The centrosymmetric space group $P\bar{1}$ was indicated by both the *E*-statistics and by the Patterson function. The positions of the three chlorine atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.046$, a difference map gave the positions of all nine hydrogen atoms which were included in subsequent cycles of refinement with isotropic thermal parameters. The scattering factors of ref. 10 were used for non-hydrogen atoms and those of ref. 11 for hydrogen atoms. Anomalous scattering factors from ref. 12 were used for the Cl atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. Convergence was reached at $R = 0.030$ and $R_w = 0.036$ for 1795 reflections with $I \geq 3\sigma(I)$. For all 2617 reflections $R = 0.059$ and $R_w = 0.038$. The function minimized was $\sum w(|F_o| - |F_c|)^2$, $R = \sum||F_o| - |F_c||/\sum|F_o|$ and $R_w = (\sum w(|F_o| - |F_c|)^2/\sum w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.03 and 0.34σ, respectively. The mean error in an observation of unit weight was 1.797. A final difference map showed no unusual features. The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (13). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.009 Å^2. Analysis of all non-hydrogen atoms gave rms $\Delta U_{ij} = 0.0028$ Å^2 and physically reasonable rigid-body parameters. The appropriate bond distances have been corrected for libration (14), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of the five- and six-membered rings are listed in Table 5. Tables 6–8, containing bond lengths and angles involving hydrogen atoms and a complete list of torsion angles, have been deposited.[1]

Results and Discussion

The crystal structure of **1** consists of discrete molecules separated by normal van der Waals distances. Each molecule (Fig. 1) contains a system

[1]The structure factor table, Table 2 (anisotropic thermal parameters), and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

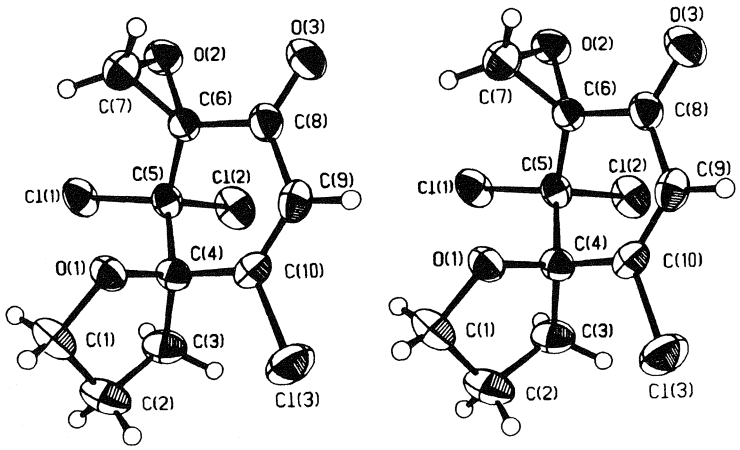

FIG. 1. Stereo view of **1**, 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned artificially small thermal parameters for the sake of clarity.

of three spiro-fused rings. The central cyclohexenone ring adopts a sofa conformation with C(5) (crystallographic numbering), which is bonded to two chlorine atoms, displaced from the approximate plane defined by the five remaining ring atoms. The conformation of the five-membered oxolane ring is best described as an "envelope", with C(2) displaced from the rough plane of the four other atoms. As expected, the oxirane and oxolane rings are oriented approximately at right angles to the central ring.

The geometry of the oxirane ring, which has an

C(2)—C(3)—C(4)—O(1)	−13.1(2)

area of 0.905 Å^2, agrees well with that reported for a number of other epoxy groups (15, 16). The geometry of the remainder of the molecule is generally as expected, distortions from "normal" geometry being explicable in terms of intramolecular steric effects. The three sp^2 hybridized carbon atoms (C(8), C(9), and C(10)) are all slightly, but significantly, displaced from the planes of their substituents (by 0.024(2), 0.012(2) and 0.029(2) Å, respectively). The double bonds of the α,β-unsaturated ketone fragment (O(3)=C(8)—C(9)=C(10)) are essentially localized, the central C(8)—C(9) bond at 1.464(3) Å being somewhat shorter than the expected C(sp^2)—C(sp^2) single bond distance of 1.485 Å. Some of this shortening, however, may result from hybridization effects. The bonds C(4)—C(5) and C(4)—C(10) are both lengthened by intramolecular steric interactions involving chlorine atoms.

