[a]Standard deviation.

mentary acid and alcohol chain lengths, for example: hexyl formate ($\Delta H_s = -11.24$ kcal mol^{-1}) and methyl hexanoate ($\Delta H_s = -10.84$ kcal mol^{-1}).

The branching of the alcohol or acid chains in esters produces a lowering of ΔH_s, an effect more pronounced in the alcohol group. In Table 2 some examples of this type are included. Logically, when both types of branching occur in the same ester, lowest values are obtained.

Table 3 shows the values obtained using the value obtained for *n*-decane as "zero" (ΔG_{s_0}). In this case, it can be observed that $\Delta G_s - \Delta G_{s_0}$ presents maximum values when the ratio n_{ac}/n_{al} is nearly one. It can be observed from Fig. 2 that the linear plots for methyl esters, ethyl esters, and so on have slopes of opposite sign to those obtained for ΔH_s. The effect of varying the —CH_2— group on values of $\Delta G_s - \Delta G_{s_0}$ is analogous to that for values of ΔH_s.

Conclusion

From the experimental data previously stated it can be concluded that in the values of ΔH_s and $\Delta G_s - \Delta G_{s_0}$ for esters, aside from the total number of carbon atoms, the ratio between the number of carbon atoms of the acid group (n_{ac}) and the alcohol group (n_{al}), the branching of these chains, and the position of the carboxylic group in the molecule are also influencing factors.

The methylene groups in the alcohol chain have a greater influence than those in the acid chain on the value of these thermodynamic quantities. The branching of the chains produces a diminution of these values, which is the more pronounced in the alcohol group. For esters with the same number of carbon atoms, the ΔH_s value is smaller the nearer the carboxylic group is to the center of the carbon chain.

The synthesis of uridine diphosphate *N*-acetylhexosamines and uridine 5′-(2-acetamido-2-deoxy-α-D-mannopyranosyluronic acid diphosphate)[1]

TATSUMI YAMAZAKI, CHRISTOPHER D. WARREN, ANNETTE HERSCOVICS, AND ROGER W. JEANLOZ

Laboratory for Carbohydrate Research, Departments of Biological Chemistry and Medicine, Harvard Medical School and Massachusetts General Hospital, Boston, MA 02114, U.S.A.

Received December 15, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

TATSUMI YAMAZAKI, CHRISTOPHER D. WARREN, ANNETTE HERSCOVICS, and ROGER W. JEANLOZ. Can. J. Chem. **59**, 2247 (1981).

2-Methyl-(2-acetamido-3,4,6-tri-*O*-acetyl-1,2-dideoxy-β-D-mannopyrano)-[2,1-*d*]-2-oxazoline was efficiently converted into 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-mannopyranosyl phosphate, by treatment with dibenzyl phosphate, followed by catalytic hydrogenolysis of the benzyl groups. Similarly, 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranosyl phosphate and -galactopyranosyl phosphate were synthesized from the respective peracetyl oxazolines. In each case, the procedures for preparing the oxazoline, and conversion into the glycosyl phosphate, were modified to give high yields of pure products. 2-Acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-mannopyranosyl phosphate was coupled with 2′,3′-di-*O*-acetyluridine 5′-monophosphate by a modification of the mixed anhydride procedure, to give 2′,3′-di-*O*-acetyluridine 5′-(2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-mannopyranosyl diphosphate), which was readily purified by preparative tlc and *O*-deacetylated to give "uridine diphosphate *N*-acetylmannosamine" in high yield. Similarly, uridine 5′-(2-acetamido-2-deoxy-α-D-glucopyranosyl- and -galactopyranosyl diphosphates) were synthesized by rapid, efficient procedures, not involving ion-exchange chromatography. Uridine 5′-(2-acetamido-2-deoxy-α-D-mannopyranosyl diphosphate) was converted into uridine 5′-(2-acetamido-2-deoxy-α-D-mannopyranosyluronic acid diphosphate), required for biosynthetic studies, without the preparation of a special platinum catalyst. All the synthetic uridine diphosphate sugars were characterized by optical rotation, ^{1}H nmr spectrum, and elemental analysis.

TATSUMI YAMAZAKI, CHRISTOPHER D. WARREN, ANNETTE HERSCOVICS et ROGER W. JEANLOZ. Can. J. Chem. **59**, 2247 (1981).

La 2-méthyl-(2-acétamido-3,4,6-tri-*O*-acétyl-1,2-didésoxy-β-D-mannopyrano)-[2,1-*d*]-2-oxazoline a été convertie avec un bon rendement en phosphate de 2-acétamido-3,4,6-tri-*O*-acétyl-2-désoxy-α-D-mannopyranosyle par traitement avec le phosphate de dibenzyle suivi par l'hydrogénolyse catalytique des groupes benzyles. D'une manière semblable, les phosphates de 2-acétamido-3,4,6-tri-*O*-acétyl-2-désoxy-α-D-glucopyranosyle et -galactopyranosyle ont été synthétisés à partir des oxazolines peracétylées respectives. Dans chaque cas, la méthode de préparation de l'oxazoline et la conversion en phosphate de glycosyle ont été modifiées pour donner d'excellent rendements en produit pur. Le phosphate de 2-acétamido-3,4,6-tri-*O*-acétyl-2-désoxy-α-D-mannopyranosyle a été condensé avec le 5′-monophosphate de 2,3-di-*O*-acétyluridine par une modification de la méthode à l'anhydride mixte, pour donner la 2′,3′-di-*O*-acétyluridine (5′-diphosphate de 2-acétamido-3,4,6-tri-*O*-acétyl-2-désoxy-α-D-mannopyranosyle). Celle-ci a été purifiée par ccm préparative et *O*-désacétylée pour donner l'"uridine diphosphate de *N*-acétylmannosamine" avec un excellent rendement. D'une manière semblable, les uridine 5′-(diphosphate de 2-acétamido-2-désoxy-α-D-glucopyranosyle et -galactopyranosyle) ont été synthétisées par des méthodes rapides et efficaces qui ne demandent pas une purification par chromatographie sur résines échangeuses d'ions. L'uridine 5′-(diphosphate de 2-acétamido-2-désoxy-α-D-mannopyranosyle) a été convertie en uridine 5′-(diphosphate de l'acide 2-acétamido-2-désoxy-α-D-mannopyranosyluronique) (produit nécessaire pour des études de biosynthèse) sans préparation d'un catalyste de platine spécial. Tous les uridine diphosphates de sucre ont été caractérisés par leurs pouvoirs rotatoires, spectre de rmn ^{1}H et analyse élémentaire.

Introduction

Nucleoside diphosphate sugars are uniquely important as glycosyl donors in a wide variety of biosynthetic processes (1), including the formation, via lipid intermediates, of antigenic polysaccharides in bacteria (2). These compounds are therefore frequently required for biosynthetic investigations, and good methods of synthesis, both chemical and enzymic, are essential.

The chemical methods available for preparing nucleoside diphosphate sugars, especially the hexosamine derivatives (3), are often inconvenient and time-consuming, especially in the purification stages, and yields are variable. This is particularly true for uridine 5′-(2-acetamido-2-deoxy-α-D-mannopyranosyluronic acid diphosphate) (**20**) (4) which was required by us for the study of the biosynthesis of the antigenic polysaccharide in the cell wall of *Micrococcus lysodeikticus* (5, 6). Furthermore, when compound **20** was prepared previously (4), it was characterized indirectly, and its properties were not recorded. We have, therefore, developed a rapid and efficient synthesis of **20**, utilizing an improved method for the coupling of

the glycosyl phosphate residue (as the peracetyl derivative) with uridine 5′-monophosphate, and show that this method is generally applicable to the synthesis of nucleoside diphosphate hexosamine derivatives. All the synthetic compounds were characterized by recording optical rotation, ^{1}H nmr spectrum, and elemental analysis. A preliminary account of part of this work has previously appeared (7).

Results and Discussion

For the synthesis of uridine 5′-(2-acetamido-2-deoxy-α-D-mannopyranosyl diphosphate) (**15**), a procedure similar to that of Salo and Fletcher (8) was followed. Thus, the oxazoline derivative **1** of 2-acetamido-2-deoxy-D-mannose was phosphorylated before being coupled with an activated derivative of uridine 5′-monophosphate. Repetition of the preparation of Khorlin *et al.* (9) of the oxazoline **1** gave, in our hands, only average yields (40–60%), and an alternative procedure was developed. Thus, 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-mannopyranosyl chloride (**2**), prepared by treatment of 2-acetamido-2-deoxy-D-mannose monohydrate with acetyl chloride for 8 h, was smoothly converted (74% yield) into 2-methyl-(3,4,6-tri-*O*-acetyl-1,2-dideoxy-β-D-mannopyrano)-[2,1-*d*]-2-oxazoline (**1**) by treatment with an excess of potassium carbonate in acetonitrile. Treatment of **1** with dibenzylphosphate, followed by catalytic hydrogenolysis of the resulting dibenzyl derivative, gave, in 61% yield, 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-mannopyranosyl phosphate (**5**), which was suitable for synthetic purposes, and was *O*-deacetylated, in quantitative yield, to give 2-acetamido-2-deoxy-α-D-mannopyranosyl phosphate (**6**).

2-Methyl-(2-acetamido-3,4,6-tri-*O*-acetyl-1,2-dideoxy-α-D-glucopyrano)-[2,1-*d*]-2-oxazoline (**3**) was prepared in quantitative yield by a method similar to that of Lemieux and Driguez (10), and then condensed with dibenzyl phosphate, followed by the same hydrogenolysis procedure as that employed for the preparation of **5** to give, in 63% yield, 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranosyl phosphate (**7**), which was characterized further as the *O*-deacetylated compound **8**. It has been shown by Khorlin *et al.* (11), and Warren *et al.* (12), that oxazolines derived from 2-acetamido-2-deoxy-D-glucose and di-*N*-acetylchitobiose yield α-D-glycosyl phosphates by this procedure, rather than the kinetic product, the β-D anomer.

The yield in the synthesis (62% yield) of 2-methyl-(3,4,6-tri-*O*-acetyl-1,2-dideoxy-α-D-galactopyrano)-[2,1-*d*]-2-oxazoline (**4**) by treatment of 2-acetamido-1,3,4,6-tetra-*O*-acetyl-2-deoxy-β-D-galactopyranose with anhydrous ferric chloride in dichloromethane according to Matta *et al.* (13) was improved to 84%. Phosphorylation performed by the same procedure as that described for **5** and **7** gave 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-galactopyranosyl phosphate (**9**) in 70% yield. *O*-Deacetylation with sodium methoxide in methanol gave 2-acetamido-2-deoxy-α-D-galactopyranosyl phosphate (**10**) in 92% yield.

The mixed anhydride method developed by Michelson (14) was selected among the methods for the synthesis of uridine diphosphate sugars (for a review, see ref. 3), as it has been successfully applied to uronic acid (15) and deoxy sugar (16) derivatives, and has been adapted in this laboratory to the synthesis of "lipid intermediates" (12). Treatment of the tributylammonium salt of uridine 5′-monophosphate with diphenyl phosphorochloridate in a mixture of 1,4-dioxane and *N*,*N*-dimethylformamide gave a precipitate of uridine 5′-(diphenyl diphosphate) (**13**), which was immediately treated with two equivalent amounts of the tribu-

13 R = H

tylammonium salt of a sugar phosphate (**6** or **8**) in a mixture of 1,4-dioxane and pyridine for 15 h at room temperature. After purification by ion-exchange column chromatography, the desired uridine 5′-(2-acetamido-2-deoxy-α-D-mannopyranosyl diphosphate) (**15**) and uridine 5′-(2-acetamido-2-deoxy-α-D-glucopyranosyl diphosphate) (**17**) were obtained in 39 and 47% yield, respectively.

In order to obtain these moderate yields, extreme care had to be taken in drying the starting materials, solvents, and apparatus. Moreover, complete drying of the uridine 5′-monophosphate and glycosyl phosphate was difficult because of the presence of traces of water tightly bound to the hydroxyl groups. Therefore, a modified procedure, in which these groups were protected by *O*-acetylation, was introduced. Per-*O*-acetylglycosyl phosphates have already been extensively used in this laboratory in the synthesis of glycosyl polyprenyl mono- and di-phosphates (12, 17). Thus, 2′,3′-di-*O*-acetyluridine 5′-monophosphate (**11**) was prepared in 72% yield from uridine 5′-(disodium monophosphate) by acetylation with acetic anhydride in a mixture of pyridine and *N*,*N*-dimethylformamide. As expected, a product containing both acetylated hydroxyl and phosphate groups was obtained. Further treatment with pyridine and methanol and subsequent evaporation gave the desired compound **11**. Condensation (14) of the tributylammonium salt **11** with diphenyl phosphorochloridate in dry 1,4-dioxane for 2 h at room temperature under nitrogen, and subsequent evaporation of the reaction mixture gave syrupy 2′,3′-di-*O*-acetyluridine 5′-(diphenyl diphosphate) (**12**), which was immediately treated with a slight excess of the tributylammonium salt of the acetylated hexosamine phosphate (**5**, **7**, or **9**) in dry pyridine for 8 to 10 h at room temperature. Evaporation of the reaction mixture, and purification by preparative tlc (eluting solvent: chloroform–methanol–water 10:10:3) gave the corresponding peracetylated uridine 2-amino-2-deoxy sugar diphosphates (**14**, **16**, and **18**), in 86, 82, and 80% yield, respectively. Each compound was converted easily by treatment with aqueous sodium hydroxide into the *O*-deacetylated uridine diphosphate derivative **15**, **17**, and **19**, in 94, 86, and 82% yield, respectively.

Anderson *et al.* (4) have described the selective oxidation at C-6 of the 2-acetamido-2-deoxy-D-mannosyl group of **15**, in 12% yield, by use of a platinum catalyst prepared by the procedure of Dutton and Slessor (18). The preparation of the catalyst is time-consuming and did not give a catalyst of consistent quality. Therefore, compound **15** was selectively oxidized, in the presence of commercially available 10% platinum-on-carbon

(Fluka-Tridom), by bubbling oxygen into a mixture of **15** in aqueous sodium hydrogen carbonate solution for 7 h at 75°C, to give uridine 5′-(2-acetamido-2-deoxy-α-D-mannopyranosyluronic acid diphosphate) (**20**) in 20% yield.

Experimental

Melting points were determined with a Mettler FP-2 apparatus and optical rotations on solutions in a 1 dm, semimicro tube with a Perkin–Elmer polarimeter, Model 141. The ir spectra were recorded with a Perkin–Elmer spectrophotometer, Model 237. Thin-layer chromatography was performed on precoated plates of Silica Gel F245 (Merck), and the spots were detected by (*a*) a spray of 5% phosphomolybdic acid in ethanol, (*b*) the spray reagent of Dittmer and Lester (19) for phosphate groups, and (*c*) uv visualization. Preparative tlc was conducted on precoated plates of Silica Gel F254 (Merck, 0.5 and 2 mm thickness). When the compound did not quench uv fluorescence, it was detected by spraying a narrow band (1–2 mm) with one or both of the spray reagents used for the analytical tlc.

The ^{1}H nmr spectra were recorded at 60 MHz with a Varian T-60 spectrometer, at 80 MHz with a Varian FT-80 spectrometer, or at 270 MHz with a Bruker WP-270 instrument. The high-field nmr experiments were performed at the NMR Facility for Biomolecular Research located at the F. Bitter National Magnet Laboratory, Massachusetts Institute of Technology, Cambridge, MA 02139. Acetonitrile was dried by distillation from phosphorus pentoxide and storage over 3 Å molecular sieves (Sigma). The microanalyses were performed by Galbraith Laboratories, Inc., Knoxville, TN 37921. The criteria for inclusion of occluded solvent molecules in the analyses are (*1*) the spectral data are consistent with their presence; (*2*) these solvents have been employed in the final purification step; (*3*) the calculated and found figures fit closely; and (*4*) the identity of the compound is unambiguously established by other data.

*2-Methyl-(2-acetamido-3,4,6-tri-*O*-acetyl-1,2-dideoxy-*β*-D-mannopyrano)-[2,1-d]-2-oxazoline (1)*

A suspension of 2-acetamido-2-deoxy-D-mannose monohydrate (500 mg, 2.1 mmol) in acetyl chloride (6 mL) was saturated with dry hydrogen chloride gas at −10°C. The reaction flask was sealed and stored at room temperature for 10 h. The dark-red solution was evaporated to dryness, and the remaining traces of solvent co-evaporated with benzene. The residue was dissolved in chloroform, and the solution was washed rapidly with aqueous potassium hydrogen carbonate, dried ($MgSO_4$), and evaporated to give a colored syrup (930 mg), which was dissolved in dry acetonitrile (6 mL). Anhydrous powdered potassium carbonate (1 g) was added, and the mixture was stirred vigorously for 2 h at room temperature under nitrogen, filtered, and evaporated to a syrup, which was applied to a short column (2 cm × 5 cm) of alumina (neutral, Sigma). Washing of the column with chloroform containing 1% of pyridine (70 mL) and evaporation gave a crystalline residue. Recrystallization from ether afforded needles (514 mg, 74%), mp 132–133°C; $[\alpha]_D^{20}$ −30° (*c* 1.0, $CHCl_3$) (lit. (9), mp 133–134°C, $[\alpha]_D^{17}$ −31 ± 2° (*c* 1.02, $CHCl_3$)); ^{1}H nmr ($CDCl_3$) δ: 5.85 (d, $J_{1,2}$ = 6 Hz, H-1).

*2-Methyl-(2-acetamido-3,4,6-tri-*O*-acetyl-1,2-dideoxy-*α*-D-glucopyrano)-[2,1-d]-2-oxazoline (3)*

2-Acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranosyl chloride (20) (**2**, 10.0 g, 22.4 mmol) was dissolved in dry acetonitrile (30 mL) containing tetraethylammonium chloride (4.0 g, 24 mmol) and anhydrous sodium hydrogen carbonate (4.0 g, 48 mmol). The mixture was kept at 55°C for 20 min, the solvent was removed *in vacuo*, and the residue was dissolved in dichloromethane (50 mL). The solution was washed three times with water (100 mL), dried (Na_2SO_4), and evaporated to give a syrup (8.9 g, 99%) that was suitable for phosphorylation without purification, and gave a single spot in tlc (R_f 0.55, ether–methanol 19:1). Purification by column chromatography on Florisil (100–200 mesh) with ethyl acetate – hexane (4:1) as eluent gave pure **3**, $[\alpha]_D^{20}$ +12° (*c* 1.0, $CHCl_3$) (lit. (9) $[\alpha]_D^{17}$ +10 ± 2° (*c* 0.97, $CHCl_3$); lit. (10) $[\alpha]_D$ +10° (*c* 1, $CHCl_3$)); ^{1}H nmr ($CDCl_3$) δ: 5.96 (d, $J_{1,2}$ = 7.8 Hz, H-1).

*2-Methyl-(2-acetamido-3,4,6-tri-*O*-acetyl-1,2-dideoxy-*α*-D-galactopyrano)-[2,1-d]-2-oxazoline (4)*

To a solution of 2-acetamido-1,3,4,6-tetra-*O*-acetyl-2-deoxy-β-D-galactopyranose (21) (100 mg) in dichloromethane (25 mL) was added anhydrous ferric chloride (100 mg). The reaction mixture was stirred for 1 h at room temperature, and then poured into cold water (100 mL). The organic layer was washed with saturated aqueous sodium hydrogen carbonate, and then with water, dried (Na_2SO_4), and evaporated to give syrupy **4**, pure according to tlc (R_f 0.57, ether–methanol 19:1) (71 mg, 84%), $[\alpha]_D^{20}$ +26° (*c* 1.0, $CHCl_3$) (lit. (13) $[\alpha]_D^{23}$ +25.8° (*c* 1.0, $CHCl_3$)); ^{1}H nmr ($CDCl_3$) δ: 5.95 (d, $J_{1,2}$ = 6.5 Hz, H-1), 5.45 (bt, $J_{2,3}$ = $J_{3,4}$ = 3.5 Hz, H-3), 4.95 (dd, $J_{1,2}$ = 6.5, $J_{2,3}$ = 3.5 Hz, H-2), 4.3–3.6 (m), 2.15 (s, N=C—Me), and 2.05 (OAc).

Dipotassium Salt of 2-Acetamido-2-deoxy-α-D-mannopyranosyl Phosphate (6)

The oxazoline **1** (700 mg, 2.12 mmol) and dibenzyl phosphate (800 mg, 2.88 mmol) were dissolved in dry benzene (50 mL). The solution was stored overnight at room temperature under nitrogen, and then diluted with methanol (60 mL) and hydrogenated at 1 atm in the presence of 10% palladium-on-charcoal (700 mg, Fluka-Tridom), for 1 h at room temperature. After filtration, the solution was concentrated to 3 mL and directly applied to four plates of silica gel (20 × 20 cm, 2 mm thickness). The band (R_f 0.75, chloroform–methanol–water 10:10:3) was scraped and eluted with the same solvent, followed by filtration, and evaporation to a syrup. A small amount of methanol was added to the residue and the undissolved material was filtered off. Ether was added dropwise to give a solid of 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-mannopyranosyl phosphate (**5**) (550 mg, 61%), $[\alpha]_D^{20}$ +25° (*c* 1.0, methanol). This product was used for coupling reactions without further purification.

Compound **5** (100 mg) was *O*-deacetylated by treatment with 1 *M* sodium methoxide in methanol (5 mL) at 0°C for 1 h. After neutralization with Dowex 50 (H+) the mixture was filtered and evaporated to a small volume of solution, which was applied to three plates (0.5 mm thickness). The band (R_f 0.15, chloroform–methanol– water 10:10:3) was scraped and extracted with the same solvent. Evaporation of the solution to dryness afforded a syrup that dissolved in water, and the solution was passed through a short column of cation-exchange resin AG 50W-X8 (pyridinium form, Bio-Rad Labs.). The pH was adjusted to 7.5–8 with a 1 *M* potassium hydroxide solution and, after evaporation to a small volume, ethanol–acetone 5:1 was added to the residual solution to give a white hygroscopic solid (83 mg, 94%), $[\alpha]_D^{20}$ +23° (*c* 1.0, H_2O) (lit. (8) $[\alpha]_D^{20}$ +21.3° (*c* 0.93, H_2O), for dicyclohexylammonium salt); ^{1}H nmr (D_2O) δ: 5.24 (bd, 1H, $J_{1,P}$ = 8.0 Hz, H-1), 4.33 (bd, 1H, $J_{2,3}$ = 4.5 Hz, H-2), 4.10 (dd, 1H, $J_{2,3}$ = 4.5, $J_{3,4}$ = 10.0 Hz, H-3), 3.85 (s, 2H, H-6a, -6b), 2.04 (s, 3H, NAc). *Anal.* calcd. for $C_8H_{14}K_2NO_9P{\cdot}0.5\ EtOH{\cdot}2H_2O$: C 24.77, H 4.85, N 3.21; found: C 24.31, H 4.64, N 3.08.

Dipotassium Salt of 2-Acetamido-2-deoxy-α-D-glucopyranosyl Phosphate (8)

This compound (459 mg) was prepared in 57% yield from the oxazoline **3** (500 mg) by the same procedure as described for **6**, $[\alpha]_D^{20}$ +61° (*c* 1.0, H_2O) (lit. (22) $[\alpha]_D^{25}$ +76.1° (*c* 3.44, H_2O)); ^{1}H

nmr (D_2O) δ: 5.30 (dd, 1H, $J_{1,2}$ = 3.0, $J_{1,P}$ = 7.5 Hz, H-1), 4.25–3.25 (m, 4H), 3.80 (s, 2H, H-6a, -6b), 2.05 (s, 3H, NAc). *Anal.* calcd. for $C_8H_{14}K_2NO_9P \cdot 3H_2O$: C 22.27, H 4.67, N 3.24; found: C 22.42, H 4.52, N 3.14.

Dipotassium Salt of 2-Acetamido-2-deoxy-α-D-galactopyranosyl Phosphate (10)

The same procedures as those employed for the preparation of **6** and **8** were used for converting the oxazoline **4** (200 mg) into **10** (yield 206 mg, 64%), $[\alpha]_D^{20}$ +107° (*c* 1.0, H_2O) (lit. (23) $[\alpha]_D^{25}$ +112.4° (*c* 2.9, H_2O)); ^1H nmr (D_2O) δ: 5.45 (dd, 1H, $J_{1,2}$ = 3.0, $J_{1,P}$ = 7.35 Hz, H-1), 4.18 (m, 2H, H-2, -4), 4.03 (bm, 1H, H-5), 3.94 (dd, 1H, $J_{2,3}$ = 10.8, $J_{3,4}$ = 3.2 Hz, H-3), 3.80 (m, 2H, H-6a, -6b), 2.03 (s, 3H, NAc). *Anal.* calcd. for $C_8H_{14}K_2NO_9P \cdot H_2O$: C 24.30, H 4.08, N 3.54; found: C 24.34, H 4.12, N 3.39.

Dilithium Salt of 2',3'-Di-O-acetyluridine 5'-Monophosphate (11)

Commercially available disodium uridine 5'-monophosphate (500 mg, Aldrich) was suspended in a mixture of pyridine (6 mL) and *N*,*N*-dimethylformamide (6 mL) containing acetic anhydride (1 mL). The mixture was stirred at room temperature for 24 h, when tlc (chloroform–methanol–water 10:10:3) indicated the formation of a major compound, R_f 0.85. The mixture was evaporated to dryness, the residue dissolved in methanol, and the solution applied to three plates of silica gel (2 mm thickness), which were developed in the same solvent as that used for the analytical tlc. The band detected by uv visualization was scraped off and eluted with the same solvent, followed by evaporation to give a syrup. Nuclear magnetic resonance analysis showed that this compound had three acetyl groups. The syrup was dissolved in aqueous methanol–pyridine 1:9 (2 mL), and the mixture was stored at room temperature for 1–2 days. Thin-layer chromatographic analysis (same solvent as just described) indicated that a compound having R_f 0.6 was formed with the disappearance of the spot having R_f 0.85. The preparative tlc as just described gave syrupy **11**, which was dissolved in a small amount of methanol and precipitated by addition of acetone–ether 3:1 (72% yield). This material was suitable for synthetic purposes without further purification. To obtain an analytically pure sample of **11**, the product was dissolved in methanol and AG 50W-X8 cation-exchange resin (300 mg, pyridinium form) was added. The mixture was stirred for 2 h at room temperature, the resin filtered off and washed with methanol, and the combined filtrate and washings evaporated. The residue was dissolved in water, the pH adjusted to 7.5 by addition of 1 *M* lithium hydroxide solution, and the resulting solution concentrated to a small volume. Addition of ether–acetone (1:1) gave a precipitate of **11** as the solid dilithium salt, $[\alpha]_D^{20}$ +6.1° (*c* 0.14, CH_3OH). *Anal.* calcd. for $C_{13}H_{15}Li_2N_2O_{11}P \cdot CH_3OH \cdot 2H_2O$: C 34.44, H 3.92, N 5.74; found: C 34.93, H 3.93, N 6.20.

General Procedure for the Preparation of Dilithium Salts of Uridine 5'-(2-Acetamido-2-deoxy-α-D-hexopyranosyl Diphosphates)

2',3'-Di-*O*-acetyluridine 5'-monophosphate (**11**) and 2-acetamido-per-*O*-acetyl-2-deoxyhexopyranosyl phosphate were each converted into the tributylammonium salts by the procedure reported earlier (24).

The tributylammonium salt of **11** (52 mg, 0.13 mmol) was dissolved in 1,4-dioxane (2 mL) containing ca. 20 mg of tributylamine. To this solution was added dropwise diphenyl phosphorochloridate (38 mg, 0.145 mmol; 0.24 mL of a solution containing 140 mg in 1 mL of 1,4-dioxane) at room temperature under nitrogen. The mixture was stirred under the same conditions for 2 h, dry methanol (1 mL) added, and stirring continued for 5 min, followed by evaporation and co-evaporation of the residual solvent with toluene to give the syrupy diphosphate **12**. A solution of this compound in dry pyridine (1 mL) was introduced dropwise into a solution of the tributylammonium salt of the peracetylglycosyl phosphate (**5**, **7**, or **9**, 64 mg, 0.14 mmol) in dry pyridine (2 mL) under nitrogen. The mixture was stirred at room temperature for 8–10 h under nitrogen, followed by evaporation. Preparative tlc (chloroform–methanol–water 10:10:3, R_f ca. 0.4), and evaporation of the eluted material gave a syrup that solidified on addition of ether, to yield the 2',3'-di-*O*-acetyluridine 5'-(2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-hexopyranosyl diphosphates **14**, **16**, and **18**), in yields of 86, 82, and 80%, respectively.

O-Deacetylation of **14**, **16**, and **18** was performed by treatment with aqueous sodium hydroxide as follows. Compound **14**, **16**, or **18** (50 mg) was treated with a mixture of 1 *M* sodium hydroxide (0.55 mL) and water (2.5 mL) at room temperature for 1 h. The base was neutralized with AG 50W-X8 (pyridinium form, Bio-Rad) cation-exchange resin and the suspension filtered. The resin was washed with water and the combined filtrates were evaporated to a small volume that was applied to four 0.25 mm thick plates of silica gel. These were developed in chloroform–methanol–water (10:10:3). The band detected by uv light ($R_f \sim$ 0.2) was scraped off and eluted with the same solvent. In some cases, the product was not completely pure in tlc and it was necessary to perform a paper chromatography (Whatman No. 3 MM, ethanol – 1 *M* ammonium acetate 5:2). The compound eluted from the tlc plate or paper chromatogram was passed through a short column of Sephadex LH-20 or Bio-gel P-6 to remove traces of silica gel or cellulose. Evaporation to a small volume, adjustment of the pH to 7.5–8 with lithium hydroxide, and addition of methanol–acetone 1:4 afforded a precipitate of the desired compounds, **15** (94%), **17** (86%), or **19** (82%), respectively.

Dilithium Salt of Uridine 5'-(2-Acetamido-2-deoxy-α-D-mannopyranosyl Diphosphate) (15)

This compound showed $[\alpha]_D^{20}$ +16° (*c* 1.0, H_2O); ^1H nmr (D_2O) δ: 7.88 (d, 1H, $J_{5,6}$ = 8.0 Hz, H-6 of uracil), 5.90 (d, 1H, $J_{1',2'}$ = 4.0 Hz, H-1 of D-ribofuranosyl), 5.88 (d, 1H, $J_{5,6}$ = 8.0 Hz, H-5 of uracil), 5.37 (bd, 1H, $J_{1,P}$ = 8.0 Hz, H-1 of 2-acetamido-2-deoxy-D-mannopyranosyl), 5.0–3.8 (m, 9H), 3.83 (s, 2H, H-6a, -6b of 2-acetamido-2-deoxy-D-mannopyranosyl), and 2.00 (s, 3H, NAc). *Anal.* calcd. for $C_{17}H_{25}Li_2N_3O_{17}P_2 \cdot CH_3OH \cdot 3H_2O$: C 30.65, H 5.00, N 5.96; found: C 30.95, H 4.44, N 5.56.

This compound was previously reported (8) as the hygroscopic dipotassium salt, and no optical rotation was recorded.

Dilithium Salt of Uridine 5'-(2-Acetamido-2-deoxy-α-D-glucopyranosyl Diphosphate) (17)

This compound showed $[\alpha]_D^{20}$ +58° (*c* 1.0, H_2O) (lit. (25) $[\alpha]_D^{25}$ +54.6° (*c* 1.0, H_2O)); ^1H nmr (D_2O) δ: 7.83 (d, 1H, $J_{5,6}$ = 8.0 Hz, H-6 of uracil), 5.86 (d, 1H, $J_{5,6}$ = 8.0 Hz, H-5 of uracil), 5.84 (d, 1H, $J_{1',2'}$ = 4.0 Hz, H-1 of D-ribofuranosyl), 5.40 (dd, 1H, $J_{1',2'}$ = 3.2, $J_{1,P}$ = 7.2 Hz, H-1 of 2-acetamido-2-deoxy-D-glucopyranosyl), and 2.05 (s, 3H, NAc). *Anal.* calcd. for $C_{17}H_{25}Li_2N_3O_{17}P_2 \cdot 4H_2O$: C 29.54, H 4.81, N 6.08; found: C 29.80, H 4.34, N 5.58.

Dilithium Salt of Uridine 5'-(2-Acetamido-2-deoxy-α-D-galactopyranosyl Diphosphate) (19)

This compound showed $[\alpha]_D^{20}$ +81° (*c* 1.0, H_2O) (lit. (23) $[\alpha]_D^{25}$ +81.7° (*c* 0.8, H_2O)); ^1H nmr (D_2O) δ: 7.86 (d, 1H, $J_{5,6}$ = 8.0 Hz, H-6 of uracil), 5.93 (d, 1H, $J_{1',2'}$ = 3.8 Hz, H-1 of ribofuranosyl), 5.90 (d, 1H, $J_{5,6}$ = 8.0 Hz, H-5 of uracil), 5.60 (dd, 1H, $J_{1,2}$ = 3.0, $J_{1,P}$ = 7.8 Hz, H-1 of 2-acetamido-2-deoxy-D-galactopyranosyl), 4.4–4.1 (m), 4.05 (d), 3.95 (q, 1H, $J_{2,3}$ = 10.5, $J_{3,4}$ = 3.4 Hz, H-3 of 2-acetamido-2-deoxy-D-galacto-

pyranosyl), 3.80 (m, 2H), and 2.00 (s, 3H, NAc). *Anal.* calcd. for $C_{17}H_{25}Li_2N_3O_{17}P_2 \cdot 4H_2O$: C 29.54, H 4.81, N 6.08; found: C 29.89, H 4.37, N 5.52.

*Trilithium Salt of Uridine 5'-(2-Acetamido-2-deoxy-α-D-mannopyranosyluronate Diphosphate) (**20**)*

10% Platinum-on-charcoal (Fluka–Tridom, 300 mg) was added to a solution of **15** (32 mg) in a mixture of 4.2% aqueous sodium hydrogen carbonate (1.65 mL) and water (4.8 mL), and oxygen was bubbled into the suspension at 75°C for 7 h. After filtration, the mixture was concentrated to a small volume, and applied to a paper chromatogram (Whatman No 3 MM), which was developed in ethanol – 1 *M* ammonium acetate 5:2 (pH 7.5). Usually, three bands were detected by uv light (R_{UDP} 1.0, 2.43, and 4.52). The compound having R_{UDP} of 4.52 was unreacted starting material **15**. The band having R_{UDP} 2.43 was eluted with water and applied to a 0.25 mm thick tlc plate of silica gel, which was developed in chloroform–methanol–water 10:10:3. The band having R_f 0.2 was scraped off and eluted with the same solvent. Evaporation gave a syrup that was further purified on a Bio-Gel P-6 column (1 cm × 100 cm) with 0.5 *M* pyridinium acetate, pH 7.0. The pooled eluant was evaporated to a small volume, and 1 *M* lithium hydroxide solution was added to give a pH of 7.5–8. Addition of methanol–acetone 1:4 precipitated **20**, $[\alpha]_D^{20}$ +19° (*c* 0.2, CH_3OH); ^1H nmr (D_2O) δ: 7.90 (d, 1H, $J_{5,6}$ = 8.0 Hz, H-6 of uracil), 5.95 (d, 1H, $J_{1',2'}$ = 4.0 Hz, H-1 of ribofuranosyl), 5.92 (d, 1H, $J_{5,6}$ = 8.0 Hz, H-5 of uracil), 5.42 (bd, 1H, $J_{1,P}$ = 8.0 Hz, H-1 of 2-acetamido-2-deoxy-D-mannopyranosyluronic acid), 5.0–3.5 (m, 9H), and 2.05 (s, 3H, NAc). *Anal.* calcd. for $C_{17}H_{22}Li_3N_3O_{18}P_2 \cdot CH_3OH \cdot 3H_2O$: C 29.81, H 4.45, N 5.79; found: C 29.69, H 4.10, N 5.40.

J. A. HOWARD, J. E. BENNETT, and G. BRUNTON. Can. J. Chem. **59**, 2253 (1981).

Although it is generally accepted that the self-reaction of cumylperoxy radicals is a second-order process, recent reports have cast doubt on the overall validity of this assumption. Therefore we have reinvestigated some aspects of the self-reaction to clarify the kinetic and mechanistic features.

Our product studies are entirely consistent with the accepted mechanism for the self-reaction of cumylperoxy radicals and no evidence was obtained for competing reactions. Results obtained with $^{36}O_2$ labelled materials confirm the previous conclusion that reversible scission of cumylperoxy radicals to give oxygen and cumyl radicals does not compete significantly with the self-reaction at ambient temperatures. Kinetic studies, under both steady-state and transient conditions, establish clearly that the self-reaction of cumylperoxy radicals is a second order process. A possible explanation is proposed to account for the previous observations which indicated that the self-reaction was a first order process. Further, we show that the changes observed in the esr spectrum of the cumylperoxy radicals, which were attributed to the formation of a complex with cumyl hydroperoxide, are caused by changes in the viscosity of the solution.

J. A. HOWARD, J. E. BENNETT, et G. BRUNTON. Can. J. Chem. **59**, 2253 (1981).

De récentes publications ont mis en doute la validité de l'hypothèse généralement acceptée à l'effet que l'autoréaction des radicaux cumylpéroxy est une réaction d'ordre 2. Nous avons donc réexaminé quelques aspects de cette réaction afin d'en clarifier les caractéristiques cinétiques et mécanistiques.

Nos études sont entièrement en accord avec le mécanisme accepté pour l'auto-réaction des radicaux cumylpéroxy et nous n'avons pas trouvé de données permettant de croire qu'il existe des réactions en compétition. Les résultats obtenus avec des produits marqués au $^{36}O_2$ confirment ce qui a été trouvé antérieurement à savoir que, à la température ambiante la scission réversible des radicaux cumylpéroxy qui donne de l'oxygène et des racidaux cumyles n'entre pas en compétition de façon significative avec l'auto-réaction. Des études cinétiques tant dans des conditions d'état stationnaire que transitoire établissent clairement que l'auto-réaction des radicaux cumylpéroxy est d'ordre 2. On propose une explication possible des observations antérieures qui indiquent une réaction du premier ordre. De plus, nous montrons que les variations observées dans les spectres rpe des radicaux cumylpéroxy, qui ont été attribuées à la formation d'un complexe avec l'hydropéroxyde de cumyle, sont provoquées par des variations dans la viscosité de la solution.

[Traduit par le journal]

Introduction

It is generally accepted (1) that the self-reaction of cumylperoxy radicals ($PhCMe_2O_2^{\cdot}$) in solution, produced either by autoxidation of cumene ($PhCMe_2H$), induced decomposition of α-cumene hydroperoxide ($PhCMe_2OOH$), or photolysis of azocumene in an oxygenated-solvent can be described by reactions [1]–[3].

The existence of the equilibrium [1] has been demonstrated by electron spin resonance spectroscopy (2) and di-α-cumyl tetroxide is a reaction intermediate with an appreciable lifetime. Irreversible decomposition of $PhCMe_2O_4CMe_2Ph$ gives α-cumyloxy radicals and a fraction, f, of these radicals escape the solvent cage while a fraction $1 - f$ combine in the cage to give di-α-cumyl peroxide. The cumyloxy radicals produced by reaction [3b] either abstract a hydrogen atom from cumene, the solvent, or a reaction product such as cumene hydroperoxide, reactions [4] and [5], or they undergo β-scission to give acetophenone and a methyl radical, reaction [6]. Methyl radicals produced by this reaction combine rapidly with molecular oxy-

[4] $PhCMe_2O^{\cdot} + PhCMe_2H \xrightarrow{k_4} PhCMe_2OH + PhCMe_2^{\cdot}$

[5] $PhCMe_2O^{\cdot} + PhCMe_2OOH \xrightarrow{k_5} PhCMe_2OH + PhCMe_2O_2^{\cdot}$

[6] $PhCMe_2O^{\cdot} \xrightarrow{k_6} PhC(O)Me + Me^{\cdot}$

[7] $Me^{\cdot} + O_2 \longrightarrow MeO_2^{\cdot}$

[8] $MeO_2^{\cdot} + PhCMe_2H \longrightarrow MeOOH + PhCMe_2^{\cdot}$

[9] $MeO_2^{\cdot} + PhCMe_2OOH \longrightarrow MeOOH + PhCMe_2O_2^{\cdot}$

[10] $MeO_2^{\cdot} + PhCMe_2O_2^{\cdot} \xrightarrow{k_{10}} CH_2O + O_2 + PhCMe_2OH$

gen to give methylperoxy radicals which either abstract a hydrogen atom, reactions [8] and [9], or react with cumylperoxy by cross-termination reaction [10].

The overall termination rate constant ($2k_t$) for autoxidation of cumene is, therefore, given by the complex expression [11].

$$[11]\quad 2k_t = 2(1-f)k_2K_1 + 2fk_2K_1\frac{k_6}{k_6 + k_4[PhCMe_2H]} \times \frac{4k_{10}[PhCMe_2O_2^{\cdot}]}{4k_{10}[PhCMe_2O_2^{\cdot}] + k_8[PhCMe_2H]}$$

where $f = k_{3b}/(k_{3a} + k_{3b})$

Consequently the magnitude of $2k_t$ depends on k_2, K_1, f, the fraction of cumyloxy radicals which undergo β-scission, and the fraction of methylperoxy radicals which are consumed in the cross-termination reaction [10] (3, 4).

Over ten years ago, Thomas (5) made the important discovery that addition of *pure* $PhCMe_2OOH$ to $PhCMe_2H$ at 57.2°C increased the rate of autoxidation. This rate increase was not due to an increase in the rate of chain initiation, as might have been expected, but to a decrease in the overall termination rate constant ($2k_t$) because cumyloxy and methylperoxy radicals undergo the chain transfer reactions [5] and [9] rather than the cross-termination reaction [10].

The termination rate constant, $2k_t'$, when all the secondary-radicals undergo reactions [5] and [9], is equal to $2(1-f)k_2K_1$, which is the rate constant for reaction of two $PhCMe_2O_2^{\cdot}$ to give di-α-cumyl peroxide.

Kinetic and product studies of the autoxidation of $PhCMe_2O_2^{\cdot}$ have usually supported this mechanism (2–10). There have, however, been several recent reports which have cast considerable doubt on the overall validity of this mechanism.

First, Fukuzumi and Ono (11, 12) reported that $PhCMe_2O_2^{\cdot}$, prepared by oxidation of $PhCMe_2OOH$ using heterogeneous catalysts like manganese dioxide and cobalt oxide supported on silica, decay with *first*-order kinetics in the cavity of an esr spectrometer at 301 K. This result prompted these workers to propose a reaction mechanism which involves a slow unimolecular decomposition of $PhCMe_2O_2^{\cdot}$ to give acetophenone and methoxy followed by a fast reaction of methoxy with $PhCMe_2O_2^{\cdot}$ to give stable products.

[12] $PhCMe_2O_2^{\cdot} \longrightarrow PhC(O)Me + MeO^{\cdot}$

[13] $MeO^{\cdot} + PhCMe_2O_2^{\cdot} \longrightarrow$ stable products

These workers also invoked the formation of a 2:1 complex between cumene hydroperoxide and the cumylperoxy radical to explain the observed effect of concentration on the initial rate of oxygen evolution during the decomposition of cumene hydroperoxide by lead dioxide (13). In their treatment they assumed that the complexed cumylperoxy radical did not undergo self-termination. To support these postulates they showed that the observed variations in the line width and g-value of the cumylperoxy radical as a function of the concentration of cumene hydroperoxide were consistent with the formation of the complex.

Secondly, Belyakov, Vasil'ev, and Fedorova (14) have argued that the general features of the chemiluminescence emitted during autoxidation of $PhCMe_2H$ are not consistent with the energetics and products of reaction [10]. They concluded that a cross-termination reaction between 2-phenyl-1-propylperoxy radicals (produced by abstraction of a primary hydrogen atom from $PhCMe_2H$) and $PhCMe_2O_2^{\cdot}$ plays an important role in termination.

According to this mechanism, $2k_t$ is larger than $2k_t'$ because of the influence of reaction [15] on termination.

[14] $PhCMe_2O^{\cdot} + PhCMe_2H \xrightarrow{O_2} PhCMe_2OH + PhCH(Me)CH_2O_2^{\cdot}$

[15] $PhCH(Me)CH_2O_2^{\cdot} + PhCMe_2O_2^{\cdot} \longrightarrow PhCH(Me)CHO + PhCMe_2OH + O_2$

Thirdly, Nangia and Benson (15) have suggested that the value of $2k_t'$ at 303 K for $PhCMe_2O_2^{\cdot}$ ($6 \times 10^3\ M^{-1}\ s^{-1}$) is 5 times larger than $2k_t'$ for t-$BuO_2^{\cdot}$ ($1.2 \times 10^3\ M^{-1}\ s^{-1}$) because k_{3b}/k_{3a} for $PhCMe_2O_2^{\cdot}$ is less than k_{3b}/k_{3a} for t-$BuO_2^{\cdot}$. In other words, the

efficiency of cage escape for $PhCMe_2O^{\cdot}$ produced by decomposition of $PhCMe_2O_4CMe_2Ph$ is less than the efficiency for production of t-$BuO^{\cdot}$ by decomposition of t-BuO_4Bu-t. They have also concluded from thermochemical calculations that β-scission of $PhCMe_2O_2^{\cdot}$ [16] at ambient temperatures and normal oxygen pressures is not fast enough to produce a significant steady-state concentration of cumyl radicals. Thus $2k_t$ for autoxidation of cumene should not contain a contribution from the rate constant for reaction of cumyl with cumylperoxy radicals [17].

[16] $PhCMe_2O_2^{\cdot} \longrightarrow PhCMe_2^{\cdot} + O_2$

[17] $PhCMe_2^{\cdot} + PhCMe_2O_2^{\cdot} \longrightarrow PhCMe_2OOCMe_2Ph$

In the present paper we present a thorough product study of the autoxidation of $PhCMe_2H$ at 303 K and at oxygen pressures from 0.5 to 100 atm with particular emphasis on the products of the self-reaction of $PhCMe_2O_2^{\cdot}$ and of the induced decomposition of $PhCMe_2OOH$ under an atmosphere of $^{36}O_2$. In addition, we report some new kinetic data for autoxidation of $PhCMe_2H$ and the self-reaction of $PhCMe_2O_2^{\cdot}$. The results of all this work are discussed in terms of the mechanisms for the self-reaction of tertiary aralkylperoxy radicals.

Experimental

Materials

Cumene, α-cumene hydroperoxide, chlorobenzene, α,α'-azo-bis-isobutyronitrile, α-cumyl alcohol, acetophenone, α-methylstyrene, and di-α-cumyl peroxide were obtained from commercial sources and were purified by standard procedures. Di-*tert*-butyl hyponitrite (16), azocumene (17), and di-α-cumyl hyponitrite (18) had been prepared previously in our laboratory. 2,2,3,3,-Tetraphenylbutane (19, 20) was a gift from Dr. L. R. Mahoney (Ford Motor Co., Dearborn). $^{36}O_2$ (99.1 at.%) was obtained from Merck, Sharp and Dohme Canada Ltd. 1-Methyl-1-phenyloxirane was prepared from α-methylstyrene and *m*-chloroperbenzoic acid (Aldrich) by the method of Bissing and Speziale (21).

Initiators

The initiators, In_2, used for thermally initiated autoxidations were di-*tert*-butyl hyponitrite, DTBH ($e = 0.9$, $k_d = 2.92 \times 10^{-6}$ s^{-1}), and 2,2,3,3,-tetraphenylbutane, TPB ($e = 1.0$, $k_d = 2.1 \times 10^{-6}$ s^{-1}), where e is the efficiency of radical production and k_d is the rate constant for unimolecular decomposition at 303 K. DTBH was also used as the thermal source of *tert*-butoxy radicals for product studies of induced decomposition of cumene hydroperoxide and measurement of steady-state cumylperoxy radical concentrations by esr spectroscopy.

Procedures

Rates of autoxidation at oxygen pressures from 0.1 to 1 atm were measured as described previously (22).

Radical Production

Cumylperoxy radicals were formed in the cavity of a Varian E-4 EPR spectrometer by photolysis of oxygen-saturated solutions of di-*tert*-butyl peroxide in cumene; cumene hydroperoxide in toluene, cumene, and *n*-hexane; azocumene in 2,2-dimethylbutane; and by thermolysis of di-*tert*-butyl hyponitrite in cumene. Steady-state radical concentrations were measured at different concentrations of the thermal initiator and at different light intensities for photochemically initiated reactions. Radical decays after the initiating light was masked were followed by standard procedures (23) and absolute radical concentrations were measured relative to a standard solution of DPPH.

Product Studies

Cumene, containing a thermal initiator in a Pyrex reactor, was either shaken rapidly with oxygen at 0.4 and 1 atm or allowed to react with O_2 at 10 and 100 atm in a high pressure stainless steel device to 5–10% conversion. The products were analysed by hplc before reduction and by glc and glc–ms after quantitative reduction of accumulated hydroperoxide with triphenylphosphine.

Cumene hydroperoxide in chlorobenzene (1 mL) was allowed to react with thermally generated *tert*-butoxy radicals from DTBH in a closed Pyrex vessel (130 mL) at 303 K under an atmosphere of $^{36}O_2$ for ten half-lives of the initiator (24). Products were identified and yields determined by standard hplc and glc procedures. Oxygen containing products, with the exception of hydroperoxides and peroxides, were analysed for ^{18}O content by mass spectrometry. The percentage of $PhCMe_2$-^{18}OH in cumyl alcohol was estimated from the ratio of peaks at m/e = 123 and 121 corresponding to m/e = parent minus 15, after correction for natural abundance ^{18}O. The percentage of $PhC(^{18}O)Me$ in PhC(O)Me was obtained from the relative intensities of the peaks at m/e = 122, 120, 107, and 105.

The production of trace amounts of 1-methyl-1-phenyl oxirane from the induced decomposition of $PhCMe_2OOH$ was deduced from the presence in the mass spectrum of a parent peak at m/e = 134.

Viscosity measurements were made with a suspended level viscometer and using standard experimental procedures (25).

Instruments

The high performance liquid chromatograph was a Waters ALC 201 model fitted with a UV detector and reverse phase column (Waters 0.65 cm id × 27 cm, μBondapak C_{18}). The initial eluting solvent was a mixture of acetonitrile and water (25:75 v/v) and the percentage of CH_3CN was gradually increased to 75% by solvent programming. A Varian 2800 gas chromatograph equipped with FC 431, FFAP, and OV-101 columns was used for glc analyses. The gc–ms analyses utilized the same columns with a Finnigan 4000 automated gas chromatograph/EI-CI mass spectrometer system, operated in the electron impact mode.

Results

Products of Autoxidation of Cumene

Analysis of cumene which had been autoxidized at 303 K and oxygen pressures from 0.4 to 100 atm for 25–35 h by hplc revealed that α-cumene hydroperoxide, α-cumyl alcohol, acetophenone, and di-cumyl peroxide were the major reactions products and that they were formed in the yields given in Table 1. Yields of $PhCMe_2OOH$ were confirmed by iodometric titration and by glc analyses for $PhCMe_2OH$ after reduction with Ph_3P. Gas–liquid chromatography also revealed the formation of a trace of α-methylstyrene.

The total concentration of oxygen absorbed by

[a] From the initiator tetraphenylbutane.

$PhCMe_2H$ was determined for the run at 1 atm of O_2 and it was approximately equal to the final concentration of $PhCMe_2OOH$, indicating a long kinetic chain length. All the other runs gave final hydroperoxide concentrations consistent with the oxidizability of $PhCMe_2H$, $k_p/(2k_t)^{\frac{1}{2}} = 1.5 \times 10^{-3}\ M^{-\frac{1}{2}}\ s^{-\frac{1}{2}}$ (26), the average calculated rate of chain initiation, R_i, and the total reaction time, t, i.e., $[PhCMe_2OOH]_f = k_p[PhCMe_2H]R_i^{\frac{1}{2}}t/(2k_t)^{\frac{1}{2}}$.

1,1-Diphenylethyl hydroperoxide was well separated from $PhCMe_2OOH$ by hplc and yields of this product from 2,2,3,3-tetraphenylbutane (TPB) initiated reactions were of the order of 85–100%, based on the total quantity of 1,1-diphenylethylperoxy radicals generated by thermolysis of tetraphenylbutane.

Di-cumyl peroxide was produced in the yields given in the penultimate column in Table 1 and these yields were compatible with yields calculated from

$$[18]\quad [PhCMe_2OOCMe_2Ph] = k_t'\,[PhCMe_2O_2\cdot]^2_{qs}t$$

and

$$[19]\quad [PhCMe_2O_2\cdot]_{qs} = (R_i/2k_t)^{\frac{1}{2}}$$

where $[PhCMe_2O_2\cdot]_{qs}$ is the quasi steady-state concentration of cumylperoxy radicals and $2k_t' = 6 \times 10^3\ M^{-1}\ s^{-1}$ and $2k_t = 1.5 \times 10^4\ M^{-1}\ s^{-1}$ (26).

Total concentrations of $PhCMe_2OH$ and PhC(O)Me were 10 to 40 times larger than concentrations of $PhCMe_2OOCMe_2Ph$, giving a rate constant ratio, $k_{3b}/k_{3a} = 5$ to 20 which can be compared with our previous estimate of 6.3 from the induced decomposition of cumene hydroperoxide (27). These results suggest that cumyloxy radicals are produced with an efficiency of 83–94% by decomposition of di-cumyl tetroxide which is similar to the efficiency with which alkoxy radicals are produced by thermolysis of di-*tert*-alkyl hyponitrites (17, 28).

Final ratios of $PhCMe_2OH$ to PhC(O)Me were quite high and were dependent on the final concentration of $PhCMe_2OOH$. This is because $PhCMe_2OOH$ is ~30 times more reactive than cumene to $PhCMe_2O\cdot$. Thus decomposition of di-α-cumyl hyponitrite in $PhCMe_2H$ (7.1 *M*) containing $PhCMe_2OOH$ (0.1 *M*) gave $[PhCMe_2OH]/[PhC(O)Me] = 30.5$, whereas in the absence of the hydroperoxide this ratio was 21.3.

Induced Decomposition of Cumene Hydroperoxide under an Atmosphere of $^{36}O_2$

$PhCMe_2OOH$ (0.62 *M*) in chlorobenzene was completely decomposed by thermally generated *t*-BuO· (0.1 *M*) in 30 days at 303 K under $^{36}O_2$ to acetophenone, α-cumyl alcohol, and di-α-cumyl peroxide in the yields given in Table 2. α-Methylstyrene was produced in low yields while 1-methyl-1-phenyloxirane was formed in trace amounts. In this experiment the total yield of $PhCMe_2OH$ and PhC(O)Me was about 20 times larger than the yield of $PhCMe_2OOCMe_2Ph$ and the final ratio of $PhCMe_2OH$ to PhC(O)Me was 6.

Under these conditions the final atmosphere contained 25% $^{32}O_2$ and both PhC(O)Me and $PhCMe_2OH$ were enriched in ^{18}O. Somewhat surprisingly, however, the percentage enrichment of PhC(O)Me (7.6%) was larger than the percentage enrichment of $PhCMe_2OH$ (1.25%), a difference that was confirmed by repeated analyses using different gas chromatography columns for product separation and preparative hplc to separate the alcohol and ketone from the rest of the reaction mixture.

The formation of $PhCMe_2{}^{18}OH$ from cumylperoxy radicals generated in the presence of $^{36}O_2$ means that these radicals must exist in equilibrium with cumyl radicals and oxygen at 303 K. It is clear from reactions [1] to [6] that there should have been no difference in the percentage enrichment of α-cumyl alcohol and acetophenone. The difference that we observed must have resulted from enrichment of the acetophenone by a nonradical process involving reaction of acetophenone with $H_2{}^{18}O$ formed in the autoxidation.

$$[20]\quad PhC(=O)Me + H_2{}^{18}O \rightleftharpoons PhC(OH)(^{18}OH)Me \rightleftharpoons PhC(=\,^{18}O)Me + H_2O$$

Reaction of the methyl radicals formed in reaction [7] with $^{36}O_2$ is an obvious route to $H_2{}^{18}O$ and the acid (formic) necessary to catalyse this exchange.

$$[21]\quad Me^{\cdot} + {}^{36}O_2 \longrightarrow Me^{36}O_2{}^{\cdot}$$

$$[22]\quad Me^{36}O_2{}^{\cdot} + PhCMe_2OOH \longrightarrow Me^{36}O_2H + PhCMe_2O_2{}^{\cdot}$$

$$[23]\quad Me^{36}O_2H \longrightarrow Me^{18}O^{\cdot} + {}^{18}OH \longrightarrow H_2{}^{18}O$$

$$[24]\quad Me^{36}O_2{}^{\cdot} + RO_2{}^{\cdot} \longrightarrow CH_2{}^{18}O + O_2 + ROH$$

$$[25]\quad CH_2{}^{18}O + O_2 \longrightarrow CH(^{18}O)OH$$

Kinetics of the Autoxidation of Cumene

Steady-state Studies

Rates of autoxidation of cumene initiated by thermolysis of α,α′-azobisisobutyronitrile and by photolysis of α,α′-azobiscyclohexane carbonitrile have been shown previously to be proportional to the square root of the initiator concentration and the light intensity, respectively (3, 5, 6, 8). Our present results show that steady-state concentrations of $PhCMe_2O_2{}^{\cdot}$ (generated by thermolysis of di-*tert*-butyl hyponitrite in oxygenated cumene) are *exactly* proportional to the square root of the thermal initiator concentration (Fig. 1). The overall rate of termination (R_t) is, therefore, given by

$$R_t = 2k_t\,[PhCMe_2O_2{}^{\cdot}]^2_{ss}$$

There is, therefore, no steady-state kinetic evidence for a termination reaction that is first-order with respect to $[PhCMe_2O_2{}^{\cdot}]$, analogous to the one that occurs during autoxidation of styrene (29).

In addition, rates of autoxidation of cumene or cumene containing cumene hydroperoxide, at a constant rate of chain initiation, do not depend on the pressure of oxygen above the liquid at oxygen pressures in the range 50–700 Torr. This indicates that the termination reaction [17] is not kinetically important.

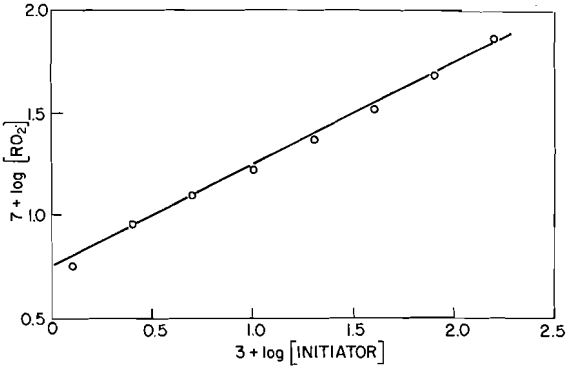

FIG. 1. A plot of log $[RO_2{}^{\cdot}]_{ss}$ against log[initiator] for the *tert*-butyl hyponitrite initiated autoxidation of cumene at 303 K.

Non-steady-state Studies

Plots of $[PhCMe_2O_2{}^{\cdot}]^{-1}$ against time for the disappearance of $PhCMe_2O_2{}^{\cdot}$ (prepared by photolysis of azocumene in oxygen-saturated 2,2-dimethylbutane for ~3 s at 303 K) were accurately linear indicating second-order radical decay with a rate constant $k_{esr} = (6.3 \pm 0.5) \times 10^4\ M^{-1}\ s^{-1}$. This rate constant is not equal to $2k_t$ or $2k_t'$ because it contains contributions from rate constants for the cross-termination of $PhCMe_2O_2{}^{\cdot}$ with peroxy radicals formed by reaction of $PhCMe_2O^{\cdot}$ (from reaction [3b]) with the solvent. The important point is, however, that the radical decays followed *second*-order kinetics.

Cumylperoxy radicals which were generated by longer periods of continuous photolysis still decayed with second-order kinetics. However, the steady-state radical concentrations were lower and values of k_{esr} were up to a factor of 3 times larger.

When toluene was used as the solvent instead of 2,2-dimethylbutane the plot of $[PhCMe_2O_2{}^{\cdot}]^{-1}$ against time for radicals produced after 3 s photolysis showed pronounced upward curvature. In fact, plots of ln $[PhCMe_2O_2{}^{\cdot}]$ against time were linear, indicating first-order radical decay, almost certainly because reaction of $PhCMe_2O_2{}^{\cdot}$ with the solvent was rate controlling.

Decays of $PhCMe_2O_2{}^{\cdot}$ prepared by photolysis of $PhCMe_2OOH$ in $PhCMe_2H$ and n-C_6H_{14} could not be analysed in terms of either second or first-order kinetics. Plots of $[PhCMe_2O_2{}^{\cdot}]^{-1}$ against time exhibited marked upward curvature even for radicals prepared after only 3 s photolysis of a freshly prepared solution. Furthermore, initial rates of radical decay increased as the length of continuous photolysis was increased.

Viscosity Measurements

Measured values for the viscosity of solutions of different concentrations of cumene hydroperoxide in carbon tetrachloride are summarized in Table 3. Over the concentration range studied (which is comparable to that used by Fukuzumi and Ono (11–13) for their esr studies) the viscosity varies, markedly, increasing four-fold between 0.5 and 5.0 M. We conclude, therefore, that in this concentration range, viscosity effects are likely to play a significant role in determining solution properties. As discussed below, they can provide an explanation for the concentration dependence of the line width and g-value of the esr spectrum of the cumylperoxy radical.

Discussion

Page 2253. In the discussion section of the paper the corrected ratio of $[PhCMe_2{}^{36}O_2{}^{\cdot}]/[PhCMe_2O_2{}^{\cdot}]$ should have been 0.015 and not 0.05 and Nangia and Benson's estimated of $\Delta H_{16}{}^0$ was −20.2 kcal mol^{-1} and not −10.2 kcal mol^{-1}.

ERRATA

reactions [1] to [16]. We could find no evidence for the formation of products from termination reactions of 2-phenyl-1-propylperoxy radicals, indicating that the involvement of these radicals in the rate-controlling termination reactions is not important at ambient temperatures. Thus we are unable to concur with the conclusions reached by Belyakov *et al.* (14), on the basis of chemiluminescence studies, that these radicals play an important role during the autoxidation of cumene.

It is possible to calculate a value for the rate constant for β-scission of $PhCMe_2O_2{}^{\cdot}$ radicals, k_{16}, from our product yields in the presence of $^{36}O_2$ and $PhCMe_2OOH$. Under these conditions:

$$+\frac{d[PhCMe_2{}^{36}O_2{}^{\cdot}]}{dt} = k_{16}[PhCMe_2O_2{}^{\cdot}] - k_{dis}[PhCMe_2{}^{36}O_2{}^{\cdot}][PhCMe_2OOH]$$

and in steady-state,

$$k_{16} = \frac{k_{dis}(PhCMe_2{}^{36}O_2{}^{\cdot}][PhCMe_2OOH]}{[PhCMe_2O_2{}^{\cdot}]}$$

where k_{dis} is the rate constant for reaction of $RO_2{}^{\cdot}$ with ROOH and can be assumed to be ca. 570 M^{-1} s^{-1} at 303 K (30). The ratio of $PhCMe_2{}^{18}OH$ to $PhCMe_2OH$ of 0.0125 (Table 2) gives $[PhCMe_2{}^{36}O_2{}^{\cdot}]/[PhCMe_2O_2{}^{\cdot}] = 0.05$ (after correction for $^{32}O_2$ evolved in the reaction). At an average hydroperoxide concentration of 0.31 M, the rate constant k_{16} is ca. 2 s^{-1}. Therefore, assuming $k_{-16} = 10^{9.5}\ M^{-1}$ s^{-1} (31), the equilibrium constant, K_{16}, is estimated to be $1.6 \times 10^9\ M^{-1}$, which is in good agreement with the value of $10^9\ M^{-1}$ estimated by Nangia and Benson from $\Delta S^0{}_{16} = -25.8$ gibbs mol^{-1} and $\Delta H^0{}_{16} = -10.2$ kcal mol^{-1} (15).

The steady-state concentration of $PhCMe_2{}^{\cdot}$ at 1 atm of O_2 ($10^{-2}\ M$) is, therefore, ca. 6×10^{-8} $[PhCMe_2O_2{}^{\cdot}]\ M$, and if k_{17} is $10^8\ M^{-1}$ s^{-1} (32), the rate reaction [17] can be calculated to be ca. 6 $[PhCMe_2O_2{}^{\cdot}]^2\ M$ s^{-1} which is insignificant compared to the rate of self-reaction of $PhCMe_2O_2{}^{\cdot}$ to give $PhCMe_2OOCMe_2Ph$. The results of our product studies are consistent with the conclusion of Nangia and Benson (15) that, at ambient temperatures and normal oxygen pressures, the β-scission of cumylperoxy radicals is not fast enough to produce a significant steady-state concentration of cumyl radicals and that $2k_t$ for autoxidation of cumene does not contain a contribution from the rate constant for reaction of cumyl with cumylperoxy radicals.

The yields of di-cumyl peroxide reported in Table 1 are consistent with a value for $2k_t' = 6 \times 10^3\ M^{-1}$ s^{-1} and yields of acetophenone plus cumyl alcohol relative to di-cumyl peroxide are consistent with k_{3b}/k_{3a} in the range 5–20. This is comparable with a previous estimate of 6.3 (27) and with the analogous ratio for the *tert*-butylperoxy radical, for which k_{3b}/k_{3a} is estimated to be in the range 6–10 (27, 33). The ratio k_{3b}/k_{3a} is thus comparable for the two alkylperoxy radicals within experimental error, and differences in the ratio cannot account for the factor of 5 difference between $2k_t'$ for the two radicals. For the five-fold difference to be accounted for solely in terms of different k_{3b}/k_{3a} ratios (i.e. different values of f, the efficiency of cage escape) the value of k_{3b}/k_{3a} for $PhCMe_2O_2{}^{\cdot}$ would have to be at least a factor of ten less than the lower limit of the experimental data. We propose that the difference in the values of $2k_t'$ for cumylperoxy and *tert*-butylperoxy radicals is due to a difference in k_2, the rate constant for unimolecular decomposition of the tertiary alkyl and aralkyl tetroxides. A difference in the stability of these two tetroxides is not unreasonable in view of Kiefer and Traylor's findings (28) that di-α-cumyl hyponitrite decomposes 10 times faster than di-*tert*-butyl hyponitrite.

Steady-state rates of termination for autoxida-

tion of cumene are accurately second-order with respect to the concentration of alkylperoxy radicals. Non-steady-state decays of cumylperoxy radicals are dependent on the initiator and solvent systems. In an alkane solvent, cumylperoxy radicals generated by photolysis of azocumene decay by clean second-order kinetics. In toluene, the decay at 294 K is first-order due to the dominance of reaction with the solvent:

[26] $PhCMe_2O_2^{\cdot} + PhCH_3 \longrightarrow PhCMe_2OOH + PhCH_2^{\cdot}$

A similar solvent effect has been observed for the decay of *tert*-butylperoxy radicals.[2]

Cumene hydroperoxide is a much less satisfactory radical source, the decay of cumylperoxy radicals produced by photolysis of the hydroperoxide obeyed neither first-order nor second-order kinetics. It should be noted that a great deal of care and patience has to be exercised to obtain cumene hydroperoxide free of phenol. The presence of even a trace of this decomposition product is likely to have a significant effect on the kinetic observations, because of the rapid rate of reaction between phenol and a tertiary alkylperoxy radical (34). Our observation that initial rates of radical decay increased as the length of continuous photolysis was increased is also consistent with the formation of a reactive decomposition product.

We believe, therefore, that first-order decays observed by time resolved esr spectroscopy for $PhCMe_2O_2^{\cdot}$ prepared by heterogenous decomposition of the hydroperoxide are fortuitous and are a result of reaction with either the solvent or adventitious impurity. This impurity could be a phenol or a transition metal ion, either of which would react with $PhCMe_2O_2^{\cdot}$ by a pseudo-first-order process. The inability to detect an esr spectrum from the transition metal ion initiator does not necessarily mean that it is insoluble, because the spectrum may be broad and the sensitivity correspondingly low. Concentrations of initiator below the limit detectable by esr could still be sufficient to markedly influence the radical kinetics (35).

At the high cumene hydroperoxide concentrations used by previous workers, viscosity effects will play an important role. The line width arising from the spin–rotation interaction is given by

$$\Delta H \propto \Delta g\ ^2T/a^3\ \eta$$

where Δg is the mean shift in g-value from the free spin value, T is the absolute temperature, a the mean diameter of the radical, and η is the solvent viscosity.

[2]J. E. Bennett and G. Brunton, unpublished results.

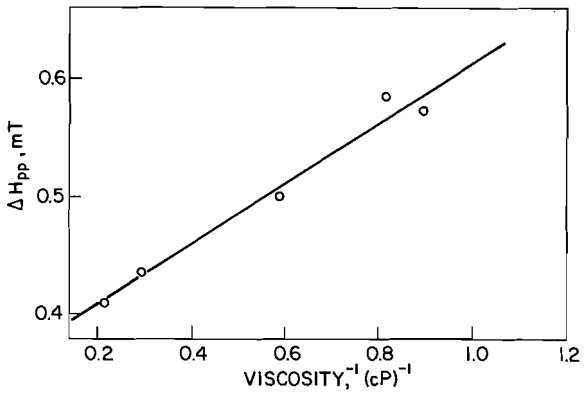

FIG. 2. Plot of peak-to-peak line width of cumylperoxy radical against viscosity of solution of cumene hydroperoxide in carbon tetrachloride.

Our results show that for a range of solutions of cumene hydroperoxide the plot of the reciprocal of the viscosity versus the line width of the cumylperoxy radical is linear (Fig. 2), which is in agreement with the above relationship. Thus the variations of line width with concentration observed by Fukuzumi and Ono (13) can be explained adequately by viscosity effects, and do not provide unambiguous evidence for a complex between cumylperoxy radicals and the hydroperoxide.

Similarly, the small g-value variations observed by these workers (13) can be explained by viscosity effects. An increase in the viscosity of the solution will cause a reduction in the degree of rotational averaging of the anisotropic components of the g-tensor. This effect will produce an apparent shift in the measured g-value as the anisotropic terms become more important.

Overall our studies show that cumene hydroperoxide is not a very satisfactory source of cumylperoxy radicals for esr investigations, and spectra and kinetic results obtained using this source should be interpreted with extreme caution.

MICHELANGELO PARRILLI, ROSA LANZETTA, VINCENZO DOVINOLA, MATTEO ADINOLFI, and LORENZO MANGONI. Can. J. Chem. **59**, 2261 (1981).

A mixture of at least four glycosides has been isolated from bulbs of *Muscari comosum*. Acidic methanolysis of this mixture afforded a crystalline fraction consisting of four diols **1***a* differing in the configuration at the epimerizable C-20 and/or C-24 centers. Benzoylation of this diol fraction allowed the isolation of one pure dibenzoate, mp 175–176°C, to which structure **1***b* was assigned on the basis of chemical and spectral evidence. This allowed the deduction that one of the aglycone moieties was 27-norlanostane triterpene eucosterol **4***a*. This conclusion has been confirmed by identification of **4***a* as the major product of the enzymatic hydrolysis of the glycoside mixture.

MICHELANGELO PARRILLI, ROSA LANZETTA, VINCENZO DOVINOLA, MATTEO ADINOLFI et LORENZO MANGONI. Can. J. Chem. **59**, 2261 (1981).

A partir des bulbes de *Muscari comosum*, on a isolé un mélange contenant au moins 4 glycosides. La méthanolyse acide de ce mélange permet d'obtenir une fraction cristalline consituée de 4 diols (**1***a*) qui diffèrent par la configuration au niveau des centres épimérisables C-20 ou C-24 ou les deux à la fois. La benzoylation de ces diols permet d'isoler un dibenzoate à l'état pur de pf 175–176°C auquel on attribue la structure **1***b* en se basant sur des preuves chimiques et spectroscopiques. Ceci permet de conclure que l'une des portions aglycone est l'eucostérol **4***a* un terpène de la famille du nor-27 lanostane. On a confirmé cette conclusion en identifiant le composé **4***a* comme produit principal de l'hydrolyse enzymatique du mélange de glycosides.

[Traduit par le journal]

The bulbs of *Muscari comosum* Mill. (Liliaceae) are a rather popular food in the Mediterranean area and are well known for their bitter taste. The aqueous extract from the plant has been reported (2) to display antitumoral activity. Following a preliminary communication (1), in this paper we present details of the structural elucidation of the products obtained by methanolysis of a glycoside mixture extracted from the bulbs and of the isolation of the authentic aglycones obtained by enzymatic hydrolysis.

Fresh sliced bulbs were extracted with boiling acetone and the resulting crude extract was washed with various solvents and fractionated by column chromatography (cellulose). Elution with water-saturated *n*-butanol gave a fraction glycosidic in nature according to the ^{1}H nmr signals in the δ 3.0–3.8 zone and the ^{13}C nmr signals in the δ 97–110 zone (3). Although tlc (cellulose) showed it to consist of at least four main compounds all migrating in a narrow range of R_f, any attempt to isolate pure glycosides yielded very poor results. Also on account of the possibility, then rejected, that they differed only in their sugar moieties, we decided to submit the whole glycoside mixture to acidic methanolysis in refluxing hydrochloric methanol.

Chromatography of the chloroform fraction of the crude product afforded a main crystalline fraction which ran as one spot on thin layers of silica gel but melted over a wide temperature range (142–155°C) in spite of repeated crystallizations. The ir and uv spectra showed the presence of hydroxyl and conjugated (and possibly unconjugated) keto groups. Spectral and chemical investigation of some readily accessible derivatives showed that the fraction consisted of four dihydroxy compounds with structure **1***a* and differing in the configuration at C-20 and/or C-24.

Benzoylation (BzCl/Py) followed by plc gave two main fractions. Their mass spectra displayed the same molecular ion peak (694 *m/e*) and, most important, an identical fragmentation pattern. On crystallization from ethanol, the less polar fraction gave finally a pure compound (mp 175–176°) having a formula of $C_{44}H_{54}O_7$ (hrms), to which was attributed structure **1***b* (the C-20 and C-24 configuration remaining unestablished) on the basis of the following evidence.

The ir spectrum of the compound melting at 175–176°C displayed ester and keto group bands, but no hydroxyl band. The ^{1}H nmr spectrum (see

1*b* R = R′ = COC_6H_5
1*c* R = R′ = Ac
1*d* R, R′ = $>C(CH_3)_2$

Fig. 1) clearly indicated the presence of four tertiary methyl groups, one secondary methyl, one primary methyl, and one methoxyl group and of one olefinic proton. It was also evident that benzoylation had occurred at a primary and at an equatorial secondary hydroxyl group (AB q at δ 4.58 and δ 4.78, J_{AB} = 12.5 Hz; dd at δ 4.92, $W_{1/2}$ = 21 Hz). The ^{13}C nmr spectra (proton decoupled, noise off resonance decoupled and single frequency off resonance decoupled) allowed detection of the signals (see Table 1) due to the carbons of a keto group (δ 211.0), of a >C=CH—CO— system (δ 185.8, 123.4, 209.5, respectively), besides two ester carbonyl groups (δ 166.4 and 167.2). The signals due to the carbons implied by one tetrasubstituted double bond (δ 132.9 s and 135.3 s) were also present in the sp^2 carbon zone. The signals of six methyl, one methoxyl, eight methylene, one oxymethylene, two methine, and two oxymethine groups and of four quaternary carbons were also observed.

TABLE 1. ^{13}C nmr (67.88 MHz) chemical shifts of dibenzoate melting at 175–176°C in $CDCl_3$ and tentative assignments of the signals[a]

[a]In ppm relative to TMS. Assignments are based on data from refs. 3, 4, and 5.
[b,d]Those assignments could be reversed.
[c]Corrected value (1).

With all the unsaturated functional groups thus established, a tetracyclic structure was to be assumed for the compound to account for the whole number of unsaturations implied by the molecular formula.

The structure of the side chain was deduced essentially from the ^1H nmr spectrum. Decoupling experiments showed that the primary methyl at δ 0.91 and the proton appearing at δ 3.53 are both coupled by the same constant value with the —CH_2— group appearing as a quintuplet at δ 1.66. These data accorded with the fragment —CO—$CH(OCH_3)$—CH_2—CH_3. On the other hand, irradiation of the sextet centered at δ 3.09 (1H) caused the further coupling of the AB q at δ 2.75 to disappear, the olefinic signal at δ 5.54 to sharpen, and the methyl doublet at δ 1.13 to coalesce into a singlet. This was rationalized by assigning the signal at δ 3.09 to the 20-proton and the double AB q at δ 2.75 to the 22-protons. The chemical shift of these latter was consistent with their adjacency to the (23)CO. Accordingly, a loss of 115 mass units due to fragmentation at the (20)C—(22)C bond was measured in the mass spectrum.

The structure of the side chain being so established (the stereochemistry at C-20 and C-24 excepted), the sharpening of the signal at δ 5.54 upon irradiation of the 20-H signal indicated that the olefinic proton was located at C-16. In an expanded spectrum the signal at δ 5.54 was observed actually to be a doublet with J = 0.6 Hz, this value according with an allylic 16,20 coupling. On the other hand, the chemical shift value suggested that this proton was located at the α-position of an α,β-unsaturated carbonyl system. Thus the conjugated keto group responsible for the cyclopentenone absorption (6) at 238 nm in diols **1***a* had to be at C-15.

The 8,9-location for the tetrasubstituted double bond discerned in the ^{13}C nmr spectrum was deduced from the obtaining of enedione **2** upon oxidation of the dibenzoate having mp 175–176°C with CrO_3 in glacial AcOH. In fact, the uv spectrum of **2** displayed a band at 273 nm (ε = 8000) which is diagnostic of an all-*trans* O=C—C=C—C=O

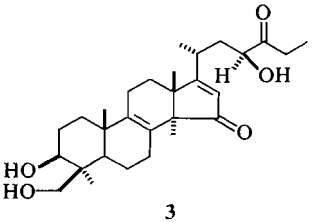
chromophore of a 7,11-diketo-$\Delta^{8,9}$-tetracyclic triterpene (7).

The diastereoisomeric relationship among diols **1***a* was shown by ^{1}H nmr examination of the remaining dibenzoate fractions. The signals of the spectrum of the solid left from evaporation of the mother liquors allowed the presence of a second diastereoisomeric dibenzoate to be inferred. On the other hand, the signals of the spectrum of the more polar fraction indicated that this latter was a mixture of two more diastereoisomers. Conclusive evidence that the four dibenzoates differ in the configuration at the epimerizable C-20 and C-24 centers came from hydrolysis both under acidic and alkaline conditions of the pure **1***b* melting at 175–176°C, which did not give a pure diol in any case but did lead to a mixture identical (^{1}H nmr) with that resulting from methanolysis of the glycosides.

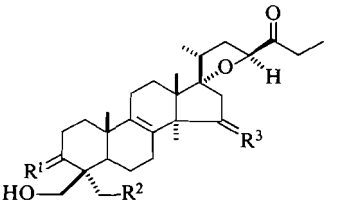
Acetylation (Ac_2O/Py) of the diol mixture from the methanolysis yielded an unseparable mixture of diacetates **1***c* whose relevant ^{1}H nmr signals at δ 4.27 (AB q, —C*H*$_2$—OAc) and δ 4.59 (m, $W_{1/2}$ = 21 Hz, >C*H*OAc) could be regarded as the signals generally detected for the 4β-C*H*$_2$OAc and (3)C*H*$_\alpha$OAc protons, respectively, in the A-ring of a triterpene diol acetate (8). On the other hand, reaction of the diol mixture with dry acetone/$CuSO_4$ gave an unseparable mixture of acetonides **4***d*, showing that the arrangement of the two hydroxyl groups was suitable for the closure of a di-*O*-isopropylidene ring.

All above data accorded with the structure **1***b* (or its euphanic counterpart) for the dibenzoate melting at 175–176°C and its accompanying stereoisomers. However, lanostane structure **1***a* turned out to be closely related to that of the compound **3**,



3

a product of alkali-catalyzed retroaddition from eucosterol **4***a*, a biogenetically interesting norlanostane triterpenoid missing the side-chain 27-carbon and carrying a spirofused tetrahydrofuran ring, previously found as a free compound in some *Eucomis* species (9). Therefore we suspected stereoisomeric diols might be not the authentic aglycones but artefacts from eucosterol. In fact, retroaddition from **4***a* to **3** may also be promoted by acid and more than one path leading from **3** to **1***a*



4*a* R^1 = β-OH, α-H; R^2 = H; R^3 = O
4*b* R^1 = R^3 = O; R^2 = H
4*c* R^1 = β-OH, α-H; R^2 = OH; R^3 = H_2
4*d* R^1 = O; R^2 = OH; R^3 = H_2

might be easily imagined. For instance, **3** might have been converted into its methyl hemiketal at C-24 and this latter dehydrated to the enol form of **1***a*. Confirmatory evidence came from the results of the enzymatic hydrolysis of the glycoside mixture obtained from *M. comosum* bulbs which was finally achieved by the use of digestive juice of *Helix pomatia* (10) after several pure glycolitic enzymes were found to be ineffective. Chromatography of the aglycone fraction yielded four pure compounds. The major one (mp 232–233°C) was identical (ir, ms, nmr, uv) with eucosterol **4***a*. Treatment of **4***a* with boiling hydrochloric methanol afforded a diol mixture which was found identical (ir, mp) both with the crystalline diol fraction (mp 142–155°C) obtained by acidic methanolysis of the glycosides and with the diol mixture obtained by hydrolysis of the pure dibenzoate, mp 175–176°C. This allowed us to definitively assign lanostane structure **1***a* to the diastereoisomeric diols.

Structural elucidation of the minor authentic aglycones **4***b*, **4***c*, and **4***d* has been reported elsewhere (11).

Experimental[4]

General

Melting points were determined on a Kofler block. The ir spectra were measured in chloroform solutions on a Perkin Elmer model 399 spectrophotometer. Rotations were determined with chloroform solutions on a Perkin Elmer model 141 polarimeter. Mass spectra were measured on an AEI model 902 instrument. The ^{1}H nmr (270 MHz) and ^{13}C nmr (67.88 MHz) spectra were recorded on a Fourier transform Bruker WH270 spectrometer with $CDCl_3$ as solvent and TMS as internal reference. The uv spectra were taken on a Perkin Elmer model 402 spectrophotometer with ethanol solutions. Silica gel 0.05–0.20 mm (Merck) and cellulose powder (Whatman, CF11) were used for column chromatography; tlc and plc were performed on silica gel F_{254} layers (Merck) of thickness 0.25 and 2 mm, respectively, and on cellulose layers (Merck) of thickness 0.1 mm.

Extraction of the Glycosides from Bulbs of Muscari comosum

Sliced fresh bulbs (1 kg) of the plant (collected in autumn in Puglia, Italy) were boiled in acetone (4 L) for 8 h. The acetone extract was evaporated *in vacuo*. The residue (50 g) was washed with water (500 mL) and then with acetone (500 mL) at room

[4]With the assistance of Italo Giudicianni.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

temperature. The solid residue (17 g) was dissolved in 1:2 water–methanol (1 L) and the solution was washed with carbon tetrachloride (5 × 100 mL). The hydromethanolic phase was evaporated *in vacuo* to give a brown powder (13 g) which was chromatographed on a cellulose (390 g) column. Elution with water-saturated *n*-butanol (2 L) gave a highly bitter yellow-brown powder (9 g). Thin-layer chromatography (cellulose, 5:1:4 *n*-butanol – methanol–water) showed that this fraction consisted of four main compounds all migrating in a narrow range of R_f; ^{1}H nmr (DMSO-d_6): relevant signals in the δ 3–3.8 zone; ^{13}C nmr (CD_3OD): relevant signals in the δ 97–110 zone.

Methanolysis of the Glycoside Mixture

A solution of the above glycoside fraction (5 g) in dry methanol (100 mL) containing HCl (2.5% w/v) was refluxed for 4 h. To the cooled solution solid Na_2CO_3 (600 mg) was added. The residue from evaporation of the solvent *in vacuo* was dissolved in chloroform and washed with saturated Na_2CO_3 and water. Evaporation of chloroform afforded a solid (1.5 g) which was chromatographed on silica gel (65 g). Elution with 3:2 benzene–ether gave a white solid (300 mg) which was crystallized from benzene–hexane to give the mixture of diols **1***a* as white crystals (260 mg), mp 142–155°C; ir: 3350, 1710–1690 cm^{-1}; uv: λ_{max} 238, $E_{1\,cm}^{1\%}$ = 94.

Diols **1***a* (150 mg) were benzoylated with BzCl/Py (room temperature, 24 h). After usual work-up, plc on silica gel (4:1 hexane – ethyl acetate, 4 runs) afforded two fractions. Their mass spectra displayed the same molecular ion peak (694 *m/e*) and an identical fragmentation pattern.

The less-polar fraction (75 mg) was crystallized from ethanol to give pure dibenzoate **1***b* (45 mg) as white needles, mp 175–176°C; $[\alpha]_D$ +211° (*c* 0.5); ir: 1740–1690 cm^{-1}, uv: λ_{max} 230 nm, ε = 31 000; ^{1}H nmr: see Fig 1; ^{13}C nmr: see Table 1. The solid left from evaporation of mother liquors displayed an ^{1}H nmr spectrum where the signals of a second diastereoisomeric dibenzoate were almost overlapping those of the dibenzoate of mp 175–176°C, whereas additional singlets at δ 3.37 and δ 5.60 were observed. Mass spectrum *m/e*: 694.38714 (M^+; calcd. for $C_{44}H_{54}O_7$: 694.38703), 614, 579.31112 ($M - C_6H_{11}O_2$; calcd. for $C_{38}H_{43}O_5$: 579.31102), 502, 464, 435, 264, 219.

The more polar fraction (85 mg) also displayed an ^{1}H nmr spectrum very similar to that of the dibenzoate of mp 175–176°C, the main differences being the presence of two singlets (1H in all) at δ 5.58 and δ 5.64 and two triplets (3H in all) at δ 0.91 and δ 0.93.

Another sample (50 mg) of diols **1***a* was acetylated with Ac_2O/Py (room temperature, 24 h). The acetate **1***c* mixture (40 mg) obtained by usual work-up and purified by filtration on silica gel (4:1 benzene–ether as eluent) was a crystalline solid; uv: λ_{max} 245 nm, ε = 6 500; ^{1}H nmr: ABq at δ 4.27 (—C*H*$_2$OAc); m at δ 4.59, $W_{1/2}$ = 21 Hz (>C*H*OAc); singlets at δ 2.04 (3H) and 2.06 (3H) (2 × OCOC*H*$_3$); ms, *m/e*: 570, M^+.

A sample of diols **1***a* (30 mg) was dissolved in acetone (10 mL) and shaken with anhydrous $CuSO_4$ (200 mg) for 12 h at room temperature. Filtration and evaporation of the solvent *in vacuo* afforded an acetonide **1***d* mixture as a solid (22 mg); ^{1}H nmr:s at δ 1.38 (3H), s at δ 1.45 (3H), ABq (2H) at δ 3.29 and 4.09 and m (1H) at δ 3.60 (—C*H*$_2$—O—C(C*H*$_3$)$_2$—O—C*H*<); ms, *m/e*: 526, M^+.

Enedione 2

Pure dibenzoate (mp 175–176°C) (20 mg) was dissolved in glacial AcOH (2 mL) and treated with 0.4 mL of a solution of CrO_3 (25 mg) in glacial AcOH (1 mL). After 2 h at 40°C, methanol (a few drops) was added to the cooled solution. Evaporation of the solvent *in vacuo* afforded a yellow solid which was dissolved in ethyl acetate and washed with water. The organic layer was evaporated to give a yellow crystalline solid (18 mg). Filtration on silica gel (1:1 hexane – ethyl acetate as eluent) and crystallization from methanol afforded pure **2** as yellow needles, mp 176.5–177.5°C; $[\alpha]_D$ +325° (*c* 0.4); uv: λ_{max} 273 nm, ε = 8000; ^{1}H nmr, δ: 0.92 (3H, t, *J* = 7 Hz, —CH$_2$—C*H*$_3$), 1.13 (3H, s, C*H*$_3$), 1.14 (3H, d, *J* = 6 Hz, >CH—C*H*$_3$), 1.28 (3H, s, C*H*$_3$), 1.32 (3H, s, C*H*$_3$), 1.37 (3H, s, C*H*$_3$), 3.36 (3H, s, —OC*H*$_3$), 3.53 (1H, t, *J* = 6 Hz, —OC—C*H*(OCH$_3$)—CH$_2$—), 4.77 (2H, AB q, —C*H*$_2$OBz), 5.00 (1H, m, >C*H*OBz), 5.70 (1H, s, >C=C*H*—CO—); ms, *m/e*: 722.34558 (M^+; calcd. for $C_{44}H_{50}O_9$: 722.34545).

Hydrolysis of Dibenzoate Melting at 175–176°C

Two samples (10 mg each) were separately treated with 10% KOH methanol and 10% concentrated HCl methanol at boiling temperature for 3 h. In both cases a diol mixture was obtained identical (^{1}H nmr, tlc) to that obtained from the methanolysis of the glycoside mixture.

Enzymatic Hydrolysis of Glycoside Mixture

To a solution of the glycoside mixture (1 g) in water (300 mL) digestive juice of *Helix pomatia* (1 mL; Industrie Biologique Francaise) was added. The solution was stirred for 40 days at room temperature. After concentration *in vacuo*, the solution was extracted with chloroform. Evaporation of the chloroform extract gave a solid (110 mg); plc on silica gel (4:1 chloroform – ethyl acetate, 4 runs) afforded four fractions: A (25 mg), B (35 mg), C (5 mg), and D (20 mg), in order of increasing polarity. Fraction B was found to consist of eucosterol **4**, mp 232–233°C (from ethanol; lit. (9) mp 235–236°C); $[\alpha]_D$ +21° (*c* 0.7; lit. (9) α_D +20.4°); ^{1}H nmr δ: 0.94 (3H, s, 18-*H*$_3$), 0.96 (3H, s, 19-*H*$_3$), 1.08 (3H, t, $J_{25,26}$ = 7.35 Hz, 26-*H*$_3$), 1.13 (3H, d, $J_{20,21}$ = 6.7 Hz, 21-*H*$_3$), 1.23 (3H, s, 30-*H*$_3$), 1.36 (3H, s, 32-*H*$_3$), 1.95 (2H, dd, $J_{22,23}$ = 9.46 Hz, $J_{20,22}$ = 3.1 Hz, 22-*H*$_2$), 2.22 and 2.72 (2H, AB q, J_{AB} = 19.4 Hz, 16-*H*$_2$), 2.35 (m, 20-*H*), 2.51 (2H, q, $J_{25,26}$ = 7.35 Hz, 25-*H*$_2$), 3.36 and 4.23 (2H, AB q, J_{AB} = 11.27 Hz, 31-*H*$_2$), 3.48 (1H, dd, $J_{3\alpha,2\beta}$ = 11.1 Hz, $J_{3\alpha,2\alpha}$ = 4.1 Hz, 3α-*H*), 4.71 (1H, t, $J_{22,23}$ = 9.46 Hz, 23-*H*) (cf. ref. 9); ^{13}C nmr and ms spectra as in ref. 9.

A sample of **4***a* (5 mg) in dry methanol (1 mL) containing HCl (2.5% w/v) was refluxed for 4 h. Work-up as above afforded a solid (5 mg) which was found identical (mp, ir, uv) to the crystalline diol fraction (mp 142–155°C) obtained by acidic methanolysis of the glycoside mixture.

HEM CHANDRA JHA, FRITZ ZILLIKEN, WERNER OFFERMANN, and EBERHARD BREITMAIER. Can. J. Chem. **59**, 2266 (1981).

^{13}C Chemical shifts and resolved carbon–proton couplings of 39 deoxybenzoins and 11 acetophenones, most of which have naturally occurring substitution patterns, are assigned. Individual benzene rings turned out to have typical parameters not affected by structural variations in the rest of the molecule. Due to substitutional saturation, however, these benzenoid carbon shifts markedly deviate from increment additivity. A few trends of these deviations are described. Phenolic hydrogens, fixed between hydroxyl and carbonyl oxygen due to internal hydrogen bonding, are shown to give rise to additional carbon-splittings.

HEM CHANDRA JHA, FRITZ ZILLIKEN, WERNER OFFERMANN et EBERHARD BREITMAIER. Can. J. Chem. **59**, 2266 (1981).

On a identifié les déplacements chimiques du ^{13}C et les couplages carbone–proton résolus de 39 déoxybenzoïnes et de 11 acétophénones qui présentent pour la plupart des schémas de substitution que l'on retrouve dans les produits naturels. On note que les cycles benzéniques individuels ont des paramètres typiques qui ne sont pas affectés par les variations structurales dans le reste de la molécule. Toutefois à cause de la saturation par substitution, les déplacements chimiques des carbones benzénoïdes dévient fortement des valeurs prédites par l'additivité des incréments. On décrit quelques tendances dans ces variations. On montre que les hydrogènes phénoliques fixés entre les oxygènes de l'hydroxyle et du carbonyle par des liaisons hydrogènes intramoléculaires provoquent une augmentation du dédoublement des carbones.

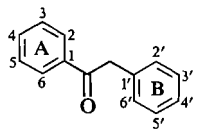
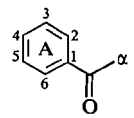
Introduction

Deoxybenzoins are the synthetic precursors as well as the alkaline degradation products of isoflavones. This fact bestows a considerable importance to this class of substances in the structural elucidation of natural isoflavones (1, 2). Deoxybenzoins, obtained by degradation of isoflavones, can be used again for the resynthesis of the corresponding isoflavones with suitable reagents to confirm their structure. They are also valuable as intermediates for other isoflavonoids such as isoflavanones, isoflavans, and pterocarpans. As one of the degradation products, they assume significance in the catabolic studies of the isoflavones with intestinal microflora (3).

We therefore performed a comprehensive carbon-13 nuclear magnetic resonance investigation of deoxybenzoins with naturally occurring substitution pattern. The present study involves 39 deoxybenzoins (dob) **1** to **39**, and eleven acetophenones (ap) **40** to **50**. Chemical shifts and one-, two-, three-, and four-bond C—H couplings have been assigned as far as possible. The structures are listed in Table 1, including a few synthetic compounds which were useful in spectral analyses.



Deoxybenzoin structures **1** to **39**



Acetophenone structures **40** to **50**

Experimental

Synthesis of the Deoxybenzoins and Ketones

The compounds have been prepared by using the Friedel–Crafts reaction, Fries rearrangement, or Houben–Hoesch condensation with suitable phenols. The known compounds have been checked for their authenticity by comparison of the mp's and bp's, and the new compounds have been verified by elemental analyses and spectroscopic methods (4).

Carbon-13 Nuclear Magnetic Resonance Spectra

The spectra were recorded on a Bruker WP 80-FT instrument operating at 20.115 MHz in the ^{13}C observation channel, 80 MHz in the proton decoupling channel, and 11.56 MHz in the deuterium lock channel. The experimental conditions were identical to those reported previously (1), but resulting in 0.6 Hz or 0.03 ppm digital resolution. Proton-coupled spectra were recorded by the gated-decoupling technique, with a 60° pulse

and 2.5 s decoupling time. Deuterium exchange of the internally chelated proton was achieved by addition of 0.2 mL CD_3OD. The spectra of **1** and **40** in H_2SO_4 ($d = 1.84$) were referenced to external TMS.

Results and Discussion

The shifts are assigned in Tables 2 to 5, which are divided into sections containing the shifts of substructures with identical substitutional pattern. This arrangement reflects the fact that A-ring, B-ring, and -CO—CH_2- can be treated as subsystems with spectral properties independent of structural changes in different parts of the molecule. For identical substructures, the average shift δ of equal carbons is given. The standard deviation from the average shift never exceeds 0.6 ppm and is, in 55% of compounds examined, equal to or smaller than 0.1 ppm. Even identical A-ring substructures in dob and ap (cf. Tables 2 and 5) agree very well.

Following the guideline of subsystem constancy, the coupling constants are grouped like the shift values. For a single carbon, the constants are given in the order of decreasing magnitude. For identical A- and B-ring substructures, the multiplicity is given, average values $\bar{J}$ and the standard deviations (sd) are calculated, and the coupling protons are identified. Again, the values within a given substructure agree well.

Chemical Shifts

Signals were assigned on the basis of signal intensities, chemical shift ranges (5, 6), comparison with shieldings calculated from substituent-induced chemical shifts (scs) (5, 7), and matching to identical substructures, multiplicities of one-bond and three-bond C—H coupling, and matching against the fine-splitting pattern of assigned signals. These familiar directives left only two ambiguities in the dob and none in the ap series. Less trivial cases are discussed in the comments on the tables (*vide infra*).

In the A- and B-substructures with more than two substituents the experimental shifts differ grossly from the values obtained by simple summation of appropriate scs, even if the internal chelation between 1- and 2-substituent is accounted for (*vide infra*). This is expected, as *para*-substitution is always involved (8). The deviation affects all ring carbons in the subsystem and ranges from 8.9 ppm downfield to 5.7 ppm upfield. For the 2,4,5-trisubstituted A- and the 3′,4′-disubstituted B-subsystems the effect can be expressed qualitatively: oxygen-carrying carbons are shifted downfield, the other carbons upfield.

The 4′-substituted B-substructure also escapes additivity, although less significantly. The experi-

*Based upon δ_2 and scs.
†Based upon δ_1 and scs.

mental shifts conform to a single parameter relationship (8)

[1] $\delta_{1'} = 135.0 + 1.15\ scs_p$ ($r^2 = 0.98$)

where scs_p is the *para*-scs of the 4′-substituent. The amplification factor (1.15) fits into the general trend found by Lynch (8).

Long range effects cause small deviations in the -CH_2—CO- subsystem. The carbonyl signals cover a range of ca. 4.6 ppm (neglecting **1**), and the methylene signals span more than 10 ppm (neglecting the ap). Table 4 arranges these shifts as A- and B-groups. A few relations are obvious although, once more, no general description can be presented.

The 2,4,6-trihydroxy-A-ring deshields the methylene signals by ca. 4.5 ppm. This polarization extends to the Cl′ carbon, which resonates ca. 1 ppm downfield from the respective average value $\delta_{Cl'}$, clearly beyond the standard deviation. The 2′-methoxy group in **12** shifts the methylene signal upfield to 38.8 ppm. Apparently, both effects are transmitted sterically. The remaining dob methylene carbons appear between 43.4 and 44.9 ppm, with no eye-catching correlation.

The series **5**, **6**, **7** and **30**, **31**, **28**, **29**, respectively, in which in a given structure only the 4′-substituent is altered, are examples of the now well documented scs via methylene insulators (9). The carbonyl shifts may be correlated to the σ_p-constants (10) of the 4′-substituents[1]

[2] **5**,**6**,**7**: $\delta_{C=O} = 202.14 - 2.005\ \sigma_p$ ($r^2 = 0.999$)

[3] **30**, **31**, **28**, **29**: $\delta_{C=O} = 201.84 - 1.961\ \sigma_p$ ($r^2 = 0.997$)

In contrast, the methylene shifts respond irregularly to 4′-substitution, similar to results of Cook and co-workers (9).

C—H Coupling Constants

The proton-coupled spectra of all compounds could be analysed by first order rules, with very few exceptions (see Tables 6 to 8). Again, less trivial splittings are referred to in the footnotes of the tables (*vide infra*).

The one-bond coupling constants ^1J follow the known trend, decreasing on electron-releasing substitution and vice versa. Exceptions are C-3,6 in **33** and **50** and C-2′,5′ in **38**, all of which are located

[1]The correlation coefficients r^2 are given for illustrative reasons only; of course, the correlations lack statistical significance because of the low number of data points. On the other hand, the close resemblance of slopes and intercepts gives some weight to the approach.

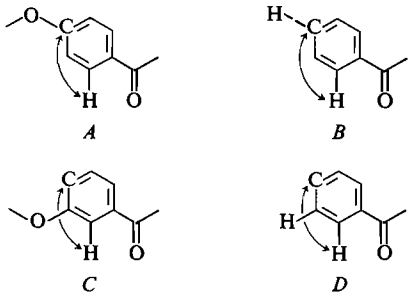
*Assignments may be reversed.

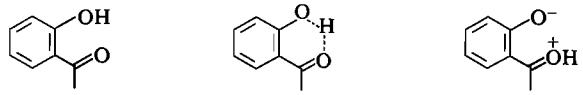
next to a five-ring acetal. Their ^1J constants are distinctly larger than those of corresponding hydroxy- and methoxy-substituted compounds (differences up to 7.9 Hz, see Table 9). Similar effects were reported for strained benzocycloalkanes relative to benzocyclohexene (11). Of the methoxy carbons, not only the chemical shift is typical of the substitutional position, but also the one-bond coupling. Both parameters are helpful in signal assignment.

As usual (12), three-bond constants ^3J are the largest observed long-range couplings. Oxy-substituents slightly affect the ^3J values. Generally, $^3J_A \geqq {}^3J_B$ (differences up to 2.6 Hz), and $^3J_C \leqq {}^3J_D$ (differences up to 2.2 Hz). Three-bond coupling exceeds the arene rings and involves more remote substituent atoms: C=O/2,6-H; C-1/2-OH; C-3/2-OH; C-2′,6′/CH_2-; C/OCH_3. The latter coupling usually makes the respective carbon appear as a broad unresolved signal. An oxy-substituent on a carbon magnifies its ^2J constants into the resolution range of the spectrometer, up to values as large as 4.9 Hz. We observe these couplings for C-2/3-H; C-2/2-OH; C-4/5-H; C-6/5-H; C-4′/3′,5′-H.



Internal Chelation

In **2** to **39** and **41** to **50**, the 2-OH proton is chelated by the carbonyl oxygen in an internal hydrogen-bond, which is reflected both in the coupled and decoupled spectra. It destroys the scs-additivity expected for the A-ring shifts of **2** and **41** (8). The experimental shifts δ_{exp} are linear combinations of the calculated values δ_0 and $\delta_\pm$ for the hypothetical structures *E* and *F*, with a slight excess of *E*.



2: $\delta_{exp} = 8.18 + 0.494\,\delta_0 + 0.442\,\delta_\pm$ ($R = 0.005$)[2]

41: $\delta_{exp} = 9.08 + 0.505\,\delta_0 + 0.424\,\delta_\pm$ ($R = 0.005$)

In order to obtain the scs of the protonated carbonyl substituents, we determined the shifts of C-1 to C-6 of H_2SO_4 solutions of **1** and **40**:

	C-1	C-2,6	C-3,5	C-4
1	128.81	135.18	130.54	144.55
40	129.78	135.43	131.12	145.08

[2] $R = \Sigma(y\text{-}y)^2/\Sigma(y\text{-}\bar{y})^2$. In contrast to r^2, $R = 0$ means ideal, $R = 1$ no correlation.

48	202.39	26.52			
49	202.48	26.61			

To our knowledge, the *para*-scs are the largest downfield shifts reported so far. The shift calculations for **3** to **39** and for **42** to **50** are based on δ_{exp} of **2** and **41**, respectively.

In contrast to ordinary hydroxy protons, the internally chelated 2-hydroxy group gives rise to carbon splittings (13, 14). ^3J coupling with C-1 and C-3 and ^2J coupling with C-2 are observed (see Tables 6 and 8). These splittings could be eliminated by deuterium exchange (13). Remarkably, the 2,4,6-trihydroxy compounds **34** to **39** lack these splittings, most probably because the 6-OH group sterically interacts with methylene (*vide supra*) and cannot be chelated as a result. Only very few ^4J constants are resolved. We observe, in **35** and **37**, C-2/5-H and C-6/3-H (^4J = 1.2, 1.5 Hz); in **33**, C-3/6-H (^4J = 1.2 Hz).

Comments on the Assignments in the Tables

C-1/C-1', C-2,6/C-3,5, C-2',6'/C-3',5' in 1 (Tables 2 and 3) A rough assessment of the arene shifts using scs values for -$COCH_3$ and -CH_3 (see Table 2) does not sufficiently discriminate the named carbons. C-1' and C-2',6'/C-3',5' are identified by matching against the spectra of **9**, **11**, **20**, **25**, and **28**, with identical B-rings; C-2',6' show more long range splitting (two *meta* couplings) than C-3',5' (one *meta*-coupling) and hence lower and broader signals (Table 8).

C-3/C-5 in 2 (Table 2) and 40 (Table 5) C-3 is recognized by its additional three-bond coupling to 2-OH found in all spectra of **2** to **33** (Table 7) and **40** to **49** (Table 9). Also, the C-5 signal shifts only slightly upon oxy-substitution (**8**, **9**, **10**, Table 2) in the 3-position.

C-2/C-4 in 11 to 19 and 25 to 27 (Table 2) The C-2 signal is dt (6-H, 3-H, 2-OH), C-4 is dd (C-6, 3-H). Also, the relative signal sequence is predicted by the calculation. Finally, the C-2 shifts agree well with those in **20** to **24**.

C-2,6/C-4 in 34 to 39 The carbons are identified by their relative signal intensities in the nOe suppressed gated-decoupling spectrum of **35** as well as in the broad-band decoupled spectra.

C-1'/C-4' in 7 (Table 3) From eq. [1] (*vide supra*), $\delta_{C\text{-}1'}$ = 132.70 ppm. This value is closer to 132.24 ppm than to 133.54 ppm.

C-3'/C-4' in 23 (Table 3) In the coupled spectrum, C-3' appears as dd (5'-H, 2'-H), C-4' as td (2'-H, 6'-H, 5'-H).

C-2'/C-5' in 23, 36, 19, 24, 32, 37 (Table 3) C-2' is identified by its long range splittings (6'-H, CH_2), whereas C-5' only couples to 5'-H (Table 7).

C-1'/C-4' in 39 (Table 3) C-4' is a long range t,

with a constant (5.8 Hz) typical of three-bond coupling.

Methoxy Carbons

From the methoxy carbon signals, δ and ^1J values are obtained. Obviously, these data have constant values, typical for any given substitution position (Tables 2, 3, 5–8). Thus, 4-OCH_3 (δ = 55.5 to 56.1 ppm; ^1J = 145.3 to 145.9 Hz), 5-OCH_3 (55.0 to 55.7 ppm; 143.9 to 144.0) are easily assigned by matching against the respective subsystem spectra. Only 3′-OCH_3 and 4′-OCH_3 cannot be discriminated in the single case where their resonances are resolved (**37**). In the spectrum of **39**, where steric crowding breaks up these rules, 3′-OCH_3 and 4′-OCH_3 are recognized from their relative signal intensities.

C—H Coupling

C-2′, C-5′, C-6′ in 1, 9, 11, 20, 25, 28 (Table 7) Low and high field parts of the ^1J-doublets are not identical. We ascribe this to spin state mixing.

C-2′,6′ in 1, 9, 11, 20, 25, 28 (Table 7) These signals appear as odd long-range multiplets. They are less intense and broader than those of C-3′,5′.

C-3′,5′ in 1, 9, 11, 20, 25, 28 (Table 7) The high field part of the ^1J-doublet is a doublet, at low field the X-part of an ABX system appears.

C-4′ in 1, 9, 11, 20, 25, 28 (Table 7) The high field part has a quintet- or septet-like shape, the low field part is more complicated.

C-1′ in 12, 3, 5, 13, 21, 26, 30, 2, 4, 6, 8, 10, 14, 22, 27, 31, 35, 16, 17, 18 (Table 7) The signals have quintet-shape, ascribed to ^3J coupling with 3,5-H and, tentatively, to ^2J coupling of similar magnitude to either 2,6-H or to the methylene protons.

C-1′ in 23, 26, 32 (Table 7) The signals are quartets, from ^3J coupling to 5-H and one pair of the above mentioned protons.

The conformational properties of seven-membered heterocycles: 1,3-dioxacyclohept-5-ene and its 2-substituted derivatives

R. ST-AMOUR AND M. ST-JACQUES[1]

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1

Received November 27, 1980

R. ST-AMOUR and M. ST-JACQUES. Can. J. Chem. **59**, 2283 (1981).

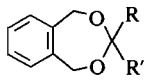
1,3-Dioxacycloheptene and its 2-CH_3, 2-OCH_3, 2-*t*-Bu, and 2,2-dimethyl derivatives were studied by ^1H and ^{13}C dnmr methods. Substituent effects and the interpretation of spectral changes in ^{13}C nmr at low temperature allow the determination of the most stable conformation of these compounds (TB for **1**–**4***b* and C for **5***b*) and the characterization of the dynamic processes observed for **2***b*, **4***b*, and **5***b*. The differences between the conformational and dynamic properties of the above compounds and their benzo analogs are rationalized in terms of different torsional interactions in the two series.

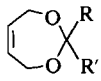
R. ST-AMOUR et M. ST-JACQUES. Can. J. Chem. **59**, 2283 (1981).

La dioxa-1,3 cycloheptene (dioxépine-1,3) et ses dérivés substitués en position 2 par les groupements -CH_3, -OCH_3, *t*-Bu et $(CH_3)_2$ ont fait l'objet d'une étude de rmn dynamique ^1H et ^{13}C. Les effets de substituants en rmn ^{13}C et la compréhension des changements spectraux à basse température ont permis de déterminer les conformations adoptées préférentiellement par tous les composés étudiés (bateau-croisé pour **1**–**4***b* et chaise pour **5***b*) ainsi que de caractériser la nature et les énergies des processus dynamiques observés pour les dérivés **2***b*, **4***b* et **5***b*. La différence des comportements conformationnels et dynamiques entre les composés dérivés de la dioxépine-1,3 et ceux de la série analogue dérivés de la benzodioxépine-1,3 est expliquée par la différence des interactions torsionnelles présentes dans les deux séries.

The conformational analysis of 1,3-dioxacycloalkanes has received considerable attention over the years and, among this group of molecules, 1,3-dioxanes have been most studied (1). As it turns out, six-membered heterocyclic conformations other than the chair form assume relatively little importance (2) (except possibly for some substituted derivatives exhibiting strong *syn*-1,3-diaxial interactions in the chair form (**2***b*)) and consequently the effects of substituents on C-2 can be explained in terms of an axial–equatorial conformer equilibrium. On the other hand, substituted derivatives of 1,3-dioxacyclopentanes (3), 1,3-dioxacycloheptanes (4), and 1,3-dioxacyclooctanes (5) potentially exhibit a more complex behaviour because of the possible existence of several low-energy ring conformations which can interconvert by low-energy (pseudorotational or other) processes.

Previous nmr studies on derivatives of cycloheptene and benzocycloheptene have provided unique information regarding the conformational changes produced in the seven-membered ring (6–10) by certain functional groups. Significant stabilization of the twist-boat conformation was observed in some cases. 1,3-Dioxabenzocycloheptene (**1***a*) and its derivatives (**2***a* to **4***a*) revealed a most interesting behaviour (7) whereby signals of molecules existing in the chair and/or the twist-boat forms were detected. Enhanced amounts of the twist-boat form were explained in terms of effects associated with steric and electronic interactions of the 2-substituents. Because previously unsuspected insight was derived from those dnmr experiments (7), it was decided to investigate the analogous series of molecules in which the benzo group is replaced by a double bond, namely 1,3-dioxacycloheptene (**1***b*) and several of its derivatives (**2***b* to **5***b*). Thus we wished to characterize the conformational effect of 2-substituents for this series of fundamental molecules and through comparison with compounds **1***a*–**5***a* determine the conformational effect brought about by the small structural change.





R = R′ = H	**1***a*	**1***b*
R = R′ = CH_3	**2***a*	**2***b*
R = CH_3, R′ = H	**3***a*	**3***b*
R = OCH_3, R′ = H	**4***a*	**4***b*
R = $C(CH_3)_3$, R′ = H	**5***a*	**5***b*

Published work aimed at defining the geometry of the stable conformations of some of these compounds is not conclusive. A previous ^1H dnmr report (8) on **1***b* and **2***b* proved to be negative while a recent ^{13}C nmr study (9) at ambient temperature indicated that the conformation of **1***b* is most elusive (9, 10) while that of **2***b* could not be determined with confidence (9). The results reported herein will show clearly that **1***b* exists predominantly in the twist-boat form (unlike **1***a*) and will

provide new information concerning the conformational changes brought about by the 2-substituents.

Results

Compounds **1***b* to **5***b* were studied by variable temperature ^1H and ^{13}C nmr and spectral changes were observed for **2***b*, **4***b*, and **5***b*.

The 80 MHz ^1H nmr spectrum of **2***b* in $CDCl_3$ at room temperature contains three signals of which the allylic methylene protons (H-4,7) doublet at δ 4.25 (separation = 1.8 Hz) undergoes a spectral change. For a solution in CHF_2Cl, as illustrated in Fig. 1, this signal consists of a slightly broadened line at −105°C which splits below −130°C (the coalescence temperature, T_c) into four broad lines which have the general appearance of an AB pattern at −149°C. Unresolved coupling with the olefinic protons appears responsible in part for the above line broadening. Analysis of the low temperature spectrum as an AB yielded a chemical shift difference of 40.5 Hz and a coupling constant of −16.0 ± 1 Hz. From the rate constant obtained at T_c, a free energy of activation of 6.8 kcal/mol was calculated at −130°C using the Eyring equation with a transmission coefficient of one (11). The 20.15 MHz ^{13}C nmr spectrum of **2***b* did not exhibit a spectral change at low temperatures. Table 1 contains the ^{13}C chemical shifts measured at room and low temperatures for compounds **1***b* to **5***b*.

The 20.15 MHz ^{13}C nmr spectra of **4***b* in CHF_2Cl, shown partially in Fig. 2 for several temperatures, reveal a spectral change whereby only the C-4,7 signal splits into a doublet below −160°C. At −163°C, the separation between the equally intense components is 77 Hz and the true chemical shift difference could be slightly larger because of the nearness to T_c. Other pertinent chemical shifts are given in Table 1. The rate constant for the averaging process underlying the spectral change was calculated (12) at coalescence from which a free energy of activation of 5.2 kcal/mol was obtained at −160°C using a transmission of one in the Eyring equation.

The 80 MHz ^1H nmr spectrum of **4***b* also showed a spectral change. The approximate AB pattern observed for H-4,7 below −100°C broadens quite significantly below −155°C to become a complex unresolved broadened pattern below −160°C. In spite of the poor resolution resulting in large part from coupling with the olefinic protons, the above behaviour is compatible with the existence of two broad and overlapping AB patterns similar to those reported (7) for **4***a* at −150°C. Thus both ^1H and ^{13}C nmr spectra point to nonequivalent allylic methylene groups.

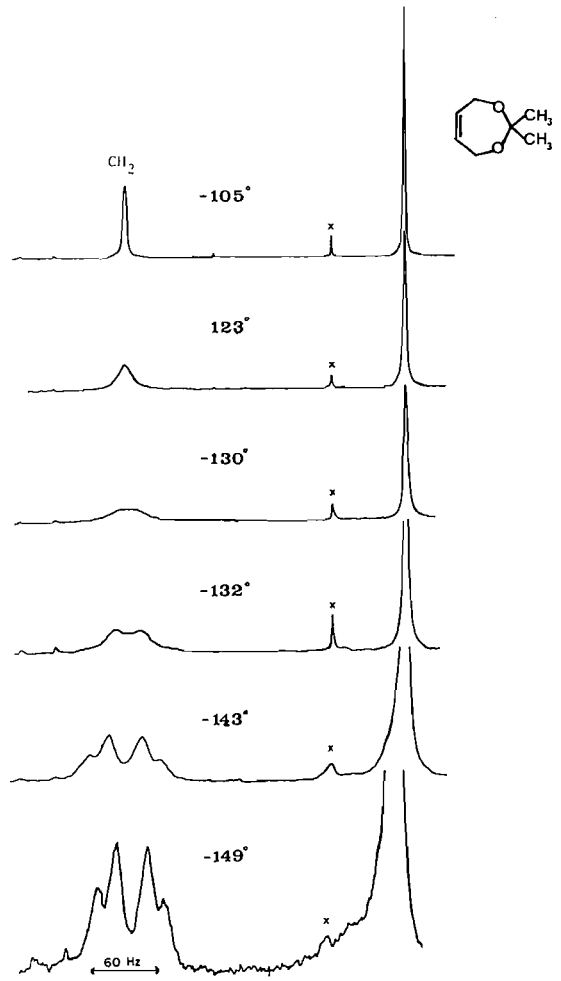

FIG. 1. Partial 80 MHz ^1H nmr spectra (CH_2 and CH_3) of **2***b* in CHF_2Cl at several temperatures (X denotes an impurity).

A spectral change was also observed for the methyl ^1H and ^{13}C signals of **5***b* which undergo a splitting from singlet to doublet with component intensities in the ratio 2:1, the more intense line appearing at low field. All pertinent ^{13}C chemical shifts are reported in Table 1. Using the two-site approximation (12), a free energy of activation of 6.1 kcal/mol was calculated at −136°C (T_c).

Discussion

Conformations of the Seven-Membered Ring

Previous work (7) has shown that only three conformations need to be considered for the seven-membered ring of cycloheptene and its derivatives: the chair (C), the boat (B), and the twist-boat (TB) forms. Furthermore, the substituent in 2-monosubstituted derivatives of 1,3-dioxepins can either be axially or equatorially oriented in the C and B forms thus giving rise to the C-a, B-a, C-e, and B-e forms.

					20.79

[a] In ppm downfield from TMS for solutions in CHF_2Cl containing TMS and CD_2Cl_2 (~15%) as lock signal.

Nuclear magnetic resonance parameters, obtained from spectra recorded at a temperature below coalescence, normally give direct information on the nature of the most stable conformation(s) of a given molecule provided further averaging does not take place through conformational processes involving low activation barriers. Of the five compounds in series *b* only **2***b* and **4***b* fall into this category. The spectral change observed for **5***b* is due to slowing down of the rotation of the *tert*-butyl group (13) and will not be considered further.

The broadened AB pattern observed for H-4,7 in the ^1H nmr spectrum of **2***b* at −149°C (Fig. 1) indicates that the nonaveraging stable conformation contains only two nonequivalent methylene proton environments and together with the ^{13}C nmr spectrum show that the two allylic carbons are equivalent. Furthermore the ^1H and ^{13}C spectra indicate that both methyl groups have the same environment. Consequently the conformation of **2***b* must be the TB form as was also determined (7) for the analogous compound **2***a*.

Similarly, ^1H and ^{13}C nmr data obtained for **4***b* below coalescence show that it exists in the TB form as was also found (7) for compound **4***a*. The nonequivalence of the allylic carbons, clearly revealed from the splitting in the ^{13}C nmr spectrum (Fig. 2 and Table 1), rules out the C-a, B-a, C-e, and B-e forms which all contain equivalent allylic carbon atoms. The absence of splitting in signals of other carbons and a comparison of the ^{13}C shift parameters for **4***a* and **4***b* rule out an equimolar mixture of two of the above conformations for **4***b*.

Unfortunately, direct evidence of this kind is not available for the identification of the stable conformation(s) of the parent compound **1***b* and of the two monoalkyl derivatives **3***b* and **5***b* because for these molecules neither ring protons nor ring carbons gave rise to a spectral change. Consequently, one of the following situations must apply to these molecules: (*1*) the existence of a single nonaveraging ring conformation, (*2*) the existence of a single but rapidly averaging (i.e. through ring inversion) conformation, or (*3*) the existence of a mixture of different but rapidly interconverting conformations. ^{13}C nuclear magnetic resonance was found to be most useful to unravel a similar conformational problem (7). The arguments are based on the C-4,7 chemical shifts measured at low temperatures which are summarized in Table 1.

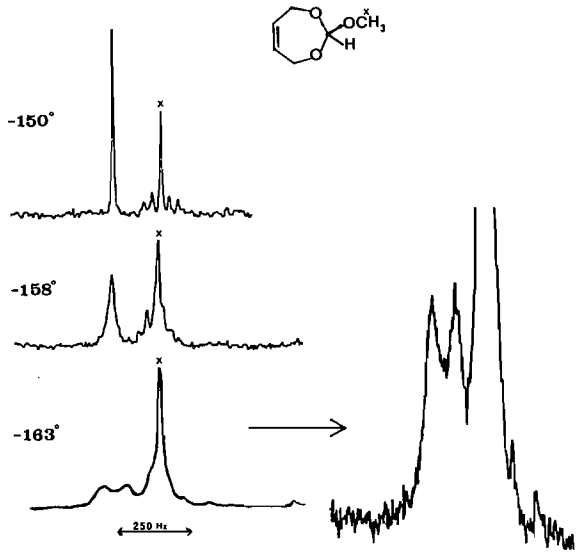

FIG. 2. Partial 20.15 MHz ^{13}C nmr spectra of the allylic carbons (signal on the left) and methyl carbon (denoted by X) of **4***b* in CHF_2Cl at several temperatures.

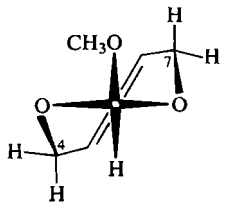
Our first objective is to determine the nature of the most stable conformation of **1***b* through analysis of the relationship between its C-4,7 chemical shift with those of **2***b* and **4***b* whose conformations are known to be TB. We must accordingly determine whether the 5.25 ppm difference between the signals of **1***b* and **2***b* as well as the 5.03 ppm difference for **1***b* and the mean of the two signals of **4***b* point to a specific form for **1***b*. Because compound **1***a* was found (7) to exist as a mixture of C (79%) and TB (21%) while both **2***a* and **4***a* exist as TB forms, data obtained from series *a* can in principle be used as reference. Thus the chemical shift difference between the benzylic C-4,7 signals of **1***a* (TB) and **2***a* is 4.87 ppm while the difference between the C-4,7 of **1***a* (TB) and the mean of the two C-4,7 signals of **4***a* is 5.18 ppm. The remarkable closeness of the shift differences in both series, which must arise from the same substituent effects, strongly indicates that **1***b* exists predominantly in the TB form at −148°C. The upfield shift of the C-4,7 signal of **2***b* relative to **1***b* therefore represents the γ-effect of the 2,2-dimethylsubstitution in the TB conformation while the upfield shifts of 3.14 and 6.93 ppm of the two TB C-4,7 signals of **4***b* relative to **1***b* are compatible with the *anti* relationship to the OCH_3 group of one of the allylic carbons (namely C-4 in structure **6**) and a *gauche* allylic carbon (namely C-7 in structure **6**). These upfield shifts, characterizing the effect of the methoxy group substitution on the TB conformation of **1***b*, are very similar to those determined previously (7) for the benzylic carbons of **4***a* which are 2.54 and 7.81 ppm. The small difference between the two series of molecules could arise in part (*a*) from imprecision in the δ_c of **4***b* because these were measured only a few degrees below T_c, and/or (*b*) from slight temperature differences, and/or (*c*) from small differences in TB ring geometries brought about by the small structural difference, and/or (*d*) from the existence of a small amount of the C form in equilibrium with TB for **1***b*, which would shift the reference used to determine the substituent parameters for **4***b*. The above reasoning in terms of γ-shifts is not quantitative enough to allow a choice to be made between these possible rationales and we are therefore not able to estimate an upper limit for the amount of the minor C form that could be present in the solution of **1***b* at low temperatures.

Let us now turn our attention to the conformations of **3***b* and **5***b*. Table 1 reveals that the C-4,7 signals have very different chemical shifts relative to that of **1***b*. In fact the 2-methyl substitution produces an upfield shift of 1.68 ppm while the *tert*-butyl substitution produces a downfield shift of 2.80 ppm. Thus the chemical shift difference between the C-4,7 signals of **3***b* and **5***b* is 4.48 ppm. By contrast, the C-4,7 chemical shifts of **3***a* and **5***a* are very similar[2] because they both exist in the C-e form.



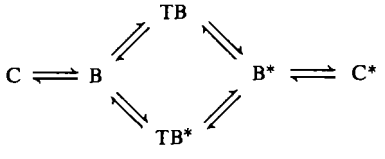
6

Now the data for **3***b* and **5***b* shown in Table 1 indicate that the most stable conformation of these two molecules must be different and because both **3***a* and **5***a*, which exist in the same C-e conformation, have larger C-4,7 chemical shifts than **1***a* (TB) (7), it then follows that **5***b* must exist in the C-e form, as does **5***a*, but that **3***b* must exist predominantly in the TB form, contrary to **3***a* which exists predominantly in the C-e form (7).

It is also interesting to point out that, even though both monosubstituted derivatives **3***b* and **4***b* exist predominantly in the TB form, the activation barrier for pseudorotation (*vide infra*) is lower for **3***b* so that rapid conformational averaging still takes place at −160°C as indicated from the absence of a spectral change for this compound. Furthermore, if **3***b* existed solely in the TB form, the 1.7 ppm upfield shift of the C-4,7 signal relative to **1***b* would represent the average of a γ-*anti* and a γ-*gauche* methyl effect. Unfortunately, reference values for these substituent parameters are not known for the seven-membered cyclic conformations so that a quantitative interpretation of the averaged γ-effect of the methyl group in **3***b* is not possible in order to determine the upper limit for the amount of the minor C form that could be present in the solution at low temperature.

Conformational Averaging Processes

The accepted conformational interconversion pathways characterizing the cycloheptene ring are illustrated in Scheme 1 where the * indicates inverted (or mirror image) conformations.



SCHEME 1

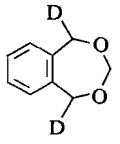
[2]R. St-Amour and M. St-Jacques, unpublished results, which gave δ = 75.40 for C-4,7 of **5***a* in CHF_2Cl at low temperature, whereas that of **3***a* is 74.67 ppm (7).

TABLE 2. Free energy barriers characterizing the conformational processes of several seven-membered cyclic molecules

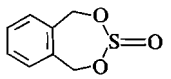
Compound	Stable conformation(s)	ΔG^* C ⇌ C* (kcal/mol)	ΔG^* TB ⇌ TB* (kcal/mol)	Reference
Benzocycloheptene	C	10.9	—	16
Cycloheptene	C	5.0	—	15
1*a*	C (79%)[a]	8.0		7
	TB (21%)		<5	See footnote 3
1*b*	TB	—	<5	This work
2*a*	TB	—	10.0	7
2*b*	TB	—	6.8	This work
4*a*	TB	—	6.7	7
4*b*	TB	—	5.2	This work
8	C (50%)[b]	8.9		18
	TB (50%)[b]		6.6	
9	TB	—	5.3	18

[a] In CHF_2Cl at −130°C.
[b] In CHF_2Cl at −100°C.

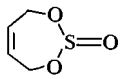
It is well known that, in the chair inversion process of cycloheptene and benzocycloheptene (6, 14), the C → B transformation is the rate-determining step for which free energy values of 5.0 and 10.9 kcal/mol were determined respectively (15, 16). The corresponding energy barrier for **1***a* was recently (7) reported to be 8.0 kcal/mol. Unfortunately, the dnmr method did not provide data allowing the determination of the free energy barrier for the pseudorotation process (i.e. TB ⇌ B ⇌ TB*) for these three fundamental molecules. Furthermore, it is interesting to point out that the 300 MHz ^{1}H nmr investigation[3] of a dideuterated derivative of **1***a* (**7**) at temperatures as low as −155°C and the 100 MHz spectrum at −170°C did not reveal a spectral change for the signals of the TB conformation. It therefore appears that the pseudorotation of **1***a* is characterized by an energy barrier of less than 5 kcal/mol.



7



8



9

The failure to detect a spectral change for **1***b* unfortunately prevents the determination of any kinetic parameter. Nevertheless, the conclusion that the TB form is very predominant for **1***b* suggests that the only process that might have been characterized by the dnmr method is the TB inversion (or pseudorotation) for which the absence of a spectral change suggests that the free energy barrier is less than 5.0 kcal/mol.

Dimethyl substitution on C-2 raises the pseudorotation barrier to 6.8 kcal/mol for **2***b*. A similar increase was observed for **2***a* ($\Delta G^* = 10.0$ kcal/mol) and interpreted in terms of increased steric interactions in the transition state for pseudorotation (7). It would then appear that a similar effect is responsible for the energy barrier difference between **1***b* and **2***b*.

The difference in dynamic behaviour for **3***b* (2-CH_3 derivative) and **4***b* (2-OCH_3) is most interesting since both compounds are found to exist predominantly in the TB form and yet only **4***b* gives rise to a spectral change at the low temperatures reached. Because the methyl group is expected to exert greater steric compression than the methoxy group, it appears reasonable to think that the observed barrier differences might arise from electronic effects either through the same pathway or through a different one.

Furthermore, data given in Table 2 for **4***a*, **4***b*, **8**, and **9** suggest that electronic effects contribute significantly to the similarity of the pseudorotation free energy barriers of the TB form of each molecule. Anet and Yavari (17) have shown that the generalized anomeric effect raises the rotational barrier of chloromethylmethyl ether and it therefore appears highly probable that stereoelectronic interactions could be responsible for the increased magnitude of the pseudorotation barrier of these four compounds.

Two pathways are available for the TB inversion of **3***b* and **4***b* as illustrated in Scheme 2 where a_1 and a_2 represent forms of intermediate geometries with five coplanar ring atoms (14) differing only by the position of the substituent. The choice between these two pathways (i.e. either through B-a or B-e) for **4***b* requires the assessment of the relative importance of steric and electronic interactions in the ground state TB conformation and along each

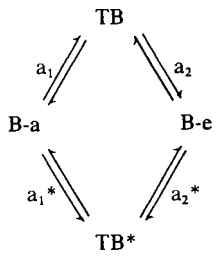


SCHEME 2

pathway. A quantitative approach to this question is beyond the scope of our present work.

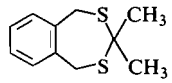
Nevertheless, a qualitative assessment of the effect of steric interactions of methyl groups on the pseudorotation of TB proves to be useful for **3***b*. The fact that **2***b* must possess a methyl group at both axial and equatorial positions of the B form suggests that it is an acceptable model for estimating the energy demand of the pathway through B-a in Scheme 2. A model for the pathway through B-e is provided by **1***b*. Consequently, the failure to observe a spectral change for **3***b* indicates that its TB form inverts through a pathway closer to that of **1***b* (i.e. B-e) rather than that of **2***b*, which gave rise to a spectral change in accord with a higher pseudorotation barrier expected for passage through B-a.

The Conformational Effect of the Benzo Group

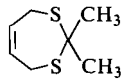
The increased stability of the TB form of the dioxepin rings of **1***a* and **1***b* relative to the corresponding hydrocarbon rings is largely a consequence of electronic interactions associated with the anomeric effect in the acetal moiety of the heterocycles (7). In addition, the results obtained for the pairs of molecules **1***a*,**1***b* and **3***a*,**3***b* provide information on the magnitude of the conformational change produced by the replacement of the double bond by a benzo group in the seven-membered ring. Together with recent results (18) for the sulfites **8** and **9**, they show that a general trend exists whereby the replacement of a benzo group by a double bond significantly stabilizes the TB conformation relative to the C form.

The explanation for the observed trend can be derived from ideas first advanced by Allinger and Sprague (14) who pointed out that differences in torsional interactions at the allylic bonds (H/H eclipsing similar to that in propene whose rotational barrier is 1.98 kcal/mol) and benzylic bonds (H/C_{sp^2} eclipsing as in toluene whose rotational barrier is about 0.5 kcal/mol) play an important role in determining the conformational properties. Thus the replacement of a benzo group by a double bond stabilizes the TB form relative to C because the higher torsional strain about the allylic bonds found in C is relieved significantly by the conformational change to TB in which torsional angles lead to reduced torsional energy.

Furthermore, results published for molecules **10** and **11** fall in line with the above conclusion, for it had been reported that **10** exists uniquely in the C form whereas **11** exists as a mixture of C and TB forms (8).



10



11

The structural change under consideration also affects the dynamic properties of the members of each pair of molecules (Table 2) by perturbing both the energy barriers of the C → B step of the C inversion as well as of the pseudorotation motion of the TB inversion. The effect of benzo substitution on the $\Delta G^{\ddagger}$ barrier for C inversion is an increase of about 6 kcal/mol for the cycloheptene–benzocycloheptene pair and about 4 kcal/mol for the **10**–**11** pair and for which free energies of 12.2 and 8.2 kcal/mol were reported (8). Relief of torsional strain about the allylic bonds in reaching the transition state for the C → B transformation was claimed to be largely responsible for the above differences (14).

Table 2 also reveals that molecules **2***a*, **4***a*, and **8** all possess slightly larger pseudorotation barriers than their counterparts **2***b*, **4***b*, and **9**. It would appear that differential changes in allylic and benzylic torsional strain during the pseudorotation cycle are responsible at least in part for this effect, although the difference in $\Delta G^{\ddagger}$ for the 2,2-dimethyl derivatives **2***a* and **2***b* suggests that other factors, possibly of electronic or solvation origin, might come into play.

Experimental

High-resolution mass spectra at 70 eV were recorded using an Associated Electrical Industries spectrometer model MS-902.

Both ^1H and ^{13}C variable temperature nmr spectra were recorded in the FT mode on a Bruker WP-80 spectrometer equipped with the standard variable temperature accessory (B-VT-1000) and operating at 80 and 20.15 MHz respectively.

All ^{13}C nmr spectra were recorded with proton decoupling for solutions in CHF_2Cl (200–270 mg in 2.5 mL of solution) containing Me_4Si and about 15–20% of CD_2Cl_2 (for locking purpose) in standard 10 mm tubes which had been degassed and sealed. The ^1H nmr spectra were also recorded in 5 mm tubes as degassed solutions in $CDCl_3$ and/or CHF_2Cl containing CD_2Cl_2 and Me_4Si; about 20–30 mg in 0.50 mL of solution were used.

The following instrumental conditions were used; ^{13}C nmr: flip angle = 35–40°, except for **4***b* below −150°C for which 90° pulses were used, SW = 6,000 Hz, data size = 8K; ^1H nmr: flip angle ≈ 10°, SW = 1,200 Hz, data size = 8K.

Temperatures were measured accurately with a calibrated copper–constantan thermocouple placed inside a solvent-containing dummy nmr tube. A precision of ± 1° is expected.

Preparation of 1b, 3b *and* 5b

These three compounds were prepared according to a published general procedure (19) from 2-butene-1,4-diol (Aldrich, 91% *cis*, distilled before use). The benzene solvent was removed by distillation at atmospheric pressures and each compound was obtained pure by reduced pressure distillation (20). The yields were 60%, 16%, and 54% respectively. The ^{1}H nmr spectra of each compound were found to be identical to those reported earlier for **1***b* (9, 21), **3***b* (21), and **5***b* (9). The ^{13}C nmr chemical shifts reported in Table 1 confirm the identity of each compound.

*2,2-Dimethyl-1,3-dioxa-5,6-cycloheptene (***2***b)*

Compound **2***b* was prepared from 2-butene-1,4-diol, dimethoxypropane, and acetone by the procedure (7) used for **2***a*. The ^{1}H nmr spectrum was found to be identical to that published (9, 21) while the ^{13}C nmr data reported in Table 1 confirm the structure.

*2-Methoxy-1,3-dioxa-5,6-cycloheptene (***4***b)*

Compound **4***b* was prepared by the procedure (7) used previously for **4***a*. After distillation of the benzene at atmospheric pressures, the product was purified by reduced pressure distillation (30°C/0.5 Torr); its yield was 20%. The ^{1}H nmr spectrum in $CDCl_3$ showed the following signals δ: 3.41 (s, OCH_3), 4.14 and 4.49 (AB pattern, CH_2), 5.40 (s, CH), and 5.72 (m, olefinic H). The ^{13}C nmr parameters, summarized in Table 1, are also compatible with structure **4***b*.

Mol. Wt. calcd. for $C_5H_7O_2$ ($M^+ - OCH_3$): 99.0446; found (mass spectrum at 70 eV): 99.0448.

Complexes of methylmercury(II) with 1-methylcytosine and crystal structure of μ-(1-methylcytosinato-N3,N4)bis(methylmercury(II)) nitrate

LEONARDO PRIZANT, ROLAND RIVEST, AND ANDRÉ L. BEAUCHAMP[1]

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal, (Qué.), Canada H3C 3V1

Received October 9, 1980

LEONARDO PRIZANT, ROLAND RIVEST, and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **59**, 2290 (1981).

Two types of solid complexes are isolated by reaction of CH_3HgX (X = NO_3 and ClO_4) with 1-methylcytosine (MCy). The CH_3Hg^+ ion is probably bonded to N(3) in the $[CH_3Hg(MCy)]X$ compounds. Mercury binding to N(3) and the deprotonated amino group in $[(CH_3Hg)_2(MCy—H)]X$ is confirmed by X-ray work on the nitrate salt. The crystals are orthorhombic, space group *Pbca*, with $a = 12.014$, $b = 13.573$, $c = 16.353$ Å, and $Z = 8$. The structure was refined on 962 independent reflections to an R factor of 0.038. The CH_3Hg^+ groups are arranged in a *syn* configuration and the angles around the mercury-bonded nitrogen atoms are severely distorted to prevent short Hg...Hg contacts. N(3)-coordination in the 1:1 complexes introduces minor changes in the infrared spectra, but the substitution of an amino proton in the 1:2 compounds produces important modifications. ^1H nmr data in DMSO-d^6 are reported for both types of compounds. This work emphasizes the important acidity enhancement experienced by the amino protons upon initial coordination to N(3), which facilitates further reaction of CH_3Hg^+ by proton displacement even in acidic media.

LEONARDO PRIZANT, ROLAND RIVEST et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **59**, 2290 (1981).

Deux catégories de complexes ont été isolées par réaction de CH_3HgX (X = NO_3 and ClO_4) avec la méthyl-1 cytosine (MCy). L'ion CH_3Hg^+ est probablement lié à N(3) dans les composés $[CH_3Hg(MCy)]X$. Dans le cas de $[(CH_3Hg)_2(MCy—H)]X$, le mercure se lie à N(3) et au groupe amino déprotoné, comme l'indique la structure cristalline du nitrate. Ce composé appartient au groupe orthorhombique *Pbca* et ses constantes réticulaires sont $a = 12{,}014$, $b = 13{,}573$, $c = 16{,}353$ Å et $Z = 8$. La structure a été affinée au moyen de 962 réflexions indépendantes jusqu'à un facteur R de 0,038. Les deux groupes CH_3Hg^+ se trouvent dans une configuration *syn* et des déformations importantes des angles touchant les atomes d'azote coordinés permettent d'éviter des contacts courts Hg...Hg. Les spectres infrarouges sont peu modifiés par coordination à N(3) dans les complexes 1:1, mais des changements majeurs se produisent lors de la substitution d'un atome d'hydrogène du groupe amino dans les composés 1:2. Les mesures de rmn ^1H sont présentées pour les composés dissous dans DMSO-d^6. Ce travail met en évidence l'accroissement considérable de l'acidité de la fonction amine par coordination initiale du mercure en N(3), ce qui rend possible le déplacement de proton par un autre groupe CH_3Hg^+ même en milieu acide.

Introduction

Spectroscopic studies have shown that amino hydrogens of adenosine and cytidine can be displaced by CH_3Hg^+ in aqueous solutions (1–3). In earlier reports (4, 5), we have presented crystallographic evidence that substitution takes place with 9-methyladenine even in moderately acidic solutions, provided another CH_3Hg^+ group is simultaneously bonded to N(1). This prompted us to examine the behavior of 1-methylcytosine (MCy), a ligand containing a similar arrangement of nitrogen atoms.

Cytosine is a versatile ligand. Most metal ions react predominantly at N(3) with a varying degree of participation of the adjacent carbonyl O(2) atom (6,7). Coordination with O(2) only has been observed so far in one crystal structure (8), but a recent nmr study indicates that in DMSO, unidentate binding through O(2) is more common than anticipated (9). Selective reaction of CH_3Hg^+ with the deprotonated amino group has been reported to take place at high pH (1, 3) and this mode of bonding has also been observed for ruthenium compounds (10, 11). Very recently, MCy has been found to be bridging via N(3) and the deprotonated amino group in dimeric platinum complexes (12).

In the present work, we have investigated the reactions of CH_3Hg^+ with MCy in aqueous media, in order to obtain solid compounds on which detailed structural analyses could be carried out. Complexes of two types have been isolated and the crystal structure of one of those is reported.

Experimental Section

Preparations

1-Methylcytosine (Vega) was used after recrystallization from 95% ethanol. CH_3HgI (Alfa) was the starting material to make solutions of methylmercury salts.

Aqueous ~1 *M* solutions of CH_3HgNO_3 were prepared by refluxing CH_3HgI (5% excess) suspended in 1 *M* $AgNO_3$ for 1 h. AgI and excess CH_3HgI were filtered and the filtrate was treated again with a small amount of CH_3HgI to remove any remaining silver. The ~1 *M* CH_3HgClO_4 solutions were similarly obtained from $AgClO_4$ solutions.

$[CH_3Hg(MCy)]NO_3$. MCy (2 mmol) was dissolved in hot water (20–30 mL) and the CH_3HgNO_3 solution (2 mmol) was added while stirring. After 24 h at room temperature, the colorless solid was filtered and dried under vacuum. Recrystallization from 95% ethanol yielded a crystalline material. *Anal.* calcd. for $C_6H_{10}N_4O_4Hg$: C 17.89, H 2.50, N 13.91, Hg 49.80; found: C 17.99, H 2.57, N 14.21, Hg 49.75.

[$CH_3Hg(MCy)$]ClO_4. Same method as above, using CH_3HgClO_4. Recrystallized from 95% ethanol as a flaky solid. *Anal.* calcd. for $C_6H_{10}N_3O_5ClHg$: C 16.37, H 2.29, N 9.55, Hg 45.57; found: C 16.09, H 2.29, N, 9.63, Hg, 45.48.

[$(CH_3Hg)_2(MCy—H)$]NO_3. MCy (2 mmol) was dissolved in water as above and 4 mmol of CH_3HgNO_3 were added while stirring. NaOH (1 mmol) was then added as a ~1 *M* solution. After 24 h, a colorless material deposited. Colorless crystals were isolated by recrystallization from 95% ethanol. *Anal.* calcd. for $C_7H_{12}N_4O_4Hg_2$: C 13.62, H 1.96, N 9.07, Hg 64.98; found: C 13.41, H 1.99, N 9.19, Hg 64.79.

[$(CH_3Hg)_2(MCy—H)$]ClO_4. Same method as the previous compound, using CH_3HgClO_4. Recrystallization from 95% ethanol yielded a flaky colorless solid. *Anal.* calcd. for $C_7H_{12}N_3O_5ClHg_2$: C 12.84, H 1.85, N 6.42, Cl 5.41, Hg 61.26; found: C 12.61, H 1.85, N 6.43, Cl 5.36, Hg 60.97.

The analyses were carried out by Schwarzkopf Laboratories, New York.

The infrared spectra (4000–300 cm^{-1}) were recorded as KBr pellets and Nujol mulls (CsI windows) using a Beckman IR4250 spectrophotometer.

The ^1H nmr spectra were taken at room temperature using a Bruker WH-90 (90 MHz) apparatus. The compounds were dissolved in DMSO-d_6 (SILANOR, Merck, Sharp & Dohme) and tetramethylsilane was used as an internal standard.

Crystal data

$C_7H_{12}Hg_2N_4O_4$ f.w. = 617.38

Orthorhombic, *Pbca*, a = 12.014(3), b = 13.573(4), c = 16.353(2) Å, V = 2667 Å^3, Z = 8, D_c = 3.075 g cm^{-3}, μ(MoKα) = 230.3 cm^{-1}, λ(MoK$\bar{\alpha}$) = 0.71069 Å (graphite monochromator), t = 23°C.

Crystallographic Measurements

A fragment of dimensions 0.27 × 0.17 × 0.33 mm^3 was cut from one of the large crystals obtained by recrystallization in 95% ethanol. Precession photographs clearly revealed *mmm* Laue symmetry and the space group was unambiguously determined from the systematic absences: $0kl$, $k \neq 2n$, $h0l$, $l \neq 2n$ and $hk0$, $h \neq 2n$.

The crystal was mounted on an Enraf-Nonius CAD4 diffractometer and the cell parameters were accurately determined by least-squares fit of the setting angles for 25 reflections centered in the counter aperture. Intensity data were collected by using the $\omega/2\theta$ scan technique. A fixed slit of 3.0 mm was used and the scan range (ω) was $(1.00 + 0.35 \tan\theta)°$ extended 25% on either side for backgrounds. Prescans at 6.7° min^{-1} were made and all reflections having $I/\sigma(I) < 1$ were labeled "weak" and not remeasured. Scan speed S between 6.7 and 0.67° min^{-1} was automatically selected to make the $I/\sigma(I) = 100$, but the scan time was limited to 135 s. Three standard reflections used as a check on instrument and crystal stability showed random fluctuations of < ±3%. Crystal orientation was checked every 100 measurements by centering three reflections. No crystal recentering was needed during data collection.

A total of 1733 independent *hkl* reflections ($2\theta \leq 45°$) were measured using Enraf-Nonius option FLAT, a procedure to measure intensity at the ψ position where absorption is minimum. Net intensity I was calculated from $I = (P - 2B)S$, where P is the peak count and B is the total background counted during one half of the scan time. Standard deviations were obtained from $\sigma^2(I) = (P + 4B)S^2 + (0.04I)^2$. A set of 962 reflections with $I < 3.0\ \sigma(I)$ was retained for structure determination. An absorption correction was applied (Gaussian integration, grid 8 × 8 × 8); the transmission factor ranged from 0.030 to 0.080. The data were finally corrected for Lp effects.

Structure Determination

The structure was solved by the heavy-atom method and refined by full-matrix least-squares. Both independent Hg atoms were positioned from a Patterson synthesis and the remaining nonhydrogen atoms were located in a subsequent difference Fourier map. Isotropic refinement using unit weights converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.108$. The nonhydrogen atoms were then refined anisotropically. Hydrogens on C(5), C(6), and N(4) were fixed at their calculated positions (assuming sp^2 hybridization and C(N)—H = 0.95 Å) with isotropic temperature factors B of 4.0 Å^2; their coordinates were recalculated after each cycle of refinement. Individual weights based on counting statistics $w = 1/\sigma^2(F_o)$ were applied in the last least-squares cycles. Anisotropic refinement converged to R = 0.038 and $R_w = \Sigma[w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.050$. The goodness-of-fit ratio was 1.63. The hydrogens of the methyl groups could not be unambiguously recognized in the final difference Fourier map. The map had a general background < ±0.7 e/Å^3, except for a few peaks of ±1.1–1.2 e/Å^3 close to Hg.

The form factors used were those of Cromer and Waber (13), except for hydrogen (14). Anomalous dispersion terms f' and f'' were used for Hg (15). The refined coordinates are listed in Table 1. The anisotropic temperature factors, and the list of observed and calculated structure factors are part of the unpublished material.[2] The computer programs used are listed elsewhere (16).

Results

Two pairs of compounds have been isolated by reacting CH_3HgX (where X = NO_3 and ClO_4) with MCy: complexes of 1:1 stoichiometry without proton substitution and 2:1 compounds in which one proton per ligand has been displaced. The ^1H nmr and ir spectra (except for bands of the anions) of corresponding compounds are very similar, indicating that both salts contain the same complex cation. In the 1:1 compounds, CH_3Hg^+ is probably bonded to N(3) as commonly observed, especially for soft metals (6, 7, 9). The crystal structure of the nitrate of 2:1 stoichiometry shows that mercury coordination takes place with N(3) and the deprotonated amino group N(4).

Description of the Crystal Structure of [$(CH_3Hg)_2(MCy—H)$]NO_3

Unexpectedly, the CH_3Hg^+ groups are in the *syn* arrangement (Fig. 1), instead of the presumably less constrained *anti* configuration already found in [(9-methyladeninato)$(CH_3Hg)_2$]ClO_4 (4). The *syn* configuration has been observed in two dimeric N(3),N(4)-bonded platinum complexes (12), but in that case the *syn* arrangement can be stabilized by the stacking of square planes commonly found with platinum (with or without Pt—Pt bonding). In the

[2]The supplementary material includes a table of temperature factors, a list of structure factors, and details of least-squares plane calculations. *Parameters not refined.

present structure, the preference for the *syn* orientation is hard to explain and ^{1}H nmr results (see below) suggest that the structure may be different in solution. Even though the distortions are severe, they are not unprecedented. For instance, the Hg(4)—N(4)—C(4) angle (133(2)°) is only slightly greater than those observed in [Ru(NH_3)$_5$(MCy—H)] (PF_6)$_2$, 129.2(7)° (11) and in [(NH_3)$_4$$Pt_2$(MCy—H)$_2$]($NO_3$)$_2$.2$H_2O$, 131(2)° (12), although the value of ~124° obtained in the 9-methyladenine complex (4) and in (H_5O_2)-[(Pt_2(NO_2)$_2$(NH_3)$_4$(MCy—H)$_2$](NO_3)$_2$ (12) appears to be more normal. On the other hand, there is a large difference of 24° between Hg(3)—N(3)—C(4) and Hg(3)—N(3)—C(2), which is not found in the platinum complexes (12). However, a similar difference has been observed in Hg_2Cl_4-(MCy)$_2$ (16) and still larger values have been reported (17). As a result of that distortion, Hg(3) lies at 2.84(2) Å from carbonyl oxygen O(2) and the angular deformation at N(3) is possibly balanced by some Hg...O bonding interaction. The resulting Hg...Hg contact (3.150(2) Å) is greater than twice the short van der Waals radius proposed by Grdenic (1.50 Å) (18), but it is shorter than the intramolecular non-bonded Hg...Hg contacts (3.27–3.31 Å) found in similar complexes (19). If severe repulsion remained between the Hg atoms, the CH_3Hg groups would be expected to slip out of the molecular plane, in *opposite* directions. They are found at large distances from the plane of the ring (Hg(3), 0.214(1) Å; C(13), 0.45(4) Å; Hg(4), 0.393(1) Å; C(14), 0.74(3) Å), but on the *same* side. Consequently, in spite of an obvious departure for

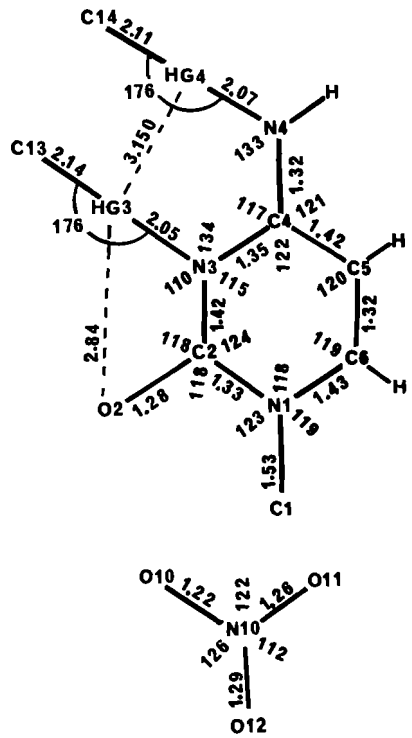

FIG. 1. Interatomic distances and bond angles in [(CH_3Hg)$_2$-(MCy—H)]NO_3. The standard deviations on distances are 0.04–0.05 Å, except for Hg—Hg, 0.002 Å, Hg—N(O), 0.02 Å, and Hg—C, 0.03–0.04 Å. On bond angles, they are 2–3°, except for N—Hg—C, 1° and O—N—O, 4°.

ideality, this molecule is probably not extremely strained.

The Hg—N and Hg—C bond lengths (ave. 2.06(2) and 2.12(3) Å, respectively) are normal and there is no appreciable departure from the usual linear coordination of mercury (C—Hg—N = 176(1)°).

Because of the large esd's, the distances and angles in the coordinated ligand show no significant differences from either neutral or protonated MCy (20), so that no effects of coordination can be detected. The six-membered ring of the ligand is planar within 1.3σ (0.04 Å) and the distances from the exocyclic groups to the plane are small: N(4), 0.08(2) Å; O(2), −0.06(2) Å; C(1), 0.03(3) Å.

The NO_3^- ion is planar within 0.5σ (0.02 Å). The bond lengths (ave. 1.26(4) Å) and angles 120(4)° are as expected.

A stereo view of the molecular packing is shown in Fig. 2. There is no long-range stacking of the bases, which is rather unusual for CH_3Hg^+ complexes with free or methylated bases. The only hydrogen bond is established between N(4)—H(4) and carbonyl group O(2) at $\frac{1}{2}-x, \frac{1}{2}+y, z$. It is rather weak (N(4)...O(2) = 3.13(3) Å) and the geometry is

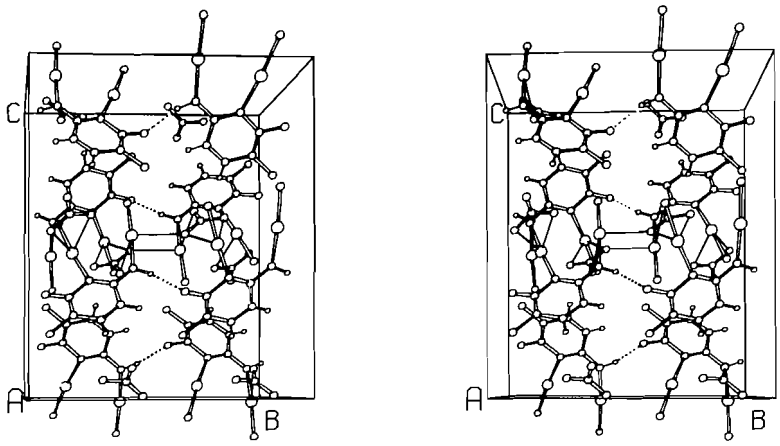

FIG. 2. ORTEP drawing of the unit cell of $[(CH_3Hg)_2(MCy—H)]NO_3$. The ring atoms can be identified by reference to Fig. 1. The larger and smaller spheres correspond to Hg and H, respectively. The secondary Hg...O bonds are shown as thin continuous lines and H-bonds, as dashed lines.

TABLE 2. Secondary bonds to mercury

Atoms	Distance (Å)	Atoms	Distance (Å)
Hg(3)—O(11)[a]	2.98(3)	Hg(4)—O(10)[b]	2.88(3)
Hg(3)—O(12)[a]	2.86(2)	Hg(4)—O(12)[c]	2.83(3)
Bonds	**Angle (deg)**	**Bonds**	**Angle (deg)**
C(13)—Hg(3)—O(11)[a]	96.1(12)	C(14)—Hg(4)—O(10)[b]	97.2(11)
C(13)—Hg(3)—O(12)[a]	97.8(12)	C(14)—Hg(4)—O(12)[c]	105.3(11)
N(3)—Hg(3)—O(11)[a]	82.0(8)	N(4)—Hg(4)—O(10)[b]	82.2(10)
N(3)—Hg(3)—O(12)[a]	83.4(8)	N(4)—Hg(4)—O(12)[c]	78.6(9)
O(11)[a]—Hg(3)—O(12)[a]	42.5(7)	O(10)[b]—Hg(4)—O(12)[c]	115.7(8)

$a = x, \frac{1}{2} - y, -\frac{1}{2} + z$; $b = -\frac{1}{2} + x, y, \frac{1}{2} - z$; $c = \frac{1}{2} - x, 1 - y, -\frac{1}{2} + z$.

not particularly favorable (C(4)—N(4)—O(2) = 101(2)°, C(2)—O(2)—N(4) = 125(2)°). Each Hg atom forms secondary bonds with two nitrate oxygens close to the equatorial plane (Table 2). Hg...O contacts in the range 2.83–2.98 Å are common with nitrate ions and definitely shorter than observed with the less basic ClO_4^- ion (19). The NO_3^- ion acts as a three-way link between complex cations: it is chelating bidentate by O(11) and O(12) toward Hg(3), while O(10) interacts with one Hg(4) atom and O(12), already bonded to Hg(3), also interacts with a different Hg(4) atom.

Infrared Spectroscopy

The spectra of MCy and both types of complexes are represented in Fig. 3. Our results for MCy are in good agreement with those published by Lord and Thomas (21). Pairs of salts of the same stoichiometry have very similar spectra, except for the bands originating from the anions. The ir-active ν_3 and ν_4 modes of ClO_4^- are easily related to the very strong bands at $\sim$1080 cm^{-1} and the medium band at $\sim$625 cm^{-1}, respectively (22). Weak bands at $\sim$928 cm^{-1} probably correspond to the ir-inactive ν_1 mode gaining some intensity by reduced site symmetry. The NO_3^- ion is identified from its very strong and broad ν_3 band at $\sim$1360 cm^{-1} and weaker absorption ν_2 at $\sim$823 cm^{-1}. Some of the weak features around 710 and 1040 cm^{-1} could correspond to ν_4 and ν_1 respectively, the latter mode being normally ir-inactive.

The ir spectra of a number of CH_3Hg^+ compounds have been discussed (23). The vibrations due to the CH_3 group are not easily identified, because the ligand shows N(1)—CH_3 or other bands in the same regions. The sharp peak at 2925 cm^{-1} is due to the superimposed ν_s modes of both methyl groups. The ν_a, δ_a, and δ_s modes expected to produce weak bands around 3000, 1410, and 1200 cm^{-1}, respectively, could not be unambiguously assigned. Comparisons with the spectra obtained for similar Ag^+—MCy compounds (24) reveals

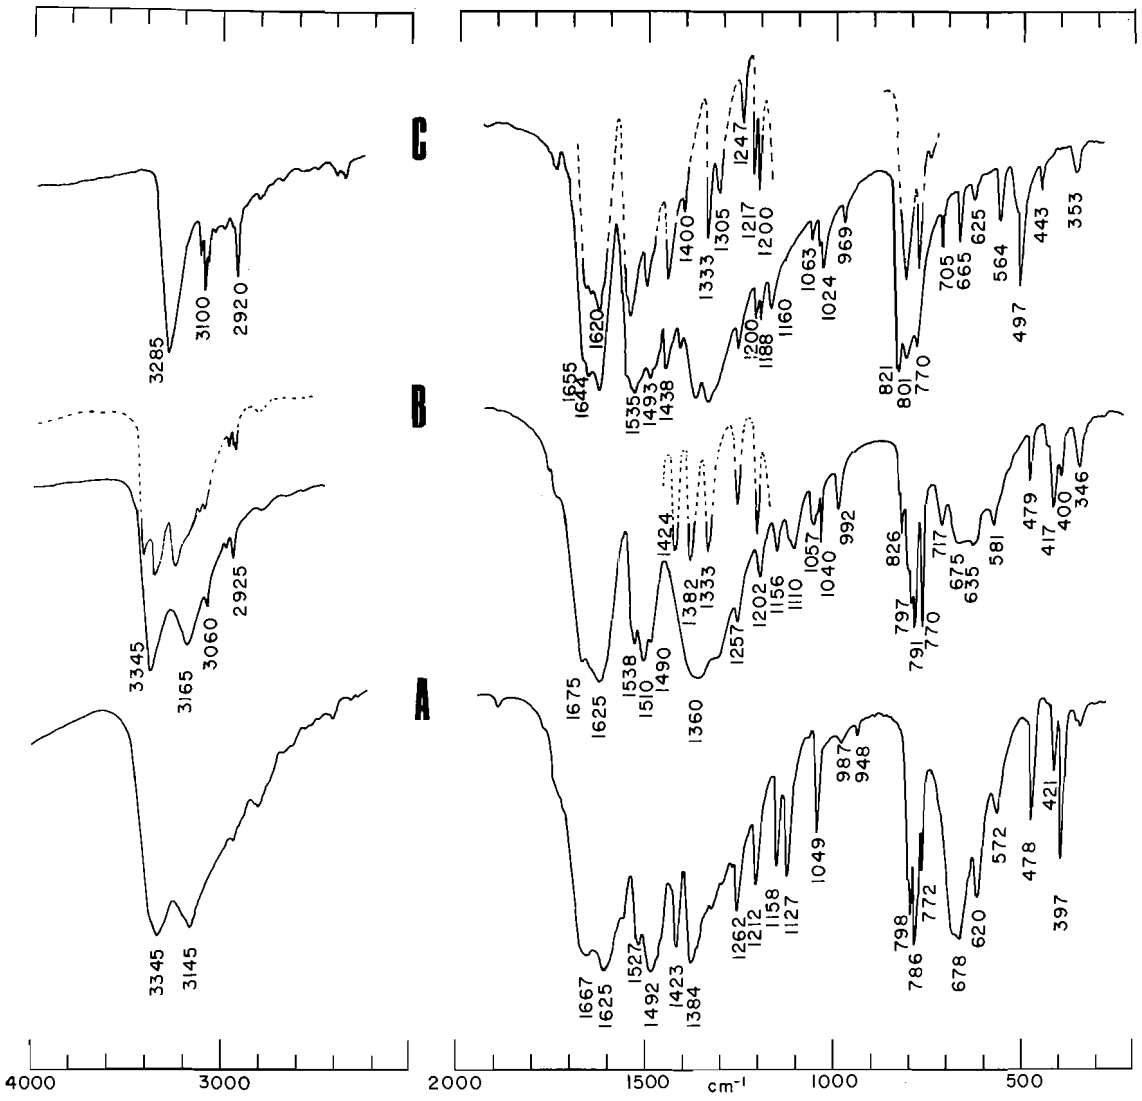

FIG. 3. Infrared spectra. A = MCy, B = $[CH_3Hg(MCy)]NO_3$, C = $[(CH_3Hg)_2(MCy\text{-}H)]NO_3$. Portions of spectra in dotted lines correspond to the perchlorate analog.

extra strong bands at 801 cm^{-1} in $[(CH_3Hg)_2$-(MCy—H)]X and ~790 cm^{-1} in $[CH_3Hg(MCy)]X$, which probably correspond to $\rho(CH_3)$. The Hg—C stretching vibration can be identified only in the N(3),N(4)-bonded complexes as a weak band at 564 cm^{-1}. In the 1:1 compounds, that absorption is masked by the very broad $w(NH_2)$ vibration found at ~680 cm^{-1} in the ligand (21, 25) and displaced to lower wavenumbers in the complexes.

N(3)-binding

The most obvious spectral changes in the N(3)-bonded compounds are associated with the NH_2 group. The N—H stretching bands at 3345 and 3145 cm^{-1} (21, 25) are not displaced appreciably, but they become sharper (and split in the case of the perchlorate) (Fig. 3). As a result, the weak C—H stretching bands of the ring and methyl groups (2900–3100 cm^{-1}) are better defined. Two ligand bands at 1127 and 1049 cm^{-1} are shifted by −17 and +8 cm^{-1} respectively in the complexes. They are believed to involve a large amount of NH_2 rocking motion (25). Those changes are likely to simply reflect different hydrogen-bonding patterns.

The most interesting spectral change is the appearance in the perchlorate salt of a well-defined band at 1333 cm^{-1}, where free MCy does not absorb appreciably. According to Tsuboi *et al.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

(25), this vibration should be located in the N(1)—C(6)—C(5) side of the ring. The utility of this band for predicting N(3)-binding could not be checked with the nitrate, which strongly absorbs at that position.

Other regions (~1500, ~800, and ~635 cm^{-1}) have been reported to be sensitive to N(3)-coordination (2, 12), but they could not be used in this case because of insufficient resolution or interference from the CH_3Hg groups.

N(3),N(4)-bridging

This type of bonding leads to major changes in the ligand spectrum. Only one sharp ν(N—H) band at 3285 cm^{-1} is observed for the deprotonated amino group. The weak C—H stretching modes are now clearly observed. The absence of an amino group can be detected by the much sharper absorptions between 1620 and 1650 cm^{-1}, where the scissoring motion of the amino group absorbed, and by the complete disappearance of the w(NH_2) band at 680 cm^{-1}. The band at 1127 cm^{-1} involving the rocking NH_2 motion (25) is no longer present. It has apparently been replaced by a medium band at 1305 cm^{-1}, which might involve in-plane N—H bending of the substituted amino group.

A number of other modifications in positions and intensities are observed throughout the spectrum. For instance, the bands at 1024, 1200, and 1247 cm^{-1} have all been shifted with respect to the free ligand. Those wavenumbers, together with 1305 cm^{-1}, seem to correspond to characteristic values reported by Mansy *et al.* (3) for the CH_3Hg^+ species formed in basic solutions with deprotonated cytidine. The "ring breathing" region (~780 cm^{-1}) is also affected in a similar manner as in the 1:1 complexes. It is noteworthy that the band at 1333 cm^{-1}, suggested as a characteristic for N(3)-coordination, is still present in these compounds. Finally, there is a sharp absorption of medium intensity at ~497 cm^{-1}, which is found neither in the free ligand, nor in the 1:1 complexes. A similar band at ~480 cm^{-1} was assigned to the Hg—N(amino) stretching mode in 9-methyladenine complexes (26).

^1H Nuclear Magnetic Resonance Spectroscopy

The spectrum for MCy (Table 3) is in good agreement with the results of other workers (12, 27, 28). The doublets at 5.60 and 7.55 ppm are due to H(5) and H(6), coupled by 7 Hz (27). The sharp signal at 3.19 ppm originates from the N(1)—methyl group. The amino protons give a broad singlet at 6.92 ppm.

The H(5) and H(6) doublets are shifted downfield by 0.49 and 0.35 ppm, respectively, in the N(3)-bonded 1:1 complexes (Table 3). These shifts are of the same magnitude as those observed when MCy is protonated by $HClO_4$, an acid devoid of extra effects due to anion–ligand H-bonding (28). Similar shifts have been noted for other N(3)-bonded complexes with Pt (12, 29) and when $ZnCl_2$ (30) or $HgCl_2$ (31) are reacted with cytidine in DMSO. The NH_2 signal is shifted from 6.92 to 8.73 ppm and appears as two very close ($\Delta\delta = 0.08$ ppm) but resolved components of equal intensities. Signal splitting has been reported for protonation (28) and complexation with Pt (12) and Hg (31), but the separation is much greater. Splitting results from hindered rotation about the C(4)—N(4) bond, making the amino protons inequivalent. Since the NO_3^- and ClO_4^- ions used in this work have been shown not to interfere with the ligand signals through H-bonding (28), we conclude that introducing CH_3Hg^+ at N(3) led to a small, but detectable, inequivalence of the amino protons.

The spectra of the N(3),N(4)-bonded complexes show only one resonance at ~0.78 ppm for the protons of the two rapidly exchanging CH_3Hg groups. Proton substitution on the 4-NH_2 group by the electropositive Hg atom produces, as expected, an upfield shift from 8.73 ppm (1:1 complex) to 7.49 ppm. However, it is noteworthy that the remaining amino proton appears to be more acidic than it was in free MCy (6.92 ppm). In this respect, $[(CH_3Hg)_2(MCy—H)]X$ differs markedly from $[(NH_3)_4Pt_2(MCy—H)_2](NO_3)_2$, for which the same proton has a chemical shift of 6.16 ppm (12). The Pt complex was shown by X-ray diffraction to have a similar *syn* arrangement of metal atoms in the solid and the structure is likely to be retained by this non-labile system in solution. A similar spectrum was reported for a silver-cytidine species in which Ag is bonded to the deprotonated amino group and probably interacts with N(3) as well, although the exact structure is not known (32). Differences are also found for the H(5) and H(6) resonances. With Pt and Ag, both doublets shift upfield in going from the N(3)-bonded to the N(3),N(4)-bonded compounds. For $[(CH_3Hg)_2(MCy—H)]X$, the shifts are downfield for H(5) and upfield for H(6).

The above chemical shifts suggest that the CH_3Hg compounds might undergo some rearrangement in DMSO. However, the ^1H–^{199}Hg coupling constants are not inconsistent with a structure in which both CH_3Hg groups would remain coordinated.[3] With rapid exchange, the observed J value

[3]The following discussion concerning the coupling constants is largely based on suggestions of one of the referees, who also kindly provided relevant references.

TABLE 3. ^1H nmr data[a]

Molecule	δ N(1)—CH_3	H(5)	H(6)	H(41)—H(42)	Hg—CH_3	$^2J_{H5—H6}$	$^2J_{H—^{199}Hg}$
MCy	3.19s	5.60d	7.55d	6.92s		7	—
$[CH_3Hg(MCy)]NO_3$	3.34s	6.09d	7.90d	8.76b 8.71b	0.80s	7	227
$[CH_3Hg(MCy)]ClO_4$	3.34s	6.09d	7.89d	8.73b 8.64b	0.85s	7	226
$[(CH_3Hg)_2(MCy—H)]NO_3$	3.28s	6.24d	7.69d	7.48s, b	0.77s	—	207
$[(CH_3Hg)_2(MCy—H)]ClO_4$	3.28s	6.23d	7.68d	7.50s, b	0.78s	7	205

[a] In DMSO-d^6, chemical shifts (ppm) from internal tetramethylsilane. Coupling constants in Hz. s = singlet, d = doublet, b = broad.

(206 Hz) should be the average for the groups bonded to N(3) and N(4), respectively. The value for the 1:1 complex (226 Hz), which is close to the one obtained for the N(7)-bonded compound with guanosine (33), may be used as an estimate for the contribution of the N(3)-bonded group. Then, J for the other CH_3Hg ion should be ~186 Hz. There are no data in the literature for CH_3Hg compounds with RNH^- species, of which the $C_6H_5NH^-$ ion derived from aniline would be a simple example. However, the related compound $[CH_3Hg(OC_6H_5)]$ with phenol has been studied and the J value is 206 Hz (34). Comparisons of oxygen and nitrogen donors in analogous molecules reveal that the J values are lower for nitrogen: 252 Hz for $[CH_3Hg(CH_3OH)]^+$ (35) and 212 Hz for $[CH_3Hg(CH_3NH_2)]^+$ (36). Thus J should be substantially lower than 206 Hz for the complexation to the deprotonated amino group of aniline or MCy, and the above estimate (186 Hz) would be reasonable. On the other hand, there are extra possibilities if the difference of 40 Hz between the CH_3OH and CH_3NH_2 compounds would also apply to the phenolate/anilinate pair. In that case, the J value for the N(4)-coordinated CH_3Hg group in $[(CH_3Hg)_2(MCy—H)]X$ should be ~166 Hz, and the other CH_3Hg group, originally bonded to N(3) in the solid, should have a J value of 246 Hz in order to obtain an average value of 206 Hz. This would be consistent with partial dissociation of the latter CH_3Hg group (J for CH_3HgNO_3 in DMSO = 260 Hz (37)) or migration to the adjacent carbonyl group. It appears that data on a 1:1 complex of the type $[CH_3Hg(MCy—H)]$ are required to determine the nature of the 2:1 species in solution, but we have been unable to prepare this compound so far.

Discussion

Although the fixation of the first CH_3Hg^+ ion on N(3) was anticipated, its ability to acidify the amino protons was not expected to be so important. Increased acidic character is evidenced from the large downfield shift (1.8 ppm) of the ^1H nmr signal (Table 3) of the amino protons between MCy and its 1:1 complex, on the one hand, and from the possibility of preparing the $[(CH_3Hg)_2(MCy—H)]X$ compounds even under slightly acidic conditions, on the other hand. In this respect, the cytosine ring compares well with N(9)-substituted adenine, in which initial coordination to N(1) induces a similar effect on the 6-amino group (4, 5).

The availability of the 4-amino protons of cytosine for substitution suggests new possibilities for inserting ions like Ag^+ and Hg^{2+} between pairs of complementary bases in nucleic acids. Indeed, such linear two-coordinated cations are known to replace some of the hydrogen atoms normally involved in the base-pairing hydrogen bonds (38). Models in which one or two hydrogens per base pair are replaced by silver have been proposed (39). The present work supports the assumption that two metal ions can be inserted between the same pair of bases, since the positions occupied by the metal atoms would be approximately as found in the *syn* configuration revealed by the crystal structure of $[(CH_3Hg)_2(MCy—H)]NO_3$. In addition, if two metal atoms cross-link a G–C pair, the 4-NH_2 group of cytosine could be involved. Substitution of H(1) of guanine with concomitant formation of N(3C)—M—N(1G) bonds (**1**) is expected to facilitate the insertion of a second metal atom between N(4C) and O(6G), because the acidity of the amino group of cytosine would be enhanced by initial coordination with N(3C) and the basicity of O(6G) would be increased by substitution of H(1G).

The ^1H nmr results for the $[(CH_3Hg)_2(MCy—H)]X$ compounds are puzzling. In spite of a similar mode of bonding in the solid state $[(NH_3)_4Pt_2(MCy—H)_2](NO_3)_2$ (12) and the CH_3Hg complexes show strikingly different spectra in DMSO, suggesting structural reorganization in the latter case. Besides simple dissociation of a CH_3Hg group, two structural changes might take place. First, rotation about the C4—N4 bond could lead to an *anti* orientation of the CH_3Hg groups. Second, the bulkiness of the amino-bonded CH_3Hg group could promote a transfer of the other CH_3Hg group from N(3) to O(2). It has been shown that $HgCl_2$ binds to O(2) rather than N(3) in N^4,N^4-dimethyl-N^1-methylcytosine, owing to the steric hindrance of the dimethylamino group (9). From our present data, the species present in DMSO cannot be clearly identified but this problem is currently being examined.

Synthesis of α-thiohemiaminal derivatives of deoxynupharidine

ROBERT T. LALONDE AND TIMOTHY S. ECKERT

Department of Chemistry, State University of New York, College of Environmental Science and Forestry, Syracuse, NY 13210, U.S.A.

Received October 24, 1980

ROBERT T. LALONDE and TIMOTHY S. ECKERT. Can. J. Chem. **59**, 2298 (1981).

Disulfides, sulfenyl chlorides, thiosulfonates, and sulfensuccinimides were evaluated as electrophilic thiating agents for converting the enamine 6-dehydrodeoxynupharidine to α-thiohemiaminal derivatives of the alkaloid deoxynupharidine. Sulfensuccinimides were generally the most useful but other types of agents produced better yields in some individual cases.

ROBERT T. LALONDE et TIMOTHY S. ECKERT. Can. J. Chem. **59**, 2298 (1981).

On utilise les disulfures, les chlorures de sulfényles, les thiosulfonates et les sulfènesuccinimides comme agents de sulfuration électrophile pour transformer l'ènamine, déhydro-6 déoxynupharidine, en dérivés α-thiohémiaminal de l'alcaloide déoxynupharidine. Les sulfènesuccinimides sont généralement les agents les plus utiles, mais dans quelques cas individuels d'autres types de réactifs peuvent conduire à de meilleurs rendements.

[Traduit par le journal]

We have examined various electrophilic thiating agents (ArSX) for use in the conversion of 6-dehydrodeoxynupharidine, **1**, to diastereomeric α-arylthiohemiaminals **2** and **3**. Previous work had shown that **2***a* and **3***a* (1) were active against human pathogenic fungi. The α-thiohemiaminals also have pH dependent chiroptical properties (2) whose occurrence was attributed to the stabilizing intramolecular association of iminium ion with divalent sulfur (3). Here we treat the synthetic aspects of α-arylthiohemiaminal formation as it relates to the choice of the electrophilic thiating agent and the characterization of the products.

Electrophilic Thiating Agents

Enamines of cyclohexanone have been thiated by nitrophenyldisulfide (4), sulfenyl chlorides (4), and sulfensuccinimides (5). The reactive C-7 position of the enamine **1** has been thiated intentionally by phenyl benzenethiosulfonate (1) and unintentionally by *p*-toluenesulfonyl chloride (6).

As indicated by the results summarized in Table 1, *p*-nitrophenyldisulfide was the only disulfide of five which reacted with **1**. This result indicates that the nitro groups are required to make the sulfur atoms electrophilic and stabilize the leaving thiolate anion. Noteworthy, however, is the observation that even with the activating *p*-nitro groups, the *p*-nitrophenyl disulfide required a longer reaction time than any of the other nondisulfide thiating agents.

Of the other thiating agents, the sulfensuccinimides were the most dependable generally. The latter were prepared by heating a disulfide with *N*-bromosuccinimide according to a standard procedure (7). An exception was *p*-tosyloxyphenylsulfensuccinimide which could not be prepared in this manner nor by an alternative procedure whereby the corresponding sulfenyl chloride was added to succinimide in the presence of a *tert*-amine (8). However, in every case where the sulfenimide could be prepared, α-arylthiohemiaminal products were obtained in amounts adequate for the separation of C-7 epimers and the characterization of each. Sulfensuccinimides also offered the advantage that the crude thiating agent was sufficiently pure to be used directly without any purification.

The sulfenyl chlorides were judged to be of limited utility as a class because the attempted syntheses of the *p*-nitro and *p*-chloro derivatives was unsuccessful. *p*-Nitrophenyl disulfide and *p*-

chlorophenylthiol did not react reliably with chlorine under the standard conditions (9). However, *p*-tosyloxyphenylsulfenyl chloride, required for the preparation of the *p*-hydroxyphenylthiohemiaminals, was prepared from *p*-tosyloxyphenyl disulfide in this manner.

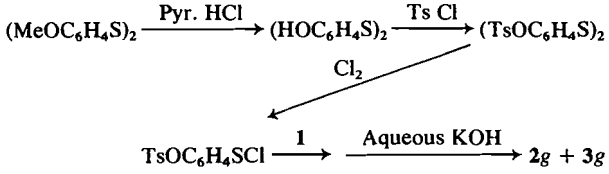
Although the sulfensuccinimides quickly found favor as the most dependable general thiating agents, representatives of all four classes were used as preferred reagents to synthesize particular α-arylthiohemiaminals. Thus the *p*-chlorophenylthiohemiaminals were prepared from the thiosulfonate, which was obtained reliably in high yield and purity by standard procedures (10, 11). The mixture of *p*-nitrophenylthiohemiaminals was prepared preferentially from the disulfide, the tosyloxy compounds from the sulfenyl chloride, and the remaining five from the sulfenimides.

Formation of α-Arylthiohemiaminals

Sulfensuccinimides in methylene chloride solution produced equal amounts of epimeric α-arylthiohemiaminals **2** and **3** as determined by integrating the axial and equatorial C-6 ^{1}H nmr signals observed in the spectra of the crude reaction products. However, phenylsulfenyl chloride in methylene chloride or phenyl benzenethiosulfonate in benzene gave mixtures rich in **2***a*.

α-Arylthiohemiaminals **2***a–f* and **3***a–f* were obtained directly from the reaction of the appropriate agent with **1**. However, to prepare **2***g–h* and **3***g–h* it was necessary to employ thiating agents wherein hydroxyl and amino groups were protected. In the case of phenolic **2***g* and **3***g*, whose formation is traced below, an arenesulfonyl protecting group was favored over an alkyl group because the 3-furyl was considered vulnerable to the anticipated vigorous acidic conditions required for alkyl removal. Since alumina column chromatography of a small portion of the hemiaminal reaction mixture resulted in a proliferation of tlc spots, presumably because of tosyloxy hydrolysis, the remaining crude mixture was heated with aqueous base to effect the direct hydrolysis of the protecting tosyl group.

Proceeding in a manner similar to the above 4-hydroxyphenyl case, the amino groups of bis-4-aminophenyl disulfide were protected by treating the latter with hot 88% formic acid. The resulting bis-4-formamido derivative was treated with NBS. The sulfensuccinimide reacted with **1** and gave the thiohemiaminal whose amino protecting group was removed directly through acyl exchange with hydrazine. Noteworthy is the unusual care required for the formation of the sulfensuccinimide from NBS. This step was achieved only when the reaction mixture was warmed two hours at 55°C, a temperature 20° below the normal. Longer reaction times or higher temperatures resulted in the rapid deterioration of the sulfensuccinimide.



Characterization and Stereochemistry of the α-Thiohemiaminals

Earlier work in this laboratory with pairs of α-thiohemiaminals (**2***a* and **3***a* (1), **2***b* and **3***b* (6), and the 7-methylthio pair (12)) showed that α-thiohemiaminals were not highly stable compounds but the **2**-series diastereomers were more stable than those of the **3**-series. Therefore in the subsequent work, reported here, elemental composition was determined by combustion analysis or high resolution mass spectrometry on a mixture of the two diastereomers, the more stable diastereomer, or a stable derivative.

Spectra were determined on samples containing only a mixture of the two diastereomers. The ir indicated the presence of the 3-furyl and 1,4-disubstituted aryl groups respectively in the appearance of 11.5 and 12 μm absorption bands. The mass spectra revealed *m/e* 248, 231, 192, 176, 107, and 94, peaks characteristic of a C-6 hemiaminal incorporated in a deoxynupharidine skeleton (13).

The ^{1}H nmr of the α-arylthiohemiaminals were in all cases consistent with the compounds of earlier work (1, 6, 12). Of particular interest were the resonance signals from the β-proton of the furan ring, the C-6 proton, and the C-7 methyl group, since stereochemically dependent chemical shifts were observed. In each case, the **2**-series diastereomer had higher field signals for β-furyl and C-6 protons and a lower field signal for the C-7 methyl protons than the **3**-series counterpart. This interpretation of the spectra was based on previous observations for the individual **2** and **3** series diastereomers and made possible the estimation of relative amounts of the two diastereomers.

All **2**-series diastereomers were isolated from the mixture of two diastereomers for the acidic solution (pH 4) cd which showed positive bands in the 270–310 nm region and as a consequence could be assigned the C-7 configuration indicated in the

[a] Isolated.
[b] CH_2Cl_2 solvent.
[c] C_6H_6 solvent.
[d] The diastereomer was produced according to tlc but the amount could not be estimated from ^1H nmr.
[e] Values are obtained from the amount of the 7-(4-hydroxyphenylthio)deoxynupharidin-6-ols produced upon hydrolysis of the tosylate.
[f] Diastereomers were produced in nearly equal amounts but the yield was not determined.
[g] Values are obtained from the amount of the 7-(4-aminophenylthio)deoxynupharidin-6-ols produced upon hydrazinolysis.

structures (2). Two **3**-series diastereomers could be isolated for cd comparison with their **2**-series counterparts. In acidic solutions **3***c* and **3***g* gave negative cd bands in the 270–310 region which were the approximate inverted images of those observed for **2***c* and **2***g*.

Experimental

Spectra were obtained as follows: infrared (ir) in dichloromethane, unless otherwise indicated, on a Perkin–Elmer 137 spectrometer (symbols s, m, w refer to strong, medium, weak, respectively; wavelength in microns); proton magnetic resonance (^1H nmr) in deuterated chloroform with 1% TMS, unless otherwise noted, on a Varian A60 A spectrometer or, if noted as 100 MHz, on a Varian XL100 spectrometer operating in the pulsed Fourier mode (symbols s, d, m, br, eq refer to singlet, doublet, multiplet, broad, equatorial, respectively; absorption δ in ppm); low resolution mass spectra (ms), *m/e* (relative intensity), on a Hitachi–Perkin–Elmer RMU6E spectrometer using a direct inlet at 70 eV, chamber temperature 200°C unless otherwise noted; high resolution mass spectra (hrms) on an AEI MS-902 spectrometer using a direct inlet at 70 eV and performed at the Cornell Mass Spectrometry Facility, Ithaca, NY; circular dichroism (cd) in 70% MeOH – water at the concentration indicated, in a cell of 0.1 dm length, using a Jasco Model 5 spectropolarimeter; ultraviolet (uv) in 95% EtOH on a Cary 15 and a Beckman Acta MVI spectrophotometer. Uncorrected melting points were determined on a Mel-Temp apparatus. Elemental analyses were performed by Galbraith Laboratories, Knoxville, TN and by Micro-analysis, Inc., Wilmington, DE. Thin-layer chromatography (tlc) was visualized with Dragendorff–Munier reagent and performed on microscope slides uniformly coated with: A, alumina, GF-254 (0.25 mm thickness); or B, silica gel, GF-254 (0.50 mm thickness) (symbols DA, UVA refer to Dragendorff-active and uv-active spots, respectively). Column chromatography was done with neutral activity 2 alumina and by eluting with 25 mL fractions, unless otherwise noted. All solvents were distilled before use. Organic solutions from work-ups were dried with sodium sulfate. Acidifications were done with 4 *N* HCl and basifications with 4 *N* NaOH unless otherwise noted.

Disulfides

4-Nitrophenyl disulfide was used as obtained from the Aldrich Chemical Co. 4-Methoxyphenyl, 4-chlorophenyl, 4-tolyl, and phenyl disulfide were prepared as follows. A solution of 1 volume of thiol in 4 volumes of acetone was heated to reflux with 1 molar equivalent of $FeCl_3$ in 12 volumes of water. The acetone was evaporated and the residue was basified to pH 10 and extracted twice with CH_2Cl_2. The organic layers were washed with water and then brine, dried, concentrated to an oil, and recrystallized from MeOH or EtOH. 4-Trifluoromethylphenyl disulfide was prepared from 4-bromobenzotrifluoride according to a literature procedure (14) and purified by elution with hexane from a column of alumina.

4-Tosyloxyphenyl disulfide was prepared as follows. A solution of 1.96 mL of C_5H_5N (24.5 mmol) was treated with 2.17 mL of 12 *M* HCl (26 mmol) until the temperature rose to 220°C. The solution was cooled under N_2, then heated under N_2 with 680 mg of 4-methoxyphenyl disulfide (2.4 mmol) at 220°C for 10 min. The solution was cooled, diluted with water, and extracted with ether (4×). The ether solution was washed with water, brine, dried, and concentrated at reduced pressure. Crystallization of the concentrate gave 170 mg of 4-hydroxyphenyldisulfide (28%): tlc (B, 40% $Et_2O - C_6H_{14}$) R_f 0.2 (UVA); mp 113–115°C; ir: 2.80 (w), 6.26 (m), 8.60 (s), 12.09 (s), but no band at 8.03 μm. 680 mg sample of 4-hydroxyphenyl disulfide (2.7 mmol) and 2.07 g of freshly recrystallized tosylchloride (10.9 mmol) slowly dissolved in 30 mL of C_5H_5N freshly distilled from KOH. The solution was kept at −4°C for 19 h and thereafter treated with water and extracted with CH_2Cl_2 (3×). The CH_2Cl_2 solution was washed with cold 4 *N* HCl, water, brine, then dried and finally concentrated at reduced pressure to give 1.15 g of crude brown oily 4-tosyloxyphenyl disulfide (76%): tlc (B, C_6H_6) R_f 0.6 (UVA); ir (neat): 6.25 (s), 8.35 (s), 11.61 (s), but no OH at 2.80 μm.

N-formyl-3-aminophenyl disulfide was prepared from 4-aminophenyl disulfide (purchased from the Aldrich Chemical Co.) as follows. The starting disulfide (2.0 mmol) was heated to reflux with 0.69 mL at 88% formic acid (16 mmol) in 10 mL of toluene in a Dean–Stark apparatus. After 0.5 h a grey solid formed; after 1.5 h water evolution ceased; after 2 h the mixture was cooled and the grey solid was collected by filtration and recrystallized from EtOH–water to obtain 460 mg (76%) of grey *N*-formyl-4-aminophenyl disulfide: tlc (A, Et_2O) R_f 0.5 (UVA); mp 160° C; ir (Nujol): 5.90 (s), 6.25 (m), 7.68 (s), 7.75 (s), 12.13 (s) μm.

Sulfensuccinimides

All the arylsulfensuccinimides, except the 4-tosyloxyphenylsuccinimide, were prepared by the following general method. The disulfide and 2 equivalents of recrystallized *N*-bromosuccinimide were heated to reflux in benzene (distilled from LAH) under N_2 for 15 min after the orange or red color no longer deepened in color (total time 0.5–1.0 h). The solvent was removed at reduced pressure to obtain an orange solid which in most cases was used in thiation without further purification. However, purification by recrystallization was performed on: 4-nitrophenylsulfensuccinimide (20% from chloroform), mp 160–171°C (lit. (7) mp 169.5°C); ir: 5.85 (s), 6.33 (w), 7.51 (s), 11.75 (m) μm; phenylsulfensuccinimide (48% from MeOH), mp 114–115°C (lit. (15) mp 116°C); ir: 5.82 μm; 4-tolylsulfensuccinimide (24% from MeOH), mp 99–106°C (lit. (7) mp 113.5°C); ir (KBr): 5.82 (s), 12.30 (s) μm.

Thiosulfonates

Phenyl benzenethiosulfonate and 4-chlorobenzenethiosulfonate were prepared from the appropriate arylthiol and sulfuryl chloride in the presence of acetic acid and water at 0–5°C according to a literature procedure (10, 11).

Sulfenylchlorides

Phenyl- and 4-tosyloxyphenylsulfenyl chlorides were prepared from the disulfides and chlorine or sulfuryl chloride according to published procedures (9). Thus in the case of 4-tosyloxyphenylsulfenyl chloride, chlorine (dried by passing through concentrated H_2SO_4) was bubbled through a solution of 870 mg of 4-tosyloxyphenyl disulfide (1.56 mmol) and a crystal of I_2 in 25 mL of $CHCl_3$ previously washed with water and distilled from $CaCl_2$. The solvent was removed at reduced pressure to obtain the crude red-orange oily 4-tosyloxyphenylsulfenyl chloride; tlc (B, benzene) R_f 0.7 UVA. This was employed in thiation without purification.

General Procedure for the Thiation of 6-Dehydrodeoxynupharidine

Thiosulfonates were used in benzene, but all other thiating agents were used in CH_2Cl_2. A CH_2Cl_2 solution of 6-dehydrodeoxynupharidine (**1**), freshly prepared from nupharidine (16), and an equal mole or one mole excess of thiating agent was flushed with N_2, sealed, and kept in the dark at 25°C until tlc showed no further increase in the relative amount of α-arylthiohemiaminal to starting amine. Unconverted enamine, **3**, and **2** ascended the plate in every case in the order just given. When sulfensuccinimides were employed, the CH_2Cl_2 solution was washed with water, brine, and then dried. The solvent was evaporated at reduced pressure and the residue was chromatographed on a column of alumina to obtain a mixture of the diastereomeric α-arylthiohemiaminals. When other thiating agents were used, the solvent was evaporated directly and the residue was chromatographed. These general work-up procedures were employed except where otherwise noted.

7β- and 7α-Phenylthiodeoxynupharidin-6-ol, **2**a *and* **3**a

The residue from a 22 h reaction of 0.3 mmol of sulfensuccinimide and 0.3 mmol of **1** gave, after chromatography, 90 mg of a mixture of **2***a* and **3***a* (84%): tlc, (A, 10% Et_2O – hexane) double spot, R_f 0.2–0.5 (DA, UVA); ^{1}H nmr: 7.28 (m, 7H, ArH, furyl α H), 6.56 (m, 0.5H, furyl β H with axial ArS), 6.15 (m, 0.5H, furyl α H with eq ArS), 4.12 (br s, 0.5H, C-6 H with axial ArS), 4.00 (br s, 0.5H, C-6 H with eq ArS), 3.70 (m, 1H, C-4 H), 3.13 (br s, 1H, OH), 1.16 (s, 1.5H, axial C-7 Me), 0.95 (m, 4.5H, eq C-7 Me). Re-chromatography gave **2***a* identical with authentic sample (1).

7β-(4-Tolylthio)-deoxynupharidin-6-ol, **2**b

The residue from a 20 h reaction of 0.3 mmol of sulfensuccinimide and 0.3 mmol of **1** gave, after chromatography, 20 mg of **2***b* (18%): tlc (A, C_6H_6 × 2) R_f 0.3 (DA, UVA); ir, ^{1}H nmr, and ms were identical with spectra of authentic sample (6); cd (70% MeOH – water, pH 4) 283 nm, [θ] 37 000°.

7β-(4-Nitrophenylthio)-deoxynupharidine-6-ol, **2**c

The residue from a 2 day reaction of 0.6 mmol of disulfide and 0.61 mmol of **1** gave, after chromatography, 100 mg of a mixture of **2***c* and **3***c* (41%): tlc (10% Et_2O – hexane) double spot, R_f 0.1 (DA, UVA); ^{1}H nmr: 7.83 (m, 6H, furyl α H, ArH), 6.55 (m, 0.5H, furyl β H with axial ArS), 6.37 (m, 0.5H, furyl β H with eq ArS), 4.36 (br s, 0.5H, C-6 H with axial ArS), 4.10 (br s, 0.5H, C-6 H with eq ArS), 3.60 (m, 1H, C-4 H), 1.17 (s, axial C-7 Me), 0.98 (m, eq C-7 Me, C-1 Me). A portion of the mixture of **2***c* and **3***c* was dissolved in dry MeOH and the solvent was evaporated at reduced pressure to obtain a yellow solid mixture of the methyl ethers of **2***c* and **3***c*: ms (130°C): 416 (3) M^+, 385 (3), 294 (8), 262 (5), 231 (100), 176 (16), 155 (9), 107 (23), 94 (50); hrms (200°C) calcd. for $C_{22}H_{28}O_4S$: M^+ 416.1770; found: M^+ 416.1803.

Another portion of the mixture of **2***c* and **3***c* was applied to a preparative layer chromatography plate (alumina, 0.5 mm thickness) which was developed twice with 25% C_6H_6 – CH_2Cl_2. From the band at R_f 0.5 (DA) was isolated **2***c*: cd (in 70% MeOH – water, pH 4) 273 nm, [θ] 10 000°. From the band at R_f 0.4 (DA) was isolated **3***c*: cd (in 70% MeOH – water, pH 4) 250 nm, [θ] −7400°; 334 nm, [θ] −7700°; cd (in 70% MeOH – water, neutral) 276 nm, [θ] −50°; 332 nm, [θ] +2300°.

7β-(4-Chlorophenylthio)-deoxynupharidin-6-ol, **2**d

The residue from a 1-day reaction of 1.7 mmol of 4-chlorophenylthio-4-chlorobenzenesulfonate and 1.6 mmol of **1** gave, after extensive chromatography of the mixture of diastereomers, 240 mg of white crystalline **2***d* (38%): mp 78–81°C; tlc (A, 20% Et_2O – hexane) R_f 0.5 (DA, UVA); ir (CCl_4): 2.85 (w), 9.24 (s), 11.45 (s) μm; uv (acidic 95% EtOH): 270 nm (ε 5300); ^{1}H nmr: 7.33 (m, 6H, ArH, furyl α H), 6.25 (m, 1H, furyl β H), 4.03 (br s, 1H, C-6 H), 3.76 (m, 1H, C-4 H), 3.05 (br s, 1H, OH), 1.15 (s, 3H, C-7 Me), 0.93 (m, 3H, C-1 Me); ms (110°C): 393 (9) M^+, 391 (24), 374 (5), 248 (100), 231 (47), 192 (27), 176 (9), 146 (10), 144 (26), 107 (45), 94 (34); cd (in 70% MeOH – water, pH 4) 284 nm, [θ] 20 000°. *Anal.* calcd. for $C_{21}H_{26}NO_2SCl$: C 64.34, H 6.69, N 3.57; found: C 64.14, H 6.78, N 3.48.

7β-(4-Methoxyphenylthio)-nupharidin-6-ol, **2**e

The residue from a 3.5 h reaction of 1.5 mmol of sulfensuccinimide and 0.74 mmol of **1** gave, after extensive chromatography of the mixture of diastereomers, 30 mg of **2***e* (10%): tlc (A, CH_2Cl_2) R_f 0.2 (DA, UVA); ir: 2.89 (w), 8.09 (s), 9.74 (s), 11.50 (s), 12.09 (s) μm; ^{1}H nmr: 7.00 (m, 6H, furyl α H, ArH), 6.20 (m,

For personal use only.

1H, furyl β H), 3.97 (s, 1H, C-6 H), 3.78 (s, 3H, MeO), 3.14 (br s, 1H, OH), 1.12 (s, 3H, axial C-7 Me), 0.93 (m, 3H, C-1 Me); ms (110°C): 387 (69) M^+, 370 (25), 248 (80), 231 (100), 192 (13), 176 (15), 140 (64), 107 (29), 94 (41); cd (70% MeOH – water, pH 4) 294 nm, [θ] 21 000°.

A portion of **2***e* was dissolved in EtOH and treated with sodium borohydride overnight. The solvent was evaporated and the residue was eluted from alumina with 10% Et_2O – hexane. Fraction 1 contained colorless and oily 7-β-(4-methoxyphenylthio)-deoxynupharidine: tlc (A, 10% Et_2O – hexane) R_f 0.9 (DA); ir: 3.60 (m), 8.17 (m), 9.70 (s), 11.45 (s), 12.02 (s) μm; ^{1}H nmr: 7.10 (m, 6H, furyl α H, ArH), 6.30 (m, 1H, furyl β H), 3.80 (s, 3H, OMe), 1.23 (s, 3H, C-7 Me), 0.93 (br s, 3H, C-1 Me). *Anal.* calcd. for $C_{22}H_{29}NO_2S$: C 71.12, H 7.87, N 3.77, S 8.63; found: C 71.35, H 8.02, N 3.89, S 8.81.

7β-(4-Trifluoromethylphenylthio)-deoxynupharidin-6-ol, 2f

The residue from a 5 h reaction of 1.4 mmol of sulfensuccinimide and 0.69 mmol of **1** gave, after chromatography, 20 mg of oil **2***f* and **3***f* (7%): tlc double spot, R_f 0.2 (DA); ir: 7.61 (s), 8.59 (s), 8.90 (s), 11.47 (m), 11.90 (m) μm; ^{1}H nmr: 7.45 (m, 6H, ArH, furyl), 6.41 (m, 0.3H, furyl β H with axial ArS), 6.21 (m, 0.7H, furyl β H with eq ArS), 4.42 (br s, 0.3H, C-6 H with axial ArS), 4.03 (br s, 0.7H, C-6 H with eq ArS), 3.70 (m, 1H, C-4 H), 1.19 (s, 1H, axial C-7 Me), 0.97 (m, 5H, eq C-7 Me and C-1 Me); ms (100°C): 425 (25) M^+, 408 (5), 248 (89), 231 (38), 218 (100), 192 (31), 178 (29), 176 (9), 107 (65), 94 (57). The mixture was chromatographed on alumina and thereby was obtained 7.5 mg of **2***f* (2.4%): cd (70% MeOH – water, pH 4) 250 nm, [θ] 22 000°.

A 170 mg sample of **2***f* and **3***f* in EtOH was reduced with $NaBH_4$ and the product was chromatographed to obtain 36 mg of a mixture of 7α- and 7β-(4-trifluoromethylphenylthio)-deoxynupharidine: tlc (A, 5% Et_2O – hexane) R_f 0.9 (DA) and R_f 0.8 (DA); ir: 3.60 (w), 7.60 (s), 8.58 (s), 8.88 (s), 11.46 (s) 11.90 (s) μm. *Anal.* calcd. for $C_{22}H_{26}F_3NO_2S$: C 64.52, H 6.40, N 3.42, S 7.83; found: C 64.51, H 6.50, N 3.40, S 8.02.

7β-(4-Hydroxyphenylthio)-deoxynupharidin-6-ol, 2g

The residue from a 3.5 h reaction of 3.1 mmol of 4-tosyloxyphenylsulfenyl chloride and 1.6 mmol of **1** was washed with aqueous base, water, and brine, dried and concentrated to 1.16 g of an orange foam, impure 7-(4-tosyloxyphenylthio)-deoxynupharidine-6-ol. This was combined with 10 mL of MeOH and 2 mL of 20% aqueous KOH and stirred at 55°C under N_2. After 6 h practically no insolubles remained. The solution was concentrated at reduced pressure, neutralized, treated with 2 mL of saturated aqueous $NaHCO_3$, and extracted three times with CH_2Cl_2. The solution was washed with brine, dried, and concentrated to 670 mg of a yellow foam of which a 59 mg portion was applied to a preparative layer chromatography plate (0.5 mm-thick silica gel) which was developed with 70% Et_2O – hexane to obtain 5 uv-active bands. The third band from the base yielded 17.3 mg of white, solid **2***g* (33% based on the proportion of the original 670 mg of yellow foam purified): tlc (B, 50% Et_2O-hexane) R_f 0.4 (DA, UVA); ir (KBr): 2.90 (s, br), 6.09 (w), 8.58 (m), 11.46 (s), 11.97 (m) μm, no tosylate; cd (70% MeOH – water, pH 4): 298 nm, [θ] 26 400°.

The iminium perchlorate salt was prepared from **2***g* and was recrystallized from MeOH–water, mp 216–220°C (dec.). *Anal.* calcd. for $C_{21}H_{26}ClNO_6S$: C 55.32, H 5.75, N 3.07, S 7.03; found: C 55.56, H 6.00, N 2.87, S 6.84.

The second band from the base of the preparative layer chromatography plate yielded 8.3 mg of a white solid **3***g* (16%): tlc (B, 50% Et_2O – hexane) R_f 0.3 (DA, UVA); ir (KBr): identical with **2***f*; ^{1}H nmr (DMSO-d_6): 7.69 (br s, 2H, furyl α H), 6.96 (m, 4H, ArH), 6.55 (m, 1H, furyl β H), 4.12 (br s, 1H, C-6 H), 0.95 (m, 3H, C-1 Me), 0.83 (s, 3H, C-7 Me); cd (2.0 mg/mL EtOH, pH 4): 295 nm, [θ] −17 500°: 270 nm (sh, [θ] −5600°; ms (130°C): 372 (< 1), 355 (1), 231 (100), 192 (1) 176 (19), 125 (56) ArS, 107 (26), 94 (100), 192 (1).

7β-(4-Aminophenylthio)-deoxynupharidin-6-ol, 2h

The residue from a 10 h reaction of 0.72 mmol of sulfensuccinimide and 0.69 mmol of **1** was heated at 55°C for 10 h under N_2 with 0.73 mL of hydrazine hydrate (15 mmol) in CH_2Cl_2–EtOH. The volatiles were removed at reduced pressure. The residue was treated with water and CH_2Cl_2 (3×). The CH_2Cl_2 solution was washed with water and brine, dried, and concentrated to 210 mg of yellow oil which was chromatographed on alumina to afford a 100 mg mixture (40%) of **2***h* and **3***h*: tlc (A, 50% ether – hexane) two spots of equal size and intensity of R_f 0.7 (DA, UVA); ir: 2.85 (w), 2.93 (w), 6.27 (m), 11.46 (s), 12.14 (m, br), no absorption at 5.90 (*N*-formyl) μm; ^{1}H nmr: 7.30 (m, 4H, furyl α H, ArH *ortho* to S), 6.50 (m, 3H, furyl β H, ArH *ortho* to N), 3.45 (br, s, 2H, amino H), 1.23 (s, C-7 axial Me), 0.93 (m, C-1 Me, C-7 eq Me). A portion of the mixture of diastereomers was applied to a preparative layer chromatography plate (0.5 mm alumina) and developed with CH_2Cl_2 to obtain three UVA bands. The first band from the base yielded **17**: tlc (A, CH_2Cl_2) R_f 0.1 (DA, UVA); cd (70% MeOH – water, pH 4) 310 nm, [θ] 11 000°.

A 38 mg portion of **2***h* and **3***h* was dissolved in CH_2Cl_2, diluted with EtOH, and treated with 20 mg of NaBH initially and then with 10 mg more of NaBH at 1 h intervals. After 4 h the mixture was concentrated to dryness, dissolved in CH_2Cl_2, washed with aqueous base, water, and brine, then dried and concentrated to 28 mg of a yellow-brown gum. This was chromatographed on alumina to obtain 10 mg of a yellow gummy, 7-(4-aminophenylthio)-deoxynupharidine: tlc (A, benzene) one spot, R_f 0.5 (DA, UVA); ir: 2.95 (w), 3.60 (m) 6.20 (s), 11.49 (s), 12.10 (s) μm; ^{1}H nmr (100 MHz): 7.22 (m, furyl α H, ArH *ortho* to S), 6.55 (m, furyl β H with axial ArS, ArH *ortho* to N), 6.29 (br s, furyl β H with eq ArS), 3.56 (m, amino H), 1.22 (s, C-7 axial Me), 0.84 (d, 5 Hz, C-1 Me); ms (110°C): 356 (2) M^+, 232 (100), 178 (3), 124 (75), 107 (15), 94 (28); hrms (125°C) calcd. for $C_{21}H_{28}N_2OS$: M^+ 356.1920; found: M 356.1893.

Received February 24, 1981

M. J. STILLMAN, J. B. STOTHERS, and A. STOESSL. Can. J. Chem. **59**, 2303 (1981).

Application of the exciton chirality method has confirmed that capsidiol, a unique eremophilane, has the absolute stereochemistry depicted in **1**. The ^{1}H and ^{13}Cmr, circular dichroism, and magnetic circular dichroism spectra of capsidiol and 1-epicapsidiol dibenzoates are discussed.

M. J. STILLMAN, J. B. STOTHERS et A. STOESSL. Can. J. Chem. **59**, 2303 (1981).

La méthode de la chiralité de l'exciton a confirmé que le capsidiol, une eremophilane spéciale, a la stéréochimie absolue décrite en **1**. On discute des spectres de rmn du ^{1}H et du ^{13}C, des spectres de dichroisme circulaire et de dichroisme circulaire magnétique des dibenzoates et de l'épi-1 capsidiol.

[Traduit par le journal]

Capsidiol, an antifungal stress compound ("phytoalexin") produced by *Capsicum frutescens, Datura stramonium,* and *Nicotiana* spp. (1, 2), is almost unique as a 4,5-*trans*-eremophilane.[3] Its structure **1** and relative stereochemistry have been established by chemical and nmr studies (4, 5) and by single crystal X-ray analysis (5) but assignment of the absolute configuration, as shown in **1**, was based on transparent biogenetic relationships to other bicyclic, sesquiterpenoidal stress metabolites of the Solanaceae (1, 2). A recent preparation, in another context, of capsidiol dibenzoate (**2**) gave the opportunity to confirm this assignment by Nakanishi's exciton chirality method (6). The method has been used previously for the determination of the absolute configurations of the dibenzoates of rishitin (**3**) (7) and 3-hydroxylubimin (**4**) (8) but it should be noted that these compounds are vicinal diols.

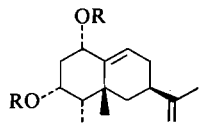
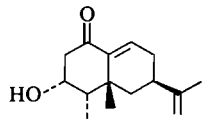
4



5 R = COPh
6 R = H



7

Except for the anticipated acylation shifts, all relevant parameters in the ^{1}H and ^{13}Cmr spectra of **2** are very similar to those of **1** (see Table 1). It follows that the relative stereochemistry and conformation of **2** are correctly depicted by the structural drawing. If this also corresponds to the absolute configuration, then Fieser molecular models indicate an angle of about 110° between the BzO-C-3—C-1-OBz bonds, with a clockwise (right-handed) sense of rotation as in Fig. 1. According to the dibenzoate rule (6), the cd curve should therefore exhibit a positive Cotton effect, of predictably small amplitude, near 233 nm, whereas a negative Cotton effect would be observed if the assignment needed reversal.

The optical absorption, cd, and magnetic circular dichroism (mcd) spectra of a solution of capsidiol dibenzoate (**2**) in EtOH are shown in Fig. 2A. As expected (6), the most intense natural cd bands arise from exciton mixing of the charge transfer

bands located on the two benzoate chromophores. There is little absorption or cd intensity for the $^{1}A_{1g} \rightarrow {}^{1}B_{2u}$ transition in the 280 nm region. The positive sign of the 239 nm cd band confirmed the right-handedness of the orientation of the two benzoate groups. The rather reduced intensities of $+7.5 \times 10^3$ deg dL dm^{-1} mol^{-1} at 239 nm and -1.6×10^4 deg dL dm^{-1} mol^{-1} at 220 nm, compared with bands observed for compounds with adjacent benzoates (6), presumably arises from the increased separation of the two chromophores in capsidiol dibenzoate. The cd spectrum thus confirms that the stereochemistry of the dibenzoate **2**, and hence also that of **1**, is correctly represented in Fig. 1.

To obtain further confirmation of the stereochemistry of **1**, we also prepared the dibenzoate **5** of the readily accessible 1-epicapsidiol (**6**). The ^{1}H and ^{13}C spectral data for **5** and **6** are listed in Table 1. As noted above, the expected shifts produced by benzoylation are apparent, with upfield shifts exhibited by C-2, -4, and -10 which flank the carbinyl carbons, while the latter (C-1, -3) and their protons shift downfield. The nuclei of the 14-methyl group also show downfield shifts. It is interesting that C-9 and its proton are both significantly deshielded by benzoylation of the axial 1-hydroxyl in capsidiol, whereas much smaller shifts accompany benzoylation of its equatorial epimer **6**.

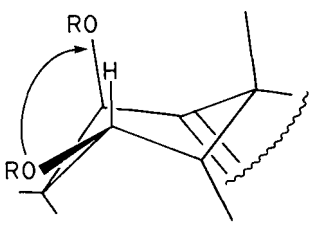

FIG. 1. A stereo representation of capsidiol dibenzoate (**2**).

Molecular models for the 1-epi case indicated that the angles between the benzoate groups would be very small or even close to zero, which would result in an almost zero exciton splitting (6) and hence negligible cd intensity. Both the absorption spectrum and, especially, the mcd spectrum of **6** confirm the close similarity between the electronic states of **6** and **2** (Fig. 2B). However, the cd band envelope of **6**, unlike that of **2**, was extremely weak and almost completely buried in noise. This implies that the two benzoate chromophores are indeed eclipsed.

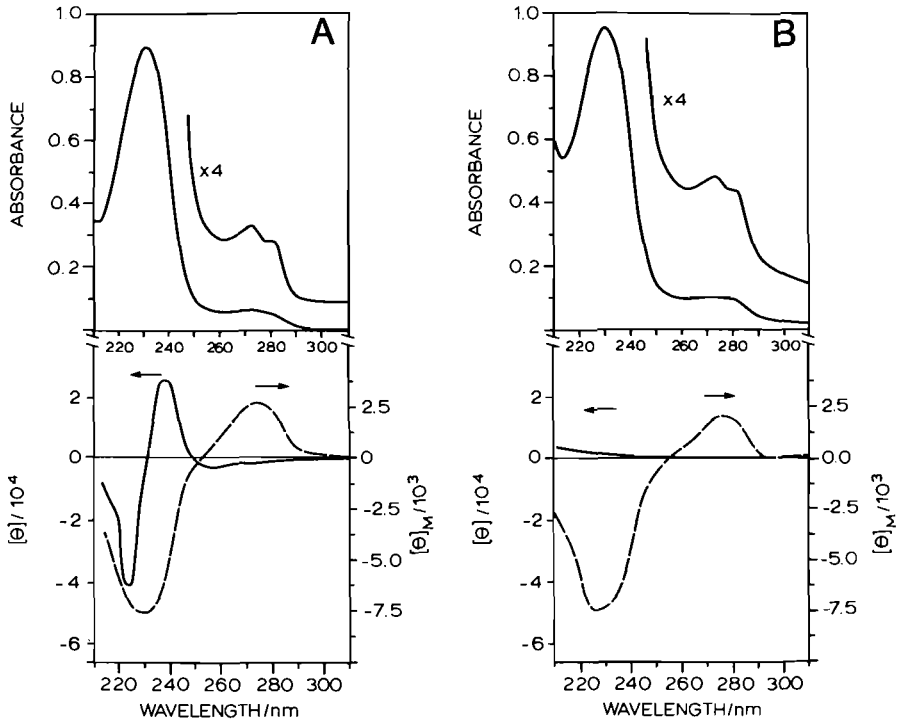

FIG. 2. Absorption (upper), cd (lower, solid line) and mcd (lower, broken line) spectra of 3.55×10^{-5} *M* capsidiol dibenzoate (A) and 3.96×10^{-5} *M* epicapsidiol dibenzoate (B) in 95% ethanol solutions.

Experimental

The ^{1}H and ^{13}Cmr spectra were determined on deuteriochloroform solutions, with TMS as internal reference, using a Varian XL-100 system operating in the Fourier transform mode. Optical absorption, cd, and mcd spectra were measured at room temperature on ca. 3.5×10^{-5} *M* solutions in 96% EtOH, using a Cary 219 for the absorption spectra, a Jasco J5-ORD/CD spectrometer modified to Sproul SS-20 specifications for cd spectra, and an Oxford Instruments SM2 superconducting magnet operating at 5.5 T in the Jasco for mcd measurements; 1 cm path length cells were used in all experiments. The cd and mcd spectra were calibrated conventionally and as previously described (9). The natural cd spectra have been subtracted from the mcd spectra recorded in Fig. 2. The cd intensities are reported as molar ellipticities, $[\theta]$, with units of deg dL dm^{-1} mol^{-1}, while the mcd intensities, $[\theta]_M$, have units deg dL dm^{-1} mol^{-1} T^{-1}; conversion to scales with $\Delta\varepsilon$ and $\Delta\varepsilon_M$ units is accomplished by multiplying each of the present scales by 1/3300.

Capsidiol (**1**) and capsenone (**7**) were available from earlier studies. 1-Epicapsidiol was prepared from **7** as previously described (5). Benzoylations were done at room temperature, by adding benzoyl chloride (0.2 mL) to the substrate (20 mg) in pyridine (0.5 mL) containing a few small crystals of 4-dimethylaminopyridine. The crude products, isolated after 2 days by dropwise addition to ice (10 mL) and extraction into ether, were purified by repeated chromatography over silica gel (BDH, 60–120 mesh, 20 g) with increasing concentrations of ether (0–10%) in light petrol. Both compounds, **2** and **6**, were obtained as syrups homogeneous by tlc.

Pyrolysis of bacterial polyalkanoates

HIROMICHI MORIKAWA[1] AND ROBERT H. MARCHESSAULT[2]

Département de Chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3V1

Received August 7, 1980[3]

HIROMICHI MORIKAWA and ROBERT H. MARCHESSAULT. Can. J. Chem. **59**, 2306 (1981).

Pyrolysis products from bacterial polyesters, poly-β-hydroxybutyrate (PHB), and from a heteropolyester (β-hydroxyvalerate and β-hydroxybutyrate) were identified. Different physical forms of PHB were studied: PHB purified by dissolution in chloroform, native granules of PHB, and PHB in bacterial cells. The products were characterized by gc, ms, and nmr analysis. The yield of crotonic acid obtained by the pyrolysis of purified PHB was 60 to 65%. Pyrolysis of PHB native granules yielded crotonic acid as well as oligomers of PHB with a terminal crotonate. Upon direct pyrolysis of dry bacterial cells, the yield of crotonic acid was 20 to 25% of the PHB in the cells. From the heteropolymer, 2-pentenoic acid and terminally unsaturated oligomers of polyhydroxyvalerate were obtained. The usefulness of the pyrolysis method for obtaining vinyl compounds from bacterial cultures containing polyalkanoates is discussed.

HIROMICHI MORIKAWA et ROBERT H. MARCHESSAULT. Can. J. Chem. **59**, 2306 (1981).

On a identifié les produits provenant de la pyrolyse des polyesters bactériens poly-β-hydroxybutyrate (PHB) et du polyester hétérogène (β-hydroxyvalérate et β-hydroxybutyrate). On a étudié les différentes formes physiques du PHB: le PHB purifié par dissolution dans le chloroforme, les granules naturels de PHB et le PHB des cellules bactériennes. On a caractérisé les produits par chromatographie en phase gazeuse, par spectrométrie de masse et par la rmn. Le rendement en acide crotonique provenant de la pyrolyse du PHB purifié est de 60 à 65%. La pyrolyse des granules naturels de PHB conduit aussi bien à l'acide crotonique qu'à des oligomères du PHB avec un crotonate terminal. La pyrolyse directe des cellules bactériennes sèches conduit à un rendement en acide crotonique qui représente 20 à 25% du PHB contenu dans les cellules. On a obtenu du polymère hétérogène l'acide penten-2 oique et des oligomères du polyhydroxyvalérate insaturé en position terminale. On discute de l'utilité de la méthode de pyrolyse en vue d'obtenir des composés vinyliques à partir des cultures bactériennes contenant des polyalcanoates.

[Traduit par le journal]

Introduction

Because of the increasing cost of petroleum, the need for new types of chemical feedstocks has focussed attention on renewable resources (1, 2). Obviously, bacterial fermentation is an established way for obtaining useful products from biomass or industrial wastes. Aside from ethanol and other small molecules (3), important polysaccharides (4) and proteins (3) are obtained as products of fermentation.

Poly-β-hydroxybutyrate (PHB) is an example of a microbial polyester. This chiral polymer occurs as spherical hydrophobic granules in the cells of a wide variety of bacteria (5) and is easily harvested by a simple cell rupture (6, 7). The solid state structure of this polymer has been studied intensively (8–11). Because of its β-hydroxyalkanoate structure, PHB and its related family of poly-β-hydroxyalkanoates (PHA) are thermally unstable (12) and have potential as a source of small molecule organic chemicals rather than as thermoplastics (cf. Fig. 1). It is well known (12–14) that, on heating, PHB produces crotonic acid. Treatment of PHB with methanolic BF_3 produces β-hydroxybutyrate oligomers with ester endgroups (15, 16).

A bacterial polyester heteropolymer, composed primarily of β-hydroxyvalerate and β-hydroxybutyrate (HV-HB heteropolymer), has been isolated from activated sludges by Wallen and co-workers (17, 18). Usefulness of this polymer as a raw material has not been explored. Wallen and Rohwedder (18) have reported that, upon thermal degradation, this polymer produces crotonic acid and 2-pentenoic acid. This material, along with PHB, were the substrates for this pyrolytic study.

The pyrolysis method in combination with other physical methods has been extensively used for identification and characterization of various synthetic and biological polymers (19–23). The utility of the pyrolysis method for production of important chemicals such as levoglucosan and dextrins from cellulose (24) and starch (25) is well known. Recently Soltes and co-workers (26) have reported characterization of various phenolic compounds obtained from pine waste in a pyrolysis pilot plant.

DeJongh and co-workers have developed a controlled pyrolysis method (27–29) and applied it to polyesters (30, 31). In the present study we employed this same method and identified vinyl compounds derived from the pyrolysis of PHB before and after isolation from bacterial cells.

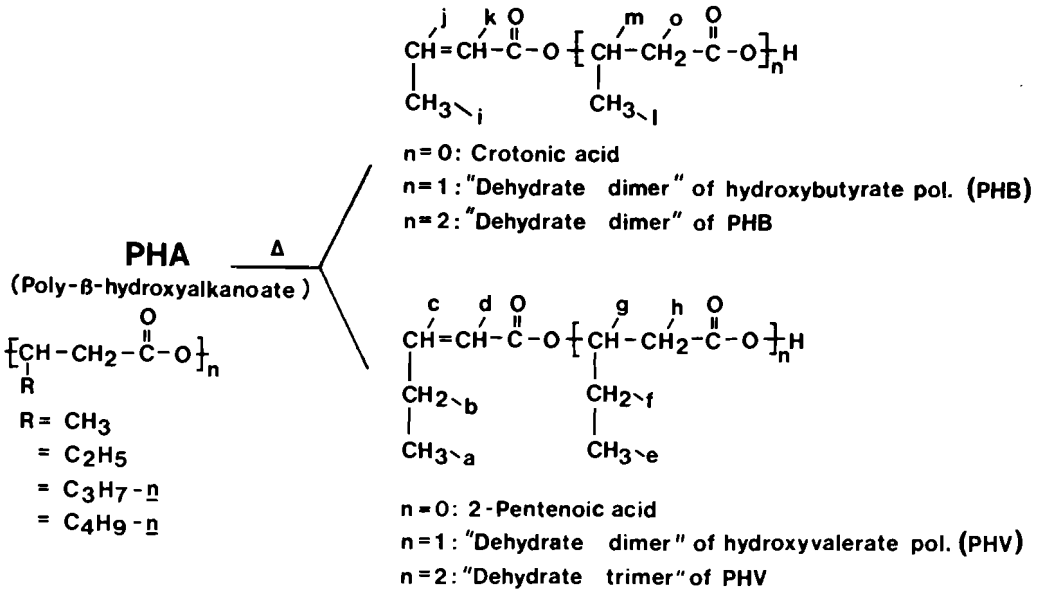

FIG. 1. Monomers and oligomers obtained by pyrolysis of bacterial poly-β-hydroxyalkanoates (PHA). The reaction scheme is shown for only two different R substituents (18). The oligomers with a vinylic endgroup are referred to as "dehydrates".

Experimental

Cultivation of Bacillus cereus *Cells*

Bacillus cereus TATCC14579 was grown in "1.5% Tryptic Soy Broth" (Difco) in a 25-liter carboy at 37°C under agitation with bubbling air. Preliminary experiments showed that the best yield of PHB was obtained 9 h after the inoculation under the present culture condition, after which the cells were harvested by centrifugation in a Sharples Continuous Centrifuge. The cell paste thus obtained was suspended in cold distilled water and washed twice by centrifugation. The washed cells were then suspended in acetone, filtered, and again suspended in a fresh portion of acetone to stand for 15 h at room temperature. After another filtration, the bacterial cells were air-dried at room conditions until the odor of acetone disappeared.

Preparation of PHB Samples

The isolation of PHB from the dry cells was made according to the method of Williamson and Wilkinson (6). About one gram of dry cells was suspended in 5% of hypochlorite (Baker) and stirred at 37°C for 2 h. The suspension was then centrifuged and a white granular PHB preparation was obtained and washed with distilled water, ethanol, and acetone. The washed PHB preparation was dissolved in chloroform and the solution was filtered. The filtrate was evaporated to dryness under reduced pressure at room temperature yielding a translucent film (purified PHB). The yield of PHB was 10.0% of the initial dry cells.

The PHB "native" granules isolated from *Bacillus megaterium* according to the method of Merrick and Doudoroff (7) were kindly supplied by Dr. J. M. Merrick, Department of Bacteriology, State University of New York, Buffalo, NY. The HV-HB heteropolymer sample, as a purified powder, was kindly supplied by Dr. L. L. Wallen, Northern Regional Research Laboratory, Peoria, IL. This material and PHB were the compounds used for this pyrolytic study.

Pyrolysis

The pyrolysis was made in accord with the method of Messier and DeJongh (30) and Messier (31). Briefly, a sample of 10 to 100 mg in a platinum boat was pyrolyzed in a quartz tube under a constant flow of dried nitrogen gas. The pyrolysis was conducted at atmospheric pressure and controlled temperature between 250 and 600°C. The sample was usually placed near the exit of the heated zone although pyrolysis with the sample near the entrance of the heated zone was also studied. The travel distances for volatile product through the heated zone were about 5 and 20 cm respectively. The pyrolysate was collected in cold traps connected to the end of the pyrolysis tube. Usually the sample was kept at a specified temperature for 30 min though the pyrolysis was observed to be complete within 5 to 10 min. The pyrolysate collected in the traps was recovered by dissolving in chloroform followed by evaporation to dryness at room temperature under reduced pressure.

Gas Chromatography and Mass Spectrometry

The pyrolysate was dissolved in chloroform, derivatized into *O*-trimethylsilyl (O-TMS) esters with *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) and analysed by gas chromatography in combination with mass spectrometry. The gas chromatographic analysis was carried out with a Tracor Model 550 instrument equipped with a flame ionization detector (FID). The column (6 ft × 4 mm id) had Silicone OV-17 as the liquid phase on a solid support of 60–80 mesh Chromosorb W/AW DMCS. Helium carrier gas flowed at the rate of 60 mL/min. The detector block temperature was 330°C and the injection port temperature was 240°C. Runs were usually initiated at a column temperature of 50°C and programmed at 15°C/min to a maximum operating temperature of 270°C. The mass spectrum was obtained with a Hitachi Model RMU-6D GC/MS instrument operated at 70 eV, ion source temperature and gas chromatography conditions are same as above.

Proton-nmr Spectrometry.

Proton-nmr spectra were recorded on a Bruker Model WH-90 pulsed spectrometer using deuterated chloroform as solvent and tetramethylsilane as an internal standard.

Chemicals

BSTFA was purchased from Chromatographic Specialties

Ltd., London, Ont., crotonic acid was obtained from ICN Pharmaceuticals, Inc., Plainview, NY, and *trans*-2-pentenoic acid was obtained from Fluka AG, Chemische Fab., Buchs SG. All other chemicals were reagent grade.

Results and Discussion

Pyrolysis of Purified PHB

A typical gas chromatogram of the O-TMS derivative of the pyrolysate of purified PHB is shown in Fig. 2 (top), where the polymer was pyrolyzed at 400°C. In the chromatogram, after the peaks due to the solvent and by-products of BSTFA, one major peak (A) was observed. The retention time of this peak was identical with that of the derivative of authentic crotonic acid. The mass spectrum corresponding to this peak and the interpretation of the spectrum are shown in Scheme 1. The molecular ion was not detected in the mass spectrum but the fragment-ion at *m/z* 143 was detected corresponding to the loss of the $\cdot CH_3$ group from the molecular ion. The ion at *m/z* 99 is due to the loss of CO_2 from the ion at *m/z* 143. This type of fragmentation is known in the case of bis-TMS derivatives of *p*-aminobenzoic acid (32). The ion at *m/z* 69 corresponds to the fragment $C_4H_5O^+$.

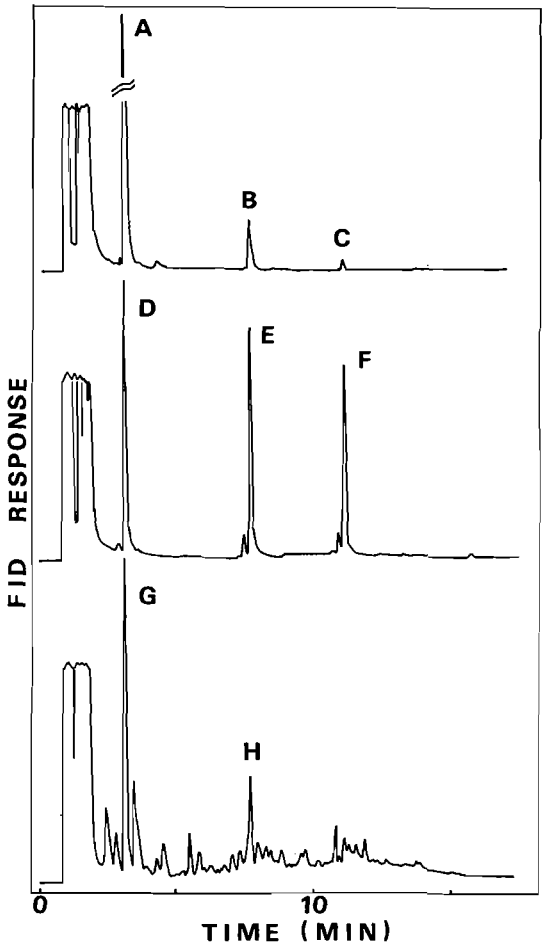

FIG. 2. Gas chromatograms of O-TMS derivatives of pyrolysate of purified PHB (top), that of PHB native granules (middle), and that formed by direct pyrolysis of PHB in *Bacillus cereus* cells (bottom). Pyrolyses were made at 400°C with the sample near the exit of the heated zone.

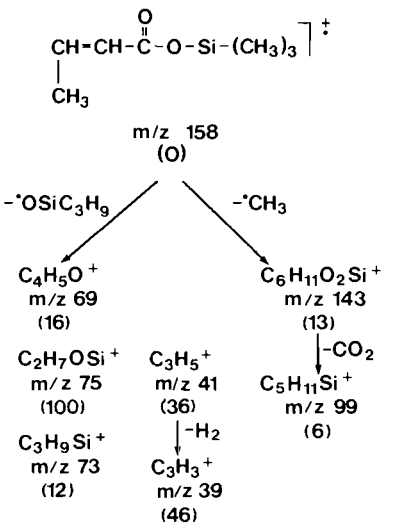

Note:
Relative abundances to 70 eV are shown in parentheses

SCHEME 1

In a pyrolysate of PHB, Messier (31) isolated and identified the "dehydrate dimer" of PHB, which is composed of the crotonate and β-hydroxybutyrate moieties (see Fig. 1). The retention time of peak B in Fig. 2 was the same as found by Messier (31) for the derivative of the dimer. Peak C in Fig. 2 can be attributed to the "dehydrate trimer" of PHB (see Fig. 3). The presence of crotonic acid monomer and "dehydrate oligomers" of PHB in the pyrolysate was confirmed by the proton nmr spectra.

Figure 3 (upper curve) shows the proton nmr spectrum of the pyrolysate of purified PHB. In the spectrum the signals at 1.9, at 5.8, and at 7.1 ppm are assignable to the protons of the CH_3, CH (bonded to C=O), and CH (bonded to CH_3) groups, respectively, of crotonic acid and the crotonate moiety of the "dehydrate oligomers" in the pyrolysate. Less intense but distinct signals were also observed at 1.3, 2.6, and 5.6 ppm for PHB native granule pyrolysate (Fig. 3). Since the same nmr peaks were observed in the spectra of PHB oligomers (Fig. 4), these signals were assigned to the protons of the CH_3, CH_2, and CH groups, respectively, of the β-hydroxybutyrate

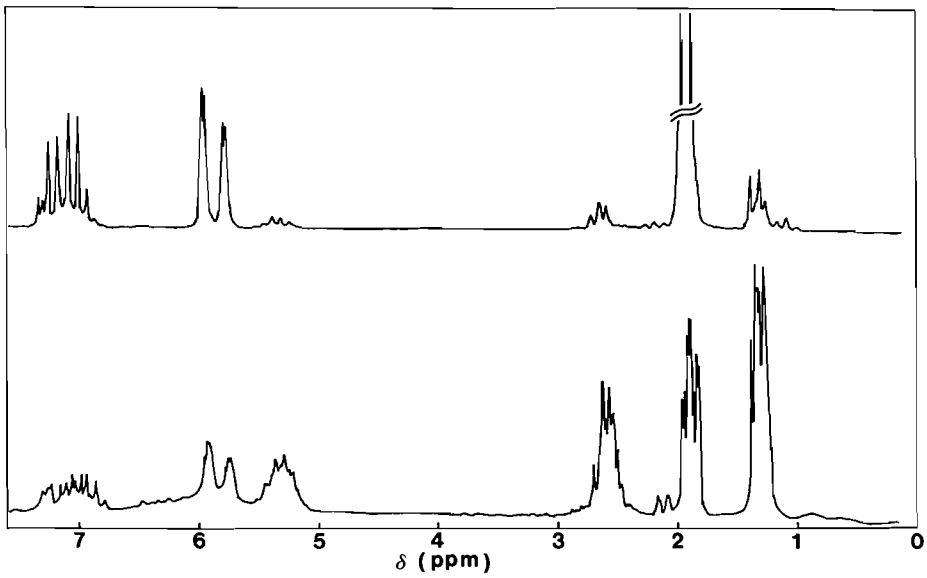

FIG. 3. Proton nmr spectra of pyrolysates: purified PHB (upper curve), PHB native granules (lower curve). Pyrolysis conditions as in Fig. 2.

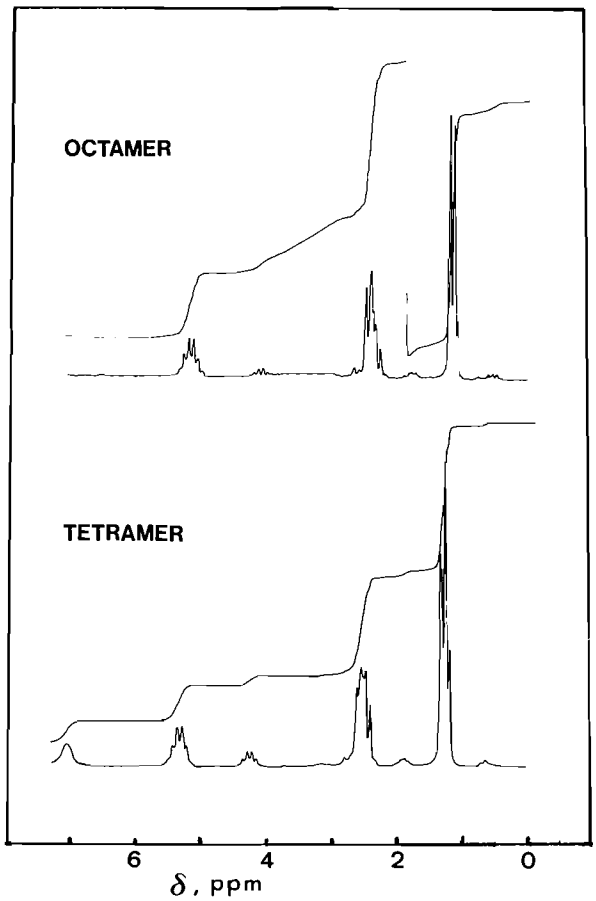

FIG. 4. Proton nmr spectra of PHB oligomers (tetramer and octamer).

moiety in the "dehydrate oligomers" of PHB in the pyrolysate.

The results of the pyrolysis of purified PHB at three different temperatures are listed in Table 1. The pyrolysis results were not significantly changed by temperature. The major product was crotonic acid and the yield was 60 to 65% of the initial amount of PHB. The results are in good agreement with those obtained by Messier (31) using a different preparation of PHB.

Pyrolysis of Native Granules of PHB

The gas chromatogram of the O-TMS derivative of the native granule pyrolysate is shown in Fig. 2 (middle). Three major peaks were observed (peaks D, E, and F). Based on a comparison of the retention times, the peaks in this figure can be attributed to the derivatives of crotonic acid (D), "dehydrate dimer" of PHB (E), and "dehydrate trimer" of PHB (F). This conclusion was confirmed by the proton nmr analysis on the pyrolysate (Fig. 3; lower curve). In the spectrum the signals attributable to the crotonate were observed near 1.9, 5.8, and 7.1 ppm. In these regions of the spectrum some unidentified signals were also observed (see below). Significant signals were observed at 1.3, 2.6, and 5.3 ppm which are attributable to the β-hydroxybutyrate moiety in the oligomers as discussed above. Note that these oligomer signals are much more intense than in the case of the pyrolysate of purified PHB (see Fig. 3).

Coulombe (15) has shown that in the proton nmr spectra of β-hydroxybutyrate oligomers (tetramer

TABLE 1. Summary of results of pyrolysis of different PHB samples[a]

Sample	Temperature °C	Pyrolysis residue %	Crude product %	Crotonic acid %	"Dehydrate dimer" of PHB %	"Dehydrate trimer" of PHB %
Purified (exit)[b]	250	9.1	83.1	64.4	7.2	1.2
	400	5.9	88.9	65.4	8.2	2.1
	600	3.4	86.1	58.3	9.0	2.7
Native granules (exit)[b]	400	10.4	82.3	25.0	18.0	15.3
	500	6.5	83.7	12.1	20.2	15.2
Bact. cells (exit)[b]	400	31.8	28.1	2.1	0.5	—
	500	22.2	30.9	2.1	0.5	—
	600	26.1	31.3	1.6	0.6	—
Bact. cells (entrance)[b]	400	34.7	27.4	2.5	—	—
	500	26.9	30.1	1.9	—	—
	600	21.4	23.7	1.3	—	—

[a]The values are expressed in per cent of the initial materials. The yield of crotonic acid was determined by comparison of the area under the peak with the area under the peak of a standard solution of O-TMS derivative of crotonic acid. (The same degree of the FID response was assumed for the derivative of the "oligomers" as for the derivative of crotonic acid).
[b]Exit, pyrolyzed near the exit of the heated zone; entrance, pyrolyzed near the entrance of the heated zone.

to octamer) a quartet is observed at 4.23 ppm (Fig. 4). This quartet arises from the proton of the CH group bonded to the terminal OH group in oligomers prepared by ester interchange. The same nmr signals were also observed in the spectrum of β-hydroxybutyric acid. Since no signals were observed at this position in the spectra of the pyrolysates (Fig. 3), the absence of β-hydroxybutyric acid and hydroxyl terminated oligomers in the pyrolysates is clearly demonstrated.

The results of the pyrolysis of PHB native granules at two temperatures are listed in Table 1. The yield of crotonic acid was decreased by half with the increase in the temperature while no appreciable changes in the yield of "dehydrate dimer" and "dehydrate trimer" of PHB were observed. Clearly, in the pyrolysate of the native granules the major products were these oligomers, which is in contrast to the case of purified PHB. It should be noted that the total yield of crotonates (the sum of the yield of crotonic acid and the oligomers) was relatively low (47.5 to58.3%) in the pyrolysis of the native granules while in the case of the purified PHB the total recovery was high (70.0 to 75.7%). With the former pyrolysate, nmr signals and gc peaks which were not identified were observed (see Figs. 2 and 3). These results suggest the presence of significant amounts of "non-crotonate" compounds in the pyrolysate of the native granules.

No complete explanation is available at present for the difference in the crotonate products between the pyrolyses of the native granules (oligomer-rich product) and of the purified PHB (monomer-rich product). Chemical impurities in these polymer preparations perhaps affect the pyrolysis products of the polymer (24). PHB native granule preparations usually contain (33) a few percent of "non-lipid" materials (mostly protein) while the purified PHB preparation used here was chemically pure based on the proton nmr and infrared analysis. The degree of polymerization (DP) of the polymer in the purified PHB is probably lower than in the native granules since the former had undergone an alkaline treatment (see the Experimental) (34). However, differences in the pyrolysis results are unlikely to be due solely to differences in DP which is known (24) to be rapidly lowered by this type of treatment. Textural differences are more likely to be the reason (8, 11, 34, 35).

Direct Pyrolysis of PHB in the Cells

The dried *Bacillus cereus* cells were pyrolyzed directly. Preliminary experiments indicated that in the direct pyrolysis at a temperature lower than 400°C the bulk of the products remained in the residue; for example, the residues amounted to 80 and 50% for the pyrolysis at 200°C and 300°C, respectively. Thus the direct pyrolysis was carried out at 400, 500, and 600°C. Also, the samples were pyrolyzed at both the exit and the entrance of the heated zone.

Fig. 2 (bottom) shows the gas chromatogram of the O-TMS derivative of the product of the direct pyrolysis of PHB in *Bacillus cereus* cells, where the cells were pyrolyzed at 400°C near the exit of the heated zone. In the chromatogram one major peak (G) was observed. This peak was attributed to the derivative of crotonic acid while peak H was attributed to the derivative of "dehydrate dimer" of PHB. The latter peak was always observed for pyrolysis near the exit of the heated zone but was

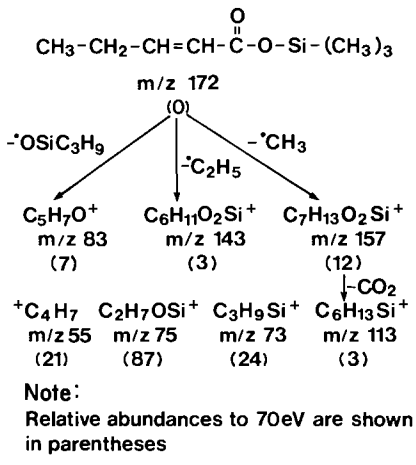
not observed when the pyrolysis was at the entrance of the heated zone. No distinct peak was observed corresponding to the "dehydrate trimer" of PHB. It should be noted that with the pyrolysate of the cells from which PHB had been extracted with a boiling mixture of chloroform and ethanol (36), no appreciable peaks corresponding to crotonic acid or the "oligomers" of PHB were observed.

Pyrolysis of HV-HB Heteropolymer

The gas chromatograms of the O-TMS derivatives of the pyrolysates of this heteropolymer produced at 250°C (lower curve) and at 400°C (upper curve) are shown in Fig. 5. Peak A in Fig. 5 was identified as the derivative of crotonic acid by the peak enrichment method; this peak is derived from the β-hydroxybutyrate moiety of the heteropolymer. Based on peak enrichment and mass spectrometry, peak B was identified as the derivative of 2-pentenoic acid which is derived from the β-hydroxyvalerate moiety of the polymer (18). The mass spectrum corresponding to this peak and the interpretation of the spectrum are summarized in Scheme 2. In the mass spectrum the molecular ion was not detected but the ions at *m/z* 157 and 143 were detected corresponding to the loss of the $\cdot CH_3$ and $\cdot C_2H_5$ groups, respectively, from the molecular ion. The ion at *m/z* 113 is due to the loss of CO_2 from the ion at *m/z* 157 (see Discussion). The ions at *m/z* 83 and 55 correspond to the ions $C_5H_7O^+$ and $C_4H_7^+$, respectively.

The retention time of peak C in Fig. 5 was much greater than that of the derivative of 2-pentenoic acid and distinctly different from that of the derivative of the "dehydrate dimer" of PHB (arrow in Fig. 5). In the light of these facts and considering



SCHEME 2

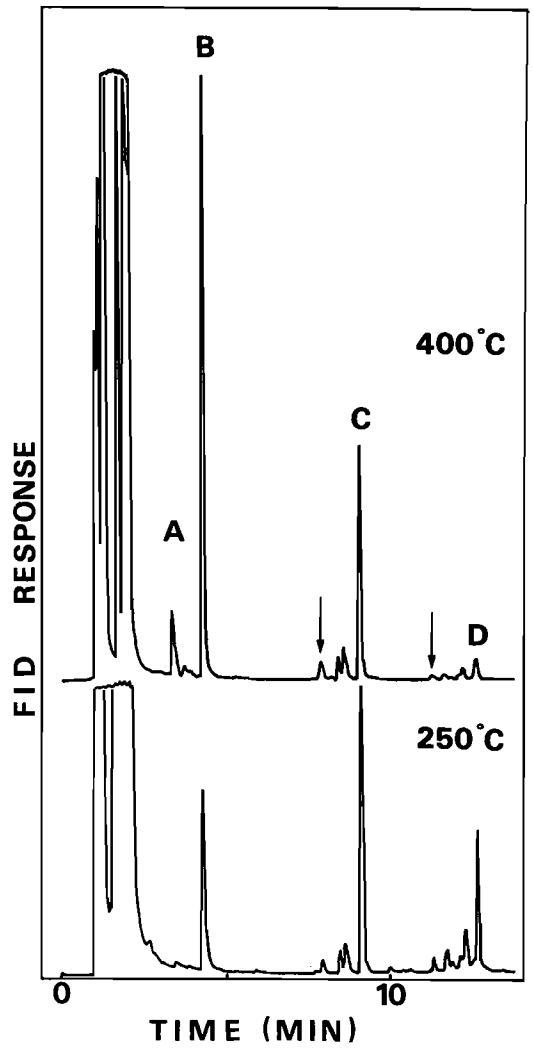


FIG. 5. Gas chromatograms of O-TMS derivatives of pyrolysate of HV-HB heteropolymer. Pyrolysis was done at 250°C (lower curve) and at 400°C (upper curve) with the sample near the exit of the heated zone. The arrows indicate the peak positions corresponding to the "dehydrate dimer" and "dehydrate trimer" of PHB.

that the major product in the pyrolysate is 2-pentenoic acid, it is reasonable to conclude that peaks C and D are due to the "dehydrate dimer" and "dehydrate trimer" of polyhydroxyvalerate (PHV) (Fig. 1). With the increase of the pyrolysis temperature, the peaks due to crotonic acid and 2-pentenoic acid were much intensified (see also Table 3). The presence of these oligomers was confirmed by proton nmr analysis on the pyrolysate.

Table 2 summarizes the proton nmr results on the pyrolysate of the HV-HB heteropolymer produced at 400°C. In the spectrum of the pyrolysate the signal characteristic of the α-proton in *trans*-2-

TABLE 2. Tentative assignment of proton nmr spectrum of pyrolysate[a] of HV-HB heteropolymer

δ (ppm)	Relative intensity	Assignment[b]
0.9	27	e
1.1	100	a
1.3	16	l
1.7	29	f
1.9	20	i
2.2	58	b
2.6	21	h
2.7	19	o, b
5.2	19	g, m
5.8	46	c (*cis* and *trans*), j
6.3	5	d (*cis*)
7.1	41	d (*trans*), k

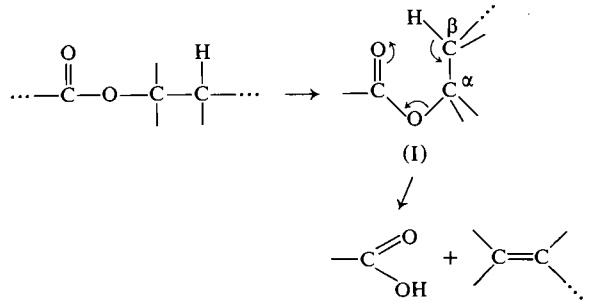
[a]Pyrolysis was made at 400°C with the sample near the exit of the heated zone.
[b]See Fig. 1.

pentenoic acid was observed at 7.1 ppm, and the signal characteristic of the α-proton in *cis*-2-pentenoic acid (37) was observed at 6.3 ppm. Thus one can conclude that *cis* and *trans* isomers of 2-pentenoic acid are present in the pyrolysate. These isomers can be present either as monomer or as the terminal unit of "dehydrate oligomers" of PHV in the pyrolysate. The presence of crotonic acid is shown by the characteristic allylic proton signals at 1.9 ppm. A relatively intense signal for the butyrate oligomers was observed at 1.3 ppm indicating that the "dehydrate oligomers" of PHB are present in the pyrolysate (see Table 3). The presence of the "dehydrate oligomers" of PHV in the pyrolysate was confirmed by the presence of the signals at 0.9, 1.7, and 2.6 ppm in the spectrum, assignable to the protons of the CH_3, CH_2 (bonded to CH_3), and CH_2 (bonded to CH) groups, respectively, of the hydroxyvalerate moiety in the oligomers (18).[4]

Table 3 summarizes the results of the pyrolysis of the HV-HB polymer at two temperatures. At 250°C the bulk of the polymer weight remained in the residue and the pyrolysate yield was very low. At 400°C the pyrolysis yield was much enhanced and high yields of 2-pentenoic acid (53.3% of the initial polymer) and the "dehydrate dimer" of PHV (18.7%) were obtained. The high yield of 2-pentenoates is an indication that this heteropolymer is composed mainly of β-hydroxyvalerate (18).

Pyrolysis Mechanisms

The family of aliphatic polyesters including PHB (31), poly-β-propiolactone (38), and poly-α-methyl-β-propiolactone (31) and the aromatic polyesters such as poly(ethylene terephthalate) (39) demonstrate a typical ester-pyrolysis mechanism (or intramolecular *cis*-elimination) (40) in which a cyclic transition state (I) is involved followed by synchronous breakage of the C(α)—O and C(β)—H bonds. Because of the similarity in chemical structures between PHB and HV-HB heteropolymer one can expect that this heteropolymer undergoes the same pyrolysis mechanism as proposed for these polyesters. However, a marked temperature effect was observed on the pyrolysis of the heteropolymer while no appreciable temperature effect was observed in the case of PHB. This suggests that the "small" difference in chemical structures of these two polymers can affect the pyrolysis mechanism.



Conclusions

Crotonic acid is a 1,2-disubstituted ethylene and is known not to homopolymerize as readily as its isomer, methacrylic acid (41). However, copolymers with vinyl acetate have been fabricated in the 1 to 30 mol% range of crotonic acid (41). These copolymers are used commercially as adhesives and sizing agents. The usefulness of 2-pentenoic acid has not been explored but a reactivity similar to that of crotonic acid can be expected. The vinyl "oligomers" of PHB and PHV are also interesting raw materials since they retain the optical activity of their parent polymers in the side chain.

In the bacterial cells used in this study the PHB content was relatively low. Nevertheless the formation of crotonic acid upon direct pyrolysis of the dry cells is interesting. Under optimum growth conditions, PHB is accumulated to as much as 70 to 80% of the weight of dry cells (42) whereupon the direct pyrolysis yield should be considerably enhanced. Wallen and Rohwedder (18) have suggested the presence of a homologous series of bacterial polyesters, including poly-β-hydroxyhexanoate and poly-β-hydroxyheptanoate (see Fig. 1), in activated sludges which leads to still further expectations in terms of potential pyrolysis products.

The results of this study demonstrate that the

[a]Pyrolyzed near the exit of the heated zone. Values are expressed in per cent of the initial polymer. Determination of the yield of crotonic acid and 2-pentenoic acid (using *trans*-2-pentenoic acid as standard) was made as specified in the footnote in Table 1. (The same degree of the FID response was assumed for the derivatives of the "oligomers" as for the derivative of 2-pentenoic acid.)

pyrolysis products of the HB moiety in the HV-HB heteropolymer are derived from macromolecular segments and not just from isolated hydroxybutyrate comonomers. In the latter case only crotonic acid would have been found. The significant yield of "dehydrate oligomers" of PHB in Fig. 5 argues for the presence of at least blocks of PHB in the HV-HB heteropolymer. X-ray studies have confirmed this conclusion.[4]

Acknowledgements

We are grateful to Prof. Don DeJongh as well as Drs. F. Messier and A. Martineau for their valuable discussions and their help in performing this study. Professors L. G. Mathieu, J. De Repentigny, and G. R. Drapeau of the Department of Microbiology, Université de Montréal, kindly provided facilities for microbial culture. We wish to thank Mr. Robert Mayer for his help in nmr analyses. Our thanks are extended to Miss Suzanne Coulombe for providing nmr data for PHB oligomers. The financial support of the Natural Sciences and Engineering Research Council of Canada and of the Ministère de l'Education du Québec is also acknowledged.

ALFRED FISCHER and GEORGE N. HENDERSON. Can. J. Chem. **59**, 2314 (1981).

The diastereoisomers of 4-ethyl-1-methyl-4-nitrocyclohexa-2,5-dienyl acetate (**1**) and 1-ethyl-4-methyl-4-nitrocyclohexa-2,5-dienyl acetate (**2**) are stereospecifically reduced to the corresponding nitrocyclohexadienols with aluminum hydride. Each dienol is stereospecifically methylated to the corresponding methyl ether with methyl iodide, silver oxide, and potassium hydroxide. Acid-catalysed solvolysis of the acetates **1** and **2** results in the substitution of the acetate moiety by other nucleophiles and these reactions are not stereospecific. The products of rearomatization of dienyl acetates, dienols, and dienyl methyl ethers depend on the acidity and ionizing power of the solvents and are readily explained in terms of reactions involving a nitrocyclohexadienyl cation or acetoxy- (hydroxy-, methoxy-)cyclohexadienyl cation as key intermediates. In the 4-acetoxy-4-alkylcyclohexadienyl cation 1,2-migration of the acetoxyl group is more rapid than alkyl migration, but 1,2-alkyl migration is faster than migration of the hydroxyl or methoxyl groups in the corresponding cations. 1-Ethyl-4-methoxy-4-methylcyclohexa-2,5-dien-1-ol and 4-ethyl-3-nitrotoluene are significant minor products in the solvolysis of 1-ethyl-4-methyl-4-nitrocyclohexa-2,5-dien-1-ol in aqueous methanol. Nitration of *p*-ethyltoluene in the presence of sulfuric acid or in trifluoroacetic anhydride gives a mixture of 4-ethyl-2-nitro- and 4-ethyl-3-nitrotoluene in a 2:1 ratio.

ALFRED FISCHER et GEORGE N. HENDERSON. Can. J. Chem. **59**, 2314 (1981).

L'hydrure d'aluminium permet de réduire stéréospécifiquement les diastéréoisomères de l'acétate de l'éthyl-4 méthyl-1 nitro-4 cyclohexadiène-2,5 yle (**1**) de l'acétate de l'éthyl-1 méthyl-4 nitro-4 cyclohexadiène-2,5 yle (**2**) en nitrocyclohexadiènols correspondants. Sous l'influence de l'iodure de méthyle en présence d'oxyde d'argent et d'hydroxyde de potassium, chaque diénol peut être transformé stéréospécifiquement en éther méthylique correspondant. La solvolyse des acétates **1** et **2**, catalysée par un acide, provoque la substitution des acétates par d'autres nucléophiles; ces réactions ne sont pas stéréospécifiques. La nature des produits de réaromatisation des diénylacétates, des dièenols et des méthoxydiényles dépend de l'acidité et du pouvoir ionisant des solvants; on peut facilement expliquer la formation de divers produits sur la base de réactions impliquant, comme intermédiaire clé, soit un cation nitrocyclohexadiényle ou un cation acétoxy (hydroxy ou méthoxy) cyclohexadiényle. Dans le cation acétoxy-4 alkyl-4 cyclohexadiényle, la migration-1,2 du groupe acétoxy est plus rapide que la migration alkyle, mais la migration-1,2 des groupes alkyles est plus rapide que la migration correspondante des groupes hydroxyle ou méthoxyle. L'éthyl-1 méthoxy-4 méthyl-4 cyclohexadiène-2,5 ol-1 et l'éthyl-4 nitro-3 toluène sont des produits secondaires importants de la solvolyse de l'éthyl-1 méthyl-4 nitro-4 cyclohexadiène-2,5 ol-1 dans le méthanol aqueux. La nitration du *p*-éthyltoluène en présence d'acide sulfurique ou dans l'anhydride trifluoroacétique donne un mélange d'éthyl-4 nitro-2 et d'éthyl-4 nitro-3 toluène dans un rapport 2:1.

[Traduit par le journal]

In an earlier report we described the nitration of *p*-ethyltoluene in acetic anhydride which gave as the main products a mixture of the diene adducts 4-ethyl-1-methyl-4-nitrocyclohexa-2,5-dienyl acetate (**1**) and 1-ethyl-4-methyl-4-nitrocyclohexa-2,5-dienyl acetate (**2**). Each of the structurally isomeric adducts was obtained as a pair of diastereoisomers and the isomers were separated by chromatography on alumina (1). In each case the lower melting diastereoisomer (**1***a*, **2***a*) was eluted before the high melting diastereoisomer (**1***b*, **2***b*). The (*E*)-configuration has been assigned to the *a* diastereomers and the (*Z*)-configuration to the *b* diastereomers (2). In the series of *p*-alkyltoluenes (R = Me, Et, *i*-Pr, *t*-Bu) *p*-ethyltoluene is the only member which gives structurally isomeric 1,4-adducts as a consequence of nitration *ipso* to both alkyl groups (3–5).[2] Such structurally isomeric 1,4-adducts are particularly useful for the study of adduct reactions since they allow the elucidation of the regiospecificity of the reactions. In the earlier paper examples of two such reactions were reported (1). Reaction of both **1***a* and **1***b* in trifluoroacetic acid – trifluoroacetic anhydride gave exclusively 4-ethyl-3-nitrotoluene whereas **2***a* and **2***b* gave 4-ethyl-2-nitrotoluene. The observations are in accord with the mechanism (1, 7, 8) in which the acetate is first protonated and then expelled as acetic acid to generate the *ipso*-nitrocyclohexadienyl cation (**3***i* from **1** and **4***i* from **2**). A 1,2 shift of the nitro group followed by deprotonation then gives the observed products. Solvolysis of both **1***a*

[1]For Part XXII, see ref. 2.

[2]*p*-Xylene is nitrated at both *ipso* positions but the same products are formed in each case. *p*-Cymene is also nitrated at both *ipso* positions but nitration at the isopropyl position results in de-isopropylation (4, 6).

and **1***b* in 50% (v/v) aqueous methanol gave 5-ethyl-2-methylphenyl acetate whereas solvolysis of **2***a* and **2***b* gave 2-ethyl-5-methylphenyl acetate. According to the proposed mechanism (1, 8) initial ionization of the nitro group as nitrite anion gives the *ipso*-acetoxycyclohexadienyl cation (**4***j* from **1** and **3***j* from **2**). A 1,2 shift of the acetate, presumably through the bicyclic ions **5** and **6**, followed by deprotonation, gives the observed acetates with the appropriate regiospecificity. The present paper reports other reactions of the adducts **1** and **2**.

Studies of the solvolysis of nitronium acetate adducts have been carried out by Myhre and his co-workers[3] and by Moodie and co-workers (9). Both groups have studied the solvolysis of the *p*-xylene adduct in conditions of varied acidity. The products obtained in these and in our previous studies of rearomatization of tertiary acetate adducts can be explained in terms of the formation of cyclohexadienyl cations and their subsequent reactions. The set of five reactions 2–6 and the analogous set 2′–6′ shown in Scheme 1 are sufficient to account for essentially all of the products they observed or those observed in the present work.[4,5]

Results and Discussion

Formation of Nitrodienols, Nitrodienyl Methyl Ethers, and Related Diene Derivatives

Reaction of the nitrodienyl acetates **1***a*, **1***b*, **2***a*, and **2***b* with excess aluminum hydride in tetrahydrofuran gave, in each case, an essentially quantitative yield of the corresponding nitrodienol **7***a*, **7***b*, **8***a*, and **8***b*, respectively. The reaction involves acyl–oxygen cleavage in the acetate group and thus the stereochemistry at C-1 of the cyclohexadiene ring is not disturbed. Thus **1***a* and **7***a* have the same stereochemistry (*E*) as do **1***b* and **7***b* (*Z*), **2***a* and **8***a* (*E*), and **2***b* and **8***b* (*Z*). Reaction of the nitrodienols **7***a*, **7***b*, **8***a*, and **8***b* with methyl iodide in the presence of silver oxide and potassium hydroxide gave, in close to quantitative yield, the corresponding ethers **9***a*, **9***b*, **10***a*, and **10***b*, respectively. As in the reaction of acetates with aluminum hydride, the alkyl–oxygen bond is not broken and the stereochemistry at C-1 is undisturbed. Thus **1***a*, **7***a*, and **9***a* all have the same stereochemistry (*E*) as do **1***b*, **7***b*, and **9***b* (*Z*). Similarly, **2***a*, **8***a*, and **10***a* have the (*E*)-configuration and **2***b*, **8***b*, and **10***b*, the (*Z*)-configuration.

The acetates **1** and **2** are both tertiary and di-allylic: they each give a cyclohexadienyl cation (**3***i* and **4***i*, respectively) on heterolysis of the acetate group. Not surprisingly, the acid-catalysed loss of acetate is very facile. Thus, on treatment with acidified aqueous acetone, acetate **1***b* gave both diastereoisomers **7***a* and **7***b* of the dienol, and, on reaction with acidified methanol, both diastereoisomers **9***a* and **9***b* of the ether. Similarly, acetate **2***a* gave dienols **8***a* and **8***b* and ethers **10***a* and **10***b* and acetate **2***b* likewise gave both diastereomers of the dienol (**8***a* and **8***b*) and ether (**10***a* and **10***b*). These reactions are examples of $A_{AL}1$ ester hydrolysis or methanolysis. From the perspective of the cyclohexadienyl groups they are S_N1 reactions. Other examples of such reactions are: the reaction of acetate **2***b* with trifluoroacetic acid (3% v/v) in acetic anhydride, where initial isomerization to a mixture of the diastereoisomers **2***a* and **2***b* occurred; with acetic anhydride in acetic acid initial partial isomerization to **2***a* occurred; the reaction of

[3]P. C. Myhre. Personal communication.

[4]Note that the set of reactions 2′–6′ can be generated from the set 2–6 by (*i*) replacing X by Y and (*ii*) interchanging the methyl and ethyl groups.

[5]The ethyl group would of course be replaced by methyl in the *p*-xylene series. Note also the isomeric series in which the positions of the methyl and ethyl groups are interchanged.

2*a* with hydrogen chloride in ether, which gave the nitrochlorodienes **11***a* and **11***b*; and the reactions of acetate **2***b* with formic acid in deuteriochloroform, which gave (as initial products) the nitrodienyl formates **12***a* and **12***b*. Most of these acid-catalyzed S_N1 reactions[6] were accompanied by simultaneous or subsequent rearomatization reactions. Study of the results (see Experimental) shows that conditions most conducive to the observation of the S_N1 reactions uncomplicated by rearomatization reactions are increased acidity (which speeds up the acid-catalysed loss of acetate relative to the competing uncatalysed solvolysis of the nitro group), low temperature (which suppresses the solvolytic reaction), and weakly ionizing solvents (good ionizing solvents aid the solvolysis of the nitro group (8)). However, if conditions are too acidic, the immediate product of the S_N1 reaction, e.g., the dienol, will reform the cyclohexadienyl cation and this will eventually give aromatic products (see below). This unfavourable consequence of increased acidity can be mitigated by working at low temperature (−30 to −40°C). This slows the acid-catalysed rearomatization reactions and thus allows the acidity to be raised to levels which would lead to rearomatization at ambient temperature. There is no reason to doubt that in those acid-catalysed reactions carried out at 35°C, in which only rearomatization products were observed, S_N1 type reactions did occur but on too short a time scale for detection.

Dienol **8***a* predominated (67–82%) in the mixture of **8***a* and **8***b* obtained on acid-catalysed hydrolysis of both **2***a* and **2***b*. This presumably reflects a kinetically controlled situation since under the reaction conditions the product dienols were not observed to equilibrate (nor expected to do so: hydroxyl is a poorer leaving group than acetate). In the single acid-catalysed hydrolysis experiment carried out in the **1** series **1***b* gave marginally more of **7***a* than **7***b*. The acid catalysed methanolysis results were more ambiguous. Acetate **2***a* gave more of **10***b* than **10***a* in acidified methanol and, to a lesser extent, in 50% trifluoroacetic acid in methanol. However, **2***b* gave more of **10***a* in acidified methanol and also in neutral methanol, but approximately equal amounts of **10***a* and **10***b* in acidified methanolic acetone. In the **1** series only the isomer **1***b* was investigated and it gave more of **9***b* than **9***a* when reacted in both acidified methanol and acidified methanolic acetone.

When both **2***a* and **2***b* were treated with nitric acid in acetic anhydride at −40°C, less than 5% isomerisation and less than 5% rearomatization occurred in each case. This indicates that the dienes are not equilibrated under the conditions under which they are formed in nitration. The experiment also illustrates the particular advantage of acetic anhydride as a solvent for nitration studies involving adduct formation. The acidity of the system is greatly reduced by the formation of acetyl nitrate and the complication of reversible formation of the *ipso*-nitrocyclohexadienyl cation from the adduct is thereby removed. Such reformation of the cation would eventually lead to aromatic products (Scheme 1).

All of the above S_N1, $A_{AL}1$, or "exchange" reactions are encompassed by reactions 1 and 6a (X = NO_2, Y = OAc) of Scheme 1 for the acetates **2** or reactions 1′ and 6′a (X = OAc, Y = NO_2) for the acetates **1**, and in which HA = H_2O, HOMe, HOAc, HCl, or HOCHO.

Rearomatization Reactions

As indicated above, observation of reactions in which the diene system is retained requires carefully chosen and controlled conditions to prevent the too successful competition by rearomatization. Rearomatization also involves the initial formation of the cyclohexadienyl cation as depicted in Scheme 1; the stabilization energy of this cation makes it the preferred intermediate for reaction paths to both dienyl and aromatic products.

Scheme 1 shows that starting from one diene it is possible in principle to generate all of the isomeric A-1-ethyl-4-methylcyclohexadienyl cations by a series of ionizations and S_N1 substitutions, and S_N1' substitutions with rearrangement. If the group A is not present in the original diene it can be introduced at either tertiary position by the exchange process (reaction 1 followed by 6a, or their counterparts 1′ and 6′a). Reaction 1 followed by 5a, or 1′ followed by 5′a will introduce the group A at the 2- or 3-position. Reactions 3a and 3′a provide for A to rearrange from a tertiary position to the adjacent secondary position and since A can be introduced at both tertiary positions it can appear through rearrangement at both secondary positions. Furthermore, the 1-A-4-ethyl-2-methyl and 1-A-2-ethyl-4-methyl cations can be generated by migration of the methyl or ethyl group (reactions 2a or 2′a) in the appropriate precursor cation. Thus, in principle it is possible to obtain (after deprotonation) any of the isomeric benzene derivatives containing 2-A-1-ethyl-4-methyl, 3-A-1-ethyl-4-methyl, 2-A-1-ethyl-5-methyl, or 2-A-5-ethyl-1-methyl substitution patterns, from a single diene. The only restriction on the group A is that it be present in the solvent as a nucleophile (or that it

[6]In an earlier paper these reactions were described as "exchange reactions" (3).

must have been present in the original adduct). In practice, the number of products is limited by the normal preferential formation of one or the other of the X- or Y-substituted cations and by both reaction conditions and the nature of the substituent (X, Y, A) which result in a particular reaction or reactions in the sets 1–6 and 1′–6′ being favoured; e.g., we have described the reaction of **2** in strongly acidic conditions which involves preferential formation of cation **4*i*** followed by 1,2-nitro group migration and deprotonation to 4-ethyl-2-nitrotoluene, formed exclusively. Three points with respect to Scheme 1 are to be noted here: (*i*) formation of one cation (reaction 1: X = NO_2, Y = OAc) is favoured; (*ii*) reaction of this cation with solvent nucleophile (which must be weak in the strongly acidic conditions) to give either a new diene (reactions 5a or 6a) or, through deprotonation, a triene (reaction 4a), is not competitive with rearrangement (reaction 3a), or is rapidly reversible; in the latter case ionization of the nitro group as shown in reactions 5b and 6b is not competitive with the reverse reaction of 5a or 6a: (*iii*) migration of the nitro group (reaction 3a) is preferred to migration of the methyl group (reaction 2a). We have also described the reaction of **2** in 50% aqueous methanol involving preferential formation of cation **3*j*** followed by a 1,2 shift of the acetate group and formation of 2-ethyl-5-methylphenyl acetate. Here we may note (*i*) formation of one cation Y = OAc (reaction 1′) is favoured under these conditions; (*ii*) reaction of this cation with solvent nucleophile (reactions 5′a and 6′a) or with solvent base (reaction 4′a) is not competitive with rearrangement (reaction 3′a): the cyclic acetoxonium cation **6** presumably provides a particularly favourable pathway for 1,2 migration of the acetate function; (*iii*) migration of acetate (reaction 3′a) is preferred to migration of the ethyl group (reaction 2′a), again a reflection of the favoured cyclic acetoxonium ion pathway.

It is possible to gradually change reaction conditions from strongly acidic, favouring formation of the nitrocyclohexadienyl cation (**3*i*** or **4*i*** in the present study), to neutral ionizing, favouring formation of the acetoxycyclohexadienyl cation (**4*j*** or **3*j***). In some intermediate conditions both cations should be formed. Also in some intermediate conditions there exists the possibility of reactions other than the 1,2 shift of the hetero group. Such other reactions would lead to a greater variety of aromatic products than the regiospecifically formed 2,5-dialkylnitrobenzene and 2,5-dialkylphenyl acetate. We have made studies of this type in other systems and as mentioned both Moodie and co-workers (9) and Myhre and co-workers have also made investigations of product distribution as a function of acidity with the *p*-xylene adducts and some other substrates (ref. 8 and footnote 3).

Aromatic products obtained on the reaction of dienes **2*a*** and **2*b*** in acidified methanol, methanol, and aqueous methanol are shown in Table 1. Reaction of dienes **2*a*** and **2*b*** with acidified methanol resulted in the initial formation of the methoxy dienes **10*a*** and **10*b*** (Scheme 1, X = NO_2, HA = HOMe, reaction 1, 6a) which then rearomatized. At high acidities (80–100% trifluoroacetic acid), 4-ethyl-2-nitrotoluene was the only aromatic product. Protonation and loss of the methoxyl group as methanol results in the reformation of cation **4*i*** (reverse of reaction 6a) which eventually rearranges by the 1,2-nitro shift to (after deprotonation) the nitroarene (reaction 3). At lower acidities deprotonation of the ethyl group at the α-position in

4*i* to form a triene (reaction 4a) is competitive with the rearrangement (reaction 3a). Thus in 65% trifluoroacetic acid the side-chain nitro derivative was formed (reaction 4b,c, A = NO_2). At still lower acidities (0.1 mol dm^{-3} H_2SO_4) formation of the nitroarene was completely suppressed and formation of the side-chain derivative (1-methoxy-1-(*p*-tolyl)ethane, 82%) was the dominant reaction (reaction 4, HA = HOMe). At still lower acidities and/or more strongly ionizing conditions (10–50% trifluoroacetic acid) ionization of the nitro group to form the cation **3*k*** (reaction 6b, HA = HOMe) becomes competitive with the reversion of the methoxydiene **10** to the cation **4*i*** (reverse of 6a). Consequently, the yield of the side-chain derivative (by reaction 4, for which **4*i*** is an essential precursor) was suppressed, only a minor amount being formed, and the rearranged ether 3-ethyl-4-methoxytoluene was the major product. Here we may note that under these conditions the acid-catalysed loss of the acetate group of **2** (reaction 1, X = NO_2, Y = OAc) is apparently faster than ionization of the nitro group (reaction 1′), hence, the initial rapid formation of **10**. However, the ionization of the nitro group of **10** (reaction 6b, X = NO_2, A = OMe) and subsequent reaction of the methoxy-cation **3*k*** (reaction 2′, Y = OMe) is faster than the acid-catalysed loss of the methoxyl group (reverse of reaction 6a) and subsequent reaction (reaction 4) of the nitro-cation **4*i***. Furthermore, it is to be noted that whereas migration of the hetero group is preferred to migration of the alkyl group in cations **4*i*** and **3*j***, migration of the methyl group is preferred to migration of the methoxyl group in **3*k***. The sequence OAc > Me > OMe is the same as the sequence of relative migration tendencies in the acid-catalysed dienone–phenol rearrangement, a reaction involving a similar transition state (10, 11). A substantial amount of 4-ethyl-2-methoxytoluene was also obtained in the reactions carried out in 10% and 50% trifluoroacetic acid. The pathway here is presumably that involving the conjugated diene (reaction 5, HA = HOMe). As in the case of the 1,4-diene **10** in the 1,3-diene isomer the loss of the nitro group (reaction 5b, A = OMe) and subsequent reaction (here, deprotonation, reaction 5c) of the resulting methoxycyclohexadienyl cation is faster than the reprotonation and loss of methanol (reverse of reaction 5a) followed by reaction 4 of the nitro-cation **4*i***. The reverse reactions of reactions 5a and 6a may themselves be fast, such that **10** and its 1,3-diene isomer are in equilibrium through **4*i***. However, provided that the stationary state concentration of **4*i*** is sufficiently low, its reactions, other than the forward reactions to **10** and its isomer (reactions 5a and 6a: we know that 6a is faster than all other reactions of **4*i***), cannot compete with the alternative reactions of **10** (reaction 6b, A = OMe and 2′, Y = OMe) and its isomer (reactions 5b,c). Such an equilibrium, with the conjugated diene present to a minor extent, coupled with a higher rate constant for reaction of the conjugated diene than of **10**, could account for the facts that, although a substantial amount of the product from the conjugated diene is formed in 10% and in 50% trifluoroacetic acid, the conjugated diene is not present at such a level as to be clearly evident by nmr in these experiments. Indeed, to account for the observations it is not even necessary that **10** and its isomer be in equilibrium, only that **10** be in equilibrium with **4*i*** and that the rate of the reaction sequence 5 be comparable to the rate of the sequence 6b (A = OMe), 2′(Y = OMe). It should be noted that the foregoing arguments are not dependent on the assumption expressed in Scheme 1 that the elimination of methanol from the conjugated diene follows an E1 pathway. The two-step elimination pathway was postulated by analogy with the known E1 mechanism for elimination of nitrous acid in nitrocyclohexa-1,4-dienyl secondary acetates (8).

As the acidity is reduced still further, the ionization of the nitro group in the nitrodienyl acetate to form cation **3*j*** (reaction 1′, X = NO_2, Y = OAc) becomes competitive with the protonation and loss of acetate to form cation **4*i*** (reaction 1). Correspondingly, in neutral methanol and in neutral 10% aqueous methanol the amount of methoxydiene **10** formed and of the aromatic ethers derived from this declined and 2-ethyl-5-methylphenyl acetate became an increasingly important product (reaction 3′). The aryl acetate was the only product in neutral 50% aqueous methanol (1). In the experiments carried out in methanol and 10% aqueous methanol, some of the methoxy-aromatics could have arisen from thermolysis of methoxynitrocyclohexadienes **10** in the glc inlet. Although we could not distinguish between 3-ethyl-4-methoxytoluene and 4-ethyl-3-methoxytoluene in these experiments (by glc), the former is the expected solvolytic product since the latter is not found in other experiments in which the distinction is possible and this accords with the expected preferential migration of ethyl rather than methoxyl in the ion **3*k***.

Solvolysis of the nitrodienyl acetates **1** was investigated much less extensively than that of the isomer **2**. In acidified methanol the dienyl ethers **9*a*** and **9*b*** were formed (reactions 1′ and 6′a, X = OAc, Y = NO_2, A = OMe) and subsequent aromatization gave 4-ethyl-3-methoxytoluene as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

the major product (86%). Presumably, this was formed through the conjugated diene by reversion of **9** to cation **3*i*** (reverse of reaction 6′a followed by 5′, HA = HOMe). Although the corresponding reaction for **2** was not observed to be the major reaction, it was significant in 10% and 50% trifluoroacetic acid as noted above and it may well be that it would be the dominant reaction under correctly chosen conditions of acidity. In 10% aqueous methanol, ionization of the nitro group of **1** was able to compete effectively with loss of the acetate. As a consequence, the yield of aryl ethers was reduced and 5-ethyl-2-methylphenyl acetate became the major product, and the only product in 50% aqueous methanol (reactions 1 and 3, X = OAc, Y = NO_2).

Reactions of **2** in acetic anhydride, acetic acid, and formic acid solutions followed similar pathways to those described for methanol (Scheme 1). As already discussed, the S_N1 exchange of the acetate for solvent nucleophile to form a new or isomeric diene occurred (reactions 1 and 6a) and this reaction was most cleanly observed in the more acidic mixtures. Further reaction led to aromatic products derived from the cation **4*i***, 4-ethyl-2-nitrotoluene predominating under the most strongly acidic conditions (reaction 3, X = NO_2) and 1-(*p*-tolyl)ethyl derivatives predominating under somewhat less acidic conditions (reaction 4). Under the most mildly acidic conditions formation and reaction of cation **3*j*** from the dienyl acetate **2** (reactions 1′ and 3′, X = NO_2, Y = OAc), is competitive with formation and reaction of cation **4*i*** and 2-ethyl-5-methylphenyl acetate predominates. Thus 4-ethyl-2-nitrotoluene (40%) was the major aromatic product recognised when **2*b*** was reacted with trifluoroacetic acid (3% v/v) in acetic anhydride. The nitro compound became a minor product (7%) when the reaction was carried out in acetic acid containing 0.2% sulfuric acid and 10% acetic anhydride. In this case, 1-(*p*-tolyl)ethane derivatives derived from cation **4*i*** by reaction 4 were the dominant products: *p*-methylacetophenone (24%), 1-(*p*-tolyl)ethyl acetate (20%), and 1-nitro-(*p*-tolyl)-ethane (31%). The *p*-methylacetophenone was presumably formed from 1-(*p*-tolyl)ethyl nitrite (cf. 3, 12, 13) or equivalent species such as the alcohol and nitrous acid. *p*-Ethyltoluene (10%) was also formed in this reaction and is likely to originate by loss of the nitronium ion from cation **4*i***. *p*-Ethyltoluene was also detected in other reactions but in those few cases some dienes were present in the mixture subjected to glc analysis and the arene could have arisen by thermolysis of the dienes. Side-chain product 1-(*p*-tolyl)ethyl acetate was also the major product on reaction of diene **2*b*** with 0.1% sulfuric acid in acetone containing 10% acetic anhydride. At lower acidity, on reaction in acetic acid containing 10% acetic anhydride, the side-chain products were still formed: 1-(*p*-tolyl)ethyl acetate (24%), 1-(*p*-tolyl)ethanol (11%), and 1-nitro-(*p*-tolyl)-ethane (9%). However, the major product was 2-ethyl-5-methylphenyl acetate, indicating the solvolysis of the nitro group (reaction 1′, X = NO_2, Y = OAc) was competitive with formation of cation **4*i*** (reaction 1) and its subsequent reaction. The fact that the acetate group was exchanged with the solvent ([$^2H_4$]acetic acid was used) indicates that under these conditions formation of cation **4*i*** is faster than formation of cation **3*j***, i.e., loss of the acetate group (reaction 1) is faster than solvolysis of the nitro group (reaction 1′), but the rearrangement of cation **3*j*** by reaction 3′ is faster than the further reaction (deprotonation) of cation **4*i*** (reaction 4a). Thus cation **4*i*** recombines with acetic acid to regenerate diene **2** (reverse of reaction 1), accounting for both the isomerization (epimerization) of the original diene **2*a*** and the presence of the labelled acetate in the aryl acetate ultimately obtained. 2-Ethyl-5-methylphenyl acetate (51%) was again the major product on solvolysis of diene **2*b*** in aqueous acetic acid. Only a small amount of side-chain products (4%) was formed under these conditions and the other significant products were two ethylmethylnitrophenols, presumably formed via the dienol **8** whose presence was noticed in the course of the reaction. Although the structures of these nitrophenols were not elucidated, it seems likely that the major one was 2-ethyl-4-methyl-6-nitrophenol (29%) formed by nitration (nitrosation and oxidation) of 2-ethyl-4-methylphenol, itself determined to be the major solvolysis product of diene **8** (see below). The minor nitrophenol was probably 3-ethyl-6-methyl-2-nitrophenol, obtained on nitration of 5-ethyl-2-methylphenol, the expected minor product of solvolysis of **8**. The solvolysis reaction generates nitrous acid which reacts rapidly with phenols.

Reaction of diene **2*b*** with formic acid in chloroform resulted as previously mentioned in initial exchange to form the formyloxydiene **12** (reactions 1 and 6a, X = NO_2, Y = OAc, A = OCHO). Subsequent aromatization gave 2-ethyl-5-methylphenyl formate (44%) as the major product and presumably formed like the corresponding acetate through ionization of the nitro group (reaction 6b) and migration of the formate group (reaction 3′, Y = OCHO) through a bicyclic cation analogous to **6**. The other significant product was 4-ethyl-2-nitrotoluene (30%). Formic acid is a significantly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

stronger acid than acetic acid and it appears to be sufficiently strong to allow the concentration of cation **4*i*** to rise to such a level that its reactions competed with the rearrangement of cation **3*l***. Moreover, the formic acid is less likely to accept a proton from cation **4*i*** than acetic acid, hence although the side-chain product 1-(*p*-tolyl)ethyl formate (7%) is formed by reaction 4 (X = NO_2, A = OCHO), the competing nitro group rearrangement product is dominant (reaction 3, X = NO_2).

Solvolysis of Dienol **8**a *and Dienyl Ether* **10**a

Solvolysis of the dienol **8*a*** in aqueous methanol gave 2-ethyl-4-methylphenol as the major aromatic product. The pathway here involves reaction 1′ (X = NO_2, Y = OH) to form cation **3*m*** which undergoes ethyl group migration: reaction 2′. In dienone–phenol rearrangement hydroxyl, like methoxyl, migrates less readily than alkyl (14). Both we and Myhre and co-workers have noted similar behaviour in the dienes obtained from *p*-xylene.[3,7] When the solvolysis was repeated in aqueous methanol in the presence of *N*,*N*-diisopropylethylamine (to neutralize acid formed which would catalyse aromatization of diene) the cation **3*m*** was partially trapped and the diastereoisomers of 1-ethyl-4-methoxy-4-methylcyclohexa-2,5-dien-1-ol (19%) obtained, together with the expected 2-ethyl-4-methylphenol (65%) and 4-ethyl-3-nitrotoluene (16%). The formation of the last product can be accounted for by reaction of cation **3*m*** with nitrite ion released on ionization, most likely while the ions are still closely associated as an ion pair, followed by subsequent elimination of water (reaction 5′, Y = OH, A = NO_2).[8] Minor amounts of 4-ethyl-3-nitrotoluene were observed in some of the solvolytic reactions described above and a similar pathway is likely in those cases.

Solvolysis of the methoxydiene **10*a*** in aqueous [$^2H_4$]methanol (20:80 v/v) gave 3-ethyl-4-methoxytoluene (71%) and 4-ethyl-2-methoxytoluene (24%) as the major products. The product ethers contained 75% [$^2H_3$]methoxyl, indicative of the formation of **4*i*** (reaction 1, X = NO_2, Y = OMe), which allowed exchange (reaction 6a, A = OCD_3). The major product was obtained via reaction 1′ (X = NO_2, Y = OMe) or reaction 6b (A = OCD_3), followed in either case by reaction 2′ (Y = OMe or OCD_3). The 4-ethyl-2-methoxytoluene presumably was formed by reaction 1 to give cation **4*i*** followed by reaction 5 (A = OCD_3).

The rearranged phenols were obtained in essentially quantitative yield when the dienyl acetates were reacted with sodium methoxide in methanol. Thus **2*b*** gave 2-ethyl-4-methylphenol, **1*b*** gave 4-ethyl-2-methylphenol, and 1,4-dimethyl-4-nitrocyclohexa-2,5-dienyl acetate gave 2,4-dimethylphenol. The analogous reaction of 1-isopropyl-4-methyl-4-nitrocyclohexa-2,5-dienyl acetate to give 2-isopropyl-4-methylphenol has been reported previously and a mechanism involving concerted migration of alkyl group and loss of nitrite in the diene alkoxide ion obtained on $B_{AC}2$ hydrolysis proposed (4).

Nitration of p-*Ethyltoluene with Mixed Acid and with Nitric Acid in Trifluoroacetic Anhydride*

Nitration of *p*-ethyltoluene in trifluoroacetic anhydride gave a small amount (5%) of dienes, probably the trifluoroacetate analogues of **1** and **2**. The major products were the 4-ethyl-2-nitro- and 4-ethyl-3-nitrotoluenes formed in a 3:2 ratio. Indubitably a major portion of the two nitroarenes was formed by *ipso* attack by the nitronium ions to form the cations **3*i*** and **4*i*** which then rearranged by reactions 3′ (Y = NO_2) and 3 (X = NO_2), respectively. The nitration of *p*-ethyltoluene with nitric acid and sulfuric acid in acetic acid likewise gave a similar mixture of the ethylnitrotoluenes.

Shift Reagent Studies

Shift reagent effects with tris(1,1,1,2,2,3,3-heptafluoro-7,7,-[$^2H_6$]dimethyl-4,6-[$^2H_3$]octanedionato)-europiumIII (Eu([$^2H_9$]fod)$_3$) on the ^{13}C nmr spectra of the acetates **2*a*** and **2*b*** and on the ^1H nmr spectra of the acetates **1*a***, **1*b***, **2*a***, and **2*b*** have been reported previously (1, 2). Table 2 shows the effect of the reagent on the ^1H nmr spectra of the nitrodienols **7*a***, **7*b***, **8*a***, and **8*b***. As expected, relative shift gradients decline with increasing distance of the proton from the site of complexation: the hydroxyl group. The differences between the relative gradients of the 4-CH_3 or 4-CH_2 groups in the pairs of diastereoisomers is too small to be of any value in assigning the configurations. In fact, the differences are in the wrong direction with the (*E*)-isomer (the *a* isomers) having the smaller relative gradients. A seemingly significant difference between the members of each pair of diastereoisomers is in the overall sensitivity to the shift reagent. The gradient of a plot of the chemical shift of the 1-CH_3 or 1-CH_2 group vs. Eu/mg is ca. 50% greater in the *a* isomers than in the *b*. For **7*a*** and **7*b*** the measurements were made simultaneously by addition of shift reagent to a mixture of the pair

[7]A. Fischer, G. N. Henderson, and T. A. Smyth. Unpublished work.

[8]The elimination of water could follow an E2 or E1cb pathway.

TABLE 2. Relative gradients (gradient 1-CH_2 or 1-CH_3 = 1.00) of proton chemical shifts for diene adducts from addition of Eu([$^2H_9$]fod)$_3$

Compound	1-CH_2CH_3	1-OH	2-H	3-H	4-CH_3 or 4-CH_2CH_3	4-CH_2CH_3	1-CH_2/Eu[a]
7*a*	—	—	0.96	0.38	0.24	0.22	0.08
7*b*	—	—	1.07	0.46	0.28	0.25	0.53
8*a*	0.40	5.22	0.88	0.35	0.21	—	0.73
8*b*	0.37	5.06	0.89	0.38	0.24	—	0.44

of diastereoisomers. Thus although the absolute values of shift sensitivity will depend on the concentrations, the relative shift sensitivities for the two isomers will not. The diastereoisomers **8***a* and **8***b* were investigated separately. However, solutions of identical concentrations were used and again the relative shift sensitivities for the two isomers should be concentration independent. The results suggest that the (*E*)-isomers are complexed to a greater extent by the reagent than are the (*Z*)-isomers.

Experimental

General experimental methods have been described previously (1, 15). The preparation of the acetates **1***a*, **1***b*, **2***a*, and **2***b* has been described (1). The C-2 and C-3 carbon atoms of the acetates were incorrectly assigned in the ^{13}C nmr spectra reported in the earlier paper. The correct (interchanged) assignments are reported in ref. 2. Shift reagent studies on the dienols **7***a*, **7***b*, **8***a*, and **8***b* were carried out as described for the acetates (1). Reaction mixtures containing product dienes were worked up by first quenching at low temperature with liquid ammonia and extracting the products with ether after evaporation of excess ammonia. Aromatization reactions were worked up by first neutralizing with liquid ammonia at low temperature or with aqueous bicarbonate at 0°C followed by ether extraction. In appropriate cases where both solvent and reagent (if any) were volatile (e.g., neutral methanol), these were simply pumped off at reduced pressure.

1-Ethyl-4-methyl-4-nitrocyclohexa-2,5-dienols (8)

Acetate **2***a* (1 g, 4.4 mmol) in dry tetrahydrofuran (5 cm^3) was added dropwise with stirring to a solution of aluminum hydride (37 mmol) in tetrahydrofuran (100 cm^3) at −20°C, under an argon atmosphere, and the resulting solution stirred for 15 min. The solution was cooled to −40°C and excess aluminum hydride decomposed by the careful addition of water. Cold work-up gave colourless crystals (0.73 g, 90%) of 1-ethyl-4-methyl-4-nitrocyclohexa-2,5-dienol (**8***a*), mp 97–98°C; ir (Nujol): 3270 (OH), 1540, and 1335 (NO_2) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.77 (t, 3, *J* = 7.2 Hz, CH_2CH_3), 1.65 (q, 2, *J* = 7.2 Hz, CH_2CH_3), 1.73 (s, 3, 4-CH_3), 2.12 (broad s, 1, O*H*), 6.00 (d, 2, *J* = 10.4 Hz, 2-*H* and 6-*H*), 6.08 (d, 2, *J* = 10.4 Hz, 3-*H* and 5-*H*) ppm; ^1H nmr (CD_3COCD_3) δ: 0.73 (t), 1.61 (q), 1.69 (s), 4.10 (s, O*H*), 6.02 (s, 2-*H*, 3-*H*, 5-*H* and 6-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 8.3 (CH_2CH_3), 27.1 (4-CH_3), 33.2 (CH_2CH_3), 68.8 (*C*-1), 83.7 (C-4), 126.5 (*C*-3 and *C*-5), 136.0 (*C*-2 and *C*-6) ppm.

Similar reduction of acetate **2***b* (0.70 g) gave a 96% yield of the other diastereoisomer of 1-ethyl-4-methyl-4-nitrocyclohexa-2,5-dienol (**8***b*), mp (needles from ether–pentane at −20°C) 56°C; ir (film): 3400 (OH), 1545 and 1337 (NO_2) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.75 (t, 3, *J* = 7.2 Hz, CH_2CH_3), 1.64 (q, 2, *J* = 7.2 Hz, CH_2CH_3), 1.67 (s, 3, 4-CH_3), 3.06 (s, 1, O*H*), 5.97 (d, 2, *J* = 10.4 Hz, 2-*H* and 6-*H*), 6.07 (d, 2, *J* = 10.4 Hz, 3-*H* and 5-*H*) ppm; ^1H nmr (CD_3COCD_3) δ: 0.75 (t), 1.59 (q), 1.64 (s), 3.6 (broad s, O*H*), 5.95 (d), 6.07 (d) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 8.4 (CH_2CH_3), 27.2 (4-CH_3), 32.7 (CH_2CH_3), 68.4 (*C*-1), 83.9 (C-4), 126.6 (*C*-3 and *C*-5), 135.3 (*C*-2 and *C*-6) ppm.

4-Ethyl-1-methyl-4-nitrocyclohexa-2,5-dienols (7)

Reduction of acetate **1***a* (0.30 g) gave a 98% yield of 4-ethyl-1-methyl-4-nitrocyclohexa-2,5-dienol (**7***a*) as colourless needles, mp 82–84°C; ir (Nujol): 3300 and 1080 (OH), 1557 and 1360 (NO_2) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.86 (t, 3, *J* = 7 Hz, CH_2CH_3), 1.33 (s, 3, 1-CH_3), 2.10 (q, 2, *J* = 7 Hz, CH_2CH_3), 2.29 (broad s, 1, O*H*), 5.97 (d, 2, *J* = 10 Hz, 3-*H* and 5-*H*), 6.16 (d, 2, *J* = 10 Hz, 2-*H* and 6-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 8.5 (CH_2CH_3), 27.8, (1-CH_3), 32.5 (CH_2CH_3), 65.4 (*C*-1), 87.6 (*C*-4), 123.6 (*C*-3 and *C*-5), 138.6 (*C*-2 and *C*-6) ppm.

Reduction of acetate **1***b* (0.30 g) gave a 95% yield of 4-ethyl-1-methyl-4-nitrocyclohexa-2,5-dienol (**7***b*) as colourless needles, mp 56–58°C; ir (Nujol): 3310 and 1080 (OH), 1555 and 1360 (NO_2) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.80 (t, 3, *J* = 7 Hz, CH_2CH_3), 1.28 (s, 3, 1-CH_3), 2.05 (q, 2, *J* = 7 Hz, CH_2CH_3), 2.74 (broad s, 1, O*H*), 5.97 (d, 2, *J* = 10 Hz, 3-*H* and 5-*H*), 6.12 (d, 2, *J* = 10 Hz, 2-*H* and 6-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 8.3 (CH_2CH_3), 27.8 (1-CH_3), 32.9 (CH_2CH_3), 65.0 (*C*-1), 87.6 (*C*-4), 123.4 (*C*-3 and *C*-5), 137.8 (*C*-2 and *C*-6) ppm.

1-Ethyl-4-methyl-4-nitrocyclohexa-2,5-dienyl Methyl Ether (10)

A mixture of 1-ethyl-4-methyl-4-nitrocyclohexa-2,5-dien-1-ol, (**8***a*, 250 mg), freshly precipitated silver oxide (920 mg), potassium hydroxide (23 mg), and methyl iodide (2.5 cm^3) was stirred for 6 h at ambient temperature in a closed vessel. Ether (10 cm^3) and magnesium sulfate were added, the mixture filtered, and the residue washed with ether. Evaporation of the combined filtrate and ether washings gave, as an oil, 1-ethyl-4-methyl-4-nitrocyclohexa-2,5-dienyl methyl ether (**10***a*, 260 mg); ir (film): 2855 (OCH_3), 1565 and 1352 (NO_2), 1060 (COC) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.76 (t, 3, *J* = 7 Hz, CH_2CH_3), 1.64 (q, 2, *J* = 7 Hz, CH_2CH_3), 1.74 (s, 3, 4-CH_3), 3.04 (s, 3, OCH_3), 5.83 (d, 2, *J* = 10 Hz, 2-*H* and 6-*H*), 6.27 (d, 2, *J* = 10 Hz, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 8.1 (CH_2CH_3), 27.2 (4-CH_3), 32.6 (CH_2CH_3), 51.9 (OCH_3), 74.6 (*C*-1), 84.0 (*C*-4), 129.8 (*C*-3 and *C*-5), 134.6 (*C*-2 and *C*-6) ppm.

Similar methylation of the dienol **8***b* gave the corresponding diastereoisomer of the methyl ether **10***b* (229 mg); ir (film): 2822 (OCH_3), 1547 and 1342 (NO_2), 1072 (COC) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.73 (t, 3, *J* = 7 Hz, CH_2CH_3), 1.60 (q, 2, *J* = 7 Hz, CH_2CH_3), 1.69 (s, 3, 4-CH_3), 3.08 (s, 3, OCH_3), 5.79 (d, 2, *J* = 10 Hz, 2-*H* and 6-*H*), 6.25 (d, 2, *J* = 10 Hz, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 8.3 (CH_2CH_3), 27.4 (4-CH_3), 32.6 (CH_2CH_3), 52.3 (OCH_3), 74.3 (*C*-1), 83.6 (*C*-4), 127.9 (*C*-3 and *C*-5), 133.9 (*C*-2 and *C*-6) ppm.

4-Ethyl-1-methyl-4-nitrocyclohexa-2,5-dienyl Methyl Ether (9)

Methylation of the dienol **7***a* following the procedure for the methylation of **8***a* gave the methyl ether **9***a* (225 mg); ir (film):

2820 (OCH_3), 1547 and 1347 (NO_2), 1102 (COC) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.91 (t, 3, J = 7 Hz, CH_2CH_3), 1.28 (s, 3, 1-CH_3), 2.14 (q, 2, J = 7 Hz, CH_2CH_3), 3.03 (s, 3, OCH_3), 6.00 (d, 2, J = 10 Hz, 2-*H* and 6-*H*), 6.12 (d, 2, J = 10 Hz, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 8.6 (CH_2CH_3), 27.3 (1-CH_3), 32.9 (CH_2CH_3), 52.5 (OCH_3), 70.9 (*C*-1), 87.6 (*C*-4), 126.9 (*C*-3 and *C*-5), 137.6 (*C*-2 and *C*-6) ppm.

Similar methylation of the dienol **7***b* (240 mg) gave the methyl ether **9***b* (220 mg); ir (film): 2820 (OCH_3), 1547 and 1347 (NO_2), 1100 (COC) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.83 (t, 3, J = 7 Hz, CH_2CH_3), 1.26 (s, 3, 1-CH_3), 2.08 (q, 2, J = 7 Hz, CH_2CH_3), 3.03 (s, 3, OCH_3), 5.94 (d, 2, J = 10 Hz, 2-*H* and 6-*H*), 6.16 (d, 2, J = 10 Hz, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 8.3 (CH_2CH_3), 27.8 (1-CH_3), 32.9 (CH_2CH_3), 52.3 (OCH_3), 70.4 (*C*-1), 87.4 (*C*-4), 126.9 (*C*-3 and *C*-5), 136.2 (*C*-2 and *C*-6) ppm.

Hydrolysis of the Dienyl Acetates 1 and 2 in Acidified Aqueous Acetone

A solution of acetate **2***a* (35 mg) in aqueous [$^2H_6$]acetone (350 mm^3; 10:90, v/v) containing sulfuric acid (0.05 mol dm^{-3}), at 35°C was observed by ^1H nmr. A mixture of the dienols **8***a* and **8***b* was slowly formed ($t_{1/2}$ = 2 h). After hydrolysis was complete the reaction mixture was worked up. The presence of the diastereoisomeric dienols was confirmed by ^1H nmr in $CDCl_3$ and the ratio **8***a*:**8***b* = 67:33 was determined after addition of Eu([$^2H_9$]fod)$_3$, which increases the separation of the signals.

The hydrolysis of acetate **2***b* in aqueous [$^2H_6$]acetone containing sulfuric acid (0.05 mol dm^{-3}) had $t_{1/2} \approx$ 2 h and gave **8***a*:**8***b* = 70:30. When the hydrolysis was carried out with more dilute acid (0.01 mol dm^{-3}) the half-life was increased (~ 6 h) and the product ratio was **8***a*:**8***b* = 82:18.

Reaction of acetate **1***b* under the same conditions as **2***a* gave the diastereoisomeric dienols **7***a* and **7***b*, with $t_{1/2}$ = 1.3 h. The ratio **7***a*:**7***b* = 55:45 was determined after work-up and addition of shift reagent.

Reaction of Dienes 2a *and* 2b *with Acidified Methanol*

A solution of diene **2***b* (35 mg) in [$^2H_4$]methanol containing sulfuric acid (0.01 mol dm^{-3}), at 35°C, was observed by nmr. The conversion of the acetoxydiene **2***b* into a mixture of the diastereoisomers of 1-ethyl-4-methyl-4-nitrocyclohexa-2,5-dienyl [$^2H_3$]methyl ether (**10***a* and **10***b*) was complete in 30 min. After work-up **10***a* (62%) had nmr ($CDCl_3$) δ: 0.75 (t, J = 7.6 Hz, CH_2CH_3), 1.64 (q, J = 7.6 Hz, CH_2CH_3), 1.74 (s, 4-CH_3), 5.84 (d, J = 9.9 Hz, 2-*H* and 6-*H*), and 6.31 (d, J = 9.9 Hz, 3-*H* and 5-*H*) ppm; and **10***b* (38%) had nmr ($CDCl_3$) δ: 0.75, 1.60, 1.70, 5.82, and 6.31 ppm.

The reaction was repeated with less acid (0.005 mol dm^{-3}) when aromatic compounds were formed as well as the dienyl methyl ether. When the reaction was carried out in the absence of acid it required 72 h for completion and 65% of aromatic products and 35% of [$^2H_3$]methoxydienes (**10***a*:**10***b* = 60:40) were formed. Analysis by glc and glc–ms showed that the products were, in order of retention time on FFAP, *p*-ethyltoluene (0.3%), 1-[$^2H_3$]methoxy-1-*p*-tolylethane (10%), 3-ethyl-4-[$^2H_3$]methoxytoluene[9] (31%), 4-ethyl-2-[$^2H_3$]methoxytoluene (14%), 2-ethyl-5-methylphenyl acetate (42%), and 5-ethyl-2-methylphenyl acetate (3%). At 35°C in methanol-[$^2H_6$]acetone (10:90 v/v) containing sulfuric acid (0.01 mol dm^{-3}) the acetoxy diene **2***b* was completely converted into approximately equal amounts of the methoxydienes **10***a* and **10***b* in 20 min. When the reaction was repeated with more sulfuric acid (0.1 mol dm^{-3}) formation of the methoxydienes was complete in less than 5 min and subsequently the latter slowly aromatized ($t_{1/2}$ ~ 4 h) to a mixture of 1-methoxy-1-(*p*-tolyl)ethane (82%) and 3-ethyl-4-methoxytoluene and/or 4-ethyl-2-methoxytoluene (18%).

Reaction of diene **2***b* in aqueous [$^2H_4$]methanol (10:90 v/v), at 35°C, gave methoxydienes (10%) and aromatic compounds (90%) within 24 h; glc and glc–ms analysis gave, in order of retention time, *p*-ethyltoluene (4%), 1-[$^2H_3$]methoxy-1-(*p*-tolyl)-ethane (9%), 3-ethyl-4-[$^2H_3$]methoxytoluene[9] (10%), 4-ethyl-2-[$^2H_3$]methoxytoluene (7%), 2-ethyl-5-methylphenyl acetate (66%), 5-ethyl-2-methylphenyl acetate (4%). Each of the identified components had a retention time identical to that of a co-injected authentic sample.

Diene **2***a* with sulfuric acid (0.01 mol dm^{-3}) in methanol at 35°C gave the methoxydienes **10***a* (36%) and **10***b* (64%) in 30 min. Trifluoroacetic acid (315 mm^3) was added to a solution of diene **2***a* (35 mg) in [$^2H_4$]methanol (35 mm^3) at −78°C and the mixture warmed to 0°C. The nmr taken at 0°C within 2 min of mixing showed only 4-ethyl-2-nitrotoluene, confirmed by glc after work-up. In similar experiments in 80% trifluoroacetic acid – 20% [$^2H_4$]methanol the acetoxydiene **2***a* was completely converted into a mixture of the methoxydienes **10***a* and **10***b* (70%) and 4-ethyl-2-nitrotoluene (30%) in 1 min; in 5 min 90% of the methoxydienes had been converted into the nitroarene and in 10 min 4-ethyl-2-nitrotoluene was the only product, confirmed by glc after work-up. In 65% trifluoroacetic acid the [$^2H_3$]methoxydienes **10***a* and **10***b* formed within 4 min and then rearomatized over 2 h to a mixture of 4-ethyl-2-nitrotoluene (80%) and 1-nitro-(*p*-tolyl)ethane (20%). In 50% trifluoroacetic acid the [$^2H_3$]methoxydienes **10***a* and **10***b* were formed in 11 min with **10***b* being present in slightly greater amount than **10***a*. Subsequently rearomatization occurred to the extent of 35% in seven days (0°C). After a further twelve days at ambient temperature rearomatization was complete. After work-up, analysis by ^1H nmr and glc identified the products as 1-[$^2H_3$]methoxy-1-(*p*-tolyl)ethane (4%), 3-ethyl-4-[$^2H_3$]methoxytoluene (73%), and 4-ethyl-2-[$^2H_3$]methoxytoluene (23%). In 10% trifluoroacetic acid (1.4 mol dm^{-3}), approximately equal amounts of the [$^2H_3$]-methoxydienes **10***a* and **10***b* were formed with a half-life of 11 h (0°C). The methoxydienes subsequently rearomatized with a half-life of ca. 20 days at ambient temperature. After completion of the reaction ^1H nmr and glc identified the products as 1-[$^2H_3$]methoxy-1-(*p*-tolyl)ethane (3%), 3-ethyl-4-[$^2H_3$]methoxytoluene (59%), and 4-ethyl-2-[$^2H_3$]methoxytoluene (38%).[10]

Diene **1***b* in [$^2H_4$]methanol containing sulfuric acid (0.01 mol dm^{-3}), at 35°C, was completely converted into the diastereoisomers of 4-ethyl-1-methyl-4-nitrocyclohexa-2,5-dienyl [$^2H_3$]-methyl ether (**9***a* (44%) and **9***b* (56%)) in 9 min. Subsequent aromatization of the [$^2H_3$]methoxydienes ($t_{1/2}$ = 27 h) gave, after work-up and analysis by ^1H nmr and glc, 1-[$^2H_3$]methoxy-1-(*p*-tolyl)ethane (3%), 4-ethyl-3-[$^2H_3$]methoxytoluene (86%), 4-ethyl-2-[$^2H_3$]methoxytoluene (5%), and 5-ethyl-2-[$^2H_3$]methoxytoluene (6%).

In methanol – [$^2H_6$]acetone (10:90 v/v) containing sulfuric acid (0.01 mol dm^{-3}), at 35°C, the conversion of **1***b* to the methoxydienes was complete in 11 min. After work-up and addition of Eu([$^2H_9$]fod)$_3$ the methoxyl peaks could be separately integrated and showed **9***a*:**9***b* = 42:58.

Diene **1***b* rearomatized ($t_{1/2}$ = 12 h) in aqueous [$^2H_4$]methanol

[9]Not distinguishable from the 4-ethyl-3-[$^2H_3$]methoxy isomer by glc.

[10]The ^1H nmr showed three aromatic methyl peaks at δ 2.27 (5%, 1-methoxy-1-*p*-tolylethane and/or 4-ethyl-3-methoxytoluene), 2.24 (60%, 3-ethyl-4-methoxytoluene), and 2.15 ppm (35%, 4-ethyl-2-methoxytoluene). Co-injection of authentic samples identified the three glc peaks, in order of retention time, as 1-methoxy-1-*p*-tolylethane (3%), 3-ethyl-4-methoxytoluene and/or 4-ethyl-3-methoxytoluene (59%), and 4-ethyl-2-methoxytoluene (38%). The combined analysis allowed the unambiguous assignment of the product.

For personal use only.

(10:90 v/v) and gave after work-up: 1-[$^2H_3$]methoxy-1-(*p*-tolyl)ethane (1%), 4-ethyl-3-[$^2H_3$]methoxytoluene (29%), 4-ethyl-2-[$^2H_3$]methoxytoluene (5%), 5-ethyl-2-[$^2H_3$]methoxytoluene or 4-ethyl-1-[$^2H_3$]methoxymethylbenzene (4%), 2-ethyl-5-methylphenyl acetate (7%), and 5-ethyl-2-methylphenyl acetate (54%).

Reaction of Diene 2 in Acetic Anhydride, Acetic Acid, and Formic Acid Solutions

A solution of **2***b* in acetic anhydride containing trifluoroacetic acid (3% v/v) was observed by nmr at −30°C. Isomerization of **2***b* to a 1:1 mixture of **2***a* and **2***b* occurred over 30 min and the dienes subsequently slowly aromatized ($t_{1/2}$ = 30 h). 4-Ethyl-2-nitrotoluene (~40%) was present in the aromatic products.

Reaction of diene **2***b* in acetic anhydride – [$^2H_6$]acetone (10:90, v/v) containing sulfuric acid (0.01 mol dm^{-3}), at 35°C, resulted in complete rearomatization in 7 min. The major product was 1-(*p*-tolyl)ethyl acetate.

Reaction of diene **2***b* in acetic anhydride – [$^2H_4$]acetic acid (10:90, v/v) containing sulfuric acid (0.02 mol dm^{-3}), at 35°C, resulted in complete rearomatization in < 2 min. The distinctive signals of 1-nitro-(*p*-tolyl)ethane were evident in the nmr of the mixture (δ 1.46 (d), 2.26 (s), 5.83 (q)). Work-up and analysis by glc and glc–ms (FFAP column) indicated the following composition (relative retention time, *m/e* of the characteristic ion in the chemical ionization ms, % composition): *p*-ethyltoluene (0.25, 121 (*M* + 1), 10); unknown (0.53, —, 2); *p*-methylacetophenone (0.83, —, 24); 1-(*p*-tolyl)ethyl acetate (0.89, 119 (*M* − OCOCH$_3$), 20); 2-ethyl-5-methylphenyl acetate (1.00, —, 2); 5-ethyl-2-methylphenyl acetate (1.05, —, 2); 4-ethyl-3-nitrotoluene (1.43, 166(*M* + 1), 1); 4-ethyl-2-nitrotoluene (1.60, 166 (*M* + 1), 7); 1-nitro-(*p*-tolyl)ethane (2.38, 119 (*M* − NO$_2$), 31). With the exception of the last compound, which partially decomposed on glc, each of the identified compounds had a retention time identical to that of a co-injected authentic sample.

Reaction of diene **2***b* in acetic anhydride – [$^2H_4$]acetic acid (10:90, v/v) at 35°C led to partial isomerization to **2***a* and rearomatization ($t_{1/2}$ = 20 h); glc and glc–ms analysis of the worked-up product gave: 1-(*p*-tolyl)ethyl acetate (0.90, 119 (*M* − OCOCH$_3$), 24); 2-ethyl-5-methylphenyl acetate (1.00, 179 (*M* + 1, 25%) and 182 ([$^2H_3$]*M* + 1, 75%), 53); 1-(*p*-tolyl)ethanol (1.19, 119 (*M* − OH), 11); 4-ethyl-3-nitrotoluene (1.42, 166 (*M* + 1), 3); 4-ethyl-2-nitrotoluene (1.56, 166 (*M* + 1), 1); 1-nitro-1-(*p*-tolyl)ethane (2.16, 119 (*M* − NO$_2$), 9). With the exception of the 1-nitro-1-(*p*-tolyl)ethane, which partially decomposed on the column, the components had retention times identical to those of co-injected authentic samples.

Reaction of diene **2***b* in [$^2H_2$]water – [$^2H_4$]acetic acid (10:90, v/v), at 35°C, resulted in partial hydrolysis to form hydroxydiene **8** (45% after 1 h) and concurrent rearomatization and aromatization of the hydroxydiene, which was completed in 16 h. The glc and glc–ms analyses of the worked-up product gave 1-(*p*-tolyl)ethyl acetate (0.86, 119 (*M* − OAc), 2); 2-ethyl-5-methylphenyl acetate (1.00, 179 (*M* + 1, 66%) and 182 ([$^2H_3$]*M* + 1, 34%), 51); 5-ethyl-2-methylphenyl acetate (1.03, —, 8); 1-(*p*-tolyl)ethanol (1.22, 119 (*M* − OH), 2); 2-ethyl-4-methyl-6-nitrophenol (1.85, 182 (*M* + 1) and 164 (*M* − OH), 29); and 3-ethyl-6-methyl-2-nitrophenol (1.93, 182 (*M* + 1) and 164 (*M* − OH), 8). The substitution pattern of the nitrophenols was not determined and the assignment is based on the structures of the expected phenol solvolysis products and the most likely position of nitration of these phenols (see Discussion).

A solution of acetyl nitrate in acetic anhydride was prepared by adding acetic anhydride (5 cm^3) to nitric acid (1.89 g), each at −70°C. The mixture was warmed to 0°C and cooled again to −70°C. The acetyl nitrate solution (250 mm^3) was added to a solution of diene **2***a* (112 mg) in acetic anhydride (250 mm^3) at −78°C and the mixture warmed to −40°C and maintained at that temperature for 30 min with occasional shaking. After work-up analysis by nmr indicated that < 5% of the diastereomer **2***b* and < 5% of aromatic compounds had been formed. A similar experiment starting with diene **2***b* showed a similar small amount of isomerization and rearomatization.

Reaction of **2***b* in formic acid – [$^2H_3$]chloroform (33:67) at 0°C resulted in the formation of the formyloxydienes and subsequent aromatization. After work-up, glc and glc–ms gave 2-ethyl-5-methylphenyl formate (0.78, 165 (*M* + 1) 44); 1-(*p*-tolyl)-ethyl formate (0.90, 119 (*M* − OCHO), 7); 2-ethyl-5-methylphenyl acetate (1.00, —, 5); 4-ethyl-3-nitrotoluene (1.34, 166 (*M* + 1), 8); 4-ethyl-2-nitrotoluene (1.50, 166 (*M* + 1), 30); and 2-ethyl-4-methyl-6-nitrophenol (1.96, 182 (*M* + 1) and 164 (*M* − OH), 6). The aryl acetate and nitroarenes had retention times identical to those of authentic samples. The side-chain formate and acetate have similar retention times. However, the protons of the ethylidene group were shifted to distinctly lower field (δ 1.56 and 5.99) compared with those of 1-(*p*-tolyl)ethyl acetate (δ 1.45 and 5.83) and on this basis the formate structure was assigned.

Reaction of Diene 2a with Hydrogen Chloride

Hydrogen chloride was passed through a solution of diene **2***a* (100 mg) in anhydrous ether (10 cm^3) at −78°C, for 10 min. After work-up, ^{1}H nmr showed that the acetoxydiene had been converted into another diene (presumably the chlorodiene **11**) and 30% rearomatization had occurred. The chlorodiene was formed as the expected pair of diastereoisomers since, although there was only a single vinyl peak at δ 6.14 ppm, there were two singlet methyl peaks at δ 1.72 and 1.76 ppm in the ratio 65:35.

Solvolysis of Dienol 8a

Dienol **8***a* in aqueous [$^2H_4$]methanol (20:80, v/v), at 35–45°C over 12 h, gave as the major product 2-ethyl-4-methylphenol, with nmr and glc retention time identical to that of an authentic sample and chemical ionization ms *m/e* 137 (*M* + 1).

Solvolysis in $^2H_4$[methanol] containing *N*,*N*-diisopropylethylamine (10% v/v) at 60°C gave, with a half-life at 44 min (by ^{1}H nmr) 4-ethyl-3-nitrotoluene (16%), 2-ethyl-4-methylphenol (65%), and the diastereoisomers of 1-ethyl-4-[$^2H_3$]methoxy-4-methylcyclohexa-2,5-dien-1-ol (19%); glc of the product confirmed the presence of 4-ethyl-3-nitrotoluene (and the absence of its 2-nitro isomer) and of 2-ethyl-4-methylphenol.

Solvolysis of Methoxydiene 10a

The ether **10***a* in D_2O–CD_3OD (20:80 v/v) at 35°C rearomatized with a half-life of 11.5 h. After complete rearomatization had occurred, ^{1}H nmr indicated that 75% of the methoxyl function had exchanged with the solvent. The ^{1}H nmr and glc of the worked-up product showed that it was composed of 3-ethyl-4-methoxytoluene (71%) and 4-ethyl-2-methoxytoluene (24%) (containing 75% of the [$^2H_3$]methoxy compounds) with minor amounts of 2-ethyl-4-methylphenol[11] (3%) and 5-ethyl-2-methylphenol (2%).

Reaction of Tertiary 1,4-Dialkylnitrocyclohexadienyl Acetates with Sodium Methoxide

A solution of sodium methoxide (0.31 mmol) in methanol (200 mm^3) was added to a solution of diene **2***b* (35 mg, 0.16 mmol) in methanol. The diene rearomatized over 30 min at 35°C to give 2-ethyl-4-methylphenol with identical ^{1}H nmr and retention time on glc to that of an authentic sample. In a similar experiment diene **1***b* was converted, in 3 h at 35°C, into 4-ethyl-2-methylphenol, identified by ^{1}H nmr and glc retention time comparison with an authentic sample. Similarly 1,4-dimethyl-4-

[11]Not distinguishable from 2-ethyl-5-methylphenol in this experiment. The 2-ethyl-4-methylphenol is the more likely product (see Discussion).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

nitrocyclohexa-2,5-dienyl acetate gave 2,4-dimethylphenol with ^{1}H nmr and glc retention time identical to an authentic sample (Aldrich).

Nitration of p-*Ethyltoluene with Mixed Acid*

A mixture of nitric acid (14.8 g) and sulfuric acid (22 cm^3) at −5°C – 0°C was added, with stirring, over 45 min to a solution of *p*-ethyltoluene (20 g, 0.17 mol) in sulfuric acid (22 cm^3) and acetic acid (12 cm^3) at −15°C – −10°C (cf. ref. 16). Stirring was continued for 15 min and the mixture was then poured onto crushed ice. After neutralization with solid sodium carbonate, extraction with ether gave a mixture of unreacted *p*-ethyltoluene, 4-ethyl-2-nitrotoluene, and 4-ethyl-3-nitrotoluene. The *p*-ethyltoluene was removed by distillation under reduced pressure and a mixture of the pure 4-ethyl-nitrotoluenes (19 g, 0.12 mol) was obtained, confirmed by ir 1530 and 1350 cm^{-1} (NO_2), ^{1}H nmr (1), and glc and glc–ms: 4-ethyl-3-nitrotoluene (*m/e* 166 (*M* + 1), 39%) and 4-ethyl-2-nitrotoluene (*m/e* 166 (*M* + 1), 61%).

Nitration of p-*Ethyltoluene with Nitric Acid in Trifluoroacetic Anhydride*

A solution of nitric acid in trifluoroacetic anhydride (25 cm^3) was prepared at −70°C, warmed to 0°C and recooled to −65°C, and added, with stirring, to a solution of *p*-ethyltoluene (6.1 g, 0.05 mol) in trifluoroacetic anhydride (25 cm^3), at −70°C. The mixture was warmed to −40°C, maintained at −40°C for 30 min, then warmed to ambient temperature and allowed to stand for 30 min. Nuclear magnetic resonance data indicated that 75% of 4-ethyl-nitrotoluenes and 5% of dienes had been formed. After work-up, the product was absorbed on alumina and the *p*-ethyltoluene eluted with petroleum ether. The nitrotoluenes were eluted with ether and the presence of 4-ethyl-2-nitrotoluene and 4-ethyl-3-nitrotoluene confirmed by ^{1}H nmr (1), ^{13}C nmr (1), and glc: 4-ethyl-3-nitrotoluene (36%), 4-ethyl-2-nitrotoluene (64%).

*Preparation of 1-(*p*-Tolyl)ethane Derivatives*[12]

1-(*p*-Tolyl)ethanol, pure by glc, was obtained in quantitative yield on reduction of 4-methylacetophenone (40 g) with excess lithium aluminum hydride (10 g) and had ^{1}H nmr ($CDCl_3$) δ: 1.34 (d, 3, *J* = 6 Hz, CH(OH)C*H*$_3$), 2.24 (s, 3, *p*-C*H*$_3$), 3.42 (d, 1, *J* = 2.5 Hz, O*H*), 4.66 (octet, 1, *J* = 6 Hz and 2.5 Hz, C*H*(OH)CH$_3$), 7.03 (d, 2, *J* = 8 Hz, *m-H*), 7.13 (d, 2, *J* = 8 Hz, *o-H*) ppm, on addition of D_2O the OH doublet disappeared and the methine octet was converted into a quartet; ^{13}C nmr ($CDCl_3$) δ$_c$: 21.0 ($C_6H_4CH_3$), 25.1 (CH*C*H$_3$), 69.7 (*C*HCH$_3$), 125.4 (*C*-2′ and *C*-6′), 128.9 (*C*-3′ and *C*-5′), 136.4 (*C*-4′) and 143.1 (C-1′) ppm.

1-(*p*-Tolyl)ethyl acetate, pure by glc, was obtained in 80% yield by acetylation of the alcohol (2.5 g) with acetic anhydride (25 cm^3) in the presence of pyridine (10 cm^3) and had ir (film): 1740 and 1245 (OCOC*H*$_3$) cm^{-1}; ^{1}H nmr ($CDCl_3$), δ: 1.45 (d, 3, *J* = 6.5 Hz, CHC*H*$_3$), 1.94 (s, 3, OCOC*H*$_3$), 2.25 (s, 3, $C_6H_4C\mathit{H}_3$), 5.83 (q, 1, *J* = 6.5 Hz, C*H*CH$_3$), 7.08 (d, 2, *J* = 8 Hz, *m-H*), 7.19 (d, 2, *J* = 8 Hz, *o-H*) ppm; ^{13}C nmr ($CDCl_3$) δ$_c$: 21.1 (OCOCH$_3$ and $C_6H_4C\mathit{H}_3$), 22.1 (CH*C*H$_3$), 72.1 (*C*HCH$_3$), 126.1 (*C*-2′ and *C*-6′), 129.1 (*C*-3′ and *C*-5′), 137.4 (*C*-4′), 138.8 (*C*-1′), and 169.9 (O*C*OCH$_3$) ppm; ms (70 eV), *m/e* (relative intensity) 178.098 (42, M_r ($^{12}C_{11}$ $^1H_{14}$ $^{16}O_2$) 178.099), 136 (46, *M* − CH_2CO), 121 (48), 119 (60), 118 (100, *M* − CH_3CO_2H), 117 (60), 91 (32), 77 (12).

Methyl 1-(*p*-tolyl)ethyl ether was obtained in 87% yield by refluxing the alcohol (0.02 mol) with sodium (0.024 mol) in toluene (25 cm^3) for five days to form the alkoxide which was then reacted with excess methyl iodide (5 cm^3). It had ir (film): 2830 (OCH$_3$) and 1105 (COC) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.38 (d, 3, *J* = 6.5 Hz, CHC*H*$_3$), 2.27 (s, 3, $C_6H_4C\mathit{H}_3$), 3.12 (s, 3, OC*H*$_3$), 4.19 (q, 1, *J* = 6.5 Hz, C*H*CH$_3$), 7.12 (s, 4, $C_6\mathit{H}_4$) ppm; ^{13}C nmr δ$_c$: 21.1 ($C_6H_4CH_3$), 23.9 (CH*C*H$_3$), 56.2 (O*C*H$_3$), 79.5 (*C*HCH$_3$), 126.2 (*C*-2′), 129.1 (*C*-3′), 136.9 (*C*-4′), 140.6 (*C*-1′) ppm; ms (70 ev), *m/e* (relative intensity) 150.098 (14, M_r ($^{12}C_{10}$ $^1H_{14}$ ^{16}O), 150.104), 135 (100, *M* − CH_3), 118 (55, *M* − CH_4O), 105 (10), 91 (34).

1-Bromo-1-(*p*-tolyl)ethane was obtained from 1-(*p*-tolyl)-ethanol by reaction with a saturated solution of hydrogen bromide in ether for two days and had ^{1}H nmr ($CDCl_3$) δ: 1.98 (d, 3, *J* = 7 Hz, CHBrC*H*$_3$), 2.28 (s, 3, *p*-C*H*$_3$), 5.12 (q, 1, *J* = 7 Hz, C*H*BrCH$_3$), 7.06 (d, 2, *J* = 8.5 Hz, *m-H*), 7.25 (d, 2, *J* = 8.5 Hz, *o-H*) ppm. A solution of the bromide in ether was stirred with silver nitrite for 24 h in the dark and gave, as the major product (65%), 1-nitro-1-(*p*-tolyl)ethane, ir (film): 1570 and 1370 (NO_2) cm^{-1}; ^{1}H nmr δ: 1.54 (d, *J* = 7 Hz, CH(NO$_2$)C*H*$_3$), 2.28 (s, *p*-C*H*$_3$), 6.32 (q, *J* = 7 Hz, C*H*(NO$_2$)CH$_3$), 7.11 (s, $C_6\mathit{H}_4$) ppm. Attempts to purify the nitroethane by extraction into base and re-precipitation were unsuccessful.

Preparation of p-*Ethylbenzyl Derivatives*

p-Ethylbenzyl alcohol was obtained in 92% yield by reduction of p-ethylbenzoic acid with excess lithium aluminum hydride and had ir (film): 3280 (OH), 1005 (C—O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.17 (t, 3, *J* = 7.5 Hz, $CH_2C\mathit{H}_3$), 2.57 (q, 2, *J* = 7.5 Hz, C*H*$_2$CH$_3$), 2.96 (t, 1, *J* = 5 Hz, O*H*), 4.46 (d, 2, *J* = 5 Hz, C*H*$_2$OH), 7.11 (s, 4, $C_6\mathit{H}_4$) ppm; ^{13}C nmr ($CDCl_3$) δ$_c$: 15.7 (CH_2CH_3), 28.6 (*C*H$_2$CH$_3$), 64.3 (*C*H$_2$OH), 127.2 and 127.8 (*C*-2, *C*-3, and *C*-5, *C*-6), 138.4 (*C*-1), 143.1 (*C*-4) ppm; ms *m/e* 136.097 (M_r ($^{12}C_9$$^1H_{12}$$^{16}O$) 136.089).

p-Ethylbenzyl acetate, pure by glc, was obtained in 93% yield by acetylation of the alcohol (1.5 g) with acetic anhydride (15 cm^3) in the presence of pyridine (6 cm^3), ir: 1745 and 1225 (OCOCH$_3$) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.15 (t, 3, *J* = 7.5 Hz, $CH_2C\mathit{H}_3$) 1.96 (s, 3, OCOC*H*$_3$), 2.55 (q, 2, *J* = 7.5 Hz, C*H*$_2$CH$_3$), 4.99 (s, 2, C*H*$_2$OCOCH$_3$), 7.09 (d, 2, *J* = 9 Hz, 3-*H* and 5-*H*), 7.18 (d, 2, *J* = 9 Hz, 2-*H* and 6-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ$_c$: 15.6 (CH_2CH_3), 20.8 (OCOCH$_3$), 28.7 (*C*H$_2$CH$_3$), 66.2 (*C*H$_2$OCOCH$_3$), 128.0 and 128.6 (*C*-2, *C*-6 and C-3, *C*-5), 133.4 (*C*-1), 144.3 (*C*-4), 170.8 (OCOCH$_3$) ppm; ms, *m/e* 178.100 (M_r ($^{12}C_{11}$ $^1H_{14}$$^{16}O_2$) 178.099).

p-Ethylbenzyl methyl ether, pure by glc, was obtained in 81% yield from the alcohol as described for methyl 1-(*p*-tolyl)ethyl ether, ir: 1095 (C—O—C) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.19 (t, 3, *J* = 7 Hz, $CH_2C\mathit{H}_3$), 2.57 (q, 2, *J* = 7 Hz, C*H*$_2$CH$_3$), 3.28 (s, 3, OC*H*$_3$), 4.33 (s, 2, C*H*$_2$OCH$_3$), 7.10 (d, 2, *J* = 8.5 Hz, 2-*H* and 6-*H*), 7.19 (d, 2, *J* = 8.5 Hz, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ$_c$: 15.7 (CH_2CH_3), 28.6 (*C*H$_2$CH$_3$), 57.8 (O*C*H$_3$), 74.6 (*C*H$_2$OCH$_3$), 127.9 (*C*-2, *C*-3, *C*-5, *C*-6), 135.4 (*C*-1), 143.7 (*C*-4) ppm; ms, *m/e* 150.100 (M_r ($^{12}C_{10}$$^1H_{14}$$^{16}O$) = 150.104).

p-Ethylbenzyl chloride, pure by glc, was obtained in 73% yield after distillation by reaction of the alcohol (7.1 g) with thionyl chloride in benzene (cf. ref. 17), ^{1}H nmr ($CDCl_3$) δ: 1.17 (t, 3, *J* = 8 Hz, $CH_2C\mathit{H}_3$), 2.57 (q, 2, *J* = 8 Hz, C*H*$_2$CH$_3$), 4.45 (s, 2, C*H*$_2$Cl), 7.13 (d, 2, *J* = 9 Hz, 3-*H* and 5-*H*), 7.21 (d, 2, *J* = 9 Hz, 2-*H* and 6-*H*) ppm. A mixture of the chloride (1.54 g, 0.01 mol) and silver nitrite (3.05 g, 0.02 mol) in anhydrous ether (15 cm^3) was stirred for nine days in the dark, in a closed vessel at ambient temperature. Analysis by ^{1}H nmr indicated that 36% of the chloride was still present and more silver nitrite (3 g) and ether (10 cm^3) were added and stirring continued for a further nine days, when ^{1}H nmr analysis indicated complete reaction. On work-up a mixture (1.47 g) of *p*-ethylbenzyl alcohol (8%, δ 4.46 ppm), *p*-ethylbenzyl nitrite (28%, δ 5.60 ppm), and *p*-ethylbenzyl nitrate plus *p*-ethylphenylnitromethane (64%, δ

[12]Enumeration of the 1-(*p*-tolyl)ethane derivatives starts at the carbon *ipso* to the substituent ethyl group as 1′. This is different from the enumeration used previously for 1-(*p*-tolyl)ethyl nitrate in which the carbon *ipso* to the methyl group was 1 (1).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

5.30 ppm) was obtained. Analysis by ^{13}C nmr indicated that approximately equal amounts of nitrate (δ_c 75.1 ppm) and nitromethane (δ_c 79.7 ppm) with a smaller amount of nitrite (δ_c 70.1 ppm). A portion of the crude product (0.8 g) was reacted with sodium methoxide (1.3 g) in methanol (12 cm^3). After 10 min the methanol was evaporated at ambient temperature, water added, and the mixture extracted (×3) with ether. The aqueous layer was cooled to 5°C and neutralized with solid hydroxylamine hydrochloride (2 g). After 30 min the mixture was extracted with ether. Evaporation of the ethereal extract gave *p*-ethylphenylnitromethane (0.22 g, 25% from the chloride), ir (film): 1580 and 1390 (NO_2) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.17 (t, 3, J = 7.5 Hz, CH_2CH_3), 2.59 (q, 2, J = 7.5 Hz, CH_2CH_3), 5.27 (s, 2, CH_2NO_2), 7.17 (d, 2, J = 9 Hz, 3-*H* and 5-*H*), 7.27 (d, 2, J = 9 Hz, 2-*H* and 6-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 15.3 (CH_2CH_3), 28.6 (CH_2CH_3), 79.8 (CH_2NO_2), 127.1 (*C*-1), 128.5 (*C*-3 and *C*-5), 130.0 (*C*-2 and *C*-6), 146.3 (*C*-4) ppm.

Preparation of Ethylmethylphenols and Methyl Ethers

2-Ethyl-5-methylphenyl methyl ether, pure by glc, was obtained in 78% yield by methylation of the phenol (1) with dimethyl sulfate, ir: 1262 and 1042 (C—O—Ar) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.14 (t, 3, J = 7 Hz, CH_2CH_3), 2.27 (s, 3, 5-CH_3), 2.57 (q, 2, J = 7 Hz, CH_2CH_3), 3.72 (s, 3, OCH_3), 6.61 (s, 1, 6-*H*), 6.65 (d, 1, J = 8 Hz, 4-*H*), 6.98 (d, 1, J = 8 Hz, 3-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 14.4 (CH_2CH_3), 21.4 (5-CH_3), 22.9 (CH_2CH_3), 55.2 (OCH_3), 111.2 (*C*-6), 120.9 (*C*-4), 128.7 (*C*-3), 129.6 (*C*-2), 136.5 (*C*-5), 157.2 (*C*-1) ppm; ms (70 ev), *m/e* (relative intensity): 150.097 (50, M_r ($^{12}C_{10}{}^1H_{14}{}^{16}O$) 150.104), 135 (100, $M - CH_3$), 105 (49), 91 (18).

2-Hydroxy-5-methylacetophenone was obtained by treatment of *p*-cresol with acetyl chloride in the presence of titanium tetrachloride. After crystallization from pentane it was pure by glc; ^1H nmr ($CDCl_3$) δ: 2.26 (s, 3, 5-CH_3), 2.54 (s, 3, $COCH_3$), 6.84 (d, 1, J = 8.1 Hz, 3-*H*), 7.25 (d of d, 1, J = 8.1 Hz, J = 2 Hz, 4-*H*), 7.46 (d, 1, J = 2 Hz, 6-*H*), 11.97 (s, 1, O*H*) ppm. Reduction of the 2-hydroxy-5-methylacetophenone with amalgamated zinc and hydrochloric acid gave 2-ethyl-4-methylphenol, pure by glc, ir (film): 3400 (OH), 1225 (C—OH) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.15 (t, 3, J = 7 Hz, CH_2CH_3), 2.18 (s, 3, 4-CH_3), 2.53 (q, 2, J = 7 Hz, CH_2CH_3), 5.15 (s, 1, O*H*), 6.53 (d, 1, J = 8 Hz, 6-*H*), 6.78 (d of d, 1, J = 8 Hz, J = 2 Hz, 5-*H*), 6.86 (d, 1, J = 2 Hz, 3-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 14.1 (CH_2CH_3), 20.5 (4-CH_3), 23.0 (CH_2CH_3), 115.3 (*C*-6), 127.3 (*C*-5), 130.0 (*C*-2, *C*-3, *C*-4), 151.1 (*C*-1) ppm; mass spectrum (70 eV), *m/e* (relative intensity): 136.090 (48 M_r ($^{12}C_9{}^1H_{12}{}^{16}O$) = 136.089), 122 (12), 121 (100, $M - CH_3$), 107 (10), 91 (19), 77 (19). Methylation of the phenol with dimethyl sulfate gave 2-ethyl-4-methylphenyl methyl ether, pure by glc, ir (film): 2865 ($ArOCH_3$), 1260 and 1045 (C—O—Ar) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.16 (t, 3, J = 7 Hz, CH_2CH_3), 2.24 (s, 3, 4-CH_3), 2.58 (q, 2, J = 7 Hz, CH_2CH_3), 3.74 (s, 3, OCH_3), 6.70 (d, 1, J = 8 Hz, 6-*H*), 6.92 (m, 2, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 14.3 (CH_2CH_3), 20.5 (4-CH_3), 23.2 (CH_2CH_3), 55.4 (OCH_3), 110.2 (*C*-6), 126.9 (*C*-5), 129.5 (*C*-4 or *C*-2), 129.8 (*C*-3), 132.4 (*C*-2 or *C*-4), 155.3 (*C*-1) ppm; ms *m/e* (relative intensity): 150.093 (70, M_r ($^{12}C_{10}{}^1H_{14}{}^{16}O$) 150.104), 135 (100, $M - CH_3$), 113 (30), 105 (55), 91 (25), 85 (20), 77 (15).

3-Hydroxy-4-methylacetophenone was obtained by reaction of the dilithium salt of 3-hydroxy-4-methylbenzoic acid (Aldrich) with methyllithium (18) and had ^1H nmr ($CDCl_3$) δ: 2.25 (s, 3, 4-CH_3), 2.49 (s, 3, $COCH_3$), 7.09 (d, 1, J = 8 Hz, 5-*H*), 7.33 (d of d, 1, J = 8 Hz, J = 1.5 Hz, 6-*H*), 7.41 (d, 1, J = 1.5 Hz, 2-*H*) ppm. Clemmensen reduction of the acetophenone gave 5-ethyl-2-methylphenol with identical ^1H nmr, ^{13}C nmr, and glc retention time to that prepared from 4-ethyl-2-nitrotoluene (1) and mass spectrum (70 ev) *m/e* (relative intensity): 136.086 (42, M_r ($^{12}C_9{}^1H_{12}$-QYO) = 136.089), 121 (100, $M - CH_3$), 103 (60), 91 (15), 77 (13).

Methylation of 3-hydroxy-4-methylbenzoic acid with dimethyl sulfate gave methyl 3-methoxy-4-methylbenzoate, ^1H nmr ($CDCl_3$) δ: 2.22 (s, 3, 4-CH_3), 3.84 (s, 3, OCH_3 or CO_2CH_3), 3.86 (s, 3, CO_2CH_3 or OCH_3), 7.14 (d, 1, J = 8 Hz, 5-*H*), 7.47 (d, 1, J = 1.5 Hz, 2-*H*), 7.53 (d of d, 1, J = 1.5 and 8 Hz, 6-*H*) ppm. Hydrolysis of methyl 3-methoxy-4-methylbenzoate with aqueous sodium hydroxide gave 3-methoxy-4-methylbenzoic acid, ^1H nmr ($CDCl_3$) δ: 2.25 (s, 3, 4-CH_3), 3.85 (s, 3, OCH_3), 7.18 (d, 1, J = 8 Hz, 5-*H*), 7.52 (d, 1, J = 1.5 Hz, 2-*H*), 7.64 (d of d, 1, J = 1.5 and 8 Hz, 6-*H*) ppm. Reaction of the lithium salt of the acid with methyllithium gave 3-methoxy-4-methylacetophenone, needles from pentane, mp 132–134°C; ir (film): 1705 (C═O), 1285 and 1045 (C—O—Ar) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.23 (s, 3, 4-CH_3), 2.53 (s, 3, $COCH_3$), 3.84 (s, 3, OCH_3), 7.16 (d, 1, J = 8 Hz, 5-*H*), 7.41 (d, 1, J = 1.5 Hz, 2-*H*), 7.42 (d of d, 1, J = 1.5 and 8 Hz, 6-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 16.5 (4-CH_3), 26.4 ($COCH_3$), 55.3 (OCH_3), 108.4 (*C*-2), 121.5 (*C*-6), 130.4 (*C*-5), 133.0 (*C*-4), 136.3 (*C*-1), 157.9 (*C*-3), 197.7 ($COCH_3$) ppm; mass spectrum (70 eV), *m/e* (relative intensity): 164.083 (62, M_r ($^{12}C_{10}{}^1H_{12}{}^{16}O_2$) = 164.084), 149 (100, $M - CH_3$), 121 (20), 91 (33), 83 (20), 77 (15). Clemmensen reduction of the ketone gave 5-ethyl-2-methylphenyl methyl ether, distilled at 30–70°C/1 kPa, as a colourless oil, ir (film): 1270 and 1050 (C—O—Ar) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.20 (t, 3, J = 7 Hz, CH_2CH_3), 2.15 (s, 3, 2-CH_3), 2.57 (q, 2, J = 7 Hz, CH_2CH_3), 3.77 (s, 3, OCH_3), 6.64 (d, 1, J = 1 Hz, 6-*H*), 6.67 (d of d, 1, J = 1 and 8 Hz, 4-*H*), 7.00 (d, 1, J = 8 Hz, 3-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 15.8 (2-$CH_3CH_2CH_3$), 29.0 (CH_2CH_3), 55.1 (OCH_3), 109.8 (*C*-6), 119.5 (*C*-4), 123.7 (*C*-2), 130.5 (*C*-3), 143.1 (*C*-5), 157.7 (C-6) ppm; mass spectrum (70 eV), *m/e* (relative intensity): 150.102 (65, M_r ($^{12}C_{10}{}^1H_{14}{}^{16}O$) = 150.104), 135 (100, $M - CH_3$), 121 (19), 105 (12), 91 (31), 77 (16).

4-Hydroxy-3-methylacetophenone was obtained by titanium tetrachloride catalysed acetylation of *o*-cresol and was recrystallized from ether at −20°C, ^1H nmr ($CDCl_3$) δ: 2.25 (s, 3, 3-CH_3), 2.51 (s, 3, $COCH_3$), 6.87 (d, 1, J = 8 Hz, 5-*H*), 7.68 (d of d, 1, J = 2 Hz, J = 8 Hz, 6-*H*), 7.74 (d, 1, J = 2 Hz, 2-*H*), 7.95 (s, 1, O*H*) ppm. Clemmensen reduction of the 4-hydroxy-3-methylacetophenone gave 4-ethyl-2-methylphenol, ir (film): 3390 (OH) and 1260 (C—O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.14 (t, 3, J = 7 Hz, CH_2CH_3), 2.15 (s, 3, 2-CH_3), 2.48 (q, 2, CH_2CH_3), 5.66 (s, 1, O*H*), 6.62 (d, 1, J = 8 Hz, 6-*H*), 6.82 (d of d, 1, J = 8 Hz, J = 2 Hz, 5-*H*), 6.88 (d, 1, J = 2 Hz, 3-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 15.9 (2-CH_3,CH_2CH_3), 27.9 (CH_2CH_3), 115.0 (*C*-6), 124.1 (*C*-2), 126.1 (*C*-5), 130.5 (*C*-3), 136.5 (*C*-4), 151.6 (C-1) ppm, ms (70 eV), *m/e* (relative intensity): 136.091 (43, M_r ($^{12}C_9{}^1H_{12}{}^{16}O$) = 136.089), 121 (100, $M - CH_3$), 91 (12), 77 (12). Methylation of the phenol with dimethyl sulfate gave 4-ethyl-2-methylphenyl methyl ether, obtained on molecular distillation as a colourless oil, ir (film): 1257 and 1042 (C—O—Ar) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.18 (t, 3, J = 7 Hz, CH_2CH_3), 2.17 (s, 3, 2-CH_3), 2.52 (q, 2, J = 7 Hz, CH_2CH_3), 3.75 (s, 3, OCH_3), 6.71 (d, 1, J = 8 Hz, 6-*H*), 6.93 (m, 2, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_c: 16.0 (CH_2CH_3 or 2-CH_3), 16.2 (2-CH_3 or CH_2CH_3), 28.0 (CH_2CH_3), 55.3 (OCH_3), 109.9 (*C*-6), 126.4 (*C*-2), 127.7 (*C*-5), 130.3 (*C*-3), 136.0 (*C*-4), 155.9 (*C*-1) ppm; ms (70 eV), *m/e* (relative intensity): 150.098 (55, M_r ($^{12}C_{10}{}^1H_{14}{}^{16}O$) = 150.104), 135 (100, $M - CH_3$), 91 (26), 77 (18).

Observation of two oxa-azabicyclo[2.2.0]hexenone intermediates along the reaction pathway of the photochemical isomerization of 1,3-oxazin-6-ones[1]

PAUL DE MAYO, ALAN C. WEEDON, AND RALPH W. ZABEL
Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received February 25, 1981

PAUL DE MAYO, ALAN C. WEEDON, and RALPH W. ZABEL. Can. J. Chem. **59**, 2328 (1981).

Irradiation of 4-methyl-2-phenyl-1,3-oxazin-6-one, **1**, yields a photochemical equilibrium between **1** and 2-methyl-4-phenyl-1,3-oxazin-6-one, **2**. The isomerization proceeds through two intermediates, the oxa-azabicyclo[2.2.0]hexenones **3** and **4**, both of which can be observed spectroscopically (ir, uv, ^{1}H nmr) at low temperature.

PAUL DE MAYO, ALAN C. WEEDON et RALPH W. ZABEL. Can. J. Chem. **59**, 2328 (1981).

L'irradiation de la méthyl-4 phényl-2 oxazine-1,3 one-6 (**1**) conduit à un équilibre photochimique entre le composé **1** et la méthyl-2 phényl-4 oxazin-1,3 one-6 (**2**). L'isomérisation implique deux intermédiaires, les oxa-azabicyclo[2.2.0] hexenones **3** et **4**, que l'on peut observer par spectroscopie (i.r., uv, rmn du ^{1}H) à basse température.

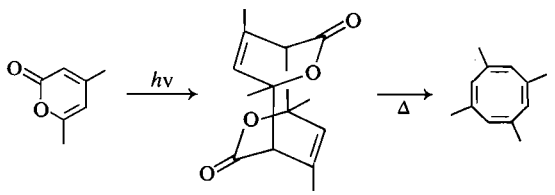
[Traduit par le journal]

Introduction

The irradiation of α-pyrones is known to result in the formation of a mixture of isomeric dimers, which on heating extrude carbon dioxide to yield cyclooctatetraenes (1) (Scheme 1). By analogy we considered that photochemical dimerization of oxazinones could yield dimers which on thermolysis might give the diazocine ring system (2) (Scheme 2). However, we have found that direct irradiation of the 1,3-oxazin-6-one **1** results in a novel photochemical isomerization, the details of which we describe here (3).

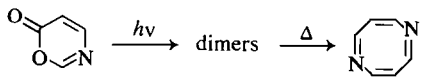
Results and Discussion

Thermolysis of ethyl 3-benzamidocrotonate (4) at 300°C is reported to give the oxazinone **1** in poor yield (5). In our hands the thermolysis gave a mixture of the desired oxazinone **1**, 2,6-diphenyl-4-methylpyrimidine, 4,6-dimethyl-2-phenylpyridine, ethyl benzoate, and benzamide along with unconverted ethyl 3-benzamidocrotonate. The pyrimidine and pyridine derivatives are presumably derived



+ isomers

SCHEME 1



+ isomers

SCHEME 2

from Diels–Alder dimerization of the oxazinone **1** followed by extrusion of propyne or benzonitrile from the intermediate adducts (5). Ethyl benzoate and benzamide are most probably derived from ethanolysis of the ethyl 3-benzamidocrotonate by ethanol released in the formation of **1**. Isolation of **1** from the product mixture proved to be difficult; it was found, however, that heating ethyl 3-benzamidocrotonate in dilute diphenyl ether solution reduced the rate of bimolecular side reactions considerably (6). Furthermore, purging the reaction solution with nitrogen gas removed ethanol being formed and avoided undesirable ethanolysis of the starting material. With these modifications the isolated yield of the oxazinone **1** was raised from 37% (5) to 85%.

Irradiation through Pyrex of the oxazinone **1** in chloroform or benzene resulted in the appearance of a single discrete product as judged by ir and nmr although it was indistinguishable from starting material by tlc. At extended irradiation times the ratio of **1** to product became static (2:3) suggesting that a photostationary state had been attained. That a photostationary state had indeed been formed, rather than inhibition of the reaction owing to light absorption by the product, was suggested by the fact that the absorption spectrum of the product was subsequently found to be less intense than that of **1** at the irradiating wavelengths.

The single product of the reaction was separated

6 7 9

from the starting material **1** by fractional crystallization from ethanol in 45% yield. The ir and mass spectra of the product suggested it to be an isomeric oxazinone, and in the ^{1}H nmr spectrum recorded in chloroform-*d* the methyl and methine protons present in **1** at 2.30 and 6.05 ppm had shifted to 2.47 and 6.52 ppm respectively. Furthermore, in **1** these protons showed allylic coupling ($J \approx 0.5$) which was absent in the product and this is consistent with a number of oxazinone structures in which the methyl and methine groups have become separated. Subsequent observations, described below, suggested structure **2** for the product and this was confirmed by its synthesis from thermolysis of ethyl 3-acetamidocinnamate (7) in diphenyl ether. No evidence was observed for dimer formation during direct irradiation of **1**.

The formation of **2** represents an example of a previously unobserved photochemical ring scrambling reaction. A reasonable mechanism for the isomerization is shown in Scheme 3, and is suggested by two previous reports concerning the photochemistry of oxazinones. The parent oxazinone **6** when irradiated in an argon matrix at 8 K gives, initially, a substance tentatively assigned the oxa-azabicyclo[2.2.0]hexenone structure **7**, ν_{max} 1840 cm^{-1}, along with other species. Further irradiation gave carbon dioxide, hydrogen cyanide, and acetylene (8). More recently, Maier and Schafer (9) have shown that the oxazinone **8**, when irradiated in tetrahydrofuran-d_8 at −70°C, gives the oxa-azabicyclo[2.2.0]hexenone **9** which reverts thermally to **8**, or breaks down photochemically to give acetonitrile, 3,3-dimethyl-1-butyne, carbon dioxide, 2,2-dimethylpropionitrile, and propyne via the presumed intermediate, 2-methyl-4-*tert*-butylazacyclobutadiene. Also, an intermediate zwitterion similar to **5** has been proposed to account for the products obtained from the irradiation of pyrone (10).

In order to test the mechanism outlined in Scheme 3, the irradiation of oxazinones **1** and **2** was carried out at low temperatures in the hope of detecting the intermediates **3** and **4**. This was successful, and evidence was also obtained for the intermediacy of the zwitterion **5**.

Irradiation of the oxazinone **1** through Pyrex in toluene-d_8 at −78°C and monitoring of the ^{1}H nmr spectrum allowed the observation of clean conversion to a new species, identified as **3**. At high conversion extra peaks consonant with the formation of secondary products were seen. These are assumed to arise from secondary irradiation of **3**. Both Krantz and Hoppe (8) and Maier and Schafer (9) observed photochemical extrusion of carbon dioxide from oxa-azabicyclo[2.2.0]hexenones, and subsequent thermal fragmentation of the azacyclobutadienes presumed to be produced gave a mixture of acetylenes and nitriles.

The oxa-azabicyclo[2.2.0]hexenone **3** appeared to be stable at −78°C, but warming to −40°C resulted in clean rearrangement to a second intermediate, identified as the isomeric oxa-azabicyclo-[2.2.0]hexenone **4**. The conversion of **3** to **4** was quantitative, as indicated by ^{1}H nmr, and a typical experiment is shown in Fig. 1 where the transformation was monitored at −55°C. In toluene-d_8 the intermediate **4** was stable at 0°C and at room temperature was converted quantitatively into a mixture of oxazinones **1** and **2**, as judged by ^{1}H nmr spectroscopy. The ratio of **1** to **2** produced by the thermal opening of **4** was approximately 1:1. The conversion of **3** to **4** at −55°C along with the production of *both* **1** and **2** on warming **4** to room temperature suggests that an equilibrium exists between **3** and **4** in which **4** is thermodynamically the more stable. This stability may be attributed to conjugation of the phenyl and imine functions of **4**.

The apparent formation of a photostationary state between **1** and **2** when **1** was irradiated at room temperature in benzene and chloroform-*d* was further confirmed by irradiation of **2** in toluene-d_8 at −78°C. Clean conversion to **4** was observed by ^{1}H

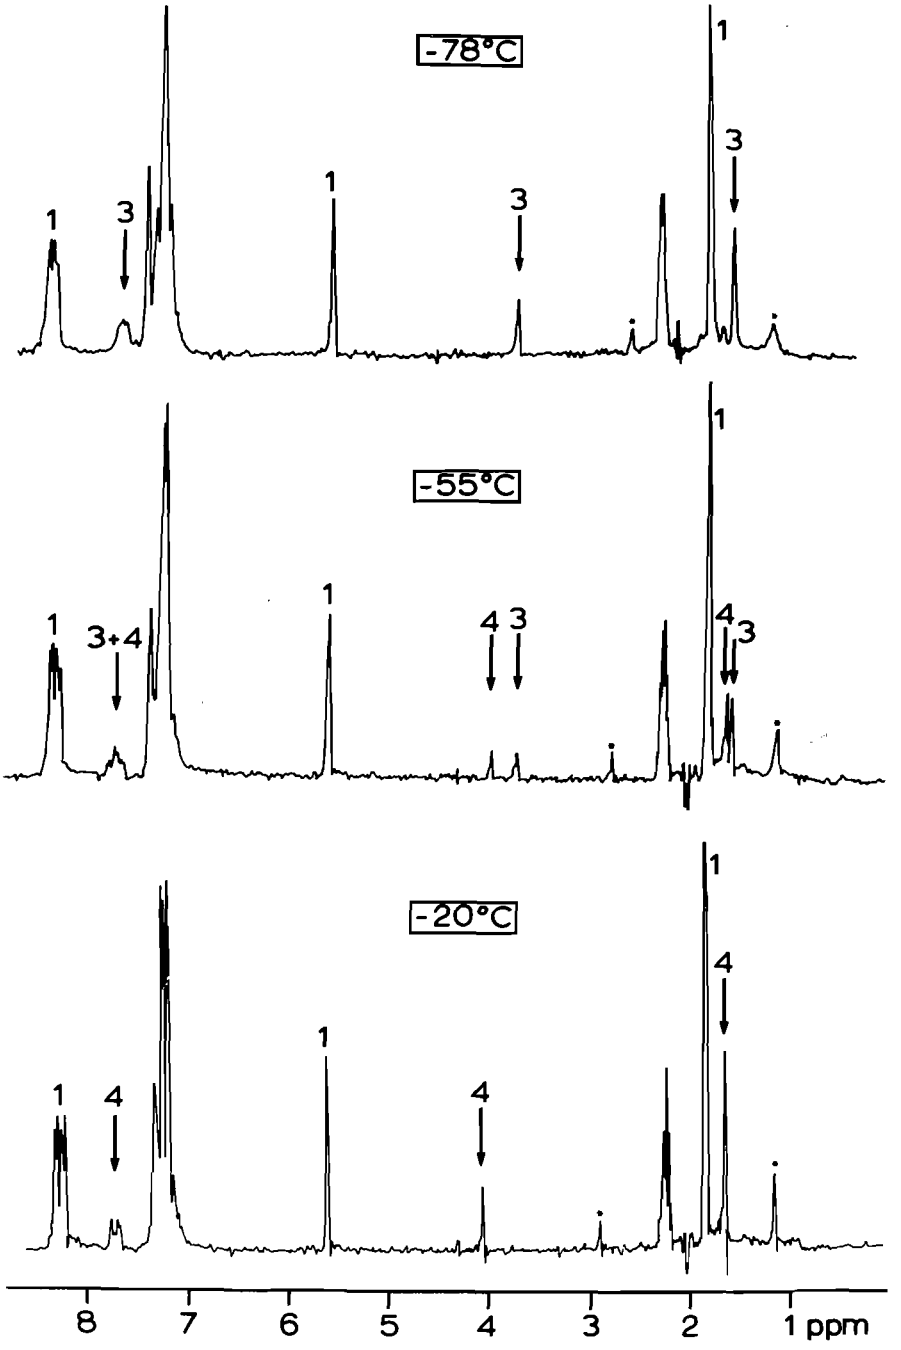

FIG. 1. The ^{1}H nmr spectra of oxa-azabicyclo[2.2.0]hexenone intermediates **3** and **4** in toluene-d_8. The top spectrum is of the intermediate **3** at −78°C, following partial conversion of oxazinone **1** by irradiation through Pyrex. The bottom spectrum is that of the same solution after warming to −20°C and shows the second intermediate **4**. The middle spectrum was recorded at −55°C whilst intermediate **3** was rearranging to **4**. The peak at ca. 2.2 ppm corresponds to toluene containing some protium. The peaks marked by asterisks correspond to photodecomposition products of **3**.

nmr. Warming the solution of **4** resulted in no change until room temperature was reached, when a mixture of **1** and **2** in the ratio approximately 1:1 was again produced, quantitatively.

When the oxazinone **1** was irradiated in methylene chloride-d_2 at −78°C, the intermediate **2** was not detected by ^{1}H nmr. Instead the oxa-azabicyclo[2.2.0]hexenone **4** was apparently formed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

directly. This is consistent with the intermediacy of zwitterion **5** in the reversible transformation between **3** and **4**; thus in methylene chloride-d_2 the zwitterion is sufficiently stabilized that **3** has the necessary activation energy at −78°C to open to **5** and hence be transformed into **4**, whereas in the less polar solvent toluene-d_8 **3** must be warmed to −55°C before opening to **5** can occur.

In Table 1 are given the chemical shifts of the methyl and methine protons in oxa-azabicyclo-[2.2.0]hexenones **3** and **4** along with those of the previously reported analogous compounds (9). As can be seen, the chemical shifts are extremely susceptible to solvent effects, and it was also observed that they varied considerably with temperature.

The oxa-azabicyclo[2.2.0]hexenones were also generated under conditions such that their ir and uv absorption spectra could be observed. Oxazinone **1** was irradiated in methylene chloride and toluene at −78°C and the ir spectra were monitored between 2000 and 1700 cm^{-1}. The formation of a band at 1830 cm^{-1} was observed in both cases and is assigned to the β-lactone function of **3**. No change was observed on warming until room temperature was reached, when the band disappeared. A similar result was obtained when oxazinone **2** was used indicating that both **3** and **4** have ν_{max} at ~1830 cm^{-1}.

Irradiation of oxazinone **1** in anhydrous ether or hexanes (10^{-1} *M*) resulted in the disappearance of the electronic absorption spectrum and appearance of a weak band (ε approximately 250, assuming complete conversion of **1** to **2**) centred around 260 nm, which possessed vibrational structure. This band was very similar to that obtained when the uv spectrum of toluene was recorded under identical conditions, and is assigned to the isolated phenyl group of **3**. Warming to −40°C caused a stronger absorption to emerge with its maximum at 255 nm (ε ca. 6000 assuming complete conversion of **1**) tailing to long wavelengths, and assigned to the conjugated phenyl group of **4**. Further warming resulted in the disappearance of the chromophore responsible for the 255 nm band and the appearance of bands consistent with a mixture of **1** and **2**. As could be expected for a transformation of a single component to two different products, no isobestic points were observed. When the isomeric oxazinone **2** was irradiated in hexanes at −78°C, or the oxazinone **1** was irradiated in methylene chloride at −78°C, only the absorption at 255 nm was observed following disappearance of the spectra of **1** and **2**, as expected for the formation of **4** directly. Warming to room temperature again gave a spectrum consistent with a mixture of **1** and **2**, and no isobestic point was observed. Some of these spectral changes are shown in Fig. 2.

In Fig. 3 is shown a potential energy surface diagram for the reversible photochemical transformation between **1** and **2**. Excitation of **1** onto the excited surface followed by a crossing onto the ground state surface gives **3** which in the nonpolar solvents at −78°C is stable. In polar solvents at −78°C, or on warming nonpolar solvents to −40°C, **3** equilibrates with the more stable isomer **4**, via the

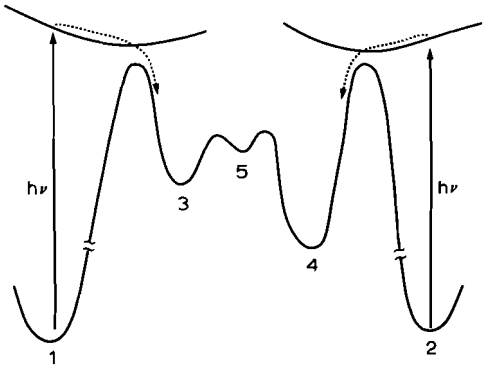

FIG. 3. Potential energy diagram for part of the ground state and excited state surfaces relating oxazinones **1** and **2**.

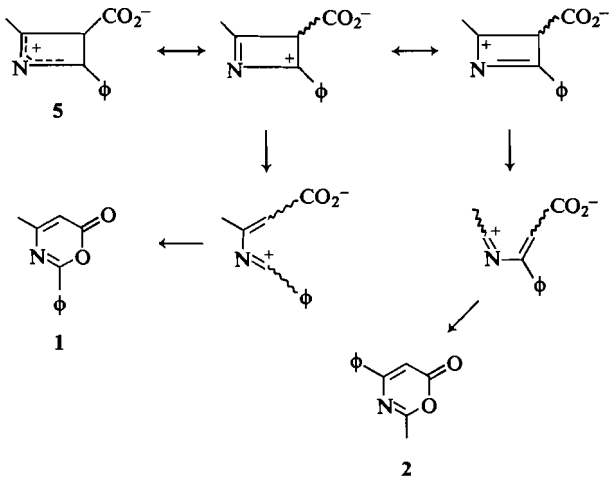
presumed zwitterionic intermediate **5**. Similarly, excitation of **2** gives **4** directly.

The opening of **3** and **4** to give **1** and **2** is analogous to the case of Dewar benzenes. Disrotatory opening to give the product is forbidden, whilst conrotatory opening also involves a high energy transition state as it leads to a *trans* double bond in a six membered ring. The fact that approximately equal amounts of **1** and **2** are obtained when **4** is heated suggests that the barriers leading to the products are of similar magnitude or possibly that an alternative route through a common intermediate exists. Such a route is shown in Scheme 4 where the zwitterion **5** is identified as the common intermediate. This scheme may have some relevance for the transformation of bicyclo[2.2.0]pyrones to benzvalene structures (11) and is supported by the observation of thermal equilibria between azetines and azabutadienes (12).



SCHEME 4

Experimental

Room temperature irradiations were performed using medium and high pressure mercury sources, and a high pressure xenon source. Low temperature irradiations for ^{1}H nmr experiments were carried out in 5 mm od nmr tubes submerged in transparent Dewars containing Dry Ice and methanol as coolant. Low temperature ^{1}H nmr measurements were made on a Varian XL 100 machine, irradiated samples being rapidly transferred from the irradiation Dewar to the precooled probe. Low temperature uv experiments were performed in quartz cells mounted in a cryostat capable of being cooled to temperatures down to 77 K and designed to allow periodic monitoring of the electronic absorption spectrum of the sample undergoing irradiation. Low temperature ir experiments were performed in a similar apparatus in sodium chloride cells. Solutions for uv and ^{1}H nmr experiments were degassed by three freeze–pump–thaw cycles to a residual pressure of 5×10^{-5} Torr and were sealed into their cells and tubes respectively.

Preparation of 4-Methyl-2-phenyl-1,3-oxazin-6-one

Ethyl acetoacetate was converted to ethyl 3-aminocrotonate by the method of Collie (13) and had δ ($CDCl_3$): 6.60 (b, 2H), 3.74 (q, 2H, J = 7 Hz), 1.60 (s, 3H), 0.90 (t, 3H, J = 7 Hz). Ethyl 3-aminocrotonate was converted to the benzoyl derivative by the method of Benary (4) as follows.

Benzoyl chloride (22 g) was dropped into an ice-cooled solution of pyridine (13.5 g), anhydrous ether (75 mL), and ethyl 3-aminocrotonate (21 g). At completion of addition the mixture was given an aqueous work-up and the crude product was crystallized from ether to give *E* ethyl 3-benzamidocrotonate; evaporation of the mother liquors and crystallization from ethanol gave *Z* ethyl 3-benzamidocrotonate. The combined yield was 81%. The *E*-isomer had mp 94–95°C (lit. (4) mp 95°C) and δ ($CDCl_3$): 11.94 (b, 1H), 8.13–7.90 (m, 2H), 7.70–7.35 (m, 3H), 5.09 (q, 1H, J = 1 Hz), 4.26 (q, 2H, J = 7.5 Hz), 2.58 (d, 3H, J = 1 Hz), 1.32 (t, 3H, J = 7.5 Hz). The *Z*-isomer had mp 44–46°C (lit. (4) mp 44–48°C) and δ ($CDCl_3$): 8.2–7.2 (b, 1H), 7.78–7.19 (m, 5H), 6.79 (q, 1H, J = 1 Hz), 4.09 (q, 2H, J = 7 Hz), 2.42 (d, 3H, J = 1 Hz), 1.21 (t, 3H, J = 7 Hz).

Condensation of ethyl 3-benzamidocrotonate was initially attempted by the method of Steglich (5). A mixture of *E*- and *Z*-isomers of ethyl 3-benzamidocrotonate was heated under nitrogen at 300°C in a Woods metal bath (the isomers interconvert at 200°C) for 3 h. Bulb to bulb distillation of the product gave an oil (44–54°C, 0.2 Torr) which on the basis of nmr, ir, and mass spectra contained ethyl benzoate and benzonitrile. A second fraction (100–105°C, 0.2 Torr) was a solid identified as benzamide (mixture mp). The nondistilled residue was separated by preparative tlc to give 2,4-diphenyl-6-methyl pyrimidine, δ ($CDCl_3$): 8.54–8.27 (m, 2H), 8.14–7.94 (m, 2H), 7.53–7.25 (m, 6H), 7.03 (s, 1H), 2.61 (s, 3H); *m/e*: 246 (39%), 160 (29), 105 (100), 77 (38), and 4,6-dimethyl-2-phenyl pyridine, δ ($CDCl_3$): 7.86–7.64 (m, 2H), 7.41–7.03 (m, 4H), 6.72 (s, 1H), 2.54 (s, 3H), 2.30 (s, 3H); *m/e*: 183 (100%) 167 (25), 105 (19), 77 (24), along with ethyl 3-benzamidocrotonate and 4-methyl-2-phenyl-1,3-oxazin-6-one, **1**.

The yield of **1** was greatly improved by performing the condensation in diphenylether solution. This method has also been reported elsewhere (6). A mixture of the *E*- and *Z*-isomers of ethyl 3-benzamidocrotonate (1.0 g) in diphenyl ether (20 mL) was heated at 255°C for 1.5 h whilst nitrogen gas was bubbled through the solution. The diphenyl ether was distilled off under vacuum to yield crude oxazinone in 94% yield. Crystallization from ethanol gave pure oxazinone (0.67 g, 85%), mp 89–90°C (lit. (5) mp 93°C). Oxazinone **1** had λ_{max} (EtOH) (ε): 301 (14 200),

238 (10900), 222 nm (6400); ν_{max} (Nujol): 1770, 1622 cm^{-1}; δ (toluene-d_8): 8.08 (m, 2H), 7.08 (m, 3H), 5.45 (q, 1H, J = 1 Hz), 1.72 (d, 3H, J = 1 Hz); *m/e* 187 (14%), 159 (23) 105 (100%) 77 (96); $C_{10}H_9NO_2$ requires 187.0633; found, 187.0631.

Preparation of 2-Methyl-4-phenyl-1,3-oxazin-6-one, 2

(a) *By Irradiation of 1*

The oxazinone **1** (0.830 g) in benzene (3.5 mL) was irradiated under a nitrogen blanket and at room temperature using a Pyrex filtered medium pressure mercury lamp until no further change occurred, as judged by ^1H nmr (191 h). The benzene was removed and the residue was passed through a short column of silica gel with chloroform to remove polymeric material. Removal of solvent gave a yellowish solid (0.752 g) which from its ^1H nmr spectrum consisted of a mixture of oxazinones **1** and **2** in the ratio 38:60 with ~2% minor products. Fractional crystallization from ethanol gave **2** (0.374 g, 45%).

(b) *By Condensation of Ethyl 3-Acetamidocinnamate*

Ethyl 3-aminocinnamate was prepared by the method of Lukes and Kloubek (14), by addition of phenyl magnesium bromide to ethyl cyanoacetate, and had ν_{max}: 3460, 3350, 1670, 1660 cm^{-1}; δ ($CDCl_3$): 7.30 (m, 5H), 6.47 (b, 2H), 4.06 (q, 2H, J = 7 Hz), 1.26 (t, 3H, J = 7 Hz). The product was acetylated by the method of Kato *et al.* (7) to give ethyl 3-acetamidocinnamate as a mixture of *E*- and *Z*-isomers in the ratio 3:2 (nmr). The mixture had λ_{max} (hexanes) (ε): 291 (13300), 221 nm (7100); ν_{max}: 3290, 1720, 1672 cm^{-1}. For the *E*-isomer, δ ($CDCl_3$): 10.48 (s, 3H), 7.26 (bs, 5H), 5.20 (s, 1H), 4.16 (q, 2H, J = 7 Hz), 2.14 (s, 3H), 1.27 (t, 3H, J = 7 Hz). For the *Z*-isomer, δ ($CDCl_3$): 7.28 (bs, 5H), 7.14 (s, 1H), 5.42 (b, 1H), 3.67 (q, 2H, J = 7 Hz), 2.28 (s, 3H), 0.67 (t, 3H, J = 7 Hz). The ^1H nmr spectra were recorded on a mixture of the isomers and were assigned by identification of the intramolecularly hydrogen-bonded N—H group of the *E*-isomer.

The acetamidoester was condensed to give **2** as follows: ethyl 3-acetamidocinnamate (0.80 g, mixture of isomers) in diphenyl ether (18 mL) was heated at 255°C whilst nitrogen gas bubbled through the solution to remove ethanol. The progress of the reaction was followed by examination of the ^1H nmr spectra of removed aliquots; after 5 min, all of the *Z*-isomer had converted to the *E*-isomer. After 3 h no starting material remained and a single product was observed. The solvent was removed under vacuum and the residue was chromatographed on silica gel with chloroform to give 2-methyl-4-phenyl-1,3-oxazin-6-one, **2** (0.46 g, 72%), mp (EtOH) 109–110°C. The oxazine had λ_{max} (EtOH), (ε): 296 (7900), 254 (6100), 226 nm (10400); ν_{max} (Nujol): 1766, 1627 cm^{-1}; δ (toluene-d_8): 7.69 (m, 2H), 7.08 (m, 3H), 6.12 (s, 1H), 1.76 (s, 3H); *m/e*: 187 (35%), 172 (10), 159 (48), 105 (100%), 77 (89); $C_{10}H_9NO_2$ requires 187.0633, found 187.0633.

A study related to biological detoxification of kraft pulp mill effluent is presented. A series of fungal and bacterial preparations were evaluated for their action on dehydroabietic acid (DHA), one of the effluent constituents toxic to fish. *Mortierella isabellina* was the organism selected for the biodegradation of DHA and subsequent chemical studies established the structures of four novel diterpenoid substances with very much lower acute toxicity to *Daphnia pulex*.

JAMES P. KUTNEY, MAHATAM SINGH, GARY HEWITT, PHILLIP J. SALISBURY, BRIAN R. WORTH, JAMES A. SERVIZI, DENNIS W. MARTENS et ROBERT W. GORDON. Can. J. Chem. **59**, 2334 (1981).

On présente une étude portant sur la désintoxication du résidu du moulin à pâte de kraft. On a évalué l'action d'une série de préparations fongiques et bactériennes sur l'acide déhydroabiétique (DHA), l'un des constituants, toxiques pour les poissons, présents dans le résidu. On a choisi l'organisme *Mortierella isabellina* pour la biodégradation du DHA et les études chimiques subséquentes établissent la structure de 4 nouvelles substances diterpéniques avec une toxicité beaucoup plus faible envers le *Daphnia pulex*.

[Traduit par le journal]

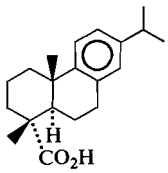
Introduction

It is generally conceded that microbiological treatment is one of the best available methods for detoxifying kraft pulp mill effluents (KME). Although the activated sludge process and aerated lagoons have found extensive use, they have not proved reliable in every case and their effects have not been readily quantified (1).

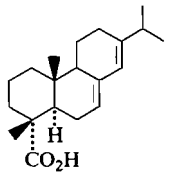
The major toxicity from KME has been shown to arise from the significant resin acid content, in particular: dehydroabietic (DHA) (**1**), abietic (**2**), isopimaric acids (**3**) (2).

Biodetoxification of KME from B.C. mills by aerated lagoons and activated sludges has been studied and in fact shown to be partially successful (1, 3). However, treatment times up to 14 days were necessary for detoxification and statistics from operating lagoons reveal that the method is not always dependable (1). Furthermore, no detailed studies have been made of the actual biodegradation products or the environmental consequences of the discharge of these metabolites to waters associated with fisheries resources.

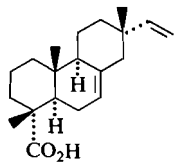
Work in these laboratories has been directed towards four strategic goals: (*i*) determination and quantitation of the specific biodegradation products from the major resin acid toxicants; (*ii*) elucidation of the sequential pathway(s) of metabolism; (*iii*) measurement of the toxicity of the metabolites; (*iv*) identification of a readily available stable organism which might be used as a supplement to existing biological treatment basins to enhance the efficiency of detoxification.



1(DHA)



2



3

The information from (*i*)–(*iii*) is needed to fill an important gap in our knowledge concerning the environmental consequences of currently widely used waste treatment practices in the Canadian pulp and paper industry. Achievement of the fourth goal is expected to significantly enhance performance control over bio-basins and perhaps allow

the practice of secondary treatment at mills where there is a limited amount of available land.

Although a large number of fungal and bacterial preparations (Table 1) were tested for their action on DHA (**1**), greatest success was attained with *Mortierella isabellina*, an organism we had already shown effective in the biodegradation of other complex organic molecules (4). The present work deals mainly with the biodegradation of DHA (**1**) by *M. isabellina*.

Methods and Results

Growth and Microbial Activity of Various Organisms

Preliminary screening of numerous microorganisms (Table 1) for the ability to degrade DHA revealed that 12 fungi and 9 bacteria possessed this capability. Quantification of the degree of degradation by these organisms (Table 2) showed that *M. isabellina* (5) was the most effective over short incubation periods. The incubation times shown in Table 2 reflect the relative growth rates of the different microbes since cultures were harvested only after good growth, as assessed visually. *M. isabellina* has a further advantage of being a prolific spore former that allows for heavy spore inocula which result in rapid growth and reduced mycelial balling in liquid culture.

A typical growth curve for *M. isabellina* grown in dextrose–yeast extract broth (DYE) at 27°C and 200 rpm is presented in Fig. 1. After a lag phase of approximately 12 h, the culture grew quickly to reach a maximum dry weight of about 2.8 mg/mL by 24 to 30 h. There was a growth-associated decrease in pH from 6.8 to 2.8. Inclusion of 250 mg/L of DHA resulted in retardation of growth rate and a slightly higher final pH. Cultures were inhibited to a lesser degree if only 80 mg/L DHA was added.

TABLE 2. Microbial degradation of dehydroabietic acid with various microorganisms. Dehydroabietic acid analysis performed using hplc

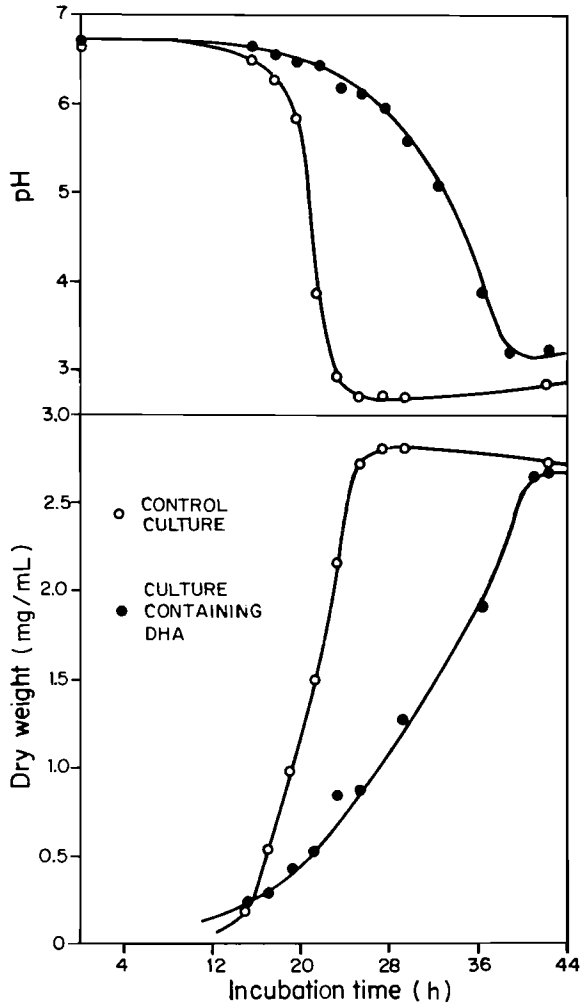

FIG. 1. Growth of *M. isabellina* in DYE and DYE plus DHA (250 mg/L).

biodegradation, it was essential to develop analytical methods for the quantitative determination of DHA.

(*i*) Radiotracing: DHA, tritium labelled in the aromatic ring, was prepared by catalysed exchange with CF_3CO_2T (see Experimental). Repeated purification gave Ar-^{3}[H]-DHA with activity of 1.0471 $\times$ 10^9 dpm/mmol. Labelled material was fed to *M. isabellina* (and other organisms) for various time periods, the culture extracted, and the organics separated by chromatography (usually preparative tlc). Scintillation counting of the various fractions then gave values for residual DHA and an indication of the location and concentration of different biodegradation products.

(*ii*) High pressure liquid chromatography: a quantitative analysis of DHA was developed using Waters Associates hplc equipment standardized as shown in Fig. 2.

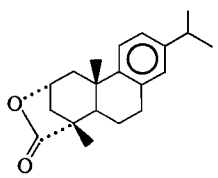
The screening results shown in Table 2 indicate the utility of this hplc analysis.

Biodegradations of DHA

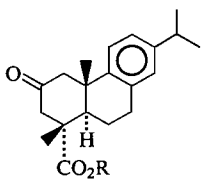
Results from the preliminary screen (Table 2) clearly showed *M. isabellina* to be the most efficient microorganism for our purposes and it was used in all subsequent experiments.

In a typical experiment, ca. 0.5 g of DHA was converted to its sodium salt and incubated with *M. isabellina* for 24 h. The harvested mixture was acidified and extracted to give the crude mixture of metabolites; hplc examination of the crude metabolites (e.g. see Fig. 4) indicated four major products (**4**–**7**). These were isolated by preparative layer chromatography and each acid identified after purification of its corresponding methyl ester (viz. **8**–**11**, Fig. 3).

The methyl ester **8** of the major component **4** had molecular formula $C_{21}H_{30}O_3$ indicating the introduction of one additional oxygen to the skeleton. The uv spectrum was very similar to that of DHA (**1**) strongly suggesting no change in ring C. The ir spectrum did, however, indicate hydroxyl stretching at ν 3700–3400 cm^{-1}. The ^{1}H nmr spectrum revealed a nine line, one proton absorbance at δ 4.1 for a ring proton geminal to the hydroxyl group. The splitting pattern (tt, J_{aa} = 12 Hz, J_{ae} = 4 Hz) was consistent with an axial proton split by two adjacent methylenes. Thus the hydroxyl group was situated at $C_{2\alpha}$, confirmed by a downfield shift of 1.12 ppm for H-2β in the corresponding acetate (**12**, mp 74–75°C). Further proof of this structure was obtained by formation of the lactone **13** by treatment of **4** with *p*-toluenesulphonic acid (PTS) in refluxing benzene. Absorption at 1768 cm^{-1} confirmed the γ-lactone function. Furthermore, oxidation of **8** with pyridinium chlorochromate gave the ketone **14** in high yield. The spectral data for **14** were dissimilar to those reported for the corresponding 6-ketone (6).



13



14 R = CH_3

One of the other metabolites (as the methyl ester) also had molecular formula $C_{21}H_{30}O_3$ and its spectral data suggested a secondary alcohol (**9**) isomeric with **8**. This assignment was supported by data from the acetate **15** and confirmed by pyridinium chlorochromate oxidation of **15** to give the ketone **14**, identical with that obtained from **8**.

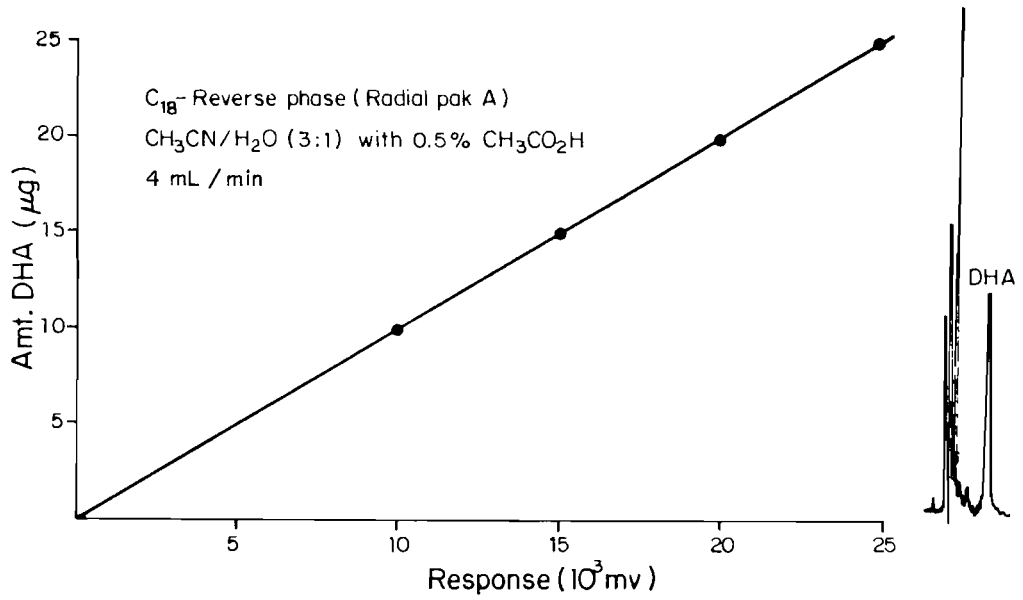


FIG. 2. The hplc quantitation of DHA. Response as measured on a Shimadzu Chromatopac-E1A integrator and Waters Associates Model 440 detector (at 280 nm and sensitivity 0.1).

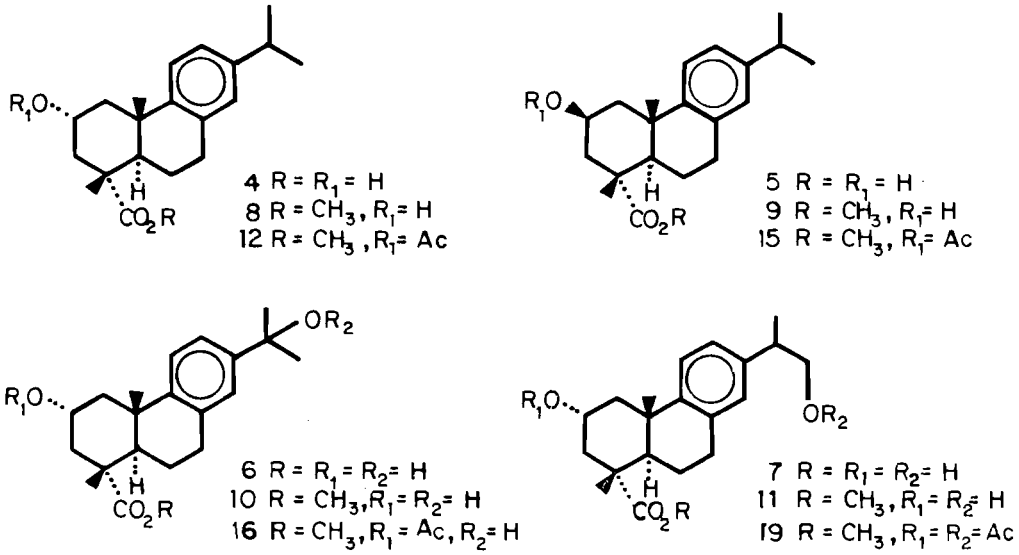

FIG. 3.

The methyl ester (**10**) of the second most predominant product (**6**) had molecular formula $C_{21}H_{30}O_4$. The ^1H nmr spectra of **10** and the corresponding acetate (**16**) showed the characteristic splitting pattern for H-2β as found in the 2α-oxygenated derivatives **8** and **12**. The six proton doublet for the isopropyl methyls of DHA was replaced by a six proton singlet at δ 1.56 suggesting a C_{15}-hydroxyl as shown. These assignments were confirmed by several chemical transformations (Fig. 5). Lactonization of **6** gave the olefin lactone **17** in 88% yield. The spectral data for this product were consistent with structure **17**: M^+ *m/e* 296; λ_{max} 248 (14000) nm, ν_{max} 1768 cm^{-1}; ^1H nmr signals at δ 5.0 and 5.28 (vinylic H) and δ 2.1 ppm (vinyl methyl). Similar treatment (PTS in C_6H_6) of the acetate **16** gave the isopropenyl derivative **18** which on hydrogenation over Adams catalyst gave **12**, identical with that obtained from the major biodegradation product (**4**).

The methyl ester (**11**) of the fourth product (**7**) of the biodegradation of DHA was also a dihydroxy

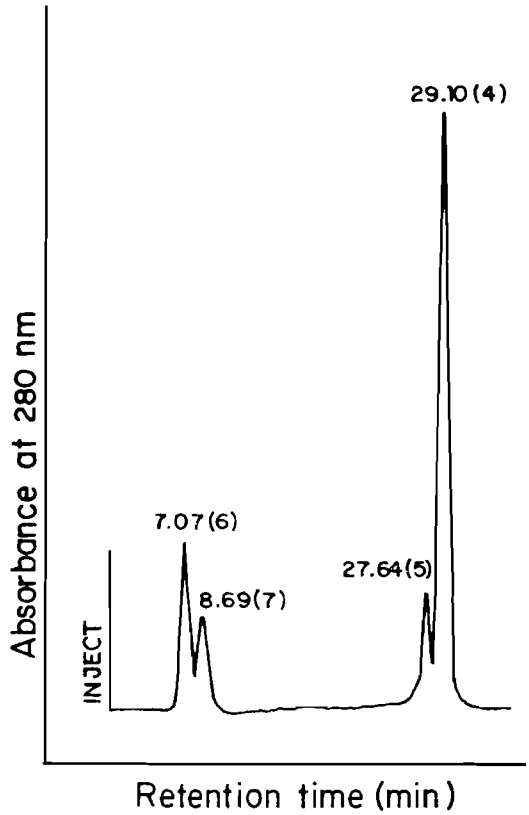

FIG. 4. Chromatogram. Column: reverse phase C_{18}; radial pak A. Solvent: 75% H_2O + 25% CH_3CN for 10 min followed by linear gradient to 55% H_2O + 45% CH_3CN over 20 min. Flow: 4 mL/min. Detector: Waters Associates Model 440 uv (at 280 nm).

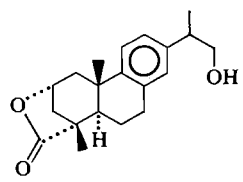
compound; $C_{21}H_{30}O_4$. The ^1H nmr spectrum of **11** again indicated 2α-hydroxylation but also showed one of the isopropyl methyl groups to be missing, suggesting primary hydroxylation. This was supported by the appearance of a two proton doublet at δ 3.68 which suffered a 0.5 ppm downfield shift on formation of the diacetate (**19**). Once again, reaction of the hydroxy acid (**7**) with PTS in refluxing benzene gave the corresponding lactone (**20**) in high yield.



20

Discussion

The experiments outlined above clearly indicate the tendency for *M. isabellina* to oxygenate the DHA molecule at C_2 (α and β), C_{15}, and C_{16}. That C_2 oxygenation was the first step in the biodegradation was confirmed by separate degradation of the major catabolite (**4**) to give both **6** and **7**, identified as their corresponding methyl esters **10** and **11**. Thus the sequence of reactions may be described as:

$$\begin{array}{l} \mathbf{1} \rightarrow \mathbf{4} + \mathbf{5} \\ \quad\quad\downarrow \\ \quad\quad\mathbf{6} + \mathbf{7} \end{array}$$

Preliminary toxicity measurements on the crude degradation mixture and on the specific major products indicate very efficient detoxification of DHA by *M. isabellina*. Quantitative evaluation is presently underway.

Recent investigations by Biellmann *et al.* (7) revealed that DHA is attacked by two bacterial strains, *Flavobacterium resinovorum* and *Pseudomonas resinovorum*, to provide products oxygenated at positions 3, 7, 11, or 12, in some cases with concomitant decarboxylation. Similar results have been obtained by other workers (8, 9). *M. isabellina*, however, offers a uniquely different mode of microbial transformation, efficiently, to what appear to be nontoxic products. Investigations with other resin acids (e.g. **2** and **3**) are continuing.

Experimental

Ultraviolet spectra were recorded on a Cary 15 spectrophotometer. Low resolution mass spectra were recorded on either an Atlas CH-4B or an AEI MS-902 spectrometer. High resolution mass measurements were made on an AEI MS-50 spectrometer. The ^1H nmr spectra were recorded on Varian XL-100 and Nicolet Oxford H-270 instruments. Chemical shifts are reported as ppm from tetramethylsilane, used as internal standard. Microanalyses were carried out by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia.

Screening of Microorganisms for the Ability to Degrade DHA

To media containing 40 mg/L of DHA were added either one mL of a cell suspension resulting from washing of a slant culture with some sterile water or a loopful of culture picked from a slant culture. Cultures were incubated at room temperature and 120 rpm on a rotary shaker until visual examination revealed good growth. Harvested cultures were tested for the presence of DHA using hplc. Bacterial slant cultures were prepared on nutrient agar (Difco) and tested against DHA in nutrient broth (Difco). Fungal slant cultures were prepared on potato–dextrose agar (PDA; Difco) and tested against DHA in dextrose–yeast extract broth (DYE) (5.0 g dextrose, 0.5 g yeast extract, 1.0 g KH_2PO_4, 1.0 g $(NH_4)_2HPO_4$, 1.0 g NaCl, and 0.5 g $MgSO_4 \cdot 7\ H_2O$, in a liter of distilled water).

Maintenance and Growth of Mortierella isabellina

M. isabellina stock culture (5) was maintained in PDA and grown in DYE. Cultures to be used as inocula were grown on 100 mL PDA in Roux bottles at room temperature. Inocula were prepared by washing the surface of a confluent mature culture with 50 mL of sterile distilled water or 50 mL of sterile detergent solution (450 μL Aerosol OT (Fisher Scientific) per liter distilled water). One mL of the spore suspension containing 4.4×10^5 to 3.7×10^7 spores per mL (as determined using a Howard mold counting chamber) was used to inoculate each 50 mL of liquid medium. Cultures of 50 or 100 mL were grown in 250 or 500 mL

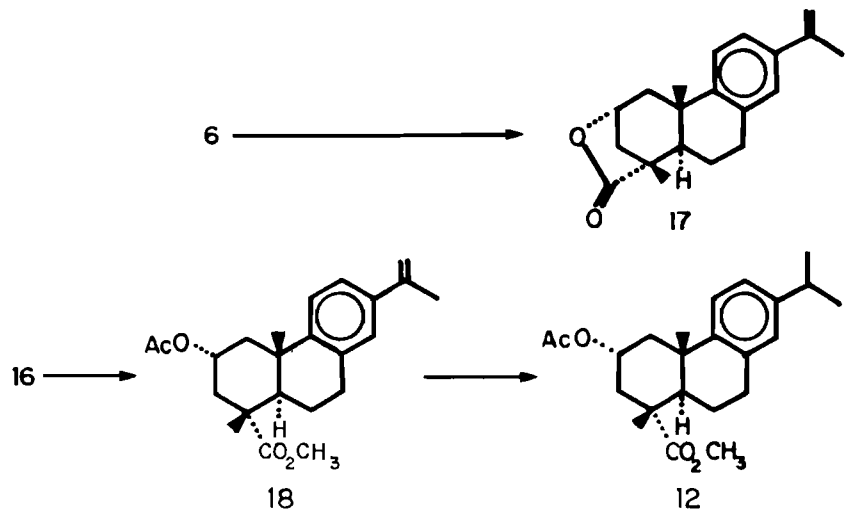


FIG. 5.

Erlenmeyer flasks, respectively. Cultures were incubated at room temperature (ca. 21 to 25°C) or at 27°C on a rotary shaker at 120 or 200 rpm.

Culture dry weight (mg/mL) was determined by suction filtering a whole culture through a cellulose acetate membrane filter (0.45 μm pores, Millipore Corporation), washing twice with about 10 mL distilled water, freezing the cell mat, and freeze drying to constant weight.

Biodegradation of DHA by M. isabellina

In a typical large-scale experiment designed to obtain large amounts of the degradation products, DYE broth was prepared at double concentration and dispensed at half the normal culture volume into a series of flasks. To each flask an equivalent volume of DHA solution (500 mg/L) was added. The DHA solution was prepared by dissolving 500 mg of DHA in a mixture of 1 *N* NaOH (2.20 mL) and EtOH (1.25 mL) and making up to volume with H_2O. The media was then autoclaved at 121°C for 15 min. In order to recover residual DHA and its breakdown products, harvested cultures were acidified (pH ca. 2) with 6 *N* HCl and extracted with EtOAc (3×). The extracts were washed with water (3×) and brine, dried (Na_2SO_4), and concentrated to give the crude metabolite mixture. The mixtures were chromatographed (on silica gel preparative plates using $CHCl_3$–MeOH (9:1) containing 0.5% HOAc) to give several products which were converted to their methyl esters by treatment with diazomethane.

Quantitative Analysis for DHA

DHA (56 mg) was dissolved in acetonitrile, and the solution made up to 50 mL. Aliquots of this solution were injected into an hplc instrument comprised of the following: Waters Associates U6K injection loop, M-6000A delivery systems, RCM module with C_{18}-radial pak-A column, Model 440 UV detector (280 nm at sensitivity 0.1). Electrical response was measured using a Shimadzu Chromatopak-E1A integrator. A solvent system of CH_3CN–H_2O (3:1), each containing 0.5% HOAc, was used at a flow rate of 4 mL/min. The standard curve generated is shown in Fig. 2, and was used for the determination of DHA in culture extracts.

Ar-[^{3}H]-DHA

Trifluoroacetic anhydride (3.2 mL) was distilled (bulb to bulb under high vacuum) into T_2O (0.4 mL, 400 mCi) maintained at −78°C. The system was allowed to attain atmospheric pressure with N_2 and brought to ambient temperature. The CF_3COOT thus formed was then distilled (bulb to bulb under high vacuum) into a mixture of DHA (90 mg), CCl_4 (5 mL), and Pt/C/CCl_4 suspension (0.4 mL) maintained at −78°C. The system was filled with N_2 and the mixture stirred at ambient temperature for 40 h. The mixture was filtered, the residue washed (2 × 5 mL) with CH_2Cl_2 and the combined organics extracted with H_2O (6 × 10 mL), dried (Na_2SO_4), and concentrated *in vacuo*. Five recrystallizations from EtOH–H_2O gave labelled DHA (30 mg) with constant activity of 1.047×10^9 dpm/mmol.

Methyl-2α-hydroxyabieta-8,11,13-trien-18-oate (8)

This compound was obtained as a white solid (335 mg, 57%), mp 155–157°C (ether – petroleum ether 30–60°C); uv (EtOH) λ_{max}: 272 (690), 265 (632) nm; ir ($CHCl_3$) ν_{max}: 3700–3400, 1720 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.22 (6H, d, *J* = 7 Hz, C16 and C17-methyls), 1.30 (3H, s, C20-methyl), 1.35 (3H, s, C19-methyl), 3.70 (3H, s, $-CO_2CH_3$), 4.1 (1H, tt, *J* = 12, 4 Hz, C2β-*H*), 6.87 (1H, brs, C14-*H*), 7.07 (1H, brd, *J* = 8 Hz, C12-*H*), 7.17 (1H, d, *J* = 8 Hz, C11-*H*); ms *m/e*: 330 (M^+), 315, 312, 297, 283, 255, 253, 237, 195. *Anal.* calcd. for $C_{21}H_{30}O_3$: C 76.36, H 9.09; found: C 76.13, H 9.34. High resolution molecular weight determination, calcd. 330.2195; found 330.2185.

Methyl 2α-Acetoxyabieta-8,11,13-trien-18-oate (12)

A mixture of the hydroxy ester **8** (33 mg), pyridine (2 mL), and acetic anhydride (1.0 mL) was stirred overnight at ambient temperature, diluted with anhydrous toluene (10 mL), and concentrated under reduced pressure to give the acetate **12** (100%) as a thick liquid which solidified after standing; mp 74–75°C (petroleum ether 30–60°C): uv (EtOH) λ_{max}: 273 (685), 265 (631) nm; ir ($CHCl_3$) ν_{max}: 1720 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.22 (6H, d, *J* = 7 Hz, C16- and C17-methyls), 1.3 (3H, s, C20-methyl), 1.35 (3H, s, C19-methyl), 2.07 (3H, s, $-OCOCH_3$), 2.23 (1H, dd, *J* = 8 Hz and 3 Hz, C5α-*H*), 2.81 (1H, septet, *J* = 6 Hz, C15-*H*), 2.88 (2H, dd, *J* = 8, 4 Hz, C7-*H*), 3.68 (3H, s, CO_2CH_3), 5.22 (1H, tt, *J* = 12, 4 Hz, C2β-*H*), 6.87 (1H, bs, C14-*H*), 7.07 (1H, bd, *J* = 8 Hz, C11-H); ms *m/e*: 372 (M^+), 253, 237, 195. *Anal.* calcd. for $C_{23}H_{32}O_4$: C 74.19, H 8.60; found: C 73.51 H 9.08. High resolution molecular weight determination, calcd. 372.2301; found 372.2312.

Methyl 2β-Hydroxyabieta-8,11,13-trien-18-oate (9)

This compound was obtained as a white solid (15 mg, 2.5%), mp 126–129°C (ether – petroleum ether 30–60°C); uv (EtOH) λ_{max}: 272 (688), 265 (632) nm; ir ($CHCl_3$): ν_{max}: 3700–3400, 1720 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.23 (6H, d, *J* = 7 Hz, C16- and

Methyl 2β-Acetoxyabieta-8,11,13-trien-18-oate (15)

The acetate derivative was obtained in 95% yield from **9** by the procedure described earlier; uv (EtOH) λ_{max}: 272 (683), 265 (632) nm; ir ($CHCl_3$) ν_{max}: 1720 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.22 (6H, d, J = 7 Hz, C16- and C17-methyls), 1.3 (3H, C20-methyl), 1.35 (3H, s, C19-methyl), 2.07 (3H, s, C2β-OCOC*H*$_3$), 2.23 (1H, dd, J = 8, 3 Hz, C5α-*H*), 2.81 (1H, septet, J = 6 Hz, C15-*H*), 2.88 (2H, dd, J = 8, 4 Hz, C7-*H*), 3.68 (3H, s, CO_2CH_3), 5.22 (1H, m, C2d-*H*), 6.87 (1H, bs, C14-*H*), 7.07 (1H, bd, J = 8 Hz, C12-*H*), 7.17 (1H, d, J = 8 Hz, C11-*H*); ms *m/e*: 372 (M^+), 253, 237. *Anal.* calcd. for $C_{23}H_{32}O_4$: C 74.19, H 8.60; found: C 73.63 H 8.23. High resolution molecular weight determination, calcd. 372.2300; found 372.2309.

Methyl 2α,15-Dihydroxyabieta-8,11,13-trien-18-oate (10)

This compound was obtained as a white solid (60 mg, 10%), mp 128–130°C (ether – petroleum ether 30–60°C); uv (EtOH) λ_{max}: 273 (685), 265 (630) nm; ir ($CHCl_3$) ν_{max}: 3700–3400, 1725 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.26 (3H, s, C20-methyl), 1.32 (3H, s, C19-methyl), 1.56 (6H, s, C16- and C17-methyls), 2.26 (1H, dd, J = 9, 4 Hz, C5-H), 3.7 (3H, s, CO_2CH_3), 4.14 (1H, tt, J = 12, 4 Hz, C2β-H), 7.25 (3H, m, aromatic); ms *m/e*: 346 (M^+), 331, 328, 253, 236, 235, 195. *Anal.* calcd. for $C_{21}H_{30}O_4$: C 72.83, H 8.67; found: C 72.51, H 8.26. High resolution molecular weight determination, calcd. 346.2143; found 346.2143.

Methyl 2α-Acetoxy-15-hydroxyabieta-8,11,13-trien-18-oate (16)

Compound **10** was acetylated in the manner described previously to furnish a solid (93%), which after crystallization from petroleum ether (30–60°C) containing traces of ether had mp 137–139°C; uv (EtOH) λ_{max}: 273 (690), 265 (623) nm; ir ($CHCl_3$) ν_{max}: 3700–3400, 1725 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.3 (3H, s, C20-methyl), 1.35 (3H, s, C19-methyl), 1.56 (6H, s, C16- and C17-methyls), 2.07 (3H, s, OCOC*H*$_3$), 2.27 (1H, dd, J = 8 and 3 Hz, C5-*H*), 2.93 (2H, dd, J = 8 and 4 Hz, C7-*H*), 3.68 (3H, s, $-CO_2CH_3$), 5.22 (1H, tt, J = 12 and 4 Hz, C2-H), 7.2 (3H, m, aromatic): ms *m/e*: 388 (M^+), 370, 313, 253, 235, 195. *Anal.* calcd. for $C_{23}H_{32}O_5$: C 71.13, H 8.24; found: C 70.86, H 8.45. High resolution molecular weight determination, calcd. 388.2249; found 388.2248.

Methyl 2α,16-Dihydroxyabieta-8,11,13-trien-18-oate (11)

This compound was obtained as a white solid (25 mg, 4%); crystals from ether – petroleum ether (30–60°C), mp 140–143°C; uv (EtOH) λ_{max}: 273 (682), 266 (638) nm; ir ($CHCl_3$) ν_{max}: 3700–3400, 1725 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.25 (3H, d, J = 7 Hz, C17-methyl), 1.24 (3H, s, C20-methyl), 1.32 (3H, s, C19-methyl), 3.68 (2H, d, J = 7 Hz, C16-methylene), 3.7 (3H, s, CO_2CH_3), 4.12 (1H, tt, J = 12, 4 Hz, C2β-H), 6.9–7.26 (3H, m, aromatic); ms *m/e*: 346 (M^+) 331, 315, 253, 235, 131. *Anal.* calcd. for $C_{21}H_{30}O_4$: C 72.83, H 8.67; found: C 72.43, H 8.49. High resolution molecular weight determination, calcd. 346.2143; found 346.2139.

Methyl 2α,16-Diacetoxyabieta-8,11,13-trien-18-oate (19)

The diacetyl derivative **19** was prepared in 90% yield from the dihydroxy compound **11** by following the procedure described above; uv (EtOH) λ_{max}: 274 (692), 266 (628) nm; ir ($CHCl_3$) ν_{max}: 1720 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.24 (3H, d, J = 7 Hz, C17-methyl), 1.25 (3H, s, C20-methyl), 1.32 (3H, s, C19-methyl), 2.04 (3H, s, C16-OCOC*H*$_3$), 2.07 (3H, s, C2α-OCOC*H*$_3$), 2.25 (1H, dd, J = 8, 3 Hz, C5α-*H*), 2.92 (2H, dd, J = 8, 4 Hz, C7-*H*), 3.03 (1H, sextet, J = 6 Hz, C15-*H*), 3.7 (3H, s, CO_2CH_3), 4.15 (1H, d, J = 7 Hz, C16-methylene), 4.16 (1H, d, J = 7 Hz, C16-methylene), 5.24 (1H, tt, J = 12, 4 Hz, C2β-*H*), 6.94 (1H, bs, C14-*H*), 7.1 (1H, bd, J = 8 Hz, C12-*H*), 7.20 (1H, d, J = 8 Hz, C11-*H*); ms *m/e*: 430 (M^+), 388, 370, 357, 295, 269. *Anal.* calcd. for $C_{25}H_{34}O_6$: C 67.76, H 7.90; found: C 69.50, H 8.12. High resolution molecular weight determination, calcd. 430.2355; found 430.2354.

Methyl 2-Oxoabieta-8,11,13-trien-18-oate (14)

Pyridinium chlorochromate (20 mg, 0.09 mmol) was suspended in methylene chloride (1.5 mL), and the alcohol **8** (13 mg, 0.039 mmol) in 1.0 mL of CH_2Cl_2 was rapidly added at room temperature. The solution became briefly homogeneous before depositing the black insoluble reduced agent. After stirring the reaction mixture for 1.5 h it was diluted with 20 mL of anhydrous ether, the solvent was decanted, and the black solid was washed twice with ether. The combined extract was dried ($MgSO_4$) and the solvent removed *in vacuo*. Chromatography on silica gel furnished the ketone (**14**) (11.5 mg, 89%); uv (EtOH) λ_{max}: 298 (60), 273 (688), 264 (634), 258 (464) nm; cd (molecular ellipticity σ): −3734.41; ir ($CHCl_3$) ν_{max}: 1710, 1725 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.25 (6H, d, J = 7 Hz, C16- and C17-methyls), 1.28 (3H, s, C20-methyl), 1.31 (3H, s, C19-methyl), 3.75 (3H, s, CO_2CH_3), 7.0 (2H, bd, J = 8 Hz, C11-*H* and C12-*H*), 7.07 (1H, bs, C14-H); ms *m/e*: 328 (M^+), 313, 269, 253, 204. *Anal.* calcd. for $C_{21}H_{28}O_3$: C 76.82, H 8.53; found: C 76.53, H 8.72. High resolution molecular weight determination, calcd. 328.2038; found 328.2038.

The Lactone 13

To hydroxy acid **4** (22.12 mg, 0.07 mmol), taken up in 20 mL of benzene, was added 15 mg of *p*-toluenesulphonic acid and the reaction mixture was refluxed for 20 min, cooled, washed with water, and dried ($MgSO_4$). Solvent removal followed by chromatography on silica gel afforded the lactone **13** (17.73 mg, 85%); uv (EtOH) λ_{max}: 272 (694), 266 (624) nm; ir ($CHCl_3$) ν_{max}: 1768 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.22 (6H, d, J = 7 Hz, C16- and C17-methyls), 1.28 (3H, s, C20-methyl), 1.38 (3H, s, C19-methyl), 4.8–5.0 (1H, m, $W/2$ = 12 Hz, C2β-*H*), 6.85–7.1 (3H, m, aromatic); ms *m/e*: 298 (M^+), 283, 239, 197, 159. *Anal.* calcd. for $C_{20}H_{26}O_2$: C 80.53, H 8.72; found: C 80.16, H 8.91. High resolution molecular weight determination, calcd. 298.1932; found 298.1936.

The Lactone 20

The dihydroxy acid **7** (20.12 mg, 0.06 mmol) was lactonized to the compound **20** in 80% yield by the procedure described above; uv (EtOH) λ_{max}: 274 (696), 265 (631) nm; ir ($CHCl_3$) ν_{max}: 3700–3550, 1768 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.23 (3H, d, J = 7 Hz, C17-methyl), 1.28 (3H, s, C20-methyl), 1.37 (3H, s, C19-methyl), 3.69 (2H, d, J = 7 Hz, C16-OC*H*$_2$), 4.8–5.0 (1H, m, $W/2$ = 12 Hz, C2β-H), 6.85–7.1 (3H, m, aromatic); ms *m/e*: 314 (M^+), 296, 283, 253, 235. *Anal.* calcd. for $C_{20}H_{26}O_3$: C 76.43, H 8.28; found: C 76.01, H 8.37. High resolution molecular weight determination, calcd. 314.1881; found 314.1882.

The Lactone 17

The dihydroxy carboxylic acid **6** (20.12 mg, 0.06 mmol) was refluxed in benzene containing a catalytic amount of *p*-toluenesulphonic acid and worked up in the manner mentioned earlier to give **17** (15.7 mg, 88%); uv(EtOH) λ_{max}: 248 (14 000) nm; ir ($CHCl_3$) ν_{max}: 1768 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.27 (3H, s, C20-methyl), 1.35 (3H, s, C19-methyl), 2.1 (3H, bs, vinyl methyl at C15), 4.75–4.95 (1H, m, $W/2$ = 12 Hz, C2β-*H*), 5.0 (1H, m, C16-*H*), 5.28 (1H, m, C16-*H*), 6.82–7.22 (3H, m, aromatic); ms *m/e*: 296 (M^+). *Anal.* calcd. for $C_{20}H_{24}O_2$: C 81.08, H 8.10;

found: C 80.73, H 8.67. High resolution molecular weight determination, calcd. 296.1776; found 296.1781.

Methyl 2α-Acetoxyabieta-8,11,13,15-tetraen-18-oate **18**

To a suspension of calcium chloride (20 mg) in benzene (20 mL) was added the hydroxy acetate **16** (19.4 mg, 0.05 mmol) and *p*-toluenesulphonic acid (5 mg) and the mixture was refluxed for 20 min. The cooled mixture was filtered, washed with water, and dried ($MgSO_4$). Concentration under vacuum furnished the product **18** (17.52 mg, 94%) as a thick oil, sufficiently pure for spectral purposes; uv (EtOH) λ_{max}: 248 (14 200) nm; ir ($CHCl_3$) ν_{max}: 1720 cm^{-1}; ^1H nmr δ: 1.3 (3H, s, C20-methyl), 1.36 (3H, s, C19-methyl), 2.07 (3H, s, C2α-OCOCH_3), 2.14 (3H, bs, vinyl methyl at C15), 3.7 (3H, s, CO_2CH_3), 5.06 (1H, m, C16-*H*), 5.24 (1H, m, C2β-H), 5.34 (1H, bs, C16-*H*), 7.1–7.28 (3H, m, aromatic); ms *m/e*: 370 (M^+). High resolution molecular weight determination, calcd. for $C_{23}H_{30}O_4$: 370.2143; found: 370.2140.

Catalytic Reduction of Methyl 2α-Acetoxyabieta-8,11,13,15-tetraen-18-oate

The acetate **18** (8 mg, 0.021 mmol) in anhydrous methanol (5 mL) was hydrogenated over platinum–charcoal (10 mg, 10%) at room temperature and atmospheric pressure. After the reaction was complete, as monitored by tlc, the mixture was filtered through Celite, the Celite cake washed with anhydrous methanol (3 × 5 mL), and the combined extracts evaporated under reduced pressure. The residue (8 mg), after purification over silica gel, was identical with a sample of **12** obtained earlier.

CHOI CHUCK LEE, CRAIG A. OBAFEMI, J. WILSON QUAIL, and ZVI RAPPOPORT. Can. J. Chem. **59**, 2342 (1981).

Acetolyses of a 15 m*M* solution of a doubly labeled trianisylvinyl substrate, 1,2-dianisyl-2-*p*-[^{14}C]methoxyphenyl[2-^{13}C]vinyl bromide (1-Br-2-^{13}C-2-methoxy-^{14}C), were carried out in the presence of different amounts of added NaOAc (30–450 m*M*) or NaOAc (30 or 300 m*M*) and Et_4NBr (75–1000 m*M*). Isotopic scramblings of the ^{13}C or ^{14}C label from C-2 to C-1 were observed in both the reaction product and the recovered unconsumed reactant, indicating the occurrence of cycles of ionization, 1,2-anisyl shift, and return. The extent of scrambling was found to decrease with increasing concentrations of NaOAc, and a further decrease in scrambling was noted with the additional presence of Et_4NBr. These findings are attributable to a competition between the 1,2-shift process and capture of the cation by the added nucleophiles. Analysis of the experimental data suggests that the nucleophilic species chiefly involved in the product-forming capture reaction is the acetate ion rather than HOAc or the Na^+OAc^- ion-pair. Comparisons of the scrambling data, expressed as "% rearrangement", with the assumption that 100% rearrangement corresponds to 33.3% and 50.0% scramblings of the ^{14}C ring label and the ^{13}C chain label, respectively, led to the conclusion that complete equilibration of the labels is achieved in that portion of the molecules that have undergone rearrangement only when the acetolyses are carried out in the presence of high concentrations of added salts. Mechanistic implications of these observations are discussed.

CHOI CHUCK LEE, CRAIG A. OBAFEMI, J. WILSON QUAIL et ZVI RAPPOPORT. Can. J. Chem. **59**, 2342 (1981).

On a réalisé l'acétolyse d'une solution 15 m*M* du substrat trianisylvinyle doublement marqué, le bromure de dianisyl-1,2-*p*-[^{14}C] méthoxy-2 phényle[^{13}C-2] vinyle (Br-1-^{13}C-2 méthoxy-2 ^{14}C) en présence de différentes quantités de AcONa (30–450 m*M*) ou de AcONa (30 ou 300 m*M*) et de Et_4NBr (75–450 m*M*). On a observé des mélanges isotopiques des marqueurs ^{13}C ou ^{14}C de C-2 à C-1 dans les deux produits de réaction et dans le réactif résiduel indiquant ainsi l'existence de cycles d'ionisation, glissement anisyle-1,2 puis retour à l'état initial. On a trouvé que le taux de mélange diminue quand les concentrations en AcONa augmentent et on a noté que le mélange diminue encore d'avantage lorsque Et_4NBr est également présent. Ces observations sont attribuables à une compétition entre le glissement-1,2 et la capture d'un cation par les nucléophiles ajoutés. L'analyse des données expérimentales suggère que l'ion acétate plutôt que AcOH ou la paire d'ions Na^+AcO^- est le nucléophile impliqué principalement dans le composé provenant de la réaction de capture. En comparant les données de mélange exprimés en "% de transposition" en partant du fait qu'une transposition à 100% correspond à des mélanges respectifs de 33,3% et de 50,0% du ^{14}C du cycle et du ^{13}C de la chaîne conduit à conclure qu'il s'établit un équilibre complet entre les marqueurs dans cette position des molécules qui se transposent uniquement lors de l'acétolyse en présence de fortes concentrations de sels. On discute également des implications mécanistiques de ces observations.

[Traduit par le journal]

The first kinetic study on the solvolysis of trianisylvinyl substrates was reported in 1969 by Rappoport and Gal (1). The data led to the conclusion that the reaction proceeded via the trianisylvinyl cation without anchimeric assistance by β-anisyl participation. Additional studies on the trianisylvinyl and related systems by Rappoport and co-workers (2–4) all provided further kinetic evidence in support of the dissociated trianisylvinyl cation as reaction intermediate. The first degenerate rearrangement arising from 1,2-anisyl shifts in the trianisylvinyl cation to give scrambling of the isotopic label was observed in 1975 by Oka and Lee (5) in the reaction of trianisyl[2-^{13}C]vinyl bromide (1-Br-2-^{13}C) with HOAc–AgOAc or with CF_3COOH–CF_3COOAg. Subsequently, similar degenerate rearrangements from 1,2-shifts were reported for the solvolyses of 1,2-dianisyl-2-*p*-[$^2H_3$]methoxyphenylvinyl bromide (1-Br-2-methoxy-d_3) (6) and for the decomposition of trianisyl[2-^{14}C]vinylphenyltriazene (1-NNNHPh-2-^{14}C) (7). Recently, Lee *et al.* (8) studied the acetolysis (9:1 HOAc–Ac_2O) of trianisyl[2-^{14}C]vinyl bromide (1-Br-2-^{14}C) in the presence of various amounts of added NaOAc or NaOAc and LiBr. The results were interpreted by a mechanism involving formation of the dissociated trianisylvinyl cation which could competitively undergo 1,2-anisyl shifts to give scrambling, be captured by Br^- ion to return to scrambled reactant, and be captured by solvent or by OAc^- ion to give

scrambled product. Since many cycles of ionization, return, and 1,2-shift could influence the overall extent of scrambling in the product and in the unconsumed reactant, the use of double labeling may be capable of providing information on such repeated cycles of processes. The present paper reports on the results from a study using both ^{14}C and ^{13}C as labels in the acetolysis of trianisylvinyl bromide.

Results and Discussions

The preparation of the labeled substrate was carried out using procedures similar to those employed in the synthesis of *cis*- and *trans*-1,2-dianisyl-2-phenyl[2-^{13}C]vinyl bromides (9). 1,2-Dianisyl[1-^{13}C]ethanone was prepared as described previously (9). Instead of reaction with C_6H_5MgBr (9), this ^{13}C-labeled ketone was treated with *p*-[^{14}C]methoxyphenylmagnesium bromide to give the tertiary alcohol, 1,1,2-trianisylethanol, with the ^{13}C-label at C-1 and with the *p*-CH_3O group of one of the C-1 anisyl groups labeled with ^{14}C. Treatment of this tertiary alcohol with Br_2 in HOAc (5, 9) gave the desired trianisylvinyl bromide with the ^{13}C label at C-2 and with the *p*-CH_3O group of one of the C-2 anisyl groups labeled with ^{14}C, namely, 1,2-dianisyl-2-*p*-[^{14}C]methoxyphenyl[2-^{13}C]vinyl bromide (**1**-Br-2-^{13}C-2-methoxy-^{14}C).

The solvolytic experiments with **1**-Br-2-^{13}C-2-methoxy-^{14}C were carried out in glacial acetic acid containing different amounts of NaOAc or NaOAc and Et_4NBr. These conditions differed slightly from those used in the earlier study with **1**-Br-2-^{14}C (8) since no acetic anhydride was added to the reaction medium and Et_4NBr was employed instead of LiBr. Besides the experiments with the doubly labeled **1**-Br-2-^{13}C-2-methoxy-^{14}C, control experiments were also carried out using singly labeled **1**-Br-2-^{13}C or **1**-Br-2-methoxy-^{14}C as well as an intermolecular mixture of these two singly labeled substrates.

Scramblings of both the ^{13}C and ^{14}C labels from C-2 to C-1 were determined in the reaction product, and in the unconsumed reactant when the reaction was not carried to completion and a recoverable amount of reactant was obtained. The degradation procedures were the same as those used in the earlier study with **1**-Br-2-^{14}C (8). Upon two successive treatments with $LiAlH_4$ (5, 8), the reaction product, trianisylvinyl acetate, with the ^{13}C and ^{14}C labels scrambled (**1**-OAc-1,2-^{13}C-1,2-methoxy-^{14}C), was converted to the scrambled 1,2,2-trianisylethanol (**2**-1,2-^{13}C-1,2-methoxy-^{14}C) and, at the same time, any unconsumed reactant, **1**-Br-1,2-^{13}C-1,2-methoxy-^{14}C, would be converted to the scrambled trianisylethene (**3**-1,2-^{13}C-1,2-methoxy-^{14}C) (10). The alcohol, **2**-1,2-^{13}C-1,2-methoxy-^{14}C, and the olefin, **3**-1,2-^{13}C-1,2-methoxy-^{14}C, were then separated by passage through an alumina column (8). To determine the scrambling of the ^{14}C label, after the addition of an appropriate amount of inactive carrier, $KMnO_4$ oxidation of the alcohol **2** and ozonolysis of the olefin **3** both gave dianisyl [^{14}C]ketone and the scrambling of the [^{14}C]-methoxy-labeled anisyl group from C-2 to C-1 in the reaction product and in the unconsumed reactant, respectively (8).

To determine the scrambling of the ^{13}C-label in the reaction product, the alcohol **2**-1,2-^{13}C-1,2-methoxy-^{14}C, derived from the product, was analyzed by ^{13}C nmr as described by Oka and Lee (5). The ^{13}C contents at C-1 and C-2, and hence the scramblings from C-2 and C-1, were measured quantitatively using the relative intensities of the C-1 and C-2 absorptions with the CH_3O absorption containing ^{13}C in its natural abundance as an internal standard (5). To determine the scrambling of the ^{13}C label in the unconsumed reactant, the olefin **3**-1,2-^{13}C-1,2-methoxy-^{14}C, derived from the unconsumed reactant, was hydrogenated to give the corresponding 1,1,2-trianisylethane (**4**-1,2-^{13}C-1,2-methoxy-^{14}C). It is to be noted that C-1 and C-2 of hydrocarbon **4** would correspond to C-2 and C-1, respectively, of the reactant **1**-Br. Again by means of the relative intensity method (5), and using the ^{13}C absorptions of CH_3O, C-1, and C-2 of **4**-1,2-^{13}C-1,2-methoxy-^{14}C at 53.6, 50.6, and 40.3 ppm, respectively, the ^{13}C contents at C-1 and C-2, and hence the scrambling of the ^{13}C label from C-2 to C-1 in the unconsumed reactant, were measured.

Table 1 shows the isotopic scrambling data from the acetolyses of various singly or doubly labeled trianisylvinyl bromides under comparable experimental conditions. Comparisons of the extents of scrambling, both in the reaction product and in the recovered reactant, from the sets of experiments A, B, C, and D indicate that the doubly labeled substrate, **1**-Br-2-^{13}C-2-methoxy-^{14}C, gave the same scrambling results, within the usually observed precision of about $\pm 1\%$ scrambling, as the 1:1 intermolecular mixture of the singly labeled **1**-Br-2-^{13}C and **1**-Br-2-methoxy-^{14}C. These findings are not unreasonable since the scrambling of the ^{14}C label was measured by its radioactivity while the ^{13}C scrambling was determined by ^{13}C nmr, the two methods being independent of and not affecting each other. Thus with the presently employed doubly labeled **1**-Br-2-^{13}C-2-methoxy-^{14}C as sub-

strate, any scrambling results may be treated as if they were obtained from simultaneous experiments with two singly labeled substrates.

Previously, we have reported that the use of ^{13}C as label coupled with analysis by ^{13}C nmr and the use of the ^{14}C tracer technique gave essentially the same extent of scrambling in the reaction of triphenyl[2-^{13}C]vinyl or triphenyl[2-^{14}C]vinyl bromide with HOAc–AgOAc (11). A comparison of the data from the sets of experiments D and E in Table 1, with **1**-Br-2-^{13}C or **1**-Br-2-^{14}C as substrate, again showed that the two methods of determining scrambling gave results that were within the expected precision of ±1% scrambling. It may also be of interest to note that recently Oka and co-workers (12, 13) have reported on the use of the ^{13}C nmr technique in their studies of acid catalyzed rearrangements in a number of aliphatic ketones.

Given in Tables 2 and 3 are the scrambling data from the acetolyses of **1**-Br-2-^{13}C-2-methoxy-^{14}C carried out in the presence of different amounts of NaOAc or NaOAc and Et_4NBr, the results from Expt. A-1 to A-5 in Table 1 being included in Table 2 for completeness. It can be seen from Tables 2 and 3 that in all cases, the % scrambling of the chain labeled C-2 is greater than that of the corresponding ring labeled anisyl group. This finding is not unreasonable since the maximum extents of scrambling for the chain and ring labels are 50.0% and 33.3%, respectively. The observed extents of scrambling of both the chain and ring labels also confirm our previous finding from the acetolysis of **1**-Br-2-^{14}C (8) that repeated cycles of ionization, 1,2-shift, and return could occur, giving rise to isotopic scramblings in both the reaction product and recovered unconsumed reactant. A simple mechanism depicting these processes is given in Scheme 1, where I and I′ are the isotopically unrearranged and rearranged trianisylvinyl cations or ion-pairs, RX and R′X are the unrearranged and rearranged reactants, and RY and R′Y are the unrearranged and rearranged products.

It is clearly seen from Table 2 that increasing amounts of added NaOAc resulted in lower extents of isotopic scrambling. Similarly, from Table 3, the presence of Et_4NBr in addition to NaOAc gave rise to a further decrease in scrambling (compare, for example, Expt. A-1 with A-20 and Expt. A-21 with

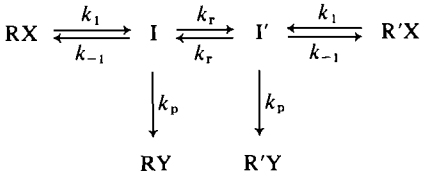
A-24). These findings can be attributed to the competitive occurrence of scrambling arising from 1,2-anisyl shifts (the k_r process in Scheme 1) and capture reactions of the trianisylvinyl cation with the nucleophiles (the k_p and k_{-1} processes in Scheme 1). An increase in the concentration of the more nucleophilic acetate ion will enhance the product-forming capture of the unrearranged trianisylvinyl cation, thereby decreasing the relative extent of scrambling from the 1,2-shift process. Similarly, in the presence of added bromide ions, a further decrease in 1,2-shifts will occur because of the additional capture reaction between the unrearranged trianisylvinyl cation and the added bromide ion.