A number of mechanisms may be postulated to explain the formation of a spirochlorocyclohexenedione such as **2** during bleaching of kraft pulp with chlorine. The compound could be formed either by direct degradation of lignin, a polymer of coniferyl alcohol (17) or by oxidation and chlorination of one of the monomeric phenols containing a three carbon side chain associated with pulping processes.

Acknowledgments

This work was funded by a contract with the Environmental and Occupational Toxicology Division, Environmental Health Directorate, Health Protection Branch, Health and Welfare Canada. X-ray crystallographic analysis was made possible by financial support from the Natural Sciences and Engineering Research Council of Canada and the Xerox Corporation, and assistance from the University of British Columbia Computing Centre.

Reverse phase high pressure liquid chromatography of Amphotericin B samples provides one means of cleanly separating Amphotericin B from a strongly fluorescent contaminant. Purified Amphotericin B does not exhibit any fluorescence.

NILS O. PETERSEN et PAUL F. HENSHAW. Can. J. Chem. **59**, 3376 (1981).

On décrit la séparation efficace par chromatographie liquide à haute pression en phase renversée de l'amphotéricine B et de son contaminant fluorescent. L'amphotéricine B ne présente aucune fluorescence.

[Traduit par le journal]

Amphotericin B is one of a series of polyene antibiotics isolated from several species of *Streptomycetes* (1). Amphotericin B is purported to interact with sterols, notably ergosterol and cholesterol, in cell membranes to form cylindrical complexes with hydrophilic channels along their axes (2). Hereby, Amphotericin B and similar polyene antibiotics generate conductive paths for Na^+ and K^+ ions across the membrane. The resultant loss of osmotic control can lead to cell lysis and death.

Amphotericin B and several of the other polyene antibiotics are currently being investigated for their potential use as anti-tumor agents (3) and for their role as immunoadjuvants in mice (4). All actions of polyene antibiotics are thought to depend critically on their binding affinities to sterols in membranes. *In vitro* studies of polyene antibiotic – sterol binding have exploited changes in both optical and fluorescence properties (5, 6). We report here on our findings that, contrary to published data (6), Amphotericin B does not exhibit intrinsic detectable fluorescence in any of several solvent systems. Rather, the fluorescence arises from an impurity easily separable by high pressure liquid chromatography.

Figure 1*A* shows the optical spectrum (---) (Varian Assoc. Cary 219), the fluorescence emission spectrum (·····), and the fluorescence excitation spectrum (—) (Perkin Elmer MPF-4) of a sample of Amphotericin B (Lot #800254, Calbiochem, La Jolla, CA) in dimethyl sulfoxide. It is apparent that the optical spectrum and the fluorescence excitation spectrum do not match, suggesting that the fluorescing and absorbing species are different. Simple polyenes generally show good correlations between optical and fluorescence excitation spectra, and the lowest energy allowed transition ($A_g \rightarrow B_u$) corresponds to the strongest fluorescent band (7).

In order to ascertain whether Amphotericin B was the fluorescing species, the material was purified by analytical high pressure liquid chromatography (Varian Instruments Model 5000) on a reverse phase column (Waters Assoc. Column model 8C1810μ) eluting at 2 mL per min with a buffer mixture containing 35% (v/v) acetonitrile and 65% (v/v) 0.05 *M* aqueous sodium citrate buffered at pH = 5.3. The elution profile (monitored continuously at 254 nm) is shown in Fig. 2*A* trace *b* compared to the elution of the dimethylsulfoxide solvent in trace *a*. The elution profile is similar to that reported (8) for Amphotericin B in a different reverse phase system and shows three minor peaks (I–III) and a major band (IV) which is slightly asymmetric. Two millilitre fractions (labelled 1–20) were collected as marked in Fig. 2. Each fraction was diluted 1:1 (v/v) with the elution buffer. Optical and fluorescence emission and excitation spectra were recorded. The optical (---), fluorescence emission (·····) and excitation (—) spectra of a 10 μL sample of stock solution in dimethyl sulfoxide diluted into 5 mL elution buffer is shown in Fig. 1*B*. The corresponding spectra for fractions 2 and 14 are shown in Figs. 1*C* and 1*D*, respectively. Based on the absorption spectra of fractions 13–15 (Fig. 1*D*) we assign peak IV to Amphotericin B. Further characterization by chemical means and by biological activity assays should confirm this assignment. Clearly, the fluorescence in fraction 2 does not co-chromatograph with the absorption in fraction 14. This is illustrated more clearly in Fig. 2*B*, which shows the peak

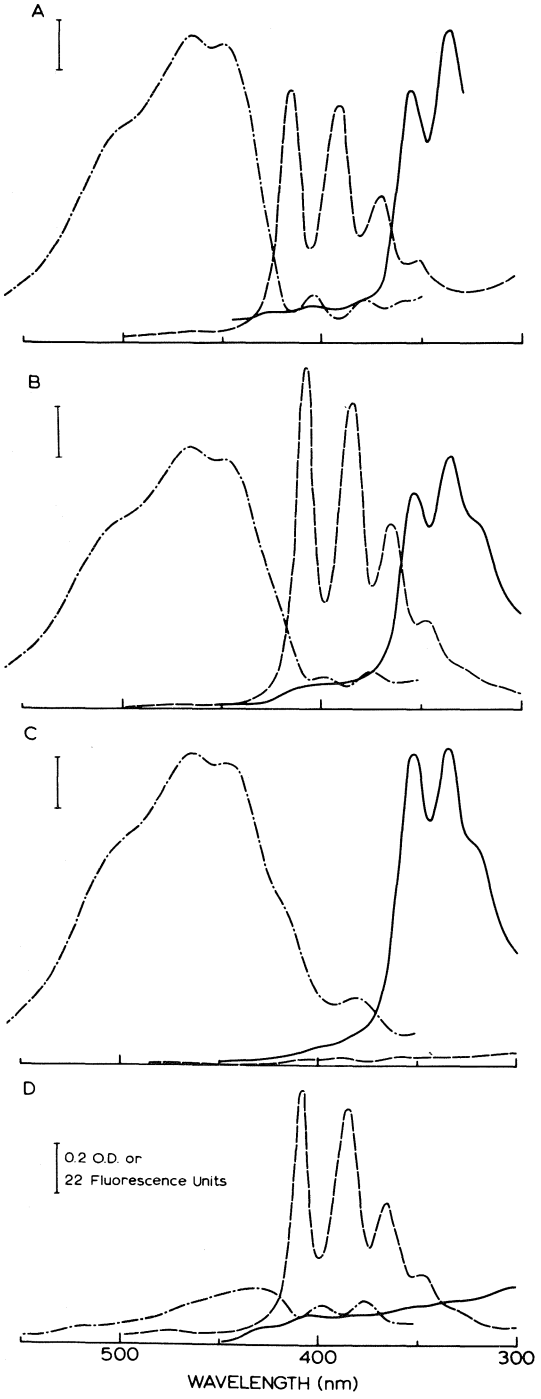

FIG. 1. Optical spectra (---), fluorescence emission spectra (-·-·-), and fluorescence excitation spectra (—) of Amphotericin B in dimethylsulfoxide at 7.0 μg/mL (*A*) and in elution buffer at 11.6 μg/mL (*B*) and of fractions 2 (*C*) and 14 (*D*) from the high pressure liquid chromatography elution. The fluorescence emission was measured with λ_{EX} = 335 nm while the fluorescence extinction was measured with λ_{em} = 465 nm. In each graph the bar represents 0.2 OD units or 22 fluorescence units as indicated in *D*.