SCHEME 1

In a review on ions and ion-pairs in solvolysis reactions, Raber *et al.* (14) have pointed out that since inorganic salts are known to be largely undissociated in glacial acetic acid (15–17), the free ions are in equilibrium with ion-pairs. Consequently, for salts with univalent cations and anions such as NaOAc, the concentration of the free ions would be proportional to the square root of the concentration of the added salt. When the % scramblings in the reaction products from various sets of experiments with different amounts of added NaOAc were extrapolated to 100% reaction, the values obtained are given in parentheses in Table 2. Plotting of these values vs. the square roots of the concentrations of added NaOAc gave reasonably good linear correlations as shown in Fig. 1. Such linear behavior thus suggests that the free acetate ion may be chiefly responsible for the observed decrease in scrambling with increasing added NaOAc concentration; that is, under the conditions employed in the present work, the nucleophile involved in the product-forming capture reaction may chiefly be the acetate ion rather than HOAc or the Na^+OAc^- ion-pair. This finding thus constitutes a further confirmation of previous conclusions that in the solvolysis of certain vinylic substrates including **1**-Br in HOAc–NaOAc, the capturing nucleophile is the acetate ion, as discussed recently by Rappoport and co-workers (18).

It is also of interest to note from Tables 2 and 3 that under any given set of experimental conditions, at the early stages of reaction, the scrambling in the recovered reactant is less than the scrambling in the corresponding reaction product. This is to be expected since there would be a relatively large amount of unchanged reactant remaining in the reaction mixture. In the later stages of reaction and with added NaOAc concentrations of 30 or 60 m*M*, the scrambling in the recovered reactant becomes higher than that found in the corresponding product (e.g. Expts. A-3 to A-5 and A-25 to A-27). This can be explained by the occurrence of cycles of ionization, 1,2-shift, and return, leading to the accumulation of a greater amount of scrambling in the relatively small amount of unconsumed reactant (8). When the concentration of added NaOAc is higher at 150, 300, or 450 m*M*, even after prolonged reaction times as in Expts. A-13, A-16, A-19, and A-29, the scrambling in the recovered reactant is still lower than that found in the product. It appears that with such high concentrations of added NaOAc, the return process competes less effectively with the second order product-forming capture reaction by the acetate ion, resulting in a lesser accumulation of scrambling in the recovered reactant.

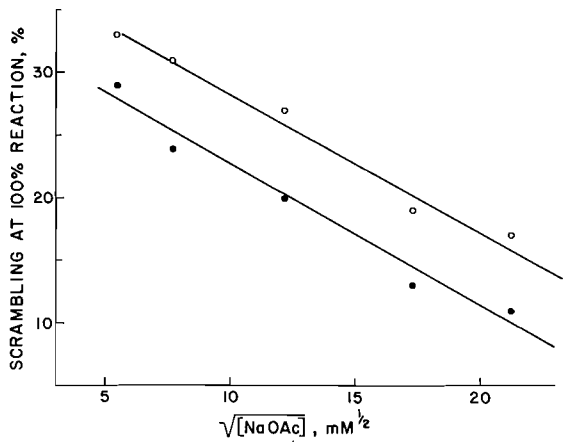

FIG. 1. Plot of % scrambling in the acetolysis product from **1**-Br-2-^{13}C-2-methoxy-^{14}C at complete reaction vs. the square root of the concentration of added NaOAc; open circles, scrambling of ^{13}C-labeled C-2, closed circles, scrambling of [^{14}C]-CH_3O-labeled anisyl.

Previously, Rappoport and co-workers (6) had expressed the scrambling data in triarylvinyl systems in terms of % rearrangement, with the assumption that 100% rearrangement corresponds to 33.3% and 50.0% scrambling, respectively, for **1**-Br-2-methoxy-^{14}C and **1**-Br-2-^{13}C. The data in Tables 2 and 3 may be converted to "% rearrangements" by multiplying the % scramblings for the ring and chain labels by factors of 3 and 2, respectively, and these values are summarized in Table 4. It is of interest to note from Table 4 that, on comparison of the % rearrangements for the ring and chain labels, two types of behavior appear. In most of the experiments, the % rearrangement found for the ring label is greater than that observed for the corresponding chain label. In some cases, however, such as Expts. A-17 to A-19 and A-27 to A-29, the % rearrangements found for both the ring and chain labels are about equal, and these cases generally involve the presence of large amounts of added salts as can be seen from the reaction conditions given in Tables 2 and 3. At high salt concentrations, apparently complete statistical equilibration of the labels has been achieved in that portion of the molecules which has undergone isotopic rearrangement. Thus in Expt. A-27, for example, the % scrambling for the ring label is 11.2% (Table 3). For the fraction of molecules that have rearranged, complete equilibration would correspond to

$$\underset{22.4\%}{An^*AnC{=}\overset{+}{C}An} \underset{2k_r}{\overset{k_r}{\rightleftharpoons}} \underset{11.2\%}{{}^*An\overset{+}{C}{=}CAn_2}$$

[a]Complete. 100% rearrangement for 1-Br-2-methoxy-^{14}C and for 1-Br-2-^{13}C corresponds to 33.3% and 50.0% scramblings, respectively; thus the % rearrangement was obtained by multiplying the % scrambling of the [^{14}C]CH_3O-labeled anisyl group and the % scrambling of the ^{13}C-labeled C-2 (Tables 2 and 3) by factors of 3 and 2, respectively.

The chain label in the same experiment gave 16.9% scrambling (Table 3). Again for the fraction of molecules that have rearranged, complete equilibration would correspond to

$$\underset{16.9\%}{An_2{}^*C{=}\overset{+}{C}An} \underset{2k_r}{\overset{2k_r}{\rightleftharpoons}} \underset{16.9\%}{An{}^*\overset{+}{C}{=}CAn_2}$$

Thus the "% rearrangement", 3 × 11.2 = 33.6% and 2 × 16.9 = 33.8% (Table 4) are about equal.

When the equilibration is not complete, the conversion of % scrambling by multiplication with a factor of 3 or 2 would not give equal % rearrangements. In the extreme case when there is an irreversible 1,2-shift with no equilibrating at all, suppose a 1% An shift occurs, the following situation would result:

$$An{}^*AnC{=}\overset{+}{C}An \longrightarrow \underset{1\%}{{}^*An\overset{+}{C}{=}CAn_2}$$

$$An_2{}^*C{=}\overset{+}{C}An \longrightarrow \underset{1\%}{An{}^*\overset{+}{C}{=}CAn_2}$$

If the factors of 3 and 2 were applied, one would get 3% rearrangement for the ring label and 2% rearrangement for the chain label; i.e., the % rearrangement of the ring label would be greater than the % rearrangement for the chain label. It may be pointed out that the data in Table 4 show that in the experiments where the % rearrangement of the ring label is greater than that of the corresponding chain label, the difference is never greater than the ratio of 3:2. Thus under the conditions employed in the present study, some equilibration from reversible 1,2-anisyl shifts took place in all cases.

The question arises as to why, in the experiments with high salt concentrations, for the molecules that have rearranged, the equilibration of the labels is complete, while with low salt concentrations, the equilibration is not complete. As a working hypothesis, it may be suggested that in glacial HOAc, under conditions which did not give complete equilibration, some of the 1,2-shifts might have occurred in the ion-pair stage. The presence of the counterion would give rise to a frontside hindrance by the leaving group, resulting in an incomplete equilibration of the labels. When the dissociation proceeds further, the 1,2-shifts are unhindered by any counterion and complete equilibration of the labels is attained. As suggested in Ingold's qualitative explanation of the normal salt effect (14, 19), an increase in salt concentration increases the polarity of the medium, which would give rise to a greater stabilization of the ionic transition state and hence promote the formation of the dissociated trianisylvinyl cation. Thus with high salt concentrations, complete equilibration was observed in those molecules that have undergone rearrangement. It is worth noting that these findings were obtained as a result of the use of double labeling or the simultaneous use of two singly labeled substrates. It would not have been detected if only singly labeled **1**-Br were employed as substrate.

Very recently, Rappoport and co-workers (18) reported the simultaneous studies on the kinetics of solvolysis and ^{82}Br exchange for a number of vinyl substrates including **1**-Br. The reactions were carried out mostly in the presence of 87 m*M* NaOAc and 71 m*M* Et_4Br. These conditions are similar to, though not identical with, those employed in the present work to obtain the data given in Table 3. Over the range of NaOAc concentrations of 87 to 175 m*M*, it was noted that the rate of solvolysis of **1**-Br in HOAc–NaOAc–Et_4NBr showed a first order dependence on NaOAc concentration. Thus the S_N1 process becomes the rarely observed $S_N2(C^+)$ process with the cation–nucleophile reaction becoming rate determining. This finding, while demonstrating the importance of added nucleophiles such as OAc^-, does not affect the present discussion which deals qualitatively with the observed isotopic scrambling behavior that arose from 1,2-shifts in the cationic species.

It has been pointed out that while ion-pairs from the acetolysis of triarylvinyl substrates may be involved in the return process, their reactions are intramolecular and they are unreactive toward external nucleophiles (18, 20). It has also been suggested that while the presence of added NaOAc can decrease the extent of scrambling that takes place in the dissociated triarylvinyl cation, the scrambling that occurs in the ion-pair stage may be insensitive to added NaOAc (7, 21, 22). In many of the present experiments which did not give rise to an equal amount of "% rearrangement" for the ring and chain labels (Table 4), ion-pairs possibly may have played at least a minor role. Thus the observed decrease in the extent of scrambling with increasing amounts of added NaOAc may be due only to the effect of NaOAc on the scrambling that occurred in the dissociated ion, the scrambling that took place in the ion-pair stage being unaffected by NaOAc. The deviations in Fig. 1 from a perfectly linear correlation might be due at least in part to perturbations by minor amounts of scrambling in the ion-pair stage which were insensitive to the presence of added NaOAc.

Experimental

*1,2-Dianisyl-2-*p*-[^{14}C]methoxyphenyl[2-^{13}C]vinyl Bromide (**1**-Br-2-^{13}C-2-methoxy-^{14}C)*

1,2-Dianisyl[1-^{13}C]ethanone (carbonyl-labeled desoxyanisoin) was prepared as described by Lee and Oka (9). *p*-[^{14}C]-methoxybromobenzene was obtained by methylation of *p*-bromophenol with [^{14}C]methyl iodide supplied by New England Nuclear Canada.

A solution of 10.0 g (30 mmol) of 1,2-dianisyl[1-^{13}C]ethanone in 150 mL of tetrahydrofuran (THF) was added dropwise over a period of 45 min to a Grignard solution prepared from 15.0 g (80 mmol) of *p*-[^{14}C]methoxybromobenzene and 2.4 g (100 mmol) of Mg in 150 mL of THF. The mixture was refluxed for 4.5 h and the resulting material was concentrated by the removal of most of the THF by distillation. The residual material was then poured into 600 mL of a 5% solution of NH_4Cl containing 7.5 mL of 25% NH_4OH. After cooling, the solid product was collected by filtration, washed with H_2O, and then recrystallized from methanol–acetone to give 11.4 g (80%) of 1,2-dianisyl-1-*p*-[^{14}C]methoxyphenyl[1-^{13}C]ethanol, mp 129–131°C (lit. (23) mp 130–131°C). This doubly labeled tertiary alcohol was then converted to 1,2-dianisyl-2-*p*-[^{14}C]-methoxyphenyl[2-^{13}C]vinyl bromide (**1**-Br-2-^{13}C-2-methoxy-^{14}C) by treatment with Br_2 in HOAc as described previously by Oka and Lee (5).

Acetolysis Reactions

A solution of 640 mg (1.5 mmol) of **1**-Br-2-^{13}C-2-methoxy-^{14}C in 100 mL of HOAc, containing various amounts of NaOAc or NaOAc and Et_4NBr as given in Tables 2 and 3, was placed in a sealed tube and heated at 120 ± 2°C for the desired length of time. After cooling in an ice-bath, the tube was opened and its content was poured into 200 mL of ether. The ether solution was extracted three times with 50-mL portions of H_2O. The combined aqueous extract was titrated potentiometrically with 0.1 *M* $AgNO_3$ to give the amount of liberated Br^- ion and hence the extent of reaction. The ether solution was dried over $MgSO_4$ and the solvent was removed under reduced pressure to give a residual oil containing the scrambled reaction product, **1**-OAc-1,2-^{13}C-1,2-methoxy-^{14}C, and any scrambled unconsumed reactant, **1**-Br-1,2-^{13}C-1,2-methoxy-^{14}C.

Analyses for Isotopic Scrambling

The residual oil containing the reaction product and the unconsumed reactant from each acetolysis experiment was treated twice successively with $LiAlH_4$ as previously described

(8) to give the scrambled 1,2,2-trianisylethanol, **2**-1,2-^{13}C-1,2-methoxy-^{14}C, derived from the acetate product, and the scrambled trianisylethene, **3**-1,2-^{13}C-1,2-methoxy-^{14}C, derived from the unconsumed reactant. Separation of the alcohol from the olefin was effected by passage through an alumina column again as previously described (8). The olefin, **3**-1,2-^{13}C-1,2-methoxy-^{14}C, was eluted first with a 9:1 mixture of petroleum ether and diethyl ether, and then the alcohol, **2**-1,2-^{13}C-1,2-methoxy-^{14}C, was recovered after the eluant was changed to $CHCl_3$.

The ^{13}C nmr spectrum of the alcohol **2**-1,2-^{13}C-1,2-methoxy-^{14}C was then obtained and it was used for the analysis of the ^{13}C contents at C-1 and C-2, the method employed for the analysis being the same as was described by Oka and Lee (5). The ^{13}C contents at C-1 and C-2 of the alcohol **2**-1,2-^{13}C-1,2-methoxy-^{14}C thus gave the % scrambling of the ^{13}C-label from C-2 to C-1 in the reaction product. After the ^{13}C nmr spectrum was obtained, the entire sample of **2**-1,2-^{13}C-1,2-methoxy-^{14}Cwas diluted with inactive carrier (about 500 mg) and then oxidized with $KMnO_4$ to give dianisyl ketone (8), whose ^{14}C activity, when compared with that of the alcohol **2**, gave the % scrambling of the [^{14}C]CH_3O-labeled anisyl group from C-2 to C-1 in the reaction product (8).

The scrambled trianisylethene, **3**-1,2-^{13}C-1,2-methoxy-^{14}C, eluted from the alumina columns, was divided into two portions. One portion (about 50 mg), without dilution by any carrier, was catalytically hydrogenated (H_2–PtO_2) in ethyl acetate to give 1,1,2-trianisylethane (**4**-1,2-^{13}C-1,2-methoxy-^{14}C), mp 88–89°C (lit. (23) mp 86–87°C). Control experiments show that this hydrogenation gave yields of about 90%. The ^{13}C nmr spectrum of hydrocarbon **4** showed C-2, C-1, and CH_3O absorptions at 40.3, 50.6, and 53.6 ppm, respectively, and these absorptions were utilized for the analysis of the ^{13}C contents at C-1 and C-2 by the intensity ratio method as described by Oka and Lee (5), thus giving the % scrambling of the ^{13}C-label from C-2 to C-1 in the recovered unconsumed reactant. The second portion of the olefin **3**-1,2-^{13}C-1,2-methoxy-^{14}C was diluted with inactive carrier (about 300 mg) and then it was degraded by ozonolysis to give dianisyl ketone (8), whose ^{14}C activity when compared with that of olefin **3** gave the % scrambling of the [^{14}C]CH_3O-labeled anisyl group from C-2 to C-1 in the recovered unconsumed reactant.

Multivariate analysis of data for the ionization of weak acids in water – dimethyl sulfoxide solvent mixtures

JOHN T. EDWARD,[1] MICHAEL SJÖSTRÖM, AND SVANTE WOLD

Research Group for Chemometrics, Department of Chemistry, Umeå University, S-901 87 Umeå, Sweden

Received January 5, 1981

JOHN T. EDWARD, MICHAEL SJÖSTRÖM, and SVANTE WOLD. Can. J. Chem. **59**, 2350 (1981).

The ionization constants $p({}_sK_a)$ reported for 41 weak acids of varying chemical type in ten water–DMSO solvent mixtures have been analysed by the SIMCA version of principal components analysis. This shows the data to fit a two-component model. The significance of the results for acidity function theory is discussed.

JOHN T. EDWARD, MICHAEL SJÖSTRÖM et SVANTE WOLD. Can. J. Chem. **59**, 2350 (1981).

On a analysé, par la version SIMCA de l'analyse des composants principaux, les constantes d'ionization $p({}_sK_a)$ de 41 acides faibles en dix solvants mixtes eau–DMSO. Les résultats indiquent un modèle à deux composants. On démontre la pertinence des résultats pour la théorie de la fonction d'acidité.

Introduction

The basicity of a solution of tetramethylammonium hydroxide in water – dimethyl sulfoxide (DMSO) solvent mixtures, as measured by the ionization of weak acids AH, becomes enormously greater as the water is progressively replaced by DMSO (1–4). Dolman and Stewart (4) constructed a H_- scale for 0.11 *M* tetramethylammonium hydroxide at 25°C in water–DMSO mixtures containing up to 99.6 mol% DMSO, and used this scale to determine the ionization constants $p({}_wK_a)$ at 25°C (referred to infinite dilution in water as the standard state) of very weak acids.

Schaal, Hallé, and their colleagues (5–10) also studied the ionization (but at 20°C) of weak acids in water–DMSO mixtures; however, their ionization constants $p({}_sK_a)$ are referred to infinite dilution in the mixed solvent as the standard state. They used a variety of procedures. In some determinations (7) they used an electrochemical cell containing a hydrogen electrode to measure the activity $\{S^+\}$ of the solvated proton S^+ in a series of colourless buffers in different water–DMSO solvent mixtures. The variation of the standard potential of this cell with $\{S^+\}$ had been determined previously using dilute solutions of hydrochloric acid (assumed to be completely ionized) in the same water–DMSO mixtures. The buffer could then be used to regulate pS^+ ($\equiv -\log\{S^+\}$) in any given water–DMSO mixture. When ionization of AH took place in this pS^+ range, and could be followed spectrophotometrically at concentrations of AH too low to affect pS^+, the ionization constant was given by:

[1] $$p({}_sK_a) = pS^+ - \log[A^-]/[AH] - \log {}_s\gamma_{A^-}$$

where ${}_s\gamma_{A^-}$ is the molar activity coefficient of the anion A^-. Measurements were made at different ionic strengths, and the apparent pK_a values thus obtained extrapolated to zero ionic strength, when $\log {}_s\gamma_{A^-}$ should become zero.

For weaker acids a small amount *b* of a strong base (sodium hydroxide) was added to the dilute solution of AH in water–DMSO. The equilibrium constant ${}_sK_b$ for the reaction

$$AH + S^- \rightleftarrows A^- + SH$$

was given by

[2] $${}_sK_b = \frac{[A^-]}{[AH][S^-]}\,\frac{{}_s\gamma_{A^-}}{({}_s\gamma_{AH})({}_s\gamma_{S^-})}$$

For a weak acid in low concentration, $[S^-] \approx b$, and rearrangement of [2] gives

[3] $$\frac{1}{[A^-]} = \frac{1}{([A^-]+[AH])} \times \left[1 + \frac{{}_s\gamma_{A^-}}{{}_sK_b b({}_s\gamma_{AH})({}_s\gamma_{S^-})}\right]$$

At low ionic strengths ${}_s\gamma_{A^-} \approx {}_s\gamma_{S^-}$ and $\gamma_{AH} \approx 1$, so that plots of $1/[A^-]$ against *b* should be linear. This in fact was found, and from the slopes of the plots ${}_sK_b$ could be obtained, and thence ${}_sK_a$:

[4] $$p({}_sK_a) = pK_s + p({}_sK_b)$$

This required a knowledge for each solvent mixture of the autoprotolysis constant K_s defined by:

[5] $$K_s = \{S^+\}\{S^-\} = [S^+][S^-]({}_s\gamma_\pm)^2$$

where $[S^+]$ designates the molar concentration of

the solvated proton in its diverse forms, $[S^-]$ the molar concentration of anions formed by removal of a proton from one or other of the solvent species, and ${}_s\gamma_\pm$ the mean ion activity coefficient. The pK_s ($\equiv -\log K_s$) values had been determined, and changed progressively from 14.32 in 10.8 (w/w)% DMSO to 24.0 in 95.5 (w/w)% DMSO (5) at 20.0°C. For 100% DMSO at 25°C a pK_D of 31.3 has been reported (11).

For reasonably strong acids (carboxylic acids, ammonium ions), $p({}_sK_a)$ can be determined by potentiometric titration in water–DMSO (12).

Hallé, Schaal, *et al.* (8–10, 12) showed that $p({}_sK_a)$ varies with solvent composition, and that different classes of compounds behave differently. In the present paper we apply the methods of principal components (pc) analysis (13–16) to the $p({}_sK_a)$ values reported by them for 41 weak acids, listed in Table 1, in ten water–DMSO solvent mixtures, listed in Table 2.

Methods

To apply pc analysis, the data were set up in a matrix containing the elements $y_{is} = p({}_sK_{a(i)})$ values for M compounds (the variables) in N solvents (the objects). Index i is used for the compounds and index s for the solvents. This data matrix can then be approximated by the statistical model:

$$[6] \qquad y_{is} = p({}_sK_{a(i)}) = \alpha_i + \sum_{a=1}^{A} \beta_{ia}\theta_{as} + \varepsilon_{is}$$

In this model θ are parameters varying with solvent composition, α and β are parameters characteristic of the acidic compound, and ε are residuals not explained by the α, β, and θ parameters. If the correct number of terms A is used, the parameters α, β, and θ describe the systematic part of the data and the residuals ε contain only "noise", which consists both of model errors and errors of measurement.

Hence one crucial objective of the data analysis is to find out whether [6] with $A = 1$ is sufficient to model the data. If a second term is required, its magnitude relative to the first is also of great interest. The appropriate number of terms can be determined for a matrix without missing data by the cross-validation (cv) technique (17).

For our calculations we used the statistical package SIMCA (16, 18). This package includes pc analysis, cv, and has proved successful in application to other chemical problems (16, 19).

The principal components model [6] has the same form as an A-term linear free energy relationship (LFER). Thus the data analysis conforms to the LFER treatments of acidity function by Bunnett and Olsen (20) and others (21). A single term model (i.e. $A = 1$) would correspond to the ordinary acidity function concept where shift in equilibria of all compounds undergoing protonation is modelled by a linear function.[2]

It must be understood that a data analysis of this type only gives parameters θ_{as} which best approximate the systematic information in the data. These parameters are such that θ_{1s} describes as much as possible of the linear correlations between the indicators, θ_{2s} as much as possible of the linear deviations from the first correlation structure, i.e. quadratic terms, θ_{3s} (if significant) as much of the linear deviation from the first two correlations, and so on.

The chemical interpretation of these parameters is more difficult, in particular since any rotations, θ_{as}' are also adequate chemical descriptors. In case more fundamental variables are thought to be involved, such rotations can be tried. See, further, the footnote to Table 2.

Results

Twelve different data analyses were made of different submatrices of the Schaal–Hallé data. In order to allow a cv choice of A, only complete submatrices with data for all i and s were analysed. Table 3 summarizes the results.

Set 1

Data set 1 ($N = 9$, $M = 9$) contains three compounds of the set used by Stewart and Dolman (4) to establish their H_- scale. In all, three types of compounds (diphenylamines, anilines, and aminopyridines) are included. The published data give $p({}_sK_a)$ values for these compounds in nine solvent compositions from 31.7 to 95.5 (w/w)% DMSO. Data sets of this range of solvent compositions are henceforth called "long" matrices.

The data analysis shows convincingly that a linear model ($A = 1$) is *not* sufficient to describe the data. Cross-validation shows that $A = 2$, and it is seen from S_1 and S_2 in Table 3 that the second component is highly significant. Thus, the RSD after one component (S_1) is 0.155 and after two components (S_2) is 0.038. The precision of the data is estimated to be about 0.03. Hence with $A = 1$ the unexplained variation of 0.12 (=0.155 − 0.038) is

[2]The function need not, of course, be linear in terms of solvent composition. Linearity in this context means that if the protonation data for one compound are plotted against the data for another, the plot is linear.

TABLE 2. Parameters for water–DMSO solvent mixtures[a]

S	% (w/w) DMSO	θ_1	θ_2
1	21.3	5.506	1.552
2	31.7	4.954	1.123
3	41.4	4.335	0.530
4	51.2	3.502	−0.004
5	61.2	2.250	−0.638
6	70.5	0.705	−0.922
7	80.4	−1.42	−0.874
8	86.4	−3.17	−0.610
9	91.0	−4.59	0.109
10	95.5	−6.56	1.285

[a] The $\beta_{i\alpha}$ and $\theta_{\alpha k}$ parameters are not uniquely defined in [6] and they can be arbitrarily rotated Φ degrees to $\beta_{i\alpha}'$ and $\theta_{\alpha s}'$. With two components as in the present case:

$$y_{is} - \alpha_i - \varepsilon_{is} = \beta_{i1}\theta_{1s} + \beta_{i2}\theta_{2s} = \beta_{i1}\theta_{1s}' + \beta_{i2}\theta_{2s}'$$
$$= (\beta_{i1}\cos\Phi + \beta_{i2}\sin\Phi)(\theta_{1s}\cos\Phi + \theta_{2s}\sin\Phi)$$
$$+ (\beta_{i1}\sin\Phi - \beta_{i2}\cos\Phi)(\Phi_{1s}\sin\Phi - \theta_{2s}\cos\Phi)$$
$$= [(\beta_{i1}b_1 + \beta_{i2}b_2)(\theta_{1s}b_1 + \theta_{2s}b_2) + (\beta_{i1}b_2 - \beta_{i2}b_1)(\theta_{1s}b_2 - \theta_{2s}b_1)]/(b_1^2 + b_2^2)$$

Thus, the θ_{sk} values can be rotated in such a way that θ_{1s}' will correlate to an external variable vector. As suggested by a referee, such a rotation can be done against pK_s, the autoprotolysis of water (5). This is accomplished by determining b_1 and b_2 by fitting pK_s by multiple regression to θ_{1s} and θ_{2s}. Thus $pK_s = a + b_1\theta_{1s} + b_2\theta_{2s} + e$, (SD(e) = 0.063, r = 0.9998, n = 10, a = 18.5178, b_1 = −0.7766, b_2 = 0.2468). Rotated $\theta_{\alpha s}'$ can now be calculated as:

$$\theta_{1s}' = (b_1\theta_{1s} + b_2\theta_{2s})/(b_1^2 + b_2^2)^{1/2}$$
$$\theta_{2s}' = (b_2\theta_{1s} - b_1\theta_{2s})/(b_1^2 + b_2^2)^{1/2}$$
$$\beta_{i1}' = (b_1\beta_{i1} + b_2\beta_{i2})/(b_1^2 + b_2^2)^{1/2}$$
$$\beta_{i2}' = (b_2\beta_{i1} - b_1\beta_{i2})/(b_1^2 + b_2^2)^{1/2}$$

Notice, however, that the $\theta_{\alpha s}$ and $\theta_{\alpha s}'$ scales will give identical models from the statistical point of view.

From the good description of pK_s of water by the two $\theta_{\alpha s}$ scales, our conclusion is that water (that can also be considered as an indicator) is behaving in a similar way to the other indicators.

significant compared with the original data variability (S_0 = 0.583) and the estimated error of 0.03.

We conclude that two components are needed to get an adequate modelling of the data in set 1.

Set 2

Set 2 includes more compounds of the three types found in set 1 but to keep the matrix complete a restriction to six solvents was necessary (short, fat matrix).

The results are precisely the same as those of the previous analysis.

Sets 3, 4

To investigate the generality of the two-component model, the data set was expanded to include more types of compounds: five types in set 3, seven types in set 4. Cross-validation (cv) analysis of these "long" matrices shows A = 2, with no indication of a third component. It is interesting to note that the RSD after two components remains very stable at around 0.040.

To get θ-values for the first solvent composition (21.3 (w/w)%DMSO), a solvent vector corresponding to this composition was fitted to the pc model obtained in the analyses of set 4. We note that such fitting can be made even when the fitted vector is incomplete (17). The compounds having values defined for this solvent composition were 1, 2, 3, 5, 15, 20, 21, and 23.

Sets 5, 8

Subanalyses of data set 4 were then performed to investigate the possibility that one-component models might describe sets which are more homogeneous with respect to compound types (sets 6, 8) or solvents (set 5). This was not the case; A = 2 was required (but sufficient) for these subsets also.

Sets 9, 10

Further restrictions in the diversity of compounds were then introduced: set 9 contains only diphenylamines, set 10 only anilines. Even for these matrices (one long; one short, fat) it was found necessary to include second components.

Sets 11, 12

Data set 11 was confined to aminopyridines and data set 12 to dinitrodiphenylamine carboxylates. Here we finally find one-component models adequate, but the RSD's are rather large. This result is explained by the very small number of compounds (M = 4) included in each set. In this case the size of the data matrices is too small to carry statistically the second components, even if they are required from the chemical point of view (to reproduce the precision of the measurements).

Discussion

The analysis above show convincingly that two solvent parameters, θ_1 and θ_2, are required to describe the acidity (basicity) of water–DMSO mixtures, and hence the tendency of weak acids to dissociate in these solvent mixtures, and that one parameter is not sufficient.

Plots of θ_1 and θ_2 against solvent composition are shown in Fig. 1. Extrapolation of the curves gives θ_1 = 6.60 and θ_2 = 1.87 for 100% water, and θ_1 = −8.75 and θ_2 = 3.50 for 100% DMSO; however, the extrapolations are rather lengthy, and these values should be regarded as provisional until more experimental data are available.

Using these values and [6] it becomes possible to calculate for those examples of compounds 1–41 for which β_1 and β_2 values are listed the ionization constants in water, $p({}_wK_a)$, and in DMSO, $p({}_DK_a)$. This has been done for six compounds in Table 4.

Agreement between values thus calculated and values obtained by other routes is reasonable, although only in the case of compound 3 (and, to a lesser extent, of compounds 36 and 39) are these other routes free from objection. For the remaining

[c]Determined using M.C.P. approach in DMSO–water.
[d]Determined using H_- values in DMSO–water.
[e]Determined using H_- values of concentrated aqueous NaOH or KOH.
[f]By extrapolation to 100% water.
[g]By extrapolation to 100% DMSO.

three compounds $p({}_WK_a)$ values were obtained by the H_- route. We show below that in principal this method is defective. However, its results are least erroneous when solvent systems as close as possible to 100% water are used; this is the case for compounds 6, 20, and 22 of Table 4. Values of $p({}_WK_a)$ determined by the H_- method can be expected to diverge increasingly from values calculated from [6] as the solvent mixture becomes richer in DMSO.

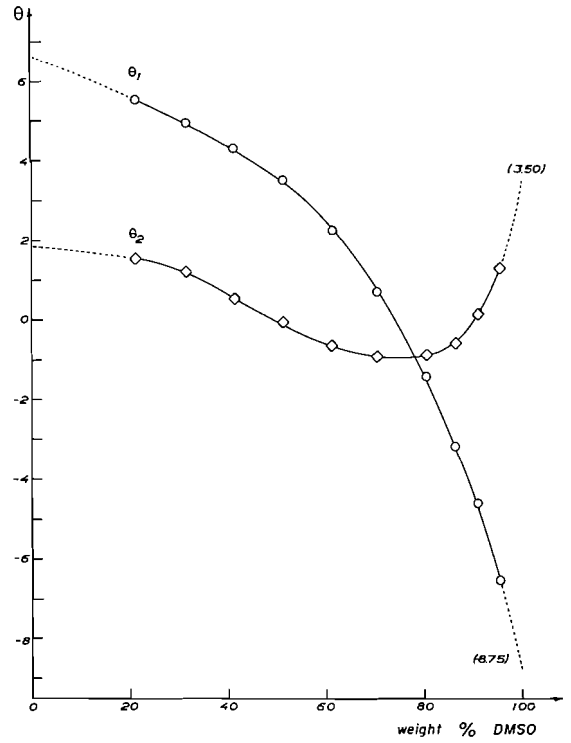

FIG. 1. Variation of θ_1 and θ_2 with DMSO content of water–DMSO solvent mixtures.

Equation [6] provides a bridge linking pK_a values in the two important solvents, water and DMSO. Unfortunately, no $p({}_DK_a)$ values are yet available from the researches of Bordwell and his collaborators (23, 24) for any of the compounds 1–41 of Table 1.

Thermodynamic Interpretation of the Results

The change in pK_a with solvent composition is a manifestation of the "medium effect" (25):

$$[7] \quad \Delta pK_a = p({}_sK_a) - p({}_wK_a) = \log ({}_m\gamma_{H^+})({}_m\gamma_{A^-}) - \log ({}_m\gamma_{AH})$$

where ${}_m\gamma_i = {}_w\gamma_i/{}_s\gamma_i$ measures the change in activity coefficient of solute i with change of solvent from water to water–DMSO. The effect of changing solvent on the activity coefficient of ions and molecules (referred to infinite dilution in water) has been discussed by King (25), Buncel and Wilson (26), Parker (27) and others, and so it becomes tempting to try to relate [7] to our empirical [6*a*]:

$$[6a] \quad p({}_sK_a) = \alpha_1 + \beta_1\theta_1 + \beta_2\theta_2$$

It is admitted that any such attempt can only be speculative, but the exercise may be useful in giving an intuitive appreciation of the terms of [6*a*].

In general, ion–solvent interactions are stronger than molecule–solvent interactions, and so it is possible to assume that $\beta_1\theta_1$ is affected chiefly by such interactions. The increase in $\beta_1\theta_1$ for carboxylic acids (compounds 39–41 of Table 1) with increase in DMSO content of solvent can then be ascribed to an increase in both ${}_m\gamma_{H^+}$ and ${}_m\gamma_{A^-}$: these small ions of localized charge are solvated and stabilized well by H_2O, less well by DMSO (26, 27), and this first term is proportional to the free energy of transfer of the ions from infinite dilution in water to infinite dilution in water–DMSO. Thus for cyclohexane – carboxylic acid (compound 39) we note a monotonic increase in $\beta_1\theta_1$ from −2.72 in 5.9 mol% DMSO to +3.24 in 83.1% DMSO.

On the other hand, for 3′-chloro-2,4,6-trinitrodiphenylamine (compound 1) over this solvent range $\beta_1\theta_1$ changes monotonically from +1.02 to −1.21. The anion A^- derived from compound 1 has an extensively delocalized charge; such ions are found to be well solvated and stabilized by DMSO (27), and hence ${}_m\gamma_{A^-}$ can be expected to decrease with increasing DMSO content.

The term $\beta_2\theta_2$ may reflect chiefly the solvent activity coefficient ${}_m\gamma_{AH}$ of AH with increasing concentration of DMSO in the solvent. It has been found that ${}_m\gamma_i$ of nonelectrolytes such as diethylacetal and ethyl acetate first increase and then decrease with increase in DMSO content of solvent (27). Similar data are not available for any of the compounds 1–41 of Table 1, but would be most useful to have in the present connection.

Extrathermodynamic Interpretation of the Results

In the present case we study the process of ionization of a weak acid. This process is modified in two ways, (*i*) by substitution in the acid (change of indicator) and (*ii*) by changing the solvent composition. The output of the process, y, (here $y = p({}_sK_a)$) can be described as a continuous function in terms of vector variables relating to the two modes of change. If this function is differentiated with respect to these vector variables and if the modes of change are sufficiently small, one can derive a model from the output as eq. [8], see (13, 14).

$$[8] \quad y = \alpha + \sum_{a=1}^{A} \beta_a\theta_a + R(g)$$

Here the parameters α and β relate only to the first mode of change and θ only to the second mode, respectively. The remainder $R(g)$ contains terms of a Taylor expansion of gth degree and higher. $R(g)$ can be made arbitrarily small by making the two modes of change sufficiently small.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

The two simplest models corresponding to the least pertubation of the system, i.e. the most minute amounts of change, are

$$[9a] \quad y = \alpha + \beta\theta + R(g)$$

and

$$[9b] \quad y = \alpha + \beta_1\theta + \beta_2\theta^2 + R(g)$$

The first of these two models [9*a*] corresponds to the single one-term LFER and is valid for any process provided that its pertubation is sufficiently small. When the pertubation is larger, however, the data are not well approximated by [9*a*] but one must use first eq. [9*b*] and then more complicated models like eq. [8] with $A \geq 2$. In the present case we note that eq. [9*b*] turns out to be adequate. Figure 2, displaying a plot of θ_1 against θ_2, clearly shows that θ_2 is quadratically related to θ_1. The extrathermodynamic interpretation of this result is that the change of solvent composition corresponds to the change in a single "effect" in the process. This effect shows a quadratic behaviour over larger intervals of solvent composition. This interpretation is consistent with the thermodynamical interpretation above, where the "activity coefficient" is included to describe the quadratic change of the main effect, "the solvent interaction."

Consequence of Two Terms for Validity of Acidity Functions

The various acidity function treatments (Bunnett–Olsen (20), Marziano–Cimino–Passerini (28), Cox–Yates (29)) require the term log ($\gamma_A\gamma_{H^+}/\gamma_{HA}$) to be a linear function of the term log ($\gamma_P\gamma_{H^+}/\gamma_{HP}$) in a series of solutions of varying acidity (PH being a set of acids which obey an acidity function H_P), or alternatively the term log ($\gamma_A/\gamma_{HA}\gamma_{OH^-}$) to be a linear function of the term log ($\gamma_P/\gamma_{HP}\gamma_{OH^-}$) in a series of solutions of varying basicity. In such a case a single solvent term θ_1 should describe the change in acidity or basicity of the solvent. We see that in the case of water–DMSO solutions such a treatment is inadequate.

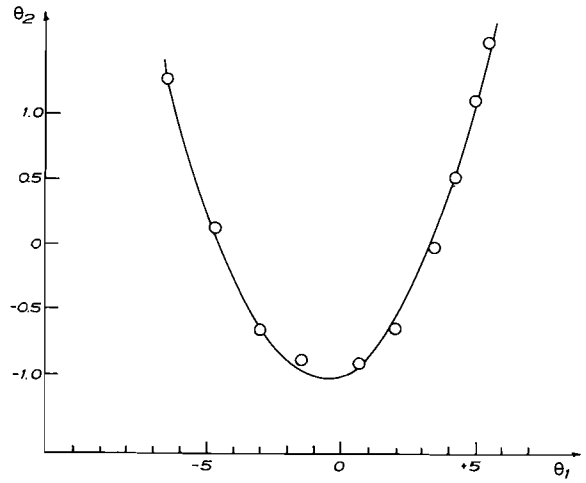

FIG. 2. θ_2 can be approximated by a function of θ_1:$\theta_2 = a + b\theta_1 + c\theta_1^2$.

However, for very short intervals of solvent composition, θ_1 and θ_2 are approximately linear to each other, see Fig. 2. Thus one might be misled to believe that a linear model ($A = 1$) is applicable for larger variations of solvent composition as assumed in the stepwise construction of acidity scales.

Further, it is seen from data set analyses 11 and 12 that by limiting the number of compounds to four or less, a second component is masked. This has nothing to do with limiting the diversity of compounds (see results for data analyses 6–10) but is just a consequence of having too few data to allow a statistical calculation of the second component. We note that in the Hammett "overlap procedure" generally used to establish acidity scales both for the basic and acidic regions, one compares only two compounds at a time, thereby ensuring that a second component is not seen.

Acknowledgments

A reinvestigation of the rate of reaction of *N*-decylimidazole with *p*-nitrophenyl decanoate

J. PETER GUTHRIE AND STELLA O'LEARY

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 28, 1981

J. PETER GUTHRIE and STELLA O'LEARY. Can. J. Chem. **59**, 2358 (1981).

Reinvestigation of the reaction of *p*-nitrophenyl decanoate with *N*-decylimidazole shows that the rate enhancement attributable to 1 : 1 complex formation between reactants is small (12-fold), consistent with what we have found in related systems, and much less than values reported by other workers. Kinetics were carried out at very low concentrations to avoid problems of aggregation, and at pH 8.0 to minimize the contribution from solvolysis. Numerous difficulties were encountered with reactive degradation products from Tris buffers. At pH 8.0 the apparent second order rate constant was $2.25 \pm 0.64\ M^{-1}\ s^{-1}$.

J. PETER GUTHRIE et STELLA O'LEARY. Can. J. Chem. **59**, 2358 (1981).

Une nouvelle étude de la réaction du décanoate de *p*-nitrophényle avec le *N*-décylimidazole montre que l'augmentation de vitesse attribuable à la formation de complexe 1:1 entre les réactifs est faible (12 fois) en accord avec nos résultats relatifs à des systèmes apparentés et elle est de beaucoup inférieure aux valeurs rapportées par d'autres chercheurs. Pour éviter les problèmes d'association on a réalisé l'étude cinétique à de très faibles concentrations, et à un pH de 8,0 pour minimiser la contribution de solvolyse. On a rencontré plusieurs difficultés avec des produits de dégradation réactifs provenant du tampon de Tris. A un pH de 8,0 la constante de vitesse apparente d'ordre 2 est de $2{,}25 \pm 0{,}64\ M^{-1}\ s^{-1}$.

[Traduit par le journal]

Introduction

Numerous studies have been reported (1–6) of systems which might show rate enhancements due to stabilization of the transition state as a result of hydrophobic interactions involving two (or more) alkyl chains. Large rate effects have been claimed in several of these systems, (1–3, 5, 6), and the effects have been attributed to what has been assumed (implicitly or explicitly) to be a 1:1 interaction. We have had occasion to cast doubt upon the validity of this interpretation of the rate phenomena which were observed (7, 8, 10). In the first place, some of the early work was done at concentrations of substrate such that most of the substrate was aggregated (7–9). In the second place, the steroidal imidazole **1**[1] which should be similar to an alkyl imidazole in its hydrophobic binding properties, though it is much more soluble and does not form micelles (both effects resulting from the presence and location of the two ammonium groups) (11–13), showed *small* (1.6-fold) rate enhancements for *p*-nitrophenyl alkanoates relative to the acetate, although the rate enhancements which were observed increased in a regular fashion with increasing chain length (10).

Oakenful and Fenwick have recently reinvestigated the reaction of *N*-decyl imidazole with *p*-nitrophenyl alkanoates (2). They have confirmed our observation that, e.g., *p*-nitrophenyl decanoate can only be used at concentrations less than $2 \times 10^{-6}\ M$ if aggregation is to be avoided (7, 8). However, they report even larger rate constants than were reported by Blyth and Knowles (1), with similarly large rate enhancements (228-fold) for the reaction with *p*-nitrophenyl decanoate. The obvious discrepancy between our claim that alkyl groups can only give *small* rate enhancements and Oakenful's claim that they can give *large* rate enhancements has prompted us to study the reaction of *p*-nitrophenyl decanoate with *N*-decyl imidazole. We now report that at *low* concentrations of *N*-decyl imidazole the limiting second order rate constant corresponds to a *small* (12-fold) rate enhancement, which is consistent with the results we have reported for the reaction of **1** with *p*-nitrophenyl decanoate.

[1]Compound **1** is 17β-(4-imidazolyl)-5α-androstane-3β,11β-diamine (11–13).

Results

The reaction was studied both at pH 10 (carbonate buffer) and at pH 8 (Tris buffer). The studies at pH 10 were intended to reproduce the conditions employed by Knowles and Oakenful; however, these experiments suffered from the anticipated problem of a major contribution from hydroxide catalyzed reaction. At pH 8 this background rate was much smaller: unfortunately, major experimental difficulties were encountered as a result of decomposition of the Tris buffer. These buffer solutions were made up from either primary standard grade Tris (Fisher) (which had been recrystallized prior to use) or else from Sigma "Trizma Base" using glass distilled water in every case. With either sample of Tris, within about a week some reactive impurity was generated, which led to

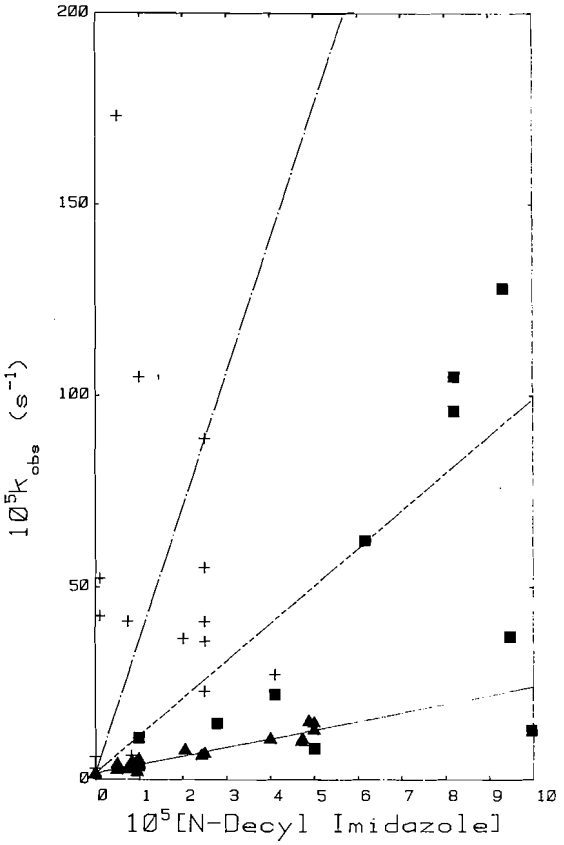

FIG. 1. Observed rate constants for *N*-decylimidazole catalyzed hydrolysis of *p*-nitrophenyl decanoate at pH 8.0, 25°C. (+) Reactions in aged Tris buffer (more than a week old). (■) Runs which were not included in the least squares fit. (●) Runs which were used in the least squares fit. (—) Best line by least squares. (-·-) Line calculated using the second order rate constant from ref. 2. (— - - —) Line calculated using the second order rate constant from ref. 1.

anomalously fast reactions. In an attempt to compensate for this problem, we have run replicate reactions, always using fresh buffer solutions, using two sources of Tris, and two different preparations of *N*-decylimidazole. Runs which did not give linear pseudo-first order plots were discarded as were runs leading to anomalously high rates. Since decomposition of the buffer leads to spuriously *fast* reactions, we should at least be able to put an *upper* limit on the true rate constants.

The rate constants which we obtained are found in the Supplementary Table,[2] and are compared with the predicted values based upon the published second order rate constants of Blyth and Knowles (1) and Oakenful and Fenwick (2) in Figs. 1 and 2. Qualitatively it is clear, particularly at pH 8, that our pseudo-first order rate constants correspond to a *much* smaller second order rate constant than those reported by Knowles (1) and Oakenful (2) and co-workers. At pH 10 the discrepancy between our results and those of Knowles is much less marked. Under either set of conditions the discrepancy between our results and those of Oakenful is enormous and inexplicable. Our kinetics were done with substrate concentrations of 1×10^{-6} *M* or 5×10^{-7} *M* which we and Oakenful agree is below the critical concentration for this ester. We have employed 10 cm cells, and a Gilford model 240 spectrophotometer, following a total absorbance change of ≥0.080, so that with an instrumental

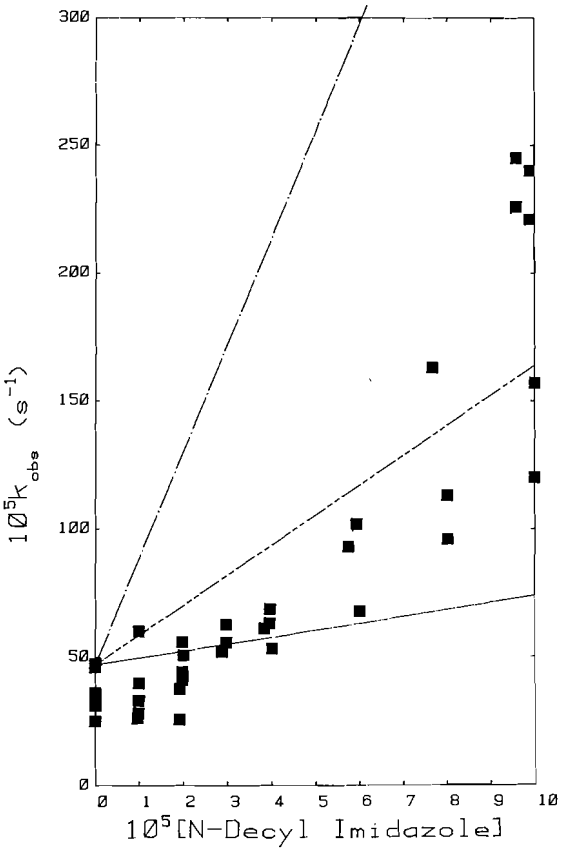

FIG. 2. Observed rate constants for *N*-decylimidazole catalyzed hydrolysis of *p*-nitrophenyl decanoate, pH 9.9, 25°C. error of ca. 0.002 in absorbance we anticipate that the maximum uncertainty in pseudo-first order rate constants attributable to the uncertainty in absorbance change should be ca. 20%, and in fact this is approximately the scatter which is observed.

For the data at pH 8 we endeavored to determine the best second order rate constant by fitting the data to $k_{obs} = k_0 + k_2$ [catalyst]. In order to do this it was necessary to discard various points which deviated drastically from the best line. First, all runs carried out using old Tris solutions were discarded. Then all runs for decyl imidazole concentrations greater than 5×10^{-5} M were discarded, because most of these points (but not all, see Fig. 1) were drastically faster than predicted by the best line. Then points deviating by more than two standard deviations from the best line by least squares were discarded and the least squares calculation was repeated to give $k_0 = 1.65 \pm 1.63$ s^{-1} and $k_2 = 2.25 \pm 0.64$ M^{-1} s^{-1}. An extreme, but defensible, position regarding these experiments would be that systematic errors are going to be in the sense of anomalously fast reaction rates; in general this is illustrated by Fig. 1. A line fitted to the lowest values at each concentration of *N*-decylimidazole would have a significantly lower slope. We must regard our least squares line as an upper limit to the true value, which may be smaller.

The data at pH 10 do not permit evaluation of a line: the scatter is greater, the background rate is higher, and there is a clear upward curvature to the plot of k_{obs} vs. [catalyst]. We did not attempt to determine a second order rate constant from these data: Fig. 2 shows that a line corresponding to the second order rate constant determined at pH 8 can give a plausible fit to the data for catalyst concentrations below 5×10^{-5} M. The second order rate constant was corrected for partial protonation of the imidazole at pH 8, using an estimated pK_a for *N*-decylimidazole of 7.30 (the value for *N*-ethylimidazole (19)). The line corresponding to the second order rate constant reported by Blyth and Knowles (1) is also consistent with the data (and would pass through our data at all concentrations of *N*-decylimidazole if a lower intercept were used). Once again, the line corresponding to the second order rate constant reported by Oakenful and Fenwick (2) is not consistent with our data.

Discussion

The use of linear alkyl groups as hydrophobic binding regions in enzyme models has had a considerable appeal, since very simple syntheses lead to incorporation of these groups. Although it has generally been recognized that micellization will be a problem, attempts have been made to circumvent this difficulty and numerous claims of large rate enhancements are to be found in the literature (1–3, 5). A summary of the results of these studies is to be found in Table 1. The most striking feature of this table is the remarkable inconsistency in rate enhancements from one experiment to the next. If the simplest interpretation of the data in this table, namely that they all represent the consequences of 1:1 association, were true, one would expect that the rate enhancements in part (a) of this table would be similar for each of the three systems for constant n, and that there would be a regular increase in rate enhancement with increasing n, as is found. Furthermore, one would expect, in the absence of extraneous factors such as strain in the transition state, that the systems in part (b) of the table would show larger rate enhancements than the analogous systems in part (a). In general this is not what is seen, but on careful examination some pattern can be discerned. Two of the systems in part (b) are probably artefactural; these are the $n = 10$ case of system (*v*), for which the substrate was apparently used at a concentration greater than its solubility limit; and system (*viii*), for which the catalyst is a very large hydrophobic molecule with very few hydrophilic residues to draw it into solution, and the substrates, *p*-nitrophenyl decanoate, dodecanoate, and hexadecanoate were used at concentrations above their solubility limits. The remaining systems in parts (b) and (c) of the table can be taken as giving reliable data, with two perturbing features which lead to apparent inconsistencies. The binding sites differ in the degree to which they can remove the alkyl chain of the substrate from solution. Systems (*v*) (*vi*), and (*viii*) are the ones expected to give the most complete removal, and for (*v*) and (*vi*), plots of log (rate enhancement) vs. π (14, 15) have slopes of 1.04 and 1.06 respectively. For systems (*iv*) and (*vii*), part of the alkyl chain may not be in contact with the binding site, and there may be some strain introduced in achieving a conformation which permits binding. Both of these effects will lead to lower rate enhancements than would otherwise be expected. The large slope (0.94) observed for the dependence of log (rate enhancement) upon n for system (*iv*) is surprising and a source of some concern. System (*viii*) used large hydrophobic compounds, and one must suspect that the components were not in true solution.

After all of these caveats have been considered, there remains the general picture that where the rate enhancements in part (b) might have been expected to be significantly larger than the analogous

rate enhancements in part (a), they are in fact either similar or even smaller. The three systems in part (a) of the table appear to be out of line, and it is this feature which led us to reinvestigate the *N*-decylimidazole – *p*-nitrophenyl decanoate reaction. For system (*iii*), although the authors (3) clearly state that they interpret their rate enhancements in terms of 1:1 complex formation, it seems highly probable that mixed micelles are present. For systems (*i*) and (*ii*), three factors seem

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

to be involved. First, some of the experiments in system (*i*) were carried out at concentrations of ester greater than the solubility limit (8, 9). Second (and related), the relative rate constant for *p*-nitrophenyl decanoate (with the acetate as standard) reacting with *N*-ethylimidazole is ten times smaller than expected, i.e. than the relative rate constant for the analogous reaction with imidazole, and adequately low concentrations of ester (8). Since the rate constant for *N*-ethylimidazole with *p*-nitrophenyl decanoate is spuriously low the apparent rate enhancement for *N*-decylimidazole is spuriously high. Thirdly, it appears on the basis of the work reported in this paper that the second order rate constant for the reaction of *N*-decylimidazole with *p*-nitrophenyl decanoate is too high, in part because the earlier studies were not done at low enough concentrations. Our rate enhancement was calculated using the value for the rate constant for the reaction of *N*-decylimidazole with *p*-nitrophenyl acetate reported by Blyth and Knowles (1), and our rate constants for the reactions of imidazole with *p*-nitrophenyl acetate and decanoate (8), as well as the rate constant for the reaction of *N*-decylimidazole with *p*-nitrophenyl decanoate determined in the present work; the value so obtained is 12-fold. This rate enhancement appears more reasonable than the larger values previously claimed for an association process which involves partial removal of alkyl chains from water. There should be only modest strain involved in achieving the transition state with hydrophobic contact between alkyl chains, so that most of the potential rate enhancement should be manifested.

Why is a linear alkyl chain so poor as a binding site for hydrophobic stabilization of a transition state? In part this reflects the fact that in a 1:1 complex, only about a quarter of the surface area will be removed from contact with water, unless the alkyl chain binds to a cavity. Rather more serious is the problem of loss of conformational flexibility imposed by the requirement that the chain be in contact with another molecule along its entire length. Only a small fraction of the available conformations will satisfy this constraint, so that there is a serious loss in conformational entropy if binding occurs. As a consequence, the binding is weak unless the binding site is a cavity. This entropic constraint does not apply so seriously to binding to a micelle, since the interior of the micelle is liquid-like in nature and most conformations of the alkyl chain are accessible.

Why has it proven so difficult to obtain reproducible and reliable rate constants in the experiments reported here? We believe that the problem is, in part, the extreme sensitivity to traces of catalytic agents, of whatever nature such as appeared in aged Tris solutions. Using fresh solutions and glass distilled water was a workable solution. Nitrophenyl esters are very sensitive to nucleophilic impurities in solvents: we have always purified our acetonitrile by passage through active alumina. It seems very probable that results are sensitive to the technique of reaction initiation, since a relatively concentrated solution of a very water insoluble compound is being added to an aqueous reaction medium. Minor delays in mixing can lead to formation of slowly dissolving microdroplets, which could conceivably serve as nuclei for some sort of micellar aggregation which would lead to enhanced reaction rates at concentrations where micelles are thermodynamically unstable. Although we can speculate about the reasons for the observed erratic behavior, we wish to stress the severe problems which were encountered in this work, and caution anyone planning to investigate related systems to be suitably cautious.

Conclusions

1. In accord with our earlier statements, 1:1 binding of alkyl chains produces *small*, up to 12-fold, rate enhancements.

2. Because of the extreme experimental difficulties which may be encountered in obtaining reliable rate constants, and the many artefacts which can arise, we recommend that chains longer than eight carbons not be used except when micellar catalysis is desired, and that even for eight-carbon chains, low concentrations should be employed, with long path length cells for spectrophotometric studies.

3. We suggest that plots of log (rate enhancement) vs. π be constructed whenever hydrophobic rate enhancements are reported, and that the magnitude of the slope be used as a criterion of reasonableness: the slope should be similar to the fraction of total hydrophobic surface removed from contact with water. In the present case the slope (based on decanoate and acetate) is 0.24, which appears reasonable.

Experimental

Materials

Trishydroxymethylaminomethane was obtained from two sources, Fisher Chemical Co. (recrystallized before use) and Sigma Chemical Co., "Trizma Base," used without further purification.

KCl, $NaHCO_3$ and Na_2CO_3 were reagent grade chemicals used without further purification.

N-Decylimidazole was prepared according to the method of Haring (18). Acetonitrile (Fisher Scientific Co.) was passed through a column of grade I neutral alumina (Woelm) to remove nucleophilic impurities.

Kinetic Procedures

Reactions were initiated by adding a small portion of a solution of substrate in purified acetonitrile to temperature-equilibrated buffer in a 10 cm spectrophotometer. All solutions of *N*-decylimidazole at pH 8, buffered with trishydroxymethylaminomethane, were made up freshly every 3–4 days. Solutions at pH 9.8, buffered with carbonate, were made up freshly every 5 days. The solutions were made up by weighing out the *N*-decylimidazole in an aluminium foil boat, which was then transferred to a volumetric flask. The solutions were stirred overnight before use, to ensure complete solution of the *N*-decylimidazole in the water. Changes in absorbance were followed using a Gilford Model 240 spectrophotometer. pH values were measured at the end of the reaction using a Radiometer pH Meter 25 SE with a GK 2301C combined electrode. Reactions were followed for at least three half-lives.

Crystals of the title compound are orthorhombic, $a = 7.387(1)$, $b = 8.502(2)$, $c = 14.662(2)$ Å, $Z = 4$, space group *Pnma*. The structure was solved by direct methods and refined by least-squares procedures to a final R of 0.058, $R_w = 0.097$ for the 530 reflections with $I > 3\sigma(I)$. The P_3N_3 ring is slightly but significantly non-planar with a crystallographically-imposed mirror plane normal to the ring, and the PN bond lengths in order from the PMe_2 group are 1.601(7), 1.552(7), and 1.560(6) Å. The ring angles are 114.0(4)°, (PMe_2); 120.0(4)°, PF_2; 123.2(5)°, N(3); 119.6(5)°, N(4). The mean exocyclic bond lengths are P—C, 1.77(1), P—F, 1.522(6), and the exoangles are 107.4(4)° (PMe_2) and 97.2(3)°, (PF_2). The bond lengths within the ring are well described in terms of simple perturbation theory, but comparison with the structures of other molecules shows the importance of factors other than π-electron distribution.

A. WALLACE CORDES, PAUL N. SWEPSTON, RICHARD T. OAKLEY, NORMAN L. PADDOCK et T. N. RANGANATHAN. Can. J. Chem. **59**, 2364 (1981).

Les cristaux du composé mentionné dans le titre sont orthorhombiques avec $a = 7,387(1)$, $b = 8,502(2)$, $c = 14,662(2)$ Å, $Z = 4$, groupe d'espace *Pnma*. On a résolu la structure par les méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs de $R = 0,058$ et de $R_w = 0,097$ pour 530 réflexions avec $I > 3\sigma(I)$. Le cycle P_3N_3 dévie légèrement, mais d'une façon significative, du plan et il comporte un plan miroir imposé cristallographiquement qui est normal au cycle; les longueurs de la liaison PN, à partir du groupe PMe_2, sont: 1,601(7), 1,552(7) et 1,560(6) Å. Les angles du cycle sont: 114,0(4)°, (PMe_2); 120,0(4)°, PF_2; 123,2(5)°, N(3); 119,6(5)°, N(4). Les longueurs moyennes des liaisons exocycliques sont P—C, 1,77(1), P—F, 1,522(6) et les angles *exo* sont de 107,4(4)° (PMe_2) et de 97,2(3)° (PF_2). Les longueurs des liaisons à l'intérieur du cycle sont bien décrites par la théorie de perturbation simple; toutefois la comparaison avec des structures d'autres molécules révèle l'importance de facteurs autres que la distribution des électrons π.

[Traduit par le journal]

Introduction

An interesting feature of the geometry of inhomogeneously substituted cyclophosphazenes is that the lengths of the bonds within the ring are often significantly unequal. One example is $N_4P_4F_6Me_2$ (1) (the 1,1-dimethyl isomer), in which it is supposed (2) that electron release by the methyl groups reduces the electronegativity of the phosphorus atom to which they are attached, so altering the π-electron distribution within the ring. The large bond length inequalities found experimentally (1) parallel the changes in bond order estimated by a perturbation treatment (2).

Another important source of information has been the study of the effect of the number of PN units in the ring on chemical and physical properties. Such studies have been used, through photoelectron spectroscopy, to identify the π-systems (3), and through nmr spectroscopy (4), to assess the separate inductive and conjugative interactions between phenyl and phosphazenyl rings.

In the simplest case, approximated by methyl substitution, the interaction is purely inductive. The preparation of *gem*-$N_3P_3F_4Me_2$ (5) allows us to examine the comparative effects of inductive interactions in 6- and 8-membered rings, and to see whether simple perturbation theory adequately describes the effect of ring size on the bond length inequalities.

Experimental

A mixture of methylfluorocyclotriphosphazenes was prepared by the addition of a two-fold excess of methyllithium in ether to hexafluorocyclotriphosphazene $N_3P_3F_6$ in ether at −20°C. The principal product was the monomethyl derivative $N_3P_3F_5Me$ (bp 105.7/752, lit. (6) 65/280). It was accompanied by a small amount of a volatile crystalline solid, which was recrystallised from $CHCl_3/CCl_4$ as $N_3P_3F_4Me_2$, mp 127.5–128°C. *Anal.* calcd for $C_2H_6F_4N_3P_3$: C 9.93, H 2.30, N 17.17; found C 10.19, H 2.48, N 17.40. High resolution mass measured 240.970; calcd for $N_3P_3F_4Me_2$, 240.971. The nmr spectra show that methyl substitution is geminal. Details are given in Table 1.

The crystal of $N_3P_3F_4Me_2$ used for all X-ray data collection was bounded by five pairs of parallel faces, parallel to the (010), (100), (001), (102), and ($\bar{1}02$) planes, at face-to-center distances of 0.16, 0.10, 0.10, 0.10, and 0.10 mm (all ±0.02 mm). The crystal was mounted on a fiber with the b axis parallel to the φ axis of the diffractometer. A least-squares refinement of 18 values of 2 sin θ/λ gave cell constants for $P_3N_3F_4C_2H_6$ (fw =

[b]In solution in $CDCl_3$; $^4J_{PH}$ = 1.90 Hz, $^3J_{PP}$ = 45.0 Hz.
[c]Neat liquid. $^4J_{PH}$ = 1.4 Hz.
[d]PF_2 group remote from PMe_2.

241.01) of $a = 7.387(1)$, $b = 8.502(2)$, $c = 14.662(2)$ Å, $V = 920.9$ Å^3; and ρ_{calcd} (for $Z = 4$) = 1.74 g cm^{-3}. The Laue symmetry and the systematic absences of the orthorhombic crystal indicated space group *Pnma*; four molecules per unit cell in this space group imposes either a mirror plane (the case here) or an inversion center on the molecules.

A Datex-automated General Electric XRD 6 diffractometer was used with Ni-filtered CuKα (λ = 1.5418 Å) radiation. For the intensity data a θ–2θ scan over a range of (1.80 + 0.86 tan θ)° in 2θ was made at a speed of 4° min^{-1}; stationary crystal – stationary counter background readings were taken for 10 s at each end of the scans. All reflections (732) with $2\theta < 120°$ were scanned. Of these, 530 had $I > 3\sigma(I)$ and were used for the solution and refinement of the structure. A check reflection measured every 50 reflections during data collection indicated an 18% decay during the last half of data collection, due to crystal decomposition, for which a simple linear correction was made. The extent of decay, which was also found to occur in a second crystal, precluded the collection of data beyond $2\theta = 120°$. The crystal has a value of 55.6 cm^{-1}; an absorption correction with summation points every 0.004 cm gave a range of correction factors (for I) of 0.34 to 0.44.

The structure was solved by direct methods and refined by full-matrix least-squares procedures. One P atom, one N atom, two C atoms, and two H atoms are located on the mirror at $y = 0.25$. Neutral atom scattering factors were used (7) and real and imaginary anomalous dispersion corrections were made for P (8). Least-squares weights of $w = 1/(2|F_{min}| + |F_{obs}| + 2|F_{obs}|^2/|F_{max}|)$ for the 530 observed reflection, 71 parameter, refinement gave a final $R = 0.068$, $R_w = 0.097$, a standard deviation of observation of unit weight of 0.46, and no dependence of $\Delta F/\sigma(F)$ on either F or sin θ. The final least-squares cycle included refinement of the positional parameters of the methyl hydrogen atoms, with constrained isotropic temperature factors of $B = 5.0$. No parameter shifted by more than 0.3σ in the final cycle, and a final difference Fourier showed no peaks above 0.3 e/Å^3. Final positional parameters are listed in Table 2. Observed and calculated structure factors and thermal parameters have been placed in the Depository of Unpublished Data.[1] Bond lengths and angles are shown in Fig. 1.

Results and Discussion

All the intermolecular distances exceed the normal Van der Waals distances, so that the molecular geometry is unlikely to be affected significantly by intermolecular interaction. Figure 1 shows a general view of the molecule, with the crystallographic numbering scheme and the principal molecular dimensions. The six ring atoms are coplanar within 0.02(1) Å ($\chi^2 = 20.0$); N(3) and N(3′) are 0.019(6) Å above the P_3 plane, and N(4) is 0.022(10) Å below (details deposited).[1] The PF_2 plane makes a dihedral angle of 88.9(2)° with the best plane of the ring. The deviations from the ideal symmetry of C_{2v} are small enough to allow averaging of related lengths and angles.

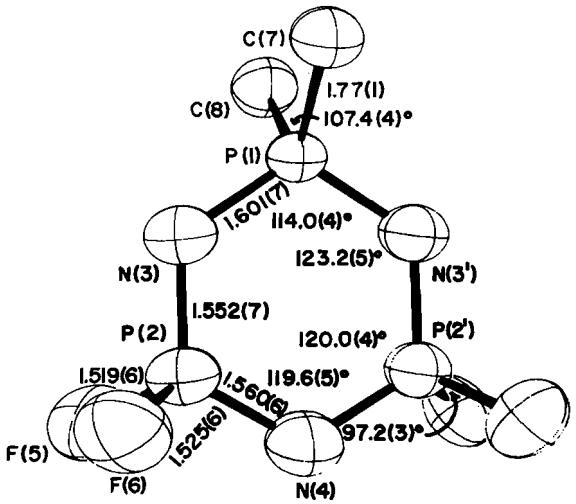

FIG. 1. Molecular diagram of $N_3P_3F_4Me_2$, showing bond lengths (Å) and angles (deg).

To some extent, the mean geometry of the ring can be correlated with ligand electronegativity. The ring angle at phosphorus decreases in the series $N_3P_3F_6$, 119.6° (9), $N_3P_3Cl_6$, 118.4 (10), $N_3P_3Me_6$, 116.8 (11), as the π-electron density moves from phosphorus towards nitrogen. Correspondingly, the P—N bond lengths increase; 1.570, 1.581, 1.605 Å. In $N_3P_3Ph_6$, P—N = 1.597 Å, $\hat{P}$ = 117.8° (12), so that, from this point of view, the phenyl group is slightly more electronegative than the methyl group. The implication is corroborated by the PPh_2 and PF_2 chemical shifts in $N_3P_3F_4Ph_2$, which are −82.1, −101.1 ppm respectively (13),

and indicate a greater polarisation of charge in the methyl derivative. The small variations of P—N bond lengths within the structure of $N_3P_3Ph_4Me_2$ (14) show that the electronegativity difference in this sense is small. It is not surprising, therefore, that the mean PN bond lengths in $N_3P_3F_4Me_2$ and $N_3P_3F_4Ph_2$ (15) should be so nearly equal (1.571, 1.572 Å), but the bonds are unexpectedly short; simple averaging of the bond lengths in $N_3P_3F_6$, $N_3P_3Me_6$ would suggest 1.582 Å as a likely value. Such a shortening is found in other compounds — in $N_3P_3F_4(NH_2)_2$ (16) the mean P—N bond length is 1.562 Å, shorter than in $N_3P_3F_6$ itself — but it is at present unexplained.

Perhaps the greatest interest in the structures of inhomogeneously substituted phosphazenes is in the inequality of ring bond lengths induced by the substituents, here the pair of methyl groups. They reduce the electronegativity of the phosphorus atom to which they are attached, so weakening the π-interaction in the immediate P—N bonds. The weakening, indicated by a slightly greater bond length of 1.601 Å, is accompanied by a decrease of angle at P(1) to 114.0°, which is even less than in $N_3P_3Me_6$ (116.8°). The corresponding exo-angle increases from 102.6° to 107.4° in $N_3P_3F_4Me_2$, a greater change than the 2° increase expected from the change in σ-hybridisation. The increased localisation of π-bonding in the second and third bonds is accompanied by an increase of 0.4° in the ring angle at P(2) compared to that at N(4).

The application of HMO theory shows that if $\alpha_N = \alpha_p + 2\beta$, an assumption which is not critical, the deviations of the successive π-bond orders from the mean should be in the ratio −1:0.7:0.3. The deviations from the mean bond length are in the ratio 1, −0.63, −0.37, as good an agreement as can be expected, since the difference between the lengths of the second and third bonds is not crystallographically significant. In $N_3P_3F_4Ph_2$ the agreement is even closer. The structure of $N_4P_4F_6Me_2$ makes an interesting comparison. As pointed out earlier (2), the variation of bond lengths away from the perturbing centre is paralleled by the calculated bond-atom polarisabilities, which is good evidence that the bond length changes are well described in terms of the π-inductive effect of the methyl substituents. However, the deviations of the π-bond orders from the mean, calculated as just described for those of the trimeric derivatives, are in the ratios −1:0.57:0.16:0.27. The deviations of the bond lengths from the mean are in the ratios 1:−0.73:0.21:−0.47. Both sets of numbers oscillate, but the bond lengths have greater variation. In $N_3P_3F_4Me_2$, the mean deviation from the calculated mean bond order is 0.042, and the mean deviation from the mean bond length is 0.020 Å. In the tetrameric derivative, a calculated smaller bond order deviation (0.036) is associated with a larger mean bond length deviation (0.039 Å); localisation of the double bonds is more pronounced.

These comparisons show that, although the qualitative variations in bond length in inhomogeneously substituted phosphazenes are well described in terms of the perturbation of a π-electron system, bond order calculations by themselves are not enough for a quantitative treatment. The problem is related to that of bond alteration in annulenes (17), with the difference that the bonds are highly polar, and it may be that, in so far as the π-systems involved are homomorphic, the π-electron energy (per electron) to be set against σ-bond compression energy (18) is smaller in the 8-membered than in the 6-membered ring. At present, too little is known of the ring force constants. It is likely that a full discussion would require both these and the use of the theoretical concepts developed earlier (19).

Dynamic aspects of the behavior of aromatic ketone triplets in anionic micelles. A laser flash photolysis study[1]

J. C. SCAIANO AND J. C. SELWYN[2]

Division of Chemistry, National Research Council, Ottawa, Ont., Canada K1A 0R6

Received January 20, 1981

J. C. SCAIANO and J. C. SELWYN. Can. J. Chem. **59**, 2368 (1981).

The behavior of several aromatic ketone triplets has been examined in sodium dodecyl sulfate micelles using laser flash photolysis techniques. The molecules examined, acetophenone, propiophenone, isobutyrophenone, *p*-methoxyacetophenone, benzophenone, and xanthone are mainly resident in the micellar phase. Phenyl alkyl ketones show considerable self-quenching, a process that is rather sensitive to steric factors. All the molecules examined seem to reside near the Stern layer. Typical rate constants for triplet state entry into the micelle are around $1.8 \times 10^{10}\ M^{-1}\ s^{-1}$.

J. C. SCAIANO et J. C. SELWYN. Can. J. Chem. **59**, 2368 (1981).

Faisant appel à la technique de photolyse flash au laser, on a étudié le comportement de diverses cétones aromatiques à l'état triplet dans des micelles de dodécylsulfate de sodium. Les molécules étudiées, l'acétophénone, la propiophénone, l'isobutyrophénone, la *p*-méthoxyacétophénone, la benzophénone et la xanthone, résident principalement dans la phase micellaire. Les phénylalkylcétones présentent beaucoup d'autopiégeage, un processus sensible aux facteurs stériques. Toutes les molécules étudiés semblent demeurer près de la couche de Stern. La constante typique de vitesse d'entrée de l'état triplet dans la micelle est d'envirion $1{,}8 \times 10^{10}\ M^{-1}\ s^{-1}$.

[Traduit par le journal]

Introduction

Carbonyl triplets, and in particular the triplet state of aromatic ketones, have been the subject of considerable attention (1–4). While their behavior in homogeneous solution is relatively well understood, their behavior in organized assemblies, such as micelles, is not. A few aspects have received some attention, for example, benzophenone probes have been used to examine the conformation of hydrocarbon chains in micelles (5); de Mayo and co-workers have studied the effect of the micellar environment upon the dimerization of 3-*n*-butylcyclopentenone (6) and its photocycloaddition to alkenes (7); the Norrish Type II process of carbonyl compounds has been examined by Whitten and co-workers (8, 9), Turro *et al.* (10), and ourselves (11). Among other aspects of the behavior of carbonyl compounds in micelles which have also been examined are: the Norrish Type I cleavage (12–16), energy migration (11), the decay of benzophenone ketyls (17), and the initiation of emulsion polymerization (18, 19).

Most of the studies mentioned above have been published during the last two or three years, a fact that emphasizes the current interest in using organized assemblies to change the course of photochemical reactions. Despite these studies, many fundamental questions, such as the triplet lifetimes in micellar solution, the location of the excited chromophores in the system, the rates of exit and entry, and the possible role of intramicellar self-quenching frequently remain unanswered. In this study we use nanosecond laser flash photolysis techniques in an attempt to answer some of these questions.

Results

All our experiments were carried out under oxygen-free conditions using the pulses (337.1 nm, ~8 ns, up to 10 mJ) from a nitrogen laser for excitation and a computerized system with nanosecond response to monitor the transient signals (20).

The decay of the triplet state was monitored following the decrease of the absorption due to T–T transitions with time. We find that the lifetimes of phenyl alkyl ketones depend upon the bulk ketone concentration. Acetophenone, which is known to undergo self-quenching in homogeneous solution (21), shows the highest sensitivity.

Concentration effects were not examined in the case of xanthone because all experiments (see below) could be carried out under conditions where the occupancy levels were substantially lower than one; self-quenching could be expected to be of importance at higher concentrations (20, 21). Benzophenone triplet lifetimes were quite insensitive to the ketone bulk concentration, even when the average occupancy was well over two.

Table 1 summarizes the triplet lifetimes measured in 0.23 *M* sodium dodecyl sulfate (SDS) solution. All values have been extrapolated to zero ketone concentration (not just to single occupancy)

[d]Wavelength used to monitor T–T absorptions (in nm).

using a plot of τ_T^{-1} vs. the ketone concentration; the corresponding slopes (k_{app}) are also given in Table 1, and representative plots shown in Fig. 1. The values of k_{app} are formally rate constants for the self-quenching process, and are a function of the surfactant concentration. Typical occupancy levels in our experiments were in the 0.2 to 10.0 range for the phenyl alkyl ketones and lower for the others. Micellar occupancies were calculated using CMC = 0.0082 *M* and an aggregation number of 62 (22). Experiments at lower surfactant concentrations (but over CMC) showed similar effects and led to τ_T^0 values consistent with those in Table 1.

It is interesting to note that even in cases where the triplet lifetimes were short enough to suggest chemical decay, the yield of detectable ketyl radicals was quite low. For example, in the case of benzophenone the triplet lifetime in SDS micelles was 360 ns at 26°C. This value compares well with the 330 ns obtained in decane solution (23); however, the yield of ketyl radicals in SDS is only ca. 7% of that in decane. We have also observed that the yield of the so-called "light absorbing transients" (24–26) is much higher in micelles than in homogeneous solution. It is not clear at this point if these two phenomena are related. This aspect of the problem will be discussed in detail elsewhere.

The triplet state of aromatic ketones in micellar solution can also be quenched by water soluble quenchers. We chose nitrite ions for these experiments because the negative charge is expected to prevent any significant association with the micelles (27). Plots of τ_T^{-1} vs. the nitrite concentration were expected and confirmed to be nonlinear, approaching, at the high limit the sum of rates of triplet decay in the micelle and of triplet exit from the micelle.

The experimentally observed rate of triplet decay ($k_{expt} = \tau_T^{-1}$) is given by eq. [1].

$$[1] \quad k_{expt} = k_0 + \frac{k_- k_q[Q]}{k_q[Q] + k_+[M]}$$

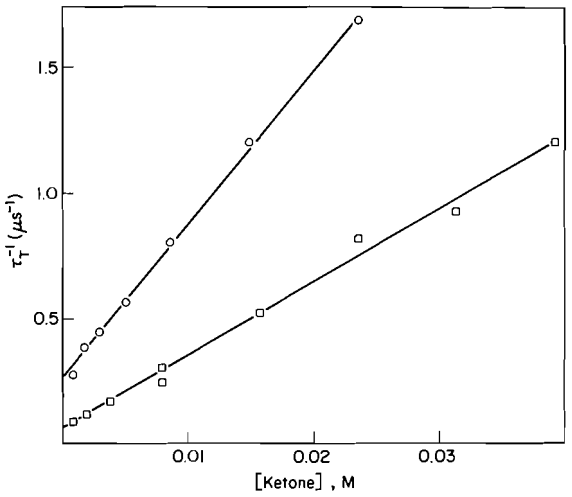

FIG. 1. Dependence of the triplet lifetimes on the ketone bulk concentration for SDS 0.23 *M* at 26°C, for acetophenone (○) and isobutyrophenone (□).

where k_0 is the rate of triplet decay in the absence of quencher Q, k_- and k_+ are the rate constants for exit and entry into the micelle, respectively, [M] is the concentration of micelles, and k_q is the rate constant for triplet quenching in the aqueous phase. Equation [1] assumes that the ketone is largely solubilized in the micellar phase, that its triplet state does not decay in the water phase by any process other than quenching by Q, and that Q is insoluble in the micellar phase. When $[Q] \rightarrow \infty$ the experimental rate constant is given by eq. [2].

$$[2] \quad k_{expt} = k_0 + k_-$$

In the intermediate concentration range eq. [3] provides an adequate type of linear representation (27).

$$[3] \quad \frac{1}{k_{expt} - k_0} = \frac{1}{k_-} + \frac{k_+[M]}{k_- k_q[Q]}$$

Figure 2 shows representative plots according to

TABLE 2. Kinetic and equilibrium data for the exit and entry of aromatic ketones in sodium dodecyl sulfate micelles

Ketone	$k_+[M]/k_-k_q$[a]	k_+/k_-[b]	k_-[c]
Acetophenone	1.13×10^{-9}	2040	7.8×10^6[d]
Propiophenone	2.63×10^{-9}	4700	3.0×10^6[d]
Isobutyrophenone	4.14×10^{-9}	7500	1.6×10^6[d]
p-Methoxyacetophenone	1.66×10^{-9}	3000	(9.2×10^6)[e]
Benzophenone	(1.5×10^{-8})	(26000)	(2×10^6)[f]
Xanthone	3.52×10^{-9}	6300	2.7×10^6

[a]In units of M s at 26°C for [SDS] = 0.23 M.
[b]In units M^{-1}.
[c]In units of s^{-1}.
[d]From energy transfer studies, see ref. 11.
[e]Intercept poorly defined.
[f]All values for benzophenone are subject to considerable error (approx. a factor of two) because its short triplet lifetime and the possible overlap of ketyl signals (at 540 nm) or very weak absorptions (at 590 nm) make the measurements quite difficult.

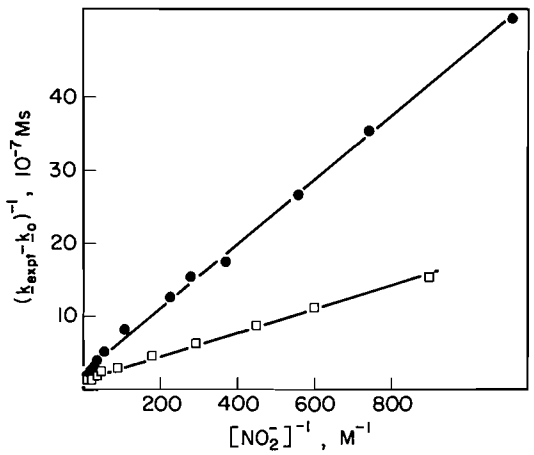

FIG. 2. Plot according to eq. [3] for isobutyrophenone (●) and *p*-methoxyacetophenone (□) in SDS 0.23 M using sodium nitrite as quencher.

eq. [3] for [SDS] = 0.23 M (corresponding to [M] = 0.0036 M) at 26°C.

In order to determine the k_+/k_- ratio it is necessary to have some knowledge of the value of k_q. In order to obtain this value we carried out experiments with xanthone, which has a large extinction coefficient at the excitation wavelength (337 nm) so that measurements are viable using the saturated solution in water. From a study at 26°C in which xanthone triplets were monitored at 600 nm we obtained $k_q = 6.5 \times 10^9\ M^{-1}\ s^{-1}$. The value of k_q may be slightly dependent upon the ketone used; however, we expect this dependence to be quite small, since all sensitizers used are in a relatively narrow triplet energy range, i.e. ~69 to 73 kcal/mol (28), and nitrite anions are reported to have a triplet energy of 53 kcal/mol (27, 29). The same value of k_q was used for all the systems examined. Table 2 summarizes the data obtained. It should be noted that according to eq. [3] one can obtain the separate values of k_- and k_+, if k_q is known. In some cases the intercept from plots such as those in Fig. 2 is not very well defined. In a few cases the values of k_- had been obtained before from energy migration studies; whenever available (11) we have preferred these values of k_- rather than those derived from eq. [3] (see Table 2). The average value of k_+ that can be obtained from the data in Table 2 is $1.8 \times 10^{10}\ M^{-1}\ s^{-1}$. In principle, all values of k_- could have been accurately determined by working at very high nitrite concentration; in practice this would lead to a new problem, i.e. the change in micellar properties due to excessive changes in the ionic strength.

Discussion

It is important to emphasize that all the kinetic parameters obtained in this study correspond to the triplet state; rates of exit and entry could be somewhat different for the ground state.

Triplet ketones are far from being static probes. For example, in the case of acetophenone, if we combine the data obtained here with rates of exit determined from energy transfer studies (11), we conclude that in dilute solution every acetophenone triplet will on average visit ca. 30 micelles before decay occurs.

Self-quenching plays an important role in the decay of acetophenone triplets. For example the lifetime of 3.8 μs for C → O is reduced to ca 1.45 μs when the occupancy level is two. The literature gives no indication whether the rate constant for self-quenching (k_{SQ}) reported for acetophenone (21) can be regarded as a representative value for other phenyl alkyl ketones. Our results indicate that self-quenching in acetophenone is considerably faster than in other phenyl alkyl ketones. The increased efficiency of self-quenching in micellar solution seems to somewhat exceed the concentration effect expected in the micelles. For example, for SDS 0.23 M a plot of τ_T^{-1} vs. $[\text{acetophenone}]_{bulk}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

gives an apparent rate constant $k_{app} = 6.2 \times 10^7 M^{-1}$ s^{-1}, and the reported (21) value of k_{SQ} in carbon tetrachloride is $1.1 \times 10^6 M^{-1}$ s^{-1}. That is, the effect on the rates is around a factor of sixty while the effect of reagent concentration due to micellization for SDS 0.23 M is only ca. one order of magnitude. The enhanced rates of self-quenching may be partially reflecting the anchoring of the ketone *and* the ketone triplet near the micellar surface, with the quenching occurring in this area and with the reaction partners in adequate orientation for interaction. The dependence of product ratios in the photochemistry of 3-*n*-butylcyclopentenone upon micellization (6, 7) has been explained using similar arguments.

We carried out a few exploratory experiments using benzaldehyde; we found that triplet lifetimes are much shorter than in the case of acetophenone, and it becomes virtually impossible to work at the very dilute limit and still have enough light absorbed at the excitation wavelength (337.1 nm).

In the case of benzophenone, no significant self-quenching was observed; this agrees with the data in homogeneous solution, which also showed relatively inefficient quenching (21). The highest occupancy level in these experiments was 2.9.

No attempt was made to measure self-quenching in the case of xanthone; the process is extremely fast in homogeneous solution (20, 21) and one should probably expect self-quenching to manifest itself as a static process.

The lifetime of xanthone triplets has been shown to be very sensitive to the polarity of the media (20, 30), being as long as 17.2 μs in 1:1 water–acetonitrile and only 22 ns in cyclohexane. The sensitivity of xanthone triplet lifetimes to the media is the result of an inversion of the triplet n,π^* and π,π^* states and the changes in reactivity which frequently accompany such an inversion of states. It is interesting to note that the lifetime measured in SDS compares well with those measured in methanol and in acetonitrile (20); we take this result to mean that the ketone triplet resides in a very polar environment, probably with the carbonyl group in the Stern layer, as proposed by de Mayo and co-workers (6, 7). It is interesting to note that earlier results, showing that the Norrish Type II process occurs with high quantum yields (10) and that the biradical has a relatively long lifetime (11), can only provide information on the location of the biradical, not the triplet state.

The relatively long lifetimes of triplet phenyl alkyl ketones (at zero concentration) are consistent with the decrease in hydrogen abstraction ability frequently observed in polar media (31). *p*-Methoxyacetophenone was quite unreactive, as expected (32, 33).

Benzophenone, which is known to remain with predominant n,π^* character even in polar media (1, 31), where it is highly reactive, showed triplet lifetimes similar to those obtained in hydrocarbons with abundant secondary C—H bonds, such as decane. Much to our surprise, ketyl radicals seem to be produced very inefficiently. Whether the explanation for this effect is that ketyls are not formed, that the radical-pair loses its triplet character quite rapidly, or that new decay paths become of importance in micellar solution, remains to be resolved. Preliminary results indicate that the so called "light absorbing transients" (24–26) are formed more efficiently than in homogeneous solution.

In conclusion, our results show that aromatic ketones, particularly phenyl alkyl ketones, are very mobile probes; further, self-quenching is in many cases an important phenomena, which in some cases (e.g. acetophenone) can become the predominant triplet decay mode. Micellization produces a substantial enhancement of the self-quenching process, which under these conditions reveals its sensitivity to substitution at the carbonyl centre. All the ketones examined are largely resident in the micellar phase, but their exit and entry rates are quite large, thus making them very dynamic probes.

Lifetimes, reactivities, and self-quenching effects all are consistent with the assumption that ketones reside in a highly polar environment.

Experimental

Materials

Xanthone was a Fluka product, acetophenone was from BDH, and all other ketones were from Aldrich; they were distilled or recrystallized before use. A sample of acetophenone purified by preparative vpc gave the same results as the distilled material. Sodium dodecyl sulfate (BDH, specially purified) was used as received. Sodium nitrite was a Fisher product.

Sample Preparation

The samples were contained in Suprasil cells made of 3 × 7 mm rectangular tubing (Vitro Dynamics). All experiments were carried out under oxygen-free conditions. Other details are similar to those reported previously (34).

Laser Flash Photolysis

The samples were excited with the pulses from a Molectron UV-24 nitrogen laser. Our facility has been fully interfaced with a PDP11-03L computer which controls the experiment and processes the data initially acquired by an R-7912 Textronik transient digitizer. Further details have been given elsewhere (20).

Lactonisation par ouverture, en milieu acide, de cyclopropanes γ-carboxyliques

LAURENT CHICHE, HENRI CHRISTOL, JACQUES COSTE ET FRANÇOISE PLÉNAT[1]

ERA No 610, Laboratoire de Chimie Organique, E.N.S. Chimie, 8, rue de l'Ecole Normale, 34075 Montpellier Cédex. France

Reçu le 25 avril 1980[2]

LAURENT CHICHE, HENRI CHRISTOL, JACQUES COSTE et FRANÇOISE PLÉNAT. Can. J. Chem. **59**, 2373 (1981).

L'ouverture dans l'acide formique de composés cyclopropaniques porteurs d'une fonction carboxyle conduit à des mélanges complexes contenant moins de 30% de lactones, dues à l'intervention du nucléophile interne au cours de la réaction. On montre que la stéréochimie relative de la fonction carboxyle vis-à-vis du cycle à trois carbones n'est pas déterminante quant à la proportion de lactonisation obtenue. En revanche, lorsque l'ouverture est réalisée par un acide de Lewis (BF_3–OEt_2), la lactonisation devient très prépondérante (84%); bien que le mécanisme de la cyclisation intramoléculaire n'ait pu être clairement établi dans ce cas, la réaction constitute une bonne voie d'accès aux lactones.

LAURENT CHICHE, HENRI CHRISTOL, JACQUES COSTE, and FRANÇOISE PLÉNAT. Can. J. Chem. **59**, 2373 (1981).

The opening of cyclopropanes, bearing a carboxyl group, in formic acid leads to complex mixtures containing less than 30% lactones formed by an intramolecular nucleophilic process during the reaction. We show that the relative stereochemistry of the carboxyl group and the cyclopropyl group does not determine the proportion of lactone formed. On the other hand, when the opening is performed by a Lewis acid (BF_3–etherate), lactonisation is the major route (84%) and although the mechanism of intramolecular cyclisation is not yet clear, this reaction provides a good route to lactones.

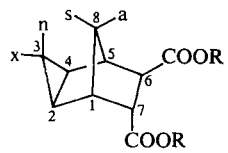
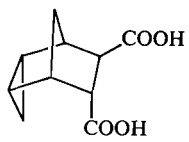
La participation de nucléophiles internes à l'ouverture de cyclopropanes activés ou lors de la solvolyse de cyclopropyl-carbinols s'est révélée utile en synthèse organique (1). Nous avons pour notre part envisagé de faire intervenir un tel processus dans l'ouverture acidocatalysée de cyclopropanes non activés; cet objectif n'a en effet suscité que peu de travaux qui montrent toutefois qu'il est formellement réalisable (2, 3). Nous avons donc entrepris d'observer les possibilités de lactonisation d'acides γ-cyclopropyliques en milieu acide, qui n'ont pas encore été étudiées à notre connaissance. Nous avons choisi les composés tricycliques **1** et **2**. En effet, ceux-ci sont après protonation, formellement comparables à certains composés d'addition électrophile sur des norbornènes analogues, pour lesquels la γ-lactonisation est un processus souvent exclusif (4). Le groupement carboxylique en position 6-*exo* est destiné à éviter, par son caractère attracteur d'électrons, la transposition de Wagner–Meerwein de la simple liaison (C-5)—(C-6), processus qui a été observé (3) lors de l'ouverture acidocatalysée de l'*exo*-tricyclo[3.2.1.$0^{2,4}$]octane.

Synthèse des composés 1 et 2

Le composé **1***a* a pu être obtenu par transfert de méthylène, selon la méthode de Simmons–Smith modifiée par Rawson et Harrison (5), sur le diméthoxycarbonyl-2 *endo*-3 *exo* bicyclo[2.2.1]heptène-5 (6). Pour que la réaction procède à une vitesse suffisante, nous avons dû utiliser un large excès de



1*a* R = Me
b R = H



2

FIG. 1

réactif; il est probable que les deux substituants carboxyliques, en appauvrissant la double liaison en électrons, la rendent peu réactive (7).

La formation exclusive d'*exo*-tricyclo[3.2.1.$0^{2,4}$]-octane **1***a* est attendue; en effet, sur les composés norbornéniques, les additions *cis*, se font de façon très préférentielle en *exo* (7*b*, 8–11). La structure proposée pour les composés **1** est confirmée par leur spectre de rmn.[3] On observe pour **1***a*, à δ = 0,03 ppm, un signal de quatre raies correspondant à H-3x ($J_{3x-2} = J_{3x-4} \simeq 7$ Hz; $J_{3x-3n} = 6{,}5$ Hz); H-3n résonne à δ = 0,44 ppm sous la forme de cinq raies ($J_{3n-3x} = 6{,}5$ Hz; $J_{3n-2} = J_{3n-4} \simeq 3$ Hz). Ces deux signaux sont en parfait accord avec les données de la littérature pour la structure *exo*-tricyclo-[3.2.1.$0^{2,4}$]octane (11*b*, 12), notamment du point de vue de la différence de déplacement chimique entre H-3x et H-3n qui se trouve déblindé.

Le composé **2** a été préparé à partir de l'oléfine **3**. On sait en effet qu'en série norbornadiénique, la cyclopropanation se fait en *exo* et en *endo* (7*b*, 11*a*, 13). En outre, étant donné la présence de deux

SCHÉMA 1

doubles liaisons différentes dans le composé **3**, nous avons généré le carbène par le diazométhane en présence de chlorure cuivreux (14), méthode connue pour ne pas donner d'adduit sur des doubles liaisons appauvries en électrons (15); nous avons ainsi obtenu un mélange dont les caractéristiques spectrographiques correspondent aux composés **4** et **5** attendus; on note en particuler la disparition des protons vinyliques.

Lors de l'hydrogénation catalytique du mélange précédent, l'approche du catalyseur favorisée en *exo* (16) conduit aux composés **6** et **7** possédant les deux groupes esters méthyliques en *endo*. Le composé **6** est connu (7*b*). En ce qui concerne le composé **7** inconnu, la simplicité du spectre de rmn montre clairement que le produit est symétrique. En outre, on observe un signal (δ = 3,03 ppm, 2H, signal large, $W_{\frac{1}{2}}$ = 5 Hz) très similaire au signal obtenu pour les protons H-6 et H-7 du composé **6** (δ = 2,92 ppm, 2H, signal large, $W_{\frac{1}{2}}$ = 4,7 Hz), ce qui dénote l'identité de stéréochimie des fonctions méthoxycarbonyles entre les produits **6** et **7**. La stéréochimie *endo* du cyclopropane du composé **7** a été attribuée sur la base des arguments suivants: (*a*) il n'apparait pas de signal vers 0 ppm présent dans les spectres de **1***a* et **6** et dû au proton H-3x d'un pont méthylénique *exo*; (*b*) d'autre part, il est connu que, pour la structure tricyclo[3.2.1.$0^{2,4}$]octanique, les protons H-2 et H-4 *endo* (au pied d'un cyclopropane *exo*) sont très faiblement couplés avec les protons têtes de pont H-1 et H-5 (17), alors que ce couplage est d'environ 4 Hz pour des protons H-2 et H-4 *exo* (au pied d'un cyclopropane *endo*) (18); on observe effectivement une largeur à mi-hauteur du pic correspondant à H-1 et H-5, nettement plus importante pour le composé **7** que pour le composé **6** *exo* (9,0 Hz au lieu de 5,4 Hz).

L'hydrolyse basique du diester **7** s'accompagne de l'épimérisation de l'un des carboxyles et conduit au diacide recherché **2**. La perte de symétrie est évidente à la vue du spectre de rmn; le proton H-6, blindé par rapport au même proton du composé **7** (2,43 ppm au lieu de 3,03 ppm) résonne maintenant sous forme d'un doublet (couplé avec H-7, J = 4,5 Hz) alors que H-7, inchangé quant au déplacement chimique, résonne sous la forme d'un triplet (couplé de façon équivalente avec H-6 et H-1); les couplages ainsi observés sont semblables à ceux relevés sur le spectre de rmn du composé **1***a*, ce qui confirme la stéréochimie *trans* des deux substituants en position −6 et −7. Par ailleurs, l'absence de signal vers 0 ppm traduit le maintien de la stéréochimie *endo* du cyclopropane.

Ouverture en milieu acide du noyau cyclopropanique des composés 1 et 2; détermination des structures

Les ouvertures ont été réalisées dans l'acide formique pur utilisé comme solvant; nous l'avons choisi pour son caractère suffisamment polaire et peu nucléophile, mais aussi parce que c'est ce réactif qui a été utilisé dans l'ouverture de noyaux cyclopropaniques lors de la mise en évidence de la participation de l'oxygène d'un éther (2*e*).

Par chauffage à 80°C pendant 6 h dans l'acide formique, le composé **1***b* conduit à un mélange complexe (schéma 2) ne présentant plus, en rmn, les caractéristiques du noyau cyclopropanique. Une séparation partielle a été réalisée par chromatographie au niveau des acides ou de leurs dérivés; nous n'avons cependant pas pu isoler tous les isomères.[4]

Composé **8**b

Il s'agit d'une γ-lactone acide; en effet le spectre ir de l'ester correspondant **8***a* montre deux vibrations

[4]Dans tout les cas, produits purs ou mélanges, l'analyse élémentaire concorde avec la structure proposée.

*Les esters méthyliques dérivés des acides portent le même numéro suivi de la lettre *a*

SCHÉMA 2

$\nu_{C=O}$ à 1762 cm^{-1} (γ-lactone) et 1730 cm^{-1} (ester méthylique). En outre, l'allure et l'intégration du spectre de rmn de **8***b* correspondent bien à une telle structure; en particulier, nous avons vérifié, par double résonance, que le proton au pied de l'oxygène lactonique est bien couplé avec le proton tête de pont H-1 (J = 9 Hz).

Composé **9**b

Le spectre de rmn de l'ester correspondant **9***a* montre la présence d'un seul groupement ester méthylique ainsi qu'un signal (δ = 4,65 ppm) pouvant correspondre au proton situé au pied de l'oxygène lactonique. Ce composé montre en ir une seule vibration $\nu_{C=O}$ à 1738 cm^{-1} qui peut traduire la présence d'une δ-lactone ou d'une lactone à cycle plus grand, simultanément à celle de l'ester méthylique. La valeur faible du couplage observé pour le proton au pied de l'oxygène lactonique permet d'éliminer la structure de la figure 2 pour laquelle les modèles moléculaires indiquent un angle dièdre (H-4)–(C-4)–(C-5)–(H-5) voisin de 0°. Par ailleurs les caractéristiques spectrographiques de la lactone **9***a* sont similaires à celles de la lactone de l'acide hydroxy-3 *endo* bicyclo[3.2.1]octane carboxylique-6 *endo* décrite récemment par Moriarty *et al.* (19).

Fraction ***10***b

La troisième fraction lactonique issue de **1***b*, de même formule brute que les précédentes, est con-

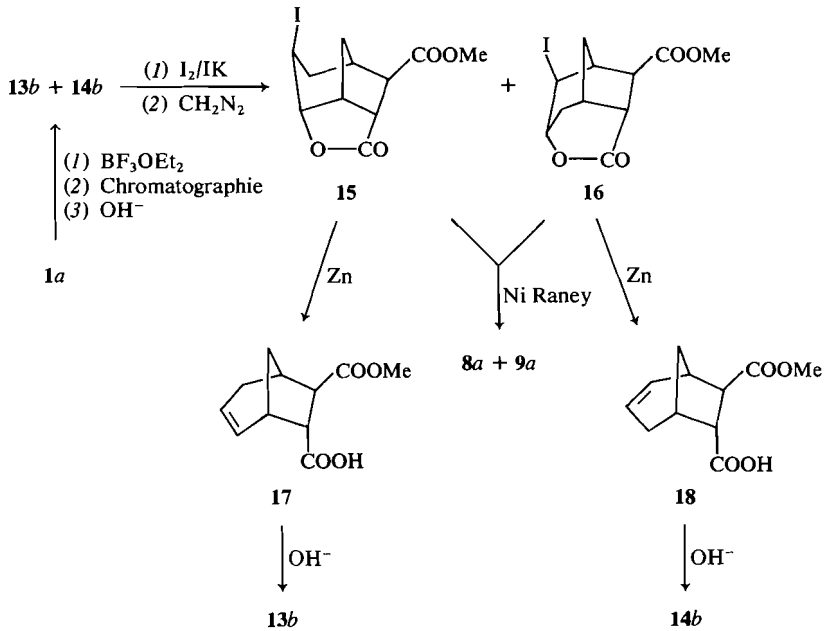

SCHÉMA 3

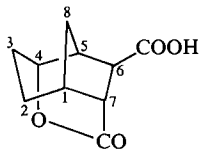

FIG. 2

stituée d'un mélange. Sur la base des spectres ir et de rmn des esters méthyliques dérivés **10***a*, et par comparaison avec des produits du même type (20), il est vraisemblable qu'il s'agit du mélange des deux isomères indiqués, à méthyles *exo* et *endo*. La présence inattendue d'un produit à méthyle *endo* pourrait résulter d'une isomérisation préalable du diacide **1***b* en composés méthyl-bicyclo[2.2.1]-hepténiques.

*Fraction 11*b

Il s'agit d'un mélange complexe constitué de formiates diacides de structure bicyclo[3.2.1]octanique comme l'indiquent les spectres ir et rmn des alcools-esters dérivés (deux isomères ont été isolés aprés acétylation: cf. Partie expérimentale).

*Fraction 12*b

Le spectre de rmn montre, outre des fonctions formiates, la présence de deux méthyles secondaires. Nous proposons donc qu'il s'agit d'un mélange de deux composés de structure méthyl-bicyclo[2.2.1]-heptanique indiqués.

*Fraction 13*b + *14*b

Le spectre de rmn dénote qu'il s'agit d'oléfines. Nous avons pu préparer un mélange des mêmes oléfines, en quantités plus importantes, par isomérisation du composé **1***a* en présence de BF_3–OEt_2, puis hydrolyse basique. La séparation des deux isomères s'est révélée possible au niveau des deux iodolactones (produits γ et δ lactoniques) formées intermédiairement (Schéma 3). Les identifications s'appuient sur les corrélations chimiques renforcées par les propriétés spectrographiques des composés.

Dans les mêmes conditions que pour le composé à cyclopropane *exo* **1***b*, l'isomère *endo* **2** s'ouvre en 0,5 heure et conduit à un mélange plus simple:

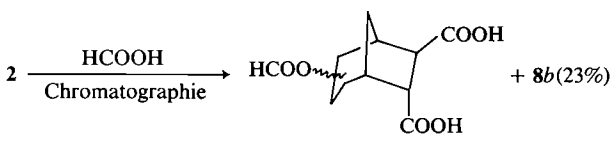

SCHÉMA 4

Le composé lactonique obtenu ici est absolument identique (ir, rmn) à la lactone **8***b* résultant de l'ouverture du composé **1***b*. On obtient également un mélange de formiates diacides en quantité importante (48%) dont nous n'avons pas jugé indispensable de séparer et identifier avec précision les composantes.

Discussion

Chacun des produits **8***b* et **9***b* ainsi que le mélange de **10***b*, **11***b* et **12***b* restent inchangés dans les conditions de la réaction. Le mélange **13***b* + **14***b* évolue peu mais conduit cependant à 2% des composés **10***b*, **11***b*, **12***b*, 2,5% de lactone **8***b* et 7,3% de lactone **9***b*; étant donné le pourcentage réduit d'oléfines **13***b* + **14***b* obtenu dans la réaction, on peut considérer, en première approximation, que les produits obtenus par formolyse proviennent directement de l'ouverture de **1***b* et **2**.

Le composé **1***b* a donc conduit en milieu acide à: (*a*) 16% d'oléfines résultant d'une isomérisation du noyau cyclopropanique; (*b*) 28% de formiates provenant de l'entrée du solvant (HCOOH) en tant que nucléophile; (*c*) 26,5% de lactones résultant de l'intervention de l'acide carboxylique interne. Notons que la formation de la lactone **9***b* implique une migration d'hydrure, phénomène déjà demontré dans certaines ouvertures de cyclopropanes en milieu acide (21).

On observe donc un taux de lactonisation réduit. Pour comparaison, l'ouverture en milieu acide de l'*exo*-tricyclo[3.2.1.$0^{2,4}$]octane avait donné lieu à 20% de transposition de Wagner–Meerwein (3). On peut s'étonner alors que la fonction carboxylique en position-7 dans le composé **1***b* n'ait pas participé de façon plus importante; en effet, il avait été constaté au cours de travaux sur l'ouverture d'époxy-bicyclo[2.2.1]heptanes (4*a*, 22) que la participation d'une fonction carboxyle est généralement beaucoup plus importante que celle d'une simple liaison par transposition de Wagner–Meerwein.

Il était cependant possible que l'attaque du nucléophile interne de **1***b*, qui doit prendre place en position-2 *endo* pour conduire à la lactone **8***b*, soit défavorisée par une exigence stéréoélectronique d'entrée en *exo* du nucléophile: en effet l'acétoxy-2 *exo* bicyclo[3.2.1] octane est le composé majoritaire formé lors de l'ouverture de l'*exo*-tricyclo[3.2.1.$0^{2,4}$]-octane (3), conformément à l'inversion de configuration souvent observée pour l'attaque nucléophile sur un cyclopropane protoné (23).

Il devenait alors interessant d'observer le comportement du composé **2**, à cyclopropane *endo*, pour lequel l'entrée du nucléophile interne en position-2 *endo* devrait être favorisée pour les mêmes raisons stéréoélectroniques que précédemment. On constate qu'en effet la proportion de lactone **8***b* augmente (23% contre 12% précédemment). Toutefois le pourcentage global de lactonisation reste sensiblement inchangé. Il est clair que la participation d'acides carboxyliques à l'ouverture acidocatalysée de cyclopropanes n'est pas aussi facile que celle qui avait été constatée lors de la solvolyse de cyclopropyl-carbinols (1*d*), ou encore au cours d'additions électro-

philes sur des norbornènes porteurs d'une fonction carboxylique (4).[5] Nous pensons que la différence réside dans la complexité du mécanisme d'ouverture acidocatalysée des cyclopropanes due à la présence de plusieurs sites et modes de protonations possibles (23*a*).

Puisque la participation du nucléophile interne n'est pas ici favorisée vis-à-vis de l'entrée du nucléophile externe, un procédé éventuel pour favoriser la lactonisation consistait à éliminer le nucléophile externe. En catalyse par le PTS dans le benzène, nous n'avons pas obtenu de résultats exploitables. En revanche, l'utilisation d'un acide de Lewis (BF_3–OEt_2), à la fois comme catalyseur et comme solvant, a permis l'obtention d'une forte proportion de lactones à partir du composé **1***b*:[6]

$$\mathbf{1}b \xrightarrow[(2)\quad OH^-]{(1)\ BF_3\text{–}OEt_2} \mathbf{8}b(56\%) + \mathbf{9}b(14{,}7\%) + \mathbf{10}b(13{,}3\%) + \mathbf{13}b \text{ et } \mathbf{14}b(10{,}9\%)$$

La γ-lactone **8***b* est maintenant le composé majoritaire avec 56% de rendement, le pourcentage global de lactone s'élevant à 84%. On peut cependant envisager ici que le processus de lactonisation soit consécutif, au moins en partie, à une isomérisation du cycle à trois carbones en oléfines **13***b* et **14***b*: en effet, placés dans des conditons parfaitement identiques, ces composés évoluent pour donner 47% de lactone **8***b* et 13,9% de lactone **9***b*, 26,1% des composés **13***b* et **14***b* restant inchangés. En effectuant, par rmn, une analyse à différents temps de réaction, de l'ouverture du noyau cyclopropanique, et de la lactonisation des composés éthyléniques, il nous est apparu difficile de trancher en faveur de l'une ou l'autre possibilité mécanistique. Ce travail nous a cependant permis de montrer que les acides γ-cyclopropyliques constituent une source valable de lactones.

Partie expérimentale

Indications générales

Les points de fusion, non corrigés, ont été déterminés en capillaires à l'aide de l'appareil du Dr. Tottoli. Les points d'ébullition sont indiqués par le sigle Eb_x où x représente la pression en Torr. Les chromatographies en phase vapeur (cpv) ont été réalisées dans l'une des conditions suivantes précisées pour chaque cas; condition A: appareil Carlo Erba Fractovap GT série 200 à ionisation de flamme, équipé d'une colonne de 2 m × 2 mm et de remplissage 5% SE 30 sur CGLA 80/100 mesh; condition B: appareil Intersmat IGC 120 DFL à ionisation de flamme, équipé d'une colonne de 1,5 m × 3,2 mm et de remplissage 10% SE 30 sur PAW 80/100 mesh; on indiquera le temps de rétention (t_r), la température de colonne (T_c) et la pression de gaz vecteur (P). Les spectres de résonance magnétique nucléaire du proton (rmn) ont été enregistrés à 60 MHz et température ambiente sur appareil Varian modèle EM-360 ou A-60; pour les spectres enregistrés à 90 et 100 MHz (précisé dans chaque cas), nous avons utilisé les modèles EM-390 et HA-100; les valeurs des déplacements chimiques sont données en ppm (référence interne TMS); les lettres s, d, t, q et m signifient respectivement singulet, doublet, triplet, quadruplet et multiplet. Les spectres d'infrarouge (ir) ont été enregistrés sur spectrophotomètre Perkin Elmer 221 ou 377, en solution 0,2 *M* sauf indication contraire; on indiquera pour les bandes principales les valeurs de ν_{max} en cm^{-1}. L'éther de pétrole utilisé pour les chromatographies et recristallisations a un point d'ébullition de 45°C à 60°C sous 760 Torr. Les analyses centésimales ont été effectuées au laboratoire de Microanalyse du C.N.R.S. à l'E.N.S.C. de Montpellier.

Diméthoxycarbonyl-6 exo, *7*-endo *H-2* endo *H-4* endo *tricyclo[3,2,1,0^{2,4}]octane*, ***I***a

On utilise en la modifiant légérement la méthode de Rawson et Harrison (5), le traitement du produit réactionnel étant effectué selon Shank et Shechter (25). On porte au reflux pendant 0,5 h, sous agitation et courant d'azote sec, un mélange constitué de 120 g de Zn en poudre, 18 g de CuCl, et 100 cm^3 d'éther anhydre (un barbotteur à H_2SO_4 est disposé en fin de montage). On laisse ensuite évaporer l'éther; lorsque le mélange est à sec, on ajoute 150 cm^3 d'éther anhydre, 15 g de diméthoxycarbonyl-2 *endo*, 3 *exo* bicyclo[2.2.1]heptène-5, puis goutte à goutte 75 cm^3 de CH_2I_2. On porte au reflux et suit l'avancement par cpv. Après 9 h le produit de départ a disparu.[7] Le mélange réactionnel est étendu à l'éther, filtré, acidifié (HCl 5%) et lavé ($NaHCO_3$ 10% puis H_2O/NaCl). On sèche (Na_2SO_4), concentre et distille. On obtient 12 g (75%) du composé **1***a*: $Eb_{0,05}$ 100–105°C; cpv (condition A, T_c 195°C, P 0,5 bar): 11 min 31 s; ir (CCl_4): 3075 et 3017 (CH cyclopropyliques), 1739 (C=O) cm^{-1}; rmn (CCl_4, 100 MHz) δ: 3,62 (s, 3H, COOMe), 3,59 (s, 3H, COOMe), 3,10 (t, 1H, J = 4,5 Hz, H-7), 2,82 (d, 1H, J = 4,5 Hz, H-6), 2,6 (m, 1H, $W_{\frac{1}{2}}$ = 7 Hz, H-1), 2,52 (1H, $W_{\frac{1}{2}}$ = 4 Hz, H-5), 0,93 (1H, $W_{\frac{1}{2}}$ = 4 Hz, H-8), 0,6 à 0,9 (8 raies; d'autres raies se trouvent sous le signal dû aux H-8, H-2 et H-4), 0,04 (5 raies, ddd, 1H, $J \simeq$ 6,5 Hz, 3 Hz et 3 Hz, H-3n), 0,03 (4 raies, ddd, 1H, $J \simeq$ 6,5 Hz, 7 Hz et 7 Hz, H-3x). *Anal.* calc. pour $C_{12}H_{16}O_4$: C 64,28, H 7,14; trouvée: C 64,0, H 7,1%.

Acide H-2 endo *H-4* endo *tricyclo[3.2.1.0^{2,4}]octane dicarboxylique-6* exo, *7* endo ***I***b

On agite 15 h un mélange de 12 g du diester **1***a* et 250 cm^3 d'une solution de soude 2,17 *M*. On lave à l'éther, acidifie à froid (HCl 50%) et extrait à AcOEt; la phase organique, séchée (Na_2SO_4) et concentrée, laisse 9,5 g (90%) du diacide **1***b* pratiquement homogène en ccm: *F* 187–188°C (AcOEt); ir (KBr): 2400 à 3600 large (OH acide), 1730 et 1710 (C=O) cm^{-1}; rmn (DMSO-d_6) δ: 11,6 (signal large, 2H, COOH), 3,01 (dd ≃ t, 1H, J = 4,5 et 4 Hz, H-7), 2,69 (d, 1H, J = 4,5 Hz, H-6), 2,4 à 2,6 (m, 2H, H-1 et H-5), 0,6 à 1,0 (m, 4H), 0,35 à 0,65 (m, 1H, H-3n), 0,06 (quatre raies, ddd, 1H, J = 6,5 Hz, H-3x). *Anal.* calc. pour $C_{10}H_{12}O_4$: C 61,22, H 6,17; trouvée: C 61,1, H 6,1%.

Mélange des diméthoxycarbonyl-6,7 tricyclo[3.2.1.0^{2,4}]-octénes-6 ***4*** *et* ***5***

On utilise le mode opératoire de Pincock et Wells (26); pour

[5]Afin d'éliminer l'influence d'éventuels caractères spécifiques des substrats utilisés, nous avons également étudié, dans les mêmes conditions, l'ouverture des acides *cis* et *trans* (bicyclo[3.1.0]hexyl)-2 acétiques. Nous avons obtenu un résultat semblable, soit 35% de lactonisation. Ce travail est décrit par ailleurs (24).

[6]Dans ces conditions, les fonctions carboxyliques libres ont conduit en partie à des esters éthyliques dûs à l'action de l'éthérate de trifluorure de bore.

[7]Le temps de réaction peut varier de 8 à 24 h selon les essais.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

4,16 g d'oléfine **3** (27), on utilise 4,95 g de CuCl et 3 cm³ d'éther et fait barbotter huit équivalents de CH_2N_2 générés au fur et à mesure (à partir de 25 g de *N*-nitrosométhylurée). Après 48 h, on filtre, concentre et distille. On obtient 3,3 g des composés **4** et **5** contenant également 7% d'oléfine **3** (rmn): *Eb* 115–125°C; ir (CCl_4): 3075 (CH cyclopropyliques), 1720 (C=O) et 1613 (C=C) cm^{-1}; rmn (CCl_4) on note en particulier δ: 3,68 (s, COOMe), 3,12 (signal large, 2H, $W_{\frac{1}{2}}$ = 4 Hz, H-1 et H-5), 0,65 à 1,65 (m, 6H).

Diméthoxycarbonyl-6,7 diendo *tricyclo[3.2.1.0^{2,4}]octanes* ***6*** et ***7***

On hydrogène, sous pression atmosphérique à température ambiante, 6,6 g de mélange ci-dessus dans 100 cm³ d'éthanol en présence de 666 mg de Pd/C 10%. Après 5 h, on filtre, concentre et chromatographie sur colonne de silice avec éther – éther de pétrole (25:75). On isole: (*a*) 4,73 g d'isomère **6** (liquide); cpv (condition B, T_c 170°C, *P* 1,3 bar): 14 min 18 s; rmn (CCl_4) δ: 3,6 (s, 6H, COOMe), 2,92 (signal large, 2H, $W_{\frac{1}{2}}$ = 4,7 Hz, H-6 et H-7), 2,52 (signal large, 2H, $W_{\frac{1}{2}}$ = 5,4 Hz, H-1 et H-5), 1,0 à 1,4 (m, 3H, H-2, H-4 et H-8), 0,75 (Partie A de AB à composantes élargies, *J* = 11,0 Hz, $W_{\frac{1}{2}}$ = 4 Hz, H-8), 0,42 (cinq raies: ddd, 1H, *J* = 6,5, 3 et 3 Hz, H-3n), 0,01 (quatre raies: ddd, 1H, *J* = 6,5, 7 et 7 Hz), spectre en accord avec celui décrit dans la littérature (*7b*); (*b*) 1,47 g de mélange **6** + **7**; (*c*) 0,42 g d'isomère **7**, souillé d'environ 10% de l'isomère *exo* **6** (rmn), *F* 62°C; cpv (condition B, T_c 170°C, *P* 1,3 bar): 14 min 18 s; caractéristiques rmn du composé **7** (CCl_4) δ: 3,75 (s, 6H, COOMe), 3,03 (signal large, 2H, $W_{\frac{1}{2}}$ = 5 Hz, H-6 et H-7), 2,73 (signal large, 2H, $W_{\frac{1}{2}}$ = 9,0 Hz, H-1 et H-5), 2,22 (dt, 1H, *J* = 8,5 et 2 Hz), 0,8 à 1,9 (m, 5H).

Acide H-2 exo *H-4* exo *tricyclo[3.2.1.0^{2,4}]octane dicarboxylique-6* exo, *7* endo, ***2***

On agite 0,448 g du diester **7** dans une solution aqueuse contenant 0,4 g de NaOH et quelques gouttes de méthanol pendant 15 h à température ambiante. On lave (Et_2O), acidifie à froid (HCl 50%), extrait à l'acétate d'éthyle; la phase organique est séchée (Na_2SO_4) et concentrée. On obtient 0,356 g (90%) d'acide **2** pratiquement homogène en ccm: *F* 230°C (AcOEt–Et_2O); ir (KBr): 2400 à 3600 large (O—H), 1690 avec épaulement à 1705 (C=O) cm^{-1}; rmn (DMSO-d_6, 90 MHz) δ: 11,2 à 11,8 (2H, COOH), 3,06 (t, 1H, *J* = 4,5 Hz, H-7), 2,35 à 2,75 (m, 2H, H-1 et H-5), 2,43 (d, 1H, *J* = 4,5 Hz, H-6n), 1,87 (Partie A de AB, 1H, *J* = 9 Hz, H-8s), 1,65 (Partie B de AB, 1H, *J* = 9 Hz, H-8a), 1,3 à 1,7 (m, 2H, H-2 et H-4), 0,60 à 1,15 (m, 2H, H-3); l'irradiation du massif dû à H-2 et H-4 affine le massif dû à H-1 et H-5 et modifie fortement le multiplet dû à H-3; l'irradiation de H-6n transforme H-7x en d et affine les signaux de H-8s de 1 Hz environ; l'irradiation de H-1 et H-5 transforme H-7x en singulet large, améliore le découplage du massif dû à H-2 et H-4 et affine le système AB dû aux H-8. *Anal.* calc. pour $C_{10}H_{12}O_4$: C 61,22, H 6,17; trouvée: C 60,8, H 6,1%.

Ouverture du diacide ***1***b

On porte à 80°C, 1,9 g de diacide **1***b* dissous dans 10 cm³ d'acide formique pur. L'avancement est suivi par rmn. Après 6 h, on élimine l'acide formique sous pression réduite et récupère un produit brut présentant quatre taches en ccm (silice, éther – éther de pétrole – acide formique 49,5:49,5:1). Par chromatographie sur colonne (mêmes conditions), on isole quatre fractions: (*a*) 235 mg (12%) de lactone **8***b*; (*b*) 200 mg (11%) de lactone **9***b*; (*c*) 1,04 g de mélange **10***b* + **11***b* + **12***b*; (*d*) 310 mg (16%) de mélange **13***b* + **14***b*.

Lactone de l'acide hydroxy-2 endo *bicyclo[3.2.1]octane dicarboxylique-6* exo, *7* endo, ***8***b

F 149–150°C (Ether–acétone); ir ($CHCl_3$): 2500 à 3500 large (OH), 1760 (C=O lactone), 1710 (C=O acide) cm^{-1}; rmn ($CDCl_3$, 100 MHz) δ: 10,86, (s, 1H, COOH), 4,96 (d, 1H, *J* = 9 Hz, $W_{\frac{1}{2}}$ = 13,5 Hz, H-2), 3,38 (dd, 1H, *J* = 8 et 1,8 Hz, H-7), 3,13 (six raies: ddd, 1H, *J* = 3,5, 9 et 9 Hz, H-1), 2,85 (signal large, 1H, $W_{\frac{1}{2}}$ = 4 Hz, H-6), 2,71 (dd, 1H, *J* = 10,0 et 3,5 Hz, H-5), 1,2 à 2,4 (m, 6H); l'irradiation de H-1 transforme H-2 en singulet large ($W_{\frac{1}{2}}$ = 8 Hz) et H-7 en massif ($W_{\frac{1}{2}}$ = 7 Hz); l'irradiation de H-2 transforme H-1 en massif ($W_{\frac{1}{2}}$ = 15 Hz). *Anal.* calc. pour $C_{10}H_{12}O_4$: C 61,22, H 6,17; trouvée: C 61,0, H 6,1%.

L'action d'un excès de diazométhane en solution éthérée sur 220 mg de **8***b* conduit à 210 mg (90%) de l'ester correspondant **8***a* pratiquement homogène en ccm (silice, éther – éther de pétrole 60:40), que l'on purifie par filtration sur colonne (mêmes conditions); ir ($CHCl_3$): 1762 (C=O lactone), 1730 (C=O ester) cm^{-1}; rmn ($CDCl_3$) δ: 4,95 (d, 1H, *J* = 8,2 Hz, $W_{\frac{1}{2}}$ = 12 Hz, H-2), 3,70 (s, 3H, COOMe), 2,9 à 3,5 (m, 2H), 2,4 à 2,9 (m, 2H), 1,1 à 2,4 (m, 6H).

Lactone de l'acide hydroxy-3 endo *bicyclo[3.2.1]octane dicarboxylique-6* exo, *7* endo, ***9***b

F 159–160°C (Ether–acétone); ir (KBr): 2500 à 3600 large (OH), 1720 (C=O) cm^{-1}; rmn (DMSO-d_6, 100 MHz) δ: 12,48 (signal large, COOH), 4,53 (signal large, 1H, $W_{\frac{1}{2}}$ = 8 Hz, H-3), 3,26 (d, 1H, *J* = 8 Hz, H-7), 2,90 (signal large, 1H, $W_{\frac{1}{2}}$ = 3,4 Hz, H-6), 2,45 à 2,75 (m, 2H, H-1 et H-5), 1,5 à 2,0 (m, 6H); l'irradiation de H-1 et H-5 transforme H-3 en multiplet ($W_{\frac{1}{2}}$ = 7 Hz) et H-7 en singulet. *Anal.* calc. pour $C_{10}H_{12}O_4$: C 61,22, H 6,17; trouvée: C 61,1, H 6,1%.

L'action d'un excès de diazométhane en solution éthérée sur 0,8 g de **9***b* dissous dans quelques cm³ de diméthoxy-1,2 éthane conduit, après dilution à AcOEt, lavage (Na_2Co_3 10%, puis à l'eau), séchage (Na_2SO_4) et concentration à 0,8 g (90%) de l'ester correspondant **9***a*: *F* 113°C (éther–acétone); ir ($CHCl_3$): 1738 (C=O ester et lactone) cm^{-1}; rmn ($CDCl_3$) δ: 4,65 (signal large, 1H, $W_{\frac{1}{2}}$ = 9 Hz, H-3), 3,72 (s, 3H, COOMe), 3,52 (d, 1H, *J* = 7, 7 Hz, H-7), 3,05 (signal large, 1H, $W_{\frac{1}{2}}$ = 3,5 Hz, H-6), 2,77 (signal large, 2H, $W_{\frac{1}{2}}$ = 11 Hz, H-1 et H-5), 1,45 à 2,25 (m, 6H). *Anal.* calc. pour $C_{11}H_{14}O_4$: C 62,85, H 6,71; trouvée: C 62,9, H 6,6%.

Analyse du mélange des composés ***10***b + ***11***b + ***12***b

On agite 3,8 g du mélange considéré pendant 15 h à température ambiante dans 50 cm³ de NaOH à 8%. On dilue (H_2O), lave (Et_2O), acidifie à froid (HCl 50%) et extrait à AcOEt. La phase organique est séchée (Na_2SO_4) et concentrée sous vide (1 Torr). On obtient 3,1 g de produit brut que l'on estérifie par un excès de diazométhane dans du diméthoxy-1,2 éthane. Après traitement, on récupère 5,3 g de produit brut que l'on chromatographie sur colonne de silice avec éther – éther de pétrole (50:50). On obtient: (*a*) 293 mg (3,5% par rapport à **1***b*) de **10***a*; (*b*) 250 mg (3% par rapport à **1***b*) de **12***a*-OH; (*c*) 2,16 g (25% par rapport à **1***b*) de **11***a*-OH.

Fraction ***10***a: ir ($CHCl_3$): 1772 (C=O lactone), 1732 (C=O ester) cm^{-1}; rmn ($CDCl_3$) δ: 4,92 (signal large, 0,3H, $W_{\frac{1}{2}}$ = 15 Hz, H-2), 4,35 (d, 0,7H, *J* = 4,7 Hz, $W_{\frac{1}{2}}$ = 8 Hz, H-2), 3,73 (s, 3H, COOMe), 2,9 à 3,4 (m, 2H), 2,74 (signal large, 1H, $W_{\frac{1}{2}}$ = 4,5 Hz), 2,51 (signal large, 1H, $W_{\frac{1}{2}}$ = 5 Hz), 1,2 à 2,4 (m, 3H), 1,01 (d, 2,1 H, *J* = 6,5 Hz, CH—*Me*), 0,96 (d, 0,9H, *J* = 6,5 Hz, CH—*Me*). *Anal.* calc. pour $C_{11}H_{14}O_4$: C 62,85, H 6,71; trouvée: C 62,8, H 6,8%.

Fraction ***12***a-*OH*: rmn ($CDCl_3$) δ: 3,6 à 4,0 (m, 1H, *CH*—OH), 3,71 (s, 6H, COOMe), 3,14 (dd, 1H, *J* = 6 et 4 Hz), 2,6 à 2,9 (m, 2H avec signal se déplaçant par dilution), 2,47 (signal large, 1H), 2,15 à 2,55 (m, 1H), 1,2 à 1,1 (m, 3H), 1,14 (d, 0,9H, *J* = 7,2 Hz, CH—*Me*), 0,93 (d, 2,1H, *J* = 7,5 Hz, CH—*Me*); ce mélange d'alcools est acétylé: à 0,168 g de ces derniers on ajoute à 0°C, 0.2 cm³ d'Ac_2O et 2 cm³ de pyridine,

puis abandonne 15 h. On ajoute de la glace, puis extrait à AcOEt. On élimine la pyridine (lavage par $CuSO_4$ en solution aqueuse saturée), lave (H_2O, Na_2CO_3 10% puis H_2O/NaCl), sèche (Na_2SO_4), concentre et filtre sur colonne de silice avec éther – éther de pétrole (80:20). On obtient 143 mg (78%) de mélange d'acétates **12***a*-OAc; ir ($CHCl_3$): 1730 (C=O), 1200 large (C—O—C) cm^{-1}; rmn ($CDCl_3$) δ: 4,5 à 5,0 (signal large, 1H, avec d à 4,86, J = 7, 4 Hz, CH—OAc), 3,70 (s, 6H, COOMe), 3,05 à 3,35 (m, 1H), 1,2 à 3,0 (m, 7H), 2,05 et 2,02 (deux s, 3H, O—CO—CH_3), 1,07 (d, 0,9H, J = 7, 3 Hz, CH—*Me*), 0,86 (d, 2,1H, J = 7,3 Hz, CH—*Me*). *Anal.* calc. pour $C_{14}H_{20}O_6$: C 59,14, H 7,09; trouvée: C 59,8, H 7,1%.

Fraction **11***a*-*OH*: celle-ci se compose de deux sous fractions séparées par chromatographie sur colonne de silice avec éther – éther de pétrole (60:40). La 1ère sous-fraction (48%): rmn (DMSO-d_6) on note en particulier à δ: 4,3 à 4,6 (six raies qui disparaissent par addition de CF_3–COOH, 1H, OH), 3,67, 3,64 et 3,62 (trois s, 6H, COOMe). 0,29 g de ce mélange est acétylé selon la technique utilisée pour les alcools **12***a*-OH. Après filtration sur colonne de silice avec éther – éther de pétrole (80:20), on obtient 262 mg d'acétates (77%); ir ($CHCl_3$): 1729 (C=O), 1200 large (C—O—C) cm^{-1}. *Anal.* calc. pour $C_{14}H_{20}O_6$: C 59,14, H 7,09; trouvée: C 59,1, H 7,0%. La 2ème sous-fraction (52%): rmn (DMSO-d_6) on note en particulier à δ: 4,70 (d, 0,7H, J = 3,5 Hz, OH disparaît par addition de CF_3-COOH), 4,61 (d, 0,3H, J = 3,5 Hz, OH, disparait par addition de CF_3–COOH), 3,65 et 3,62 (deux s, 6H, COOMe); 1,2 g de ce mélange est acétylé comme précédemment. On obtient 1,2 g (91%) d'acétates; ir ($CHCl_3$): 1730 (C=O), 1250 et 1202 (C—O—C) cm^{-1}. *Anal.* calc. pour $C_{14}H_{20}O_6$: C 59,14, H 7,09; trouvée: C 59,2, H 7,1%. Par cpv préparative (colonne 200 × 1 cm de SE 30 15% sur CPLA 30/60 mesh, T_c 200°C, P 0,8 bar), on parvient à isoler le diméthoxycarbonyl-6 *exo*, 7 *endo* acétoxy-4 *exo* bicyclo-[3.2.1]octane; rmn ($CDCl_3$, 100 MHz) δ: 4,94 (signal large, 1H, $W_{\frac{1}{2}}$ = 11 Hz, H-4), 3,73 (s, 3H, COOMe), 3,46 (t, 1H, J = 6 Hz, H-7), 3,16 (d, 1H, J = 6 Hz, H-6), 2,65 (m, 2H, $W_{\frac{1}{2}}$ = 11 Hz, H-1 et H-5), 2,06 (s, 3H, O—CO—CH_3), 1,4 à 2 (m, 6H, H-3, H-4 et H-8); et le diméthoxycarbonyl-6 *exo*, 7 *endo* acétoxy-2 *exo* bicyclo[3.2.1]octane; rmn ($CDCl_3$, 100 MHz) δ: 4,86 (signal large, 1H, $W_{\frac{1}{2}}$ = 9 Hz, H-2), 3,74 (s, 3H, COOMe), 3,70 (s, 3H, COOMe), 3,51 (t, 1H, J = 6,5 Hz, H-7), 3,19 (d, 1H, J = 6,5 Hz, H-6), 2,75 (signal large, 1H, $W_{\frac{1}{2}}$ = 18 Hz, H-1), 2,49 (signal large, 1H, $W_{\frac{1}{2}}$ = 11 Hz, H-5), 2,05 (s, 3H, O—CO—CH_3), 1,45 à 2 (m, 6H).

Analyse du mélange des composés **13**b *et* **14**b

Ce mélange présente le spectre de rmn suivant (DMSO-d_6, 100 MHz) δ: 5,2 à 6,2 (m, 2H, H éthyléniques), 3,1 à 3,45 (m, 1,57H), 2,86 (d, large, 0,43H, J = 7 Hz), 1,5 à 2,8 (6H). La présence d'un signal d'intégration inférieure à 1H montre qu'il s'agit d'un mélange; l'obtention des produits purs exposée ci-dessous a permis d'en établir la composition par rmn, soit 43% de **13***b* et 57% de **14***b*.

Isomérisation du composé **1**a

On place 5,1 g du composé tricyclique **1***a* dans 11 cm^3 de BF_3–OEt_2 préalablement distillé sur CaH_2. On porte à 90°C et suit l'avancement par rmn. Après 2 h 50 min on étend à l'éther, neutralise (K_2CO_3 10%), décante et extrait la phase aqueuse à l'éther. Les phases organiques jointes sont séchées (K_2CO_3) puis concentrées et chromatographiées sur colonne de silice avec éther – éther de pétrole (20:80). On obtient: (*a*) 3,7 g de mélange des esters méthyliques et éthyliques des composés **13** et **14**. Ce mélange est agité 15 h avec une solution de soude à 8%. On acidifie à froid (HCl 50%) et extrait à AcOEt. La phase organique est séchée (Na_2SO_4) et concentrée, puis estérifiée par un excès de diazométhane en solution éthérée. On obtient 3,2 g (63% global) d'un mélange contenant 64% de **13***a* et 36% de **14***a*; rmn ($CDCl_3$) δ: 5,2 à 6,2 (m, 2H), 3,7 (s, 6H, COOMe), 3,3 à 3,7 (m, 1,36H), 3,15 (d, 0,64H, J = 7 Hz, H-6 de **13***a*), 1,5 à 3,0 (m, 6H); (*b*) 113 mg (2,2%) de l'ester éthylique du mélange **10***b*, structure attribuée par comparaison du spectre de rmn avec celui de **10***a*: rmn ($CDCl_3$): 4,90 (signal à allure de t, 0,4H, J = 6 Hz), 4,19 (q, 2,6H, J = 7 Hz se superpose à un autre signal), 2,9 à 3,3 (m, 2H), 2,74 (signal large, 1H, $W_{\frac{1}{2}}$ = 4,5 Hz), 2,50 (signal large, 1H, $W_{\frac{1}{2}}$ = 5 Hz), 1,9 à 2,4 (m, 1H), 1,5 à 1,9 (m, 2H), 1,28 (t, 3H, J = 7 Hz), 1,02 et 0,96 (deux doublets, 3H, J = 7 Hz, CH_3), contient également des esters méthyliques à 3,73 (COOMe); (*c*) 430 mg (9%) du mélange **10***a*.

Iodolactonisation du mélange des composés **13**b *et* **14**b

On opère selon la référence 28 à partir de 7,3 g de mélange d'olefines **13***b* et **14***b* (dans le rapport 64:36), 28,5 cm^3 de MeOH, 12,5 cm^3 de soude à 20% et 118 cm^3 de bicarbonate de soude à 5%. Après traitement, on sèche (Na_2SO_4), concentre et estérifie par un excès de diazométhane en solution éthérée. On obtient 11,7 g de produit brut présentant deux taches en ccm (silice, benzène–éther 97:3) dans les proportions 57:43 (rmn). Par recristallisation on isole 470 mg (3,7%) de l'iodolactone minoritaire, soit la lactone de l'acide hydroxy-3 *endo* iodo-4 méthoxycarbonyl-6 *exo* bicyclo[3.2.1]octane carboxylique-7 *endo*, **16**; F 120–121°C (benzène–éther); ir ($CHCl_3$): 1740 (C=O δ-lactone et ester) cm^{-1}; rmn ($CDCl_3$) δ: 4,76 (signal large, 1H, $W_{\frac{1}{2}}$ = 7,5 Hz), 4,63 (m, 1H, $W_{\frac{1}{2}}$ = 7,5 Hz), 3,72 (s, 3H, COOMe), 3,54 (d, 1H, J = 8 Hz, H-7x), 3,13 (signal large, 2H, $W_{\frac{1}{2}}$ = 5 Hz), 2,5 à 3,0 (m, 1H), 2,2 à 2,5 (m, 1H), 1,5 à 2,2 (m, 3H). *Anal.* calc. pour $C_{11}H_{13}O_4I$: C 39,28, H 3,86, I 37,79; trouvée: C 39,0, H 4,0, I 37.8%.

Une chromatographie, sur colonne de silice avec benzène–éther (97:3), des eaux-mères de la recristallisation ci-dessus permet d'isoler 1,23 g (9,8%) de la lactone de l'acide hydroxy-2 *endo* iodo-3 méthoxycarbonyl-6 *exo* bicyclo[3.2.1]octane carboxylique-7 *endo*, **15**; ir ($CHCl_3$): 1778 (C=O γ-lactone), 1735 (C=O ester) cm^{-1}; rmn ($CDCl_3$) δ: 5,28 (d, 1H, J = 7,4 Hz, CH—OCO), 4,36 (d, 1H, J = 7 Hz, CH—I), 3,73 (s, 3H, COOMe), 1,5 à 3,6 (8H). *Anal.* calc. pour $C_{11}H_{13}O_4I$: C 39,28, H 3,86, I 37,79; trouvée: C 39,3, H 4,1, I 36,9%.

Deshalogénation des composés **15** *et* **16**

On opère selon la référence 29: on porte au reflux 45 min, 336 mg de mélange de **15** et **16** (59:41, rmn), 2,8 g de Ni Raney et 18 cm^3 d'EtOH. On étend à l'eau, extrait à l'acétate d'éthyle. La phase organique est séchée (Na_2SO_4), concentrée et chromatographiée sur colonne de silice avec éther – éther de pétrole (30:70). On obtient 51 mg (26%) de **8***a* et 35 mg (18%) de **11***a* (ccm, ir).

Acide méthoxycarbonyl-6 exo *bicyclo[3.2.1]octène-2 carboxylique-7* endo, ***17***

On opère selon la référence 30. On porte au reflux 1 h, 560 mg de l'iodolactone **15**, 250 mg de Zn en poudre et 10 cm^3 de pyridine anhydre; on étend à l'eau, acidifie à froid (HCl 20%) et extrait (AcOEt). La phase organique est lavée (H_2O), séchée (Na_2SO_4), concentrée et chromatographiée sur colonne de silice avec éther – éther de pétrole – acide formique (14,5:84,5:1). On obtient 179 mg (55%) du composé **17**; F 120–121°C (éther – éther de pétrole); ir ($CHCl_3$): 2400 à 3600 large (OH acide), 1730 (C=O ester), 1710 (C=O acide) cm^{-1}; rmn ($CDCl_3$) δ: 11,2 (s large, 1H, COOH), 5,3 à 6,1 (m, 2H, H éthyléniques), 3,71 (s, 3H, COOMe), 3,51 (dd, 1H, J = 5,5 et 7 Hz, H-7), 3,10 (dd, 1H, J = 7 et 1 Hz, H-6), 2,45 à 3,0 (2H), 2,0 à 2,45 (2H), 1,5 à 2,0 (2H). *Anal.* calc. pour $C_{11}H_{14}O_4$: C 62,85, H 6,71; trouvée: C 62,9, H 6,5%.

Acide bicyclo[3.2.1]octène-2 dicarboxylique-6 exo, *7* endo, ***13***b

On agite 200 mg du composé précédent, 15 h dans 4 cm³ de NaOH 8% et 5 cm³ de MeOH. On lave (Et_2O), acidifie à froid (HCl 50%) et extrait (AcOEt). La phase organique est lavée (H_2O), séchée (Na_2SO_4) et concentrée. On obtient 150 mg (81%) de **13***b* purifié par filtration sur silice; *F* 195–197°C; ir (KBr): 2300 à 3600 large (OH acide), 1710 et 1692 (C=O) cm^{-1}; rmn (DMSO-d_6, 100 MHz) δ: 10,9 (2H, COOH), 5,77 (dd large, 1H, J = 6,0 et 10 Hz, $W_{\frac{1}{2}}$ = 18 Hz, H-2), 5,46 (d large, J = 10 Hz, $W_{\frac{1}{2}}$ = 16 Hz, H-3), 3,23 (dd, 1H, J = 5 et 6,5 Hz, H-7), 2,86 (d, 1H, J = 6,5 Hz, H-6), 2,6 à 2,8 (1H), 2,25 à 2,6 (2H), 1,8 à 2,15 (1H), 1,45 à 1,80 (2H). *Anal.* calc. pour $C_{10}H_{12}O_4$: C 61,22, H 6,17; trouvée: C 60,9, H 6,1%.

Acide méthoxycarbonyl-7 exo *bicyclo[3.2.1]octène-2 carboxylique-6* endo, ***18***

Comme précédemment, mais à partir de 337 mg d'iodolactone **16**, on obtient 139 mg (66%) du composé attendu; *F* 99–100°C; ir ($CHCl_3$): 2400 à 3600 large (OH acide), 1725 (C=O ester), 1710 (C=O acide) cm^{-1}; rmn ($CDCl_3$) δ: 11,3 (s, 1H, COOH), 6,0 (dd, 1H, J = 9,5 et 7 Hz, H-2), 5,44 (dt, 1H, J = 9,5 et 3 Hz, H-3), 3,70 (s, 3H, COOMe), 3,3 à 3,7 (m, 2H, H-6 et H-7), 2,5 à 3,1 (2H), 2,0 à 2,4 (2H), 1,7 à 2,0 (2H). *Anal.* calc. pour $C_{11}H_{14}O_4$: C 62,85, H 6,71; trouvée: C 62,8, H 6,7%

Acide bicyclo[3.2.1]octène-2 dicarboxylique-6 endo, *7* exo, ***14***b

On hydrolyse 100 mg du composé précédent selon la méthode utilisée pour l'obtention de **13***b*. On obtient 77 mg (82%) de diacide **14***b*; *F* 215–217°C; ir (KBr): 2300 à 2600 large (OH acide), 1700 (C=O) cm^{-1}; rmn (DMSO-d_6, 100 MHz) δ: 10,7 (large, 2H, COOH), 5,95 (dd, 1H, J = 9,5 et 7 Hz, H-2), 5,37 (dt, 1H, J = 9,5 et 3 Hz, H-3), 3,34 (Partie A de AB, J_{AB} = 5 Hz, dédoublée, J = 7 Hz, H-6x), 3,18 (Partie B de AB, J_{AB} = 5 Hz, H-7n), 1,5 à 2,8 (6H). *Anal.* calc. pour $C_{10}H_{12}O_4$: C 61,22, H 6,17; trouvée: C 60,9, H 6,1%.

Ouverture du diacide ***2***

On porte à 80°C, 150 mg de diacide **2** dans 1 cm³ d'acide formique et suit l'avancement en rmn. Après 0,5 h on concentre et chromatographie sur colonne de silice avec éther – éther de pétrole – acide formique (64,5:34,5:1). On obtient (*a*) 15 mg (10%) du composé de départ; (*b*) 90 mg (48%) des composés **19** qui présentent deux taches en ccm (éther – éther de pétrole – acide formique: 79,5:19,5:1); ir ($CHCl_3$): 2400 à 3600 large (OH acide), 1712 (C=O) cm^{-1}; rmn ($CDCl_3$) δ: 10,7 (large, 2H, COOH), 8,12 (s, 0,68H, O—COH), 7,00 (s, 0,32H, O—COH), 5,07 (signal large, 2H, $W_{\frac{1}{2}}$ = 14 Hz, *CH*—OCOH), 3,2 à 3,7 (2H), 2,72 (signal large, 2H, $W_{\frac{1}{2}}$ = 14 Hz), 1,2 à 2,2 (6H); (*c*) 34 mg (23%) de lactone **8***b* (ir, rmn).

Stabilité des produits dans les conditions réactionnelles

Chacun des produits ou mélanges est porté 6 h à 80°C dans l'acide formique. La lactone **8***b*, la lactone **9***b*, le mélange **10***b* + **11***b* + **12***b* restent inchangés (CCM, rmn); 440 mg d'un mélange **13***b* + **14***b* (80:20, rmn) conduisent, après chromatographie sur colonne de silice avec éther – éther de pétrole – acide formique (49,5:49,5:1) à: (*a*) 385 mg (88%) de mélange **13***b* + **14***b* (80:20) (ccm, rmn); (*b*) 8 mg (2%) de mélange de **10***b* + **11***b* + **12***b* (ccm, rmn); (*c*) 11 mg (2,5%) de lactone **8***b* (CCM); (*d*) 32 mg (7,3%) de lactone **9***b* (ccm, ir).

Ouverture du diacide ***1***b *par* BF_3–OEt_2

On porte à 90°C, 1,4 g de diacide **1***b* dans 5 cm³ de BF_3–OEt_2 préalablement distillé sur CaH_2. La disparition du noyau cyclopropanique est suivie par rmn. Après 2 h, on étend à l'éther, neutralise à froid (K_2CO_3 10%) puis acidifie toujours à froid (HCl 50%). On décante et extrait à AcOEt. La phase organique, lavée (H_2O), séchée (Na_2SO_4) puis concentrée, laisse 1,46 g de produit brut. Après hydrolyse (NaOH 8%, 15 h), les composantes, séparées par chromatographie sur gel de silice, sont reconnues par rmn et ir pour les lactones **8***b* et **9***b*, et rmn pour les autres fractions. Le rendement global après chromatographie est de 95%, les proportions relatives étant indiquées dans la discussion.

Action de BF_3–OEt_2 *sur les oléfines diacides* ***13***b *et* ***14***b

Dans les mêmes conditions que ci-dessus, 490 mg de mélange **13***b* + **14***b* (73:27, rmn) conduisent à 26,1% de mélange **13***b* + **14***b* (80:20, rmn) qui n'a pas réagi, 47% de lactone **8***b* et 13,9% de lactone **9***b*.

Synthesis and bromination of 3-alkyl-5α-cholestan-2-one

C. AKIRA HORIUCHI AND J. YASUO SATOH

Department of Chemistry, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-ku, Tokyo, Japan

Received January 27, 1981

C. AKIRA HORIUCHI and J. YASUO SATOH. Can. J. Chem. **59**, 2382 (1981).

3β-Alkyl-5α-cholestan-2-ones (R = CH_3, C_2H_5, and $CH_3CH_2CH_2$) were prepared by the direct alkylation of 5α-cholestan-2-one with alkyl iodide and potassium *tert*-butoxide in a reflux of *tert*-butyl alcohol – benzene. The bromination of these 3β-alkyl ketones gave 3α-bromo-3β-alkyl-5α-cholestan-2-one.

C. AKIRA HORIUCHI et J. YASUO SATOH. Can. J. Chem. **59**, 2382 (1981).

On a préparé les alkyl-3β cholestan-5α ones-2 (R = CH_3, C_2H_5 et $CH_3CH_2CH_2$) en alkylant directement la cholestan-5α one-2 avec un iodure d'alkyle en présence du *tert*-butylate de potassium dans un mélange d'alcool *tert*-butylique – benzène au reflux. La bromation des cétones alkylées en position 3β conduit à la bromo-3α alkyl-3β cholestan-5α one-2.

[Traduit par le journal]

The methylation of steroids which have an oxo group in ring A has been investigated (1–4), and the preparation of methyl ketones using hydroxymethylene derivatives of 5β-stigmast-22-en-3-one (5) and of pregn-4-ene-3,20-dione (6) has also been described. More recently, the present authors reported (7) the direct alkylation of 5β-cholestan-2-one and the bromination of these alkyl ketones. In the present paper, the direct alkylation of 5α-cholestan-2-one with alkyl iodide (RI; R = CH_3, C_2H_5, or $CH_3CH_2CH_2$) and potassium *tert*-butoxide is described, together with the bromination of these alkyl derivatives.

Results and Discussion

The reaction of 5α-cholestan-2-one (**1**) with alkyl iodide (RI; R = CH_3, C_2H_5, and $CH_3CH_2CH_2$) and potassium *tert*-butoxide yielded the corresponding alkylated ketones (**2***a* (8, 9), **2***b*, and **2***c*). Each alkylated ketone showed a weak positive Cotton effect in the cd spectrum compared with that of 5α-cholestan-2-one (**1**). By comparison with the cd spectra of the 3β-methyl ketone (**2***a*), the alkyl ketones (**2***b* and **2***c*) were presumed to be 3β-ethyl- (**2***b*) and 3β-propyl-5α-cholestan-2-one (**2***c*). Spencer *et al.* (10) had reported that the methylation of the α-bromo ketone with zinc powder – methyl iodide in benzene – dimethyl sulfoxide (10:1) in a nitrogen atmosphere gave the α-methyl ketone. The reaction of 3α-bromo-5α-cholestan-2-one (**4**) with methyl iodide in the presence of zinc powder according to the procedures described by Spencer afforded compound **5***a* in 80% yield. This product **5***a* was isomerized by treatment with concentrated sulfuric acid in ethanol to give the stable compound **2***a*. On the synthesis of 3α-methyl-5α-cholestan-2-one, Jones and Grayshan (8) reported that a 2β-hydroxy-3α-methyl derivative was obtained from 2β,3β-epoxy-5α-cholestane through the epoxy ring opening with 2-lithio-1,3-dithian and desulfurization. The method used in the present work, which was that described by Spencer *et al.*, gave a better yield than Jones and Grayshan's method.

The bromination of the alkylated ketones (**2***a*, **2***b*, and **2***c*) gave the bromo derivative (**3***a*, **3***b*, or **3***c*). On the basis of the cd, ir, and nmr spectral data for **3***a*, **3***b*, and **3***c*, these bromo derivatives were determined to be 3α-bromo-3β-alkyl-5α-cholestan-2-ones. This finding was supported by the fact that the bromo derivatives (**3***a*, **3***b*, and **3***c*) were reduced with sodium borohydride to give the bromohydrins (**6***a*, **6***b*, and **6***c*). The nmr spectra of these bromohydrins showed a quartet at δ 2.94 ppm (J = 4.5 and 11.25 Hz) for **6***b*, and a multiplet at δ 3.00 ppm ($W/2$ = 33 Hz) for **6***c* assignable to the 2β-H of an axial character. Compound **6***a* was converted to the bromohydrin acetate (**7***a*). The nmr spectrum of this bromohydrin acetate showed a quartet at δ 4.21 ppm (J = 5.0 and 11.0 Hz) assignable to the 2β-H of an axial character. Therefore, **6***a*, **6***b*, and **6***c* were presumed to be 2α-hydroxy-3α-bromo-3β-alkyl-5α-cholestane. By treating these bromohydrins with potassium hydroxide, the corresponding 3β-alkyl ketone (**2***a*, **2***b*, or **2***c*) was obtained. These results showed that a hydroxyl group and a bromine atom of the bromohydrins (**6***a*, **6***b*, and **6***c*) were *cis*, and this led to 3α-bromo-3β-alkyl-2α-hydroxy-5α-cholestane structures for these bromohydrins.

It was found that the enolisation of the methyl ketone (**2***a*) with 60% perchloric acid – acetic anhydride occurred in the direction of a carbon atom possessing a methyl group, as shown by the nmr spectra. The bromination of the enolisation product (**8***a*) of the methyl ketone yielded the 3α-bromo-3β-methyl ketone (**3***a*).

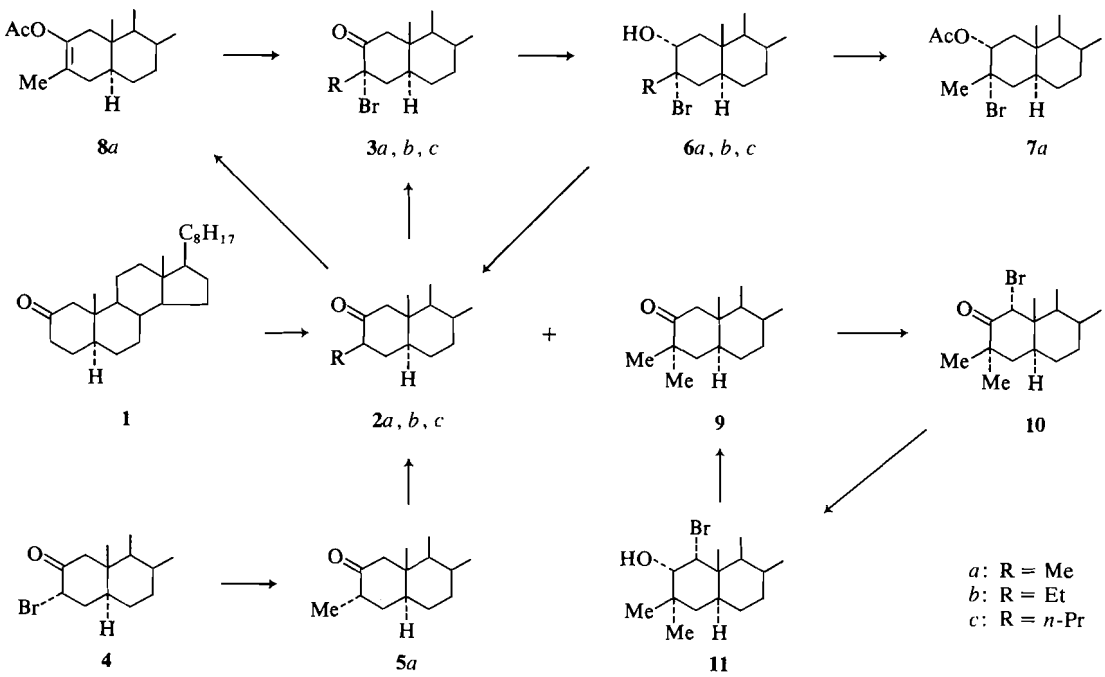

SCHEME 1

These results show that the enolisation of the alkylated ketone occurs at the C(2)—C(3) position. The bromination of the 3β-alkyl ketone occurs at a carbon atom having an alkyl group, namely, the C(3)α-bond, as has been reported for the bromination of the alkylated ketone (2).

The reaction of 5α-cholestan-2-one (**1**) with excess methyl iodide yielded the dimethylated ketone (**9**) and 3β-methyl ketone (**2***a*). The bromination product of the former was presumed to be 1α-bromo-3,3-dimethyl ketone (**10**) from the sign of the Cotton effect, and Δ[θ]- and $\Delta\lambda_1$-values (+15 600 and +30 nm, as compared with the corresponding values for the dimethylated ketone (**9**)) in the cd spectrum, the shift of the C=O stretching band (1700 cm^{-1}) in the ir spectrum, and from the signal (δ 4.04 ppm, singlet) due to the C(1)HBr in the nmr spectrum. From these spectral data, it can be considered that the conformation in the A-ring of **10** is a little distorted due to the 1:3-interaction between the C(1)α—Br bond and the C(3)α—Me bond.

The bromo ketone (**10**) was then converted to the dimethylated bromohydrin (**11**) by reduction with sodium borohydride, as described above. By treatment of **11** with potassium hydroxide in ethanol under refluxing conditions, the dimethylated ketone (**9**) was obtained. From these results, the dimethylated bromohydrin (**11**) was identified as 1α-bromo-2α-hydroxy-3,3-dimethyl-5α-cholestane.

Thus, on the basis of all of the foregoing results, it was concluded that the α-alkylation of 5α-cholestan-2-one (**1**) occurred at the C(3) position, as has been reported for the case of the condensation (9) of 5α-cholestan-2-one (**1**) with ethyl formate. It was further concluded that the enolisation of the alkylated ketone occurred in the direction of C(3), and that the bromination of these alkylated ketones gives the 3α-bromo-3β-alkyl ketones. These results are also in agreement with the facts that the alkylation of 5β-cholestan-2-one occurs at the C(3) position, and the enolisation and the bromination of the alkylated ketone occur in the direction of C(3).

Experimental

All the melting points are uncorrected. The ir and cd spectra were measured using a Hitachi model 215 grating infrared spectrophotometer and a model J-20 spectropolarimeter. The nmr spectra were measured in carbon tetrachloride, with TMS as the internal standard, using a nuclear magnetic resonance spectrometer, Hitachi-Perkin Elmer R-20A. The high-resolution mass spectra were recorded on JMS-O1SG-2 (JEOL) instrument with direct inlet at 75 eV.

*3β-Methyl-5α-cholestan-2-one (***2a***)*

A mixture of **1** (1.0 g), methyl iodide (9.5 mL), and potassium *tert*-butoxide (400 mg) in *tert*-butyl alcohol – dry benzene (1:1) (20 mL) was refluxed under stirring in a nitrogen atmosphere for

4 h. The solvent was then removed under reduced pressure; the residue was poured into water and extracted with ether. The ethereal solution was washed with water, dried, and evaporated under reduced pressure. Crystallization of the residue from ethanol–acetone gave needles of **2***a* (383 mg), mp 149–151°C (lit. (8) mp 151–153°C); ir (KBr): 1708 cm^{-1}; cd (*c* 0.0806, Di) at 24.5°C: $[\theta]_{302}$ +6517 (peak), $[\theta]_{298}$ +6268 (trough), and $[\theta]_{293}$ +6566 (peak).

The mother liquor was evaporated under reduced pressure and the resultant oil was chromatographed on silica gel. Elution with benzene gave needles of **1** (490 mg), mp 127–129°C.

*3β-Ethyl-5α-cholestan-2-one (***2b***)*

A mixture of **1** (1.69 g), potassium *tert*-butoxide (680 mg), and ethyl iodide in *tert*-butyl alcohol – benzene was treated according to the procedure described for the methylation of **1**. After the usual work-up, the resultant oil was chromatographed on silica gel. Elution with hexane–benzene (1:1) gave needles of **2***b* (357 mg) from ethanol, mp 110–113°C; ir (KBr): 1705 cm^{-1}; cd (*c* 0.427, Di) at 20°C: $[\theta]_{312}$ +2912 (shoulder), $[\theta]_{302}$ +4707 (peak), $[\theta]_{298}$ +4561 (trough), and $[\theta]_{295}$ +4658 (peak). *Anal.* calcd. for $C_{29}H_{50}O$: C 83.99, H 12.15; found: C 84.22, H 11.94.

*3β-Propyl-5α-cholestan-2-one (***2c***)*

A mixture of **1** (1.69 g), potassium *tert*-butoxide (680 mg), and propyl iodide (6.3 mL) in *tert*-butyl alcohol – benzene (1:1) was treated according to the procedure described for the methylation of **1**. After the usual work-up, the resultant oil (1.99 g), on crystallization from ethanol, gave needles of **2***c* (835 mg), mp 118–120°C; ir (KBr): 1707 cm^{-1}; cd (*c* 0.360, Di) at 23°C: $[\theta]_{363}$ +5740 (peak), $[\theta]_{299}$ +5574 (trough), and $[\theta]_{295}$ +5693 (peak). *Anal.* calcd. for $C_{30}H_{52}O$: C 84.04, H 12.23; found: C 84.35, H 12.40.

*3α-Methyl-5α-cholestan-2-one (***5a***)*

The bromo ketone (**4**) (1.0 g) in benzene – dimethyl sulfoxide (10:1) (55 mL) was stirred with zinc powder (2.5 g) and methyl iodide (12.5 mL) in a nitrogen atmosphere at 40–45°C for 3 h. After the usual work-up, crystallization from methanol afforded plates of **5***a* (690 mg), mp 124–125°C (lit. (8) mp 127–128°C); ir (KBr): 1705 cm^{-1}; cd (*c* 0.199, Di) at 23°C: $[\theta]_{304}$ +8256 (peak), $[\theta]_{301}$ +8175 (trough), and $[\theta]_{296}$ +8578 (peak).

*Isomerization of 3α-Methyl-5α-cholestan-2-one (***5a***)*

3α-Methyl ketone (**5***a*) (15 mg) in ethanol (10 mL) was treated with a few drops of concentrated sulfuric acid under reflux for 2 h. After the usual work-up, crystallization from methanol afforded needles of **2***a* (10 mg) (mp 150–152°C).

*3α-Bromo-3β-methyl-5α-cholestan-2-one (***3a***)*

The methylated ketone (**2***a*) (260 mg) in acetic acid (16 mL) was treated with bromine (114 mg) in acetic acid (3.2 mL) containing a few drops of 48% hydrobromic acid at room temperature for 20 min. The reaction mixture was taken up in ether, and the ethereal extracts were washed with a sodium hydrogen carbonate solution and water, then dried and evaporated. Crystallization of the residue from methanol gave needles of **3***a* (213 mg), mp 192–195°C; ir (KBr): 1708 cm^{-1}; cd (*c* 0.102, Di) at 24.5°C: $[\theta]_{314}$ +25797 (peak). *Anal.* calcd. for $C_{28}H_{47}OBr$: C 70.11, H 9.88; found: C 70.09, H 9.86.

*3α-Bromo-3β-ethyl-5α-cholestan-2-one (***3b***)*

The bromination of **2***b* (250 mg) was carried out using the technique described for the synthesis of 3α-bromo-3β-methyl-5α-cholestan-2-one. After the usual work-up, the resultant oil, on crystallization from methanol–ether, gave plates of **3***b* (213 mg), mp 154–156°C; ir (KBr): 1705 cm^{-1}; cd (*c* 0.367, Di) at 20°C: $[\theta]_{315}$ +18846 (peak). *Anal.* calcd. for $C_{29}H_{49}OBr$: C 70.57, H 10.01; found: C 70.64, H 10.19.

*3α-Bromo-3β-propyl-5α-cholestan-2-one (***3c***)*

The bromination of **2***c* (400 mg) was carried out using the technique described for the synthesis of 3α-bromo-3β-methyl-5α-cholestan-2-one. After the usual work-up, the resultant oil, on crystallization from ethanol, gave needles of **3***c* (278 mg), mp 100–102°C; ir (KBr): 1707 cm^{-1}; cd (*c* 0.470, Di) at 23°C: $[\theta]_{317}$ +12529 (peak). *Anal.* calcd. for $C_{30}H_{51}OBr$: C 70.98, H 10.13; found: C 70.85, H 9.80.

*3,3-Dimethyl-5α-cholestan-2-one (***9***)*

The ketone (**1**) (1.0 g) in *tert*-butyl alcohol – dry benzene (1:1) (25 mL) was treated with methyl iodide (4.0 mL) and potassium *tert*-butoxide (3.0 g) under refluxing in a nitrogen atmosphere for 5 h. After the usual work-up, the resultant oil (1.06 g) was chromatographed on silica gel (100 g). Elution with benzene (300 mL) gave plates of **9** (317 mg) from acetone, mp 156–157.5°C; ir (KBr): 1700 cm^{-1}; cd (*c* 0.293, Di) at 26°C: $[\theta]_{304}$ +12791 (peak), $[\theta]_{300}$ +12225 (trough), and $[\theta]_{296}$ +12791 (peak). *Anal.* calcd. for $C_{29}H_{50}O$: C 83.99, H 12.15; found: C 84.04, H 12.16.

Eluted with the same solvent (200 mL), the next fraction, on crystallization from ethanol–acetone, gave 3β-methyl-5α-cholestan-2-one (**2***a*) (130 mg), mp 149–150°C.

*1α-Bromo-3,3-dimethyl-5α-cholestan-2-one (***10***)*

The bromination of **9** (667 mg) was carried out using the technique described for the synthesis of **3***a*. After the usual work-up, the resultant oil, on crystallization from acetone, gave plates of **10** (534 mg), mp 134–134.5°C; ir (KBr): 1700 cm^{-1}; nmr (CCl_4) δ: 4.04 (1H, s); cd (*c* 0.253, Di) at 26°C: $[\theta]_{324}$ −2807 (trough). *Anal.* calcd. for $C_{29}H_{49}OBr$: C 70.57, H 10.01; found: C 70.34, H 9.95.

*The Enolisation of 3β-Methyl-5α-cholestan-2-one (***2a***)*

This enolisation was carried out according to the method described for 5β-cholestan-2-one (11). The reaction product gave plates of 2-acetoxy-3-methyl-5α-cholest-2-ene (**8***a*) from ethanol, mp 69–71°C; ir (KBr): 1754 and 1712 cm^{-1}; nmr (CCl_4) δ: 2.05 (3H, s). *Mol. Wt.* calcd. for $C_{30}H_{50}O_2$: 442.3808; found (ms): 442.3814. A mixture of **8***a* (20 mg), bromine (7.9 mg) in tetrachloromethane, and tetrachloromethane (10 mL) containing a few drops of epichlorohydrin was prepared in accordance with the directions described for 2-acetoxy-5β-cholest-1-ene (11). After the usual work-up, the resultant oil, on crystallization from ethanol, gave needles of **3***a* (16 mg), mp 192–195°C.

*Confirmation of the Configuration of 3α-Bromo-3β-alkyl-5α-cholestan-2-one (***3a***, 3b, or 3c) by Chemical Reactions*

The bromo derivative (**3***a*) (30 mg) in methanol–ether (1:2) (10 mL) was treated with sodium borohydride (10 mg) at room temperature. After 10 min, water was added and the mixture was extracted with ether. The ethereal solution was washed with water, dried, and evaporated under reduced pressure. Attempts to crystallize the resultant oil (**6***a*) were unsuccessful, and the product was used for the next step without purification (ir (NaCl): 3550 cm^{-1}). In the case of **3***b* (100 mg) and **3***c* (100 mg), crystallization from ethanol afforded plates of **6***b* (23 mg), mp 133–134°C; ir (KBr): 3410 cm^{-1}; nmr (CCl_4) δ: 2.94 (1H, dd, J = 4.5 and 11.5 Hz); *Mol. Wt.* calcd. for $C_{29}H_{51}OBr$: 494.3121; found (ms): 494.3061; and **6***c* (52 mg), mp 133–135°C; ir (KBr): 3550 cm^{-1}; nmr (CCl_4) δ: 3.00 (1H, m, $W/2$ = 33 Hz). *Mol. Wt.* calcd. for $C_{30}H_{53}OBr$: 508.3278; found (ms): 508.3286. A mixture of the methyl bromohydrin (**6***a*) (30 mg), acetic anhydride (5 mL), and pyridine (5 mL) was allowed to stand at room temperature overnight. After the usual work-up, the resultant oil, on crystallization from ethanol, afforded needles of **7***a*, mp 123–125°C; ir (KBr): 1735 and 1240 cm^{-1}; nmr (CCl_4) δ:

4.21 (1H, dd, J = 5 and 11 Hz). *Mol. Wt.* calcd. for $C_{30}H_{51}O_2Br$: 522.3070; found (ms): 522.3085. The alkylated bromohydrin (**6***a*, **6***b*, or **6***c*) (15 mg) in ethanol (5 mL) was treated with a solution of potassium hydroxide (9 mg) in the same solvent (3 mL) and the mixture was refluxed for 2 h. Ethanol was then removed under reduced pressure, and the residue was diluted with water and extracted with ether. The ethereal solution was washed with water, dried, and evaporated under reduced pressure. Crystallization of the residue from ethanol gave needles of **2***a* (10 mg), mp 149–151°C, **2***b* (11 mg), mp 109–112°C, and **2***c* (8 mg), mp 108–113°C, respectively.

*Confirmation of the Configuration of 1α-Bromo-3,3-dimethyl-5α-cholestan-2-one (**10**) by Chemical Reactions*

The dimethylated bromo ketone (**10**) (134 mg) in methanol–ether (26 mL) was treated with sodium borohydride (45 mg) at room temperature. After the usual work-up, the resultant oil, on crystallization from ethanol–ether, gave needles of dimethylated bromohydrin (**11**) (74 mg), mp 125.5–127°C; ir (KBr): 3550 cm^{-1}; nmr (CCl_4) δ: 4.48 (1H, d, J = 3.0 Hz) and 3.51 (1H, d, J = 3.0 Hz). *Mol. Wt.* calcd. for $C_{29}H_{51}OBr$: 494.3121; found (ms): 494.3088. A mixture of **11** (300 mg) and potassium hydroxide (24 mg) in ethanol (10 mL) was allowed to react according to the procedure described for the synthesis of 3β-methyl ketone (**2***a*) from 3-methyl bromohydrin (**6***a*). After the usual work-up, the resultant oil, on crystallization from ethanol, gave needles of **9** (17 mg), mp 153–155°C.

Deuterium isotope exchange between molecular hydrogen and cyclopentylamine[1]

E. ALLAN SYMONS[2] AND MICHEL J. CLERMONT

Physical Chemistry Branch, Atomic Energy of Canada Limited, Research Company, Chalk River Nuclear Laboratories, Chalk River, Ont., Canada K0J 1J0

Received February 9, 1981

E. ALLAN SYMONS and MICHEL J. CLERMONT. Can. J. Chem. **59**, 2386 (1981).

Over the temperature range −68 to −10°C the ability of the alkali metal cyclopentylamide salts to catalyze deuterium exchange between D_2 and cyclopentylamine (CPA) is in the order CsCPA ≥ KCPA > NaCPA ≫ LiCPA. The rate constant ratio at −68°C for CsCPA/LiCPA is $> 10^3$. The measured Arrhenius activation parameters and kinetic isotope effect data are only slightly different for the Li and Na salts. The in-solution exchange reaction is so fast for the KCPA and CsCPA catalysts that rate constants independent of mass transfer could not be measured for them in the stirred gas/liquid reactor even at −68°C.

The gas solubility isotope effect, sie = $[D_2]/[H_2]$, has been determined in CPA over the range −50 to +25°C. From the values obtained (e.g. 1.08 at 25°C, 1.10 at −25°C) and the limited literature data available it appears that the sie for hydrogen gas may be greater for polar than for nonpolar solvents.

E. ALLAN SYMONS et MICHEL J. CLERMONT. Can. J. Chem. **59**, 2386 (1981).

Dans l'intervalle de température allant de −68 à −10°C la tendance des sels de cyclopentylamide de métal alcalin à catalyser l'échange de deutérium entre le D_2 et la cyclopentylamine (CPA) est dans l'ordre suivant: CsCPA ≥ KCPA > NaCPA ≫ LiCPA. Le rapport des constantes de vitesse à −68°C est $> 10^3$ pour le CsCPA/LiCPA. Les paramètres d'activation d'Arrhénius mesurés et les données d'effet isotopique cinétique sont légèrement différentes pour les sels de Li et de Na. La réaction d'échange en solution est si rapide avec les catalyseurs KCPA et CsCPA qu'on ne peut pas mesurer leurs constantes de vitesse indépendantes du transfert de masse dans un réacteur gaz/liquide sous agitation même à −68°C.

On a déterminé l'effet isotopique de la solubilité du gaz eis $[D_2]/[H_2]$ dans le CPA dans l'intervalle de −50 à 25°C. A partir des valeurs obtenues (par exemple 1,08 à 25°C, 1,10 à −25°C) et à partir des données limitées disponibles il apparait que le eis de l'hydrogène à l'état gazeux peut être plus grand dans les solvants polaires que dans les solvants non polaires.

Introduction

Hydrogen isotope exchange between molecular hydrogen and organic amines is of interest for possible development of more efficient deuterium extraction processes. We have previously reported the results for a study of catalysis of exchange between D_2 and cyclohexylamine (CHA) by alkali metal cyclohexylamides (1). Two particular problems were encountered in trying to determine kinetic isotope effects in that system: (*a*) for the cesium and potassium salts the exchange reaction was so fast even at −15°C that rate constants independent of stirring rate in the gas/liquid reactor could not be obtained, and (*b*) for the sodium and lithium salts, although chemically-limited rate constants were measured, it was difficult to derive completely reliable k_{HD} values by computer analysis of the experimental data (eq. [1]). It was suggested that a change to the similar cyclopentylamine (CPA) as solvent, with its much lower freezing point (−85.7°C vs. −17.8°C for CHA), would permit kinetic measurements at lower temperature where mass transfer effects in the apparatus should be reduced (1).

$$[1]\quad D_2 \xrightarrow{k_{D_2}} HD \xrightarrow{k_{HD}} H_2$$

Several series of kinetic runs have been carried out using various CPA salts as catalysts, and with D_2 and HD gases, at temperatures as low as −68°C. The solubilities of both H_2 and D_2 in CPA have been measured over the temperature range +25 to −70°C.

Experimental

Reagents

The H_2, D_2, methylamine, alkali metals, and alkali metal hydrides were obtained and used as previously described (1). Cyclopentylamine was purchased from both Aldrich Chemical Co. and Tokyo Kasei Kogyo Co. Ltd., Japan (through CTC Organics, Atlanta, GA). It was first purified by fractional distillation (main fraction 107.4–108.4°C at 100.4 kPa; lit. (2) 108.5°C, and (3) 108.0°C at 101.3 kPa). Drying was done under vacuum over fresh potassium metal, ultimately with the solvent temperature raised above 64°C to provide molten K spheres.

A lecture bottle of compressed HD (30 L at STP) was purchased from Merck, Sharp & Dohme Canada Ltd. Mass spectral analysis indicated a purity of 98.4 mol% HD, with most of the balance being D_2. *CAUTION*. We originally attempted to synthesize a large batch of HD by scaling up a literature procedure for controlled reaction between $LiAlH_4$ and D_2O (4). A one litre stainless steel tank system had been pressure-tested to the equilibrium pressure expected for 2.6 moles of HD. The tank (containing $LiAlH_4$, distilled dimethoxydiethyl ether as a powder-dispersing agent, and D_2O added at liquid nitrogen

temperature) was being "warmed" in an ice/water bath when a poorly connected metal fitting failed. Considerable damage was done to a fumehood in the chemical explosion that followed blowout of the contents. Although failure of the fitting was important it is possible that the accident was precipitated by a rapid pressure rise (i.e. a thermal runaway process (5)) caused by poor heat transfer through the steel tank wall.

CPA Vapour Pressure

The vp of purified CPA was determined using the isoteniscope method (6) over the temperature range −23 to +25°C. The bulb volume was 25 mL. The pressure was measured with a Heise gauge. The experimental data are given in Table 1. Agreement with values calculated using the equation of Good *et al.* (7) is within ± 0.04 kPa (0.3 mm) over most of the temperature range.

Hydrogen Solubility in CPA

Solubilities were determined by a gas chromatographic procedure as before (1). The instrument response was calibrated with H_2 and D_2 gas as appropriate. A net hydrogen pressure of 101 kPa was maintained in the gas/liquid equilibration flask; the solvent vapour pressure was interpolated from the data in Table 1.

Catalyst Solutions and Kinetic Runs

The LiCPA, NaCPA, KCPA, and CsCPA catalyst solutions were prepared and analyzed as described for the corresponding CHA solutions (1). As with CHA, only Cs metal reacts directly with the cyclic amine; the methylamide salts were used as the intermediates for the others. KH does react with CPA, but only slowly at 90°C, while LiH is unreactive.

Most isotope exchange runs were carried out in the modified gas/liquid reactor (1). Analysis of the $D_2/HD/H_2$ gas mixtures was by mass spectrometry; the calibration problems encountered in the earlier work were only partly alleviated by incorporating D^+ corrections of 1–2% for the equilibrated standard mixtures and kinetic samples.

For the LiCPA and NaCPA catalysts, rate constants independent of stirring rate were obtained above 8000 r min^{-1}. However, for the KCPA and CsCPA catalysts, rate constants independent of mass transfer effects could not be determined even at −68°C and 20 000 r min^{-1}.

The vapour/solution conversion factors used to calculate the in-solution rate constants for exchange ranged between 200 and 400 depending on reaction vessel volume and temperature; k_{obs}(solution) = factor × k_{obs}(vapour) (1).

A calibration curve relating the solution temperature in the stirred reactor to the bath temperature (Neslab LT9 unit) was prepared by using a thermocouple inserted in the solution compartment of the reactor. The differential between the solution and bath temperatures increased with decreasing bath temperature and increasing stirring rate (10 000 to 20 000 r min^{-1}). The correction to the solution temperature varied from +0.2 at −10°C to +1.0–1.8 at −50°C and +2.2–3.8 at −70°C. The time to reach "operating" solution temperature from stirrer startup increased from < 5 min at −10°C to 10 min at −50°C and 30 min at −70°C; kinetic samples were not usually taken during this period.

Results

H_2 and D_2 Solubility in CPA

The data are plotted in Fig. 1. Computer analysis of each set, via a linear least squares program, produced the following second order fit equations, where the concentrations are expressed as mole fraction and T is the solution temperature in °C:

$$10^4\,[H_2] = 2.041 + 0.0178\,T + 0.0000452\,T^2$$

$$10^4\,[D_2] = 2.235 + 0.0188\,T + 0.0000339\,T^2$$

The standard deviations for H_2 and D_2 were ± 0.040 × 10^{-4} and ± 0.056 × 10^{-4} respectively.

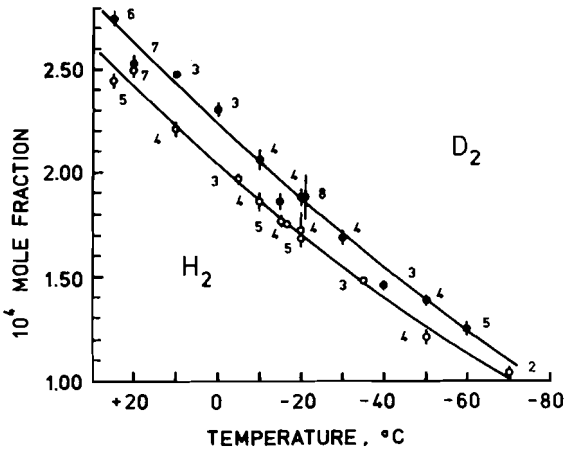

FIG. 1. The solubility of H_2 and D_2 in cyclopentylamine at 101 kPa gas pressure. The figures beside the points refer to the number of experimental measurements averaged for each point, while the range is indicated by the vertical bars.

Where solubility data were required as mol L^{-1} (e.g. for calculation of the vapour/solution conversion factors (1)), the mole fraction values were converted using solvent density. The limited data available for CPA density at 0 to 30°C (2) were extrapolated linearly down to −70°C. The resulting error should be less than one percent; for example, the density of liquid methylamine is known to be very nearly a linear function of temperature over the same temperature range (8).

The measured enthalpies of solution for H_2 and D_2 are 5.4 ± 0.5 and 5.2 ± 0.5 kJ mol^{-1} at 0°C; the ln (mol fraction) versus $1/T$ plots (9) are slightly curved, with ΔH being larger at higher T. The entropies of solution, obtained from plots of ln (mol fraction) versus ln T (9), are 19.7 ± 2.0 and 19.4 ± 2.0 J mol^{-1} K^{-1} for H_2 and D_2 over the range −50 to +25°C (standard state 101 kPa gas pressure). The corresponding enthalpy and entropy values for H_2 in CHA were 6.6 ± 0.4 kJ mol^{-1} and 24.4 ± 2.0 J mol^{-1} K^{-1} at 0°C (1).

D_2 and HD Exchange with CPA

Activation energies, E_a, determined from the temperature dependence of the k_{obs} (solution) rate constants for exchange of D_2 and HD with CPA, catalyzed by LiCPA (0.23 mol L^{-1}, −10 to −50°C, 3–4 points) and NaCPA (0.07–0.10 mol L^{-1}, −20 to −50°C, 3–4 points), are given in Table 2. The Arrhenius plots were all quite linear ($R = 0.998 - 1.000$). These results were obtained with different batches of catalyst solution over a period of more than a year; the reproducibility is clearly better in the case of LiCPA.

The averaged values of E_a for these two catalysts (Table 2) were used with kinetic rate constant data at −50°C (k_2(solution) = k_{obs}(solution) ÷ [catalyst]$_{stoich}$) to calculate the entropies of activation. The results were: for LiCPA, −158 J mol^{-1} K^{-1}; for NaCPA, −143 J mol^{-1} K^{-1}.

Even at −70°C the KCPA (0.048 mol L^{-1}) and CsCPA (0.15 mol L^{-1}) catalyzed reactions were not independent of stirring rate up to 20 000 r min^{-1}, the limit available. The following are, therefore, only the minimum k_2(solution) rate constants for these two very effective catalysts for D_2 exchange: for KCPA at −67°C, 10 L mol^{-1} s^{-1}; for CsCPA at −67°C, 10 L mol^{-1} s^{-1}.

The kinetic isotope effect values, $2k_{HD}/k_{D_2}$, presented in Table 3, were obtained in one of three ways from the "vapour phase" (1) rate constant data. For separate kinetic runs involving D_2 and HD with the same catalyst solution, the independent rate constants were used. For individual D_2 runs carried out under conditions of no interference from mass transfer effects, a "best fit" k_{HD} can be calculated from the D_2/HD/H_2 distribution as a function of time (1). Also, for the HD runs the decreasing D_2 concentration, initially ca. 2 mol%, could be employed to obtain k_{D_2}. As can be seen in Table 3, the magnitude of the isotope effect was somewhat dependent on the method of calculation.

TABLE 2. Activation energies for LiCPA and NaCPA catalyzed deuterium exchange between D_2, HD, and CPA at −10 to −50°C

LiCPA(0.23 mol L^{-1})		NaCPA(0.07–0.10 mol L^{-1})	
Gas	E_a, kJ mol^{-1}	Gas	E_a, kJ mol^{-1}
D_2	28.9	D_2	29.9
D_2	29.5	D_2	21.1†
D_2	27.9*	HD	23.7†
HD	32.4*		

*Same catalyst solution stock.
†Same catalyst solution stock.
Averaged values: for LiCPA, 30 ± 2 kJ mol^{-1}; for NaCPA, 25 ± 4 kJ mol^{-1}.

TABLE 3. Kinetic isotope effects for exchange between D_2/HD and CPA*

Catalyst	$2k_{HD}/k_{D_2}$	Temperature °C	Method†
LiCPA	2.7	−10	A
(0.23 mol L^{-1})	2.2	−30	A
	1.8	−30	A
	2.4	−30	B
	1.5	−10	C
	1.2	−30	C
NaCPA	2.4	−20	A
(0.07–0.10 mol L^{-1})	2.4	−30	A
	2.0	−50	A
	2.9	−20	B
	3.8	−20	B
	2.9	−30	B
	3.0	−50	B
	1.6	−20	C
	1.6	−30	C
	1.4	−50	C
KCPA	2.2‡	−58	A
(0.048 mol L^{-1})	2.0‡	−58	A
	1.2‡	−69	A

*Values are based on "vapour phase" (1) rate constants. Since HD is probably about 5% less soluble than D_2 (cf. D_2 and H_2 solubility data, Fig. 1 and text), the pn-solution kie figures will be about 5% greater than shown.
†Method A: independent D_2 and HD runs; B: computer fit of data for D_2 runs; C: D_2 decrease during HD runs (see text for details).
‡k_{obs} data *not* independent of mass transfer interference.

Discussion

H_2 and D_2 Solubility in CPA

Over the temperature range −60 to +25°C the curve for H_2 solubility in CPA falls between those for H_2 in methylamine (lower) and ethylamine (10). Also, H_2 is about 15% less soluble in CPA than in CHA above the latter's freezing point (1).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

H_2 and D_2 concentrations obtained from the equations given above were used to calculate the following values of the $[D_2]/[H_2]$ ratio as a function of temperature: 1.08 at 25°C, 1.09 at 0°C, 1.10 at −25°C, and 1.09 at −50°C. The estimated error ranges from ± 0.03 to ± 0.05. There is very little data in the literature pertaining to the solubility isotope effect for hydrogen gas in polar liquids. In water, D_2 is reported to be more soluble than H_2, with the ratio being 1.065 at 30°C and 1.086 at 5°C (11). More recent data for water are the following (12): 1.055 at 60°C, 1.066 at 30°C, and 1.074 at 5°C. In dimethyl sulfoxide $[D_2]/[H_2] = 1.050$ at 25°C (17).

Cook *et al.* (13) had earlier found that D_2 was 2–4 percent more soluble than H_2 in a series of eight nonpolar solvents (including benzene, carbon tetrachloride, and octane) over the temperature range −35 to +35°C. Thus the solubility isotope effect for D_2/H_2 would appear to be significantly larger for polar than nonpolar solvents, judging from the information available to date.

It is usual for the heavier isotopic species of a pair to have the higher solubility. The difference in zero point energy of the isotopic gas molecules oscillating in solvent cages is considered to be a major contributor to the observed effect (11).

D_2 and HD Exchange with CPA

The catalytic reactivity of the CPA salts is in the order CsCPA ≥ KCPA > NaCPA ≫ LiCPA, the same as observed for the CHA salts in cyclohexylamine (1). Although a literature value for the dielectric constant of CPA was not found, it is likely to be quite low, comparable to that for CHA (4.5 at 20°C). As a result, the catalyst solutions will contain ion pairs and larger ion aggregates but few free cyclopentylamide ions (14).

It is not possible to compare directly the kinetic reactivity of all the alkali metal salts in the CHA and CPA systems for D_2 exchange catalysis, since the temperature regions examined do not overlap significantly (−15 to +15°C for CHA (1) versus −67 to −9°C for CPA). However, in-solution rate constants for the Li salts are similar at −9°C: 2.0×10^{-2} s^{-1} for 0.23 mol L^{-1} LiCPA and 0.9×10^{-2} s^{-1} for 0.08 mol L^{-1} LiCHA.

The measured Arrhenius activation energies are higher in CPA than CHA, e.g. 25 versus 11 kJ mol^{-1} for the sodium salt, while $\Delta S^{\ddagger}$ values average −150 cal mol^{-1} K^{-1} for CPA and −200 cal mol^{-1} K^{-1} for CHA (1). For both CHA and CPA solvents E_a is ca. 5 kJ mol^{-1} lower for the sodium than the lithium salt. It is probable that differences in the extent of ion aggregation are responsible for these effects.

The available kinetic isotope effect (kie) data for the Li, Na, and K salts of CPA, recorded in Table 3, show a significant dependence on the method of calculation. However, two trends are clear: the kie values generally decrease with decreasing temperature for a given method; and the values are comparable for the three catalyst salts, within an experimental error of ±0.2, for a given temperature and method. The reason for the dependence on method of determination is not known. Method B (Table 3) should be valid for experimental conditions where the measured rate constants are independent of mass transfer (1).

The kie values appear fairly small, in the approximate range 2 to 3, but this is still quite consistent with rate-determining proton transfer from molecular hydrogen (15). The mechanism for the exchange reaction involving CPA should parallel that for the CHA system; detailed discussion for the latter is available (1).

It was originally hoped that the various kinetic parameters associated with the D_2/CPA exchange reaction could be determined for the full range of alkali metal cations (Li^+ to Cs^+), in order to identify the role of the cation–cyclopentylamide anion interaction in the reaction. However, it has proved to be impossible to obtain kinetically usable rate constant data for the very active potassium and cesium salts, using the stirred gas/liquid reactor. A thin liquid film type of apparatus, such as the single sphere absorber system of Kalra and Otto (16), would be more suitable.

Crystal and molecular structures of three transition metal complexes incorporating the anionic tridentate chelating ligands $[Me_2Ga(N_2C_5H_7)OCH_2CH_2SR]^-$ where R = Et or Ph

STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received January 23, 1981

STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **59**, 2391 (1981).

X-ray crystallographic studies of three transition metal complexes incorporating the novel anionic tridentate chelating ligand $[Me_2Ga(N_2C_5H_7)OCH_2CH_2SR]^-$ (R = Et or Ph) show that the ligand is facially coordinated in each case. Crystals of [dimethyl(3,5-dimethyl-1-pyrazolyl) (2-thioethoxyethoxy)gallato(*N*(2), *O*,*S*)]nitrosylnickel(I) are monoclinic, a = 8.8313(4), b = 7.2402(2), c = 26.539(1) Å, β = 94.390(3)°, Z = 4, space group $P2_1/c$, R = 0.040 and R_w = 0.050 for 2489 reflections. The Ni atom is in a distorted tetrahedral environment with bond angles about Ni ranging from 87.90(7) to 127.9(1)°. The nitrosyl coordination is slightly non-linear with Ni—N—O = 170.1(4)°. Important bond lengths (corrected for libration) are: Ni—S, 2.326(1), Ni—O, 2.019(2), Ni—N(pyrazolyl), 1.980(3), Ni—N(O), 1.633(3) and N—O, 1.156(4) Å. Crystals of [dimethyl(3,5-dimethyl-1-pyrazolyl) (2-thiophenoxyethoxy)gallato(*N*(2),*O*,*S*)]tricarbonylmanganese(I) are triclinic, a = 9.4911(5), b = 10.4323(6), c = 11.7618(7) Å, α = 86.17(1), β = 69.547(5), γ = 81.402(4)°, Z = 2, space group $P\bar{1}$, R = 0.029 and R_w = 0.035 for 2496 reflections. The Mn atom is coordinated to the *fac*-tridentate gallate ligand and to three carbonyl ligands resulting in a slightly distorted octahedral geometry. Important corrected bond lengths are: Mn—S, 2.397(1), Mn—O, 2.055(2), Mn—N, 2.082(3), and Mn—C, 1.794(4), 1.807(4), and 1.807(4) Å. Crystals of [dimethyl(3,5-dimethyl-1-pyrazolyl) (2-thioethoxyethoxy)gallato(*N*(2),*O*,*S*)][η^3-cycloheptatrienyl)dicarbonylmolybdenum are monoclinic, a = 17.030(3), b = 19.097(2), c = 15.908(3) Å, β = 115.99(1)°, Z = 8, space group $P2_1/n$, R = 0.036 and R_w = 0.043 for 4477 reflections. The two crystallographically independent molecules differ primarily in the orientation of the *S*-ethyl moiety and each contains an η^3-C_7H_7 ligand which occupies one coordination site of a distorted octahedron as a π-donating ligand. Important corrected bond distances are: Mo—S, 2.527(2) and 2.541(2), Mo—O, 2.241(5) and 2.237(4), Mo—N, 2.277(5) and 2.254(5), Mo—C(O), 1.940(7)–1.960(7), and Mo—C(C_7H_7), 2.198(6)–2.391(7) Å.

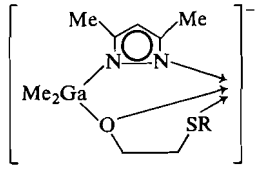
STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **59**, 2391 (1981).

Des études par diffraction des rayons-X des complexes métalliques tridimensionnels incorporant le nouveau ligand chélatant tridentate anionique $[Me_2Ga(N_2C_5H_7)OCH_2CH_2SR]^-$ (R = Et ou Ph) révèlent que le ligand est coordonné dans chaque cas d'une manière faciale. Les cristaux de [diméthyl(diméthyl-3,5 pyrazolyl-1) (thioéthoxy-2 éthoxy) gallato (*N*(2),*O*,*S*)] nitrosylnickel(I) sont monocliniques avec a = 8,8313(4), b = 7,2402(2), c = 26,539(1) Å, β = 94,390(3)°, Z = 4, groupe d'espace $P2_1/c$, R = 0,040 et R_w = 0,050 pour 2489 réflexions. L'atome de Ni se situe dans un environnement tétraédrique déformé avec des angles de liaison autour du Ni que se situent entre 87,90(7) et 127,9(1)°. La coordination du nitrosyle dévie légèrement de la linéarité avec Ni—N—O=170,1(4)°. Les longueurs importantes de liaison (corrigées pour la libration) sont: Ni—S, 2,326(1), Ni—O, 2,019(2), Ni—N(pyrazolyl), 1,980(3), Ni—N(O), 1,633(3) et N—O, 1,156(4) Å. Les cristaux de [diméthyl(diméthyl-3,5 pyrazolyl-1)-(thiophénoxy-2 éthoxy)gallato(*N*(2),*O*,*S*]tricarbonylmanganèse(I) sont tricliniques avec a = 9,4911(5), b = 10,4323(6), c = 11,7618(7) Å, α = 86,17(1), β = 69,547(5), γ = 81,402(4)°, Z = 2, groupe d'espace $P\bar{1}$, R = 0,029 et R_w = 0,035 pour 2496 réflexions. L'atome de Mn est coordonné au ligand gallate *fac* tridentate et à trois ligands carbonyles; sa géométrie est octaédrique et légèrement déformé. Les longueurs importantes de liaison corrigées sont: Ms—S, 2,397(1), Mn—O, 2,055(2), Mn—N, 2,082(3) et Mn—C, 1,794(4), 1,807(4) et 1,807(4) Å. Les cristaux de [diméthyl(diméthyl-3,5 pyrazolyl-1) (thioéthoxy-2 éthoxy) gallato (*N*(2),*O*,*S*] (η^3-cycloheptatriényl) dicarbonylmolybdène sont monocliniques avec a = 17,030(3), b = 19,097(2), c = 15,908(3) Å, β = 115,99(1)°, Z = 8, groupe d'espace $P2_1/n$, R = 0,036 et R_w = 0,043 pour 4477 réflexions. Les deux molécules cristallographiquement indépendantes diffèrent principalement par l'orientation de la portion *S*-éthyl et contiennent chacune un ligand η^3-C_7H_7 lié sous forme de ligand donneur π à un site de coordination d'un octaèdre déformé. Les distances importantes de liaison sont Mo—S, 2,527(2) et 2,541(2), Mo—O, 2,241(5) et 2,237(4), Mo—N, 2,277(5) et 2,254(5), Mo—C(O), 1,940(7)–1,960(7) et Mo—C(C_7H_7) 2,198(6)–2,391(7) Å.

[Traduit par le journal]

Introduction

Numerous crystal structures of transition metal complexes incorporating the $[Me_2Ga(N_2C_3H_3)OCH_2CH_2NH_2]^-$ ligand, or its methyl-substituted derivatives, have been reported (1–9). The present paper describes the structures of three transitional metal complexes which incorporate the new ligand systems **1**.



R = Et or Ph

1

The synthesis and characterization of these complexes are detailed in a recent publication (10), and the X-ray structural data reported herein provide conclusive evidence for some of the arguments based on nmr, ir, and mass spectral results.

Experimental

[Dimethyl(3,5-dimethyl-1-pyrazolyl)(2-thioethoxyethoxy)-gallato(N(2),O,S)]nitrosylnickel(I), 2

A crystal ca. 0.22 × 0.56 × 0.12 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Cu K_α radiation (λ = 1.54184 Å). Crystal data at 22°C are:

$C_{11}H_{22}GaN_3NiO_2S$ f.w. = 388.81
Monoclinic, a = 8.8313(4), b = 7.2402(2), c = 26.539(1) Å, β = 94.390(3)°, V = 1691.9(1) Å^3, Z = 4, ρ_c = 1.526 g cm^{-3}, $F(000)$ = 800, μ(Cu K_α) = 42.4 cm^{-1}. Absent reflections: $h0l$, $l \neq 2n$ and $0k0$, $k \neq 2n$ uniquely indicate the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured with graphite-monochromatized Cu K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.18–10.06° min^{-1} over a range of (0.80 + 0.14 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 150°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, remained constant to within 1%. After data reduction, an absorption correction was applied using the Gaussian integration method (11, 12). Transmission factors ranged from 0.249 to 0.650 for 336 sampling points. Of the 3449 independent reflections measured, 2489(72%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

The coordinates of the gallium, nickel, and sulfur atoms were determined from the three-dimensional Patterson function and those of the remaining non-hydrogen atoms from a subsequent Fourier map. Full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters gave R = 0.055. A difference map at this point gave positions for all 22 hydrogen atoms which were included in subsequent cycles of refinement with isotropic thermal parameters. The scattering factors of ref. 13 were used for non-hydrogen atoms and those of ref. 14 for hydrogen atoms. Anomalous scattering factors from ref. 15 were used for the Ga, Ni, and S atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (16–18). The final value of g was 0.124(9) × 10^4. Convergence was reached at R = 0.040 and R_w = 0.050 for 2489 reflections with $I \geq 3\sigma(I)$. For all 3449 reflections R = 0.055 and R_w = 0.053. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.08 and 0.77σ respectively. The mean error in an observation of unit weight was 1.918. A final difference map showed no unusual features. The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

[Dimethyl(3,5-dimethyl-1-pyrazolyl)(2-thiophenoxyethoxy)-gallato(N(2),O,S)]tricarbonylmanganese(I), 3

Experimental details for **3** and **4** are as for **2** except where noted. The crystal used for data collection had dimensions of ca. 0.32 × 0.44 × 0.23 mm and graphite-monochromatized Mo K_α radiation (λ = 0.71073 Å) was used for both **3** and **4**. Crystal data are:

$C_{18}H_{22}GaMnN_2O_4S$ f.w. = 487.11
Triclinic, a = 9.4911(5), b = 10.4323(6), c = 11.7618(7) Å, α = 86.17(1), β = 69.547(5), γ = 81.402(4)°, V = 1079.5(1) Å^3, Z = 2, ρ_c = 1.499 g cm^{-3}, $F(000)$ = 496, μ(Mo K_α) = 18.68 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (C_i^1, No. 2) from structure analysis.

An ω–2θ scan at 0.91–10.06° min^{-1} over a range of (0.60 + 0.35 tan θ)° in ω was employed. Of 3774 reflections measured (to 2θ = 50°), 2496(66.1%) had intensities greater than 3σ(I) above background. An absorption correction was applied, transmission factors ranging from 0.516 to 0.686 for 202 sampling points.

Analysis was initiated in the centrosymmetric space group $P\bar{1}$ on the basis of the E-statistics. The coordinates of the Ga, Ni, and S atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent Fourier map. Refinement of the non-hydrogen atoms with anisotropic thermal parameters gave R = 0.044. The hydrogen atoms were all located from a difference map at this point and were included in the final stages of refinement with isotropic thermal parameters; no extinction correction was applied. Convergence was reached at R = 0.029 and R_w = 0.035 for 2496 reflections with $I \geq 3\sigma(I)$, R = 0.066 and R_w = 0.038 for all 3774 reflections. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.13 and 2.8σ respectively. The mean error in an observation of unit weight was 1.192. A final difference map showed no unusual features.

[Dimethyl(3,5-dimethyl-1-pyrazolyl)(2-thioethoxyethoxy)-gallato(N(2),O,S)](η^3-cycloheptatrienyl)dicarbonyl-molybdenum, 4

Crystal dimensions were ca. 0.25 × 0.35 × 0.46 mm. Crystal data are:

$C_{20}H_{29}GaMoN_2O_3S$ f.w. = 543.19
Monoclinic, a = 17.030(3), b = 19.097(2), c = 15.908(3) Å, β = 115.99(1)°, V = 4651(1) Å^3, Z = 8, ρ_c = 1.552 g cm^{-3}, $F(000)$ = 2208, μ(Mo K_α) = 17.9 cm^{-1}. Absent reflections: $h0l$, $h + l \neq 2n$ and $0k0$, $k \neq 2n$ uniquely indicate the space group $P2_1/n$ (non-standard setting of $P2_1/c$; C_{2h}^5, No. 14).

An ω–2θ scan at 1.06–10.06° min^{-1} over a range of (0.65 + 0.35 tan θ)° in ω was employed. Of 8159 reflections measured, 4477(54.9%) had intensities greater than 3σ(I) above background. An absorption correction was applied, transmission factors ranging from 0.492 to 0.668 for 160 sampling points.

The structure was solved by direct methods, the coordinates of the metal and sulfur atoms of each of the two crystallographically independent molecules being determined from an E-map and those of the remaining non-hydrogen atoms from a subsequent difference map. After refinement of all non-hydrogen atoms with anisotropic thermal parameters to R = 0.047, a difference map gave the positions of 50 of the 58 hydrogen atoms. In subsequent cycles of refinement only the protons associated with the coordinated cycloheptatrienyl carbons were refined, the remaining hydrogen positions were calculated and included as fixed atoms. Convergence was reached at R = 0.036 and R_w = 0.043 for 4477 reflections with $I \geq 3\sigma(I)$, R = 0.106 and R_w = 0.050 for all 8159 reflections. The mean and maximum parameter shifts on the final cycle of refinement were 0.12 and 1.2σ respectively and the mean error in an observation of unit weight was 1.275. A final difference map showed maximum fluctuations of ±1.1 e Å^{-3} near the molybdenum atoms and ±0.25 e Å^{-3} away from the heavier atoms. The thermal parameters indicate probable disordering of the S-ethyl group of molecule A (which contains Mo(1)). Since no such problem is evident for the second independent molecule, no attempt to resolve this

[1]The structure factor table and Table 2 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

disorder was made. The thermal parameters for molecule A were found to be generally larger than those for molecule B.

Analysis of Thermal Motion

The thermal motion in each of the molecules (shown in Figs. 1 and 2) has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (19). The rms errors in the U_{ij} (derived from the least-squares analyses) are 0.0022, 0.0025, and 0.0047 Å^2 respectively for **2**, **3**, and **4**. Two successful analyses were carried out for **2**; one rigid group included all non-hydrogen atoms except the nitrosyl oxygen and the second consisted of the gallium and the four atoms bonded to it (rms ΔU_{ij} = 0.0059 and 0.0023 Å^2, respectively). For molecule **3** two analyses were again performed, one including the entire molecule and the other the gallium coordination group (rms ΔU_{ij} = 0.0099 and 0.0022 Å^2 respectively; the first value being somewhat higher than desired, independent motion being indicated for carbonyl oxygen atoms and phenyl carbons. Separate analysis of the phenyl group failed). Each of the two independent molecules of **4** was analysed; for molecule A all non-hydrogen atoms excluding carbonyl oxygens, the *S*-ethyl carbons and all methyl carbons gave rms ΔU_{ij} = 0.0080 Å^2. Molecule B was treated in the same way except that the *S*-ethyl α-carbon was included in the rigid body and resulted in rms ΔU_{ij} = 0.0047 Å^2. All of the above analyses yielded physically reasonable rigid body parameters. The appropriate bond distances have been corrected for libration (20), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear along with the uncorrected values in Table 3 and corrected bond angles are all within one standard deviation of the uncorrected values listed in Table 4. Intra-annular torsion angles defining chelate (and C_7H_7 for **4**) ring conformations are given in Table 5.

Results and Discussion

The X-ray crystallographic analyses of **2–4** have shown that the ligands **1** are tridentate chelating ligands, displaying "facial" coordination in each case and being stereochemically equivalent to *fac*-coordinated ligands of the type $[Me_2Ga(N_2C_3HR_2)OCH_2CH_2NR_2']^-$ (R, R′ = H or Me) (2–4, 6, 8, 9). Although there are several significant differences between the geometry of the ligand **1** in the tetrahedral complex **2** and that observed in the octahedral complexes **3** and **4**, the overall arrangement is quite similar. Chelation of a transition metal ion by the ligand **1** results in a system of three fused five-membered rings with the central GaOMNN ring being approximately coplanar with the pyrazolyl ring and perpendicular to the MOCCS ring. The pyrazolyl rings are planar within experimental error (χ^2 = 3.3, 1.0, 0.4, and 0.8 for N_2C_3 in **2**, **3** and the two molecules of **4** respectively) with the metal atoms considerably displaced from the pyrazolyl mean planes (for **2**, Ga 0.0489(4), Ni 0.2100(5), for **3**, Ga 0.3329(4), Mn −0.3338(5), and for **4**, Ga 0.3141(9) and −0.2471(8), Mo −0.2911(5) and 0.1767(5) Å). The MOCCS rings in **2–4** are very similar, each having an envelope conformation with the carbon atom bonded to oxygen displaced from the approximate plane defined by the four other atoms (see torsion angles in Table 5). In each case the trivalent S and O atoms have distinctly pyramidal coordination.

The intraligand bond distances and angles in **2**, **3**, and **4** all assume normal values. The gallium atoms in all three molecules have distorted tetrahedral coordination geometry with bond angles ranging from 90.4(1)–92.6(1)° for O—Ga—N to 117.2(3)–124.7(3)° for C—Ga—C. The Ga—O and Ga—N distances in **2** (1.921(2) and 2.001(3) Å respectively) differ slightly but significantly from those in **3** and **4** (mean values: 1.931(3) and 1.985(3) Å).[2] The Ga—C bonds in all three molecules are equal within experimental error, mean Ga—C = 1.975(6) Å.

$[Me_2Ga(N_2C_5H_7)OCH_2CH_2SC_2H_5]Ni(NO)$, 2

The crystal structure of **2** consists of discrete molecules separated by normal van der Waals distances. The geometry of **2** is very similar to that of the closely related complex $[Me_2Ga(N_2C_5H_7)OCH_2CH_2NMe_2]Ni(NO)$, **5** (4). The coordination geometry about the Ni atom is distorted tetrahedral, bond angles ranging from 87.90(7)° for S—Ni—O(1) to 127.9(1)° for O(1)—Ni—N(3). The magnitude of the distortion from ideal tetrahedral geometry in **2** is not as great as in **5** where bond angles range from 84.4(1) to 133.5(1)°, likely a result of the larger radius of the sulfur atom. The rt ^{1}H nmr spectrum of **2** is explicable in terms of a square-planar coordination geometry about Ni but low-temperature studies confirm a tetrahedral geometry and suggest that the complex is fluxional in solution at ambient temperature (10).

The nitrosyl coordination is slightly non-linear with Ni—N—O = 170.1(4)°, Ni—N = 1.633(3) and N—O = 1.156(4) Å, compared to corresponding values of 162.3(4)°, 1.632(4), and 1.147(4) Å in **5**. It has been shown that as the coordination geometry of a $\{MNO\}^{10}$ complex changes from tetrahedral towards square-planar, the M—N—O angle decreases from 180° towards the square-planar limit of ~120° with a corresponding increase in the M—NO distance (21–23). On the basis of this argument, the Ni—NO bond in **5** is presumably stronger than that in **2** even though the two bond lengths are essentially equal. The Ni—O and Ni—N(pyrazolyl) distances in **2** (2.019(2) and 1.980(3) Å) are shorter than those in **5** (2.045(2) and 1.989(3) Å) while the Ga—O and Ga—N distances in the two molecules are equal within experimental error. Based on the difference between the covalent radii of nitrogen and sulfur, the Ni—S bond in **2**

[2]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

should be longer than the Ni—N(amino) bond in **5** by 0.33 Å. The actual difference is 0.255 Å (2.326(1) vs. 2.071(3) Å) and indicates a relatively stronger bond in the present structure, due in part to lower strain in chelated ligands **1** than in their ethanolamine counterparts.

[$Me_2Ga(N_2C_5H_7)OCH_2CH_2SPh$]$Mn(CO)_3$, 3

The crystal structure of **3** consists of discrete molecules, joined across an inversion centre by weak C—H···S interactions (C(10)—H(10a)···S(1 − *x*, 1 − *y*, 1 − *z*), C···S = 3.847(4), H···S = 2.91(4) Å, C—H···S = 148(2)°) to form weakly associated dimeric units. All other intermolecular interactions correspond to normal van der Waals contacts.

This manganese tricarbonyl derivative is the only $LM(CO)_3$ complex (where L = **1** or [$Me_2Ga(N_2C_3HR_2)OCH_2CH_2NR_2'$]$^-$; R, R′ = H or Me) structurally characterized to date and is also the only fully characterized compound of the ligand **1** with R = Ph (10). It was postulated that the steric requirements of the ligand **1** (R = Ph) do not allow more bulky groups to coordinate to the transition metal and are responsible for the failure of the *S*-phenyl ligand to form complexes easily prepared with the *S*-ethyl analog. The crystal structure of **3**, however, shows no close contacts of the *S*-phenyl group with any other part of the molecule. Although the possibility of steric interference in solution cannot be ruled out, the differing donor properties of the aryl- relative to the alkyl-substituted sulfur may be partially responsible for the differences in reactivity of the ligands **1** where R = Et or Ph.

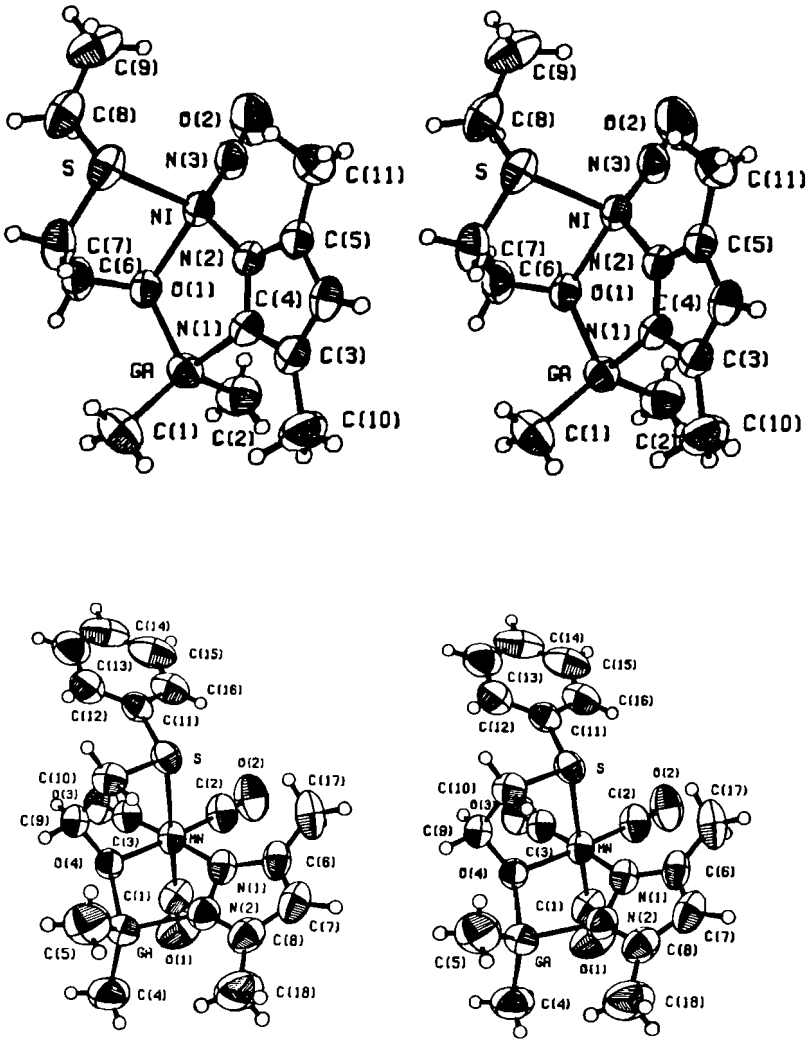

FIG. 1. Stereo views of **2** (top) and **3** (bottom). 50% probability thermal ellipsoids are shown for non-hydrogen atoms, hydrogen atoms assigned artificially small spheres for clarity.