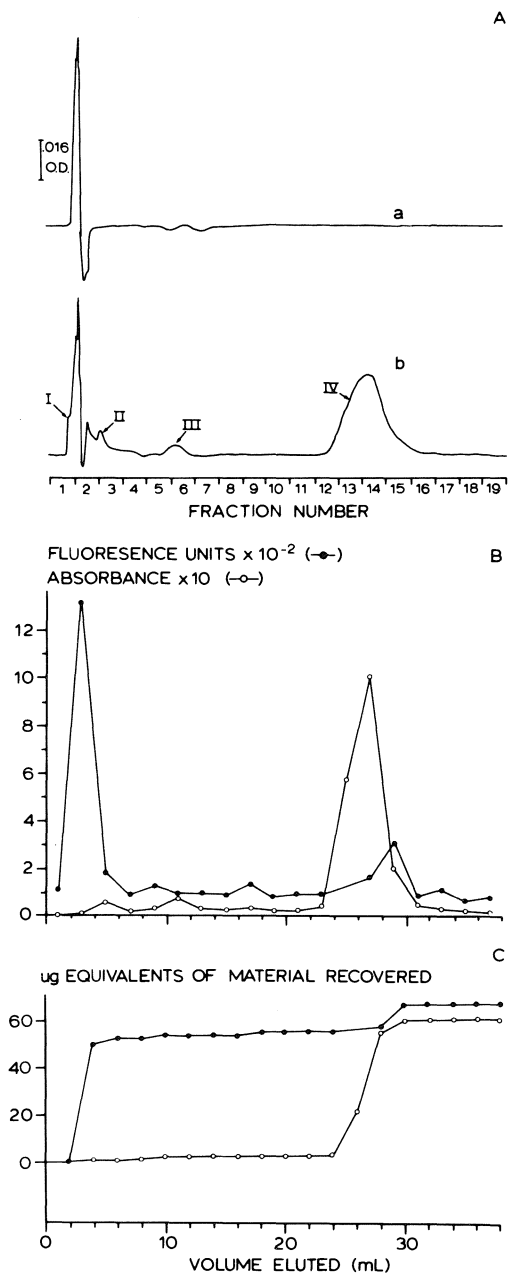

FIG. 2. (*A*) Elution profiles monitored at 254 nm of 10 μL dimethylsulfoxide (trace *a*) and of about 58 μg Amphotericin B in 10 μL dimethylsulfoxide. Peaks I to IV are absent in the pure solvent and are attributed to Amphotericin B (peak IV) and impurities (peaks I to III). Peak I co-chromatographs with the solvent and is the predominant fluorescent impurity. (*B*) Absorbance amplitude at 408 nm (—○—) and fluorescence emission amplitude at 465 nm (λ_{EX} = 335 nm) (—●—) as a function of elution volume from the reverse phase column. The peak fluorescence appears in fraction 2 while the peak absorbance occurs in fraction 14. (*C*) The total amount of material recovered as a function of elution volume in microgram equivalents based on the fluorescence (—●—) and the absorbance (—○—) of Fig. 2*B*.

amplitude of the fluorescence emission at 465 nm ((—•—), λ_{EX} = 335) and the absorbance at 408 nm (—○—). Fractions 2 and 3 contained most of the fluorescence whereas fractions 13–15 contained all of the absorbance. A small amount of fluorescence is detectable in fractions 14 and 15 (Fig. 2*B*) but this appears to elute slightly later than the major absorbance. Although the resolution is insufficient to provide strong evidence, we believe this fluorescence does not arise from Amphotericin B but rather from yet another impurity.

The extinction at 408 nm in the elution buffer is approximately 0.118 OD units per (μg/mL) of the impure material. Similarly, the fluorescence emission at 465 nm (λ_{EX} = 335 nm) is approximately 10 fluorescence units per (μg/mL) of the impure material. Using these numbers and the measured absorbance and emission of each fraction, it was possible to calculate the microgram "equivalents" of the original material recovered in each fraction as measured by the optical and fluorescence properties respectively. These data are shown in Fig. 2*C* and demonstrate that most of the fluorescence (—•—) added to the column is recovered in fraction 2 whereas all of the absorbance (—○—) is recovered in fractions 13–15. The recovery is quantitative since 58 ± 5 μg material was added, while 66 μg equivalents of fluorescent material was recovered and 60 μg equivalents of absorbant material was recovered. This quantitative recovery of both fluorescence and absorbance, together with the lack of observable changes in either the fluorescence or absorption spectra, provide strong evidence that the materials eluted from the column were present prior to injection on the column. We, therefore, feel it is unlikely that any of the elution peaks arise from chemical degradation or reaction on the column.

These experiments demonstrate unambiguously that virtually all the fluorescence observed from Amphotericin B solutions prepared prior to high pressure liquid chromatography purification arises from a highly polar impurity which co-chromatographs with the solvent (dimethylsulfoxide) in this system. Even solutions which are allowed to sit in the dark contain larger proportions of this fluorescent species, as judged both from the fluorescence emission amplitude relative to the optical spectrum, and from the peak areas of the high pressure liquid chromatography elution profiles. It is possible that this impurity represents a degradation product of Amphotericin B. The fluorescence spectra properties are similar to those of tetraenes (5, 6).

We conclude that Amphotericin B does not exhibit significant intrinsic fluorescence in any of the solvents tested (dimethylsulfoxide, *N,N*-dimethylformamide, ethanol, methanol, water, and aqueous buffers). We still need to investigate whether complexes of Amphotericin B and sterols can exhibit fluorescence particularly when formed in membranes.