The Mn atom in **3** is in a trigonally distorted octahedral environment, mean bond angles at Mn being: L—M—L, 84.4(6), OC—Mn—CO, 88.6(4), *cis* and *trans* L—Mn—CO, 93.3(20) and 176.2(10)° respectively (L = S, O, or N). Bond distances involving Mn all lie within the ranges normally observed for such bonds. The carbonyl groups are all slightly, but significantly, non-linear with Mn—C—O angles ranging from 175.2(4) to 177.2(3)°. The Mn—CO bond *trans* to O is marginally shorter than the other two Mn—CO bonds (1.794(4) vs. 1.807(4) Å) and a corresponding difference in the C—O distances is also noted (1.156(4) *trans* to O, mean of 1.143(4) Å for the others). These small differences between the carbonyl groups are probably the result of structural *trans* effects (3, 6, 9).

Comparison of the ligand geometries in **2** and **3** illustrates the general structural differences between the "facially" coordinated ligand of the types **1** and $[Me_2Ga(N_2C_3HR_2)OCH_2CH_2NR_2']^-$ (R, R' = H or Me) in octahedral transition metal complexes compared to tetrahedral complexes. The intraligand bond angles at the metal (in particular the *S*/*N*(amino)—M—N(pyrazolyl) angle) are greater and vary over a wider range in tetrahedral complexes (4, 8) than in octahedral (2) or pseudo-octahedral complexes (3, 6, 7, 9). The M—O distance is significantly longer than the M—N(pyrazolyl) distance in the tetrahedral complexes, whereas the converse is true for octahedral complexes. These differences arise from a combination of sterically induced hybridization and electronic effects.

The phenyl ring is planar within experimental

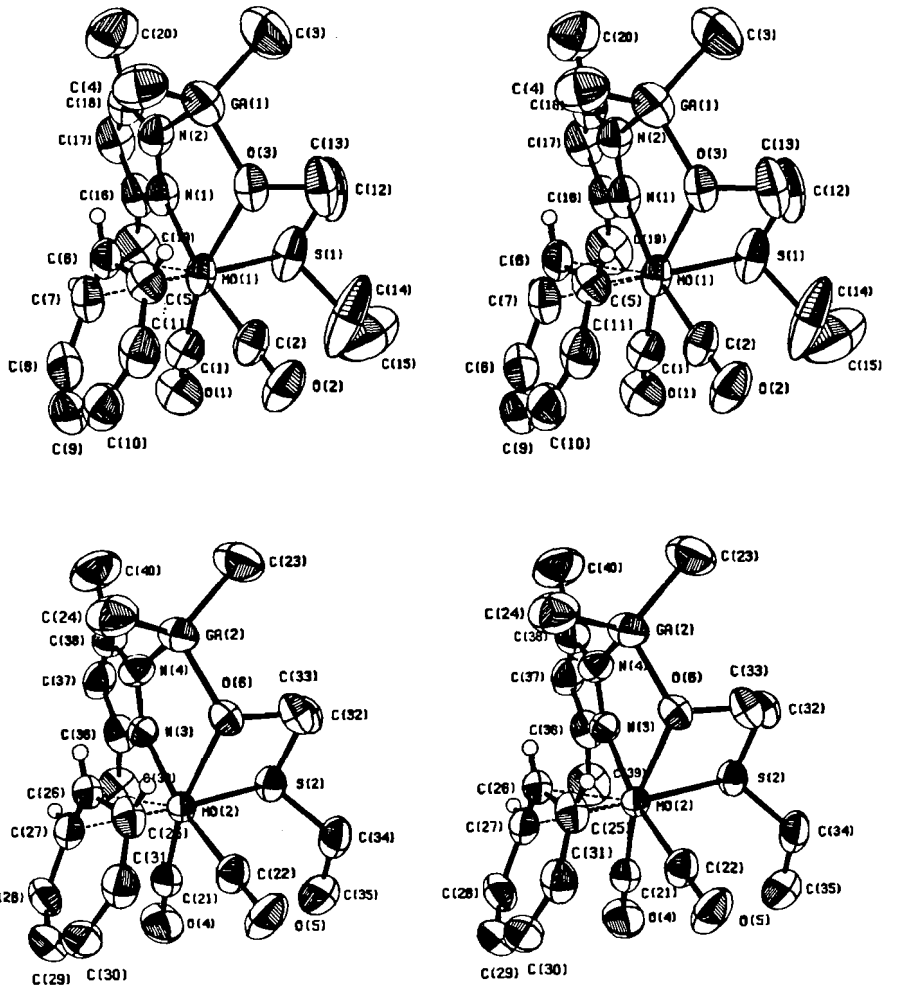

FIG. 2. Stereo views of the two independent molecules of **4**: molecule A (top) and molecule B (bottom). 50% probability thermal ellipsoids are shown for the non-hydrogen atoms, all H atoms except those bonded to the coordinated C_7H_7 atoms have been omitted for clarity.

error (χ^2 = 5.8 for C_6), the sulfur atom being significantly displaced from the phenyl mean plane (by 0.0354(8) Å).

$[Me_2Ga(N_2C_5H_7)OCH_2CH_2SC_2H_5]Mo(CO)_2(\eta^3\text{-}C_7H_7)$, 4

The crystal structure of **4** consists of discrete molecules separated by normal van der Waals distances. The asymmetric unit contains two crystallographically independent molecules (shown in Fig. 2), the most obvious differences between them being the orientation of the *S*-ethyl group and the generally larger thermal motion observed for molecule A (which contains Mo(1)). There are a number of small but statistically significant differences between corresponding geometrical parameters for the two molecules of **4**, presented side by side in Tables 3–5 for ease of comparison.

In each of the two independent molecules of **4** the coordination about the Mo atom may be regarded as distorted pseudo-octahedral with an η^3-C_7H_7 ligand occupying one coordination site as a π-donor. The η^3-C_7H_7 ligand is situated *trans* to the sulfur, thus the complex is stereochemically equivalent to the related molecule $[Me_2Ga(N_2C_5H_7)OCH_2CH_2NH_2]Mo(CO)_2(\eta^3\text{-}C_7H_7)$, **6** (9), in which the substitution occurs *trans* to the amino nitrogen. As noted earlier (3, 10), in η^3-C_3H_5 and η^3-C_4H_7 analogs of **4** and **6** the allylic ligand is situated *trans* to the pyrazolyl nitrogen. The Mo coordination spheres of **4** and **6** are so similar that the differences between the two crystallographically independent molecules of **4** are roughly the same as those between the two different compounds.

The significant differences between the Mo coordination groups of the two molecules of **4** involve

*Coordinates for molecule B have been inverted through the centre of symmetry for direct comparison with molecule A.

the Mo—S and Mo—N distances, the former being shorter and the latter longer in molecule A than in molecule B. The mean Mo—C(C_7H_7) distance in molecule A is longer than that in molecule B by 0.018(11) Å, not significant, but consistent with the observed Mo—S distances. On the basis of the same argument invoked above for **2**, the Mo—S bonds in **4** are relatively stronger than the Mo—N(amino) bond in **6**. As a result of the stronger bond *trans* to the η^3-C_7H_7 ligand in **4** the Mo—C(C_7H_7) distances are slightly longer than in **6**. The distances from the metal to the centre of mass of the three coordinated C_7H_7 carbon atoms are 2.077 and 2.062 Å for molecules A and B of **4** respectively compared to 2.051 Å for **6**. The Mo—N(pyrazolyl), Mo—O, and Mo—CO distances in **4** and **6** are not significantly different although the Mo—N and Mo—O distances are marginally shorter and the Mo—CO distances marginally longer in **4**.

The carbonyl groups are slightly, but significantly, non-linear and the mean C—O distance of 1.152 Å is somewhat shorter than the corresponding value of 1.171 Å observed in **6**. This difference must be attributed to solid-state effects since the ν_{CO} values for **4** and **6** in cyclohexane solutions differ by no more than 2 cm^{-1} (3, 10). The conformations of the C_7H_7 rings in **4** and **6** are also very similar and have six atoms roughly coplanar with the central coordinated carbon displaced from this plane.

CAMILLE CHAPADOS, DENIS GERMAIN, and ROGER M. LEBLANC. Can. J. Chem. **59**, 2402 (1981).

The aim of this paper is to examine the direct effect of polluting gases on chlorophyll *a* (chl *a*) multilayer arrays. The pollutants studied are CO, CO_2, SO_2, H_2S, NO, and NO_2. Electronic and infrared spectroscopies were used to monitor the time effect of the polluting gases on chl *a* molecules. TLC, atomic absorption, and electronic spectroscopies were used to characterise the reaction products. The results show that neither CO nor CO_2 affect the chl *a* molecules in the multilayer arrays. Upon exposure to SO_2, we notice many modifications on the electronic and ir spectra. All the evidence confirms that one of the reaction products is pheophytin *a*. A mechanism is presented to explain the reaction of SO_2 with chl *a*. The effect of H_2S on chl *a* is less pronounced than that of SO_2, but the end products are the same. NO and NO_2 have exactly the same effect on the chl *a* multilayer. The reaction is much more drastic than the reaction of chl *a* with either SO_2 or H_2S. There is opening of the cycle and nitration of the chl *a* molecule.

CAMILLE CHAPADOS, DENIS GERMAIN et ROGER M. LEBLANC. Can. J. Chem. **59**, 2402 (1981).

On a étudié l'effet de polluants gazeux (CO, CO_2, SO_2, H_2S, NO et NO_2) sur les molécules de chlorophylle *a* (chl *a*) dans un arrangement multicouche. Les spectroscopies électronique et infrarouge ont été utilisées pour déterminer l'effet de ces polluants sur la chl *a*. La chromatographie sur couche mince ainsi que les spectroscopies d'absorption atomique et électronique ont été employées pour caractériser les produits de réaction. Les résultats montrent que le CO_2 et le CO n'ont pas d'effet sur la multicouche de chl *a*. En présence de SO_2, on note des modifications importantes sur les spectres électroniques et les spectres infrarouges de la chl *a*. Toutes les évidences expérimentales indiquent qu'un des produits de la réaction est la phéophytine *a*. Un mécanisme réactionnel est présenté pour expliquer l'interaction du SO_2 avec la chl *a*. L'effet du H_2S sur la chl *a* est moins prononcé que dans le cas du SO_2 bien que les produits de la réaction soient les mêmes. Avec le NO et le NO_2, qui se comportent d'une façon identique avec la chl *a*, l'effet est plus drastique que dans le cas du SO_2 et H_2S. Il se produit une ouverture du cycle avec nitration de la chl *a*.

Introduction

Vegetation is affected to various degrees by atmospheric pollution. In addition to killing plants when the air pollution is high, the atmospheric pollutants adversely affect plants in various ways (1–3).

Pollution injuries are usually classified as (*i*) acute, when the tissue of the plant is killed (necrosis); (*ii*) chronic or chlorotic, when there is yellowing of the leaves, progressing slowly to a whiter color as the chlorophyll (chl) and the carotenoid in the plant are destroyed; or (*iii*) hidden when the growth of the plant is inhibited without visible marks on the leaves of the plant (1). Although the mechanisms of pollution injury to plants are complex, necrosis and chlorosis of the leaves in vascular plants indicate damage to chlorophyll by the polluting gases. In lichens, especially the epiphetic ones, no such injury can be seen but the scarcity of these species in polluted areas where other factors are favorable suggests the destruction of the chlorophyll molecules by the atmospheric pollutants (4).

Among the gaseous pollutants, SO_2 is the most important in any major agglomeration and it is the resultant of smelting mineral ore and of burning fossil fuels. This pollutant is responsible for the partial destruction of crops and the defoliation of forests near the sources of this gas (1–6). In most cases, it results in discoloration of the plant, suggesting a partial destruction of the chlorophyll molecules which are responsible for the green color in plants. With more resistant plants or at lower dosages of SO_2, the pollutant is either absorbed by the plant without visible effects or reduced to H_2S and given off as such (6). In lichens exposed to SO_2, the chl molecules are transformed to pheophytin; in dry lichens, this process is reduced (4). H_2S is a natural pollutant (3 to 30 $\mu g\ m^{-3}$), and it may sometimes be a man-made pollutant near D_2O generation plants and Kraft paper mills. It is not usually considered a pollution problem except in topical places and at low concentration it may serve as a source of sulfur to the plant (6). NO and NO_2 are major pollutants in urban areas resulting from combustion processes by heat-induced combination of atmospheric N_2 and O_2 (1). NO and NO_2 (50 parts $\times$ 10^{-8}) reduce net photosynthesis before there is any externally visible effect (7–10). Higher concentrations of the pollutant and longer exposures will produce symptoms of plant injury similar to those caused by sulfur dioxide (11). Although CO and CO_2 are not considered pollutants for the plants, they are gases which result from the combustion of fossil fuel that may affect the chl molecules in various ways.

The studies of the air pollution on chlorophyll usually start with the study of the plant (1, 2, 4, 5).

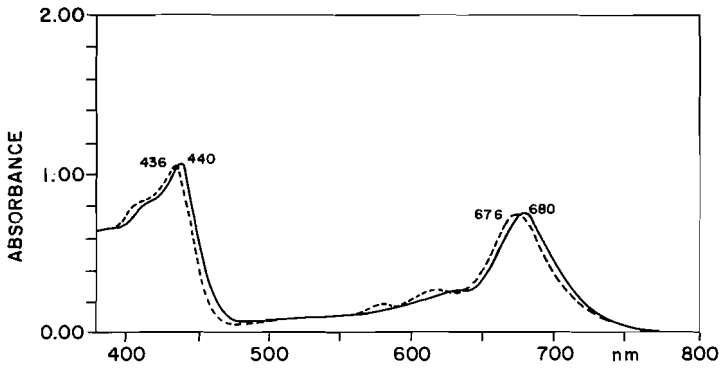

FIG. 1. CO_2 effect (29 kPa) on the absorption spectra of chl *a* multilayer (2 × 40 layers): initial spectrum (—); in CO_2 vapors for 2 days (---).

There is little study on the direct effect of the polluting gases on chlorophyll. Having been involved in several studies on the aggregation of chlorophyll in mono- and multilayer arrays (12–14), we pursued the study on the effect of gaseous pollutants on chlorophyll *a* in a multilayer state.

To simulate the *in vivo* system, we used a chlorophyll *a* multilayer. The main reasons for using this model are the following: (*i*) uniform deposition of the pigment at the air–solid interfaces; (*ii*) high concentration of the pigment (number of molecules per unit area); (*iii*) orientation of the pigment at an angle similar to the one *in vivo*.

The pollutants we studied are the following: CO, CO_2, SO_2, H_2S, NO, and NO_2. Since we were concerned with the overall effect of the pollutant molecules on chl *a* molecules, we have used much higher concentrations than the ones usually present in a highly polluted environment.

Experimental

The extraction and purification of chl *a* was done from spinach leaves by the standard method of Strain and Svec (15). Chlorophyll obtained from Sigma Chemical Company, St. Louis, MO gave the same results.

The materials, the preparation of slides, the deposition of monolayers and the Langmuir film balance apparatus have previously been described in detail (16).

Electronic Spectra

Thirty-two to forty layers of chl *a* were deposited, at a surface pressure of 20 mN m^{-1}, on both sides of a quartz slide. The slide was enclosed in a vacuum tight brass cell having quartz windows. The mean deposition ratio was 1.00 ± 0.01; the deposition ratio is defined as A_w/A_s where A_w is the decrease of area occupied by the monolayer at the air–water interface and A_s is the area coated by the monolayer at the air–solid interface.

The absorption measurements were carried out on a Unicam SP1800 spectrophotometer.

A vacuum of 0.1 Pa was maintained on the sample for 10 min, then the dry gas was introduced. Spectra were obtained at different time intervals.

Infrared Spectra

Thirty-two to forty layers of chl *a* were deposited at a surface pressure of 20 mN m^{-1} on each side of a germanium multiple internal reflexion (MIR) plate using the Langmuir film balance to monitor the deposition. The mean deposition ratio was 1.00 ± 0.01.

When the multilayer of chl *a* has reached equilibrium (14), the ir spectrum is taken, and the chl *a* multilayer is placed in a desiccator where a vacuum of 0.1 Pa is obtained. The dry gas is introduced and made to react with chl *a*. After a certain period of time, the ir spectrum is obtained. If there is reaction, the sample is washed with hot water to get rid of any inorganic water soluble substances, and the ir spectrum taken. Another sample of chl *a* having reacted with the gas is washed with diethyl ether to get rid of any organic substances, and the ir spectrum taken.

The ir spectra were recorded on a Perkin Elmer model 180 spectrometer using a FMIR accessory to increase the signal of the absorbing bands. The resolution was around 2 cm^{-1} in the carbonyl region and around 4 cm^{-1} in the C—H and O—H regions.

Thin layer chromatography, atomic absorption spectroscopy, and electronic spectroscopy were used to characterise the washing products.

Results and Discussion

The Effect of CO and CO_2 on Chlorophyll a Multilayer

As the two gases behave the same way after exposure to the chlorophyll *a* multilayer, we present only the results on CO_2 gas.

The electronic spectrum of 40 layers of chl *a* deposited on each side of a quartz slide is shown in Fig. 1. The spectrum is similar to that used in ref. 14. Following the exposure of the multilayer to CO_2 vapors (P = 29 kPa) for 2 days, we observed a 4 nm blue shift of the band maxima. Since the hypsochromic shift is identical to the one for a multilayer kept in the same conditions but without exposure to the gas, the results show that the CO_2 has no effect on the chl *a* multilayer. The hypsochromic shift is explained by a reorganisation of the chl *a* molecules in the array with time (14). To confirm the

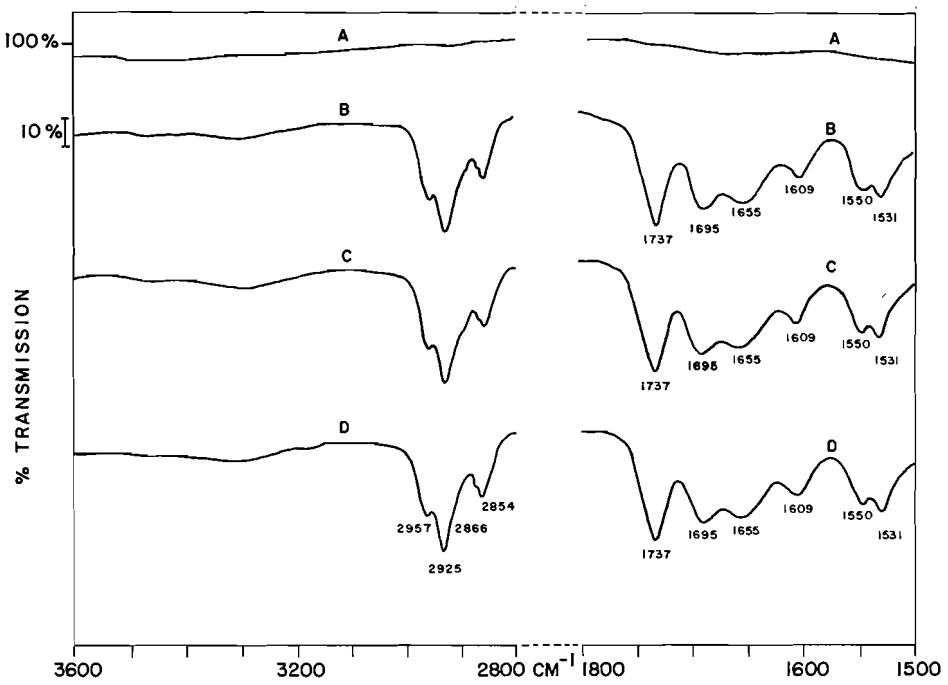

FIG. 2. CO_2 effect (28 kPa) on the infrared spectra of chl *a* multilayer (2 × 40 layers). *A*, background spectrum; *B*, multilayer after reorganisation; *C*, 24 h in CO_2 vapors; *D*, 48 h in CO_2 vapors.

absence of an effect, we have exposed 40 layers of chl *a* deposited on each side of a Ge MIR plate to CO_2. There is no modification in the ir spectrum as seen in Fig. 2 between spectrum *B* taken after the chl *a* multilayer has reorganised and spectrum *C* taken after the chl *a* molecules have been in contact with the gas for 24 h. After 2 days of exposure to the gas there was no change in the ir spectrum (Fig. 2*D*). The assignment of the bands is given in Table 1. Similar results have been obtained for CO. From our results, we conclude that neither CO nor CO_2 affect the chl *a* molecules in the multilayer arrays. Our conclusions confirm the observation made on the fluorescence intensity showing that CO_2 does not affect the chlorophyll-containing monolayers at the vapor–liquid interface (17).

The Effect of SO_2 on chl a *Multilayer*

The electronic spectra of 32 layers of chl *a* deposited on each side of a quartz slide and exposed to SO_2 vapors (P = 37 kPa) are presented in Fig. 3. Spectra at time intervals up to 12 h are given. Upon exposure to SO_2, we notice a rapid decrease of the band intensities and a displacement of the band maxima. There are two isobestic points situated at 572 nm and 465 nm indicating a one-to-one conversion. To determine the nature of these modifications, we have taken some ir spectra of the multilayer of chl *a* (2 × 36 layers) in contact with SO_2 vapors (P = 37 kPa) for 24 h and 36 h. These are presented in Fig. 4 *C* and *D*, respectively. In the OH region, a strong broad band has appeared at 3395 cm^{-1} with a shoulder at 3280 cm^{-1}. In the carbonyl region, the C=O ester group situated at 1737 cm^{-1} in the spectrum of chl *a* multilayer (Fig. 4*B*) is broadened and displaced to 1740 cm^{-1}. The free carbonyl band at 1692 cm^{-1} increases in intensity and is displaced to 1700 cm^{-1} upon fumigation. The coordinated C=O ketone is modified to a sharper band at 1655 cm^{-1} and has a shoulder at 1622 cm^{-1}. The 1609 band has almost disappeared and a new weaker band has appeared at ~1580 cm^{-1}. The doublet at 1550–1535 is modified, leaving a small structureless band at 1550 cm^{-1}. When the SO_2 exposed chl *a* sample is washed with hot water to remove all the water soluble substances in the multilayer, we are left with the sample that gives the spectrum presented in Fig. 4*E*. In the 3400 cm^{-1} region, the broad band has disappeared, leaving a small band that can be assigned to a N—H stretch vibration. In the carbonyl region, the band situated at 1655 cm^{-1} has disappeared, and the shoulder at 1622 cm^{-1} has become a weak band. The weaker band at 1580 cm^{-1}, not modified after the hot water treatment, can be assigned to a N—H deformation vibration. The spectrum in Fig. 4*E* can be compared with the spectrum of pheophytin *a* (18); the positions of the bands of both species are

*This position has been measured on the spectra given in ref. 18, although the authors give a value of 3400 cm^{-1} in the text.

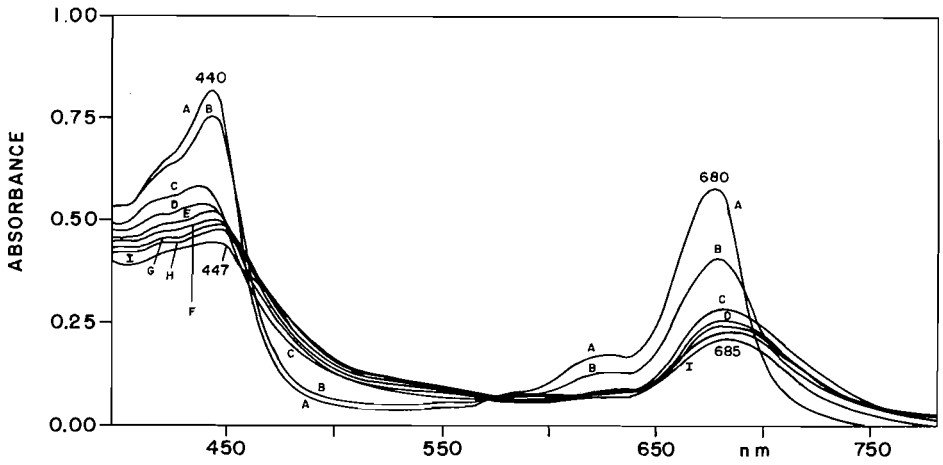

FIG. 3. SO_2 effect (37 kPa) on the absorption spectra of chl *a* multilayer (2 × 32 layers). *A*, initial spectrum; *B*, after the introduction of SO_2 vapors; in contact with SO_2 vapors: *C*, 8 min, *D*, 16 min, *E*, 24 min, *F*, 32 min, *G*, 45 min, *H*, 60 min, *I*, 12 h.

tabulated in Table 1. An atomic absorption spectrum of the water washings has revealed the presence of Mg. From this evidence, we conclude that one of the reaction products of the SO_2-treated chl *a* is pheophytin *a*. The determination of the other reaction products has been done in the following way: a multilayer of chl *a* was treated with SO_2 in a fashion similar to that previously described so that its spectrum was similar to the one given in Fig. 4*D*; the sample was then washed with diethyl ether and the remaining substance gave a spectrum presented in Fig. 4*F*. The broad bands in this spectrum can be assigned to water molecules where 3395 cm^{-1} is the O—H stretch vibration and 1655 cm^{-1} is the O—H deformation vibration. Since this water is not volatile, it must be bounded to an inorganic sulfur containing magnesium salt. The reaction of SO_2 with chl *a* would then proceed in the following way:

[1] chl $a \cdot H_2O + SO_2 \rightleftharpoons$ chl $a + SO_2 \cdot H_2O$
[2] chl $a \cdot H_2O + SO_2 \cdot H_2O \rightleftharpoons$ chl $a + HSO_3^- + H_3O^+$
[3] chl $a \cdot H_2O + HSO_3^- \rightleftharpoons$ chl $a + SO_3^{2-} + H_3O^+$
[4] chl $a + 2H_3O^+ \rightleftharpoons$ Pheophytin $a + 2H_2O + Mg^{2+}$
[5] $H_2O + SO_2 \rightleftharpoons SO_2 \cdot H_2O$

In reaction [1], the water molecule is tightly bound to chl *a* by a coordination bond with magnesium (14). SO_2 will react with H_2O to give the species $SO_2 \cdot H_2O$ which will then react with another chl $a \cdot H_2O$ to generate HSO_3^- and H_3O^+ species. The bisulfite ion will react further with chl $a \cdot H_2O$ to give SO_3^{2-} and another hydronium ion. These hydronium ions will react with the liberated chl *a* to produce pheophytin *a*, magnesium ion, and two water molecules. The latter molecules will associate with SO_2 to give $SO_2 \cdot H_2O$ species which will then proceed as in reaction [2]. The magnesium

NO_2-exposed chl *a* washed with diethyl ether	3395	~3270	~2950			~1730	1655	This work (Fig. 10*E*)

produced in reaction [4] will form with the sulfite ion in reaction [3], a sulfite salt which can be hydrated with up to six water molecules (19). If SO_2 is oxidised to SO_3 by the catalytic action of the chl *a* molecules, a sulfate salt would then be formed which can also be hydrated.

Figure 4*F* is mainly the spectrum of water, and the association of water with either SO_3^{2-} or SO_4^{2-}. These species will not be spectroscopically very different. Nevertheless since Mg^{2+} cation does not influence the association of water molecules with the anion to a great degree, we can compare the spectrum of this species (Fig. 4*F*) with the spectrum of different mixtures of water in sulfuric acid (20). The position of the bands of different mixtures of H_2O and H_2SO_4 is given in Table 2. From this table, we gather that the species most comparable with ours is the one containing 46% SO_4^{2-} in H_2O. This value is, of course, only approximate and will vary from experiment to experiment depending on the water available and is given only to show that the association of the water molecules with an anion will displace slightly the position of H_2O vibration bands. Some examples of such a dis-

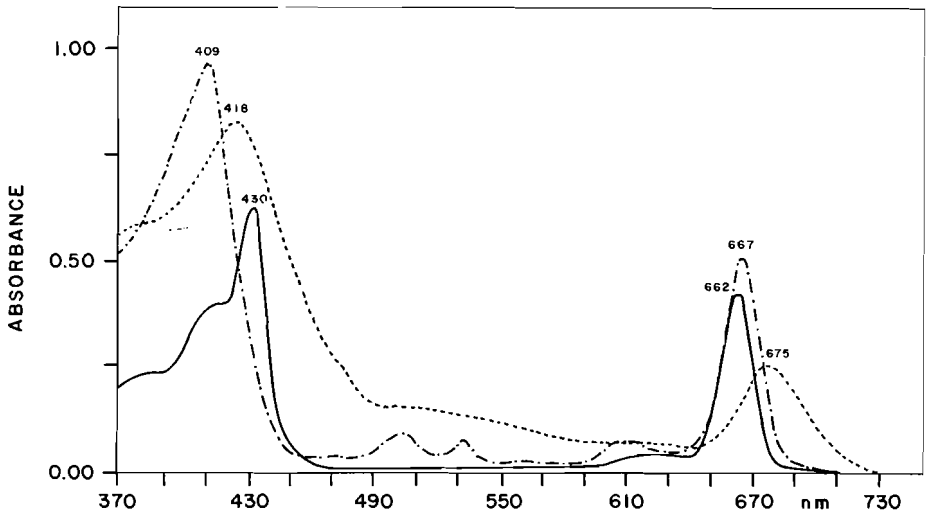

FIG. 5. Absorption spectra in diethyl ether of the reaction products of chl *a* with different pollutants: pure chl *a* (—); with SO_2 or H_2S vapors (-·--); with NO or NO_2 (---).

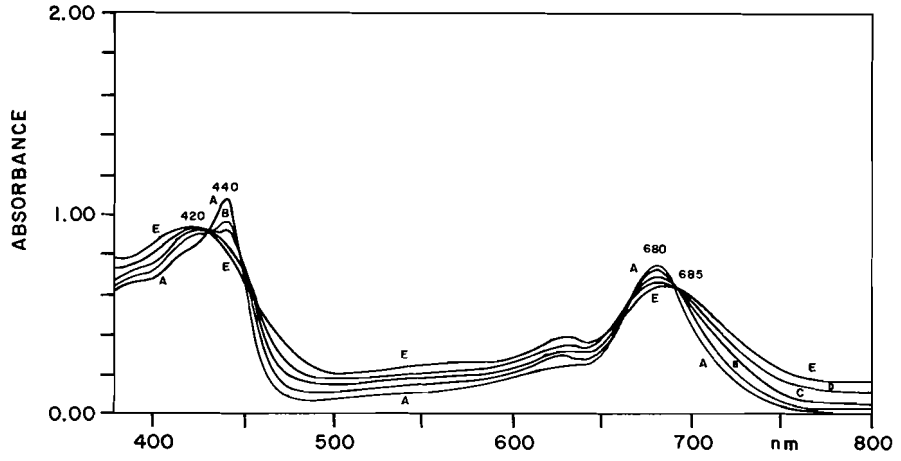

FIG. 6. H_2S effect (37 kPa) on the absorption spectra of chl *a* multilayers (2 × 40 layers). *A*, initial spectrum; in contact with H_2S vapors: *B*, 30 min, *C*, 60 min, *D*, 90 min, *E*, 120 min.

placement are given in the work of Miller and Wilkins (21).

The electronic spectrum of the diethyl ether washing of the reaction product of chl *a* with SO_2 (Fig. 5) is identical to the spectrum of pheophytin *a*. A thin layer chromatography of this solution has revealed that the reaction product is mainly pheophytin *a* with traces of chl *a*.

This evidence confirms that one of the products of chl *a* hydrate reacting with SO_2 is pheophytin *a*. The reaction can only proceed in the presence of water. In the absence of water, chl *a* molecules do not react with SO_2 molecules even after an exposure of 48 h (14). The other reaction product is a hydrate of a magnesium salt: a sulfite, a sulfate, or a combination of the two.

The Effect of H_2S on chl a *Multilayer*

The electronic spectra of 40 layers of chl *a* deposited on each side of a quartz slide and exposed to the vapors of H_2S (P = 37 kPa) are shown in Fig. 6. Spectra at time intervals up to 2 h are presented. With contact with H_2S, there is a decrease of the band intensities and a shift of the maxima. There are four isobestic points situated at 689, 664, 465, and 430 nm indicating a one-to-one conversion of chl *a* to a new species. The decrease of the band intensities is less rapid and is less pronounced than with the SO_2 reaction, but the red bands are situated at the same position in the two cases. In the blue region, the bands are broad and structureless in reactions with either SO_2 or H_2S, so that it is not possible to account for the differ-

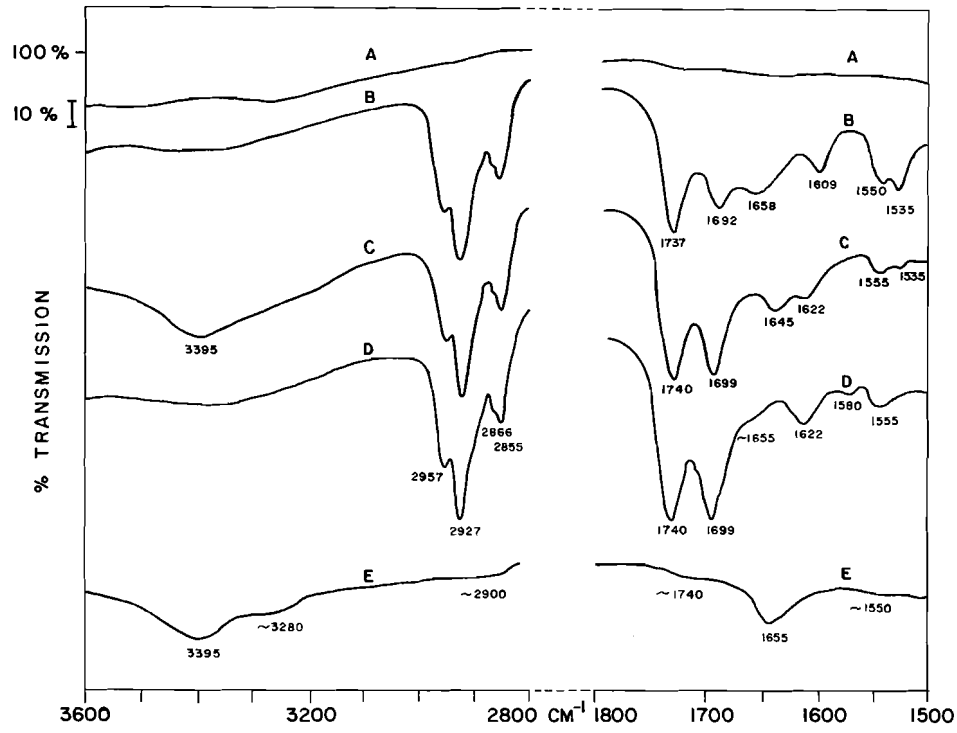

FIG. 7. H_2S effect (36 kPa) on the infrared spectra of chl *a* multilayer (2 × 36 layers). *A*, background spectrum; *B*, multilayer after reorganisation; *C*, 36 h in H_2S vapors; *D*, sample washed with hot water; *E*, another sample treated with H_2S vapors for 38 h, and then washed with diethyl ether.

ence in λ_{max} of the two reactions. To determine the nature of the end product of the reaction of H_2S with chl *a*, a stable multilayer (2 × 36 layers) of chl *a* (Fig. 7*B*) has been put in contact with H_2S ($P = 36$ kPa) for 36 h and the ir spectrum taken (Fig. 7*C*), then washed with hot water (Fig. 7*D*). The procedure is repeated using a similar multilayer and after it has been exposed to H_2S, it is washed with diethyl ether. This spectrum is presented in Fig. 7*E*. The ir spectra of the H_2S exposed chl *a* multilayer are similar to the ones exposed to SO_2, indicating that the end products are the same. In the case of the multilayer washed with hot water (Fig. 7*D*) this product is pheophytin *a*, and when the multilayer is washed with diethyl ether (Fig. 7*E*), the product is water bound to a magnesium salt. There are some small differences between the spectra of Fig. 4 and those of Fig. 7; these can be explained in the following way: first, in the stable multilayer of chl *a* in Fig. 7*B*, there is a weak broad band appearing at $\sim 3400\,cm^{-1}$ which persists after H_2S fumigation (Fig. 7*C*) followed by the hot water treatment (Fig. 7*D*). On the other hand the water band that appeared in Fig. 7*C* disappeared in Fig. 7*D*. The weak broad band can hardly be assigned to water, in good agreement with previous work (18), but it can not be assigned to an overtone either, as was speculated in that work, since this band is not always present as in Fig. 4*B*. The origin of this band is not known. Secondly, the small N—H strech band at $\sim 3400\,cm^{-1}$ has not appeared in Fig. 7*D* (it is probably smeared out) but the N—H deformation band is present at $1580\,cm^{-1}$ confirming the formation of pheophytin *a*. Thirdly, the weak shoulder at $\sim 1655\,cm^{-1}$ can be assigned to unreacted chl *a*. All these small differences can be attributed to the fact that the samples vary somewhat from experiment to experiment. H_2S-exposed chl *a* multilayer washed with diethyl ether (Fig. 7*E*) is similar to the SO_2-exposed one (Fig. 4*F*), confirming that this product is water bound to a magnesium salt. The position of the bands and even the shoulder bands appearing at ~3280, ~2900, ~1740, and $\sim 1550\,cm^{-1}$ are coincident with the ones of Fig. 4*F*. This indicates that the inorganic matrix has the same properties for the H_2S- and the SO_2-exposed chl *a* multilayer.

The electronic spectrum of the diethyl ether washing (Fig. 5) indicates that the end product of the reaction between H_2S and a multilayer of chl *a* is pheophytin *a*. Thin layer chromatography revealed the presence of mostly pheophytin *a* with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

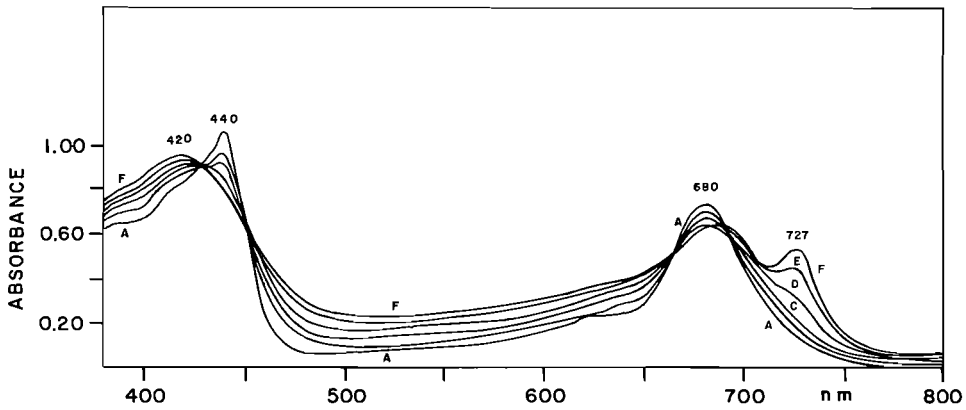

FIG. 8. H_2S effect (36 kPa) on the absorption spectra of chlorophyll *a* multilayer (2 × 40 layers) saturated with water. *A*, initial spectrum; in contact with H_2S vapors: *B*, 1 min, *C*, 8 min, *D*, 16 min, *E*, 24 min, *F*, 32 min.

traces of chl *a*. The reaction between chl *a* and H_2S would proceed in the following way:

[6] chl $a \cdot H_2O + H_2S \rightleftharpoons$ chl $a + H_2S \cdot H_2O$
[7] chl $a + H_2S \cdot H_2O \rightleftharpoons$ chl $a + HS^- + H_3O^+$
[8] chl $a \cdot H_2O + HS^- \rightleftharpoons$ chl $a + S^{2-} + H_3O^+$
[9] chl $a + 2H_3O^+ \rightleftharpoons$ Pheophytin $a + 2H_2O + Mg^{2+}$
[10] $H_2O + H_2S \rightleftharpoons H_2S \cdot H_2O$

Based on the pK_a values for reactions [7] and [8], only the former is favored (22). The HS^- will be oxidised before reacting with Mg^{2+}. The magnesium salt formed will interact with the available water to form a stable hydrate.

The Effect of H_2S on a chl a *Multilayer Saturated with Water*

Eighty layers (2 × 40) of chl *a* freshly prepared and still containing the characteristic water mist was put in an H_2S atmosphere (P = 36 kPa). The electronic spectra are presented in Fig. 8. Spectra at time intervals up to 32 min are presented. The end products have major bands situated at 727, 685, and 420 nm and isobestic points at 696, 662, 450, and 430 nm. The major bands have been displaced from the position of chl *a* (680 and 440 nm) and two are at the same position as pheophytin *a* (685 and 420 nm), but there is a new band situated at 727 nm which can be assigned to a complex containing chl *a*, pheophytin *a*, and water. Such a complex has been postulated (23) where a maximum at 720 nm was observed in a non-polar solvent. In our case, we obtain a maximum at 727 nm; the difference is explainable by the fact that the band is broad and a multilayer arrangement was used. The complex protects the Mg of chl *a* from being leached away by the anion formed from H_2S as was done in the previous case. Water plays an ambiguous role in the reaction of H_2S with chl *a*; if there is too little, there is no reaction, if there is too much, the reaction is stopped by the formation of a complex.

The Effect of NO and NO_2 on a chl a *Multilayer*

These two gases have exactly the same effect on the chl *a* multilayer. Therefore we will only present the results of NO_2 on chl *a*.

The electronic spectra of 2 × 34 layers of chl *a* in contact with NO_2 vapors (P = 26 kPa) are presented in Fig. 9. After 3 min of contact, the reaction is complete and the main bands of chl *a* have disappeared, leaving two weak bands situated at 688 and 457 nm. The overall absorption is due to NO_2 and to scattering. The reaction products dissolved in diethyl ether gave the spectrum presented in Fig. 5. A TLC of this solution has shown that there is no migration of the reaction products.

To determine the end products, a stable multilayer (2 × 32 layers) of chl *a* has been put in contact with NO_2 vapors (P = 29 kPa) for 15 h. The ir spectra are presented respectively in Fig. 10*B* and *C*. After washing the sample with hot water, ir spectrum is taken (Fig. 10*D*). In this spectrum, we notice that there is not much modification from the previous spectrum, except for a decrease in the overall intensity, and for the fact that the small water band noticed in spectrum *C* at ~1650 cm^{-1} has disappeared in spectrum *D*. Repeating the experiment, but washing the reaction product with diethyl ether instead, gave the spectrum in Fig. 10*E*. In this figure, the bands can be identified with water bands but the intensity is smaller than what has been obtained for the reaction between chl *a* and SO_2 or H_2S. The positions of the main bands are the same as the previous ones, but the secondary features are different indicating that the inorganic matrices are different. Following the reaction

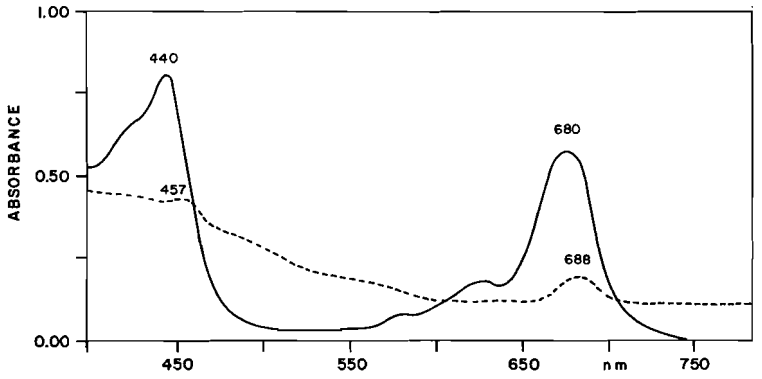

FIG. 9. NO_2 effect (29 kPa) on the absorption spectra of chlorophyll *a* multilayer (2 × 34 layers): initial spectrum (—); in NO_2 vapors for 3 min (---).

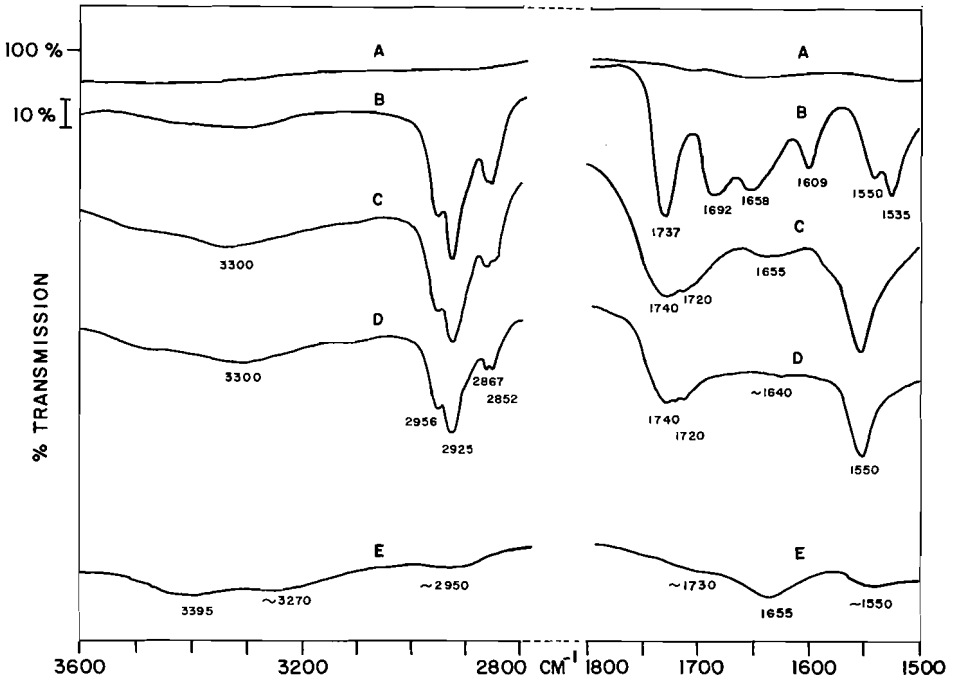

FIG. 10. NO_2 effect (29 kPa) on the infrared spectra of chl *a* multilayer (2 × 32 layers). *A*, background spectrum; *B*, multilayer after reorganisation; *C*, 15 h in NO_2 vapors; *D*, sample washed with hot water; *E*, another sample treated with NO_2 vapors for 16 h, and then washed with diethyl ether.

of NO_2 on the chl *a* multilayer (Fig. 10*C*), there is a formation of a strong band centered at ~3300 cm^{-1} which does not completely disappear upon washing with hot water. The C=O ester band at 1737 cm^{-1} is broadened to a 1740 cm^{-1} band with a shoulder at 1720 cm^{-1}, the C=O ketone bands at 1692 and 1658 cm^{-1} have disappeared, the C=C, C=N band at 1609 cm^{-1} and the skeletal doublet at 1550, 1535 cm^{-1} are modified leaving a strong structureless band which can be identified with a nitro group at 1550 cm^{-1}. This nitro group will render the molecule partly soluble, and this is the reason for the decrease of the intensity of the bands after the hot water washing. Although it is difficult to propose a mechanism for the reaction of NO_2 on chl *a*, the following observations can be made: first, the reaction is much more drastic than the reaction of chl *a* with either SO_2 or H_2S; secondly, there seems to be opening of the cycle; and thirdly, there is nitration of the chlorophyll *a* molecule.

The gas phase reactivity of the dimethylchloronium ion with alkylbenzenes

JOHN A. STONE, MARGARET S. LIN, AND JEFFREY VARAH
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received July 29, 1980

JOHN A. STONE, MARGARET S. LIN, and JEFFREY VARAH. Can. J. Chem. **59**, 2412 (1981).

The reactivity of the dimethylchloronium ion with a series of aromatic hydrocarbons has been studied in a high pressure mass spectrometer ion source using the technique of reactant ion monitoring. Benzene is unreactive but all others, from toluene to mesitylene, react by CH_3^+ transfer to yield σ-bonded complexes. The relative rate of reaction increases with increasing exothermicity in line with current theories of nucleophilic displacement reactions.

JOHN A. STONE, MARGARET S. LIN et JEFFREY VARAH. Can. J. Chem. **59**, 2412 (1981).

Faisant appel à la technique de l'enregistrement de l'ion réactif dans un spectromètre de masse à haute pression on a étudié la réactivité de l'ion diméthylchloronium avec une série d'hydrocarbures aromatiques. Le benzène ne réagit pas mais tous les autres à partir du toluène jusqu'au mésitylène réagissent par transfert de CH_3^+ en donnant des complexes liés par des liaisons σ. La vitesse relative de la réaction augmente avec le caractère exothermique en accord avec les théories courantes sur les réactions de déplacements nucléophile.

[Traduit par le journal]

Introduction

Dialkylhalogenonium cations (RXR^+, X = Cl, Br, I) have been formed in strong acid solution by the reaction of RX with SbF_5–SO_2, HF–SbF_5 or anhydrous silver hexafluoroantimonate in SO_2 (1). The ions are good alkylating agents in the condensed phase for aromatic compounds, for example $C_2H_5XC_2H_5^+$, yields ethylbenzene by reaction with benzene and $CH_3XCH_3^+$ forms *o*-, *m*-, and *p*-xylene with toluene (2).

Dialkylfluoronium cations cannot be formed in strong acid solution but their presence as intermediates in γ-irradiated gaseous CH_3F has been postulated (3). When a small amount of aromatic (~0.1%) was present in CH_3F at 760 Torr the methyl addition product, toluene, was observed in good yield ($G \approx 1$, i.e. one molecule per 100 eV of absorbed energy). The relative rates of methylation as determined by competition studies were about the same for benzene, toluene, the xylenes, and mesitylene. When, however, a small amount of benzene was irradiated in either gaseous CH_3Cl or CH_3Br the yield of toluene was small ($G < 0.01$). This lack of alkylating ability of $CH_3ClCH_3^+$ towards benzene was confirmed by icr double resonance experiments at much lower pressures. Whereas $CH_3FCH_3^+$ was a precursor of $C_7H_9^+$ in CH_3F–C_6H_6 mixtures, $CH_3ClCH_3^+$ was not a precursor of $C_7H_9^+$ in CH_3Cl–C_6H_6 mixtures. This different behaviour was ascribed to the different geometries of the methyl group in $CH_3XCH_3^+$. It was suggested that $CH_3FCH_3^+$ possesses the higher degree of charge delocalization, i.e. the carbon atoms have the greater sp^2 character. This more planar —CH_3 group aids attack by the aromatic base. Conversely the much lower reactivity of $CH_3ClCH_3^+$ is due to a higher activation barrier engendered by the greater sp^3 character of the —CH_3 group. In this argument, the nature of the nucleophilic substrate is not considered.

We have therefore studied the reaction of $CH_3ClCH_3^+$ with an extended series of alkylbenzenes in a high pressure mass spectrometer in order to examine the influence, if any, of the structure of the nucleophile on the reaction rate. We have measured relative rates of reaction using the technique of reactant ion monitoring (RIM) (4, 5).

Experimental

The equipment used and the technique of reactant ion monitoring have been previously described in detail (5). The field-free photoionization source was operated at 300 K. Argon resonance radiation (11.7 eV) was used for ionization of CH_3Cl (~0.25 Torr) in helium (0.6–0.7 Torr). The signal due to $CH_3{}^{35}ClCH_3^+$ was monitored as small amounts of aromatic compounds entered the ion source from a chromatograph. From the relative decreases in signal for the different compounds, relative rate constants are obtained (4, 5). The 1 μL samples injected into the chromatograph contained ~0.1% of each of four aromatics in *n*-hexane as solvent. The amount of sample injected was such that the maximum decrease in monitored ion current was always less than 10% of the steady state value and under these conditions the relative rate constants obtained are independent of sample size.

Results and Discussion

The molecular ion (CH_3Cl^+) is the only ion formed when CH_3Cl is ionized by 11.7 eV photons. At pressures greater than 50 mTorr this ion disappears completely, being replaced by the halonium ion (6, 7)

[1] $CH_3Cl^+ + CH_3Cl \rightarrow CH_3ClH^+ + CH_2Cl$

[2] $CH_3ClH^+ + CH_3Cl \rightarrow CH_3ClCH_3^+ + HCl$

Figure 1 shows both a gc trace and the monitored $CH_3{}^{35}ClCH_3^+$ ion signal for a sample containing fluorobenzene, toluene, ethylbenzene, and mesitylene in roughly equal concentrations. The same relative decreases in ion signal were observed when $CH_3{}^{37}ClCH_3^+$ was monitored. Obviously mesitylene is much more reactive than the other aromatics and although the *n*-hexane solvent also causes a decrease in the monitored ion current, the magnitude of the decrease is not very different from that due to mesitylene. The *n*-hexane, present at much higher concentration than the aromatics as shown by the gc trace, could be reacting either with $CH_3ClCH_3^+$ or with its precursor CH_3ClH^+ since the reaction product is $C_6H_{13}^+$, presumably formed by hydride transfer

[3] $CH_3ClCH_3^+ + n\text{-}C_6H_{14} \rightarrow CH_3Cl + CH_4 + C_6H_{13}^+$

[4] $CH_3ClH^+ + n\text{-}C_6H_{14} \rightarrow CH_3Cl + H_2 + C_6H_{13}^+$

When the *n*-hexane is present at a concentration comparable with that of the aromatics shown in Fig. 1, it has no observable effect on the monitored ion current.

Figure 2 shows the relative rates of reaction of a series of alkylaromatics and of aniline and nitrobenzene. In all cases the only observable product of reaction when the decrease in monitored ion current is less than 10% of the steady state value, is the methyl cation adduct, MCH_3^+, of the neutral M.

[5] $M + CH_3ClCH_3^+ \rightarrow MCH_3^+ + CH_3Cl$

Neither benzene nor fluorobenzene is found to react (rate of reaction < 10% that of ethylbenzene). This confirms the icr observation of Speranza and Pepe (3) and also substantiates our method. Both compounds would react exothermically with the precursors of $CH_3ClCH_3^+$, with CH_3ClH^+ by proton transfer and with CH_3Cl^+ by charge transfer. We are therefore studying the reaction of the $CH_3ClCH_3^+$ ion under the stated experimental conditions.

The nature of reaction [5] is of interest. It may be regarded as a nucleophilic displacement reaction, the nucleophile M displacing CH_3Cl from $CH_3ClCH_3^+$. If this is a direct displacement then either a σ complex is formed directly

[6] $CH_3ClCH_3^+ +$  $+ CH_3Cl$

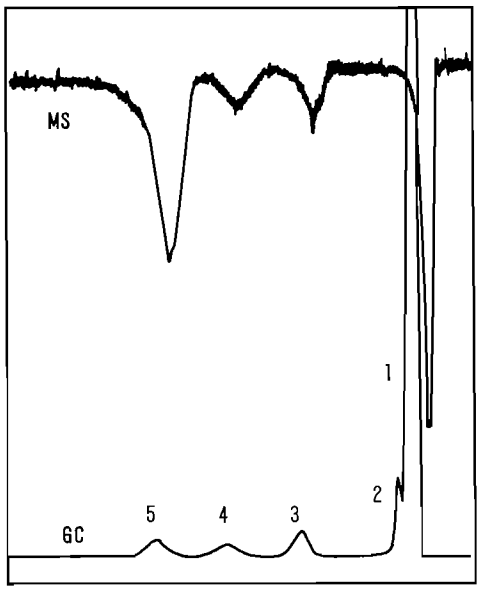

FIG. 1. Lower curve, flame ionization detector trace; upper curve, $CH_3{}^{35}ClCH_3^+$ signal. *1*, *n*-Hexane (solvent); *2*, fluorobenzene; *3*, toluene; *4*, ethylbenzene; *5*, mesitylene. The traces are offset by the dual pen strip-chart recorder.

or a π complex is formed which might or might not pass over into the more stable σ form. The relative rates of reaction provide no details of the reaction mechanism but the trend shown is more consistent with that for liquid phase S_N2 reactions which are presumed to proceed via a σ complex formation (8).

The participation of π complexes in condensed phase displacement reactions has been strongly advocated (9) but the concept has not received widespread support (10). A similar situation prevails for the gas phase. Arguments have been advanced for prior π complex formation in gas-phase aromatic methylenation by $C_2H_5O^+$ (11) and for acetylation of anisoles by $CH_3COCO(COCH_3)$-CH_3^+ (12). In each case anomalous substituent effects on reaction rate was cited as evidence. In neither case was the character of the product ion probed, it being presumed to be the final, more stable σ complex.

Direct evidence for the formation of a stable π complex in the gas phase nitrosation of benzene by CH_2ONO^+ was obtained using icr by Reents and Freiser (13). The $C_6H_6NO^+$ formed was found to transfer only NO^+ to toluene, a stronger NO^+ acceptor than benzene, whereas there was no proton transfer to pyridine as should occur for a σ-bonded complex. We confirmed this finding under different conditions. In a 60/40/0.01 He/NO/C_6D_6 mixture,

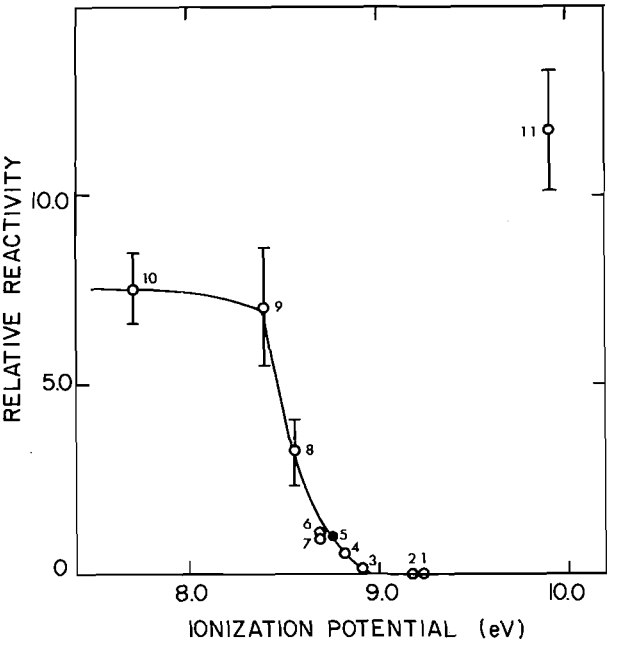

FIG. 2. The dependence of the relative reactivity of neutral molecules towards $CH_3ClCH_3^+$. *1*, Benzene; *2*, fluorobenzene; *3*, *m*-fluorotoluene; *4*, toluene; *5*, *n*-butylbenzene; *6*, ethylbenzene (standard); *7*, isopropylbenzene; *8*, *o*-xylene; *9*, mesitylene; *10*, aniline; *11*, nitrobenzene. The error bars show the precision obtained from four experiments.

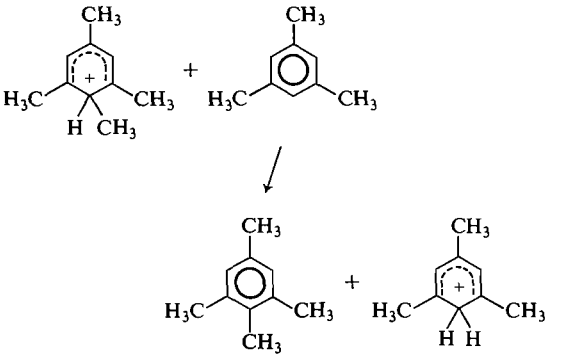
the $C_6D_6NO^+$ formed transfers NO^+ but not D^+ to pyridine. The same behaviour is found for the toluene-d_8 NO^+ complex.

We have examined the MCH_3^+ ions formed by the aromatic hydrocarbons in a similar manner but find no evidence for the formation of a stable π complex. These experiments were performed in a field-free, electron impact, chemical ionization source (14) which has a greater sensitivity for product detection than the photoionization source but operates at a slightly higher temperature (60°C) and also generates other ions from CH_3Cl in addition to the molecular ion.

The CH_3^+ adduct of nitrobenzene-d_5 formed in a 60/40/0.02 $He/CH_3Cl/C_6D_5NO_2$ mixture at a total pressure of 0.9 Torr transfers only CH_3^+ to pyridine whereas when ring deuterated mesitylene-d_3 or *o*-xylene is substituted for the nitrobenzene, CH_3^+ is not transferable but $D^+(H^+)$ is. Therefore CH_3^+ is on oxygen in the nitrobenzene complex and a σ complex is formed with the hydrocarbons.

This conclusion is supported by observation of the further reaction of MCH_3^+. A 60/40/0.04 He/CH_3Cl/mesitylene mixture was examined at different pressures from 0.7 to 1.5 Torr (Fig. 3). At high pressure the predominant peaks are MH^+ and MCH_3^+ with the former growing at the expense of the latter. The ion arrival time distribution obtained by pulsing the electron beam, confirms that MCH_3^+ is the precursor of MH^+ (Fig. 4). The reaction is proton transfer from the product of reaction [6], i.e. ipso-protonated 1,2,3,5-tetramethylbenzene, to mesitylene and the rate of reaction, estimated from the normalized curves of Fig. 4, is $\sim 6 \times 10^{11}$ cm^3 molecule^{-1} s^{-1}.

[7]



Such a low rate constant implies that the ipso-proton affinity of the tetramethylbenzene must be very close to that of mesitylene and hence a little lower than the proton affinity for a non-substituent site. Although the latter value is not available, proton affinity for the methylbenzenes appears to increase monotonically with the number of methyl groups (15). Calculation suggests that ipso-protonated toluene is $\sim$6 kcal mol^{-1} less stable than the *para*-protonated form but that such differences decrease with increasing alkyl substitution on the ring (16). The energy difference between ipso and non-ipso-protonation is obviously still significant for tetramethylbenzene.

The calculated exothermicities for reaction [5], i.e. formation of a σ complex are large for benzene through mesitylene (20–35 kcal mol^{-1}), increasing with increasing alkyl substitution, i.e., with decreasing ionization potential of M.[1] On this basis it is surprising that benzene shows no reaction but this is in keeping with the present theory of nucleophilic displacement reactions. Olmstead and Brauman (17) have shown that many other gas phase nucleophilic displacement reactions, although also highly exothermic, may be very slow. Their explanation of such behaviour is given in terms of a potential energy surface which has a double minimum corresponding to the formation of two intermediate complexes. For CH_3Cl displacement from $CH_3ClCH_3^+$ this corresponds to a

[1]The CH_3Cl—CH_3^+ dissociation energy is 64 kcal mol^{-1} (P. Kerbarle, private communication) so that $\Delta H_f^\circ(CH_3ClCH_3^+) = 177$ kcal mol^{-1}).

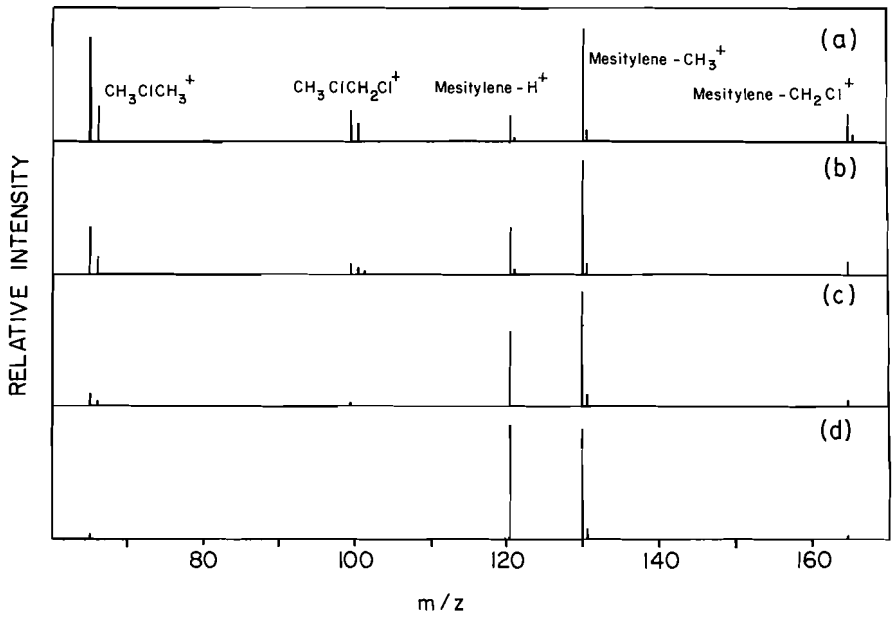


FIG. 3. The mass spectrum of a He (60%), CH_3Cl (40%), mesitylene (0.04%) mixture at 60°C as a function of total pressure. (*a*) 0.87 Torr, (*b*) 1.0 Torr, (*c*) 1.2 Torr, (*d*) 1.7 Torr.

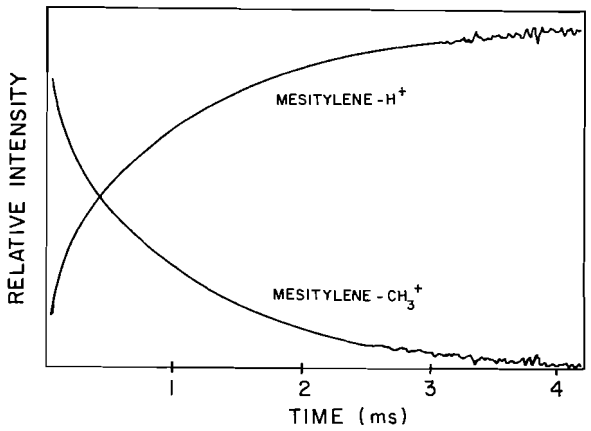

FIG. 4. Time dependence of the relative intensities of ions observed at 1.5 Torr and 60°C in a mixture containing He (60%), CH_3Cl (40%), mesitylene (0.04%). Duration of electron pulse 30 μs.

scheme for reaction [3] of the form

$$M + CH_3ClCH_3^+ \rightarrow (M \cdots CH_3ClCH_3)^+ \rightarrow$$

A

$$(MCH_3 \cdots ClCH_3)^+ \rightarrow MCH_3^+ + CH_3Cl$$

B

In order to pass from **A** to **B** the CH_3 group must invert, i.e. pass through a tight transition state complex whereas for the reaction to regenerate products the transition state is very loose. The latter has much more closely spaced energy levels and so although the overall reaction is exothermic, entropy considerations favour product regeneration. As the potential energy difference between reactants and products increases with increasing methyl substitution, presumably the level of the central potential energy maximum decreases relative to that of the reactants. Thus with increasing exothermicity, energetic factors overcome entropic factors and the relative rate of reaction increases. If this mechanism is correct the reaction rate constants should exhibit negative temperature coefficients. Unfortunately the necessary temperature studies cannot be performed with the present photoionization source due to the decrease in intensity of an already weak signal when the ion source temperature is raised above 298 K.

There is a similarity between the shape of the curve in Fig. 2 and similar plots for the reactions of NO_2^+ and $C_2H_5ONO_2NO_2^+$ with a series of aromatics (18). The threshold for reaction by these ions is attributed to an initial step which is thermoneutral electron transfer from the aromatic to the attacking electrophile. The major product under these conditions is the NO_2^+ adduct. With increasing exothermicity, i.e. decreasing ionization potential of the aromatic, charge transfer soon predominates to yield the aromatic ion as the major product. This does not appear to be the mechanism for $CH_3ClCH_3^+$ since (*a*) the relative rate constant for nitrobenzene is large, even though its ionization potential (9.9 eV (19)) is well above threshold and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

(*b*) we see no evidence for the formation of aromatic molecular ions even with mesitylene and aniline for which charge transfer would be exothermic by ≥ 0.5 eV.

The slope of the curve in Fig. 2 is, as noted, similar to those for the reactions of NO_2^+ and $C_2H_5ONO_2NO_2^+$ (19). The measured absolute rate constants for these ions become equal to the rate constants for collision at an ionization potential of the neutral about 0.5 eV below the threshold for reaction. By analogy we propose that the plateau drawn in Fig. 2 also signifies reaction at every collision for mesitylene and aniline (and therefore also for nitrobenzene). In support of this suggestion, the relative rates of reaction and collision (calculated using the average dipole orientation theory (20), values in parentheses)) are mesitylene 1.0 (1.0), aniline 1.1 (1.0), and nitrobenzene 1.7 (1.7). The generalization of Speranza and Pepe (3) that $CH_3ClCH_3^+$ is a poor alkylating agent for aromatics in general is therefore not borne out, although the lack of significant reaction with benzene is confirmed. The dimethylchloronium ion is a selective methylating agent.

A spectroscopic investigation of trimethyl- and triphenyl-arsine adducts of boron trihalides

JOHN E. DRAKE, LAYLA N. KHASROU, AND ABDUL MAJID

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received January 6, 1981

JOHN E. DRAKE, LAYLA N. KHASROU, and ABDUL MAJID. Can. J. Chem. **59**, 2417 (1981).

Trimethyl- and triphenyl-arsine adducts of the type $(CH_3)_3AsBX_3$ and $(C_6H_5)_3AsBX_3$, X = Cl, Br, I, have been prepared and characterised by infrared, Raman, ^1H and ^{13}C nmr spectroscopy. The vibrational assignments based on normal coordinate analysis are presented for the series $(CH_3)_3AsBX_3$. Potential energy distributions and modified Urey–Bradley potential parameters are reported.

JOHN E. DRAKE, LAYLA N. KHASROU et ABDUL MAJID. Can. J. Chem. **59**, 2417 (1981).

On a préparé les adduits triméthyl- et triphénylarsine du type $(CH_3)_3AsBX_3$ et $(C_6H_5)_3AsBx_3$ (X = Cl, Br, I) et on les a caractérisés par la spectroscopie infrarouge, Raman et rmn du ^1H et du ^{13}C. Dans le cas des séries $(CH_3)_3AsBX_3$, on a identifié les mouvements de vibration en se basant sur une analyse normale de coordonnées. On rapporte les distributions d'énergie potentielle et les paramètres de potentiel modifiés de Urey–Bradley.

Introduction

Although numerous studies have been undertaken of amines as Lewis bases and the properties of phosphine–boranes have been investigated with the use of nmr spectroscopy (1–4), relatively little has been reported on the simple adducts of trimethylarsine and triphenylarsine with boron halides. A thorough vibrational analysis of $(CH_3)_3AsBH_3$ and $(CH_3)_3AsBD_3$ has been reported (5) as has the preparation of $(CH_3)_3AsBCl_3$ (6, 7) and the ^1H and ^{11}B nmr spectra of $(CH_3)_3AsBBr_3$ and $(CH_3)_3AsBI_3$ (8). There have also been gas phase calorimetric studies of tertiary phosphines, arsines, and stibines with boron trihalides (9) and a brief report on infrared and Raman spectra (10). We describe the ^1H and ^{13}C nmr, spectra of $(CH_3)_3AsBX_3$ and $(C_6H_5)_3AsBX_3$, X = Cl, Br, I as well as carrying out an analysis of their vibrational spectra. As this manuscript was being prepared, a vibrational analysis of the $(CH_3)_3AsBX_3$ series appeared in the literature (11). This work emphasized the assignments and calculations of the As—B stretch and related force constants. While in general their conclusions are in agreement, our assignments of the modes in the region below 800 cm^{-1} do differ in detail and as a result so do the values of the force constants.

Experimental

The adducts $(CH_3)_3AsBX_3$ were prepared under vacuum line conditions by the same method of molecular addition outlined previously (12). The formation of the $(C_6H_5)_3AsBX_3$ adducts was achieved under moisture-free conditions in a standard nitrogen glove box.

Trimethylarsine (Strem Chemicals), triphenylarsine (ROC/RIC), and the boron trihalides (ROC/RIC) were all commercially available.

The ^1H nmr spectra were recorded, using a high resolution JEOL C60-HL nmr, spectrometer operating at 60 MHz. The ^{13}C nmr spectra were recorded on a Bruker CXP 100 multinuclear pulsed Fourier transform spectrometer operating at 22.64 MHz at a probe temperature of 35°C, under ^1H noise decoupling conditions. Chemical shifts were calculated as parts per million from TMS as internal standard in CH_2Cl_2 and in the case of the ^{13}C nmr, CD_2Cl_2 was used as internal lock. The adducts are at best only slightly soluble in all solvents tried. Thus, for example the ^1H nmr peaks of the methyl groups in $(CH_3)_3AsBCl_3$ are not very much more intense than those of the proton impurity in the CD_2CL_2 solvent, and we could not possibly identify the positions of $\delta(C_x)$ in two cases, for $(C_6H_5)_3AsBX_3$ compounds.

Mid ir spectra were recorded on a Beckman IR-12 instrument and the far ir spectra were recorded, for solid compounds, as Nujol mulls between two polyethylene plates on a Perkin-Elmer 180 spectrometer operating in conjunction with an Interdata model 6/16 computer. Difference routines were used to subtract the Nujol and CH_2Cl_2 peaks. Raman spectra of the solid and of solutions in CH_2Cl_2 and CH_3I were recorded on a Spectra-Physics 700 spectrometer, using the argon line at 488.0 nm.

The normal coordinate analysis was performed using an IBM S/360-50 series computer with a program written by Dr. J. L. Hencher of this Department. The assignments of the fundamental vibrations were made assuming that the $(CH_3)_3AsBX_3$ molecules have C_{3v} symmetry.

All angles at carbon and boron were assumed to be tetrahedral. The other dimensions (C—H 109, C—As 195, As—B 203, B—Cl 184, B—Br 202, B—I 226 pm, and ∠CAsC 105.5, ∠AsBX 109.5 deg) were based on related molecules (13) such as $(CH_3)_3As$ (14) and $(CH_3)_3AsBH_3$ (5). A cross section of adducts was analyzed to confirm that they were 1:1 adducts.

Anal. calcd. for $(CH_3)_3AsBCl_3$: C 15.19, H 3.83, Cl 44.84; found C 15.15, H 3.57, Cl 40.01; calcd. for $(CH_3)_3AsBBr_3$: C 9.73, H 2.45, Br 64.70; found C 9.90, H 2.45, Br 64.83; calcd. for $(CH_3)_3AsBI_3$: C 7.04, H 1.77, I 74.43, found C 7.32, H 1.89, I 74.01; calcd. for $(C_6H_5)_3AsBCl_3$: C 51.06, H 3.57, Cl 25.12, found C 51.62, H 3.66, Cl 25.20.

All compounds are white or off-white and are moisture-sensitive solids.

Results and Discussion

The ^1H Nuclear Magnetic Resonance Spectrum of $(CH_3)_3AsBCl_3$ is displayed in Fig. 1 and the ^1H and ^{13}C nmr chemical shifts for $(CH_3)_3AsBX_3$ and $(C_6H_5)_3AsBX_3$, X = Cl, Br, I, are listed in Table 1. The ^1H nmr signal of the methyl group in $(CH_3)_3As$ is broadened considerably on adduct formation as had been noted previously (10). However, under higher resolution these broad singlets appear as distorted quartets. These can be assigned as arising from the overlapping of a 1:1:1:1 quartet from coupling with the ^{11}B nucleus ($I = 3/2$; 81.2%) with a 1:1:1:1:1:1:1:1 septet from coupling with the ^{10}B nucleus ($I = 3$; 18.8%). If the value of $^3J(^{11}BH)$ is estimated as ca. 1.9 Hz from the positions of the two outermost peaks and then the value of $^3J(^{10}BH)$ is assumed to be ca. 0.7 Hz from the gyromagnetic ratios ^{11}B and ^{10}B, then a theoretical schematic spectrum can be sketched. Considering the broadening effect of the boron quadrupole, this fits the observed spectrum reasonably well (see Fig. 1). Similar long range BH coupling has been observed in amine adducts (4, 15). The values of the ^1H chemical shifts for these $(CH_3)_3AsBX_3$ species are very close to those in the corresponding $(CH_3)_3PBX_3$ (16).

By contrast the ^{13}C chemical shifts are closer to TMS for the $(CH_3)_3AsBX_3$ than the corresponding values in $(CH_3)_3PBX_3$ ($\delta(^{13}C$ for $(CH_3)_3PBCl_3$ 6.30, $(CH_3)_3PBBr_3$ 6.72, and $(CH_3)_3PBI_3$ 7.12 ppm). In fact, the shifts are very close to those of the methyl carbons in $(CH_3)_3GeCl$ (17). However, as with the ^1H shifts, there is a steady increase along the series $BCl_3 < BBr_3 < BI_3$ which is consistent with the concept of an increasing deshielding as the acidity of the boron halide increases. The same trend, to a slightly lesser degree, is seen for the $(C_6H_5)_3AsBX_3$ series.

In $(C_6H_5)_3As$, the ^{13}C chemical shifts are observed as four distinct signals for the *ortho* $\delta(C_o)$, *para* $\delta(C_p)$, *meta* $\delta(C_m)$ and substituted carbon atom $\delta(C_x)$. The latter signal is often not readily detected (18) and indeed is only identified for the BCl_3 adduct. The assignment of our ^{13}C spectrum of triphenylarsine is based largely on the previous results for the diphenylarsine (19). It has been

reported that substituent effects on the π-electron distribution in benzene derivatives can be related to the Hammett–Taft constants σ_R^0 (20) which can be calculated from $\delta_p(^{13}C) - \delta_m(^{13}C) = 22.06\ \sigma_R^0$ (18). The σ_R^0 value for Ph_2As was found to be −0.0099 while for Ph_3As it is −0.0090. This implies that the phenylarsenic π interactions are negligible and if occurring at all, indicate an electron release from arsenic towards the phenyl ring. By contrast, the significant positive values obtained for the adducts indicate that delocalization of π charge has occurred from the phenyl group to the vacant, low energy $3d_\pi$ orbitals of arsenic. The values obtained for Ph_3AsBX_3 are relatively similar to values obtained for $^+As(C_6H_5)_3I^-$ 0.149 (18). On formation of the adducts, arsenic would indeed be expected to become relatively more electropositive, thus allowing for the ($\pi \rightarrow d$) transitions to occur. The trend of increasing values of σ_R^0 along the series $BCl_3 < BBr_3 < BI_3$ is also consistent with their increase in Lewis acidity.

The infrared and Raman spectra of the $(CH_3)_3AsBX_3$ adducts are displayed in Figs. 2–4 to show features of the solid Raman, mid-infrared, and solution Raman spectra. Complete spectroscopic information, along with the calculated frequencies and assigned frequencies and potential energy distributions are given for $(CH_3)_3AsBCl_3$, $(CH_3)_3AsBBr_3$ and $(CH_3)_3AsBI_3$ in Tables 2–4 respectively. The conventional descriptions of the fundamental vibrations are presented in Table 5 and the derived force constants in Table 6. The methyl group stretching vibrations are observed in the same region as the free Lewis base (21). The three asymmetric CH_3 stretches, ν_1, ν_{16}, ν_{17}, are contained in a single envelope in the region 3000–2980 cm^{-1} in all three adducts. Both of the symmetric CH_3 stretches, ν_2 and ν_{18}, are assigned to the more intense, polarised Raman band at 2931, 2920, and 2923 cm^{-1} in the chloride, bromide, and iodide respectively. The intensity of these bands in the Raman is apparently greater than that reported by previous workers (11) (see Fig. 2) possibly because of a different excitation source (22). These CH_3 stretches are essentially pure modes, well described by fCH^2 which has a marginally higher value than in the free base, while the interaction constant fCH/CH, has a slightly lower value. The CH_3 asymmetric deformations, ν_3, ν_{19}, ν_{20}, lead to broad features in both effects and show minimal changes in frequency in all adducts, compared with free methylarsines such as $(CH_3)_3As$ (21), $(CH_3)_2AsH$ (23), and CH_3AsH_2 (24). The symmetric CH_3 deformations, ν_{21} and ν_4, show up as two peaks in all adducts, the splitting of the e and a_1 modes

being also demonstrated in the calculations. Once again, the distribution of force constants $fHCH^2$, $fHCAs^2$, and $fHCAs/HCAs$ are virtually the same in all adducts, with slightly changing values for the latter two along the series. The values of fCH^2, fCH/CH and $fHCH^2$ are very similar to those used in the treatment of the $(CH_3)_3PBX_3$ adducts (25), those of $fHCAs^2$ are slightly lower, as might be expected, than those of $fHCP^2$, and the interaction constants $fHCAs/HCAs$ are again negative. The CH_3-rocking modes ν_{22}, ν_5, ν_{23} are assigned to the next three features, close to ca. 920, 850, and 800 cm^{-1} in all three adducts. The two stronger peaks in the infrared spectra, at ca. 920 and 800 cm^{-1}, which have corresponding weak depolarised Raman bands, are assigned to ν_{22} and ν_{23}, leaving ν_5 to be assigned to ca. 850 cm^{-1} (as can be seen in Figs. 2 and 3). Once again, the distribution of the force constants is essentially unchanged for all three adducts. The interaction term, *fcis*-HCAs/HCAs, which allows for the interaction of an HCAs angle on one methyl group with an HCAs angle on another methyl in the *cis*-position, is

needed to reproduce the splitting of these rocking modes. Thus, it is clear that the $(CH_3)_3As$ entity behaves very much as an isolated group being little effected by the change of halogen on boron. The AsC_3 stretching vibrations, ν_{24} and ν_7, are therefore expected to behave in a similar manner and indeed in all three adducts can be identified as depolarised, ν_{24}, and polarised, ν_7, bands in the regions 630–642 cm^{-1} and 578–598 cm^{-1} respectively, with corresponding bands in the infrared spectra (Fig. 3). These bands and their relative intensities are typical of the bands noted for $(CH_3)_3AsBH_3$ and $(CH_3)_3AsBD_3$ (5, 22) and by the previous workers (11). The shift to higher wavenumber is to be expected for a shortening of the As—C bond as was demonstrated for $(CH_3)_3AsBH_3$ (1.945 ± 0.01 Å) (5) relative to $(CH_3)_3As$ (1.959 ± 0.01 Å) (14). A high frequency shift was also observed for the quaternarization of $(CH_3)_3As$ to $(CH_3)_4As^+$ (26). The values in the latter case are very close to those observed for these $(CH_3)_3AsBX_3$ adducts, suggesting that the formation of the strong adducts with BX_3 has a similar effect on the As—C bond as does the quaternary salt. This is a clear indication that the re-arrangement of the CAsC angles is approaching tetrahedral as was illustrated for $(CH_3)_3AsBH_3$ (5). Our calculations, in contrast to those reported in the recently published paper (11) suggest that the value of $fCAs^2$ progressively increases from the free base to the chloride, then bromide, than iodide in accord with the expected increase in base strength. The AsC_3 asymmetric, ν_{26}, and symmetric, ν_9, deformation modes are assigned at ca. 225 cm^{-1} and 210 cm^{-1} in all adducts (Fig. 4) with the former, being weak and depolarised in the Raman effect and the latter stronger and polarised. The corresponding lines in the far-infrared spectra show up as medium intensity bands for the asymmetric mode with weak shoulders assignable as the symmetric AsC_3 deformations. Surprisingly, in view of the opening-up of the C—As—C angle, the value of $fCAsC^2$ is much lower than in the free arsine. Finally, for modes involving the $(CH_3)_3As$ group, the AsC_3 rocking mode, ν_{27}, is assigned to a weak, broad, depolarised band in the Raman at 170 cm^{-1} with a corresponding broad band in the far-infrared at ca. 172 cm^{-1}, in $(CH_3)_3AsBCl_3$. The band is slightly split, probably reflecting a loss of degeneracy. (The previous workers assigned this band as the symmetric, a_1, BCl_3 deformation mode but this is

For personal use only.

unlikely in view of the depolarisation (Fig. 4). Similar comments apply to their assignments in the other adducts.) The AsC_3 rock is seen, with similar features in the two effects, at around 140 cm^{-1} in the bromide and 110 cm^{-1} in the iodide. The AsC_3 rock involves a number of force constants, as might be expected, principally fCAsB^2. In other words, it might be better considered as arising from CAsB angle bending.

The BX_3 asymmetric mode, ν_{25}, is typically a strong, distinctive band in the infrared spectrum with a corresponding medium intensity, depolarised band in the Raman spectrum. It can be identified at 700 cm^{-1} in the chloride, 615 cm^{-1} in the bromide, and 548 cm^{-1} in the iodide. The values of K_{BX} are similar in value to those in the $(CH_3)_3PBX_3$ series (25) as is to be expected, because the peaks are actually seen at 712, 621, and 556 cm^{-1} within that series. Thus, the same trend of a weakening of the BX bond as the boron adopts an "sp^3" rather than "sp^2" configuration is observed. We had previously noted, in the spectra of the $(CH_3)_3PBX_3$ series, that this mode was one of two for which the calculations predicted and the spectra showed a weaker feature to higher wave-numbers corresponding to the $^{10}BX_3$ asymmetric stretch. In the chloride this is seen as a depolarised band at 745 cm^{-1} but in the bromide it is masked by the AsC_3 asymmetric stretch and in the iodide by the AsC_3 symmetric stretch. The assignment of the BX_3 symmetric stretch, ν_8, is probably one of the easiest because this appears as an intense polarised band in the Raman at 373, 245, and 172 cm^{-1} in the three adducts as expected at the slightly lower wave-number than that observed in $(CH_3)_3PBX_3$ (25). It is interesting to note the increasing dependence of this motion on the force constant F_{XX}, the Urey–Bradley nonbonded repulsion constants (27) along the series Cl < Br < I. The BX_3 deformations, ν_{28} and ν_{10} show the usual general trend in their frequencies with decreasing values along the adduct series, as indicated in the far-infrared spectra of the trichloride, tribromide, and triiodide adducts with 255, 160; 180, 130 and 117, 95 cm^{-1} respectively. The corresponding peaks in the Raman for the asymmetric mode are depolarised but the peaks corresponding to the symmetric mode are weak and too close to the exciting line to give clear polarisation data. However, once again there is an obvious increasing dependence on F_{XX}, particularly for the asymmetric mode, from Cl< Br < I, while for the symmetric mode, H_{AsBX} makes a significant contribution. Finally, for the BX_3 group, the BX_3 rock is assigned in all adducts to the lowest frequency fundamental at 132, 94, and 80 cm^{-1}

	ν_{14}	ν_{30}	CH_3 torsion
	ν_{15}		Frame torsion

[a]The 45 fundamentals are distributed, in C_{3v} symmetry, as $10A_1 + 5A_2 + 15E$; the A_1 and E modes being active in both ir and Raman and the A_2 modes inactive.

where once again their positions are very close to those observed in $(CH_3)_3PBX_3$.

The only fundamental remaining to be assigned is thus the As—B stretch, ν_6. As is typical of many boron adducts, this is not only the mode of most interest but also the hardest to assign with reasonable certainty. However, in all three adducts, there is indeed one feature remaining, which is polarised in the Raman effect and which is seen with reasonable clarity in the infrared. Because of its central importance this mode is marked with an asterisk in Fig. 2. Thus, the assignment to the As—^{11}B stretch, ν_6, is at 670, 660, and 651 cm^{-1} respectively in the chloride, bromide, and iodide, In the spectrum of $(CH_3)_3AsBCl_3$, previous workers (11) placed ν_6 as coincident with the BCl_3 asymmetric stretch at ca. 701 cm^{-1}, but the relative intensity of the band at 670 cm^{-1} and the fact that it is polarised make our assignment acceptable. As we had noted in the case of the $(CH_3)_3PBX_3$ adducts (25), this mode is one in which the calculations predict and one can normally detect a sufficient difference between the As—^{10}B and As—^{11}B stretches and the additional low-intensity peak can be seen clearly in the bromide and iodide and is presumably masked by ν_{25} in the chloride. This splitting has subsequently been confirmed (11). The same trend of slightly decreasing wave-number along the series $BCl_3 > BBr_3 > BI_3$ was also seen in the phospine adducts. However, as can be seen from the calculations, this does not indicate a weakening of the As—B bond. On the contrary, the value of K_{AsB} increases steadily in accord with the increasing acidity of the BX_3 group with $BCl_3 < BBr_3 < BI_3$. The values are about 15% lower than that found for K_{PB} in each case and change by some 18% from the chloride to iodide. This seems a more reasonable degree of change than the 40% claimed by others (11).

The infrared and Raman spectra of the $(C_6H_5)_3AsBX_3$ adducts in the region below 1600 cm^{-1} are summarized in Table 7, together with the suggested assignments. The investigation of the spectra of the trimethylarsine adducts provided a general background to the assignment and comparisons were also made with the reported assignments of some substituted benzenes (28–31), phenylarsines (26, 32), and phenylphosphine (33). The vibrations associated with the phenyl ring can be classified in accord with Hertzberg's notation (34). The high frequency region of the spectra (above 1600 cm^{-1}) can be satisfactorily correlated with the corresponding benzene vibrations (35, 36). These vibrations are expected to be substituent-insensitive ν(C—H) vibrations, while the six substituent-sensitive modes, Whiffen's (29) q, r, t, y, u, and x (X-sensitive, see Table 7) are all expected to be below 1600 cm^{-1}.

The l, k, ν(C—C) stretches are known to appear near 1600 cm^{-1} and are seen as one strong Raman line at 1573 cm^{-1} in $(C_6H_5)_3As$. This band is virtually unchanged in the adducts appearing at 1575, 1570, and 1575 cm^{-1} in the chloride, bromide, and iodide respectively. The other ν(C—C) bands, m, n, o, are present as a strong infrared absorption in the region just below the l, k frequencies, again essentially unchanged in the free arsine and the adducts. The in-plane C—H deformations (B) are almost unchanged from those of monohalosubstituted benzenes (29). The extremely strong polarised Raman band at 997 in $(C_6H_5)_3As$ and 999, 991, and 995 cm^{-1} in the BCl_3, BBr_3, and BI_3 adducts respectively, arises from ring breathing modes in which a substituent is not involved. The lowest of the out-of-plane C—H deformations f, γ(C—H) at 738 cm^{-1} in $(C_6H_5)_3As$ and at 735, 732, and 750 cm^{-1} in the adduct series are known to give very strong infrared absorptions, while the g, i, h, j, γ(C—H) deformations are indicated by medium or weak intensity bands in both the ir and Raman effects. This corresponds to what was found in $(C_6H_5)_2AsX_2$, X = Cl, Br (32). The out-of-plane ring deformation ϕ(C—C) is seen as a very strong infrared absorption 695, 685, and 700 cm^{-1} in the adducts, in agreement with the observed and calculated values of 698 cm^{-1} for benzene and deuterated benzene (35). The in-plane ring deformation, α(C—C—C), is seen in the Raman spectra at 617, 618, and 610 cm^{-1} in the $(C_6H_5)_3AsBX_3$ adducts in agreement with all substituted benzenes and $(C_6H_5)_3As$. Thus, for halosubstituted benzenes there is a clear trend to lower wave-number

for these frequencies along the series F > Cl > Br > I. The values do not change from $(C_6H_5)_3As$ to the various adducts, but in all cases (X-sensitive) are close to the values found for bromo substitution (29). The X-sensitive bands in phenylphosphine (33) are similarly close to those in chloro-substituted benzene (29). Thus, the relationship of the position of the X-sensitive bands to the mass of the atom joined to the ring is reinforced.

In the region of the C—As stretching frequencies coupling is to be expected between the C—As vibration and the mass sensitive vibrations of the phenyl group. Thus, the q, r, and t, X-sensitive modes are normally assumed to be those most closely corresponding to C—X stretches (29). In a study of phenylarsenic(III) halides, it was suggested that the strongest coupling occurs with the t vibrations (37). Similar conclusions have been reached for other arsenic compounds (38) and have been shown to be valid for a variety of phenylsilanes (19) and germanes (39), which are supported by calculation (40). The C—As stretches in trimethylarsine adducts with BX_3 are assigned in the regions of ca. 635 and 585 cm^{-1}, while the polarised q, r, and t lines in $(C_6H_5)_3AsBX_3$ (where X = Cl, Br, I) adducts are placed at 1082, 1088, 1080 cm^{-1}; 660, 655, 650? cm^{-1}; and 300, 292, 305 cm^{-1}. The skeletal region also contains low frequency ring modes and it is the most difficult region in the spectrum to assign.

Modes involving compression or bending of the C_3As bonds and the low lying X-sensitive ring vibrations are expected to be mixed with the BX_3 vibrations, especially the BCl_3 vibrational activity. By selecting the BX_3 mode by comparison with the corresponding modes in $(CH_3)_3AsBX_3$ and other related adducts (25) we are able to distinguish tentatively the low-lying X-sensitive vibrations in the skeletal region from those of the BX_3 groups.

The selection is rather difficult because the BX_3 modes are always associated with phenyl vibrations. Thus, for example, the out-of-plane α(C—C—C) deformation is expected to occur close to the asymmetric, ν_{as}(B—Br) vibration in $(C_6H_5)_3AsBBr_3$ so that a broad feature would not be surprising and is indeed seen. The ν_{as}(B—Cl) stretching mode is, however, one which can be seen clearly and is assigned to the band of medium intensity in the infrared at 722 cm^{-1}. This is consistent with the assignment of ν_{as}(B—Cl) to 720 cm^{-1} in $(CH_3)_3AsBCl_3$. Accordingly, the frequency at 370 cm^{-1} in the Raman spectrum of the triphenylarsine chloride adduct is assigned to the ν_s(B—Cl) stretching mode, while ν_s(B—Br), ν_s(B—I) are assigned to 228 and 153 cm^{-1} where a very strong Raman band is seen in the solid spectrum of

$(C_6H_5)_3AsBBr_3$ and $(C_6H_5)_3AsBI_3$ respectively. The region below 300 cm^{-1} also contains absorptions due to vibrations arising from skeletal $(C_6H_5)_3As$ deformations, in particular the *u* and *x* species. Tentative assignments of the BX_3 deformation modes are shown in Table 7. That the assignments can be made on the assumption that the BX_3 bands are essentially in the same positions in the triphenyl series as in the trimethyl suggests a similarity in the B—X bond strengths. However, given the uncertainty inherent in these assignments, this is perhaps a circular argument.

No features that could be definitely assigned to an isolated As—B frequency are observed in the $(C_6H_5)_3AsBX_3$ adducts, but a medium broad band in the Raman with a maximum at 640 cm^{-1} in $(C_6H_5)_3AsBCl_3$, 639 cm^{-1} in $(C_6H_5)_3AsBBr_3$ and 630 cm^{-1} in $(C_6H_5)_3AsBI_3$ can be reasonably assigned to the As—B stretching frequency. Because of the uncertainty in the polarisation data and broad nature of these bands, the assignment cannot be more than tentative. The presence of *r*, X-sensitive $(C_6H_5)_3As$ vibrations in this region further complicates the spectra and decreases the certainty of assignment. If correct, however, they do imply only a slight decrease from the assignment in the $(CH_3)_3AsBX_3$ adducts.

Received December 15, 1980

NORMAN L. PADDOCK, T. N. RANGANATHAN, STEVEN J. RETTIG, RAJENDRA D. SHARMA, and JAMES TROTTER. Can. J. Chem. **59**, 2429 (1981).

Dodecamethylcyclohexaphosphazene $N_6P_6Me_{12}$, **1**, forms 1:1 complexes with palladium(II) chloride, **2**, and platinum(II) chloride, **3**. Their ^{31}P, ^1H, and ^{13}C nmr spectra show them to be rigid molecules in solution, with an approximate plane of symmetry. Crystals of **2** are orthorhombic, $a = 17.4030(3)$, $b = 15.4897(5)$, $c = 10.7417(2)$ Å, $Z = 4$, space group $P2_12_12$. The structure was determined from diffractometer X-ray data and refined by full-matrix least-squares methods to $R = 0.031$ for 3545 reflections with $I \geq 3\sigma(I)$. The metal atom has square planar coordination, and forms 6- and 10-membered chelate rings with the phosphazene ligand. The mean P—N bond length is 1.609 Å; the variation of bond lengths within the ring is consistent with model calculations of changes in bond order arising from the localization of bonding electrons.

NORMAN L. PADDOCK, T. N. RANGANATHAN, STEVEN J. RETTIG, RAJENDRA D. SHARMA et JAMES TROTTER. Can. J. Chem. **59**, 2429 (1981).

La dodécaméthylcyclohexaphosphazène $N_6P_6Me_{12}$, **1**, forme les complexes 1:1 avec le chlorure du palladium(II), **2**, et du platine(II), **3**. Leurs spectres rmn ^{31}P, ^1H et ^{13}C indiquent que les molécules sont rigides en solution, et elles ont approximativement un plan de symétrie. Les cristaux de **2** sont orthorhombiques, $a = 17.4030(3)$, $b = 15.4897(5)$, $c = 10.7417(2)$ Å, $Z = 4$, groupe d'espace $P2_12_12$. On a résolu la structure au moyens de données diffractométriques des rayons X et on l'a raffinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de $R = 0.031$ pour 3545 réflexions avec $I \geq 3\sigma(I)$. L'atome du métal a la coordination d'un plan carré, et forme les cycles chélatés de six et dix membres avec le ligand phosphazène. La longeur moyenne des liaisons P—N est de 1.609 Å; la variation des longeurs de liaisons au dedans la cycle est en accord avec des calculations modèles de variation de l'ordre des liaisons, qui résultent des localizations des électrons liants.

Introduction

An earlier study (1) described the donor properties of the cyclic dimethylphosphazenes $(NPMe_2)_{3-5}$. The larger ring compounds $(NPMe_2)_{6-10}$ which are now available (2) have a greater number of donor sites, and can coordinate with metals in various ways. In this paper we describe the complexes of palladous and platinous chloride with dodecamethylcyclohexaphosphazene $(NPMe_2)_6$, **1**, and the crystal and molecular structure of its palladium complex.

Experimental

The ligand **1** was prepared from the fluoride by a Grignard reaction (2). Solvents were dried over lithium aluminum hydride or phosphorus pentoxide. Nuclear magnetic resonance spectra were obtained on a Varian XL-100FT instrument with heteronuclear decoupling, a Nicolet-Oxford H-270 instrument (270 MHz), and a Bruker WH400 (400 MHz).

Palladium Complex

A filtered solution of dichlorodibenzonitrilepalladium(II) (3) (0.138 g; 0.36 mmol) in 40 mL benzene was added dropwise over 30 min to **1** (0.171 g; 0.38 mmol) in 30 mL benzene under nitrogen, a yellow solid being precipitated. The solution was filtered under nitrogen, and the solid $(N_6P_6Me_{12})PdCl_2$, **2**, was washed with and recrystallized from benzene (0.206 g, 90%); dec. 250°C. *Anal.* calcd. for $C_{12}H_{36}Cl_2N_6P_6Pd$: C 23.0, H 5.8, Cl 11.3, N 13.4; found: C 23.1, H 5.7, Cl 11.2, N 13.2. The complex was a non-conductor in nitrobenzene.

Platinum Complex

A similar reaction with dichlorodibenzonitrileplatinum(II) occurred less rapidly, and required heating under reflux for 72 h. The 1:1 complex was obtained as a yellow powder, which was recrystallized from dichloromethane as $(N_6P_6Me_{12})PtCl_2$, **3**, dec. 250°C. *Anal.* calcd. for $C_{12}H_{36}Cl_2N_6P_6Pt$: C 20.1, H 5.1, Cl 9.9, N 11.7; found: C 20.5, H 5.1, Cl 9.8, N 11.4. The nmr parameters for both complexes are given in Table 1.

X-ray Analysis

Crystals of the sesquihydrate of **2** were obtained by recrystallization from aqueous nitromethane. A crystal ca. 0.30 × 0.20 × 0.50 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Cu K_α radiation (λ = 1.54184 (Cu) and 0.71073 (Mo) Å). Crystal data at 22°C are:

$C_{12}H_{36}Cl_2N_6P_6Pd \cdot 1.5\ H_2O$ fw = 654.64

Orthorhombic, $a = 17.4030(3)$, $b = 15.4897(5)$, $c = 10.7417(2)$ Å, $V = 2895.6(1)$ Å^3, $\rho_m = 1.50(1)$ (flotation in aqueous KI), $Z = 4$, $\rho_c = 1.502$ g cm^{-3}, $F(000) = 1340$, μ(Mo K_α) = 11.6 cm^{-1}. Absent reflections: $h00$, $h \neq 2n$ and $0k0$, $k \neq 2n$ uniquely indicate the space group $P2_12_12$ (D_2^3, No. 18).

Intensities were measured with graphite-monochromatized Mo K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–1.33θ scan at 0.91–6.71° min^{-1} over a range of (0.70 + 0.35

TABLE 1. Nuclear magnetic resonance parameters of palladium and platinum complexes[a]

Complex	Group A[b]		Group B[b]		Group C[b]	
	δ_P	δ_H[d]	δ_P	δ_H[d]	δ_P	δ_H[d]
2[c]	(1)-83.24	(2)2.78(13.9)	(2)-86.06	(2)2.21(12.2)	(1)-105.27	(2)1.61(13.0)
	(1)-83.61	(2)1.72(14.0)		(2)1.85(10.8)	(1)-105.56	(2)1.59(12.7)
3	(1)-83.32	(2)2.64(13.9)	(2)-85.16[e]	(2)2.23(13.0)	(1)-104.72	(1)1.56(12.5)[f]
	(1)-82.76	(1)1.75(13.8)		(2)1.86(10.3)	(1)-105.16	(1)1.56(11.9)[f]
		(1)1.74(13.9)				(2)1.52(13.0)

[a]All in $CDCl_3$, relative to internal tetramethylsilane (^1H, ^{13}C) or external P_4O_6 (^{31}P). Positive shifts to low field of reference. Shifts in ppm, preceded by the number of Me or P groups, and followed by J_{PH} (Hz), both in parentheses.
[b]See Fig. 1.
[c]^{13}C frequencies at 100.60 MHz: 1982.898, 2066.263, 2071.474, 2169.725, 2265.744, 2272.443, 2286.585, 2374.416 (×2), 2398.235, 2459.270, 2496.487 Hz. Parameters tentatively assigned as: $C_{A'}$, $C_{A''}$, −24.21 (122.1), −23.59 (172.7); $B_{B'}$, $C_{B''}$, −23.21 (125.8), −23.06 (108.7); $C_{C'}$, $C_{C''}$, −21.05 (103.5), −20.15 (88.6). For **1**, δ_C, (J_{CP}) = −22.53 (95.2).
[d]Detailed configuration of methyl groups unknown; those in a particular Group are associated jointly with the one or two phosphorus environments observed.
[e]J_{P-N-Pt}: 99.0 Hz.
[f]Chemical shift difference 0.002 ppm.

tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to $2\theta = 60°$. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, remained constant to within ±3.5%. After data reduction, an absorption correction was applied using the Gaussian integration method (4, 5). Transmission factors ranged from 0.745 to 0.823 for 216 sampling points. Of the 4660 independent reflections measured, 3545 (76%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

The positions of the Pd, Cl, and two of the P atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. After full-matrix least-squares refinement of all non-hydrogen atoms except O(2) with anisotropic thermal parameters (O(2) having an isotropic temperature factor[1]) to $R = 0.048$, a difference map gave positions for most of the methyl hydrogen atoms. The hydrogen atoms associated with the solvent molecules were not located. Ideal positions were calculated for all methyl hydrogen atoms (C—H = 0.98 Å, $U_H = 1.2 \times U_c$) which were included as fixed atoms in subsequent cycles of refinement. The scattering factors of ref. 6 were used for non-hydrogen atoms and those of ref. 7 for hydrogen atoms. Anomalous scattering factors from ref. 8 were used for the Pd, Cl, and P atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (9–11). The final value of g was $1.0(3) \times 10^4$. Convergence was reached at $R = 0.031$ and $R_w = 0.037$ for 3545 reflections with $I \geq 3\sigma(I)$. For all 4660 reflections $R = 0.051$ and $R_w = 0.039$.

The absolute configuration of the structure has been determined through the anomalous scattering of the heavier atoms. Parallel refinements of the structure represented by the coordinates in Table 2 and its mirror image were undertaken resulting in R and R_w ratios of 1.56 and 1.22 respectively, clearly indicating the correct structure. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.14 and 1.0 σ respectively. The mean error in an observation of unit weight was 1.207. A final difference map showed maximum fluctuations of ±0.8 e Å^{-3} near the palladium atom and was essentially featureless elsewhere. The final positional and thermal parameters appear in Tables 2, 3 and 4.[2] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (12) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0040 Å^2. Analyses of each of the six phosphorus tetrahedra and the nine-atom group consisting of the coordination group of Pd and the four attached P atoms all gave physically reasonable rigid-body parameters and rms ΔU_{ij} values of 11, 13, 6, 19, 8, 19, and 22 (all × 10^4) Å^2. The appropriate bond distances have been corrected for libration (13), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear along with the uncorrected distances in Table 5 and corrected bond angles do not differ by more than 1 standard deviation from the uncorrected values listed in Table 6. Intra-annular torsion angles defining the conformations of the phosphazene and chelate rings are given in Table 7.

Results and Discussion

The nmr results for both **2** and **3** (Table 1) are uniquely consistent with the qualitative coordination scheme of Fig. 2 in which the dotted line denotes an approximate plane of symmetry relating such atoms as A′, A″. The ^{31}P shifts are assigned to atoms P_A, P_B, P_C on the basis of charge densities obtained from an HMO calculation. As expected, the shift of P_C is closest to that of the uncomplexed ligand (−109.3 ppm (14)). The resonances of P_A and

[1]Refinement of O(2) with anisotropic thermal parameters resulted in a non-positive-definite thermal parameter, possibly due to a minor disordering of the water molecule about the twofold axis. The high temperature factor observed for this atom probably results from the fact that this water molecule is well separated from the rest of the structure.

[2]The structure factor table, Table 3 (calculated hydrogen coordinates and thermal parameters) and Table 4 (anisotropic thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

P_C are each split into two close lines, so illustrating the imperfection of the mirror symmetry. The proton spectrum of **2** shows six distinct environments (Fig. 3), all downfield of **1** (1.50 ppm, J = 12.3 Hz (14)). Selective decoupling identified methyl groups 1 and 4 as belonging to P_A, 2 and 3 to P_B and 5 and 6 to P_C. The two methyl groups attached to a particular phosphorus atom are strongly differentiated, especially those which are near the metal atom, whereas methyl groups which are symmetrically related by the "plane" of Fig. 2 are not differentiated. The molecule is evidently made rigid in solution, with the approximate symmetry indicated, by coordination of the phosphazene to the metal. In this respect, its behavior contrasts with the flexibility of the parent ligand, whose ^{1}H spectrum consists of a simple doublet, even though the methyl groups are not symmetrically related in the crystal (15). The rigidity of **2** in solution (unusual among phosphazenes) is confirmed by its ^{13}C spectrum. Eleven lines are seen (one of double intensity), as expected, but the doublet structure is not obvious, and, since decoupling from phosphorus was not available, the parameters derived from the frequencies given in Table 1 are tentative. The ^{1}H nmr spectrum of **3** is almost identical to that of **2**, the principal qualitative difference being a small further splitting of doublets 4 and 5, implying a small but significant inequivalence in those methyl groups at P_A and P_C which correspond in the sense of Fig. 2. The ^{1}H spectrum of **3** also showed it to contain a minor but persistent impurity, which could not be removed chromatographically. It was possibly an ionic complex, which would account for the small electrical conductivity of **3** observed in nitrobenzene.

The crystal structure of **2** consists of discrete molecules which are linked by N···H—O hydrogen bonds to water molecules of crystallization to form helices of alternating molecules of water and **2** extending along a about the twofold screw axes (O(1)···N(2) = 2.99(1) Å and O(1)···N(4) ($1/2 + x$, $3/2 - y$, $2 - z$) = 3.02(1) Å). The second water of crystallization, located on the twofold axis, is not involved in hydrogen-bonding, the shortest nonbonded distance involving O(2) (O(2)···H(8b) = 2.62 Å) corresponding to a normal van der Waals

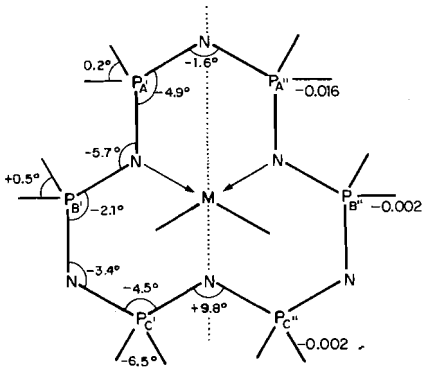

FIG. 2. Coordination diagram of **2** and **3**, the dashed line representing an approximate plane of symmetry. The diagram also shows (for **2**) the mean deviations (4 P—C bonds at each of P_A, P_B, P_C) from the geometry of the free ligand.

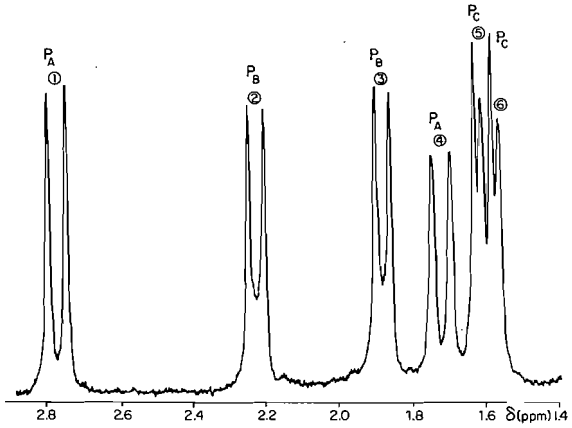

FIG. 3. The ^1H nmr spectrum of **2** (270 MHz).

contact. There are two weak intramolecular C—H···Cl hydrogen bonds present (C(3)—H(3b)···Cl(1), C···Cl = 3.571(8), H···Cl = 2.74 Å, C—H···Cl = 144° and C(9)—H(9b)···Cl(2), C···Cl = 3.525(8), H···Cl = 2.77 Å, C—H···Cl = 136°).

The molecular structure of **2** confirms the coordination scheme of Fig. 2 and adds important numerical detail. A stereoscopic view of the molecule is shown in Fig. 1, and another view in Fig. 4. The palladium atom is coordinated at N(1) and N(5), and the molecule is clearly almost symmetrical across the plane N(6)PdN(3). Corresponding P—N bond lengths are in fact very nearly equal (mean and maximum differences 0.004 and 0.009 Å); there are small differences between corresponding bond angles and torsion angles. In contrast, the lengths of successive bonds differ significantly in a pattern which will be discussed below.

The metal has the expected planar coordination, and the individual bond angles differ little from 90°: the Pd—Cl and Pd—N bond lengths are normal.

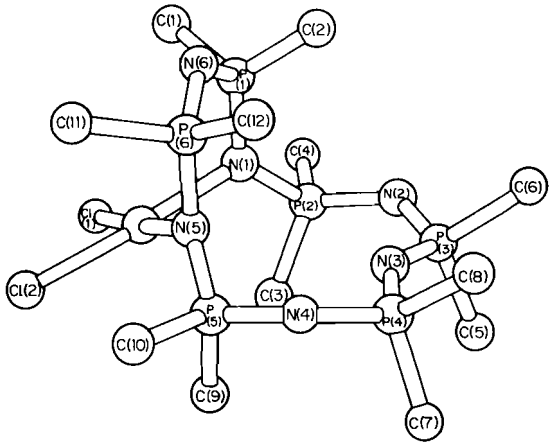

FIG. 4. General view of **2**.

The Pd—N vectors are almost coplanar with the local PNP planes (deviations: Pd—N(1), 4.0°; Pd—N(5), 8.0°), but the coordination directions at nitrogen are not quite those expected from idealized lone pairs at nitrogen, since the (mean) angles there are Pd—N—P = 124.0, 108.3°. The molecule is evidently slightly strained at these points. The pairs of methyl groups on P(6), P(1), and on P(3), P(4) are related by the approximate mirror plane through N(3)PdN(6), and are hence nearly eclipsed. Some steric strain is relieved by the large angles at N(3), N(6).

The structure can be understood in terms of the localization of electrons at N(1) and N(5), and the angular constraints imposed by the coordination at these positions. The mean P—N bond length is 1.609 Å, compared with 1.593 Å in the free ligand (15). The small increase on complexing can be attributed partly to the localization of bonding electrons, and partly to changes in σ-hybridization. The effect of coordination is to reduce most of the angles, as shown in Fig. 2. It is surprising that there is no significant compensatory increase of the exocyclic angles, and except at P_A, the P—C bond lengths are hardly changed; the effect of coordination largely confined to the P_6N_6 ring. The geometrical effects differ in the complexes of $N_6P_6(NMe_2)_{12}$ (16). In $[N_6P_6(NMe_2)_{12}](CoCl_2)_2$, for instance (17), in which the metal is bound to four nitrogen atoms, the mean length of the ring bonds is greatly increased, and the decrease in the ring angles is accompanied both by an increase in exocyclic angle and a decrease in exocyclic bond length; the ligand differs from **1** in being a stronger donor with extensive conjugative release from the exocyclic nitrogen atoms.

The localization of electrons in **2** at N(1) and N(5)

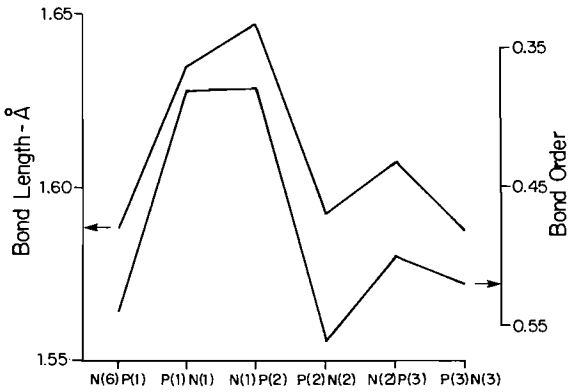

FIG. 5. Comparison of lengths of successsive bonds in **2** with bond order calculations (HMO, $\alpha_N = -1$, $\alpha_P = +1$, all β's $= -1$. For atoms coordinated at N(1), N(5), $\alpha = -0.3$).

by complex formation has a significant effect on the lengths of symmetrically related bonds, which is illustrated in Fig. 5 in comparison with calculated bond orders. The qualitative correspondence confirms that the metal withdraws bonding electrons from the ring, thereby changing the bond lengths, but there is no evidence for any more specific interaction between the metal and the ring.

It does not appear that the detailed electronic structure of the ligand has any important bearing on the coordination. Model calculations on an N_6P_6 ring in which electrons are supposedly localized at N(1) show that the charge density is highest and the second localization energy lowest at the antipodal position N(4), and, from this point of view, the metal might be expected to bridge the ligand so as to form two eight-membered rings. The reason it does not do so may be that, once the metal is coordinated at N(1), it interacts most easily with the nearest nitrogen atom with which it can form a stable ring, i.e., N(5). As the reported results show, the molecule is then rigid, and any further interaction is likely to be with the near atoms N(2) and N(4), as found in the complexes of $N_6P_6(NMe_2)_{12}$ (16). Coordination of $PtCl_2$ to $N_4P_4(NHCH_3)_8$ (18) and to $N_4P_4Me_8$ (19) occurs similarly, antipodal substitution giving two six-membered rings, with similarly pronounced inequalities in the lengths of the ring bonds. If the six-membered chelate ring retains its stability in complexes of the larger phosphazenes, so that the metal remains near one end of the molecule, it may be possible to include two or more atoms within the same ligand, as in the crown ethers (20).

The preparation and crystal structure of η^2-nitrato(η^4-hexadecamethylcyclooctaphosphazene (N^1,N^2,N^4,N^5))cobalt(II) nitrate

KEITH D. GALLICANO, NORMAN L. PADDOCK, STEVEN J. RETTIG, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received January 8, 1981

KEITH D. GALLICANO, NORMAN L. PADDOCK, STEVEN J. RETTIG, and JAMESTROTTER. Can. J. Chem. **59**, 2435 (1981).

Hexadecamethylcyclooctaphosphazene $N_8P_8Me_{16}$, **1**, forms a 1:1 complex, **2**, with cobalt(II) nitrate. Crystals of **2** are triclinic, $a = 10.891(2)$, $b = 11.201(2)$, $c = 14.944(2)$ Å, $\alpha = 93.21(1)$, $\beta = 95.66(1)$, $\gamma = 104.69(1)°$, $Z = 2$, space group $P\bar{1}$. The crystal structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.037$ and $R_w = 0.047$ for 5165 reflections with $I \geq 3\sigma(I)$. All the hydrogen atoms were found. The structure consists of a cation $[N_8P_8Me_{16}\ CoNO_3]^+$ and a free nitrate anion. The cobalt atom is coordinated by an unsymmetrical bidentate nitrate ion and by four nitrogen atoms of the phosphazene ring. The metal is attached near one end of the ring, forming six-, ten-, and two four-membered chelate rings, and induces bond length variations which are independent of local conformation and which arise from the localization of bonding electrons.

KEITH D. GALLICANO, NORMAN L. PADDOCK, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **59**, 2435 (1981).

Hexadécaméthylcyclooctaphosphazène $N_8P_8Me_{16}$, **1**, forme un complexe 1:1, **2**, avec le nitrate du cobalt(II). Les cristaux de **2** sont tricliniques, $a = 10.891(2)$, $b = 11.201(2)$, $c = 14.944(2)$ Å, $\alpha = 93.21(1)$, $\beta = 95.66(1)$, $\gamma = 104.69(1)°$, $Z = 2$, groupe d'espace $P\bar{1}$. On a résolu la structure au moyens de méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de $R = 0.037$ et de $R_w = 0.047$ pour 5165 refléxions avec $I \geq 3\sigma(I)$. La structure se compose d'un cation $[N_8P_8Me_{16}\ CoNO_3]^+$ et d'un anion libre du nitrate. L'atome de cobalt est coordiné par un anion du nitrate asymétrique et bidenté, et par quatre atomes d'azote du cycle phosphazène. Le métal est lié presqu'une extrémité du cycle, en formant les cycles chelatés de six, dix, et deux de quatre membres, et il amène aux variations des longeurs des liaisons qui sont indépendantes de la conformation locale et qui résultent des localizations des électrons de liaisons.

Introduction

In previous papers, we have described the donor properties of $(NPMe_2)_{3-5}$ (1), and complex formation by $(NPMe_2)_6$ (2). Even in a 12-membered ring, however, the possible range of coordination types is restricted, and we have therefore studied complex formation by the 16-membered ring compound $(NPMe_2)_8$, **1**. The preparation of this compound has been outlined (3) and its crystal structure determined (4). Part of the interest in its coordination behavior lies in its high symmetry (C_4) in the crystal, four nitrogen atoms being well adapted to square planar or tetrahedral geometry. The present paper describes the preparation and crystal structure of $(NPMe_2)_8 \cdot Co(NO_3)_2$, **2**.

Experimental

A solution of $Co(NO_3)_2$ (0.252 mmol) in 15 mL dry acetonitrile was added under a stream of nitrogen to a solution of **1** (0.151 g, 0.252 mmol) in 15 mL acetonitrile. The purple solution was heated under reflux for 24 h. After removal of the solvent, the residual purple solid was washed with light petroleum to remove unchanged **1**. The complex **2** (75%) was recrystallized from acetonitrile/toluene as purple air-stable crystals, mp 223–224°C. *Anal.* calcd for $C_{16}H_{48}CoN_{10}O_6P_8$: C 24.5, H 6.2, N 17.9; found: C 24.8, H 6.4, N 17.7. The infrared spectrum (Nujol) showed a band at 1345 cm^{-1} (br), attributed to the E' asymmetric NO_3 stretching mode of a free nitrate ion (5). The asymmetric NO_2 stretching frequency (B_1) of a coordinated nitrate ion can be seen at 1483 cm^{-1}; the symmetric NO_2 stretching frequency (A_1) near 1280 cm^{-1} is easily confused with ligand vibrations and is not assigned. The numerical values resemble those found for the bound bidentate nitrate ion (1280 (s) and 1490 cm^{-1} (s)) and the free nitrate ion (1375 cm^{-1} (s, br)) in a complex of a cyclic tetramine $[Ni(tet\ b)NO_3]NO_3$ (6), and those (~1470, ~1300 cm^{-1}) in an unsymmetrical bidentate nitrato complex $(Ph_4As)_2[Co(NO_3)_4]$ (7).

X-ray Analysis

Crystals suitable for X-ray analysis were obtained by recrystallization from acetonitrile/toluene. A crystal ca. 0.06 × 0.27 × 0.30 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Mo K_α radiation (λ = 0.71073 Å). Crystal data at 22°C are:

$C_{16}H_{48}CoN_{10}O_6P_8$ f.w. = 783.35

Triclinic, $a = 10.891(2)$, $b = 11.201(2)$, $c = 14.944(2)$ Å, $\alpha = 93.21(1)$, $\beta = 95.66(1)$, $\gamma = 104.69(1)°$, $V = 1748.6(5)$ Å^3, $Z = 2$, $\rho_c = 1.488$ g cm^{-3}, $F(000) = 818$, μ(Mo K_α) = 8.32 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (C_i^1, No. 2) from structure analysis. Cell constants refer to the Delaunay reduced cell.

Intensities were measured with graphite-monochromatized Mo K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 0.65–6.71° min^{-1} over a range of (0.60 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 57.5°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, remained constant to within ±4%. After data reduction, an absorption correction was applied using the Gaussian integration method (8, 9). Transmission factors ranged from 0.790 to 0.948 for 120 sampling points. Of the 9034 independent reflections measured, 5165 (57%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

Analysis was initiated in the centrosymmetric space group $P\bar{1}$

on the basis of the *E*-statistics. The structure was solved by direct methods, the coordinates of the Co and P atoms being determined from an *E*-map and those of the remaining non-hydrogen atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.082$, disordering of the free nitrate anion was apparent from anomalously large thermal parameters and the appearance on a difference map of several large peaks in the vicinity of the free anion. This nitrate group was then left out of the calculations and the remainder of the structure refined to $R = 0.086$. A difference map was calculated and a three-dimensional contour map of the free nitrate region was constructed. Careful examination of the difference map indicated threefold disorder with near coincidence of the nitrogen atoms. The disorder was accounted for by three rigid groups with idealized geometry (N—O = 1.25 Å), only group parameters and group temperature factors being varied. Occupancy factors were initially estimated from peak heights of non-superimposed oxygen atoms and later adjusted to give nearly equal group temperature factors.

All 48 hydrogen atoms were located and refined with isotropic thermal parameters. The scattering factors of ref. 10 were used for non-hydrogen atoms and those of ref. 11 for hydrogen atoms. Anomalous scattering factors from ref. 12 were used for the Co and P atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. Convergence was reached at $R = 0.037$ and $R_w = 0.047$ for 5165 reflections with $I \geq 3\sigma(I)$. For all 9034 reflections $R = 0.095$ and $R_w = 0.047$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.26 and 1.54σ respectively. The mean error in an observation of unit weight was 1.439. A final difference map showed maximum fluctuations of −2.3 to 0.75 e Å^{-3} in the vicinity of the disordered nitrate group and ±0.25 e Å^{-3} elsewhere. The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1] Rigid group parameters are given in Table 3.[1]

The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (13) using the computer program MGTLS (described in ref. 13). The rms standard error in the temperature factors U_{ij} (derived from the least-squares analysis) is 0.0021 Å^2. Analysis of the entire cation gave rms $\Delta U_{ij} = 0.0075$ Å^2 and indicated some independent motion of the methyl and nitrate groups. Each of the eight phosphorus tetrahedra was separately analysed giving rms ΔU_{ij} values of 12, 15, 11, 14, 10, 15, 12, and 10 (all × 10^{-4}) Å^2 respectively for P(1)—P(8). The Co coordination group gave a non-positive-definite libration tensor thus corrections to bonds involving the Co atom were based on the analysis of the cation as a whole. The appropriate bond distances have been corrected for libration (14), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 4 along with the uncorrected values and corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 5[1]. Intra-annular torsion angles defining the conformations of chelate and phosphazene rings are listed in Table 6. Details of the weak C—H···O interactions are given in Table 7.[1]

[1]The structure factor table, Tables 2 (thermal parameters), 3 (rigid group parameters), 5 (bond angles) and 7 (C—H···O interactions) and Fig. 2 (stereo view of the cation) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

Results and Discussion

The crystal structure of **2** consists of discrete $N_8P_8Me_{16}\cdot CoNO_3^+$ cations and NO_3^- anions which are linked by an extensive network of weak C—H···O interactions (details in Table 7). These weak interactions are probably responsible for the observed disordering of the free nitrate anion since for each of the three orientations there is at least one O···H contact of less than 2.4 Å. There are also two weak intramolecular C—H···O interactions of possible significance, also included in Table 7.

A general view of the cation is shown in Fig. 1, and stereoscopic view in Fig. 2.[1] Contrary to what might have been expected from the structure of the free ligand (4), coordination of the metal atom does not preserve fourfold symmetry. The cobalt atom is coordinated by a bidentate nitrate group and by the ring nitrogen atoms N(1), N(2), N(4), and N(5), so forming, within the PN ring, one six-membered and two four-membered rings. This coordination scheme is the same as that found in complexes of $N_6P_6(NMe_2)_{12}$ (15, 16), and presumably arises from the same cause. It seems likely that the second coordination takes place at the nitrogen atom with which it can form a stable ring, which is a six-membered ring for a cyclic phosphazene. This is what is found in the complex (η^2-$N_6P_6Me_{12}$)$PdCl_2$ (2) and in (η^2-$N_4P_4Me_8$)$PtCl_2$ (17). Subsequent coordination then takes place at the nearest donor sites, to form four-membered rings, rather than at the remote site, which is the most nucleophilic, or at the intermediate sites, which would allow the formation of four stable six-membered rings. In complexes of larger phosphazenes, we can expect the metal atom to occupy one corner of the ligand, so allowing the possible incorporation of additional metal atoms.

The irregular coordination scheme of the metal is shown in Fig. 3. Because of the small angular "bite" of the ligands (which are temporarily regarded as chemically identical), the stereochemistry cannot be regular octahedral, but moves towards trigonal prismatic configuration. The distortion is such that N(1)CoN(4) are nearly colinear (164.7(1)°), and form the axis of a nearly trigonal bipyramidal arrangement, the equatorial sites being occupied by N(2), N(5), and the η^2-nitrato ligand. The significant variation in the Co—N distances (2.113(3)–2.197(3) Å) reflects the trigonal bipyramidal character of the complex **2**, the "equatorial" bond lengths being significantly shorter than the "axial" distances with the exception of the pair Co–N(1)/N(2).

All of the Co—N distances in **2** are intermediate between the mean[2] equatorial and axial Co—N distances of 2.058(8) and 2.248(15) Å in the unambiguously five-coordinate complex cation $[\eta^4\text{-}N_6P_6(NMe_2)_{12}]CoCl^+$ (15) and in spite of the wide variation in the individual values the average Co—N distance is the same (2.15 Å) in both structures. In **2**, the non-spherical electron distribution of the d^7 Co(II) ion shows up in a different way. The metal is truly six-coordinate, and perhaps the most striking feature of the local geometry is the unsymmetrical coordination of the nitrate group, the Co—O distances differing by 0.193(5) Å. Other examples of unsymmetrical bidentate coordination by a nitrate group are known, especially with transition metal ions, like Co(II) and Cu(II), which are not spherically symmetrical (18).

The geometry of the phosphazene ring shows several interesting features. The lengthening of the mean P—N bond distance, to 1.613(20) Å from 1.590(13) Å in the ligand, corresponds to the withdrawal of bonding electrons by the cobalt. It should be noted that in both the free ligand **1** (4) and in **2** there is considerable variation in the P—N distances, ranging from 1.575(2) to 1.606(2) Å in **1** and from 1.579(3) to 1.645(3) Å in **2**. In both molecules hybridization effects are an important

[2]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

factor in the P—N length variation while in **2** perturbations which result from coordination to the Co are also important (see below). The P—C bond lengths do not vary greatly within the molecule, P—C = 1.786(4)–1.813(5), mean 1.799(7) Å, somewhat shorter than in the ligand (1.811(2) Å). Since coordination draws the molecule together, the ring angles decrease, especially near the coordination centres, and resemble those in the ligand at P(7) and P(8). In **1** the mean N—P—N angle (117.2(10)°) is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

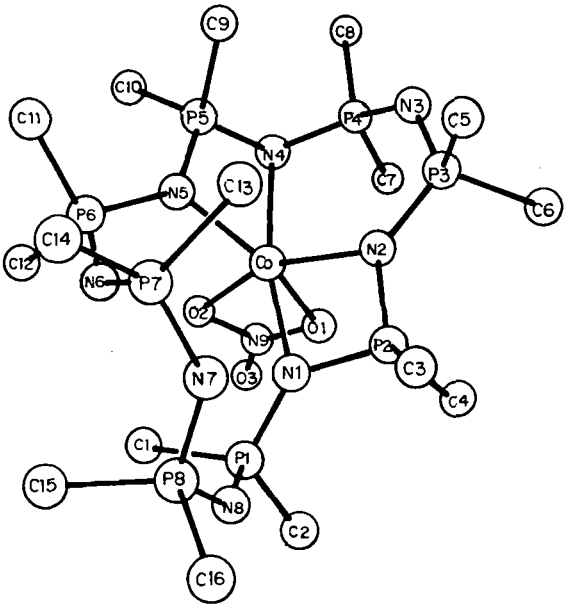

FIG. 1. General view of the $N_8P_8Me_{16}\cdot CoNO_3^+$ cation.

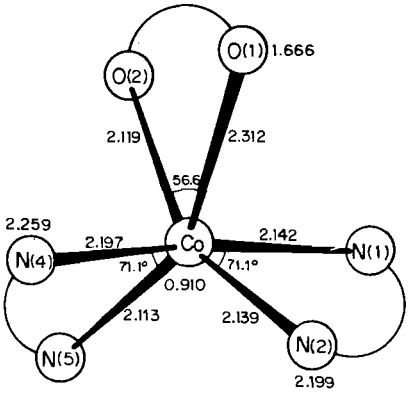

FIG. 3. Coordination scheme of Co, viewed perpendicular to the N(1)O(2)N(5) plane, showing heights (Å) above this plane, bond lengths (Å, σ = 0.003–0.004) and bond angles (deg, σ = 0.1°).

associated with a mean C—P—C angle of 103.5(10)°; *s*–*p* hybridization[3] would require 103.2°. In the complex **2**, the decreased ring angles at phosphorus (100.5(2)–117.8(2), mean 112(7)°) are associated with slightly increased C—P—C angles, but the effect is not large, and even at P(2) and P(5), the exocyclic angle is only 105.8(3)°; from *s*–*p* hybridization, 120.5° would be expected. Electronic effects within the ring have little effect on the geometry of the exocyclic groups.

[3]Given the N—P—N angle, the opposite C—P—C angle may be calculated assuming that the bonding orbitals are hybrids of *s* and *p* orbitals only by the formula: $\theta' = 2\ \mathrm{csc}^{-1}\ [3 - \mathrm{csc}^2(\theta/2)]^{1/2}$, where θ' = C—P—C and θ = N—P—N.

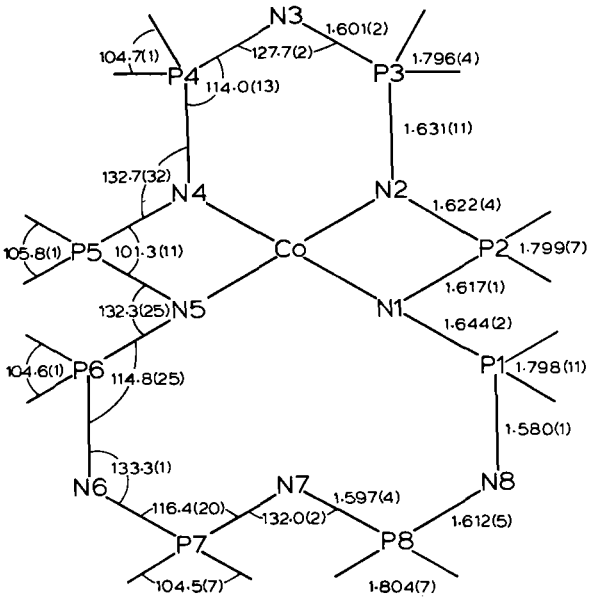

FIG. 4. Averaged geometry of **2** (rms deviations from the mean in parentheses). The P—C bond lengths are averaged in sets of four, other parameters in corresponding pairs.

Although the mean P—N bond length does not differ greatly from that in the ligand, coordination causes the systematic variations in bond length which are illustrated in Fig. 4. Except for P(3)–N(2) and P(4)–N(4), which differ by 0.016(4) Å, all pairs of bonds which are symmetrically related in Fig. 4 differ by 0.007(4) Å or less, and are averaged. This closeness to equality is interesting, in view of the total lack of symmetry in the ten-membered ring CoN(5)···N(1)Co; the systematic inequalities of bond length seen in Fig. 4 are independent of conformation. Qualitatively, the bond length varia-

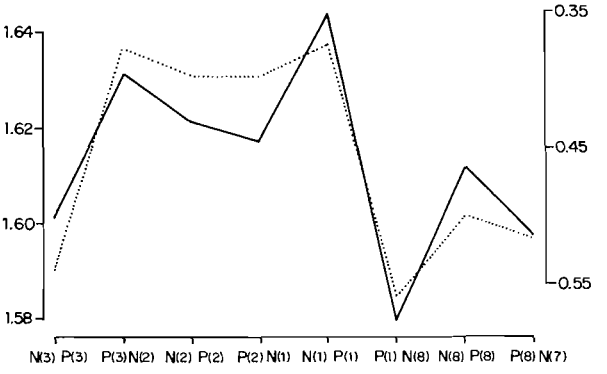

FIG. 5. Comparison of averaged P—N bond lengths (full line, l.h. scale) with calculated bond orders (dashed line, r.h. scale) (HMO, $\alpha_N = -1$, $\alpha_P = +1$, $\alpha_{pert.} = -0.3$, all β's = -1).

tion follows the trend of bond orders calculated for electron withdrawal by four acceptor atoms from the ring through the coordinated nitrogen atoms (Fig. 5). The major geometrical change occurs in the region N(1)—P(1)—N(8), where there is a marked disporportionation in bond length. In the region most remote from the coordination sites, both the bond lengths and the calculated π-bond order resemble those of the free ligand (1.590(13) Å, 0.517). It is also interesting that if the four donor sites, and hence the remainder of the molecule, are allowed to interact by conjugation through the acceptor atom, a different pattern of bond orders is found, P(3)–N(2) and P(1)–N(1) being greatly strengthened. It is clear that conjugative interactions between the metal and the ring are quite insignificant. As concluded earlier (16), phosphazenes resemble simple amines in their donor properties.

Site selective fluorescence and purity of a rare earth garnet crystal[1]

L. V. HALEY, B. JACQUIER,[2] AND J. A. KONINGSTEIN
Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6
Received December 16, 1980

L. V. HALEY, B. JACQUIER, and J. A. KONINGSTEIN. Can. J. Chem. **59**, 2441 (1981).

Site selective fluorescence spectroscopy of a crystal of europium gallium garnet containing Cr^{3+} as an impurity has been carried out. An analysis of the experimental results reveals that the strongest fluorescence spectrum between 590.0 nm and 620.0 nm is due to emission from an Eu^{3+}–Cr^{3+} pair. Fluorescences of farther removed pairs and that of Eu^{3+} occupying the 8-coordinated *d* site and 6-coordinated Ga^{3+} site are also assigned. Energy transfer between the various sites occurs while the excitation spectra for the R lines of Cr^{3+} show that extremely fast transfer takes place between the R_2 and R_1 levels.

L. V. HALEY, B. JACQUIER et J. A. KONINGSTEIN. Can. J. Chem. **59**, 2441 (1981).

On a étudié la spectroscopie de fluorescence par sélection d'un cristal de grenat d'europium gallium contenant du Cr^{3+} comme impureté. Une analyse des résultats expérimentaux révèle que le spectre de fluorescence le plus intense entre 590,0 nm et 620,0 nm est dû à l'émission par la paire Eu^{3+}–Cr^{3+}. On a également identifié les fluorescences des paires éloignées et celles du Eu^{3+} occupant 8 sites *d* coordonnés et 6 sites Ga^{3+} coordonnés. L'énergie de transfert entre les différents sites qui apparait, lors du spectre d'excitation, des lignes R du Cr^{3+}, montre que ce transfert extrêmement rapide à lieu entre les niveaux R_2 et R_1.

[Traduit par le journal]

I. Introduction

Rare earth garnets have in the past been studied in great detail; in particular, the refinement of the energy level diagram for the trivalent lanthanide ions (1–4). This diagram is composed of the crystal field levels of the split *LSJ* manifolds arising from the ($4f$) configuration of the trivalent lanthanides, and is normally arrived at from a comparison of spectroscopic results which include absorption, fluorescence, and light scattering studies in various parts of the electromagnetic spectrum. The assignment of the spectra is not always straightforward in that the identification of pure electronic transitions is made difficult as a result of the appearance of vibronic transitions. These vibronic effects, for instance, dominate the absorption and fluorescence spectrum of the ytterbium aluminum and gallium garnet to such a degree (5) that the assignment of the 0–0 transitions could only be made after elaborate studies.

Apart from such spectral complications as vibronic coupling effects, information has recently become available (6–8) that not all rare earth ions replace the 8-coordinated yttrium ions which occupy the orthorhombic *d* sites in the unit cell of the cubic garnet crystals (space group O_h^{10}). Some of the trivalent lanthanide ions are thought (7) to be substituted for the 6-coordinated Al^{3+} (or Ga^{3+}) ions in the *a* sites. Also, nearly all these garnet crystals could contain Cr^{3+} as an impurity and transitions of europium gallium garnet (EuGaG) have already been observed (9) which are assigned to Eu^{3+}–Cr^{3+} pairs. The energy level diagram of rare earth ions being part of a pair is of course different if compared to that of the lanthanide ions in the orthorhombic *d* sites and hence the appearance of another type of spectral interference. The latter, however, are more easily assigned (8) than the vibronic features because the method of site selective spectroscopy may be applied to distinguish transitions from one site to those from others. In the present article, we discuss site selective spectroscopy of a single crystal of EuGaG which contains a small amount (50 ppm) of Cr^{3+}. The europium compound is ideally suited for site selective spectroscopy with cw lasers in that the position of the $^5D_0$ excited state (which is some 17 200 cm^{-1} above the $^7F_0$ ground state) can be probed with the radiation from the rhodamine 6G dye laser, and both states are not split by crystal field effects. The laser radiation can be used to (*i*) induce the $^5D_0$–^7F_J (J = 0, 1, 2, ..., 6) fluorescence transitions, and because the crystal field levels of $^7F_1$ are some 200–450 cm^{-1} above $^7F_0$, we can (*ii*) also probe absorptions of $^5D_0 \leftarrow {}^7F_{0,1}$ with the tunable laser source.

Our results show that for EuGaG containing Cr^{3+} as an impurity, we have besides transitions of Eu^{3+} occupying the orthorhombic sites also those of Eu^{3+}–Cr^{3+} pairs and Eu^{3+} replacing the Ga^{3+} ions. In particular, we demonstrate that the excitation spectrum of the Cr^{3+} R_1 line contains important

information on the type of sites which are present in this and perhaps other rare earth garnet crystals. We also present evidence that the strongest among the fluorescence transitions is not due to europium ions of the orthorhombic sites but that of nearest neighbour Cr^{3+}–Eu^{3+} pairs.

II. Specific Fluorescence and Absorptions

The absorption and fluorescence spectrum of a single crystal of EuGaG containing Cr^{3+} as an impurity has been discussed by van der Ziel and Van Uitert (9). These authors found, apart from the well known $^5D_0$–^7F_J fluorescence which occurs between 590–850 nm, evidence of fluorescence of Eu^{3+}–Cr^{3+} pairs. The spectrum assigned to transitions of the pair is in the region of 710–1100 nm and can be interpreted as originating in the components of the ^2E_g state of a Cr^{3+}–Eu^{3+} pair and terminating on those of the pair ^7F_J states. The Eu^{3+} ions of EuGaG-space group O_h^{10} occupy 8-coordinated *d* sites with D_2 symmetry, and the Cr^{3+} ions substitute (10) for Ga^{3+}, occupy 6-coordinated *a* sites having C_{3i} symmetry. The Eu^{3+}–Cr^{3+} pair is bridged (11) via an O^{2-} ion, and the overall situation resembles that of the Cr^{3+} pairs in ruby (12). Neither the number of components nor the position of the ^7F_J and ^2E_g states of the pair equals that of the crystal field levels of the non-paired Eu^{3+} ions. If for instance spin–spin exchange interaction of the type $^7F_J(Eu^{3+})$–$^4A(Cr^{3+})$ is introduced, then a doubling of the number of crystal field levels of the ^7F_J series is computed (for a total of 98 components). The position of these levels depends on the value of the coupling parameter, and a rather complex energy level diagram is anticipated if apart from nearest neighbours next to nearest neighbours pairs etc. are taken into consideration. The situation with regard to the Cr^{3+} ion is different in that contrary for Eu^{3+} — assuming all Eu^{3+} occupies the *d* sites — all these transitions metal ions are part of a pair. Because the position of the ^5D_J manifolds of Eu^{3+} is closest in energy to that of ^2E_g of Cr^{3+} in the 6-coordinated C_{3i} sites, one finds that to a first approximation the E_g levels can split into two main components each one being composed of five Kramers pairs. On the other hand, the $^5D_0$ state of Eu^{3+} is nearly isoenergetic with $^2T_{1g}$ of Cr^{3+}, and as a result, we expect six levels for the pair as compared to only one crystal field level for the non-paired ion.

Van der Ziel and Van Uitert indeed found a rather complicated pair fluorescence spectrum (9) of an EuGaG crystal containing Cr^{3+} as the impurity, but the absorption spectrum from 590–600 nm which is due to $^5D_0 \leftarrow {}^7F_1$ is rather simple in that it consists of three lines. These lines have their counterpart in the emission spectrum and are thought to be due to europium ions experiencing a site of lower than tetragonal symmetry. Furthermore, it appears from the number of absorptions due to $^5D_0 \leftarrow {}^7F_1$ transitions that the majority of Eu^{3+} occupies this site which must be the 8-coordinated *d* sites. Of relevance here is a recent study of Eu doped yttrium aluminum garnet where arguments (8) were presented that the strongest fluorescence lines of the $^5D_0 \rightarrow {}^7F_1$ series is not due to Eu^{3+} ions replacing the Y^{3+} of the *d* sites. The same apparently also holds for EuGaG because van der Ziel and Van Uitert found that if excited with blue light, those $^5D_0 \rightarrow {}^7F_1$ fluorescence lines which have their counterpart with the $^5D_0 \leftarrow {}^7F_1$ absorption spectrum are weaker than other features due to europium ions experiencing a different environment than those in the *d* sites.

Figure 1 shows part of the absorption spectrum of our EuGaG single crystal in the region of 579.0–600.0 nm. These spectra are difference spectra and were recorded with a tunable cw dye laser having a band width of ~0.025 nm. The laser beam was chopped and, after passing through a beam splitter, entered the crystal. Reference and sample beams were directed towards two diodes and their signals were processed by a boxcar integrator. We find a rather pronounced decrease in the line width of the $^5D_0 \leftarrow {}^7F_1$ transitions upon a decrease of the temperature of the sample. The relevant part of the energy level diagram of Eu^{3+} of EuGaG is also shown in Fig. 1, and the $^7F_1$ intermanifold electronic Raman spectrum (3) at 77 K is shown in Fig. 2. Note that if the FWHM of the bands of the fluorescence spectrum ($^5D_0 \rightarrow {}^7F_1$) is taken as the actual width of the $^7F_1$ crystal field levels, the FWHM of the electronic Raman transitions is much smaller. The phenomenon is similar to experimental features recently (13) recorded for Cr^{3+} in αAl_2O_3 and YAlG, and the seeming decrease in line width has its origin in the dynamical nature of the homogeneous broadening processes (14) which govern the linewidths at ambient and lower temperatures.

The absorption band of EuGaG at ~580.67 nm (see Fig. 1) is due to the $^5D_0 \leftarrow {}^7F_0$ transitions. This transition is highly forbidden, and only a weak band is recorded. This band, however, appears to have a shoulder towards lower wavelength.

III. Site Selection Fluorescence and their Excitation Spectrum

A. The Europium System

Five distinct sets of fluorescence spectra of EuGaG containing Cr^{3+} are excited and recorded if the cw laser is tuned from 579.0–581.0 nm. These

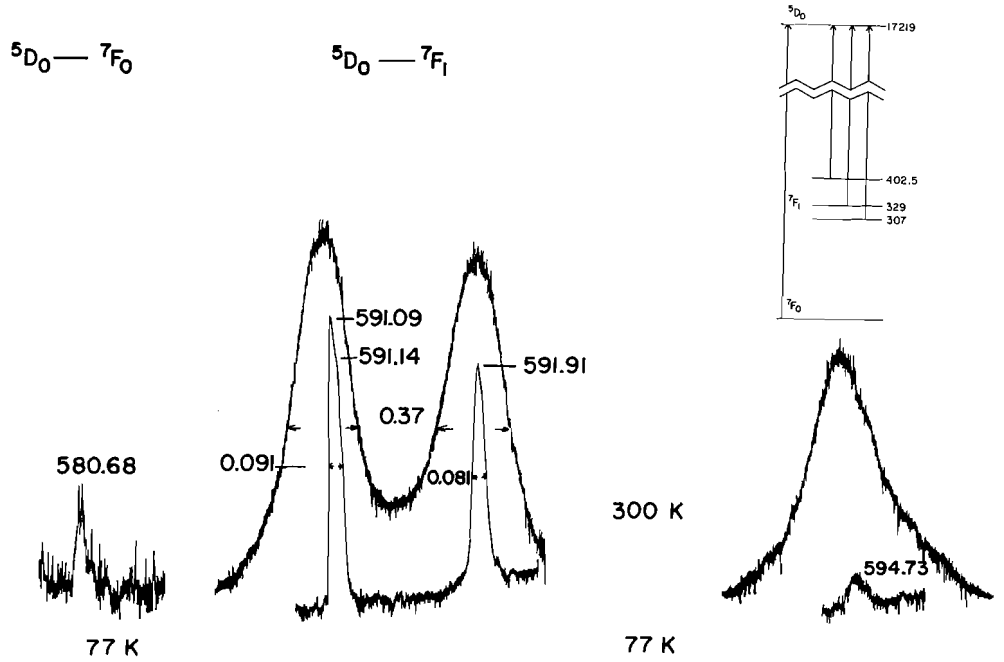

FIG. 1. The $^5D_0 \rightarrow {}^7F_0$ absorptions due to Eu^{3+} occupying the 8-coordinated orthorhombic *d* sites of EuGaG. All wavelengths are in nm and part of the relevant energy level diagram is indicated.

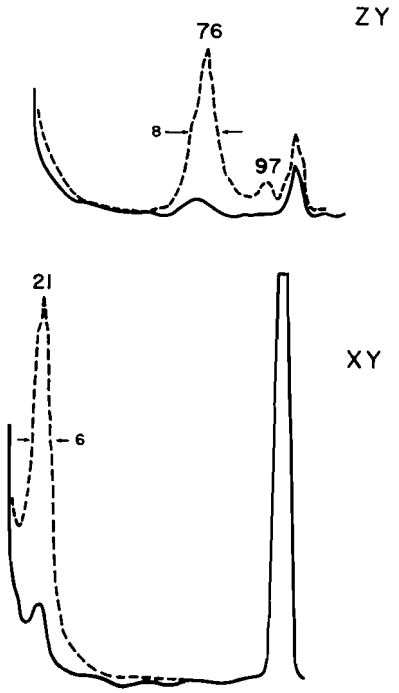

FIG. 2. Part of the Raman spectrum at 300 K (---) and 77 K (—) of EuGaG excited with $\lambda_l = 488.0$ nm showing the $^7F_1$ intramanifold transitions of Eu^{3+} in the *d* sites of EuGaG. The shift at $\sim 21\ cm^{-1}$ is due to transitions between the $^7F_1$ levels at 307 and $329\ cm^{-1}$ (see Fig. 1). The width of these levels as determined from the $^5D_0 \rightarrow {}^7F_1$ absorption spectrum is $\sim 11\ cm^{-1}$ while the width of the electronic Raman transition is $6\ cm^{-1}$.

fluorescence spectra are weak, and the intensity of the transition is comparable to those of the stronger Raman phonon bands of this crystal. The intensity of these phonons have been used as a standard which permits a comparison of the intensity of the fluorescence line of the five sites. Some representative spectra are shown in Fig. 3, and all data are collected and presented as stick spectra in Fig. 4. Two of the spectra, those of sites I and II, are unique in that the region where $^5D_0 \rightarrow {}^7F_1$ transitions of Eu^{3+} are expected, three lines are recorded and fluorescence due from other sites are not present. On the other hand, the spectra of sites III, IV, and V always contain fluorescence lines from site II. Also, while tuning the wavelength λ_l of the tunable dye laser from one specific excitation value to another, we find that the intensity of the fluorescence spectra goes through a minimum (zero intensity). The spectrum of site II is important from another point of view in that the position of the $^5D_0 \rightarrow {}^7F_1$ lines, contrary to those of the other sites, is within experimental error equal to those of the absorption transitions $^5D_0 \leftarrow {}^7F_1$ shown in Fig. 1 (see also Table 1). We assign the spectrum of site II to that of the majority of Eu^{3+} ions of EuGaG which occupy the orthorhombic *d* sites and note in passing that (compared to the phonon at $346.5\ cm^{-1}$) the fluorescence spectrum of site V and not that of site II is the most intense. Excitation spectra of the fluorescence lines at 591.95 nm (site II) and 592.14 nm

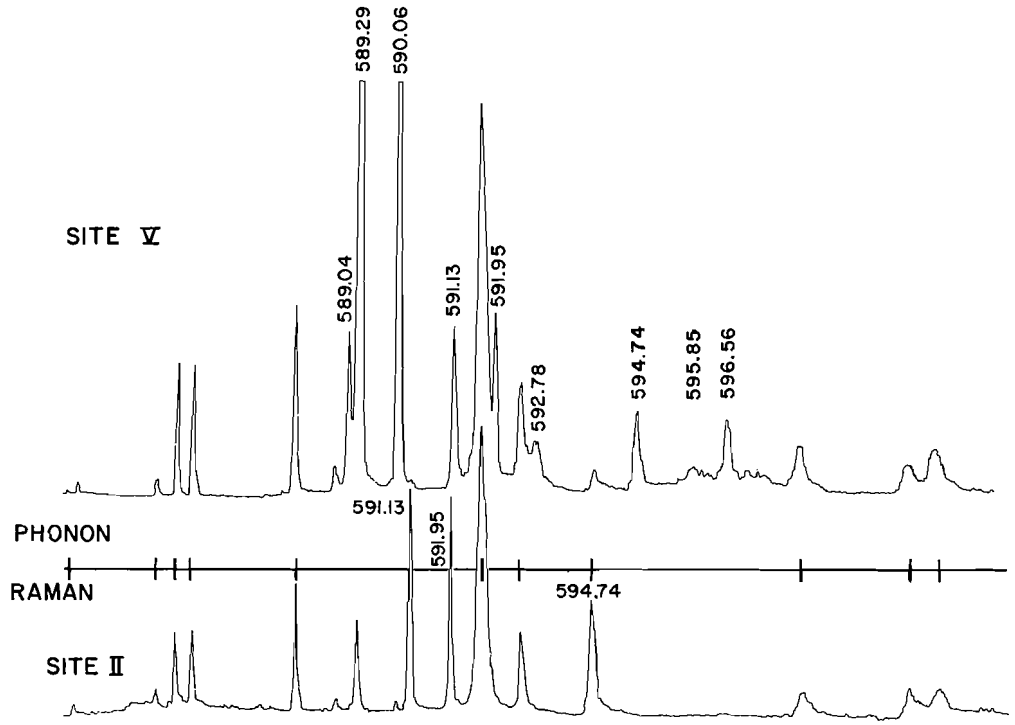

FIG. 3. $^5D_0 \rightarrow {}^7F_1$ fluorescence at 77 K due to site V representing the nearest neighbour Eu^{3+}–Cr^{3+} pair of EuGaG containing Cr^{3+}. This fluorescence is excited with $\lambda_l = 579.34$ nm. Also indicated is fluorescence due to site II (Eu^{3+} in the orthorhombic *d* sites) which is excited with $\lambda_l = 580.72$ nm. The position of the bands for site II is equal to that of the $^5D_0 \leftarrow {}^7F_1$ absorptions at 77 K (see Fig. 1). The Raman spectrum of EuGaG is also excited and the corresponding phonon Raman shifts are marked.

(site I) are displayed in Fig. 5. These spectra reveal, apart from the six relatively sharp maxima, two rather broad features. They are not part of the excitation spectrum but represent Raman scattering from phonons at 346 cm^{-1} and 366 cm^{-1} which occurs at the wavelength 591.95 nm (and 592.14 nm) to which the monochromator is tuned when the wavelength of the tunable laser is at 580.08 nm and 579.40 nm. The wavelength for which the sharp maxima occurs for fluorescence from site II are within experimental error equal to the wavelength for λ_l which yields the spectra of sites II–V of Fig. 4 (see also Table 1). A close examination of the data reveals that there exists another site, but the fluorescence spectrum of this site II*a* is so close to that of site II that its fluorescence cannot be separately recorded.

The excitation spectrum of that of site I, on the other hand, is rather simple (one maximum) and the fluorescence due to this site is the weakest among the series.

B. The Chromium System

Van der Ziel and Van Uitert found fluorescence (9) for a crystal of EuGaG containing Cr^{3+} as an impurity which is due to transitions of the type $^2E_g(\text{pair}) \rightarrow {}^7F_J(\text{pair})$, where ^2E_g and ^7F_J pair states are those discussed in section II. The $^2E_g \rightarrow {}^7F_0$ pair transitions are recorded at 698.8 nm (R_2) and 695.6 nm (R_1) and in Fig. 6 we show the excitation profiles for these lines in the range of 579.0–581.0 nm.

We note that the profile of the R_1 line is similar to that of the fluorescence from site II but different from that for site I. As a consequence of these observations, we conclude that while pumping in the $^5D_0$ state of sites II–V, energy is transferred into the ^2E_g pair level which in turn suggests that spectra of sites III–V are due to Eu^{3+}–Cr^{3+} pairs. Apparently, the position of the ^2E_g states of nearest neighbour (first), second and third pairs, etc. is not shifted significantly from each other, and emission to the ground state occurs in one band (the R_1 line). Of relevance here is the fact that for Cr^{3+}:EuGaG all Cr^{3+} are part of an Eu^{3+}–Cr^{3+} pair but not vice versa. The Eu^{3+} ions giving rise to the spectral features of sites III–V are associated with such pairs. Energy, however, is also transferred among these pairs because (see Table 1) the emission spectrum of site V contains the features of sites III and IV. Also at 77 K, energy transfer takes place from the excited non-paired Eu^{3+} ions (occupying to 8-coordinated *d* site II) to the various pairs (sites

III, IV, and V) and vice versa. The appearance of fluorescence of site II in the spectra of sites III, IV, and V (see Fig. 3) demonstrates energy transfer from Eu^{3+} in the *d* sites to the pairs, while the excitation profile of Fig. 4 suggest energy transfer from the pairs to the non-paired europium ions. The excitation profile for the R_1 line, however, shows that energy is not transferred from site I to the pairs, and we assign (6) the fluorescence spectrum of site I to Eu^{3+} ions which substitute for the gallium ions in the *a* sites. The actual site symmetry for these sites is C_{3i} but replacement of Ga^{3+} by Eu^{3+} causes a distortion towards lower symmetry and hence the complete removal of the threefold degeneracy of the $J = 1$ manifold. From a comparison of the fluorescence and absorption spectra, we estimate that not more than 10% of all europium ions are occupying these *a* sites. This concentration is small, and the ions of that site may be looked upon as being another impurity. Consequently, the probability of forming pairs with the Cr^{3+} impurity is small (compared to that for the pairs involving Eu^{3+} of the *d* site) and this explains the absence of a maximum of 580.80 nm in the excitation profile of the R_1 line. The profile for the R_2 line (see Fig. 5) does not exhibit maxima, which presently is interpreted as being due to extreme fast energy relaxation from R_2 to R_1. It appears that the excitation profiles of these R lines yield important information on the formation of pairs in garnets.

The fluorescence spectrum of site V is assigned to that of the nearest neighbour pair because its intensity and frequency spectrum differs more from that of site II (if compared to those of III and

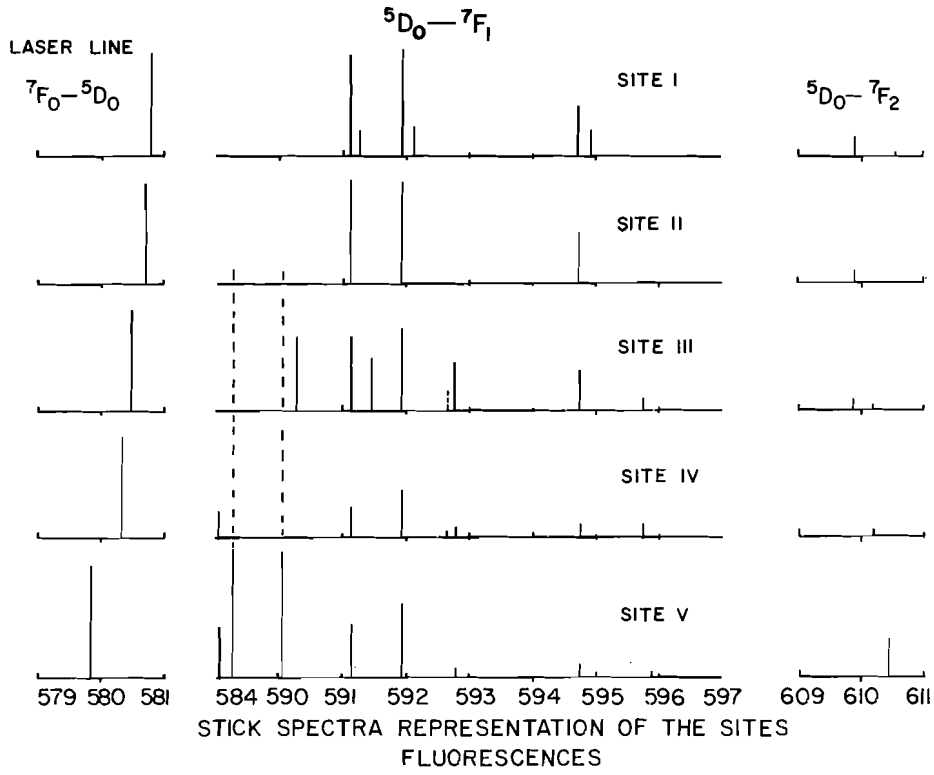

FIG. 4. Stick spectra of the (fluorescence) transitions of all five sites of EuGaG containing Cr^{3+}.

IV). The Cr^{3+} ion of this nearest neighbour pair interacts also with europium ions in other and more removed *d* sites and gives rise to the spectra of sites IV, III, and II*a* respectively. Finally for even larger distances, the interactions become smaller and smaller, and the fluorescence spectra due to such loosely bound pairs approaches that of the unpaired ion of site II. Shown in Fig. 7 is a comparison of spectra excited with $\lambda = 580.75$ nm of cw and pulsed dye lasers. Whereas the fluorescence features associated with sites I and II are recorded for the former, we did not record their features with the pulsed laser and as a result were not in a position to determine the lifetime of the various excited states of europium ions and Eu^{3+}–Cr^{3+} pairs. The absence of the fluorescence is presumably due to the population of $^5D_0$ and the subsequent absorption of another photon with $\lambda = 580.70$ nm to an even higher lying excited state. Thus, the energy reaches $^5D_0$ via a path which does not involve $^5D_0 \rightarrow {}^7F_1$ emission.

IV. Concluding Remarks

The results discussed in the preceding section suggest that the excitation profile of the R lines of a Cr^{3+} in the rare earth garnet crystal may be used to determine the presence of Eu^{3+}–Cr^{3+} pairs. The $^5D_0$–^7F_J fluorescence spectrum of a single crystal of $Eu_{0.03}Y_{2.97}Al_5O_{12}$ was recently investigated (8), but contrary to EuGaG we found evidence of two, rather than five centres. Relevant information on the position of some of the ^7F_J and $^5D_0$ states of Eu:YAlG are given in Table 2. This crystal also contains Cr^{3+} as an impurity, and part of the emission spectrum due to $^2E_g \rightarrow {}^4A$ transitions is shown in Fig. 8. The four transitions are at 686.2 nm, 687.1 nm, 688.2 nm, and 689.3 nm and the position of these lines may be compared with those of the R lines at 686.7 nm and 687.6 nm of YAlG containing Cr^{3+}. Because the intensity of the R_1 line of non-paired Cr^{3+} is larger than that of the R_2 line we assign the R lines of non-paired Cr^{3+} of Eu:YAlG so that $R_1 = 686.2$ nm and $R_2 = 687.6$ nm. The lines at 688.2 nm and 689.3 nm are assigned to those belonging to the nearest neighbour Eu^{3+}–Cr^{3+} pair in the crystal. Following the discussion of the results obtained for EuGaG, we assign the strongest of the fluorescence $^5D_0 \rightarrow {}^7F_1$ to that originating from the pair, see Table 2. This assignment is consistent with a crystal field analysis of the splitting pattern of the ^7F_J manifolds to Eu^{3+} ions in Eu:YAlG.

the $^5D_0 \rightarrow {}^7F_J$ fluorescence of sites I and II. The excitation profiles are all equal because contrary to EuGaG the europium fluorescence of Eu:YAlG is much stronger. Thus by pumping into $^5D_0$ of sites I and II, the sample emits strongly in the spectral range of 590 nm–850 nm and the radiation between 590 nm–670 nm is reabsorbed by Cr^{3+} and Eu^{3+}–Cr^{3+} of the sample, hence the similarity of the excitation profiles.

V. Acknowledgements

The authors wish to thank Dr. L. G. Van Uitert for providing them with a crystal of EuGaG. They also wish to thank Mr. M. Kilpatrick for recording the fluorescence spectra.

SUHASCHANDRA GHOSH, SATYA P. MOULIK, and AKHIL R. DAS. Can. J. Chem. **59**, 2449 (1981).

The results of dye–dye interactions for the pairs, acridine orange – methylene blue, acridine orange – phenosafranine, and acridine orange – disulphine blue have been presented. It has been found that at comparable concentrations the interaction is rather weak, and the formation of mixed entities is only possible at relatively high proportions of one of the components. However, the evidence of mixed dimers in the form of a new absorption band is lacking. Phenosafranine remarkably promotes dimerization of acridine orange. An experimental demonstration of the dimer spectra of acridine orange has thus been possible. The interaction of the anionic dye disulphine blue with cationic acridine orange has been observed to be the weakest of all the pairs, indicating the vital role of the structural parity for interaction. At comparable low concentrations, none of the dye-pairs studied have revealed compound metachromasy in the presence of a polyelectrolyte, suggesting unfavorable mixed dye aggregation under ordinary conditions.

SUHASCHANDRA GHOSH, SATYA P. MOULIK et AKHIL R. DAS. Can. J. Chem. **59**, 2449 (1981).

On présente les résultats relatifs aux interactions colorant – colorant dans les paires de colorants suivants: acridine orange – bleu de méthylène, acridine orange – phénosafranine et acridine orange – bleu de disulfine. L'interaction est plutôt faible si les colorants ont des concentrations comparables et la formation d'entités mixtes est possible uniquement si l'un des constituants est dans une proportion relativement élevée. Cependant, on constate l'absence d'une nouvelle bande d'absorption qui indiquerait la présence de dimères mixtes. La phénosafranine favorise remarquablement la dimérisation de l'acridine orange. Il est alors possible de démontrer expérimentalement le spectre du dimère de l'acridine orange. L'interaction du colorant anionique, bleu de disulfine, avec le colorant cationique, acridine orange, est la plus faible de toutes les paires étudiées, ceci constitue une indication du rôle vital de la parité structurale lors de l'interaction. A de faibles concentrations aucune des paires de colorants étudiées ne révèlent la métachromasie composée en présence d'un polyélectrolique, suggérant ainsi une association défavorable du colorant mixte dans les conditions ordinaires.

Introduction

Interactions of large charged organic molecules in aqueous medium in the presence of salts, co-solvents, and other additives have been considered important over the last decade in view of their relevance to biology (1). Dyes may serve as models for such organic molecules and have been used in many instances of physico-chemical investigations (2). The self association (mainly dimerization) has been the focus of such studies. Investigations on the mixtures of dyes have been rarely done. Only a few reports of mixed dimer formation (3–7) and compound metachromasy (8, 9) in the presence of polymers appear in the literature.

In the present work, we have described the interactions of acridine orange (AO) dye cation with two other cationic dyes, methylene blue (MB) and phenosafranine (PSAF), and an anionic dye disulphine blue (DSB) from spectrophotometric studies.

Of the four dyes, AO and MB are structurally comparable; PSAF is also not very different except for the bulky phenyl ring attached to one of the central ring nitrogens. Apart from it being anionic, DSB has a completely different structure. According to our knowledge, the present elaborate spectrophotometric report dealing with different types of dyes, studied at relatively excess concentrations of one of the components, is the first of its kind.

Experimental

The specification of AO was the same as reported earlier (10). Both MB and PSAF were BDH Analar products. MB showed a shoulder at 610 nm and a main band at 660 nm. PSAF had only a broad band at 525 nm without any discernible shoulder. All these corresponded well with literature reports (11, 12). The DSB was the same sample as that used by Mandal *et al.* (13).

Other chemicals used were either BDH Analar or E. Merck pro-analysis grades. Double distilled water was used as the solvent. The non-aqueous solvents used were purified by following standard procedures.

All measurements were taken in a Hilger-Watts digital spec-

trophotometer using 1 cm and 0.5 cm cuvettes at a constant temperature of 25 ± 0.1°C.

In general, each set of experiments was done keeping the concentration of one of the components constant and varying that of the other. Each experimental set was repeated to check the reproducibility of the systems. For other details of spectrophotometric measurements we refer to our earlier publication (10).

Results

(1) AO–MB pair

MB has a small absorption peak at 490 nm, the wave length of the maximum absorption of the AO monomers. At lower MB:AO ratios, the spectrum of a low concentration of AO (2.5 μ*M*) is not affected, and the absorbances are all additive. Higher proportions of MB helped increasing the monomer absorption peak of AO at 490 nm. At a relatively high concentration of AO (20 μ*M*), increased proportion of MB perceptibly increased the monomer peak of AO at this wave length. The calculated absorbances (the sum of the absorbances of the individual dyes) of the mixtures were significantly different than the experimental values. The departure from additivity is the evidence for AO and MB interaction. The reverse set of experiments, i.e., the effect of increasing proportions of AO on MB (20 μ*M*) studied at its long wavelength monomer band revealed a remarkable difference (Fig. 1). At lower AO:MB ratios, the absorbance at 660 nm increased a little and the usual dimer shoulder was there at 610 nm. At ratios of 4 or greater, the absorbance at the same wavelength decreased with increasing AO:MB ratio and the band was slightly red-shifted. At larger proportions (ratios 50 and 75) of AO, the band shifted further to 673 nm along with significant lowering of absorbance. In this process of red shift and concomitant lowering of intensity, the family of curves passed through an isosbestic point at 680 nm. The results suggest an interaction of AO with MB at higher proportions of the latter.

The interactions of AO and MB were also studied in the presence of KCl and ethanol. MB also influenced the effect of both the salt and the

alcohol on the monomer–dimer equilibrium of AO prevalent at the concentration used. On the other hand, the AO induced depression of MB spectra (Fig. 1) was considerably influenced by both the salt and the alcohol. The salt induced dimer peak at 610 nm of MB was considerably lowered and practically disappeared in the presence of high proportions of AO and AO plus salt. A product of the $(AO)_n$–$(MB)_m$ type is suggested.

(2) AO–PSAF Pair

The spectra of AO and PSAF were affected by each other. With increasing proportions of PSAF, the 465 nm dimer shoulder of AO became prominent along with a corresponding decrease of the monomer peak at 490 nm. The 465 nm shoulder ultimately became a well shaped symmetric peak and in the presence of a large excess of PSAF, the band suffered a gradual blue shift. Figures 2 and 3 illustrate these results.

In the presence of 200 μM PSAF (sufficient to produce a distinct 465 nm band symmetric on both sides), the spectra of AO at different concentrations along with Beer's law plots at 465 nm and 490 nm are shown in Fig. 4. The dimer extinction coefficients at 25°C were calculated to be 4.65×10^4 (465 nm) and 2.76×10^4 (490 nm) L mol^{-1} cm^{-1}.

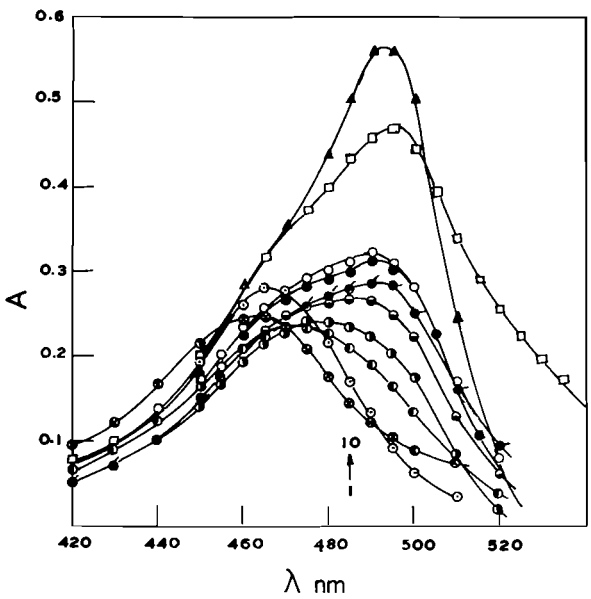

FIG. 2. The spectra of AO and PSAF mixtures containing a constant concentration of AO. Curve *7*, 20 μM AO in water vs. a water blank. Curves *1–6* and *8*, AO–PSAF mixtures, each with 20 μM AO and PSAF:AO ratios of 10, 8, 5, 4, 3, and 2 respectively, each recorded vs. a solution containing an equal concentration of PSAF as blank. Curves *9* and *10*, 1:1 AO–PSAF mixture and AO in 80% v/v alcohol respectively, each recorded vs. a water blank.

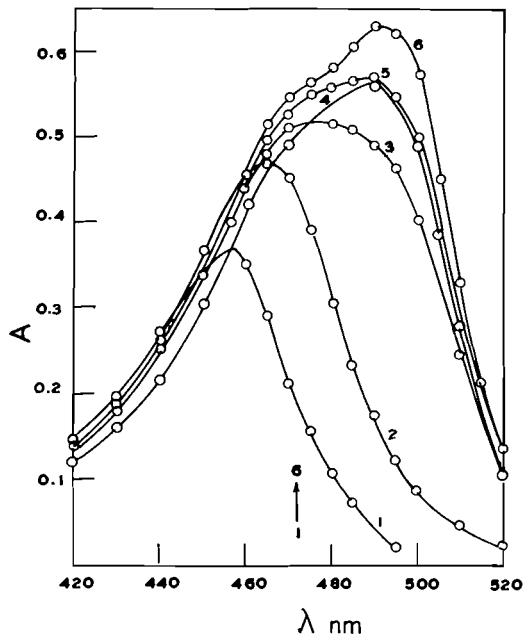

FIG. 3. The spectra of AO and PSAF mixtures containing a constant concentration of AO. Curve *6*, 40 μM AO in water vs. a water blank. Curves *1–5*, AO–PSAF mixtures, each with 40 μM AO and PSAF:AO ratios of 8, 5, 2, 0.5, and 1 respectively, each recorded vs. a solution containing an equal concentration of PSAF as blank.

The results of the reverse experiments, i.e., the effect of increasing the AO:PSAF ratio are presented in Fig. 5. The 525 nm PSAF band slightly improved at lower AO:PSAF ratios, but was depressed subsequently. At lower ratios a shoulder appeared at 485 nm but became flat at higher ratios. All these facts indicate a strong AO–PSAF interaction. The effects of salts and alcohol on the spectra of PSAF are also shown in the figure for a comparison.

(3) AO–DSB Pair

Shown in Fig. 6*a* are the effects of AO on the spectrum of DSB. In the region where DSB absorbs most, AO has little absorbance. In excess AO, a weak band at 500 nm appeared. The reverse, that is the effect of DSB on the spectrum of AO (Fig. 6*b*), was also not appreciable. Excess DSB could, however, slightly affect the spectra of AO by an initial increase in the 490 nm band of AO followed by a decrease; at still higher DSB:AO ratios, it started rising again. In this process, the spectral shape did not alter. AO–DSB interactions were thus seen to be weak indeed.

(4) The Effects of a Surfactant and a Polyelectrolyte

The effects of sodium dodecyl sulfate (SDS), an

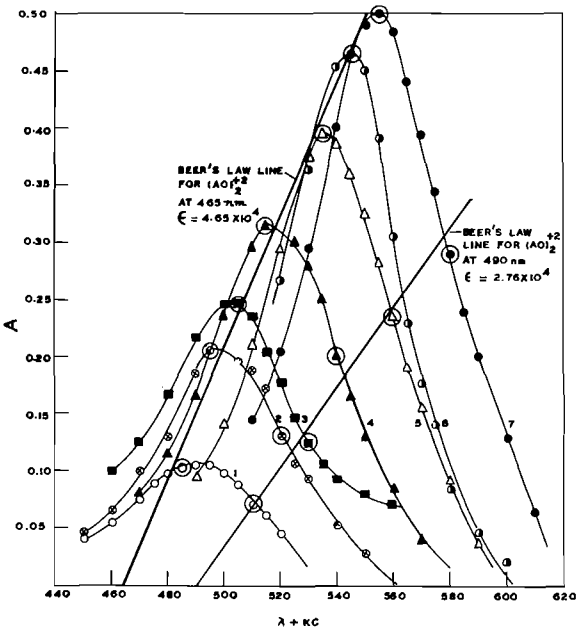

FIG. 4. The PSAF induced dimer spectra of AO. Also shown are Beer's law plots for the dimer at 465 nm and 490 nm. Curves *1*, *2*, *4–7*, AO–PSAF mixtures each with 200 μ*M* PSAF and AO concentrations of 10, 15, 25, 35, 40 and 45 μ*M* respectively, each recorded vs. a solution of 200 μ*M* PSAF as blank. Curve *3*, AO–PSAF mixture of 320 μ*M* PSAF and 20 μ*M* AO recorded vs. a solution of 320 μ*M* PSAF as blank. The value of the constant *K* (on the *X*-axis) is 20×10^{-5}.

anionic surfactant, and the Na-salt of carboxymethyl cellulose, a polyelectrolyte, on the spectra of the dyes, singly and in pairs, are presented in Fig. 7. While the presence of the polyelectrolyte revealed normal metachromasy, SDS, at a concentration below the critical micelle concentration (cmc), only depressed the bands. DSB was not affected by the polyelectrolyte or SDS. The effect of SDS on PSAF, though not insignificant, was much less than that on AO. The spectra of the three pairs of the dyes used in presence of the polyelectrolyte were conspicuous by the absence of any new metachromatic band to be assigned to any mixed dimer formation.

Discussion

Binary mixtures of dyes such as AO–MB, MB–PSAF, MB–pyronine G, crystal violet – rohdamine 6G, etc. have been reported to form mixed dimers in solution (4, 5, 7). This was anticipated not because of the appearance of a new absorption band in each case but mainly due to the nonadditivity of the absorbance. Pal and Schubert (8) reported compound metachromasy in the presence of certain polyanions. In the present binary dye systems using AO as one of the components, we have observed interactions of different types. For the AO–MB system, the absorbance of AO increased in the presence of MB resulting in an upward displacement of the spectra as a whole. No new absorption band or shoulder appeared to indicate the formation of a new entity in solution by interaction. Addition of more and more MB increased the probability of the electronic transition of AO leading to increased absorbance. When we explored the effect of AO on the spectra of MB, we noticed that the 660 nm monomer absorption peak of MB got depressed after an initial rise and was red shifted to 673 nm. The spectrum shifted towards the red as a whole (Fig. 1). Pal and Schubert (8) missed this observation in their work with AO–MB system since they did not use one of the components in large excess. Such spectral perturbations of MB in the presence of large excess of AO are unlikely to be due to mixed dimers since AO existed in highly aggregated state at such high concentrations. We anticipated that MB cations (both monomeric and dimeric) are incorporated in the stacks of oligomers and their transition dipoles are perturbed in the new environment.

PSAF influenced AO much more markedly than AO did PSAF. A clear monomer–dimer conversion of AO took place in the presence of a suitable excess of PSAF. At sufficiently high proportions of PSAF, AO showed typical metachromatic behavior (Figs. 2 and 3). Dimerization of a dye in the presence of another dye, particularly one which does not differ radically in structural pattern, has not been reported in the past. Neglecting other effects, the extinction coefficient of the AO dimer has been evaluated and compared with the earlier reports.

Extinction coefficient of the AO dimer at 25°C (ε_d^{490} L mol^{-1} cm^{-1})	Authors
1.55×10^4	Lamm and Neville (14)
1.60×10^4	Ballard and Parks (15)
1.30×10^4	Robinson *et al.* (2)
2.70×10^4	Present work

While our value resulted from an experimental demonstration of the dimer spectra, the other previously reported values were obtained by indirect methods.

The influence of AO on PSAF was not as remarkable as the reverse; but the spectra showed considerable variation. A shoulder appeared at some AO:PSAF ratios (2:1 and 0.5:1) around 485 nm (Fig. 5). At higher ratios, it disappeared and the absorbance remained significantly constant over a considerable region of wavelength up to 495 nm,

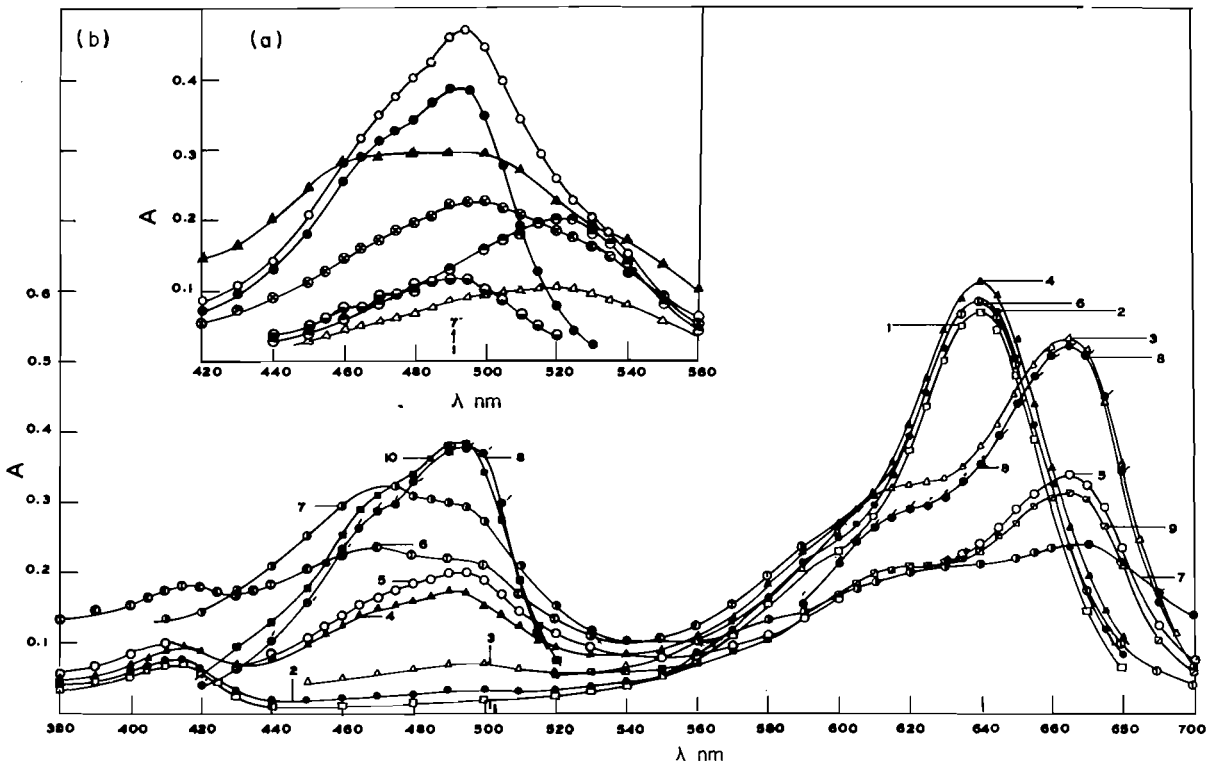

FIG. 7. (*a*) The spectra of AO, PSAF, and their 1:1 mixture in water, SDS, and CMC (Na salt) solutions. Curves *1* and *3*, 20 μ*M* PSAF in 60 μ*M* aqueous SDS and in water respectively. Curves *4*, *5*, and *7*, 20 μ*M* AO plus 20 μ*M* PSAF in 60 μ*M* aqueous SDS, in 0.35% aqueous CMC and in water respectively. Water, 60 μ*M* aqueous SDS, and 0.35% aqueous CMC were used as the respective blanks. (*b*) The spectra of AO and 1:1 mixtures of AO–MB and AO–DSB containing a constant concentration (20 μ*M*) of AO in water, aqueous SDS and aqueous CMC media. Curves *1*, *3*, *8*, and *10*, that of DSB, MB, AO plus MB, and AO respectively in water. Curves *2*, *4*, *5*, and *9*, that of DSB, DSB plus AO, AO plus MB, and MB in 60 μ*M* aqueous SDS respectively. Curves *6* and *7*, that of AO plus DSB and AO plus MB in 0.35% aqueous CMC respectively. Water, 60 μ*M* aqueous DSB, and 0.35% aqueous CMC were used as the respective blanks.

which was indicative of the formation of a new entity.

In spite of the opposite charge, DSB revealed little interaction with AO. The spectral pattern of DSB remained almost unaffected in the presence of AO; no new band appeared on the higher wavelength side of DSB absorption peak but a weak band appeared at 500 nm (Fig. 6*a*).

The above discussed results have shown significant effects of PSAF on AO and AO on MB. The effect of MB on AO is moderate. PSAF has helped dimerizing the AO while MB reduced the extent of dimerization. When present in large excess, AO complexes with MB monomers. A quantitative approach of the above phenomena has been attempted in the following.

The monomer–dimer equilibrium has been considered to calculate the percent of AO monomer and the dimerization constant, K_d, under the influences of PSAF and MB.

$$[1] \quad 2\,AO \overset{K_d}{\rightleftharpoons} (AO)_2$$

Also,

$$[2] \quad A = \varepsilon_m C_m + \varepsilon_d C_d$$

where, A, ε_m, C_m, ε_d, and C_d are the absorbance, the extinction coefficient of the monomer, the concentration of the monomer, the extinction coefficient of the dimer and the concentration of the dimer respectively.

The estimated ε_m used earlier (10) and the ε_d evaluated under the influence of excess PSAF and reported herewith have been used in the calculation. Thus, C_m and C_d are obtained from the relations,

$$[3] \quad C_m = (A - \tfrac{1}{2}\varepsilon_d C_t)/(\varepsilon_m - \tfrac{1}{2}\varepsilon_d)$$

and

$$[4] \quad C_d = \tfrac{1}{2}(C_t - C_m)$$

where the new term C_t denotes the total AO concentration.

The dimerization constant has been calculated from the relation,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

[5] $K_d = C_d/(C_m)^2$

Since activity is uncorrected, the K_d values are not truly thermodynamic but they are not far from this as the solutions employed were dilute and the arguments given earlier (16) in this regard favor low significance of such a correction. The calculated parameters are given in Tables 1 and 2.

The following model has been chosen for MB–AO complexation to calculate the uncomplexed (free) MB in solution in AO environment.

[6] $MB + nAO \rightleftharpoons MB(AO)_n$

where n is greater than one but the value is at present unknown. Without known values of n, the system cannot be fully characterized.

The free MB has been considered to be monomers because of rapid loss of dimer shoulder in the spectra with AO addition. Besides, calculations have been made on mixtures that did not register dimer shoulders. The limiting absorbance of the solutions containing constant MB and increased AO has been considered to be the absorbance of the complex. The concentration of MB thus equals the concentration of the complex (according to eq. [6]) and the extinction coefficient of the complex ($\varepsilon_{comp} = A/C_{MB}$) has been calculated to be 4.98×10^4 L mol^{-1} cm^{-1}.

The absorbance of the mixed dye solution is given by

[7] $A = A_{MB} + A_{comp} + A_{AO}$

TABLE. 1. Dimerization of AO by PSAF*

PSAF:AO	% AO(monomer)	$K_d \times 10^{-5}$ (L mol^{-1})
0	23.31	3.57
1	25.09	3.17
2	23.21	3.57
3	19.64	5.53

8	8.08	35.20
10	7.32	43.24
12	3.27	226.15

*$\varepsilon^{480}_{AO(monomer)} = 9.0 \times 10^4$ L mol^{-1} cm^{-1}; $\varepsilon^{480}_{AO(dimer)} = 2.7 \times 10^4$ L mol^{-1} cm^{-1}; $C_{AO} = 2.0 \times 10^{-5}$ M; $T = 25$°C.

TABLE 2. Monomerization of AO by MB*

MB:AO	% AO(monomer)	$K_d \times 10^{-5}$ L mol^{-1}
0	23.21	3.57
1	33.01	1.54
2	32.88	1.55
4	47.72	0.57
8	55.9	0.35
10	53.4	0.41

*$\varepsilon^{480}_{AO(monomer)} = 9.0 \times 10^4$ L mol^{-1} cm^{-1}; $\varepsilon^{480}_{AO(dimer)} = 2.7 \times 10^4$ L mol^{-1} cm^{-1}; $C_{AO} = 2.0 \times 10^{-5}$ M; $T = 25$°C.

Since at the experimental wave length (660 nm) AO hardly absorbs, eq. [7] becomes

[8] $A = A_{MB} + A_{comp} = \varepsilon_{MB}C_{MB} + \varepsilon_{comp}(C_t - C_{MB})$

Therefore,

[9] $C_{MB} = (A - C_t\varepsilon_{comp})/(\varepsilon_{MB} - \varepsilon_{comp})$

In Table 3, the concentration of the MB monomer and its percentages are shown. Lack of exact knowledge of the composition of the complex has restricted calculation of the equilibrium constant.

The results given in the tables offer some quantitative aspects of the interactions of the dye pairs. Powerful effect of PSAF on the dimerization of AO is revealed through very large K_d values at PSAF:AO ratios >12. Complexation of MB monomers with AO is prominent at ratios 16 and above.

In the presence of the polyelectrolyte, carboxymethylcellulose (Na salt), no compound metachromasy was observed in the binary mixtures of AO and MB. Only the normal metachromatic behavior of the individual dyes was evident. Compound metachromasy was also not observed in the AO–PSAF and the AO–DSB systems (Fig. 7 *a* and *b*). Such behaviors were not unexpected as interactions in all the cases were apparent only at higher proportions of one of the components. The polyelectrolyte effect was studied at a comparable dye concentration of 20 μM for all the combinations. The carbohydrate origin polymer γ-carrageenan, however, induced compound metachromasy in the AO–MB pair at 1:1 composition (12.5 μM) as reported by Pal and Shubert (8). The present observations revealed that even a polymer chain with suitable binding sites was not good enough to induce dye–dye interaction; only normal metachromasy of the individual dyes was observed. Once a given dye cation is bound to a site, for nearest neighbor interaction there is an equal choice (considering the comparable dye concentration) between a dye cation of its own type and a different type. The results indicated that for the

TABLE 3. Percentage of uncomplexed MB in excess AO*

*$\varepsilon^{660}_{MB} = 9.6 \times 10^4$ L mol^{-1} cm^{-1}; $\varepsilon^{660}_{comp} = 4.98 \times 10^4$ L mol^{-1} cm^{-1}; $C_t = 2.0 \times 10^{-5}$ M; $T = 25$°C.

pairs of the dye studied, mixed dimer formation is less favorable.

Since SDS was used at a concentration below cmc, it depressed the spectra of both MB and AO as a whole without much altering the monomer–dimer ratios of the dyes, a behavior that may be noticed in individual dyes in the presence of SDS (17). Similar behaviors were obtained for the AO–PSAF pair. For the AO–DSB pair, the AO part of the spectrum underwent similar changes as with pure AO and the DSB part remained unaltered (Fig. 7). These results suggested that the anionic surfactant, SDS, could not induce interactions of AO with MB, PSAF, and DSB in their binary mixtures.

The following general conclusions can be made from the present results on the dye systems studied. (*1*) To get an appreciable spectral change one of the two dyes must be in significant excess. (*2*) The effect of the added dye on AO and vice-versa can become noteworthy if it is not structurally much different from AO. (*3*) If the structure of the added dye is significantly different from AO (AO–DSB pair), the interaction is minimum even though the dyes are oppositely charged. (*4*) An anionic polyelectrolyte or an anionic surfactant cannot bring about in solution any altered metachromasy other than that exhibited by the individual dyes.

Received January 19, 1981

MARGARET M. KAYSER and ODILE EISENSTEIN. Can. J. Chem. **59**, 2457 (1981).

Ab initio molecular orbital calculations have been carried out for the series of succinic, maleic, and phthalic anhydrides unsymmetrically substituted with CH_3, CH_3O, Cl, F, and CN. The size of the LUMO coefficient on the carbon atom of the carbonyl group provides a reliable guide to the relative reactivities of the two carbonyl functions. The predictions based on the intrinsic reactivities are in good agreement with the regioselectivities observed in metal hydride reductions of succinic anhydrides. In the series of maleic and phthalic anhydrides the above considerations are applicable only to methyl derivatives. The compounds substituted with lone pairs-bearing groups (OCH_3, Cl, F) form stable chelates with the cations present in the reaction media. Since the chelated carbonyl group is strongly activated toward the nucleophilic addition, the "bridging" effect is the dominant factor controlling orientation of hydride addition. The optimum position for the nucleophilic attack in cyclic anhydrides was calculated. The results confirm the generality of the nonperpendicular, restricted path of nucleophilic attack on the carbonyl group in succinic anhydride.

MARGARET M. KAYSER et ODILE EISENSTEIN. Can. J. Chem. **59**, 2457 (1981).

Une série d'anhydrides succiniques, maleiques et phtaleiques substitués de façon non symétrique ont été calculés par une méthode *ab initio*, base minimale. La réactivité intrinsèque des deux fonctions carbonyles en présence des substituants est donnée par la valeur du coéfficient du carbone dans la LUMO. Les résultats théoriques et expérimentaux sont en bon accord pour la série des anhydrides succiniques réduits par $LiAlH_4$ et $NaBH_4$. Dans la série des anhydrides maleiques et phtaleiques, l'indice de réactivité ainsi défini ne permet d'expliquer que la réduction des dérivés méthylés. Lorsque les anhydrides en question portent des substituants possédant des paires libres, des chélates sont formés avec le cation présent dans le milieu réactionnel. Comme le carbonyle chélate est fortement activé par le cation, il sera sélectivement réduit par le nucléophile. La direction optimum d'attaque par le nucléophile sur les anhydrides cycliques a également été examinée. Les résultats confirment la généralité de l'approche non perpendiculaire.

Introduction

Cyclic anhydrides may be converted directly to the corresponding lactones by reduction with metal hydrides (1). Unsymmetrically substituted anhydrides such as, for example, 2,2-dimethylsuccinic anhydride **1** can potentially yield isomeric lactones **2** and **3**. In fact, lactone **2** is the major product obtained in a large excess (the ratio **2**:**3** = 19:1) (2). A similar regioselectivity has been observed in metal hydride reductions of a variety of unsymmetrical cyclic anhydrides belonging to vastly different classes of compounds (3). At present only a few exceptions (i.e., cases of selective reduction at the less hindered carbonyl group or reduction without preference for either group) are known (2, 4).

The marked preference for nucleophilic attack to occur at the sterically more hindered site has provoked some speculation (3, 5), particularly as such regioselectivity is not restricted to cyclic anhydrides. Unsymmetrically substituted succinimides (6*a*), diesters, and diacids (6*b*) are also reduced by metal hydrides selectively at the more sterically encumbered carbonyl group.

Why metal hydrides attack the more hindered carbonyl function is still not clear.[1] This "unusual" regioselectivity has been considered in terms of steric and stereoelectronic effects and several mechanisms were proposed, each explaining some but not all of the results obtained experimentally (2, 3, 5). The anhydrides most exhaustively studied can be divided, on the basis of their geometry, into two groups: (*1*) unsymmetrically substituted succinic anhydrides with substituents projected above and below the plane of the ring **4**, and (*2*) planar, conjugated maleic and phthalic anhydrides **5** and **6**.

1 **2** **3**

[1]In contrast, Grignard reagents add preferentially in a "normal" manner to the less hindered carbonyl group in substituted succinic anhydrides (P. Canonne, private communication).

Preferential reduction of the carbonyl group α, adjacent to the most fully substituted carbon atom in succinic anhydrides, has been described in terms of the most favourable path for the nucleophilic attack on the carbon atom of the carbonyl group (7). Since at a moderate distance to the molecular plane the best angle for nucleophilic approach is about 110° to the C=O double bond (8, 9), the carbonyl function α next to the substituents is effectively less hampered than the carbonyl group β, viewed from the position of approaching nucleophile **4**. This argument explains preferential reduction of the α-carbonyl group in succinic anhydrides but fails to account for the selectivities observed in reductions of planar maleic and phthalic anhydrides where both carbonyl functions are equally accessible to the nonperpendicular attack (10). Obviously in the latter case factors other than "the most favourable path of nucleophilic approach" must be responsible for the regioselectivities observed.

We have suggested previously (2) that a preferential attack by metal hydrides on the carbonyl group adjacent to the most highly substituted carbon atom is linked to the discrete characteristics of the two groups. This study was undertaken for the following specific purposes: (*1*) to probe the intrinsic differences in reactivity of the carbonyl functions in unsymmetrical cyclic anhydrides; (*2*) to examine the effect of the counterion on the regioselectivity of metal hydride reductions; (*3*) to compute the optimum geometry for the nucleophilic (H^-) attack on the surface of succinic anhydride, in order to confirm generality of the nonperpendicular approach.

Discussion

Ab initio molecular orbital calculations using the Gaussian 70 programme (11) with the minimal STO-3G basis set were performed for a number of substituted succinic, maleic, and phthalic anhydrides. The geometries for the parent succinic and maleic anhydrides were obtained from the crystallographic data (12). For the substituted compounds standard bond lengths and bond angles were used (13).

Intrinsic Differences Between the Two Carbonyl Groups in "Naked" (i.e., Not Associated with a Cation) Unsymmetrical Cyclic Anhydrides

From the perturbational viewpoint (14), the electrophilic reactivity of a molecule resides fundamentally in the energy and localization of its low lying vacant orbitals. Thus in terms of the perturbational theory a nucleophile should add preferentially to the atom bearing the largest coefficient on the lowest unoccupied molecular orbital (LUMO).

The *ab initio* calculations performed on the series of "naked" succinic, maleic, and phthalic anhydrides show in most cases a small but significant difference in the magnitude of the LUMO coefficients on the carbon atoms of the two carbonyl functions (Table 1). This suggests that there is an intrinsic difference in reactivity between the two carbonyl groups in unsymmetrical cyclic anhydrides. How do theoretical predictions compare with the available experimental data?

In succinic anhydrides, the LUMO coefficient on the carbon atom of the α-carbonyl group is consistently larger than the coefficient on the β-carbonyl function (Table 1). As a result the orbital interaction with a nucleophile's highest occupied molecular orbital (HOMO) is more favourable at the α-carbon atom. According to theory, preferential attack should be directed at the α-carbonyl function. The experimental results show that, despite intrinsic difference in electronic nature between chloro and methyl groups, compounds **4***a*, **4***b*, and **4***d* are all reduced selectively at the carbonyl group adjacent to the substituent(s).

If our argument, suggesting that the localization of the LUMO coefficients is an important factor in orienting regioselectivity of metal hydride reductions, is correct, we may also predict preferential reduction of the α-carbonyl function in fluoro and cyanosuccinic anhydrides **4***e*, **4***f*, and **4***g* (Table 1).

[a] $NaBH_4$ reduction of chloromaleic anhydride occurs in 1,2 and 1,4 fashion. Under the reaction conditions the competitive 1,4 addition yields chlorosuccinic anhydride which is further reduced to give β-chloro-γ-butyrolactone.
[b] For computational reasons methoxy and nitro substituted phthalic anhydrides could not be calculated.

We should point out that similar regioselectivity was forecast on the basis of the nonperpendicular approach (7). The computations of the optimal geometry for the nucleophilic attack on the unsubstituted succinic anhydride show that at the distance of 2 Å the optimal location for the hydride ion is at 110° to the carbon–oxygen double bond (Fig. 1).

In planar, conjugated anhydrides, the localization of LUMO cannot serve as a guide in forecasting the reaction site since there is no systematic correspondence between the calculated LUMO coefficients and the experimental facts (Table 1). Thus the difference between coefficients C_α and C_β is moderately large in favour of C_α in methoxymaleic anhydride **5***b*, smaller in methylmaleic anhydride **5***a*, and negligible in chloromaleic and 3-methylphthalic anhydrides **5***c* and **6***a*. In fluoro and chloro substituted phthalic anhydrides **6***d* and **6***c* the largest LUMO coefficients are on the carbon atom of the β-carbonyl group. As a result our qualitative analysis should predict an excess of the α reduction for methoxy and methylmaleic anhydrides, an equal mixture of the two lactones for the chloromaleic and methylphthalic anhydrides, and a preferential reduction at the β site for the remaining compounds. In contrast, $NaBH_4$ and $LiAlH_4$ reductions occur consistently at the α-carbonyl function (Table 1). Apparently factors other than those mentioned above make one of the two carbonyl groups a better target for the nucleophilic attack.

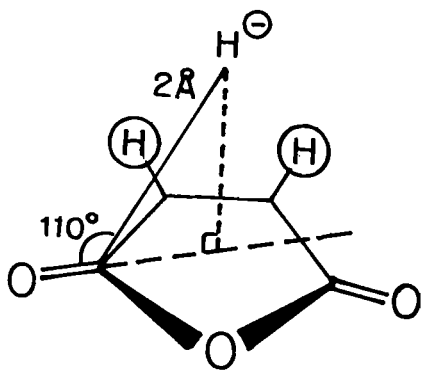

FIG. 1. The optimal position for hydride attack in the H^--succinic anhydride "super-molecule".

Influence of a Cation and Chelating Effects

We would like to point out that our discussion so far was limited to the consideration of "naked molecules" and did not allow for the intervention of a cation. Nevertheless, it is well documented that the association of a cation with the carbonyl function increases the reactivity (15) of the latter by lowering the LUMO π* of the substrate to the level of the nucleophile's HOMO, hence permitting a better interaction (16).

The cyclic anhydrides are not different in this respect. Indeed, the presence of an appropriate crown ether prevents reduction of 2,2-dimethylsuccinic anhydride by $LiAlH_4$.[2] In principle a

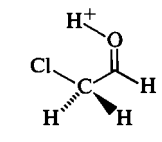
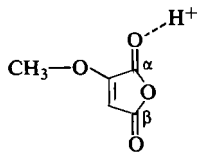
cation can interact with any of the three negatively charged centres of the cyclic anhydride: the oxygen atoms of the two carbonyl groups and the oxygen atom of the ring.[3] However, the study of protonation of formic acid by the *ab initio* method (17) predicts that the carbonyl protonated formic acid is considerably more stable than the hydroxy protonated isomer. The nmr results confirm the theoretically obtained relative stabilities (17*b*). We may anticipate similar selectivity in anhydrides, i.e., preferential association of a proton or a cation with the oxygen atom of a carbonyl group. However, in unsymmetrically substituted anhydrides, a proton (or a cation) has an additional choice between the two carbonyl groups.

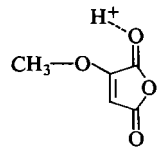
The calculations show that in unsymmetrically substituted succinic anhydrides both carbonyl groups have similar affinity for a cation.[4] Thus it is not a cation which determines the preferred site for the reduction but the intrinsic reactivity of each carbonyl group. Here, the cation's role is essentially to speed up the reaction. The situation is quite different in maleic and phthalic anhydrides. Due to the planar geometry of these compounds, the cation may form a bridge between the oxygen atom of the α-carbonyl group and the substituent, in those cases where the latter has lone pairs capable of interacting with a cation (OCH_3, Cl, F). It has been shown (19) that in protonated α-haloacetaldehydes **7** the proton preferred the *syn* position



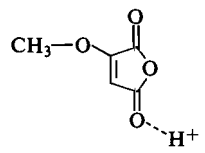
7 *syn*



8 *anti*

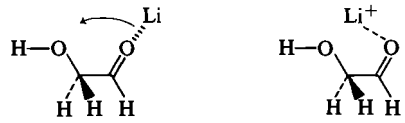


9 *syn*



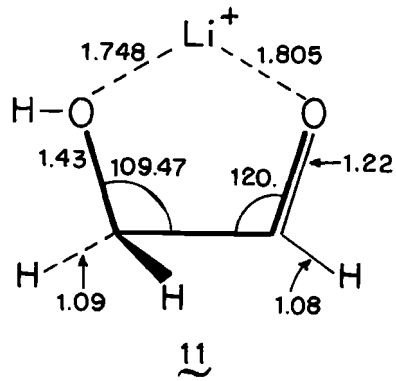
10

between the substituent and the oxygen atom by 5 kcal when the carbon–halogen bond was eclipsing the carbonyl group. A similar but weaker effect was observed in methoxymaleic anhydride. The *syn* isomer **9** was favoured over the *anti* isomer **8** by 3 kcal, suggesting the existence of intramolecular hydrogen bonding and the possibility of a proton being simultaneously bound to both oxygen atoms. However, to our dismay the ultimately preferred site for the protonation proved to be the β-carbonyl group, **10**. Actually, this situation could have been anticipated since the total and π electron density is higher on the oxygen of the β-carbonyl group (Table 2) and a proton used in our calculations is too small to be able to chelate effectively the two oxygen atoms. We expected that the larger cation such as Li^+ or Na^+ should prefer the "bridging" position between the oxygen atom and π-electron donating substituent to any other site in the molecule.



11

In order to determine if the chelating effect is in fact involved we have explored association of Li^+ with the model compound **11**. The optimum distances for Li^+—O in carbonyl and Li^+—O in ether have been reported to be 1.76 Å and 1.81 Å respectively (20). When Li^+ is placed simultaneously at approximately those distances from the two oxygen atoms in a model compound the situation should correspond to an important chelating effect. The optimization of Li^+ position in fact gives energy which is considerably lower (48.8 kcal) than the energy of the usual complex in which Li^+ is aligned with the carbonyl group (Fig. 2).



11

FIG. 2. Optimum geometry for Li^+ chelated in α-hydroxy ketone. The standard geometry was assumed for the compound **11** (13).

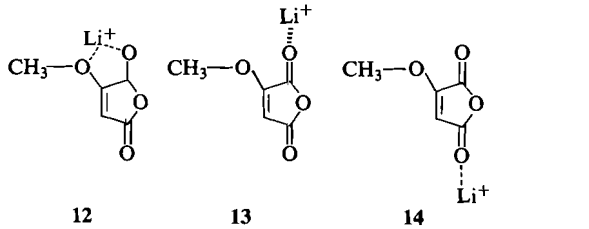
[3]We are neglecting in this discussion the possibility of a cation being associated with a substituent.

[4]Since the order of Li^+ and H^+ affinities for carbonyl functions was found to be similar (18) we have represented a cation by a proton in a study of cationic effects on succinic anhydrides. The optimum geometry for the protonated formaldehyde has been calculated (16). The distance O—H was found to be 0.96 Å and the angle C—O—H^+ 120°. We have used the same geometry for the succinic anhydride – proton complexes.

TABLE 2. Methoxymaleic anhydride: electron density on the carbonyl oxygen atoms and the relative energy of protonated methoxymaleic anhydride

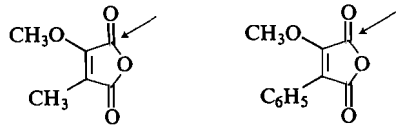
	Density on oxygen atom	π Density on oxygen atom	Relative energy of the protonated molecule, kcal/mol
α Oxgen	8.215	1.186	*anti* Structure **8** 0 *syn* Structure **9** −3.2
β Oxygen	8.232	1.203	Structure **10** −11.8

Using optimized binding distances we have calculated the energy of the methoxymaleic anhydride – Li^+ chelate **12**. The chelated structure **12** was compared with the alternative isomeric forms **13** and **14**. It was gratifying to see that in contrast with



12 $E = -10$ **13** $E = 0$ **14** $E = -4 \rightarrow$ (kcal/mol)

the proton, Li^+ cation does prefer to complex the α-carbonyl group when there is a possibility of simultaneous binding with the substituent. Since the cation activates the carbonyl function to which it is attached toward the nucleophilic addition, the regioselective reduction of the α-carbonyl group in methoxy and chloromaleic anhydrides is principally due to the chelating effect. It is worthwhile to note that 1-methoxy-2-methylmaleic anhydride **15** and 1-methoxy-1-phenylmaleic anhydride **16** are

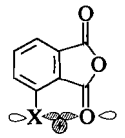


15 **16**

specifically reduced by $LiAlH_4$ at the carbonyl group neighbouring the methoxy substituent (3*d*). Consequently, electronic influences of alkyl and aryl groups apparent in monosubstituted methyl and phenylmaleic anhydrides, are unable to reverse directional effects resulting from the formation of chelates.

The cation binding the "bridged" position should also determine regioselectivity of nucleophilic addition in phthalic anhydrides substituted with lone pairs-bearing groups (CH_3O, Cl, F). The geometry of the molecule is particularly suitable for the formation of six centre chelates, **17**. Such an arrangement corresponds to the strong overlap between the cation and the lone pairs on the oxygen and the substituent atoms. This prediction is in agreement with the experimental results.

In 3-methylphthalic anhydride **6***a* the chelating effect is absent. Moreover, the LUMO coefficients on the carbon atoms of the two carbonyl groups are nearly identical (α:β = 0.329:0.328), therefore we should expect no selectivity. This prediction is confirmed experimentally as the ratio of the two lactones obtained is found to be 53:47.



17

Conclusion

In this study we have demonstrated that in order to predict regioselectivity of nucleophilic addition to the unsymmetrically substituted cyclic anhydrides the following factors must be taken into consideration: (*1*) intrinsic reactivity of the two carbonyl functions represented by the size of the LUMO coefficient, (*2*) direction of the nucleophilic approach, (*3*) the preferred binding sites for the cation, as the energy-favoured formation of chelates may override any effects due to the intrinsic reactivities of the carbonyl groups involved.

We believe that the chelating effect (*3*), where applicable, is a determining factor controlling regioselectivities of metal hydride reductions. When chelation cannot occur other influences become more evident. Here, we should point out that the intrinsic reactivities of the two carbonyl functions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

represented by the sizes of the LUMO coefficients (*1*) may be modified, i.e., amplified or diminished by the effects whose relative importance is difficult to estimate: for example, the direction of nucleophilic attack (*2*) which itself is dependent on the geometry of the substrate molecule and the coordination of the carbonyl function with a cation or a protic solvent.

Reçu le 13 février 1981

ALAIN BOTREL et PAUL CAILLET. Can. J. Chem. **59**, 2463 (1981).

Les spectres de vibration du biphényldicarboximide-2,2' ont été déterminés et ont permis le calcul d'un champ de forces de valence. Les ordres de liaison issus de ce calcul ont été confrontés à l'analyse de population et aux énergies électroniques bicentriques déterminées par l'intermédiaire d'un calcul CNDO/2, permettant ainsi une double approche de la délocalisation électronique sur la molécule de biphényldicarboximide-2,2'.

ALAIN BOTREL and PAUL CAILLET. Can. J. Chem. **59**, 2463 (1981).

Vibrational spectra for 2,2'-diphenyldicarboximide have been determined and allow for a valence force field calculation. Bond orders obtained in this way have been compared with a population analysis and to the bicentric electronic energies determined by a CNDO/2 calculation, thus providing a twofold approach to the electron delocalization in 2,2'-diphehyldicarboxamide.

[Journal translation]

Introduction

La molécule du biphényldicarboximide-2,2' (ou B.P.I.) a déjà fait l'objet d'une étude expérimentale et théorique (1). Les calculs, effectués dans le cadre de la méthode EHT, avaient permis de proposer une structure pour ce composé en procédant, en particulier, à une étude systématique du cycle imidique grâce à un calcul de minimisation de tensions associé aux résultats énergétiques fournis par la méthode EHT.

Plus récemment, Caillet et Le Marouille (2) ont déterminé la structure de la molécule de B.P.I. à l'état solide.

La géométrie issue des calculs et la géométrie expérimentale diffèrent principalement par la position relative des deux cycles benzéniques, qui avaient été choisis coplanaires dans le premier cas, alors qu'ils sont caractérisés par une torsion d'environ 30° autour de la liaison C(1)—C(7) (cf. Fig. 1).

Il nous a alors paru intéressant de reprendre les calculs théoriques sur la molécule non substituée en utilisant, cette fois, la géométrie expérimentale, afin de pouvoir, en particulier, comparer les résultats obtenus pour l'analyse de population avec les ordres de liaison calculés selon la formule de Siebert (3) après le calcul d'un champ de forces de valence effectué à partir des spectres de vibration.

Après la partie expérimentale, nous discuterons brièvement de l'analyse vibrationnelle puis les résultats du calcul du champ de force seront confrontés aux conclusions de l'étude théorique pour permettre la discussion des liaisons chimiques.

Partie expérimentale et méthodologie

Le B.P.I. monodeutérié $(C_6H_4CO)_2ND$ est préparé par recristallisation du composé hydrogéné dans de l'alcool éthylique C_2H_5OD à 95% dans D_2O. Après 5 recristallisations, le spectre de masse montre que le composé est monodeutérié à plus de 95%.

Les spectres d'absorption infrarouge, entre 4000 et 200 cm^{-1}, ont été réalisés au Laboratoire de Chimie Minérale B de l'Université de Rennes sur un spectrophotomètre Beckmann IR 12. Le solide est finement broyé puis mis en suspension dans le Nujol entre deux lames d'iodure de césium.

Les spectres de diffusion Raman, entre 4000 et 10 cm^{-1}, ont été effectués au Laboratoire de Spectroscopie Infrarouge de l'Université de Bordeaux I sur un spectrophotomètre Coderg T800.

Quel que soit l'appareil utilisé, la précision est de ± 1 cm^{-1} sur les bandes les plus fines.

Les calculs ont été effectués au C.I.C.B. de Rennes, à l'aide des programmes de l'Université de Bordeaux I pour la partie vibrationnelle, et suivant la méthode CNDO/2 (4) pour la partie théorique.

Nous nous sommes plus spécialement intéressés dans le cadre de cette dernière à l'analyse de population entre les atomes et pour ce faire nous avons déterminé l'indice de liaison[1]:

$$[1] \quad p_{AB} = \sum_{\mu}^{A} \sum_{\nu}^{B} \rho_{\mu\nu} S_{\mu\nu}$$

TABLEAU 1. Paramètres géométriques de la molécule de B.P.I.

Liaison	Distances (Å)	Angles de liaisons	Degrés	Angles de torsion	Degrés
C—C (benzénique)	1,395	C—C—C (cycle benzénique)	120,0	Entre les deux cycles benzèniques	30,0
C(1)—C(7)	1,487	C(6)—C(1)—C(7)	124,5	C(15)—C(13)—C(6)—C(1)	−42,078
C(6)—C(13)	1,494	C(1)—C(6)—C(13)	127,0		
C(13)—N(15)	1,382	C(6)—C(13)—N(15)	121,0		
C(13)—CO(16)	1,223	C(13)—N(15)—C(14)	129,64		

où $\rho_{\mu\nu}$ et $S_{\mu\nu}$ représentent respectivement un élément de la matrice densité et une intégrale de recouvrement; l'indice de liaison calculé selon Wiberg (5)

$$[2] \quad p_{AB}{}^{W} = \sum_{\mu}^{A} \sum_{\nu}^{B} \rho_{\mu\nu}{}^{2}$$

et l'énergie électronique bicentrique E_{AB} que l'on peut décomposer en trois parties (6):

$$[3] \quad E_{AB} = E_{AB}{}^{(1)} + E_{AB}{}^{(2)} + E_{AB}{}^{(3)}$$

avec

$$[4]^{2} \quad E_{AB}{}^{(1)} = 2 \sum_{\mu}^{A} \sum_{\nu}^{B} \rho_{\mu\nu} S_{\mu\nu} \beta_{AB}{}^{0}$$

$$[5]^{2} \quad E_{AB}{}^{(2)} = -\frac{1}{2} \sum_{\mu}^{A} \sum_{\nu}^{B} \rho_{\mu\nu}{}^{2} \gamma_{AB}$$

$$[6] \quad E_{AB}{}^{(3)} = q_{A} q_{B} \gamma_{AB} + Z_{A} Z_{B} \left(\frac{1}{R_{AB}} - \gamma_{AB} \right)$$

Géométrie et notation

Nous avons, tout en conservant les caractéristiques géométriques principales de l'analyse cristalline, effectué tous les calculs sur une molécule admettant un axe de symétrie C_2 (cf. Fig. 1). Nous avons, en particulier, utilisé pour les cycles benzéniques une géométrie régulière (distances C—C de 1,395 Å et angles de liaison de 120°).

Les principaux paramètres géométriques ainsi adoptés sont réunis dans le tableau 1 (cf. Fig. 1 pour la numérotation).

Dans le but d'obtenir une meilleure comparaison des résultats, tous les calculs ont été effectués en considérant une molécule isolée possèdant la géométrie indiquée dans le tableau 1; celle-ci n'a donc pas été optimisée dans le calcul CNDO/2.

Etude vibrationnelle

Interprétation des spectres et détermination du champ de force

Une molécule isolée de B.P.I. de symétrie C_2 possède 72 vibrations (36A + 36B), toutes actives en infrarouge et en Raman. A l'état solide, la molécule est placée dans un site de symétrie C_1 et la présence de deux molécules dans la maille primitive amène, dans le groupe facteur C_{2h}, à la représentation $\Gamma = 78\,Ag + 78\,Bg + 77\,Au + 76\,Bu$. En réalité, même à l'état solide, la molécule est très voisine de la symétrie C_2 (2), l'effet du "champ cristallin" consistera donc essentiellement en l'éclatement de chaque vibration de type A (ou B) en deux composantes Ag et Au (ou Bg et Bu) l'une active en Raman et l'autre en infrarouge.

Les fréquences observées ainsi que les attributions sont données dans le tableau 2. Ces dernières tiennent compte des intensités relatives des bandes ir et des raies Raman et sont effectuées par comparaison avec les résultats que nous avons obtenus pour le maléimide (7) et le benzène (8), ainsi qu'avec les résultats de Zerbi et Sandroni concernant le biphényle (9). Les vibrations qui font intervenir les cycles benzéniques sont désignées suivant la numérotation classique (8, 10).

Précisons que les fréquences à 1362 et 1361 cm^{-1} pour le dérivé hydrogéne sont attribuées à la fois à νCN et δNH, tandis que δND apparait dans le composé deutérié à 1031 cm^{-1}.

Les coordonnées utilisées sont les coordonnées internes "de groupe" déjà précisées lors de précédents calculs (7, 8). Le champ de force de départ a été construit à partir des valeurs obtenues pour le mésitylène (11) pour les cycles aromatiques, et de celles du maléimide (7) pour la fonction imide; il comprenait, en outre, toutes les constantes d'interaction entre des coordonnées possèdant au moins 1 atome commun. Un premier calcul montre qu'un certain nombre de ces dernières sont pratiquement sans influence sur les valeurs des fréquences calculées, elles ont été fixées à zéro pour la suite. Le champ de force utilisé comporte finalement 21 constantes de forces principales et 69 d'interactions, 45 d'entre elles sont transférées du mésitylène, 39 du maléimide, les 6 dernières sont des interactions qui sont nouvelles.

Dès le premier calcul, les fréquences attribuées aux cycles benzéniques sont toutes voisines des valeurs observées et, en l'absence de dérivés isotopiques sur les cycles benzèniques, nous n'avons pas cherché à améliorer cet accord et avons conservé dans la suite du calcul les valeurs des 52 constantes de forces correspondantes.

Par contre, il apparaît que les fréquences calculées pour δNH et γNH sont trop basses et que les fréquences attribuées au cycle imidique sont mal ajustées par suite de la différence de géométrie, sensible surtout au niveau des angles, entre le maléimide et le B.P.I. Nous avons donc augmenté

[2] γ_{AB} et $\beta_{AB}{}^{0}$ sont l'intégrale coulombienne bicentrique et le paramètre de liaison habituels de la méthode CNDO/2 (4).

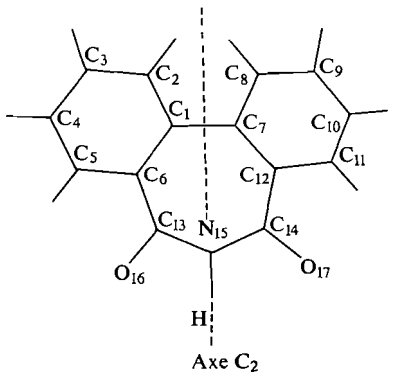

FIG. 1. Numérotation utilisée pour la molécule de B.P.I.

les valeurs des constantes de force δNH et γNH et modifié les valeurs de celles relatives aux angles intérieurs du cycle. En ce qui concerne les fréquences νCN, c'est à la fois ν_aCN et ν_sCN qui sont mal ajustées et la simple modification de la constante de force principale ne permettrait, au mieux, que d'ajuster l'une d'entre elles. Nous avons donc modifié les constantes d'interaction, entre νCN, νCO et νCC en particulier, pour obtenir à la fois un meilleur accord de fréquence et des effets isotopiques corrects. Au total 6 constantes de forces principales et 14 interactions ont été modifiées dans cette étape du calcul.

Pour conclure, nous avons soumis les 38 constantes de force non fixées à un affinement qui n'a pratiquement pas modifié les valeurs précédemment obtenues, l'écart absolu moyen entre fréquences calculées et observées est inférieur à 6 cm^{-1}. Les valeurs des constantes de force les plus significatives sont données dans le tableau 3.

Modes de vibrations

La distribution de l'énergie potentielle (tableau 2) et l'analyse de la matrice L des vecteurs propres montrent que les attributions qui ont été faites par comparaison des spectres ne sont qu'une grossière approximation. En effet, en ce qui concerne les cycles benzéniques, les vibrations 8a et 8b donnent ensemble les quatre modes situés vers 1600 cm^{-1}, de même 5 et 17b conduisent, également ensemble, aux quatre modes situés entre 950 et 1000 cm^{-1}. Les modes faisant intervenir le groupement imide résultent également de couplages, et on observe même de nombreux modes dans lesquels interviennent à la fois les cycles benzéniques et le groupement imide; c'est le cas, par exemple, des vibrations "νCO", ou encore de celles situées à 1247, 1200, 1150 ou encore 616 cm^{-1}. Enfin, du fait des torsions entre les cycles, on observe également des modes dans lesquels interviennent à la fois des torsions ou des mouvements "hors du plan" (γCH,γCO) et des mouvements "dans le plan" en particulier pour les modes situés aux basses fréquences.

En conclusion, on peut dire qu'à l'exception des modes situés au-dessus de 2000 cm^{-1} et qui sont bien décrits par les mouvements νCH et νNH tous les autres modes de vibration sont complexes et font intervenir de nombreuses coordonnées.

Liaisons chimiques: résultats et discussion

Les constantes de forces caractéristiques du B.P.I. sont données dans le tableau 3, où elles sont comparées aux valeurs obtenues pour le triméthylbenzène (T.M.B.) d'une part, et pour le maléimide d'autre part.[3]

Nous avons regroupé dans le tableau 4 l'ensemble des résultats obtenus (p_{AB}, p_{AB}^{W} et énergies électroniques bicentriques) sur les molécules de B.P.I. et de maléimide en CNDO/2, ainsi que les ordres de liaison déterminés à partir du champ de forces (p_{AB}^{S}) par la formule de Siebert (3).

Enfin, nous donnons dans le tableau 5 les valeurs des charges nettes CNDO des atomes principaux de la molécule de B.P.I.

Précisons que la valeur calculée du moment dipolaire de la molécule de B.P.I. (3,38 D) est en bon accord avec la valeur expérimentale 3,34 D (1).

Comparaison "Théorie–Expériences"

Les comparaisons entre ordres de liaisons calculés à partir des constantes de forces d'une part, et les résultats CNDO/2 d'autre part sont illustrés par des corrélations du type:

$$p_{AB}^{S} = aX_{AB}^{CNDO} + b$$

où X_{AB}^{CNDO} représente les indices ou les énergies électroniques fournis par la méthode CNDO sur la molécule de B.P.I.

Les valeurs des constantes a, b et du coefficient de régression linéaire r, déterminées par une méthode de moindres carrés, sont regroupés dans le tableau 6.

Précisons que les calculs du tableau 6 ont été effectués en prenant pour les liaisons C—C des cycles benzéniques des valeurs moyennes (déterminées à partir des résultats du tableau 4) des X_{AB}^{CNDO}.

Les résultats de l'analyse expérimentale (p_{AB}^{S}) et de l'analyse théorique (p_{AB}, p_{AB}^{W} et E_{AB}^{T}) sont dans l'ensemble cohérents.

Toutefois, les valeurs relativement médiocres obtenues pour les coefficients r des deux premières

[3]Le tableau complet des constantes de forces utilisées peut être demandé à P. Caillet.

corrélations (0,919 et 0,901) sont dues, de façon générale, au petit nombre de points utilisés (6 compte tenu des valeurs moyennées pour les liaisons C—C des cycles benzéniques) et à leur dispersion insuffisante. Elles proviennent également: (*1*) pour la corrélation $p_{AB}^S - p_{AB}$ des valeurs certainement trop faibles obtenues pour le p_{AB} des liaisons C—O et C—N (inférieures au p_{AB} moyen d'une liaison C—C benzénique). L'indice p_{AB}, qui peut être considéré comme étant une mesure de la force d'une liaison covalente (12), ne semble pas donner une bonne image de la liaison quand celle-ci est assez fortement polarisée (cas de CO et CN; voir tableau 5) et présente donc un caractère ionique non négligeable; et (*2*) pour la corrélation $p_{AB}^S - p_{AB}^W$: d'une part, de l'inversion observée pour les indices p_{AB}^W des liaisons C(1)—C(7) et C(6)—C(13) par rapport aux valeurs correspondantes des p_{AB}^S, inversion dont il est difficile, cependant, de tenir compte de façon sérieuse compte tenu des valeurs très voisines des indices; d'autre part, des valeurs relatives des indices p_{AB}^W et p_{AB}^S de la liaison C(13)—O(16), le premier mettant en évidence un caractère marqué de double-liaison, le second, caractérisant (en accord avec l'indice p_{AB}^S de la liaison C(13)—N(15)) une délocalisation sensiblement plus importante sur l'ensemble du groupement imidique.

La troisième corrélation (indice p_{AB}^S – énergie électronique bicentrique E_{AB}^T) apparaît ici comme la plus représentative de la comparaison expérience–théorie, sans doute parce que l'énergie E_{AB}^T rend compte pour une grande part de toutes les caractéristiques d'une liaison donnée (cf. les expressions [3] à [6]); cette analyse se trouve confirmée par l'étude des corrélations entre l'indice p_{AB}^S et les différents termes de l'énergie E_{AB}^T (cf. tableau 6): si l'énergie $E_{AB}^{(1)}$, ou terme d'énergie covalente, apparaît la mieux corrélée à p_{AB}^S, il est clair que les énergies $E_{AB}^{(2)}$ (terme d'échange) et $E_{AB}^{(3)}$ (terme d'interaction électrostatique) apportent une contribution non négligeable à l'énergie électronique bicentrique totale.

Conjugaison et délocalisation

Signalons tout d'abord que, dans le cas des cycles benzéniques, les valeurs moyennes $\bar{E}_{AB}^T$ et

$\bar{p}_{AB}^{W}$ par exemple sont très proches de celles obtenues dans le cas de la molécule de benzéne isolée (−37,4 eV pour −37,9 eV et 1,42 pour 1,45).

De façon plus générale, les valeurs obtenues pour p_{AB}^{W}, E_{AB}^{T}, p_{AB}^{S} et pour les constantes de forces d'interaction montrent que la molécule de B.P.I. peut se décomposer en trois fragments principaux si on considère la délocalisation électronique: chacun des deux cycles benzéniques et le groupement imidique. On constate, en effet, une très sensible diminution des différents indices et une nette déstabilisation des énergies électroniques bicentriques pour les liaisons C(1)—C(7), C(6)—C(13) et C(12)—C(14).

Ceci rappelle des résultats que nous avions déjà obtenus dans le cas du maléimide pour lequel on constatait (cf. tableaux 3 et 4 et Fig. 2) une coupure très semblable au niveau des atomes C(2) et C(3) (ou C(4) et C(5)), bien que la molécule plane du maléimide ne présentât pas les torsions observées dans le B.P.I.

En ce qui concerne le groupement imidique les valeurs de p_{AB}^{W}, E_{AB}^{T} et p_{AB}^{S} obtenues pour le maléimide et le B.P.I. sont très proches, ou même identiques, et ne permettent que difficilement une comparaison des délocalisations sur la chaîne O—C—N—C—O. Par contre, la comparaison des constantes de forces d'interactions montre que la délocalisation électronique est plus élevée pour le B.P.I. puisque la constante νCN, νCN passe de

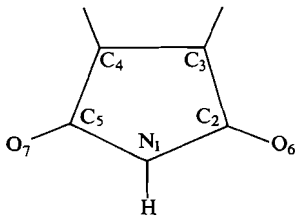

FIG. 2. Numérotation utilisée pour la molécule de maléimide.

0,314 pour le maléimide à 0,904 pour le B.P.I.; cette dernière valeur est même supérieure à celle observée au niveau du cycle benzénique (0,848). Les valeurs élevées trouvées pour les autres interactions (cf. tableau 3) confirment les conjugaisons des différentes liaisons de la fonction imide.

Enfin, les valeurs trouvées pour la liaison C(1)—C(7) montrent que cette liaison est proche d'une simple liaison C—C et constitue une coupure à la délocalisation électronique entre les deux cycles. Ce résultat, qui est en accord avec les conclusions de Zerbi et Sandroni (9*b*) sur le biphényle, et la coupure constituée par les liaisons C(6)—C(13) et C(12)—C(14), ne doivent pas être attribués aux torsions entre les cycles ou entre cycle et groupement imide puisque les mêmes conclusions sont obtenues pour le biphényle (9) et le maléimide (7) qui sont plans.

Conclusion

Nous avons déterminé et interprété les spectres de vibration du biphényldicarboximide-2,2'. La détermination d'un champ de force de valence, jointe aux résultats d'un calcul théorique par la méthode CNDO/2, permet la discussion des liaisons de cette molécule. Nous montrons qu'il existe trois fragments pour lesquels la délocalisation électronique est très élevée ce sont: les deux cycles benzéniques et le groupement imide. Chacun de ces groupements est bien isolé des autres par de simples liaisons C—C qui constituent autant de coupures des conjugaisons.

ERWIN BUNCEL, ROBERT Y. MOIR, ALBERT R. NORRIS, and ALAIN-PIERRE CHATROUSSE. Can. J. Chem. **59**, 2470 (1981).

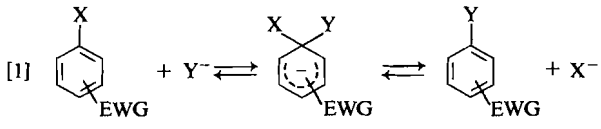
Reaction of 1,3,5-trinitrobenzene with potassium 2,4,6-trimethylphenoxide in dimethyl sulfoxide solution leads to σ-complex formation concurrently with displacement of a nitro group. The results provide definitive evidence for σ-complex formation via the oxygen of aryloxide ion in this system, and contrast with the situation that obtains with phenoxide ion itself, which under corresponding conditions yields the carbon-bonded σ-complex as the product of thermodynamic control. Stereoelectronic factors in σ-complex formation and in the diaryl ether resulting from nitro displacement are also discussed.

ERWIN BUNCEL, ROBERT Y. MOIR, ALBERT R. NORRIS et ALAIN-PIERRE CHATROUSSE. Can. J. Chem. **59**, 2470 (1981).

La réaction du trinitro-1,3,5 benzène avec le triméthyl-2,4,6 phénolate de potassium, en solution dans le diméthylsulfoxyde, conduit à la formation de complexes σ en même temps qu'au déplacement du groupe nitro. Les résultats confirment définitivement la formation des complexes σ par l'intermédiaire de l'oxygène de l'ion arylate de ce système et ils sont contraires à ceux obtenus avec l'ion phénolate lui-même, qui dans les mêmes conditions conduit à un complexe σ lié par le carbone en tant que produit de contrôle thermodynamique. On discute également des facteurs stéréoélectroniques lors de la formation des complexes σ et de l'éther diarylique provenant du déplacement du groupe nitro.

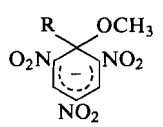
[Traduit par le journal]

Investigation of the anionic covalent adducts (Meisenheimer or σ-complexes) resulting from nucleophilic attack on aromatic systems has been of considerable interest recently (1–7). Such a process is shown in eq. [1] with EWG representing two or more electron withdrawing groups, e.g. NO_2, CN etc., as a general condition for the adduct **2** to be a spectrally detectable species. In cases where X is a displaceable group, these adducts are believed to be formed as reaction intermediates in the overall nucleophilic aromatic substitution (SNAr) process (8–10).

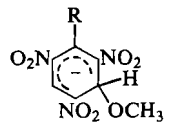


1 **2** **3**

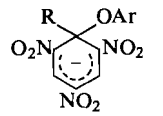
The σ-complexes **4** and **5** formed from the reaction of methoxide ion with 1,3,5-trinitrobenzene (TNB) and 2,4,6-trinitroanisole (TNA), respectively, have been formulated structurally since ca. 1900 (11) while **6** was detected by nmr in 1965 as the kinetically preferred species (12). Many other σ-complexes of these types have been characterized in recent years (1–7, 13).



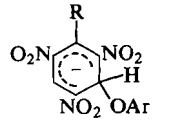
4 (R = H)
5 (R = OCH_3)



6 (R = OCH_3)



7 (R = H)
8 (R = OCH_3)



9 (R = OCH_3)

Surprisingly, though, aryloxide σ-complexes have received attention only relatively recently and have been the subject of considerable controversy. In fact, a stable aryloxide σ-complex of the type **7–9**, corresponding to **4–6**, has not yet been observed, though such species have been reported to be formed as transient intermediates.

The reason for this anomaly is that phenoxide ion can act in an ambident manner, either as an oxygen or as a carbon nucleophile, as shown in Scheme 1 (14, 15). It is also apparent from Scheme 1 that whereas oxygen attack will occur reversibly, carbon attack can become effectively irreversible on loss of a proton from the initially formed adduct **11**. Thus, whereas **7** may be formed initially as the

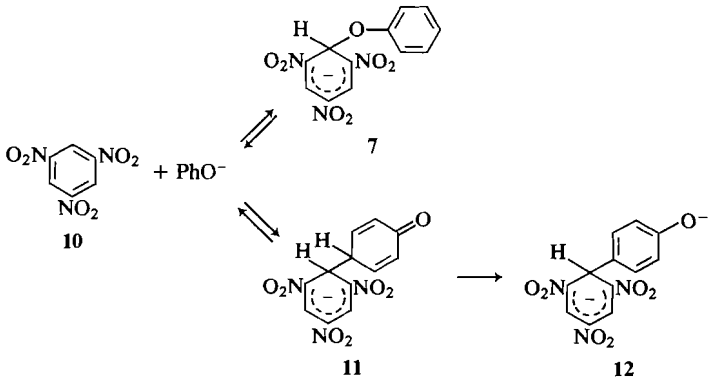
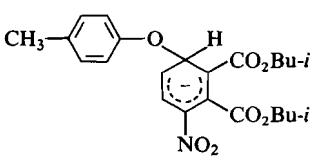


SCHEME 1

product of kinetic control, **12** will be obtained eventually as the product of thermodynamic control.

Shein and Byval'kevich (16) had initially reported that only the oxygen-bonded species **7** is formed in the reaction between TNB and phenoxide ion in dimethyl sulfoxide (DMSO), while Buncel *et al.* (15) observed only the carbon-bonded adduct **12** under apparently similar conditions. However, in DMSO–methanol (80:20 vol/vol) solution, it was found that the TNB–OMe^- σ-complex **4** was formed first as the kinetically preferred species and was followed by the formation of the carbon-bonded adduct **12** as the eventual reaction product (15). Subsequently, Shein *et al.* (17) reported also the obtention of **12** but claimed that **7** was formed as a transient species, observable through its transient nmr spectrum. Sterba and co-workers (18) investigated the reaction of TNB with 2-naphthoxide ion and reported results analogous to those observed by Buncel *et al.* (15). However, in this system (18), a 2:1 ArO^-–TNB carbon-bonded adduct, as well as the 1:1 adduct, was obtained. Bernasconi and Muller (19), using fast reaction techniques, observed the formation of **8** (rather than **7**) as the initially formed species in the interaction of phenoxide ion with TNA but did not examine the products at long reaction times. Relles *et al.* (20) proposed the formation of the oxygen-bonded adduct **13** in the interaction of 4-methylphenoxide ion with diisobutyl 3-nitrophthalate. Interestingly, they suggested that **13** could lose an electron by reaction with diisobutyl 3-nitrophthalate to yield the corresponding radical and the radical anion.



13

In view of the variance in these results and the hypotheses regarding aryloxide σ-complexes, it was desirable to investigate a system which would lead definitively to the formation of an oxygen-bonded aryloxide σ-complex and that such species should preferably be characterized by nmr. The present work was undertaken with that end in view, and while this objective could not be reached totally, this work has contributed to it in large measure. Our choice of 2,4,6-trimethylphenoxide ion was based on the assumption that this would react only as an oxygen nucleophile towards TNB (1–5).

Results and Discussion

The Reaction Pathways

The reaction of TNB (0.40 *M*) with potassium 2,4,6-trimethylphenoxide (**14**, 0.35 *M*) in DMSO solution at room temperature was followed by nuclear magnetic resonance and uv–visible absorption spectroscopy. An nmr spectrum of the dark red solution 2 min after mixing of the reagents showed the absence of the absorptions due to TNB (δ 9.20) or **14** (δ 6.38 (H-3,5), 1.97 (4-CH_3), 1.85 (2,6-$(CH_3)_2$)) but exhibited instead resonances at 8.48 (t, J = 2 Hz), 8.35 (d, J = 1 Hz), 7.88 (d, J = 2 Hz), 7.06 (s), 6.67 (s), 6.20 (t, J = 1 Hz), 2.31 (s), 2.10 (s), and 2.06 (s). On further scanning of the solution at ambient temperature, the signals at δ 8.35, 6.67, 6.20, and 2.10 decreased in intensity while those at δ 8.48, 7.88, 7.06, and 2.31 increased relative to the common signal at δ 2.06. After 48 h only the second set remained.

The uv–visible spectrum of the reaction solution 2 min after preparation was taken on appropriate dilution and showed absorptions at 432 and 500 nm, with a ratio of the absorbance values at λ_{max} being 1.5:1. On further sampling and scanning of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

For personal use only.

solution at various intervals these absorptions steadily decreased in intensity, becoming negligibly small after 48 h. Acidification of the solution at any given time led to the destruction of the 432/500 nm absorptions.

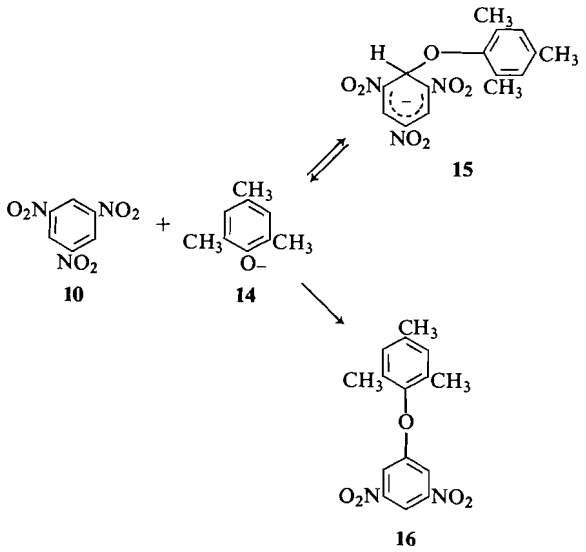
The electronic absorption spectra of σ-complexes have been found to be characteristic of their structures (1–7). Thus the TNB–OMe^- σ-complex **4** in DMSO solution exhibits absorption maxima at 428 and 505 nm, the molar extinction coefficients at λ_{max} being in the ratio 1.5:1 (1–4). The oxygen-bonded TNA–phenoxide σ-complex **8** has been reported to have an electronic absorption spectrum very similar to that of the corresponding TNA–methoxide complex **5** (19). On the other hand, the carbon-bonded TNB–phenoxide complex **12** exhibits absorption maxima at 468 and 570 nm (15). Moreover, the spectral absorption due to this σ-complex is found to be stable in dilute acid media (15), whereas oxygen-bonded σ-complexes such as **4** do not survive acidification. These results concerning the uv–visible spectral characteristics of σ-complexes provide strong evidence that the interaction between TNB and **14** leads to the formation of the oxygen-bonded σ-complex **15**.

The proton nmr spectra also agreed fully with the initial formation and slow decomposition of the σ-complex **15**, represented by signals at δ 8.35, 6.67, 6.20, 2.10, and 2.06. Comparison with the TNB–OMe^- σ-complex **4**, for which the signals due to the aromatic protons occur at δ 8.48 while the sp^3 proton resonance is found at δ 6.17, reveals a close similarity between the two sets of data. On this basis, it is concluded that the δ 8.35 and 6.20 signals arising in the interaction of TNB with **14** are assignable, respectively, to the aromatic protons and the sp^3 proton of the σ-complex **15**.

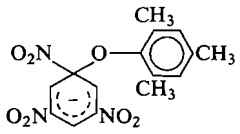
The nmr signals which are observed to be increasing with time can be attributed to the diaryl ether **16**. Thus work-up of the reaction mixture, when there were no longer any changes observed in the nmr spectra, yielded a pale yellow solid with characteristics completely in accord with the structure **16** (δ 8.48, 7.88, 7.06, 2.31, and 2.06).

Our observations are in accord with the reaction pathways indicated in Scheme 2. Thus interaction of TNB with **14** acting as an oxygen nucleophile can occur by two concurrent pathways: reversible formation of σ-complex **15** through nucleophilic addition at an unsubstituted carbon, and substitution of NO_2 to yield the diphenyl ether **16** in an irreversible SNAr process. Displacement of NO_2 in SNAr processes has been observed previously (8, 21*a*).

It is interesting to note that there was no evidence in the nmr spectra for the formation of the σ-complex **17**, the intermediate in displacement of NO_2^- from TNB. Such species can hence be present in only very small concentration.



SCHEME 2



Stereoelectronic Factors in σ-Complex and Aryl Ether Formation

Complementary evidence concerning the structure of **15** was obtained from detailed analysis of its nmr spectrum in comparison with related σ-complexes (14, 15, 21). This study also brought to light a most interesting contrast between the principal conformation of **15** and the related diaryl ether **16**, especially in the light of previous studies of conformations of diphenyl ethers (22–24).

The nmr parameters of **15** and **16** are given below, and those of the TNB–OMe^- σ-complex **2** and 2,4,6-trimethylphenol, **18**, are shown for comparison. A striking feature of these parameters is that in **15** the chemical shifts of the protons in the 2,4,6-trinitrohexadienate moiety are changed only slightly with respect to σ-complex **2**, while those of the 2,4,6-trimethylphenoxy moiety resemble the phenol **18**. On the other hand, in the diphenyl ether **16**, the chemical shifts of protons in the 2,4,6-trimethylphenoxy moiety differ appreciably from **18**.

Two possible conformational structures of **15** are given below; namely **15***a* which can be termed a "butterfly" conformation, and **15***b* which is termed

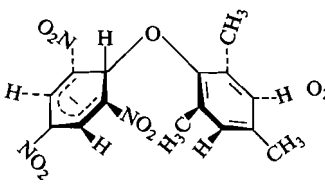
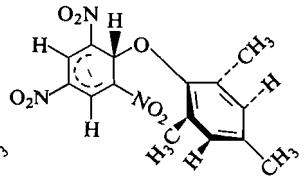
18

the "NO_2 inside" conformation. A structure corresponding to **15***b* (not shown) would be the "CH_3 inside" conformation. The latter is disregarded since models show that this conformation would entail severe steric interaction between the "inside methyl" and the cyclohexadienate aromatic ring, which would not be relieved by even large oscillations of the rings. The "butterfly" conformation **15***a* is also considered improbable owing to the large interactions between the *ortho* methyl and nitro groups of the two rings.



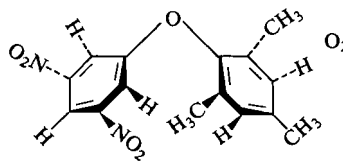
15*a* ("butterfly")



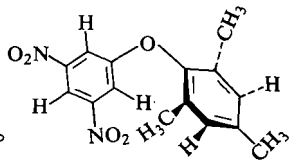
15*b* ("NO_2 inside")

Since the "butterfly" and the "CH_3 inside" conformations have been shown to be improbable, this would leave the "NO_2 inside" conformation **15***b* as the most likely candidate. This conformation allows large oscillations about the aromatic rings, making it both energetically and entropically favorable. The 2(6)-CH_3 groups in such a conformation would be expected to be shielded by the ring current of the cyclohexadienate moiety, as the results indicate, but this effect would be opposed by its electron withdrawing effect (14, 25). The resultant of these two effects is not readily predictable and further progress must await the preparation of other phenoxy complexes.

Considering next the diphenyl ether **16**, analogous reasoning shows that this could exist in the "butterfly" conformation **16***a*, the "H-inside" conformation **16***b*, as well as a "CH_3 inside" conformation (not shown). The latter is expected to be sterically much less favored in comparison with **16***b*. The "butterfly" conformation, though less crowded than **15***a*, is nevertheless considered unlikely by analogy with numerous diphenyl ethers which have been found *not* to exist in such a conformation (22–24). A possible factor contributing to this result is that the butterfly conformation does not permit overlap between the *p* orbital on the ether oxygen and either of the aromatic ring π systems.



16*a* ("butterfly")



16*b* ("H inside")

Good overlap between the oxygen *p* orbitals and the aromatic π system occurs in the "H-inside" conformation **16***b*. However, optimum overlap need not occur at the exact rotational position represented by the "pure" conformation, in which the left hand ring is coplanar with the oxygen bonds and the right hand ring is perpendicular to them. In agreement with this, large angular distortions have frequently been observed in the crystal structures of diphenyl ethers (26).

Other major factors are also operative in compound **16**. Interaction between the *ortho* methyls and *ortho* hydrogens would be minimized by large (45°) *concerted* rotations of both rings away from the pure conformation **16***b*. However, this optimum rotation is much reduced by the interaction between the *ortho* methyls and the neighbouring vertices and edges of the other ring.[2] Confirmation of the existence of this distortion is most clearly shown by the observed shielding of the *ortho* methyl protons. Calculations show that in the pure conformation **16***b* the ring current of the left hand ring has little effect upon the methyls; concerted rotation of both rings leads to shielding (as observed) while antisymmetrical rotations lead to deshielding.

Our conclusions are strongly supported by comparison of the chemical shift of the *ortho* hydrogens in **16** with the corresponding value for 3,5-dinitroanisole (δ $H_{2,6}$ 8.14, H_4 8.43). As expected for the H-inside conformation, the *ortho* hydrogens in **16** are notably shielded, but calculation again shows the presence of considerable concerted rotation from "pure" **16***b*.

The method of calculation is an extension of that

[2]Diagrams summarizing the van der Waals interactions of various *ortho* substituents for a large number of rotational positions are given in ref. 27.

used previously (23). A description, together with tabulated data obtained from the present system, is available as Supplementary Material.[3]

Experimental

Potassium 2,4,6-trimethylphenoxide (**14**) was prepared from the phenol **18** (Aldrich, recrystallized twice from petroleum ether, mp 72°C) by a procedure based on the method given by Kornblum and Laurie (28). The treatment of a methanolic solution of **18** with KOH in MeOH–H_2O (85 : 15 v/v) and removal of solvent under *vacuum* yielded a violet liquid. Repeated extraction of this liquid with petroleum ether yielded as residue an off-pink powdery material which was dried *in vacuo* to yield a faint brown solid. This substance was kept under nitrogen and handled in the dry-box. Nuclear magnetic resonance (DMSO-d_6, relative to tetramethylsilane): δ 6.38 (2H, s), 1.97 (3H, s), 1.85 (6H, s).

The course of the reaction between TNB (0.40 *M*) and **14** (0.35 *M*) in DMSO-d_6 solution was followed at ambient temperature on a Varian EM 360 nmr spectrometer, spectra being taken at various intervals of time. For observation of the electronic absorption spectrum, 20 μL aliquots of the reaction solution were withdrawn periodically, diluted to 10 mL with DMSO, and the spectrum recorded in a 1 mm cell on a Unicam SP800B spectrophotometer. The uv–visible spectrum was recorded again following acidification with 2 μL of trifluoroacetic acid. A small but constant residual absorption in the visible region was noted for all the acidified solutions, presumably as a result of formation of a minor side product. At the completion of the reaction, when there were no further changes seen in the nmr spectra, the DMSO was removed under vacuum and the dark solid residue was extracted with ether. Evaporation of the ether and recrystallization from methanol yielded a yellow crystalline material, mp 128–130°C. After several more recrystallizations the pale yellow solid had mp 131.0°C; nmr (DMSO-d_6, Brucker 60 MHz HFX-60) δ: 8.48 (1H, t, J = 2.0 Hz), 7.88 (2H, d, J = 2.0 Hz), 7.06 (2H, s), 2.31 (3H, s), 2.06 (6H, s). *Anal.* calcd. for $C_{15}H_{14}N_2O_5$: C 59.60, H 4.64, N 9.27%; found: C 59.78, H 4.72, N 9.21%.

The nmr spectrum of 3,5-dinitroanisole, previously reported for dioxane as solvent (29), was recorded in DMSO-d_6, δ: 8.43 (1H, t, J = 2.0 Hz), 8.14 (2H, d, J = 2.0 Hz), 3.33 (3H, s).

Effect of bis(acetylacetonato) copper(II) catalyst on the reaction of benzoylphenyldiazomethane with primary amines. A novel example of insertion of benzoylphenylcarbene into N—H bonds of amines

S. B. SINGH AND K. N. MEHROTRA

Department of Chemistry, Banaras Hindu University, Varanasi-221005, India

Received December 29, 1980

S. B. SINGH and K. N. MEHROTRA. Can. J. Chem. **59**, 2475 (1981).

Bis(acetylacetonato) copper(II) catalysed thermal decomposition of benzoylphenyldiazomethane (**1**) leads to the insertion of benzoylphenylcarbene into the N—H bond of amines; the insertion products undergo facile air oxidation giving rise to ketoimines. The uncatalysed thermal decomposition of benzoylphenyldiazomethane yields the corresponding diphenylacetamide derivatives of amines.

S. B. SINGH et K. N. MEHROTRA. Can. J. Chem. **59**, 2475 (1981).

La décomposition thermique du benzoyldiphénylméthane (**1**) catalysée par le bis(acétylacétonato) cuivre II conduit à l'insertion du benzoylphenylcarbène dans la liaison N—H des amines; le produit d'insertion s'oxyde facilement à l'air en cétoimines. La décomposition thermique non catalysée du benzoylphényldiazométhane conduit aux dérivés diphénylacétamide des amines correspondantes.

The thermal decomposition of benzoylphenyldiazomethane in the presence of substituted anilines yields diphenylacetamides and 1,2-diphenyl-2(arylamino)ethanones (1). Wolff rearrangement of α-diazoketones has been prevented in the presence of copper powder (2), cupric chloride (3), or bis(acetylacetonato) copper (II) (4). Modified carbenes, having enhanced electrophilic character, are produced in the decomposition of diazocompounds catalysed by copper or its salts (5). Similar reaction of diaryldiazomethanes in the presence of 1,1-diphenylmethyleneimine has been shown to lead to an unusual insertion of diarylcarbenes into the N—H bond of imine (6). We now report the thermal decomposition of benzoylphenyldiazomethane (**1**) in the presence of amines **2***a–c* which produces *N*-substituted diphenylacetamides **4***a–c* in excellent yields. The bis(acetylacetonato) copper(II) (**3**) catalysed thermal decomposition of **1** in the presence of amines **2***a–c* may lead to the insertion of benzoylphenylcarbene into the N—H bond of the amines **2***a–c*. Subsequent air oxidation of the insertion products yields ketoimines.

Results and Discussion

The reaction between benzoylphenyldiazomethane (**1**) and benzhydrylamine (**2***a*) afforded a white crystalline solid, identified as *N*-benzhydryldiphenylacetamide (**4***a*) by the analytical and spectral (ir, uv, and nmr) data. Similar treatment of **1** with amines **2***b*, *c* gave *N*-substituted diphenylacetamides **4***b*, *c* characterized on the basis of the analytical and spectral data (Tables 1 and 2). The product **4***b* has been identified as *N*-(α-phenylethyl)diphenylacetamide.

The reaction mixture obtained with benzhydrylamine (**2***a*) from the bis(acetylacetonato) copper (II) (**3**) catalysed decomposition of **1** was separated by elution chromatography and crystallisation from ethanol to give a yellow solid characterized as benzilmonobenzhydrylimine (**5***a*) by analytical and spectral data (Tables 3 and 4). Similar treatment with amines **2***b*, *c* gave benzilmonoimines **5***b*, *c* characterized by analytical and spectral data (Tables 3 and 4). Authentic samples of ketoimines **5***a–c* were prepared according to the reported methods (7, 8) and were identical to the products (ir, nmr, and mmp). The product **5***b* has been identified as benzilmono-α-phenylethylimine.

Since the amine **2***b* is racemic, the products derived from it, **4***b* and **5***b*, are also racemic. The probable reaction sequence for the formation of *N*-substituted diphenylacetamides (**4***a–c*) and benzilmonoimines (**5***a–c*) can be shown in Scheme 1.

The thermal decomposition of benzoylphenyldiazomethane (**1**) may lead to the formation of benzoylphenylcarbene, which on Wolff rearrangement may give diphenylketene (9). The reaction of diphenylketene with amines **2***a–c* leads to the formation of *N*-substituted diphenylacetamides **4***a–c*. The catalysed thermal decomposition of **1** may lead to the formation of a complex of benzoylphenyldiazomethane (**1**) and bis(acetylacetonato) copper (**3**) which on elimination of nitrogen may give rise to carbene complex. Similar complexes of bis(acetylacetonato) copper(II) with benzoyldiazo-

methane (4) or diphenyldiazomethane (5) leading to the formation of esters and cyclopropane derivatives, respectively, have been proposed earlier. The benzoylphenylcarbene, from the carbene complex, may insert into N—H bonds of amines **2***a–c* to form ketoamines **6***a–c* which on facile air oxidation during purification (column chromatography or crystallization) may lead to the benzilmonoimines **5***a–c*. Absence of products **4***a–c* in the catalysed decomposition of **1** in the presence of **3** indicates that the carbene complex does not form diphenylketene.

Experimental

Melting points were determined on a Büchi apparatus (capillary method) and have been uncorrected. Ultraviolet spectra were obtained in 95% ethanol on a Cary-14 spectrophotometer. Infrared spectra were recorded in Nujol mull on a Perkin-Elmer 720 spectrophotometer. Proton nuclear magnetic resonance

data were obtained on a Varian A-60D spectrometer in CCl_4 or $CDCl_3$ using TMS as an internal standard.

Materials

Benzophenone and aniline were obtained from BDH India, benzil and bis(acetylacetonato) copper(II) from EGA Chemicals, West Germany, and benzoylphenyldiazomethane (10), benzhydrylamine (11), and (±) α-phenylethylamine (12) were prepared according to the reported methods.

General Procedure for Preparation of N-*Substituted Diphenylacetamides* 4a–c

A mixture containing benzoylphenyldiazomethane (0.01 mol) and amine (0.01 mol) in 80 mL of dry benzene (thiophene free), in a 250 mL three-necked round bottom flask equipped with condenser and a mercury trap, was heated under reflux for 6 h under a nitrogen atmosphere. The reaction mixture was kept overnight at room temperature. The solvent was removed on a rotatory evaporator and the residual material was triturated with ethanol. The solid obtained was crystallized from ethanol to afford the products. The analytical results are given in Table 1 and the spectral data of the products in Table 2.

General Procedure for Bis(acetylacetonato) Copper(II) (3) Catalysed Thermal Decomposition of Benzoylphenyldiazomethane (1) in Presence of Amines 2a–c

To a suspension containing 2 mmol of bis(acetylacetonato) copper(II) in 30 mL of dry benzene (thiophene free) heated under reflux with stirring, a solution containing benzoylphenyldiazomethane (10 mmol) and amine (10 mmol) in 80 mL of dry benzene (thiophene free) was slowly added over 3 h from a pressure-equalizing funnel under a nitrogen atmosphere. The contents were heated under reflux for 5 h and kept overnight at room temperature. The reaction mixture was passed through a neutral alumina (10 g, 1.2 × 10 cm) column and the products were eluted with benzene to remove the copper salt. The solvent was removed on a rotatory evaporator and the residual material was triturated with ethanol.

The solid obtained was crystallized from ethanol to afford the products. The analytical results are given in Table 3 and spectral data of the products in Table 4. The authentic samples of **5***a*–*c* were prepared for comparison (mixture melting point, ir, and nmr spectra) by the condensation of benzil and appropriate amine according to the reported methods (7, 8).

The total synthesis of (±)-N_α-methyl-N_β-acetylphlegmarine

ANDRZEJ LENIEWSKI,[1] JERZY SZYCHOWSKI,[1] AND DAVID B. MACLEAN
Department of Chemistry, McMaster University, Hamilton, Ont., Canada, L8S 4M1

Received February 23, 1981

ANDRZEJ LENIEWSKI, JERZY SZYCHOWSKI, and DAVID B. MACLEAN. Can. J. Chem. **59**, 2479 (1981).

(±)-N_α-Methyl-N_β-acetylphlegmarine has been synthesized in a manner that defines the relative configuration at four of the five chiral centres of the molecule. Five isomers of the title compound have also been prepared and characterized.

ANDRZEJ LENIEWSKI, JERZY SZYCHOWSKI et DAVID B. MACLEAN. Can. J. Chem. **59**, 2479 (1981).

On a synthétisé la (±)-N_α-méthyl-N_β acétylphlégmarine selon une méthode qui permet de définir la configuration relative de quatre des cinq centres chiraux de la molécule. On a également synthétisé et caractérisé cinq isomères du composé mentionné dans le titre.

The phlegmarines **1** are a group of Lycopodium alkaloids that were described by Nyembo *et al.* (1) in 1978. The basic carbon skeleton of phlegmarine itself and its *N*-substituted derivatives was established by spectroscopic studies. A synthesis of a mixture of stereoisomers of the naturally occurring bases was also achieved and the spectroscopic properties of the natural and synthetic materials compared. These studies, particularly the mass spectrometric work, left no doubt that the natural and synthetic materials had the same carbon skeleton but they shed no light on the stereochemistry of the phlegmarines. Here we report a synthesis of N_α-methylphlegmarine and its N_β-acetyl derivative that has defined the stereochemistry of four of the five chiral centres in the molecule.

When we began this synthesis we set out to prepare a phlegmarine with the relative stereochemistry shown in Scheme 1. This arrangement was chosen for two reasons. Firstly, the configuration shown at C-5, C-7, and C-10 is the same as that found in the majority of Lycopodium alkaloids (2, 3) at corresponding centres. One would expect the same relative configuration if the phlegmarines are biosynthetic intermediates on the pathway to other alkaloids as suggested by Nyembo *et al.* (1). Secondly there is a close structural and seemingly biosynthetic relationship between the phlegmarines **1** and luciduline **2** (4) and the recently described lycolucine **3** (5). Both **1** and **2** may be derived from a common biosynthetic precursor such as **4** or the corresponding amino acid as already suggested (1). Luciduline contains all the carbon atoms of **4** and its formation from **4** is easily envisaged and has been effected chemically (6). The phlegmarines in turn have been postulated (1) to arise by combination of piperideine **5** and the

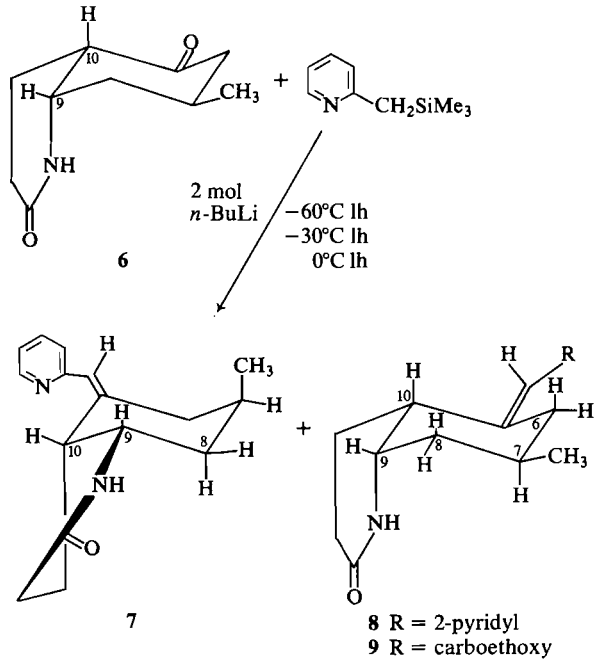

SCHEME 2

amino acid related to **4**, accompanied by loss of CO_2. Examination of the structure of lycolucine **3** shows that it contains within its structure both a phlegmarine unit and a unit related to **4** minus CO_2 (**1** and **4** may be combined in two different ways). Alternatively, **3** may be considered to be derived from two units of **4** minus two moles of CO_2 and one unit of **5** as pointed out by Ayer *et al.* (5). It seemed reasonable therefore that phlegmarine would have incorported into its structure the stereochemical features present in the related systems shown in Scheme 1. We made no attempt, however, to predict the stereochemistry at C-2′. We therefore set about to synthesize the phlegmarines in a manner that would define the stereochemistry in the tetrahydroquinoline portion of the molecule. As it turned out, our predicted configuration was not correct.

The approach used to prepare the phlegmarine skeleton (Scheme 2) was similar to that used in the early stages of the synthesis of luciduline (6). Lactam **6** (prepared as before (6)) was treated in the presence of a strong base with 2-trimethylsilylmethylpyridine, prepared, with some modifications, according to the procedure of Musker and Scholl (7). Two products were isolated from this reaction that are assigned structures **7** and **8** on the basis of spectroscopic examination. As in the previous study on luciduline (6), the signal at H-9 proved to be the key to the assignment of the conformation of the hydroquinoline ring system. Not only is this signal normally well separated from others but it also sharpens on D_2O exchange because of removal of NH coupling. In isomer **7**, the major component of the reaction, the signal at H-9 appears (after D_2O exchange) at 3.60 δ as a quintet (from superposition of a doublet of triplets) and this is compatible with the conformation shown for **7**. Another lower field signal at 4.14 δ also appears as a near quintet, also from superposition of a doublet of triplets, and has been assigned to H-10. By decoupling experiments it was shown that these two protons are coupled, $J = 6$ Hz. Both H-9 and H-10 must be coupled to two other protons with coupling constants of ca. 6 Hz each and to one other proton with coupling constants of 12 Hz and 10 Hz, respectively. In the case of H-9 the 6 Hz couplings are to H-10 and H-8e and the 12 Hz coupling to H-8a, while for H-10 the 6 Hz couplings are to H-9 and H-4e and the 10 Hz coupling to H-4a. The low field position of H-10 is compatible with the *Z* configuration about the bond bearing the pyridyl group. H-10 is allylic to the double bond and is also deshielded by the pyridine ring in the conformation shown.

Isomer **8**, the minor component of the reaction (ratio **7** to **8** = 4:1), shows a pattern for H-9 similar to that of ketolactam **6**. The signal at H-9 appears at 3.83 δ as a near quartet from superposition of a doublet of triplets, $J = 4.5$, 4.5, and 6 Hz. A signal at 2.83 δ has been assigned to H-6e which shows one large and one small coupling, $J_{6e,7a} = 4$ and $J_{6e,6a} = 14$ Hz. This behaviour is very similar to that of **9** which was the main product of reaction of $(Me_3SiCHCO_2Et)^-Li^+$ with **6** as discussed in a previous paper (6). For similar reasons we assign **8** the *E* configuration about the double bond and the conformation shown.

The hydrogenation of **7** was brought about with H_2 over Adams' catalyst. This reaction was highly stereoselective giving a single product, assigned structure **10**, in which the methyl and the pyridylmethyl groups occupy equatorial positions on the carbocyclic ring. The *E* isomer **8** on similar treatment yielded a mixture of two isomers, the minor component was identical with **10** on tlc while the major component was assigned structure **11**. (The ratio **10**:**11** = 1:4.) The configurational assignments to **10** and **11** are based upon ^1H nmr examination of the two isomers and in particular on the signals associated with H-9 and the *C*-methyl group. In **10** the signal for H-9 appears as a near quartet at 3.71 δ with couplings of ca. 3 Hz with each of H-10, H-8a, and H-8e. The *C*-methyl signal of **10** appears at 0.83 δ. On the other hand the signal of H-9 in **11** appears at 3.55 δ as a broad multiplet

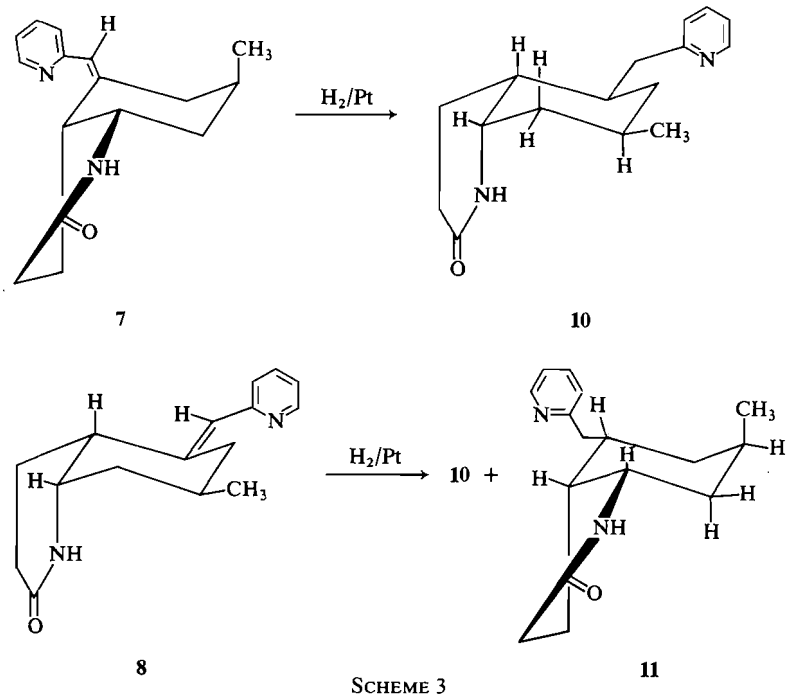

SCHEME 3

overlapping with another signal, probably that of H-11. The *C*-methyl group of **11** appears at 0.96 ppm considerably shifted from that of **10**, reflecting its axial character. Compound **11** was, however, not obtained free of its isomer **10** and the spectral data cited are extracted from the spectrum of the mixture (see Scheme 3).

Compound **10** was converted next to the quaternary salt, **12**. The ^{1}H nmr examination of **12** revealed that there was no change in conformation on quaternization.

The pyridine ring of **12** was now reduced (H_2/Pt) yielding a substance that appeared from its behaviour to be a single component but which on the basis of its subsequent reaction must have been a mixture of epimers at C-2′. In any event the reaction product was treated with lithium aluminum hydride to reduce the lactam function. The product derived from this reaction showed no amide absorption in the infrared and showed two spots on tlc. An nmr examination of the reaction mixture showed two *N*-methyl signals of almost equal intensity indicating for the first time that both epimers at C-2′ had formed in the catalytic reduction. Hydride reduction would not be expected to bring about isomerization at any centre in the transformation of the amide to the secondary amine. The two components of the mixture were separated by column chromatography on alumina yielding **14***a* and **14***b* but there was no way to differentiate between the two although they did show slightly different ^{1}H nmr spectra.

In the final stage of this synthesis both **14***a* and **14***b* were converted separately to their acetyl derivatives, **15***a* and **15***b*, respectively, by treatment with acetyl chloride – pyridine. The ^{1}H nmr spectra of both isomers showed very broad signals for the protons adjacent to the acylated nitrogen atom, which are attributed to the presence of two rotamers caused by restricted rotation about the amide linkage. The presence of rotamers was confirmed by a variable temperature study. At −61°C it was possible to observe signals for both rotamers but unfortunately the solubility at this temperature was low and the resolution poor. However there were two N—$COCH_3$ signals differing by 0.03 to 0.06 ppm, and two *N*-methyl signals differing by ca. 0.10 ppm and two pairs of multiplets associated with the protons vicinal to the *N*-acetyl group differing by 0.9 to 0.8 ppm. The situation was the same for both **15***a* and **15***b* and consequently there was no basis to differentiate between them in a stereochemical sense. The *C*-methyl absorption at 1.05 δ and 1.06 δ in **15***a* and **15***b*, respectively, suggests that on *N*-acylation the conformations of the molecules change (the *C*-methyl in both **14***a* and **14***b* appears at 0.85). Similar conformational changes were observed on *N*-methylation in the luciduline synthesis (6). This change would now place the *C*-methyl and the

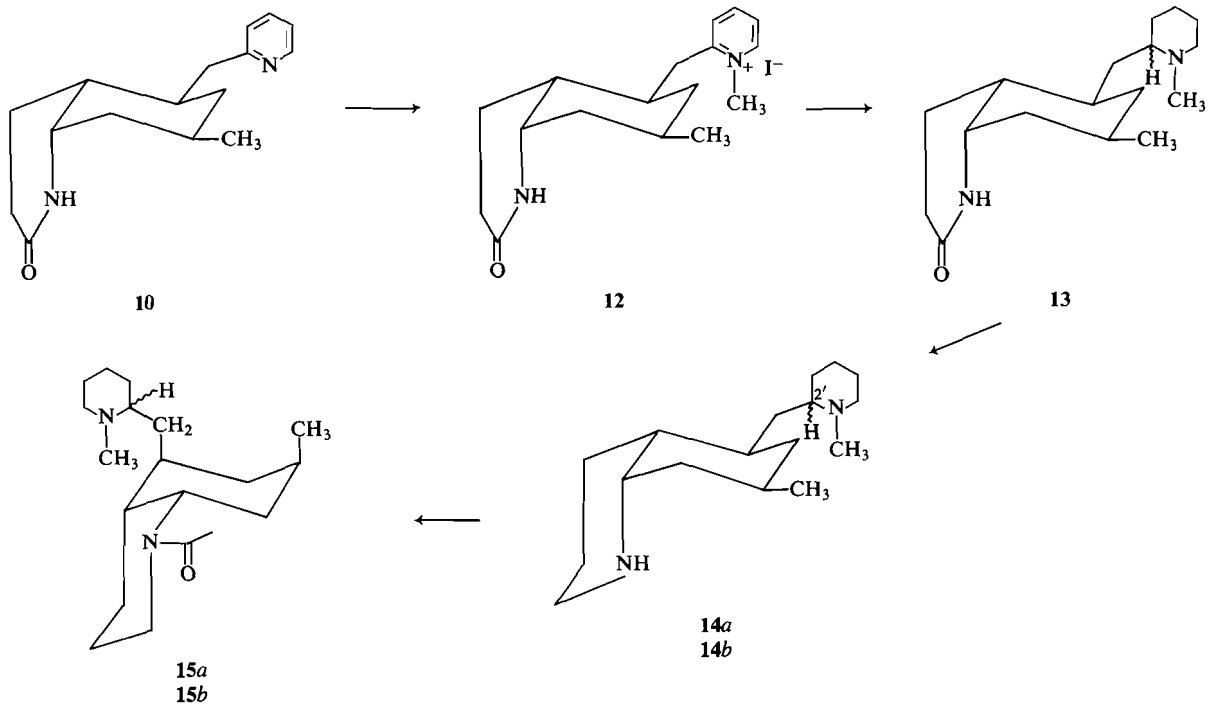


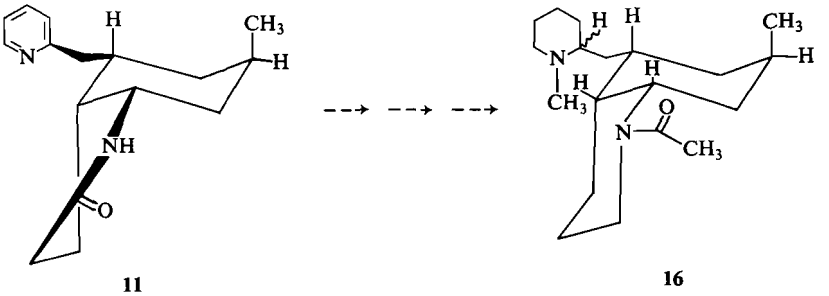
SCHEME 4

piperidyl groups in an axial orientation as shown but the steric crowding of the *N*-acetyl group that would exist in a conformation similar to **14***a* and **14***b* is relieved (see Scheme 4).

When the ^{1}H nmr spectra of **15***a* and **15***b* were compared with the reported ^{1}H nmr spectrum of the compound derived from nature there were distinct differences (1). Thus neither **15***a* nor **15***b* represents the stereochemistry of N_β-acetyl-N_α-methylphlegmarine.

The conversion of **11** to compounds of structure **16** (Scheme 5) was not pursued. It has been shown that the methyl group of **11** must be in the axial orientation because of the conformation of the molecule. In **16** this conformation would be even more favoured because of the acetyl group on nitrogen. In the light of previous results discussed in this paper the CHCH_3 resonance in **16** in the conformation shown would be predicted to be considerably greater than 0.90 δ, the value recorded for N_β-acetyl-N_α-methylphelgmarine (1). Therefore it seemed pointless to pursue further studies in the *cis*-series. Accordingly we turned our attention to the preparation of compounds with a *trans* ring fusion.

The most likely alternative configuration of the phlegmarines has the epimeric configuration at C-9. Their synthesis would require as starting material *trans*-ketolactam **17**, a compound reported to form along with isomer **6** (6) but in low yield and difficult to separate from the *cis* compound. We therefore investigated other routes to its preparation based upon reduction of **18**, a compound that is available in high yield by treatment of 2-(2-cyanoethyl)-5-



SCHEME 5

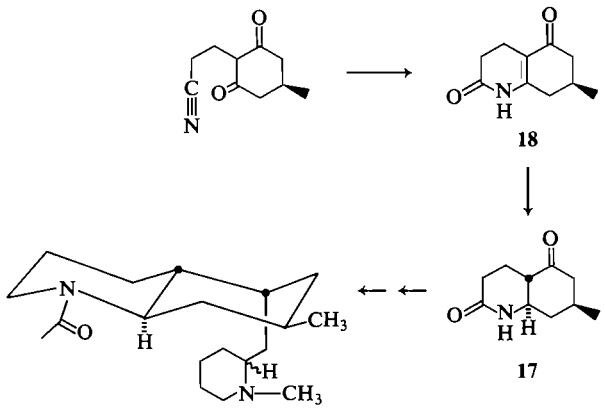


SCHEME 6

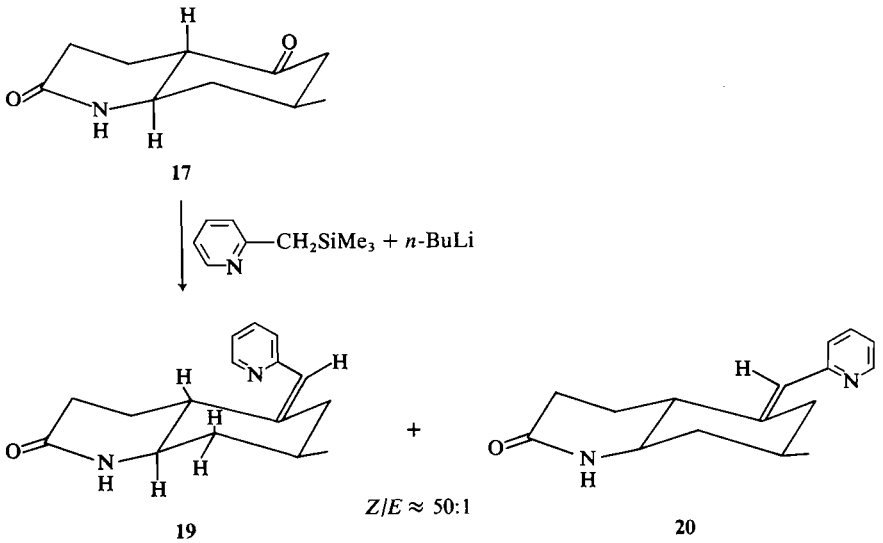
methyl-1,3-cyclohexanedione with 50% acetic acid according to the general method described by Vill *et al.* (8). A number of reducing agents were therefore investigated to effect the conversion of **18** to **17**. Among the reagents investigated were the following: $NaCNBH_3$, $TiCl_3/H_2O$ (9), Zn/AcOH, Mg/MeOH (10), $NaBH_4$/EtOH, H_2/Pd, and Li/NH_3. Only the last three showed promise and the results are reported in the Experimental. The most effective proved to be treatment with Li in liquid ammonia, a reaction that proceeded in 30% yield. The reaction is instantaneous and on work-up gave **17** but none of its isomer **6** nor starting material **18**. The bulk of the product was comprised of highly polar substances from which **17** was easily separated by crystallization from methanol or water (see Scheme 6).

The *trans*-ketolactam **17** was now subjected to the same series of reactions as its isomer **6**. Reaction with 2-trimethylsilylmethylpyridine in the presence of *n*-butyllithium gave compounds **19** and **20** in a ratio of ca. 50:1. Molecular models show that there is strong interaction between the pyridyl substituent and the lactam ring in the case of the *Z* isomer, **19**. This is reflected in the ultraviolet spectrum of **19** in which the absorption maxima are shifted to shorter wavelengths and the extinction coefficients are smaller that those observed for **20** (see Scheme 7).

In the ^1H nmr spectrum of **19** the signal at H-9 is observed at 3.30 δ as a triplet split into doublets (J = 13 and 3 Hz) corresponding to the pattern observed for H-9 in **17** (6). In the spectrum of **20** there is a two-proton multiplet in the 3.4 δ region probably formed by the overlap of signals from H-9 and H-6e.

Hydrogenation of **19** over Pt was not selective. It gave, besides some starting material, the isomers **21** and **22** in nearly equal amount (*vide infra*) and also products formed by partial reduction of the pyridine ring. To ensure that **19** was completely consumed (it was difficult to separate from the reduction products) the reaction was allowed to continue until a 10–15% excess of H_2 was consumed. We were unable to separate the epimers **21** and **22** by tlc or by column chromatography. However their *N*-oxides, **23** and **24**, formed by oxidation with *m*-chloroperbenzoic acid, were separable on an alumina column. The faster moving epimer has the pyridylmethyl group at C-5 in the equatorial position (see Scheme 8).

The configuration at C-5 was resolved by examination of the 360 MHz ^1H nmr spectra of **23** and **24**. In the case of **23** the chemical shift of every proton



SCHEME 7

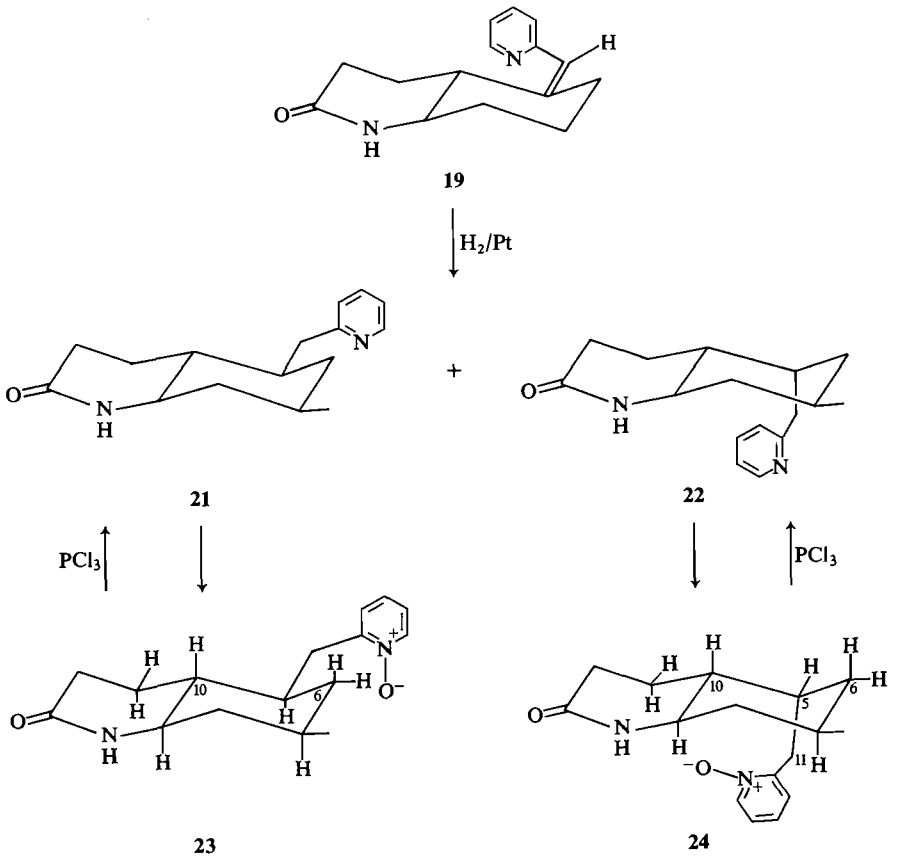


SCHEME 8

and nearly all coupling constants with adjacent protons could be assigned. In the case of **24**, however, the signals of four protons overlapped in a complex multiplet but the rest were clearly differentiated. In both cases the assignments were made by double irradiation using the signals for H-9 and the $CHCH_3$ group as points of reference. The signals at H-10 and H-6a provide the clue to the configuration at C-5. Thus in **24**, H-10 appears at 1.63 δ as a triplet split into triplets (i.e. flanked by two axial and two equatorial hydrogens) and in **23** this signal appears at 1.18 δ as a quartet split into doublets (i.e. flanked by three axial hydrogens and one equatorial hydrogen). Thus in **24** the substituent at C-5 is axial, in **23** it is equatorial.

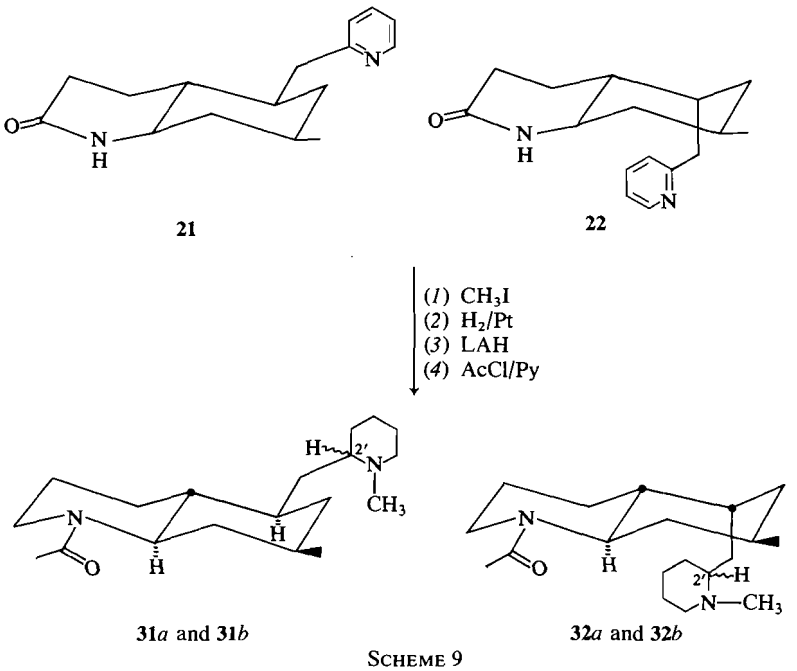
A high field signal at 0.79 δ in **23**, a quartet, showing three identical coupling constants, J = 10 Hz, has been assigned to H-6a. The same proton in **24** appears at 1.12 δ as an almost regular triplet split into doublets showing two large couplings (J_1 = 13.8 and J_2 = 13.0 Hz) and one small coupling (4.5 Hz). The 13.8 Hz coupling is attributed to geminal coupling to H-6e, the 13.0 Hz coupling to vicinal coupling to H-7a. The small coupling to H-5e indicates that the pyridylmethyl group is axial in **24**.

The presence of a doublet split into doublets at 3.53 δ in the spectrum of **23** has been assigned to one of the "benzylic" protons at C-11. This signal is part of an AMX spin system involving H-11′, H-11″, and H-5a appearing at 3.53, 2.53, and 1.96 ppm, respectively. These observations imply that substitution at the nitrogen atom of the pyridine ring strongly restricts rotation of the pyridylmethyl substituent about the C-5—C-11 bond. Similar behaviour is observed in the case of **24** and in the methiodides, **25** and **26** (*vide infra*).

These stereochemical assignments at C-5 were confirmed by examination of the ^{13}C nmr spectra of **23** and **24**. In **24**, with an axial group at C-5, the signals at C-7, C-9, and C-11 should be shielded by 4–7 ppm relative to the same signals in **23** (12). The actual shieldings observed were −4.4, −5.0, and −6.5 ppm for C-7, C-9, and C-11, respectively. The pyridines **21** and **22** derived from the *N*-oxides through treatment with PCl_3 showed almost identical behaviour in their ^{13}C spectra.

The pure pyridines **21** and **22** were transformed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.



SCHEME 9

into their methiodides **25** and **26**, respectively, whose spectra are in accord with the assigned structures. Reduction of the methiodides (H_2/Pt) gave mixtures of piperidines **27** and **28**, epimeric at C-2′, but we were unable to effect their separation. The mixtures were therefore reduced with lithium aluminum hydride to mixtures of diamines, **29***a*, and **29***b* and **30***a* and **30***b*, and again separation was not effected. The mixtures were therefore acylated with acetyl chloride in pyridine to mixtures of *N*-acyl compounds, **31***a* and **31***b* and **32***a* and **32***b*. Each pair of epimers was separable by chromatography over basic alumina (activity 3) yielding four pure isomers as colorless oils. Isomer **32***b*, the more polar of the pair with the axial group at C-5, proved to be identical in its tlc behaviour in several solvent systems with a sample supplied to us by J.-C. Braekman. Unfortunately we did not have sufficient amounts of the natural material to make direct spectroscopic comparison with our synthetic material. It is of interest that the four *N*-acyl compounds give distinct spots on tlc and that **31***a* and **31***b* have higher R_f values than **32***a* and **32***b* (see Scheme 9). The four compounds all gave distinct ^{13}C nmr spectra which will be discussed in a forthcoming publication.

In summary this work has resulted in a total synthesis of N_α-acetylphlegmarine and has established the relative configuration of four of its five chiral centres. As it stands the synthesis suffers from a lack of stereoselectivity in the reduction of **19** but studies to improve this aspect of the work will be undertaken.

Experimental

Apparatus, Methods, and Materials

The infrared spectra were determined on a Perkin Elmer 383 spectrophotometer in chloroform solution. The nmr spectra were run at 90 MHz on a Varian EM 390 spectrometer or Bruker WP80 or Bruker WH 90 spectrometer. The 360 MHz proton spectra were recorded at the University of Toronto through the courtesy of Dr. A. A.Grey. Chemical shifts are reported in ppm (δ) from tetramethylsilane unless otherwise specified. The symbols s (singlet), d (doublet), t (triplet), q (quartet), and m (multiplet) are used to report the multiplicity of signals. Coupling constants are accurate within ± 0.5 Hz. Mass spectra were recorded on a CEC 21-110B mass spectrometer at an ionizing voltage of 80 eV and a source temperature of 150–200°C or on a VG 7070F mass spectrometer under similar source conditions and are reported as *m/e* values with relative intensities in brackets. High resolution measurements were performed by the method already described (11). Natural abundance ^{13}C nuclear magnetic resonance spectra were recorded on a Bruker WP80 Fourier transform spectrometer at 20.115 MHz and a probe temperature of +35.0°C. Samples were 0.08–0.15 *M* in $CDCl_3$; TMS was used as an internal reference.

Melting points and boiling points are uncorrected.

The purity of all samples was checked by thin-layer chromatography in several solvent systems. Silica gel 60F-254 (Merck) was used for tlc and for column chromatography. Aluminum oxide GF-254 (type 60/E, Merck) was used for tlc and Fischer neutral and basic alumina for column chromatography.

2-Trimethylsilylmethylpyridine

The compound was prepared using the method of Musker and Scholl (7) with some modifications. *n*-Butyllithium (80 mL, 2.47 *M* in hexane, ca. 0.2 mol) was added with stirring to solution of α-picoline (0.2 mol) in ether (250 mL) at −40 to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

−30°C, under an argon atmosphere. The reaction mixture was stirred for 0.5 h and then allowed to come slowly to room temperature (some orange precipitate appeared). The solution was cooled to −30°C and trimethylchlorosilane (0.1 mol) was added dropwise. The suspension was allowed to warm to room temperature and stirred for a further 1 h. Water (1.8 g, 0.1 mol) was added and stirring was continued for an additional 0.5 h whereupon the solution was filtered and then distilled through a Vigreux column. 2-Trimethylsilylmethylpyridine (10 g) was obtained as a colorless oil, bp 114–116°C at 67 Torr; yield 60%, based on trimethylchlorosilane. Musker and Scholl (7) report a bp of 113–116°C at 63 Torr, and a yield of 40%. ^{1}H nmr (90 MHz), δ: 0.02 (9H, s, $(CH_3)_3Si$), 2.30 (2H, s, CH_2), and overlapping aromatic protons centred at 6.89 (1H, m, $J_{3,4}$ = 7.7 Hz, $J_{3,5}$ = 1.0 Hz and $J_{3,6}$ = 0.7 Hz, H-3), 6.92 (1H, m, $J_{4,5}$ = 7.6 Hz, $J_{5,6}$ = 4.3 Hz, H-5), 7.43 (1H, m, $J_{4,6}$ = 1.8 Hz, H-4), 8.38 (1H, m, H-6) ppm.

Reaction 2-Trimethylsilylmethylpyridine with Lactam 6

2-Trimethylsilylmethylpyridine (1.32 g, 8 mmol) in THF (25 mL) was treated with 2.47 *M* *n*-butyllithium (3.2 mL, ca. 8 mmol) at −65°C with stirring under an argon atmosphere. The solution was allowed to warm to room temperature and kept there for 0.25 h. It was then cooled to −65°C and lactam **6** (6) (0.652 g, 3.6 mmol) was added. The mixture was maintained at −65°C for 0.5 h, next at 1.0 h at −30°C, and finally at 0°C for an additional hour before treatment with 1 mL of 50% acetic acid. The solution was decanted from a small amount of precipitate and the latter washed with ether (5 mL) and benzene (5 mL). The combined organic phase was evaported and the residue (0.9 g) showed two products as well as starting material on tlc (silica; ether–methanol, 8:1). The products were separated from one another and from starting material by column chromatography on silica (100 g, SiO_2 for tlc; ether–methanol, 8:1). The first compound eluted, **7** (0.35 g, 38%), was followed by starting lactam (0.32 g, with traces of **7**), and this in turn by the second product, **8** (0.09 g, ca. 10%).

Compound **7**, the *Z* isomer, melted at 181–182°C after recrystallization from acetone and had the following properties. Infrared (ir) ν_{max}: 3400 (NH), 1655 (lactam), 1590, 1560 (pyridine) cm^{-1}; ^{1}H nmr (90 MHz), δ: 0.98 (3H, d, J = 7 Hz, CHCH_3), 3.60 (1H, br sextet, changes to sharp quintet after D_2O exchange, superposition of a doublet of triplets, J = 6 and 12 Hz, H-9), 4.14 (1H, near quintet from superposition of two triplets, J = 6 and 10 Hz, H-10), 6.30 (1H, d, J < 1 Hz, =C*H*), 6.65 (1H, br s, disappears on D_2O exchange, NH), 7.10 (2H, m, pyridine protons in β-positions), 7.63 (1H, m, pyridine proton in γ-position), 8.60 (1H, m, pyridine proton in α-position) ppm. *Exact Mass* calcd. for $C_{16}H_{20}N_2O$: 256.157; found (hrms): 256.156.

Compound **8**, the *E* isomer, melted at 211–212°C, with sublimation, after recrystallization from acetone, and had the following properties; ir ν_{max}: 3400 (NH), 1655 (lactam), 1590, 1560 (pyridine) cm^{-1}; ^{1}H nmr (90 MHz), δ: 0.90 (3H, d, J = 6 Hz, CHCH_3), 283 (1H, d of d, J = 4 and 14 Hz, partly superimposed on another proton, probably H-6e), 3.83 (1H, near quartet that is better defined after D_2O exchange, superposition of a doublet of triplets, J = 4.5 and 6 Hz, H-9), 6.53 (1H, s, =C*H*), 6.63 (1H, s, disappears on D_2O exchange, NH), 7.15 (2H, m, pyridine protons in β-positions), 7.66 (1H, m, pyridine proton in γ-position), 8.60 (1H, m, pyridine proton in α-position). *Exact Mass* calcd. for $C_{16}H_{20}N_2O$: 256.157; found (hrms): 256.156.

Hydrogenation of the Z *Isomer, 7*

A solution of **7** (0.3 g) in ethanol (10 mL) and acetic acid (0.5 mL) was treated with hydrogen over Adams' catalyst (60 mg) at atmospheric pressure. The reaction was terminated after 1.1 mole equivalent of hydrogen was consumed (ca. 3 h) whereupon the solution was decanted from the catalyst. The residue remaining after removal of solvent was homogeneous on tlc and melted at 179–181°C, after recrystallization from ether–THF. The product **10**, obtained in greater than 90% yield, had the following physical properties. Infrared ν_{max}: 3400 (NH), 1650 (lactam), 1590, 1570 (pyridine) cm^{-1}; ^{1}H nmr (90 MHz), δ: 0.83 (3H, d, J = 6 Hz, CHCH_3), 3.10 (1H, d of d, J = 4 and 14 Hz, probably H-11), 3.71 (1H, near quartet, J = 3 Hz, H-9), 6.00 (1H, s, disappears on D_2O exchange, NH), 7.16 (2H, m, pyridine protons at the β-positions), 7.66 (1H, m, pyridine proton at the γ-position), 8.56 (1H, m, pyridine proton at the α-position) ppm. *Exact Mass* calcd for $C_{16}H_{22}N_2O$: 258.173; found (hrms): 258.175.

Preparation of Methiodide 12

Compound **10** (0.166 g) was dissolved in acetone (10 mL) and treated with an excess of methyl iodide (0.5 g). The solution was set away and over a period of 72 h at room temperature the product **12** slowly crystallized from solution. The quaternary salt so obtained (0.135 g, 75%) melted at 272–273°C and had the following physical properties. Nuclear magnetic resonance ^{1}H nmr (90 MHz, CD_3OD), δ: 0.85 (3H, d, J = 6 Hz, CHCH_3), 3.60 (1H, d of d, J = 4 and 15 Hz, probably H-11), 3.80 (1H, near quartet, J = 3 Hz, H-9), 4.42 (3H, s, N—CH_3), 7.96 and 8.06 (2H, overlapping multiplets, pyridine protons at the β-positions), 8.50 (1H, m, pyridine proton at γ-position), 8.90 (1H, br d, J = 7 Hz, pyridine proton at α-position) ppm.

Hydrogenation of 12

A solution of **12** (0.2 g, 0.5 mmol) in water (10 mL) was hydrogenated over Adams' catalyst (60 mg) at atmospheric pressure for 6 h during which time 34.6 mL hydrogen (theoretical = 33.6 mL) were consumed. The solution was decanted from the catalyst, the solution made basic with ammonia, and the aqueous solution extracted with chloroform (3 × 5 mL). Evaporation yielded 140 mg (100% yield) of a crystalline solid, **13***a* and **13***b*, that melted at 169–170°C after recrystallization from acetone and had the physical properties listed below. This product gave a single spot on tlc and otherwise appeared to be a single compound. Subsequent reduction of the lactam function (*vide infra*) gave, however, two isomers indicating that this product must have been a mixture.

Infrared ν_{max}: 3400 (NH), 1655 (lactam), 2790 (N—CH_3) cm^{-1}; ^{1}H nmr (90 MHz), δ: 0.90 (3H, d, J = 6 Hz, CHCH_3), 2.24 (3H, s, N—CH_3), 2.80 (1H, br d, J = 14 Hz, probably H-11), 3.70 (1H, br s, $W_{1/2}$ = 7 Hz, probably H-9), 5.77 (1H, br s, disappears after D_2O exchange, NH) ppm. *Exact Mass* calcd. for $C_{17}H_{30}N_2O$: 278.236; found (hrms): 278.236.

*Reduction of 13*a *and 13*b *with Lithium Aluminium Hydride*

The epimeric amides (130 mg) in THF (5 mL) were added to a suspension of lithium aluminum hydride (100 mg) in ether (30 mL) and the mixture boiled for 1.5 h. The excess of LAH was decomposed with wet ether, the ether solution separated from the suspended solid, and the precipitate washed with ether (2 × 5 mL). The combined extract was dried over $MgSO_4$ and evaporated, yielding a colorless oily residue (118 mg, 95% yield). Examination of the residue by tlc on alumina showed two spots and an nmr spectrum of the crude showed two *N*-methyl resonances at 2.29 and 2.27 ppm of almost equal intensity. The two components of the mixture were separated by column chromatography on alumina (15 g, activity 3). Isomer **14***a* (40 mg) was eluted with benzene–chloroform 1:1 and isomer **14***b* (54 mg) with chloroform; both isomers were obtained as oils and had the following physical properties.

Isomer **14***a*: ir ν_{max}: 3150 (br) NH, 2790 (N—CH_3) cm^{-1}; ^{1}H nmr (90 MHz), δ: 0.85 (3H, d, J = 6 Hz, CHCH_3), 2.27 (3H, s, N—CH_3), 2.5–3.2 (4H, m, N—C*H* protons) ppm.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Isomer **14***b*: ir ν_{max}: 3150 br (NH), 2790 (N—CH_3) cm^{-1}; ^1H nmr (90 MHz), δ: 0.85 (3H, d, J = 6 Hz, CHCH_3), 2.29 (3H, s, N—CH_3), 2.5–3.2 (4H, m, N—C*H* protons) ppm.

Acylation of the Isomeric Amines ***14****a and* ***14****b*

The procedure was identical for each isomer and is reported here for amine **14***a* only. Amine **14***a* (30 mg) in pyridine (1 mL) was treated with a few drops of acetyl chloride. The solution was held at room temperature for 0.5 h, then quenched with water (10 mL), and extracted with chloroform (2 × 5 mL). The residue from the chloroform extract was a colorless oil which was purified by filtration through alumina in a chloroform solution. There was obtained 20 mg of **15***a* as a colorless oil with the following properties. Infrared ν_{max}: 2800 (N—CH_3), 1625 (amide) cm^{-1}; ^1H nmr (90 MHz), δ: 1.05 (3H, d, J = 7 Hz, CHCH_3), 2.06 (3H, s, CH_3CO), 2.29 (3H, s, N—CH_3), 2.90 (2H, m, N—C*H* protons from piperidine ring), 3.8–5.0 (3H, very br m, N—C*H* protons adjacent to CH_3(CO)N) ppm. *Exact Mass* calcd. for $C_{19}H_{34}N_2O$: 306.267; found (hrms): 306.265.

Compound **15***b* was also obtained as a colorless oil in comparable yield from **14***b*; ir ν_{max}: 2800 (N—CH_3), 1625 (amide) cm^{-1}; ^1H nmr (90 MHz), δ: 1.06 (3H, d, J = 7 Hz, CHCH_3), 2.07 (3H, s, CH_3CO), 2.29 (3H, s, N—CH_3), 2.90 (2H, m, N—*CH* protons of piperidine ring), 3.6–5.0 (3H, m, protons adjacent to CH_3(CO)N). *Exact Mass* calcd. for $C_{19}H_{34}N_2O$: 306.267; found (hrms): 306.265.

Hydrogenation of the E *Isomer* ***8***

The procedure followed was identical with that used for the *Z* isomer **7** but the reaction was carried out on 53 mg of **8** and 10 mg of PtO_2. The tlc showed a spot of the same R_f as **10**, another new major component, and a trace of starting compound. An nmr spectrum showed that the reduction product was a mixture of **10** and **11** in a ratio of ca. 1:4. The nmr of **11**, extracted from the spectrum of the mixture, was as follows; ^1H nmr (90 MHz), δ: 0.96 (3H, d, J = 7 Hz, CHCH_3), 3.55 (2H, br m, H-9 and probably H-11), 9.3 (1H, br s, disappears on D_2O exchange, NH), 7.2 (2H, m, pyridine protons in β-positions), 7.7 (1H, m, pyridine proton in γ-position), 8.6 (1H, m, pyridine proton in α-position).

5-Keto-7-methyl-1,2,3,4,5,6,7,8-octahydro-2-quinolone ***18***

The ketoenamide was prepared using the method of Vill *et al.* (8). A mixture of 2-(2′-cyanoethyl)-5-methyl-1,3-cyclohexanedione (35.8 g, 0.2 mol) and 50% aqueous acetic acid (2 mL) was heated in a sealed tube for 4 h at 200°C. The yellow solid that separated on cooling was dissolved in boiling chloroform (100 mL) and precipitated by addition of petroleum ether (30–60°C, 450 mL). The product so obtained (a light yellow powder, 34.4 g, 96% yield) melted at 197–199°C. An analytical sample was recrystallized from water (methanol or ethanol) with activated charcoal, colorless crystals, mp 199°C (lit. (8) mp 198–199°C). Infrared ν_{max} ($CHCl_3$): 3400 (NH), 1706 (unsaturated C=O), 1634 (C=O lactam) cm^{-1}; ^1H nmr (90 MHz), δ: 1.12 (3H, d, J = 4.5 Hz), 8.9 (1H, br s, NH), 2.0–3.0 (10H, m) ppm; ms: 179 (M^+, 100), 178 (31), 151 (23), 150 (66), 109 (37), 108 (21), 81 (76), 55 (25), 41 (34%).

Reduction of ***18***

Hydrogenation in the Presence of Palladium on Charcoal

A solution of ketoenamide **18** (145 mg, 0.81 mmol) in ethanol (10 mL) was treated with hydrogen at room temperature and atmospheric pressure over 10% Pd/C (100 mg). The reduction was complete in 2.5 h and the volume of hydrogen consumed was 42.3 mL. The catalyst was filtered off and washed with ethanol. To the oily residue remaining after removal of ethanol, benzene (10 mL) was added and the solution evaporated to dryness yielding a colorless solid (133 mg) which contained four products (tlc on silica, diethyl ether – methanol 3:1 as the solvent system). Three of the products were obtained pure by column chromatography on silica (15 g) using ether–methanol (10:1) as the developing system.

The first compound, assumed to be 7-methyl-3,4,5,6,7,8,9,10-octahydro-2-quinolone (42 mg), melted at 129–130°C; ir ν_{max}: 3385 (NH), 1644 (C=O) cm^{-1}; ^1H nmr, δ: 0.90 (3H, d, J = 6 Hz, CH—CH_3), 3.64 (1H, q, J = 3 Hz, H-9), 6.9 (1H, br s, NH); ms: 167 (M^+, 82), 110 (82), 97 (32), 96 (29), 82 (65), 69 (52), 55 (100%).

The second compound was the *trans*-ketolactam **17** (17 mg, mp 225–227°C with sublimation). It had the same spectral properties (ir, ^1H mnr, ms) as described (6) and the same R_f value on silica when compared with an authentic sample. The third product, *cis*-ketolactam **6** (61 mg), after recrystallization from benzene, had the same spectral and physical properties as described (6). The fourth compound has not been isolated in a pure state.

Sodium Borohydride Reduction

A solution of ketoenamide **18** (670 mg, 3.7 mmol) and sodium borohydride (400 mg, 10.5 mmol) in absolute ethanol (25 mL) was strirred at room temperature for 22 h. Then glacial acetic acid (0.6 mL) was added and stirring continued for another 40 min. The reaction mixture was evaporated to dryness, water (10 mL) was added, and the mixture extracted with chloroform (2 × 10 mL). The combined extracts were washed with water and dried over anhydrous sodium sulfate. After removal of the solvent a pale yellow, partly solidified, oil was obtained (282 mg). The main product of reduction, possessing an R_f value identical with **6** on silica (but different on alumina) was purified by column chromatography on alumina (13 g, activity 3). The fractions eluted with chloroform – 0.5–1% methanol contained 227 mg of colorless solid, mp 125–128°C, assumed to be 5-hydroxy-7-methyl-3,4,5,6,7,8-hexahydro-2-quinolone. After crystallization from chloroform it melted at 128–129°C. Infrared ν_{max}: 3580 (OH), 3403 (NH), 1701 (shoulder), and 1674 (C=O), 1452, 1374, 997 cm^{-1}; ^1H nmr (80 MHz), δ: 1.03 (3H, d, J = 5.9 Hz, CH—CH_3), 1.8 (OH), disappears in D_2O, 4.28 (1H, m, H-5), 7.61 (1H, br s, NH) ppm, disappears in D_2O; ms: 181 (M^+, 65), 180 (49), 164 (76), 163 (50), 148 (100), 139 (78), 138 (38), 120 (23), 111 (22), 110 (37), 93 (22), 83 (20), 55 (74).

Reduction with Lithium in Liquid Ammonia

To liquid ammonia (700 mL, distilled from sodium), lithium (2.3 g, 0.33 g atom) was added and the mixture stirred for 0.5 h. Solid ketoenamide **18** (17.9 g, 0.1 mol) was then added at −33°C. After 1 min the deep-blue solution was quenched with ammonium chloride (16 g, 0.3 mol) and the ammonia allowed to evaporate overnight. Water and chloroform (50 mL of each) were added to the residue. The aqueous layer was extracted with an additional two portions of chloroform. The combined extracts were washed with water and dried over anhydrous magnesium sulfate. After removal of the solvent under reduced pressure the colorless solid residue (14.4 g) was dissolved in boiling methanol (50 mL), filtered from a small amount of white powdered substance, diethyl ether (200 mL) added, and the solution set aside to crystallize in the refrigerator. The *trans*-ketolactam **17** (5.8 g, 32%) melted at 224–227°C with sublimation (lit. (6) mp 225–227°C). The pure compound may be obtained by continuous extraction of the crude (crystallized) material with anhydrous ether or by sublimation at 120–140°C/0.25 Torr followed by recrystallization from water or methanol. Melting point 229°C (with sublimation).

Reaction of 2-Trimethylsilylmethylpyridine with Lactam ***17***

The reaction of *trans*-ketoamide **17** (2.715 g, 15 mmol), trimethylsilylmethylpyridine (5.95 g, 36 mmol), and 1.60 *M* solution of *n*-butyllithium – hexane (22.5 mL, 36 mmol) in THF (150 mL) yielded a mixture from which *Z*-isomer **19** separated as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

a solid after quenching the reaction mixture with 50% aqueous acetic acid (4.0 mL). The THF solution was decanted from the white precipitate, and the latter washed with benzene (20 mL) and dissolved in chloroform (45 mL) and water (15 mL). The aqueous layer was removed and the organic extract was shaken with water and dried over anhydrous magnesium sulphate. After removal of the solvent, chromatographically pure **19** was obtained (2.30 g), mp 210–212°C (tlc on silica in $CHCl_3$–MeOH 10:1). Evaporation of the tetrahydrofuran solution gave a partly solidified residue (5.66 g). Petroleum ether (40 mL) was added to the residue and the crystals (0.56 g) that separated were recrystallized from methanol (6 mL) and ether (20 mL) yielding 0.40 g of pure **19**. The mother liquor and petroleum ether residues were collected and chromatographed on a Lobar Si 60 column (size B) using chloroform–methanol (100:3, v/v) as the developing system. Another portion of the *Z*-isomer **19** (0.29 g, overall yield 2.99 g or 77.9%) and 51 mg of the *E*-isomer **20** (yield 1.3%, mp 200–202°C) were obtained.

Compound **19**, the *Z*-isomer, melted at 213–214°C after recrystallization from methanol–ether; uv λ_{max} (MeOH) (ε): 223 (4800), 262 (4200) nm; ir ν_{max}: 3400 (NH), 1662 and 1648 (lactam), 3070, 1590 and 1568 (pyridine) cm^{-1}; ^1H nmr (80 MHz), δ: 1.02 (3H, d, J = 5.6 Hz, $CHCH_3$), 3.30 (1H, td, J = 12.7 and 3.2 Hz, H-9), 6.12 (1H, br s, disappears on D_2O exchange, NH), 6.53 (1H, s, =C*H*), 7.19 (2H, m, pyridine protons in β-positions), 7.60 (1H, td, J = 7.6 and 1.7 Hz, pyridine proton in γ-position), 8.55 (1H, m, pyridine proton in α-position) ppm; ms: 256 (M^+, 65), 255 (47), 241 (13), 224 (12), 214 (100), 198 (34), 184 (39), 170 (26), 144 (17), 143 (18%). *Exact Mass* calcd. for $C_{16}H_{20}N_2O$: 256.158; found (hrms): 256.156.

Compound **20**, the *E*-isomer, melted at 202°C after recrystallization from acetone; uv λ_{max} (MeOH) (ε): 240 (16500), 274 (10400) nm; ir ν_{max}: 3393 (NH), 1662 and 1650 (lactam), 3084, 1588 and 1564 (pyridine) cm^{-1}; ^1H nmr (80 MHz), δ: 0.98 (3H, d, J = 4.2 Hz, $CHCH_3$), 3.45 (2H, m, H-9 and H-6e), 6.48 (1H, s, =C*H*), 6.93 (1H, br s, disappears on D_2O exchange, NH), 7.19 (2H, m, pyridine protons in β-positions), 7.63 (1H, td, J = 7.8 and 2.0 Hz, pyridine proton in λ-position), 8.58 (1H, m, pyridine proton in α-position) ppm; ms: 256 (M^+, 56), 255 (41), 241 (53), 224 (14), 214 (100), 198 (69), 197 (59), 184 (86), 170 (54), 169 (54), 168 (68), 167 (40), 165 (54), 144 (50), 143 (54), 130 (64%). *Exact Mass* calcd. for $C_{16}H_{20}N_2O$: 256.158; found (hrms): 256.155.

Treatment of Z-Isomer 19 with H_2

Hydrogenation of the *Z*-isomer **19** (1.53 g, 6.0 mmol) in ethanol was performed in the presence of Adams' catalyst (200 mg) without acetic acid. After absorption of 160 mL of hydrogen (4.5 h) the reaction was stopped. The usual work-up gave 1.52 g of partly solidified product. Thin-layer chromatography on silica (developed three times in ether–methanol 4:1) showed three spots: traces of the starting material, the inseparable epimers **21** and **22**, and a spot (R_f = 0), inactive in uv light but developable in the presence of iodine vapour. The mixture of **21** and **22** was separated by column chromatography on silica using ether–methanol (6:1) as the developing system. From 530 mg of the crude product (50 g SiO_2), the starting material (34 mg) and the epimeric products **21** and **22** (393 mg of a solid melting at 148–186°C) were obtained; ir ν_{max}: 3390 (NH), 1655 (lactam C=O), 1594 and 1572 (pyridine) cm^{-1}; ^1H nmr (90 MHz), δ: 0.89 and 0.88 (doublets, J = 6.3 and 6.0 Hz, respectively, $CHCH_3$), 6.87 (1H, br s, disappears on D_2O exchange, NH), 7.01 (2H, m, pyridine protons in β-positions), 7.52 (1H, td, pyridine proton in γ-position), 8.50 (1H, m, pyridine proton in α-position) ppm. ms: 258 (M^+, 12), 93 (100%).

Pure epimers **21** and **22** were obtained by transformation of the mixture to their pyridine *N*-oxides, separation by column chromatography on alumina, and regeneration of the pyridines using phosphorus trichloride (see below).

Conversion of 21 and 22 to Their N*-Oxides*

The mixtures of epimers **21** and **22** (ca. 1:1, 760 mg) was dissolved in chloroform (15 mL) and 85% *m*-chloroperbenzoic acid (630 mg) was added. The oxidation was monitored by tlc on alumina (chloroform–methanol 50:1). The reaction was complete after 8 to 10 h at 25°C. The oily residue obtained after removal of the solvent was chromatographed on an alumina column (activity 1, 120 g) using progressively increasing concentrations of ethanol in chloroform. *N*-oxide **23** (338 mg) was obtained as colorless crystals, after crystallization from methanol – ethyl acetate, that melted at 259–261°C (with sublimation). The second fraction, *N*-oxide **24** (180 mg), melted at 274–277°C.

N-oxide **23**: ir ν_{max}: 3400 (NH), 1660 (lactam) cm^{-1}; ^1H nmr (80 MHz), δ: 0.87 (3H, d, J = 6.5 Hz, $CHCH_3$), 3.11 (1H, td, J = 10.0 and 3.0 Hz, H-9), 3.52 (1H, dd, J = 12.5 and 2.7 Hz), 6.31 (1H, br s, disappears on D_2O exchange, NH), 7.21 (3H, m, pyridine protons in β- and γ-positions), 8.24 (1H, m, pyridine proton in α-position) ppm; ^1H nmr (360 MHz), δ: 2.40 (H-3a, $J_{3a,3e}$ = 18.8, $J_{3a,4a}$ = 7.3 Hz), 2.55 (H-3e, $J_{3e,3a}$ = 18.8, $J_{3e,4a}$ = 6.3, $J_{3e,4e}$ = 1.3 Hz), 1.58 (H-4a, $J_{4a,4e}$ = 10, $J_{4a,3a}$ = 7.3, $J_{4a,3e}$ = 6.3, $J_{4a,10a}$ = 12.0 Hz), 2.30 (H-4e, overlapped with high field signal H-11″ at δ 2.35 ppm), 1.96 (H-5, $J_{5,10a}$ = $J_{5,6a}$ = 10, $J_{5,11'}$ = $J_{5,6e}$ = 3 Hz), 0.79 (H-6a, $J_{6a,6e}$ = $J_{6a,5}$ = $J_{6a,7}$ = 10 Hz), 1.50 (H-6e and H-7, $J_{6e,5}$ = 3, $J_{6e,6a}$ = $J_{7,6a}$ = $J_{7,8a}$ = 10), $J_{7,CH3}$ = 6.5, $J_{7,8e}$ = 2 Hz), 1.04 (H-8a, $J_{8a,7}$ = 10, $J_{8a,8e}$ = 12.5, $J_{8a,9}$ = 12.0 Hz), 1.77 (H-8e, $J_{8e,8a}$ = 12.5, $J_{8e,7}$ = 2.0, $J_{8e,9}$ = 3.8 Hz), 3.11 (H-9, $J_{9,10}$ = 12.5, $J_{9,8a}$ = 12.0, $J_{9,8e}$ = 3.8 Hz), 1.18 (H-10, $J_{4a,10}$ = 12.0, $J_{4e,10}$ = 3.0; $J_{5,10}$ = 10, $J_{9,10}$ = 12.5 Hz), 2.35 (H-11″), 3.53 (H-11′, $J_{11',11''}$ = 13.8, $J_{11',5}$ = 3.0 Hz), 0.86 (CH_3, $J_{CH_3,7}$ = 6.5 Hz), 5.99 (NH), 7.21 (pyridine protons in β- and γ-positions), 8.24 (pyridine proton in α-position) ppm. ms: 274 (M^+, 1) 258 (18), 257 (62), 166 (16), 164 (100), 120 (21), 109 (65), 94 (43), 93 (72), 92 (18), 55 (13%). *Exact Mass* calcd. for $C_{16}H_{22}N_2O_2$: 274.168; found (hrms): 274.165.

added at 0°C and the mixture kept at room temperature for 17 h. After removal of volatile substances at reduced pressure dilute aqueous sodium carbonate solution was added and the mixture was extracted with chloroform. Almost quantitative yields of pyridines **21** and **22** were obtained.

Epimer **21**, colorless crystals, melted at 170°C after recrystallization from ethyl acetate; ir ν_{max}: 3400 (NH), 1659 (lactam), 1596 and 1572 (pyridine) cm^{-1}; ^1H nmr (80 MHz), δ: 0.86 (3H, d, J = 5.9 Hz, CHCH_3), 3.09 (2H, d, $J_{11,5}$ = 3.9 Hz, H-11), 3.11 (1H, td, J = 11.7 and 3.4 Hz, H-9), 6.17 (1H, br s, NH), 7.10 (2H, m, pyridine protons in β-positions), 7.59 (1H, td, J = 7.9 and 1.7 Hz, pyridine proton in γ-position), 8.54 (1H, m, pyridine proton in α-position) ppm; ms: 258 (M^+, 40), 257 (28), 241 (4), 240 (4), 146 (8), 144 (5), 132 (5), 130 (6), 120 (16), 118 (8), 93 (100%).

Epimer **22**, colorless crystals, mp 180.5–182°C; ir ν_{max}: 3400 (NH), 1660 (lactam), 1598 and 1577 (pyridine) cm^{-1}; ^1H nmr (80 MHz), δ: 0.88 (3H, d, J = 6.1 Hz, CHCH_3), 3.38 (1H, td, J = 11.2 and 4 Hz, H-9), 5.85 (1H, br s, NH), 7.10 (2H, m, pyridine protons in β-positions), 7.60 (1H, td, J = 8.0 and 1.9 Hz, pyridine proton in γ-position), 8.54 (1H, m, pyridine proton in α-position) ppm; ms: 258 (M^+, 10), 120 (26), 106 (9), 93 (100%). *Exact Mass* calcd. for $C_{16}H_{22}N_2O$: 258.173; found (hrms): 258.175.

Preparation of Quaternary Salts 25 and 26

Quaternization of **21** and **22** under similar conditions to those described before gave methiodides **25** and **26** in yields of 92 and 93%, respectively.

Methiodide **25**, mp 257–258°C (methanol–acetone); ir ν_{max} (KBr): 3200 (NH), 1655 and 1635 (lactam), 1579 and 1517 (pyridine) cm^{-1}; ^1H nmr (80 MHz, D_2O), (sodium β-trimethylsilypropionate-d_4 (TSP) as the internal standard): 0.88 (3H, d, J = 6 Hz, CHCH_3), 2.97 (1H, dd, J = 16 and 4.4 Hz, H-3e), 3.24 (1H, m, H-9), 3.59 (1H, dd, J = 14 and 3.2 Hz, H-11′), 4.33 (3H, s, $\overset{+}{N}$—CH_3), 7.96 (2H, m, pyridine protons in β-positions), 8.43 (1H, m, pyridine proton in γ-position), 8.71 (1H, m, pyridine proton in α-position) ppm.

Methiodide **26**, mp 177–178°C (methanol–acetone); ir ν_{max} (KBr): 3480, 3400, and 3220 (NH), 1645 and 1636 (lactam), 3080, 3050, 1577 and 1512 (pyridine) cm^{-1}; nmr (80 MHz, D_2O), (TSP) δ: 0.93 (3H, d, J = 6.1 Hz, CHCH_3), 3.17 (2H, m), 3.52 (1H, td, J = 11 and 3.5 Hz, H-9), 4.33 (3H, s, $\overset{+}{N}$—CH_3), 7.92 (2H, m, pyridine protons in β-positions), 8.41 (1H, m, pyridine proton in γ-position), 8.72 (1H, m, pyridine proton in α-position) ppm.

Reduction of Methiodides 25 and 26

The methiodides were reduced catalytically as previously described. From methiodide **25** (170 mg) a mixture of *N*-methylpiperidines **27***a* and **27***b* was obtained (116 mg, 96% yield) as a colorless solid (120–176°C). This product gave also a single spot in tlc; ir ν_{max}: 3400 (NH), 2795 (NCH_3), 1661 and 1655 (C=O) cm^{-1}; ^1H nmr (90 MHz) δ: 0.94 (3H, d, J = 6 Hz, CHCH_3), 2.23 (3H, s, N—CH_3), 2.3–3.3 (m, 5H, N—CH protons), 6.80 (1H, br s, NH) ppm; ms: 278 (M^+, 3), 277 (5), 263 (1), 223 (2), 166 (2), 164 (3), 98 (100), 93 (16), 84 (13), 70 (12).

From methiodide **26** (309 mg) an inseparable mixture of **28***a* and **28***b* was obtained (194 mg, 88% yield); mp 98–170°C; ir ν_{max}: 3400 (NH), 2780 (NCH_3), 1659 (C=O) cm^{-1}; ^1H nmr (90 MHz), δ: 0.92 and 0.93 (3H, two doublets, J = 6 Hz, CHCH_3), 2.27 (3H, s, NCH_3), 2.3–2.6 (3H, m), 2.83 (1H, m), 3.23 (1H, m), 6.40 (1H, br s, NH); ms: 278 (M^+, 8), 277 (12), 223 (2), 166 (2), 164 (2), 98 (100%). *Exact Mass* calcd. for $C_{17}H_{30}N_2O$: 278.236; found (hrms): 278.235.

*Reduction of the Mixture (27*a *and 27*b*) with Lithium Aluminum Hydride*

The lactams were reduced as previously described. The epimeric amides (**30***a* and **30***b*, 110 mg) gave 84 mg of a mixture of **29***a* and **29***b* (yield 80%) as a partly solidified colorless oil; ir ν_{max}: 3170 (br, NH), 2800 (N—CH_3) cm^{-1}; ^1H nmr (90 MHz), δ: 0.83 (1H, br s, NH), 0.92 (3H, d, J = 6 Hz, CHCH_3), 2.25 (3H, s, NCH_3), 2.3–3.2 (5H, m) ppm; ms: 264 (M^+, 2) 263 (6), 152 (20), 150 (20), 99 (97), 98 (100), 96 (34), 83 (30), 70 (97), 55 (48%).

*Reduction of the Mixture 28*a *and 28*b *with Lithium Aluminum Hydride*

The epimeric amides (**28***a* and **28***b*, 190 mg) gave 141 mg of a mixture of **30***a* and **30***b* (yield 78%) as a partly crystalline colorless oil; ir ν_{max}: 3160 (br, NH), 2798 (N—CH_3) cm^{-1}; ^1H nmr (90 MHz), δ: 0.88 and 0.89 (3H, two doublets, J = 6 Hz, CHCH_3), 1.6 (NH), 2.25 and 2.26 (3H, two s, N—CH_3), 2.3–3.2 (5H, m) ppm; ms: 264 (M^+, 3), 263 (8), 152 (22), 150 (21), 98 (100%).

*Acetylation of Amine Mixtures (29*a *and 29*b*) and (30*a *and 30*b*)*

Mixtures of the epimeric diamines **29***a*, **29***b* and **30***a*, **30***b* gave after acetylation by the previously described procedure the two pairs of epimeric acetamides **31***a*, **31***b* and **32***a*, **32***b*, respectively. Each of the four compounds showed a separate spot on tlc on alumina (chloroform – 5% diethylamine in methanol, 50:1). Components **31***a* and **31***b* possess higher R_f values than **32***a* and **32***b*. Isomer **32***b* had identical tlc behaviour with an authentic sample of N_β-acetyl-N_α-methylphlegmarine derived from natural sources in several solvent systems as shown in Table 1.

The crude yellow oils obtained from the acetylation reaction (96 mg of **31***a*, **31***b* from 80 mg of diamines **29***a*, **29***b*, and 160 mg **32***a*, **32***b* from 138 mg of **30***a*, **30***b*) were separated on basic alumina (activity 3) yielding four pure isomers as colourless oils: **31***a* (29 mg), **31***b* (16 mg), **32***a* (26 mg), and **32***b* (45 mg). *Exact Mass* calcd. for $C_{19}H_{34}N_2O$: 306.267; found: 306.266, 306.263,

Acidité dans les mélanges H_2O–ODPN. I. Etude de l'acidité dans l'oxydipropionitrile pur

M. PERSIN ET J. Y. GAL

Laboratoire de Chimie Analytique de l'Université des Sciences et Techniques du Languedoc, Place E. Bataillon, 34060 Montpellier Cedex, France

Reçu le 19 janvier 1981

M. PERSIN et J. Y. GAL. Can. J. Chem. **59**, 2491 (1981).

L'étude des réactions acide–base dans l'oxydipropionitrile à l'aide des électrodes de verre et à hydrogène nous a permis de déterminer les pK_A de quelques couples acide–base. L'utilisation de l'hypothèse de Strehlow permet de corréler les échelles d'acidité dans l'eau, l'acétonitrile et l'oxydipropionitrile. Par suite de la dégradation du solvant en milieu trop alcalin il n'a pas été possible de déterminer le produit ionique du milieu et par conséquent les pK_B des divers couples. La faible basicité de la molécule d'ODPN permet de titrer facilement des bases très faibles dans l'eau comme l'urée, le DMSO, le HMPT. Dans le cas des acides faibles HA il a été clairement mis en évidence l'importance des phénomènes d'homoconjugaison qui résultent à la fois de la faible aptitude du milieu à solvater les anions et le proton. Quelques constantes d'homoconjugaison ont pu être déterminées à partir de l'analyse des courbes de titrage potentiométrique. Enfin l'étude sommaire du couple quinone–hydroquinone montre qu'il est également indicateur du pH dans l'oxydipropionitrile. En l'état actuel de nos travaux nous disposons d'une échelle de pK d'environ 20 unités utilisable pratiquement.

M. PERSIN and J. Y. GAL. Can. J. Chem. **59**, 2491 (1981).

The study of acid–base reactions in oxydipropionitrile (ODPN) by means of glass and hydrogen electrodes allows us to determine the pK_A's of several acid–base pairs. Use of Strehlow's hypothesis leads to a correlation of acidity scales in water, acetonitrile and oxydipropionitrile. Because of solvent degradation in highly alkaline solution it proved impossible to determine the ionic product of the medium and consequently the pK_B's of several acid–base pairs. The weak basicity of ODPN allows for the easy titration of very weak bases such as urea, DMSO, and HMPT in water. For weak acid the importance of homoconjugation is clearly shown leading to the weak ability of the medium to solvate both anions and protons. Some homoconjugation constants have been determined by the analysis of the potentiometric titration curves. Finally a study of the quinone–hydroquinone couple shows that this is also a pH indicator in ODPN. At the present time our studies provide a pK scale of practical use over 20 units.

Introduction

L'oxydipropionitrile est un solvant très polaire $\mu = 4{,}91$ D[1] et de forte constante diélectrique $\varepsilon = 66{,}6$ (1), il constitue un milieu fortement dissociant et nous avons pu montrer au cours de nos travaux antérieurs que de nombreux électrolytes y sont totalement dissociés (2). A l'heure actuelle, l'oxydipropionitrile sert principalement de phase stationnaire en chromatographie, certains auteurs l'ont également mentionné pour effectuer la séparation des paraffines et des carbures aromatiques (3–6). Depuis quelque temps nous étudions les possibilités d'emploi de ce solvant en extraction liquide–liquide du fait de l'existence d'une importante zone de démixtion avec l'eau. Des séparations peuvent être mises au point et la connaissance des propriétés solvatantes des deux milieux qui se séparent permet de définir les conditions optimales (7).

De manière à accroître les possibilités d'utilisation en extraction, il est intéressant de pouvoir disposer de quelques couples acide–base pouvant servir de tampons permettant de fixer le pH dans les deux phases.

Aucune étude relative à l'acido-basicité dans le solvant pur n'ayant été entreprise, il nous a paru nécessaire de préciser nos connaissances dans ce milieu et de définir une échelle d'acidité. Celle-ci a été établie au moyen de titrages potentiométriques à l'électrode de verre et les résultats comparés avec ceux obtenus en utilisant l'électrode à hydrogène. Notre étude montre que les phénomènes observés dans l'oxydipropionitrile sont complexes par suite de l'intervention d'équilibres d'homoconjugaison dont il faut tenir compte pour interpréter correctement les courbes de titrage, les résultats présentent alors beaucoup d'analogie avec ceux obtenus par Kolthoff dans l'acétronitrile. L'échelle d'acidité obtenue peut être corrélée à celle de l'eau par l'utilisation d'hypothèses extrathermodynamiques simples, nous nous sommes volontairement limités à celle de Strehlow pour comparer nos résultats à ceux obtenus dans l'eau et l'acétonitrile.

Partie Expérimentale

Synthèse et purification du solvant

L'établissement d'une échelle d'acidité dans l'oxydipropionitrile nécessite l'utilisation d'un solvant particulièrement propre difficile à obtenir. Le solvant est synthétisé au laboratoire suivant la méthode proposée par Selcer et de Barde (8) qui consiste à faire réagir l'acrylonitrile sur l'eau selon la réaction:

[1]J. C. Bollinger et M. Persin, travaux non publiés.

Celle-ci s'effectue en présence de soude, la réaction est arrêtée par neutralisation à l'acide sulfurique concentré. Après filtration du sulfate de sodium formé et élimination de l'excès d'acrylonitrile le résidu est distillé sous vide de gaz inerte; on obtient un produit incolore dont les spectres infrarouge et rmn correspondent à l'oxydipropionitrile.

L'usage d'un tel solvant ne s'est pas avéré correct pour établir une échelle d'acidité, le milieu contenant alors une impureté acido-basique à concentration voisine de 10^{-3} *M* (1) qui peut être mise en évidence par titrage acide–base en milieu aqueux. Cette impureté d'ailleurs également présente dans le produit commercial peut être totalement éliminée après passage du solvant sur colonne d'alumine neutre. Dans ces conditions on obtient un solvant "propre" de conductivité spécifique inférieure à 10^{-7} Ω^{-1} cm^{-1}. Le solvant est alors conservé sur tamis moléculaire 4A.

Réactifs

Les acides et bases utilisés sont des produits pour analyse Prolabo. Le perchlorate de tetrabutylammonium provient des établissements K et K. L'alumine utilisée pour purifier le solvant est de l'alumine neutre Merck activée contenant 0,1% d'eau.

Réalisation des mesures

Pour titrer les bases nous avons utilisé l'acide perchlorique commercial dilué dans le solvant, dans le cas du titrage des acides la butylamine sert de titrant. La force ionique est généralement maintenue constante à 0,1 *M* par le perchlorate de tetrabutylammonium. L'électrode de verre utilisée est une électrode Tacussel pour milieux aqueux; dans le cas de l'utilisation de l'électrode à hydrogène celle-ci est constituée d'un carré de platine platiné de 0,5 cm de côté. Les potentiels sont mesurés par rapport à l'électrode de référence $Ag\downarrow/Ag^+$ 10^{-2} *M* déjà décrite (9).

Les titrages conductimétriques ont été réalisés à l'aide d'un conductimètre CD7 Tacussel et d'une cellule de conductimétrie, la température étant régulée à 25°C ± 0,1°C (constante de la cellule: 0,7).

Le traitement mathématique des courbes de titrages obtenues a été effectué à l'aide d'un calculateur miniature Hewlett Packard HP 25.

Résultats

Recherche d'un acide fort dans l'oxydipropionitrile

L'obtention d'un acide fort dans le solvant permet de fixer l'origine de l'échelle d'acidité, la position de celle-ci étant conditionnée par la basicité du solvant.

La solvolyse d'un acide fort dans un solvant S peut se traduire par la réaction:

$$HA + S \rightarrow SH^+ + A^-$$

Dans ces conditions la réponse de l'électrode de verre ou de l'électrode à hydrogène en milieu acide fort dans l'ODPN doit être Nernstienne à courant nul.

$$E = A + 0{,}06 \log C_{SH^+}$$

Des acides minéraux usuels seul l'acide perchlorique est totalement dissocié dans l'oxydipropionitrile, ceci est conforme à sa position sur l'échelle générale d'acidité ($pK_{H_2O} = -8{,}6$) et à la relative solvatation de l'anion perchlorate dans ce milieu (7).

De manière à pouvoir mesurer l'influence de l'eau nous avons utilisé successivement de l'acide perchlorique préparé dans l'acide acétique anhydre et la solution commerciale à 70% en poids, les résultats sont identiques. Pour des raisons de commodités nous avons utilisé dans la suite de notre travail l'acide perchlorique commercial dilué dans l'oxydipropionitrile.

On peut noter que les résultats concernant l'acétonitrile sont tout à fait similaires, Desbarres y décrit également l'acide perchlorique comme totalement dissocié en solution diluée (10).

Comme nous le verrons par la suite l'oxydipropionitrile est moins basique que l'eau; cette dernière étant toujours présente dans le milieu [10^{-2} *M*], il est probable que le proton solvaté SH^+ puisse exister sous deux formes: $ODPNH^+$ et H_3O^+. Dans ces conditions la réaction de solvolyse d'un acide fort HA précédemment écrite constitue une simple commodité d'écriture. Par ailleurs le fait d'obtenir une réponse correcte de l'électrode de verre pour milieux aqueux laisserait même supposer que l'on soit uniquement en présence d'ions H_3O^+ dans nos conditions expérimentales. Les résultats présentés sont cependant intéressants puisqu'ils peuvent être obtenus dans des conditions opératoires usuelles qui correspondent à l'utilisation d'un mélange H_2O–ODPN de fraction molaire 0,998 en ODPN. Nous reviendrons sur cette question au cours du paragraphe concernant la corrélation des échelles d'acidité entre les divers solvants.

Etude des couples HA/A⁻

Si l'on admet la dissociation simple des acides HA selon l'équilibre:

$$HA \rightleftarrows H^+ + A^-$$

de constante K_{HA}. Au cours du titrage avant le point équivalent le pH doit varier selon:

$$pH = pK_{HA} + \log \frac{[A^-]}{[HA]}$$

L'analyse des courbes de titrages potentiométri-

For personal use only.

ques peut nous renseigner sur le mode de dissociation de ces acides. Dans le tableau 1 nous avons reporté les résultats observés dans le cas du titrage de différents acides. On peut remarquer que pratiquement pour tous les acides étudiés, la pente de la courbe $E = f\{\log[A^-]/[AH]\}$ est différente de 59 mV excepté pour l'acide picrique. Ces acides ne se dissocient donc pas selon le mode simple proposé, de tels résultats sont souvent observés dans les solvants aprotiques où l'on doit tenir compte des phénomènes d'homoconjugaison par suite du caractère peu solvatant du solvant vis à vis des anions. Ainsi dans l'acétonitrile, pratiquement tous les acides sont dissociés selon l'équilibre:

$$K_{2HA} = \frac{[HA_2^-]\,H^+]}{[HA]^2}$$

$$2\,HA \rightleftarrows HA_2^- + H^+$$

Dans ces conditions si $K_{HA_2^-}$ est la constante d'homoconjugaison relative à l'équilibre

$$K_{HA_2^-} = \frac{[HA_2^-]}{[HA][A^-]}$$

$$HA + A^- \rightleftarrows HA_2^-$$

il vient:

$$K_{2HA} = \frac{[HA_2^-]\,H^+]}{[HA]^2} = K_{HA}K_{HA_2^-}$$

Kolthoff et Chantooni (11) ont alors montré que selon les valeurs du produit $K_{HA_2^-}\,C_a$ (où C_a est la concentration initiale d'acide), la courbe de titrage par une base peut présenter deux points équivalents correspondant aux deux réactions successives:

$$2\,HA + B \rightleftarrows BH^+ + HA_2^-$$

$$BH^+ + HA_2^- + B \rightleftarrows 2\,BH^+ + 2\,A^-$$

Lorsque $K_{HA_2^-}$ est voisin de zéro la courbe retrouve son allure habituelle observée dans l'eau; si $K_{HA_2^-} \cdot C_a$ n'est pas trop grand on observe une déformation de la courbe sans apparition du point équivalent pour $x = 0{,}5$.

Récemment Courtot-Coupez et collaborateurs ont montré également l'intervention des équilibres d'homoconjugaison sur les réactions acide–base dans le carbonate de propylène (12), ces résultats permettent de mieux comprendre leurs travaux antérieurs (13).

L'oxydipropionitrile étant comme nous l'avons déjà montré (7) un milieu peu solvatant vis à vis des anions, il est normal d'y retrouver ce type d'association dont nous avons pu confirmer l'existence par l'étude des courbes de titrages conductimétriques. Ainsi dans le cas des acides chlorhydrique, nitrique, salicylique, benzoïque, acétique, les courbes de titrages conductimétriques par une base faible présentent deux points singuliers pour $x = 0{,}5$ et $x = 1$ (figures 1 et 2). Selon Kolthoff et Chantooni l'allure de ces courbes s'explique par les mobilités différentes des espèces HA_2^- et A^- et par la non totale dissociation du sel HB^+A^- aux fortes concentrations (14). Le titrage conductimétrique de l'acide picrique ne met pas en évidence la formation de l'espèce homoconjuguée $H(Pi)_2^-$ confirmant ainsi l'allure normale de la courbe de titrage potentiométrique. Comme dans d'autres solvants où des phénomènes de conjugaison sont observés l'acide picrique possède un comportement singulier s'expliquant par la relative solvatation de l'anion picrate volumineux et polarisable.

L'analyse des courbes de titrage conductimétrique et la connaissance des conductivités équivalentes limites des deux ions présents permettent théoriquement de déterminer les constantes d'homoconjugaison $K_{HA_2^-}$; Kolthoff *et al.* ont ainsi pu calculer les constantes de dissociation K_{HA} de nombreux acides faibles dans l'acétonitrile (15). Plus récemment ils ont pu étudier par cette méthode la dissociation d'acides faibles dans le carbonate de propylène (16). Si cette méthode donne de bons résultats elle présente l'inconvénient de faire appel à un solvant rigoureusement exempt de traces d'acides ou de bases qui modifient les conductivités mesurées, étant donné la difficulté de purification de l'oxydipropionitrile nous avons renoncé à son utilisation pour déterminer le pK_{HA} des acides étudiés.

L'analyse des courbes de titrage potentiométrique d'un acide par une base permet de déterminer le pK_{HA} de l'acide si l'on tient compte de toutes les espèces présentes en solution, en particulier HA_2^-.

Si C_a est la concentration d'acide initiale en solution et C_s la concentration du sel on peut écrire les bilans suivants si l'on suppose les sels $BH^+\,HA_2^-$ et BH^+A^- totalement dissociés:

$$C_a = [HA] + [HA_2^-]$$

$$C_s = [HA_2^-] + [A^-]$$

Connaissant la constante d'acidité K_{HA} et la constante d'homoconjugaison $K_{HA_2^-}$ on obtient finalement la relation de Kolthoff qui relie H^+, C_s, C_a, K_{HA}, $K_{HA_2^-}$ (11)

$$C_s[H^+]^2 - K_{HA}[H^+]\{(C_a + C_s) + K_{HA_2^-}(C_s - C_a)^2\} + K_{HA}^2 C_a = 0$$

TABLEAU 1. Caractéristiques des courbes de titrage des différents acides étudiés (référence électrode Ag/Ag^+ 10^{-2} M)

Acides	$E_{1/2}$ verre	Pente $E = f\{\log [A^-]/[HA]\}$	pK_{ODPN} ±0,1	pK_{H_2O}	pK_{ACN}* (a)	pK_{ACN}* (b)	$pK_{ODPN} - pK_{H_2O}$

*pK_{ACN} (a) résultats calculés à partir des potentiels de 1/2 neutralisation d'après Desbarres (10); (b) résultats d'après Kolthoff (23, 24); ·résultats d'après Kolthoff et Chantooni (20).

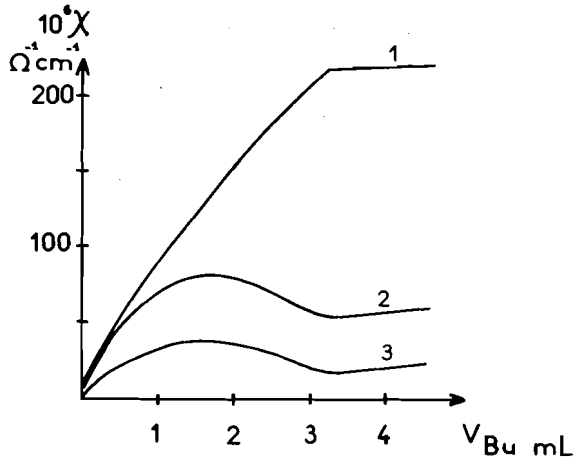

FIG. 1. Titrage conductométrique de quelques acides HA par la butylamine. (1) Acide picrique 0,05 M; (2) acide salicylique 0,05 M; (3) acid benzoïque 0,05 M.

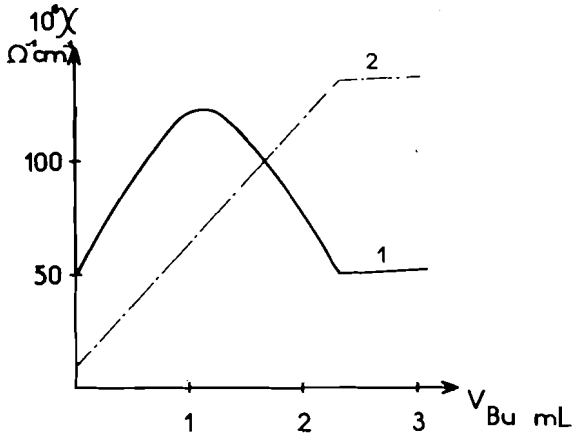

FIG. 2. Titrage conductométrique de l'acide chlorhydrique par la butylamine dans l'ODPN. (1) Dans l'ODPN [HCl] = 0,05 M; (2) courbe de titrage théorique d'un acide faible HA selon la dissociation classique.

La résolution de cette équation permet de calculer le pH en tout point de la courbe de titrage. Lorsque $C_s = C_a$, c'est-à-dire à la demi-neutralisation, l'équation précédente devient:

$$C_s[H^+]^2 - 2K_{HA}C_s[H^+] + K_{HA}^2C_a = 0$$

dont la solution est:

$$[H^+] = K_{HA}$$

Aussi quelle que soit la valeur de la constante d'homoconjugaison $K_{HA_2^-}$, le pH de demi-neutralisation est égal au pK_{HA} de dissociation classique de l'acide HA et la première partie de la courbe de titrage admet ce point comme centre de symétrie.

Dans le tableau récapitulatif 1 nous avons classé tous les acides selon leur pK déterminé par cette méthode. L'examen des résultats montre que les acides HA sont considérablement affaiblis dans l'oxydipropionitrile, seul l'acide perchlorique est un acide fort. L'ordre de force observé est conservé par rapport à l'échelle générale d'acidité rapportée à l'eau. L'écart de pK_{HA} mesuré par rapport à l'eau est de l'ordre de 8,5 unités ce qui est considérable; cet écart ne peut s'expliquer que par une très faible solvatation des anions A^-. Dans ce tableau nous avons reporté les valeurs de pK_{HA} des acides dans l'acétonitrile, on peut remarquer qu'elles sont très voisines de celles observées dans l'oxydipropionitrile.

D'après l'équation de Kolthoff on peut connaissant le pH et K_{HA} déterminé précédemment, calculer la constante $K_{HA_2^-}$ pour chacun des acides étudiés. Nous donnons dans le tableau 2 les constantes $K_{HA_2^-}$ pour quelques acides faibles.

A partir des constantes ainsi déterminées il est possible de prévoir la répartition de toutes les

$K_{HA} = 10^{-13,7}$; $pK_{HA_2^-} = -2,5 \pm 0,2$

*La constante n'a pu être déterminée par suite du caractère trop faible de cet acide.

espèces en solution compte tenu des divers équilibres:

$$K_{HA} = \frac{[H^+][A^-]}{[HA]}$$

$HA \rightleftarrows H^+ + A^-$

$$K_{HA_2^-} = \frac{[HA_2]}{[HA][A^-]}$$

$HA_2^- \rightleftarrows HA + A^-$

En considérant les sels totalement dissociés on peut écrire les bilans suivants:

$$C_a = [HA] + 2[HA_2^-] + [A^-]$$

$$[H^+] = [A^-] + [HA_2^-]$$

Il vient en remplaçant A^- et HA_2^- par leur expression en fonction de HA:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

$$[H^+]^2 = K_{HA}[HA] + K_{HA_2^-}K_{HA}[HA]^2$$

$$C_a = [HA] + K_{HA}\frac{[HA]}{[H^+]} + \frac{2K_{HA}K_{HA_2^-}[HA]^2}{[H^+]}$$

Si l'acide est suffisamment faible et la concentration initiale suffisamment forte, il est logique de supposer:

$$[HA] \# C_a$$

Dans ces conditions l'expression de K_{HA} permet de déterminer aisément la concentration en protons libres, la concentration en ions A^- et en espèces conjuguées HA_2^- sont obtenues par les relations:

$$[A^-] = K_{HA}\frac{[HA]}{[H^+]}$$

$$[HA_2^-] = K_{HA_2^-}[HA][A^-]$$

Sur les figures 3 et 4 nous avons reporté les variations des concentrations des différentes espèces en fonction de la concentration analytique initiale dans le cas des acide chlorhydrique et nitrique; l'intérêt de ces graphiques est de montrer de façon claire l'influence de la concentration sur le mode de dissociation de l'acide envisagé. Dans le cas de l'acide HCl la variation du pH s'effectue en 1/2 log C_a pour des concentrations d'acide inférieures à 10^{-4} M, c'est-à-dire pour les solutions les plus diluées, l'acide se dissocie ici comme dans l'eau selon l'équilibre simple:

$$HCl \rightleftarrows H^+ + Cl^-$$

Le pH est donné par la formule:

$$pH = \tfrac{1}{2}\,pK_{HA} - \tfrac{1}{2}\log C_a$$

Au contraire pour des concentrations supérieures à 10^{-2} M la variation du pH s'effectue en log C_a, l'acide se dissocie alors principalement selon l'équilibre:

$$2\,HCl \rightleftarrows H^+ + HCl_2^-$$

Le pH est donné par la formule:

$$pH = \tfrac{1}{2}\,pK_{2HA} - \log C_a$$

La figure 4 montre qu'il y a exaltation de l'acidité lorsque ce mode de dissociation prédomine. Lorsque la concentration d'acide évolue entre 10^{-2} M et 10^{-4} M, c'est-à-dire aux concentrations analytiques courantes il y a superposition des deux équilibres. Les résultats sont tout à fait analogues dans le cas de l'acide nitrique et des autres acides étudiés.

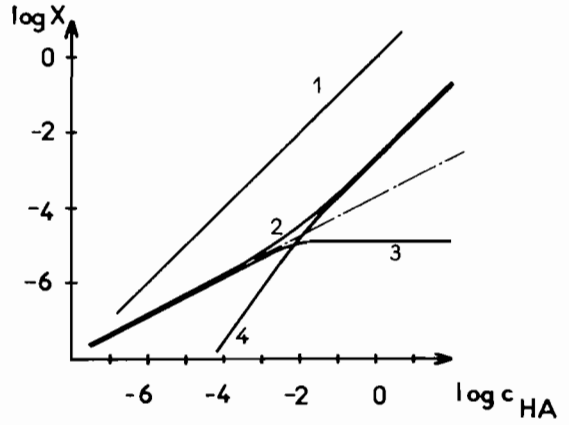

FIG. 3. Concentration des différentes espèces X en fonction du log de la concentration d'acide nitrique. (1) HNO_3; (2) H^+; (3) NO_3^-; (4) $H(NO_3)_2^-$.

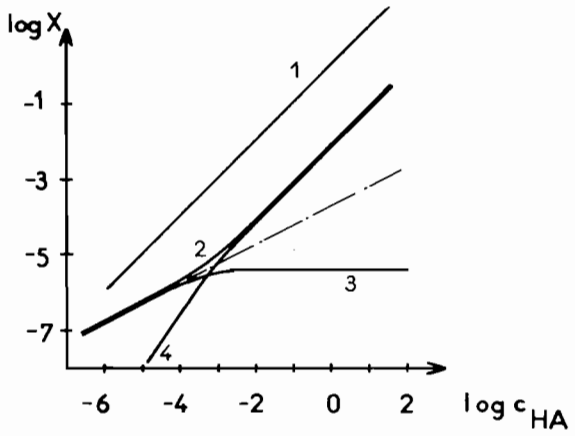

FIG. 4. Concentration des différentes espèces X en fonction du log de la concentration d'acide chlorhydrique. (1) HCl; (2) H^+; (3) Cl^-; (4) $H(Cl)_2^-$.

Sur les figures 5 et 6 relatives à l'acide chlorhydrique nous avons également représenté le pourcentage des différentes espèces en fonction du logarithme de la concentration d'acide C_0 et du pH. Cette dernière représentation est intéressante car elle matérialise l'évolution des concentrations au cours du titrage de l'acide. Le calcul a été effectué pour deux concentrations, on y voit en particulier que le pourcentage d'espèces HA_2^- formé passe par un maximum pour pH = pK_{HA} et qu'il est d'autant plus important que la concentration initiale est grande ainsi que la constante $K_{HA_2^-}$. Dans le cas de l'acide chlorhydrique à la concentration 0,004 M le pourcentage d'espèces HCl_2^- formé à la demi-équivalence n'excède pas 30% alors que la formation quantitative correspondrait à 50% de la concentration initiale d'acide.

Etude des couples B/BH⁺

Nous avons étudié la neutralisation de nombreuses bases faibles B dans l'oxydipropionitrile, contrairement au cas des acides les courbes de titrages potentiométriques à l'électrode de verre ou à hydrogène sont facilement interprétables dans la plupart des cas.

L'analyse mathématique de la courbe de titrage avant le point équivalent montre que le potentiel adopté par l'électrode répond à l'équation:

$$E = A + 0{,}06 \log \frac{[B]}{[HB^+]}$$

L'équilibre de dissociation de l'acide HB^+ est donc de la forme:

$$K_{HB^+} = \frac{[B][H^+]}{[HB^+]}$$

$$HB^+ \rightleftarrows B + H^+$$

Dans ce cas, l'absence de phénomène d'homoconjugaison du type:

$$B + HB^+ \rightarrow B_2H^+$$

peut s'expliquer par la possibilité pour l'ion HB^+ d'être solvaté par échange de liaison hydrogène avec une molécule d'oxydipropionitrile. Dans le tableau 3 sont reportés les pK_{HB^+} pour un certain nombre de couples B/HB^+. L'examen des résultats montre que les acides HB^+ sont très affaiblis par rapport à l'eau, cependant la force des bases B ne peut être déterminée étant donné l'inconnue concernant le produit ionique de l'oxydipropionitrile probablement non accessible.

Néanmoins la connaissance du pK_{HB^+} des couples B/HB^+ permet d'apprécier l'importance du saut de pH lors du titrage d'une base B par un acide.

L'écart ΔpK_{HB^+} mesuré dans l'eau et l'oxydipropionitrile pour les couples B/HB^+ permet grossièrement de les répartir en deux groupes. Le premier groupe comprend les bases ayant une structure d'aniline pour lequel ΔpK_{HB^+} est voisin de 3,5 unités; le second groupe comprend les autres bases étudiées pour lesquelles ΔpK_{HB^+} est de l'ordre de 6,5 unités (tableau 3).

Dans l'oxydipropionitrile des bases aussi faibles que l'urée, la *méta*-nitroaniline, la *para*-nitroaniline, le DMSO, le HMPT peuvent être dosées; nous verrons que le décalage de l'échelle d'acidité vers les milieux acides permet d'expliquer ce comportement.

Remarque: l'analyse des courbes de titrage conductimétriques de bases faibles B par des acides très faibles HA dans l'oxydipropionitrile (benzoïque, salicylique) montre que ces courbes n'ont pas même allure que dans l'eau (fig. 7). La première partie est semblable et correspond à la formation de l'espèce HB^+A^-, au-delà du point équivalent on constate que la conductivité continue de croître, ceci est dû à la formation de l'espèce homoconjuguée $HB^+HA_2^-$. Lors du titrage par l'acide picrique l'allure de la courbe est identique à celle observée dans l'eau, ceci confirme le comportement différent de cet acide dans l'oxydipropionitrile.

Corrélation des échelles d'acidité; discussion des résultats

La connaissance du paramètre de solvatation du proton $\gamma_{t(H^+)E\rightarrow S}$ permet de situer l'échelle d'acidité dans l'oxydipropionitrile par rapport à celle de l'eau par exemple, il est alors nécessaire d'évaluer

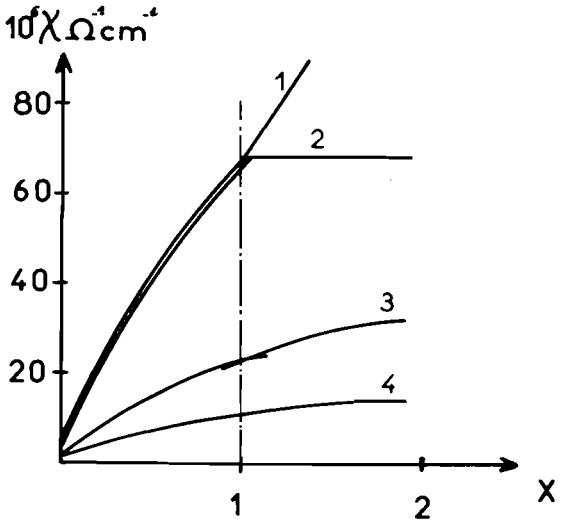

FIG. 7. Titrage conductométrique de la butylamine 0,01 *M* par différents acides. (1) Par acide perchlorique; (2) par acide picrique; (3) par acide salicylique; (4) par acide benzoïque.

le potentiel normal de l'électrode à hydrogène par rapport à une référence de potentiel commune à tous les milieux. Pour des raisons de commodité, nous utiliserons l'hypothèse de Strehlow malgré ses inconvénients déjà cités (17, 18).

Le potentiel normal du système H^+/H_2 a été déterminé au moyen de l'électrode à hydrogène en étudiant la partie située au-delà du point équivalent du titrage d'une base par un acide fort. Les électrodes de verre et à hydrogène ayant un fonctionnement correct dans l'oxydipropionitrile comme le montre la courbe $(E_{1/2})_{H_2} = f(E_{1/2})_{verre}$[2] qui est une droite de pente 1; on peut facilement connaissant le potentiel mesuré à l'électrode de verre pour une solution 1 *M* en déduire le potentiel normal apparent du couple H_2/H_S^+, les résultats sont équivalents. La mesure ayant été effectuée par rapport à l'électrode de référence Ag/Ag^+ 10^{-2} *M*, il suffit d'effectuer le décalage correspondant:

$$E^0_{H^+/H_2(Fc/Fc^+)} = E^0_{H^+/H_2(Ref)} - E^0_{Ref(Fc/Fc^+)}$$

Dans ces conditions Strehlow définit la fonction Redox $R_0{}^0(H^+)$ qui s'identifie à $\log \gamma_{t(H^+)}$ au signe près:

$$R_0{}^0(H^+) = \frac{{}^E E^0_{H^+/H_2} - {}^S E^0_{H^+/H_2}}{0{,}06}$$

$$= \frac{-0{,}390 + 0{,}143}{0{,}06} = -3{,}95$$

[2]$E_{1/2}$ = potentiel de demi-neutralisation d'une base ou d'un acide.

Le proton est donc beaucoup moins solvaté dans l'oxydipropionitrile (en réalité le mélange ODPN + H_2O = 0,01 *M*) que dans l'eau et l'échelle est décalée de 4 unités vers les milieux acides. La comparaison avec l'acétonitrile où log $\gamma_{t(H^+)}$ = +5,95 (19) montre que le proton est légèrement plus solvaté dans l'oxydipropionitrile (figures 8 et 9). L'obtention de la véritable valeur de log $\gamma_{t(H^+)}$ en milieu rigoureusement anhydre se heurterait aux mêmes difficultés que dans d'autres solvants peu basiques.

Force des acides HB^+

Connaissant ${}^{E}pK_{HB^+}$, ${}^{S}pK_{HB^+}$ et log $\gamma_{t(H^+)}$ on calcule aisément le terme log $\gamma_{t(B)}/\gamma_{t(HB^+)}$ qui est voisin de −0,2 dans le cas des différentes anilines étudiées. Dans ces conditions l'augmentation du pK_{HB^+} de cette catégorie d'acide n'est due qu'à la plus faible solvatation du proton et les pK_{HB^+} de ces couples dans l'eau, l'acétonitrile et l'ODPN se situent approximativement sur des horizontales (fig. 8). Ceci permet de vérifier approximativement l'hypothèse de Hammett puisque log $\gamma_{t(B)}$ # log $\gamma_{t(HB^+)}$.

Dans le cas des autres acides HB^+ l'affaiblissement de la force est dû à la faible solvatation du proton et à l'augmentation du terme log $\gamma_{t(B)}/\gamma_{t(HB^+)}$ qui varie d'ailleurs selon l'acide.

Force des acides HA

L'affaiblissement des acides HA est dû à la faible solvatation du proton et à la très faible solvatation de l'anion A^- qui se traduit par l'importance du terme log $\gamma_{t(A^-)}/\gamma_{t(HA)}$ voisin de 6 unités. Ces résultats sont tout à fait en accord avec l'existence des phénomènes d'homoconjugaison précédemment démontrés pour la plupart des acides HA. On peut observer que l'ODPN permet de différencier les acides forts dans l'eau, il n'y a pas d'effet nivelant du milieu.

Mesure du pH par utilisation du couple quinone–hydroquinone

Dans l'eau le système quinone–hydroquinone est un indicateur de pH utilisable pratiquement entre 0 et 8 de façon commode. L'acide H_2Q étant un acide HA, on peut prévoir d'après les résultats précédents un affaiblissement de cet acide permettant d'envisager une utilisation dans un domaine de pH plus important dans l'ODPN.

Nous avons représenté sur la figure 10 la courbe de titrage d'un mélange de pyridine et de triéthanolamine par l'acide perchlorique. Le traitement mathématique de chaque partie de la courbe de titrage montre que le potentiel de l'électrode à quinhydrone varie linéairement avec une pente de 60 mV en fonction de log [B]/[HB^+], l'hydroquinone se trouve donc sous forme H_2Q dans ce domaine de pH.

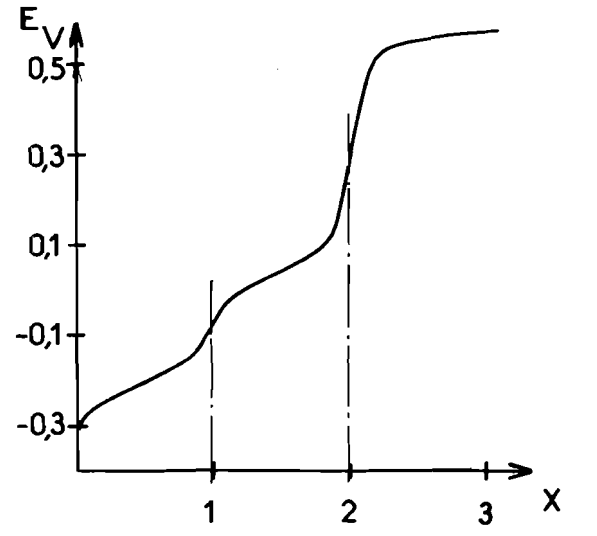

FIG. 10. Titrage potentiométrique d'un mélange pyridine–triéthanolamine par l'acide perchlorique (électrode indicatrice à quinhydrone).

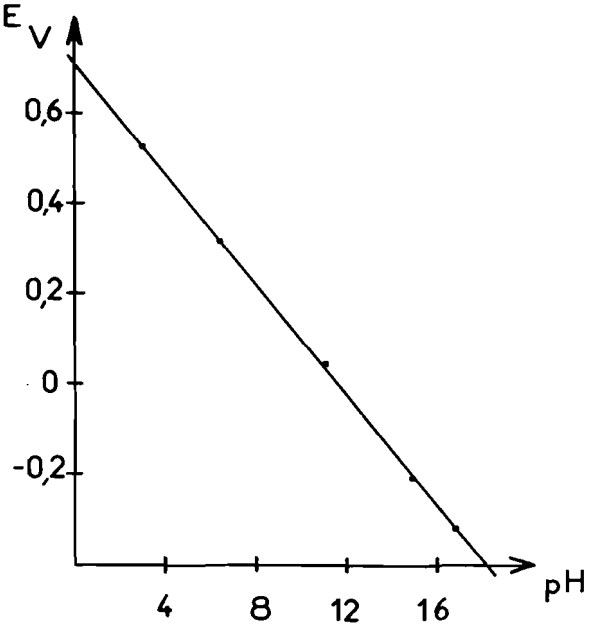

FIG. 11. Diagramme potentiel pH du système quinone hydroquinone.

L'équation de réponse de l'électrode est donnée par:

$$E = E_0 - 0{,}06\ pK_{HB^+} - 0{,}06 \log \frac{[B]}{[HB^+]}$$

Sur la figure 11 sont reportées les variations du potentiel de l'électrode H_2Q/Q en fonction du pH

de demi-neutralisation de quelques amines, on observe une variation linéaire permettant de déterminer le potentiel normal apparent du couple H_2Q/Q.

E^0 = 0,720 V par rapport à la référence Ag/Ag^+ $10^{-2}M$

Le résultat est identique à celui obtenu en étudiant la réponse de l'électrode en milieu acide fort.

Conclusion

Cette étude nous a permis de montrer que les électrodes de verre et à hydrogène sont indicatrices de l'activité du proton dans l'oxydipropionitrile. Malgré la forte constante diélectrique de ce milieu les acides HA sont très peu dissociés par suite de la faible solvatation des anions, l'allure des courbes de titrage montre qu'il faut tenir compte des phénomènes d'homoconjugaison. Par suite du décalage de l'échelle d'acidité dans les milieux acides, on peut titrer des bases très faibles dans l'eau avec une meilleure précision, de même il est possible de différencier facilement les acides forts dans l'eau. L'ensemble de ces propriétés laisse apparaître un comportement de l'oxydipropionitrile voisin de l'acétonitrile vis à vis des acides et des bases. Si l'origine de l'échelle d'acidité a pu être déterminée il n'est pas de même du pK_i de l'oxydipropionitrile, le solvant apparaît comme non limitant vers les milieux basiques, néanmoins il paraît exclu d'y trouver une base forte ne le décomposant pas.

Enfin l'utilisation du couple oxydoréducteur H_2Q/Q faisant intervenir le pH permet de couvrir en partie l'échelle d'acidité déterminée; l'étude plus approfondie d'autres systèmes quinoniques indicateurs du pH semblerait pouvoir être envisagée.

Actuellement notre travail porte plus spécialement sur la définition d'une échelle d'acidité dans les mélanges eau–oxydipropionitrile se séparant lors de la démixtion il fera l'objet d'un prochain mémoire rassemblant les résultats concernant l'acidité dans les mélanges H_2O–ODPN.

Thermal fragmentation of 3-alkyl-2-phenyloxetanes, 3,3-dimethyl-2-aryloxetanes, and related compounds. A case study of 2-aryl-substituted oxetanes

TOSHIRO IMAI AND SHINYA NISHIDA[1]

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo, Hokkaido 060, Japan

Received August 19, 1980[2]

TOSHIRO IMAI and SHINYA NISHIDA. Can. J. Chem. **59**, 2503 (1981).

Thermolyses of epimeric 3-alkyl-2-phenyloxetanes (**1***c*, **1***t*, **2***c*, **2***t*, **3***c*, and **3***t*), 3,3-dimethyl-2-aryloxetanes (**4**, **5**, **6**, **7**, and **8**), 3,3,4,4-tetramethyl-2,2-diphenyloxetane (**9**), and 3,3-dimethyl-2,2-diphenyloxetane (**10**) were studied in degassed *N,N,N',N'*-tetramethylethylenediamine at 270–350°C. Although the fragmentation of **9** and **10** can be understandable on the basis of a diradical mechanism, there were several observations, in the reaction of certain other oxetanes, which could hardly be explained simply in terms of such a mechanism. Namely, (*1*) less strained **1***t* reacted faster than more strained **1***c*; (*2*) a major mode of the fragmentation for **1***c*, **2***c*, and **3***c* was "B" (forming an alkene and benzaldehyde), whereas that for **1***t*, **2***t*, and **3***t* was "A" (forming an alkenylbenzene and formaldehyde); (*3*) the apparent energy of activation for the "B" process seemed to be larger than that for the "A"; (*4*) a dramatic change of the major fragmentation mode from "B" to "A" was brought about by a substituent on the phenyl group, as was observed in **4**–**8**. These results may be explained reasonably by assuming that the fragmentation proceeds, at least, in dual reaction courses. In competition with an anticipated diradical pathway, there will be another process, which is energetically little more favorable than the diradical fragmentation, rather specific to the "A" mode of fragmentation, and important particularly in the reaction of the *trans* isomers. Probable candidates for the second process are discussed.

TOSHIRO IMAI et SHINYA NISHIDA. Can. J. Chem. **59**, 2503 (1981).

Dans la *N,N,N',N'*-tétraméthyléthylènediamine dégazée à 270–350°C on a étudié la thermolyse des alkyl-3 phényl-2 oxetannes (**1***c*, **1***t*, **2***c*, **2***t*, **3***c* et **3***t*), des diméthyl-3,3 aryl-2 oxetannes (**4**, **5**, **6**, **7** et **8**) épimères, du tétraméthyl-3,3,4,4 diphényl-2,2 oxetanne (**9**) et de la diméthyl-3,3 diphényl-2,2 oxetanne (**10**). On peut comprendre la fragmentation des composés **9** et **10** en fonction d'un mécanisme biradicalaire, mais certains faits observés dans la réaction de certains autres oxétannes, ne peuvent être interprétés selon ce mécanisme. En particulier (*1*) le composé le moins encombré **1***t* réagit plus rapidement que le composé **1***c* plus encombré; (*2*) la voie principale de fragmentation de **1***c*, **2***c* et **3***c* est la voie "B" (conduisant à un alcène et à la benzaldéhyde) tandis que les composés **1***t*, **2***t* et **3***t* se fragmentent suivant la voie "A" (conduisant à un alcénylbenzène et à la formaldéhyde); (*3*) l'énergie apparente d'activation de la voie "B" semble être plus élevée que celle de la voie "A"; (*4*) dans le cas des composés **4**–**8** la présence d'un substituant sur le groupe phényle provoque un changement radical dans la fragmentation qui passe de la voie "B" à la voie "A". On peut raisonablement expliquer ces résultats en admettant que la fragmentation se fait au moins des deux façons au cours de la réaction. Il existe un autre processus énergiquement plus favorisé qui entre en compétition avec la fragmentation biradicalaire et qui est plus spécifique à la voie de fragmentation "A". Ce processus est particulièrement plus important dans la réaction des isomères *trans*. On discute des substances qui éventuellement se fragmenteront selon ce second processus.

[Traduit par le journal]

Introduction

The thermal fragmentation of oxetanes has most frequently been discussed in terms of a stepwise diradical mechanism (1) although several workers have stated that a concerted pathway cannot be rigorously ruled out (1*d*,*f*,*g*). We noted some time ago that the thermal behavior of isomeric 3-propyl-2-phenyloxetanes in decane seems to indicate an intervention of a nonradical pathway, particularly in the reaction of the *trans* isomer (2). Shortly after our communication, however, Jones and Kleinman (3) demonstrated that both rates and modes of the oxetane fragmentation are influenced by impurities, probably acidic contaminants, in the reaction system. Several other workers also noted high sensitivity of the cleavage modes to wall effects in the vapor phase thermolysis (1*h*, *j*, *k*). These observations suggest that the oxetanes are quite sensitive to the acidic sites in the reaction system. It turns out that our previous results may possibly be an outcome of the thermal process intermingled with acid-catalyzed decomposition. Accordingly, we re-examined the thermolyses of several representative 2-aryloxetanes (**1**–**10**) under conditions which may guarantee us the reaction free from the stain of the acid-catalyzed process. The solvent we chose is *N,N,N',N'*-tetramethylethylenediamine (TMEDA), which has been used to investigate the thermal behavior of extremely acid-sensitive compounds, such as bicyclobutane (4). In TMEDA, it was demonstrated that the acid-catalyzed process was absent, but the products were not stable enough to allow us to carry out the kinetic studies. The thermolysis was, therefore, examined only qualitatively.

Results and Discussion

Preparation of Oxetanes

cis and *trans*-3-Methyl-2-phenyloxetanes (**1***c* and **1***t*) and *cis*-3-*tert*-butyl-2-phenyloxetane (**3***c*) were synthesized from corresponding *erythro*- and

threo-2-alkyl-1-phenyl-1,3-propanediols according to the procedures described by Balsamo *et al.* (5). The other oxetanes, including *cis*- and *trans*-3-isopropyl-2-phenyloxetanes (**2***c* and **2***t*), *trans*-3-*tert*-butyl-2-phenyloxetane (**3***t*), 3,3-dimethyl-2-*p*-methoxyphenyloxetane (**4**), 3,3-dimethyl-2-*p*-methylphenyloxetane (**5**), 3,3-dimethyl-2-phenyloxetane (**6**), 3,3-dimethyl-2-*p*-chlorophenyloxetane (**7**), 3,3-dimethyl-2-*m*-chlorophenyloxetane (**8**), 3,3,4,4-tetramethyl-2,2-diphenyloxetane (**9**), and 3,3-dimethyl-2,2-diphenyloxetane (**10**), were prepared by the Paterno–Büchi reaction (6). Compounds **2***t* and **2***c* were separated and purified by vpc. Compound **4** was readily decomposed under the vpc conditions, but its purification was accomplished successfully by medium-pressure liquid chromatography followed by repeated vacuum distillations. The stereochemical assignment of **1***c*, **1***t*, and **3***c* based on the ^{1}H nmr data was in accordance with that deduced from the consequence of the ring closure process (5). The configurations of **2***c*, **2***t*, and **3***t* were assigned from the characteristics observed in the ^{1}H nmr spectra: $J_{2,3}(cis) > J_{2,3}(trans)$, $\delta_{C2\text{-}H}(cis) > \delta_{C2\text{-}H}(trans)$, and $\delta_{C3\text{-}H}(cis) > \delta_{C3\text{-}H}(trans)$.

Thermolysis of 9 and 10; Examination of Reaction Conditions

As reported by Jones and Kleinman (3), the fragmentation of **9** was indeed sensitive to the reaction conditions. Base treatments of solvent and/or the reaction vessel resulted in an increase in the amount of benzophenone and 2,3-dimethyl-2-butene ("B" mode product)[3] at the expense of the amount of 1,1-diphenyl-2-methylpropene and acetone ("A" mode products).[3] For example, at 310°C, the A/B ratio was 4:96 in simply dried and distilled decane, but it was 2:98 in repeatedly base-washed, dried, and distilled decane. Similarly, varing degrees (1–4%) of the "A" mode fragmentation were observed in diphenylmethane, diphenyl ether, and *N*,*N*-dimethylformamide. Finally, we found that the "A" products (A/B = 0.4:99.6) were produced in least amount in organic bases, such as TMEDA and *N*,*N*-dimethylaniline.

In order to see whether the extreme A/B ratio observed in the amines was meaningful or not, we evaluated the relative importance of the two modes in the diradical fission of **9**. Among four possible diradicals expected from **9** in the first step of the homolytic ring cleavage, **11** and **12** may be worthy

12

of consideration, since only these two held a benzhydryl radical portion. We, therefore, assume that the relative rates of producing **11** and **12** will be reflected in the A/B ratio. As mentioned in the following section, the geometrical isomerization of the starting oxetane is slower than its fragmentation. Therefore, the first bond fission will practically be a product controlling step, as has been concluded in the thermolysis of 2,3-dimethyloxetanes (**1***c*).

Now, the evaluation of the heat of formation of **11** and **12** meets with difficulties, because two key values, namely $\dot{C}\text{-}(C_B)_2(O)$ and $\dot{C}\text{-}(C)(C_B)_2$, are not available in the literature (7). We, therefore, used kinetic data in the following estimation. At first, we assume that the cleavage of the 1–2 (C—O) bond and the 2–3 (C—C) bond will occur with nearly equal ease provided that the substituent effects are common to both cleavages. This assumption is based on the fact that the precise thermochemical calculations have shown that all four bonds in parent oxetane are approximately equally easily broken (**1***f*, *g*). Experimental verification of this assumption is found in the thermolysis of 2-ethyloxetane (**1***h*), which produces the "A" and "B" products in nearly the same amounts (A/B = 53:47). A similar result has been obtained in the photolysis of 2,2-dimethyloxetane (A/B = 54:46) (**1***l*). The second assumption we made is that the substituent effects exerted by the groups at C3 and

[3]For convenience, the terms "A" and "B" are used in the present paper. The "A" mode refers to a cleavage of 1–2 and 3–4 bonds to produce a styrene derivative, which is a preferred mode observed in the acid-catalyzed decomposition.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

C4 in the remote 1–2 bond cleavage will be small enough to neglect, compared to those in the 2–3 cleavage. If these assumptions are accepted, the difference in the activation barriers leading to **11** and **12** may be estimated simply from two factors operating in the 2–3 bond fission. Namely, (*a*) the electronic effect of the substituents at C3, and (*b*) the steric effect caused by the interactions between the groups at C2 and C3. For (*a*), it has been reported that 3,3-dialkyloxetanes have E_a lower than the parent compound by ca. 3 kcal/mol (1*g*). It suggests that the two methyl groups at C3 in **9** will lower the energy barrier of the 2–3 fission by ca. 3 kcal/mol relative to that of the 1–2 cleavage. As to (*b*), the steric repulsion between the methyls at C3 and phenyls at C2 may be estimated from the "*cis* correction terms" (7*a*), which suggests that the strain release of ca. 3 kcal/mol will be anticipated in going from **9** to **12**. As a total, the process producing **12** will be energetically more favorable than that yielding **11** by ca. 6 kcal/mol. Although the energy difference thus estimated will be valid only in round numbers, it may safely be concluded that the "B" fragmentation will be favorable over the "A" process by several kcal/mol. It turns out that the A/B ratio at 310°C will be ca. 0.6:99.4.

Experimentally, the A/B ratio observed in the thermolysis of **9** was 0.4:99.6. Compound **10** also gave a close A/B ratio, 0.3:99.7, although **10** lacked the two methyl groups at C4. This result, therefore, supports the previous assumption that the 3–4 and 1–4 cleavages are of negligible importance as the first step of the homolytic decomposition of **9**. Since the observed ratio is close to that estimated, it may safely be said that the reaction in the amine is totally the homolytic process free from the stain of the acid-catalyzed fragmentation. In addition, the exclusion of oxygen was necessary to obtain reproducible results. Thus, the thermolyses described hereafter were carried out in degassed TMEDA.

Regioselectively in the Thermolysis of 3-Alkyl-2-phenyloxetanes

In degassed TMEDA, **1***c*, **1***t*, **2***c*, **2***t*, **3***c*, and **3***t* were pyrolyzed. Unfortunately, benzaldehyde (one of the "B" mode products) was unstable under the reaction conditions. The resultant alkenyl benzene (the "A" mode product) isomerized slowly to the geometrical isomer in hot TMEDA, as well. Accordingly, kinetic studies could not adequately be carried out. We therefore examined the reaction qualitatively and paid special attention to the A/B ratio. The reaction was interrupted at relatively early stages and the figures were calibrated for the decreased amount of benzaldehyde under the given reaction conditions.

From the results summarized in Table 1, we can note several characteristic points of the present thermolyses. (*1*) The extent of the decomposition of **1***t* was apparently greater than that of **1***c* after the same reaction period at 270°C or 310°C. This was further confirmed in the competitive thermolysis. Thus, after heating a 1:1 mixture of **1***t* and **1***c* at 310°C for 3.5 h, the consumption of **1***t* was 37% whereas that of **1***c* was 28%. In contrast, **2***c* and **3***c* were more reactive than **2***t* and **3***t*, respectively. (*2*) The major mode of the fragmentation was different in the epimeric pair of these oxetanes. In the reaction of the *cis* isomers, the "B" mode was major (79–97%), whereas it was minor (ca. 30%) in the thermolysis of *trans* isomers. (*3*) The proportion of the "B" process in a given oxetane increased at the higher temperature, suggesting that the "B" fragmentation will have a greater apparent energy of activation than the "A" process has.

Epimerization of Oxetanes during the Thermolysis

3-Alkyl-2-phenyloxetanes isomerized in hot TMEDA, but the extent of the epimerization remained small, as has been reported for the thermolyses of 2,3-dimethyloxetanes and 1,2-dimethylcyclobutanes (1*c*, 8*a*). After 3 h at 310°C, the amount of the epimer present in the recovered oxetane was 2.2% for **1***c* (21% conversion), 1.4% for **1***t* (29%), 2.7% for **2***c* (25%), 0.7% for **2***t* (14%), 15% for **3***c* (62%), and none for **3***t* (14%). Except for the *tert*-butyl derivatives, the extent of the isomerization after 50% conversion may be calculated as ca. 5% for the *cis* isomers and ca. 2.5% for the *trans* isomers, if both the fragmentation and epimerization are assumed to be the unimolecular process. The decomposition is clearly faster than the *cis*–*trans* isomerization of the reactant. Even in the case of **3***c*, the epimerization will occur to the extent of only 12.5% after 50% conversion. Therefore, the epimerization of the starting oxetanes is neglected in the following discussion.

Mechanistic Consideration

In the homolytic decomposition of 3-alkyl-2-phenyloxetanes, four diradicals, **13** and **14** from C—C fission and **15** and **16** from C—O fission, are possibly produced. Among them, **13** and **15** will play the major role in determining the preferential mode of the fragmentation, because they place an electron at the benzylic carbon atom whereas the other two do not. Now, certain results may be explained simply by the diradical mechanism. Namely; the most highly strained **3***c* exhibits the highest reactivity, **3***c* gives overwhelmingly the

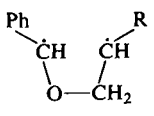
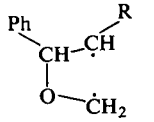
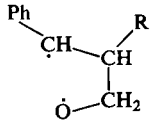
"B" products (97%),[4] **2***c* and **3***c* react faster than **2***t* and **3***t*, respectively, and the *cis* isomer produces a larger amount of the "B" fragments than the corresponding *trans* isomer does. Partial isomerization of the reactant will also be compatible with such a mechanism, although a possibility that the epimerization takes place not in the ring cleavage–reclosure process but via a benzylic carbanion produced by the deprotonation with hot TMEDA may not be ruled out.



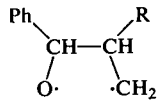
13



14



15



16

On the other hand, the features (*1*)–(*3*) summarized in the previous section may not adequately be explained by the diradical mechanism alone. In the thermolytic studies of *cis*- and *trans*-2,3-dimethyloxetanes, Holbrook and Scott (1*c*) have shown that *the* cis *isomer exhibits a higher reactivity than the* trans *isomer* and *that propene formation ("B" process) is favoured over 2-butene production ("A" process) in both isomers*; the [propene]/[butene] ratio is 1.7 for *cis* and 1.3 for *trans*. Similar results ([propene]/[butene] = 2.1 for *cis* and 1.2 for *trans*) have also reported by Carless (1*e*). These results are qualitatively the same as those observed in the thermolysis of 1,2-dimethylcyclobutane (8*a*), although the more pronounced preference for propene formation has been noted. A higher reactivity and a larger [propene]/[butene] ratio for the *cis* isomer is attributed to the *cis* effect, which has been considered as an important factor in the cyclobutane fragmentation (8). The fact that the propene formation is the major course even in the reaction of the *trans* isomer sounds reasonable, because a large portion of propene may be produced from a more stable secondary–secondary diradical. In the oxetane fragmentation, as discussed in the previous section, we need practically no discrimination for the intrinsic ease of C—C and C—O fissions. Therefore, the secondary–secondary carbon–carbon diradical will be produced more favorably, at least to a small extent, than other diradicals including a secondary carbon–oxygen diradical. The experimental results have been in accordance with these arguments (1*c*, *e*).

After this discussion, it may be found that the feature (*2*) in the previous section seems to be unexpected. Diradical **13** will be slightly more stable than, or as stable as, **15** and hence the "B" process should occur to an extent at least similar to that of the "A" process, if the reaction proceeds totally via the diradical intermediates. The temperature dependency of the A/B ratio also seems to contradict the presumed relative stability of **13** and **15**. Finally, the most peculiar result was (*3*); the less strained **1***t* reacted faster than the more

[4]Since a considerable extent of epimerization was observed in **3***c*, the "B" process in genuine **3***c* should be larger than 97%.

strained **1***c*. All these contradictions seem to suggest that there could be a second reaction pathway, which is in narrow competition with the diradical process. The second pathway should be energetically more favorable than the diradical fission, rather specific to the "A" cleavage, and important especially in the reaction of the *trans* isomer. A possible candidate for such a process will be either a stepwise process via a zwitterionic intermediate or a concerted cycloreversion (1*d*, *f*, *g*, 9).

Interposition of the stepwise ionic process may satisfy the above requirements in the following way. The ionic cleavage wil be energetically more favorable than the diradical fission in TMEDA and specific to the "A" fragmentation, since a benzylic cation and an oxy-anion should be preferentially produced. A reason for the unimportance of the ionic process in the reaction of *cis* isomer will be the steric effect. As suggested by Mulzer *et al.* (10) in the thermolytic studies of 2-oxetanones, the phenyl group may not rotate in the plane of the developing sp^2 carbon atom in the transition state of the *cis* isomer.

Alternatively, intervention of the concerted fragmentation may fulfill the requirements in the following manner. The concerted process may be the pathway of lower energy barrier. The preferred "A" mode in the cycloreversion will be due to the more favorable HOMO–LUMO interaction for the "A" fragmentation than for the "B" (11). In the "A" fission, the HOMO–LUMO pair should be styrene and formaldehyde, whereas it should be ethylene and benzaldehyde in the "B" process. From the ionization potential data (12) and n–π^* transition energies (13), we can estimate that the HOMO–LUMO gap of the "A" cleavage will be 1.7 eV, which is substantially smaller than that of the "B" fission, 4.8 eV. Unimportance of the concerted cycloreversion in the *cis* isomers, as well as in **9** and **10**, may be due to the steric destabilization of the transition state. In the thermolytic studies of 2-oxetanones, we[5] have demonstrated that the *cis* isomer reacts more slowly than the corresponding *trans* isomer and proposed that the important factor is the steric destabilization of the concerted transition state (14).

Among these alternatives, we prefer to take the concerted fragmentation as a possibility for the second reaction pathway. This is because we could find no anomaly in the thermal behavior of **9** and **10**; the results were consistent with the diradical mechanism. The aforementioned steric destabilization of the ionic process will be most important in the *cis-tert*-butyl derivative, but only moderately in the *cis*-methyl derivative (10). In **9** and **10**, the substituent at C3 *cis* to the phenyl group at C2 is a methyl group. Therefore, a certain degree of stabilization of the incipient cation will be provided by the phenyl groups in the reaction of **9** and **10**. In such a case, the ionic process should take a part in the reaction and the results may not simply be analyzed by the diradical mechanism alone.

A possibility that the concerted fragmentation may be feasible in the fragmentation of oxetanes has been pointed out by several workers (1*c*, *d*, *f*, *g*), but the experimental verification of such a process has not yet been carried out successfully. The present results suggest that, if our conclusion is valid, the concerted process will be favored over the diradical process only to a small magnitude. The 2-aryloxetanes will indeed be decomposed in the competing dual reaction courses. Small steric destabilization of the transition state will easily make an intervention of the second reaction pathway obscure. The reactivity reversal was in fact observed only in the 3-methyl derivatives, **1***c* and **1***t*. In the literature, somewhat unusual behavior of 2-phenyloxetane has occasionally been described (1*j*, *k*, *l*). The HOMO–LUMO gap may be sufficiently small in 2-aryloxetanes but may not be so in other oxetanes, including 2-alkyl derivatives. After all, it will be concluded that the diradical fission is, in general, the preferred mode of the oxetane fragmentation. 2-Aryloxetanes seem to be exceptional.

Thermolysis of 3,3-Dimethyl-4-aryloxetanes; the Substituent Effect on the A/B Ratio

Parent oxetane **6** gave an A/B ratio of 7:93 at 270°C. The fragmentation will proceed primarily via the diradical intermediates. In contrast, the oxetanes substituted by an electron-donating group at the benzene ring showed dramatic changes in the A/B ratio: A/B = 37:63 for **5** and 91:9 for **4**. Introduction of an electron-withdrawing chlorine to the aromatic ring yielded a small, opposite effect on the A/B ratio (Table 1). Again, the results may be explained by the dual mechanism, with intervention of either the stepwise ionic process or the concerted cycloreversion in addition to the diradical fission in the reaction of **4** and **5**. In terms of the concerted process, it can be anticipated that the

[5]We have thermolyzed 4-aryl-2-oxetanones in decane and found that $\rho = -1.52$ (14). Together with the clean stereospecificity of the reaction, we have proposed a concerted mechanism. Recently, however, Mulzer *et al.* (10) have examined the reaction in 1,2-dichlorobenzene. They have observed $\rho = -3.4$ and proposed an ionic process. The usage of a relatively polar solvent ($\varepsilon = 9.93$) seems to result in more pronounced charge development at the transition state.

*Only after 1.5 h.

electron-releasing substituent wil lower the HOMO level of the styrene moiety and hence reduce the HOMO–LUMO gap for the "A" fragmentation. At present, however, we cannot rule out a possibility that the second process for **4** and **5** is the stepwise ionic pathway.[6]

Stereochemical Results of the "A" Fragmentation

If the concerted process intervenes in the "A" fragmentation to a significant extent, the alkenylbenzene produced should retain the configuration of the starting oxetane to a considerable degree. Unfortunately, however, alkenylbenzenes were found to isomerize significantly to the geometrical isomer under the reaction conditions. For example, 1-propenylbenzene produced in the thermolysis of **1***c* at 310°C was a mixture of *cis* and *trans* isomers in a ratio of 83 : 17 after 1.5 h, but in a ratio of 69 : 31 after 3 h (Table 2). The epimerization of the starting oxetane also took place to a certain extent in hot TMEDA, as mentioned in the previous section. Moreover, the "A" process will not totally be the concerted cycloreversion. It is, therefore, meaningless to draw any conclusion regarding the stereochemical consequence of the present fragmentation. Qualitatively, we can point out that the degree of the retention of configuration observed in the present study is higher than that observed in the thermolysis of 2-alkyl substituted oxetanes (1*c*, *d*, *e*).

Experimental

Infrared spectra were recorded on a Hitachi 215 grating spectrophotometer. The ^{1}H nmr spectra were obtained with a JEOL PS-100 spectrometer; the chemical shifts are given in parts per million from tetramethylsilane. Vapor phase chromatography work was done on a Hitachi 063 gas chromatograph. For the analysis of oxetanes, the Pyrex vpc column and solid supports (Celite 545) were pretreated with a 5% solution of chlorotrimethylsilane in toluene. Liquid phases used were Apiezon grease L (15%), polyethyleneglycol 20M (20%), and polyethyleneglycol succinate (15%). High-pressure liquid chromatography was carried out with a Hitachi 635 liquid chromatograph. Microanalyses were performed by the Center for Instrumental Analysis of Hokkaido University. Melting points and boiling points are uncorrected.

Oxetanes

Most of the oxetanes were prepared by the Paterno–Büchi reaction (6). Since the separation and purification of **1***c* and **1***t* obtained in the photoreaction were troublesome, they were synthesized from *erythro*- and *threo*-2-methyl-1-phenyl-3-(*p*-toluenesulfonyloxy)-1-propanols by following the reported procedures (5). The photoreaction of benzaldehyde with 3,3-dimethyl-1-butene gave a mixture rich in **3***t*. Compound **3***c* was prepared by the cyclization reaction.

The known oxetanes were identified by comparing their spectral data with those described in the literature: **1***c*, bp 60°C/3 Torr, n_D^{25} 1.5195 (5); **1***t*, bp 68–72°C/3 Torr, n_D^{25} 1.5145 (5); **6**, n_D^{25} 1.5073 (lit. (15) n_D^{20} 1.5118); **9**, mp 124–125°C (lit. (16) mp 123–125°C); **10**, mp 87–89°C (lit. (16) mp 88.5–90°C).

3-Isopropyl-2-phenyloxetanes (2c and 2t)

A benzene (100 mL) solution of benzaldehyde (2.9 g, 27 mmol) and 3-methyl-1-butene (7.8 g, 111 mmol) was irradiated with a high-pressure mercury lamp in a Pyrex reaction vessel under an argon atmosphere. After all benzaldehyde was consumed, the solvent was removed and the residue (4.5 g) was distilled under vacuum. A fraction, bp 59–69°C/1 Torr (1.6 g), was collected, which contained **2***c* and **2***t* in a 43 : 57 ratio as the major components (69%); **2***c* and **2***t* were isolated in a pure form by vpc. Compound **2***c*, ir (thin film) ν: 985 cm^{-1}; ^{1}H nmr (CCl_4) δ: 0.40 (d, J = 7 Hz, 3H), 0.65 (d, J = 7 Hz, 3H), 1.60 (m, 1H), 2.81 (m, 1H), 4.36 (t, J = 6.5 Hz, 1H), 4.67 (d of d, J = 8 and 6 Hz, 1H), 5.69 (d, J = 8 Hz, 1H), 7.28 (m, 5H); n_D^{25} 1.5106. *Anal.* calcd. for $C_{12}H_{16}O$: C 81.77, H 9.15; found: C 81.58, H 9.10. Compound **2***t*, ir (thin film) ν: 980 cm^{-1}; ^{1}H nmr (CCl_4) δ: 0.90 (t, J = 7 Hz, 6H), 2.1 (m, 1H), 2.4 (m, 1H), 4.32 (t, J = 6 Hz, 1H), 4.60 (d of d, J = 8 and 6 Hz, 1H), 5.28 (d, J = 6 Hz, 1H), 7.28 (m, 5H); n_D^{25} 1.5066. *Anal.* calcd. for $C_{12}H_{16}O$: C 81. 77, H 9.15; found: C 81. 87, H 9.12.

trans-*3-tert-Butyl-2-phenyloxetane (3t)*

From 8.9 g of benzaldehyde (84 mmol) and 7.4 g of 3,3-dimethyl-1-butene (88 mmol), a colorless liquid, bp 70–90°C/1 Torr (5.2 g), was obtained as above. The fraction contained 43% of **3***c* and **3***t* in a 25:75 ratio, from which **3***t* was isolated by vpc. Compound **3***t*, ir (thin film) ν: 985 cm^{-1}; ^{1}H nmr (CCl_4) δ: 0.95 (s, 9H), 2.57 (d of t, J = 8.7 and 6.8 Hz, 1H), 4.30–4.66 (m, 2H), 5.34 (d, J = 6.5 Hz, 1H), 7.28 (m, 5H); n_D^{25} 1.5048. *Anal.* calcd. for $C_{13}H_{18}O$: C 82.06, H 9.54; found: C 81.96, H 9.53.

3,3-Dimethyl-2-aryloxetanes (4, 5, 7, and 8)

The Paterno–Büchi reaction of *p*-methoxybenzaldehyde, *p*-methylbenzaldehyde, *p*-chlorobenzaldehyde, and *m*-chlorobenzaldehyde with 2-methylpropene proceeded without trouble to give **4**, **5**, **7**, and **8**. In all cases, a regioisomer was also produced but the desired oxetane was the major product (in a ratio of 8:2). Isolation and purification of **5**, **7**, and **8** were carried out as above, but **4** was unstable under the vpc conditions. Accordingly, **4** was isolated with a medium-pressure liquid chromatograph (Merck Lichroprep Si 60, hexane–ether 9:1 as an eluant) followed by vacuum distillation. Compound **4**, bp 60–65°C (bath temperature)/10^{-4} Torr; ir (thin film) ν: 980 cm^{-1}; ^{1}H nmr (CCl_4) δ: 0.75 (s, 3H), 1.33 (s, 3H), 3.76 (s, 3H), 4.10 (d, J = 5.2 Hz, 1H), 4.37 (d, J = 5.2 Hz, 1H), 5.29 (s, 1H), 6.79 (d, J = 8.5 Hz, 2H), 7.08 (d, J = 8.5 Hz, 2H); n_D^{25} 1.5177. *Anal.* calcd. for $C_{12}H_{16}O_2$: C 74.97, H 8.39; found: C 74.67, H 8.43. Compound **5**, ir (thin film) ν: 980 cm^{-1}; ^{1}H nmr (CCl_4) δ: 0.79 (s, 3H), 1.35 (s, 3H), 2.33 (s, 3H), 4.11 (d, J = 5.3 Hz, 1H), 4.37 (d, J = 5.3 Hz, 1H), 5.31 (s, 1H), 6.9–7.3 (m, 4H); n_D^{25} 1.5072. *Anal.* calcd. for $C_{12}H_{16}O$: C 81.77, H 9.15; found: C 81.92, H 9.12. Compound **7**, ir (thin film) ν: 980 cm^{-1}; ^{1}H nmr (CCl_4) δ: 0.77 (s, 3H), 1.37 (s, 3H), 4.12 (d, J = 5.3 Hz, 1H), 4.41 (d, J = 5.3 Hz, 1H), 5.33 (s, 1H), 7.0–7.4 (m, 4H); n_D^{25} 1.5227. *Anal.* calcd. for $C_{11}H_{13}OCl$: C 67.17, H 6.68, Cl 18.02; found: C 66.94, H 6.69, Cl 17.88. Compound **8**, ir (thin film) ν: 985 cm^{-1}; ^{1}H nmr (CCl_4) δ: 0.80 (s, 3H), 1.38 (s, 3H), 4.14 (d, J = 5.3 Hz, 1H), 4.40 (d, J =

cis-*3*-tert-*Butyl-2-phenyloxetane (3c)*

erythro-2-*tert*-Butyl-1-phenyl-3-(*p*-toluenesulfonyloxy)-1-propanol was prepared from the corresponding diol (5): mp 115–116°C; ir (KBr disk) ν: 3530, 1355, and 1175 cm^{-1}; ^1H nmr (acetone-d_6) δ: 1.06 (s, 9H), 1.7–2.0 (m, 1H), 2.47 (s, 3H), 3.63 (d of d, J = 10 and 3.3 Hz, 1H), 4.17 (d of d, J = 10 and 3.3 Hz, 1H), 4.25 (d, J = 4.1 Hz, 1H, disappeared by the addition of D_2O), 4.87 (d of d, J = 8.0 and 4.1 Hz, 1H, became d, J = 8.0 Hz, by the addition of D_2O), 7.21 (m, 5H), 7.44 (d, J = 8.0 Hz, 2H), 7.68 (d, J = 8.0 Hz, 2H). *Anal.* calcd. for $C_{20}H_{26}O_4S$: C 66.27, H 7.23, S 8.84; found: C 66.28, H 7.30, S 8.78. The treatment of this hydroxytosylate with potassium *tert*-butoxide gave **3***c* (16%) and benzaldehyde. Compound **3***c* was purified by vpc: ir (thin film) ν: 985 and 965 cm^{-1}; ^1H nmr (CCl_4) δ: 0.66 (s, 9H), 3.16 (nearly d of t, J = 7.3 and 8.7 Hz, 1H), 4.50 (d of d, J = 7.4 and 6.0 Hz, 1H), 4.67 (d of d, J = 8.8 and 6.0 Hz, 1H), 5.83 (d, J = 8.6 Hz, 1H), 7.1–7.5 (m, 5H); n_D^{25} 1.5109. *Anal.* calcd. for $C_{13}H_{18}O$: C 82.06, H 9.54; found: C 81. 98, H 9.50.

Thermolysis of Oxetanes

In general, a TMEDA solution of an oxetane (0.1–0.4 *M*) and diethylaniline (an internal standard for the vpc analysis) was introduced into a freshly base-treated Pyrex tube, degassed by several freeze–thaw cycles, sealed, and heated in an oven controlled at the desired temperature (± 0.5°C). TMEDA and diethylaniline were freshly distilled over potassium hydroxide pellets just before use. The product analyses were carried out by vpc for styrene derivatives, the aromatic carbonyl compounds, and/or alkene. All products are known compounds and hence they were characterized by comparing the spectral data of the isolated sample with those reported in the literature (14).

Since the amount of the aromatic aldehyde decreased gradually in TMEDA at 270–350°C, control experiments were carried out for the calibration of the results. After 16 h at 270°C, 3 h at 310°C, and 0.5 h at 350°C, benzaldehyde decreased to 51%, 73%, and 71% of the starting quantity. The amount of *p*-methylbenzaldehyde decreased to 46% after 16 h at 270°C and to 77% after 3 h at 310°C. Corrections for the amount of these aldehydes were made by assuming that the extent of the aldehyde consumption should be half of that observed in the control experiments. Since *p*-methoxybenzaldehyde, *p*-chlorobenzaldehyde, and *m*-chlorobenzaldehyde were much more unstable than benzaldehyde in hot TMEDA, the proportion of the "B" process in the reaction of **4**, **7**, and **8** was determined from the amount of isobutene produced. The figures obtained as an average of two to four runs are summarized in Table 1.

In an experiment, a 1:1 mixture of **1***c* and **1***t* was heated at 310°C in TMEDA. After 3.5 h, the consumption of **1***t* was 37% whereas that of **1***c* was 28%.

As described in the text, the produced alkenylbenzenes isomerized slowly to the corresponding geometrical isomer under reaction conditions. In the control experiments, authentic alkenylbenzenes were found to isomerize in hot TMEDA, but the extent of the isomerization was far less than that observed during the pyrolysis. For example, after heating at 310°C for 3 h in TMEDA, authentic *cis*-1-propenylbenzene isomerized to the *trans* isomer to an extent of only 4.2%. Similar results were obtained in other alkenylbenzenes: *trans*-1-propenylbenzene 1%, (*cis*-3-methyl-1-butenyl)benzene 2.3%, its *trans* isomer 0.2%, (*cis*-3,3-dimethyl-1-butenyl)benzene 6.5%, its *trans* isomer none. Some catalytic isomerization took place in the pyrolysis mixture. The results summarized in Table 2 are the compositions of the resultant mixtures without any corrections.

The stereochemistry and regiochemistry of the Diels–Alder reactions of 6-acetoxy-2,6-dimethyl-2,4-cyclohexadienone

HILLAR AUKSI[1] AND PETER YATES

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received February 13, 1981

HILLAR AUKSI and PETER YATES. Can. J. Chem. **59**, 2510 (1981).

6-Acetoxy-2,6-dimethyl-2,4-cyclohexadienone (**1**) and maleic anhydride in boiling benzene give a single adduct, *exo*-5-acetoxy-1,5-dimethyl-6-oxobicyclo[2.2.2]oct-7-ene-*endo*-2,3-dicarboxylic acid anhydride (**2**). With propiolic acid **1** gives *exo*-5-hydroxy-1,5-dimethyl-6-oxobicyclo[2.2.2]octa-2,7-diene-2-carboxylic acid (**15**). The high stereoselectivity and regioselectivity of these reactions is interpretable in terms of orbital overlap, closed-shell repulsion, steric, and van der Waals – London effects.

HILLAR AUKSI et PETER YATES. Can. J. Chem. **59**, 2510 (1981).

L'acétoxy-6 diméthyl-2,6 cyclohexadiénone-2,4 (**1**) et l'anhydride maléique dans le benzène au reflux donnent un adduit unique l'anhydride de l'acide acétoxy-5-*exo* diméthyl-1,5 oxo-6 bicyclo[2.2.2] octène-7 dicarboxylique-2,3-*endo* (**2**). Le composé **1** en présence de l'acide propiolique conduit à l'acide hydroxy-5-*exo* diméthyl-1,5 oxo-6 bicyclo[2.2.2] octadiène-2,7 carboxylique-2 (**15**). On peut interpréter la stéréosélectivité et la régiosélectivité élevées de ces réactions en fonction d'un recouvrement d'orbitales, de la répulsion des couches électroniques complètes, des effects stériques et des effets de van der Waals – London.

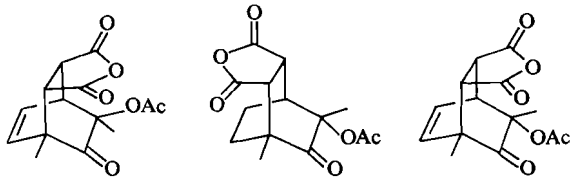
[Traduit par le journal]

In the course of our studies on the intramolecular Diels–Alder reactions of 6-acryloxy-2,6-dimethyl-2,4-cyclohexadienone derivatives formed by "modified" Wessely oxidation (1), we had occasion to investigate two intermolecular Diels–Alder reactions of 6-acetoxy-2,6-dimethyl-2,4-cyclohexadienone (**1**) formed by conventional Wessely oxidation. We report now on the elucidation of the stereochemical and regiochemical courses of these reactions.[2]

Reaction of Maleic Anhydride with 6-Acetoxy-2,6-dimethyl-2,4-cyclohexadienone

Reaction of maleic anhydride with 6-acetoxy-2,6-dimethyl-2,4-cyclohexadienone (2,6-dimethyl-*o*-quinol acetate; **1**) in boiling benzene gave a single adduct, whose structure has been established as **2**. Its ir and ^{1}H nmr spectra are given in Table 1;[3] these confirm its gross structure, but do not distinguish unambiguously between structure **2** and the stereoisomeric structures **3**–**5**.

Catalytic hydrogenation of **2** proceeded rapidly and cleanly with the uptake of one molar equivalent of hydrogen to give the dihydro product **6** (Scheme 1). Comparison of its ^{1}H nmr spectrum (Table 1) with that of **2** shows that the H.2 and H.3 signals of **2** undergo an upfield shift of ca. 0.1 ppm on saturation of the ethylenic bond. This indicates that the adduct has the 2,3-*endo* configuration as in **2** (or **4**) rather than the 2,3-*exo* configuration as in **3** (or **5**), since in the latter cases the H.2 and H.3 protons are expected to be shielded by the ethylenic bond and thus show a downfield shift of their signals upon hydrogenation (4).



3 **4** **5**

Hydrolysis of **2** with 0.2 *N* aqueous sodium hydroxide at room temperature followed by acidification and sublimation gave the hydroxy anhydride **7**, which on hydrogenation as before gave the corresponding dihydro compounds **8** (Scheme 1). The ir and ^{1}H nmr spectra of these compounds (Table 1) show that reclosure of the anhydride ring has occurred. Comparison of the latter spectra with the ^{1}H nmr spectra of compounds **2** and **6** shows that while the H.2 and H.3 signals of **2** and **6** have very similar chemical shifts, those of **7** and **8** are significantly different ($\Delta\delta$ 0.7–0.9 ppm), largely owing to a downfield shift of the H.3 signal ($\Delta\delta$ 0.5–0.6 ppm). This effect can be interpreted in

[1]Present address: Raylo Chemicals Ltd., 8045 Argyll Road, Edmonton, Alta., Canada T6C 4A9.

[2]For earlier work that established the gross structure, but not the stereochemistry, of the adduct of maleic anhydride with **1**, see ref. 2.

[3]The ^{13}C nmr spectra of **2** and related compounds have been discussed elsewhere (3).

[4]This conclusion is more rigorously based in the case of **2** and **7** than that of **6** and **8**, since the spectrum of **8** was recorded in a mixture of $CDCl_3$ and DMSO-d_6 rather than in $CDCl_3$.

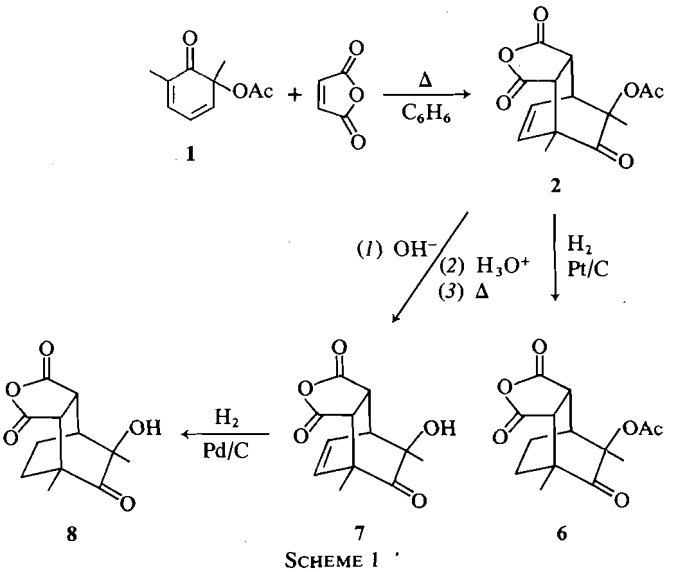

SCHEME 1

terms of shielding of H.3 by the acetyl group in **2** and **6**, which is absent in **7** and **8**.[4] Shielding of this magnitude requires that H.3 be spatially proximate to the acetyl group and again shows that the adduct has the 2,3-*endo* stereochemistry as in **2** or **4**, and indicates further that cycloaddition has occurred on the acetoxy face of **1** to give **2** rather than on the methyl face to give **4**.

Corroboration of these stereochemical assignments was sought by the utilization of a technique that has been introduced by Verma *et al.* (5–7) for determining the *exo* or *endo* stereochemistry of Diels–Alder adducts of maleic anhydride. In one variant of this method (6) the anhydride is converted to the corresponding *N'*,*N'*-diacetyl-*N*-aminosuccinimide and the difference between the

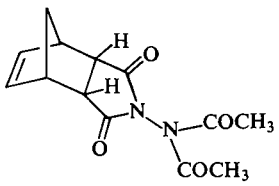
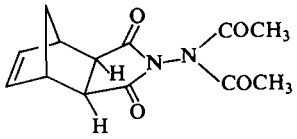
chemical shifts of the two acetyl signals is used as a probe of the stereochemistry of the adduct. Thus in the case of **9**, the imide formed from the *endo* adduct of cyclopentadiene and maleic anhydride, the acetyl chemical shift difference, although small (Δδ 0.33 ppm) (5), is identical with that (Δδ 0.33 ppm) in a related case that has been interpreted in terms of shielding by the olefinic bond of the acetyl group *syn* to that bond (6). However, we have found that the difference in the case of the *exo* adduct **10** (Δδ 0.28 ppm) is very similar and clearly this method cannot be used in cases of this kind. Verma and Singh have reached a similar conclusion (8).

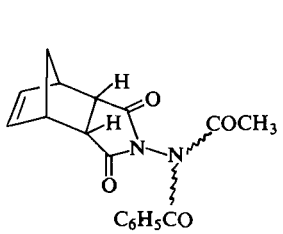


9

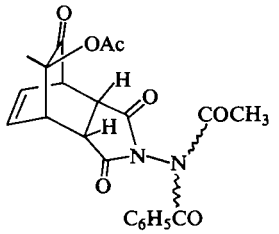


10

The second variant involves conversion of the adduct to the corresponding *N'*-acetyl-*N'*-benzoyl-*N*-aminosuccinimide (5, 7) and comparison of the chemical shifts of the olefinic protons in the resulting pair of conformational isomers. In the case of the imide **11** from the *endo* adduct of maleic anhydride and cyclopentadiene a large chemical shift difference (Δδ 1.0 ppm) was observed between the two sets of olefinic signals arising from the two conformational isomers. This was interpreted as resulting from shielding of the vinyl protons by the benzene ring in the isomer in which the benzoyl group is *syn* to the olefinic bond. We have prepared the imide **12** from the adduct **2** and find that one rotational isomer has vinyl proton signals (δ 5.93 and 6.35 ppm) at similar positions to those of **2** itself (δ 6.03 and 6.48 ppm), while the other has these signals shifted greatly upfield (δ 4.93 and 5.53 ppm); the differences in the chemical shifts for the two isomers (Δδ 1.00 and 0.82 ppm) are similar to those in the case of **11** (Δδ 0.97 ppm) (5). Since shift differences of these magnitudes appear to be impossible in the case of a 2,3-*exo* isomer, we conclude that the original adduct must have the



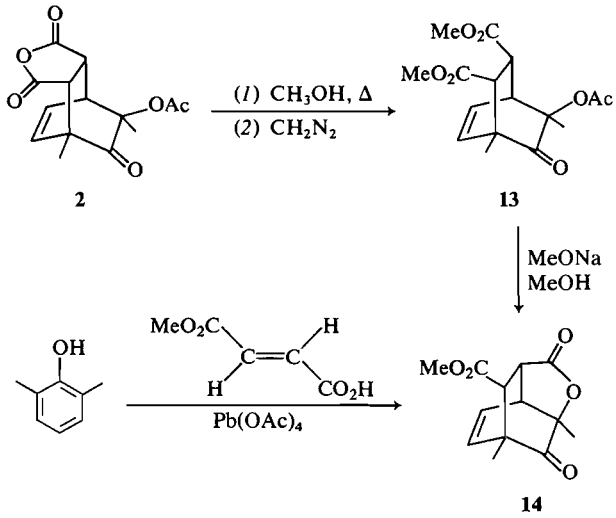
11



12

2,3-*endo* stereochemistry as in **2** (or **4**). It is noteworthy that in these terms the preponderant rotational isomer of both **11** and **12** is that with the *N*-benzoyl group *syn* to the olefinic bond (cf. ref. 7).

The assignment of structure **2** rather than **4** to the original adduct was confirmed by the transformations shown in Scheme 2. Methanolysis of **2** gave a mixture of two acid esters, which was converted to the diester **13** with diazomethane. Treatment of this with methanolic sodium methoxide at room temperature gave the lactone **14**, which was shown to be identical with the product obtained by "modified" Wessely oxidation of 2,6-dimethylphenol in the presence of methyl hydrogen fumarate (1). Formation of **14** from **13** must involve epimerization at C.3 prior to lactonization. The latter process can occur only if the acetoxyl group in **13** has the *exo* orientation, thus confirming that the structure of the original adduct is **2** rather than **4**.



SCHEME 2

Reaction of Propiolic Acid with 6-Acetoxy-2,6-dimethyl-2,4-cyclohexadienone

Reaction of **1** with propiolic acid in boiling benzene for 25 days gave a product in 46% yield that is assigned structure **15**: the only other compounds detected in the reaction mixture were the dimer of **1** (9) (*vide infra*) and unconsumed starting material. The ir and ^{1}H nmr spectra of **15** (Table 2) establish its gross structure and the latter spectrum permits the assignment of the regiochemistry of the product as in **15** or **16** rather than as in **17** or **18**. This follows from the fact that the signal at δ 7.47 ppm, which from its chemical shift can be unambiguously assigned to the vinylic proton in the β relationship to the carboxylic acid (i.e., H.3), is a

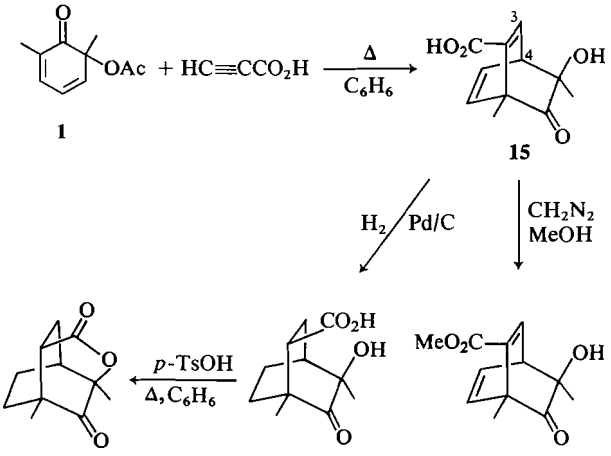
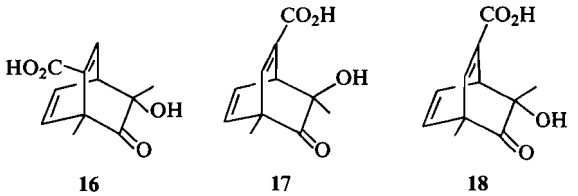


SCHEME 3

doublet with J = 6.5 Hz. The magnitude of this coupling constant clearly shows that the coupling is vicinal rather than allylic, requiring the presence of a hydrogen atom at C.4 as in **15** or **16**. Esterification of **15** with diazomethane gave **19** (Scheme 3), whose ^1H nmr spectrum (Table 2) shows an analogous doublet (J = 6 Hz) at δ 7.39 ppm. In this case the validity of the basis of the assignment of regiochemistry could be tested directly by comparison with the spectrum of the ester **23**, formed on treatment of **22** with methanol and *N*,*N*-dimethylhydrazine (Scheme 4) (1), which corresponds to the acid **17**. This spectrum shows a doublet at δ 6.98 ppm that can be assigned unambiguously to H.3; the coupling constant is 2 Hz, showing allylic rather than vicinal coupling with the bridgehead proton H.1. Further, the signal of the bridgehead proton in **23** (δ 4.35 ppm) is at considerably lower field than that in **15** (δ 3.83 ppm) in accord with the expectation that the ester group will exert a strong anisotropic deshielding effect in the case of the former but not the latter compound.

Distinction between the stereoisomeric structures **15** and **16** was made on the following basis. Hydrogenation of **15** gave the tetrahydro compound **20**, which on dehydration gave the lactone **21** (Scheme 3). This lactone underwent very facile hydrolysis to return **20**. The ir and ^1H nmr spectra of the hydrogenated product (Table 2) are in accord with the gross structure of **20** and its stereochemistry can be assigned on the basis of its reversible lactonization, establishing that the original adduct has the stereochemistry of **15** and not **16**. The



16 **17** **18**

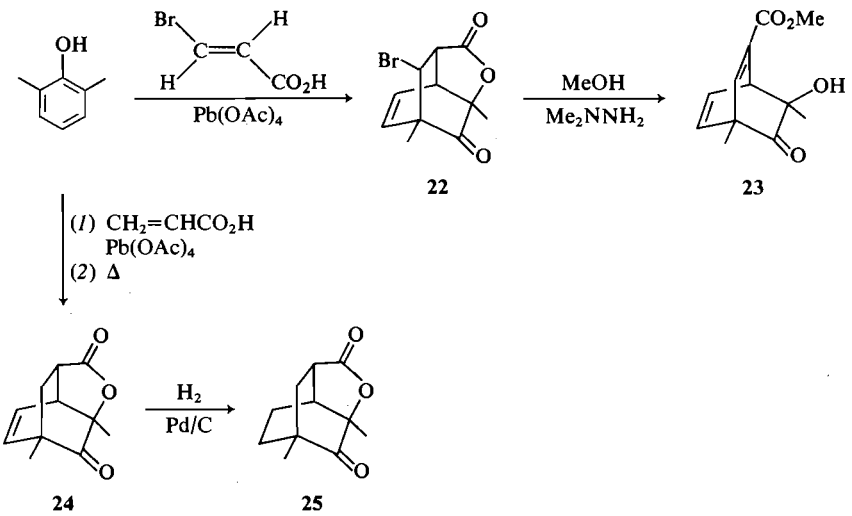
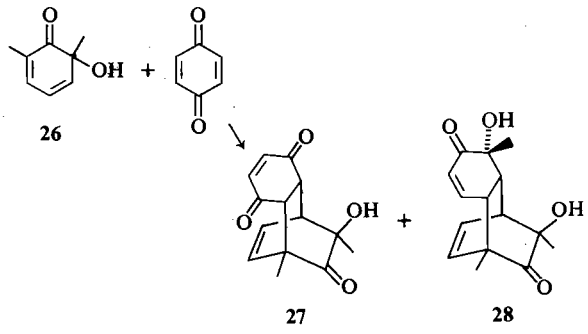


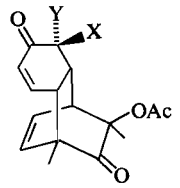
SCHEME 4

formation of the lactone **21**, which is different from the lactone **25** obtained on hydrogenation of **24** (Scheme 4) (1), also confirms that the adduct has the regiochemistry of **15** and not **17**. The ir spectrum of **21** shows it to be highly strained, as also indicated by its very ready hydrolysis.

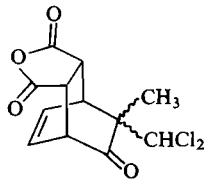
Discussion

The reaction of the 6-acetoxy-2,4-cyclohexadienone **1** is highly stereoselective in that no adduct other than **2** could be detected in the reaction mixture. Since the reaction occurs under mild conditions it is most probable that **2** is formed under kinetic control. Such high stereoselectivity has also been observed in the addition of 6-hydroxy-2,4-cyclohexadienones to *p*-benzoquinones under conditions of kinetic control (10). For example, reaction of 6-hydroxy-2,4-cyclohexadienone (**26**), formed by treatment of 2,6-dimethylphenol with sodium metaperiodate, with *p*-benzoquinone in aqueous ethanolic solution at room temperature gives a single adduct, which has been assigned structure **27**, together with **28**, a dimer of **26**. Formation of the Diels–Alder dimer is also highly stereoselective (and in addition highly chemoselective and regioselective) for only a single such product is observed. A number of analogous dimers of 6-hydroxy- and 6-acetoxy-2,4-cyclohexadienones have been prepared, and in several cases their structures have been demonstrated by X-ray crystallography to be analogous to **28** (8, 11). In the case of **29**, the dimer of **1**, it has been shown that this is formed under kinetic control at 120°C since at this temperature it is the only dimer formed, while at 160–190°C it is converted to a mixture of **29** and its epimer **30** (9).





29 X = CH_3, Y = OAc
30 X = OAc, Y = CH_3



31

In all of these cases, like that of **2**, the Diels–Alder reaction gives the *endo* product.[5] This, of course, is frequently observed with dienophiles such as maleic anhydride and *p*-benzoquinone and has been interpreted in terms of secondary orbital overlap and closed-shell repulsion (13–15). A less frequently encountered aspect of the stereochemistry of these products concerns the relative configuration at the carbon atoms that were originally C.6 in the 2,4-cyclohexadienone. This is determined by which face of the dienone undergoes bonding with the dienophile (and, in the case of the

[5]This has also been shown to be the case for the adduct **31** from 6-dichloromethyl-6-methyl-2,4-cyclohexadienone (12).

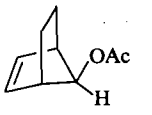
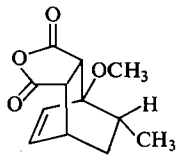
dimers, by which face of the dienophile undergoes attack by the diene). Compound **2**, like compounds of type **27–29**, is formed with high stereoselectivity by attack on the acetoxyl- (or hydroxyl-) bearing face of the dienone. This can be interpreted in terms of a combination of steric, van der Waals – London, and secondary orbital overlap factors (16). It can be compared with the exclusive formation of **32** from 5-acetoxycyclopentadiene and ethylene (17) and contrasted with the exclusive formation of **33** from 1-methoxy-6-methyl-1,3-cyclohexadiene and maleic anhydride (18) and the formation of a ca. 1:1 mixture of **34** and **35** from 5-methylcyclopentadiene and *N*-phenylmaleimide and a 1:12 mixture of **36** and **37** from 5-methylcyclopentadiene and maleic anhydride (19). In this connection it may be suggested that the very much greater rate of dimerization of 6-hydroxy-2,4-cyclohexadienones of type **26** relative to that of their acetoxy analogues of type **1** reflects both a reduced steric effect and enhanced secondary orbital overlap with the unshared electron pairs on the oxygen atom.

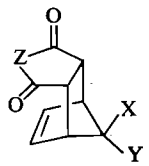
The reaction of **1** with propiolic acid to give **15** is highly regioselective. Although the extended reaction time (25 days) might have resulted in thermodynamic rather than kinetic control there was no evidence for the presence of the other regioisomer at intermediate reaction times. The sense of the regioselectivity, which is analogous to that in the dimerization of **1** and **26**, is in accord with expectation based on consideration of terminal and secondary orbital overlap (14, 20). The reaction is also highly stereoselective and the relative configuration at the carbon atom that was originally C.6 in the 2,4-cyclohexadienone again shows that attack occurs on the acetoxyl-bearing face of the dienone.



32



33



34 X = CH_3, Y = H, Z = NC_6H_5
35 X = H, Y = CH_3, Z = NC_6H_5
36 X = CH_3, Y = H, Z = O
37 X = H, Y = CH_3, Z = O

The formation of the hydroxy compound **15** is thought to involve hydrolysis of the corresponding acetoxy compound by adventitious water during the lengthy reaction period. It is considered to be unlikely that it arises by hydrolysis of **1** and **26** followed by addition of propiolic acid to the latter since none of **27**, the dimer of **26**, was observed to be present in the reaction mixture nor was any formed on treatment of **1** with propiolic acid in boiling benzene in the presence of water for 24 h.

Experimental

Melting points are uncorrected. Unless otherwise specified, ir spectra were recorded in chloroform, uv spectra in methanol, and ^1H and ^{13}C nmr spectra in deuteriochloroform. Solutions in organic solvents were dried over anhydrous $MgSO_4$.