Incomplete studies of other polyene antibiotics suggest that many, and perhaps all, of these are intrinsically fluorescent. It is then possible that Amphotericin B is unique in its non-fluorescent properties among the class of polyene antibiotics.

A. K. CHENG, A. K. GHOSH, I. (TSE) SHEEPY, and J. B. STOTHERS. Can. J. Chem. **59**, 3379 (1981).

Under homoenolization conditions (*t*-BuO$^-$, *t*-BuOH, 185°C), 7,7-dimethyltricyclo[3.2.1.0^{2,4}]octan-6-one (**5**) readily rearranges to 4,4-dimethyltricyclo[3.3.0.0^{2,8}]octan-3-one (**6**) which subsequently suffers reduction of the three-membered ring, presumably by electron transfer from the *tert*-butoxide anion for which some evidence has been obtained. The conversion of **5** to **6** constitutes one of very few examples of rearrangement via a γ-enolate. From reactions in *tert*-butyl alcohol-*O*-d_1, deuterium incorporation at the several sites in **5** and **6** undergoing H/D exchange was directly monitored by ^{2}Hmr spectroscopy; these results shed light on the stereochemistry of homoenolate formation and cleavage.

A. K. CHENG, A. K. GHOSH, I. (TSE) SHEEPY et J. B. STOTHERS. Can. J. Chem. **59**, 3379 (1981).

Dans des conditions d'homoénolisation (*t*-BuO$^-$, *t*-BuOH, 185°C), la diméthyl-7,7 tricyclo[3.2.1.0^{2,4}]octanone-6 (**5**) se transpose facilement en diméthyl-4,4 tricyclo[3.3.0.0^{2,8}]octanone-3 (**6**) dont le cycle à 3 chaînons est réduit ensuite probablement par transfert d'électron de l'anion *tert*-butylate; nous avons obtenu quelques données supportant cette hypothèse. La transformation du composé **5** en composé **6** constitue un des rares exemples de transposition par l'intermédiaire d'un γ-énolate. A partir des réactions dans le *tert*-butanol-*O*-d_1 on a pu enregistrer directement, par rmn du ^{2}H, l'échange H/D conduisant à l'incorporation du deutérium dans plusieurs positions des composés **5** et **6**; ces résultats permettent de mieux comprendre la stéréochimie et le clivage des homoénolates.

[Traduit par le journal]

Since the initial discovery (1) that a ketonic carbonyl group can activate proton abstraction from remote carbon atoms in strong base (homoenolization), several examples in acyclic and cyclic systems have been described as recently reviewed (2). In the majority of cases, proton abstraction occurs at β-carbons, i.e. β-enolization, but there are a few examples involving γ-carbons. The latter include the rearrangement of half-cage ketone **1** to its isomer **2** upon treatment with *t*-BuO$^-$/*t*-BuOH at elevated temperatures, the typical homoenolization conditions, and for which it was established that homoketonization of the bird-cage alcohol **3** gave the same mixture of **1** and **2** (3). Also, H/D exchange at the *syn*-methyl (C-8) of camphor (4) and at C-6 and -7 in 3,3-dimethylbicyclo[3.3.0]octan-2-one (5) is consistent with the formation of γ-enolates. In fact for the former system strong support has been provided by the synthesis of the corresponding alcohol **4** by reductive cyclization of 8-bromocamphor, homoketonization of which in a deuterated medium provided 8-deuteriocamphor exclusively (6). A γ-enolate may also be implicated in the conversion of *sym*-tetramethyldiphenylacetone to 2-isopropylbenzoic acid (7). Our interest in homoenolization has led us to examine systems potentially able to rearrange via γ-enolates and in this communication we wish to describe preliminary results from the study of 7,7-dimethyltricyclo[3.2.1.0^{2,4}]octan-6-one (**5**). We have found that **5** is readily transformed to 4,4-dimethyltricyclo[3.3.0.0^{2,8}]octan-3-one (**6**) upon treatment with *t*-

BuO^-/t-BuOH at 185°C, constituting a third example of rearrangement via γ-enolization. Furthermore **6** is unstable under these conditions and is slowly converted to a mixture of the bicyclic octanone **7***a* and its *exo*-6-*tert*-butoxy derivative **7***b*. Experiments in *tert*-butyl alcohol-*O*-d_1 permitted identification of the sites of H/D exchange in **5** and **6**.