6-Acetoxy-2,6-dimethyl-2,4-cyclohexadienone (2,6-Dimethyl-o-quinol Acetate; 1)

A solution of 2,6-dimethylphenol (9.00 g, 73.7 mmol) in dry dichloromethane (50 mL) was added dropwise over a 10 min period with stirring to a solution of lead tetraacetate (36.40 g, 82.2 mmol) in dry dichloromethane (700 mL), and stirring was continued at room temperature for 1 h. Ethylene glycol (1 mL) was added to destroy excess Pb(IV). Filtration followed by evaporation gave a reddish amber oil, which was taken up in benzene (250 mL). The solution was washed with water (2 × 250 mL) and aqueous 1% sodium carbonate (250 mL), dried, and evaporated to give a red oil (11.4 g). Distillation (60°C/0.005 Torr) gave **1** as a pale yellow liquid (9.04 g, 68%), which solidified on standing. Recrystallization from ether at −78°C gave **1** as a pale yellow solid, mp 34–35°C (lit. (21) mp 35°C).

exo-*5-Acetoxy-1,5-dimethyl-6-oxobicyclo[2.2.2]oct-7-ene*-endo-*2,3-dicarboxylic Acid Anhydride (2)*[6]

A solution of 2,6-dimethyl-*o*-quinol acetate (**1**) (freshly distilled; 5.45 g, 30.2 mmol) and maleic anhydride (2.97 g, 30.3 mmol) in benzene (100 mL) was boiled under reflux for 26 h. Evaporation gave a bright yellow oil, which crystallized on standing. The solid material was dissolved in benzene (25 mL), cyclohexane was added (50 mL), and the solution was heated on a steam bath until material began to precipitate. After the solution had cooled to room temperature, filtration gave a white crystalline solid (4.74 g). Recrystallization from chloroform/cyclohexane gave **2** as a white crystalline solid (4.44 g, 53%). Sublimation (80°C/0.005 Torr) gave **2**, mp 159.5–160.5°C; $\lambda_{max}(\varepsilon)$: 301 (70) nm; C nmr δ: 201.4 (s), 171.4 (s), 170.0 (s), 169.4 (s), 134.9 (d), 134.0 (d), 77.0 (s), 50.4 (s), 47.0 (d), 43.2 (d), 42.5 (d), 23.4 (q), 21.2 (q), 14.7 (q); ms *m/e* (M^+): 278. *Anal.* calcd. for $C_{14}H_{14}O_6$: C 60.43, H 5.07; found: C 60.20, H 5.02.

exo-*5-Acetoxy-1,5-dimethyl-6-oxobicyclo[2.2.2]octane*-endo-*2,3-dicarboxylic Acid Anhydride (6)*

exo-5-Acetoxy-1,5-dimethyl-6-oxobicyclo[2.2.2]oct-7-ene-*endo*-2,3-dicarboxylic acid anhydride (**2**) (500 mg, 1.80 mmol) was hydrogenated in acetic acid (20 mL) over 5% Pd/C (50 mg) at room temperature and atmospheric pressure until uptake of hydrogen ceased. Filtration followed by evaporation gave a

[6]The following convention has been used to describe the stereochemistry of bicyclo[2.2.2]octanone derivatives: substituents are designated as being *exo* or *endo* with respect to the unsaturated bridge of lowest priority, and in saturated compounds to the bridge of lowest priority.

For personal use only.

clear, colorless oil which was taken up in dichloromethane (30 mL). The solution was extracted with aqueous 1% sodium bicarbonate (30 mL). The organic layer was dried and evaporated to give a clear, colorless oil (0.43 g), which crystallized on standing. Sublimation (85°C/0.005 Torr) gave **6** as a white crystalline solid (0.40 g, 80%), mp 187–188°C; $\lambda_{max}(\varepsilon)$: 305 (30) nm; C nmr δ: 206 (s), 172.3 (s), 170.3 (s), 170.1 (s), 80.2 (s), 46.2 (d), 44.9 (d), 44.9 (s), 41.8 (d), 39.0 (d), 26.1 (t), 21.8 (q), 21.1 (q), 18.7 (t), 17.2 (q); ms *m/e* (M^+): 280. *Anal.* calcd. for $C_{14}H_{16}O_6$: C 59.99, H 5.75; found: C 59.88, H 5.75.

exo-*5-Hydroxy-1,5-dimethyl-6-oxobicyclo[2.2.2]oct-7-ene*-endo-*2,3-dicarboxylic Acid Anhydride (7)*

exo-5-Acetoxy-1,5-dimethyl-6-oxobicyclo[2.2.2]oct-7-ene-*endo*-2,3-dicarboxylic acid anhydride (**2**) (0.59 g, 2.12 mmol) and sodium hydroxide (0.5 *N*; 15 mL, 7.50 mmol) were dissolved in water (30 mL) and the solution was stirred at room temperature for 48 h. Acidification with dilute hydrochloric acid to pH 5 followed by evaporation gave a white solid. The solid was extracted repeatedly with ether and the extract was evaporated to give a white crystalline material (0.48 g). Sublimation (135°C/0.005 Torr) gave **7** as a white crystalline solid (0.43 g, 86%), mp 158.0–160°C; $\lambda_{max}(\varepsilon)$: 310 (70) nm; C nmr δ: 208.7 (s), 172.0 (s), 169.3 (s), 134.5 (d), 133.7 (d), 70.7 (s), 49.9 (s), 46.5 (d), 44.8 (d), 42.0 (d), 25.4 (q), 14.5 (q); ms *m/e* (M^+): 236. *Anal.* calcd. for $C_{12}H_{12}O_5$: C 61.01, H 5.12; found: C 60.85, H 5.13.

exo-*5-Hydroxy-1,5-dimethyl-6-oxobicyclo[2.2.2]octane*-endo-*2,3-dicarboxylic Acid Anhydride (8)*

exo-5-Hydroxy-1,5-dimethyl-6-oxobicyclo[2.2.2]oct-7-ene-*endo*-2,3-dicarboxylic acid anhydride (**7**) (223 mg, 0.94 mmol) was hydrogenated in ethyl acetate (15 mL) over 5% Pd/C (20 mg) at room temperature and atmospheric pressure until uptake of hydrogen ceased. Filtration followed by evaporation gave a white solid. Sublimation (82°C/0.005 Torr) gave **8** as a white crystalline solid (221 mg, 99%), mp 179–180°C; $\lambda_{max}(\varepsilon)$: 305 (30) nm; C nmr δ: 214.3, 172.5, 170.1, 73.7, 46.0, 43.9, 40.8, 40.0, 25.1, 23.1, 17.9, 16.9; ms *m/e* (M^+): 238. *Anal.* calcd. for $C_{12}H_{14}O_5$: C 60.50, H 5.92; found: C 60.63, H 5.90.

N′,N′-*Diacetyl*-N-*aminobicyclo[2.2.1]hept-5-ene*-exo-*2,3-dicarboximide (10)*

Bicyclo[2.2.1]hept-5-ene-*exo*-2,3-dicarboxylic acid anhydride (0.705 g, 4.29 mmol) and hydrazine hydrate (0.162 g, 4.30 mmol) were dissolved in 95% ethanol (70 mL) and the solution was boiled at reflux for 1 h. Evaporation gave *N*-aminobicyclo[2.2.1]hept-5-ene-*exo*-2,3-dicarboximide (0.76 g). The *N*-amino dicarboximide (0.215 g, 1.21 mmol) was dissolved in acetic anhydride (25 mL) and the solution was heated on a steam bath for 1 h. Evaporation gave a gummy material (0.341 g) which was chromatographed on a silica gel plate (0.5 mm) with 20% ethyl acetate in benzene to give two major bands (R_f = 0.1 and 0.4). The leading band (R_f = 0.4) gave an oil (0.200 g) which crystallized on standing. The crystalline material was chromatographed on a silica gel plate (0.25 mm) with ether to give two bands (R_f = 0.3 and 0.6). The leading band (R_f = 0.6) gave **10** (0.163 g, 51% based on the anhydride) as an oil which slowly crystallized on standing. Sublimation (60°C/0.005 Torr) gave **10**, mp 107–108°C; λ_{max}: 5.55 (w), 5.75, 6.20 (w) μm; H nmr δ: 1.4–2.1 (m, 2H), 2.22 (s, 3H), 2.50 (s, 3H), 2.7–2.8 (m, 2H), 3.3–3.5 (m, 2H), 6.3–6.5 (m, 2H); C nmr δ: 179.5 (s), 169.3 (s), 168.3 (s), 137.9 (d), 46.0 (d), 45.5 (d), 43.3 (t), 25.3 (q), 23.6 (q); ms *m/e* (M^+): 262. *Anal.* calcd. for $C_{13}H_{14}O_4N_2$: C 59.53, H 5.38, N 10.68; found: C 59.54, H 5.45, N 10.53.

N′-*Acetyl*-N′-*benzoyl*-N-*amino*-exo-*5-acetoxy-1,5-dimethyl-6-oxobicyclo[2.2.2]oct-7-ene*-endo-*2,3-dicarboximide (12)*

A solution of *exo*-5-acetoxy-1,5-dimethyl-5-oxobicyclo[2.2.2]oct-7-ene-*endo*-2,3-dicarboxylic acid anhydride (2.50 g, 8.98 mmol) and hydrazine hydrate (0.49 g, 8.32 mmol) in 95% ethanol (125 mL) was boiled at reflux for 1.25 h. Evaporation gave a white solid, which was dissolved in hot benzene (40 mL), ether (190 mL) was added, and the resulting solution was cooled to −70°C. Filtration gave a white crystalline solid (1.76 g). The filtrate was evaporated and the residue was taken up in hot benzene (15 mL), ether (90 mL) was added, and the resulting solution was cooled to −78°C. Filtration gave additional white crystalline material (0.18 g). The two crops were combined to give *N*-amino-*exo*-5-acetoxy-1,5-dimethyl-6-oxobicyclo-[2.2.2]oct-7-ene-*endo*-2,3-dicarboximide (1.94 g, 74%), mp 171–172°C; λ_{max}: 5.57 (w), 5.72 μm; λ_{max} (ε): 300 (55) nm; H nmr δ: 1.51 (s, 3H), 1.61 (s, 3H), 2.08 (s, 3H), 3.12 (m, 2H), 4.03 (ddd, J = 6.5, 2.5, 2 Hz, 1H), 4.37 (bs, 2H, variable), 5.88 (dd, J = 8, 2 Hz, 1H), 6.30 (dd, J = 8, 6.5 Hz, 1H); C nmr δ: 202.7 (s), 173.9 (s), 172.5 (s), 169.8 (s), 134.0 (d), 134.4 (d), 77.6 (s), 50.7 (s), 44.1 (d), 42.5 (d), 39.8 (d), 23.1 (q), 21.4 (q), 15.0 (q); ms *m/e* (M^+): 292. *Anal.* calcd. for $C_{14}H_{16}O_5N_2$: C 57.53, H 5.52, N 9.95; found: C 57.57, H 5.50, N 9.57.

N-Amino-5-acetoxy-1,5-dimethyl-6-oxobicyclo[2.2.2]oct-7-ene-*endo*-2,3-dicarboximide (2.43 g, 8.31 mmol), pyridine (1.40 g, 17.70 mmol), and benzoyl chloride (1.17 g, 8.32 mmol) were dissolved in benzene (150 mL), and the solution was allowed to stand for 1.5 h. Acetyl chloride (0.65 g, 8.28 mmol) was added to the reaction mixture, and the solution was allowed to stand for 5 h. The reaction mixture was filtered, the solid residue was extracted with boiling benzene (50 mL), and the extract was filtered. The benzene solutions were combined and extracted with water (100 mL), aqueous 1% sodium bicarbonate (100 mL), and aqueous 1% hydrochloric acid. The organic phase was dried, filtered, and evaporated to give a pale yellow oil (2.87 g), which crystallized on standing. The crude product was chromatographed on a silica gel column (300 g) with ether. The fractions that contained both a benzoyl group and an acetyl group, as indicated by ^{1}H nmr spectroscopy, were combined and evaporated to give a white crystalline solid. This was chromatographed on a silica gel column (40 g) with ether. The fractions that contained both a benzoyl and an acetyl group were combined and evaporated to give a white crystalline solid (1.09 g). Two recrystallizations from ether at −30°C gave **12** (0.18 g), mp 149–180°C; λ_{max}: 5.57 (w), 5.74 μm; H nmr δ: 2.03, 2.06 (2 s, 3H), 2.43 (s, 0.9H), 2.60 (s, 2.1H), 4.93 (dd, J = 8, 2 Hz, 0.7H), 5.53 (dd, J = 8, 7 Hz, 0.7H), 5.93 (dd, J = 8, 2 Hz, 0.3H), 6.35 (dd, J = 8, 7 Hz, 0.3H); ms *m/e* (M^+): 438. *Anal.* calcd. for $C_{23}H_{22}O_7N_2$: C 63.01, H 5.06, N 6.39; found: C 63.02, H 5.18, N 6.63.

Dimethyl exo-*5-Acetoxy-1,5-dimethyl-6-oxobicyclo[2.2.2]oct-7-ene*-endo-2-endo-*3-dicarboxylate (13)*

exo-5-Acetoxy-1,5-dimethyl-6-oxobicyclo[2.2.2]oct-7-ene-*endo*-2,3-dicarboxylic acid anhydride (**2**) (1.10 g, 3.95 mmol) was dissolved in methanol (50 mL), and the solution was boiled at reflux for 21 h. Evaporation gave a clear, colorless oil, which was taken up in ether (100 mL). The solution was titrated with ethereal diazomethane until the yellow color persisted. Evaporaion gave a clear, colorless oil, which crystallized on standing. Recrystallization from methanol at −20°C gave **13** as a white crystalline solid (1.15 g, 90% from **2**). Recrystallization from methanol gave **13**, mp 137.5–138°C; λ_{max}: 5.76 μm; λ_{max} (ε): 302 (90) nm; H nmr δ: 1.27 (s, 3H), 1.55 (s, 3H), 2.06 (s, 3H), 3.31 (s, 2H), 3.62 (s, 3H), 3.66 (s, 3H), 4.08 (br d, J = 7 Hz, 1H), 5.87 (dd, J = 8, 2 Hz, 1H), 6.61 (dd, J = 8, 7 Hz, 1H); C nmr δ: 203.0 (s), 171.7 (s), 171.2 (s), 169.8 (s), 134.9 (d), 131.5 (d), 79.4 (s), 52.0 (q), 51.9 (q), 50.3 (s), 49.5 (d), 44.4 (d), 42.6 (d), 21.7 (q), 15.6 (q); ms *m/e* (M^+): 324. *Anal.* calcd. for $C_{16}H_{20}O_7$: C 59.25, H 6.22; found: C 59.24, H 6.15.

exo-*5-Hydroxy-1,5-dimethyl-6-oxobicyclo[2.2.2]octa-2,7-diene-2-carboxylic Acid (15)*

2,6-Dimethyl-*o*-quinol acetate (**1**) (3.00 g, 16.65 mmol) and propiolic acid (1.16 g, 16.56 mmol) were dissolved in benzene (100 mL) and the solution was boiled at reflux for 600 h. The reaction mixture was extracted with aqueous sodium hydroxide (0.666 g, 16.65 mmol) in 80 mL of water. The aqueous phase was acidified with concentrated hydrochloric acid to pH 5 and extracted with ether (5 × 5 mL). The ethereal extracts were combined, dried, filtered, and evaporated to give a brown oil (2.06 g), which slowly crystallized on standing. Sublimation (170°C/0.005 Torr) followed by a second sublimation (100°C/0.005 Torr) gave a pale amber solid. Two recrystallizations from ether/benzene gave **15** (1.57 g, 46%) as a white crystalline solid. Recrystallization from ether/benzene gave **15**, mp 196–196.5°C; λ_{max} (ε): 237 (2200), 306 (90) nm; C nmr δ: 205.7 (s), 167.6 (s), 147.5 (d), 137.4 (d), 136.3 (s), 136.0 (d), 68.8 (s), 50.5 (d), 57.8 (s), 27.3 (q), 14.9 (q); ms *m/e* (M^+): 208. *Anal.* calcd. for $C_{11}H_{12}O_4$: C 63.45, H 5.81; found: C 63.31, H 5.86.

exo-*5-Hydroxy-1,5-dimethyl-6-oxobicyclo[2.2.2]octane-exo-2-carboxylic Acid (20)*

exo-5-Hydroxy-1,5-dimethyl-6-oxobicyclo[2.2.2]octa-2,7-diene-2-carboxylic acid **15** (81.6 mg, 0.392 mmol) was hydrogenated in methanol (50 mL) over 5% Pd/C (52 mg) at room temperature and atmospheric pressure until uptake of hydrogen ceased. Filtration followed by evaporation gave a clear, colorless oil, which solidified slowly on standing. Sublimation (140°C/0.005 Torr) gave **20** (81.5 mg, 98%) as a white crystalline solid, mp 158–158.5°C; λ_{max} (ε): 292 (41), 303 (39) nm; C nmr δ: 216.3 (s), 180.1 (s), 74.9 (s), 48.6 (d), 44.5 (s), 37.9 (d), 30.4 (t), 25.8 (t), 23.1 (q), 22.0 (t), 18.0 (q); ms *m/e* (M^+): 212. *Anal.* calcd. for $C_{11}H_{16}O_4$: C 62.25, H 7.60; found: C 62.29, H 7.58.

exo-*5-Hydroxy-1,5-dimethyl-6-oxobicyclo[2.2.2]octane-exo-2-carboxylic Acid Lactone (21)*

exo-5-Hydroxy-1,5-dimethyl-6-oxobicyclo[2.2.2]octane-*exo*-2-carboxylic acid (**20**) (58 mg, 0.27 mmol) and *p*-toluenesulfonic acid (4 mg) were dissolved in dry benzene (100 mL). The solution was boiled under reflux in a Soxhlet apparatus containing calcium hydride in the extraction thimble for 18 h. Evaporation gave a white solid which was sublimed (35°C/0.001 Torr) to give **21** (49 mg, 92%) as a white crystalline solid. Addition of calcium hydride to a benzene solution of **21**, followed by evaporation after evolution of hydrogen ceased, and then sublimation (35°C/0.001 Torr) gave **21**, mp 42–47°C; C nmr δ: 208.1 (s), 173.0 (s), 85.5 (s), 46.4 (d), 41.4 (s), 36.4 (d), 31.7 (t), 26.8 (t), 23.0 (t), 17.2 (q), 14.7 (q). On exposure to the atmosphere **21** was rapidly hydrolyzed to **20**, and a satisfactory elemental analysis could not be obtained.

Some regularities in the behavior of salting constants for polar molecules in aqueous electrolyte solutions

CLAUDE TREINER

Laboratoire d'Electrochimie, Université P. et M. Curie, 4, place Jussieu, 75230 Paris, France

Received December 19, 1980

CLAUDE TREINER. Can. J. Chem. **59**, 2518 (1981).

The salting effect of polar molecules in aqueous electrolyte solutions has been examined in the case of 22 solute molecules. It is observed that the salting constants of polar and nonpolar molecules of the same size in a given salt solution are close to each other and are generally greater than a critical diameter of the solute molecules. Using the available data from the literature, the salting constants k_s of neutral polar molecules by univalent cation electrolytes has been classified in three groups: (*1*) Organic molecules and inorganic salts: for a given electrolyte k_s is a monotonous function of the solute size and the nonelectrolyte dipole moment plays no role. (*2*) Organic molecules and organic salts: again a smooth variation of k_s with size is observed whatever the polar mono-functional molecule. (*3*) Inorganic molecules and inorganic salts: a correlation is exhibited between k_s and the solute dipole moment. These observations may be interpreted by assuming that both ends of a dipole are to be available to solute + solvent interactions for a dipole effect to be observed.

Furthermore it is shown that in case *1*, the scaled-particle theory with incorporation of a preferential solvation phenomenon may be useful for predicting salting out effects of polar molecules in inorganic salt solutions. In case *2* an approach based on microscopic surface tension and molecular surface area is also considered.

CLAUDE TREINER. Can. J. Chem. **59**, 2518 (1981).

L'effet de sel de molécules polaires dans des solutions aqueuses électrolytiques a été considéré dans le cas de 22 molécules de soluté. On a observé que les constantes de relarguage de molécules polaires et non polaires de même taille dans une solution électrolytique donnée sont proches les unes des autres et généralement égales au dessus d'un diamètre critique des molécules de soluté. En utilisant les données de la littérature concernant les constantes de relarguages k_s de molécules polaires neutres dans des solutions électrolytiques de cations monovalents, trois types de comportement ont été analysés. (*1*) Molécules organiques et sels inorganiques: pour un sel donné, k_s est une fonction monotone croissante de la taille du soluté et son moment dipole permanent ne joue aucun rôle. (*2*) Molécules organiques et sels organiques: à nouveau k_s varie de manière linéaire avec la taille du soluté polaire mono fonctionnel. (*3*) Molécules inorganiques et sels inorganiques: une corrélation est observée entre k_s et le moment dipolaire du soluté. Ces observations peuvent être interprétées en admettant que les deux extrémités d'un dipole doivent être disponibles à une interaction soluté + solvant pour observer un effet dipolaire.

De plus, on a montré que dans le cas *1*, la théorie des sphères rigides avec incorporation d'un phénomène de solvatation préférentielle peut être utile pour prédire l'effet de sel de molécules polaires par des sels inorganiques. Dans le cas *2*, une approche basée sur la tension interfaciale microscopique et sur la surface moléculaire de contact est également considérée.

Introduction

The salting effect of a nonpolar molecule in an electrolyte aqueous media has been the subject of a number of developments in recent years (1–6). Electrostatic, thermodynamic, and mixed models have been able to characterize the essential features of the salting phenomenon (7); thus the salting constant of a nonpolar molecule in an aqueous electrolyte solution may be predicted with reasonable success using, for example, the scaled-particle theory (3–5, 8) (SPT). The case of polar solutes is much less documented although some attempts of generalization have been made in the reviews by McDevit and Long (9) and by Sergeeva (10).

The usual way of investigating ion + solvent interactions in solution is to use a polar component as a cosolvent to water for example, the electrolytes being used as solutes. There is a very large literature on such systems because mixed solvents are useful media for a number of chemical reactions (11). However, mixed solvents are very difficult media to deal with from a theoretical point of view, in particular because structural effects are responsible for many of the essential phenomena which occur in these mixtures; moreover, there are some reasons to believe that the investigations of solute + solvent interactions using solutes standard thermodynamic quantities as obtained by extrapolation procedures at constant solvent composition may lead to difficulties in their interpretation (12). Some attempts have been made to apply the SPT to large ions considered as nonpolar solutes (13–16) in mixtures of polar solvents, the influence of the charge being neglected, an approach which cannot be generalized.

Several investigations have also applied the SPT approach to the salting effect of polar molecules by organic and inorganic electrolytes in water (17–21) but the reasons of the semi-success of these at-

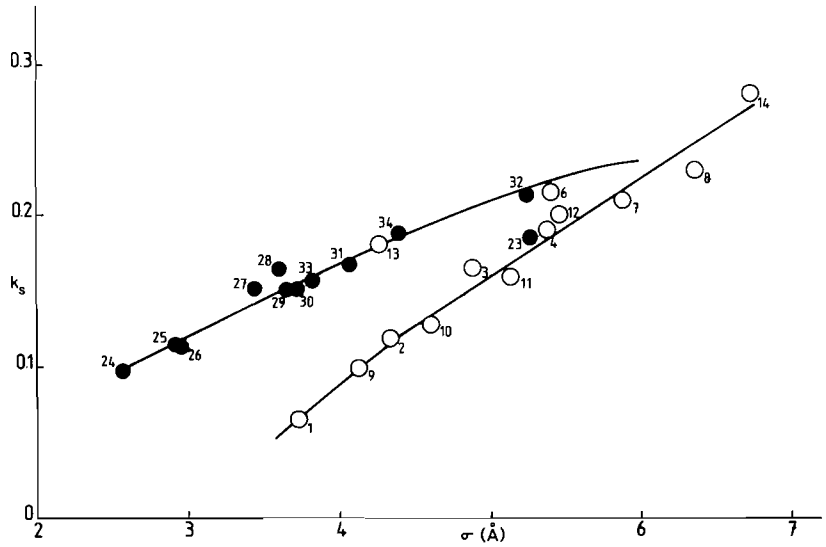

FIG. 1. Salting constant versus hard-sphere diameter for polar ○ and nonpolar ● solutes in aqueous NaCl solutions (chart for polar, see Table 3; for nonpolar: He = 24, Ne = 25, H_2 = 26, Ar = 27, Kr = 28, O_2 = 29, N_2 = 30, Xe = 31, SF_6 = 32, CH_4 = 33, C_2H_6 = 34).

tempts has not been discussed. This is surprising since the permanent dipole of the solute molecules was ignored in these developments (5).

In this article we shall try to consider the different types of behavior of polar molecules with respect to electrolytes in aqueous media by comparing the experimental data available for a large number of molecules in a given electrolyte solution; we shall also show under which conditions the SPT might be useful as a predictive tool in the case of polar solutes in inorganic salt solutions, and suggest some directions for future research in the field of ion–molecule interactions.

Presentation of Data

There are several formal definitions of the salting constant k_s of a molecule in a given medium. The following definition may be preferred (22):

$$k_s = -\left(\frac{\partial \ln m_{NE}}{\partial m_E}\right)\mu_{NE}$$

This equation represents the variation of m_{NE}, the molal solubility of a nonelectrolyte (NE), with electrolyte molality m_E at constant NE chemical potential in a given solvent. k_s is the Setchenov constant. In the case of a soluble volatile solute, m_{NE} may be replaced by applying Henry's law.

All data are presented on the molarity scale as advocated by Ben-Naim (23). Before any discussion on the behavior of polar molecules as such, it may be instructive to compare the Setchenov constant of polar and nonpolar molecules in a given electrolyte solution. We have chosen firstly NaCl as the electrolyte because the most extensive and accurate set of data are available for NaCl aqueous solutions. Figure 1 presents these data as a function of the hard sphere diameter of the solute molecule. We shall return to this parameter in the following section. We have avoided some nonpolar molecules such as CO_2 which presents some complications with water (24) and polar molecules such as acids or bases with specific properties in aqueous solutions. The solutes of Figs. 1 to 3 should be considered as neutral molecules as defined by Long and McDevit (9).

The essential characteristic of the curves of Fig. 1 is their amazing regularity. k_s increases with increasing size of the solute for nonpolar and for polar solutes and the two lines seem to join each other for a solute molecule with $\sigma \sim 6$ Å: thus benzene is on the polar line and *tert*-butanol on the nonpolar one. Clearly the salting effect is not very different for both classes of solutes for a given size, and the dipole moment of the polar molecules plays no role (μ ranges from 1.6 to 3.4 D); no correlation can be found between k_s and the dipole moment of these organic molecules.

There are two exceptions among the monofunctional organic molecules for which data were available from the literature: one is nitromethane which seems to behave as a nonpolar molecule although its dipole moment is μ = 3.37 D and the other (not

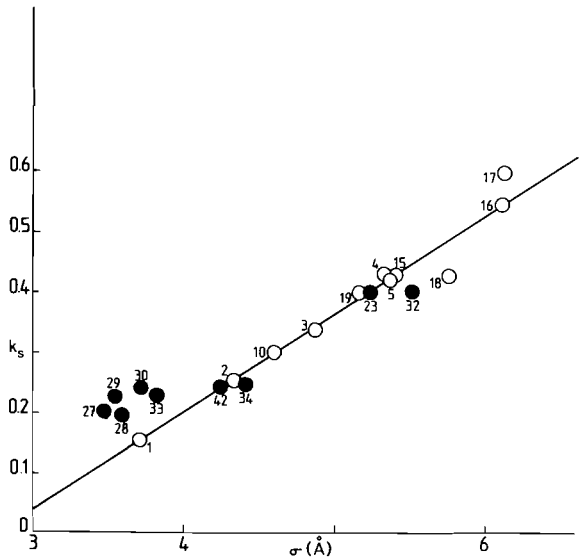

FIG. 2. Salting constants versus hard-sphere diameters for polar ○ and nonpolar ● solutes in aqueous $(NH_4)_2SO_4$ solutions. (C_2H_4 = 42 otherwise as Fig. 2).

shown here) is the *n*-alkylacetate series of Cross and McTigue (25) which is essentially below the polar line and joins it only for the tetrapropylacetate. Whether this is the result of a specific behavior or is related to some experimental difficulty cannot be identified at the present time.

Figure 2 presents another series of salting constants of polar molecules with ammonium sulfate as the electrolyte, taken from the Deno and Spink compilation (26). We observe a smooth variation of k_s with solute size. The aldehyde series is an exception just like the alkylacetate was for sodium chloride with only butyraldehyde on the polar line. The solutes represent a large variety in monofunctional group molecules and dipole moments; the figure again stresses the importance of the volume effect. Data for nonpolar solutes were not available for a valuable comparison of polar and nonpolar molecules in this case; however, as the SPT theory has been shown to be able to predict the salting constant of nonpolar molecules by aqueous inorganic salt solutions (3–5), we have calculated theoretical values for a number of nonpolar molecules of Fig. 1 using Masterton and Lee (3) equations (see Appendix) and the physical parameters quoted therein. The difference between the nonpolar and the polar molecules is even smaller than in the case of NaCl. There may be a certain degree of coincidence in this case but for other less well documented cases such as sodium sulfate, the difference between nonpolar and polar salting effects is also small and decreases with increasing size of the solute molecule.

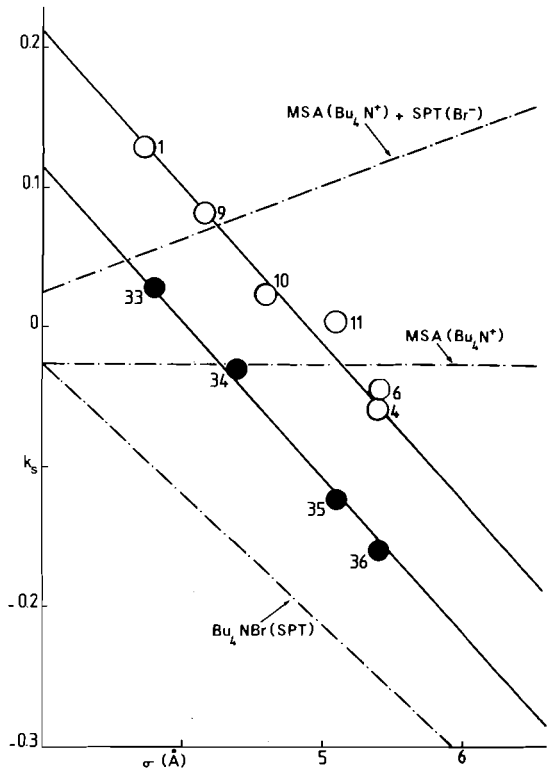

FIG. 3. Salting constants versus hard-sphere diameters for polar ○ and nonpolar ● solutes in aqueous $n Bu_4NBr$ solutions. Full curves (experimental), dotted curves (calculated); SPT = scaled-particle theory, MSA (molecular surface area concept, eq. [7]).

This rule seems general enough at least in the case of inorganic electrolytes with monovalent cations to be used as a criterion for testing the accuracy of salting constants in a given electrolyte solution.

Salting constant values of polar molecules by salts with multivalent cations such as transition metal ions are unfortunately scarce. The available data (20, 21, 27) suggest that the situation is more complex than in the case of monovalent cations; this might be true even for nonpolar molecules with hardly any data at all.

Figure 3 presents an apparently different situation of a salting effect of polar molecules by a classical organic electrolyte: tetrabutylammonium bromide. We also observe a smooth variation of k_s with solute size and the passage of a salting-out to a salting-in effect with increasing size of the solutes. The hydrocarbon gases are more salted-in than the polar molecules; the difference observed is relatively small (the same order of magnitude as for the preceding cases) but the two lines run parallel to each other. A known exception among the nonpolar molecules is benzene which is much more

For personal use only.

salted-in than the other solutes in Fig. 3. However, for aromatic molecules as a class of compounds, the salting-in effect is also a quasi-linear function of the size of the substituents. Again the dipole moment plays no role and benzene with a dipole moment of zero and nitrobenzene with a dipole moment of $\mu = 3.99$ D have nearly the same k_s value in aqueous NaCl solutions. Other examples of that sort may be found in Long and McDevit (9) review or in Aveyard and Heselden paper (18).

Interpretation of Salting Constants

(A) The Scaled-particle Theory

We have observed that the salting effect of polar organic molecules by electrolytes in water is essentially a size- or volume-effect. The scaled-particle theory approach is then the most obvious model to be used in the complex situation we are dealing with.

Formally the SPT model (28, 29) as used by most authors (3) in the case of the salting effect may be described by the following relationship:

$$[2] \quad k_s = \frac{1}{2.303RT}\left(\frac{\partial G(\mathrm{CAV})}{\partial m_E}\right)_{m_E \to 0} + \frac{1}{2.303RT} \times \left(\frac{\partial G(\mathrm{INT})}{\partial m_E}\right)_{m_E \to 0} + \left(\frac{\partial \log \rho_i}{\partial m_E}\right)_{m_E \to 0}$$

where G(CAV) is the free energy of cavity formation, G(INT) the free energy interaction term between the solute and all solvent molecules, and ρ_i the density of each particular species. G(CAV) may be calculated from a knowledge of the hard sphere diameter of the solute and solvent molecules and the partial molar volume at infinite dilution of the ions.

The free energy interaction term that is proposed by Shoor and Gubbins or by Lucas (4, 5) is an enthalpy term (the entropy of interaction is assumed negligible). In the present formulation (see Appendix) the only forces taken into account are the dispersion forces between solute and all solvent particles (Lennard–Jones potential), and induction forces between solute and water dipoles; in particular no induction forces are introduced between the ion and the solute molecules. This is a simplification even for a nonpolar molecule (5) as it assumes that the radial distribution function $g_{1j}(r) = 1$ for the solute molecule in the interaction term:

$$[3] \quad G(\mathrm{INT}) \approx \sum_{j=1}^{m} \int_{r=a_{1j}}^{\infty} u_{1j}(r) g_{1j}(r) \rho_j 4\pi r^2 \, dr$$

where u_{1j} is the pair potential, ρ_{1j} the particle density, 1 stands for the solute and j for all solvent molecules (2 for water, 3 and 4 for the ions). In other words, the distribution of the ions is supposed to be uniform around the solute molecule (5). This assumption is certainly wrong for a polar solute. We have shown recently (21) that a reasonable agreement may be found between theory and experiment if we assume that polar molecules, unlike nonpolar ones, induce a preferential solvation phenomenon. Numerous investigations on the behavior of electrolytes in mixed aqueous solvents using extrathermodynamic approaches have shown that the standard free energy of transfer of cations or anions from water to mixed solvents is of opposite sign; this empirical finding has been widely interpreted as a consequence of a preferential solvation of cations by the organic component of the mixture and of anions by water (30). This conclusion may be introduced into eq. [3] by assuming that $g_{13}(r) = 0$ for anions and $g_{14}(r) = 1$ for cations. Of course the real situation is not as clear-cut but there is no way of calculating the distribution of ions around a solute and with these assumptions we avoid the introduction of an adjustable parameter. Finally, the interactions between water molecules and ions are taken into account through the cavity term by making use of the partial molar volume of the ions at infinite dilution in water.

The physical parameters used in the calculations were chosen as follows:

(*1*) The hard-sphere diameters: they were deduced, in the case of the polar solutes, from de Ligny's empirical formula (24) in order to get a consistent set of data.

$$[4] \quad \tfrac{1}{6}\pi N \sigma_1^3 = -10 + 1.13 V_W$$

where V_W is Bondi's van der Waals volumes (31). These values (Table 1) are close to those derived by Kim (32) from an empirical correlation between hard sphere diameters and solvent molar volumes. It is noteworthy that in the case of a salting-out phenomenon G(CAV) and G(INT) are of opposite sign so that relatively small errors on σ mostly cancel out. The hard-sphere diameters for the ions (Table 2) were deduced from SPT calculations for the case of nonpolar solutes using appropriate combination of salts (case of ammonium sulfate) and the set of eqs. [8] to [10] (see Appendix). Crystallographic radii were used for Na^+ and Cl^-. Finally Hirschfelder values (33) were adopted for the nonpolar molecules of Figs. 1 to 3.

(*2*) The energy parameter ε/k: the energy parameters of the Lennard–Jones potential for the ions were calculated using Mavroyannis–Stephen theory as recommended by Shoor and Gubbins (5); the recommended values of Mauritz and Rummens

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

were used for the polar molecules (34). The same value was used for a series of compounds (e.g. alkylethers) as the dependence of ε/k on size is small in a polar series (34).

(*3*) The polarizability of the molecules was calculated using the refraction index additivity principle with

$$[5] \quad \alpha = 3R/4\pi N$$

where N is Avogadro's number.

Before presenting the results of these calculations it is interesting to note that ε/k averages a value of 417 ± 60 for all polar solutes of Table 1. As for the nonpolar molecules, ε/k varies from 10 for the smallest molecule of the nonpolar series of Fig. 1 (helium) to 200 for hexafluorosulfide (33). Thus, the G(INT) term being negative it is clear that k_s will be less for a polar molecule than for a nonpolar one of equal size simply because the interaction parameter ε/k is larger in the former case than in the latter. The relative position of the two lines of Fig. 1 is therefore a consequence of the value of a parameter which concerns only the nonpolar part of the molecules.

Table 2 presents the results of our calculations in the case of the inorganic salts, assuming preferential solvation of the anions by water; note that as an average $k_{s(calc)}$ is off by $0.04k_s$ unit with a systematic deviation towards high values; this is a remarkable result as no adjustable parameter was introduced and that precision of the order of ± 0.02 is common

TABLE 1. Some physical properties of polar molecules

Solutes	σ_1 (Å)	(ε/k) (K)	$\alpha_1\ 10^{-24}$ ($cm^3\ mol^{-1}$)	μ (D)

in the case of the salting parameter of polar molecules due to the experimental conditions. The reason for the presentation of data for NaCl and $(NH_4)_2SO_4$ is not only that a relatively large amount of experimental values were available for these salts but also because they present the extreme cases of most common inorganic salts from the simpler ones to more complicated structures. We believe therefore that the SPT model can be used to predict within a few percent the salting constant of a polar molecule by an inorganic salt solution. This procedure may be useful when no data are available; it can also be used to estimate the precision of a series of solutes in a given electrolyte solution as the dispersion of experimental values around a single line should be minimum.

The above procedure is not feasible in the case of organic electrolytes. The dotted line in Fig. 3 shows the importance of the cavity term alone for a round value of the hard-sphere diameters of Bu_4NBr ($\sigma = 8.0$ Å). The result is known, i.e. the SPT alone can predict a salting-in effect and, as shown in Fig. 3, also the rate of change of k_s with solute size. This means that the free energy of interaction is also size dependent. However, we know that the interaction of organic compounds in water is essentially an entropic phenomenon. Thus it is unjustified to use Shoor and Gubbins' purely enthalpic term for G(INT), an approach which is acceptable for inorganic ions; moreover there is a great deal of compensation between enthalpy and entropy in aqueous media so that the error on evaluation of k_s is less by assuming only a cavity term than by adding an oversimplified interaction term. One of the consequences of this situation is that the use of the SPT approach to obtain the size of organic ions using nonpolar solutes such as the hydrocarbon series (35) may not be valid: a value of 7.81 Å is found for the hard sphere diameter of n-Bu_4NBr.

(B) Model Based on Molecular Surface Area and Surface Tensions

The difficulties related to the choice of the size of the organic ions and especially with the interaction term may lead to an alternative path such as that proposed by Herman (36) and extensively used by Yalkowsky *et al.* (37, 38) in the case of the solubility of scarcely soluble compounds in water and in mixed solvents. As k_s is a standard thermodynamic quantity it can be divided into a cationic contribution and an ionic contribution; we thought it would be interesting to apply this approach to the large organic cation in the present situation of the salt effect, the case of the bromide ion being treated by the SPT as shown in the preceding section.

The solubility of nonpolar compounds in water and in mixed aqueous solvents has been described by the classical relationship (37):

$$[6] \quad \log X/X_0 = k_s x$$

This is the equivalent of the Setchenov equation which can be deduced as eq. [6] from the regular solution theory (39); x is the mole fraction of co-solvent which can be, under ideal or dilute conditions, any of the three components of the solution. Thus k_s may characterize the solute or the co-solvent. It has been shown experimentally that k_s is the same for both components in the present case of a dilute ternary solution (40). Herman (36) and Yalkowsky and co-workers (37) have shown that k_s may be considered a function of the molecular surface area (MSA) of the nonpolar molecule and of the microscopic surface tension of that molecule with each solvent in the case of a ternary solution.

One gets the following relation in the mole fraction scale:

$$[7] \quad k_s = \frac{C\Delta\gamma^0(\mathrm{MSA})M_1}{2.303kT\ 1000}$$

$C = 0.55$ represents a curvature factor, $\Delta\gamma^0$ is the difference of macroscopic surface tensions between the nonpolar component (the tetrabutylammonium ion surface will be assumed to be similar to that of a hydrocarbon solvent such as tetradecane) and water and with the polar component, M_1 is the water molecular weight, k the Boltzmann constant. We have applied eq. [7] to some of the solutes of Table 3. The MSA for Bu_4N^+ is estimated from group values assuming minimum areas (38) to be about 280 Å^2. $\Delta\gamma^0$ was obtained from a plot of surface tension against interfacial tension values obtained with tetradecane (37). The surface tensions of the polar solvents were taken from the literature (41); they are close to each other. As a result the $k_s^{(+)}$ values obtained from eq. [7] are nearly identical: $k_s^{(+)} = -0.026 \pm 0.003$ mol^{-1} in the molarity scale. The contribution of the bromide ion may be calculated using the SPT theory and the

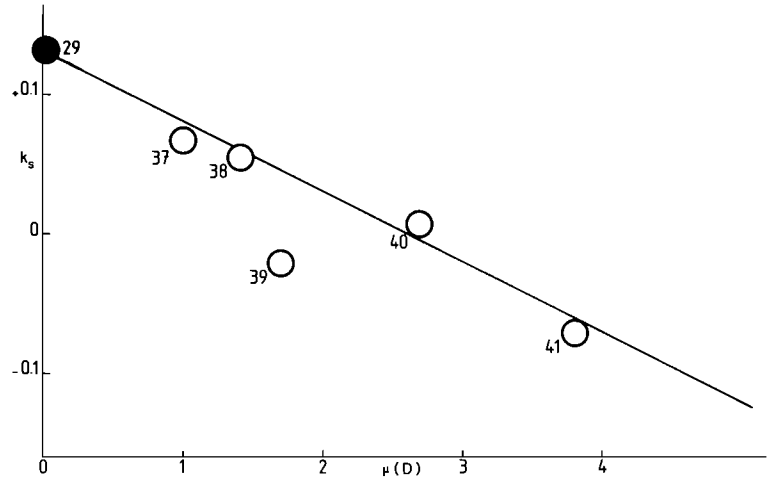

FIG. 4. Salting constant versus dipole moment for polar molecules in aqueous KCl solutions; H_2S = 37, NH_3 = 38, SO_2 = 39, HCN = 40, $N_2H_2NO_2$ = 41.

data of Table 3. The results of these calculations are shown in Fig. 3. The order of magnitude is correct but the bromide ion contribution, being highly size dependent, determines the wrong trend of the variation of k_s with size. It should be pointed out that in deriving eq. [7] it is assumed that the microscopic interfacial tension is an additive combination of its constituent values (37). Figure 3 shows that this assumption is not valid. Again a preferential solvation phenomenon occurs which cannot be taken care of by simple models (additive effects).

Exceptions to the Predominant Volume Effect

There are at least three types of exceptions to the above observations.

The first one is obviously the case of specific interactions, e.g. complexation; they are difficult to predict. Examples are the specific interaction of the silver ion with acetonitrile (21) or that of benzene with tetraalkylammonium ions: k_s for benzene (in aqueous Bu_4NBr solution) is -0.53 and only -0.16 for butane. Specific interactions of aromatic molecules such as naphthalene with a cationic surfactant such as cetyltrimethylammonium bromide has been proposed in order to interpret a high solubility of the solute molecule in these surfactant solutions (43).

The second type of exception is that of polar molecules with polyfunctional groups. It had been already noted by Long and McDevit that when two or more functional groups are attached to the same molecule the resultant effect is not an average value of the effect of each group alone. This is also true for two identical groups: *p*-dioxane for example is situated much below the line corresponding to the regular curve of Fig. 3 with $(NH_4)_2SO_4$. Another characteristic example may be given with the salting constants of compounds with alcohol groups in aqueous *n*-hexylaminobenzoate solutions (38).

TABLE 3. Physical parameters of ions

Ion	σ (Å)	α × 10^{24}	$V_0^{a,b}$
NH_4^+	2.86	1.43	12.46
SO_4^{2-}	4.51	5.83	24.8
Na^+	1.90	0.21	−6.6
Cl^-	3.62	3.02	23.2
Bu_4N^+	8.0	31.2	270.26
Br^-	3.90	4.17	30.1

[a] References 49, 50.
[b] $V_0(H^+) = -5.4\ cm^3\ mol^{-1}$.

We observe the following decreasing order:

ethanol > ethylene glycol > glycerol

Evidently the reverse order would be found from the relative size of each molecule.

In these cases it seems that the prediction of salting constants can only be deduced from some group additivity approach such as that of Savage and Wood (44) specialized to three component systems (45). This approach, however, necessitates a very large number of data which are not available for the moment.

A third type of exception is the most obvious one: the case for which the dipole moment of the solute plays the major role. This case has been noted by Long and McDevit for aqueous KCl with a number of inorganic polar solutes (9). Figure 4 presents the salting constant of such molecules as a function of the dipole moment of the molecule. There is indeed a good correlation which could not be found were the size of the molecules taken as the variable parameter. Thus this observation is in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

direct contrast to that of Figs. 1 to 3 as it implies that the permanent dipole moment of the molecule should be taken into account for the prediction of salting constants of these polar molecules.

The following arguments may reconcile these apparently conflicting observations. It has been pointed out before that for all aprotic organic polar molecules the negative end of the dipole is much more accessible than the positive end (46). This is also the case for alcohols and indeed all the molecules of Figs. 1 and 2. The first consequence of this situation is that most organic molecules solvate preferentially cations but a second consequence might be that the positive charge of the dipole is shielded in such a way that the molecule does not behave as a permanent dipole. This would be due to the presence of the methyl group in small molecules which usually bears the positive charge of the dipole. In the case of the inorganic molecules of Fig. 5 both ends of each dipolar molecule are equally accessible and thus the molecules do behave as effective dipoles.

Furthermore there are indications that dipole–dipole and ion–dipole interactions in the gas phase are stronger than in the liquid phase. It can be shown that a Setchenov constant is proportional to the free energy of pair wise interactions in solution and that it is equivalent to a second virial coefficient in the liquid phase (22): Rossky and Friedman (47) have shown that the second virial coefficient B_{12} of benzene in aqueous solution is about half its value in the gas phase. The same general conclusion has been noted by Wood (48); the solvent mediates the dispersion forces and the structural effects and this may diminish the dipole–dipole interactions in the liquid phase. The same reasoning may be applied to ion–molecule interactions. Kebarle and co-workers (46) have indeed convincingly proven the importance of the change of solvation free energy in the gas phase when several solvent molecules compete to build the solvation shell of the ion and its relation to structural effects. Thus a single acetonitrile molecule is a better ion solvating agent than a water molecule but the opposite is true when several molecules participate to form the solvation shell.

Finally one cannot rule out completely the possibility of partial cancellation of opposite effects although the cancellation would be almost perfect in the cases of Figs. 1 and 2 especially. For example, permanent dipole–dipole forces between the polar components would contribute to increase k_s whereas the permanent dipole–ion interactions would decrease the salting constant. We have also noted that the entropic interaction term has been ignored. Thus the set of eqs. [9] to [11] may be considered (in the case of polar molecules) as a useful predicative instrument of partly empirical origin.

Conclusions

The previous discussion has shown that the salting constant of neutral mono-functional polar molecules in aqueous electrolyte with univalent cationic solutions may be classified in several groups: (*1*) Organic molecules in aqueous inorganic salt solutions are systematically salted out, the k_s values present an almost linear dependence upon the solute size for a given electrolyte; as a result of the absence of specific interactions the SPT model may be used together with an interaction term between the polar molecule and the cation in order to predict the salting-out effect with a surprisingly good agreement with experiment. The theoretical reasons for such an agreement may only be guessed at the present time. (*2*) Organic molecules in aqueous organic salt solutions may be salted-in or -out according to the respective size of the molecules. A linear dependence upon size is also noted. However, the interaction term between the organic ions and the organic molecules cannot be calculated using simple classical models; an empirical approach based on molecular surface areas reveals the same shortcomings due to the difficulties to incorporate the preferential solvation phenomenon. (*3*) Inorganic molecules in inorganic salt solutions show a salting dependence upon the dipole moment of the molecules which might be related to the availability of both ends of the dipole to interactions with the ions. (*4*) The interaction of inorganic molecules with organic ions is not experimentally known at all and experiments in this area may be found very useful.

Appendix

The three terms of eq. [2] as obtained by Masterton and Lee (3) may be put under the form:

[8] $k_s = k_\alpha + k_\beta + k_\gamma$

with

[9] $$k_\alpha = 2.15 \times 10^{20}(\sigma_3^3 + \sigma_4^3) - 2.47 \times 10^{-4}V_0 + \sigma_1[6.45 \times 10^{20}(\sigma_3^2 + \sigma_4^2) + 1.34 \times 10^{28}(\sigma_3^3 + \sigma_4^3) - 4.23 \times 10^4 V_0] + \sigma_1^2[6.45 \times 10^{20}(\sigma_3 + \sigma_4) + 4.01 \times 10^{28}(\sigma_3^2 + \sigma_4^2) + 1.32 \times 10^{36}(\sigma_3^3 + \sigma_4^3) - 4.17 \times 10^{12}V_0]$$

[10] $$k_\beta = -1.85 \times 10^{14}\left(\frac{\varepsilon_1}{k}\right)^{1/2}\left[\alpha_3^{3/4}Z_3^{1/4}\left(\frac{\sigma_1+\sigma_3}{\sigma_3^3}\right)^3 + \alpha_4^{3/4}Z_4^{1/4}\left(\frac{\sigma_1+\sigma_4}{\sigma_4^3}\right)^3 + 6.26 \times 10^{17}V_0\left(\frac{\varepsilon_1}{k}\right)^{1/2}(\sigma_1+\sigma_2)^3 + 4.00 \times 10^{-2}\frac{(V_0\alpha_1)}{(\sigma_1+\sigma_2)^3}\right.$$

[11] $$k_\gamma = 0.016 - 4.34 \times 10^{-4}V_0$$

Indices 1 to 4 refer respectively to solute, water, and ions. (See Tables 1 and 3.) In order to simulate preferential solvation of anions by water molecules α_4 (for example) is put equal to zero, and $V_0 = V_0(+)$ in eq. [10]. Z is the total number of electrons on an ion. The physical constants for water have been already introduced in the calculations of the terms of eqs. [9] to [11] (3).

Nuclear magnetic resonance studies of proton exchange in imidate esters and amides in strong acid

CHARLES L. PERRIN AND ERIC R. JOHNSTON

Department of Chemistry, D-006, University of California at San Diego, La Jolla, CA 92093, U.S.A.

Received January 6, 1981

CHARLES L. PERRIN and ERIC R. JOHNSTON. Can. J. Chem. **59**, 2527 (1981).

Saturation-transfer or lineshape measurements of kinetics of proton exchange show that H_Z of ethyl acetimidate in 46% H_2SO_4 or ethyl *N*-methylformimidate in 40% H_2SO_4 exchanges faster than H_E, and H_E of protonated 2-iminotetrahydrofuran exchanges faster than H_Z, as expected on the basis of the stabilities of the stereoisomeric imidate esters. In contrast, amide exchange is too fast to measure in aqueous H_2SO_4, but can be measured in 100% H_2SO_4, where H_E and H_Z exchange at equal rates. Also, there is intramolecular exchange occurring at this same rate. These results are interpreted as evidence for exchange in amides via the *N*-protonated intermediate, whose lifetime in H_2SO_4 is sufficiently long to permit the protons on nitrogen to become equivalent. By comparing OH exchange with NH exchange, it is concluded that *N*-protonation is the rate-limiting step. Even though this is a thermodynamically favorable proton transfer in H_2SO_4, its rate constant is significantly lower than the diffusion-controlled limit. The contrasts between imidate esters and amides and between dilute solutions and H_2SO_4 are discussed.

CHARLES L. PERRIN et ERIC R. JOHNSTON. Can. J. Chem. **59**, 2527 (1981).

Le transfert de saturation ou les mesures de la forme des lignes de la cinétique d'échange du proton montre que le H_z de l'acétimidate d'éthyle dans du H_2SO_4 à 46% ou du *N*-méthylformimidate d'éthyle dans du H_2SO_4 à 40% s'échange plus rapidement que H_E, tandis que le H_E de l'imino-2 tétrahydrofuranne protoné s'échange plus rapidement que le H_z tel qu'attendu en se basant sur les stabilités des stéréoisomères des esters imidates. L'échange d'amide, au contraire, est trop rapide pour être mesuré dans du H_2SO_4 aqueux mais il peut être mesuré dans du H_2SO_4 à 100%, où les vitesses d'échange du H_E et du H_z sont égales il y a également un échange intramoléculaire qui s'effectue à cette même vitesse. Les résultats prouvent que l'échange dans les amides se fait via un intermédiaire *N* protoné dont le temps de vie dans le H_2SO_4 est suffisamment long pour permettre aux protons sur l'azote de devenir équivalents. En comparant l'échange de OH à celui du NH ou conclut que la protonation de l'azote est l'étape déterminante. Bien que le transfert de proton dans le H_2SO_4 soit thermodynamiquement favorisé, sa constante de vitesse est significativement plus faible que la limite contrôlée de diffusion. On discute des différences entre les esters imidates et les amides et entre les solutions diluées et de H_2SO_4.

[Traduit par le journal]

Introduction

Two mechanisms have been proposed for acid-catalyzed proton exchange in amides, one involving *N*-protonation (k_p in Scheme 1) (1) and the other a more circuitous one involving the imidic acid (k_o and k_{-i}) (2). We originally sought to distinguish between these by comparing rates of exchange of H_E and H_Z in primary amides (**1**) (3). We observed that H_E exchanges faster, whereas analogy to imidate esters (4) would require H_Z to exchange faster if exchange proceeded via the imidic acid. We therefore concluded (3) that exchange proceeds via *N*-protonation. However, to account for the greater reactivity of H_E, we proposed the additional feature that $RCONH_3^+$ is so strong an acid that its lifetime is too short to permit rotational equilibration about the C—N single bond. Additional evidence for this mechanism has recently been obtained by lineshape (5) and saturation-transfer methods (6–8), as well as evidence for the imidic-acid mechanism for amides with electron-withdrawing substituents (6, 8). In this paper we present our results for exchange in imidate esters, and we compare them with amides.

$$\begin{array}{lll} RCONHR' + H^+ \underset{k_d}{\overset{k_p}{\rightleftharpoons}} RCONH_2{}^+R' & & K_a{}^N = k_d/k_p \\ k_o \Big\| \; k_{-o} & & K_a{}^O = k_{-o}/k_o \\ RC(OH){=}NHR'^+ \underset{k_i}{\overset{k_{-i}}{\rightleftharpoons}} RC(OH){=}NR' + H^+ & \text{imidic acid} & K_a{}^I = k_{-i}/k_i \end{array}$$

SCHEME 1. *N*-protonation and imidic-acid mechanisms for acid-catalyzed proton exchange in amides.

Exchange in protonated imidate esters (**2**) is a good model for exchange via the imidic acid. (Protonated imidate esters have often been used as models of protonated amides, for study of hydrolysis kinetics (9).) Deprotonation of **2** ought to be comparable to k_{-i} of Scheme 1, so that a determination of the relative reactivities of H_E and H_Z can test whether the imidic-acid mechanism really requires H_Z to exchange faster. Also, a comparison of the

relative reactivities of amides and imidate esters might permit assessment of the significance of the imidic-acid route.

A definitive distinction between the *N*-protonation and imidic-acid mechanisms is that only the former involves intramolecular exchange. Specifically, it can be derived (8) that for the *N*-protonation mechanism in primary amides

$$[1] \quad k_{ZS} = k_{ZE} = k_{EZ}$$

where k_{ij} is the pseudo-first-order rate constant for exchange of protons from site i (H_E, H_Z, $H_{Solvent}$) to site j. In contrast, the imidic-acid mechanism requires that

$$[2] \quad k_{EZ} = 0 = k_{ZE}$$

Intramolecular exchange cannot occur, since the lifetime of the imidic acid before reprotonation is far too short to permit rotation or inversion (10). Thus the two mechanisms may be distinguished by comparing the rates of intramolecular and intermolecular exchange. Moreover, intramolecular exchange is again impossible for imidate esters, so that these can serve as a check on the experimental methods.

With secondary amides, eqs. [1] and [2] hold only qualitatively. The counterpart of intramolecular exchange is *E*/*Z* isomerization accompanying proton exchange. Such isomerization can occur only in the *N*-protonation mechanism, and not in the imidic-acid mechanism, nor in imidate esters.

It is not easy experimentally to distinguish intramolecular exchange or isomerization from intermolecular proton exchange. The familiar line-broadening or lineshape methods (11) do not measure individual rate constants, but rather the lifetime of a nucleus in each site, whose reciprocal is the sum of all the rate constants for exchange from that site. These methods are adequate for qualitative conclusions regarding secondary amides, but totally inadequate for primary amides. Fortunately, the saturation-transfer method (12, 13) is capable of measuring each individual rate constant. Thus we can test for intramolecular exchange or isomerization.

Experimental

Ethyl acetimidate hydrochloride was prepared according to MacKenzie *et al.* (14); nmr (DMSO-d_6) δ: 1.32 (t, 3H), 2.45 (s, 3H), 4.50 (q, 2H), 11.25 (br s, 1H), 12.20 (br s, 1H). Ethyl *N*-methylformimidate·HBF_4 was prepared according to Kohn and Olofson (15) and extracted from CH_2Cl_2 into aqueous H_2SO_4; nmr (54 wt.% H_2SO_4) δ: 9.7 (v br), 8.32 (d, under solvent peak, visible in 40% H_2SO_4), 4.66 (q, J = 7 Hz, 2H), 3.04 (dd, J = 5.4, 1.2 Hz, 3H), 1.42 (t, J = 7 Hz, 3H); there is also a minor doublet (J = 5 Hz) at δ 3.16, present to the extent of 8%. 2-Iminotetrahydrofuran hydrochloride was prepared from 4-hydroxybutyronitrile (16) according to Nohira *et al.* (17); nmr (DMSO-d_6) δ: 2.30 (m, 2H), 3.20 (t, 2H), 4.80 (t, 2H), 11.49 (br s, 1H), 11.75 (br s, 1H). Other imidates and amides (Aldrich, Fluka, Eastman) and sulfuric acid (Mallinckrodt AR or fuming, standardized vs. NaOH) were commercially available and used without further purification. Samples for nmr studies were quite concentrated, up to 2.5 *M* in amide or 4.5 *M* in imidate. The ratio of solvent protons to NH protons was determined from the weights of the components used to prepare the solutions, or by integrating the nmr spectrum.

The nmr measurements were performed on a Varian HR-220 FT spectrometer at 23°C, except for ethyl *N*-methylformimidate, which was studied on a Varian EM-390 spectrometer at 34°C. Simulation was by Nicolet's ITRCAL program. Details of the methods, including saturation transfer and the advantages of viscous solvents, have been described (13, 18, 19). Specifically, we measure six values of $t_i(j)$, the transfer of saturation (18) from each site j (H_E, H_Z, $H_{Solvent}$) to each other site, i, or the fractional loss of intensity at site i, I_i, on saturating site j:

$$[3] \quad t_i(j) = \frac{I_i^0 - I_i(j)}{I_i^0}$$

and we also measure $M_S(E, Z)$, the apparent spin–lattice relaxation rate constant ($=1/T_{1S}^{app}$) of solvent protons, under conditions that both H_E and H_Z are saturated, as well as $M_E(S)$ and $M_Z(S)$, apparent spin–lattice relaxation rate constants of H_E and H_Z under conditions of solvent saturation. Rate constants were then calculated from equations adapted from Perrin and Johnston (13). In particular,

$$[4] \quad k_{ES} = M_S(E, Z)\frac{t_S(E) - t_S(Z)t_Z(E)}{1 - t_E(S)t_S(E)}\frac{p_S}{p_E}$$

where p_i is the relative population of site i. Also,

$$[5] \quad k_{SE} = M_E(S)\frac{t_E(S) - t_E(Z)t_Z(S)}{1 - t_E(Z) + t_S(Z)[t_E(S) - t_Z(S)]}\frac{p_E}{p_S}$$

$$[6] \quad k_{ZE} = M_E(S)\frac{t_E(Z) - t_E(S)t_S(Z)}{1 - t_E(Z) + t_S(Z)[t_E(S) - t_Z(S)]}\frac{p_E}{p_Z}$$

The equations for k_{ZS}, k_{SZ}, and k_{EZ} are analogous.

Results

Signal Assignments

The downfield substituent of various *N*,*N*-disubstituted imidates and protonated amides has been assigned (20–22) as *E*, just as in amides (23). The only assignment (22) for a protonated primary amide was by analogy of $^1J_{^{15}NH}$ in amides, and this is opposite to the assignment based on long-range couplings. We therefore sought unambiguous assignments.

Figure 1 shows the nmr spectrum of formamide in 100% H_2SO_4(**2**, R = H = R′), along with two simulated spectra. In Fig. 1b the coupling constants of the CH to the downfield and upfield NH are taken as 7 and 15 Hz, respectively (cf. 5 and 14 Hz observed (24) in protonated ethyl formimidate); in Fig. 1c they are reversed. The observed spectrum (both the CH regions and the broadened NH regions) is in better agreement with Fig. 1b. Since $^3J_{trans} > {}^3J_{cis}$, we conclude that H_E is downfield. Figure 2 shows results of an nOe (25) experiment on

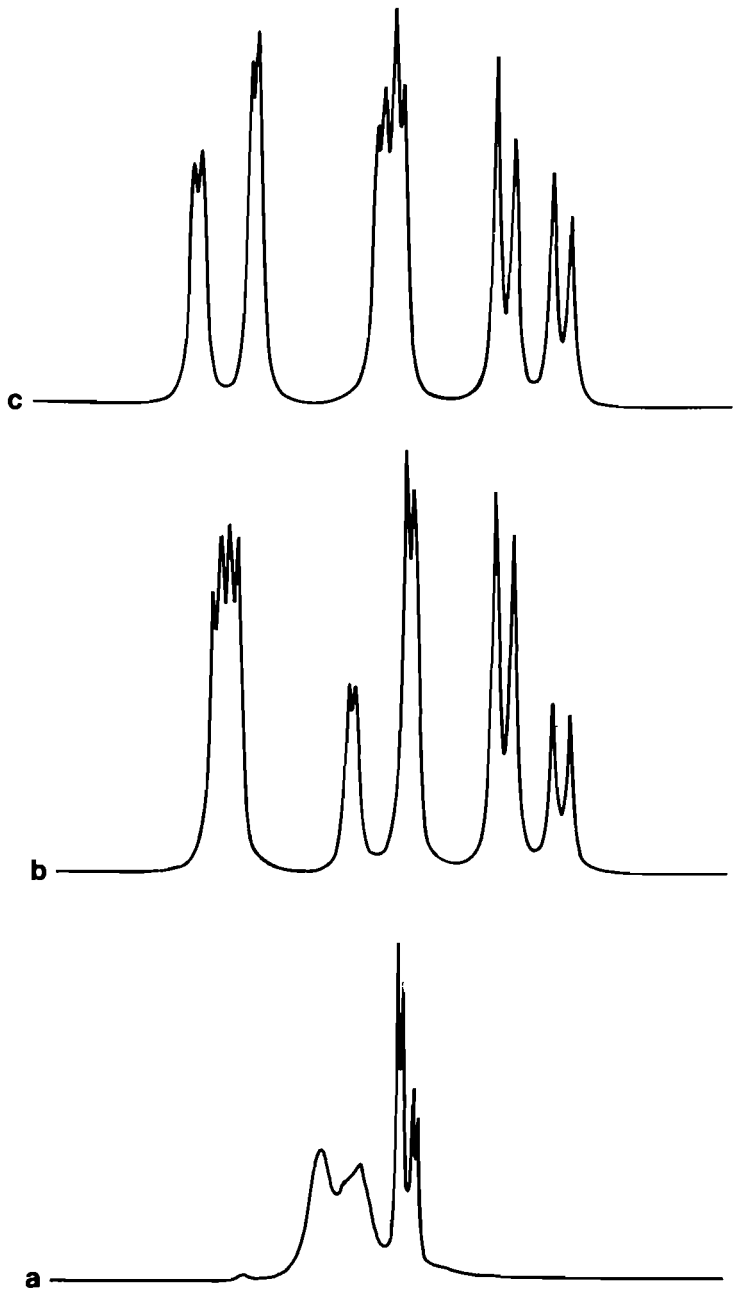

FIG. 1. (a) The nmr spectrum of *O*-protonated formamide. Plot width 600 Hz at 220 MHz. (b,c) Simulated spectra, expanded (see text).

methyl trichloroacetimidate (**2**, R = Cl_3C, R′ = CH_3) in 95% H_2SO_4: $f_{OCH_3}(NH_{upfield})$ = 3.7%, also (not shown) $f_{NH_{downfield}}(OCH_3)$ = 3.8% and $f_{OCH_3}(NH_{downfield})$ = 1.2% (from "spillover"). Therefore we conclude that H_E is again downfield. Since there are no known exceptions, we assume that this assignment also holds for all the other protonated amides and imidates under study.

Exchange Rates

Figure 3 shows a saturation-transfer spectrum of ethyl acetimidate (**2**, R = CH_3, R′ = C_2H_5); the greater transfer of saturation to H_Z shows clearly that this proton exchanges faster. Saturation-transfer data for various imidates and amides are summarized in Table 1, and the kinetic results are in Table 2. The rate constants for intramolecular

exchange in ethyl acetimidate and acetamide have been corrected for dipole–dipole cross-relaxation (25), determined in 57% H_2SO_4 and fuming H_2SO_4, respectively, where exchange is slow. This correction is small, less than 1.0 s^{-1}, and has been neglected in 3,5-dinitrobenzamide. Figure 4 shows the nmr spectrum of *N*-methylformamide exchanging in ca. 100% H_2SO_4.

Exchange of imidate esters in dilute solutions is too fast to measure. Since the pK_a of a protonated imidate ester is ca. 7.6 (ethyl acetimidate (26)), and since reprotonation of an imidate by H_3O^+ would be diffusion-controlled (27), the lifetime of a protonated imidate in aqueous solution must be ca. 10^{-3} s, far too short for our nmr methods. To reduce the exchange rate, it is necessary to reduce the activity of water. Thus we find that exchange in ethyl acetimidate is slow in 57% H_2SO_4 and measurable by saturation transfer in 46% H_2SO_4. Similarly, exchange in ethyl *N*-methylformimidate, $HC(OC_2H_5)=NHCH_3^+$, is slow in 54% H_2SO_4 and measurable by lineshape analysis in 40% H_2SO_4. Therefore we are definitely dealing with a base-catalyzed exchange, with water as base, quite analogous to k_{-i} in the imidic-acid mechanism for amides. (Hydroxide concentration in these solutions is too low to contribute even at a diffusion-controlled rate.)

Kinetics of amide exchange are quite different, both in dilute acid and in H_2SO_4. Although imidate esters exchange too fast to measure in aqueous solutions, amide exchange is readily measurable (1, 2, 5–8). Of course this difference arises merely because amide exchange requires protonation, whereas the imidate ester is already *O*-alkylated.

The contrast in H_2SO_4 is of greater interest. In stronger acid the amide is converted to its *O*-protonated conjugate acid, so that it is quite

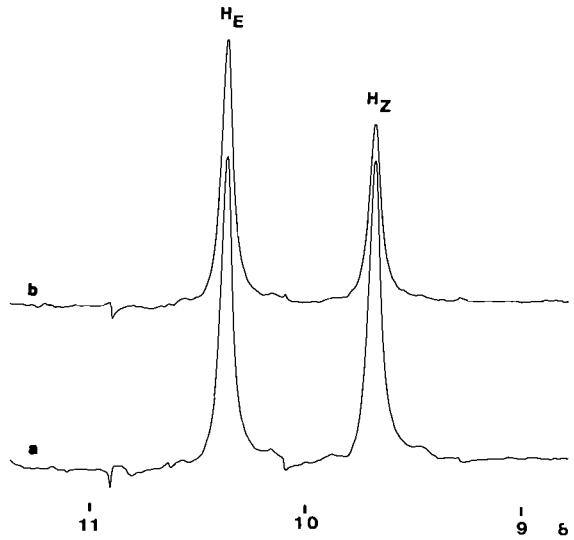

FIG. 3. Saturation-transfer experiment on ethyl acetimidate in 46% H_2SO_4. (a) Off-resonance spectrum. (b) Spectrum with solvent peak (offscale to right) saturated.

comparable to a protonated imidate ester. Then, if the imidic-acid pathway contributes to amide exchange, the two types of substrates should exchange at comparable rates. Nevertheless in 40–50% H_2SO_4, where imidate-ester exchange is readily measurable, amide exchange is too fast to measure. To measure exchange in amides, it is necessary to retard the exchange by going to concentrated H_2SO_4. The reaction is still a base-catalyzed exchange, with HSO_4^- as base (28), since less basic amides exchange faster (29) and since we find that the exchange is stopped in fuming H_2SO_4, where HSO_4^- is converted to the less basic $HS_2O_7^-$. The marked contrast between imidate esters and amides might suggest that different mechanisms are operative. This is discussed below.

Discussion

Exchange in Imidate Esters

The data of Table 2 show that there is no intramolecular proton exchange in ethyl acetimidate; within experimental error k_{EZ} and k_{ZE} are zero. Of course, none is expected, since the lifetime of the imidate before reprotonation by solvent is ca. 10^{-11} s (30), far too short to permit rotation or inversion (10, 22). Thus this result shows that the saturation–transfer method is valid for quantitatively distinguishing intramolecular exchange from intermolecular.

Similarly, there is no *E*/*Z* isomerization accompanying proton exchange of ethyl *N*-methylformimidate. Even in 29% H_2SO_4, where proton exchange is quite fast, the methyl doublets of the *E*

and *Z* forms are seen to coalesce to separate signals. Of course, this is exactly as expected for imidate esters, and gives us confidence that we can distinguish isomerization from proton exchange in secondary amides.

The data also show that in all three imidate esters the more acidic proton exchanges faster. In protonated ethyl acetimidate (**2**, R = CH_3, R′ = C_2H_5) H_Z exchanges significantly faster than H_E, as expected on the basis of the greater stability of the *E* configuration of imidate esters (4). Likewise, H_Z of the *E* isomer of protonated ethyl *N*-methylformimidate, $HC(OC_2H_5)$=$NHCH_3^+$, exchanges much faster than H_E of the *Z* isomer. (This is an intermolecular comparison, and the disparity in rates precluded accurate measurement.) The greater reactivity of H_Z in both these imidate esters is a partial justification for having excluded (3) the imidic-acid mechanism for amide exchange on the basis of the observation that H_E is more reactive. In contrast to the other two imidate esters, in protonated 2-iminotetrahydrofuran (**2**, RR′ = $CH_2CH_2CH_2$), it is H_E that exchanges faster (by 15%, assuming equal T_1's for the two protons). This result is also expected, since 2-(phenylimino)-tetrahydrofuran is predominantly *Z* (31), and since MO calculations (32) on the parent HC(OH)=NH suggest that if the C—O bond is fixed in the less stable *syn*-periplanar conformation, as required by the ring structure, then the *Z* configuration is the more stable.

Exchange in Amides

In contrast to imidate esters, amides show substantial intramolecular exchange accompanying intermolecular. Within experimental error (apparently underestimated for k_{ZE} of acetamide), rate constants for intramolecular exchange, k_{EZ} and k_{ZE}, in acetamide and 3,5-dinitrobenzamide are the same as the rate constant k_{ZS}. This is the requisite condition, eq. [1], and constitutes strong evidence against the imidic-acid mechanism (k_{-i} of Scheme 1) and for the *N*-protonation mechanism (k_{-o} and k_p), not only for acetamide, which exchanges via

this mechanism in dilute acid (8), but also for 3,5-dinitrobenzamide, which presumably exchanges via the imidic acid in dilute acid. Similarly, Fig. 4 shows that the doublets of the two stereoisomers of *N*-methylformamide coalesce and coalesce with each other. In less concentrated acid (not shown) only one singlet is seen; k_{ZE} is definitely nonzero, although the spectrum is not of sufficient quality to permit a quantitative comparison of isomerization and proton exchange. Since the imidic-acid mechanism does not permit isomerization, this result is evidence that the *N*-protonation mechanism (k_{-o} and k_p of Scheme 1) is also operative for secondary amides in concentrated H_2SO_4.

In contrast to imidate esters, where H_E and H_Z exchange at different rates, and in contrast to the behavior of amides in dilute acid, where H_E exchanges up to 70% faster than H_Z (for benzamide in ethylene glycol (8)), in strong acid H_E and H_Z exchange at the same rate, within experimental error, for all three primary amides, by two different nmr methods, saturation transfer and line broadening. Of course, the equal reactivityof H_E and H_Z is just what would be expected naively for the *N*-protonation mechanism. In $RCONH_3^+$ the protons become equivalent and must exchange at equal rates. The unusual feature of exchange in dilute acid is that $RCONH_3^+$ is so acidic ($pK_a \cong -9$ (33)) that deprotonation is diffusion-controlled and occurs faster than the protons can become equivalent through rotation about the C—N bond. But relative to 100% H_2SO_4 ($H_o = -12.2$ (34)) $RCONH_3^+$ is *not* a strong acid, so its lifetime becomes long enough that the protons become equivalent and do exchange at the same rate. This change, from unequal rates in dilute acid to equal rates in concentrated H_2SO_4, is strong evidence for competition in dilute solution between deprotonation and rotation.

Comparison of Dilute Solutions with H_2SO_4

The contrast in reactivity between ethyl acetimidate and acetamide or between ethyl *N*-methylformimidate and *N*-methylformamide is due to the availability of the *N*-protonation mechanism for amides, in both dilute solution and H_2SO_4. Yet trichloroacetamide (and presumably 3,5-dinitrobenzamide) exchanges via the imidic acid in dilute solution (8) but via *N*-protonation in H_2SO_4, since eq. [1] is obeyed. This change of mechanism may be understood by steady-state analysis of Scheme 1, plus microscopic reversibility, so as to express rates in terms of the equilibrium constants and the rate constants for the diffusion-controlled proton transfers. The rates of exchange via *N*-protonation and imidic acid are

$$[7] \quad v_N = \frac{k_d}{K_a^N} \frac{K_a^O[H^+]}{K_a^O + [H^+]} C_A$$

$$[8] \quad v_I = k_i \frac{K_a^I[H^+]}{K_a^O + [H^+]} C_A$$

where C_A is the stoichiometric concentration of amide. This readily leads to eq. [8] of ref. 8, and the conclusion that electron-withdrawing substituents favor the imidic-acid mechanism. In strong acid we must replace each $[H^+]$ by an appropriate acidity function. For *O*-protonation of amides (35) or *N*-protonation of imidate esters this is $h_A = 10^{-H_A}$, but the acidity function governing *N*-protonation of amides is unknown. According to rates of acid-catalyzed isomerization of tertiary amides (36), this acidity function might increase slightly less rapidly than h_A. However, for simplicity we use h_A. Then, in sufficiently strong acid we may neglect K_a^O relative to h_A, to obtain

$$[9] \quad v_N = k_d \frac{K_a^O}{K_a^N} C_A$$

$$[10] \quad v_I = (k_i h_A) \frac{K_a^I}{h_A} C_A$$

We have written v_I so as to emphasize the feature that reprotonation of the imidic acid is a diffusion-controlled process whose rate constant, $k_i h_A$, approaches a limiting value when the solvent becomes the proton donor. Despite sulfuric acid's high viscosity, proton mobility (37) is nearly as large as in water, so we take (18) 10^{11} s^{-1} for this limiting value of $k_i h_A$. Thus under these conditions v_I is inhibited by acid, as observed for imidate esters, but v_N becomes nearly acidity-independent (36), so that the mechanism changes, as observed for 3,5-dinitrobenzamide and trichloroacetamide.

Qualitative considerations of the transition-state structures lead to the same conclusion. Since both mechanisms involve diffusion-controlled proton transfer (38), the transition states resemble $RCONH_3^+$ and RC(OH)=NH. Therefore exchange via *N*-protonation involves only tautomerism, so it is nearly acidity-independent. In contrast, exchange via the imidic acid requires deprotonation, so that this mechanism is retarded by strong acid, and becomes negligible compared to the *N*-protonation mechanism.

In very strong acid, the *N*-protonation mechanism changes in that $RCONH_2R'^+$ becomes a weaker acid than solvent, so that its deprotonation is no longer diffusion-controlled. Also we must

adapt Scheme 1 so that HSO_4^- is the base that removes the proton (28). Then steady-state analysis leads to

$$[11] \quad v_N = (k_o[H_2SO_4]) \frac{K_a^{o}}{K_a^{H_2SO_4}} \frac{[HSO_4^-]}{[H_2SO_4]} \times \frac{k_p}{k_o + k_p} C_A$$

where $k_o[H_2SO_4]$ cannot exceed the first-order limit of 10^{11} s^{-1}. As evidence for the change from diffusion-controlled deprotonation of $RCONH_3^+$ (eq. [9]) to diffusion-controlled protonation (eq. [11]), we do observe that in 100% H_2SO_4 the exchange rate increases with $[HSO_4^-]$.

For generality eq. [11] does not distinguish which step is rate-limiting. Exchange requires initial deprotonation, by HSO_4^-, to form the amide, which then partitions between *O*-protonation, with probability $k_o/(k_o + k_p)$, and *N*-protonation, with probability $k_p/(k_o + k_p)$. In sufficiently strong acid both *O*-protonation and *N*-protonation of an amide are exergonic, and therefore diffusion-controlled (38). We might then expect both k_o and k_p to equal 10^{11} s^{-1}, so that neither step alone would be rate-limiting.

However, it is possible to demonstrate that *N*-protonation is the rate-limiting step. To do so we must compare the observed rate of exchange with the rate of formation of the intermediate amide, estimated from its steady-state concentration and an assumed diffusion-controlled lifetime of 10^{-11} s. For acetamide $pK_a^{o} = -0.90$ (39) and H_A in 100% H_2SO_4 is -7.24 (40), so the rate constant for amide formation may be estimated as ca. $10^{11} K_a^{o}/h_A$, or 5×10^4 s^{-1}, far greater than the observed 3.1 ± 0.3 s^{-1}. Admittedly our solution was only approximately 100% H_2SO_4, but it is quite unlikely that this estimate is vastly too high. Furthermore a high rate of deprotonation is consistent with the absence of an OH peak for the protonated amide, which appears only at low temperature in FSO_3H (20, 29, 41). Since the observed rate is much less than the rate of OH exchange, we conclude that *N*-protonation must be rate-limiting, with k_p/k_o only ca. 10^{-4}. Thus the rate constant for *N*-protonation is only ca. 10^7 s^{-1}, considerably lower than that of other thermodynamically favored proton transfers involving *N* and *O* (27, 38). We suggest that the slowness of this "diffusion-controlled" protonation is a manifestation of a solvent structure that is strongly hydrogen-bonded to the oxygen but not to the nitrogen line pair.

Comparison of Amides with Imidate Esters

The contrast between the reactivities of imidate esters and amides strongly suggests that there is an additional pathway available for exchange in amides, namely *N*-protonation. This contrast is so extreme (a $>10^8$-fold difference in water activity (42) between 50 and 100% H_2SO_4) as to suggest that the *N*-protonation mechanism is tremendously faster than the imidic-acid mechanism, and that the latter cannot possibly compete. This conclusion is correct in H_2SO_4, but not in dilute solution (8). The error in extrapolating from H_2SO_4 to dilute solution is revealed through eqs. [9] and [10], which show that only the imidic-acid mechanism is strongly inhibited by acid, so that although it does not contribute in strong acid, it can do so in aqueous solution. Moreover, the observation that amides with electron-withdrawing substituents show a changeover in behavior (from $k_{ES} \neq k_{ZS}$, without extensive intramolecular exchange, in dilute solution (8) to $k_{ES} = k_{ZS} = k_{ZE} = k_{EZ}$ in H_2SO_4) is evidence for a changeover in mechanism, and difficult to rationalize by exclusive *N*-protonation, as has been proposed (7).

1-Sterpurene-3,12,14-triol and 1-sterpurene, metabolites of silver-leaf disease fungus *Stereum purpureum*

WILLIAM A. AYER AND M. HOSSEIN SAEEDI-GHOMI
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 30, 1981

WILLIAM A. AYER and M. HOSSEIN SAEEDI-GHOMI. Can. J. Chem. **59**, 2536 (1981).

Two new sterpurane-type sesquiterpenes, sterpurene-3,12,14-triol (**4**) and 1-sterpurene (**5**), 2,6,10,10-tetramethyltricyclo-[6.3.0.$0^{3,6}$]undec-1-ene, have been isolated from among the neutral metabolites of the fungus *Stereum purpureum*. The structures were determined mainly on the basis of mass and nuclear magnetic resonance spectrometry.

WILLIAM A. AYER et M. HOSSEIN SAEEDI-GHOMI. Can. J. Chem. **59**, 2536 (1981).

A partir des métabolites neutres du champignon *Stereum purpureum*, on a isolé deux nouveaux sesquiterpènes du type sterpurane, le sterpurenetriol-3,12,14 (**4**) et le sterpurene-1 (**5**) (tétraméthyl-2,6,10,10 tricyclo[6.3.0.$0^{3,6}$]undecène-1). On a déterminé les structures en se basant principalement sur la spectrométrie de masse et sur la rmn.

[Traduit par le journal]

Recently we reported the isolation and structure determination of sterpuric acid (**1**) and hydroxysterpuric acid (**2**), metabolites of the fungus *Stereum purpureum* (Pers. ex Fr.) Fr., the causative agent of the so-called "silver-leaf disease" of a variety of trees and scrubs (1). The sterpuric acids represent a type of sesquiterpenoid not previously found in nature. We have also reported on the sterepolides (e.g., sterepolide (**3**)), new isolactarane-type sesquiterpenes produced by *S. purpureum* (2). We now wish to report on the isolation and structure determination of sterpurene-3,12,14-triol (**4**) and 1-sterpurene (**5**) from the neutral metabolites of this fungus.

Sterpurene-3,12,14-triol, $C_{15}H_{24}O_3$, mp 146–148°C, was isolated by flash chromatography (3) of the neutral fraction of the *S. purpureum* culture broth extracts (1). The mass spectrum of the triol shows an intense peak at $M^+ - 28$ due to the loss of ethylene from the cyclobutane ring, a characteristic feature of compounds with the sterpurane (**6**) skeleton (1). The infrared spectrum shows hydroxyl but no carbonyl absorption. The ^{1}H nmr spectrum displays AB quartets at δ 4.22 (J = 12 Hz) and 3.39 (J = 2 Hz), indicative of the presence of two hydroxymethyl groups, one of which is allylic (C-12, see **6** for numbering system). As is the case with sterpuric acid, the allylic proton at C-8 appears as a broad multiplet at δ 2.62. The highest field signal, a double doublet at δ 0.91 (J's 11 and 13 Hz), is also reminiscent of the sterpuric acids where this high field signal is attributed to one of the hydrogens on C-7 (1)[1].

Acetylation of triol **4** provides the diacetyl derivative **4***a*, which shows hydroxyl as well as acetoxyl absorption in the ir. The 400 MHz ^{1}H nmr spectrum of **4***a* is extremely informative in that almost all of the protons may be distinguished and assigned. The signals for the C-12 protons appear at δ 4.72 (AB q, J = 12 Hz) and those for the C-14 protons at δ 3.90 (AB q, J = 12 Hz). The C-12 protons show a

large pyridine shift ($\delta_{CDCl_3} - \delta_{py} = -0.46$ ppm) in agreement with their proximity to the C-3 hydroxyl function (4). The methyl group at C-6 also shows an appreciable (−0.2 ppm) pyridine shift. The proton at C-8 appears as a broad multiplet and is coupled to the C-7 methylene protons and the C-9 methylene protons. The allylic methylene group at C-11 gives rise to an AB quartet at δ 2.33 (J = 17 Hz). As expected, the C-4 and C-5 protons give rise to complete multiplets.[1] The ^{13}C nmr spectrum shows the presence of two olefinic carbons (δ 147.6, 127.2) and three carbons attached to oxygen (δ 72.9, 72.4, 62.1) and is otherwise in accord with the structure formulated.

The 1,3-relationship of the C-3 and C-12 hydroxyl groups in **4** was confirmed by acid-catalyzed treatment with 2,2-dimethoxypropane which provided the acetonide **7**. The assignment of the stereochemistry of the hydroxymethyl group on C-10 is tentative and is made on the assumption that the oxygenation pattern is the same on that carbon as for sterpuric acid (**1**). The similarity of the ^1H nmr coupling constants observed for the protons on C-7, C-8, and C-9 to those observed for the same spin system in **1** and **2** (1) is the basis for the stereochemical assignment at C-8.

Chloroform extraction of the mycelium obtained from liquid cultures of *S. purpureum* provided a dark brown oil which was partially dissolved in Skellysolve B. Chromatography of the hydrocarbon soluble portion provided a volatile, colorless oil[2] which we believe to be the "parent" hydrocarbon of this series of compounds, 1-sterpurene (**5**).[3] High resolution mass spectrometry indicates the molecular formula $C_{15}H_{24}$ and shows the prominent $M^+ - C_2H_4$ peak, characteristic of this ring system. The ^1H nmr spectrum shows three quaternary methyl signals (δ 1.23, 1.10, 1.08) and a vinylic methyl signal (δ 1.53). The allylic proton at C-8 appears as a broad multiplet at δ 2.65, coupled to the methylene groups at C-9 and C-7. Again one of the protons of the C-7 methylene group is at abnormally high field (δ 0.69). The allylic methine proton at C-3 appears as a double doublet (J's 10.5 and 13.5 Hz) at δ 2.39.[1] Treatment of 1-sterpurene with *m*-chloroperbenzoic acid gives the epoxide **8** as a single isomer. The ^1H nmr spectrum of **8** does not show a vinylic methyl. The four quaternary methyls give rise to singlets at δ 1.19, 1.18, 1.15, and 1.12 which cannot be individually assigned. Attempts to bring about acid-catalyzed rearrangement (or ring-opening) of the epoxide led to an intractable mixture of compounds. Lack of material prevented us from carrying out further studies on this hydrocarbon, but we feel that the structural asignment, although based on limited evidence, is both chemically and biogenetically sound.

[2]Since only 12 mg of the oil was isolated, its boiling point has not been determined.

[3]The systematic name for **5** is 2,6,10,10-tetramethyltricyclo-[6.3.0.0^{3,6}]undec-1-ene.

Experimental

General

Mass spectra were recorded on an AEI model MS-50 mass spectrometer. The formulas of all peaks reported were determined by high resolution measurements. Infrared spectra were recorded on a Nicolet 7199 FT interferometer. Optical rotations were measured on a Perkin-Elmer model 141 automatic polarimeter. The ^1H nmr spectra were determined on a Bruker WH 400 spectrometer with TMS as internal standard. The ^{13}C nmr spectra were measured on a Bruker HFX-90 spectrometer interfaced to a Nicolet 1085 computer. Melting points were recorded on a Fisher-Johns melting point apparatus and are uncorrected. Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C. Column chromatography was carried out using Macherey Nagel Kieselgel 60 (100 g/g substrate). Preparative layer chromatography (plc) was carried out on silica gel G (E. Merck, 0.75 mm layers) containing 1% electronic phosphor (General Electric, Cleveland). All solvents were distilled prior to use. All compounds for which spectral data are reported showed single spots on tlc using at least two different solvent systems.

Isolation of Sterpurene-3,12,14-triol (4)

The crude neutral metabolites of *S. purpureum* (0.52 g) (1) were subjected to flash chromatography (eluent chloroform–methanol (19:1)) (3) to give the crude triol **4** (75 mg). Further purification by column chromatography (eluent benzene–acetone (3:1)) provided a crystalline sample of **4** (42 mg) which was recrystallized from ether to give pure sterpurene-3,12-14-triol (**4**, 30 mg) as white needles, mp 146–148°C, $[\alpha]_D^{25}$ +64° (*c* 0.1, CH_3OH); ir (film): 3315, 1436, 1420, 1368, 1207, 1170, 1138, 1072, 1027, 998 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.22 (2H on C-12, AB quartet, J = 12 Hz), 3.39 (2H on C-14, AB quartet, J = 12 Hz), 2.86 (3H (OH), br, exchangeable), 2.62 (1H on C-8, br mult), 2.57 (1H on C-11, d, J = 18 Hz), 2.24 (1H on C-9, dd, J's 11 and 19 Hz), 2.10 (1H on C-11, d, J = 18 Hz), 2.04 (1H, complex mult), 1.68 (1H, m), 1.48 (1H on C-9, dd, J's 9.5 and 19 Hz), 1.22 (2H, complex mult), 1.21 (3H, s), 1.10 (3H, s), 0.91 (1H on C-7, dd, $J_{7,8}$ = 11 Hz, J_{gem} = 13 Hz); ms (probe, 150°C): *m/e* calcd. for $C_{15}H_{24}O_3$: 252.1725; found: 252.1730 (3), 234 (46), 224 (49), 216 (20), 204 (24), 203 (67), 188 (94), 175 (100), 173 (36), 159 (54), 145 (25), 131 (22), 119 (27), 107 (20), 105 (44), 91 (40).

Acetylation of Sterpurenetriol (4)

Acetic anhydride (0.25 mL) was added to a solution of triol **4** (5 mg) in pyridine (0.5 mL). The reaction mixture was stirred at room temperature for 0.5 h, then toluene (5 mL) was added and the solvents were evaporated under reduced pressure. Column chromatography (eluent benzene–ether (9:1)) provided the diacetate **4*a*** as a colorless oil (5 mg); ir (film): 3455, 1737, 1450, 1422, 1365, 1929, 1130, 1021 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.74 (2H on C-12, AB quartet, J = 12 Hz), 3.90 (2H on C-14, AB quartet, J = 12 Hz), 2.68 (1H on C-8, br mult), 2.42 (1H on C-11, d, J_{gem} = 17 Hz), 2.25 (1H on C-11, d, J_{gem} = 17 Hz), 2.20 (1H on C-4 or 5, m), 2.08 (3H, acetyl methyl, s), 2.07 (1H on C-4 or 5, m), 2.06

(3H, acetyl methyl, s), 1.71 (1H on C-9, dd, $J_{8,9}$ = 12 Hz, J_{gem} = 12.5 Hz), 1.63 (1H on C-7, dd, $J_{7,8}$ = 6 Hz, J_{gem} = 13 Hz), 1.55 (1H on C-5 or 4, m), 1.30 (1H on C-5 or 4, m), 1.26 (1H on C-9, $J_{8,9}$ = 6 Hz, J_{gem} = 12.5 Hz), 1.24 (3H on C-13, s), 1.14 (3H on C-15, s), 0.88 (1H on C-7, dd, $J_{7,8}$ = 11 Hz, J_{gem} = 13 Hz). The assignments of the coupling partners were confirmed by double irradiation experiments; ^{1}H nmr (Py-d_5) δ:5.20 (2H on C-12, AB quartet, J = 12 Hz), 4.03 (2H, AB quartet, J = 12 Hz), 2.71 (1H, br mult), 2.06 (3H, s), 1.55 (1H, m), 1.42 (3H on C-13, s), 1.32 (1H, m), 1.12 (3H, s), 0.84 (1H, dd, J's 11 and 13 Hz); ^{13}C nmr ($CDCl_3$ δ: 20.9, 21.0, 23.9, 24.9 (CH_3); 22.1, 35.2, 35.3, 40.0, 42.9, 62.1, 72.4 (CH_2); 37.1 (CH); 40.6, 44.6, 72.9, 127.2, 147.6 (C); 171.2 (2 × C=O); ms (probe, 150°C): the highest peak corresponded to $M^+ - H_2O$); *m/e* calcd. for $C_{19}H_{26}O_4$ ($M^+ - H_2O$): 318.1831; found: 318.1851 (0.5), 308 (14), 276 (20), 247 (21), 216 (41), 203 (33), 188 (100), 175 (55), 173 (44), 105 (21), 91 (20). Chemical ionization (NH_3) ms shows an $M^+ + 18$ (*m/e*) 354 peak.

Sterpurene-3,12,14-triol Acetonide (7)

Sterpurene-3,12,14-triol (7 mg) was dissolved in 2,2-dimethoxypropane (0.5 mL) and a catalytic amount of *p*-toluenesulfonic acid added. After two hours stirring at room temperature, ether (50 mL) was added and the solution was washed successively with saturated sodium bicarbonate, water (three times), and brine. The solution was dried (Na_2SO_4) and evaporated to give the crude product which was purified by chromatography (eluent benzene–ether (19:1)) to provide acetonide **7** as a colorless oil (7 mg); ir (film): 3385, 1453, 1378, 1240, 1192, 1087, 1030 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 4.33 (2H on C-12, AB quartet, J = 12 Hz), 3.47 (2H on C-14, s), 2.64 (1H, br mult), 2.38 (1H, d, J_{gem} = 17 Hz), 2.17 (1H, m), 1.92 (1H, d, J_{gem} = 17 Hz), 1.44 (3H, s), 1.25 (3H, s), 1.18 (3H, s), 1.10 (3H, s), 0.92 (1H on C-7, dd, $J_{7,8}$ = 11 Hz, J_{gem} = 13 Hz); ms (probe, 25°C): *m/e* calcd. for $C_{18}H_{28}O_3$: 292.2039; found: 292.2034 (0.7), 235 (27), 234 (100), 216 (29), 206 (38), 204 (39), 203 (89), 189 (21), 188 (78), 187 (33), 175 (41), 159 (27), 119 (23), 105 (35), 91 (41), 79 (20), 77 (20), 55 (23).

Extraction of the Mycelium of S. purpureum *and the Isolation of 1-Sterpurene (5)*

The mycelium from a 10 L growth of *S. purpureum* (1) was kept at −12°C for three months. It was then extracted with chloroform for 2 days in a Soxhlet apparatus. The chloroform extract was washed with water and brine, dried (Na_2SO_4), and concentrated under reduced pressure to provide the crude mycelium extract as a dark brown oil (0.62 g). Skellysolve B (10 mL) was added to the crude extract and the mixture was heated at 60°C for 5 min. After cooling to room temperature, the Skellysolve B soluble portion was evaporated to give a yellow oil (0.35 g). The latter was subjected to column chromatography (eluent Skellysolve B) to provide 1-sterpurene as a colorless oil (12 mg); ir (film): 1457, 1445, 1433, 1372, 1361, 1355 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.65 (1H on C-8, br mult), 2.39 (1H on C-3, dd, J's 10.5 and 13.5 Hz), 2.16 (1H, m), 2.10 (2H on C-11), 1.94 (1H, m), 1.68 (1H on C-9, dd, $J_{8,9}$ = 7.5 Hz, J_{gem} = 12 Hz), 1.58 (1H on C-7, m), 1.53 (3H on C-12, s), 1.48 (1H, m), 1.44 (1H, m), 1.23 (3H, s), 1.10 (3H, s), 1.08 (3H, s), 0.94 (1H, m), 0.69 (1H on C-7, dd, $J_{7,8}$ = 11 Hz, J_{gem} = 13 Hz); ms (probe, 100°C): *m/e* calcd. for $C_{15}H_{24}$: 204.1878; found: 204.1878 (34), 176 (100), 175 (82), 161 (81), 149 (24), 121 (37), 120 (41), 119 (43), 111 (26), 107 (42), 105 (54), 97 (32), 95 (29), 93 (32), 91 (32), 85 (28), 83 (30), 81 (29), 79 (22), 71 (35).

Epoxidation of 1-Sterpurene (5)

m-Chloroperbenzoic acid (10 mg of 85%) was added to an ice cold solution of 1-sterpurene (**5**, 7 mg), in methylene chloride (0.8 mL). The reaction mixture was kept in the fridge for 1 h, then for an additional 0.5 h at room temperature. Ether (25 mL) was added and the resultant solution was washed successively with saturated sodium bicarbonate, water (two times), and brine. Drying (Na_2SO_4) and evaporation of the solvents gave the crude product (7 mg) which was purified by chromatography (eluent Skellysolve B) to provide epoxide **8** as a colorless oil (4 mg); ir (film): 1600, 1455, 1445, 1432, 1363, 1355, 1280, 1188 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.45 (1H, br mult), 2.14 (2H, m), 1.95 (1H, d, J = 15 Hz), 1.85 (1H, br mult), 1.67 (1H, dd, J's 7 and 12 Hz), 1.60–1.30 (6H, complex), 1.19 (3H, s), 1.18 (3H, s), 1.15 (3H, s), 1.12 (3H, s); ms (probe, 100°C): *m/e* calcd. for $C_{15}H_{24}O$: 220.1827; found: 220.1819 (24), 129 (22), 163 (21), 149 (91), 95 (100), 57 (65), 55 (33).

Acknowledgements

We wish to thank the Natural Sciences and Engineering Research Council of Canada for financial support and Dr. Y. Hiratsuka for the cultures of *S. purpureum*. We wish to thank Dr. T. T. Nakashima for his assistance in determining the nmr spectra.

Received March 18, 1981

BYRON KRATOCHVIL, JAMES NOLAN, FREDERICK F. CANTWELL, and ROBERT B. FULTON. Can. J. Chem. **59**, 2539 (1981).

A scheme for the purification of the azo dye calmagite is described which involves solvent extraction, column partition chromatography, and adsorption chromatography on a nonpolar adsorbent. The final product, analyzed by thin-layer chromatography and by acid–base and ion-pair titrations, is of >99% purity. Molar absorptivities and acid ionization constants are reported for the conjugate species.

BYRON KRATOCHVIL, JAMES NOLAN, FREDERICK F. CANTWELL et ROBERT B. FULTON. Can. J. Chem. **59**, 2539 (1981).

On décrit un procédé de purification du colorant azoté, la calmagite, qui fait intervenir une extraction à l'aide de solvants, une chromatographie de partage sur colonne et une chromatographie d'adsorption sur un adsorbant non polaire. Le produit final, analysé par chromatographie sur couches minces et par des titrages acide–base et de paire d'ions, a une pureté >99%. On rapporte les capacités molaires d'absorption et les constantes d'ionisation de ces espèces conjuguées.

[Traduit par le journal]

The dihydroxyazo dye calmagite, 3-hydroxy-4-[(2-hydroxy-5-methylphenyl)azo]-1-napthalene sulfonic acid, was introduced by Lindstrom and Diehl in 1960 as an indicator for the EDTA titration of calcium and magnesium (1). The indicator properties of calmagite are similar to those of Eriochrome Black T, the first dye used for this purpose, but solutions of Eriochrome Black T are not stable, whereas those of calmagite are stable indefinitely. Both indicators form red complexes with both calcium and magnesium; however, the formation constant between calmagite and magnesium is approximately one hundred times greater than that with calcium. Because of this selectivity, calmagite has also been used for the spectrophotometric determination of free or ionic magnesium in biological materials which contain calcium (2, 3). This application is of particular interest because an ion selective electrode for the determination of ionic magnesium in the presence of calcium is not yet commercially available.

A recent paper proposed a modified spectrophotometric method for the determination of free metal ion concentrations which extends the range and applicability of previous methods but which requires indicators of high purity (4). Most commercially available calmagite has a purity of less than 60 percent, the major impurities being inorganic salts. A number of organic impurities are also present, the kind and amount depending on the purity of the starting materials and the care taken in synthesis.

Lindstrom and co-workers studied in detail the properties of calmagite, and outlined procedures for preparation of pure dye (5, 6). The procedure described by Lindstrom and Isaac (5) involves washing the synthesized material repeatedly to remove KCl, extracting for several hours with petroleum ether, and then extracting for several more hours with dry chloroform. The air-dried material is then dissolved in a mixture of 200 mL of 95% ethanol and 150 mL of dilute HCl (1:50), and the alcohol is evaporated gently over a warm steam bath. Upon slow cooling, microscopic crystals of pure calmagite form.

We found the last stage of the above procedure to be difficult to control, and the purity of the final product to be variable. Accordingly, we turned to purification of commercial material. The procedure of Lindstrom and Isaac is not suitable for commercial calmagite, probably because the starting materials are less pure. Kendrick (7) has described a procedure for purification of Arsenazo III, a dye similar in structure to calmagite, in which the dye is first passed through a column of Chelex-100 chelating ion exchange resin to remove calcium contamination, and then through a column of DEAE cellulose using *n*-butanol – pyridine – acetic acid – water, 15:10:3:12, as mobile phase. However, the procedure is tedious; about five days are required for the purified dye to be eluted from the second column alone.

Because of its excessive length, Kendrick's procedure was not considered for calmagite. Instead, a faster method involving both solvent extraction and column chromatography was developed. This procedure takes less than two days and yields calmagite of high purity as shown by thin-layer chromatography, and by acid–base and ion-pair extraction titrations.

Experimental

Apparatus

Spectrophotometric measurements were made with a Cary 118 spectrophotometer (Varian Associates, Palo Alto, CA) using either a standard 1 cm cuvette or a 1 cm flow cell (Hellma Co., Toronto). An Accumet Model 520 pH meter with separate glass and calomel electrodes (Fisher Scientific Co.) was used for pH measurements. The meter was standardized with standard buffers prepared according to Bates (8).

Reagents and Materials

Calmagite was obtained from Aldrich Chemical Co. Inc. (Lot No. 060647), Eastman Kodak Co. (Lot No. A6D), and G. Frederick Smith Chemical Co. (Lot No. 278). Precoated silica gel tlc plates (0.25 mm coating with fluorescent indicator and organic binder) were purchased from Brinkmann Instruments Inc. Dextromethorphan hydrobromide, used as a titrant, was obtained from Endo Laboratories, Inc. (Garden City, NY) and assayed by nonaqueous, Fajan's, and both acid–base and ion-pair two-phase titrations as 95.4% (9), the remainder being water. The support in the liquid–liquid chromatography work, Whatman CC-41 cellulose powder, was used as supplied. All solvents and inorganic chemicals were ACS Reagent Grade or better. Demineralized water was used throughout.

Thin-Layer Chromatography Techniques

Purity of the commercial material and of that isolated at each stage of the purification procedure was monitored by thin-layer chromatography on silica gel plates using as developer a mixture of butanol, ethanol, 1.5 *M* aqueous ammonia, and pyridine (BEAP) in the volume ratio 4:1:3:2. For reproducible results the plates, once spotted, were equilibrated with the solvent atmosphere in a developing chamber (Gelman Instruments Co., Model 51325-1) for at least 10 min prior to development. Under these conditions calmagite migrates as a purple spot with $R_f = 0.4$. To prevent interference from calcium, plates with $CaSO_4$ binder were not used.

Procedure for Solvent Extraction

A preliminary solvent extraction sequence was used to reduce the level of impurities to the point where a much larger loading of calmagite could be applied to the liquid–liquid partition chromatography column in the next step. The solvent extraction procedure is as follows.

Dissolve 2.0 g of the crude commercial calmagite in 80 mL of 0.10 *M* sodium acetate. Adjust the pH of the solution to 4.5 with glacial acetic acid and extract four times with 40 mL portions of 1-butanol, readjusting the pH of the aqueous layer to 4.5 with glacial acetic acid after each extraction. Pool the butanol fractions, which contain most of the calmagite, and back-extract the dye four times with 50 mL portions of 0.01 *M* NaOH. Because some acetic acid is extracted from the aqueous phase into the butanol phase during the first set of extractions, and is back-extracted in the second set, it is necessary to neutralize this acid during the first NaOH back-extraction by dropwise addition of 2.5 *M* NaOH until both the aqueous and organic phases remain blue after shaking. Subsequent back-extractions with 0.01 *M* NaOH do not require this pH adjustment. After the last extraction discard the butanol layer and combine the four aqueous NaOH extracts.

Precipitate the dye from the combined extracts by slowly adding with stirring a volume of concentrated HCl equal to 10% of the volume of the combined extracts. This produces a solution 1.2 *M* in HCl and precipitates the neutral sulfonic acid form of calmagite. Recover the gel-like precipitate by vacuum filtration on a 10–20 μm sintered-glass funnel and dry it overnight in a vacuum desiccator over $Mg(ClO_4)_2$.

Column Chromatography

Purification of the solvent-extracted dye is achieved using liquid–liquid partition chromatography followed by adsorption chromatography. The procedure is as follows.

For the partition chromatography, prepare the stationary aqueous phase by adjusting the pH of a 0.10 *M* solution of EDTA to 11.0 with 2.5 *M* NaOH solution. As the mobile phase use 1-butanol presaturated with the stationary phase. Add dropwise, with vigorous mixing, 100 mL of the stationary aqueous phase to 250 g of Whatman CC-41 cellulose powder (used as received). Next add 800 mL of mobile phase to form a slurry, pack it into a 4 × 60 cm glass chromatography column, and continue to pass mobile phase through the column until the volume of the bed no longer shrinks; this will require on the order of 4 h and 250 mL of mobile phase. The final bed should be about 50 cm long.

Dissolve 1 g of the solvent-extracted dye in a minimum volume of presaturated butanol mobile phase (about 15 mL) and load it onto the column. Elute with the mobile phase at a flow rate of 50 mL/h. The calmagite elutes as a purple-blue band after about 400 mL of eluent has passed. It is preceded by a brown band and followed by several bands of various colors. As soon as the calmagite begins to elute, collect the eluate in 5 mL fractions, subjecting the early and late fractions to thin-layer chromatography in order to locate the middle cut which is free of colored impurities. Pool the fractions in this middle cut and remove the solvent in a rotary evaporator. The cellulose powder can be reused after clean-up and drying.

For the adsorption chromatography, pack a 2 × 20 cm column with 60–80 mesh Amberlite XAD-2 resin (Rohm and Haas Co., Philadelphia, PA) in 40% MeOH/60% 1:10 HCl (v/v). Prepare a saturated solution of the product from the liquid–liquid partition column by dissolving about 1 g in 75 mL of methanol and adding 1:10 HCl until the first appearance of a precipitate, then adding sufficient methanol to just clear the solution. Load this solution onto the column and pass 250 mL of 40% MeOH/60% 1:10 HCl mobile phase through the column at a flow rate of 1 mL per min. Under these conditions calmagite is completely retained on the resin as the neutral sulfonic acid form while salt impurities are eluted. (Care should be taken that the dye does not precipitate during loading owing to evaporation of methanol.) Elute the purified calmagite with 95% ethanol and precipitate it as the sulfonic acid as follows.

Add to the ethanol eluate an equal volume of 1:10 HCl followed by sufficient ethanol to just dissolve the resulting precipitate. Warm the solution gently to remove the ethanol, thereby allowing the calmagite to precipitate slowly. Filter the precipitate and store it in a vacuum desiccator over $Mg(ClO_4)_2$ to prevent the uptake of atmospheric moisture by this highly hygroscopic material.

Spectral Properties and Acid Dissociation Constants

The spectral properties of the various protonated forms of purified calmagite were measured as a test of the purity of the material. The second and third acid dissociation constants were measured by the spectrophotometric procedure described in Albert and Serjeant (10) at 25°C and an ionic strength of 0.1. The

following buffers were used for the determination of pK_{a2}^M (for H_2In^-): acetic acid – acetate from pH 4.2 to 5.3, THAM from 7.3 to 8.8, and ethanolamine from 9.1 to 10.1. For the determination of pK_{a3}^M (for HIn^-) the pH was adjusted with 0.1 *M* sodium hydroxide. Values of the constants are reported in Table 1 as "mixed ionization constants" (10).

Titrimetric Assay of Calmagite

Due to the hygroscopic nature of calmagite, samples were first dried overnight in a vacuum oven at 80°C and then weighed out, taking care to minimize exposure to the atmosphere. In the potentiometric acid–base titration 50 mg portions of purified calmagite were titrated with 0.05 *M* NaOH, using a glass and saturated calomel electrode pair to monitor pH.

For the two-phase photometric titration a porous Teflon membrane "filter-probe" phase separator was employed to facilitate monitoring the absorbance of the chloroform phase at 520 nm. The titration was performed in an apparatus previously described (11) with 70.0 mL of chloroform and 30.0 mL of aqueous 0.059 *M* phosphate buffer of pH 3.0 containing 2.20 mg of calmagite sample. Because of a slight amount of interfacial adsorption of the ion-pair, the magnetic stirrer was turned off during the absorbance measurement (11). The titrant was an aqueous solution of dextromethorphan hydrobromide.

Results and Discussion

Thin-layer chromatographic analysis of the three lots of commercial calmagite as received revealed the presence of two major types of organic impurities, colored impurities visible to the naked eye and fluorescent impurities appearing under 365 nm radiation. All lots tested contained significant quantities of impurities from each class. No attempt was made to isolate or characterize the impurities.

Further tlc analysis using the BEAP – silica gel system showed a considerable increase in purity of the calmagite after the initial liquid–liquid extraction. Significant amounts of colored impurities were shown by tlc to be retained in the original aqueous phase, while the butanol layer was found to contain the major proportion of the fluorescent impurities originally present. Only small amounts of calmagite were detected in the discarded layers; much of the weight loss during the extraction procedure was the result of removal of inorganic salts, which constitute the major impurity in commercial calmagite.

Product yields for the extraction step varied between 51 and 55% for the three batches of commercial calmagite studied. The yield from the combined partition and adsorption chromatographic steps varied from 60 to 80%, giving an overall yield of 30 to 40% purified calmagite.

The tlc analysis of the partition chromatographic fractions containing colored material showed that all of the fractions containing significant amounts of calmagite were free of colored impurities. A trace fluorescent impurity was still detectable just ahead of the calmagite spot. The same impurity was also detected in the final product.

Titrimetric assay of the purified product with sodium hydroxide gave a value of 99.4% ± 0.1% rsd, and the ion-pair titration gave 98.9% ± 0.3% rsd. The H_3In (sulfonic acid) form of calmagite is very hygroscopic and the product likely contains several tenths of a percent water.

Spectral properties and acid dissociation constants obtained for the purified product in the present study are shown in Table 1 along with the corresponding values reported by Lindstrom and Diehl (1). The spectrum of the species H_2In^- is concentration dependent with both the molar absorptivity (ε) and wavelength of maximum absorbance (λ_{max}) of this species decreasing with increasing concentration. Below about 2×10^{-5} *M* calmagite the concentration dependence is negligible and Beer's law is observed. The value of ε and λ_{max} for H_2In^- reported by Lindstrom and Diehl was measured at 9.1×10^{-5} *M*. When this concentration was used with the purified material obtained in the present study ε was found to be 1.96×10^4, and λ_{max} was 525 nm; both values are in good agreement with the earlier reported values (Table 1). The difference between the values of λ_{max} obtained for the HIn^{2-} species in the present and the previous studies may be largely caused by uncertainty in reading the broad absorption band.

No accurate values of ε and λ_{max} could be obtained for the In^{3-} species of calmagite because of the large value of pK_{a3}^M and the instability of calmagite at high pH.

The value obtained here for pK_{a2}^M at an ionic strength of 0.1 was 7.91 which is lower than the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

earlier reported value of 8.14 (Table 1). This is because the spectrophotometric measurements in the present study were performed at a sample concentration ($2 \times 10^{-5} M$) sufficiently low that Beer's law is observed for the H_2In^- species, as discussed above. The earlier value of 8.14 was obtained at a sample concentration of $9 \times 10^{-5} M$ (1), while a value of 8.00 ± 0.02 was obtained at an intermediate concentration of $4.4 \times 10^{-5} M$.[2]

The values of pK_{a3}^M from both studies agree well. The proton on the sulfonic acid group in the H_3In species is almost completely dissociated, so no attempt was made to measure a pK_{a1}^M value.

Conclusion

In summary, a convenient method for the purification of commercially available calmagite has been developed and the product has been shown to conform on the basis of chromatographic, chemical, and optical properties to pure calmagite obtained by others through careful synthesis and exhaustive recrystallization. The partition chromatography column and procedure described here should be applicable to other indicators, particularly those of the *o,o'*-dihydroxyazo class. By varying the pH of the stationary phase buffer it is possible to optimize separation of the desired component. In a future communication we shall describe the application of purified calmagite to the determination of free magnesium ion concentration using the sample ion increment method (4).

The thermotropic phase behavior of ascorbyl palmitate: an infrared spectroscopic study[1]

HELMUT SAPPER,[2] DAVID G. CAMERON, AND HENRY H. MANTSCH

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received March 27, 1981

HELMUT SAPPER, DAVID G. CAMERON, and HENRY H. MANTSCH. Can. J. Chem. **59**, 2543 (1981).

The infrared spectra of aqueous potassium ascorbyl palmitate were studied as a function of temperature using Fourier transform infrared techniques. From a light scattering experiment the Krafft point of 0.1 *M* potassium ascorbyl palmitate was determined to be 48°C. The temperature-induced changes in infrared spectral parameters such as frequency and bandwidth characterize this Krafft point as a phase transition from a conformationally ordered, poorly hydrated solid phase, to an isotropic micellar phase. The phase transition of this "pseudosoap" occurs over a temperature range of about 10°C, reflecting the progressive hydration of the solid upon micellization, a behavior typical of surfactants such as soaps.

HELMUT SAPPER, DAVID G. CAMERON et HENRY H. MANTSCH. Can. J. Chem. **59**, 2543 (1981).

En utilisant les techniques infrarouges de la transformation de Fourier, on a étudié les spectres infrarouges des solutions aqueuses de palmitateascorbyle de potassium en fonction de la température. A partir d'un expérience de dispersion de la lumière, on a déterminé que le point Krafft pour une solution 0,1 *M* de palmitateascorbyle de potassium est de 48°C. La température provoque des changements dans les paramètres spectraux tels la fréquence et la largeur des bandes qui caractérisent ce point Krafft en tant que transition de phase à partir d'une conformation ordonnée, mal hydratée dans la phase solide, jusqu'à une phase micellaire isotropique. La transition de phase de ce "pseudo" savon se produit au dessus d'un intervalle de température de 10°C environ réflétant ainsi l'hydratation progressive du solide lors de la formation des micelles, c'est un comportement typique des savons.

[Traduit par le journal]

Introduction

Ascorbyl palmitate, the C-6 monoester of vitamin C with palmitic acid, was first synthesized by Swern *et al.* in 1943 (1) with the intention in mind to combine the reductive properties of ascorbic acid with the lipid solubility of a fatty acid. This derivative of ascorbic acid is actually a lipophilic vitamin C and has been shown to be as biologically active as its original hydrophilic counterpart (2, 3). Since both vitamin C and palmitate esters are natural food ingredients, ascorbyl palmitate is now widely used in the food industry as a natural preserver of oils and fats (4, 5).

The effectiveness of ascorbyl palmitate in protecting against oxidation is similar to that of other commercial lipid antioxidants, such as α-tocopherol (vitamin E). In fact, it has been shown that tocopherols become more powerful antioxidants when used in combination with ascorbyl palmitate (5, 6) and this effect can be further enhanced by addition of lecithin (3, 6). The synergism between vitamin C and vitamin E when used as antioxidants in biomembranes has been recently confirmed by pulse radiolysis measurements (7). Thus, the chemical behavior of ascorbyl palmitate as a lipophilic analogue of vitamin C is of interest not only in view of its value as a food additive, but also with respect to its possible biological role as a lipophilic vehicle of vitamin C.

Despite its importance to the food industry, there are few data in the literature regarding the structure and physicochemical properties of ascorbyl palmitate or its salts. In principle, one would expect these properties to reflect both those of vitamin C and those of a fatty acid ester. In addition, the salts of ascorbyl palmitate (at neutral pH ascorbyl palmitate is always a salt) are amphiphilic molecules and structurally similar to soaps such as the *n*-alkanoates or the *n*-alkyl sulphates. A common property of such surfactants is that above a certain temperature, referred to as the Krafft point (8–14), the solubility of the surfactant in water increases dramatically. The salts of ascorbyl palmitate exhibit the same behavior. Using a light scattering technique and Fourier transform infrared spectroscopy we have studied the Krafft point transition, and report on the data herein.

Experimental

Materials and Sample Preparation

Ethyl palmitate was from Sigma, St. Louis, MO and sodium ascorbate from Merck, Darmstadt, Germany. Ascorbyl palmitate (O^6-palmitoyl-L-ascorbic acid) was a commercial product from the U.S. Biochemical Corporation, Cleveland, OH. The potassium (or sodium) salts were prepared from equimolar amounts of ascorbyl palmitate and KOH (or NaOH), each dissolved in the minimal amount of absolute ethanol. The salts which precipitated upon mixing the two ethanolic solutions were filtered off, washed with absolute ethanol, and dried under vacuum.

Samples of aqueous 0.1 *M* (4.5 wt.%) potassium or sodium ascorbyl palmitate were obtained by warming the solid salt in the corresponding amount of D_2O to about 50°C in a closed flask; above 40°C the opaque suspension becomes a clear solution which upon cooling turns into a uniform curd at room temperature. The pD (meter reading) of the clear solution was 8.1. Thin samples (15 μm thick in CaF_2 cells) of the curd were prepared for infrared spectroscopy according to the detailed methods reported elsewhere (15, 16).

Spectra and Data Processing

Infrared spectra were recorded with a Digilab FTS-11 Fourier transform infrared spectrometer equipped with a mercury cadmium telluride detector (Infrared Associates, New Brunswick, NJ). Typically, six hundred scans were accumulated and co-added using a maximal optical retardation of 0.5 cm and a moving mirror velocity of 0.6 cm/s. The resultant interferograms were triangularly apodized and Fourier transformed with one level of zero filling to yield a resolution of $\sim 2\,cm^{-1}$. The spectra of solid samples were recorded as KBr pellets (1 mg sample in 100 mg KBr) of 1 cm^2 surface area. Temperature control was achieved by using a hollow cell mount thermostated by a flow of ethanol–water which gives a temperature stability of better than ±0.1°C (17). The temperature was monitored with a thermocouple located against the cell window, and temperatures were continuously recorded by a Newport digital pyrometer equipped with a printer. The spectrometer computer controlled the complete operation of recording a spectrum, printing and incrementing the temperature, waiting for temperature equilibration, and then repeating the sequence (18). Frequencies were measured by determining the center of area of the top five data points of a peak. Bandwidths were obtained by digitally subtracting a linearly interpolated baseline extending from 3000 to 2800 cm^{-1} and computing the widths at ¾ of the peak height. The precision (and reproducibility) of measuring temperature-induced changes in frequency and bandwidth is better than ±0.05 cm^{-1} (19).

The light scattering experiment was performed by measuring the light transmitted at 580 nm through a 1 mm quartz cell containing the system under study. A Cary 219 uv–vis spectrophotometer equipped with the automated temperature reactant accessory and a coupled chart drive was employed.

Results and Discussion

General Thermal Properties

At room temperature potassium ascorbyl palmitate (APK) and sodium ascorbyl palmitate (APNa) are insoluble in water except at extremely low concentrations. However, on heating a water–APK (or water–APNa) mixture, the solubility increases rapidly above a certain temperature, and a clear solution is formed. If the solution is then cooled it solidifies as an opaque curd.

This behavior is well known in ionic surfactant–water systems (8–15). The curd is a semicrystalline mesophase in which the surfactant molecules form lamellar structures. According to the degree of hydration and three dimensional ordering it may be referred to as a gel (well hydrated and unilamellar) or a coagel (poorly hydrated and multilamellar) (20). While X-ray measurements are required to unequivocally determine if at a given temperature a system forms a gel or a coagel, the extreme opacity observed in the aqueous ascorbyl palmitate salts is indicative of a coagel system.

The temperature at which the transition occurs from the coagel (or gel) to the micellar phase is generally referred to as the Krafft point or as the "melting" point of the hydrated solid surfactant. However, the physical meaning of the solubility curve is different from that of ordinary solid–solute equilibrium curves and a stricter definition of the Krafft point is that of the concentration at which the coagel, monomers, and micelles are in equilibrium (10).

The Krafft point is dependent on the concentration and the type of counterion. In the case of 0.1 *M* potassium and sodium palmitate soaps, Krafft points of 30°C and 60°C respectively have been reported (21). Using light scattering techniques we find Krafft points of 48°C and 44°C for 0.1 *M* APK and APNa respectively. That is, the influence of the counterion is much smaller and, contrary to the behavior of the corresponding palmitate soaps, that of sodium ascorbyl palmitate is lower than that of potassium ascorbyl palmitate.

Infrared Spectra

The thermotropic properties of potassium ascorbyl palmitate were investigated in detail by infrared spectroscopy. The 1800–1300 cm^{-1} region of the spectra of the anhydrous solid, the ordered coagel, and the isotropic micellar phase of APK are shown in the bottom segment of Fig. 1. The top segments show spectra of sodium ascorbate and ethyl palmitate, accurate frequencies are given in Table 1. It can be seen that, in general, the spectrum of APK is comprised of the summation of the palmitate and ascorbate spectra, particularly in the micellar phase.

Of more significance to this study are the differences between the spectra of the solid, the coagel, and the micellar phases of APK. Considering first the spectra of the solid and the coagel (Fig. 1, C and B respectively), it can be seen that the C=O stretching bands at 1744 and 1735 cm^{-1} are broad-

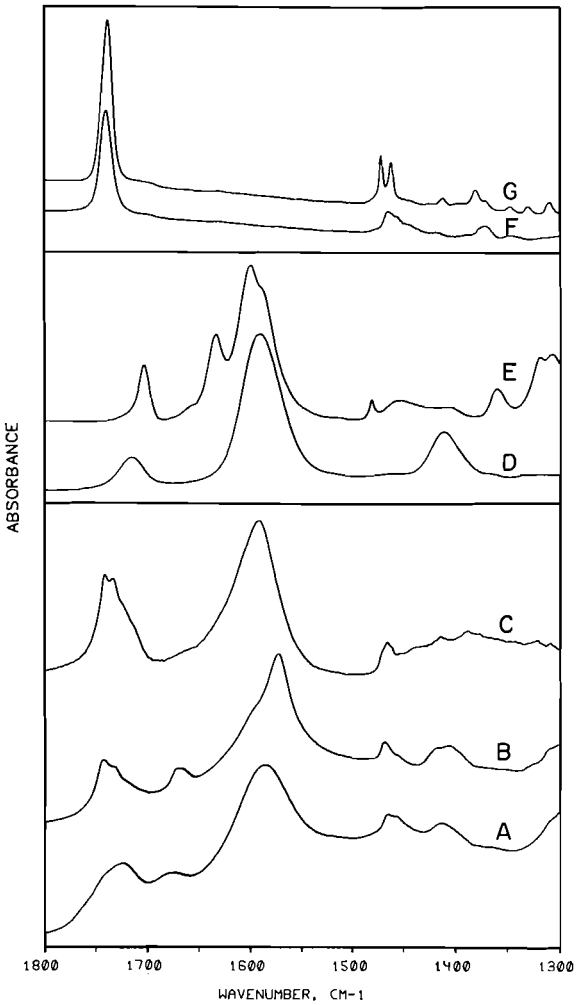

FIG. 1. Infrared spectra in the 1800–1300 cm^{-1} region of 0.1 *M* potassium ascorbyl palmitate in D_2O at 56°C (A) and at 20°C (B), polycrystalline APK at 20°C (C), sodium ascorbate in D_2O (D) and as polycrystalline solid (E), and ethyl palmitate in KBr at 30°C (F) and at 8°C (G).

ened on formation of the coagel, suggesting some degree of hydrogen bond formation with water of hydration. Rather more dramatic changes are evident in the C=C stretching bands. The weak broad band at ~1660 cm^{-1} in the spectrum of the solid gains intensity and has two components in the coagel (see Table 1). Even greater changes are observed in the strong C=C stretching band near 1600 cm^{-1}. Formation of the coagel results in a strong narrow band at 1574 cm^{-1}, while a weak band near 1600 cm^{-1} is retained. The shift to lower frequency of the main C=C stretching band suggests a reduction of the double bond character of the C(2)=C(3) bond. The sensitivity of this bond to the state of the ascorbate moiety has already been demonstrated. Formation of the sodium salt shifts the C=O stretching band from 1753 to 1702 cm^{-1}, and the C(2)=C(3) stretching band from 1670 to 1593 cm^{-1} (23), and increases the C=O and C(2)=C(3) double bond lengths by 0.017 Å and 0.035 Å respectively (24).

The interaction resulting in the shift of the C(2)=C(3) stretching band to 1574 cm^{-1} is specific to the coagel and must result from a particular intra- or intermolecular interaction, possibly involving partial hydration. At this point, we are unable to assign the individual C=C stretching bands, other than to give them the general classification of double bond stretching vibrations associated with the ascorbyl moiety.

The spectrum of the micellar phase is somewhat simpler than that of the coagel. The broad bands in this region are typical of those encountered in solution spectra of materials capable of engaging in extensive hydrogen bond formation, while the bandshapes indicate an enhanced mobility of the particular functional groups. Nonetheless, discrete absorptions are still present, as suggested by the asymmetry of the C=O stretching band contour, and demonstrated by the distinct frequency maxima found after Fourier self-deconvolution (see Table 1).

Another vibrational mode of interest is the CH_2 scissoring band around 1468 cm^{-1}, which is used extensively for the characterization of the packing of acyl chains in solid hydrocarbons, lipids, and surfactants (25, 26). Its observation at 1471.5 cm^{-1} in the coagel is indicative of a triclinic packing of

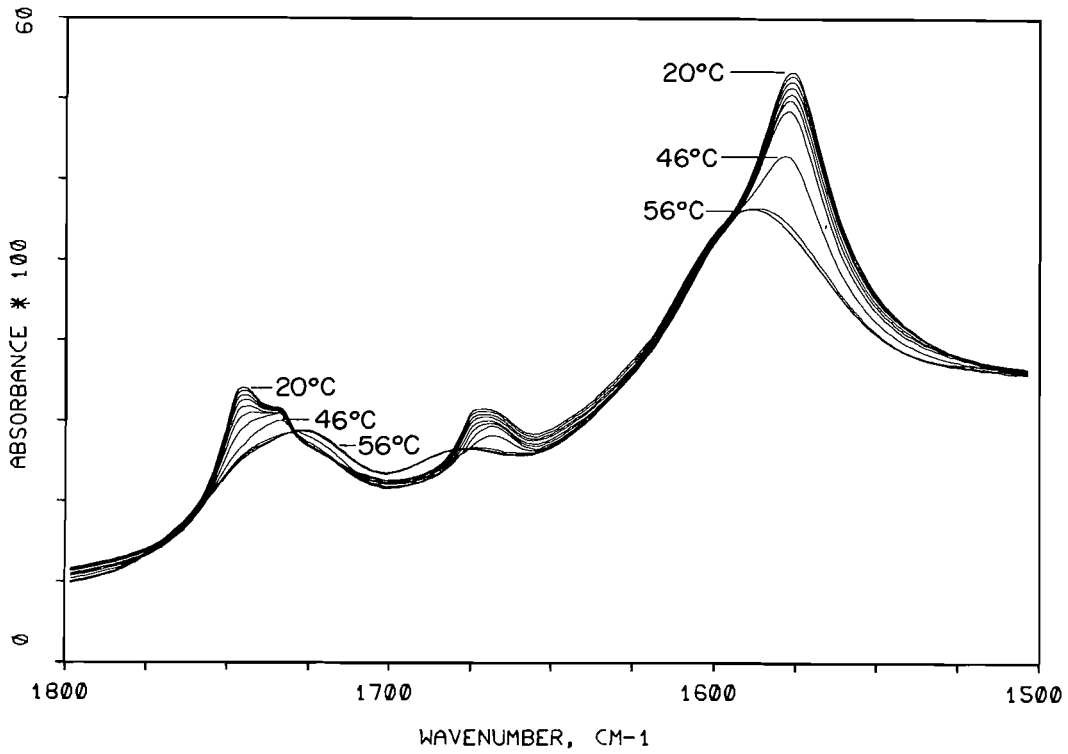

FIG. 2. Infrared spectra in the 1800–1500 cm^{-1} region of 0.1 *M* APK in D_2O as a function of temperature. There are 11 individual spectra taken in 3.6°C intervals; the top spectrum (with the largest peak height) is at 20°C, and the bottom spectrum (with the smallest peak height) at 56°C.

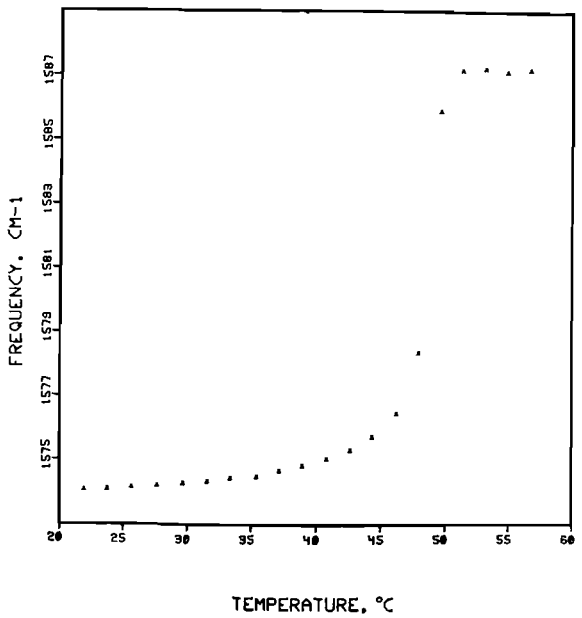

FIG. 3. Temperature-dependence of the frequency (band maximum) of the C=C stretching vibration of APK in D_2O.

this surfactant below the Krafft point. Such packing has previously been observed in solid *n*-alkanoates (27).

The temperature dependence of the 1800–1500 cm^{-1} region of the infrared spectrum of 0.1 *M* APK is shown in Fig. 2. The abrupt changes on transition from the coagel to the micellar phase are clearly evident. Also demonstrated are continuous spectral changes prior to micellization. As the temperature is raised from 20°C to ~40°C these changes are evident as reductions in the heights of the bands at 1745, 1673, and 1574 cm^{-1}. Other bands characteristic of the coagel (1733 and 1663 cm^{-1}) do not change as rapidly. Although there will be a slight increase in the monomer concentration in this range, these spectral changes are too large to be simply accounted for in terms of a decrease in the coagel concentration. Therefore we believe that these changes result from progressive hydration of the palmitate C=O group and of the ascorbate moiety prior to micellication.

In the range 40 to 51°C, the rate of change is much greater. This is illustrated in Fig. 3, which shows a

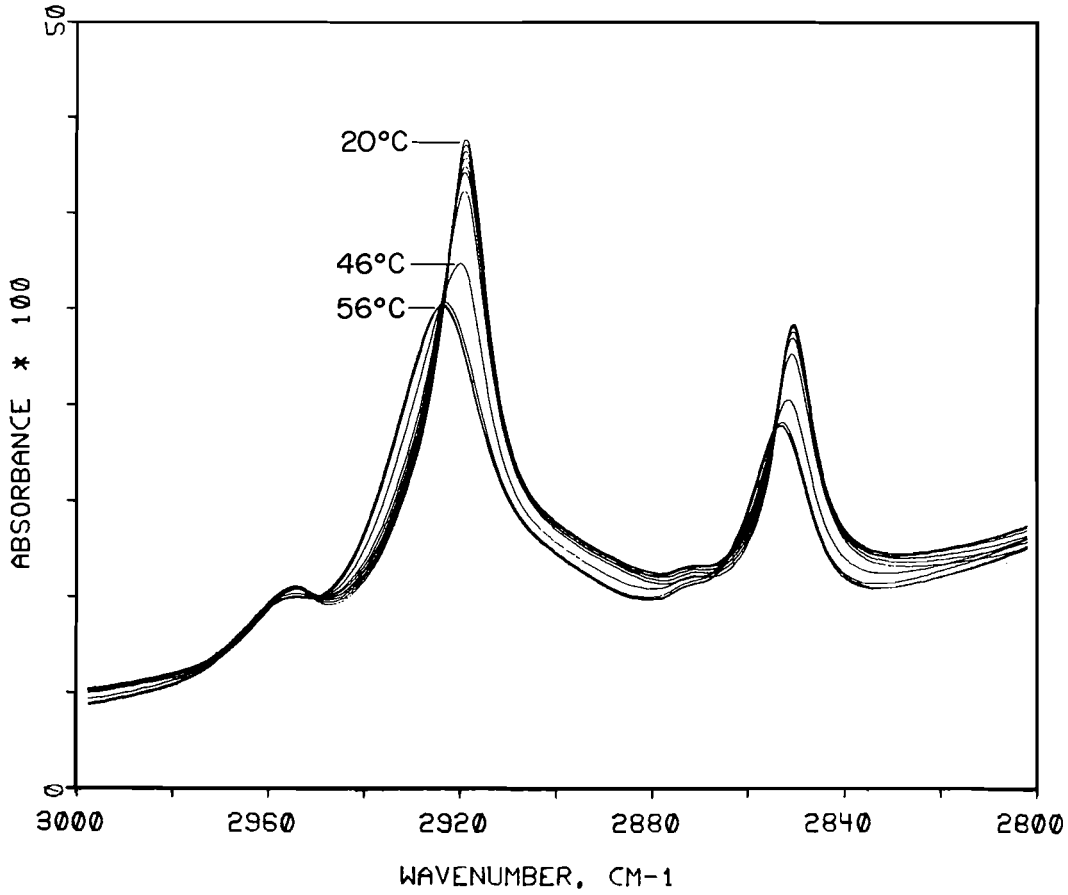

FIG. 4. Infrared spectra in the C—H stretching region of 0.1 *M* APK in D_2O. For further details, see caption to Fig. 2.

plot of the temperature dependence of the position of the maximum of the C=C stretching band contour at 1574 cm^{-1}. Although the parameter reflects the sum of the changes in the two component bands, it does provide an excellent monitor of the rate of change of the bands. It can be seen that the frequency varies throughout the entire temperature range with a maximal rate of change (>90% of the entire change) between 45 and 51°C (48 ± 3°C). Within this range the changes can be attributed to the continuously changing concentrations of the coagel and micellar phases.

The C—H stretching region of the infrared spectrum is shown in Fig. 4. There are four distinct groups of absorption bands in this region, the strong antisymmetric and symmetric CH_2 stretching bands around 2920 and 2850 cm^{-1}, respectively, and the weaker asymmetric and symmetric CH_3 stretching bands at 2955 and 2873 cm^{-1}, respectively. Also evident is a weak Fermi resonance band near 2900 cm^{-1}. These bands exhibit a thermotropic behavior similar to that of the vibrational modes originating in the head group.

Two distinct types of spectra are observed in Fig. 4. The spectra at temperatures below 40°C are narrow, indicating relatively low acyl chain mobility and the absolute frequencies are characteristic of fully extended all-*trans* acyl chains. As the temperature is raised, continuous changes are observed prior to the transition to the micellar phase. These changes were monitored by plotting the temperature dependence of the frequency and bandwidth of the symmetric CH_2 stretching band, and are shown in Fig. 5. Identical plots (not shown here) were obtained from the temperature-dependence of the antisymmetric CH_2 stretching mode.

Below 40°C the frequency indicating all-*trans* acyl chains in the ordered coagel is almost invariant, whereas the bandwidth shows continuous changes between 20 and 40°C. This demonstrates an increase in the acyl chain mobility within this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

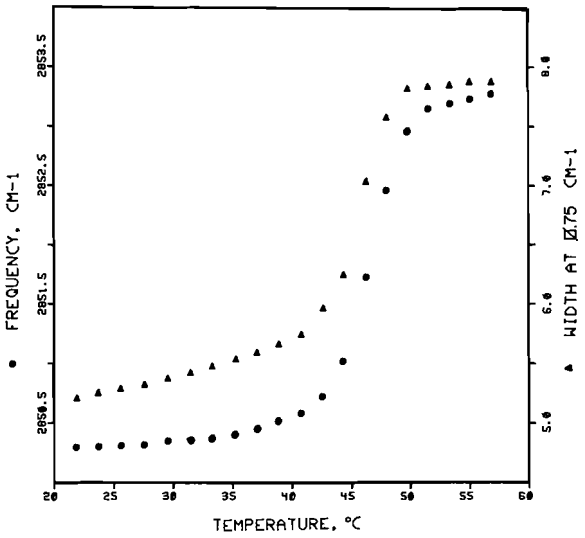

FIG. 5. Temperature-dependence of the frequency (●) and the width at ¾ height (▲) of the symmetric CH_2 stretching band of APK in D_2O.

temperature range, behavior which has also been observed prior to the melting transition of phospholipids (19, 28).

As the temperature is raised above 40°C progressive changes in both frequency and bandwidth are evident, the maximum rate of change being observed between 45 and 51°C. As with the head group absorptions this reflects the continuously changing concentrations of the coagel and micellar species. Confirmation that this is indeed the case comes from two sources. Firstly, the changes in frequency and bandwidth are not concerted. Rather, the maximum rates of change of frequency are observed at higher temperatures than those of the bandwidth. This is particularly evident in the plots in Fig. 5 in which the bandwidth is constant in the temperature range 49 to 51°C while the frequency is still changing. This behavior is typical of that resulting from the overlap of similar bands from two different species and has previously been observed in studies of the critical micelle concentration of *n*-alkanoates (29). Secondly, the contours of the CH_2 stretching bands at 46°C (Fig. 4) show flattened peak tops and are highly asymmetric compared to the spectra recorded at either higher or lower temperatures, indicating that at this temperature the two component spectra have roughly equal intensities.

The frequencies and bandwidths of the symmetric and antisymmetric CH_2 stretching vibration of an aqueous suspension of potassium ascorbyl palmitate increase dramatically between 45 and 51°C. The shift to higher frequencies is due to the appearance of a large number of *gauche* conformers in the all-*trans* acyl chains, whereas the increased bandwidth is the consequence of an increase in the mobility of the palmitate chains. Both phenomena are typical of acyl chain melting phase transitions (19, 28, 29) and were also observed at the melting point of solid ethyl palmitate (Table 1).

Conclusions

Aqueous suspensions of potassium and sodium ascorbyl palmitate show thermotropic behavior typical of dilute ionic surfactant systems. In 0.1 *M* suspensions of potassium ascorbyl palmitate in D_2O abrupt increases in the solubility are observed at 48 ± 3°C, as are spectral changes typifying a transition from a conformationally ordered, poorly hydrated, solid state to an isotropic micellar state. The transition generally occupies about 10°C, and within this range continuously changing concentrations of both species are present. This behavior is typical of that observed in aqueous *n*-alkyl carboxylate ions (soaps). However, unlike in soaps, due to the different nature of the head group, the transition temperature of the sodium salt of ascorbyl palmitate is lower than that of the corresponding potassium salt.

OSVALD KNOP, T. STANLEY CAMERON, MARGARET ANN JAMES, and MICHAEL FALK. Can. J. Chem. **59**, 2550 (1981).

The crystal structure of $(Et_3NH)_2SnCl_6$ at room temperature consists of a monoclinically distorted antifluorite packing of Et_3NH^+ and $SnCl_6^{2-}$ ions. Each anion has two cations centrosymmetrically associated with it through bifurcated hydrogen bonds to four of the Cl atoms, leaving two of the six chlorines unengaged. The bifurcation is nearly symmetric and the N—H···2Cl group is nearly planar. Infrared spectra of undeuterated and partially deuterated polycrystalline $(Et_3NH)_2SnCl_6$ show that the NH stretching vibration is essentially uncoupled while the corresonding ND vibration undergoes a complex Fermi resonance resulting in a multiplet in the spectrum of even weakly deuterated material. The hydrogen bonding in $(Et_3NH)_2SnCl_6$ is stronger than in the corresponding ammonium compound. A negative temperature coefficient of the NH and ND stretching frequencies is consistent with the bifurcation of the hydrogen bond. If a low-temperature transition exists, it was not evident in the NH and ND stretching absorptions.

OSVALD KNOP, T. STANLEY CAMERON, MARGARET ANN JAMES et MICHAEL FALK. Can. J. Chem. **59**, 2550 (1981).

La structure cristalline du $(Et_3NH)_2SnCl_6$ comporte, à la température ambiante, un assemblage de type antifluorine déformée des ions Et_3NH^+ et $SnCl_6^{2-}$. Chaque anion est associé, d'une façon centrosymétrique, à deux cations par des liaisons hydrogène bifurquées; ces liaisons engagent quatre des six atomes chlore de l'anion, laissant libres les deux autres. La bifurcation est presque symétrique et le groupement N—H···2Cl est presque plan. Les spectres infrarouges du $(Et_3NH)_2SnCl_6$ polycristallin non-deutéré ainsi que partiellement deutéré montrent que la vibration NH de valence est essentiellement découplée, tandis que la vibration ND correspondante subit une résonance Fermi complexe, ce qui donne lieu à un multiplet dans le spectre du composé même légèrement deutéré. La liaison hydrogène dans le $(Et_3NH)_2SnCl_6$ est plus forte que celle dans le composé ammonium correspondent. Le coefficient de la variation thermique des fréquences NH et ND de valence est négatif, ce qui s'accorde bien avec la bifurcation de la liaison hydrogène. Si une transition à basse température existe dans le $(Et_3NH)_2SnCl_6$, elle n'est pas évidente dans les absorptions dues aux vibrations NH et ND de valence.

Study of the spectroscopic manifestations of hydrogen bonding in crystals is complicated by a number of factors. One of them, vibrational coupling of XH groups in neighbouring X—H···Y bonds, may modify the frequency, shape, and breadth of ir absorptions involving XH to such an extent that it precludes extraction of numerical parameters required in comparisons of the strength and type of hydrogen bonding in different classes of compounds. Detailed analysis of the ir spectrum should, of course, determine the nature and magnitude of the coupling and thus remove the difficulty, but in practice this is possible only in relatively simple cases and even then not without a considerable effort. In general it is preferable to secure the desired information by the use of the isotopic isolation technique (1, 2), which yields decoupled XH (or XD) absorption bands. This approach is workable provided the pertinent decoupled absorptions can be resolved and identified. Occasionally, however, situations are encountered where the XH absorptions are sufficiently free from complications to yield the information without further analysis or sample manipulation, viz. where the coupling is minimal owing mostly to wide separation of the XH groups in the crystal. Apart from the simplicity of the XH spectra such situations are of interest in their own right in that they permit the conditions to be investigated beyond which effective coupling can no longer be expected to exist. Because of this they seemed to us to merit a closer look in the context of our continuing study of hydrogen bonding in crystals.

In searching for suitable compounds trialkylammonium salts appeared promising for several reasons, among them the possibility of comparison with the corresponding ammonium salts that had been studied previously. Exploratory trials with several such salts led to the selection of the title compound as the first to be examined in some detail. The crystal is ionic, which indicated that the structure would be determined primarily by Coulombic interactions and thus likely to be related to one of the simple AB_2 types of packing of cations

and anions. This and the low NH/Cl ratio in turn implied that the N—H···Cl bonds would not share Cl atoms or form continuous networks, thereby minimizing the opportunity for effective coupling; coupling across $SnCl_6^{2-}$ octahedra would involve appreciable H···H distances and heavy intervening atomic masses and therefore be weak. Thus each crystallographically nonequivalent cation would be expected to give rise to *one* NH stretching vibration. Barring fortuitous complications arising from Fermi resonance, the number of observed NH stretching bands would (except for accidental overlap) then correspond to the actual number of crystallographically distinct sets of cations in the crystal, analogous to what is observed for ND stretching absorptions in spectra of isotopically isolated NH_3D^+ species (2). In the following we describe the room-temperature crystal structure of $(Et_3NH)_2SnCl_6$ and the conclusions, from the ir spectra of undeuterated and partially deuterated polycrystalline material, relevant to hydrogen bonding.

Experimental

Preparation and Infrared Spectra

$(Et_3NH)_2SnCl_6$ was prepared by combining a solution of Et_3N in 95% EtOH with an equivalent amount of an aqueous solution of H_2SnCl_6. The large, colourless crystals which appeared on slow evaporation at room temperature were recrystallized from EtOH. Low-level deuteration (1–5% replacement of the amino H) was achieved by recrystallization from weakly deuterated EtOH.

Spectra were recorded on a Perkin-Elmer model 180 spectrophotometer fitted with a closed-cycle He refrigerator (Displex model 202, Air Products and Chemicals Co.). Suitable samples were obtained by mulling finely ground crystals with fluorocarbon (4000–1330 cm^{-1}) or hydrocarbon (1330–400 cm^{-1}) oil. The mulls were sandwiched between KBr or CaF_2 plates.

Crystal Data

$C_{12}H_{32}Cl_6N_2Sn$ f.w. = 535.8

Monoclinic, $P2_1/n$ (systematic absences: $h0l$, $h + l = 2n + 1$; $0k0$, $k = 2n + 1$); $a = 9.950(2)$ Å, $b = 10.698(2)$ Å, $c = 10.767(3)$ Å, $\beta = 100.22(2)°$, $V = 1127.9$ Å^3, $Z = 2$, $\rho_0 = 1.585$ g/cm^3, $\rho_c = 1.577$ g/cm^3 (20 ± 2°C); Mo $K\alpha_1$, $\lambda = 0.70926$ Å (graphite monochromator), $\mu_{Mo} = 17.05$ cm^{-1}, $F(000) = 540$ e.

Structure Determination

A CAD-4 four-circle diffractometer was used to determine the unit-cell dimensions from 25 general reflections with $12 < \theta < 15°$. 1976 unique reflections in the range $1 < \theta < 25°$ were measured, of which 1301 had $I > 3\sigma(I)$. The intensities were reduced by routine procedures which are described in ref. 3. Lorentz and polarization corrections were applied but no absorption or extinction corrections. The scattering factors for neutral atoms were taken from ref. 4. The structure was solved using the SHELX system (5).

The Sn atoms were located from the *E*-map and all other nonhydrogen atoms were found on a subsequent Fourier map. Full-matrix least-squares ($w\Delta F^2$ = min.) refinement was carried out with isotropic temperature factors on heavy atoms until $R = 0.081$. The hydrogens were located from a difference Fourier map calculated at this stage. Refinement was continued with anisotropic temperature factors on the nonhydrogen atoms and isotropic factors on the hydrogens until $R = 0.022$, based on 1297 reflections; the reflections 110, $\bar{1}01$, 101, and 011 were omitted because of extinction effects. The least-squares weights[2] were calculated from $w^{-1} = \sigma^2|F_0| + 0.000553|F_0|^2$, where σ is the weight for an individual reflection derived from the diffractometer counting statistics. The atomic and thermal parameters are given in Tables 1 and 2, interactomic distances and bond angles in Table 4.[3].

Results and Discussion

Description of the Structure

The structure (Figs. 1 and 2) is a distorted version of the *fcc* antifluorite-type packing represented by $(NH_4)_2PtCl_6$. The centrosymmetric $SnCl_6$ octahedra, which are close to regular, are rotated by significant amounts from the edges of the cuboid cells defined by the Sn sublattice. The Et_3NH^+ ion in each of these cells is hydrogen-bonded to two Cl atoms of an $SnCl_6$ octahedron. This bifurcated N—H···2Cl bond is nearly symmetric; the H atom is only about 0.16 Å away from the respective N—Cl(1)—Cl(2) plane, and the N—H—Cl angle is 138(3)° for Cl(1) and 136(3)° for Cl(2). The hydrogen bonding results in centrosymmetric $Et_3NH···SnCl_6···HNEt_3$ units which are arranged in layers approximately coincident with the 200 planes. The C—H bond lengths are unexceptionable.

The shortest interatomic distances between NH groups are ca 6.2 Å for N···N and ca 6.7 Å for H···H. The NH groups are thus well separated. Considering that the H···H separation in an $Et_3NH···SnCl_6···HNEt_3$ unit is 7.3 Å, vibrational coupling of the NH groups across the bulky, heavy $SnCl_6$ anion would be expected to be weak.

The H···Cl distances in the bifurcated hydrogen bonds, 2.50(5) and 2.67(5) Å, are somewhat shorter than the H···Cl distance in the cubic $(NH_4)_2SnCl_6$, 2.79 Å (assuming symmetric trifurcation N—H···3Cl). Unlike in the latter crystal, the N—H vectors in $(Et_3NH)_2SnCl_6$ point in the direction of the Sn atoms; the N, H, and Sn atoms are almost collinear and in a direction that corresponds to a cube diagonal in $(NH_4)_2SnCl_6$.

In its general organization the structure resembles that of $(Et_3NH)_2CuCl_4$ (6) (Fig. 3). Both structures contain discrete $Et_3NH···anion···HNEt_3$

units held together by bifurcated hydrogen bonds[4] but the tetrachlorocuprate structure is less symmetric, as evidenced by the existence of two nonequivalent sets of Et_3NH ions and the dissimilarity of the two shortest N(2)···Cl distances, 3.17 and 3.59 Å respectively (the H positions were not determined). In neither case was there evidence of significant disorder in the structure. This is in contrast to Et_3NHCl, where the ethyl groups are statically disordered with respect to planes of reflection through the N atoms (7); the N—H···Cl bonds in this structure ($P6_3mc$) are in threefold axes and hence constrained by symmetry to be normal (N···Cl, 3.11 Å).

Infrared Spectra: NH Stretching

The NH stretching band in the room-temperature spectrum of undeuterated $(Et_3NH)_2SnCl_6$ is

[4]This similarity is not obvious in the description of the tetrachlorocuprate structure in ref. 6.

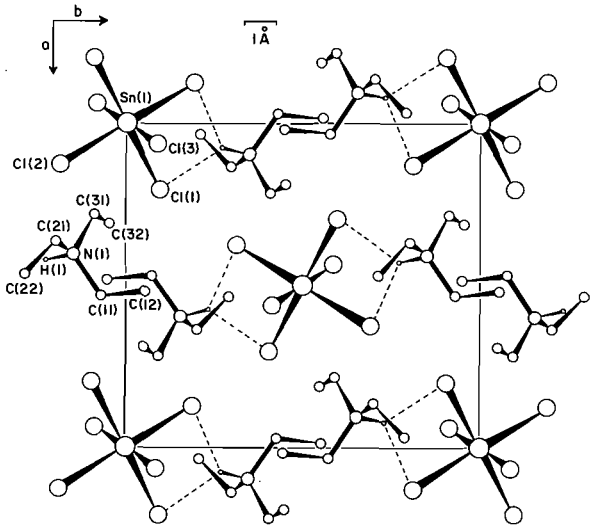

FIG. 1. Projection of the $(Et_3NH)_2SnCl_6$ structure along *c*. *Dashed lines represent H···Cl bonds.*

simpler in shape and much narrower than the corresponding band of $(NH_4)_2SnCl_6$, $\Delta\nu_{1/2} \sim 25\,cm^{-1}$ as against $>100\,cm^{-1}$ (Figs. 4 and 5). On deuterating the crystal to a varying degree the frequency of the band was practically unaffected and its halfwidth was reduced by no more than $5\,cm^{-1}$, while in the ammonium compound a drastic narrowing occurred. From this we concluded that in the triethylammonium compound, unlike in the ammonium salt, the NH stretching vibrations are essentially uncoupled, thus confirming the expectation from the geometry of the structure.

Cooling the crystal caused the ν(NH) band to sharpen, $\Delta\nu_{1/2}(10\,K) \sim 10\,cm^{-1}$ (Fig. 5). The frequency *increased* on cooling, by about $8\,cm^{-1}$ between 293 and 10 K (Fig. 6), consistent with the criterion formulated previously for highly-bent hydrogen bonds (8). The changes in the frequency, halfwidth, and shape of the ν(NH) band were gradual and gave no indication of a low-temperature transition.

The room-temperature frequency of ν(NH) in the triethylammonium compound is about $130\,cm^{-1}$ lower than in $(NH_4)_2SnCl_6$. The N···Cl (3.33 and 3.46 Å) and H···Cl (2.50 and 2.67 Å) distances in $(Et_3NH)_2SnCl_6$ are shorter than the corresponding distances in the ammonium compound (3.55 and 2.79 Å respectively), hence the hydrogen bonding in the alkyl compound is stronger. To what extent this strengthening reflects the effects of the shorter H···Cl distances, the alkyl substitution, and the change from trifurcation (in the ammonium compound) to bifurcation can only be answered when more information on compounds of this type has accumulated. However, the effect of structure expansion on ν(NH), important in the $(NH_4)_2MX_6$ compounds (8, 9), is probably absent in $(Et_3NH)_2SnCl_6$, owing to the lower connectivity of the hydrogen-bond system in the latter structure. A discussion of this point is reserved for another occasion.

Infrared Spectra: ND Stretching

Instead of the expected replication of the simple

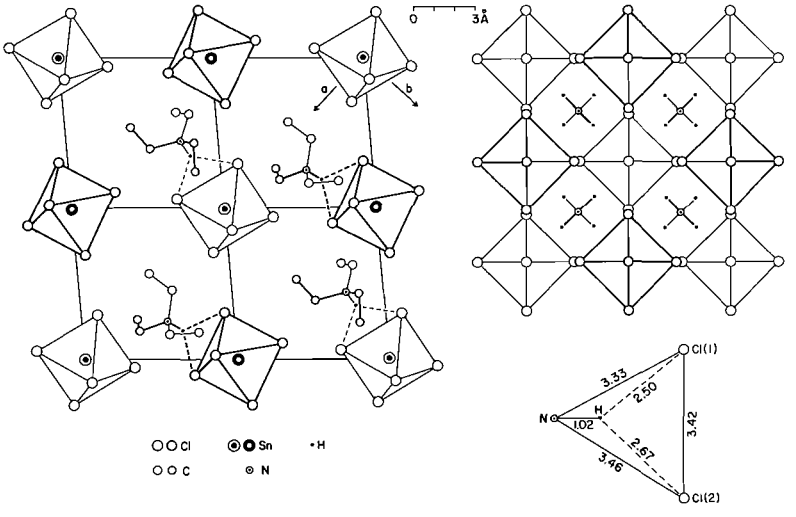

FIG. 2. (*Left*) Projection of a slab (parallel to 001) of the $(Et_3NH)_2SnCl_6$ structure along *c* displaying the face-centred antifluorite packing of cations and anions. (*Top right*) A similar projection of the cubic $(NH_4)_2SnCl_6$ structure. (*Bottom right*) The hydrogen-bonding geometry in $(Et_3NH)_2SnCl_6$. The H atom is only about 0.16 Å out of the N—Cl(1)—Cl(2) plane.

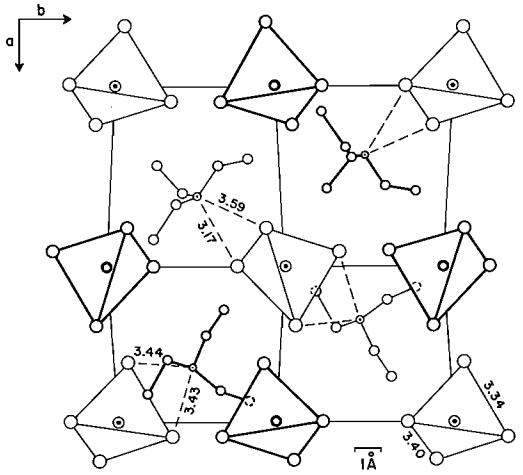

FIG. 3. A slab (parallel to 001) of the $(Et_3NH)_2CuCl_4$ structure (after ref. 6) projected along c so as to display the similarity with $(Et_3NH)_2SnCl_6$; compare with Fig. 2. For legend, see caption of Fig. 2, substituting Cu for Sn. Hydrogen positions have not been determined.

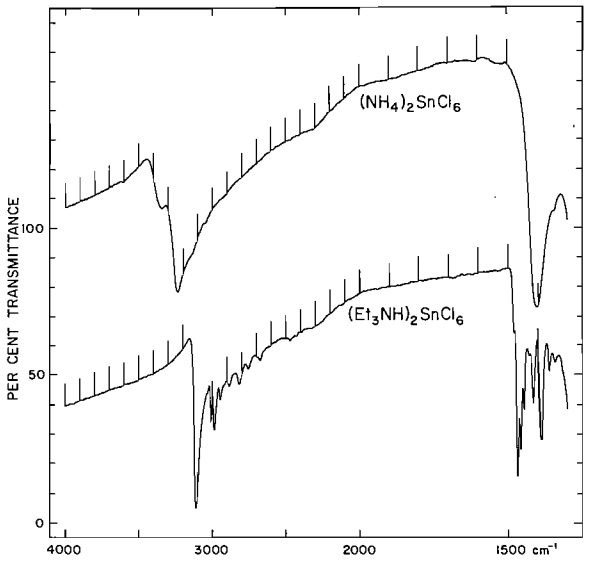

FIG. 4. Survey spectra of undeuterated $(Et_3NH)_2SnCl_6$ and $(NH_4)_2SnCl_6$ in the 4000–1330 cm^{-1} region (fluorocarbon mulls, room temperature).

NH band a complex absorption was observed in the ND stretching region of a weakly deuterated sample (Fig. 7). This absorption at first sight appeared to be a doublet, but comparison with spectra of the undeuterated compound showed it to contain additional minor components. The entire group of peaks between 2350 and 2270 cm^{-1} increased in intensity roughly in proportion to the D content of the sample. The structure of the absorp-

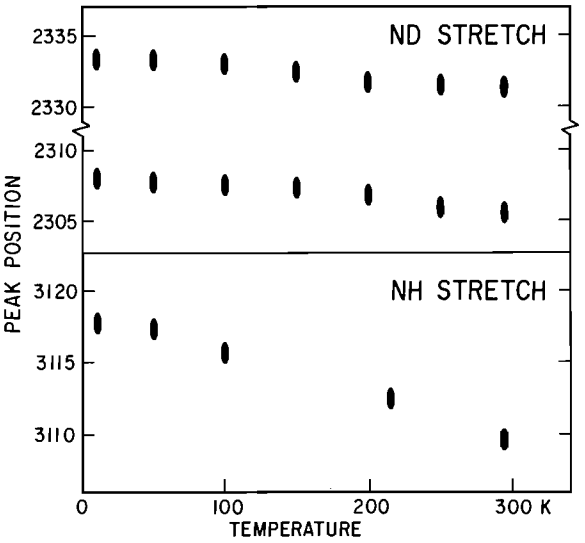

FIG. 6. Temperature variation of the peak position (cm^{-1}) of the NH and ND stretching absorptions of $(Et_3NH)_2SnCl_6$ (6% D). For ND the peak positions of the two most intense components are plotted.

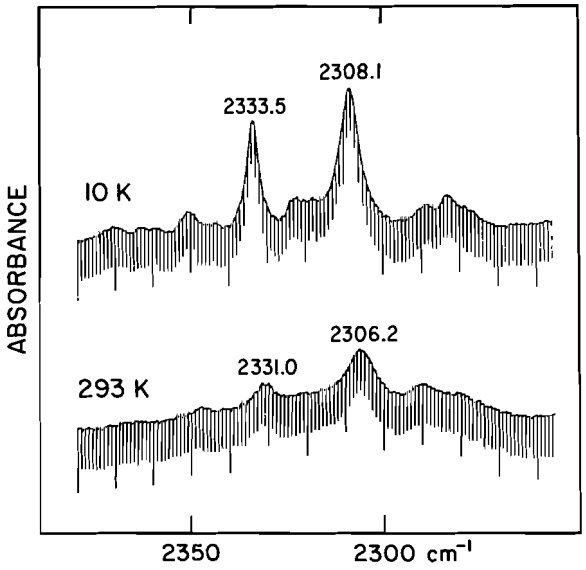

FIG. 7. The ND stretching region of $(Et_3NH)_2SnCl_6$ (6% D). The two most prominent features of the complex of bands corresponding to ND stretching are identified.

tion no doubt arises from a complex Fermi resonance between the ND fundamental and overtones and combinations of the vibrations of the Et_3N part of the cation. The frequency variation of the ND stretching vibration would be expected to parallel that of the NH stretching vibration and thus to increase by about $5\,cm^{-1}$ on cooling from 293 to 10 K (the observed increase in $(NH_4)_2SnCl_6$ is about $6\,cm^{-1}$, cf. ref. 10). However, the increase is only about $2\,cm^{-1}$ for the most intense component of the multiplet and the frequencies of the other components shift in the same direction by similar amounts (Fig. 6). This means that the increase in ν(ND) which would be expected to occur in the absence of Fermi resonance is counteracted by the resonance and reduced to a fraction of the estimate based on the ν(NH) shift. Fermi resonances involving ν(ND) are known to occur in other trialkylammonium salts (results to be published), but the present case is unusual in that the resonance gives rise to an absorption sufficiently complex to preclude the use of the ND stretching for structural deductions.

The estimated mean of the ν(ND) frequencies of the two most intense components of the multiplet is $2321\,cm^{-1}$ at 100 K. This is $54\,cm^{-1}$ lower than the ν(ND) frequency in $(NH_4)_2SnCl_6$, which is consistent in direction and magnitude with the corresponding lowering observed for ν(NH).

Secondary deuterium isotope effects on both rate and product determining steps in the thermolysis of 4-methylene-1-pyrazoline

MOON HO CHANG AND ROBERT J. CRAWFORD

Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 16, 1980

MOON HO CHANG and ROBERT J. CRAWFORD. Can. J. Chem. **59**, 2556 (1981).

The secondary deuterium kinetic isotope effect in the thermolysis of 4-methylene-1-pyrazoline and four of its deuterated isomers has been studied. The value of $\delta\Delta G^{\ddagger}/n$ is 142 cal mol^{-1} if it is a single C—N cleavage process or 71 cal mol^{-1} if it is a concerted rupture of two C—N bonds. The product distributions can only be rationalized in terms of a mechanism involving a rate determining C—N bond rupture to form a diazenyl diradical intermediate which then can close to methylenecyclopropanes by three possible modes. This requires a secondary isotope effect in the product determining step of 1.33 ± 0.05, for the rotation of CH_2 (CD_2) out of the plane of the allylic radical in the intermediate.

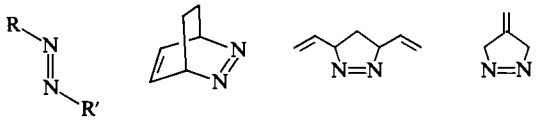
MOON HO CHANG et ROBERT J. CRAWFORD. Can. J. Chem. **59**, 2556 (1981).

On a étudié l'effet isotopique cinétique secondaire du deutérium lors de la thermolyse de la méthylène-4 pyrazoline-1 et de 4 de ses isomères deutérés. La valeur de $\delta\Delta G^{\ddagger}/n$ est de 142 cal mol^{-1} s'il s'agit d'un processus de rupture de la liaison simple C—N ou de 71 cal mol^{-1} dans le cas d'une rupture concertée de deux liaisons C—N. On peut rationaliser la distribution des produits uniquement en fonction d'un mécanisme impliquant dans l'étape déterminante la rupture de la liaison C—N pour former un intermédiaire diazényle biradicalaire qui peut alors s'approcher des méthylènecyclopropanes de trois façons possibles. Ceci exige un effet isotopique secondaire dans l'étape déterminante de 1,33 ± 0,05 pour la rotation de CH_2 (CD_2) hors du plan du radical allylique de l'intermédiaire.

[Traduit par le journal]

Introduction

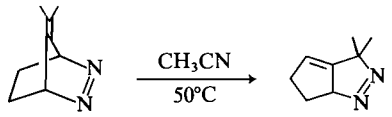
Unsymmetrical azoalkanes (**1**) have been shown to undergo thermolysis by a step-wise sequence of carbon–nitrogen bond cleavages (1) and evidence for diazenyl radicals has been provided by several research groups (2). The case for the step-wise cleavage of symmetrical azoalkanes (**1**, R = R′) is not so clear (1, 3). With cyclic azo compounds there is strong evidence to indicate that compounds such as **2** and **3** undergo cleavage of both C—N bonds in the rate determining step (3) and that the diazenyl radical is not implicated.



1 **2** **3** **4**

To date the information pertaining to the mechanism of thermolysis of 4-methylene-1-pyrazolines (**4**) has been inconclusive (5). Berson *et al.* (6) have provided convincing data that diyl-species are present in the photolysis and thermolysis of **5**, but as yet we do not know whether the C—N bond cleavages are sequential or concerted. The rearrangement of **5** to **6** is readily explained in terms of a diazenyl radical (7).

The 4-methylene-1-pyrazoline system is unique in that if it undergoes concerted cleavage of both C—N bonds the diradical produced would be the trimethylenemethane (TMM) species, which can exist in the all-planar configuration **7**, or the orthogonal form **8**.



5 **6**

The planar TMM has been the subject of much theoretical and experimental work since it has a triplet ground state which is significantly below the singlet state (9). The singlet would be expected from the thermolysis of **4** on the basis of conservation of spin. Indeed Dowd *et al.* (8) have demonstrated that the triplet is the ground state for **7** and that it can be generated photochemically from **4**. While our first efforts to define the mechanism of thermolysis of **4** suggested that, on the basis of secondary deuterium kinetic isotope effects, both C—N bonds are cleaving in the rate determining step, our later work with methylated derivatives suggests that the system is very sensitive to steric factors, and that the mechanism changes on going from **4** to 3,3,5,5-tetramethyl-4-methylene-1-pyrazoline (**9**); the activation energy increases from 32 kcal mol^{-1} for **4** (10) to 40 kcal mol^{-1} for **9** (11). Consequently we have undertaken a detailed study of the secondary deuterium

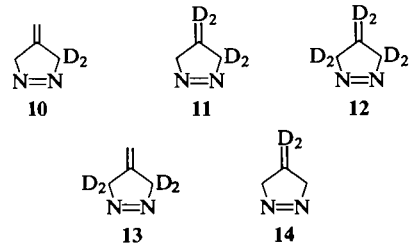
isotope effects on **10–14**, both of the kinetics and of the product distributions. Compounds **10–12** have been examined earlier (5). In our earlier experiments with these compounds we did not have access to ^{2}Hmr and we have significantly improved our temperature control on the reaction vessel, thus increasing the precision with which we can measure secondary deuterium kinetic isotope effects. Compounds **13** and **14** are new and provide an interesting set of data as to product ratios and tests for common intermediates with **11** and **10** respectively.



Results

Synthesis

The deuterated 4-methylene-1-pyrazolines, **10**, **11**, and **12** were prepared by methods described earlier (10) and their deuterium content assessed by (*a*) low ionization potential mass spectrometry, (*b*) ^{1}Hmr, and (*c*) ^{2}Hmr. The tetradeuterio compound **13** was prepared by the methods outlined in Scheme 1. The synthesis of **14** was achieved from the acetal (**22**) as outlined in Scheme 2. The ketone (**23**) in Scheme 2 was produced in a substantially improved yield over that reported earlier (11) by periodate oxidation under carefully buffered conditions.

The isotopic purity for samples **10–15** is given in Table 1. In each case ^{1}Hmr and ^{2}Hmr indicated that no scrambling of the label had occurred during synthesis.

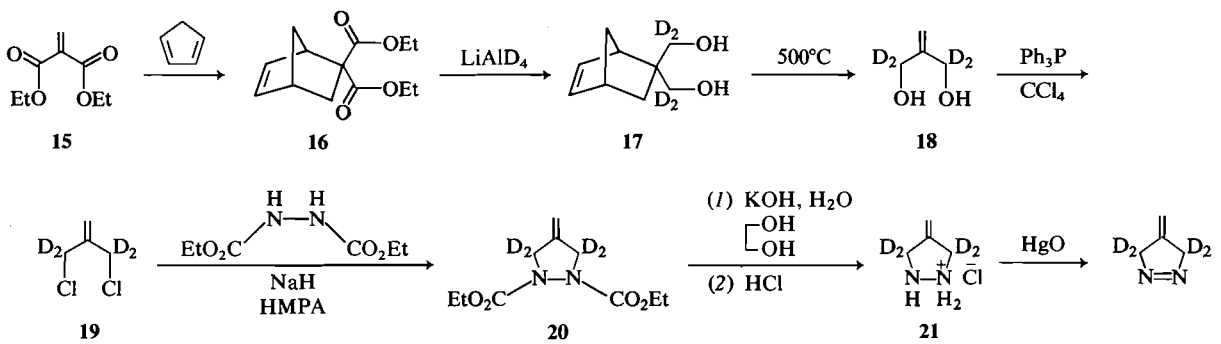
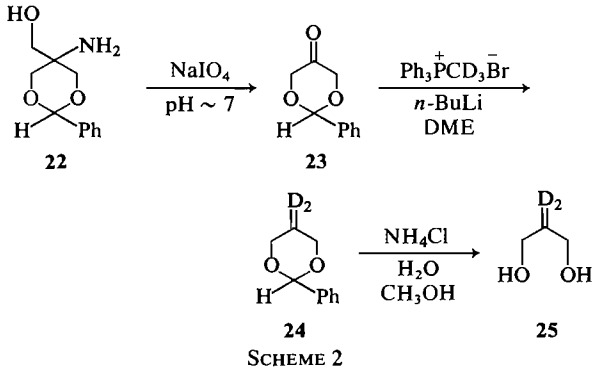
Kinetics

The gas phase thermolyses of the 4-methylene-1-pyrazolines were carried out in a 250 mL stainless steel reaction vessel contained in a well-thermostatted air bath; the details of the injection and pressure monitoring equipment are described in the Experimental. The reaction was always accompanied by the isomerization of the 1-pyrazolines to the more stable 2-pyrazoline tautomers, however, the observed thermolysis rate constants were found to be independent of the percent conversion. The kinetic results were obtained by following the increase of pressure with time. The pressure inside the reaction vessel would be expected to double upon completion. The pressure was measured as an emf by a pressure transducer connected to a voltmeter and digital printer. The transducer emf was calibrated and was found to be directly proportional to the pressure used (0–200 Torr). The long term stability of the transducer emf was found to be better than ±0.002 V throughout the reaction and an emf of 1 V was equivalent to 75 Torr. Reproducible first-order kinetics were observed only after repeated thermolyses in the stainless steel reaction vessel. The percent conversion increased dramatically from 37 to 92% after 10 samples had been run at 175°C, and the rate constants were reproducible to ±1%. The introduction of air into the reaction vessel caused the surface to be destroyed, and reconditioning to be required. The kinetic data used to calculate the activation energy and log A values are given in Table 2 along with the probable error at the 90% confidence limit.

The activation parameters calculated from these data are E_a = 33.6 ± 0.7 kcal mol^{-1} and log A =



SCHEME 1



SCHEME 2

13.75 ± 0.35, which gives $\Delta S_{443}^{\ddagger}$ of +1.3 ± 1.6 eu, and are comparable to our earlier results of E_a = 32.8 ± 0.2 and log A = 13.31 ± 0.10 (5).

Table 3 gives the observed and corrected rate constants, at 170°C, for the deuterated 4-methylene-1-pyrazolines. The correction applied is to accommodate the incomplete incorporation of deuterium into the indicated position. The percentage deuterium incorporation was determined by low ionization potential mass spectrometry on the methylenecyclopropane produced and the rate constant corrections were made using the equation $k_D = (k - f_H k_H)/f_D$, where f_H and f_D are the mole fractions of **4** and the deuterated compound. This approximation gives the same result, within experimental error, as the more lengthy equation used for correcting at each level of deuterium incorporation.

Product Studies

Samples of deuterated 4-methylene-1-pyrazolines (ca. 60 Torr) were heated in the thermostatted bath at 175°C for 20 min (93% completion). Control runs indicated that the interconversion of deuterated methylenecyclopropanes is negligible at this temperature. The thermolysis products were condensed in a liquid nitrogen cooled tube and upon warming to 0°C the methylenecyclopropanes were transferred to an nmr tube and any tautomeric pyrazolines stayed behind. Chloroform-d_1 or carbon tetrachloride was then added and the 100 MHz ^{1}Hmr or 13.8 MHz ^{2}Hmr spectra were obtained. It should be noted that the isomer proportions were calculated directly without concern for the isotopic purity when ^{2}Hmr data were used. Each value of the percentage distribution in Table 4 is the average from three analyses carried out on each of three independently obtained samples, and the error quoted is the 90% confidence limit. The isomer proportions obtained from **10** and

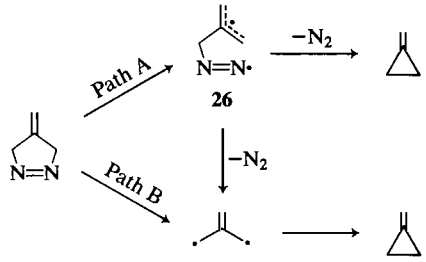
11 are the same, within experimental error, as those reported earlier (10).

Discussion

The activation energy for the thermolysis of 4-methylene-1-pyrazoline (**4**) is 33.6 ± 0.7 kcal mol^{-1} which is 8.9 kcal mol^{-1} less than the value of 42.5 kcal mol^{-1} ascribed to the parent 1-pyrazoline (12). It is attractive to rationalize such a decrease in activation energy as being due to the allylic resonance in the putative diazenyl radical, **26**. Our earlier work



(5) indicated that on the basis of the generally accepted value of $\delta\Delta G^{\ddagger}$ of 90–120 cal mol^{-1} per deuterium (13), the secondary deuterium isotope effects of **10–12** were larger than expected for path A and smaller than anticipated for path B. Two possible reasons come to mind, firstly that the rigid ring system of the 4-methylene-1-pyrazolines may distort the value of the kinetic isotope effect, or secondly that possible pivoting of the *exo*-methylene deuteriums in the thermolysis of **11** and **12** had been underestimated in our earlier work (10), an aspect which has recently been brought to our attention by the work of Gajewski and Chou (14) and that of Roth and Wegener (15). In both of these latter cases evidence suggests that a remote methylene group rotates, possibly giving rise to a torsional isotope effect, so as to avoid an all-planar TMM configuration. To this end we have examined by FT–ir the gas phase spectrum of **10–14** and the principal assignments are made in Table 5. Using the data in Table 5 and assuming the C–N stretch to be the reaction coordinate we have evaluated the change in zero point energy for the series **10–14**. As our model for the transition state we considered the change of the sp^3 α-methylene group to the sp^2 methylene of the diazenyl radical **26** using the methylenecyclopentane (**27**) and **28** assignments of Malloy *et al.* (16). The predicted changes in zero point energies are summarized in Tables 6 and 7 for both the one-bond cleavage, path A, and the two-bond cleavage, Path B.

27 **28**

Using the model that the secondary kinetic isotope effects are the result of the creation, or deletion, of isotopically sensitive vibrational frequencies on going from the reactant to the transition state (17) and eq. [1] we obtain the predicted values in Table 7. It

Observed	142	1.38[b]	71	1.38[b]

[a]Using data from Table 6 and eq. [1].
[b]Using data from Table 3 and the equation $\delta\Delta G^{\ddagger}/n = (RT/n) \ln k_H/k_D$.

should be noted that the values $\Delta\omega_1$ and $\Delta\omega_2$ in Table 6 represent the values for four deuteriums in **13** and the value for two deuteriums in **28** respectively. Therefore, for the two-bond cleavage pathway, $\delta\Delta\omega = \Delta\omega_1 - 2(\Delta\omega_2) = 313\ cm^{-1}$. Since $E_0 = hc\omega/2$, this is an energy difference ($\delta\Delta G^{\ddagger}$) of 448 cal mol^{-1} for four α-deuteriums. For the one-bond cleavage process, $\delta\Delta\omega = \frac{1}{2}\Delta\omega_1 - \Delta\omega_2 = 156\ cm^{-1}$ which gives $\delta\Delta G^{\ddagger}$ of 224 cal mol^{-1} for two α-deuteriums. By using these data, the values of $\delta\Delta G^{\ddagger}$ per deuterium, the kinetic isotope effects for the two pathways are calculated and presented in Table 7.

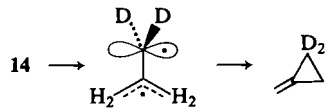
The calculated $\delta\Delta G^{\ddagger}/n$ value of 112 cal mol^{-1} in Table 7 is within the range of the frequently observed values of 90–120 cal mol^{-1} (13, 17). These results are suggestive of a one-bond cleavage mechanism, but the observed value is not compelling in that the free energy is large for the implication of two deuteriums, but not large enough to clearly implicate four.

Product Studies

Lacking a clear cut decision from the kinetic data we then examined the product proportions, as in Table 4, in search of a rational explanation for the nonstatistical product distributions.

It is clear from the data in Table 4 that a fully concerted pathway, wherein the sp^3 carbons of the reactant become the ring carbons of the product, can be rejected. Similarly a concerted or sequential rupture of both carbon–nitrogen bonds to form a planar TMM intermediate can be ruled out since the distribution of products from **10** and **14**, and from **11** and **13**, wherein a common intermediate is expected, is different. For the same reasons the data in Table 4 rule out the possibility of a rapidly equilibrating set of orthogonal-TMM intermediates. The orthogonal-TMM is an attractive possibility in that it is the ground state geometry for singlet TMM (**8**) and has been implicated by Chesick (18) and others in the isomerization of methylenecyclopropanes (14).

The work of Roth and Wegener (15) and that of Gajewski and Chou (14) leads us to examine the possibility of the *exo*-methylene group rotating to form an orthogonal-TMM, and then closure of the diradical by rotation of one of the allylic methylenes e.g.

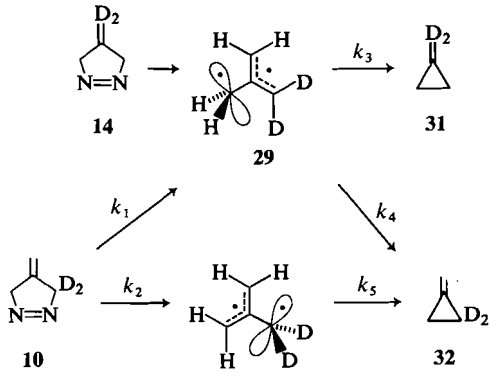


Such a mechanism can be ruled out on the basis that only one isomer would be expected from **13**, and one from **14**.

An attractive mechanism is that represented by Scheme 3 wherein the orthogonal-TMM intermediate is generated by simply rotating one of the nitrogen-bearing methylenes of the reactant. The thermolysis of **14** produces one such intermediate **29** whereas the thermolysis of **10** gives **30** as well as **29**. If k_1 and k_2 are the first order rate constants for the formation of **29** and **30** from **10**, and k_3 and k_4 are the rate constants for the product-determining steps, then using the steady state approximation for **29** and **30** we can calculate the ratio k_1/k_2 by using the product data in Table 4. Using the steady state approximation for **29** and **30** in Scheme 3, the ratio of **31**:**32** produced from **10** is given by eq. [2], provided none of the reactions is reversible, and control reactions indicate no interconversion of **10** and **14**, nor of **31** and **32**

$$[2]\quad \frac{[31]}{[32]} = \frac{k_3k_1}{k_4k_1 + k_2(k_3 + k_4)} = \frac{k_3/k_4}{1 + (k_2/k_1)(k_3/k_4 + 1)}$$

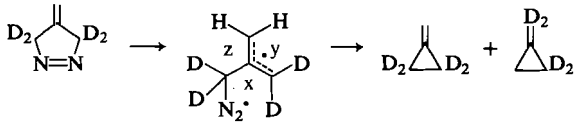
under the reaction conditions. The value k_3/k_4 is the ratio of [**31**]/[**32**] obtained from **14** and is 0.52 ± 0.02, a value difficult to justify in terms of the process involved as it would require the CD_2 group of **29** to be essentially twice as facile as the CH_2 group in rotating out of the allylic plane into the ring methylene position. Scheme 3 would predict that a larger proportion of **32** should be produced from **10** than from **14**, since **30** gives rise to only **32**. Using the aforementioned ratio of 0.52 in eq. [2] and the product proportions from **10**, the value of $k_1/k_2 = -0.17$ is the unique solution and is not possible. An analogous treatment of the product proportions for the isomeric pair **11** and **13** similarly gives an irrational result. It is thus apparent that none of the reasonably possible two-bond cleavage processes can explain the product distribution in Table 4.



SCHEME 3

Stepwise One C—N-bond Cleavage

Allylic resonance may be effective in bringing about one-bond cleavage in the rate-determining step and as a result an α-methylene group of **13** will have to rotate into the plane to give the allylic diazenyl species **33**. In order to examine the product



13 **33** **34** **35**

forming step, we define the displacement of nitrogen by the allylic terminus which was originally the α-methylene as x-closure, the displacement of nitrogen by the allylic terminus which was the *exo*-methylene as z-closure, and the electrocyclic closure of the two allylic termini as y-closure. Any mechanism that uses only one mode of closure (x, y, or z) for the intermediate diazenyl species can be rejected since such a scheme would predict a single product from each of the deuterated pyrazolines. The formation of **31** from **14**, and of **34** from **13** requires that x-closure be included in the product-forming process but other processes (y and/or z) must be involved to account for the isomeric products **32** from **14**, and **35** from **13**. Thus we must, at a minimum, consider three possibilities, i.e. (x + y)-closure, (x + z)-, or (x + y + z)-closure, as possible mechanisms. It is convenient to examine the (x + y + z)-closure initially as the most general case, and then the other two closures can be treated as extreme cases wherein y = 0 and z = 0.

Information about the relative proportions of the three modes of closure for the diazenyl species from 4-methylene-1-pyrazoline is required. We chose the product distribution from 4-methylene-1-pyrazoline-3-^{13}C (**36**) as the best model for **4**.

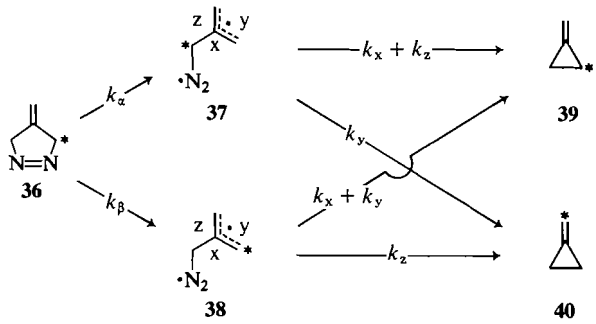
If k_x, k_y, and k_z represent the partial relative rate factors (i.e. $k_x + k_y + k_z = 1.0$) for x-, y-, and z-closure from each diazenyl species produced from the reactant then the isotopic substitution (^{13}C for ^{12}C) should give rise to a minimal difference on going from **4** to **36**. Defining k_α and k_β as the partial relative rate factors (i.e. $k_\alpha + k_\beta = 1.0$) for the faster and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

slower steps for the C—N bond-breaking process and using the normal ^{13}C isotope effect of 1.03 (61),[1] we obtain the ratio k_α/k_β as 0.505:0.495. Substituting this ratio and the product ratio of 64:36 for **39**:**40** into eq. [3] the ratio $k_x(\mathbf{36})/k_y(\mathbf{36})/k_z(\mathbf{36})$ can be calculated by adding the relationship that

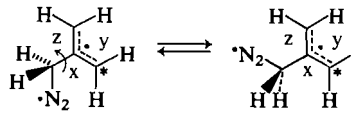
$$[3]\quad \frac{[\mathbf{39}]}{[\mathbf{40}]} = \frac{0.64}{0.36} = \frac{0.505[k_x(\mathbf{36}) + k_z(\mathbf{36})] + 0.495[k_x(\mathbf{36}) + k_y(\mathbf{36})]}{0.505k_y(\mathbf{36}) + 0.495k_z(\mathbf{36})}$$

$k_x(\mathbf{36}) = k_z(\mathbf{36})$. This gives the ratio 0.28:0.44:0.28. Chemically such would be the case if the diazenyl radical were an intermediate of sufficient lifetime



SCHEME 4

that the rotamer equilibrium **41** ⇌ **42** could be achieved (or if frontside and rearside attack in the initially produced rotamer were of equal importance in the closure step).



In generalizing this mechanism to the other deuterated compounds (**10**–**13**) to see whether or not the product proportions in Table 4 can be accounted for, we must first decide which modes of closure are isotopically sensitive for the diazenyl radical going to product, and then attempt to evaluate them. If **14** generated the diazenyl radical as in Scheme 5 and there were no deuterium isotope effect, we would expect the product proportions from x-, y-, and z-closure to give **32**:**31** in the ratio 72:28. Because $k_y(\mathbf{14})$ and $k_z(\mathbf{14})$ involve a rotation of the allylic CD_2 bond, and $k_x(\mathbf{14})$ has minimal change at the isotopically substituted position, we have assumed that the isotope effect R is associated with the former two modes. Using eq. [4] the value of R is found to be

$$[4]\quad \frac{[\mathbf{32}]}{[\mathbf{31}]} = \frac{66}{34} = \frac{k_y(\mathbf{14}) + k_z(\mathbf{14})}{k_x(\mathbf{14})} = \frac{k_y(\mathbf{36})/R + k_z(\mathbf{36})/R}{k_y(\mathbf{36})}$$

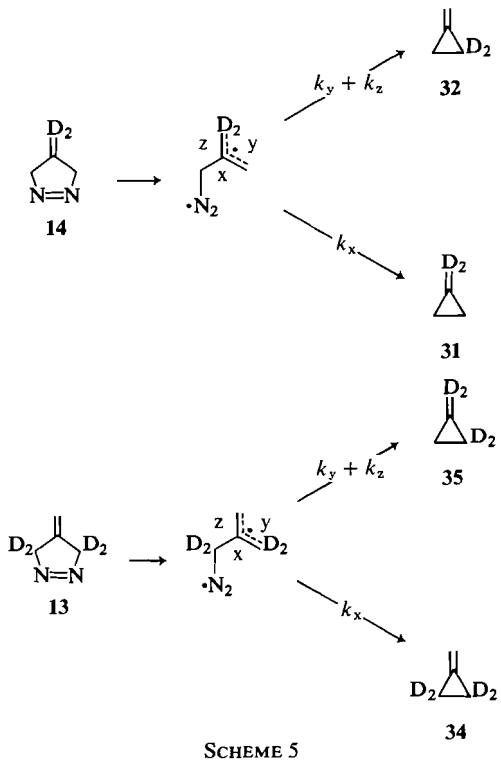
[1]The ratios calculated are quite insensitive to this isotope effect, a value of 1.1 giving essentially the same result.

1.33 ± 0.05 (using the ^{2}Hmr data from Table 4). If we use this value for **13** and assume that the secondary deuterium kinetic isotope value for the closures x, y, and z from the diazenyl intermediate are unaffected by the deuteriums on the diazenyl methylene group[2] then eq. [5] can be used to predict the product proportions for **35** and **34**. The value obtained

$$[5]\quad \frac{[\mathbf{35}]}{[\mathbf{34}]} = \frac{k_y(\mathbf{13}) + k_z(\mathbf{13})}{k_x(\mathbf{13})} = \frac{k_y(\mathbf{36}) + k_z(\mathbf{36})\cdot R}{k_x(\mathbf{36})}$$

75 ± 2:25 ± 2 compares favourably with that found in Table 4.

Carrying out the same analysis for **10** and **11** as outlined in Scheme 6 requires the use of two diazenyl species for each. We have used the kinetic data from Table 3 and have assumed that the rate constant for the faster bond, k_α in Scheme 6, is one half the value of the rate constant for **10**, and that the value for the



SCHEME 5

[2]This assumption is made on the basis of the generally small value of the isotope effect for S_N2 type processes (19).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

slower rate, k_β, is one half the value of the rate constant for **13**. Thus the intermediates **43** and **44** (and similarly **45** and **46**) occur in the proportions 0.58:0.42.

Equations [6]–[9] are used to predict the product proportions by inserting the value $R = 1.33$ wherever

$$[6]\quad k_x(\mathbf{10}):k_y(\mathbf{10}):k_z(\mathbf{10}) = k_x(\mathbf{36}):k_y(\mathbf{36}):k_z(\mathbf{36}) = 0.28:0.44:0.28$$

$$[7]\quad k_x'(\mathbf{10}) : k_y'(\mathbf{10}) : k_z'(\mathbf{10}) = \frac{k_x(\mathbf{36})}{R} : \frac{k_y(\mathbf{36})}{R} : k_z(\mathbf{36}) = 0.26 : 0.40 : 0.34$$

$$[8]\quad k_x(\mathbf{11}) : k_y(\mathbf{11}) : k_z(\mathbf{11}) = k_x(\mathbf{36}) : \frac{k_y(\mathbf{36})}{R} : \frac{k_z(\mathbf{36})}{R} = 0.34 : 0.40 : 0.26$$

$$[9]\quad k_x'(\mathbf{11}) : k_y'(\mathbf{11}) : k_z'(\mathbf{11}) = \frac{k_x(\mathbf{36})}{R} : \frac{k_y(\mathbf{36})}{R} : \frac{k_z(\mathbf{36})}{R} = 0.31 : 0.37 : 0.31$$

applicable (i.e. whenever CD_2 rotation competes with CH_2, effectively $k_H/k_D = 1.33 \pm 0.05$). The values given have been normalized to satisfy $k_x + k_y + k_z = 1.0$ (for the major intermediate) and $k_x' + k_y' + k_z' = 1.0$ (for the minor intermediate). The product ratios for **10** and **11** can be calculated using eqs. [10] and [11].

$$[10]\quad \frac{[\mathbf{32}]}{[\mathbf{31}]} = \frac{k_\alpha[k_x(\mathbf{10}) + k_z(\mathbf{10})] + k_\beta[k_x'(\mathbf{10}) + k_y'(\mathbf{10})]}{k_\alpha k_y(\mathbf{10}) + k_\beta k_z'(\mathbf{10})} = \frac{0.60}{0.40}$$

$$[11]\quad \frac{[\mathbf{35}]}{[\mathbf{34}]} = \frac{k_\alpha[k_x(\mathbf{11}) + k_y(\mathbf{11})] + k_\beta[k_x'(\mathbf{11}) + k_z'(\mathbf{11})]}{k_\alpha k_z(\mathbf{11}) + k_\beta k_y'(\mathbf{11})} = \frac{0.70}{0.30}$$

The calculated product ratios obtained above are summarized in Table 8 along with data for a mechanism having no z-closure (z = 0), and for when there is no y-closure (y = 0). These latter two modes do not predict the correct product proportions for **10**, **11**, and **13**. It should be noted that the case for (x + y + z)-closure in Table 8 is that wherein $k_x = k_z$. Attempts to fit $k_x = 0.8\,k_z$ and $k_x = 1.25\,k_z$ caused one or more of the predicted values to move away from the observed by greater than ±2%.

TABLE 8. Predicted and observed product ratios for the thermolysis of deuterated 4-methylene-1-pyrazolines using (x + y + z)-closure from diazenyl intermediates

		Product ratio			
		Predicted[b]			Observed[a]

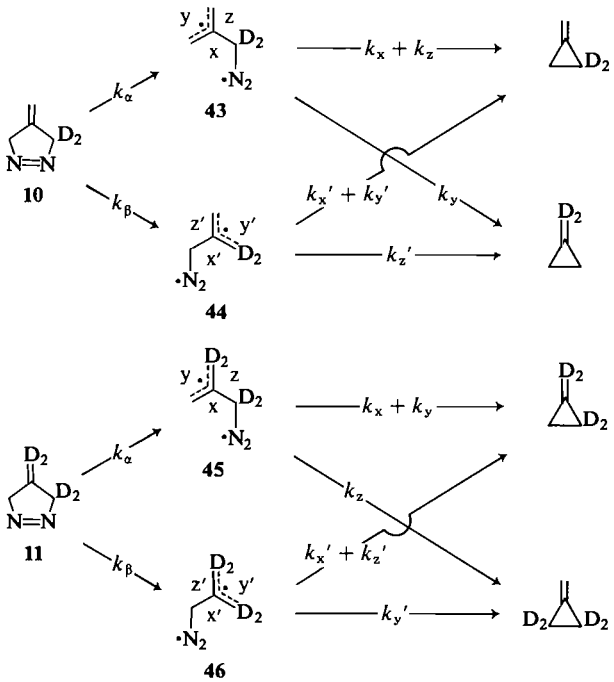
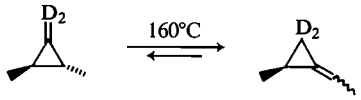


SCHEME 6

The secondary deuterium kinetic isotope effect value of 1.33 ± 0.05 is at first glance larger than one might have expected, but Gajewski and Chou (14) have observed a value of 1.31 ± 0.04 for the thermal isomerization of the methylenecyclopropane (**47**) to the ethylidenecyclopropane (**48**) and have explained the result in terms of the torsional vibrational mode of the vinylic hydrogens (deuteriums) (20).



We conclude that the secondary deuterium kinetic isotope effects and product isotope effects can be explained by a mechanism involving diazenyl intermediates such as **43–46**. These intermediates appear to have a sufficient stability that if backside displacement is the principle mode (2*d*) then the energy barrier for rotation about the C—CH_2N_2• bond is smaller than the energy for ring closure. Baird and Kathpol (21) have carried out *ab initio* MO calculations using the STO-3G basis set and suggest that species of the type R—N = N• are discrete intermediates requiring an energy barrier for conversion to R• and N_2.

Experimental

All boiling points are uncorrected.

Gas chromatographic separations on a preparative scale were achieved on a Nester Faust Model 850 "Prepkromat" connected to an Elecktronik 18 strip chart recorder.

The proton nuclear magnetic resonance spectra were obtained using a Varian A-60 spectrometer, a Varian HA-100 spectrometer, and a Bruker WH-400 high field cryospectrometer. The deuterium nuclear magnetic resonance analyses were carried out on a Bruker HFX 90 spectrometer in the Fourier transform mode, and a Bruker WH-400 high field cryospectrometer.

Exact masses were determined on an A.E.I. MS9 mass spectrometer. The mass spectra analyses at low ionization potential were performed on an A.E.I. MS2 instrument.

The Fourier transform infrared spectra were obtained using a Nicolet 7199 Transform Interferometer.

Microanalyses were performed by the Microanalytical Laboratory of the Department of Chemistry, University of Alberta.

Kinetic Measurements

The kinetic experiments in the thermolysis of the 4-alkylidene-1-pyrazolines were conducted in a static vacuum system. Transducer emf was shown to be directly proportional to the pressure used (0–200 Torr) by plotting emf against the pressure as recorded on a mercury manometer. The system was equipped with Hoke stainless steel diaphragm and bellow valves. A 250 mL cylindrical type stainless steel reaction vessel (6.5 cm × 7.0 cm id) was situated in a well-insulated air bath (10) with fast air circulation provided by a high-speed fan located at the bottom of the bath. The main heater, controlled by a Variac variable resistance, was used to bring the temperature to about 20° below the desired operating temperature, and a secondary heater controlled by a Melabs Model CTCIA proportional temperature controller was used to maintain the desired temperature.

The temperature was measured by a Hewlett-Packard (HP) Model 2802A thermometer system calibrated against an ice-point reference. The temperature of the system was monitored by an HP Model 3470A digital display system, and the long term stability of the temperature was better than ±0.1°.

The measurement of the transducer emf was performed using an HP Model 34701A DC voltmeter coupled to an HP Model 34721B BCD module which was connected to a National Semiconductor LX 1702A transducer functional in the pressure range of 0–1 atm. The emf was monitored by an HP Model 3470A digital display system and was then recorded as a function of time by an HP Model 5150A thermal printer. The stability of the emf was better than ±0.002 volt during the measurements.

4-Methylene-1-pyrazoline (4), 4-Methylene-1-pyrazoline-3,3-d_2 (10), and 4-Methylene-d_2-1-pyrazoline-3,3-d_2 (11)

These compounds were prepared as described earlier (4). Each was checked for isotopic purity by mass spectrometry and for positional purity by both ^{1}Hmr and ^{2}Hmr.

5-Oxo-2-phenyl-1,3-dioxan (23)

The method of synthesis by Marei and Raphael (11) was modified to improve the yield considerably and to achieve a one-step synthesis of the product without the intermediate formation of 5,5-dihydroxy-2-phenyl-1,3-dioxan. A mixture of 5-amino-5-(hydroxymethyl)-2-phenyl-1,3-dioxan (70.6 g, 0.338 mol) (**22**) and pH 6 buffer solution (2.0 L) in a 3-L round-bottomed flask was stirred mechanically at room temperature. The reaction mixture initially became homogeneous when sodium metaperiodate (72.3 g, 0.338 mol) was added all at once with vigorous stirring. Later a white solid appeared. After 15 min of stirring, the product was extracted with dry dichloromethane (3 × 2.0 L), the extract was dried over

For personal use only.

anhydrous sodium sulfate, and the solvent was evaporated using a rotatory evaporator at less than 20°C. A slightly yellow solid (55.7 g) was produced. The solid was dissolved in boiling dry pentane (6.0 L). Decantation of the clear solution, followed by cooling and evaporation of the solvent using a rotatory evaporator at less than 20°C, gave a white solid (50.7 g, 0.285 mol, 84.3% yield) which was pure, judging from the ^{1}Hmr spectrum, and mp 68–69°C (lit. (11) mp 69–71°C). The product should be stored in a freezer below −20°C to prevent it from decomposing slowly into a yellow oil. The 100 MHz ^{1}Hmr spectrum TMS ($CDCl_3$) showed δ: 4.47 singlet, 4H), 5.87 (singlet, 1H), and 7.42 (complex multiplet, 5H).

5-Methylene-2-phenyl-1,3-dioxan-7,7-d_2 *(**24**)*

The procedure was a modification of that of Malloy *et al.* (22). A 3-L three-necked round-bottomed flask was fitted with a reflux condenser, a dropping funnel, a mechanical stirrer, and a gas inlet tube. A gentle flow of dry argon through the apparatus was maintained throughout the reaction. Dry 1,2-dimethoxyethane (0.8 L, freshly distilled three times from lithium aluminum hydride) and methyl-d_3-triphenylphosphonium bromide (151 g, 0.423 mol) were added to the flask which was cooled in an ice–water bath. While stirring vigorously, a hexane solution (111 mL) of 2.29 *M* *n*-butyllithium was added through a dropping funnel. The temperature of the reaction mixture was then raised to 65°C over a period of 2 h and maintained at this temperature for 3 h to give a yellow to brown solution of methylenetriphenylphosphorane. This solution was cooled in an ice–water bath and 5-oxo-2-phenyl-1,3-dioxan (40.6 g, 0.228 mol; freshly purified from *n*-pentane before use) in dry 1,2-dimethoxyethane (0.4 L) was added through a dropping funnel while stirring vigorously. The temperature of the reaction mixture was then gradually increased over 3 h until the solvent began to reflux. After refluxing for a day, the reaction mixture was cooled to room temperature. Acetone (50 mL) was added and the mixture was stirred for 30 min. This was followed by the addition of ether (1 L) and stirring was continued for a further 30 min. Solids were removed by filtration and the solvents including benzene and 1,2-dimethoxyethane were almost completely evaporated using a rotatory evaporator. The residual solution was extracted with *n*-pentane (3 × 500 mL). After evaporating the *n*-pentane from the combined extracts, the residual solution distilled at reduced pressure to give the product (32.5 g, 0.183 mol, 80.2% yield), bp 68–69°C/0.15 Torr (lit. (23) bp 76–78°C/3 Torr for nondeuterated material).

The 100 MHz ^{1}Hmr spectrum TMS ($CDCl_3$) showed δ: 4.47 (singlet, 4H), 5.57 (singlet, 1H), and 7.37 (complex multiplet, 5H). The mass spectrum indicated 95 ± 1% isotopic purity (D_0 = 0.9, D_1 = 7.9, D_2 = 91.2). The 13.6 MHz ^{2}Hmr spectrum (CCl_4) indicated >99.8% of total deuterium at the *exo*-methylene position.

2-(Methylene-d_2*)-1,3-propanediol (**25**)*

5-Methylene-2-phenyl-1,3-dioxan-7,7-d_2 (31.1 g, 0.175 mol) in methanol (1.0 L) was added to ammonium chloride (165 g) in distilled water (400 mL) in a 3-L three-necked round-bottomed flask fitted with a reflux condenser and a mechanical stirrer. The mixture was vigorously stirred at 40°C for three days and then neutralized with 5% sodium bicarbonate solution. After evaporation of solvents using a rotatory evaporator, acetone (600 mL) was added to the residue. The solid was filtered and the solvents were again evaporated. The residue was extracted with acetone (400 mL) and the solvent was evaporated completely under reduced pressure (1 Torr) at room temperature. The residue was then extracted with ether (3 × 250 mL) and the extracts were dried over anhydrous magnesium sulfate. The ether was evaporated to give yellow crude product. Distillation of the remaining solution gave a colorless liquid (13.0 g, 0.145 mol, 83% yield), bp 96.5–97.5°C/3.5 Torr (lit. (24) bp 127–129°C/32 Torr). The 100 MHz ^{1}Hmr spectrum TMS (DMSO-d_6) showed δ: 3.91 (doublet, J = 5.5 Hz, 4H) and 4.66 (triplet, J = 5.5 Hz, 2H), and indicated 95 ± 1% isotopic purity.

3-Chloro-2-(chloromethyl)propene-1,1-d_2

The procedure was a modification of that of Hooz and Gilani (25). Freshly prepared dry triphenylphosphine (dried at room temperature at 0.2 Torr overnight; 95.5 g, 0.365 mol) was added to a mechanically stirred solution of glycol **25** (12.6 g, 0.140 mol) in dry tetrahydrofuran (110 mL; distilled twice from lithium aluminum hydride) and carbon tetrachloride (255 mL; distilled from phosphorous pentoxide) in a 2-L three-necked round-bottomed flask fitted with a mechanical stirrer, a reflux condenser, and a gas inlet tube. A gentle flow of dry argon through the apparatus was maintained throughout the reaction. After refluxing for 2 h a light reddish solution formed and a large quantity of white solid appeared. *n*-Pentane (700 mL) was added, and the reaction mixture was stirred for 10 min. The solid was filtered and washed with *n*-pentane (250 mL). The solvents were removed by distillation below 37°C. Distillation of the residue yielded the product (9.3 g, 73.2 mmol, 52% yield), bp 57.0–58.0°C/40 Torr (lit. (26) bp 137–138°C/756 Torr).

The 100 MHz ^{1}Hmr spectrum TMS ($CDCl_3$) showed δ: 4.19 (singlet), and indicated 95 ± 1% isotopic purity. The mass spectrum indicated 94 ± 1% isotopic purity (D_0 = 1.8, D_1 = 9.0, D_2 = 89.2). The 13.6 MHz ^{2}Hmr spectrum (CCl_4) indicated >99.8% of total deuterium at the *exo*-methylene position.

1,2-Dicarbethoxy-4-methylenepyrazolidine-6,6-d_2

The procedure was adapted from that used by Rubottom and Chabala (27). A solution of *sym*-dicarbethoxyhydrazine (12.1 g, 68.4 mmol; purified by recrystallization from 95% ethanol and drying under high vacuum (28) in hexamethylphosphoramide 100 mL; dried over Molecular Sieves 4A) was placed in a 500-mL three-necked round-bottomed flask fitted with a reflux condenser, a mechanical stirrer, and a gas inlet tube. A gentle flow of dry argon was maintained in the apparatus during the reaction. The reaction mixture was cooled in an ice–salt bath. Sodium hydride (57% dispersion, 2.88 g, 68.4 mmol) which had been washed three times to remove protective oil, was added to the reaction mixture in small portions with the aid of *n*-pentane. The mixture was allowed to warm to room temperature, and stirred mechanically for 6 h. After cooling in an ice–salt bath, 3-chloro-2-(chloromethyl)propene-1,1-d_2 (8.5 g, 66.9 mmol) was added dropwise. The mixture was then allowed to warm to room temperature and kept at this temperature for 3 days. After cooling in an ice-salt bath, sodium hydride (57% dispersion; 2.88 g, 68.4 mmol; washed with *n*-pentane) was slowly added in small portions with the aid of *n*-pentane. Once more, the reaction mixture was allowed to warm to room temperature and kept at this temperature for a day. After cooling in an ice–water bath, distilled water (150 mL) was slowly added, and the mixture was stirred vigorously for 30 min. Extraction of the product with absolute ether (5 × 200 mL), and evaporation of the solvent using a rotatory evaporator followed by distillation of the residue yielded the liquid product (10.9 g, 47.4 mmol, 71% yield), bp 88–89°C/0.08 Torr.

The 100 MHz ^{1}Hmr spectrum TMS ($CDCl_3$) showed δ: 1.20 (triplet, J = 7.3 Hz, 6H) and 4.16 (quartet + broad peak, J = 7.3 Hz, 8H; ester CH_2 + ring methylene) and indicated 94 ± 1% isotopic purity. The mass spectrum indicated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

94.8 ± 0.1% isotopic purity ($D_0 = 0.7$, $D_1 = 9.1$, $D_2 = 90.2$) based on the molecular ion peak. The 13.6 MHz ^{2}Hmr spectrum (CCl_4) indicated >99.8% of total deuterium at the *exo*-methylene position.

4-Methylenepyrazolidine-6,6-d_2 *Hydrochloride*

The procedure was that described previously for the synthesis of 4-methylenepyrazolidine hydrochloride from 1,2-dicarbethoxy-4-methylenepyrazolidine (10). Ethylene glycol (70 mL), distilled water (17 mL), potassium hydroxide (16.4 g, 295 mmol), 1,2-dicarbethoxy-4-methylenepyrazolidine-6,6-d_2 (10.0 g, 43.5 mmol), and concentrated hydrochloric acid (4.3 mL, 51.8 mmol) reacted to give the product (4.8 g, 39.2 mmol, 90.1% yield).

The 60 MHz ^{1}Hmr spectrum, external TMS (D_2O) showed δ: 4.04 (singlet, 4H) and 4.88 (singlet, 3H), and indicated 94 ± 1% isotopic purity.

4-Methylene-1-pyrazoline-6,6-d_2 *(14)*

The procedure was that described previously for the synthesis of 4-methylene-1-pyrazoline from 4-methylenepyrazolidine hydrochloride (10). 4-Methylenepyrazolidine-6,6-d_2 hydrochloride (4.4 g, 36.7 mmol), red mercuric oxide (50 g), and anhydrous sodium sulfate (50 g) in absolute ether (100 mL) reacted to give the product (1.4 g, 16.7 mmol, 45.5% yield).

The 100 MHz ^{1}Hmr spectrum TMS (benzene-d_6) showed δ: 4.47 (singlet), and indicated 95 ± 1% isotopic purity. The mass spectrum indicated 95.0 ± 1% isotopic purity ($D_0 = 0.4$, $D_1 = 9.2$, $D_2 = 90.4$). The 13.6 MHz ^{2}Hmr spectrum (CCl_4) indicated >99.8% of total deuterium at the *exo*-methylene position.

5,5-Dicarbethoxy-2-norbornene (16)

Freshly prepared cyclopentadiene (60.0 g, 0.910 mol) was added slowly to diethyl methylenemalonate (**15**) (110.0 g, 0.640 mol) (29) which had been cooled in an ice–water bath. The reaction mixture was warmed to room temperature and kept at this temperature for an hour. It was then heated to 100°C over a period of 1 h and kept at this temperature for 3 h. Distillation of the mixture gave a colorless liquid (122.6 g, 0.516 mol, 80.6%), bp 107–108.5°C/2.5 Torr. The ir spectrum ν_{max}: 1733 (C=O) cm^{-1}. The 100 MHz ^{1}Hmr spectrum TMS ($CDCl_3$) showed δ: 1.21 (triplet, J = 7.3 Hz, 3H), 1.23 (triplet, J = 7.3 Hz, 3H), 1.57 (multiplet, 2H), 2.04 (multiplet, 2H), 2.89 (singlet, 1H), 3.37 (singlet, 1H), 4.10 (quartet, J = 7.3 Hz, 2H), 4.17 (quartet, J = 7.3 Hz, 2H), 5.95 (multiplet, 1H) and 6.24 (multiplet, 1H). *Exact Mass* calcd. for $C_{13}H_{18}O_4$: 238.2828; found: 238.2806. *Anal.* calcd. for $C_{13}H_{18}O_4$: C 65.53, H 7.61, O 26.86; found: C 65.34, H 7.75, O 26.91.

5,5-Bis(hydroxymethyl-d_2*)-2-norobornene (17)*

The procedure was an adaptation of that of Moffet (30). In a 2-L three-necked round-bottomed flask fitted with a reflux condenser, a dropping funnel, a gas inlet tube, and a mechanical stirrer, pulverized lithium aluminum deuteride (13.5 g, 0.321 mol) in absolute ether (600 mL) was refluxed overnight in an oil bath under a gentle flow of dry argon. After the oil bath had been removed, 5,5-dicarbethoxy-2-norbornene (63.0 g, 0.264 mol) in dry ether (100 mL) was added with vigorous stirring at such a rate that the solvent refluxed gently. The reaction mixture was refluxed for 4 h and then cooled. Distilled water (12 mL), 15% sodium hydroxide solution (12 mL), and distilled water (36 mL) were added successively to destroy the excess lithium aluminum hydride, and the mixture was stirred for 5 h. Dry ether (500 mL) was added, and the solution was warmed almost to boiling, since the product is quite soluble in hot ether but not in cold. After filtration by vacuum, the residue was extracted with hot ether (2 × 0.5 L) and the combined ethereal solutions were evaporated to dryness on a rotatory evaporator under reduced pressure (0.1 Torr) overnight. Recrystallization from hot benzene (ca. 300 mL) and washing with cold Skelly B gave the product (34.3 g, 0.216 mol, 82% yield) in needles, mp 112–112.5°C (23).