Ketone **5** (8) was dissolved in anhydrous t-BuO^-/t-BuOH (1.27 *M*) to furnish a solution 0.26 *M* in ketone; aliquots were transferred to glass tubes under nitrogen, sealed under vacuum, and heated at 185°C for various times. Gas–liquid chromatography (glc) of the neutral product (pentane extraction, >80% yields) revealed the presence of three new ketones in addition to starting material, isolable by preparative glc. (Three minor components constituting <5% of the product in the longest runs were not identified.) The major new component **6** in the earlier samples reached a maximum concentration which then decreased progressively. With increasing reaction times the proportion of the other two new ketones **7** increased (see Table 1).

Ketone **6** (1713 cm^{-1}, $CHCl_3$) gave the following ^{1}Hmr data (δ, $CDCl_3$): 0.85 (s, 3H), 1.10 (s, 3H), 2.66 (bq, 1H), 2.43 (bt, 1H), 1.35 (m, 1H), and complex absorption 1.6–2.1 (5H). Its ^{13}Cmr spectrum contained 10 signals: methyl (2), methylene (2), methine (4), quaternary (1), and one carbonyl peak. *Exact Mass* calcd. for $C_{10}H_{14}O$: 150.1044; found (high resolution ms); 150.1044. These data are consistent with **6** and the structure was confirmed by methylation ($NaNH_2$–CH_3I) of the parent ketone, prepared as described by Monti *et al.* (9).

The major ketone (1730 cm^{-1}) in the later samples exhibited a ^{1}Hmr spectrum (δ, $CDCl_3$) containing two methyl singlets (1.03, 1.08), with multiplets centred at 2.70 (2H), 2.25 (1H), 2.04 (1H), and complex absorption 0.9–1.9 (6H). Its ^{13}Cmr spectrum contained 10 signals: methyl (2), methylene (4), methine (2), quaternary (1), and one carbonyl peak. *Exact Mass* calcd. for $C_{10}H_{16}O$: 152.1206; found (high resolution ms): 152.1200. These data indicated this ketone to be **7***a* and identical material could be generated by reduction of **6** with potassium in alcohol followed by CrO_3 oxidation of the resulting alcohols. The remaining ketonic product (1740, 1130 cm^{-1}) appeared to contain an ethereal linkage. Its ^{1}Hmr spectrum included (δ, $CDCl_3$): 1.00 (s, 3H), 1.05 (s, 3H), 1.20 (s, 9H), 3.80 (m, 1H), and 1.30–3.00 (complex absorptions, 8H). The ^{13}Cmr spectrum contained 3 methyl signals, one of which was ~3 times as intense as the others, 3 methylene, 3 methine, 2 quaternary, and a carbonyl signal. *Exact Mass* calcd. for $C_{14}H_{24}O_2$: 224.1775; found (high resolution ms): 224.1764. These data accord well with structure **7***b*. Upon treatment with t-BuO^-/t-BuOH at 185°C, **6** is smoothly converted to a mixture of **7***a* and **7***b*.

TABLE 1. Distribution [a] of components in the neutral product obtained upon treatment of **5** with t-BuO^-/t-BuOH at 185°C

Time (h)	**5**	**6**	**7***a*	**7***b*
6	55	27	15	Trace
13	45	36	18	Trace

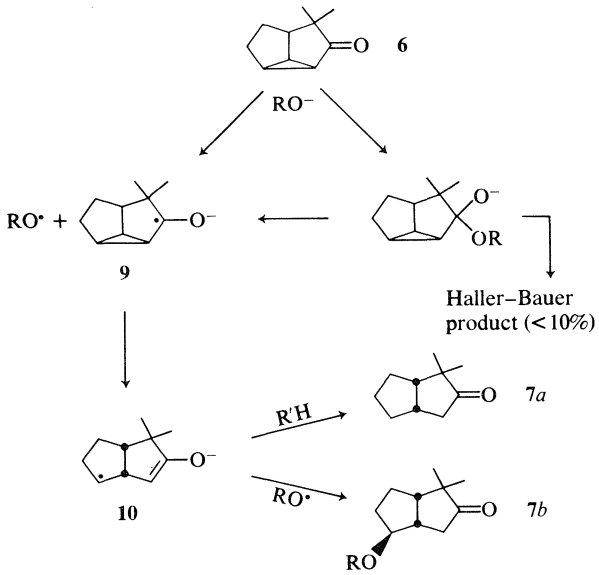
47	8	58	24	9
63	3	57	29	10
76	—	48	33	16
95	—	40	38	17

[a]Determined as % of the total by glc using a 6% FFAP column at 155°C.