The 100 MHz ^{1}Hmr spectrum TMS (DMSO-d_6) showed δ: 0.46–1.60 (multiplet, 4H), 2.59 (1H), 2.61 (1H), 4.16 (singlet, 1H), 4.40 (singlet, 1H), and 6.08 (2H).

2-Methylene-1,3-propanediol-1,1,3,3-d_4 *(18)*

The procedure used was an adaptation of that of Corey and Suggs (31). A 22 cm quartz column (2.54 cm id) was packed with Pyrex beads which were heated to 480–520°C by a heating tape wrapped around the column. To the column was added neat 5,5-bis(hydroxymethyl-d_2)-2-norbornene (**17**) (32.9 g, 0.208 mol) in small portions. Argon was passed through the apparatus so that the contact time of the vaporized reagent with the column was 7–10 s. The crude product was collected, in two successive traps cooled to −78°C, under slightly reduced pressure (500 Torr). Water was added to the crude product, and the aqueous solution was washed once with *n*-pentane. After concentration of the aqueous extract using a rotatory evaporator, distillation gave the colorless liquid (14.0 g, 0.152 mol, 73% yield).

The 100 MHz ^{1}Hmr spectrum TMS (DMSO-d_6) showed δ: 4.64 (singlet, 2H) and 4.97 (singlet, 2H), and indicated 96 ± 1% isotopic purity.

3-Chloro-2-(chloromethyl-d_2*)-propene-3,3-*d_2 *(19)*

The procedure was that described previously for the synthesis of 3-chloro-2-(chloromethyl)propene from 2-methylene-1,3-propanediol.

The 100 MHz ^{1}Hmr spectrum TMS ($CDCl_3$) showed δ: 4.19 (triplet, J = 0.6 Hz, 4H) and 5.32 (pentet, J = 0.6 Hz 2H).

4-Methylene-1-pyrazoline-3,3,5,5-d_4 *(13)*

The procedure was that described previously for the synthesis of 4-methylene-1-pyrazoline from 4-methylenepyrazolidine hydrochloride. 4-Methylenepyrazolidine-3,3,5,5-d_4 hydrochloride (4.7 g, 37.8 mmol), red mercuric oxide (52 g), and anhydrous sodium sulfate (52 g) in absolute ether (100 mL) were reacted to give the product (1.4 g, 16.3 mmol, 43.1% yield).

The 100 MHz ^{1}Hmr spectrum TMS (benzene-d_6) showed δ: 4.70 (singlet), and indicated 95 ± 1% isotopic purity. The mass spectrum indicated 95.4 ± 0.1% isotopic purity ($D_0 = 0.6$, $D_1 = 0.0$, $D_2 = 7.0$, $D_3 = 2.0$, $D_4 = 90.4$). The 13.6 MHz ^{2}Hmr spectrum (CCl_4) indicated >99.8% of total deuterium at the 3- and 5-methylene (ring methylene) positions.

Conclusion

Secondary deuterium kinetic isotope effects do not allow a decision between one-bond and concerted two-bond cleavage for 4-methylene-1-pyrazoline. The product proportions from the various deuterated substrates cannot be rationalized in terms of a trimethylenemethane intermediate. The kinetic data and product proportions can be readily rationalized in terms of a diazenyl radical which is long enough lived that the allylic termini become equivalent, and for which the rotation of the methylene group out of

the allylic plane has an isotope effect k_H/k_D of 1.33 ± 0.05.

Acknowledgements

We wish to acknowledge the assistance of Dr. H. Tokunaga in many aspects of this work, and the help of Dr. A. Hogg in terms of the mass spectrometry. The efforts of Dr. T. Nakashima in obtaining the ^{2}Hmr spectra are most appreciated and finally the authors wish to acknowledge the financial support of the Natural Sciences and Engineering Research Council of Canada and of the University of Alberta.

Analytic solution of relaxation and dissociation of ozone and sulphur dioxide at low pressures

WENDELL FORST

Centre de Recherches sur les Atomes et les Molécules (CRAM) and Department of Chemistry, Université Laval, Québec (Qué.), Canada G1K 7P4

Received December 15, 1980

WENDELL FORST. Can. J. Chem. **59**, 2569 (1981).

The analytic solution of vibrational relaxation in a low-pressure gas is applied to the thermal dissociation of O_3 in helium and of SO_2 in argon. Use is made of experimental relaxation times to obtain average energy lost per collision. Calculated weak-collision rate constants are in very good agreement with experiment in the case of SO_2, but only in fair agreement in the case of ozone. Several curious aspects of the ozone system, both experimental and theoretical, are discussed.

WENDELL FORST. Can. J. Chem. **59**, 2569 (1981).

On se sert d'une solution analytique de la relaxation vibrationnelle dans un gaz à basse pression pour l'appliquer à la dissociation thermique de O_3 dans l'hélium et du SO_2 dans l'argon. On fait usage des temps de relaxation expérimentaux pour calculer l'énergie moyenne perdue par collision. Les constantes de vitesse calculées pour des collisions faibles s'accordent très bien avec l'expérience dans le cas du SO_2, mais seulement assez bien dans le cas de l'ozone. On discute, du point de vue expérimental et théorique, plusieurs aspects curieux du système ozone.

1. Introduction

The general relaxation problem in a gas at low pressure can be solved analytically for the case of exponential transition probabilities, as we have shown in recent publications (1–4). The calculations were tested, with good results, on the (spin-forbidden) dissociation and relaxation of two triatomics, N_2O and CO_2, both of which are linear. Since relaxation data in O_3 and SO_2 have recently become available (5, 6), we now propose to do the same kind of calculations for the relaxation and the (spin-allowed) dissociation of O_3 and SO_2, which are both non-linear. This should allow a further test of the theory, in that the number of rotational degrees of freedom is now increased to three, relative to two in the linear triatomics. Also, the relaxation data have some unusual features, which should give some idea of the sensitivity of the theory to the relaxation data input.

2. Theory

Since the theory has been adequately described before (1, 2), we give only those equations that are necessary for the comprehension of the text. For a transition from an initial state of energy y to final state of energy x, the exponential transition probability (per collision and per unit energy), which we call Model B, is given by

$$[1] \quad q(x,y) = \begin{cases} C(x)\exp[-(y-x)\gamma] & x < y \text{ (down)} \\ C(y)\exp[-(x-y)\gamma'] & x > y \text{ (up)} \end{cases}$$

where the constant γ is to a very good approximation the average energy transferred in a down-collision (i.e. lost), and $\gamma' = 1/\gamma + 1/kT$. The explicit form of the factors $C(x)$ and $C(y)$ is known (ref. 2, eq. [3]). The $q(x,y)$ of eq. [1] is normalized in $(0, \infty)$ and satisfies detailed balance in the form

$$q(x,y)\exp(-y/kT) = q(y,x)\exp(-x/kT)$$

The time-dependent population density is written in the form of an eigenfunction expansion (ref. 2, eq. [26]) which makes use of two parameters, S and R_j. The first is the solution of

$$[2] \quad \frac{2S}{2+(\gamma/kT)(1-S^2)} = \tanh\left(\frac{SE_0^*}{2kT}\right)$$

and the R_j's are the solutions of

$$[3] \quad \frac{2R}{2+(\gamma/kT)(1+R^2)} = \tan\left(\frac{RE_0^*}{2kT}\right)$$

where E_0^* is the effective threshold to reaction. Once S and the R_j's are known, all steady-state and pre-steady-state properties of the system can be calculated. Given the nature of the available experimental data for O_3 and SO_2, we shall need only the steady-state rate constant for dissociation $k_0\dagger$ (cm^3 $molecule^{-1}$ s^{-1}) which is given by

$$[4] \quad k_0\dagger = \frac{Z(\gamma/kT)^2(1-S^2)}{(\gamma/kT)^2(1-S^2)+4(1+\gamma/kT)}$$

where Z is the collision number, and the first relaxation time τ_1 which is given, in dimensionless form, by

$$[5] \quad \omega\tau_1 = 1 + \frac{4}{1+R_1}\left[\left(\frac{kT}{\gamma}\right)^2 + \frac{kT}{\gamma}\right]$$

0008-4042/81/172569-06$01.00/0

©1981 National Research Council of Canada/Conseil national de recherches du Canada

where R_1 is the first solution of eq. [3] and ω is the collision frequency. The effective threshold E_0^* is defined as (ref. 2, eq. [69])

$$[6] \quad E_0^* = E_0 - kT \ln \left\{ Q_{vr}^{-1} \int_0^\infty N_{vr}(x + E_0) \times [\exp(-x/kT)]\, dx \right\}$$

where E_0 is the (0 K) bond dissociation energy of the bond undergoing rupture, Q_{vr} is the molecular vibrational–rotational partition function, and $N_{vr}(x)$ is the vibrational–rotational density of states at energy x. It can be shown that for a threshold that is not too small ($E_0^* > kT$), eqs. [2], [4], and [6] yield

$$[7] \quad k_0\dagger = \frac{Z \int_{E_0}^\infty N_{vr}(x)[\exp(-x/kT)]\, dx}{Q_{vr}(1 + kT/\gamma)^2}$$

which is the analytic approximation to the "exact" weak-collision rate constant.

The only parameter that remains to be specified is γ, and it is obtained from experiment. The experimentally measured relaxation time τ_{expt} is identified with τ_1, and eq. [5] is then solved for γ; the γ so obtained is called γ_{exptl}.

The integral in eq. [6] is calculated using a 15-point Gauss–Laguerre integration (7), and the densities of states by the method of steepest descents (8) for a collection of (in the present case) three harmonic oscillators and three rigid rotors. Equations [2] and [3] are solved by the usual Newton–Raphson method. For the sake of consistency, Q_{vr} is calculated by the same 15-point Gauss–Laguerre integration as

$$Q_{vr} = \int_0^\infty N_{vr}(x)[\exp(-x/kT)]\, dx$$

3. Results

(a) *The Low-pressure Dissociation $O_3 + He \rightarrow O + O_2 + He$*

Relaxation times in O_3 have been measured several times in the past (9–11), but only recently Moy, Mao, and Gordon (5) have measured them over a range of temperatures in the presence of helium. They used a pulsed CO_2 laser to excite the stretching mode (001) in O_3 in the presence of NO and the relaxing gas, and from the decay of the laser-enhanced chemiluminescence of NO_2^* they obtained the thermally averaged relaxation rate for the bending mode (010) of O_3. A least-squares fit of their data (ref. 5, Table II) over the range 164 to 444 K yields for the dimensionless relaxation time $\omega\tau_{exptl}$ (which is equal to the inverse of the transition probability)

$$[8] \quad \omega\tau_{exptl} \equiv \omega\tau_1 = 4.2925 \exp(46.603/T^{1/3})$$

based on the hard-sphere collision frequency ω (using the collision diameter $\sigma = 3.42$ Å for ozone–He collisions (9)). Owing to the uncertainty in the Lennard–Jones (LJ) well-depth parameter ε for O_3, it is not useful to calculate collision numbers under LJ potential (Z_{LJ}), which would probably be more appropriate.

Vibrational frequencies of ozone necessary for calculating $N_{vr}(x)$, and the O_2—O bond energy in O_3 used for E_0 in eq. [6] were all taken from Johnston (12) ($E_0 = 24.25$ kcal mol^{-1}).

The results are shown in Table 1, where γ_{exptl} is the solution of eqs. [5] and [8], while $k_0\dagger$ and $\omega\tau_1$ are calculated from eqs. [4] and [5], respectively, the latter merely as a check that numerical values of the relaxation times given by eq. [8] are in fact recovered. Least-squares fit of $k_0\dagger$ in Table 1 gives

$$k_0\dagger = 1.70 \times 10^{-9} \times [\exp(-12752/T)] \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

Although there are numerous determinations of the dissociation rates of ozone at high temperature, and of the reverse association $O_2 + O + M$ at low temperature, few have been done for helium as third body. However, recently Endo, Glänzer, and Troe (EGT) (13) have determined relative efficiencies of various M at 300 and 800 K. Using their $k_{exptl}(He)/k_{exptl}(Ar) = 2.8$ at 800 K, the "best" rate constant for O_3 dissociation in argon $k_{exptl}(Ar)$ given by Baulch (14) can be converted into dissociation rate in helium, with the result $k_{exptl}(He) = 7.26 \times 10^{-16}$ cm^3 molecule^{-1} s^{-1} at 800 K. EGT's direct determination gives $k_{exptl}(He) = 7.47 \times 10^{-16}$ cm^3 molecule^{-1} s^{-1} at the same temperature. The rate constant expression for $k_{exptl}(O_3)$ given by Heimerl and Coffee (15) cannot be usefully converted in $k_{exptl}(He)$ because it is based mainly on data for M = Kr and M = Ar that have been converted into $k_{exptl}(O_3)$ using temperature-independent relative efficiencies that are probably inappropriate in this case.

At room temperature, it can be calculated from EGT's data that at 300 K $k_{exptl}(He)/k_{exptl}(Ar) = 1.82$, $k_{exptl}(He)/k_{exptl}(N_2) = 0.90$, the latter of which agrees with Johnston's (12) 300 K value, but the former is about 40% higher. Based on the above relative rate constants of EGT, and using JANAF (16) values for the equilibrium constant, the more recent determinations (refs. 17, 18 for M = N_2; refs. 19, 20 for M = Ar) of the association rate all yield

*Powers of ten in parentheses.

the remarkably consistent value for the dissociation rate $k_{exptl}(He) \sim 2 \times 10^{-26}$ cm^3 molecule^{-1} s^{-1} at 300 K, which is substantially the same result that can be obtained by extrapolating Baulch's (14) expression for $k_{exptl}(Ar)$ to 300 K and multiplying by 1.82, the helium rate relative to argon.

Alternatively, we can make use of data for relaxation of ozone in presence of argon which are known only at one temperature. Gordon and Liu (11) report that the ratio of transition probabilities for He and Ar is ~3.5 at room temperature, which agrees fairly well with the results of Rosen and Cool (9) and Kaldor and co-workers (10). Thus $\omega\tau_1$ (Ar) $\sim 1.5 \times 10^4$ at 298 K. Calculation then gives for argon as heat bath gas $\gamma_{exptl} \sim 3.5\,cm^{-1}$, $k_0\dagger \sim 10^{-28}$ cm^3 molecule^{-1} s^{-1}, so that $r = k_0\dagger(Ar)/k_0\dagger(He) \sim 0.25$, which is the calculated argon rate relative to He. This is based on hard-sphere collisions; for collisions under LJ potential, the relative rate is 1.5 times larger, owing to the small LJ well depth ε for He (note that in taking the ratio of rate constants, the unknown ε for O_3 drops out). Thus $r \sim 0.4$, which compares reasonably well with EGT's $k_{exptl}(Ar)/k_{exptl}(He) = 0.55$ at 300 K.

The results in Table 1 show a considerable discrepancy between experiment and theory at room temperature. Quite obviously relaxation data give a γ_{exptl} that is about right in relative terms (γ_{He} vs. γ_{Ar}), but too small in absolute value.

(b) The Low-pressure Dissociation $SO_2 + Ar \rightarrow SO + O + Ar$

Relaxation times in SO_2–Ar mixtures have been measured behind incident shock waves by Kishore, Babu, and Rao (6) between 700 and 2100 K who obtained

$$p\tau_{exptl} = 9.562 \times 10^{-3} \exp(40.32/T^{1/3}) \text{ atm-}\mu s$$

which leads to

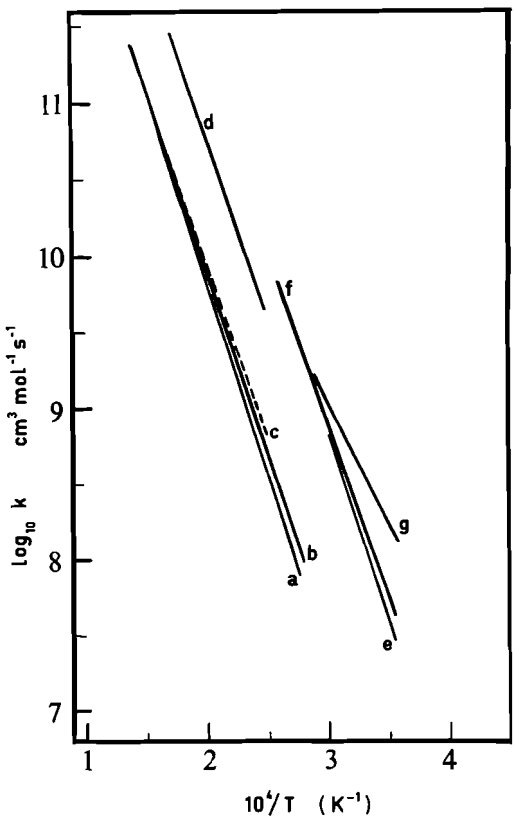

FIG. 1. Comparison of calculated and experimental Arrhenius plots for the decomposition of SO_2 in argon at low pressure. (*a*) is calculated, the rest are experimental. (*a*), this work; (*b*), ref. 28; (*c*), ref. 33; (*d*), ref. 31; (*e*), ref. 27; (*f*), ref. 29; (*g*), ref. 25.

$$[9] \quad \omega\tau_{exptl} \equiv \omega\tau_1 = \frac{1.445 \times 10^4}{T^{1/6}} \exp(40.32/T^{1/3})$$

based on Z_{LJ}. LJ parameters for SO_2 were taken from Monchick and Mason (21) ($\varepsilon/k = 363°$, $\sigma = 4.026$ Å), vibrational frequencies from Shimanouchi

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

(22), and the SO—O bond energy from Darwent (23) (E_0 = 130.8 kcal mol^{-1}).

The results are shown in Table 1; least-squares fit gives

$$k_0\dagger = 8.82 \times 10^{14} \times \exp(-117.3 \text{ kcal mol}^{-1}/RT) \quad \text{cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

There are numerous experimental investigations of this reaction (24–33), the more recent of which are compared in Fig. 1 with the present results. There appears to be agreement now that the decomposition of SO_2 is complex in mixtures (33) containing more than about 0.1% SO_2, but that at lower concentrations the elementary reaction of decomposition into SO + O can be measured. Thus the two measurements (28, 33) done at very low concentrations are now in substantial agreement, the most recent result being (33)

$$k_{\text{exptl}} = 3.55 \times 10^{14} \times \exp(-104.92 \text{ kcal mol}^{-1}/RT) \quad \text{cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

It can be seen that the calculated results agree quite well with the experimental rate constant for the elementary step.

It should be noted nevertheless that agreement between theory and experiment would look much worse if we were to take the group of experimental measurements that give much higher values for the rate constant (cf. Fig. 1), of which one (curve *e*, ref. 27) was also done at very low (~ppm) concentrations of SO_2. It now appears, however, that there was an experimental problem associated with the measurement of ref. 27 (cf. footnote 12 in ref. 33).

4. Discussion

Equation [60] in ref. 2 makes it clear that τ_1 refers to bulk relaxation of average internal energy. At first sight, this may appear not to be what has been measured in either the O_3–He or SO_2–Ar relaxation measurements.

While in the O_3–He case ozone was pumped by a nonthermal process, there is good reason to believe (34) that the cited relaxation measurements nevertheless represent bulk relaxation at the temperature of the experiment via the slowest V–T mode. Thus even if the present calculations at 600 and 800 K make use of relaxation data extrapolated beyond the temperature range actually covered by experiment, it is clear from Table 1 that in the case of ozone the theory has not been successful in fitting simultaneously the rate constant and the relaxation time. Part of the problem may be that the calculated rate constants $k_0\dagger$ are based on hard-sphere collision numbers. If we take Troe's (35) value ε/k = 162.2° for the LJ well depth in O_3–Ar collisions, one gets ε/k = 47.0° for O_3–He collisions, which means that in order to correct for collisions under the more appropriate LJ potential, the calculated $k_0\dagger$ in Table 1 should be multiplied by 1.46 at 300 K, and by 1.05 at 800 K. This does not significantly improve agreement with experiment.

Alternatively, we may compare with other information the values of γ_{exptl} in Table 1, which is the average energy loss in a collision as calculated from the measured relaxation time. In terms of EGT's (13) measured collision efficiency β_c,

$$\gamma = \beta_c^{1/2} kT/(1 - \beta_c^{1/2})$$

(Note that EGT give their results in terms of $\langle \Delta E \rangle$, the average energy transferred in *all* collisions, up *and* down; thus $\langle \Delta E \rangle = -\gamma\beta_c^{1/2}$). From their data on O_3 + He, one gets γ = 146.3 cm^{-1} at 300 K, γ = 106.9 cm^{-1} at 800 K, which, if used in the present calculations, would yield $k_0\dagger = 9.3 \times 10^{-26}$ at 300 K, $k_0\dagger = 1.3 \times 10^{-15}$ at 800 K in units of cm^3 molecule^{-1} s^{-1}. Compared with experiment, the rate constants are now too large, but the discrepancy is much smaller in absolute terms, especially at low temperature. The most striking is the difference in the temperature dependence of γ: when calculated from relaxation times, it *increases* with temperature, as a result of the $T^{-1/3}$ temperature dependence of the usual Landau–Teller plot, whereas γ calculated from β_c *decreases* with temperature.

Stace and Murrell (36) have done a trajectory study of collisional energy transfer in ozone, and their calculations also give a γ that invariably *increases* with temperature. At the temperatures of interest here, they only give data for the O_3 + Ar system at 500 and 1000 K, from which one obtains by interpolation γ = 244 cm^{-1} at 800 K, and, by extrapolation, $\gamma \sim 7$ cm^{-1} at 300 K. EGT (3) give β_c = 0.019 (800 K) and 0.19 (300 K), i.e. γ = 88.9 cm^{-1} (800 K) and 161.1 cm^{-1} (300 K) for M = Ar. Thus the trajectory study also gives a γ that disagrees with that obtained from β_c with respect to both magnitude and temperature coefficient.

The dissociation of ozone consequently represents a real difficulty for theory, especially at low temperature. The problem could be that the present theory gives an incorrect relation between γ and the relaxation time. One would then have to ask why ozone is the only case so far where such difficulty has come up, and why apparently the trajectory study calculation suffers from the same disability. Or it could be that the cited relation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

between γ and β_c is not correct, or that there is some difficulty with the experimental rate measurements. At room temperature, this means the reverse association

$$O(^3P) + O_2(^3\Sigma_g^-) + M \rightarrow O_3(^1A_1) + M$$

It has been reported recently (37, 38) that more than half the ozone is first formed in the $^3B_2$ state which subsequently relaxes to $^1A_1$, so that presumably the experimental rates refer to this two-stage process rather than to the direct formation of $O_3(^1A_1)$ supposedly represented (via the equilibrium constant) by k_{exptl} in Table 1. It is not clear at present how large the correction (if any) of the 300 K value of k_{exptl} would have to be in order to account for the two-stage process. Until this problem is resolved, the exact nature of the disagreement at room temperature between theory and experiment is in doubt. The choice is clearly this: either k_{exptl} is too large, or γ based on relaxation data is too small. Conceivably kinetic decomposition (or association) experiments do not measure the same γ as do relaxation experiments, in view of the different temperature dependence of γ that the two methods produce.

In the SO_2–Ar case, the problem is of a different nature. Here the cited relaxation measurements in shock waves represent bulk relaxation of average energy, but eq. [5] assumes that there is just one (principal) relaxation time, and this is usually the case. However, SO_2 is a well-known (39) example where there is more than one relaxation time because of a large gap between the two lowest vibrational modes (518 and 1151 cm^{-1}, respectively). The shorter relaxation time (which could not be measured in the experiments of Kishore *et al.*) corresponds to relaxation of the lowest bending mode, while the slower relaxation, measured in the experiments on which eq. [9] is based, corresponds to relaxation of the two higher stretching modes. It can be argued that this is not a very serious handicap since the dissociation of SO_2 proceeds by excitation of the antisymmetric stretch at 1362 cm^{-1}, and therefore it is the relaxation of the stretching modes that is most important for the process of dissociation. As a result, the rate constant, though calculated by means of a theory that recognizes only one relaxation time for average energy, nevertheless agrees quite well with experimental result. The agreement in fact supports the interpretation of the low-concentration measurements in terms of the elementary step $SO_2 \rightarrow SO + O$.

The values of γ_{exptl} obtained in the SO_2 case fit in with the results of calculations for the other triatomics. For example, at 2000 K, we have (2) γ_{exptl} = 42 cm^{-1} for CO_2 + Ar, 59 cm^{-1} for N_2O + Ar, and 111 cm^{-1} for SO_2 + Ar. The higher value for SO_2 dissociation is what one would expect for energy transfer involving a highly polar molecule like SO_2, relative to the weakly polar N_2O and non-polar CO_2.

Table 1 includes also values of the dimensionless incubation time $\omega\tau_{inc}$ calculated from the large-threshold expression (ref. 2, eq. [39])

$$[10] \quad \omega\tau_{inc} = \frac{(E_0^*/kT)(1 + \gamma_{exptl}/kT) - (3 + 2\gamma_{exptl}/kT)}{(\gamma_{exptl}/kT)^2}$$

Although this incubation time has not yet been measured in either of the systems discussed here, it is useful as an indication of the number of collisions the system must undergo before reaching steady state.

In common with previous work, experimental relaxation data, in particular in the SO_2 case, had to be extrapolated to temperatures higher than those at which they were measured, in order to calculate the rate constants. This of course introduces an additional uncertainty. However, the present work shows that useful, and fairly accurate, results can be obtained for the rate constants even if the relaxation data, in addition to the extrapolation, are not exactly of the kind required by the theory. This is another example of the well-known fact that thermal systems can be successfully described on the basis of very limited information.

Internal energy randomisation in weak-collision unimolecular reaction systems

H. O. PRITCHARD AND S. R. VATSYA

Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received January 20, 1981

H. O. PRITCHARD and S. R. VATSYA. Can. J. Chem. **59**, 2575 (1981).

We examine the conjecture that the principal difference between weak-collision and strong-collision behaviour in thermal unimolecular reaction systems arises from a difference in internal energy randomisation rates. To do this, we solve analytically the strong-collision master equation for a thermal unimolecular reaction including explicit allowance for the randomisation processes, and we show that all weak-collision effects so far observed in thermal systems can be accommodated within this framework.

In an appendix, we give the extension of this analytic solution for reactions yielding two (or more) distinct sets of products.

H. O. PRITCHARD et S. R. VATSYA. Can. J. Chem. **59**, 2575 (1981).

Nous examinons l'hypothèse relative au fait que la différence principale de comportement entre une collision faible et collision forte, dans les systèmes de réactions thermique unimoléculaire, provient de la différence entre les vitesses de distribution au hasard de l'énergie interne. Pour ce faire nous résolvons analytiquement l'équation principale de collision forte pour une réaction thermique unimoléculaire incluant une correction explicite pour le processus de distribution au hasard, et nous montrons que tous les effets de collision faible observés dans les systèmes thermiques peuvent s'intégrer dans ce cadre.

En appendice nous donnons le développement de cette solution analytique pour les réactions conduisant à deux (ou plus) ensembles distincts de produits.

Introduction

The concept of a strong collision has been bound intimately with the development of the theory of unimolecular reactions ever since its inception in the 1920's (1–5). The usual manner in which a strong collision was described was an intuitive one, generally adequate within the framework of a steady-state treatment of the reaction process, but not always consistent with the principle of detailed balancing. Recently, however, Nordholm (6) has given precision to the definition of a strong collision, although his statement is recognisably the same as the qualitative one given by Bunker (2, 5). At about the same time, Yau and Pritchard (7) showed that it was possible to derive an analytic solution to the master equation for a thermal unimolecular reaction by using a particular set of collisional transition probabilities for the activation–deactivation processes; it was realised subsequently that this set of transition probabilities was identical with the definition given by Nordholm for strong collisions (8). The beauty of Nordholm's definition is that it can be extended unambiguously to describe collision processes which take place more slowly than "on every collision", and this extended definition is in fact the one used by Yau and Pritchard. By this definition, it is perfectly legitimate therefore to say (provided that one does not need to know the actual *pathways* by which the relaxation took place) that a certain non-equilibrium distribution was reduced to a Boltzmann distribution on a time scale of 10 collisions, or 1000 collisions, — or for that matter, one-thousandth of the period between collisions — and describe all processes with the same form of *strong-collision* relaxation matrix.

This realisation presents us with a dilemma when we come to discuss weak-collision systems. No such precise definition has ever, to our knowledge, been given for a weak collision; the definition, if there is one, is one of the exception — in other words, if it is not a strong collision, then it is a weak collision. But how can we draw a distinction between a weak collision as we normally imagine it, and an inefficient strong collision having the same relaxation rate? Theoretically it is quite straightforward, for any relaxation matrix which has more than one non-zero eigenvalue describes a weak collision process; from a practical point of view, a more useful concept would be that there are some very fast processes and also some rather slow ones, and hence that the eigenvalues are well spaced out — perhaps over two orders of magnitude or more. The determination of such eigenvalues experimentally is rather difficult, and in general we have found ourselves in the position of trying to draw qualitative inferences by making observations on bulk reaction rates. The observation of the rate of formation of some reaction product gives us the integral of the product of the $k(E)$ function with the steady-state distribution — and since the $k(E)$ function is usually taken to be fixed, changes in reaction rate reflect changes in the steady-state distribution. However, by using the result of Lemma 2 from another paper (9), we can conclude that in the weak-collision case, the prin-

cipal determinant of the steady-state distribution is the perturbation of the Boltzmann distribution by the $k(E)$ function, and that contributions to the perturbation from the detailed forms of the relaxation processes are of only secondary importance.[1] Thus, unless we are fortunate in our choice of initial distribution, we cannot hope to discriminate decisively between various transition probability models, and in fact this is precisely what we have come to expect from a long series of chemical activation studies (3, 13); gross insensitivity of computed reaction rates to the assumed transition probability models has been commonplace for a decade now in another closely related problem, that of the dissociation of a diatomic gas (14).

If we specialise the argument to the study of thermal unimolecular reactions, the situation is even more clear cut. Typically, the time scale (t) on which the reaction rate is measured is several orders of magnitude greater than the internal relaxation time (τ); values of $t/\tau > 10^6$ are not uncommon. At these long times, the choice of initial distribution is quite irrelevant and the only information in the steady-state distribution comes from the perturbed eigenvector ψ_0 itself.[2] Consequently, there is little scope for deducing information about weak-collision effects from bulk measurements on thermal reactions. During the incubation period, however, this is not the case,[2] but as yet, no such measurements appear to have been made. Knowledge of the *length* of the incubation period provides no further information, because this is determined solely by ψ_0 and $\eta(0)$, the initial distribution (15). Here again, this conclusion is reinforced by the complete insensitivity of computed values for the ratio of the relaxation time to the incubation time for widely differing sets of transition probabilities (15, 16) (note also that there is a marked divergence between the calculated ratios and the experimental ones for N_2O (17) — perhaps indicating that the theoretical approach may be deficient). We conclude therefore that as far as *current* experimental data on thermal unimolecular reactions are concerned, it cannot matter much what kind of transition probability model we use, step-ladder, Poisson, Gaussian, exponential — or strong, but rendered inefficient by the inclusion of a scale factor in the manner of Nordholm (6) or of Yau and Pritchard (7).

Consequently, we have to re-examine the distinction we usually make between strong collisions and weak collisions to see if there is, in fact, a distinction to be made. In one case, we know already that there is not: we have shown recently (18) that a strong-collision treatment of chemical activation gives rise to a "low-pressure turn-up". In other words, low-pressure turn-up in chemical activation is a result of inefficient collisions, not weak collisions.[3]

On the other hand, we know that there are certain properties of unimolecular reactions which cannot be accommodated within the usual strong-collision formalism, even with the scaling to allow for inefficient energy transfer. Most obvious is the shape of the fall-off curves in so-called weak-collision reactions. For example, if we were to perform a standard strong-collision calculation (7) for the thermal dissociation of CO_2, then the fall-off curve would be far too broad, and would not fit the experimental data in the way such a calculation would fit for a larger molecule; clearly the strong-collision assumption is defective in some way in this case. In his dis-

[1]The key equation here is that the perturbed eigenvector Ψ_0 (which determines the steady state) is given by

$$\Psi_0 = S_0 - \sum_{j=1}^{n-1} \frac{p_j}{\lambda_j - \gamma_0} \mathbf{D}^{1/2} \left[\mathbf{1} + \mathbf{D}^{1/2} \sum_{j=1}^{n-1} \frac{p_j}{\lambda_j - \gamma_0} \mathbf{D}^{1/2} \right]^{-1} \mathbf{D}^{1/2} S_0$$

where S_0 is the unperturbed eigenvector, $\mathbf{D}$ is a diagonal matrix representing the $k(E)$ function in discrete form, λ_j and p_j are the eigenvalues and eigenprojections respectively for the unperturbed matrix, and γ_0 is the rate constant. Given that for weak collisions the λ_j are well spaced, the dominant contribution in the perturbation term will come from λ_1 and p_1, the vibrational relaxation, and a series of numerical experiments (10–12) on H_2 suggests that the form of *this* relaxation is generally determined by the energy-level spectrum rather than by the detailed forms of the transition probabilities.

[2]The important equation here is that the population evolution is given by (7)

$$\eta_i(t) = \tilde{n}_i^{1/2} \sum_j \exp(-\gamma_j t)(\Psi_j)_i \sum_k (\Psi_j)_k \eta_k(0) \tilde{n}_k^{-1/2} \xrightarrow[t \to \infty]{} \tilde{n}_i^{1/2} \exp(-\gamma_0 t)(\Psi_0)_i \sum_k (\Psi_0)_k \eta_k(0) \tilde{n}_k^{-1/2}$$

From the equation given in footnote 1, the dominant term in Ψ_0 is S_0, so that the steady state, to a first approximation, is the equilibrium distribution, independent of the starting distribution $\eta(0)$, depreciated by the factor $\exp(-\gamma_0 t)$. Modification of this Boltzmann distribution to give the actual steady state arises from the perturbation term, which we have already argued in footnote 1, is dominated by the contribution from $k(E)$. This perturbation also introduces into the steady state a memory of the initial distribution $\eta(0)$, which we normally regard as being irrelevant when we discuss thermal reactions. Finally, a still smaller contribution to the determination of the steady state comes from the nature of the normal modes of relaxation themselves, viz. the p_j, λ_j of footnote 1, and are clearly irrelevant if the memory effects are ignorable.

The only way in which the initial distribution and the detailed forms of the relaxation processes can enter is if we consider times $t \sim \gamma_1^{-1}, \gamma_2^{-1}, \ldots$ etc.

[3]We note, however, that there has yet to be a modelling of a real chemical activation process using the inefficient-strong-collision formalism, to see whether the shape of the turn-up is reproduced as well by this method as it is by others, or not.

For personal use only.

course on the theory of unimolecular reactions, Bunker (2) discussed two possible (assumedly complementary) reasons for such a failure; the breakdown of the strong-collision assumption, or the breakdown of the randomisation hypothesis. We have already ruled out, in the arguments just presented, the transition probability model as the cause of the failure, and we will now assert that it is due, in fact, to an inability to achieve full randomisation of the internal energy in these small molecules.

Existing discussions of the problem of internal energy randomisation in thermal unimolecular reactions range over a wide spectrum, from those which partition the molecule into two oscillator pools with an appropriate time delay for transfer of energy between them, all the way to those which try to account for the multiplicity of the quantum states within the system and recognise detailed mechanisms for interchange between the states (1, 19–28). From this range, the treatments of Gelbart, Rice, and Freed (23), Wilson (26), and Nordholm (27) have the most in common with the present approach. Both Wilson and Nordholm wrote down a total master equation which may be represented as follows

$$[1] \qquad d\boldsymbol{\eta}(t)/dt = (\mathscr{A} + \mathscr{V} - \mathbf{D})\boldsymbol{\eta}(t)$$

where $\boldsymbol{\eta}(t)$ is a vector having $\eta_i(t)$ as the fractional population of the quantum state i at time t. $\mathscr{A}$ is a matrix which contains the collisional activation and deactivation rate constants, $\mathscr{V}$ is a matrix constructed from the rate constants for the randomisation processes, and $\mathbf{D}$ is a (diagonal) matrix containing elements d_i, ... which are the specific rate constants for decay of states, i, ... to products. The matrix $\mathscr{A}$ has dimensions equal to the number of states considered to be important in the molecule, but $\mathscr{V}$ is a band matrix of rather limited bandwidth, coupling only states whose energies are rather close together. Nordholm showed (27) that we can only consider the collisional activation–deactivation processes and the randomisation processes independently of each other if the matrix $\mathscr{A}$ commutes with the matrix $(\mathscr{V} - \mathbf{D})$; this is an impossibly stringent condition, but Nordholm goes on to discuss the conditions under which it is plausible to make this separation. Along rather similar lines, Pritchard (28) assumed a specific form for the matrix $(\mathscr{V} - \mathbf{D})$, and accepting separability on the reasonable grounds that the time constant for the relaxation described by $\mathscr{V}$ was always orders of magnitude faster than that of the relaxation described by $\mathscr{A}$, went on to perform a practical calculation on the methyl isocyanide reaction.

In what follows, we do not have to make the assumption of separability. Instead, we choose a form for the matrix elements in eq. [1] which leads to an analytic solution for the unimolecular rate: this form of eq. [1] is very similar to that proposed in ref. 28, but not quite equivalent; however, the arguments upon which the choice of the elements of $\mathscr{V}$ and $\mathbf{D}$ was made remain essentially unchanged.

An Exactly Solvable Model for Unimolecular Reaction with Internal Randomisation Processes

We index the individual rotation–vibration states of the molecule in order of increasing energy, with $\tilde{n}_i$ being the equilibrium population of state i, and with the $\tilde{n}_i$ normalised so that $\sum_i \tilde{n}_i = 1$. We then subdivide this energy-level spectrum into "grains", designated by the index r. It is assumed that all the states within one grain are capable of being transformed into each other by the randomising mechanism (whatever that may be) with a rate constant μ_r; according to our previous arguments (28), μ_r will probably have both first-order and second-order components, i.e.

$$[2] \qquad \mu_r = \mu_1 + \mu_2 p$$

where p is the pressure, and μ_r can vary from grain to grain. The equilibrium population in each grain is designated by

$$\beta_r = \sum_i \tilde{n}_{i,r}$$

For the matrix $\mathscr{A}$, describing the collisional relaxation among the various states of the molecule, we choose as before the scaled strong-collision form

$$[3a] \qquad a_{ij} = \mu\{(1 - \delta_{ij})\tilde{n}_i - \delta_{ij}(1 - \tilde{n}_i)\}$$

where μ is the collisional relaxation rate constant in s^{-1} (μ is implicitly proportional to the pressure, p). In view of the arguments presented in the preceding paragraphs, there can now no longer be any doubts about the validity of using this form to describe all thermal unimolecular reactions in the long-time regime.

For the matrix $\mathscr{V}$, describing the randomisation processes, we assume that it can be broken down into small components $\mathscr{V}_r$, each describing the relaxation only within the grain r. We will assume likewise that the elements of $\mathscr{V}_r$ are given by

$$[3b] \qquad v_{ij,r} = \mu_r\{(1 - \delta_{ij})\tilde{n}_{i,r}/\beta_r - \delta_{ij}(1 - \tilde{n}_{i,r}/\beta_r)\}$$

where μ_r is the randomisation rate constant, again in s^{-1}; μ_r is generally expected to be very much greater than μ. For the first-order randomisation processes, the use of [3b] is equivalent to the assumption of exponential decay within the grain, which is reasonably acceptable within the framework of con-

temporary discussions of radiationless transitions; for the second-order randomisation processes, we have already given arguments (28) for representing them by [3*b*]. The total $\mathscr{V}$ matrix, which is the sum of the individual $\mathscr{V}_r$ components, is therefore block-diagonal, and as such it excludes the possibility of transfer of population *between* grains by the randomisation processes; in view of the infinitesimal breadth of the grains when compared with the dimensions of the whole matrix, we regard this as a relatively minor flaw in the model, and one whose effects can be delineated by numerical calculation using different grain sizes.

The matrix **D** is a diagonal matrix of rate constants for decay to products, and following the concept of Polanyi and Wigner (29) as we have reinterpreted it (28, 30), the elements of **D** are either zero or

[4*a*] $d = 2cv \quad s^{-1}$

where c is the velocity of light and v is the vibration frequency in wavenumber units of that vibration which, if sufficiently excited, leads to the products in question. Remembering that the specific rate constant $k(E)$ can be deduced with good accuracy as the inverse Laplace transform of the infinite-pressure rate law (7, 31), we have that for each grain

[4*b*] $k_r(E) = dg_{r1}/g_r \simeq d\beta_{r1}/\beta_r = 2cv\beta_{r1}/\beta_r$

where β_{r1} is the sum of the equilibrium populations of the *reactive* states within the grain (28, 30), i.e. those for which d is non-zero. Thus, despite the puzzles that still exist in using the Polanyi–Wigner concept to make *a priori* estimates of $k(E)$, we know that given $k(E)$ from experiment, choice of the frequency v for the local mode which leads to reaction tells us the fraction of the states g_{r1}/g_r at any energy E having more than the required number of quanta for reaction to occur.

Having defined all the elements of the total matrix $(\mathscr{A} + \mathscr{V} - \mathbf{D})$, it can be symmetrised as before (18, 32) to give an equivalent matrix $(\mathbf{A} + \mathbf{V} + \mathbf{D})$. It is then a straightforward matter to derive an exact solution for the rate constant (i.e. the smallest eigenvalue) by using the results already derived in our earlier paper on the strong-collision problem (18).

Spectral Structure of (V + D)

Let $\mathbf{I}_r$ be the projection on the subspace corresponding to the rth grain, and let

$$\rho_{r0} = I_r S_0 (I_r S_0, \quad)/(S_0, I_r S_0)$$

where S_0 is the vector whose elements are $\tilde{n}_i^{1/2}$ (9, 18, 32) and the notation (,) represents the scalar product of two vectors. By definition,

$$\mathbf{V} = \sum_{r=1}^{M} \mathbf{V}_r$$

where

$$\mathbf{V}_r = \mu_r(I_r - \rho_{r0}) = \mathbf{V}I_r = I_r\mathbf{V}$$

and M is the number of grains. Since **D** is a diagonal matrix, we also have that

$$\mathbf{D} = \sum_{r=1}^{M} \mathbf{D}_r$$

where

$$\mathbf{D}_r = \mathbf{D}I_r = I_r\mathbf{D};$$

hence

$$(\mathbf{V} + \mathbf{D}) = \sum_{r=1}^{M} (\mathbf{V}_r + \mathbf{D}_r)$$

such that for each r, $(\mathbf{V}_r + \mathbf{D}_r)$ commutes with I_r. It is now clear that the set of eigenvalues of $(\mathbf{V} + \mathbf{D})$ is the collection, for all r, of the eigenvalues of $(\mathbf{V}_r + \mathbf{D}_r)$, with corresponding eigenprojections satisfying

$$\bar{\rho}_{rj} = I_r\bar{\rho}_{rj} = \bar{\rho}_{rj}I_r$$

The required results on the spectral structure of $(\mathbf{V}_r + \mathbf{D}_r)$, which we have derived previously (18), are now collected here.

Let I_r^0 be the projection defined by $I_r^0\mathbf{D}_r = 0$. Since $\mathbf{D}_r$ is a diagonal matrix with only one numerical value d for the non-zero elements, and since $\mathbf{V}_r = \mu_r(I_r - \rho_{r0})$, $(\mathbf{V}_r + \mathbf{D}_r)$ has four eigenvalues with corresponding eigenspaces within the range of I_r as follows:

$$\kappa_{r0} < \kappa_{r2} = \mu_r < \kappa_{r1} < \kappa_{r3} = \mu_r + d$$

The multiplicities of κ_{r2}, κ_{r3} are $[\dim(I_r^0) - 1]$, $[\dim(I_r - I_r^0) - 1]$ respectively, where dim( ) denotes the dimension (of the range). The simple eigenvalues (18) κ_{r0}, κ_{r1} are the solutions of

$$[5] \qquad \mu_r(\boldsymbol{S}_0, [\mu_r - \kappa + \mathbf{D}_r]^{-1} I_r \boldsymbol{S}_0) = (\boldsymbol{S}_0, I_r \boldsymbol{S}_0)$$

and are easily seen to be

$$[6] \qquad \kappa_{r0,1} = \frac{\mu_r + d}{2} \mp \left[\frac{(\mu_r + d)^2}{4} - \frac{\mu_r d \beta_{r1}}{\beta_r}\right]^{1/2}$$

where

$$\beta_{r1} = (\boldsymbol{S}_0, [I_r - I_r^0]\boldsymbol{S}_0)$$

and

$$\beta_r = (\boldsymbol{S}_0, I_r \boldsymbol{S}_0)$$

Thus, all the eigenvalues of $(\mathbf{V}_r + \mathbf{D}_r)$ are known exactly. The eigenspaces corresponding to κ_{rj} $(j = 0, 1)$ are spanned by $[\mu_r - \kappa_{rj} + \mathbf{D}_r]^{-1} I_r \boldsymbol{S}_0$ and thus

$$[7] \qquad (\boldsymbol{S}_0, \bar{\rho}_{rj}\boldsymbol{S}_0) = \frac{(\boldsymbol{S}_0, [\mu_r - \kappa_{rj} + \mathbf{D}_r]^{-1} I_r \boldsymbol{S}_0)^2}{(\boldsymbol{S}_0, [\mu_r - \kappa_{rj} + \mathbf{D}_r]^{-2} I_r \boldsymbol{S}_0)} = \frac{(\boldsymbol{S}_0, I_r \boldsymbol{S}_0)^2}{\mu_r^2 (\boldsymbol{S}_0, [\mu_r - \kappa_{rj} + \mathbf{D}_r]^{-2} I_r \boldsymbol{S}_0)}$$

from [5]. The eigenprojections corresponding to κ_{r2}, κ_{r3} are uniquely determined by

$$\bar{\rho}_{r2} = I_r^0 \bar{\rho}_{r2} = \bar{\rho}_{r2} I_r^0; \qquad \bar{\rho}_{r2} I_r^0 \boldsymbol{S}_0 = 0$$
$$\bar{\rho}_{r3} = (I_r - I_r^0)\bar{\rho}_{r3} = \bar{\rho}_{r3}(I_r - I_r^0); \qquad \bar{\rho}_{r3}(I_r - I_r^0)\boldsymbol{S}_0 = 0$$

Consequently,

$$\bar{\rho}_{rj}\boldsymbol{S}_0 = 0, \quad j = 2, 3$$

Exact Solution for the Rate Constant γ_0

Let ρ_0 be the eigenprojection corresponding to the smallest eigenvalue γ_0 of $[\mu(1 - p_0) + \mathbf{V} + \mathbf{D}]$, where p_0 is defined as usual (18) to be $\boldsymbol{S}_0(\boldsymbol{S}_0,)$. Since $\mathbf{D}_r = 0$ for at least one r (i.e. for each of the unreactive grains below threshold) and $(\mathbf{V} + \mathbf{D}) \geq 0$, the smallest eigenvalue of $(\mathbf{V} + \mathbf{D})$ is zero. Further, since $\mu p_0 \geq 0$, $\gamma_0 \leq \mu$.

Consider

$$\bar{\phi}(x) = \mu(\boldsymbol{S}_0, [\mu + \mathbf{V} + \mathbf{D} - x]^{-1}\boldsymbol{S}_0)$$

for x in $(-\infty, \mu)$. We have

$$\lim_{x \to -\infty} \bar{\phi}(x) = 0, \qquad \lim_{x \uparrow \mu} \bar{\phi}(x) = \infty, \qquad \text{and} \quad \frac{d\bar{\phi}(x)}{dx} \geq 0.$$

In fact, $d\bar{\phi}(x)/dx > 0$ for x in $(-\infty, \mu)$, for the equality implies that $[\mu + \mathbf{V} + \mathbf{D} - x]^{-1}\boldsymbol{S}_0 = 0$ and hence $\boldsymbol{S}_0 = 0$. Thus, $\bar{\phi}(x_0) = 1$ has a unique solution $x_0 < \mu$. It is easy to see that

$$\psi_0 = \mu[\mu + \mathbf{V} + \mathbf{D} - x_0]^{-1}\boldsymbol{S}_0$$

solves the eigenvalue equation

$$[8] \qquad [\mu + \mathbf{V} + \mathbf{D} - x_0]\psi_0 = \mu \boldsymbol{S}_0 = \mu p_0 \psi_0$$

and hence x_0 is an eigenvalue of $[\mu(1 - p_0) + \mathbf{V} + \mathbf{D}]$. It is also the smallest eigenvalue, for if $\gamma_0 < x_0$, then it is easy to see that $\bar{\phi}(\gamma_0) = 1, \gamma_0 < \mu$ and x_0 has been established to be the unique solution of $\bar{\phi}(x) = 1$ in $(-\infty, \mu)$. Since $\gamma_0 < \mu$, $[\mu + \mathbf{V} + \mathbf{D} - \gamma_0]$ is invertible. From [8], it follows that the range of ρ_0 is spanned by ψ_0 and hence γ_0 is a simple eigenvalue; also, from [8], we have that

$$[9] \quad \gamma_0 = (\boldsymbol{S}_0, [\mathbf{V} + \mathbf{D}]\psi_0) = \mu(\boldsymbol{S}_0, [\mu + \mathbf{V} + \mathbf{D} - \gamma_0]^{-1}[\mathbf{V} + \mathbf{D}]\boldsymbol{S}_0)$$
$$= \mu \sum_{\substack{r=1 \\ \mathbf{D}_r \neq 0}}^{M} \sum_{j=0}^{1} \frac{\kappa_{rj}}{\mu - \gamma_0 + \kappa_{rj}} \|\bar{\rho}_{rj}\boldsymbol{S}_0\|^2 = \phi(\gamma_0)$$

i.e. γ_0 is a fixed point of $\phi(x)$; in [9], $\| \ . \ \|$ denotes the norm and is given by [7] i.e. $\|\bar{\rho}_{rj}\boldsymbol{S}_0\|^2 = (\boldsymbol{S}_0, \bar{\rho}_{rj}\boldsymbol{S}_0)$. As before (9), if $\gamma_0 < \mu$, then it is easy to conclude that γ_0 is uniquely defined by [9]; also, it follows (9) that γ_0 is the unique fixed point of $\chi(x)$ in $(-\infty, \mu)$ where

$$[10] \quad \chi(x) = ([\mathbf{V} + \mathbf{D}]^{1/2}\boldsymbol{S}_0, [1 + (\mu - x)^{-1}(\mathbf{V} + \mathbf{D})^{1/2}(1 - p_0)(\mathbf{V} + \mathbf{D})^{1/2}]^{-1}[\mathbf{V} + \mathbf{D}]^{1/2}\boldsymbol{S}_0)$$
$$= \frac{\|J(x)\boldsymbol{S}_0\|^2}{1 - (\mu - x)^{-1}\|J(x)\boldsymbol{S}_0\|^2}$$

and

$$J(x) = [1 + (\mu - x)^{-1}(\mathbf{V} + \mathbf{D})]^{-1/2}[\mathbf{V} + \mathbf{D}]^{1/2}$$

i.e.

$$[11] \quad \|J(x)\boldsymbol{S}_0\|^2 = \sum_{\substack{r=1 \\ \mathbf{D}_r \neq 0}}^{M} \sum_{j=0}^{1} \frac{\kappa_{rj}}{1 + (\mu - x)^{-1}\kappa_{rj}} \|\bar{\rho}_{rj}\boldsymbol{S}_0\|^2$$

The convergence properties of the iterative sequences generated by $\phi(x)$ and $\chi(x)$ have already been given in detail before (9, 18).

Limiting Behaviour of γ_0 with μ and with μ_r

According to the conjecture which led to this formulation of the unimolecular reaction process, we should recover the usual strong-collision behaviour in the limit of $\mu_r \to \infty$, and as a corollary, the limiting weak-collision behaviour as $\mu_r \to 0$. Therefore, we now examine the four limits $\mu, \mu_r \to 0, \infty$.

$$\text{(i)} \quad \lim_{\mu \to \infty} \gamma_0 = (\boldsymbol{S}_0, \mathbf{D}\boldsymbol{S}_0) = d \sum_{\substack{r=1 \\ \mathbf{D}_r \neq 0}}^{M} (\boldsymbol{S}_0, [I_r - I_r^0]\boldsymbol{S}_0) = d \sum_{\substack{r=1 \\ \mathbf{D}_r \neq 0}}^{M} \beta_{r1}$$

Since (9)

$$\chi(0) \geq \gamma_0 > 0$$

and

$$\lim_{\mu \to \infty} \chi(0) = (\boldsymbol{S}_0, [\mathbf{V} + \mathbf{D}]\boldsymbol{S}_0) = (\boldsymbol{S}_0, \mathbf{D}\boldsymbol{S}_0),$$

γ_0 remains finite in the limit of $\mu \to \infty$; the result now follows from [10]. Remembering that

$$k_\infty = \sum_{\substack{r=1 \\ k_r(E) \neq 0}}^{M} k_r(E)\beta_r,$$

substitution for $k_r(E)$ from [4*b*] shows that this limit is the usual high-pressure limit.

$$\text{(ii)} \quad \lim_{\mu \to 0} (\gamma_0/\mu) = 1 - \sum_{\substack{r=1 \\ \mathbf{D}_r = 0}}^{M} (\boldsymbol{S}_0, I_r\boldsymbol{S}_0) = 1 - \sum_{\substack{r=1 \\ \mathbf{D}_r = 0}}^{M} \beta_r = \sum_{\substack{r=1 \\ \mathbf{D}_r \neq 0}}^{M} \beta_r$$

From [9] we have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

$$\gamma_0/\mu = (\boldsymbol{S}_0, [\mu - \gamma_0 + \mathbf{V} + \mathbf{D}]^{-1}[\mathbf{V} + \mathbf{D}]\boldsymbol{S}_0)$$

and since $0 < \gamma_0 < \mu$

$$\lim_{\mu\to 0}(\gamma_0/\mu) = \lim_{\varepsilon\downarrow 0}(\boldsymbol{S}_0, [\varepsilon + \mathbf{V} + \mathbf{D}]^{-1}[\mathbf{V} + \mathbf{D}]\boldsymbol{S}_0) = \lim_{\varepsilon\downarrow 0}\sum_{r=1}^{M}\sum_{k=0}^{3}\frac{\kappa_{rk}}{\varepsilon + \kappa_{rk}}(\boldsymbol{S}_0, \bar{\rho}_{rk}\boldsymbol{S}_0)$$

$$= \sum_{\substack{r=1\\ \mathbf{D}_r\neq 0}}^{M}\sum_{k=0}^{3}(\boldsymbol{S}_0, \bar{\rho}_{rk}\boldsymbol{S}_0) = \sum_{\substack{r=1\\ \mathbf{D}_r\neq 0}}^{M}(\boldsymbol{S}_0, I_r\boldsymbol{S}_0)$$

Thus, provided that μ_r is finite, this is the same low-pressure limit as we proved for the strong-collision case previously (18).

(iii) $$\gamma_0^{\infty} = \lim_{\mu_r\to\infty}\gamma_0 = \mu d\sum_{\substack{r=1\\ \mathbf{D}_r\neq 0}}^{M}\frac{\beta_{r1}}{\mu - \gamma_0^{\infty} + d\beta_{r1}/\beta_r}$$

We have the following limits:

$$\lim_{\substack{\mu_r\to\infty\\ \mathbf{D}_r\neq 0}}\kappa_{r0};\ \|\bar{\rho}_{r0}\boldsymbol{S}_0\|^2;\ \|\bar{\rho}_{r1}\boldsymbol{S}_0\|^2;\ \kappa_{r1} = \frac{d\beta_{r1}}{\beta_r};\ \beta_r;\ 0;\ \infty \text{ respectively.}$$

Thus, since $\gamma_0 < \mu$, the result follows from [7], [10], and [11]. With the appropriate transcription of symbols, viz. $d_k \equiv d\beta_{k1}/\beta_k$ and $\bar{n}^k \equiv \beta_k$, this is the same expression as the standard strong-collision result, i.e. eq. [11] of ref. 18, or the analogous eq. [20] of ref. 6.

(iv) $$\lim_{\mu_r\to 0}\gamma_0 = \frac{\mu + d}{2} - \left[\left(\frac{\mu + d}{2}\right)^2 - \mu d\sum_{\substack{r=1\\ \mathbf{D}r\neq 0}}^{M}\beta_{r1}\right]^{1/2}$$

Since

$$\lim_{\substack{\mu_r\to 0\\ \mathbf{D}_r\neq 0}}\kappa_{r0};\ \kappa_{r1};\ \|\bar{\rho}_{r1}\boldsymbol{S}_0\|^2 = 0;\ d;\ \beta_{r1} \text{ respectively,}$$

we have that

$$\lim_{\mu_r\to 0}\|J(x)\boldsymbol{S}_0\|^2 = \frac{d}{1 + (\mu - x)^{-1}d\sum_{\substack{r=1\\ \mathbf{D}_r\neq 0}}^{M}\beta_{r1}} = \|J_0(x)\boldsymbol{S}_0\|^2$$

Now solving

$$x_0 = \frac{\|J_0(x_0)\boldsymbol{S}_0\|^2}{1 - (\mu - x_0)^{-1}\|J_0(x_0)\boldsymbol{S}_0\|^2}$$

and observing that $x_0 = \lim_{\mu_r\to 0}\gamma_0$ yields the desired result.

Note that this final limiting form is the *exact* solution for the case of a unimolecular reaction when $k(E)$ is constant — the particular case for which we have already deduced that an *approximate* solution, γ_{ap}, is strict Lindemann in form (9). Thus, all four limits behave in a perfectly acceptable fashion: when μ_r is finite, the limits for $\mu \to 0, \infty$ are the usual ones we have already established (18); when $\mu_r = 0$, the fall-off is very close to being strict Lindemann, and when $\mu_r = \infty$, we recover the standard strong-collision result.

Practical Calculations

The exact solution for the rate constant given either in [9] or in [10] and [11] is in an iterative form: a trial value of $x = x_0 < \mu$ is substituted in each denominator to give the first approximation to γ_0, viz. $\phi(x)$ or $\chi(x)$, and this new value is resubstituted until convergence is achieved; with this initial choice, the $\phi(x)$ series will converge from below, whereas the $\chi(x)$ series will converge in an alternating fashion (9, 18). However, for thermal reactions at ordinary temperatures where $\mu \gg \gamma_0$, an extremely good approximation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

to γ_0 (which we have previously called γ_{ap}) is obtained without iteration simply by substituting $x = 0$ in [10] and [11]. Thus, we can perform a direct calculation for the rate constant at all pressures by evaluating

$$[12] \quad \gamma_{ap} = \frac{\|J(0)\boldsymbol{S}_0\|^2}{1 - \mu^{-1}\|J(0)\boldsymbol{S}_0\|^2}$$

where

$$[13] \quad \|J(0)\boldsymbol{S}_0\|^2 = \sum_{\substack{r=1 \\ D_r \neq 0}}^{M} \sum_{j=0}^{1} \frac{\left[\beta_{r0} + \beta_{r1}\left(1 + \frac{d}{\mu_r - \kappa_{rj}}\right)^{-1}\right]^2}{\left[\beta_{r0} + \beta_{r1}\left(1 + \frac{d}{\mu_r - \kappa_{rj}}\right)^{-2}\right]} \frac{\kappa_{rj}}{1 + \mu^{-1}\kappa_{rj}}$$

In [13], κ_{rj} ($j = 0, 1$) are the simple eigenvalues for grain r, given by eq. [6], d is the rate constant for decay of the reactive vibrational states to products, i.e. eq. [4], and β_r, β_{r0}, and β_{r1} are respectively the equilibrium populations of grain r, of the passive states in grain r, and of the reactive states in grain r. In both equations, μ is the rate constant for collisional relaxation at the pressure in question, in units of s^{-1}, and likewise, in [13], μ_r is the randomisation rate constant in grain r in the same units.

There are neater and more elegant ways of writing [13], by using [11] and [7], whereas we have used [11] and [5]. This is because the numerical calculation is susceptible to underflow and overflow difficulties at the extremes of μ, μ_r, and as written in [13], the expressions can easily be rearranged to avoid these problems should they arise (c.f. also Appendix 4 of ref. 7 where a similar procedure is used).

The behaviour of these rate constants is shown in Figs. 1 and 2 for a model simulating the thermal dissociation of carbon dioxide; the details of the model are not important.[4] For simplicity, μ_r was taken to be the same for all grains, although this is not a necessary restriction. In Fig. 1, μ_r is taken to be constant (i.e. a first-order randomisation process), and from top to bottom, the values of μ_r are ∞, 10^{11}, 10^{10}, ... 10^5, 10^4, 0 s^{-1} respectively; with $\mu_r = 10^{12}$ s^{-1}, the calculated fall-off curve is virtually coincident with the strong-collision ($\mu_r = \infty$) curve. In Fig. 2, μ_r is taken to be $\mu_2 p$ (i.e. second-order randomisation) and from top to bottom, the values of μ_2 are ∞, 10^8, 10^7, ... 10^5, 10^4, 0 $Torr^{-1}$ s^{-1} respectively.

The behaviour shown in Fig. 2 is very similar in form to that found by using the separable model

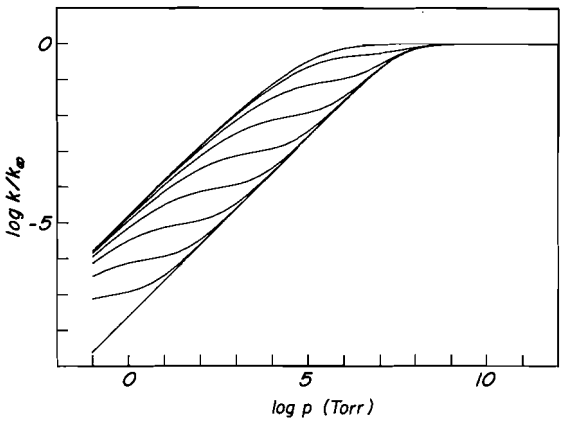

FIG. 1. Fall-off curves for the thermal dissociation of carbon dioxide, model calculation, at 4000 K, considering only first-order randomisation. In descending order, $\mu_1 = \infty$, 10^{11}, 10^{10}, 10^9, 10^8, 10^7, 10^6, 10^5, 10^4, 0 s^{-1} respectively.

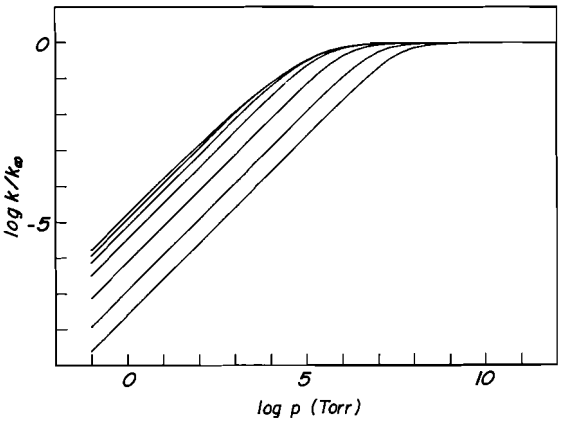

FIG. 2. Fall-off curves for the thermal dissociation of carbon dioxide, model calculation, at 4000 K, considering only second-order randomisation. In descending order, $\mu_2 = \infty$, 10^8, 10^7, 10^6, 10^5, 10^4, 0 $Torr^{-1}$ s^{-1} respectively.

previously (28). However, in the first-order randomisation case (Fig. 1) the high-pressure limits are all the same, unlike the behaviour found for the separable model. This is because the two models are

[4]The energy-level spectrum of the model CO_2 comprises 2.0401×10^{11} states spanning the first 200 kcal; no reactive states occur below 120 kcals. Above threshold, the grains are each taken to be 1 kcal wide, and reactive states each having the value $d = 10^{11}$ s^{-1} (c.f. ref. 30) are distributed in increasing numbers according to the relation $[(E - E_{threshold})/E]^s$, i.e. in RRK form with $s = 4$. The collisional relaxation rate constant μ is taken to be 2.5×10^3 $Torr^{-1}$ s^{-1} and $T = 4000$ K.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

not quite equivalent in the high-pressure limits: the present model admits a relaxation process within each grain with relaxation rate constant μ, which is absent from the separable model;[5] in this respect, the present behaviour is consistent with earlier calculations showing false high-pressure limits (19–25).

Because of this difference between the two models, we have repeated the calculations for the isomerisations of CH_3NC and CD_3NC reported in the earlier paper (28), by using eqs. [12] and [13]. The new rate constants agree with the old ones to better than 4 decimal places over the whole range of pressures, so that our earlier conclusions remain unchanged. This was to be expected because our present analysis shows that the separable method will give the correct solution when $\mu_r \to \infty$, and the intuitive reasoning which led to the separable model depended on the fact that $\mu_r \gg \mu$.

Discussion

We have presented here a complete formulation and solution of the thermal unimolecular reaction problem including explicit consideration of the internal energy randomisation processes. This formulation rests upon our reinterpretation (30) of the Polanyi and Wigner concept (29) — that in the conventional strong-collision case, the $k(E)$ function is simply the fraction of the states of energy E having more than the critical energy in a chosen oscillator divided by half the vibrational period of that oscillator. There still remain, however, some points to be solved before practically useful correlations can be made between $k(E)$ functions and molecular vibrational properties; the majority of these are evident from our earlier discussion (30). Nevertheless, the use of the Polanyi–Wigner concept provides us with the opportunity to describe unimolecular reactions in purely molecular dynamic terms, and therefore seems preferable in the long run to existing procedures (3, 4).

We do not specify for the time being the precise mechanisms by which the internal energy randomisation processes occur but, based on our previous discussion (28), we accept that both first-order and second-order processes may be important. Nor have we yet specified the limits of the range of states which may be coupled by these processes: we have chosen so far to use a grain as the domain, and clearly the final result may be subject to errors in the same way as any numerical integration depends upon the step size; other choices are equally possible — for example the domains could be restricted not only by energy, but by vibrational symmetry type and/or rotational angular momentum as well.[6] Our equations will admit any kind of definition of the domain of the randomising processes and will also allow each individual domain to have its own randomisation rate constant μ_r.

We then argue that if the value of μ_r for any grain r is too small, the rate of decay from that grain will be limited by the randomisation rate, and the $k(E)$ will have a fallen-off value rather than its limiting value according to the Polanyi–Wigner concept. And it is at this juncture that the Polanyi–Wigner concept is crucial, for in its simplest form there is only one type of vibration leading to reaction, whence all the decay rate constants d are the same: this assumption simplifies the eigenvalue spectrum enormously for the grain r, and allows a completely analytic solution for γ_{ap}. The solution remains tractable, however, as we show in the Appendix, if any number of different decay constants occurs in **D**.

We have argued in the opening paragraphs that hitherto, there has been an insufficient distinction between inefficient collisions and weak collisions, and that experiments purporting to measure the effects of weak collisions cannot distinguish between weak collisions and inefficient collisions. We have already mentioned incubation times and "low-pressure turn-up", and should also include in this context the inefficiency of gas–gas collisions relative to gas–wall collisions found in many thermal reactions (33–37); likewise, neither measurement of relative collision efficiencies in the fall-off region (38–40) nor of absolute collision efficiencies, viz. $\bar{\lambda} = \mu/Z[M]$ (7), provides us with any discriminating power. Probably the only symptom of weak-collision effects that can be observed in thermal systems

[5]The original separable model is readily made consistent with the present treatment by redefining $\mu_r = \mu + \mu_1 + \mu_2 p$ instead of simply $\mu_1 + \mu_2 p$ as before. Re-examination of the series of model calculations carried out in ref. 28 reveals only one small difference with the new results, when μ_r is small and p is very high, viz. $\mu_1 = 10^{10}\ s^{-1}$ for $p > 10^3$ Torr.

[6]It may sometimes be possible to deduce information concerning the domains within which randomisation occurs by analysis of energy distribution among the products of a reaction. It is clear that if $\mu_r = \infty$, the internal degrees of freedom of the reaction products will be fully equilibrated. The corollary is not true, however, because the residual interaction between two product fragments as they recede may be sufficient to cause complete randomisation among the product states even though they were not initially formed in that way. It is true, however, that the observation of non-statistical distributions of internal energy in the product states presents clear evidence of the failure to achieve complete randomisation in the reactant molecule before fragmentation occurred. There is an analogous connection between the relaxation rate μ and the translational energy distribution of the fragments: thus, a non-Boltzmann translational distribution shows that μ is insufficiently large for the reaction to be at its high pressure limit, but again, the corollary is not necessarily true.

lies in the observation of a fall-off curve which is more severe than would be predicted by using strong-collision formulae. There are two possibilities here. One is the case of multi-channel reactions where the fall-off curves for upper channels are more severe than that for the dominant channel (41). However, there are too few reliably documented examples of this behaviour so far (41–43) and it is not yet clear whether such behaviour is adequately described by the formulae given in the Appendix of this paper.[7] Better documented is the almost Lindemann shape of the fall-off in many reactions of very simple molecules (45).[8] It is clear from the results shown in Figs. 1 and 2 that any shape of fall-off curve from the standard strong-collision one to strict Lindemann can be reproduced by appropriate choices for the randomisation rates μ_r; in fact, we can get a monotonic change from strict Lindemann to strong-collision behaviour simply by increasing μ_2 from zero to infinity in the absence of μ_1. Useful values for the two randomisation rate constants can only be deduced by detailed comparison of theoretical and experimental fall-off curves, as we showed before (28). The present calculation is only schematic, but comparison with the experimental fall-off curves for CO_2 (46) suggests that in this case, $\mu_1 < 10^9\ s^{-1}$ and $\mu_2 < 10^8\ Torr^{-1}\ s^{-1}$, *very* approximately.

[7]An alternative so-called weak-collision treatment of this problem (44) falls into the category where the distinction between weak collisions and inefficient collisions is unclear: this study shows that the shape of the fall-off curve for the upper channel is quite sensitive to the form of the transition rate matrix. However, our conclusions in footnote 2 about the lack of connection between the steady-state distribution and the form of the relaxation matrix probably remain valid, whence randomisation failure is the more likely determinant of the shapes of the fall-off curves in such systems.

[8]Our original conjecture that fall-off curves for small molecules become more Lindemann with increasing temperature (45) because of a bottleneck in the activation process, together with our subsequent analysis (9), could perhaps provide a false clue in the light of the present discussion: we do not need bottleneck effects of this type to cause strict Lindemann behaviour. There are *small* differences in the shapes of Figs. 1 and 2 with varying temperature, but they should be examined using more realistic models before any conclusions are drawn concerning temperature effects.

Appendix: Reaction by Two or More Pathways

Suppose that the molecule breaks up in two distinct ways by accumulating energy in either one or other of two types of vibration with decay constants d^1 and d^2 respectively. Suppose also that within any one grain, provided that the energy is above *both* thresholds, both manifolds of decaying states are coupled to the remaining unreactive states with the same randomisation rate constant μ_r. As before (18), we have

$$[A1] \quad \gamma_0 = \lim_{t\to\infty} \frac{1}{N(t)} \frac{dN(t)}{dt}$$

where

$$[A2] \quad N(t) = \sum_{i=0}^{n-1} \eta_i(t) \sim \exp(-\gamma_0 t)(\boldsymbol{S}_0, \boldsymbol{\Psi}_0)(\boldsymbol{\Psi}_0, \mathbf{E}^{-1/2}\boldsymbol{\eta}(0))$$

and

$$[A3] \quad \frac{dN(t)}{dt} = -\sum_{i=0}^{n-1} d_i\eta_i(t) \sim \exp(-\gamma_0 t)(\boldsymbol{S}_0, \mathbf{D}\boldsymbol{\Psi}_0)(\boldsymbol{\Psi}_0, \mathbf{E}^{-1/2}\boldsymbol{\eta}(0))$$

In these equations, $N(t)$ is the total population of molecules remaining at time t, $\eta_i(t)$ is the population remaining in the ith state, $\boldsymbol{\eta}(0)$ is the initial distribution at time $t = 0$, and $\mathbf{E}^{-1/2}$ arises from the original symmetrising transformation (18, 32). Thus

$$[A4] \quad \gamma_0 = (\boldsymbol{S}_0, \mathbf{D}\boldsymbol{\Psi}_0)/(\boldsymbol{S}_0, \boldsymbol{\Psi}_0) = (\boldsymbol{S}_0, [\mathbf{V} + \mathbf{D}]\boldsymbol{\Psi}_0)/(\boldsymbol{S}_0, \boldsymbol{\Psi}_0)$$

as expected. Now

$$\mathbf{D} = \sum_{r=1}^{M} \mathbf{D}_r$$

where $\mathbf{D}_r$ can have two non-zero elements d^1, d^2. The required decomposition is $\gamma_0 = \gamma_0{}^1 + \gamma_0{}^2$ where

$$[A5] \quad \gamma_0{}^{1,2} = \lim_{t\to\infty} \sum_{i=0}^{n-1} d_i{}^{1,2}\eta_i(t) \Big/ \sum_{i=0}^{n-1} \eta_i(t) = (\boldsymbol{S}_0, \mathbf{D}^{1,2}\boldsymbol{\Psi}_0)/(\boldsymbol{S}_0, \boldsymbol{\Psi}_0)$$

$$= \mu(\boldsymbol{S}_0, \mathbf{D}^{1,2}[\mu - \gamma_0 + \mathbf{V} + \mathbf{D}]^{-1}\boldsymbol{S}_0)$$

and

$$\mathbf{D}^{1,2} = \sum_{r=1}^{M} \mathbf{D}_r{}^{1,2}$$

with $\mathbf{D}_r{}^{1,2}$ being a diagonal matrix with only one non-zero element $d^{1,2}$ exactly where it appears in $\mathbf{D}$ while the other elements are zero.

$\mathbf{D}$ now has three distinct elements along the diagonal: 0, d^1, d^2 and hence

$$(\mathbf{V}_r + \mathbf{D}_r) = (\mathbf{V}_r + \mathbf{D}_r{}^1 + \mathbf{D}_r{}^2)$$

has *six* distinct eigenvalues:

$$\kappa_{r0} < \mu_r = \kappa_{r3} < \kappa_{r1} < \mu_r + d^1 = \kappa_{r4} < \kappa_{r2} < \kappa_{r5} = \mu_r + d^2$$

assuming that $d^1 < d^2$. Since $\bar{\rho}_{rj}\boldsymbol{S}_0 = 0$ for $j = 3, 4, 5$, we have

$$[A6] \quad \gamma_0{}^{1,2} = \mu \sum_{\substack{r=1 \\ \mathbf{D}_r \neq 0}}^{M} \sum_{j=0}^{2} \frac{1}{\mu - \gamma_0 + \kappa_{rj}} (\mathbf{D}^{1,2}\boldsymbol{S}_0, \bar{\rho}_{rj}\boldsymbol{S}_0) = \phi^{1,2}(\gamma_0)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

where $\kappa_{rj}, j = 0, 1, 2$ are the solutions of eq. [5] which is now a polynomial of degree three, and

$$[A7] \quad (\mathbf{D}^{1,2}\boldsymbol{S}_0, \bar{\rho}_{rj}\boldsymbol{S}_0) = \frac{(\mathbf{D}^{1,2}\boldsymbol{S}_0, \boldsymbol{I}_r\boldsymbol{S}_0)^2}{\mu_r{}^2(\boldsymbol{S}_0, [\mu_r - \kappa_{rj} + \mathbf{D}_r]^{-2}\boldsymbol{I}_r\boldsymbol{S}_0)}$$

An alternative expression for $\gamma_0{}^{1,2}$ may be obtained by realising that

$$\boldsymbol{\Psi}_0 = \frac{[1 + (\mu - \gamma_0)^{-1}(\mathbf{V} + \mathbf{D})]^{-1}\boldsymbol{S}_0}{1 - (\mu - \gamma_0)^{-1}\|J(\gamma_0)\boldsymbol{S}_0\|^2}$$

Hence

$$[A8] \quad \gamma_0{}^{1,2} = (\mathbf{D}^{1,2}\boldsymbol{S}_0, [1 + (\mu - \gamma_0)^{-1}(\mathbf{V} + \mathbf{D})]^{-1}\boldsymbol{S}_0)/(\boldsymbol{S}_0, [1 + (\mu - \gamma_0)^{-1}(\mathbf{V} + \mathbf{D})]^{-1}\boldsymbol{S}_0)$$

$$= \sum_{\substack{r=1 \\ \mathbf{D}_r \neq 0}}^{M} \sum_{j=0}^{2} \frac{(\mathbf{D}^{1,2}\boldsymbol{S}_0, \bar{\rho}_{rj}\boldsymbol{S}_0)}{1 + (\mu - \gamma_0)^{-1}\kappa_{rj}} \Bigg/ \sum_{\substack{r=1 \\ \mathbf{D}_r \neq 0}}^{M} \sum_{j=0}^{2} \frac{(\boldsymbol{S}_0, \bar{\rho}_{rj}\boldsymbol{S}_0)}{1 + (\mu - \gamma_0)^{-1}\kappa_{rj}} = \chi^{1,2}(\gamma_0)$$

Extension to more pathways is now straightforward, although it will become necessary to solve eq. [5] numerically for the κ_{rj} if there are too many distinct values of d in $\mathbf{D}_r$.

Received April 6, 1981

D. W. DAVIDSON, S. R. GOUGH, J. A. RIPMEESTER, and HARUO NAKAYAMA. Can. J. Chem. **59**, 2587 (1981).

From the effect of added methanol on the decomposition temperatures of the clathrate hydrates of ethylene oxide and tetrahydrofuran, it was recently reported that methanol can be readily enclathrated in hydrates of both structure I and II. Dielectric and nmr studies of these two hydrates prepared in the presence of methanol do not support this conclusion. It is shown thermodynamically that the original measurements may be interpreted without the need for incorporation of methanol in the hydrates formed.

D. W. DAVIDSON, S. R. GOUGH, J. A. RIPMEESTER et HARUO NAKAYAMA. Can. J. Chem. **59**, 2587 (1981).

A partir de l'effet du méthanol sur les températures de décomposition des hydrates de clathrate d'oxyde d'éthylène, et de tétrahydrofuranne, on a rapporté récemment que le méthanol peut être facilement inséré dans les hydrates de structures I et II. Les études diélectriques et de rmn de ces deux hydrates préparés en présence de méthanol ne confirment pas cette conclusion. On a montré thermodynamiquement que les mesures initiales peuvent être interprètées sans incorporer le méthanol dans les hydrates obtenus.

[Traduit par le journal]

Nakayama and Hashimoto recently reported (1) that methanol has the ability to form both structure I and structure II gas hydrates. Since large quantities of MeOH are used each year to inhibit gas hydrate formation in natural gas distribution systems, this conclusion warrants careful examination.

The evidence for incorporation of MeOH in clathrate hydrates is based on the melting-point behaviour of the hydrates formed in the ethylene oxide (EO) – MeOH – H_2O and tetrahydrofuran (THF)–MeOH–H_2O systems (1). Hydrate decomposition temperatures were plotted against the total mole fraction $x = x_2 + x_3$ of the non-aqueous components, where x_2 is the EO or THF mole fraction and x_3 that of MeOH, for a constant mole ratio $C = x_3/x_2$ (Fig. 1 *b* and *c*). The value of x at the temperature maximum appeared to be independent of C and to correspond to $x_{max} = 1/(n + 1)$, where n is the number of moles of water per mole of EO or THF in the hydrate in the absence of MeOH.[2] Similar (but less unexpected) behaviour was found (1) when known hydrate forming species (1,3-dioxolane, acetone) were added to the THF–H_2O system (e.g., Fig. 1*a*).

We report here the results of nmr and dielectric studies of EO and THF hydrates prepared in the presence of MeOH. These show no sign of enclathration of MeOH. It is demonstrated by simple thermodynamic arguments that lack of dependence of x_{max} on the value of C does not require incorporation of the third component in the hydrate and is in fact predicted for ideal liquid-phase behaviour.

Experimental Methods

Proton nmr spectra were obtained with a Bruker CXP-180 spectrometer for samples prepared from EO, MeOH, and D_2O. Liquid-phase spectra (recorded without spinning) showed peaks arising from OH, CH_3, and C_2H_4O protons, respectively, in the direction of increasing magnetic field (cf. Fig. 2). Results are reported for a sample containing 0.057 and 0.079 mole fraction of EO and MeOH respectively. To provide information about the water content, sufficient H_2O was added to bring the H content of the water (mainly HDO) and the hydroxyl group of methanol to about 16%, complete exchange being assumed. Peaks due to the OH group in methanol and water were not resolved. The sealed sample was cooled to −20°C, allowed to equilibrate, and spectra were recorded at a number of temperatures until the hydrate decomposition temperature (10°C) was reached. The broad line from ice and solid hydrate was unstructured over this temperature range (cf. ref. 2) and the analysis is based on liquid spectra alone. These were recorded under conditions (a sweep width setting of 10 kHz) for which the solid line was not observed.

Dielectric measurements were made on a sample of composition 0.5THF·0.5MeOH·17H_2O at temperatures to as low as 7 K. Instrumentation was as described elsewhere (3), except for the use of a Hewlett-Packard 4275A meter for capacitance and conductance measurements between 10 kHz and 4 MHz. The particular interest was to define the dielectric absorption arising from the encaged species and to measure the methanol-rich eutectic temperature.

[1]NRCC No. 19453.

[2]Because of the flat tops of the melting point curves, x_{max} is not accurately defined.

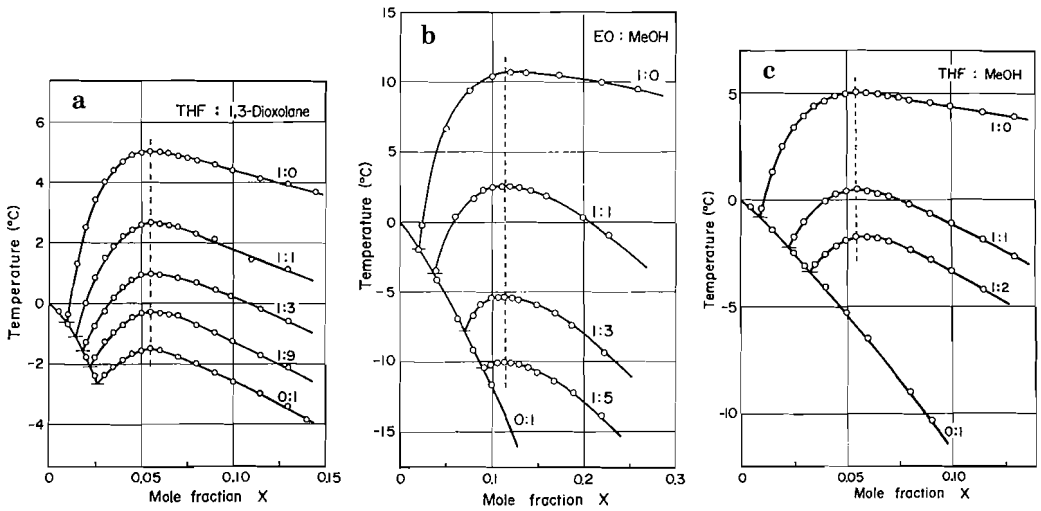

FIG. 1. Dependence of hydrate melting points on composition in (*a*) H_2O–THF–1,3-dioxolane, (*b*) H_2O–EO–MeOH, and (*c*) H_2O–THF–MeOH systems. The curves are drawn for constant mole ratios of the second to third component; x is the combined mole fraction of the non-aqueous components. Reproduced from ref. 1 by permission of the Editor of the Bulletin of the Chemical Society of Japan.

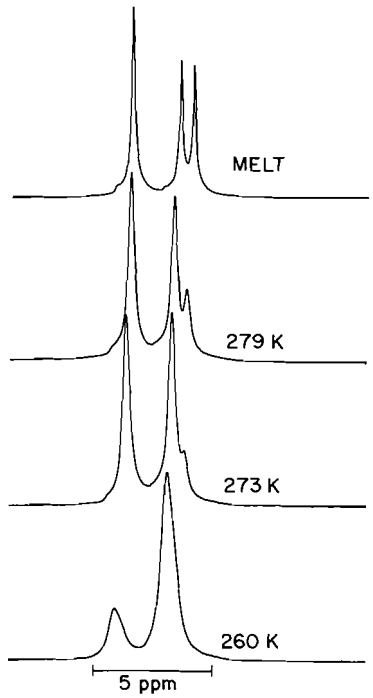

FIG. 2. Liquid-phase proton magnetic resonance spectra of an ethylene oxide – methanol – water sample in which the hydroxyl groups are 84% deuterated.

Results

Proton nmr spectra of the liquid phase in the EO–methanol–water system are shown for a number of temperatures in Fig. 2. The ratios of peak heights were used to estimate the liquid-phase mole ratios plotted in Fig. 3. The water/methanol ratio was obtained by assuming the same OH/OD ratio for methanol as for water.

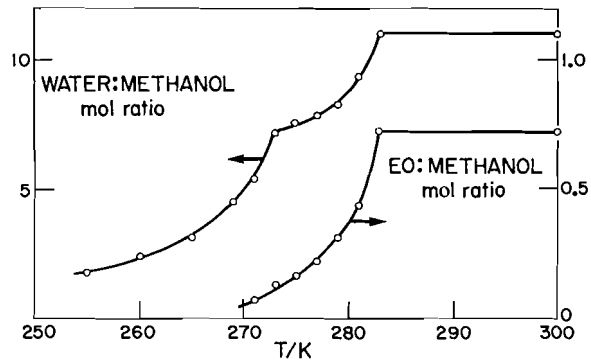

FIG. 3. Mole ratios of water to methanol and ethylene oxide to methanol in the liquid in equilibrium with solid hydrate.

Figure 3 clearly shows that the formation of the structure I hydrate removes both EO and water from the equilibrium liquid phase to a much greater extent than methanol. The hydrate can contain little or no methanol. Water is removed also as ice, the formation of which is marked in Fig. 3 by a rapid fall in liquid water content below 272 K. At 255 K the remaining liquid consists of water and methanol in about 2:1 mole ratio compared to the 11:1 ratio in the unfrozen sample.

The most relevant results of the dielectric studies of the THF–MeOH–H_2O system are contained in Figs. 4 and 5. The dielectric absorption at very low temperatures (Fig. 4) was identical to that shown by THF hydrate itself (3) except for an amplitude

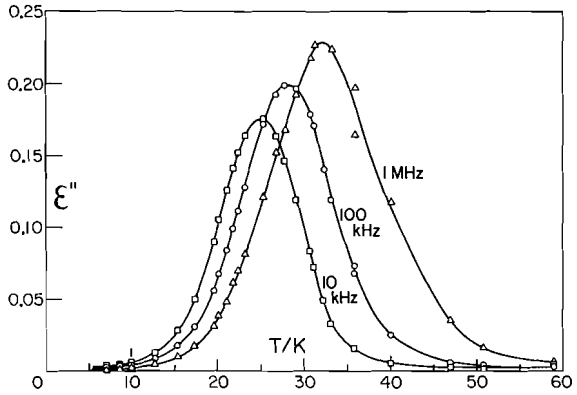

FIG. 4. Dielectric absorption at low temperatures in the 0.5THF·0.5MeOH·17H_2O sample.

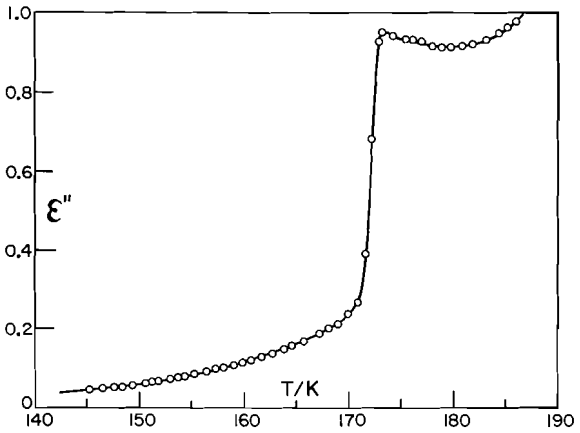

FIG. 5. Temperature dependence of the dielectric loss measured at 4 MHz for the THF–MeOH–H_2O sample.

only about 38% as large. This absorption arises from the reorientation of enclathrated THF molecules, the smaller amplitude reflecting the lower concentration of such molecules within the present sample. No additional absorption of the kind expected for an encaged molecule of the size of methanol was found over the temperature range between 7 and 150 K. The change in dielectric loss measured at 4 MHz as the sample was heated between 145 and 185 K at a rate of 0.44 K/min is shown in Fig. 5. Initial melting occurs sharply at $172\pm\frac{1}{3}$K. This is significantly higher than the eutectic temperature reported for the binary MeOH–H_2O system (156 K, eutectic liquid with ~82 mol% MeOH (4)) and is only a few degrees below the melting point of pure MeOH (175 K). Clearly the liquid present at very low temperatures in the three-component system consists largely of MeOH.

Two dielectric absorption-dispersion regions which occur at relatively high temperatures are ascribed

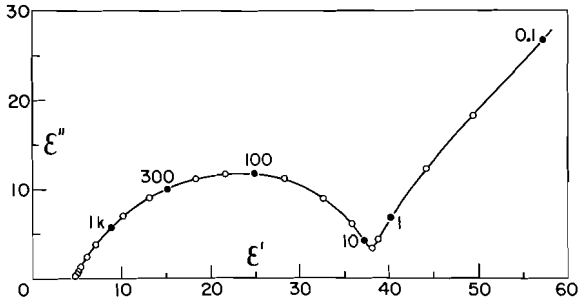

FIG. 6. Cole–Cole plot of the complex permittivity of the THF–MeOH–H_2O sample at 128.6 K. The numbers refer to frequencies in Hz.

to reorientation of the water molecules in THF hydrate and ice, respectively. The former (Fig. 6) is of about one-third the amplitude of that found in "pure" THF hydrate and, as expected from the sample heterogeneity and an increased concentration of "extrinsic" Bjerrum orientational defects (5), is shifted to somewhat higher frequencies. The ice dispersion region which occurs to the high-temperature (low-frequency) side of the hydrate dispersion is poorly defined mainly because of conductivity and space charge effects associated with the distribution of liquid within the sample.

The evidence is thus that no significant amounts of methanol are encaged in either structure I or structure II hydrates. It is possible that small quantities of methanol may participate as impurity in the hydrogen-bonded lattices but no indication of this is provided by the present results.

Discussion

It is possible to account for the effect of methanol on clathrate hydrate melting shown in Fig. 1 *b* and *c* by straightforward thermodynamic analysis without the need for incorporation of methanol in the hydrate.

Under equilibrium conditions, the Gibbs free energy of clathrate hydrate formation by a water-soluble species like EO or THF may be written

$$\Delta G(\mathrm{l} \rightarrow \mathrm{h}) = \mu^0(\mathrm{h}) - \mu_2(\mathrm{l}) - n\mu_1(\mathrm{l}) = 0$$
$$= \Delta H(\mathrm{l} \rightarrow \mathrm{h}) - T\Delta S(\mathrm{l} \rightarrow \mathrm{h})$$

where $\mu^0(\mathrm{h})$ is the chemical potential of the hydrate $\mathrm{M}\cdot n\mathrm{H_2O}$. The chemical potentials of the liquid components are

$$\mu_1(\mathrm{l}) = \mu_1^0(\mathrm{l}) + RT \ln x_1\gamma_1$$
$$\mu_2(\mathrm{l}) = \mu_2^0(\mathrm{l}) + RT \ln x_2\gamma_2$$

where the x's are mole fractions, the γ's are activity coefficients, and the standard states are those of the pure liquids.

The standard thermodynamic functions for hydrate formation from the separate liquids are then

$$\Delta G^0(l_1 + l_2 \rightarrow h) = \mu^0(h) - \mu_2{}^0(l) - n\mu_1{}^0(l)$$
$$= RT \ln x_2\gamma_2 + nRT \ln x_1\gamma_1$$
$$= \Delta H^0(l_1 + l_2 \rightarrow h) - T\Delta S^0(l_1 + l_2 \rightarrow h)$$

Thus,

$$[1] \quad \ln x_2 + n \ln x_1 + \ln \gamma_2 + n \ln \gamma_1 = \frac{\Delta H^0(l_1 + l_2 \rightarrow h)}{RT} - \frac{\Delta S^0(l_1 + l_2 \rightarrow h)}{R}$$

This equation describes the variation of the hydrate melting point with composition $x_2 = (1 - x_1)$ of the binary system in terms of the activity coefficients.

With the assumption of negligible dependence of ΔH^0 and ΔS^0 on temperature, the right-hand-side of eq. [1] is greatest (since ΔH^0 is negative) when T is greatest, that is, at the maximum of the hydrate melting curve. The value of x_2 at this temperature, by differentiation with respect to x_2, is given by

$$[2] \quad \frac{1}{x_2} - \frac{n}{1 - x_2} + \frac{d}{dx_2}(\ln \gamma_2 + n \ln \gamma_1) = 0$$

For the binary system the Gibbs–Duhem relationship

$$x_2 \, d \ln \gamma_2 + (1 - x_2) \, d \ln \gamma_1 = 0$$

ensures that the third term in eq. [2] is zero at the same concentration $x_2 = 1/(n + 1)$ that makes the sum of the first two terms zero. The maximum melting temperature thus corresponds to congruent melting of the hydrate in the binary system, even for a non-ideal solution.

It is now supposed that a third component (e.g., MeOH) is added to the binary system and that this component does not change the nature of the hydrate formed. Equation [1] is still valid, the effect of the third component being to change the activity coefficients and therefore the melting temperatures. It is convenient, as in ref. 1, to consider the case where $x_3 = Cx_2$ and the total solute mole fraction is $x = x_2 + x_3 = (C + 1)x_2$. With constant C, the condition at the maximum hydrate melting temperature is now

$$[3] \quad \frac{1}{x_2} - \frac{(C + 1)n}{1 - (C + 1)x_2} + \frac{d}{dx_2}(\ln \gamma_2 + n \ln \gamma_1) = 0$$

Under conditions (as in ideal solutions) where the derivative term is negligibly small, the maximum melting point occurs at $x_2 = 1/[(C + 1)(n + 1)]$ or $x = 1/(n + 1)$, just as for the binary system. Melting is of course no longer congruent.

The water activity coefficient in aqueous solutions of MeOH is not far from unity (6) and it is perhaps not surprising that the derivative term in eq. [3] varies little with C. The effect of large departures from ideality may be clearly seen, however, when the third component is diethylene glycol dimethyl ether. Nakayama and Hashimoto (1) show that in this case the maximum temperature of melting of THF hydrate moves increasingly to lower values of x as C increases, probably because of an increasingly large negative value of $d(n \ln \gamma_1)/dx_2$.

A maximum melting point, of course, may also occur at a value of x close to $1/(n + 1)$ when the third component forms a hydrate isostructural with that formed by the second component. The thermodynamics then become somewhat more complex. The mixed hydrate formed will not, in general, contain guest molecules in the same proportion as the solution in equilibrium with the hydrate because of the difference in the values of the Langmuir constant which relates cage occupancy to the activity of the corresponding species in solution (7). A larger value of the Langmuir constant for THF than for 1,3-dioxolane probably accounts for the relatively high values of the maximum melting points observed for the mixed hydrate (Fig. 1*a*) compared with those calculated from simple linearity between the melting points of the individual hydrates.

We conclude that hydrate melting point measurements alone are not sufficient to establish whether or not a third component can be enclathrated in a gas hydrate.

ROBIN A. COX, ÜLO L. HALDNA, K. LORALEE IDLER, and KEITH YATES. Can. J. Chem. **59**, 2591 (1981).

Principal factor analysis has been applied to Raman spectra of 26 sulfuric acid/water mixtures covering the 0–100% H_2SO_4 concentration range. The analysis greatly facilitates the identification of peaks due to different species. The results show that SO_4^{2-} ions and "free" HSO_4^- ions do not co-exist with undissociated H_2SO_4 molecules in solution and that two water molecules rather than one are required for the first ionization of H_2SO_4. A species with the composition $H_2SO_4 \cdot 2H_2O$, assigned a hydrated ion pair structure, reaches maximum concentration at the same medium composition at which SO_4^{2-}, free HSO_4^-, and H_2SO_4 are at concentration minima, about 75% w/w. The only species apparent in the more concentrated solutions are the ion pair and undissociated H_2SO_4, which could be taken to mean that H_2SO_4 is a weaker acid than H_3O^+, but a stronger one than $H_3O^+ \cdot H_2O$ (or $H_5O_2^+$, if this entity has a real existence). Separate peaks due to the postulated $H_3O^+ \cdot H_2SO_4$ (or $H_5SO_5^+$) were not observed.

ROBIN A. COX, ÜLO L. HALDNA, K. LORALEE IDLER et KEITH YATES. Can. J. Chem. **59**, 2591 (1981).

On a appliqué l'analyse du facteur principal aux spectres Raman de 26 mélanges d'acide sulfurique/eau ayant des concentrations en acide sulfurique allant de 0 à 100%. L'analyse facilite grandement l'identification des pics des différentes espèces. Les résultats indiquent que les ions SO_4^{2-} et les ions "libres" HSO_4^- ne coexistent pas avec les molécules de H_2SO_4 non dissociées en solution et que deux molécules d'eau plutôt qu'une sont nécessaires lors de la première ionisation du H_2SO_4. Une espèce ayant la composition $H_2SO_4 \cdot 2H_2O$ à laquelle on attribue une structure de paire d'ions, atteint la concentration maximum pour la même composition moyenne où SO_4^{2-}, HSO_4^- libre et H_2SO_4 sont à une concentration minimum, environ 75% w/w. Dans des solutions plus concentrées les seules espèces apparentes sont la paire d'ions et le H_2SO_4 non dissocié, qui peuvent signifier que H_2SO_4 est un acide plus faible que H_3O^+, mais plus fort que $H_3O^+ \cdot H_2O$ (ou $H_5O_2^+$ si cette entité existe réellement). On n'a pas observé de pics séparés provenant du $H_3O^+ \cdot H_2SO_4$ (ou $H_5SO_5^+$) proposé.

Introduction

Factor analysis (1, 2) is an impartial mathematical technique, able to isolate individual variables from experimental data which are functions of two or more different variables. It is becoming quite widely used in chemistry, for instance in the study of solvent effects on proton chemical shifts (3), on thermodynamic data (4), and on equilibrium and rate constants (5), and in the analysis of ir (6, 7), Raman (8), and uv–visible (9) spectra. Simonds (10) has given a simple formulation for the first stage of factor analysis, principal factor analysis (PFA) (1); Simonds' method has been used to isolate medium effects from protonation effects in uv–visible spectra at different acidities by Edward and Wong (11) and others (12). In this paper PFA is used in the analysis of Raman spectra obtained at different acidities.

There have been several studies of the Raman spectra of aqueous sulfuric acid solutions (13–18). Of these, only the early study by Young's group (13) and a Russian study (17) cover the entire concentration range; most of the effort has involved the dilute acid region (14–16). However, the detailed interpretations of peak position, even the presence (14) or absence (15, 16) of certain peaks, sometimes differ considerably, as do the peak intensities or areas, from which species concentrations can be obtained. Accurate knowledge of the species present, and their concentrations, is necessary to the study of the kinetics and mechanisms of organic reactions in aqueous sulfuric acid media (19). For instance, undissociated sulfuric acid molecules are kinetically involved in the rearrangement of azoxybenzenes to hydroxyazobenzenes (20); bisulfate ions are involved in some azoxynaphthalene rearrangements (21) and in the enolization of acetone (22). Because of this, and as part of our continuing interest in this medium (19, 23, 24), we have applied PFA to Raman spectra obtained over the entire 0–100% H_2SO_4 concentration range.

Experimental

Sulfuric acid solutions were prepared and analyzed as before (24). Spectra were recorded at 25 ± 1°C on a Spex model 1401 Raman spectrophotometer, using the 488 nm exciting line from a Spectra Physics model 164 argon ion laser, at a slit width of 5 cm^{-1}. The *x*/*y* coordinates of 50–100 data points, taken from each spectral trace at about every 1 cm interval and including all peak maxima, were transferred to computer cards using a

digitalizer. Baseline points were taken from "empty" spectral regions, and baseline values for each data point, obtained from these by polynomial interpolation (25*a*), were subtracted; the area under each spectrum was then computed (25*b*), for normalization purposes (6). PFA requires intensity data at the same frequency on each spectrum; 96 frequencies were chosen from the measured x-coordinates by an averaging process, and intensity values, normalized to equal area, were computed at these points on each spectrum by polynomial interpolation (25*a*). The resulting array of 96 points for each of 26 acid solutions was treated using a computer program incorporating Simonds' PFA algorithm (10). The average row and vectors obtained were curve-fitted as a sum of Voigt peaks using the approximation to the Voigt function given by Kielkopf (26), in combination with a curve-fitting routine adapted from Bevington (25*c*). The fourth-order polynomial curves in Fig. 2 were obtained using a standard multiple linear regression program (25*d*).

Results

The Raman spectra were of 26 sulfuric acid solutions, ranging in mole fraction sulfuric acid between 0.0087 (4.53% w/w) and 0.9723 (99.48%). Before analysis the spectra were corrected, as far as possible, for baseline variations, and the effects of changing acid concentration and changing signal amplification were removed by normalizing them all to the same total area (6). Intensity data, obtained at 96 reciprocal wavelength values from each of the 26 spectra, were then subjected to PFA according to Simonds (10). In this formulation the intensities (I) are first averaged, and the eigenvectors and coefficients result from analyzing the differences between each spectrum and the average; this is covariance about the mean (1, 27), eq. [1].

$$[1] \quad I(\nu) = \bar{I}(\nu) + c_1 v_1(\nu) + c_2 v_2(\nu) + \ldots$$

It was found that the average row ($\bar{I}$) and *two* eigenvectors (v_i) accounted for essentially all of the variation, any remaining being indistinguishable from random error (1). These are given as intensity (arbitrary units) vs. wavenumber graphs in Fig. 1 (experimental points). If the normalization to equal area is omitted, three vectors result; the first appears to concern the changing amplification and total acid concentration, and the second and third strongly resemble those given in Fig. 1. Thus normalizing to equal area is justified. The coefficients (c_i) of the first and second vectors, numbers characteristic of each acid solution, are plotted as a function of mole fraction sulfuric acid in Fig. 2, together with the best fourth-order polynomial curves drawn through them. To reconstitute the observed Raman spectrum at any acid strength, eq. [1] is applied to the curves in Figs. 1 and 2; the results of this strongly resemble the experimental spectra, both ours and those obtained by others (15, 16, 28).

The alternative factor analysis formulation, covariance about the origin (1, 27), in which the average row is omitted from eq. [1], was also tried; three vectors resulted, of which the first was very similar to the average row obtained before, and v_2 and v_3 corresponded to the v_1 and v_2 of Fig. 1. The coefficients of v_1 did not vary with acid concentration, and those of v_2 and v_3 resembled Fig. 2 closely. The residual errors indicated that no advantage was gained by this alternative procedure, and it was not pursued.

Figures 1 and 2 contain all of the information present in the original 26 Raman spectra. Accordingly Fig. 1 must consist of superpositions of individual Raman peaks (some positive and some negative), just as the original spectra do, and should be resolvable into individual peaks on this basis. To do this the Raman peak shape must be specified; opinions on this differ, with Irish and Chen (28) using one Gaussian–Lorentzian product function and Turner (16) another, and Ikawa and Kimura (15) a Voigt function, which is a Gaussian–Lorentzian convolution (29). Following Ikawa and Kimura we have used Kielkopf's approximation to the Voigt profile (26), with the additional assumption that the Gaussian part of the profile comes only from the finite slit width, 5 cm^{-1} in our case, i.e. that each peak has a Gaussian half-width of 3.00 cm^{-1} (29). This means that the Raman peaks can be specified by three parameters rather than four, since the ratio of Lorentzian to Gaussian half-widths (the Voigt parameter) (26, 29) is fixed for each peak. A subroutine to a standard least-squares curve-fitting program (25*c*) was written which obtains optimum values for peak position (ν_{max}), area and Lorentzian half-width, with their errors, these probably being the most useful parameters.[3]

The results of this curve-fitting procedure are given in Table 1. The resolved peaks are illustrated in Fig. 1, and the intensity profiles resulting from the combination of individual peaks are given as the theoretical curves in Fig. 1. As can be seen, agreement with experiment is very good; a slight baseline was still present in the average row, accounted for by a quadratic curve as shown. Column three of Table 1 shows that most of the peaks are almost entirely Lorentzian, being much broader than the 3 cm^{-1} Gaussian half-width. The

[3]Peak area is directly proportional to species concentration (14, 28); Lorentzian half-widths give information on the rates of proton transfer reactions in these systems (14, 15, 30).

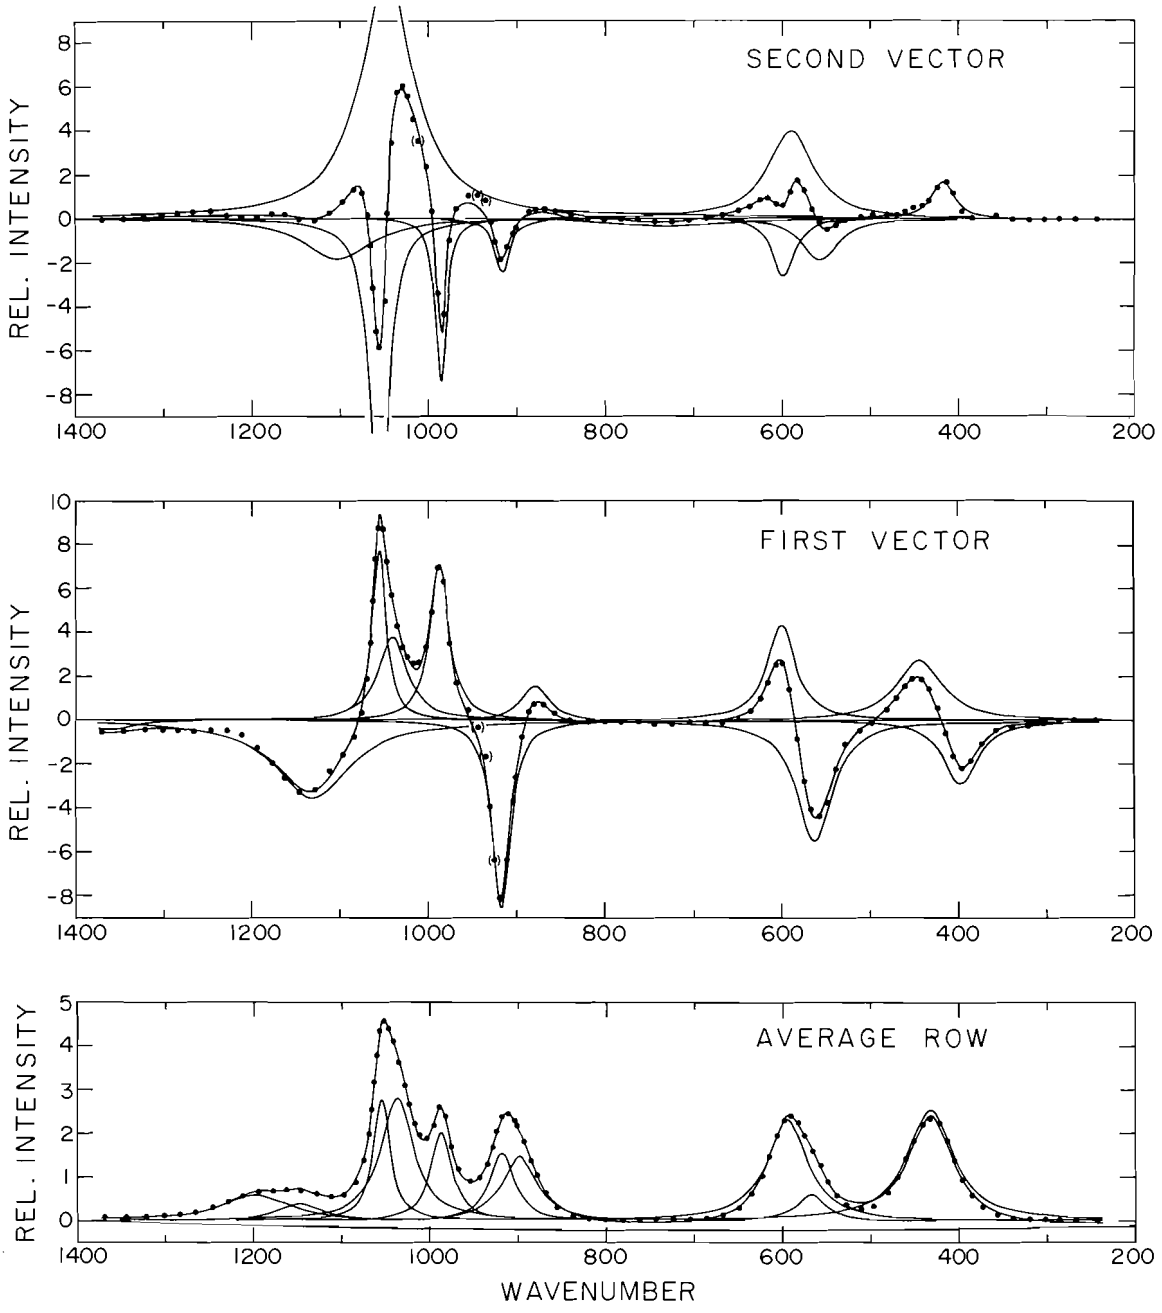

FIG. 1. Raman peaks of the sulfuric acid/water system, as given by principal factor analysis. Points are experimental; addition of the resolved peaks shown results in the theoretical curves drawn through the points.

criterion for the presence of a peak was that the standard deviation in its area should be smaller than the area itself (except in two cases, see below); this led to resolution of the average row into 10 peaks, and ν_1 and ν_2 into 11 each. Undoubtedly more data points would lead to the resolution of more peaks.[4] Overall 17, probably 18, individual peaks are involved; in Table 2 these are assigned by

[4]For instance, by using digital rather than analog recording of the spectra, unfortunately not available on the instrument used in this work.

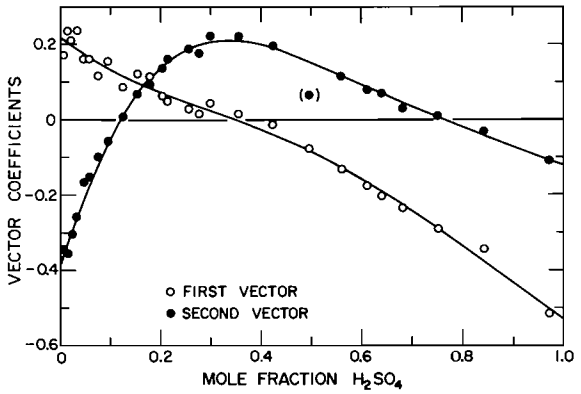

FIG. 2. Coefficients of the first and second vectors as a function of mole fraction H_2SO_4.

species, as far as possible, on the basis of previous assignments (28, 31–33).

The most evident observation from Table 2 is that two different types, or environmental variants, of bisulfate ion are present in these solutions. In every case two peaks rather than one are present, bracketing the expected frequencies (31). The sharp 1055 cm^{-1} peak, and the other peaks to higher wavenumber, are assigned to "free" aqueous HSO_4^- (HSO_4^-aq), and the broad 1040 cm^{-1} and other lower wavenumber peaks to HSO_4^- in the sulfuric acid medium, probably as an ion-pair (28) (HSO_4^-ip). Two bisulfate peaks in the 1025–1055 cm^{-1} region are generally acknowledged (15, 16, 28), but two peaks at the other frequencies have not, to the best of our knowledge, been reported before.

From Table 2 it is apparent that several peaks do not appear in all three of the average row (Av) and both vectors (ν_1 and ν_2). This does not mean that peaks are absent, but only that they could not be resolved out. For instance, an upward displacement at 1200 cm^{-1} in ν_1, and a downward one in ν_2, undoubtedly correspond to the 1200 cm^{-1} peak in Av, but when resolution was attempted the peaks which resulted had errors which were too large for the parameters to be meaningful. Of particular interest in this respect are experimental points at 935.0 and 943.5 cm^{-1} on both ν_1 and ν_2. The computer program used rejects points which fall too far away from the best regression curve,[5] and these two points are rejected as being too far above the curve for both vectors. An additional positive peak is inferred to be present at ~935 cm^{-1} on both ν_1 and ν_2, but, again, it could not be resolved out.

[5]Points which have a 95% or greater probability of not being part of the data set used to construct the regression curve, as determined by a test using t-statistics.

[a]Errors quoted are standard deviations.
[b]Peak areas in arbitrary units. Negative for negative peaks in Fig. 1.
[c]Lorentzian half-width.

Irish and Chen (28) reported a peak in this region, at 948 cm^{-1}, but its presence was not confirmed by Turner (16) or Ikawa and Kimura (15). On the basis of our results we are inclined to support Irish and Chen, but cannot do this rigorously.

Three peaks are clearly present in the 500–650 cm^{-1} region of ν_2. Resolution in terms of two positive and one negative gives better individual errors, but a worse overall error than the resolution as one positive and two negative peaks shown in Fig. 1. The latter is preferred, despite the worse individual errors, because of the better correspondence with peaks on ν_1 and Av which results. A similar situation should apply in the 350–450 cm^{-1} region of ν_2, but resolution better than one peak was not possible. In one case a weak H_2SO_4 peak at 976 cm^{-1} which should be visible (32) is not re-

solved anywhere; it appears to be "lost" as part of the excessively broad 1131 cm^{-1} H_2SO_4 feature on ν_1. This peak would undoubtedly be much sharper if better resolution of the weak peaks in the 1100–1400 cm^{-1} region on ν_1 had been possible.

The peaks in Fig. 1 are all explicable in terms of the species HSO_4^-aq, HSO_4^-ip, SO_4^{2-}, and undissociated H_2SO_4, with the possible addition of SO_4^{2-}ip (28), as indicated in Table 2. This work offers no evidence for the species $H_5SO_5^+$, or $H_3O^+ \cdot H_2SO_4$, postulated for the concentrated acid region (17*c*, 18, 34). If peaks due to HSO_4^-aq and HSO_4^-ip are resolvable, those due to H_2SO_4 and $H_2SO_4 \cdot H_3O^+$ should be resolvable also, but no extra or unexplained peaks are apparent in Fig. 1 or on the spectra themselves. We conclude that this species is absent.[6]

A comparison of Table 2 and Fig. 1 leads to the following general observations: (*a*) peaks attributable to SO_4^{2-} and HSO_4^-aq are positive on ν_1 and negative on ν_2; (*b*) H_2SO_4 peaks are negative on both ν_1 and ν_2; (*c*) peaks due to HSO_4^-ip (and SO_4^{2-}ip) are positive on ν_1 and, especially, on ν_2, the positive aspect of which is practically a Raman spectrum of this species in isolation.[7] The coefficients of the vectors, c_1 and c_2 in Fig. 2, therefore, reveal which species are predominant at a given stoichiometric H_2SO_4 concentration. At a mole fraction of 0.0 (i.e. infinite dilution in water), c_1 has its largest positive value, so the species with positive peaks on ν_1, SO_4^{2-} and HSO_4^-aq, reach their highest concentrations relative to HSO_4^-ip and H_2SO_4. The negative value of c_2 at this point reinforces this. Conversely, at mole fraction 1.0 c_1 is at its most negative, so that H_2SO_4, with negative peaks on ν_1, reaches its highest relative concentration here; c_2 makes a small but, again, reinforcing contribution. These reasonable conclusions lend confidence to the interpretation.

At a mole fraction of 0.35 (74.6% w/w) c_1 passes through zero and c_2 achieves its maximum positive value; SO_4^{2-}, H_2SO_4, and HSO_4^-aq are all at concentration minima and HSO_4^-ip is at a maximum. From this point HSO_4^-ip decreases; H_2SO_4 increases in the acid direction, and HSO_4^-aq and SO_4^{2-} increase in the aqueous direction. The experimental spectra bear this out: at 80.10% H_2SO_4 the HSO_4^-ip peaks at 1040, 900, 590, and 420 cm^{-1} are the only ones present; at 75.05% the 987 cm^{-1} SO_4^{2-} peak is just visible as a shoulder on the 1040 cm^{-1} peak; and at 84.26% the 916 cm^{-1}

[6] Professor G. E. Walrafen informs us that he abandoned the species $H_5SO_5^+$ (18) in 1964 in favour of a strong interaction between HSO_4^- and H_3O^+ where either the anion or the cation or both are hydrated, which is consistent with this work. The experimental Raman work leading to this conclusion was never published.

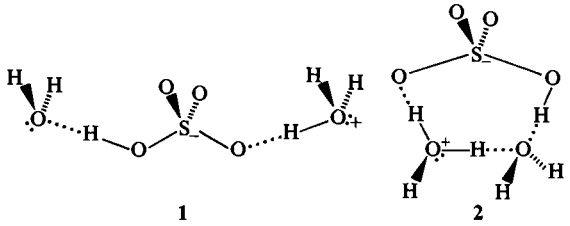
[7] Neglecting the small positive 872 cm^{-1} peak on ν_1 which may, in fact, be part of the postulated 935 cm^{-1} absorption of the SO_4^{2-} ion pair (28).

H_2SO_4 peak is becoming noticeable as an increase in intensity and a shift in ν_{max} of the broad 900 cm^{-1} peak. There is no "overlap" region where all four species are visible. The composition of the system at this point approximates $H_2SO_4 \cdot 2H_2O$, and can be further characterized as $HSO_4^- \cdot H_2O \cdot H_3O^+$ since the Raman spectrum is a bisulfate one. The conclusion seems inescapable that in the 0.3–0.4 mole fraction region practically all of the stoichiometric sulfuric acid is present in this form.

Discussion

Implicit in the above treatment is the assumption that the changing medium composition does not change the Raman peak positions. The raw spectra do show apparent shifts with increasing acidity, but most of this is due to increasing peak overlap, for instance, of the broad 1040 cm^{-1} HSO_4^-ip peak with the adjacent HSO_4^-aq and SO_4^{2-} peaks. If there is a slight residual medium effect, it would have to act in opposite directions on HSO_4^- and SO_4^{2-}, since the apparent medium shifts are to lower and higher frequencies, respectively (15), and this seems unlikely.

Another point to be considered is that the above analysis is only a PCA and not a full factor analysis with target testing (1). The first vector resulting from PCA accounts for the maximum possible data variation, the second, the maximum of the remaining variation, and so on; PCA is a mathematical process, with no chemical input, and the resulting vectors and coefficients may represent linear combinations of chemical parameters rather than the parameters themselves. This point can be decided in some cases by target testing (1). In our case this is difficult, (*a*) because the large 96 × 26 data matrix involved would make target testing costly and time-consuming, and (*b*) because the targets to be tested (presence of SO_4^{2-}, etc.) could only be specified after analysis of the PCA vectors, which presupposes the results of the tests. Accordingly we analyzed the PCA results only. There is one check that can be performed, and that is to see whether any relationship exists between v_1 and v_2, and between c_1 and c_2, by plotting them against one another; if there is a relationship, PCA has not produced fundamental chemical information. It was speedily concluded that v_1 and v_2 are unrelated; see Fig. 1. Plotting c_1 against c_2 produces two adequate straight lines, intersecting practically at right angles, so c_1 and c_2 are also unrelated over the whole composition range. The position of intersection in the latter plot corresponds almost exactly to a mole ratio H_2O:H_2SO_4 of 2:1, as would be anticipated from the appearance of Fig. 2.



1 2

The major result of this work is the observation that only *two* principal factors are sufficient to explain the data. Since three equilibria appear to be involved, two acid dissociations and an ion-pairing process, reactions [2]–[4],

[2] $H_2SO_4 + 2H_2O \rightleftharpoons H_3O^+ \cdot H_2O \cdot HSO_4^-$

[3] $H_3O^+ \cdot H_2O \cdot HSO_4^- + \text{water} \rightleftharpoons H^+ \cdot aq + HSO_4^- \cdot aq$

[4] $HSO_4^- \cdot aq + \text{water} \rightleftharpoons H^+ \cdot aq + SO_4^{2-} \cdot aq$

this means that only two of them can be important at any given acid composition. The most likely possibility is that the first dissociation of H_2SO_4 to HSO_4^- is complete before dissociation of HSO_4^- to SO_4^{2-} begins, i.e. that there is no acid solution which contains all three of H_2SO_4, HSO_4^-, and SO_4^{2-}. Sufficient water to solvate SO_4^{2-} and "free" HSO_4^- is only present on the aqueous side of the 2:1 H_2O:H_2SO_4 composition. Thus sulfuric acid solutions more dilute than this contain SO_4^{2-}aq, HSO_4^-aq, H^+aq, and HSO_4^-ip only, and more concentrated ones HSO_4^-ip and H_2SO_4 only.

The changes in c_1 and c_2 which occur at the 2:1 H_2O:H_2SO_4 mole ratio point (see Fig. 2) lead to the second major conclusion of this work, which is that *two* water molecules rather than one are required for the first ionization of H_2SO_4, reaction [2] above. The HSO_4^-ip product of reaction [2] was assigned the structure **1** by Irish and Chen (28), and a likely alternative to this is the five-membered-ring structure (4 O's, 1 S; hydrogen bonds are collinear) of **2**. It is interesting that the volume contraction upon mixing H_2SO_4 with H_2O reaches a maximum at about the 2:1 composition (35*a*), and that melting-point studies reveal the presence of $H_2SO_4 \cdot 2H_2O$ as well as $H_2SO_4 \cdot H_2O$ and $H_2SO_4 \cdot 4H_2O$ as congruent-melting compounds (36). It seems unlikely that the two types of HSO_4^- observed simply represent different solvation environments for this ion, as Turner believes (16). The HSO_4^-ip peaks are visible in both quite dilute and quite concentrated acids, including the acid region containing no free H_2SO_4, so this cannot be a solvating species.

Without getting into the argument as to whether $H_5O_2^+$ exists in solution (37), or does not (38), if H_3O^+ is a stronger acid than H_2SO_4 in solution, as it

3

is in the gas phase (39), then H_2SO_4 may be able to protonate two water molecules, to $H_5O_2^+$ or $H_3O^+ \cdot H_2O$, but not one. It is a well-known fact that water does not behave as a strong base in sulfuric acid; melting-point depression studies show that fewer than two particles per molecule of added water are formed (40). This would be expected on the basis of reaction [2]. On the other hand, conductivity studies do show water acting as a strong base (41). This is not unreasonable either, since both HSO_4^- and $H_3O^+ \cdot H_2O$ can conduct charge through the hydrogen-bond network via a Grötthus chain mechanism (35*b*); two water molecules produce two highly conductive entities, and ion-pairing to structures like **2** will not affect this type of conductivity (41).

This chain-transfer conduction of $H_3O^+ \cdot H_2O$ through the solvent network is illustrated for the 0.5 mole fraction composition (84.482%) in **3**. The only equilibrium of consequence is reaction [2]; in reality only hydrogen-bond migrations are involved. It is likely that the two water molecules formed when $H_3O^+ \cdot H_2O$ deprotonates would not have sufficient time to diffuse apart, on average, since they are in a highly structured viscous solution; the lifetimes of individual entities in the system are very short, 10^{-11} to 10^{-13} s as determined from the Raman half-widths (14, 15). Obviously many possibilities for proton transfer exist; in **3** the arrows show $H_3O^+ \cdot H_2O$ moving from the $H_3O^+ \cdot H_2O \cdot HSO_4^-$ at the top to the $H_2SO_4 \cdot 2H_2O$ at the bottom, via three intermediate H_2SO_4 molecules and one intermediate $H_3O^+ \cdot H_2O \cdot HSO_4^-$ ion pair. (The hydrogen bonds are omitted for clarity.)

Raman spectroscopy facilitates the calculation of species concentrations, from the Raman peak areas, and offers insight into the kinetics of proton transfer, from the Lorentzian half-widths (30). We will report on any differences between our results and previous studies (14, 15) elsewhere. Preliminary work supports the Raman measurements of sulfate ion concentration given by Irish and Chen (14), and the values for undissociated sulfuric acid molecule concentrations measured by Maiorov and Librovich using attenuated total internal reflection ir spectroscopy (42). However, we cannot support all of the concentration estimates in Librovich and Maiorov's summary paper (43). It seems doubtful that HSO_4^-aq and HSO_4^-ip will differ appreciably in their kinetic behaviour as base and/or nucleophile in organic reactions, so the total HSO_4^- concentration, easily calculated by subtracting $C_{SO_4^{2-}}$ and $C_{H_2SO_4}$ from the stoichiometric sulfuric acid concentration, will probably prove most useful here; however, such reactions as have been observed (21, 22) occur in acidity regions where HSO_4^-ip is dominant. The predominant acid species would appear to be H_2SO_4 and $H_3O^+ \cdot H_2O$ in the concentrated region, and higher proton hydrates in the dilute region.

Heat capacities and volumes of dilute aqueous solutions of 1,3-dioxane and trioxane

GÉRALD PERRON AND JACQUES E. DESNOYERS[1]

Department of Chemistry, Université de Sherbrooke, Sherbrooke, P.Q., Canada J1K 2R1

Received February 9, 1981

GÉRALD PERRON and JACQUES E. DESNOYERS. Can. J. Chem. **59**, 2599 (1981).

The densities and heat capacities per unit volume of 1,3-dioxane and trioxane were measured in water at 25°C in the concentration range 0.1 to 1 mol kg^{-1}. Apparent molal volumes ϕ_V and heat capacities ϕ_C were derived. The infinite dilution ϕ_V^0 shows excellent group additivity with other cyclic ethers in water but the additivity is less satisfactory for ϕ_C^0. No simple correlation can be made for the concentration dependence of these functions.

GÉRALD PERRON et JACQUES E. DESNOYERS. Can. J. Chem. **59**, 2599 (1981).

Les masses volumiques et capacités calorifiques du 1,3-dioxane et du trioxane ont été mesurées dans l'eau à 25°C pour des concentrations de 0.1 à 1 mol kg^{-1}. Les volumes et capacités calorifiques molaires apparents, ϕ_V et ϕ_C, ont été calculés. Les valeurs à dilution infinie ϕ_V^0 montrent une excellente additivité de groupe avec les autres valeurs d'éthers cycliques. Par contre l'addivité de groupe est beaucoup moins bonne dans le cas de ϕ_C^0. On ne peut pas établir de corrélation simple entre les variations de ces fonctions avec la concentration.

In a general study of Gibbs free energies and enthalpies of solute–solute interactions of cyclic ethers in water (1) it was necessary to know the heat capacities of the same systems. Tetrahydropyran (THP) and 1,4-dioxane (*p*-D) have already been investigated (2) but not 1,3-dioxane (*m*-D) and trioxane (T). The purpose of this article is to extend our heat capacity measurements to these two latter nonelectrolytes in water. Accurate densities are also required to calculate apparent molal heat capacities ϕ_C. Apparent molal volumes ϕ_V will therefore also be reported. These data, when combined with those of THP and *p*-D should be useful in discussing group additivity to the standard ϕ_V^0 and ϕ_C^0 and to the solute–solute interaction parameters.

As in previous studies (2), differences in the densities Δd of the solution and of the solvent and relative changes in the heat capacities per unit volume $\Delta\sigma/\sigma_0$ of the solution were determined with a flow densimeter and a flow microcalorimeter, both purchased from SODEV.

Reagents used in this study were obtained and purified as follows: *m*-D from Fluka (Purum) was dried over 3 Å molecular sieves; T from Matheson, Coleman and Bell was recrystallized from water and dried over $CaCl_2$. Solutions were prepared by weight with deionized distilled water. All measurements were made at 25°C.

Results of the measurements of apparent molal volumes and apparent molal heat capacities are given in Table 1. Apparent molal volumes and heat capacities were calculated in the usual method (2, 3). Results for ϕ_V were fitted as a function of concentration by the equation

$$[1] \quad \phi_V = \phi_V^0 + A_V m$$

Similarly, ϕ_C were fitted by the equation

$$[2] \quad \phi_C = \phi_C^0 + A_C m$$

Results of the least-squares fit for these and other compounds of interest from the literature are given in Table 2. Volumes of *m*-D and T were also measured by Lepori and Mollica (4) who obtained $\phi_V^0 = 80.82\,\text{cm}^3\,\text{mol}^{-1}$ and $69.51\,\text{cm}^3\,\text{mol}^{-1}$, respectively. These results agree very well with the present data.

The group additivity of ϕ_V^0 appears to be reasonably good since the average of the THP and T, $80.66\,\text{cm}^3\,\text{mol}^{-1}$, is very close to *m*-D. However, the additivity for ϕ_C^0 is less good since the average of THP and T is 287 J K^{-1} mol^{-1}, which is 44 J K^{-1} mol^{-1} larger than *m*-D. It also should be noted that ϕ_C^0 of the two isomers, *m*-D and *p*-D, differ significantly. (The experimental uncertainty in ϕ_C^0 should not be more than 5 J K^{-1} mol^{-1}). The average group contributions are

Group	ϕ_V^0 (cm^3 mol^{-1})	ϕ_C^0 (J K^{-1} mol^{-1})
CH_2	17.14±0.6	74±16
O	6.08±0.6	−16±16

These group contributions to ϕ_V^0 are in reasonably good agreement with straight chain ethers (5) but again the ϕ_C^0 are significantly different. For example, for straight chain ethers the O contribution to ϕ_C^0 is −57 J K^{-1} mol^{-1}.

The parameters A_V normally become more neg-

ative and A_C more positive as the hydrophobic character of the solute increases. This trend is followed by THP when compared with *m*-D and *p*-D. However, these parameters are not as expected for T since they are close to the values of the dioxanes. This is in contrast with enthalpic interaction parameters which showed a good additivity for all cyclic ethers.

Nucleic acid related compounds. 33. Conversions of adenosine and guanosine to 2,6-dichloro, 2-amino-6-chloro, and derived purine nucleosides[1]

MORRIS J. ROBINS and BOGDAN UZNAŃSKI[2]

Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 2, 1981

MORRIS J. ROBINS and BOGDAN UZNAŃSKI. Can. J. Chem. **59**, 2601 (1981).

Enzymatic deamination of adenosine 1-*N*-oxide gave 1-hydroxyinosine (**2***a*) which was acetylated and then chlorinated to give 2,6-dichloro-9-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)purine (**3**). Ammonia in dry 1,2-dimethoxyethane converted **3** into 2-chloroadenosine triacetate (**4***a*). Treatment of **4***a* with trimethylamine at elevated temperatures in acetonitrile resulted in formation of 2-*N*,*N*-dimethylaminoadenosine triacetate (**4***b*). Guanosine (**5**) was acetylated smoothly by an improved procedure. The resulting triacetate (**6**) was chlorinated in ~85% yield to give 2-amino-6-chloro-9-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)purine (**7**). Treatment of **7** with trimethylamine at ambient temperature for 28 hours gave the 6-*N*,*N*-dimethylamino compound (**8***d*). However, potassium fluoride or sodium azide with catalytic quantities of trimethylamine in DMF or acetonitrile gave the 2-amino-6-fluoro (**8***a*) or 2-amino-6-azido (**8***b*) products in yields of greater than 90%.

MORRIS J. ROBINS et BOGDAN UZNAŃSKI. Can. J. Chem. **59**, 2601 (1981).

La désamination enzymatique du *N*-oxyde-1 d'adénosine conduit à l'hydroxy-1 inosine (**2***a*) qui par une acétylation, suivie d'une chloration donne la dichloro-2,6 (tri-*O*-acétyl-2,3,5 β-D-ribofurannosyl)-9 purine (**3**). Le composé **3** dans l'ammoniac avec le diméthoxy-1,2 éthane anhydre se transforme en triacétate de chloro-2 adénosine (**4***a*). Ce dernier, à haute température, réagit avec la triméthylamine dans l'acétonitrile pour donner le triacétate de *N*,*N*-diméthylamino-2 adénosine (**4***b*). Grâce à une méthode convenable on a acétylé facilement la guanosine (**5**). La chloration du triacétate (**6**) ainsi obtenu conduit avec un rendement de 85% à l'amino-2 chloro-6 (tri-*O*-acétyl-2,3,5 β-D-ribofurannosyl)-9 purine (**7**). Le composé **7** réagit avec la triméthylamine pendant 28 heures à la température de la pièce en donnant le composé *N*,*N*-diméthylamino-6 (**8***d*). Cependant le fluorure de potassium ou l'azoture de sodium en présence de quantités catalytiques de triméthylamine dans le DMF ou dans l'acétonitrile conduit aux composés fluoro-6 (**8***a*) ou amino-2 azido-6 (**8***b*) avec des rendements supérieurs à 90%.

[Traduit par le journal]

Potent effects on blood pressure and platelet aggregation are exerted by 2-chloroadenosine and related nucleoside derivatives (2). The cytotoxic 2-fluoroadenosine and modified sugar analogues have been studied as anticancer agents (3). Paterson and co-workers have observed recently that 6-*S*-(*p*-nitrobenzyl)thioinosine, a strong competitive inhibitor of nucleoside transport across cell membranes, exerts protection against toxic effects of certain nucleoside antibiotics and anticancer agents in animals (4). This observation stimulated our interest in evaluation of host protection against toxicity of 2-halopurine nucleosides. We have explored alternative routes to 2- and 6-chloro 2,6-disubstituted purine nucleosides from adenosine and guanosine. We now describe improved syntheses of acetyl-protected 6-amino-2-chloro- and 2-amino-6-chloropurine ribonucleosides. These have been converted to useful related 2 and 6 disubstituted compounds by nucleophilic replacements.

Syntheses of 2-halopurine nucleosides usually have employed classical methods of coupling a purine base with an activated carbohydrate derivative (5). The Fischer–Helferich condensation of the silver salt of 2,8-dichloroadenine with tetraacetylglucosyl bromide (6) was the original prototype for synthesis of the naturally occurring purine ribonucleosides (7). Nucleophilic replacements and hydrolytic diazotizations at C-2 and C-6 provided the natural amino and oxo substituents. Unwanted halo groups were removed reductively. More recent coupling methods have employed 2 and 6 disubstituted purines to give dihalo and aminohalo nucleosides (5,8). Montgomery and co-workers have used 2,6-dichloro- (**3***b*) and 2,6-diacetamidopurine (9) in coupling reactions followed by transformations to give fluoropurine nucleosides. Robins and co-workers have performed 6-chloro- to 6-fluoropurine conversions using silver fluoride in hot xylene (10). They also have utilized diazotization in aqueous acid for the introduction of chloro and fluoro groups (11). Kiburis and Lister have reported displacement of trimethylamine from 6-*N*-purinyltrimethylammonium chloride salts using potassium fluoride (12), a procedure applied successfully by ourselves for the synthesis of the 6-fluoropurine 2′-deoxyribonucleoside (13).

Owing to the high cost and limited availability of

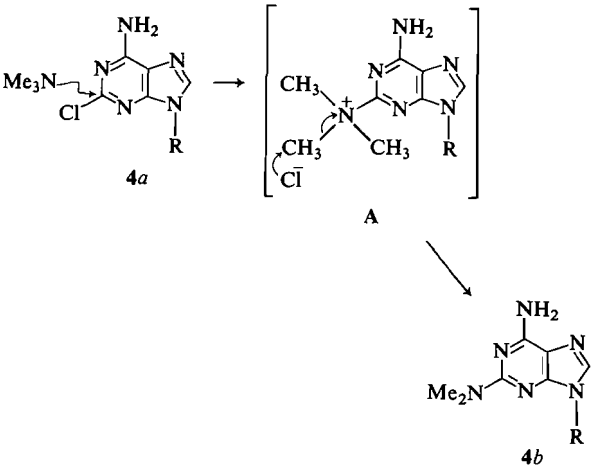
2,6-dichloropurine plus the yield and isomer considerations involved in base–sugar coupling methods (5,9), we opted for transformations of naturally occurring nucleosides (14). A sequence for conversion of adenosine (**1**) to 2,6-dichloro-9-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)purine (**3**) had been reported (15). Oxidation of **1** with *m*-chloroperoxybenzoic acid in aqueous acetic acid/dioxane gave adenosine 1-*N*-oxide in 96% yield.[3] Kawashima and Kumashiro used chemical deamination of this product to give 1-hydroxyinosine (**2***a*) in 56% crude yield (15). However, we employed adenosine deaminase to effect this conversion cleanly in 88% crystallized yield without formation of colored by-products. Acetylation of **2***a* to the tetraacetate (**2***b*) followed by treatment with aqueous pyridine gave 2′,3′,5′-tri-*O*-acetyl-1-hydroxyinosine (**2***c*). Phosphoryl chloride in hot 2-picoline converted **2***c* → **3** in 73% yield. With these improvements, the overall yield from **1** → **3** was 61%.[4]

Treatment of **3** with anhydrous ammonia in dry 1,2-dimethoxyethane (DME) effected nucleophilic replacement of the 6-chloro function without ammonolysis of the ester groups.[5] The resulting 2-chloroadenosine triacetate (**4***a*) was treated with trimethylamine in acetonitrile at elevated temperatures in a sealed pressure vessel. The sole nucleoside product isolated was 2-*N*,*N*-dimethylaminoadenosine triacetate (**4***b*). Carefully purified (dimethylamine-free) trimethylamine neat or in acetonitrile also converted **4***a* → **4***b*. The presumed intermediate 2-*N*-purinyltrimethylammonium chloride salt (**A**) was not observed. Temperatures required to effect displacement of the 2-chloro function from **4***a* apparently result in the facile displacement of amine nitrogen by attack of chloride on a methyl carbon of **A** to give **4***b*. Attempted *in situ* generation of **A** from **4***a* using excess potassium fluoride in the presence of trimethylamine again resulted in formation of **4***b*.[6] However, the *in situ* procedure functions smoothly at C-6 (*vide infra*).

A simple acetylation of guanosine (**5**) was reported in 1947 (19). However, this often quoted preparation employed inconvenient quantities of acetic anhydride and pyridine and can give rigid suspensions of incompletely acetylated products in larger scale work. An improved procedure that utilizes acetic anhydride and pyridine in *N*,*N*-dimethylformamide (DMF) to give clear solutions and yields of ~87% of 2′,3′,5′-tri-*O*-acetylguanosine (**6**) is described in the Experimental.



Chlorination of **6** has been studied previously (20) and improved procedures have been reported (21). However, the reaction conditions, especially heating, were difficult to duplicate with different sized preparations. Decomposition occurred in the heated mixtures and our yields of the crystalline 2-amino-6-chloro product (**7**) using those procedures seldom exceeded 50%.

We have examined this reaction utilizing ^{31}P nmr spectroscopy. A reference sample of $POCl_3$ in acetonitrile gave a broad ^{31}P singlet at 4.18 ppm from external H_3PO_4. Chlorination reaction conditions were simulated in an nmr tube containing phosphoryl chloride, *N*,*N*-dimethylaniline, and **6** in acetonitrile in a probe heated at 70°C. A second ^{31}P signal (sharp singlet) at −1.17 ppm (upfield from H_3PO_4) was observed immediately. A third singlet at −7.9 ppm increased steadily over a period of one hour. During this time, the peak at −1.17 ppm diminished to an insignificant intensity. Several aromatic phosphorodichloridates give ^{31}P singlets in the range of 1 to −2.5 ppm (22). A sample of dichlorophosphoric acid in acetonitrile gave a ^{31}P signal in the range of −2.96 to −8.85 depending on the amount of *N*,*N*-dimethylaniline present.

These data are compatible with phosphorylation of **6** to give the aromatic phosphorodichloridate intermediate (**B**) followed by attack of chloride at C-6 of **B** to give **7** plus dichlorophosphate (**C**). A higher concentration of external chloride anions should favor conversion of **B** → **7** before decompo-

[3]This modification of the procedures of Brown and MacCoss and their co-workers (16) will be published as part of an unrelated study with Dr. F. Hansske.

[4]An alternative synthesis was developed which requires only three steps from guanosine (**5**) and gives **3** in 64% overall yield (17).

[5]Ammonia in alcohol or liquid ammonia, used without drying, effects concomitant ammonolysis of the ester groups (18).

[6]An alternative approach employing nonaqueous diazotization has been developed for convenient fluorination at C-2 (17).

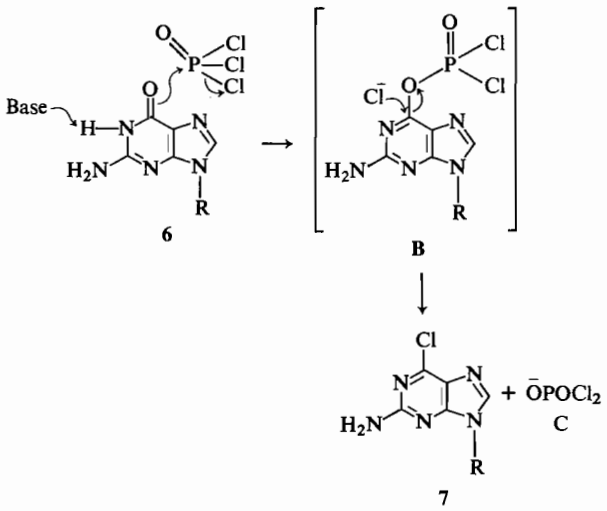
For personal use only.



sition occurred. Indeed, addition of tetraethylammonium chloride to an identically prepared nmr experiment resulted in disappearance of the intermediate ^{31}P singlet at -1.49 ppm within 10 minutes. A singlet at -10.65 ppm increased steadily over the 10 minute period. Use of analogous carefully anhydrous reaction conditions described in the Experimental gave readily repeatable yields of ~85% of crystalline **7**.

Treatment of **7** with excess trimethylamine at room temperature for an extended time resulted in formation of the 6-*N*,*N*-dimethylamino derivative (**8***d*). A fluorescent salt-like product was formed with complete disappearance of **7** (tlc) within one hour at room temperature. Treatment of this hygroscopic solid with potassium fluoride in DMF at elevated temperature resulted in formation of a mixture of 2-amino-6-fluoro (**8***a*) and 2-amino-6-chloro (**7**) nucleosides. However, treatment of **7** with a catalytic quantity of trimethylamine and excess potassium fluoride in DMF at room temperature resulted in clean conversion to **8***a* in 93% yield.

Analogous conversion of **7** to **8***b* was effected quantitatively using sodium azide in acetonitrile with trimethylamine as catalyst. The nmr spectra of **8***b* were compatible with a 6-azido ⇄ cyclic tetrazole equilibrium (23). This phenomenon was not investigated further since smooth hydrogenolysis of **8***b* occurred to give 2-aminoadenosine triacetate (**8***c*) in 98% crude yield overall from **7**.

The present improved syntheses of **6** and **7** allow convenient and high yield preparation of the useful intermediates **7** and **8***a*–*c*. The solid-solution phase transfer catalysis employed in the conversions of **7** → **8***a* or **8***b* is a useful improvement over the stoichiometric quaternary salt procedure of Lister (12). The soluble nucleoside **7** reacts with trimethylamine to give the quaternary ammonium salt. Transfer of chloride to the solid phase as its less soluble sodium or potassium salt occurs concomitantly with anion exchange for azide or fluoride. Nucleophilic replacement at C-6 by the solubilized anion releases trimethylamine for the catalytic cycle. The ambient temperature allows selective displacement at C-6 without competing formation of the 6-*N*,*N*-dimethylamino by-product (**8***d*). However, this catalytic process did not function successfully at C-2. The reduced reactivity at the 2-position results in favored nucleophilic attack at the methyl carbon of the quaternary salt leading to formation of the 2-*N*,*N*-dimethylamino compound (**4***b*) as the exclusive product. Therefore, nonaqueous diazotization reactions have been developed to provide convenient access to the 2-halopurine nucleosides (17).

Experimental

General

Melting points were obtained on a Reichert microstage block and are uncorrected. Ultraviolet (uv) spectra were recorded using a Cary 15 spectrophotometer. The ^1H nmr spectra were determined using Bruker 90 or Varian 100-MHz spectrometers with Me_4Si as internal reference and $CDCl_3$ as solvent unless Me_2SO-d_6 is specified. Acetyl methyl singlets and base proton peaks are given. Sugar proton multiplets were as expected. The ^{19}F nmr spectra were determined in $CDCl_3$ unless Me_2SO-d_6 is specified. ^{19}F chemical shifts are expressed in δ ppm upfield (minus sign) from CCl_3F as internal reference. Mass spectra (ms) were measured at 70 eV with an AEI MS-50 instrument with coupled computer analysis using direct probe sample introduction at 150–230°C by the mass spectral laboratory of this department. The molecular ion (M^+), 2,3,5-tri-*O*-acetyl-D-ribofuranosyl ion ($M^+ - B = C_{11}H_{15}O_7 = 259.0818$), and the substituted purinyl ion (B) or a protonated species (BH or BH_2) are given with their % relative intensities if observed in the spectrum.

Trimethylamine was purified by heating with acetic anhydride, distillation *in vacuo*, and storage over CaH_2. Reagent grade acetonitrile and DMF were heated with and then distilled directly *in vacuo* from P_2O_5 into a flame-dried reaction flask assembly to provide rigorously anhydrous solvents. Chloroform, pyridine, 1,2-dimethoxyethane, 1,4-dioxane, dibromomethane, dichloromethane, 1,2-dichloroethane, and methanol were distilled and stored over drying agents. Silica refers to Mallinckrodt CC-7 silica gel for chromatography.

Evaporations were effected wtih a Buchler rotary evaporator equipped with a Dewar Dry-Ice condenser at mechanical oil pump (*in vacuo*) or water aspirator vacuum at room temperature.

1-Hydroxyinosine (2a)

Adenosine deaminase (100 mg, Sigma type II, crude from calf intestinal mucosa) was added to a solution of 1.0 g (3.5 mmol) of adenosine 1-*N*-oxide (16) in 200 mL of 0.05 *M* $NaH_2PO_4/Na_2HPO_4/H_2O$ buffer at pH 7.5. The solution was allowed to stand for 3 days at room temperature and was then evaporated to ~50 mL *in vacuo*. This concentrate was applied to a column of 120 mL of Amberlite IR-120 (H^+) resin and the column was developed with

H_2O. Appropriate fractions (~3L, uv detector) were pooled and evaporated *in vacuo*. The residue was crystallized from 95% EtOH to give 875 mg (88%) of colorless crystals of **2***a*, mp ~210°C dec.; uv (0.1 *N* HCl) max:251 nm (ε 9500); (0.1 *N* NaOH) max:294, 256, 228 nm (ε 4200, 6800, 29 700); ms *m*/*z*:284.0760 (3.5%, M^+ [$C_{10}H_{12}N_4O_6$] = 284.0756), 152.0331 (100%, BH = 152.0334). Literature mp > 200°C dec (15); > 400°C with decomposition above 170°C (24); lit. uv (pH 3) max:251 nm (ε 9100); (pH 9) max:294, 256, 229 nm (ε 4000, 6300, 30 000) (24).

2′,3′,5′-Tri-O-acetyl-1-hydroxyinosine (2c)

A 1 g sample of adenosine 1-*N*-oxide was deaminated by stirring with adenosine deaminase in 100 mL of pH 7.5 buffer for 35 h at room temperature. A 50 mL portion of 1-butanol was added and the mixture was evaporated *in vacuo*. The residue was dried for 15 h at 0.1 Torr and then 10 mL of pyridine and 20 mL of Ac_2O were added. The mixture was sonicated for 1 h and then stirred at room temperature for 9 h. The mixture was cooled and 50 mL of 1-butanol was added. The volume was reduced to ~30 mL and 3 successive portions of 50 mL of 1-butanol were added and evaporated *in vacuo*. Chloroform (50 mL) was added to the heavy suspension which was filtered using a membrane filter. This filtrate contained 2′,3′,5′-tri-*O*-acetyl-1-*N*-acetyloxyinosine (**2***b*) as indicated by four ^1H nmr acetyl methyl singlets at δ 2.10, 2.12, 2.14, and 2.45 in addition to the other expected proton signals. Compound **2***b* gave ms *m*/*z*:452 (3.6%, M^+ [$C_{18}H_{20}N_4O_{10}$] = 452), 259 (100%, M^+ − B) at low resolution at 200°C and 17 eV.

The filtrate was evaporated and the residual **2***b* was dissolved in 1,4-dioxane (40 mL), pyridine (5 mL), and water (2 mL). The resulting solution was stirred for 48 h at room temperature to ensure complete hydrolysis of the 1-*N*-acetyloxy function. Addition of 50 mL of 1-butanol was followed by slow evaporation of solvents to ~30 mL, during which crystallization of product occurred. The crystals were filtered, washed with 2-propanol, and dried *in vacuo* to give 1.12 g of **2***c*. The filtrate

For personal use only.

was concentrated to ~1 mL and a further 138 mg of product was collected to give 1.26 g (88%) of **2***c*, mp 194–195°C (mp values of 203–205°C and 206–210°C also were observed depending on the rate of heating); lit. (15) mp 194.5–195.5°C; uv (0.1 *N* HCl/MeOH 9:1) max:251 nm (ε 9000); (0.1 *N* NaOH/MeOH 9:1) max:294, 256 nm (ε 4400, 6200); (MeOH) max:270 (sh), 251, 245 nm (ε 4100, 7600, 7600); ^{1}H nmr δ:2.08, 2.12, 2.14 (OAc's), 8.01 (s, 1, H-2), 8.40 (s, 1, H-8); ms *m/z*:410.1084 (2.3%, M^+ $[C_{16}H_{18}N_4O_9]$ = 410.1074, 259.0818 (100%, M^+–B), 153.0412 (14%, BH_2 = 153.0412).

*9-(2,3,5-Tri-*O*-acetyl-*β*-*D*-ribofuranosyl)-2,6-dichloropurine (**3**)*

A mixture of 0.9 g (2.2 mmol) of **2***c*, 3 mL of dried 2-picoline, and 10 mL of freshly distilled phosphoryl chloride was heated at reflux for 1 h. The red-brown solution was evaporated and the brown oily residue was dissolved in 10 mL of $CHCl_3$ and applied to a column of 30 mL of silica. The product was eluted with acetone/chloroform/cyclohexane 2:3:1. The orange eluate was evaporated and the residue again dissolved in 10 mL of $CHCl_3$ and applied to a layered column (1.5 cm dia) of 0.5 cm of silica, 5 cm of decolorizing carbon, and 1 cm of silica. The product was eluted with $CHCl_3$ and the 200 mL of eluate was evaporated. Addition of 3 mL of 1-butanol and partial evaporation resulted in separation of crystals which were filtered, washed with cold ether, and dried *in vacuo* to give 716 mg (73%) of **3**, mp 162–163°C; lit. (15) mp 160–161°C; uv (MeOH) max:273, 252 nm (ε 9100, 5100); ^{1}H nmr δ:2.04, 2.09, 2.12 (OAc's), 8.28 (s, 1, H-8); ms *m/z*:446.0392 (1.1%, M^+ $[C_{16}H_{16}Cl_2N_4O_7]$ = 446.0396), 259.0823 (100%, M^+–B).

*2',3',5'-Tri-*O*-acetyl-2-chloroadenosine (**4**a)*

Dry ammonia gas (passed through a drying tube packed with CaH_2) was bubbled slowly through a solution of 1.0 g (2.2 mmol) of **3** (dried at 60°C *in vacuo*) in 20 mL of dry 1,2-dimethoxyethane (distilled directly from NaH into the dried reaction flask) at room temperature for 8 h. The solution was evaporated and the colorless residue was treated with 10 mL of $CHCl_3$. This suspension was applied to a column of silica (50 g, 2 × 45 cm). Chloroform/acetone with an increasing gradient of acetone was used for elution. The appropriately pooled fractions were evaporated and the resulting colorless solid foam was dissolved in chloroform/2-propanol. The product crystallized upon slow evaporation of the solution. It was filtered, washed with ether, and dried to give 857 mg (91%) of **4***a*, mp 151–152°C; uv (MeOH) max:263 nm (ε 15 500); ^{1}H nmr δ:2.11, 2.17, 2.18 (OAc's) 7.97 (s, 1, H-8); ms *m/z*:427.0906 (6.1%, M^+ $[C_{16}H_{18}ClN_5O_7]$ = 427.0895), 259.0823 (100%, M^+–B). The corresponding deacylated nucleoside has a reported uv (pH 7) max:264 nm (ε 15 200) (8*e*).

*2',3,5'-Tri-*O*-acetyl-2-*N,N*-dimethylaminoadenosine (**4**b)*

A sealed ampule containing 130 mg (0.3 mmol) of **4***a* (dried *in vacuo* at 100°C for 2 h), 350 mg (6 mmol) of purified trimethylamine, and 1 mL of rigorously dried acetonitrile was heated at 100°C for 6 h inside a steel pressure bomb. After cooling to room temperature the ampule was opened and the mixture was filtered through a short column (1 × 1 cm) of silica. The column was washed with 50 mL of $CHCl_3$ and the combined eluate was evaporated to dryness. The residue was crystallized from 1-propanol, washed with ether, and dried to give 120 mg (92%) of **4***b*, mp 169–170°C; uv (MeOH) max:292, 264, 228 nm (ε 9000, 13 000, 22 400); (0.1 *N* HCl/MeOH 8:2) max:306, 260 nm (ε 9000, 16 400); (0.1 *N* NaOH/MeOH 8:2) max:294, 262 nm (ε 8400, 12 800); ^{1}H nmr δ:2.06, 2.12, 2.13 (OAc's), 3.16 (s, 6, NMe_2), 7.52 (s, 1, H-8); ms *m/z*:436.1711 (47%, M^+ $[C_{18}H_{24}N_6O_7]$ = 436.1706), 259.0817 (6.1%, M^+–B), 178.0964 (100%, BH = 178.0966). The corresponding deacylated nucleoside has reported uv (pH 1) max:305, 261 nm (ε 8760, 16 200); (pH 13) max:295, 262 nm (ε 8320, 12 500) (8*c*).

*2',3',5'-Tri-*O*-acetylguanosine (**6**)*

A mixture of 14.2 g (0.05 mol) of guanosine (**5**) (pre-dried *in vacuo* at 100°C for 2 days over P_2O_5), 30 mL of acetic anhydride, 15 mL of dry pyridine, and 40 mL of DMF was heated at 75°C with stirring for 3.75 h. The resulting clear solution was filtered while hot, cooled to room temperature, and evaporated *in vacuo* to a heavy crystalline suspension. The residue was treated with 50 mL of 2-propanol and filtered. The filter cake was washed with 2-propanol and dried to give 20.9 g (94%) of white crystals of **6** as the hemi-solvate (^{1}H nmr δ 2.82 (d, 3, 0.5 DMF)). This product was added to 750 mL of boiling 2-propanol with vigorous magnetic stirring. The partially dissolved suspension was stirred at reflux for 5 min and then was refrigerated at −5°C overnight. The product was filtered, washed with 2-propanol, and dried *in vacuo* at 80°C over P_2O_5 to give 17.88 g (87.4%) of tlc homogeneous **6**, mp ~230–233°C (softening from 195°C); lit. (19) mp 232°C; uv (MeOH) max:256 nm (ε 14 500); ^{1}H nmr (Me_2SO-d_6) δ:2.04 (s, 6, two OAc's), 2.10 (s, 3, OAc), 6.5 (s, 2, NH_2), 7.96 (s, 1, H-8).

*9-(2,3,5-Tri-*O*-acetyl-*β*-*D*-ribofuranosyl)-2-amino-6-chloropurine (**7**)*

Acetonitrile (50 mL) was distilled directly from P_2O_5 into a flask containing 10.23 g (0.025 mol) of pre-dried **6** and 8.3 g (0.05 mol) of Et_4NCl (pre-dried *in vacuo* at 85°C overnight over P_2O_5). *N,N*-Dimethylaniline (3.2 mL, 0.025 mol, dried over and distilled from CaH_2) and phosphoryl chloride (13.7 mL, 0.15 mol, freshly distilled) were added to the stirred solution at room temperature. The flask was placed in an oil bath preheated to 100°C and the solution was heated with stirring at reflux for 10 min. Volatile materials were flash evaporated immediately *in vacuo*. The resulting yellow foam was dissolved in 150 mL of $CHCl_3$ and stirred vigorously with crushed ice for 15 min. The layers were separated and the aqueous phase was extracted with 5 × 50 mL of $CHCl_3$. The combined organic phase was kept cold by addition of crushed ice. It was washed with 6 × 30 mL of cold water, 5% $NaHCO_3/H_2O$ to pH ~7, dried over $MgSO_4$ for 1 h, and filtered. A 60 mL portion of 2-propanol was added and the combined filtrate was slowly evaporated *in vacuo* to ~40 mL. The crystalline product that had separated was filtered, washed with 2-propanol (20 mL), and dried *in vacuo* overnight to give 9.31 g (87%) of crude **7**. This product was recrystallized from 90 mL of boiling 2-propanol to give 9.03 g (85%) of purified **7**, mp 152–153°C; lit. (20) mp 147.5–148.5°C; uv (MeOH) max:311, 249 nm (ε 7700, 7800); lit. (20) uv (EtOH) max:310, 249 nm (ε 7900, 8600); ^{1}H nmr δ:2.06, 2.08, 2.14 (OAc's), 5.70 (br, 2, NH_2), 7.94 (s, 1, H-8).

*9-(2,3,5-Tri-*O*-acetyl-*β*-*D*-ribofuranosyl)-2-amino-6-*N,N*-dimethylaminopurine (**8**d)*

A solution of 214 mg (0.5 mmol) of **7** (dried for 2 days over P_2O_5 in a desiccator) and 200 mg (3.4 mmol) of purified Me_3N in 4 mL of rigorously dried acetonitrile was allowed to stand at room temperature for 28 h in a sealed flask. The solution was evaporated to dryness. The residue was treated with 2 mL of $CHCl_3$ and applied to a silica column (1 × 5 cm) which was eluted with 100 mL of $CHCl_3$. The eluate was evaporated to a heavy syrup which crystallized upon exposure to ether overnight in a sealed desiccator (diffusion crystallization). The crystals were filtered, washed with ether, and dried to give 192 mg (88%) of **8***d*, mp 127–128°C; uv (MeOH) max:285, 267 (sh), 230 nm (ε 14 200, 10 600, 20 200); (0.1 *N* HCl/MeOH 8:2) max:300, 257 nm (ε 13 000, 12 000); (0.1 *N* NaOH/MeOH 8:2) max:284, 267 (sh) nm (ε 14 600, 10 400); ^{1}H nmr δ:2.05, 2.08, 2.10 (OAc's), 3.40 (s, 6, NMe_2), 4.67 (br s, 2, NH_2), 7.55 (s, 1, H-8); ms *m/z*:436.1710 (55%, M^+ $[C_{18}H_{24}N_6O_7]$ = 436.1706),259.0818 (5.7%, M^+–B), 178.0962 (100%, BH = 178.0966). The corres-

ponding deacylated nucleoside has reported uv (H_2O) max:284, 268 (sh), 228 nm (ε 15 600, 11 500, 19 100) (25).

9-(2,3,5-Tri-O-acetyl-β-D-ribofuranosyl)-2-amino-6-fluoropurine (8a)

A suspension of 4 g (69 mmol) of KF (dried *in vacuo* over a cold flame for 0.5 h) in a solution of 127 mg (2.1 mmol) of purified Me_3N (distilled directly into the flask *in vacuo* from CaH_2) and 2 g (4.7 mmol) of dried **7** in 45 mL of DMF (distilled directly into the flask *in vacuo* from CaH_2) was stirred vigorously at room temperature for 14 h. The mixture was evaporated to dryness *in vacuo*, the residue was treated with 50 mL of $CHCl_3$, and the suspension was filtered using a membrane filter. The filtrate was evaporated partially and 20 mL of 1-propanol was added. This was evaporated partially and a second 20 mL of 1-propanol was added. Evaporation was continued to ~10 mL. The separated crystalline product was filtered and washed with 1-propanol and then ether to give 1.78 g of **8a**. An additional 55 mg of product was recovered from the filtrate. The combined product was recrystallized from 14 mL of boiling 2-propanol to give 1.78 g (93%) of purified **8a**, mp 151–152°C; lit. (10) mp 144–146°C; uv (MeOH) max:289, 245 nm (ε 6800, 10 800); lit (10) uv (95% EtOH) max:289, 246 nm (ε 7000, 11 100); ^{1}H nmr δ:2.06, 2.07, 2.13 (OAc's), 5.30 (br s, 2, NH_2), 7.84 (d, $^5J_{H\text{-}8\text{-}F\text{-}6}$ = 0.45 Hz, 1, H-8); ^{19}F nmr (Me_2SO-d_6/$CDCl_3$) δ:−71.6 (s, 1, F-6); ms *m/z*:411.1190 (18%, M^+ [$C_{16}H_{18}FN_5O_7$] = 411.1190), 259.0822 (100%, M^+–B), 153.0457 (22%, BH = 153.0451).

9-(2,3,5,-Tri-O-acetyl-β-D-ribofuranosyl)-2-amino-6-azidopurine (8b)

A. A suspension of 0.5 g (7.7 mmol) of NaN_3 (dried *in vacuo* at room temperature for 3 days over P_2O_5) in a solution of 1 g (2.3 mmol) of dried **7** and 0.1 g (1.7 mmol) of purified Me_3N in 30 mL of rigorously dried acetonitrile was stirred at room temperature overnight. The mixture was evaporated *in vacuo*, the residue was treated with 30 mL of $CHCl_3$, and the suspension was applied to a column of silica (1 × 3 cm). The column was eluted with $CHCl_3$, the eluate was evaporated to dryness, and the residue was dissolved in 40 mL of 1,4-dioxane. This solution was frozen and lyophilized to give 1.09 g (quantitative) of a photosensitive white powder. The ^{1}H nmr spectrum of this powder indicated an equilibrium of two products (6-azido⇄ cyclic tetrazole) (23). Compound(s) **8b** had uv (MeOH) max: 299, 271, 238 nm; ^{1}H nmr δ:7.78 (s, 0.25, H-8), 7.95 (s, 0.75, H-8); ms *m/z*:434.1299 (13%, M^+ [$C_{16}H_{18}N_8O_7$] = 434.1299), 259.0814 (72%, M^+–B), 176.0532 (2.4%, BH = 176.0559). This material was hydrogenolyzed to a single product.

B. Alternatively, this reaction can be completed in 1.5 h at room temperature using 0.6 g (10.2 mmol) of Me_3N and 1.0 g (15.4 mmol) of NaN_3 with 0.5 g (1.2 mmol) of **7** in 30 mL of acetonitrile.

9-(2,3,5-Tri-O-acetyl-β-D-ribofuranosyl)-2,6-diaminopurine (8c)

A solution of 1.46 g (3.4 mmol) of **8b** in 50 mL of dry 1,4-dioxane was hydrogenolyzed at 30 psi with 0.5 g of 5% Pd/C catalyst at room temperature for 18 h in a Parr shaker. The mixture was filtered through a short silica column (2 × 1 cm) and the column was washed with acetone/$CHCl_3$ 1:1. The combined filtrate was evaporated to dryness and the tlc pure solid foam was dried *in vacuo* for 2 days to give 1.35 g (98%) of **8c**. A crystalline sample was obtained by diffusion of ether into a solution of **8c** in 1,4-dioxane. This sample had mp 105–106°C; uv (MeOH) max:282, 257 nm (ε 9400, 10 000); ^{1}H nmr δ:2.10 (s, 6, two OAc's), 2.14 (s, 3, OAc), 5.02 (br s, 2, 2-NH_2), 5.9 (br s overlapped by sugar protons, 2, 6-NH_2), 7.64 (s, 1, H-8); ms *m/z*:408.1385 (28%, M^+ [$C_{16}H_{20}N_6O_7$] = 408.1393), 259.0809 (M^+–B), 150.0647 (100%, BH = 150.0654). This compound has been reported previously as an amorphous intermediate (26). The corresponding deacylated nucleoside has reported uv (H_2O) max:280, 256 nm (ε 11 100, 10 700) (25).

Nucleic acid related compounds. 34. Non-aqueous diazotization with *tert*-butyl nitrite. Introduction of fluorine, chlorine, and bromine at C-2 of purine nucleosides[1]

MORRIS J. ROBINS AND BOGDAN UZNAŃSKI[2]

Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 2, 1981

MORRIS J. ROBINS and BOGDAN UZNAŃSKI. Can. J. Chem. **59**, 2608 (1981).

Treatment of 2,6-diamino-9-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)purine (**1***c*) with *tert*-butyl nitrite (TBN) in 60% anhydrous hydrogen fluoride/pyridine at −20°C gave 2-fluoroadenosine triacetate (**2**) in 48% yield. Analogous treatment of the acetylated 2-amino-6-fluoropurine nucleoside (**1***a*) gave the 2,6-difluoro compound (**3***a*) in 63% yield. Anhydrous ammonia in 1,2-dimethoxyethane converted **3***a* → **2** without ammonolysis of the acetate groups. The overall conversion of **1***a* → **3***a* → **2** without isolation of **3***a* proceeded in 80% yield. Similar diazotization of the 2-amino-6-chloro nucleoside (**1***b*) in HF/pyridine gave the 2-fluoro-6-chloro analogue (**3***b*) in 89% yield. Treatment of **1***b* with TBN and pyridine hydrochloride in dichloromethane (77%) or TBN and antimony trichloride in 1,2-dichloroethane (84%) gave the 2,6-dichloropurine nucleoside (**4***b*). The latter conditions converted **1***a* to the 2-chloro-6-fluoro product (**4***a*) in 77% yield. Conversions of **1***a* and **1***b* to the 2-bromo-6-fluoro (**5***a*, 67%) and 2-bromo-6-chloro (**5***b*, 78%) analogues were effected using TBN and antimony tribromide in dibromomethane.

MORRIS J. ROBINS et BOGDAN UZNAŃSKI. Can. J. Chem. **59**, 2608 (1981).

La diamino-2,6 (tri-*O*-acétyl-2,3,5 β-D-ribofurannosyl)-9 purine (**1***c*) réagit avec le nitrite de *tert*-butyle (NTB) dans un mélange de fluorure d'hydrogène anhydre/pyridine à 60% à −20°C en donnant le triacétate de fluoro-2 adénosine (**2**) avec un rendement de 48%. La réaction analogue du nucléoside amino-2 fluoro-6 purine acétylé (**1***a*) conduit au composé difluoro-2,6 (**3***a*) avec un rendement de 63%. L'ammoniac anhydre dans le diméthoxy-1,2 éthane permet de passer du composé **3***a* au composé 2 sans l'ammonolyse du groupe acétate. La transformation globale de **1***a* → **3***a* → **2** sans isoler le composé **3***a* se fait avec un rendement de 80%. Une diazotation analogue de l'amino-2 chloro-6 nucléoside (**1***b*) dans un mélange de HF/pyridine conduit au composé fluoro-2 chloro-6 apparenté (**3***b*) avec un rendement de 89%. Le composé **1***b* réagit avec NTB et le chlorhydrate de pyridine dans le dichlorométhane (77%) ou avec le NTB et le trichlorure d'antimoine dans le dichloro-1,2 éthane (84%) en donnant le nucléoside dichloro-2,6 purine (**4***b*). Dans les mêmes conditions le composé **1***a* se transforme en composé chloro-2 fluoro-6 (**4***a*) avec un rendement de 77%. On a réalisé la transformation des composés **1***a* et **1***b* en leurs analogues bromo-2 fluoro-6 (**5***a*, 67%) et en bromo-2 chloro-6 (**5***b*, 78%) en utilisant le NTB et le tribromure d'antimoine dans le dibromoéthane.

[Traduit par le journal]

Interest in 2-fluoroadenine nucleosides has been stimulated recently. The cytotoxic 2-fluoroadenosine and modified-sugar analogues are resistant toward deamination by the catabolic enzyme adenosine deaminase (2, 3*a*). Thus, their lifetimes in vivo are enhanced relative to their adenosine counterparts (3). It has been found that 2-fluoro-araA (9-β-D-arabinofuranosyl-2-fluoroadenine) is phosphorylated by deoxycytidine kinase. It therefore has a different mode of biochemical activation as well as different loci of action than 2-fluoroadenosine (3). It was noted recently that a protective effect against the toxicity of 5-fluorocytidine and certain other anticancer nucleosides in animals is exerted by 6-*S*-(*p*-nitrobenzyl)thioinosine, a potent inhibitor of nucleoside transport across cell membranes (4). We became interested in exploring improved routes to 2- and 6-fluoro 2,6-disubstituted purine nucleosides to make them available for examination of host toxicity protection.

Montgomery (5) and Robins (6) and their coworkers have utilized diazotization in aqueous acid media for introduction of fluorine and chlorine at C-2 of purine nucleosides. However, glycosyl and halo bond hydrolysis can occur during the heat-generating neutralization of the strong acid solutions. Direct hydrolytic dediazoniation also can give rise to the observed oxopurine base and nucleoside by-products. The low temperature limit for executing these diazotizations is defined by the freezing point of the aqueous solution.

Olah *et al.* reported conversion of aromatic amines to aryl fluorides using sodium nitrite in 70% poly(hydrogen fluoride)/30% pyridine solutions (7). A recent note described the use of *tert*-butyl nitrite and boron trifluoride etherate in methylene chloride or ether solutions to effect the conversion of aryl amines into their diazonium fluoroborate salts in high yields (8).

We began an investigation of nonaqueous diazotization of protected purine nucleosides based on these precedents. The 2,6-diamino- (**1***c*), 2-amino-6-chloro- (**1***b*), and 2-amino-6-fluoro-9-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)purine (**1***a*) precursors

were prepared by improved procedures in yields of ~70% overall from guanosine (1).

Treatment of **1***c* with *tert*-butyl nitrite (TBN) in 60% HF/pyridine at − 20°C for 10 minutes resulted in disappearance of starting material. The desired 2-fluoroadenosine triacetate (**2**) was obtained in 48% yield. A minor quantity of the 2,6-difluoro compound (**3***a*) was also formed (5*b*). However, attempts to improve the yield of **2** or to drive the reaction to give **3***a* were not promising. Analogous treatment of **1***a* at − 30°C resulted in rapid evolution of gas (N_2). The reaction was complete in less than 2 minutes. Crystalline **3***a* was isolated in 66% yield. Treatment of **3***a* with anhydrous ammonia in dry 1,2-dimethoxyethane for 15 minutes gave **2** in 85% yield. Ammonolysis of the protecting acetate esters did not occur under these carefully anhydrous conditions that effect smooth replacement of the 6-fluoro function. Alcoholic ammonia or liquid ammonia without drying convert **3***a* to the deprotected 2-fluoroadenosine (5*b*). When isolation of **3***a* was omitted, the conversion **1***a* → **3***a* → **2** proceeded to give 80% of **2**. This provides **2** in 58% overall yield from the readily available naturally occurring guanosine. Deacetylated **2** (2-fluoroadenosine) was prepared previously in 20% overall yield from **1***c* (5*b*). The 2-fluoro-6-chloro analogue (**3***b*) was prepared from **1***b* in 89% yield using identical conditions as for **1***a* → **3***a*. This transformation had been effected in 44% yield previously when aqueous fluoroboric acid conditions were employed (6*b*).

Several syntheses of the versatile intermediate 2,6-dichloropurine nucleoside (**4***b*) have been reported (see references quoted in ref. 1). These methods, again, usually involved base–sugar coupling. Treatment of **1***b* with TBN and pyridine hydrochloride in dichloromethane at − 10°C for 45 minutes gave **4***b* in 77% yield. This yield was elevated to 84% using TBN and antimony trichloride in 1,2-dichloroethane. Prior aqueous conditions were reported to effect this transformation in 43% yield (6*b*). Conversion of **1***a* into the 2-chloro-6-fluoro analogue (**4***a*) proceeded in 77% yield using our TBN/$SbCl_3$/$C_2H_4Cl_2$ conditions.

Treatment of **1***a* with TBN and antimony tribromide in dibromomethane gave the 2-bromo-6-fluoro product (**5***a*) in 69% yield. Analogous conversion of **1***b* to the 2-bromo-6-chloro compound (**5***b*) proceeded in 78% yield.

These diazotization–dediazoniation reactions (9) were monitored by tlc and in some cases by hplc. The structures of known products were confirmed by comparison of properties with literature values as well as by ^1H and ^{19}F nmr, uv, and mass spectral examination. Elemental analyses were obtained also as a check on purity and verification of the reliability of yields.

iv) TBN/$SbBr_3$ /CH_2Br_2.

SCHEME 1

These nonaqueous diazotization-replacements proceed readily at lowered temperatures. The reactions in HF/pyridine are exceptionally rapid. Complete disappearance of starting **1***a* or **1***b* occurred in less than 2 minutes at − 30°C. Montgomery had observed the formation of a hydroxybutylidene-substituted by-product nucleoside when tetrahydrofuran was used as a homogeneous cosolvent with 48% fluoroboric acid. He also had noted that 2-chloro as well as 2-fluoro substitution occurred when the 2-amino precursor was diazotized in a chloroform/48% fluoroboric acid two-phase system (5*c*).

We observed both 2-chloro and 2-fluoro products when BF_3 etherate (8) was employed with TBN in chloroform or dichloromethane solvents. Similarly, $SbBr_3$ and TBN in methylene chloride gave rise to a mixture of 2-bromo and 2-chloro compounds that were resolved by hplc and identified by mass spectrometry. Therefore, the halogen-compatible $SbBr_3$/CH_2Br_2 and $SbCl_3$/$C_2H_4Cl_2$ systems

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

were employed with TBN to give clean brominative and chlorinative diazotization–dediazoniations.

It was observed that the fluoro substitution process was inhibited by concentrations of HF/pyridine greater than ~65% HF. Use of a freshly prepared sample of 70% HF/30% pyridine resulted in the absence of gas evolution upon addition of TBN. After examination of several variables it was discovered that dilution of this reagent with anhydrous pyridine to concentrations of 45–65% HF provided reactive systems for the diazotization-replacement. We standardized our procedure using 60% HF/pyridine, but a 50% reagent functions equally well.

Nair and Richardson recently have reported some analogous nonaqueous diazotization reactions of 9-substituted adenines (10). They observed incorporation of halogen at C-6 of the purine ring upon treatment of their substrates with *n*-pentyl nitrite in halogenated solvents and interpreted their results in terms of a radical abstraction process.

Our present study provides convenient methods for the nonaqueous diazotization-replacement of the 2-amino group of protected purine nucleosides to give 2-fluoro, 2-chloro, and 2-bromo- compounds in good to high yields. These procedures are clearly superior in both convenience and yields to prior aqueous acid diazotizations. Purine nucleoside diazonium salts are presumptive unstable intermediates in these observed overall replacement reactions. Abstraction of halogen from solvent was observed. This problem was circumvented by the use of HF/pyridine and the compatible antimony trihalide/halo solvent for introduction of chloro and bromo substituents. Studies are in progress to investigate mechanistic considerations and further useful transformations of aminopurine nucleosides.

Experimental

General

General procedures and instrumentation used are given in ref. 1. Polyhydrogen fluoride/pyridine (70% HF by weight) was purchased from Aldrich Chemical Co. or was prepared by careful addition of HF to dry pyridine at − 78°C as described in ref. 7. It was diluted to 60% HF/pyridine by cautious addition of dry pyridine at − 50°C. Reactions performed in HF/pyridine were effected in polyethylene test tubes equipped with a small Teflon-coated magnetic stir bar. **CAUTIONS** in the use of HF/pyridine are noted in ref. 7. *tert*-Butyl nitrite (TBN) was prepared essentially as described in ref. 11. It was distilled at 0°C into a cold trap at − 78°C on a vacuum line. Elemental analyses were determined by the Microanalytical Laboratory of this department.

9-(2,3,5-Tri-O-acetyl-β-D-ribofuranosyl)-2,6-difluoropurine (3a)

A stirred solution of 500 mg (1.2 mmol) of **1***a* was prepared in 5.2 mL of 60% HF/pyridine at − 30°C in a Dry-Ice/acetone bath and 200 μL (1.7 mmol) of TBN was added. Vigorous evolution of gas (N_2) occurred for ~1 min. Stirring was continued for 1 min and the solution was poured into 100 g of crushed ice/H_2O. The aqueous mixture was extracted with 5 × 20 mL of $CHCl_3$. The combined organic phase was washed with 3 × 10 mL of H_2O, 5% $NaHCO_3/H_2O$ to pH~ 7, dried over $MgSO_4$ for 2 h, filtered, and 20 mL of 2-propanol was added to the filtrate. The combined filtrate was evaporated to ~2 mL and the resulting suspension was refrigerated at 5°C for 3 days. The crystalline product was filtered, washed with ether, and dried *in vacuo* to give 328 mg (66%) of **3***a*, mp 84–86°C; uv (MeOH) max: 254, 237 (sh) nm (ε 6700, 4000); lit. (5*b*) uv (pH 7) max: 253.5, 233 nm (ε 7300, 4000); ^{1}H nmr δ: 2.10, 2.18, 2.19 (OAc's), 8.26 (s, 1, H-8); ^{19}F nmr δ: − 65.8 (d, $^4J_{6-2}$ = 3.2 Hz, 1, F-6), −49.1 (d, $^4J_{2-6}$ = 3.2 Hz, 1, F-2); ms *m/z*: 414.0992 (0.3%, M^+ $[C_{16}H_{16}F_2N_4O_7]$ = 414.0987, 259.0815 (100%, M^+ −B). *Anal.* calcd. for $C_{16}H_{16}F_2N_4O_7$: C 46.39, H 3.89, N 13.52; found: C 46.15, H 3.91, N 13.51.

2′,3′,5′-Tri-O-acetyl-2-fluoroadenosine (2)

A. Dry ammonia was bubbled through a solution of 350 mg (0.85 mmol) of **3***a* in 5 mL of 1,2-dimethoxyethane (dried over NaH and distilled directly into the dried reaction flask) at room temperature for 15 min. The solution was evaporated to dryness and the residue was treated with 100 mL of hot $CHCl_3$ and filtered. A 50 mL portion of 2-propanol was added and the combined filtrate was evaporated to ~30 mL. The crystalline precipitate was filtered, washed with 2-propanol, and dried *in vacuo* to give 296 mg (85%) of **2**, mp 211–212°C; lit. (5*b*) mp 204°C; uv (MeOH) max: 261 nm (ε 15 900); lit. (5*b*) uv (pH 7) max: 261 nm (ε 14 900); ^{1}H nmr (Me_2SO-d_6) δ: 2.04, 2.06, 2.14 (OAc's), 8.34 (s, 1, H-8); ^{19}F nmr (Me_2SO-d_6) δ: −51.5 (s, 1, F-2); ms *m/z*: 411.1197 (15%, M^+ $[C_{16}H_{18}FN_5O_7]$ = 411.1190), 259.0815 (100%, M^+ −B), 153.0452 (34%, BH = 153.0451). *Anal.* calcd. for $C_{16}H_{18}FN_5O_7$: C 46.72, H 4.41, N 17.03; found: C 46.66, H 4.33, N 17.22.

B. A 500 mg (1.2 mmol) sample of **1***a* was treated with TBN/HF/pyridine as described. The resulting dried chloroform extract was filtered, 150 mL of toluene added, and evaporated to dryness. The resulting amorphous crude **3***a* was treated with dry ammonia/1,2-dimethoxyethane as described in method A to give 400 mg (80%) of **2**.

C. A stirred solution of 250 mg (0.61 mmol) of **1***c* in 1.5 mL of 60% HF/pyridine was treated at −30°C with 100 μL (0.85 mmol) of TBN. Stirring was continued at −30 to −20°C for 10 min and the reaction mixture was processed as in method A to give 120 mg (48%) of **2**.

The products from methods A, B, and C were identical by the usual direct comparisons.

9-(2,3,5-Tri-O-acetyl-β-D-ribofuranosyl)-6-chloro-2-fluoropurine (3b)

A 1.0 g (2.34 mmol) sample of **1***b* was added to 8.5 mL of 60% HF/pyridine at −50°C with stirring. The temperature was allowed to rise to −30°C and 400 μL (3.4 mmol) of TBN was added. Stirring was continued for 3 min (vigorous evolution of gas occurred for ~1 min) and the reaction was processed as in the conversion of **1***a* → **3***a*, method A. The dried $CHCl_3$ extract was treated with 5 mL of 1-propanol and evaporated to a small volume. The crystalline product that separated was filtered, washed with cold 1-propanol, and dried *in vacuo* to give 892 mg (89%) of pale yellow crystals. This product was recrystallized from 2-propanol to give 854 mg (85%) of pure **3***b*, mp 132.5–133.5°C; lit. (6*b*) mp 121–123°C; uv (MeOH) max: 269, 244 (sh)

nm (ε 9800, 3300); lit. (6*b*) uv (EtOH) max: 269 nm (ε 12 500); ^{1}H nmr δ: 2.10, 2.16, 2.17 (OAc's), 8.28 (s, 1, H-8); ^{19}F nmr δ: −50.9 (s, 1, F-2); ms *m/z*: 430.0685 (0.5%, M^+ [$C_{16}H_{16}{}^{35}ClFN_4O_7$] = 430.0691), 259.0764 (100%, M^+ −B), 173.0029 (13%, BH_2 = 173.0030). *Anal.* calcd. for $C_{16}H_{16}ClFN_4O_7$: C 44.62, H 3.74, N 13.01; found: C 44.48, H 3.74, N 12.93.

*9-(2,3,5-Tri-*O*-acetyl-*β*-*D*-ribofuranosyl)-2-chloro-6-fluoropurine (4a)*

Dry dichloroethane (15 mL) was added with stirring at 0°C to 500 mg (1.2 mmol) of **1***a* and 500 mg (2.2 mmol) of $SbCl_3$. The suspension was cooled to −10°C and 0.5 mL (4.3 mmol) of TBN was added. The mixture was stirred at −10 to −5°C for 3 h and was poured into a stirred mixture of 2 g of $NaHCO_3$ in 50 mL of crushed ice/water. The resulting mixture was filtered directly into a separatory funnel and the filtrate was extracted with 5 × 15 mL of $CHCl_3$. The combined organic phase was washed with H_2O, dried over $MgSO_4$ for 2 h, filtered, and evaporated to dryness. The pale yellow glassy residue was dissolved in 10 mL of $CHCl_3$ and filtered through a column (1 × 1.5 cm) of silica. The column was washed with $CHCl_3$ and 0.5 mL of 1-butanol was added to the combined eluate. This solution was evaporated slowly to remove most of the $CHCl_3$. The resulting suspension was refrigerated at 5°C overnight, filtered, and the crystals were washed with ether to give 403 mg (77%) of **4***a*, mp 167–168°C; uv (MeOH) max: 254, 245 nm (ε 6700, 6600); ^{1}H nmr δ: 2.13, 2.18, 2.21 (OAc's), 8.30 (s, 1, H-8); ^{19}F nmr δ: −66.3 (s, 1, F-6); ms *m/z*: 430.0681 (1.2%, M^+ [$C_{16}H_{16}{}^{35}ClFN_4O_7$] = 430.0691), 259.0683 (100%, M^+ − B), 173.0029 (23%, BH_2 = 173.0031). *Anal.* calcd. for $C_{16}H_{16}ClFN_4O_7$: C 44.62, H 3.74, N 13.01; found: C 44.40, H 3.69, N 13.03.

*9-(2,3,5-Tri-*O*-acetyl-*β*-*D*-ribofuranosyl)-2,6-dichloropurine (4b)*

A stirred solution of 2.14 g (5 mmol) of **1***b* in 80 mL of dry, 1,2-dichloroethane was cooled to −10°C and 1.6 g (7 mmol) of $SbCl_3$ in 10 mL of dry dichloroethane was added. After stirring for 5 min, 3 mL (26 mmol) of TBN was added and the suspension was stirred at −10°C for 2.5 h. Evolution of ~110 mL (~ quantitative) of N_2 was measured by displacement of water from a buret. The reaction mixture was poured over 30 g of crushed ice and stirred for 3 min. The mixture was filtered directly into a separatory funnel that contained crushed ice. The filtrate was extracted with 50 mL of $CHCl_3$. The combined organic phase was washed with 4 × 40 mL of ice and water, 5% $NaHCO_3/H_2O$ to pH ~7, dried over $MgSO_4$ for 1 h, filtered, and evaporated to ~20 mL. This yellow solution was filtered through a column (1 cm dia) of 3 cm of silica, 400 mg of decolorizing carbon, and 2 cm of silica. The column was washed with 150 mL of $CHCl_3$ and 60 mL of 2-propanol was added to the combined eluate. This solution was evaporated slowly to ~30 mL and the cream-colored crystals were filtered, washed with 2-propanol, and dried *in vacuo* to give 1.88 g (84%) of **4***b*, mp 167–168°C; uv (MeOH) max: 273, 252 nm (ε 9100, 5100); ^{1}H nmr δ: 2.08, 2.14, 2.16 (OAc's), 8.26 (s, 1, H-8); ms *m/z*: 446.0404 (1.3%, M^+ [$C_{16}H_{16}{}^{35}Cl_2N_4O_7$] = 446.0396), 259.0824 (100%, M^+ −B). This product was identical to that prepared in ref. 1.

*9-(2,3,5-Tri-*O*-acetyl-*β*-*D*-ribofuranosyl)-2-bromo-6-fluoropurine (5a)*

Dry dibromomethane (15 mL) was cooled to 0°C and added with stirring to a mixture of 500 mg (1.22 mmol) of **1***a* and 600 mg (1.66 mmol) of $SbBr_3$. The mixture was cooled to −10°C and treated with 0.5 mL (4.3 mmol) of TBN. Stirring was continued at −10° to −5°C for 3.5 h and the mixture was processed as in the conversion of **1***a* → **4***a* to give 422 mg (73%) of **5***a*, mp 186–187°C; uv (MeOH) max: 256 nm (ε 8800); ^{1}H nmr δ: 2.11, 2.16, 2.19 (OAc's), 8.24 (s, 1, H-8); ^{19}F nmr δ: −66.0 (s, 1, F-6); ms *m/z*: 474.0186 (0.5%, M^+ [$C_{16}H_{16}{}^{79}BrFN_4O_7$] = 474.0186), 259.0818 (100%, M^+ −B). *Anal.* calcd. for $C_{16}H_{16}BrFN_4O_7$: C 40.44, H 3.39, N 11.79; found: C 40.00, H 3.30, N 11.75.

*9-(2,3,5-Tri-*O*-acetyl-*β*-*D*-ribofuranosyl)-2-bromo-6-chloropurine (5b)*

A solution of 0.63 g (1.74 mmol) of $SbBr_3$ in 2 mL of CH_2Br_2 was added to a stirred solution of 0.5 g (1.17 mmol) of **1***b* in 20 mL of CH_2Br_2 at −10°C. TBN (0.75 mL, 6.4 mmol) was added, the mixture was stirred at −10°C for 2 h, and poured into a stirred mixture of 1 g of $NaHCO_3$ in 150 mL of crushed ice/H_2O. This mixture was filtered directly into a separatory funnel and extracted with 3 × 20 mL of $CHCl_3$. The combined organic phase was washed with 20 mL of H_2O, dried over $MgSO_4$ for 1 h, filtered, and evaporated to dryness. The heavy oil was dissolved in 5 mL of CH_2Cl_2 and 10 mL of MeOH and this solution was evaporated slowly to ~3 mL. The off-white crystals were filtered, washed with ether, and dried *in vacuo* to give 448 mg (78%) of **5***b*, mp 171–172°C; lit. (12) mp 153–154°C; uv (MeOH) max: 274, 253 nm (ε 9300, 5300); lit. (12) uv (MeOH) max: 274, 253 nm; ^{1}H nmr δ: 2.11, 2.15, 2.18 (OAc's), 8.28 (s, 1, H-8); ms *m/z*: 259.0826 (100%, M^+ −B), 232.9227 (11%, BH_2 = 232.9229), 231.9152 (3.6%, BH = 231.9151). *Anal.* calcd. for $C_{16}H_{16}BrClN_4O_7$: C 39.09, H 3.28, N 11.40; found: C 38.72, H 3.33, N 11.46.

Thione photochemistry: on the formation of dipyranylidenes from pyranthiones[1,2]

NADER BERENJIAN AND PAUL DE MAYO

Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received March 19, 1981

NADER BERENJIAN and PAUL DE MAYO. Can. J. Chem. **59**, 2612 (1981).

The irradiation of the pyranthione **1** has been reinvestigated. The reaction proceeds through the (n,π^*) triplet and can be quenched with ferrocene. The reaction can be sensitized with Michler's ketone or triphenylene. The elimination of sulfur from two molecules of **1** to give the dipyranylidene **2** requires, surprisingly, a hydrogen donor solvent, and the quantum yield of product has been found to increase with greater dilution, presumably because of the well-known quenching of triplet thiones by the ground state thione. A mechanism for the formation of **2** is suggested.

NADER BERENJIAN et PAUL DE MAYO. Can. J. Chem. **59**, 2612 (1981).

On a repris l'étude de l'irradiation du pyranthione **1**. La réaction se fait par l'intermédiaire d'un triplet (n,π^*) et peut être bloquée par un ferrocène. Elle peut être sensibilisée par la cétone de Michler ou le triphénylène. L'élimination du soufre à partir de deux molécules de **1** qui conduit au dipyranilidène **2** nécessite, de façon étonnante, un solvant donneur de proton. On a trouvé qu'une plus grande dilution augmente le rendement quantique probablement à cause de la propriété bien connue, que possède le thione à l'état fondamental, de bloquer les thiones à l'état triplet. On propose un mécanisme qui explique la formation de **2**.

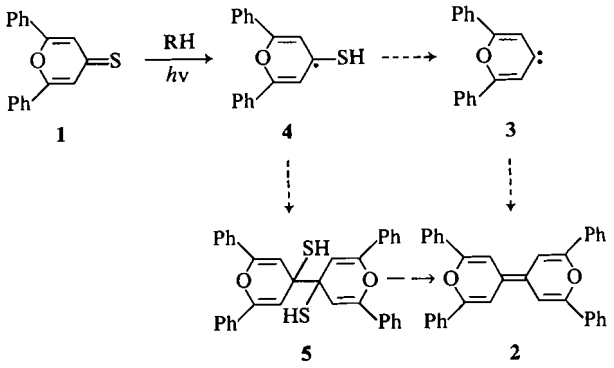
The dimerization of thiones under thermolytic conditions, with the elimination of sulphur to give ethylenes, is a well-known reaction (see for instance, refs. 1–3); the induction of the same reaction under the action of light has been less frequently reported (4–6).

The photolysis of 2,6-diphenyl-4*H*-pyran-4-thione **1** to give **2** has been described (6) and the mechanism of this reaction has already been subject to some study. These earlier findings may be summarized as follows. (*a*) The reaction proceeded far better, i.e. in greater quantum yield, in solvents capable of hydrogen donation (isopropanol, dioxan, tetrahydrofuran) than in poor donors (benzene, acetonitrile). (*b*) The quantum yields of **2** increased with increasing thione concentration. (*c*) The formation of **2** was sensitized by Michler's ketone very efficiently ($\phi = 0.8$) and could be quenched (ca. 30%) by 3.2×10^{-2} *M* piperylene ($E_T \sim 57$ kcal/mol). Further, it was found (*d*) that the sulfur was not eliminated as elemental sulfur; and that two moles of hydrogen sulfide were detected for every mole of **2** formed. On this basis the possibilities indicated in Scheme 1 were proposed, the reaction deriving from the triplet of **1**.

Our attention was attracted by a number of disturbing features in the above proposals. First, the dimerization of the carbene **3** in an alcoholic solvent seemed improbable, in view of the ready addition of alcohols to carbenes (7), yet the reported yield of **2** found in isopropanol was high. In such good reducing solvents as tetrahydrofuran and dioxan, hydrogen abstraction by a carbene would also be expected.[3] Secondly, the formation of the carbene **3** itself appears to be without precedent (see, however, ref. 8). Finally, the formation of **2** via **4**, by whatever route, requires at least *two* photons, aside from any light concerned in the conversion of **4** → **3** or of **5** → **2**. The quantum yields for formation of **2** reported are very high and, on occasion, exceed the maximal possible, i.e., 0.5 (required since *two* molecules of **4** give one of **2**). For these reasons we were led to reinvestigate the reaction. Whilst the details have not been completely elucidated the general outline seems secure.



SCHEME 1

The thione **1** and 4-thioflavone **6** were prepared

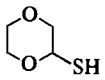
6 7

by a published procedure (2) and their properties were in accord with those in the literature (10–13).[4]

As previously described (6), **1** on irradiation through Pyrex in dioxan gave **2** in 70% yield. Irradiation of **6** gave the known **7** (2) in fair chemical yield, depending on the solvent.

We repeated the hydrogen sulfide estimation reported (6), but with an appropriate control, and we could find but 5–6% of the theoretical amount, as against the quantitative yield previously noted. This discrepancy in results may, perhaps, be attributed to iodine volatilization (see Experimental). The same low value for hydrogen sulfide formation was obtained by the precipitation and weighing of copper sulfide from acidified copper sulfate. It thus appeared that hydrogen sulfide was *not* the ultimate fate of the sulfur. It was confirmed that elemental sulfur was not present (6), and a search was, therefore, made in the solvent for sulfur-containing materials. An end-product was found in the form of 1,4-dioxan-2-thiol **8** which was present in substantial quantity: it was identified by comparison with a synthetic specimen. Unfortunately, our inability to isolate **8** in pure form precluded quantitative estimation.



8

To confirm this identification **1** was irradiated in toluene solution; amongst the many products those identified were phenylmethanethiol, benzyl disulfide, and dibenzyl disulfide. The yield of the thiol was 11%; the other compounds were not accurately estimated, but were present in comparable amounts.

The multiplicity of the reactive state was further examined. The reaction was indeed, as reported, sensitized by Michler's ketone and, in addition, was sensitized by triphenylene where the possibility of carbonyl–thiocarbonyl interaction is excluded. Quenching by piperylene was previously reported as inefficient (6), possibly because of the relative energies of the quencher and thione. We determined the latter from the 0–0 band in the phosphorescence spectrum in EPA at 77 K (Fig. 1) and found a value of 48.8 kcal/mol (λ_{max} 586 nm). For this reason, and because of its relatively low absorbance at 360 nm, ferrocene ($E_T \sim 43$ kcal/mol) (14) was selected as a quencher. A Stern–Volmer plot (**1**; [6.8×10^{-4} *M*]) gave a good ($r = 0.999$) straight line with slope 1150 M^{-1} to 90% quenching (see Fig. 2). The value of k_{diff} calculated with the modified Debye equation was 7.8×10^9 M^{-1} s^{-1} from which a value of τ, the triplet lifetime under the condition of the experiment (dioxan solution), was found to be 1.3×10^{-7} s. This is somewhat shorter than that estimated, 3.0×10^{-7} s, for a comparable concentration of xanthione, the closest available model, in isopropanol (15). It is in general agreement with that expected for triplet thione decay (16).

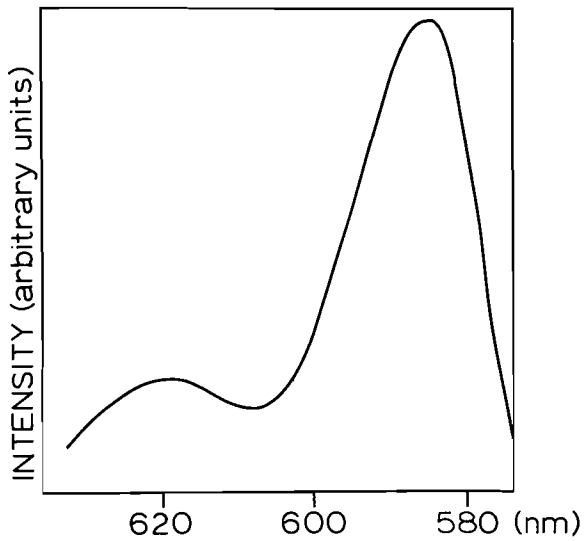


FIG. 1. Phosphorescence of **1** in EPA at 77 K.

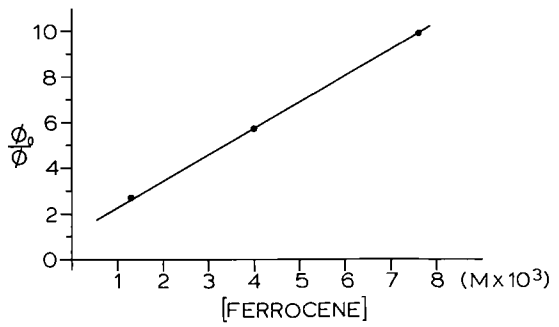

FIG. 2. Stern–Volmer plot for the quenching of **2** formation by ferrocene. The concentration of **1** was 6.8×10^{-4} *M* and the slope 1150 M^{-1} ($r = 0.999$).

[4]The data recorded for **1** in ref. 6 are not consistent with these.

TABLE 1. Quantum yields of formation of **2** in various solvents at 360 ± 5 nm

Solvent	Concentration of **1** ($M \times 10^{-4}$)	ϕ*†
Dioxan	2270‡	8.2×10^{-4}
	37	3.0×10^{-3}
	25	6.0×10^{-2}
	17	7.3×10^{-2}
	6.8	1.1×10^{-2}
Benzene	4.1	5.0×10^{-5}
Tetrahydrofuran	7.4	2.2×10^{-1}
Diethyl ether	4.5	8.0×10^{-2}
Acetonitrile	6.0	1.8×10^{-5}
Toluene	9.0	1.1×10^{-2}

*±10%.
†Irradiations were from 1–7% conversion.
‡Also irradiated at 458±9 nm; $\phi = 9.4 \times 10^{-4}$.

A common characteristic of all triplet thiones so far examined (16) is the quenching of the excited state by ground state thione. This process appears to be close to diffusion controlled (16–18). Hence, any chemical reaction proceeding from the triplet state would, unless its rate constant were comparable with that of ground state quenching, be expected to diminish in quantum yield with increasing thione concentration, and there is ample precedent to support this expectation (16). However, in the examination of **1** the reverse observation was originally reported (6). We, therefore, determined the effect of thione concentration on the quantum yield of **2** formation in dioxan solution. The results are tabulated in Table 1, and, indeed, the expected tendency was revealed.[5]

From the foregoing the following may be concluded. The reaction of **1** to give **2** proceeds from the triplet of the thione which, for spectral reasons, is designated as n,π^*. This assignment is consonant with its solution lifetime.

We have shown that the quantum yield is independent of exciting wavelength, by irradiating at 458±9 nm at the highest concentration of **1** used (Table 1). After correction for the small amount of light not absorbed, the quantum yield was identical with that obtained by excitation at 360 ± 5 nm.

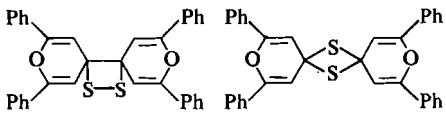
As had been previously shown (6) the reaction requires the presence of a hydrogen donor. A process such as that indicated in eqs. [1]–[3], where

[1] $^3(\mathbf{1}) + \mathbf{1} \longrightarrow \mathbf{2.1}$

[2] $^3(\mathbf{1}) + \mathbf{1} \longrightarrow \mathbf{9} \xrightarrow{?} \mathbf{2}$

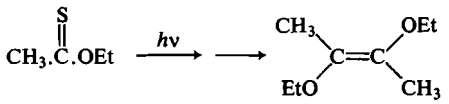
[3] $^3(\mathbf{1}) + \mathbf{1} \longrightarrow \mathbf{10} \xrightarrow{?} \mathbf{2}$

[5]We are unable to explain the fact that our quantum yields, under comparable conditions, differ by orders of magnitude, in some cases, from those previously reported (6).

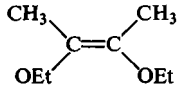


9 **10**

9 and **10** are the 1,2- and 1,3-dithietanes, respectively, must be discarded. 1,2-Dithietanes have not yet been prepared, whilst dimerization to 1,3-dithietanes has only been observed for aliphatic thiones. In its need for a hydrogen donor the present reaction differs from the only analogous process in the literature, the irradiation of **11**, in the absence of a solvent, to give **12** (4,5). In this case the ethyl group could act as donor, but the reported yield of **12** is too high for **11** to be its own hydrogen source, at least on an equivalent basis. The mechanism for the formation of **12** is unknown and 1,2-and 1,3-dithietanes have been suggested as intermediates.

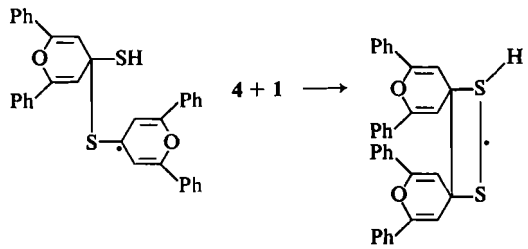


11 **12*a***

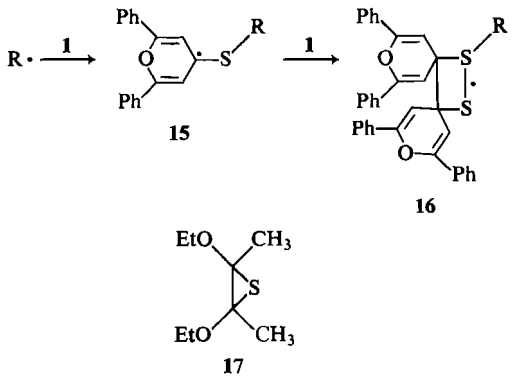


12*b*

The first step in the present reaction is most probably hydrogen abstraction by the excited **1**. Since this is the triplet (n,π^*) state the radical **4** should be the first intermediate formed, together with the radical R derived from the solvent. The following step, in view of the well-established radical scavenging abilities of thiones (19) should be reaction of **4** with **1**, in competition with disproportionation of R and **4** to regenerate starting material, **1** (15). If addition gave the radical **13** there appears no very plausible route from **13** to **2**; in particular, rearrangement to **14** would not be expected (20).



13 **14**



15 16 17

In view of the known comparative stability of radicals of the type $R_2\dot{S}SR$ (21) we suggest that cycloaddition of **4** to **1** does occur to give **14** where the extra electron is in a low-lying σ^* orbital of the S—S bond. Many possibilities are now open to **14**, including decomposition to **2** and HSS·. The latter may lead to the solvent insertion products observed. However, the situation is more complex since the solvent radical may also be trapped by thione to give **15**, itself reacting with a second molecule of **1** to give **16** which may also serve as a source of **2** (and RSS·).

The elimination of sulfur from **14** or **16** does not, howver, have to occur in one step: an episulfide may be an intermediate, and, in fact, the isolation of a small amount of **17** has already been reported in the irradiation of **11**. The elimination of sulfur from aromatic episulfides may occur easily thermolytically (see, for example, ref. 1) or by the action of alkyl radicals (9).

Experimental

General Procedure

The nmr spectra were recorded on Varian T-60 and XL 100 spectrometers with TMS as internal standard. Mass spectra were obtained on a MAT-311A spectrometer. The emission spectrum was measured in EPA at 77 K using a Jarrel-Ash model 82-020 spectrophotometer equipped with an EM1 9558QD Photomultiplier (S-20 response) which was cooled with solid carbon dioxide. This was connected to an Ortec (model 454) timing filter amplifier and fast discriminator (model 417). The signal was accumulated in a multichannel analyzer (Geos system model 7010) operating in the signal-averaging mode. The emission spectra were not corrected for photomultiplier response. The light source was a 150-W Xenon Hanovia lamp, the output of which was passed through a Bausch and Lomb 0.25-m monochromator. The spectrum is shown in Fig. 1.

Materials

2,6-Diphenyl-4*H*-pyran-4-thione **1** and 4-thioflavone **6** were prepared by a published procedure (2) and their melting points and spectra were as reported (10–12). The ultraviolet spectrum of **1** in pure dioxan showed the following bands: 256 (16 500), 233 (22 800), 378 (21 000), 538 (70) nm, unchanged on recrystallization. These data are not in accord with those recorded in ref. 6. Dioxan was purified by the method of Palyi (22). Tetrahydrofuran (Caledon Laboratories Ltd.) was purified by distillation over lithium aluminum hydride. Toluene and benzene were distilled prior to use. Diethyl ether (Fisher) and acetonitrile (Aldrich, Gold Label) were used as received.

Quantum Yield Determinations

Samples were degassed by at least three freeze–pump–thaw cycles to a residual pressure of 2×10^{-5} mm. The quantum yields were determined at 362 nm in a Spectroirradiator (Jasco). The light intensity was calibrated at 362 ± 8 nm using ferrioxalate actinometry; that at 548 nm was related to that at 362 nm using a thermopile. The results are given in Table 1. The yield of **2** was determined spectophotometrically at 458 and 480 nm on a Cary 118 spectrophotometer. At a thione **1** concentration of 6.8×10^{-4} *M* quantum yields were determined in the presence of ferrocene (Fig. 2). A plot of Φ_0/Φ versus the ferrocene concentration gave a straight line ($r = 0.999$) of slope 1150 M^{-1}. The quantum yield of **2** formation was also determined at 548 ± 9 nm (97% light absorbed) (Table 1).

Irradiations

As a control, 80 mL thione **1** solution in dioxane was irradiated under nitrogen through Pyrex with a 450 W medium pressure lamp for 6 h with almost complete consumption of starting material. The residue, after removal of solvent, was crystallized from xylene to give **2** in 70% yield.

The above irradiation was repeated, the hydrogen sulfide produced being entrained by nitrogen and passed through an acidified $CuSO_4$ solution (1 *M*). The sulfide precipitate was collected, washed, and dried (100°C) and was equivalent to a yield of hydrogen sulfide of 6%.

A similar solution was irradiated with the passage of nitrogen being directed into a standardized solution of iodine in aqueous potassium iodide. The excess iodine remaining was then estimated with sodium thiosulfate in the usual way (23). Although the vapour pressure of iodine over triiodide is less than over water it is, nonetheless, appreciable. To correct for the loss of iodine entrained by the passage of nitrogen an appropriate blank was carried out. With correction for the iodine loss the hydrogen sulfide estimated was 7%, but the correction was very large. If not made this could account for the large discrepancy between the earlier results (6) and those here reported.

Irradiation of Thioflavone 6

Thioflavone (85 mg) in diethyl ether (40 mL) was irradiated for 4.5 h through Pyrex with a 450 W medium pressure lamp. After evaporation of the solvent, crystallization (ethanol) of the residue gave 7 (9) in 33% yield, mass spectrum *m/e*: 412 (100, M^+) 413 (37), 307 (16), 206 (40), 169 (28). In other solvents, under similar conditions the following yields were obtained: dioxan (45%), cyclohexane (47%).

Analysis for Sulfur-containing Substances

(a) Irradiation with Toluene as Solvent

The thione **1** (99 mg) in toluene (40 mL) was irradiated through Pyrex with a 450 W medium pressure lamp for 13 h. The resulting solution was concentrated under reduced pressure at room temperature. The residue was analyzed by glc (5 ft. × ⅛ in., 3% SE 30 on Chromosorb P) and by glc–ms. Phenylmethanethiol, dibenzyl sulfide, and dibenzyl disulfide were identified. The yield of phenylmethanethiol (calibrating compound: diethyl succinate) was 11%.

(b) Irradiation with Dioxan as Solvent

The thione (48 mg) in dioxane (40 mL) was irradiated as described above until completion (5 h). Analysis of a portion by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

tlc (hexane as eluent) did not reveal the presence of sulfur, nor was a positive indication given with the benzoin spot-test (24).

The remainder of the irradiated solution was concentrated under reduced pressure at room temperature. Gas–liquid chromatographic analysis revealed the presence of 1,4-dioxan-2-thiol in significant amount, mass spectrum *m/e*: 120 (23, M^+), 87 (100). The thiol itself was prepared by the method of Ketcham and co-workers (25) but was not obtained completely pure though sufficiently so to establish identity. *Exact Mass* calcd. for $C_4H_8O_2S$: 120.0245; found (ms): 120.0228.

Sensitization Experiments

(a) Michler's Ketone

The thione **1** (1.28×10^{-3} *M*) and the ketone (6.12×10^{-2} *M*) were irradiated in dioxane at 360 nm so that the ketone absorbed 90% of the light. Isolation of the product in the usual way afforded **2**.

(b) Triphenylene

The thione **1** (5.6×10^{-4} *M*; 3 mL) containing triphenylene (6.2×10^{-3} *M*) in tetrahydrofuran was irradiated at 280 ± 5 nm such that 97% of the light was absorbed by the hydrocarbon. Appearance of **2** was estimated at 458 nm with a quantum yield of 0.104 ± 0.01.

A facile, versatile procedure for the preparation of fatty acid esters suitable for glc or hplc analyses

J. STUART GROSSERT,[1] W. M. NIMAL RATNAYAKE, AND TIW SWEE
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3
Received January 19, 1981

J. STUART GROSSERT, W. M. NIMAL RATNAYAKE, and TIW SWEE. Can. J. Chem. **59**, 2617 (1981).

The preparation of fatty acid methyl esters for glc analyses and of various aryl esters for hplc analyses has traditionally been carried out in totally unrelated operations. This paper draws attention to the use of fatty acid – trifluoroacetic acid mixed anhydrides which may be directly and efficiently converted into either type of ester. The utility of the method was demonstrated by the preparation of a series of methyl, 2-naphthyl, and vanillin fatty acid esters. The spectral characterization of some aryl fatty acid esters is recorded.