The transformation of **5** → **6** must involve proton abstraction from C-3 leading to γ-enolate **8**, which can suffer cleavage of the original C-5, C-6 bond to furnish **6** or return to starting material. Evidence that the formation of **8** is reversible was furnished by experiments in t-BuOD. Treatment of **5** with t-BuO^-/t-BuOD at 185°C for 6 h gave samples of **5**-d_x and **6**-d_x which were examined by ^{2}Hmr. The ^{2}H spectrum of **5**-d_x contained four signals establishing that H/D exchange occurred, in order of decreasing reactivity, at C-5, -4, -3, and the *exo*-methyl carbon.[3] Exchange at C-3 is stereospecific with deuterium found only in the *exo*-orientation, indicative of the reversible formation of **8**, and opening with *inversion* to return to **5**. This is the first such example; all other γ-homoketonizations for which the stereochemistry has been examined proceed with *retention* (2). Bridgehead (C-5) and stereoselective methyl exchange is analogous to our earlier findings for the closely-related 7,7-dimethylbicyclo[3.2.1]octan-6-one (10). The inductive effect of the carbonyl group presumably activates C-4 exchange. From these experiments **6** had seven ^{2}H signals, three of which will arise from exchange in **5** before conversion to **6**. The ^{2}H spectra of **6**-d_x contained signals for ^{2}H at C-1, -2, -7, -8, and both methyls. Since incorporation of ^{2}H in **6** results from prior exchange in **5** and from exchange after its formation, the latter processes were examined separately by treatment of **6** with t-BuO^-/t-BuOD at 185°C. The ^{2}H spectra of these **6**-d_x samples differed significantly in that only four

[3]The ^{2}H assignments were confirmed by comparison of ^{1}H and ^{2}H spectra of solutions containing Eu(fod)$_3$ in the presence of which the ^{1}H shieldings could be determined using spin-decoupling to establish individual assignments. The *exo* and *endo* methyl groups were distinguishable by selective decoupling of the ^{13}C spectrum.



SCHEME 1

signals were apparent after a 30 h treatment. No deuterium was detectable at the *endo*-methyl or at C-7! The absence of ^2H at C-7 establishes that the opening of **8** → **6** is irreversible. Only the hydrogens bonded to the *exo*-methyl and the cyclopropyl carbons undergo exchange;[3] thus, there is no evidence of γ-enolization in **6**.

The conversion **6** → **7** requires a reducing agent but we have been unable to detect an oxidized product. With lithium aluminium hydride, **6** is reduced to a mixture of the corresponding epimeric alcohols which may be oxidized to **6**; as noted above, **6** is readily reduced with K metal in *t*-BuOH to a 2:1 mixture of two bicyclic alcohols which can be oxidized to furnish **7***a*. Treatment of **6** with *t*-BuO⁻/*t*-BuOH at reflux gave no reaction even after 135 h. Thus the formation of **7***b* via Michael addition of *t*-BuO⁻ to **6** seems unlikely. Our current view is summarized in Scheme 1. We suggest that **6** → **7** occurs by electron transfer from *t*-BuO⁻, either directly or by homolysis of the addition product formed by attack of *t*-BuO⁻ at the carbonyl of **6**; Haller–Bauer cleavage of this addition product to form an ester is not a major pathway since it gives < 10% of the total product after the longest reaction times. In the resulting ketyl **9**, the three-membered ring can open to form **10**, which subsequently gains a hydrogen atom from solvent giving **7***a* or reacts with *tert*-butoxide radical formed in the generation of **9** to yield **7***b*. Other evidence for electron transfer from *t*-BuO⁻ has been presented (11).

From these results we conclude that γ-enolization occurs reversibly from **5** but the cleavage of the resulting γ-enolate **8** to **6** is unidirectional. Experiments to determine the relative rates of ^2H incorporation in **5** and **6** require lower reaction temperatures and these are in progress, as well as further work to substantiate our suggestion for the **6** → **7** transformation.