J. STUART GROSSERT, W. M. NIMAL RATNAYAKE et TIW SWEE. Can. J. Chem. **59**, 2617 (1981).

On a préparé des esters méthyliques d'acides gras en vue des analyses en cpg et différents esters aryliques en vue des analyses en clhp selon une méthode nouvelle qui utilise des réactions classiques. Cette publication attire l'attention sur l'utilisation d'anhydrides mixtes d'acides gras et d'acide trifluoroacétique qui peuvent être transformés directement et efficacement en n'importe quel type d'esters. On démontre l'utilité de la méthode en préparant une série d'esters méthyliques, naphtaliques-2 et vanilliques d'acides gras. On a enregistré les caractéristiques spectrales de quelques esters aryliques d'acides gras.

[Traduit par le journal]

The chromatographic separation and analysis of fatty acids from complex natural lipid mixtures is normally carried out on some suitable derivative of the acids (1–4). For example, gas chromatography (glc) is conveniently carried out on the reasonably volatile methyl esters (1,4). On the other hand, the best detectors available for modern liquid chromatography (hplc) work on spectrophotometric (generally at 254, 280, or 360 nm) or fluorimetric principles. Since very few naturally occurring fatty acids possess chromophores which absorb above 220 nm (5), it is necessary to derivatize the acids in order to achieve adequate sensitivity. Derivatives commonly used for this purpose, for example aryl esters, have chromophores that absorb at appropriate wavelengths (3).

There are many ways of converting carboxylic acids into esters, although in principle most reactions are of the general type set out in eq. [1], where X^+ is some electrophilic activator and YOR is some suitable oxygen nucleophile, usually an alcohol.

$$[1]\quad R\cdot CO\cdot OH + X^+ \rightarrow [RCO_2HX]^+ + YOR \rightarrow R\cdot CO\cdot OR + [HOXY]^+$$

Methyl esters are usually produced from free fatty acids by reaction with 1–2% sulfuric acid in methanol (6), with anhydrous hydrogen chloride in methanol (4), with boron trifluoride in anhydrous methanol (2), or with diazomethane (2, 7). Although the first three of these methods are popular, all suffer from the common problem of employing a strongly acidic medium which destroys acid-labile functionalities in such natural compounds as cyclopropane, cyclopropene, epoxy and phytenic acids (8–10). Other artefacts may be formed if reagents such as BF_3–MeOH are not used with caution (11). Even use of a reagent as well known as diazomethane is not without difficulties with complex naturally occurring mixtures where *rapid and quantitative reaction* is required (7); in addition, it is well known to be toxic and potentially explosive.

There are two generally used approaches to the preparation of fatty acid esters suitable for uv detection with hplc. The first approach utilizes carboxylate anions to attack reactive aralkyl halides, e.g. phenacyl bromide, to prepare phenacyl esters (2). The other major approach is to use aryldiazomethanes (2) or aryltriazenes (12) which react by loss of nitrogen. Difficulties that pertain to both the above approaches are that the reactions are not very facile and require heating, often with excesses of expensive reagents.

Carboxylic acids have also been esterified by heating with amide acetals (2), a method first developed by Meerwein *et al.* (13). This approach has been popularized commercially in that a range of acetals is readily available and carboxylic acids are heated with the acetal in pyridine to effect esterification. However, the reaction is not necessarily quantitative and relatively vigorous conditions are needed to provide a reasonable rate of reaction.

Our initial approach to facilitating ester formation was to explore activation of the carboxylic acid

TABLE 1. The yields of esters prepared by the mixed anhydride method in the presence of sodium fluoride*

Fatty acid	Oxygen nucleophile	Isolated yield of ester
Octadecanoic (**3**)	MeOH (1 mL)–pyridine (1 mL)	63
Octadecanoic (**3**)	MeOH (2 mL)–pyridine (1 mL)	62
cis-9-Octadecenoic (**4**)	MeOH (1 mL)–pyridine (1 mL)	59
Octadecanoic (**3**)	Vanillin (70 mg)–pyridine (1 mL)	72
Octadecanoic (**3**)	DMF–DMA (1 mL)†	73
dl-*cis*-9,10-Methyleneoctadecanoic (**5**)	DMF–DMA (1 mL)†	68
dl-*cis*-9,10-Epoxyoctadecanoic (**6**)	DMF–DMA (1 mL)†	‡
dl-*threo*-9,10-dihydroxyoctadecanoic (**7**)	DMF–DMA (1 mL)†	‡

*Other bases such as pyridine or sodium acetate gave much lower yields than did sodium fluoride.
†*N*,*N*-Dimethylformamide dimethyl acetal (2 mequiv./mL in pyridine; Pierce Chemical Co., Rockford, IL., U.S.A.).
‡Not isolated due to the complexity of the mixture, see Experimental.

with trifluoroacetic acid anhydride (TFAA) in the presence of sodium fluoride (to act as acid scavenger), followed by treatment with the dimethyl acetal of *N*,*N*-dimethylformamide ($Me_2NCH(OMe)_2$, **1**) (2). The reaction was rapid and facile since it would be carried out at room temperature. However, yields of methyl esters were no better than 75% (Table 1). It could well be that although the NaF would facilitate mixed anhydride formation (eq. [2]), it would suppress acylium ion formation, which is acid catalyzed (eq. [3]) (14). Presumably acylium ions are the active species that react with **1** to form the methyl esters. Furthermore the reaction was not useful for the esterification of acid-sensitive molecules such as **6** and **7** (Table 1).

[2] $RCOOH + (CF_3CO)_2O \rightleftharpoons RCOO{\cdot}COCF_3\,(\mathbf{2}) + CF_3COOH$

[3] $RCOO{\cdot}COCF_3 + H^+ \rightleftharpoons RCO^+ + CF_3COOH$

We then explored the utility of ester formation from fatty acids by a method first described by Bourne *et al.* (15), which does not appear to be widely known. The method is simple and versatile, since it involves only activation of a carboxylic acid with TFAA in an inert solvent to form **2**, which is rapidly susceptible to attack by a *wide range* of alcohols or phenols to form esters. It may be used on hindered acids (14). However, it does suffer from the drawback of being unsuited for acid-labile fatty acids. It is the purpose of this paper to draw attention to the versatility of this method of ester formation, and in particular to the fact that *both* methyl esters (for glc analyses) or aryl esters (for hplc analyses) are directly accessible from one common intermediate (eq. [4]). This is of special value for hplc analyses since a wide range of phenols and aryl-containing alcohols is readily available. Results are given in Table 2. Yields were very good, except in the cases of **6** and **7** which were obviously labile to the conditions of mixed anhydride formation (see also Table 1).

[4] $RCOOH \xrightarrow{TFAA} RCOO{\cdot}COCF_3 \xrightarrow{R'OH} RCOOR'$

In order to test the practical applicability of the method, the fatty acids from herring oil were converted into methyl esters by both the mixed anhydride method and by the commonly used BF_3–methanol method, a method recommended by the Association of Official Analytical Chemists (16). The methyl esters obtained by both methods were purified by preparative tlc and were analyzed in detail by capillary glc under identical conditions.[2] Twelve saturated, 13 monoenoic, 4 dienoic, 3 trienoic, 7 tetraenoic, 4 pentaenoic, and one hexaenoic fatty acid methyl esters were detected, quantitated, and identified by standard techniques (17). Detailed results on the analyses are presented elsewhere (18). In no case were there any significant differences between the results from the two methods, and with the small samples of acids used, conversion to esters was essentially quantitative.

The aryl esters prepared in this study were novel and their infrared, nmr, and mass spectra were studied. The infrared and nmr spectra of all esters were as expected for molecules containing their functional groups. It is worth noting that vanillin octadecanoate (4-carboxaldehydo-3-methoxyphenyl octadecanoate, **16**) has both aldehydic and methoxyl protons which are particularly characteristic in the ^1H nmr spectrum. The mass spectra of esters **13–16** were totally dominated by peaks attributable to phenol radical cations. This phenomenon is precedented for aryl esters (19), fatty acid benzyl esters (20), and for aryl carbamate esters (21), although we are not aware of any detailed studies on the mass spectrometry of fatty acid aryl esters. In contrast to the mass spectra of fatty acid methyl esters (22), the molecular ions of these aryl esters (**13–16**) were of very low intensity, as were the

[2]We thank Dr. R. G. Ackman for kindly providing the required facilities and advice to carry out these analyses.

TABLE 2. The yields of esters formed by reacting methanol or 2-naphthol with a fatty acid mixed anhydride

Fatty acid	Ester formed	Isolated yield of ester
Octadecanoic (**3**)	Methyl (**8**)	91
cis-9-Octadecenoic (**4**)	Methyl (**9**)	88

classical McLafferty rearrangement ions, $RO{\cdot}C(OH){=}CH_2]^+$ (R = aryl). Only in the case of vanillin octadecanoate (**16**) was there a significant ion at higher mass, viz. *m/z* 267 which corresponds to the ion $C_{17}H_{35}CO]^+$. The only other major ions in all four spectra were low-mass ions, typical of aralkyl precursors.

Although we have only explored the preparation of 2-naphthyl and vanillin esters, the correct choice of derivative in practice will obviously depend on the hplc column and particular separation problem at hand. We conclude by emphasizing that this mixed anhydride method offers ready access to the formation of a wide range of fatty acid derivatives which may be suitable respectively for glc or hplc analyses. This should facilitate transfer of well-established glc methodology, built on methyl esters, to hplc techniques based on ultraviolet-absorbing or fluorescent esters.

Experimental

General

Chemicals used were ACS grade, solvents were distilled and dried according to standard techniques. Trifluoroacetic acid anhydride (TFAA) was used as obtained from the Aldrich Chemical Co. Silica gel for column and thin-layer chromatography was from E. Merck & Co. Silica gel for columns was prewashed with *n*-hexane; tlc plates were developed in ligroin (bp 40–60°C) – diethylether – acetic acid (90:10:1, v/v/v), and material from preparative tlc was removed by extracting three times with chloroform – *n*-hexane (1:1, v/v). Infrared spectra were recorded as liquid films, KBr pellets, or CCl_4 solutions as appropriate; nmr spectra were recorded at 60 MHz in $CDCl_3$ containing 1% TMS as internal standard and chemical shifts are reported in ppm as δ values. Mass spectra were recorded on a DuPont-CEC 21-104 mass spectrometer equipped with a heated glass probe at an ionizing voltage of 70 eV. Gas–liquid chromatography was carried out on a Hewlett-Packard 5750 instrument with an EGSS-X column (1.8 m × 3.2 mm ss column at 180–200°C, N_2 flow 20–30 mL/min, 10% EGSS-X on Chrom W, 80–100 mesh); alternatively, on Perkin-Elmer 900 and 990 instruments with wall-coated, open-tubular capillary columns (ss, 46 m × 0.25 mm) coated with either BDS or Silar-5CP liquid phases (Perkin-Elmer Corp., Norwalk, CT., U.S.A.), He pressure 60 psig, column temp. 170–180°, injection ports and split assemblies 270°, manifold assemblies 250°C.

*Preparation of dl-*cis*-9,10-Methyleneoctadecanoic Acid, 5*

The procedure of Simmons and Smith (23) gave pure **5** in 51% yield, mp 37–38°C (lit. (23) mp 36–38°C); ν_{max}(KBr): 3500–3400 (br), 1720 (s), 1020 (m), 866 (m) cm^{-1}; nmr ($CDCl_3$) δ: −0.3 (1H, m), 0.6 (3H, m), 0.9 (3H, m), 1.3 (26H, m), 2.2–2.3 (2H, m), 9.7–10.0 (1H, br s).

*Preparation of dl-*cis*-9,10-Epoxyoctadecanoic Acid, 6*

The procedure of Swern *et al.* (24) gave pure **6** in 70% yield, mp 58.0–59.0°C (lit. (24) mp 59.5–59.8°C); ν(KBr): 3500–3400 (br), 2950 (s), 2900 (s), 1715 (s), 850 (m) cm^{-1}; nmr ($CDCl_3$) δ: 0.91 (3H), 1.25 (20H), 2.2–2.3 (6H), 2.80 (2H), 9.6–10.0 (1H).

*Preparation of dl-*threo*-9,10-Dihydroxyoctadecanoic Acid, 7*

dl-*cis*-9,10-Epoxyoctadecanoic acid (**6**, 50 mg, 0.16 mmol) in glacial acetic acid (2 mL) was heated in a boiling water bath for 3 h, after which the excess acetic acid was evaporated under reduced pressure. To the residue, 5 *N* NaOH (10 mL) was added, the mixture was heated for 1 h on a boiling water bath, cooled, neutralized with 5 *N* HCl, and extracted with diethyl ether (3 × 50 mL). The extract was washed with water, dried, and evaporated under reduced pressure to give crude **7** as a white powder (45 mg). Recrystallization from methanol gave pure **7** (38 mg, 72%), mp 93–94°C (lit. (24) mp 92–93°C).

Esterification of Fatty Acids by the Mixed Anhydride Method in the Presence of Sodium Fluoride

Fatty acid (100 mg), anhydrous NaF (50 mg), and TFAA (1 mL, added dropwise) were stirred for 5 min at 25°C and then evaporated to dryness under reduced pressure. The above process was repeated with another portion of TFAA. The solution containing the oxygen nucleophile was added slowly and the mixture was stirred for 30 min at 25°C. Isolation of methyl esters was carried out by chromatography on silica gel (6% diethyl ether in ligroin (bp 40–60°C)). Isolation of vanillin octadecanoate (**16**) was achieved by partitioning the reaction mixture between water and ligroin (bp 40–60°C), followed by sequential base and acid washing, plus drying and evaporation of the ligroin solution to give crude **16** which was recrystallized from 95% ethanol. Results are given in Table 1. The identity of the methyl esters was confirmed by comparison with authentic samples. Vanillin octadecanoate had mp 65–66°C; ir (KBr): 1760, 1700, 1690, 1610, 1595, 1150, 800 cm^{-1}; nmr ($CDCl_3$) δ: 0.9 (3H, m), 1.2–2.6 (32H, m), 3.95 (3H, s), 7.1–7.5 (3H, m), and 9.80 (1H, s); mass spectrum *m/z*: 418 ($M^{+\cdot}$, 3) 283 (1), 267 (17), 152 (100), 149 (33), 123 (3), 97 (7), 85 (12), 71 (19), 69 (11), 57 (38), 55 (16), 43 (27), 41 (10).

Methylation of Fatty Acids with Trifluoroacetic Acid Anhydride and Methanol

Fatty acid (ca. 20 mg) was dissolved in benzene (1 mL). TFAA (1 mL) was added dropwise and the solution was stirred

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

for 10 min at 25°C. Anhydrous methanol (1 mL) was then added and the solution stirred for 30 min. The solution was diluted with ligroin (bp 40–60°C, 50 mL) which was washed with sodium hydroxide solution (10%, 3 × 20 mL) and water, dried (Na_2SO_4), and evaporated under reduced pressure, which permitted determination of the percentage yields of the methyl esters. Ester purity was checked by tlc and glc.

Esterification of Fatty Acids with Trifluoroacetic Acid Anhydride and 2-Naphthol

Fatty acid (100 mg, ca. 0.3 mmol), TFAA (1 mL, 7.2 mmol), and 2-naphthol (100 mg, 0.7 mmol) were combined and reacted in benzene as detailed above. Analytical tlc showed **13–15** as major components in the reactions of **3–5**, with minor spots due to **3–5** and 2-naphthol. Reaction of **6** and 7 showed at least 6 components. The esters **13–15** were isolated by dissolving the crude product in diethyl ether (50 mL). This ether solution was washed with sodium hydroxide (10%, 3 × 30 mL), with saturated sodium chloride solution (2 × 50 mL), and then dried and evaporated, as usual. Thin-layer chromatography of all three products showed only one spot. Esters **13** and **15** were recrystallized from 95% ethanol; **14** was a pale yellow oil.

2-Naphthyl octadecanoate, **13**, had mp 70–71°C; ir (KBr): 1750, 1600, 1500, 1280 cm^{-1}; nmr ($CDCl_3$) δ: 0.9 (3H, m), 1.2–1.6 (30H, m) 2.6 (—CO·CH_2—, m), 7.0–8.0 (7H, m); mass spectrum *m/z*: 410 ($M^{+\cdot}$, 4), 144 (100), 127 (1), 115 (7), 67 (7), 65 (9), 55 (12), 43 (16).

2-Naphthyl cis-*9-octadecenoate*, **14**, had ir ($CHCl_3$): 1750, 1600, 1510, 1250, 800 cm^{-1}; nmr ($CDCl_3$) δ: 0.9 (3H, m), 1.2–1.7 (26H, m), 1.8–2.2 (—CH_2·CH=CH·CH_2—, m), 2.60 (—CO·CH_2—, t), 5.40 (—CH=CH—, t), 7.0–8.0 (7H, m); mass spectrum *m/z*: 408 ($M^{+\cdot}$, 3), 379 (0.2), 145 (43), 144 (100), 115 (11), 97 (6), 95 (6), 83 (10), 69 (20), 67 (10), 55 (35), 43 (26).

2-Naphthyl dl-cis-*9,10-methyleneoctadecanoate*, **15**, had mp 66–67°C; ir (KBr): 1750, 1600, 1500, 1280, 1020 cm^{-1}; nmr ($CDCl_3$) δ: −0.73 (1H, m), 0.53–1.0 (6H, m), 1.2–2.1 (26H, m), 2.65 (—CO·CH_2—, t), 7.0–8.0 (7H, m); *m/z*: 422 ($M^{+\cdot}$, 0.2), 393 (3), 186 (0.2), 144 (100), 115 (6), 55 (8), 43 (12).

Preparation of Fatty Acid Methyl Esters from Herring Oil

Herring oil fatty acids were prepared by saponification of herring oil, with the use of a nitrogen atmosphere for all operations. A 10 mg sample of the fatty acids was dissolved in benzene (1 mL) in a 10 mL, screw-capped (Teflon-lined) centrifuge tube. TFAA (1 mL) was added slowly and the mixture was shaken vigorously in a vortex mixer. Anhydrous methanol (1 mL) was added and the mixture shaken for 20 min. Distilled water (4 mL) was added, the mixture again shaken thoroughly, and the methyl esters were extracted with benzene (3 × 2 mL). The benzene extract was concentrated by heating in a stream of nitrogen over a 50°C water bath. Preparative tlc gave 8.7 mg of methyl esters. *Alternatively*, herring oil fatty acids (10 mg) were dissolved in benzene as above, and heated with boron trifluoride – methanol reagent (14%, 1 mL) at 100°C for 10 min. Work-up and purification as above gave a comparable quantity of fatty acid methyl esters. The two methyl ester samples were analyzed under identical conditions by glc on a Silar-5CP capillary column (18).[2]

The *sec*-butyl cation; reaction with 2-butene[1]

PIERRE LACHANCE AND ARTHUR M. EASTHAM
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received December 12, 1980

PIERRE LACHANCE and ARTHUR M. EASTHAM. Can. J. Chem. **59**, 2621 (1981).

The products from the reaction of 2-butene with $BF_3.CH_3OH$ are olefins in the range C_8 to above C_{20}; about 60% of the product is the normal dimer–trimer–tetramer material but the remaining 40% is rearranged product. We have identified most of the skeletal structures up to C_{13} and suggest that the rearrangements are most easily interpreted by postulating that alkyl transfers can occur in the same way as proton transfers.

PIERRE LACHANCE et ARTHUR M. EASTHAM. Can. J. Chem. **59**, 2621 (1981).

La réaction entre le butène-2 et $BF_3.CH_3OH$ donne, comme produit de réaction, un mélange d'oléfines possédant entre huit et plus de vingt carbones. Les dimères, trimères, tétramères normaux forment 60% du produit, tandis que 40% sont des substances transposées. Nous avons identifié la plupart des structures carbonées contenant jusqu'à treize carbones. Aussi nous apparait-il qu'une des façons les plus faciles d'expliquer les transpositions observées, est de supposer un éventuel transfert de groupe alkyle semblable au transfert de proton.

With acidic catalysts of the type $BF_3.HX$, 2-butene can undergo oligomerization to a complex mixture of mono-olefins, generally in the molecular weight range 112 (C_8H_{16}) to somewhat beyond 224 ($C_{16}H_{32}$) (1). About half of the product is the expected dimers, trimers, and tetramers formed by the simple addition reaction but the remainder consists of rearranged products which must be of mechanistic importance if, as seems probable, the rearrangement occurs during the growth-limiting, transfer-termination step of the polymerization. We report here the characterization of most structures up to the tridecenes present in the product, with some suggestions as to how they might have been formed; identification of the remainder of the material, about 25% of the total and generally in the C_{14}–C_{20} range, will be a laborious task to be undertaken only if clearly necessary for interpretation of the results.

The product mixture of olefins, containing small amounts of alkanes and diolefins, can be separated by careful fractional distillation into groups of closely related olefins, usually of a single molecular weight. Each molecular weight group consists of a number of *cis–trans* pairs, usually with more than one carbon skeleton, which cannot be separated with available techniques, so identification of the components must be made within the mixture. Simplification can sometimes be achieved by hydrogenating the fraction in order to convert olefins of the same carbon skeleton to a single alkane but the improvement is often minimal because hydrogenation leads to new asymmetric centers and therefore to stereoisomers which may be clearly visible in the capillary chromatogram. The method used for identifying complex alkanes of this kind was discussed elsewhere (2), and is briefly as follows. The molecular weight and some idea of the structure of the olefin–alkane can be obtained for individual components of the mixture from the capillary chromatograph – mass spectrometer combination. An appropriate alkane is then synthesized by at least two reliable and independent methods and compared with the unknown by retention times and mass spectrum. We are aware that this comparison is not regarded as rigorous, and have in fact experienced the dangers in comparing two compounds on a single capillary column, but we are of the opinion that it is the best method available and is reasonably safe if one uses at least two appropriate capillary columns (e.g. squalane and OV-101). If the pure alkane gives a pattern of several stereoisomers, the comparison becomes very reliable and obviously, when unknown and known have different retention times, rejection of the structure is unequivocal.

The approximate composition of the olefin mixture is as follows:

C_8	10%	C_{14}	4%
C_9	5	C_{15}	3
C_{10}	10	C_{16}	18
C_{11}	8	C_{17}	3
C_{12}	17	C_{18}	5
C_{13}	3	C_{19} and higher	16

This composition is not strongly dependent on reaction variables such as conversion, concentration, etc. Lowering the temperature shifts the product to somewhat higher molecular weights, and prolonged reaction times produce secondary

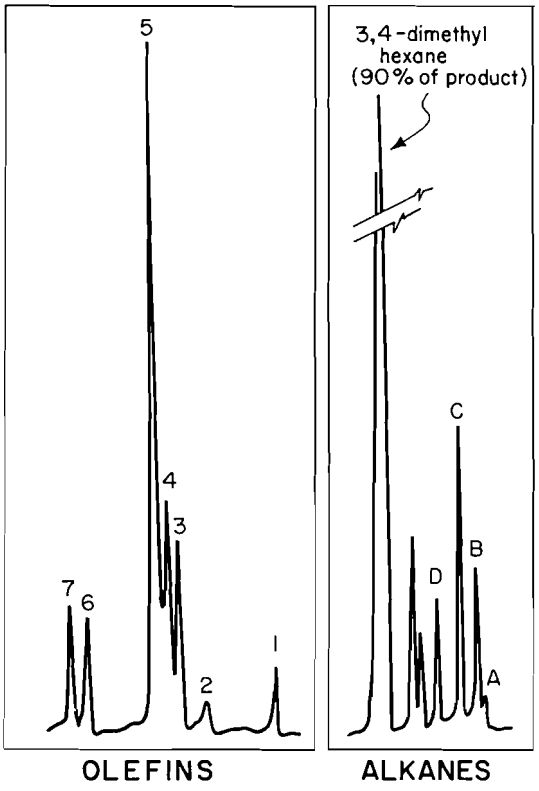

FIG. 1. Chromatograms for octenes and octanes; olefins on 150 ft × 0.01 in. WCOT OV-101 at 50°C, alkanes on 150 ft × 0.01 in. WCOT squalane at 40°C.

reaction products. We have not found products smaller than C_8 but introduction of small amounts of such materials into the reaction mixture indicates that they react with butene and disappear. Addition of small amounts of 2-butene to a nearly completed reaction mixture tends to reduce the relative amount of octenes present, presumably as a result of re-initiation of chain growth. The major peaks in the product chromatogram are, as might be expected, those corresponding to C_8, C_{12}, and C_{16} olefins, i.e. to dimer, trimer, and tetramer. Next largest is C_{10} which should perhaps be compared with $C_9 + C_{11}$, corresponding to symmetrical and unsymmetrical fission of the butene residue. Detailed description of the product follows.

Octenes

The octene fraction and its hydrogenation product are shown as capillary chromatograms in Fig. 1. Over 90% of the octene mixture has the skeletal structure of the expected butene dimer, 3,4-dimethylhexene, made up as follows. Peaks 3 and 5, *cis*- and *trans*-3,4-dimethylhexene-2; 6 and 7, *trans*- and *cis*-3,4-dimethylhexene-3, respectively; 4, 3,4-dimethylhexane. The minor peaks 1 and 2 have not been identified but 2 may be 2-ethyl-3-methyl-1-pentene. Hydrogenation gives rise to the expected large amount of 3,4-dimethylhexane but about 10% of the alkane is made up of half a dozen minor components (see Fig. 1), four of which have been tentatively identified as 2,4-dimethylhexane (A, trace only), 2,2,3-trimethylpentane (B), 3,3-dimethylhexane (C), and 2,3,4-trimethylpentane (D). Absent are 2,3- and 2,5-dimethylhexanes, 2,3,3- and 2,2,4-trimethylpentanes.

Nonenes

The nonenes on hydrogenation give exclusively 3,3,4- (**1**) and 2,3,4-trimethylhexanes (**2**) in the ratio of 2:7 respectively. The latter appears as a well-resolved doublet in both known and unknown materials.

Decenes

The C_{10} fraction consists of about a dozen olefins which on hydrogenation give rise to a very simple product chromatogram, a large singlet (90%) and a small triplet (Fig. 2). The major component was easily identified as 3,4,5-trimethylheptane (**3**) through comparison with a known sample by nmr, ir, etc; it is slightly resolved into the expected doublet by high resolution glc (very small samples, 300 ft WCOT squalane, ms detector) and shows a trace of a third component. The minor constituent alkanes have not been identified but are not 2,2,3,4-, 2,3,3,4-, or 2,3,4,4-tetramethylhexane, 2,4,5- or 3,5,5-trimethylheptane.

According to the mass spectra and retention times it seems probable that the original olefin mixture contains small amounts of two alkanes, one of which is 3,4,5-trimethylheptane.

Undecenes

The problem of identifying hydrocarbons is well illustrated by this C_{11} fraction. The mixture of several olefins, making up about 8% of the total product, upon hydrogenation gives a chromatogram showing a single large multiplet and a few very minor constituents. The multiplet was not well resolved even on 300 ft squalane, but showed identical retention times with the multiplet from an authentic sample of 3,4,5-trimethyl octane (**4**) synthesized for comparison (Fig. 3). We believe the two compounds to be identical except in their stereoisomer ratio. Scanning across the glc peaks with the ms revealed no obvious differences in cracking patterns either between or within the peaks (see ref. 2 for elaboration).

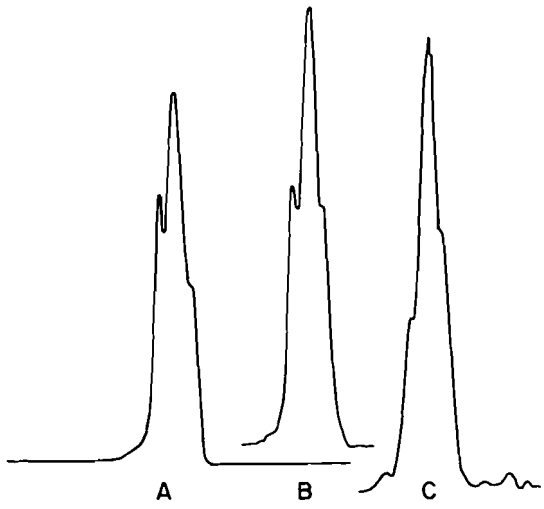

FIG. 3. C_{11} alkane. Chromatogram on 300 ft WCOT squalane at 110°C; A. synthetic 3,4,5-trimethyloctane; B. mixture of known and unknown; C. unknown.

Dodecenes

The C_{12} olefins, 15–20% of the product and therefore the major constituent, were separated from the C_{11} and C_{13} components by careful fractional distillation under reduced pressure and then examined in the glc–ms combination for molecular weight homogeneity. Most of these olefins, unlike the corresponding alkanes, give adequate parent-ion response. Both the C_{12} and C_{13} cuts showed excellent molecular weight purity and the intermediate fraction amounted to only 10–15% of the total C_{12}–C_{13} material.

The C_{12} fraction was hydrogenated to the dodecanes and then, according to glc, contained at least fifteen components, some of them undoubtedly stereoisomers. The major constituent was shown to be the expected butene trimer, 3,4,5,6-tetramethyloctane **5**, identified as described in detail elsewhere (2). In order to obtain some idea of the structure of the rest of the C_{12} constituents, distillation fractions were submitted to ozonization and the products examined by glc–ms. Fractions containing primarily olefins with the skeletal structure of **5** gave the expected C_8 and C_{10} ketones. The remaining C_{12} olefins gave rise to considerable amounts of C_7 ketones which on the basis of retention times on OV-17, OV-101, and UCON 550B were tentatively identified as 3,4- and 3,3-dimethyl-2-pentanone. The C_5 fraction was small and somewhat fleeting but reduction of the ozonide with H_2/Pd instead of low temperature Zn/HOAC gave fair yields and indicated the presence of 2-methylbutanal and 3-methyl-2-butanone. On the basis of these data it seemed probable that the C_{12} mixture contained structures analogous to 3,3,4,6-**7** and 2,3,4,6-tetramethyl octanes **6**.

The 2,3,4,6-tetramethyloctane **6** was synthesized and compared with hydrogenated fractions of the C_{12} olefins. On 150 ft of WCOT squalane the chromatogram of this compound shows a singlet and a poorly resolved multiplet which correspond exactly with an important pair of peaks in the chromatogram of the unknown (Fig. 4). On OV-101 the synthetic material shows a singlet and a nearly completely resolved doublet which match exactly the retention times of three peaks in the unknown, but the ratio of the two components of the doublet appears to be reversed in the two samples.

The 3,3,4,6-tetramethyloctane **7** was prepared by acid dehydration of 4-hydroxy-3,3,4,6-tetramethyloctane without noticeable rearrangement (see Experimental). This alkane appears, in the chromatogram, as a broad singlet which corresponds with a peak shown by the unknown.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

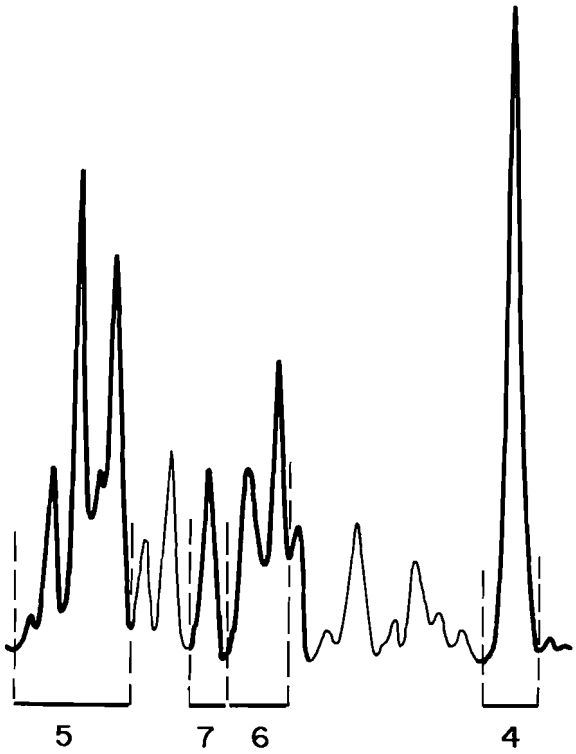

FIG. 4. C_{11} and C_{12} alkanes on 150 ft WCOT squalane at 100°C. Bold lines indicate identified sections; **4**, 3,4,5-trimethyloctane; **5**, 3,4,5,6-tetramethyloctane; **6**, 2,3,4,6-tetramethyloctane; **7**, 3,3,4,6-tetramethyloctane.

The 2,3,4,6- and 3,4,5,6-tetramethyloctanes **6**, **5**, and **7** together made up at least three-quarters of the C_{12} fraction (Fig. 4). The remainder does not include 4-ethyl-3,6-dimethyloctane, 2,3,4,5,5-pentamethylheptane, or 2,5,6,6-tetramethyloctane.

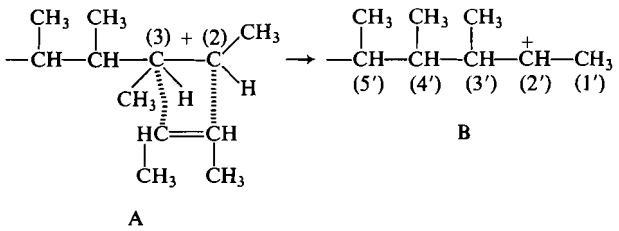
Tridecenes

The C_{13} fraction is rather small and, from analogy with the nonenes, was expected to consist primarily of olefins with skeletal structures corresponding to 2,3,4,5,6- and 3,3,4,5,6-pentamethyloctanes. Both of these were synthesized but only the first corresponded to the hydrogenated unknown. The 2,3,4,5,6-PMO shows one major and five minor peaks in its chromatogram on either squalane or OV-101 and these five peaks correspond exactly to a similar group in the unknown on the same column. The 3,3,4,5,6-isomer, if present at all, is in very small amounts compared to the 2,3,4,5,6-PMO.

The conventional view of a cationic olefin polymerization postulates initial protonation of the olefin (monomer) by the catalyst followed by rapid reaction of the resulting cation with further olefin to give either addition of monomer (chain growth), or transfer of a proton to monomer with initiation of a new polymer (chain transfer). Termination is usually regarded as transfer of the proton back to a catalyst anion but, as we have pointed out before (4), in the case of 2-butene the termination and proton transfer processes approach equivalence since the *sec*-butyl cation is more likely to lose a proton than to react with more butene.

In considering the formation of higher olefins from butene in the light of the above mechanism it is necessary to take account of the following points: (*a*) rearranged products make up over 40% of the total; (*b*) rearrangements are relatively simple; there is no indication of the mobility of groups observed by Deno (15) and others in H_2SO_4; (*c*) there is little alkane or diolefin formed; (*d*) product composition is largely independent of conversion although changes do occur on prolonged contact with catalyst.

We interpret these observations to mean that the olefins formed in the reaction are primary products and that the observed rearrangements occur in the transfer–termination step of the chain reaction. Re-activation of the chain reaction can occur by protonation of the olefin but its effect on the product mix is probably not great. We suggest that most of the observed products can be accounted for if we suppose that the transfer process is not restricted to protons but may include transfer of methyl or other group attached to the pertinent carbon. If we imagine that reaction between cation and olefin proceeds through an intermediate such as A then addition occurs upon completion of the



cation–monomer bond at carbon(2) while transfer occurs if the proton (or other group) at carbon(3) is transferred to butene. We think that these two reactions can occur separately or simultaneously and in either case will yield the "normal" addition products, viz. 3,4-dimethylhexene, 3,4,5,6-tetramethyloctene, etc., as predicted by classical concepts. The only difference in additions with or without proton transfer would be in the location of the regenerated charge at carbon(2′) or (5′) of the new ion B, and consequently either in the position of the resulting double bond, or in the structure of addition products of the new ion. These structural

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

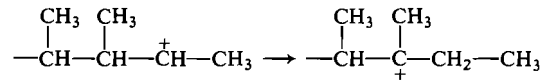
effects would be observable only at the C_{16} levels or above since in the dimer ions carbons (2′) and (5′) are equivalent.

It would be very useful from a mechanistic point of view to know the position of the double bond in a newly-formed olefin. However, we know that the catalyst used here is excellent for olefin equilibration (3), and we have shown that the octene mixture produced in these reactions is very similar to that obtained by treating any one octene isomer with catalyst. On the other hand, ozonization of the dodecanes gave primarily a single product suggesting little migration of the double bonds, but we feel that the uncertainty is too great to permit conclusions.

Consider now the case where the methyl group rather than a proton is transferred to the incoming monomer. If the transfer is accompanied by addition, then in the case of dimer → trimer, the product will be 3,5,6,7-tetramethyloctene-3 (or -4), an important reaction product and one difficult to explain by more conventional mechanisms. If the transfer were to occur at the monomer → dimer stage the hydrogenated product would be a 2,3,4-trimethylpentane which in fact seems to be present though in very small amounts. We consider below the reason why transfers might become more important as the chain lengthens. If transfer occurs without addition, then in the case of the C_{12} cation, the product would be a new C_5 cation and an olefin hydrogenated to 3,4,5-trimethyloctane, again an important reaction product. The C_5 cation $[CH_3—CH(CH_3)—CH—CH_3]^+$ by adding monomer could yield the C_9 olefins giving on hydrogenation 2,3,4- and 3,3,4-trimethylhexane, both major reaction products. According to this scheme, the C_9 olefins should balance the C_{11} and to a rough approximation they do so. We can find no evidence for a C_7 olefin, a point considered in more detail later.

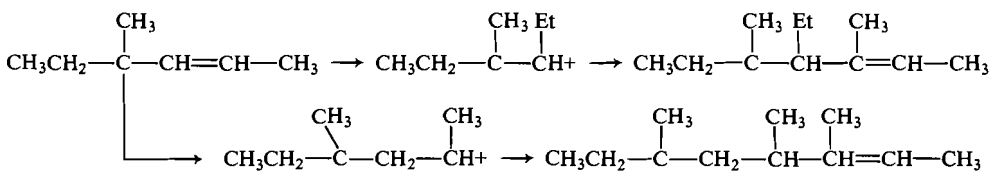
In order to account for the C_{10} olefins we may imagine the transfer of the "ethyl" group from carbon(3) to the monomer but this will require accompanying proton shifts from carbon(3) to (5)[2] and/or from carbon(3) to the leaving cation. If the transfer occurs from a C_{12} cation, then the products will be a C_{10} olefin and a C_6 cation and the latter, by adding monomer, could give rise to another molecule of C_{10} olefin; we can thus account for the large amount of decene formed in the reaction but note that it is somewhat less than the C_9 plus C_{11} formed by methyl transfer.

Perhaps a more satisfactory way of looking at ethyl transfer is to consider what happens if the secondary cation undergoes a hydride shift to give the energetically more favourable tertiary cation:



If this happens, then further addition may be very difficult because the tertiary ion is sterically hindered and because the resulting product would be secondary cation. The probable alternative reaction for the cation would then be to transfer a proton or alkyl group to monomer or catalyst. It should be noted that the difference between this view of ethyl transfer and the previous one is largely in the timing of the hydrogen shift.

The foregoing reaction scheme seems to account satisfactorily for most of the products so far identified but is less effective in dealing with compounds which are not present. Small molecules, in the C_5–C_7 range, are almost completely absent, perhaps because they undergo further reaction but their expected derivatives are also absent. For example if a dimer cation lost a methyl group by transfer one would expect to find the olefin 4-methyl-2-hexene or its derivatives, i.e.,



and these are not present. Another missing compound is the olefin giving 3,3,4,5,6-pentamethyloctane which is expected along with 2,3,4,5,6-pentamethyloctane from addition of two molecules of monomer to the postulated C_5 cation. We have synthesized both of these tridecanes but find only 2,3,4,5,6-PMO in the hydrogenated mixture; the other one is definitely absent.

We are of the opinion that small molecules are absent from the product because they are not formed rather than because they are consumed. It is clear from the formation of substantial amounts

[2]However, in the case of dimer → trimer, the new C_{12} cation, obtained by addition with proton transfer, would carry the charge on carbon(4) and therefore the proton would shift from carbon(3) to (4).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

of normal dimer and trimer (and probably tetramer) that the *sec*-butyl cation and its lower homologues react rapidly with 2-butene, certainly more rapidly than the cation can isomerize. However, it is also clear from molecular models that as the polymer chain lengthens the methyl groups along the chain become increasingly compressed until, at about the pentamer stage, one can no longer add butene units as such. Admittedly models tend to exaggerate steric effects, but when the effects are this pronounced it seems safe to assume that the propagation rate will decline as the chain becomes longer. As this rate declines, the lifetime of an individual ion will increase and with it the probability of rearrangement and termination. The results of our experiments suggest that growth occurs readily to about the trimer stage after which the transfer and termination reactions start to dominate.

We have considered and abandoned the idea that the olefins described here might arise from fission of some longer chain, say a C_{20} or C_{24} oligomer, because we have been unable to devise a convincing scheme to account for the products observed.

It is useful to compare the polymerization of 2-butene and propylene. The latter has little steric restriction to growth and with some catalysts yields very high molecular weights, but under cationic conditions the chain length is limited to about 10–20 units depending somewhat on temperature (4). Kinetic studies (4) show that the molecular weight is independent of olefin concentration, an observation which is usually taken to mean that chain growth is limited by transfer to monomer, i.e. that both growth and transfer (and/or termination) are similarly dependent on monomer concentration as they would be in the present scheme. In comparing the transfer process for these two olefins we note that in the scheme described above a propylene oligomer will have no alkyl groups at carbon(3) and no easy route from a secondary to a tertiary cation, so we would expect little rearrangement. In fact there does seem to be a small amount in the initial stages of reaction (1) but not nearly to the same extent as with 2-butene, and it may cease after the first three or four additions. Proton transfer on the other hand is a common reaction, occurring apparently in about half of the reactions with monomer according to analysis of the molecular weight distribution curve for propylene oligomerization (3*b*). Actually there is some reason to believe that the ratio of addition to transfer increases during the initial stages and then levels off, since the most probable molecular weight appears at about the hexamer and there is little trimer. It is possible that the small amount of low molecular weight products (C_{12} and lower) results from scavenging of impurities but to explain the rapid rise to the maximum one requires a high addition/termination ratio.

In stressing the importance of transfer we are in obvious disagreement with the recent views of Puskas *et al.* (5). We also disagree with those authors in the importance we attach to the position of the olefinic groups. However, our conclusions are based on vastly different kinds of data so doubtless the differences will be resolved by further experiments.

Experimental

Boiling points are uncorrected, microanalyses were performed by H. Seguin of these laboratories. Identification of compounds was done by comparison with authentic samples by glc coinjection and ^{1}H nmr when possible. Capillary WCOT columns (150 ft) with squalane or OV-101 were used for the chromatographic analysis, the OV-101 column giving a better resolution of olefins. The ir spectra were recorded on a Beckman Acculab 4 and nmr spectra on a Varian XL-100. The glc–mass spectra analyses were obtained with a Finnigan 4000.

Polymerization reactions were carried out on a vacuum line using the usual techniques. The alkanes were prepared according to schemes similar to those already published (2). Reactions with organometallic reagents, including Grignards, were performed under argon atmosphere using at least 25% excess reagent. They were worked up by treating the reaction mixtures with NH_4Cl solution and extracting with ether. The dehydrations were performed by mixing β-naphthalene sulfonic acid with the alcohol and heating to boiling for a few minutes. This acid was used because rearrangements appeared to be minimal. The reaction mixtures were then poured into water and extracted with ether or pentane and distilled. Olefin hydrogenations were accomplished at atmospheric pressure over 5% palladium on charcoal as catalyst.

All the intermediates had ir, nmr, and mass spectra consistent with structures proposed for them.

2,4-Dimethylhexane

This compound was prepared by reacting 2-methylbutanal with isopropylmagnesium chloride in ether at −25°C. The octanol obtained (80% yield) was dehydrated and the olefins hydrogenated to 2,4-dimethylhexane; bp 106–107°C, lit. (6) bp 108.5°C; n: 1.3842, lit. (6) n: 1.3967; δ_{TMS} (CCl_4): 0.85 (d, J = 6.5, CH_3—$\underset{\underset{CH_3}{\|}}{C}$H), 0.86 (t, J = 6.5, CH_3—CH_2), 0.88 (d, J = 6.5, CH_3—CH), 1.2 (m, CH_2), 1.65 (m, CH).

2,2,3-Trimethylpentane

The reaction of 3,3-dimethyl-2-butanone with ethylmagnesium bromide in ether at −25°C gave an octanol which on dehydration gave a mixture of olefins hydrogenated to 2,2,3-trimethylpentane; bp 107–108°C, lit. (7) bp 109.8°C; n: 1.3951, lit. (7) n: 1.40285. The nmr spectrum shows a major peak at 0.8 ppm (*tert*-butyl) masking the other methyl groups.

2,2,4-Trimethylpentane

2,4,4-Trimethyl-1-pentene (Aldrich) was hydrogenated and the alkane purified by distillation; bp 96–97°C, lit. (8) bp 99.2°C; n: 1.3892, lit. (8) n: 1.3914; δ_{TMS} (CCl_4): 0.88 (s, *t*-butyl), 0.91

For personal use only.

(d, $J = 7$, CH_3—$\underset{\|}{C}$H—CH_3), 1.64 (m, for CH_2 and the other proton).

2,2,3,4-Tetramethylhexane

(A) The addition of *sec*-butyllithium to 3,3-dimethyl-2-butanone in ether at 0°C gave an alcohol that was dehydrated, without purification, with $POCl_3$ in pyridine (14). The olefin obtained was hydrogenated to 2,2,3,4-tetramethylhexane; bp 155.5°C, lit. (9) bp 156.6°C; n: 1.4286, lit. (9) n: 1.4202; δ_{TMS} (CCl_4): 0.73 (d, $J = 7$, CH_3—CH), 0.77 (d, $J = 6$, CH_3—CH), 0.79 (t, $J = 6$, CH_3—CH_2), 0.87 (s, *t*-butyl), 1.19 (m, —CH_2—).

(B) 3-Methyl-3-penten-2-one was added to an ethereal solution of *tert*-butylmagnesium chloride in presence of CuCl at −30°C; 3,4,5,5-tetramethyl-2-hexanone was obtained in 63% yield; bp 82–84°C/13–15 Torr; n: 1.4385; ir ν_{max}: 1705 (carbonyl) cm^{-1}.

This ketone was reduced with $NaBH_4$ to an alcohol which on dehydration followed by hydrogenation of the olefins gave an alkane identical with the one described above.

2,4,5-Trimethylheptane

4-Methyl-2-pentanone was added to a solution of *sec*-butyllithium in hexane at 0°C to give, in 30% yield, 2,4,5-trimethyl-4-heptanol, bp 85°C/13–15 Torr. The alcohol was dehydrated with SO_2Cl_2 in pyridine and the olefin hydrogenated to 2,4,5-trimethylheptane; bp 154–155°C, lit. (10) bp 156°C; n: 1.4157, lit. (10) n: 1.4160.

3,3,5-Trimethylheptane

The 1,4-addition of ethylmagnesium bromide to 2-methyl-2-penten-4-one in ether at 35°C with CuCl gave 4,4-dimethyl-2-hexanone (yield 73%); bp 152°C, lit. (11) bp 154.4°C; n: 1.4172, lit. (10) n: 1.4185; ir ν_{max}: 1705 (carbonyl) cm^{-1}.

The ketone was then treated with an ethereal solution of ethylmagnesium bromide. The alcohol obtained was dehydrated without purification and the isolated olefins hydrogenated to 3,3,5-trimethylheptane; bp 154–155°C, lit. (12) bp 156.8°C, n: 1.4165, lit. (12) n: 1.4178. The nmr spectrum shows a great deal of overlapping, making the interpretation impossible.

2,3,3,4-Tetramethylhexane

(A) 2,3-Dimethyl-2-butene was acylated, in low yield with proprionyl chloride and $SnCl_4$, according to Colonge and Mostafavi (13), to give an unsaturated ketone which was then hydrogenated to 4,4,5-trimethyl-3-hexanone; bp 69–71°C; n: 1.4302; ir ν_{max}: 1703 (carbonyl) cm^{-1}. The ketone was allowed to react with an ethereal solution of CH_3Li at 0°C to give an alochol which was dehydrated. Hydrogenation of the resulting olefins gave 2,3,3,4-tetramethylhexane; bp 162.5°C; n: 1.4285; δ_{TMS} (CCl_4): 0.69 (d, $J = 1.5$, CH_3—$\underset{\|}{C}$—CH_3), 0.79 (d, $J = 7$, CH_3—$\underset{\|}{C}$H and CH_3—CH), 0.83 (t, $J = 7$, CH_3—CH_2—), 0.93 (m, —CH_2—), 1.68 (m, 2 CH). *Anal.* calcd. for $C_{10}H_{22}$: C 84.40, H 15.59; found: C 84.49, H 15:39.

(B) 3,4-Dimethyl-2-hexanone was brominated with Br_2 in $CHCl_3$ at 0°C. The crude bromoketone was dissolved in methanol and treated with sodium methoxide giving methyl 2,2,3-trimethylpentanoate in 39% yield; bp 67–69°C/13–17 Torr; ir ν_{max}: 1730 (ester) cm^{-1}. The ester was treated with two equivalents of CH_3Li in ether to give an alcohol. The alcohol was dehydrated and the resulting olefins hydrogenated to an alkane identical with the one described above.

2,3,4,4-Tetramethylhexane

3,4-Dimethyl-3-penten-2-one (prepared by reacting 3-methyl-2-butene with CH_3COCl and $SnCl_4$) was added to a solution of ethylmagnesium bromide in ether at −35°C with CuCl). 3,4,4-Trimethyl-2-hexanone was obtained (yield 43% in pure ketone); bp 70–75°C/13–15 Torr; n: 1.4310; ir ν_{max}: 1703 (carbonyl) cm^{-1}; ms (70 eV) m/e: 142 (M). The saturated ketone was added to CH_3Li in ether at −10°C. The alcohol obtained was dehydrated and the olefins hydrogenated to 2,3,4,4-tetramethylhexane; bp 159–160°C, lit. (11) bp 162.8°C; n: 1.4262, lit. (11) n: 1.4272; δ_{TMS} (CCl_4): 0.76 (t, $J = 7$, CH_3—CH_2), 0.79 (d, $J = 6.5$, CH_3—$\underset{\|}{C}$H—), 0.80 (s, CH_3—$\underset{|}{C}$—CH_3), 0.89 (d, $J = 6.8$, CH_3CH), 1.25 (m, CH_2), 1.91 (m, CH).

Ozonolysis

Careful distillation of polymerization products gave a fraction containing olefins having a molecular weight of 168 (C_{12}) only, of which 0.500 g were dissolved in 10 mL ethanol and the solution, kept at −78°C, was saturated with ozone (blue solution). After the solution had warmed up to room temperature, it was transferred to the hydrogenation flask and degassed. Palladium 5% on carbon was then added and the ozonides hydrogenated overnight. The mixture was poured into water and extracted with pentane. Identification of ketones and aldehydes was achieved by comparison of their retention times and their mass spectra with those of authentic material. The mixture was found to contain 3-methyl-2-butanone, 2-methylbutanal, 3,4-dimethyl-2-pentanone, 3,3-dimethyl-2-pentanone, 2-butanone, and 3-methyl-2-pentanone.

4-Ethyl-3,6-dimethyloctane

5-Methyl-3-hexanone was added to *sec*-butyllithium in hexane at −10°C. The alcohol (yield 60%) was dehydrated and the olefins hydrogenated to give 4-ethyl-3,6-dimethyloctane; bp 84°C/17 Torr; n: 1.4390. *Anal.* calcd. for $C_{12}H_{26}$: C 84.60, H 15.39; found: C 84.26, H 15.39.

2,3,4,6-Tetramethyloctane

3,4-Dimethyl-2-pentanone was treated at 0°C with a Grignard reagent prepared from 1-bromo-2-methylbutane and excess Mg. An alcohol was obtained (yield 30%); dehydration and hydrogenation of the olefins gave 2,3,4,6-tetramethyloctane; bp 86°C/17 Torr; n: 1.4320. *Anal.* calcd. for $C_{12}H_{26}$: C 84.60, H 15.39; found: C 84.53, H 15.18.

3,3,4,6-Tetramethyloctane

The 1,4-addition of *tert*-amylmagnesium chloride to 3-pentene-2-one in presence of CuCl at −25°C gave 4,5,5-trimethyl-2-heptanone (yield 38%); bp 85–86°C/17 Torr; n: 1.4381; ms (CI) m/e: 157 (M + 1). It was added at −100°C to an ethereal solution of ethylmagnesium bromide. The crude alcohol was divided into two parts. The first was dehydrated as usual and the olefins hydrogenated to an alkane. The second was added to a large excess of concentrated HCl to give the same mixture of olefins already obtained and another product (about 45% of the mixture) assumed to be the chloride, because of a positive Beilstein test. The chloride mixture was then treated with $LiAlH_4$ in THF to give the unchanged olefins and a product identified, by glc – mass spectrum analysis, as the alkane obtained from the first fraction. It seems unlikely that, under the experimental conditions, the HCl treatment gave a rearranged chloride (or olefins yielding the same chloride) which would be reduced to the isolated alkane. So this strongly suggests that no rearrangement occurs during the dehydration and that the isolated alkane is 3,3,4,6-tetramethylhexane; bp 86°C/17 Torr; n: 1.4327. *Anal.* calcd. for $C_{12}H_{26}$: C 84.60, H 15.39; found: C 84.32, H 15.10.

2,5,6,6-Tetramethyloctane

3,3-Dimethyl-2-pentanone was added at 0°C to a Grignard prepared from isoamylchloride and excess Mg. The reaction gave a mixture of products containing OH groups. The crude mixture was dehydrated and ir (peaks at 1615 and 1685 cm^{-1} for unsaturated ketone) showed that some aldol condensation had occurred. The mixture was fractionated and the fraction passing at 79°C/13–15 Torr was retained and identified by ir and nmr as a mixture of olefins with the desired structure. The mixture was then hydrogenated to 2,5,6,6-tetramethyloctane (overall yield 10%); bp 84°C/17 Torr; *n*: 1.4283. *Anal.* calcd. for $C_{12}H_{26}$: C 84.60, H 15.39; found: C 84.29, H 15.10.

2,3,4,5,5-Pentamethylheptane

The 1,4-addition of *tert*-amylmagnesium chloride to 3-methyl-3-penten-2-one with CuCl in ether at −35°C gave 3,4,5,5-tetramethyl-2-heptanone; bp 101°C/17 Torr; *n*: 1.4448. The saturated ketone was then treated with CH_3Li in ether at −10°C to give an alcohol dehydrated without purification and the olefins hydrogenated to 2,3,4,5,5-pentamethylheptane; bp 87°C/17 Torr; *n*: 1.4395. *Anal.* calcd. for $C_{12}H_{26}$: C 84.60, H 15.39; found: C 84.34, H 15.19.

Tridecanes

2,3,4,5,6-Pentamethyloctane

3,4,5-Trimethyl-2-hexanone (prepared by the addition of isopropylmagnesium chloride to 3-methyl-3-penten-2-one, bp 81–82°C/17 Torr; *n*: 1.4352 yield 70%), was treated at −10°C with a hexane solution of *sec*-butyllithium. The dehydration of the alcohol obtained and the hydrogenation of the olefins gave 2,3,4,5,6-pentamethylheptane; bp 98°C/17 Torr; *n*: 1.4382. *Anal.* calcd. for $C_{13}H_{28}$: C 84.67, H 15.32; found: C 84.85, H 15.10.

3,3,4,5,6-Pentamethyloctane

(A) 3,4,5,5-Tetramethyl-2-heptanone was added at −25°C to a 75% excess ethylmagnesium bromide in ether. The crude alcohol (yield 75%) was dehydrated and the olefins hydrogenated to 3,3,4,5,6-pentamethyloctane; bp 99°C/17 Torr; *n*: 1.4429. *Anal.* calcd. for $C_{13}H_{28}$: C 84.67, H 15.32; found: C 84.47, H 15.03.

(B) 3,4-Dimethyl-3-penten-2-one was added at 25°C to an ethereal solution of ethylmagnesium bromide and CuCl to give 3,3,4-trimethyl-2-hexanone.

The saturated ketone was treated with a solution of *sec*-butyllithium and the alcohol obtained dehydrated. The mixture of olefins was hydrogenated to give an alkane identical (glc. nmr) with the one described above.

Preparation of a series of substituted fluoromethylnaphthalenes

ELISABETH A. DIXON,[1] ALFRED FISCHER, AND FRANK P. ROBINSON
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received January 27, 1981

ELISABETH A. DIXON, ALFRED FISCHER, and FRANK P. ROBINSON. Can. J. Chem. **59**, 2629 (1981).

A series of 22 3- and 4-substituted 1-fluoromethylnaphthalenes have been synthesized. Details of practical procedures for the preparation of all intermediates are described, and physical properties for all of the substituted naphthalenes synthesized, and spectral parameters for 51 previously unknown compounds, are given.

ELISABETH A. DIXON, ALFRED FISCHER et FRANK P. ROBINSON. Can. J. Chem. **59**, 2629 (1981).

On a synthétisé une série de 22 fluoro-1 méthylnaphtalènes substitués en positions 3 et 4. On décrit en détail les méthodes utilisées pour préparer les intermédiaires et on rapporte les propriétés physiques de tous les naphtalènes substitués préparés, ainsi que les paramètres spectraux de 51 composés inconnus.

The linear correlation analysis of ^{19}F substituent chemical shifts of a series of substituted benzyl fluorides led to a rather unexpected result for the sign of the response for the substituent chemical shift (1). We wished to carry out a similar study for a series of substituted fluoromethylnaphthalenes in order to ascertain whether or not this trend is paralleled in the naphthalene series. In this paper we report the preparation of the series of fluoromethylnaphthalenes. The shift study is reported in the following paper.

Fluoromethylnaphthalenes were not known at the beginning of our study, but the synthesis of five derivatives and the isolation of four of these were reported (2) soon after our study was completed (3). Their benzene analogues, the benzyl fluorides, were first synthesized by the Ingolds (4) in 1928. Benzyl fluorides have been reported in the literature several times since then (5–9) and have been studied both in a reactivity context by kinetic studies (5–7) and in the context of correlations between substituent effects and ^{19}F nmr chemical shifts (1).

The reaction sequences for the 22 fluoromethylnaphthalenes prepared are shown in Figs. 1–7. The 4-methyl-, 4-chloro-, 4-fluoro-, and 4-bromo-1-fluoromethylnaphthalenes were synthesized according to the transformations shown in Fig. 1. Friedel–Crafts acylation of the 1-substituted naphthalene was followed by hypochlorite oxidation of the resulting acetonaphthone to the naphthoic acid which was in turn reduced by lithium aluminum hydride to the carbinol. The final two steps were bromination and fluorination. For the unsubstituted fluoromethylnaphthalenes the corresponding carboxylic acids were commercially available and the preparations involved the last three steps of Fig. 1. Six of the substituted fluoromethylnaphthalenes, the 4-methoxymethyl, 4-fluoromethyl, 4-methoxycarbonyl, 4-ethoxycarbonyl, 4-acetyl, and 4-fluoroacetyl derivatives, were synthesized from 1-acetyl-4-methylnaphthalene as shown in Fig. 2. The replacement of bromide by fluoride always involved the same procedure and this step has been omitted for simplicity in Figs. 2–7. The bromide which was replaced to generate the corresponding fluoride is indicated by an asterisk thus: Br*.

Note: Bromine atoms marked with an asterisk were replaced by fluorine by reaction with potassium fluoride in *N*-methylpyrrolidone (see text).

FIG. 2

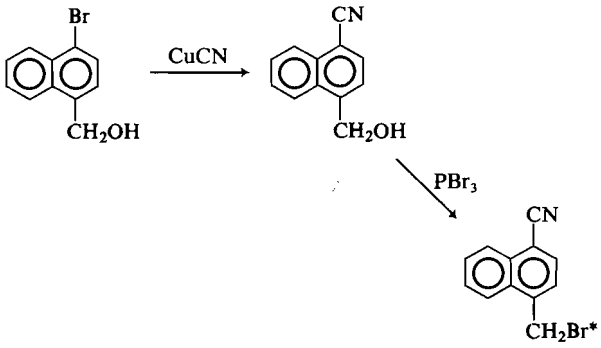

FIG. 3

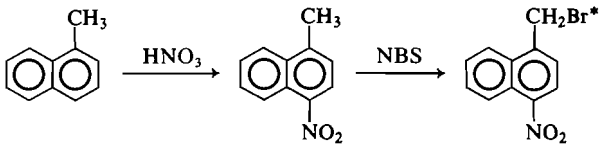

FIG. 4

mide provided access to both the 4-cyano derivative (Fig. 3) and the 3-cyano derivative (Fig. 5). The 3-cyano derivative proved to be very useful, itself giving rise to the 3-methoxycarbonyl, 3-ethoxycarbonyl, and 3-acetyl derivatives. 4-Nitro-1-fluoromethylnaphthalene was prepared from 1-methylnaphthalene according to the scheme shown in Fig. 4. 1,8-Naphthalic anhydride was the starting material for five of the 3-substituted fluoromethylnaphthalenes (Fig. 5), and 1,3-dimethylnaphthalene for two of the 3-substituted derivatives (Fig. 6). The 3-nitro compound was prepared from methyl 3-nitro-1-naphthoate (Fig. 7).

Synthetic intermediates, classified by functional group, were prepared as follows. Acetylnaphthalenes were prepared by the Friedel–Crafts acylation of the corresponding 1-substituted naphthalene (10), or by the reaction of the aromatic nitrile with methyl magnesium iodide (11). Details of yields and physical properties are shown in Table 1.

Naphthoic acids were prepared by the sodium hypochlorite oxidation of the methyl ketone, reaction of the appropriate Grignard reagent with carbon dioxide, alkaline hydrolysis of the nitrile, or by hydrolysis of the hydroxymercurinaphthoic acid with dilute hydrochloric acid. Preparative data for this group of compounds are listed in Table 2. Most of the 4-substituted-1-naphthoic acids were prepared by the sodium hypochlorite oxidation of the corresponding acetylnaphthalene. This reaction proved to be far more troublesome than was suggested by the brief accounts in the literature. After a long series of abortive attempts two factors emerged as being important. The method of preparation of the hypochlorite solution is critical; the solution must be maintained at 0–10°C and the amount of chlorine passed carefully controlled. The hypochlorite solution was eventually prepared according to the method of Newman and Holmes (12). Secondly, it is necessary to reflux the hypochlorite solution with the ketone until there is no residual ketone present as a separate phase. The period of reflux necessary to effect the oxidation was considerably longer, and the reaction temperature higher, than those recommended in the literature. 4-Methoxy-1-acetylnaphthalene underwent nuclear oxidation on treatment with hypochlorite solution and 4-methoxy-1-naphthoic acid was therefore prepared by Grignard synthesis (13). 4-Hydroxymethyl-2-naphthoic acid was prepared by alkaline hydrolysis of the corresponding nitrile; acid hydrolysis was ineffective. 3-Bromo-1-naphthoic acid was a key intermediate in the preparation of 3-substituted derivatives and was itself obtained from naphthalic anhydride by bromination, mercuridecarboxylation, and protodemercuration (14–16).

Naphthyl carbinols (Table 3) were, as indicated, prepared by reduction of the naphthoic acids with lithium aluminum hydride. However the preparation of 3-nitronaphthyl carbinol requires comment. Brown and Subba Rao have reported that the reagent sodium borohydride and anhydrous aluminum chloride in diglyme selectively reduce a nitro function in the presence of a carboxylic acid or its derivative (17). We were unable to effect the reduction of methyl 3-nitro-1-naphthoate by this reagent. Nystrom has described the selective reduction of *p*-nitrobenzaldehyde and the lack of reduction of *p*-nitrotoluene and nitrobenzene with lithium aluminum hydride and anhydrous aluminum chloride in anhydrous ether (18). We were able to selectively reduce the nitroester to the nitrocarbinol with this combination.

Bromomethylnaphthalenes (Table 4) were generally prepared from the corresponding carbinols by reaction with phosphorous tribromide (19). Bromination with *N*-bromosuccinimide (NBS) of the 1-methyl-4-nitronaphthalene gave 1-bromomethyl-4-nitronaphthalene. Similarly bromination of 1,3-dimethylnaphthalene gave 1,3-bisbromomethylnaphthalene, 3-bromomethyl-1-methylnaphthalene, and 1-bromomethyl-3-methylnaphthalene. Likewise bromination of 1-acetyl-4-methylnaphthalene gave 1-acetyl-4-bromomethylnaphthalene. Bromination of 4-methyl-1-naphthoic acid gave only 13% of 4-bromomethyl-1-naphthoic acid (a key intermediate) in a mixture of at least seven compounds, and this derivative was prepared from

[a](a)PBr_3 bromination of naphthyl carbinol; (b) *N*-bromosuccinimide bromination of methylnaphthalene; (c) cleavage of methylnaphthyl methyl ether with HBr in benzene; (d) diazomethane esterification of naphthoic acid; (e) HBr/benzene bromination of naphthyl carbinol.

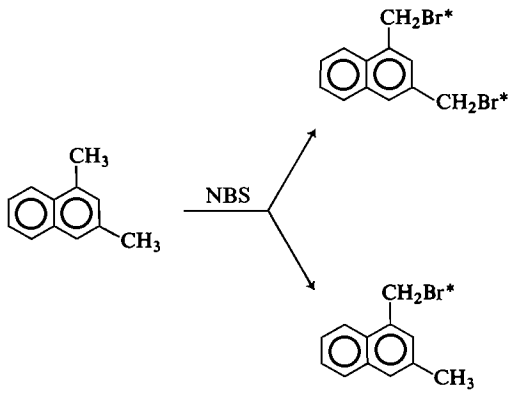

FIG. 6

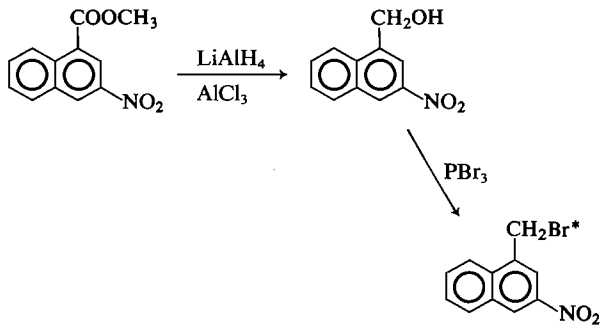

FIG. 7

the 1-acetyl-4-bromomethylnaphthalene. Oxidation of the last compound with sodium hypochlorite resulted in both functional groups being attacked. The bromomethyl group was therefore protected by conversion to the methyl ether before oxidation. After oxidation of the acetyl function, reaction of the methyl ether with hydrogen bromide regenerated the bromomethyl group.

Fluoromethylnaphthalenes (Table 5) were prepared by fluoride–bromide exchange of the corresponding bromomethylnaphthalene using anhydrous potassium fluoride in the dipolar aprotic solvent *N*-methylpyrrolidone (this provides a source of "strongly nucleophilic, weakly solvated and well dissociated fluoride ion" (20)). The fluoromethylnaphthalenes could not be characterized by their boiling points. Even on moderate warming these compounds showed a tendency towards polymerization. Polymerization of the benzyl fluorides was reported by Delpuech and Béguin (7), by the Ingolds (4), and by Bernstein *et al.* (5); it is an

[a]Detected by nmr spectroscopy (CH_2Br: CH_2F).
[b]Isolated as pure fractions by column chromatography on silica gel. Attempts were not made to maximize yields.

acid catalysed Friedel–Crafts type reaction. In the earlier preparations all the glassware was rinsed with an ethereal solution of quinoline and then dried. In later preparations one drop of *N,N*-diisopropylethylamine, a stronger but sterically hindered base, was added prior to the isolation of the fluoromethylnaphthalene to prevent the polymerization from occurring. This latter base is preferable as it does not interfere with the nmr spectra. All peaks in the spectrum of *N,N*-diisopropylethylamine appear at high field, viz. δ 1–2 ppm. Furthermore, it is considerably more volatile than quinoline and can be pumped off from the fluoromethylnaphthalenes.

In spite of the precaution of adding the base stabilizer, several samples did undergo the polymerization reaction. Addition of this trace amount of amine precluded elemental analysis and boiling point or melting point as a means of characterization. Accurate masses were determined, and the very characteristic ^1H and ^{19}F nmr spectra served to confirm the identity of the products.

Three separate attempts were made to prepare 4-methoxy-1-fluoromethylnaphthalene and in one instance a 15% yield was obtained. However, on chromatography on silica gel at −35°C to isolate the product, no fluoromethylnaphthalene was detected in any of the fractions collected. Appreciable quantities of a white solid melting at 149–150.5°C were obtained. Spectroscopic investigation of this solid indicated that it was a bis(4-methoxynaphthyl)methane.

We were unable to prepare 4-fluoromethyl-1-naphthamide from the corresponding bromide, and fluoride exchange was not attempted on 4-bromomethyl-2-naphthamide.

Experimental

The synthetic sequences used in the different preparations involve many of the same reactions carried out on the same functional group. For this reason the general synthetic method for one characteristic compound only is described and relevant data in tabular form are provided for similar transformations. Only in cases where difficulty was encountered which necessitated radical departure from the general method are details given for other compounds. Accurate mass data and C, H, N analytical data appear separately and are listed for each compound individually. Synthetic details are listed separately for compounds not included in the major groups. Spectral properties of previously unknown compounds are listed in Table 6. Infrared spectra were recorded on Perkin-Elmer model 337 spectrometer calibrated with polystyrene. Mass spectra were determined on a Hitachi Perkin-Elmer RMU-7 instrument. Nuclear magnetic resonance spectra were recorded on a Varian HA-60-IL spectrometer using tetramethylsilane as internal standard.

1-Acetyl-4-methylnaphthalene (21)

Acetyl chloride (38 cm^3; 39.3 g, 0.48 mol) was added over 45 min to a stirred mixture of 1-methylnaphthalene (Aldrich) (67.0 g, 0.48 mol), dry CH_2Cl_2 (340 cm^3), and finely ground anhydrous $AlCl_3$ (76 g, 0.57 mol) at 0°C. After the addition was complete the mixture was stirred at ambient temperature for 4 h and then heated under reflux for 2.5 h. Work-up followed by distillation under reduced pressure gave 1-acetyl-4-methylnaphthalene (71%), bp 115–120°C/0.2 Torr.

4-Methoxymethyl-2-acetylnaphthalene

4-Methoxymethyl-2-cyanonaphthalene (1.97 g, 0.01 mol) in benzene (10 cm^3) was added to a solution of methylmagnesium iodide in benzene, prepared from magnesium (0.05 mol) and methyl iodide (0.05 mol), and the solution stirred under reflux for 7 h. The solution was cooled and hydrochloric acid (0.6 mol in 100 cm^3) was added very cautiously. This solution was stirred under reflux for 36 h. The two layers were separated and the benzene layer washed with water, with 10% $NaHCO_3$ solution, and again with water (3 × 100 cm^3). The benzene solution was dried ($MgSO_4$) and evaporated. Chromatography on silica gel using a 10% benzene/petroleum ether (bp 35–45°C) mixture as the eluent gave 4-methoxymethyl-2-acetylnaphthalene in 77% yield.

4-Methyl-1-naphthoic acid

1-Acetyl-4-methylnaphthalene (40.66 g, 0.22 mol) was refluxed for 4.5 h with a hypochlorite solution prepared by dissolving NaOH (100 g, 2.5 mol) in water (135 cm^3) and ice (500 g), and bubbling Cl_2 into this solution until the increase in weight was 71 g (1 mol). The solution was allowed to cool and $NaHSO_3$ (60 g) added in order to destroy excess hypochlorite. Concentrated HCl (75 cm^3) was added to precipitate the 4-methyl-1-naphthoic acid. After recrystallization (95% EtOH)

[a]The spectra recorded as a 10% solution in CCl_4 except where specified.
[b]The nmr recorded in $(CD_3)_2CO$.
[c]On D_2O exchange the triplet signal disappeared and the doublet collapsed to a singlet.
[d]Recorded in $CDCl_3$.
[e]Recorded in D_2O.
[f]Long-range coupling with fluorine.

TABLE 7. Accurate mass data and elemental analysis for previously unknown compounds

1-Acetyl-4-methoxymethylnaphthalene, *m/e*: 214.101; $M_r(^{12}C_{14}{}^1H_{14}{}^{16}O_2) = 214.099$

2-Acetyl-4-methoxymethylnaphthalene, *m/e*: 214.108; $M_r(^{12}C_{14}{}^1H_{14}{}^{16}O_2) = 214.099$

4-Methoxymethyl-1- naphthoic acid, *m/e*: 216.080; $M_r(^{12}C_{13}{}^1H_{12}{}^{16}O_3) = 216.078$. *Anal.* calcd. for $C_{13}H_{12}O_3$: C 72.20, H 5.59; found: C 72.04, H 5.33

4-Hydroxymethyl-2-naphthoic acid, *m/e*: 202.057; $M_r(^{12}C_{12}{}^1H_{10}{}^{16}O_3) = 202.063$. *Anal.* calcd. for $C_{12}H_{10}O_3$: C 71.30, H 4.47; found: C 71.60, H 4.69

4-Methoxymethyl-1-naphthylcarbinol, *m/e*: 202.101; $M_r(^{12}C_{13}{}^1H_{14}{}^{16}O_2) = 202.099$. *Anal.* calcd. for $C_{13}H_{14}O_2$: C 77.14, H 6.97; found: C 77.44, H 6.94

4-Fluoro-1-naphthylcarbinol, *m/e*: 176.056; $M_r(^{12}C_{11}{}^1H_9{}^{16}O_1{}^{19}F_1) = 176.065$. *Anal.* calcd. for $C_{11}H_9OF$: C 74.97, H 5.15; found: C 75.14, H 5.26

4-Chloro-1-naphthylcarbinol, *m/e*: 192.041; $M_r(^{12}C_{11}{}^1H_9{}^{16}O_1{}^{35}Cl_1) = 192.034$. *Anal.* calcd. for $C_{11}H_9OCl$: C 68.59, H 4.71; found: C 68.61, H 4.70

4-Hydroxymethyl-1-naphthonitrile, *m/e*: 183.068; $M_r(^{12}C_{12}{}^1H_9{}^{16}O_1{}^{14}N_1) = 183.068$. *Anal.* calcd. for $C_{12}H_{11}O_2N$: C 78.47, H 4.95, N 7.65; found: C 78.63, H 4.89, N 7.84

3-Bromo-1-naphthylcarbinol. *Anal.* calcd. for $C_{11}H_9OBr$: C 55.71, H 3.83; found: C 55.74, H 3.83

4-Hydroxymethyl-2-naphthonitrile, *m/e*: 183.072; $M_r(^{12}C_{12}{}^1H_9{}^{16}O_1{}^{14}N_1) = 183.068$. *Anal.* calcd. for $C_{12}H_9ON$: C 78.47, H 4.95, N 7.65; found: C 78.79, H 5.26, N 7.58

Methyl 4-hydroxymethyl-2-naphthoate, *m/e*: 216.076; $M_r(^{12}C_{13}{}^1H_{12}{}^{16}O_3) = 216.079$. *Anal.* calcd. for $C_{13}H_{12}O_3$: C 72.25, H 5.59; found: C 71.97, H 5.50

4-Hydroxymethyl-2-naphthamide, *m/e*: 201.088; $M_r(^{12}C_{12}{}^1H_{11}{}^{16}O_2{}^{14}N_1) = 201.079$. *Anal.* calcd. for $C_{12}H_{11}O_2N$: C 71.63, H 5.50, N 6.96; found: C 71.50, H 5.43, N 6.71

3-Nitro-1-naphthylcarbinol, *m/e*: 203.065; $M_r(^{12}C_{11}{}^1H_9{}^{16}O_3{}^{14}N_1) = 203.058$. *Anal.* calcd. for $C_{11}H_9O_3N$: C 65.01, H 4.47, N 6.85; found: C 64.87, H 4.48, N 6.99

1-Bromomethyl-4-methoxymethylnaphthalene, *m/e*: 266.012; $M_r(^{12}C_{13}{}^1H_{13}{}^{16}O_1{}^{81}Br_1) = 266.013$. *Anal.* calcd. for $C_{13}H_{13}OBr$: C 58.5, H 4.84; found: 58.23, H 4.72

1,4-Bisbromomethylnaphthalene, *m/e*: 315.916; $M_r(^{12}C_{12}{}^1H_{10}{}^{81}Br_2) = 315.911$. *Anal.* calcd. for $C_{12}H_{10}Br_2$: C 45.90, H 3.21; found: C 45.89, H 3.14

1-Bromomethyl-4-fluoronaphthalene, *m/e*: 239.978; $M_r(^{12}C_{11}{}^1H_8{}^{19}F_1{}^{81}Br_1) = 239.978$. *Anal.* calc. for $C_{11}H_8FBr$: C 55.21, H 3.37; found: C 55.51, H 3.32

1-Bromomethyl-4-chloronaphthalene, *m/e*: 257.953; $M_r(^{12}C_{11}{}^1H_8{}^{81}Br_1{}^{37}Cl_1) = 257.945$. *Anal.* calcd. for $C_{11}H_8BrCl$: C 51.70, H 3.17; found: C 51.44, H 3.08

4-Bromomethyl-1-naphthonitrile, *m/e*: 244.978; $M_r(^{12}C_{12}{}^1H_8{}^{14}N_1{}^{79}Br_1) = 244.984$. *Anal.* calcd. for $C_{12}H_8NBr$: C 58.55, H 3.28, N 5.69; found: C 58.51, H 3.24, N 5.65

4-Bromomethyl-1-naphthoic acid, *m/e*: 265.981; $M_r(^{12}C_{12}{}^1H_9{}^{16}O_2{}^{81}Br_1) = 265.977$. *Anal.* calcd. for $C_{12}H_9O_2Br$: C 54.36, H 3.42; found: C 54.11, H 3.59

Methyl 4-bromomethyl-1-naphthoate, *m/e*: 277.997; $M_r(^{12}C_{13}{}^1H_{11}{}^{16}O_2{}^{79}Br_1) = 277.994$. *Anal.* calcd. for $C_{13}H_{11}O_2Br$: C 55.95, H 3.97; found: C 56.06, H 3.85

Ethyl 4-bromomethyl-1-naphthoate, *m/e*: 292.003; $M_r(^{12}C_{14}{}^1H_{13}{}^{16}O_2{}^{79}Br_1) = 292.010$. *Anal.* calcd. for $C_{14}H_{13}O_2Br$: C 57.38, H 4.47; found: C 57.18, H 4.40

4-Bromomethyl-1-naphthamide, *m/e*: 262.990; $M_r(^{12}C_{12}{}^1H_{10}{}^{16}O_1{}^{14}N_1{}^{79}Br_1) = 262.994$. *Anal.* calcd. for $C_{12}H_{10}ONBr$: C 52.56, H 3.26, N 5.11; found: C 52.86, H 3.46, N 5.14

1-Acetyl-4-bromomethylnaphthalene, *m/e*: 263.998; $M_r(^{12}C_{13}{}^1H_{11}{}^{16}O_1{}^{81}Br_1) = 263.997$. *Anal.* calcd. for $C_{13}H_{11}OBr$: C 59.35, H 4.21; found: C 59.10, H 4.12

1-Bromoacetyl-4-bromomethylnaphthalene, *m/e*: 341.92; $M_r(^{12}C_{13}{}^1H_{10}{}^{16}O_1{}^{81}Br_1{}^{79}Br_1) = 341.910$. *Anal.* calcd. for $C_{13}H_{10}OBr_2$: C 45.64, H 3.15; found: C 45.85, H 2.99

1-Bromomethyl-4-nitronaphthalene, *m/e*: 264.983; $M_r(^{12}C_{11}{}^1H_8{}^{14}N_1{}^{16}O_2{}^{79}Br_1) = 264.982$. *Anal.* calcd. for $C_{11}H_8NO_2Br$: C 49.63, H 3.03, N 5.26; found: C 49.53, H 3.01, N 5.31

1-Bromomethyl-3-methylnaphthalene, *m/e*: 234.002; $M_r(^{12}C_{12}{}^1H_{11}{}^{79}Br_1) = 234.004$. *Anal.* calcd. for $C_{12}H_{11}Br$: C 61.53, H 4.73; found: C 61.52, H 4.78

2-Bromomethyl-4-methylnaphthalene, *m/e*: 233.994; $M_r(^{12}C_{12}{}^1H_{11}{}^{79}Br_1) = 234.004$. *Anal.* calcd. for $C_{12}H_{11}Br$: C 61.53, H 4.73; found: C 61.82, H 4.76

1,3-Bisbromomethylnaphthalene, *m/e*: 315.914; $M_r(^{12}C_{12}{}^1H_{10}{}^{81}Br_2) = 315.911$. *Anal.* calcd. for $C_{12}H_{10}Br_2$: C 45.9, H 3.21; found: C 45.92, H 3.19

3-Bromo-1-bromomethylnaphthalene, *m/e*: 301.897; $M_r(^{12}C_{11}{}^1H_8{}^{81}Br_2) = 301.896$. *Anal.* calcd. for $C_{11}H_8Br_2$: C 44.03, H 3.09; found: C 44.20, H 2.81

4-Bromomethyl-2-naphthonitrile, *m/e*: 244.978; $M_r(^{12}C_{12}{}^1H_8{}^{14}N_1{}^{79}Br_1) = 244.984$. *Anal.* calcd. for $C_{12}H_8NBr$: C 58.56, H 3.28, N 5.69; found: C 58.54, H 3.32, N 5.59

TABLE 7 (*Concluded*)

Methyl 4-bromomethyl-2-naphthoate, *m/e*: 277.997; $M_r(^{12}C_{13}{}^1H_{11}{}^{16}O_2{}^{79}Br_1)$ = 277.994. *Anal.* calcd. for $C_{13}H_{11}O_2Br$: C 55.95, H 3.97; found: C 56.60, H 4.05

Ethyl 4-bromomethyl-2-naphthoate, *m/e*: 292.010; $M_r(^{12}C_{14}{}^1H_{13}{}^{16}O_2{}^{79}Br_1)$ = 292.010. *Anal.* calcd. for $C_{14}H_{13}O_2Br$: C 57.35, H 4.47; found: C 57.28, H 4.43

4-Bromomethyl-2-naphthamide, *m/e*: 262.991; $M_r(^{12}C_{12}{}^1H_{10}{}^{16}O_1{}^{14}N_1{}^{79}Br_1)$ = 262.995. *Anal.* calcd. for $C_{12}H_{10}ONBr$: C 52.56, H 3.26, N 5.11; found: 52.69, H 3.48, N 5.05

2-Acetyl-4-bromomethylnaphthalene, *m/e*: 262.009; $M_r(^{12}C_{13}{}^1H_{11}{}^{16}O_1{}^{79}Br_1)$ = 261.999. *Anal.* calcd. for $C_{13}H_{11}OBr$: C 59.35, H 4.21; found: C 59.09, H 4.01

1-Bromomethyl-3-nitronaphthalene, *m/e*: 264.981; $M_r(^{12}C_{11}{}^1H_8{}^{16}O_2{}^{14}N_1{}^{79}Br_1)$ = 264.968. *Anal.* calcd. for $C_{11}H_8O_2NBr$: C 49.63, H 3.03, N 5.26; found: C 49.56, H 3.31, N 5.20

1-Fluoromethylnaphthalene, *m/e*: 160.069; $M_r(^{12}C_{11}{}^1H_9{}^{19}F_1)$ = 160.068

2-Fluoromethylnaphthalene, *m/e*: 160.069; $M_r(^{12}C_{11}{}^1H_9{}^{19}F_1)$ = 160.068

the acid (37.4 g, 91%) was obtained, mp 175–175.5°C (lit. (21) mp 175°C).

4-Methoxy-1-naphthoic acid

4-Methoxy-1-naphthyl magnesium bromide was prepared from magnesium (6.12 g, 0.25 mol) and 1-bromo-4-methoxynaphthalene (59.25 g, 0.25 mol). The Grignard solution was poured onto solid CO_2 (400 g) in 800 cm^3 of ether, with vigorous manual stirring. After work-up the 4-methoxy-1-naphthoic acid was recrystallized twice from acetic acid and dried under reduced pressure to give 24 g (48%), mp 247–247.5°C (lit. (13) mp 248°C).

4-Hydroxymethyl-2-naphthoic acid

4-Hydroxymethyl-2-naphthonitrile was heated under reflux with aqueous NaOH (6 mol dm^{-3}) until only one phase was present in the reaction mixture (15 h). The white solid obtained after work-up was recrystallized from 95% ethanol to give colourless crystals of the acid, mp 293–295°C.

3-Bromo-1-naphthoic acid (14–16)

3-Bromo-1,8-naphthalic anhydride, mp 241–243°C (lit. (15) mp 244°C) was obtained in 23% yield on bromination of 1,8-naphthalic anhydride in concentrated nitric acid (14). Mercuration with yellow mercuric oxide in aqueous acetic acid gave anhydro-3-bromo-8-hydroxymercuri-1-naphthoic acid (100%) which was demercurated by boiling with aqueous hydrochloric acid. Fractional crystallization from acetic acid gave the less soluble 3-bromo-1-naphthoic acid in the early fractions in 50% yield, mp 230.5–232°C (lit. (14) mp 231–232°C). The more soluble 6-bromo isomer remained in the mother liquor.

4-Methyl-1-naphthylcarbinol (19, 22)

4-Methyl-1-naphthoic acid (4.57 g, 0.025 mol) in anhydrous ether (100 cm^3) was added over 45 min to a stirred suspension of $LiAlH_4$ (0.7 g, 0.18 mol) in anhydrous ether (50 cm^3), under an atmosphere of nitrogen, at such a rate that boiling of the solvent was maintained. After stirring under reflux for 3 h and again at

room temperature for 14 h the reaction mixture was worked up to give the carbinol. On recrystallization from petroleum ether (bp 60–70°C) 4-methyl-1-naphthylcarbinol (3.4 g, 82%) was obtained as needles, mp 76–77°C (lit. (23) mp 77°C).

3-Nitro-1-naphthylcarbinol

$LiAlH_4$ (0.38 g, 0.01 mol) was suspended in anhydrous ether (10 cm^3). Anhydrous $AlCl_3$ (1.33 g, 0.01 mol) in 15 cm^3 ether was added quickly to the vigorously stirred suspension. A suspension of methyl 3-nitro-1-naphthoate (2.0 g, 8.7 mmol) in ether (50 cm^3) was added dropwise over 30 min. Ice-cold water (100 cm^3) was added cautiously to the mixture, cooled in ice. Work-up gave the 3-nitro-1-naphthylcarbinol (1.26 g, 85%), recrystallized from a mixture of 10% benzene/petroleum ether (bp 100–110°C) as needles, mp 131.5–133.5°C.

1-Bromomethyl-4-methylnaphthalene

4-Methyl-1-naphthylcarbinol (10.3 g, 0.06 mol) was dissolved in dry benzene (100 cm^3) to which was added PBr_3 (19.5 g, 0.072 mol) and two drops of pyridine. The solution was stirred and heated at 50–55°C for 6 h; the reaction mixture was then poured onto ice (100 g), and the organic and aqueous layers were separated. The aqueous layer was extracted with benzene and the benzene solutions combined, washed with water, with 15% Na_2CO_3 solution, and again with water. After drying ($MgSO_4$) and evaporation of the benzene a dark green solid was obtained. Recrystallization (×3) from petroleum ether (bp 35–45°C) gave 1-bromomethyl-4-methylnaphthalene as needles (11.8 g, 84%), mp 77–79°C (lit. (23) mp 80°C).

1-Acetyl-4-bromomethylnaphthalene and 1-Bromoacetyl-4-bromomethylnaphthalene; 1-Bromomethyl-3-methylnaphthalene and 1,3-Bisbromomethylnaphthalene

Recrystallized *N*-bromosuccinimide (133.5 g, 0.75 mol) was added to 1-acetyl-4-methylnaphthalene (93 g, 0.5 mol) in CCl_4 (1250 cm^3) and the suspension stirred under reflux for 48 h. The residue (157.37 g) obtained after work-up contained some unreacted 1-acetyl-4-methylnaphthalene, but was comprised mainly of 1-bromoacetyl-4-bromomethylnaphthalene and 1-acetyl-4-bromomethylnaphthalene in a 1:2 ratio. Chromatography on silica gel (1400 g) and elution with petroleum ether gave in the first 8 fractions (7200 cm^3) 1-acetyl-4-methylnaphthalene (2.59 g). Fractions 9 and 10 contained pure 1-bromoacetyl-4-bromomethylnaphthalene (37.43 g). The next 25 fractions (12 L of petroleum ether/benzene, 90:10) contained both bromomethylnaphthalenes (50 g). The final 3 fractions contained 1-acetyl-4-bromomethylnaphthalene (32.8 g). Recrystallization from petroleum ether (bp 60–75°C) gave colourless platelets of 1-acetyl-4-bromomethylnaphthalene, mp 83–84°C. Fraction 10 was similarly recrystallized to give needles of 1-bromoacetyl-4-bromomethylnaphthalene, mp 118.5–119.5°C.

Bromination of 1,3-dimethylnaphthalene (0.04 mol) with *N*-bromosuccinimide (0.04 mol) in CCl_4 (500 cm^3) gave a mixture of unreacted 1,3-dimethylnaphthalene, 1,3-bisbromomethylnaphthalene, 3-bromomethyl-1-methylnaphthalene, and 1-bromomethyl-3-methylnaphthalene. Chromatography on silica gel using petroleum ether (bp 35–45°C) as eluent gave 1,3-dimethylnaphthalene in the early fractions, two bromomethylmethylnaphthalene isomers in the following fractions, and, in the final fractions, 1,3-bisbromomethylnaphthalene. The bromomethylmethylnaphthalenes were separated by fractional crystallization from petroleum ether (bp 60–75°C).

4-Bromomethyl-1-naphthoic acid

4-Methoxymethyl-1-naphthoic acid (2.16 g, 0.01 mol) was dissolved in dry benzene (300 cm^3). This solution was surrounded by an ice-bath and dry HBr gas bubbled in for 2 h. The suspension was stirred at room temperature for 12 h and at 60–75°C for 3 h, followed by a further 6 h at room temperature. The benzene was removed on a rotary evaporator and the residue was recrystallized from benzene–dichloromethane to give colourless crystals of 4-bromomethyl-1-naphthoic acid (2.65 g, 100%), mp 193–195°C.

1-Fluoromethyl-4-methylnaphthalene

1-Bromomethyl-4-methylnaphthalene (7.25 g, 0.031 mol) dissolved in dry distilled *N*-methylpyrrolidone (25 cm^3) was added over 15 min to anhydrous potassium fluoride (18.0 g, 0.31 mol), suspended in the pyrrolidone (100 cm^3), at 100°C. The reaction temperature was raised to 150°C and maintained at this temperature for 3 h. After cooling, methylene chloride (200 cm^3) was added and the solution washed with water (100 cm^3), and then thoroughly with saturated NH_4Cl solution (6 × 200 cm^3), in order to extract as much of the pyrrolidone as possible. After drying ($MgSO_4$) and evaporation of the solvent the residue (11.3 g) consisted of, by ^1H nmr, pyrrolidone plus naphthalene compounds, over 90% of the latter being the fluoromethylnaphthalene. The relative quantity of fluoromethyl compound in the mixture was estimated by comparing the integration of the readily distinguishable methylene doublet due to the CH_2F function (J_{H-F} = 48 Hz) with that of the methylene of the bromomethylnaphthalene and/or naphthylcarbinol. Chromatography on silica gel (250 g) and elution with pentane, collecting 13 fractions of 150 cm^3, gave the fluoromethylnaphthalene (1.4 g) in fractions 3 to 11.

1-Methyl-4-nitronaphthalene (24, 27)

1-Methylnaphthalene (Aldrich) was nitrated with concentrated nitric acid and the product recrystallized from petroleum ether to give 1-methyl-4-nitronaphthalene, mp 68–71°C (lit. (24) 71–72°C).

1-Acetyl-4-methoxymethylnaphthalene

1-Acetyl-4-bromomethylnaphthalene (0.15 mol) was added gradually to sodium methoxide (from sodium (4.6 g, 0.2 mol) in methanol (2.2 dm^3)) over 3 h. The solution was stirred at room temperature for 3 h and then under reflux for 14 h before work-up. 4-Methoxymethyl-1-naphthonitrile, mp 67.5–68.5°C, was prepared similarly in 90% yield.

4-Hydroxymethyl-1-naphthamide

4-Hydroxymethyl-1-naphthonitrile (1.77 g, 7.5 mmol) was dissolved in 95% ethanol (10 cm^3) and 6*N* NaOH (2 cm^3). The solution was immersed in an ice-bath and cooled to 10–15°C. Hydrogen peroxide (30%) (10 cm^3) was added. The reaction mixture was gradually heated to 55–60°C and stirred for 4 h. Ethanol was removed, the residue allowed to cool, and the solid that precipitated filtered off; the solid was recrystallized twice from warm water to give a quantitative yield of the amide, mp 146–147°C. 4-Hydroxymethyl-2-naphthamide (mp 155–156°C) was prepared in 50% yield by the same method (28).

Methyl 4-Bromomethyl-1-naphthoate

An ice-cold solution of excess diazomethane in ether was added with stirring to a suspension of 4-bromomethyl-1-naphthoic acid in ether. After work-up and recrystallization of the residue from petroleum ether (bp 60–75°C), methyl 4-bromomethyl-1-naphthoate, mp 83–85°C, was obtained in 90% yield.

Similarly were prepared methyl 4-hydroxymethyl-2-naphthoate (mp 79–80°C, 90%) and methyl 3-bromo-1-naphthoate (mp 58–59°C, lit. (14) 59°C, 95%).

Ethyl 4-Methoxymethyl-1-naphthoate

4-Methoxymethyl-1-naphthoic acid in 100% ethanol was esterified using boron-trifluoride etherate catalyst (25). Ethyl-4-methoxymethyl-1-naphthoate was obtained in 62% yield. Ethyl

For personal use only.

4-ethoxymethyl-2-naphthoate and ethyl 4-hydroxmethyl-2-naphthoate were prepared similarly.

1-Bromo-4-methoxynaphthalene (26)

A solution of bromine (25 cm^3, 0.5 mol) and iodine (127.5 g, 0.5 mol) in chloroform (500 cm^3) was added over 30 min to a stirred solution of 1-methoxynaphthalene (Eastman) (80 g, 0.5 mol) in $CHCl_3$ (250 cm^3) at 15–20°C. A constant stream of air removed the HBr as fast as it was formed. The mixture was stirred at 15–20°C for a further 45 min and was filtered to remove precipitated iodine, washed, dried, and evaporated. On distillation under reduced pressure 1-bromo-4-methoxynaphthalene (74%) was collected at 160–163°C/2 Torr (lit. (13) bp 159°C/4 Torr).

2-Acetyl-4-methoxymethylnaphthalene

4-Methoxymethyl-1-naphthonitrile (0.01 mol) in benzene (10 cm^3) was added to a solution of methylmagnesium iodide (0.05 mol) in benzene (20 cm^3). The reaction mixture was stirred under reflux for 7 h. The green reaction mixture was worked up and the residue chromatographed on silica gel using a 10% benzene/petroleum ether (bp 35–45°C) mixture as the eluent. Pure 2-acetyl-4-methoxymethylnaphthalene was obtained as a clear liquid in 77% yield.

Substituent effects in fluoromethylnaphthalenes by ^{19}F nuclear magnetic resonance

ELISABETH A. DIXON,[1] ALFRED FISCHER, and FRANK P. ROBINSON
Department of Chemistry, University of Victoria, Victoria, B. C., Canada V8W 2Y2

Received January 27, 1981

ELISABETH A. DIXON, ALFRED FISCHER, and FRANK P. ROBINSON. Can. J. Chem. **59**, 2642 (1981).

^{19}F substituent chemical shifts (SCS) are reported for a series of twenty-one 3- and 4-substituted 1-fluoromethylnaphthalenes. The fluoromethylnaphthalenes exhibit an inverse SCS dependence: electron-withdrawing substituents produce upfield shifts. The results correlate well with SCS values previously reported for substituted benzyl fluorides. Hammett correlations are poor with conjugatively electron-withdrawing substituents exhibiting weaker than expected effects in the 3-position and stronger than expected effects in the 4-position. Dual substituent parameter analysis confirms the enhanced substituent–aromatic ring resonance interaction when the substituent is in the 4-position ($\rho_R/\rho_I = 2$). There is no evidence for enhanced resonance interaction between fluoromethyl side-chain and aromatic ring. The ^{19}F chemical shift of 1-fluoromethylnaphthalene is markedly temperature dependent.

ELISABETH A. DIXON, ALFRED FISCHER et FRANK P. ROBINSON, Can. J. Chem. **59**, 2642 (1981).

On rapporte les déplacements chimiques du ^{19}F d'une série de 21 fluoro-1 méthylnaphtalènes substitués en positions 3 et 4. Dans les fluorométhylnaphtalènes les déplacements chimiques subissent une influence inverse: les substituants électro-attracteurs provoquent un déplacement vers les champs forts. Les résultats sont en parfait accord avec les valeurs des déplacements chimiques relatifs aux fluorures de benzyle substitués rapportés antérieurement. Les corrélations de Hammet sont mauvaises en ce qui a trait aux substituants électro-attracteurs conjugués qui en position 3 montrent des effets beaucoup plus faibles que ceux attendus et anormalement plus forts en position 4. L'analyse du paramètre de substituant double confirme l'augmentation de l'interaction de résonance du cycle aromatique substitué lorsque le substituant se trouve en position 4 ($\rho_R/\rho_I = 2$). On n'a pas pu prouver l'augmentation de l'interaction de résonance entre la chaîne latérale fluorométhyle et le cycle aromatique. Le déplacement chimique du ^{19}F du fluoro-1 méthylnaphtalène dépend fortement de la température.

[Traduit par le journal]

Introduction

^{19}F nmr chemical shift studies have formed an integral part of the development of the more modern treatments of substituent effects on the electron distribution within a molecule. The ^{19}F nmr chemical shift parameter, $\Delta\phi$, has been used as a sensitive probe to these electronic effects.

Gutowsky *et al.* (1) in 1952 reported that an empirical correlation of ^{19}F nmr chemical shift values for *meta*- and *para*-substituted fluorobenzenes with the corresponding Hammett substituent σ constants revealed systematic differences which were attributed to the dependence of the σ-values on the nature of the electronic interactions of the substituent. Interpretation of the data by separate solutions demonstrated a fundamental difference in the particular effects operative at the *meta* and *para* positions. With data from aliphatic series, Taft et al. (2–5) defined an inductive parameter, σ_I, which allowed a quantitative separation of the Hammett σ value into independent inductive, σ_I, and resonance, σ_R, contributions. Taft (6) reevaluated the ^{19}F nmr shielding parameters, previously reported by Gutowsky, in these terms and reported excellent correlations. The most recent refinement of the dual substituent parameter treatment was a rigorous and extensive statistical analysis of existing data by Ehrenson *et al.* (7) which led to the recognition of "four practical classes of pi-delocalization behaviour," and four classes of substituent constants. It should be noted that ^{19}F nmr data were prominent among the data sets used in this refinement.

Thus it may be seen that ^{19}F nmr substituent chemical shift studies have been of enormous utility in the development of many of the modern ideas concerning substituent effects and linear free energy relationships. And yet, in retrospect, the original successes and their interpretations appear fortuitous in that confusion did not arise from the now increasing list of examples of "anomalous" systems. Over the past 20 years there have appeared in the literature an increasing number of fluorine containing systems where, contrary to expectation, the introduction of an electron-withdrawing substituent induces a ^{19}F nmr substituent chemical shift to high field of the parent, unsubstituted, compound. We should like to report another such anomalous sytem, the fluoromethylnaphthalenes, and to offer alternative rationalizations of the observed phenomena.

Detailed structure–reactivity correlations have been carried out on the benzene analogues of the

fluoromethylnaphthalenes, the benzyl fluorides (8,9), but the fluoromethylnaphthalenes have only briefly been mentioned in the literature (10). ^{19}F nmr substituent chemical shift (SCS) values from the benzyl fluorides gave good correlations with substituent parameters and were very sensitive to the effect of a substituent, but the sign of the response was opposite to that observed in fluorobenzenes (1), fluoronaphthalenes (11), fluorobiphenyls (12), and fluoroterphenyls (12).

Experimental

The syntheses of the substituted fluoromethylnaphthalenes are described in the previous paper (13). ^{19}F spectra were recorded on a Varian HA-100 spectrometer operating at 94.08 MHz in frequency sweep mode and on a Varian HA-60-IL spectrometer operating at a frequency of 56.45 MHz in frequency sweep mode at a probe temperature of 27.5±1°C. External hexafluorobenzene and trichlorofluoromethane respectively were used as lock and reference peaks. To avoid solvent effects on the chemical shifts as far as possible, measurements of ^{19}F substituent chemical shifts were carried out on carbon tetrachloride solutions containing 8% by weight substituted fluoromethylnaphthalene and 4% by weight 1-fluoromethylnaphthalene. The carbon tetrachloride used was Fisher "Spectranalyzed" and was not purified further before use. The substituent chemical shifts were measured directly from the spectra of these solutions as the distance between the positions of the central peaks of the two triplets. The substituent chemical shift, $\Delta\phi$, was considered to be a positive value if the signal due to the substituted derivative appeared at higher field than that due to the fluoromethylnaphthalene itself. The conditions of measurement of the fluorine substituent chemical shifts and the sign conventions correspond to those described by Béguin (8) for the benzyl fluorides; the sign convention used by Bromilow *et al.* (9) is opposite to this.

Resonance signals were integrated in order to assign signals to either the substituted or unsubstituted derivative and measurements were repeated on solutions containing 4% substituted fluoromethylnaphthalene and 6% 1-fluoromethylnaphthalene. This was done for two reasons: to determine if there were significant solvent shifts, and to confirm the signal assignments made on the criterion of spectral integration. More extensive dilution studies were subsequently carried out, which showed that solvent shift effects cancelled out if all measurements were made at the same concentrations.

The chemical shifts of 1-fluoromethylnaphthalene, 2-fluoromethylnaphthalene, and benzyl fluoride were recorded under the standardization conditions of Filipovich and Tiers (14) who reported a simplified, internally referenced procedure for determining and tabulating reliable fluorine nmr shielding values. They found trichlorofluoromethane to be an excellent solvent for fluorine compounds; at the same time the solvent was used as internal reference and lock. Chemical shifts were recorded on a 5% solution by weight of fluoromethylnaphthalene or benzyl fluoride in trichlorofluoromethane.

Results and Discussion

Fluoromethylnaphthalene ^{19}F nmr Parameters

The chemical shift values of the reference compounds measured under standard conditions are shown in Table 1. ^{19}F nuclear magnetic resonance substituent chemical shifts measured at 94.08 MHz and 56.45 MHz are shown in Table 2. The most obvious point to note from these data is that the direction of the shift is the same as in the benzyl fluorides and opposite to that of the fluorobenzenes and fluoronaphthalenes: an inverse SCS dependence.

TABLE 1. Chemical shift values for reference compounds[a]

Compound	ϕ_0[b]	Reference

	209.4	10
Benzyl fluoride	211.0	This study
	205.5[c]	9
	211.3	8

[a]Measured under standard conditions (14).
[b]Measured in ppm relative to CCl_3F.
[c]93.50 ppm upfield from tetrachlorotetrafluorocyclobutane and converted to $CFCl_3$ as a reference according to Emsley and Phillips (15).

In a bisfluoromethyl substituted naphthalene it is possible to view either fluoromethyl group as substituent or side-chain probe. Thus the 3α-derivative is also a 4β-bisfluoromethylnaphthalene.

The β-CH_2F probe measured in 2-fluoromethylnaphthalene resonates at higher field than the α-CH_2F of 1-fluoromethylnaphthalene. The difference is +14.5 Hz, at 56 MHz, or +0.26 ppm (+0.28 ppm for the mean $\Delta\phi$), a considerable shift. Distinct groups of triplets for the 1,3-bis CH_2F compound would therefore be expected. However, the observed shifts for each CH_2F group are similar at 56 MHz, one triplet appears 72.5 Hz towards higher field than the standard, the other triplet at 70.5 Hz, and at 94 MHz the two triplets are superimposed and cannot be resolved. The 56 MHz values correspond to $\Delta\phi$ values of +1.28 and +1.25 respectively. Clearly, in 1,3-bisfluoromethylnaphthalene the substituent chemical shift of the 3-CH_2F substituent acting on the α-CH_2F probe is greater than the substituent chemical shift of the 4-CH_2F substituent acting on the β-CH_2F probe, the difference between the substituent chemical shifts being 0.28 (mean value).

For the β-CH_2F group regarded as a functional group in 1,3-bisfluoromethylnaphthalene the (mean) measured substituent chemical shift (from 1-fluoromethylnaphthalene) is +1.25. Of this, +0.28 is attributed to the fluoromethyl probe being located in the β- rather than the α-position, and the remainder (1.25–0.28 = 0.97) is therefore attrib-

[a]SCS (substituent chemical shift): a positive value implies a signal upfield from the unsubstituted compound, $\Delta\phi \equiv -\delta_F$ (1-fluoromethylnaphthalene reference).
[b]Measured on solutions containing 4% by weight unsubstituted fluoromethylnaphthalene and 8% by weight substituted fluoromethylnaphthalene.
[c]In ppm measured at 94.08 MHz.
[d]In ppm measured at 56.45 MHz.
[e]Mean of values measured at 56.45 MHz and 94.08 MHz on solutions containing 4% unsubstituted fluoromethylnaphthalene and 8% of substituted fluoromethylnaphthalene and at 56.45 MHz on solutions containing 6% fluoromethylnaphthalene and 4% substituted fluoromethylnaphthalene.
[f]From ref. 18.
[g]$\bar{\sigma} = (\Delta\phi + 1.16)/9.65$ (see text).
[h]Shift from the β-CH_2F group of 1,3-bisfluoromethylnaphthalene.
[i]Shift for the $COCH_2F$ group.
[j]$-\delta_F$ for 2-fluoromethylnaphthalene (1-fluoromethylnaphthalene reference).

uted to the substituent effect of the 4-CH_2F group acting on the β-CH_2F probe. We may compare this 4β effect (0.97 ppm) with that of 4α (1.31 ppm) and 3α (1.23 ppm). The response of the ^{19}F nmr signal to the substituent effect of the CH_2F function is greater when the functional centre or probe is situated in the α-position in the naphthalene. A similar observation was noted by Wells *et al.* (16) regarding the data of Adcock and Dewar (17) concerning the ^{19}F shifts of substituted fluoronaphthalenes and also for data concerning naphthalene reactivities.

It is impossible to assign the two signals of 1,3-bisfluoromethylnaphthalene on chemical shift criteria and so a comparison of various coupling constants was made. The J_{HF} coupling constants of 1-fluoromethylnaphthalene and 2-fluoromethylnaphthalene are both 48.0 Hz and so J_{HF} appears to be independent of position. For the two signals due to CH_2F in 1,3-bisfluoromethylnaphthalene to appear so close to one another, the 3α (i.e. considering the 3-CH_2F function as the substituent) orientation must be more sensitive to the influence of the substituent than the 4β orientation (the 4-CH_2F function being the substituent in this case). The value of J appeared to correlate with the substituent chemical shift, being larger for negative shifts and smaller as the shifts became more positive. Hence the CH_2F group with the larger J value was the one which had suffered a smaller substituent chemical shift effect, i.e. the β-CH_2F group.

This assignment is supported by the J_{HF} values measured from ^1H nmr spectra. The chemical shifts for these two functions are readily distinguishable in the proton nmr spectrum. The J_{HF} value assigned to the α-CH_2F in the ^1H nmr spectrum was smaller, in agreement with the assignment arrived at above.

Comparison of Fluoromethylnaphthalene and Benzyl Fluoride SCS Values

Correlation of the fluoromethylnaphthalene SCS values with the benzyl fluoride values gives a good linear relationship with slope = 0.885, intercept =

-0.13, correlation coefficient $r = 0.992$, standard deviation (SD) = 0.49, and standard deviation of the slope = 0.045. Thus substituent effects in the naphthalene series parallel those in the benzene series at a slightly reduced sensitivity. The largest individual deviation is that for the 3-nitro substituent for which the naphthalene SCS value of +3.36 is 1.02 less than the value predicted by the correlation relatonship.

Single Substituent-parameter Correlations

The correlation of the fluoromethylnaphthalene SCS values with Hammett substituent constants (18) is poor with $\rho = 9.65$, intercept = -1.16, $r = 0.815$, SD = 1.95, SD_ρ (standard deviation of rho) = 1.77. The poor correlation is indicated both by the low value of the correlation coefficient and also by the marked deviation for the hydrogen substituent, i.e., the large value of the intercept. Had the equation been constrained to zero intercept, an even lower correlation coefficient would have been obtained. Effective sigma values ($\bar{\sigma}$) were evaluated from the relationship $\bar{\sigma} = (\Delta\phi + 1.16)/9.65$ and are shown in Table 2 together with σ values and values of $\sigma - \bar{\sigma}$. A positive value of $\sigma - \bar{\sigma}$ indicates that the substituent appears to be more electron-donating or less electron-withdrawing than the Hammett substituent constant would predict and vice versa. It is apparent from Table 2 that conjugatively electron-withdrawing (−M) substituents have much weaker effects in the 3-position (mean σ deviation +0.21) and much stronger effects in the 4-position (mean σ deviation -0.21) than expected. The 4-fluoro substituent is also noticeably deviant to the extent that it exerts an electron-donating effect rather than the expected electron-withdrawing effect. Béguin reported a good correlation of benzyl fluoride SCS values with σ^+ values (8). Using his data we obtained $\rho = 9.92$, $r = 0.982$. However, this result is of questionable significance since (*i*) several of the more strikingly deviant substituents in the naphthalene correlations are not represented in Béguin's data set; (*ii*) the striking difference in the behaviour of the *conjugatively electron-withdrawing* substituents in the 3- and 4-positions of naphthalene cannot be accounted for in terms of differences between the σ and σ^+ scales for those substituents; (*iii*) the excellent naphthalene–benzene correlation discussed above implies that the benzene series would exhibit similar deviations to those of the naphthalene series; (*iv*) we also observed a better correlation of the naphthalene data with σ^+ values than with σ, viz. $\rho = 9.34$, $r = 0.916$; however, this correlation necessarily excludes the data for some of the substituents which are particularly deviant in the σ correlation.

Dual Substituent-parameter Correlations

The fluoromethylnaphthalene SCS values were correlated with the sets of resonance and polar effect parameters ($\sigma_{R(BA)}$, σ_I; σ_R^0, σ_I; σ_R^+, σ_I; $\sigma_{R(A)}^-$, σ_I) described by Ehrenson *et al.* (7), and with the resonance and inductive parameters (*F*, *R*) of Swain and Lupton (19).[2] The correlations were carried out by performing a multiple linear regression and, in contrast to the treatment by Ehrenson *et al.* (7), the fitting of the data was not constrained to zero intercept behaviour. By allowing a free fit and by not restraining the equation to zero intercept behaviour, the magnitude of the intercept provides another measure of the "goodness of fit" of the data. The results of the correlations are shown in Table 3. Important parameters derived from these analyses are the ρ_I and ρ_R parameters and particularly their signs and magnitudes. Insight is also gained into the nature of the interaction between the probe and the substituent by observing which set of the four different resonance parameters in the DSP analysis best describes the observed behaviour.

Values of σ_R and σ_I for the CH_2F and CH_2OCH_3 substituents are not listed in the compilation of Taft and co-workers (7). However, values for these substituents were reported by Sheppard (20) and the effect of including the data for these substituents in the correlations was investigated. As shown by the initial entries in Table 3 a slightly poorer correlation was obtained when these data were included. For the 4-substituted 1-fluoromethylnaphthalenes the best correlation was obtained using the *F* and *R* parameters, with that involving the $\sigma_{R(BA)}$, σ_I set yielding only slightly poorer results. These parameter sets also gave the best correlations for the *p*-substituted benzylfluorides. It is to be noted that the parameters allowing for enhanced resonance interaction, σ_R^+ and $\sigma_{R(A)}^-$, gave somewhat poorer correlations (recalling that both *R* and INT should be taken into account) in both cases, i.e. Ar–Y (aromatic-ring and side-chain) resonance interaction is apparently not significant. This reinforces the conclusion stated above that little significance should be attributed to Béguin's claim of a good correlation of the benzyl fluoride data with σ^+. The blending factor, $\lambda = \rho_R/\rho_I$, for the $\sigma_{R(BA)}$, σ_I correlations is 2.00 for the 4-substituted naphthalenes and 1.67 for the *p*-substituted benzenes. This indicates that the 4- and p-substituents exert enhanced X–Ar resonance effects (i.e. between substituent and aromatic ring)

[2]The reaction series data do not encompass a complete basis set as defined by Ehrenson, *et al.* (7). The data are substantially representative of such a basis set.

as compared with their effects on benzoic acid ionization.[3] For the *m*-substituted benzyl fluorides all of the correlations were excellent, marginally the best being that with the $\sigma_{R(BA)}$, σ_I parameters. The 3-substituted 1-fluoromethylnaphthalenes were distinctly less well correlated. The marginally best correlation was that involving the $\sigma_{\bar{R}(A)}$, σ_I parameters. It is more noteworthy that for the 3-substituted 1-fluoromethylnaphthalene correlations ρ_R is negative whereas all other ρ values, including in particular ρ_R for the *m*-substituted benzyl fluorides, are positive. It is not clear that this represents a real difference between the naphthalene and benzene series since the methoxycarbonyl and ethoxycarbonyl substituents, which were apparently electron-donating (see discussion above) in the 3-substituted naphthalene series, were not investigated in the benzene series. However, some support for the reality of the difference is provided by the fact that in the correlation of the SCS values of the fluoromethylnaphthalenes with those of the benzylfluorides the largest deviation, as mentioned above, was that for the 3-nitro substituent, which was apparently much less electron-withdrawing in the naphthalene series, and the only other −M 3-substituent common to both series, cyano, also exhibited a smaller deviation in the same direction. What is clear from Table 3 is that, whatever the sign of the ρ_R for the *m*- or 3-substituted series, $|\lambda|$ is much smaller than for the *p*- or 4-substituted series; e.g. for the $\sigma_{R(BA)}$, σ_I correlations, λ is −.0.75 for the 3-series and +0.29 for the *m*-series. This is of course in accord with general observations of substituent effects: resonance effects are much smaller for *meta*-substituents than for *para*-substituents.

[3] Because of the use of some different substituents in the two series we hesitate to attribute any significance to the difference between the two λ values; the difference is in the direction consistent with greater relative importance of resonance effects in the 4-substituted naphthalene system.

Discussion and Conclusions

The nature of the nmr response of a ^{19}F probe to the effect of a substituent has long been the subject of discussion. More recently, a great deal of evidence has accrued from model aromatic systems to suggest that in general the main polar effect is field-induced polarization of the aromatic π electron system (21–29). Various analyses of the magnitude of these effects has been proposed, and the more successful of these (22, 23, 29) include use of the Buckingham (30) equation:

$$\Delta\phi = A(\Delta E_z)$$

where ΔE_z is the difference in electric field components acting along the C—F bonds in the substituted and unsubstituted compounds.

No treatments have been entirely convincing in identifying the nature and origin of the inverse substituent dependence of the ^{19}F chemical shift in the systems where this phenomenon has been observed (8–10, 31–35). Anderson and Stock suggested that in the series of 4-substituted bicyclo-[2.2.2.]octyl-1-fluorides substituent-induced structural changes resulted in changes in carbon–fluorine bond order arising from the interaction between the endocylic carbon–carbon orbitals and nonbonding orbitals on fluorine and these were the cause of the inverse SCS response (31, 32). CNDO/2 calculations do not provide an explanation for the inverse substituent dependence of the ^{19}F response in the 4-substituted bicyclo[2.2.2.]-octyl-1-fluorides (36) and do not support the view that π-electronic effects on fluorine are responsible for the phenomenon (35). In 1974 Adcock *et al.* (10) stated that the inverse chemical shift phenomenon was not "explicable in terms of (then) current theoretical treatments of fluorine chemical shifts". Subsequently Adcock and Khor (35) attempted to relate differences in chemical shifts in the fluorobicyclooctane and 1-fluoro-4-phenylbicyclooctane series to field effect differences. Their calculations indicated that field effects alone could not account for the differences and that additional factors were required. More recently Adcock and Abeywickrema (37) reported data derived from 6- and 7-substituted 1-fluoro-4-methyl-1,4-ethano-1,2,3,4-tetrahydronaphthalenes. In these systems the C—F bond is constrained to the nodal plane of the aromatic π-system, thus precluding the possibility of fluorine hyperconjugative interaction of the C—F bond and the π electrons of the aromatic ring. Unlike the cases of the benzyl fluorides and the fluoromethylnaphthalenes, which bear close resemblance to these systems in terms of the relative positions of substituent and fluorine probe, the induced shift is in the "normal" direction and is very small. In benzyl fluorides and fluoromethylnaphthalenes carbon–fluorine hyperconjugation results in polarization of the σ electrons in the $2p_y$ orbital of fluorine, but not the π electrons in the $2p_z$ and $2p_x$ orbitals. They concluded that the overall SCS depends not only on the total fluorine charge density, but also on the symmetry of its distribution, the latter being affected by hyperconjugation. Béguin proposed a similar explanation for the inverse SCS of benzyl fluorides (and analogous compounds) (8). From Hückel molecular orbital calculations he determined that the bond order between aromatic and ring CH_2F group increased in going from benzyl fluoride to *p*-methoxybenzyl fluoride. In contrast the C—F bond order decreased in going from fluorobenzene to 4-fluoroanisole. He proposed that this was the factor which accounted for the different signs of the SCS in the two series.

A striking illustration of the complex relationship between the electron distribution on fluorine and the ^{19}F chemical shift was provided by Bromilow *et al.* (9). They measured both ^{13}C and ^{19}F chemical shifts in a series of substituted benzyl fluorides. Both the CH_2 carbon and the fluorine exhibited inverse SCS effects. The *ipso* carbon exhibited a normal effect. However, electron density calculations showed that substituent-induced changes in electron density at the *ipso* carbon paralleled those at fluorine whereas the electron density at the benzylic carbon exhibited a remarkable variation: inductive electron-withdrawing substituents reduced the electron density whereas resonance electron-withdrawing substituents increased the electron density at this site. The authors refrained from offering an explanation at these phenomena but were able to dismiss other explanations advanced for inverse fluorine SCS effects, such as substituent induced structural distortion.

Theory developed to explain the screening of a fluorine nucleus relates the chemical shift to a number of terms pertaining to the electron distribution around the fluorine (38–40). It is evident that this relationship does not approximate to a relationship involving only the total electron density at fluorine.

We should like to offer two alternative explanations for the inverse SCS effect. Our models, like the hyperconjugative model, would be expected to show some conformational dependence.

Sheppard (33), in rationalizing the +R effect of fluoralkyl groups, proposed an interaction of the *p*-electrons of the fluorine atoms with the π-system of the aromatic ring at either the *ipso* or *ortho* positions. The so-called "fluorine p–π interaction" causes significant return of electron density to the ring, and this return is more effective to the *meta* position than the *para*. Molecular orbital calculations support the feasibility of the feedback through the π-system. The net charge density in benzotrifluoride is calculated to alternate so that the *ortho* and *para* positions appear more deficient in charge density than the *meta* position. Increased electron density at the benzylic carbon reflecting a positive Ar—CH_2 inductive effect would allow

increased feedback of the fluorine p electrons to the ring. Alternatively, an Ar—CH_2 resonance effect would, through carbon–fluorine hyperconjugation, increase the electron density at the fluorine atom itself. This charge is centred on $2p_y(\sigma)$ orbitals, rather than $2p_z(\pi)$ orbitals. The electron return via $p-\pi$ interaction would reduce the charge density in the $2p_z(\pi)$ orbitals on fluorine. The π electron density on fluorine rather than total charge density is important in shift correlations. Thus, electron-donating substituents which increase the overall charge density at fluorine do so by increasing the σ charge density which is partially offset by a decrease in π charge density and it is the decrease in π charge density which is of major importance in determining the chemical shift. The signal therefore appears at lower field.

Another possible mechanism for the inversion of the sign of the response of the ^{19}F nmr SCS may arise as a result of hydrogen bonding between the fluorine and the proton in the 2-position on the naphthalene ring (the *ortho* proton). Hydrogen bonding in HF in the condensed phase has been shown to induce a shift in the fluoride resonance towards lower field by 20.5 ppm (41). Similarly Hagne and Reeves (42) showed a downfield shift due to hydrogen bonding in the BF_4^- ion. We suggest that in 1-fluoromethylnaphthalene itself the fluorine appears at an unusually low field position as a result of deshielding through hydrogen-bonding. Introduction of an electron-withdrawing substituent causes a relative increase in the effective electronegativity of the methylene carbon which shortens the C—F bond and thereby reduces the deshielding hydrogen-bonding influence.

Schaefer and co-workers (43–45) have carried out studies in conformational analysis and coupling constants in methyl substituted benzenes (43), in benzyl fluoride (44), and in benzotrifluoride, benzal fluoride, and benzyl fluoride derivatives (45). These studies showed a conformational preference of the C—F bond for the benzene plane by about 260–300 cal/mol in the case of 3,5-dichlorobenzyl fluoride. This value was in close agreement with the results from *ab initio* and MINDO/3 molecular orbital calculations. It is interesting to note that in the same analysis, for the conformation in which the C—F bond lies in a plane perpendicular to the plane of the ring the C—C—F bond angle reduces to 107.2° and the C—C—H angles increase to 116.1°, suggesting conjugation between the C—F bond or the fluorine atom with the π-electrons of the ring. The preferred conformation, however, is one in which maximum hydrogen-bonding would occur.

TABLE 4. Chemical shift temperature dependence at 56.45 MHz

Substituent	Temperature °C	Substituent chemical shift, $\Delta\phi$
4-CH_2OCH_3	+40.0	−14.0 Hz
	+27.5	−14.0 Hz
	+10.0	−12.2 Hz
	0.0	−11.0 Hz
	−10.0	−10.6 Hz
	−20.0	−10.4 Hz
	−30.0	−8.4 Hz
	−40.0	−7.4 Hz
4-$COOCH_3$	+50.0	+305.0 Hz
	+27.5	+332.5 Hz
	+10.0	+352.0 Hz
	0.0	+370.0 Hz
	−10.0	+384.0 Hz
	−20.0	+398.0 Hz
	−30.0	+416.0 Hz
1-CH_2F[a]	+50.0	11797.0 Hz
	+27.5	11780.0 Hz
	+10.0	11766.0 Hz
	0.0	11752.0 Hz
	−10.0	11747.0 Hz
	−20.0	11738.0 Hz
	−30.0	11725.0 Hz
	−40.0	11712.0 Hz

[a]1-Fluoromethylnaphthalene alone i.e. ϕ and not $\Delta\phi$ is recorded.

That the response of the ^{19}F SCS to the substituent is conformationally dependent is suggested by a series of temperature dependent substituent chemical shift studies. The results for three compounds are shown in Table 4. 1-Fluoromethylnaphthalene shows a shift to higher field with increasing temperature reflecting a decrease in the population of the deshielding conformation (by any of the conformation dependent mechanisms). The substituent chemical shift of the ester group is markedly temperature dependent and is smaller at higher temperatures. Brownlee and Craik (46) have investigated the temperature dependence of p-substituted benzyl fluorides and have explained their observations in terms of conformational effects.

A photochemical approach to the synthesis of (±)-biotin

RALPH ALLEN WHITNEY
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received March 31, 1981

RALPH ALLEN WHITNEY. Can. J. Chem. **59**, 2650 (1981).

A synthesis of (±)-biotin **1** based on a photochemical cycloaddition reaction of 1,3-diacetylimidazolin-2-one **3** is presented. Oxidative rearrangement of the cyclobutanol **5** has provided the key intermediate **6** having the necessary stereochemical features for elaboration of *n*-pentyl biotin **2**.

RALPH ALLEN WHITNEY. Can. J. Chem. **59**, 2650 (1981).

On présente une synthèse de la (±)-biotine **1** à partir de la réaction de cycloaddition photochimique de la diacétyl-1,3 imidazolinone-2 **3**. La transposition oxydante du cyclobutanol **5** fournit l'intermédiaire principal **6** avec les bonnes caractéristiques stéréochimiques nécessaires à l'élaboration de la *n*-pentyl biotine **2**.

Increased interest in the role of biotin **1** in human nutrition and therapy (1) as well as its importance as a growth factor (2) has led to the development of numerous syntheses (3) in the past decade of this vitamin of the B-complex. Since total synthesis remains as yet the only major source of this compound, the development of new synthetic strategies continues to be of interest. The use of microbiological methods (4) for conversion of *n*-pentyl biotin **2** into biotin has made **2** an important intermediate for the production of biotin. The approach herein described deals with the synthesis of *n*-pentyl biotin via a photochemical reaction (5) of 1,3-diacetylimidazolin-2-one **3** as outlined in Scheme 1.

We have reported (5) that photolysis of **3** in the presence of enol ethers using acetone as solvent and sensitizer leads to high yields of [2+2] cycloaddition products. Using the readily available (6) trimethylsilyl enol ether **4** of heptanal (a mixture of (*E*)- and (*Z*)-isomers), the photolysis was carried out at room temperature under a nitrogen atmo-

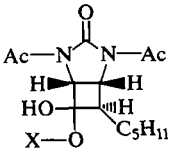
9 10

sphere with a medium pressure mercury lamp to give, after acid hydrolysis, the cyclobutanol **5** in 79% yield upon chromatographic purification. Due to the isomeric composition of the silyl enol ether and the possibility of *syn*- and *anti*-cycloaddition products, the cyclobutanol **5** consisted in principle of four diastereomeric compounds. We expected, however, that the two nitrogen atoms of the cyclic ureido moiety would be in a *cis* stereochemical relationship as desired in the synthetic target **2**. It was intended at this stage to oxidize the cyclobutanol to a cyclobutanone **9** with the anticipated epimerization of the *n*-pentyl group to an exocyclic configuration, as indicated in **10**, prior to Baeyer–Villiger oxidative rearrangement to the lactones **6** and/or **7**. Attempts at oxidation of the alcohol to a ketone using standard methods led repeatedly to complex product mixtures which gave no evidence of cyclobutanone formation. However, chromic acid oxidation (7) gave a low yield of a product identified as the lactone **7**. The regiochemical assignment of the structure was based on proton chemical shift data (8) while the stereochemical assignment was a consequence of proton coupling constants (J_{H_1,H_2} = 6.5 Hz; J_{H_2,H_3} = 1.0 Hz). It was presumed that the reaction was proceeding via a cyclobutanone hydrate **11** (X = H) with the oxidative rearrangement occurring through formation of a chromate ester **11** (X = CrO_3H). Furthermore this suggested that variation of the nature of X might alter the regiochemistry of the rearrangement process. Indeed our expectations were fulfilled when the cyclobutanol **5** was treated with ruthenium tetroxide (9) in carbon tetrachloride in the presence of aqueous hypochlorite solution, the reaction proceeding via the hypochlorite **11** (X = Cl) (10). Examination of the nmr spectrum of the crude reaction product indicated the presence of the lactones **6** and **7** in approximately equal amounts, with purification by column chromatography affording the lactone **6** in a low yield (18%). Again the regiochemistry of the rearrangement product was assigned on the basis of proton chemical shift data (8) and the stereochemistry on the basis of proton coupling constants (J_{H_1,H_2} = 8.9 Hz; J_{H_2,H_3} = 0.9 Hz). It was subsequently established that 1,3-diacetylimidazolin-2-one **3** could be converted to the lactone **6**, without purification of intermediates, in 10% overall yield with the desired product being isolated by recrystallization.



11

Definitive proof of the structure of **6** was provided by facile conversion to *n*-pentyl biotin. Reduction with lithium borohydride in diglyme (12) at room temperature gave the diol **7** as a crystalline material in 78% yield. This was converted, by analogy with literature procedures (3(*i*), (*o*)), to the corresponding bis-mesylate (which was not purified) and then to **2** in 32% yield by treatment with purified sodium sulfide in dimethylformamide at 95°C followed by chromatographic purification. This sample was identical in all respects to an authentic sample of *n*-pentyl biotin.

As stated previously, *n*-pentyl biotin has been converted microbiologically (4) to biotin. Development of this strategy to a totally synthetic route to biotin is, however, under investigation.

Experimental

General

Melting points were determined on a Fisher-Johns or a Thomas Hoover melting point apparatus and are uncorrected. Infrared spectra were recorded on either Perkin Elmer 528 or Acculab 6 instruments. Proton and carbon magnetic resonance spectra were recorded on Varian EM360, Varian HA 100, Bruker HX60, or Bruker CXP 200 spectrometers. Chemical shifts are reported in δ values relative to tetramethylsilane. Column chromatography was performed with Merck 60 mesh silica gel while high performance liquid chromatography was performed on Merck Lobar columns. Unless stated, sodium sulfate was used as drying agent for organic solutions. Microanalyses were performed by Guelph Analytical Laboratories, Guelph, Ontario.

6-Hydroxy-7-pentyl-2,4-diacetyl-2,4-diazabicyclo [3.2.0]heptan-3-one **5**

A solution of 1,3-diacetylimidozalin-2-one (3.0 g, 17.6 mmol) (11) in acetone (250 mL) was placed in a standard immersion well photochemical reactor,[1] then deoxygenated with a stream of nitrogen gas for 0.5 h. Heptanal trimethylsilyl enol ether (22.8 g, 121 mmol) (6) was added and the reaction mixture was photolyzed for 4.5 h with a 450 W Hanovia lamp through a Corex filter. The solvent was then removed by rotary evaporation under reduced pressure. Excess silyl enol ether was removed by Kugelrohr distillation (60°C, 0.5 Torr) and the residue was dissolved in acetone (50 mL) and water (5 mL), cooled in an ice bath, and acidified with dilute aqueous HCl (4 drops). After stirring for 10 h the solution was diluted with methylene chloride

(150 mL), washed with dilute aqueous K_2CO_3, dried, filtered, and evaporated to dryness under reduced pressure to give an oil. Purification by column chromatography (silica gel, CCl_3CH_3) gave a mixture of epimeric cyclobutanols **5** (3.9 g, 13.8 mmol, 79%); ir ($CHCl_3$): 3450 (broad), 2970, 2920, 1755, 1705, 1360, 1270, 1230 cm^{-1}; ^{13}Cmr ($CDCl_3$, one isomer): 171.2, 170.9, 152.9, 78.6, 55.7, 48.0, 47.2, 31.7, 27.8, 25.8, 24.1, 24.1, 22.5, 14.0.

Chromic Acid Oxidation of Cyclobutanol 5

To a stirred solution of the cyclobutanol (0.5 g, 1.77 mmol) in acetone (10 mL) was added dropwise sufficient chromic acid solution (made from 13.4 g CrO_3, 25 mL H_2O, 12 mL H_2SO_4) to sustain an orange colour. After the addition the reaction was stirred for 3 h, then diluted with ether, dried with Na_2SO_4 and K_2CO_3, filtered, and evaporated to dryness. The crude product was chromatographed (silica gel, CCl_3CH_3) to afford the lactone **7** as an oil (0.15 g, 0.51 mmol, 29%); ir ($CHCl_3$): 1780, 1760, 1700, 1460, 1440, 1210 cm^{-1}; ^{1}Hmr ($CDCl_3$): 6.35 (1H, d, J = 6.5 Hz, —OCHN—), 4.45 (1H, d of d, J = 6.5 Hz, 1.0 Hz, —CHN—), 2.9 (1H, d of t, J = 6.0 Hz, 1.0 Hz, —CCH—), 2.58 (3H, s, —CCH$_3$), 2.55 (3H, s, —CCH$_3$), 2.2–0.7 (11H, m); ^{13}Cmr ($CDCl_3$): 175.2, 170.8, 169.6, 150.3, 80.3, 57.1, 45.8, 31.4, 30.6, 25.9, 24.5, 24.1, 22.4, 14.0.

6,8-Diacetyl-2-oxo-4-pentyl-3-oxa-6,8-diazabicyclo[3.3.0]-octan-7-one 6

To a mixture of carbon tetrachloride (15 mL) and water (3 mL) containing $RuCl_3$ (30 mg) was added sufficient aqueous hypochlorite (6%, commercial bleach) to generate a yellow RuO_4 solution (9). The cyclobutanol (1.6 g, 5.67 mmol) in carbon tetrachloride (10 mL) was added dropwise to the rapidly stirred oxidizing solution. Hypochlorite solution was added as required to maintain the yellow oxidizing solution. On completion of the addition the reaction mixture was stirred for 3 h, then the organic layer was separated and washed with dilute aqueous sodium metabisulfite, dried, filtered, and evaporated to dryness. The crude product was purified on a Lobar column (ether) to give the desired lactone **6** (0.31 g, 1.05 mmol, 18%), mp 145–145.5°C (ethyl acetate, ether); ir ($CHCl_3$): 1780, 1760, 1705, 1370, 1345, 1310, 1260, 1215 cm^{-1}; ^{1}Hmr ($CDCl_3$): 5.3 (1H, d, J = 8.9 Hz, —CCHN—), 4.7 (1H, d of t, J = 4.5, 0.9 Hz, —OCH—), 4.5 (1H, d of d, J = 8.9, 0.9 Hz, —CHN—), 2.58 (3H, s, —CCH$_3$), 2.57 (3H, s, —CCH$_3$), 2.0–1.1 (8H, m) 0.9 (3H, m, —CH$_3$); ^{13}Cmr ($CDCl_3$): 171.3, 170.6, 169.0, 150.3, 83.0, 56.3, 50.4, 34.1, 31.3, 24.3, 24.1, 24.1, 22.4, 13.9. *Anal.* calcd. for $C_{14}H_{20}N_2O_5$: C 56.7, H 6.8, N 9.5; found: C 56.4, H 6.8, N 9.5.

4-(1-Hydroxyhexyl)-5-hydroxymethylimidazolidin-2-one 8

To a suspension of sodium borohydride (0.59 g, 15.5 mmol) and lithium bromide (1.28 g, 16.4 mmol) in dry diglyme (8 mL) under a nitrogen atmosphere was added with stirring the lactone **6** (0.54 g, 1.8 mmol) in diglyme (8 mL). The reaction mixture was stirred overnight at room temperature, then methanol (10 mL) was added carefully, followed by acidification with glacial acetic acid. Evaporation to dryness gave a white solid that was dissolved in methanol (20 mL) and evaporated to dryness three times. The residue was partitioned between water (25 mL) and ethyl acetate (75 mL) with the aqueous layer being washed with additional ethyl acetate (75 mL) after separation. The combined organic solutions were dried, filtered, and evaporated to dryness. The residue was crystallized from ethyl acetate to give the diol **8** (0.306 g, 1.42 mmol, 78%), mp 128°C; ir (KBr): 3350, 3290, 1675, 1450, 1310, 1270, 1220, 1105, 1075, 1050 cm^{-1}; ^{1}Hmr (DMSO-d_6): 6.30 (1H, broad s, —NH), 6.17 (1H, broad s, —NH), 5.0 (1H, m, —OH), 4.77 (1H, m, OH), 3.6–3.0 (5H, m), 1.7–0.8 (11H, m); ^{13}Cmr (DMSO-d_6): 162.9 (C=O), 68.7 (—CHOH), 60.1 (—CH$_2$OH), 59.3 (—CHN—), 55.8 (—CHN—), 33.9, 31.3, 24.2, 22.0, 13.8 (CH$_3$). *Anal.* calcd. for $C_{10}H_{20}N_2O_3$: C 55.5, H 9.3, N 13.0; found: C 55.5, H 9.2, N 13.0.

n-*Pentyl Biotin 2*

The diol **8** (50 mg, 0.23 mmol) was dissolved in dry pyridine (3 mL), then cooled in an ice–salt bath while protected by a $CaCl_2$ guard tube. Methane sulfonyl chloride (0.2 g, 0.14 mL) was added dropwise and the reaction mixture was stirred for 20 min at ca. −10°C, then 1.75 h at room temperature. Evaporation to dryness gave a residue that was dissolved in methylene chloride (45 mL), then washed with aqueous HCl (1%, 5 mL) followed by aqueous $NaHCO_3$ (5%, 5 mL), dried, filtered, and evaporated to dryness to give the bis-mesylate (0.085 g), homogeneous by thin-layer chromatography (silica, ethyl acetate); ir ($CHCl_3$): 3460, 3300, 3040, 3020, 2920, 1720, 1370, 1180, 970, 910 cm^{-1}; ^{1}Hmr ($CDCl_3$): 6.2 (broad s, NH); 6.0 (broad s, NH), 5.0–3.6 (m, —CH$_2$O, —CHO, —CHN, —CHN), 3.6 (s, —OSO$_2$CH$_3$), 3.0 (s, —OSO$_2$CH$_3$), 2.0–0.8 (m, C$_5$H$_{11}$).

The bis-mesylate (0.085 g, 0.23 mmol) was dissolved in dry dimethylformamide (2 mL) under nitrogen. Sodium sulfide (0.043 g, purified by crystallization from absolute ethanol) was added, then the reaction mixture was heated at 95°C for 0.5 h. Additional sodium sulfide (0.025 g) was added, the reaction was heated another 0.5 h, then cooled and partitioned between ethyl acetate (50 mL) and water (5 mL). The aqueous layer was washed with additional ethyl acetate (25 mL), then the combined organic layers were dried, filtered, and evaporated to dryness to give a yellow solid (0.053 g). Purification by chromatography on a Lobar column (ethyl acetate) gave *n*-pentyl biotin **2** (0.016 g, 0.075 mmol, 32%) identical with an authentic sample; ^{1}Hmr ($CDCl_3$, DMSO-d_6): 5.64 (1H, s, —NH), 5.44 (1H, s, —NH), 4.49 (1H, d of d, J = 7.5, 5.0 Hz, =CHN—), 4.28 (1H, d of d of d, J = 7.5, 4.5, 1.25 Hz, —CHN—), 3.16 (1H, d of d, J = 7.5, 5 Hz, —CHS—), 2.93 (1H, d of d, J = 12.5, 4.5 Hz, —CH$_2$S—), 2.73 (1H, d of d, J = 12.5, 1.25 Hz, —CH$_2$S—), 1.62 (2H, m, CH$_2$), 1.31 (7H, m, C$_3$H$_7$), 0.86 (3H, m, CH$_3$); ^{13}Cmr ($CDCl_3$, DMSO-d_6): 163.2 (—C—), 61.8 (—CHN—), 60.0 (—CHN—), 55.8 (—CHS—), 40.6 (—CH$_2$S—), 31.6, 28.6, 28.6, 22.3, 13.9.

The formation and reactions of carbanionic derivatives of methyl phosphazenes

KEITH D. GALLICANO, RICHARD T. OAKLEY, NORMAN L. PADDOCK,[1] AND RAJENDRA D. SHARMA

Department of Chemistry, The University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y5

Received January 30, 1981

KEITH D. GALLICANO, RICHARD T. OAKLEY, NORMAN L. PADDOCK, and RAJENDRA D. SHARMA. Can. J. Chem. **59**, 2654 (1981).

The cyclic phosphazenes $N_3P_3Ph_4Me_2$, $N_3P_3Me_6$, and $N_4P_4Me_8$ are deprotonated by alkyllithiums. The resulting carbanions react with monofunctional electrophiles to form phosphazenes carrying the groups PCH_2R (R = Me, Br, I, PhC(O), COOH $AsMe_2$, Me_3M (M = Si, Ge, Sn)). Two phosphazenyl groups can be joined either by the use of a difunctional halide or by oxidative coupling of organo-copper derivatives. The formation of the carbanions, the extent of deprotonation, substituent orientation, and the dependence of reactivity on ring size, are interpreted in terms of a balance between π-electron energies and electrostatic interactions.

KEITH D. GALLICANO, RICHARD T. OAKLEY, NORMAN L. PADDOCK et RAJENDRA D. SHARMA. Can. J. Chem. **59**, 2654 (1981).

Les méthylphosphazènes cycliques $N_3P_3Ph_4Me_2$, $N_3P_3Me_6$ et $N_4P_4Me_8$ sont déprotonés par alkyllithiums. Les carbanions formés reagissent avec des electrophiles monofonctionnels en formant des phosphazènes substitués avec les groupements PCH_2R (R = Me, Br, I, PhC(O), COOH, $AsMe_2$, Me_3M (M = Si, Ge, Sn)). Deux groupements phosphazényliques peuvent être unis, soit par un halogénure bifonctionnel, soit par couplage oxidatif de derivés organocupriens. La formation des carbanions, le degré de la deprotonation, l'orientation du substituent, et la dependence de la reactivité en fonction de la largeur d'anneau, sont interpretés en fonction de l'équilibre entre les énergies des electrons-π et des interactions électrostatiques.

Introduction

The trimeric and tetrameric methylphosphazenes $(NPMe_2)_{3,4}$ were first prepared by the ammonolysis of Me_2PCl_3 (1), and a development of the method (2) allows the relative yields of the two compounds to be controlled. The cyclic compounds $(NPMe_2)_{4,5}$ have been synthesized by the alkylation of the corresponding fluorides (3, 4), and, by the use of Grignard reagents, the series has been extended to $(NPMe_2)_{10}$ (5), and more recently to $(NPMe_2)_{12}$.[2] There is little doubt that the series of ethylphosphazenes $(NPEt_2)_{3,4}$ (6) could be extended in the same way. Until recently, the corresponding high polymers were not available; only partial alkylation of $(NPF_2)_n$ could be carried out without extensive skeletal degradation (7). A polymeric form of $(NPMe_2)_n$ ($n \sim 650$) has now been prepared by the elimination of Me_3SiX from the phosphinimine $Me_2P(X)=NSiMe_3$ (8), so that the available range of alkylphosphazenes is essentially complete.

Many investigations have centred on the behaviour of phosphazenes as donors to organic and inorganic acceptors. The reciprocal withdrawal of electrons from the substituent affects both its ^1H and ^{13}C nmr spectra (9), and separate inductive and conjugative interaction parameters, comparable to those of acyl groups, have been determined for the fluorophosphazenyl groups $N_nP_nF_{2n+1}$ (n = 3–8) (10). Conjugative interactions, especially, are apparent in the near-planarity of the Me_2NP group in the dimethylamidophosphazenes, $N_4P_4(NMe_2)_8$ (11) being the earliest such example.

The synthetic possibilities of the acceptor properties of the phosphazene ring have been exploited only to a limited extent, though they can be seen at their most direct in the reactions of the phosphazenyl anion formed from a hydridophosphazene (12). In a preliminary communication (13) we described the deprotonation of neutral methylphosphazenes, and extended the reaction to the preparation of azaphosphorins from the *N*-methyl quaternary iodides $(NPMe_2)_n \cdot MeI$, (n = 3, 4) (14). Now that alkylphosphazenes can be obtained more easily, a more detailed study of the deprotonation reaction and its synthetic possibilities is justified.

The reaction of alkylphosphazenes with strong bases is similar to the deprotonation of phosphonate esters (15), but it is unusual in that successive deprotonation of methyl groups on different phosphorus atoms occurs easily, and different substituents induce different orientation patterns. We illustrate here the scope of the synthetic possibilities through the reactions of the monocarbanionic derivative $N_3P_3Ph_4Me(CH_2Li)$. In similar reactions of $(NPMe_2)_{3,4}$ the formation of polyfunctional carbanions and the orientational effects are discussed in terms of electronic structure.

Results

The lithio derivative $N_3P_3Ph_4Me(CH_2Li)$ (**2**), re-

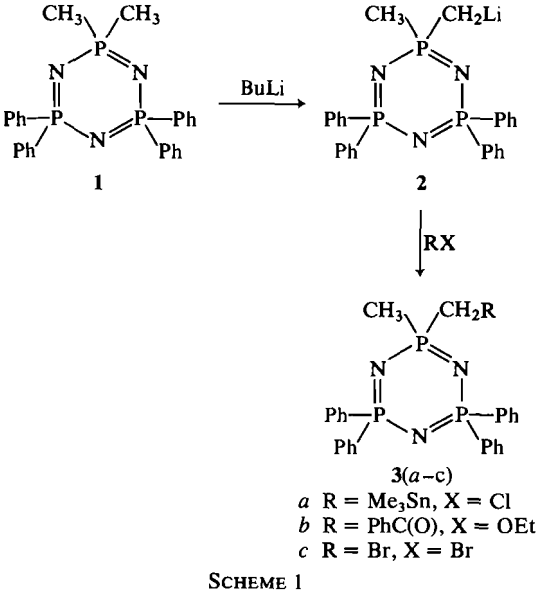

SCHEME 1

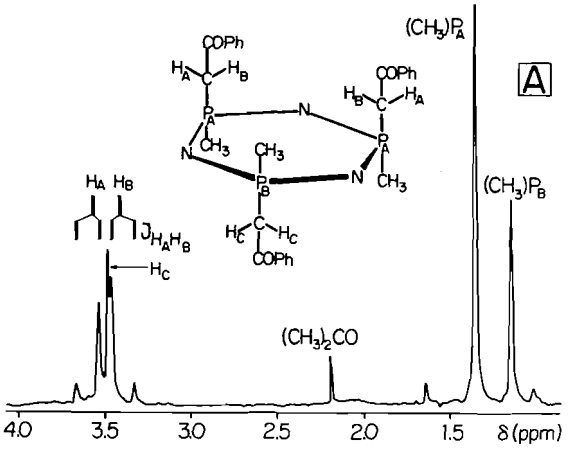

FIG. 1. The ^{31}P-decoupled ^1H nmr spectrum of **5a**. Coupling constants (Hz): P_ACH_3, 14.0; P_AH_A, 13.5; P_AH_B, 14.0, H_AH_B, 13.0; P_BCH_3, 14.6; P_BH_C, 14.9.

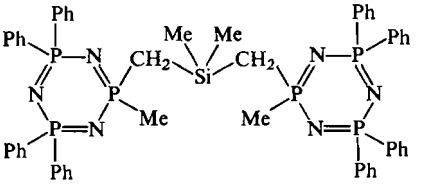

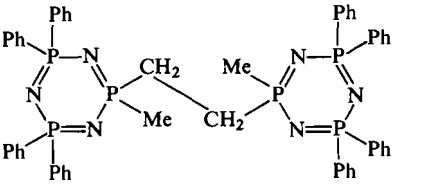

acts with the electrophiles of Scheme 1 to produce the new organophosphazenes $N_3P_3Ph_4Me(CH_2R)$ (**3**). Other derivatives prepared in similar ways include the carboxylic acid (**3d**, R = COOH), and the bridged compound $(Ph_4N_3P_3MeCH_2)_2SiMe_2$ (**3e**). Compound **3f** was prepared from the lithio derivative by an oxidative coupling reaction involving $CuCl/O_2$ (23). The nmr parameters of **1** and **3** (*a*–*f*) are given in Table 1.

Relative to **1**, the methylene protons are shielded by the Me_3Sn group, and deshielded by Br and PhC(O). Since electronegative groups concentrate π-electrons on phosphorus, the phosphorus shifts vary in the opposite sense, and shielding of the nearest phosphorus atom decreases in the order R = Br, PhC(O), COOH, H, $SnMe_3$. In general, **2** has the same synthetic possibilities as other alkyllithiums, but, as will be seen, interactions between a substituent and a phosphazene ring in which multiple deprotonation can occur have an important effect on the orientation of a second substituent.

Hexamethylcyclotriphosphazene (**4**) forms a tricarbanion, of which a tribenzoyl (**5***a*) and a tribromo derivative (**5***b*) have been prepared. The relative configurations of the benzoyl groups were determined from the ^1H and ^{31}P nmr spectra. If all the benzoyl groups were on the same side of the N_3P_3 plane, they would be equivalent on the nmr time scale, and methyl and methylene signals should appear in the ^{31}P-decoupled spectrum as singlets. The actual ^1H spectrum (Fig. 1) is a pair of singlets, intensities 1:2, for the methyl protons, and a singlet for one methylene group superimposed on an AB pattern characteristic of two equivalent methylene groups each containing diastereotopic protons.

The relative configurations of the benzoyl groups are then *cis–trans–trans*,[3] and the ^{31}P spectrum, consisting of two signals of relative intensity 1:2, shows the expected nonequivalence of the phosphorus atoms. Two forms of **5***b* were obtained. For the first, the proton signal is a pair of simple doublets, so that it is the *cis–cis–cis* isomer. In the

second isomer, although the ^{31}P signal is apparently a singlet, the differently situated methyl and methylene groups are distinguished, so that its configuration is *cis–trans–trans*. Details are given in Table 2.

The derivatives based on the eight-membered ring show additional features. Deprotonation of $N_4P_4Me_8$ (**6**) gives, in the limit of four equivalents of base, the tetracarbanion derivative $N_4P_4Me_4(CH_2Li)_4$ (**7**). The products of the reaction of this compound with several electrophiles are shown in Scheme 2. The nmr parameters of compounds **8** (*a–e*) are given in Table 3, and those of **8** (*f–l*) in Table 4. The nmr spectra of all the tetrasubstituted derivatives are qualitatively similar, in that the ^{31}P spectrum of each consists of a singlet, and the ^1H spectrum consists of two simple doublets for the methylene and methyl groups respectively. The *cis–cis–trans–trans* structure is ruled out, but no configurational choice can be made between the three more symmetrical possibilities.

The disubstituted derivatives are more generally informative. In the reaction of methyl iodide with the tetracarbanion a small amount of the diethyl derivative was obtained as its dihydrochloride (**8***p*), whose crystal structure (17) showed the molecule to be centrosymmetric, and the ethyl groups to be in *trans*-antipodal orientations. Antipodal substitution is also found in the MMe_3 derivatives (M = Ge, Sn), whose ^{31}P spectra consist of a pair of 1:2:1 triplets; the ^1H methylene and methyl spectra are simple doublets. The reaction of the tetracarbanion with ethyl benzoate is significantly different, in that it goes no further than disubstitution. Moreover, the ^1H and ^{31}P spectra of the dibenzoyl derivative are quite different from those of antipodally substituted derivatives, and depend on both solvent and time. The ^{31}P-decoupled ^1H spectrum of a fresh solution of **8***a* in $CDCl_3$ (Fig. 2A) exhibits a single AB pattern for the two methylene groups,

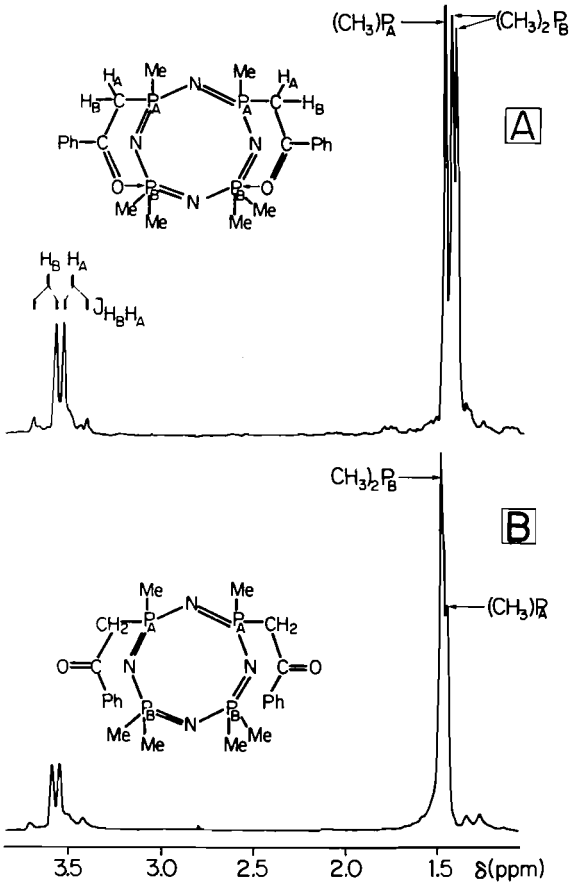

FIG. 2. The ^{31}P-decoupled ^1H nmr spectrum of **8***a* in $CDCl_3$. A, immediately; B, after standing.

and three singlets of relative intensity 1:1:1 in the methyl region, the two methyl groups of the PMe_2 group now being distinguished. The ^{31}P spectrum shows only two broadened singlets of intensity ratio 1:1, and, together with the proton spectrum, indicates vicinal substitution. If the solution is allowed to stand, a slow change occurs (Fig. 2B), and a similar but immediate change takes place in CD_3OD. The methyl signals become two singlets of relative intensity 2:1, and ^{31}P–^{31}P coupling is observed in the ^{31}P spectrum, each signal now being split into a doublet which shows virtual coupling. The AB pattern of the two equivalent methylene groups remains unchanged even at 55°C ($CDCl_3$), thereby confirming the diastereotopic nature of the methylene protons in vicinal positions. The benzoyl groups evidently form weak intramolecular bonds (possibly similar to those in a Wittig intermediate (18), as shown in Fig. 2) which are broken by competitive hydrogen bonding of the carbonyl oxygen atom, slowly with $CDCl_3$, rapidly

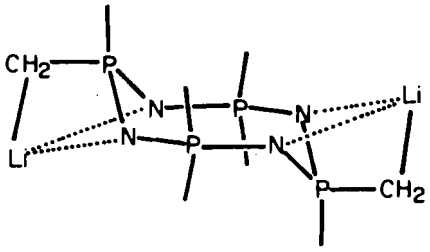

FIG. 3. Possible ion-pairing scheme of di-carbanion.

with CD_3OD. The PMe_2 group thereby becomes (accidentally) symmetrical. Other small changes in the nmr parameters reflect the altered electron distribution, the greatest of which is the upfield shift of the phosphorus signal of the Me_2P groups. Not surprisingly, the methylene protons exchange with CD_3OD. Interaction between a ring nitrogen atom and the carbon atom of a carbonyl group may also occur, as in $N_3P_3F_5(CH_2COPh)$ (19), but the evidence is inconclusive.

Discussion

The reactions of the monofunctional carbanion **2** show the scope of the reaction; it is likely that a much wider range of electrophiles can be used, so that the method should be generally useful for phosphazene synthesis. The same is true of the polyfunctional carbanions of **4** and **6**, but we need to say more about the deprotonation process itself and the orientation of the substituents.

It is striking that no derivatives of the monocarbanion of **4** or **6** could be prepared, whether by a deficit of the base or of the substituting reagent; deprotonation appears to facilitate further deprotonation. Ordinarily, a second deprotonation would be disfavoured by the electrostatic repulsion in the dianion; if the effective dielectric constant is assumed to be 2.5, ΔpK (from this cause alone) for the antipodal protons of $N_4P_4Me_8$ would be about 15, if the two carbon centres are assumed to carry a full negative charge. Two effects, both chemically significant, reduce this difference. First, the effective charge on carbon would be diminished by coordination of the lithium cations, as shown in Fig. 3. Such cation effects are important chemically; in the reaction of phosphonate carbanions with ketones, for instance, such larger cations as Na^+ increase the effective negative charge on oxygen and promote olefin formation (20). The second factor is that conjugation of a carbanionic methylene group can take place by delocalization of its charge into the ring, with consequent changes in both the electrostatic energy and the π-electron levels; these two energy changes often tend to compensate one another. They can be estimated only roughly, but they help in the interpretation of the reactions described here, specifically the occurrence of multiple deprotonation, the dependence of the degree of substitution on substituent electronegativity, the orientation of substituents, and the different reactivities of the carbanions formed from $N_3P_3Me_6$ and $N_4P_4Me_8$ to ethyl benzoate.

The following method was used for the calculations. π-Electron energies and charges were found for molecules based on an N_4P_4 ring by the HMO method (see Fig. 4 for details), and the π-charges so found were used to calculate the intramolecular electrostatic energy of a simplified model, in which all the atoms were assumed to be coplanar (PN = 1.58 Å, PC = 1.80 Å, all ring angles 135°, all exocyclic angles 112.5°; Li^+ 3.2 Å from C, along extended P—C bond). These model calculations have several limitations. The Hückel method, even if its parameters could be relied on, overestimates bond polarity, and the calculated effective electrostatic energies are too great, not only for this reason, but also because of the solvation and ion-pairing effects mentioned above. The neglect of changes in the σ-densities is perhaps a smaller source of error, since the σ-bonds would be less polarizable. For these reasons, the calculations have only qualitative significance, but they help in interpreting the chemistry, and suggest new developments.

Carbanion Formation

Carbon would normally be taken to be more electronegative than phosphorus, but the formal negative charge would raise its energy, and we have assumed $\alpha_C = \alpha_P$. The principal interaction of the carbanion centre is then with the lowest unoccupied level of the N_4P_4 ring, a nonbonding orbital (composed of phosphorus atomic orbitals), to which electrons are transferred on conjugation, as shown in Fig. 4 (level 5). The highest occupied level is appreciably lowered, and the loss of 0.862 electrons from C goes principally to P (0.780 electrons) with a smaller contribution to N (0.082 electrons). The energy changes with progressive conjugation of up to four CH_2^- groups are shown in Fig. 5. The conjugation energies are substantial, and they suggest that the antipodal dianion should be more stable than the vicinal isomer, but since the incremental conjugation energy decreases with increasing number of *exo*-groups, conjugation alone cannot explain the multiple deprotonation which occurs in practice.

An explanation is possible if we also include the electrostatic energy changes which occur as a

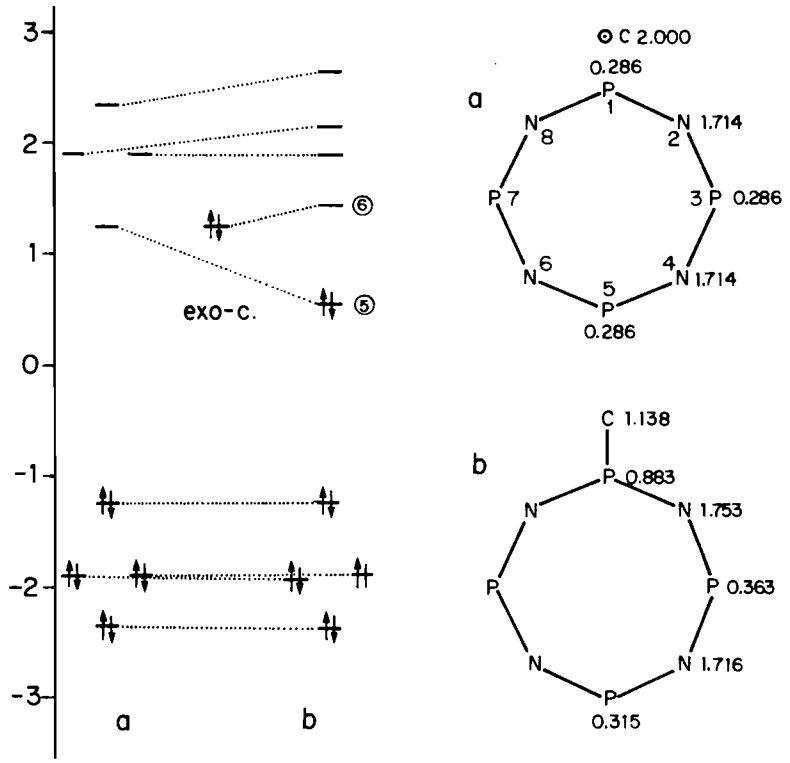

FIG. 4. Energy levels (eV) and π-charge densities of (a) an 8-membered N_4P_4 ring ($\alpha_N = -1.25$, $\alpha_P = 1.25$, $\beta_{endo} = -1$ eV) and (b) the same, but with exocyclic conjugation to form a mono-carbanion, $\beta_{exo} = -1$ eV). Different parameters have been used where stated in the text.

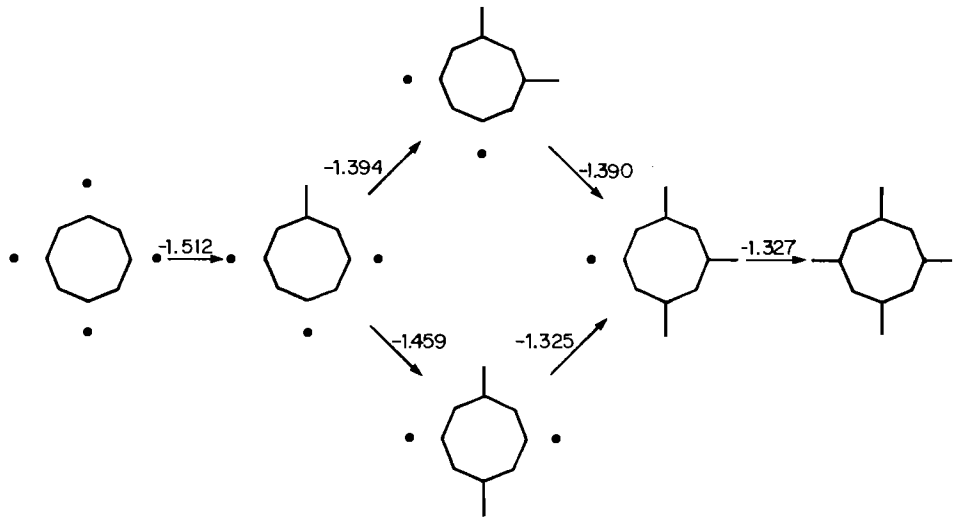

FIG. 5. Changes in conjugation (eV) with progressive conjugation. Parameters as for Fig. 4. Dots represent unconjugated electron pairs.

result of the conjugation. Some typical results are shown in Table 5. Comparison of columns 2 and 3 shows that the transfer of charge to the ring adds a substantial repulsive component to the intra-ring interactions, and a smaller repulsive component to the *exo*-ring interaction. The introduction of a second *exo*-group into the antipodal position increases the *exo*-ring interaction still further, and adds a (small) *exo-exo* contribution. The additional conjugation energy arising from this second

TABLE 5. Calculated electrostatic energies (eV) of N_4P_4 carbanions[a]

Number of formal CH_2^- groups	Charge on *exo*-group	Intra-ring	*Exo*-ring	*Exo–exo*
0	—	−25.32	—	—
1 (localized)	−1.00	−25.32	−1.09	—
1 (delocalized)	−0.11	−16.30	0.38	—
2 (antipodal, delocalized)	−0.45	−14.09	3.44	0.38

[a]$\beta_{exo} = -0.2$ eV.

step is achieved with only a small additional charge delocalization, so that the additional intra-ring repulsive energy is also small. The net changes for the first two deprotonation steps (from rows 1, 3, 4) are 9.40, 5.65 eV, so that, relative to the first step, the second step is exothermic, the energy change more than compensating for the decreased conjugation energy (Fig. 5). If we also include the cation–anion and cation–cation interactions, the conclusion is reinforced; for likely values of β_{exo}, if the added base is strong enough to remove one proton, it will also remove a second.

The third and fourth deprotonation steps can be treated similarly; as a crude approximation, we again consider only the changes in π-energy and electrostatic energy. The third and fourth stages involve increases in the electrostatic energy of the anion alone, the incremental changes for the four steps being (0), −3.75, 1.55, 0.79 eV. However, the negative charge on a single carbanionic centre increases as the number of such groups increases, and if the interactions with the cations are included, the incremental energies are (0), −4.72, −0.03, −0.87 eV. As stated above, the charges are overestimated, but their correction is unlikely to affect the qualitative conclusion that the second and fourth deprotonations should take place more easily than the first and third.

Substitution Reactions

Such calculations are helpful, but not decisive, in the prediction of reaction products. Intramolecular proton transfer in the carbanions evidently occurs more rapidly than reaction of the carbanions with electrophiles, as illustrated by the isolation of only the *cis–trans–trans* form of the tribenzoyl derivative **5***a*; both isomers of the less sterically demanding tribromo derivative **5***b* were obtained. Mostly, the products are what might be expected from equilibrium considerations, though in one case to be discussed below (benzoylation), we need to consider also the nucleophilicity of the carbanion.

Apart from this case, disubstituted derivatives $N_4P_4Me_6(CH_2R)_2$ are obtained only if a deficit of base is used, and if R is at least as electropositive as Me. Electronegative substituents, like bromine, increase the acidity of the methyl group, facilitate removal of the third proton, and displace to the right such equilibria as

[1] $N_4P_4(CH_2R)_2Me_6 + N_4P_4Me_6(CH_2^-)_2 \rightleftharpoons N_4P_4(CH_2R)_2Me_4(CH_2^-)_2 + N_4P_4Me_8$

so promoting the formation of fully-substituted derivatives; in agreement, only a tetrabromo derivative has been isolated. Electropositive groups have the opposite effect. If R = Me, a very small amount of the di-derivative is formed. More strongly electron-releasing groups, like Me_3Si, Me_3Ge, and Me_3Sn, decrease the acidity of the methyl group, and the di-derivatives can be obtained in high yield. The calculated orientation of the two groups is less clear-cut. Conjugation energies favour antipodal, electrostatic energies favour vicinal substitution; the spectroscopic evidence shows that electropositive groups substitute antipodally.

There is an important limitation to the statement that electronegative substituents facilitate full substitution, which arises from the fact that such substituents withdraw charge strongly from the *exo*-group, so that it can eventually cease to be an electrophile. Substitution is thereby restricted, and, since the electrostatic effects are now small, it is possible to make a firmer statement about orientation, on the basis of the π-energies alone. In an antipodal [1, 5] dicarbanion, levels 5 and 6 in Fig. 4 are both stabilized significantly by electronegative perturbation of atoms 3,7, and both levels are occupied. The unperturbed antipodal dicarbanion is more stable than the vicinal isomer, and the relationship is the same for the neutral molecules perturbed identically at the vicinal and antipodal positions. The combination of the two effects (the conjugative interactions in the carbanion and the electronegative perturbation of the phosphorus atoms), reverses the relative energies, for the following reason. The higher energy of the vicinal unperturbed carbanion is associated with a higher negative charge on carbon (−0.48 vs. −0.45 in the antipodal isomer). It therefore has more to gain, through charge delocalization, if the positive

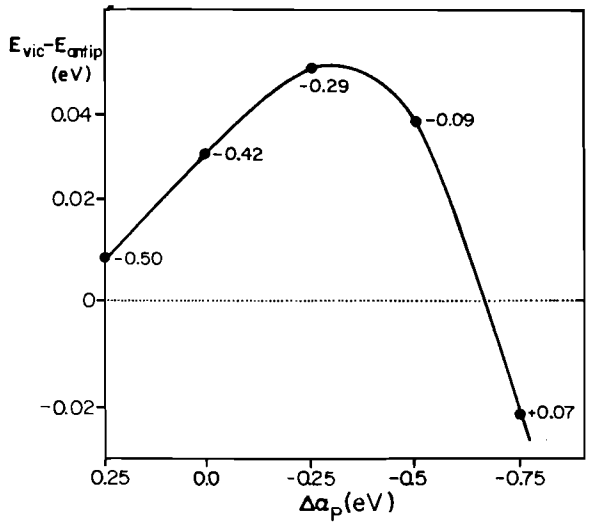

FIG. 6. π-Electron energy of vicinal relative to antipodal $N_4P_4Me_4(CH_2R)_2(CH_2^-)_2$, as a function of the perturbation $\Delta\alpha_P$ induced by R. The residual π-charge on the carbon atoms of the vicinal isomer is marked on the curve; the antipodal charges differ only slightly. The carbanion ceases to be a nucleophile at $\Delta\alpha_P \sim -0.65$ eV.

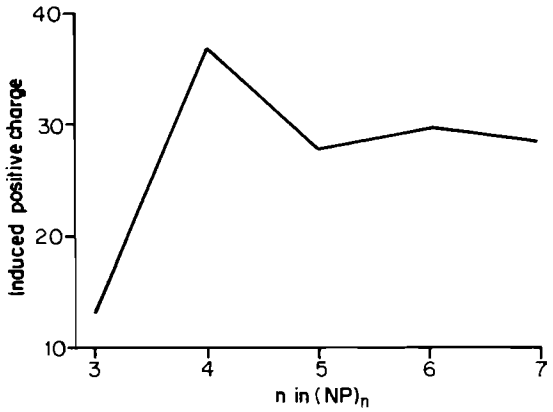

FIG. 7. Positive charge ($\times 10^4$) induced at P(2) by a perturbation of −0.5 eV at P(1). The effect at P(3) is similar, but an order of magnitude smaller.

charge on phosphorus is increased, and the antipodal preference of 0.01 eV is in fact converted to a vicinal preference of 0.02 eV ($\Delta\alpha_P = -0.5\,\beta$, $\beta_{exo} = -0.2$ eV). The energetic effect is not large, but it is accompanied by a dramatic change in charge density on carbon, to −0.03 (vicinal), −0.06 (antipodal). The electron density in nonbonding levels is especially sensitive to electronic changes, and if the substituents are sufficiently electronegative, the dicarbanion is no longer a nucleophile, and the reaction stops at that point. This is evidently what happens in the reaction of $N_4P_4Me_4(CH_2^-)_4$ with ethyl benzoate; it has not been found possible to introduce more than two benzoyl groups, which occupy vicinal positions. Fig. 6 shows the π-energy of vicinal relative to antipodal $N_4P_4(CH_2R)_2$-$Me_4(CH_2^-)_2$ for a particular value of β_{exo}, for which the vicinal form becomes stable for $\Delta\alpha_P \sim -0.65$, the charge on carbon becoming simultaneously close to zero. As in other reactions, the orientation of the substituents appears to be controlled thermodynamically; in an electronegatively monosubstituted carbanion $N_4P_4(CH_2R)Me_4(CH_2^-)_3$, the antipodal carbon carries the highest negative charge, and antipodal substitution would be expected if kinetic effects were dominant. For numerically smaller values of β_{exo}, the vicinal form becomes thermodynamically stable at smaller values of $\Delta\alpha_P$.

As an interesting contrast, the benzoylation of the trimer goes to completion, and this fact, too, has an immediate explanation in terms of π-electron theory. The effect of an electronegative perturbation at phosphorus is to concentrate electron density locally, at the expense of the nearest atoms. Just as (in a homomorphic system) the π-electron energy is an oscillating function of ring size, so is the induced electron density at a particular atom. As Fig. 7 shows, the positive charge is greatest for the eight-membered and least for the 6-membered ring, and the secondary withdrawal from the *exo*-carbon atoms must therefore be greater for the tetramer. If the same parameters are used as for the tetramer, the *exo*-charge on the carbanion of a disubstituted trimer is −0.2, when it is 0.0 in the tetramer. This is indeed much reduced from the value of −0.54 found for the unperturbed molecule, but could well account for the fact that the benzoylation of $N_3P_3Me_6$ goes to completion, whereas the reaction of $N_4P_4Me_8$ stops when two benzoyl groups have been introduced.

Experimental

Most reactions, and operations with products, were carried out under dry nitrogen. Nuclear magnetic resonance spectra were obtained on Varian XL-100, Nicolet-Oxford H-270, Bruker WH-400, and Varian CFT-20 spectrometers. Mass spectra were obtained on a Varian (Atlas) CH 4-B mass spectrometer. Microanalyses were by P. Borda.

Commercial solvents were redistilled and dried, usually over lithium aluminum hydride or sodium-benzophenone. Most reagents, including *n*-butyllithium, were reagent grade commercial products, purified if necessary. Dimethyliodoarsine (21) and the phosphazenes **1**, **4** and **6** were prepared by known methods (2, 4, 22). Methyllithium was prepared as required, by the addition of methyl iodide at −78°C to a slight excess of *n*-butyllithium in hexane (0.5 *M*). The mixture was stirred under an atmosphere of nitrogen and allowed to warm slowly to 0°C. The white precipitate of methyllithium was filtered off under nitrogen and dissolved in dry diethyl ether. The solution so

For personal use only.

formed was filtered if necessary and standardized by titration with acid. The solutions of methyllithium were used within 24 h.

Reactions of $N_3P_3Ph_4Me(CH_2Li)$ (2)

In a typical preparation, a freshly prepared solution of the alkyllithium (either *n*-butyllithium or methyllithium) in ~10% excess, was added to a solution of **1** in ether. After an induction period of a few minutes, a heavy white precipitate of **2** was formed. To ensure completion of the reaction, the mixture was gently heated under reflux for 2 h.

$N_3P_3Ph_4Me(CH_2SnMe_3)$ (3a)

A solution of Me_3SnCl (0.300 g, 1.50 mmol) in 20 mL ether was added to a slurry of **2** (0.651 mmol) in 100 mL ether. The turbidity was reduced, and the mixture was stirred overnight to ensure that reaction was complete. The mixture was filtered, and evaporation of the filtrate yielded colourless crystals, which were recrystallized from ether–hexane as needles of **3a** (0.861 g, 1.35 mmol, 97%); mp 146–148°C. *Anal.* calcd. for $C_{29}H_{34}N_3P_3Sn$: C 54.8, H 5.4, N 6.6, found: C 54.9, H 5.5, N 6.5.

$N_3P_3Ph_4Me(CH_2COPh)$ (3b)

A solution of ethyl benzoate (0.525 g, 3.5 mmol) in 30 mL ether was added dropwise to **2** (3.17 mmol) in 100 mL ether. The reaction mixture was stirred overnight, shaken with 50 mL of 0.1 *N* H_2SO_4, and the organic layer separated and dried over sodium sulphate. Evaporation of the solvent yielded a white solid, which was recrystallized from benzene–toluene and ether–hexane to give a microcrystalline mass of **3b**; mp 144–146°C; ν(C=O): 1666 cm^{-1}. *Anal.* calcd. for $C_{31}H_{30}N_3OP_3$: C 68.5, H 5.3, N 7.3; found: C 68.7, H 5.4, N 7.1.

$N_3P_3Ph_4Me(CH_2Br)$ (3c)

An ethereal (10 mL) solution (an excess) of bromine was added to **2** (1.66 mmol) in 100 mL ether at −78°C. A dilute solution of NaOH was added at room temperature, the organic layer separated, and the aqueous layer washed with 50 mL CH_2Cl_2. The combined extracts were dried over sodium sulphate and evaporated to white crystals (0.92 g), whose ^1H nmr spectrum showed it to be a mixture (~4:1) of **3c** and **2**. Analytically pure crystals of **3c** were obtained by repeated crystallization of this product from benzene–octane and chloroform–octane; mp 176–178°C. *Anal.* calcd. for $C_{26}H_{25}BrN_3P_3$: C 56.5, H 4.6, Br 14.5, N 7.6; found: C 56.9, H 4.5, Br 14.1, N 7.7.

$N_3P_3Ph_4Me(CH_2COOH)$ (3d)

Carbon dioxide was bubbled for 15 min through a slurry of **2** (0.86 mmol) in 100 mL ether. The clear reaction mixture was shaken with 50 mL of 0.1 *N* H_2SO_4, and the organic layer dried over Na_2SO_4. Evaporation of the solvent yielded a white solid, which was recrystallized from acetone as white flakes of **3d** (0.39 g, 0.75 mmol, 87%); mp 185–186°C (dec.). *Anal.* calcd. for $C_{28}H_{26}N_3O_2P_3$: C 62.7, H 5.1, N 8.1; found: C 62.9, H 5.2, N 8.0.

$(N_3P_3Ph_4MeCH_2)_2SiMe_2$ (3e)

Dimethyldichlorosilane (0.90 g, 0.70 mmol, 20% excess) in 10 mL ether was added to **2** (1.16 mmol) in 75 mL ether at −50°C. The mixture was allowed to warm slowly to room temperature and stirred for 24 h. The lithium chloride was filtered off and the solvent removed. The residual oil was dissolved in ether and eluted with 500 mL ether on a column of Silicar CC-7. The clear pale yellow oil remaining after evaporation of the solvent contained some **1**, which was distilled off at 200°C/0.03 Torr. The brown gummy residue was extracted with 4 × 50 mL hexane, and the product **3e** was freed from traces of **1** by repeated crystallization from hexane; mp 163–164.5°C. *Anal.* calcd. for $C_{54}H_{56}N_6P_6Si$: C 64.7, H 5.6, N 8.4; found: C 64.5, H 5.8, N 8.2.

$(N_3P_3Ph_4MeCH_2)_2$ (3f)

Cuprous chloride (0.296 g, 2.20 mmol) was added to **2** (2.06 mmol) in tetrahydrofuran at −40°C. As the temperature was raised to 0°C, the colour of the solution became reddish brown, which turned to green on bubbling oxygen through the solution for 3 h. The solvent was evaporated off, and the semi-solid product was acidified with dilute sulphuric acid. The greenish-white solid product was filtered off, washed with water, dissolved in ether, and passed through a silica gel column. Evaporation of the solvent from the eluate yielded colourless crystals, which were recrystallized from acetonitrile as colourless blocks of **3f**. *Anal.* calcd. for $C_{52}H_{50}N_6P_6$: C 66.1, H 5.2, N 8.9; found: C 66.5, H 5.3, N 8.8. *Exact mass* calcd.: 944.2514; found (ms): 944.2507.

$N_3P_3Me_3[CH_2C(O)Ph]_3$ (5a)

The trilithio derivative of **4** was prepared by adding 7.3 mmol of *n*-butyllithium in hexane to **4** (0.500 g, 2.22 mmol) in 125 mL ether. The mixture was heated under reflux for 75 min, cooled to −35°C, and ethyl benzoate (1.107 g, 7.37 mmol) in 60 mL ether was added over 10 min. The temperature was allowed to rise, and 75 mL 0.5 *M* aqueous potassium fluoride were added after 16 h. The ether layer was separated off and dried over Na_2SO_4. The excess of ethyl benzoate was removed at 100°C/0.1 Torr, and the residual white solid **5a** was recrystallized twice from acetone; mp 173–177°C; ν (C=O): 1673, 1659 cm^{-1} (intensities 2:1). *Anal.* calcd. for $C_{27}H_{30}N_3O_3P_3$: C 60.3, H 5.6, N 7.8; found: C 60.1, H 5.6, N 7.9.

$N_3P_3Me_3(CH_2Br)_3$ (5b)

Bromopentafluorobenzene (2.322 g, 9.40 mmol, 5% deficit) in 60 mL ether was added to the trilithio derivative (3.30 mmol) in 75 mL ether was −78°C over 15 min. The turbidity decreased, and the reaction mixture became yellow and finally dark brown on being allowed to warm to −20°C over 3.5 h; the addition of 10.2 mmol aqueous HCl removed most of the colour. The ether layer was washed with water and dried over Na_2SO_4. After removal of the solvent, the light brown residue was washed with acetone. The remaining white solid (0.152 g, 10.5%) was identified by its nmr spectra and by tlc (50:50 acetone–hexane) as a mixture of two isomers of $N_3P_3Me_3(CH_2Br)_3$. *Anal.* calcd. for $C_6H_{15}Br_3N_3P_3$: C 15.6, H 3.3, Br 51.9, N 9.1; found: C 15.9, H 3.1, Br 51.5, N 9.0. The isomers (*cis–cis–cis*: *cis–trans–trans* 1:3) were partly separated by crystallization from acetone, in which the latter compound is the more soluble. If *n*-butyllithium and bromopentafluorobenzene are used in excess, some tetrabromo derivatives are formed.

$N_4P_4Me_4Et_4$ (8f)

A solution of methyllithium (39.2 mmol) in 56 mL ether was added dropwise to a solution of **6** (2.712 g, 9.04 mmol) in 50 mL ether. When effervescence had ceased (30 min) the mixture was heated under reflux for 2 h, when a slight turbidity was apparent. An exothermic reaction took place on the addition of a large excess (~25 mL) of methyl iodide. The mixture was heated under reflux for a further 4 h. The solvent and the excess of methyl iodide were distilled off, leaving a white paste (10.75 g) which was dissolved in water and neutralized with sulphuric acid (residual alkalinity 2.15 mmol OH^-). The lithium was precipitated as fluoride, the solvent distilled off the filtered solution, and the residue extracted with 3 × 30 mL hot chloroform. Triethylamine (10 mL) was added to the extract, which was shaken for 5 min and filtered. Evaporation of the solvent from the filtrate left a crystalline mass which was extracted with 3 × 50 mL hot hexane. Evaporation of these extracts yielded colourless crystals of **8f** (2.58 g, 7.2 mmol, 80%) which was purified by sublimation *in vacuo* and by crystalliza-

For personal use only.

tion from hexane; mp 65–67°C. *Anal.* calcd. for $C_{12}H_{32}N_4P_4$: C 40.5, H 9.1, N 15.7; found: C 40.2, H 8.9, N 16.0. The dihydrochloride **8***n* was precipitated from a solution of the phosphazene and HCl in carbon tetrachloride and recrystallized from acetonitrile–benzene as $N_4P_4Me_4Et_4 \cdot 2HCl \cdot H_2O$; mp 180–185°C. *Anal.* calcd. for $C_{12}H_{36}Cl_2N_4OP_4$: C 32.2, H 8.1, Cl 15.9, N 12.5; found: C 32.3, H 8.3, Cl 15.9, N 12.7. If the chloroform extract is not treated with a base, the dihydroiodide is formed, rather than the neutral phosphazene. In one such experiment, the chloroform extract was evaporated to an oil, which was dissolved in water and eluted through an Amberlite CG400 ion exchange column charged with chloride ion. A few crystals of $N_4P_4Me_6Et_2 \cdot 2HCl$ (**8***p*) were obtained on evaporation of the solvent; mp 231–234°C. *Anal.* calcd. for $C_{10}H_{30}Cl_2N_4P_4$: C 29.9, H 7.5, Cl 17.7, N 14.0; found: C 29.6, H 7.6, Cl 18.1, N 14.1.

Trimethylsilyl, -germyl, and -stannyl derivatives of 6

An excess of Me_3SiCl (2.0 mL, 15.9 mmol) was added to **7** (2.52 mmol) in 50 mL ether. The reaction was vigorous and exothermic. The mixture was stirred overnight, the white precipitate filtered off, and the solvent removed. The colourless residual oil was distilled at ~160°/0.01 Torr to give an oil which solidified on standing. The solid was recrystallized from hexane at −23°C, to give colourless blocks of $N_4P_4Me_4(CH_2SiMe_3)_4$ (**8***g*); mp 97–102°C. *Anal.* calcd. for $C_{20}H_{56}N_4P_4Si_4$: C 40.8, H 9.6, N 9.5; found: C 40.5, H 9.6, N 9.5. The trimethylgermyl (**8***h*) and trimethylstannyl (**8***i*) derivatives were prepared similarly (yields 99, 92%). Melting point for **8***h*, 98.5–100°C. *Anal.* calcd. for $C_{20}H_{56}Ge_4N_4P_4$: C 31.3, H 7.4, N 7.3; found: C 31.4, H 7.5, N 7.1. *Anal.* calcd. for $C_{20}H_{56}N_4P_4Sn_4$: C 25.3, H 5.9, N 5.9, Sn 49.9; found: C 25.1, H 5.9, N 6.0, Sn 49.6. The same method was used for the preparation of the disubstituted derivatives, using half-quantities of methyllithium and the halide. $N_4P_4Me_6(CH_2SiMe_3)_2$ (**8***c*): mp 63–65°C. *Anal.* calcd. for $C_{14}H_{40}N_4P_4Si_2$: C 37.8, H 9.1, N 12.6; found: C 38.2, H 9.0, N 12.4. $N_4P_4Me_4(CH_2GeMe_3)_2$ (**8***d*): mp 77–79°C. *Anal.* calcd. for $C_{14}H_{40}Ge_2N_4P_4$: C 31.5, H 7.6, N 10.5; found: C 31.6, H 7.7, N 10.3. $N_4P_4Me_6(CH_2SnMe_3)_2$ (**8***e*): mp 104–106°C. *Anal.* calcd. for $C_{14}H_{40}N_4P_4Sn_2$: C 26.9, H 6.4, N 9.0; found: C 27.1, H 6.5, N 8.7.

$N_4P_4Me_4(CH_2Br)_4$ (8j)

Bromopentafluorobenzene (5.39 g, 21.8 mmol) in 50 mL ether was added to **7** (5.0 mmol) in 90 mL ether at −78°C over 10 min. The temperature was raised to −10°C over 2 h, the solution washed with water, and the golden brown ether layer dried over Na_2SO_4 and evaporated. The product **8***j* was deposited from the residual oil, and was recrystallized from hexane and chloroform (1.85 g, 60%); mp 155–156°C. *Anal.* calcd. for $C_8H_{20}Br_4N_4P_4$: C 15.6, H 3.3, Br 51.9, N 9.1; found: C 15.8, H 3.5, Br 51.8, N 9.1.

$N_4P_4Me_4(CH_2I)_4$ (8k)

Iodine (2.84 g, 11.2 mmol) was added to **7** (2.53 mmol) in 70 mL ether at −78°C. The iodine dissolved as the temperature rose. The reaction mixture was stirred at room temperature for 62 h, the ether was distilled, and the excess of iodine removed with aqueous sodium thiosulphate. The product **8***k* (0.152 g, 14.5%) was precipitated as a white solid on the addition of acetonitrile to the residual red-brown oil; mp 158.5–159.5°C. *Anal.* calcd. for $C_8H_{20}I_4N_4P_4$: C 12.0, H 2.5, I 63.2, N 7.0; found: C 12.1, H 2.4, I 62.9, N 6.9.

$N_4P_4Me_4(CH_2AsMe_2)_4$ (8l)

Dimethyliodoarsine (1.436 g, 6.19 mmol) in 60 mL ether was added to **7** (1.55 mmol) in 80 mL ether at −78°C over 10 min. Aqueous potassium fluoride was added to precipitate the lithium; the ether layer was separated and dried and the solvent evaporated off. The residual clear, colourless, hygroscopic oil was distilled under reduced pressure to yield pure **8***l* (0.61 g, 55%). *Anal.* calcd. for $C_{16}H_{44}As_4N_4P_4$: C 26.8, H 6.2, N 7.8; found: C 27.1, H 6.1, N 7.8. A quaternary salt $N_4P_4Me_4(CH_2AsMe_2)_4 \cdot 4MeI$ (**8***m*) was prepared by the addition of **8***l* to a large excess of methyl iodide. After 3 h, the white solid **8***m* (88%) was filtered off, washed with ether, and recrystallized from water as a monohydrate. It is insoluble in acetonitrile and chloroform; mp 280°C (dec.). *Anal.* calcd. for $C_{20}H_{58}As_4I_4N_4OP_4$: C 18.5, H 4.5, N 4.3; found: C 18.6, H 4.5, N 4.2.

$N_4P_4Me_6[CH_2C(O)Ph]_2$ (8a)

Ethyl benzoate (1.319 g, 8.78 mmol) in 70 mL ether was added to **7** (2.20 mmol) at −78°C over 10 min. On slow warming to room temperature the turbidity rapidly disappeared. After 5 h of stirring, the lithium was precipitated as fluoride and the solvent removed from the dried ether layer. Unchanged ethyl benzoate was distilled from the oily residue *in vacuo*. The addition of acetonitrile to the remaining pasty solid yielded white solid **8***a* (0.27 g, 24%), which was recrystallized from acetonitrile, mp 152.5–156°C; ν(C=O): 1663 cm^{-1}. *Anal.* calcd. for $C_{22}H_{32}N_4O_2P_4$: C 52.0, H 6.3, N 11.0; found: C 52.2; H 6.3, N 11.1.

The synthesis of the cyathins. Part 1. Synthesis of a tricyclic intermediate

WILLIAM A. AYER, DALE E. WARD, LOIS M. BROWNE, LOUIS T. J. DELBAERE,[1] AND YUMIKO HOYANO

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received April 14, 1981

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

WILLIAM A. AYER, DALE E. WARD, LOIS M. BROWNE, LOUIS T. J. DELBAERE, and YUMIKO HOYANO. Can. J. Chem. **59**, 2665 (1981).

The tricyclic diketoalcohol **5** (3-phenylthio-6,9,10-trimethyl-12-hydroxytricyclo[7.4.0.0^{2,6}]trideca-2,10-diene-4,8-dione), a potential intermediate in the synthesis of the cyathins, has been prepared starting from 2,5-dimethyl-*p*-benzoquinone. The structure and stereochemistry of **5** was proven by an X-ray crystallographic study of the corresponding *p*-bromobenzoate (**6**). Attempts to isomerize the *cis* BC ring junction in **5** to give the corresponding *trans* compound were unsuccessful. Removal of the thiophenyl group from **5** gave compound **18***a* which on base-catalyzed isomerization provided an equilibrium mixture of the *cis* and *trans* compounds.

WILLIAM A. AYER, DALE E. WARD, LOIS M. BROWNE, LOUIS T. J. DELBAERE et YUMIKO HOYANO. Can. J. Chem. **59**, 2665 (1981).

A partir de la diméthyl-2,5 *p*-benzoquinone on a préparé le dicétoalcool tricyclique **5** (phénylthio-3 triméthyl-6,9,10 hydroxy-12 tricyclo[7.4.0.0^{2,6}]tridécadiène-2,6 dione-4,8) un intermédiaire potentiel dans la synthèse des cyathines. On a établi la structure et la stéréochimie du composé **5** par cristallographie de rayons-X du *p*-bromobenzoate (**6**) correspondant. On a essayé en vain d'isomériser la jonction du cycle BC *cis* du composé **5** en vue d'obtenir le composé *trans*. L'élimination du groupe thiophényle du composé **5** conduit au composé **18***a* qui par une isomérisation catalysée par une base donne un mélange de composé *cis* et *trans* en équilibre.

[Traduit par le journal]

The cyathins are a unique group of diterpenoids produced by the bird's nest fungi *Cyathus helenae* (1–3), *C. africanus* (4), and *C. earlei* (5).[2] Several of the cyathins, especially cyathin B_3 (**1**) and cyathin C_3 (**2**), show strong antibiotic activity (3, 7). The transformation of cyathin A_3 (**3**), the major diterpenoid metabolite of *C. helenae*, into the biologically more active cyathin B_3 (**1**) and cyathin C_3 (**2**), as well as to allocyathin B_3 (**4**), has been achieved (3). Thus, the total synthesis of cyathin A_3 (**3**) would also represent a synthesis of cyathin B_3 (**1**) and cyathin C_3 (**2**). We have briefly described two approaches to the synthesis of these compounds which have failed to reach the tricyclic stage (6). In this paper we describe the synthesis of the tricyclic intermediate **5** and the X-ray crystal structure of its *p*-bromobenzoate **6**.

The general features of the synthetic strategy are outlined in Scheme 1. We envisioned the A and C rings of the cyathin skeleton to arise through aldol cyclizations of 1,4- and 1,6-diketones, respectively. Since a substituted cyclohexene is a latent 1,6-diketone our initial synthetic target was the substituted octalone **7**. Of crucial importance in the construction of **7**, and in any synthesis of the cyathins, is the generation of the correct *anti*-relationship between the quaternary methyl groups. We felt that by starting with 2,5-dimethyl-*p*-benzoquinone and carrying out two electrocyclic

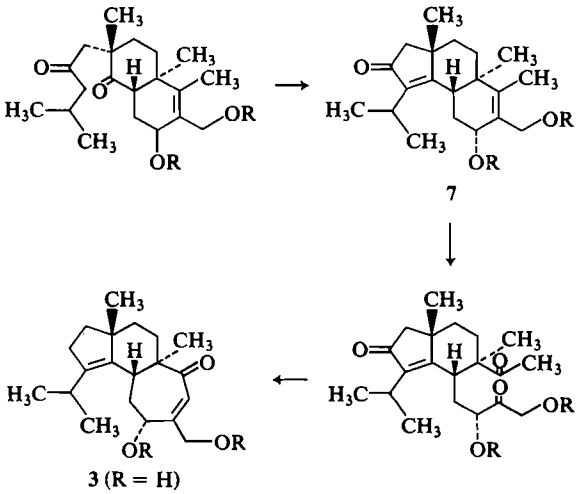

SCHEME 1

additions (one [4 + 2], the other [2 + 2]) the desired stereochemical result could be achieved.

Treatment of 2,5-dimethyl-*p*-benzoquinone with the known (8) 2,4-bistrimethylsilyloxy-1,3-pentadiene (**8**, 2.2 equivalents as a 1:1 mixture of stereoisomers) in refluxing xylene gave the adduct **9** in 91% yield. The ^{1}H nmr and ^{13}C nmr spectra showed that **9** was a single stereoisomer. The relative stereochemistry of the tertiary allylic silyl-ether was not determined, but it is not crucial since at a later stage this group is removed. The adduct **9** was further characterized by hydrolysis to the crystalline trione **10**. In the ^{1}H nmr spectrum of **10** the three nonmethyl aliphatic protons appear as an ABX pattern, with J_{AB} = 4 Hz, J_{AX} = 6 Hz, and J_{BX} = 18 Hz (the ring junction hydrogen is the A proton), confirming the stereo- and regiochemistry of the Diels–Alder addition.

The next stage in the synthesis called for a [2+ 2] photoaddition to the enedione system of **9**. Wiesner has studied the addition of allene and other olefins to enones and has described an empirical rule to predict the stereochemistry of such additions (9). The rule states that the reaction proceeds from a conformationally flexible (at least at the β-carbon) excited state in which the β-substituent of the enone assumes its thermodynamically more stable conformation. This rule is difficult to apply in the case of **9**, since in this flexible system with several sp^2 carbons it is difficult to predict the most stable conformation of the excited state. However, in the photodimerization of these types of compounds it has been shown that the product is the one with the sterically least congested *anti* stereochemistry (10). With this in mind we anticipated that addition of allene to **9** would lead to the product with the desired stereochemistry. Irradiation of a tetrahydrofuran solution of **9** in the presence of excess allene at −40° to −50°C provided a mixture of the adducts **11***a* and **11***b*. This mixture was hydrolyzed to give the triones **12***a* and **12***b* (ratio 4:1) in ca. 60% overall yield from the starting quinone.

In the 270 MHz ^{1}H nmr spectrum of compound **12**, the signals for the *exocyclic* methylene protons at C-5 (δ 5.16, 5.01) are coupled to the 4,6-ring junction proton (C-6, δ 3.70) confirming that the photoaddition had occurred with the desired regiochemistry in the major trione (**12***a*). As well, the coupling constants shown by the C-1 methine proton (δ 3.41, J = 3.8, 4.5 Hz) indicated the presence of a *cis* 6,6-ring junction in **12***a* as shown. Comparison of spectral data (^{1}H nmr and ^{13}C nmr) of the two inseparable isomers (**12***a* and **12***b*) led us to speculate that the minor isomer was the regioisomer **12***b*. This was confirmed by later experiments (*vide infra*). We were unable to assign the relative stereochemistry of the ring junctions (i.e., *cis–anti–cis* or *cis–syn–cis*). This was clarified at a later stage.

The *exocyclic* double bond in **12** was selectively oxidized with *m*-chloroperbenzoic acid to give a mixture of crystalline epoxides **13** in high yield. Hydrolysis of **13** with 1 *N* perchloric acid in refluxing tetrahydrofuran gave, after acetylation, a mixture of two monoacetates. Spectral data (ir, ^{1}H

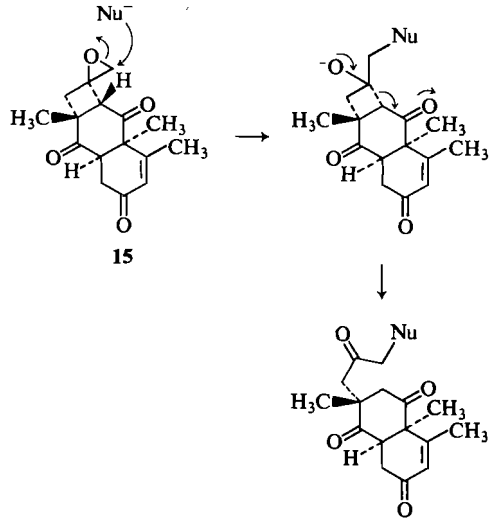
17

nmr) for the mixture was consistent with structures **14***a* and **14***b* present in a ratio of ca. 3 to 1. Significantly, in the ^{1}H nmr spectrum of the mixture, the minor isomer showed a methyl doublet at δ 1.10 which confirms the regioisomeric nature of the minor product in **11**, **12**, and **13**. The formation of **14** is a result of hydrolysis of the epoxide to a diol followed by retro-aldol fragmentation of the resulting β-hydroxyketone.

The next stage in the synthetic sequence involves the elaboration of the cyclobutane ring of compound **12** into the ring A system of the cyathins. Epoxide **13***a* can serve as a latent 1,4-diketone by nucleophilic opening of the epoxide followed by fragmentation as depicted in Scheme 2. Initial experiments suggested that 1,4-addition of the nucleophile to the enone system in ring C was occurring in competition with epoxide opening. To protect the enone system from such addition reactions, the α,β-unsaturated carbonyl group of **13** was selectively reduced with 9-borabicyclo[3.3.1]-nonane (11) to give compound **15** as indicated by the disappearance of the enone carbonyl band at 1670 cm^{-1}. We were unable to effect the desired epoxide opening reaction (cf. Scheme 2) with lithium diisopropylcuprate. However, treatment of **15** with an ethanolic solution of benzenethiol (12) containing 5 mol% aqueous KOH provided the tricyclic dione **5** which was isolated as a single component from the reaction mixture after trituration with ether.



SCHEME 2

In the ^{1}H nmr spectrum of **5** the ring junction hydrogen at C-5 appears as a doublet of doublets at δ 3.62 with axial–equatorial and axial–axial couplings (J = 4, 11 Hz). Examination of Dreiding molecular models of **5** and its diastereoisomers shows that if the methyl groups are *cis*, the most stable conformation should be one in which the C-5 proton would be in a pseudo-equatorial configuration (with respect to the cyclohexene ring) and thus the coupling constants should be small. The large coupling constant observed for the ring junction proton in **5** is indicative of an axial hydrogen and suggested that **5** possessed the desired *anti* relationship of the ring junction methyls. At this point we were unable to unambiguously assign the stereochemistry of the 6,6-ring junction (i.e., *cis* or *trans*). In order to clarify this point and to verify the structure of **5** we undertook an X-ray crystallographic analysis of its *p*-bromobenzoate derivative, **6**. Compound **6** crystallizes in the monoclinic system $P2_1/c$. The crystal structure, which was solved using the heavy atom method and refined to an R index of 0.066, showed that **6** indeed possesses *anti* methyl groups, and that the stereochemistry at the BC ring junction is *cis*. A perspective drawing of the X-ray crystal structure of **6** is shown in Fig. 1.

The cyathins possess a *trans*-fused BC ring system and thus it was desirable to effect epimerization at C-5 in the tricyclic alcohol **5**. Attempted epimerization through deconjugation–conjugation of the ring A enone by treatment with sodium methoxide in refluxing methanol gave only recovered starting compound. Treatment of compound **5**

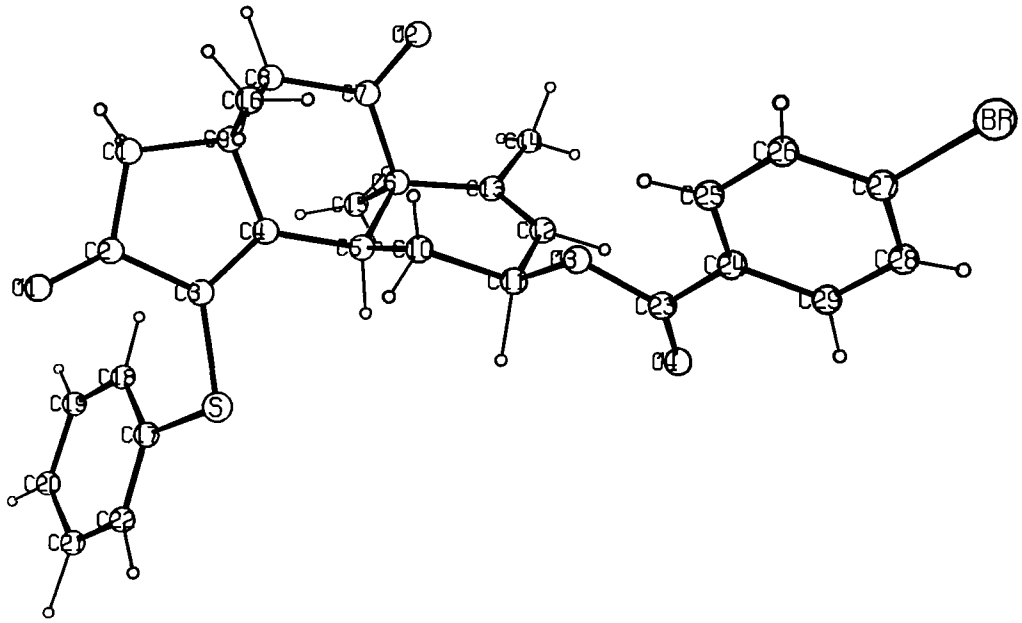

FIG. 1. Perspective drawing of the *p*-bromobenzoate of the tricyclic alcohol **5** (**6**).

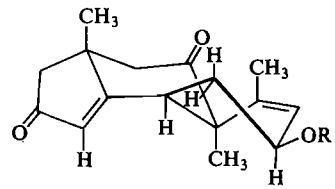
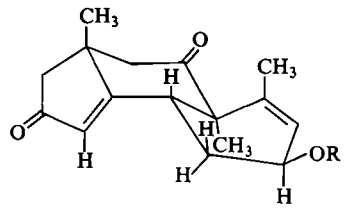
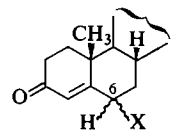
using sodium methoxide – methanol-*O*-*d* led to recovery of **5** in which the hydrogens at C-1, C-5, and C-8 had been replaced by deuterium (as evidenced by ^{1}H nmr). These results suggest that the most stable configuration of this compound is that in which the BC ring fusion is *cis*. Inspection of Dreiding molecular models of **5** and its C-5 epimer show that the thiophenyl group at C-3 has a strong nonbonded interaction with the C-9 methylene group in the *trans* epimer, thus making the *cis* epimer thermodynamically more favorable. We reasoned that if the thiophenyl group were removed, then epimerization at C-5 might occur. Tricyclic alcohol **5** was transformed in the usual way to its tetrahydropyranyl ether, **16**, and this was subjected to treatment with Raney nickel, to give, in variable yield, the dione **17**. The THP ether was hydrolyzed in the presence of pyridinium *p*-toluenesulfonate and the resultant alcohol **18***a* was treated with sodium methoxide in hot methanol. The reaction product proved to be a mixture of alcohols in the ratio ca. 1.2:1. Analysis of the ^{1}H nmr spectra of the products **18** and the acetyl derivatives **19** shows that the minor component is the starting alcohol **18***a*.[3]



18*a* R = H
19*a* R = Ac



18*b* R = H
19*b* R = Ac



20

The proton at C-5 in **18***a* (δ 3.09) appears as a double doublet (J_5 = 2.5, 13.5 Hz) in the ^{1}H nmr spectrum indicating that ring C adopts a half-chair conformation (as the crystal structure shows to be the case with **6**). In this isomer the carbinyl proton at C-11 (δ 4.20) shows an axial–axial coupling as well as two small couplings ($W_{1/2}$ = 20 Hz (13)). The olefinic proton at C-3 (δ 6.08) appears as a

[3]On the scale on which we were working it was not possible to separate the mixtures **18** and **19**. However, at 400 MHz, it is possible to analyze sufficient portions of the ^{1}H nmr spectra to draw meaningful conclusions especially since spectra of pure **18***a* and **19***a* are available.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

singlet. The major component of the reaction product is the desired *trans*-isomer **18***b*. In the spectrum of **18***b* the signal attributed to the C-5 proton (δ 3.22) is a doublet of doublet of doublets (J = 2, 7.5, 8.5 Hz). The carbinyl proton (δ 4.25) shows $W_{1/2}$ = 15 Hz. If the BC ring junction is indeed *trans*, then one would predict small to medium size couplings for the carbinyl proton. The observed coupling at C-11 ($W_{1/2}$ = 15 Hz) does not allow an unambiguous assignment in this epimer. However, the multiplicity of the C-3 proton (δ 6.0, d, J = 2 Hz) clarifies this point. Theory predicts that allylic coupling, i.e., coupling across one double and three single bonds, is zero when the allylic angle $\theta \approx 0°$ or 180° and reaches a maximum at $\theta = 90°$ (14). This allylic coupling has been amply demonstrated for several series of 6-substituted-Δ^4-3-oxosteroids (**20**) where it was found that olefinic protons at C-4 couple with the β-proton at C-6 ($\theta \sim 85°$) in the 6α-substituted series but not with the α-proton in the 6β-substituted series (allylic angle $\theta \sim 10°$) (14). The observed allylic coupling between the olefinic proton at C-3 and the ring junction proton at C-5 is 2 Hz in the case of **18***b* ($\theta \sim 80°$), confirming that epimerization has occurred. As expected, in the *cis* epimer C-3 appears as a singlet ($\theta \approx 0°$). An analysis of the ^{1}H nmr of the epimeric acetates **19** (see Experimental) is also in agreement with the assignment.

Attempts to completely transform **18***a* to **18***b* were unsuccessful as prolonged heating with sodium methoxide – methanol gave the same mixture of epimeric alcohols. Other methods to effect epimerization of **18** (e.g., through derivatization of the enone) remain to be investigated.

Compound **18** has the necessary stereochemistry for further elaboration to the cyathins. However, removal of the thioether function is undesirable in a synthetic sense, since we had hoped to utilize this functionality in the addition of the C-3 isopropyl group of the cyathins. The experiments described indicate that establishment of the *trans* BC ring junction in the decalin system of **5** is not straightforward and requires modification of the substitution pattern. It is conceivable that cleavage of the C-ring (see Scheme 1) will facilitate epimerization at C-5, or that the greater flexibility of the seven-membered ring C will allow the isomerization. Experiments to test these possibilities are in hand.

Experimental

Analytical thin layer chromatography (tlc) was carried out on glass plates (75 × 25 or 75 × 50 mm) coated (~0.3 mm) with silica gel G (W. Merck, Darmstadt) containing 1% electronic phosphor (General Electric, Cleveland). Preparative thin layer chromatography (ptlc) was carried out on glass plates (20 × 20, 10 × 20, or 5 × 20 cm) coated (0.5 mm) with the same adsorbent. Materials were detected by visualization under an ultraviolet lamp (254 or 350 nm). The plate (only a thin vertical band in the case of ptlc) was then sprayed with a solution of vanillin (1%) in concentrated sulfuric acid and charred using a heat gun.

Mass spectra (ms) were recorded on an A.E.I. MS-50 mass spectrometer coupled to a DS 50 computer, or an A.E.I. MS-9 mass spectrometer (chemical ionization). Data is reported as *m/e* (relative intensity). Unless diagnostically significant, peaks with intensities less than 20% of the base peak are omitted. Infrared spectra were recorded on a Nicolet 7199 FT interferometer or a Perkin-Elmer 297 infrared spectrophotometer and ultraviolet spectra on a Unicam SP 1700 ultraviolet spectrophotometer. The ^{1}H nmr spectra were measured on a Bruker WP-60 spectrometer interfaced to a Digilab FTS/NMR-3 data system, a Bruker WH-200 spectrometer, or a Bruker WH-400 spectrometer. The ^{13}C nmr spectra were measured on the aforementioned Bruker WP-60 instrument or a Bruker HFX-90 spectrometer interfaced to a Nicolet 1085 computer. All nuclear magnetic resonance measurements employed tetramethylsilane as an internal standard. Melting points were recorded on a Fisher-Johns melting point apparatus and are uncorrected. All compounds for which spectral data are reported showed single spots on tlc.

cis-*3,6,7-Trimethyl-7,9-bistrimethylsilyloxybicyclo[4.4.0]deca-3,8-diene-2,5-dione (9)*

A solution of 2,5-dimethyl-*p*-benzoquinone (10 g) and 2,4-bistrimethylsilyloxy-1,3-pentadiene (**8** (8), 40 g) in xylene (300 mL) was heated under reflux for 40 h. The volatiles were removed by evaporation under reduced pressure at 70°C. Bulb to bulb distillation (125°C/0.025 Torr) provided the Diels–Alder adduct **9** as a viscous orange oil (25.5 g). The ^{1}H nmr and ^{13}C nmr data suggested the adduct to be a single stereoisomer: ir (neat): 1684, 1628 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.40 (1H, q (1.3 Hz), C-4 H), 4.94 (1H, t (1.3 Hz), C-8 H), 3.28 (1H, dd (6.7, 7.3 Hz), C-1 H), 2.22 (2H, m, C-9 H's), 1.95 (3H, d (1.3 Hz), C-3 CH_3), 1.45 (3H, s) and 1.32 (3H, s) (C-6, 7 CH_3's), 0.16 (9H, s) and 0.06 (9H, s) (silyl CH_3's); ^{13}C nmr ($CDCl_3$) δ: 200.4 (s) and 200.2 (s) (C-2, 5), 149.5 (s, C-3), 146.6 (s, C-9), 137.2 (s, C-4), 112.5 (d, C-8), 74.5 (s, C-7), 56.0 (s, C-6), 51.1 (d, C-1), 29.8 (t, C-10), 27.6 (q, C-7 CH_3), 20.1 (q, C-6 CH_3), 15.5 (q, C-3 CH_3), 2.2 (q) and 0.3 (q) (silyl CH_3's); ms *m/e* calcd. for $C_{19}H_{32}O_4Si_2$: 380.1839; found: 380.1834 (2), 244 (55), 230 (21), 229 (100), 73 (31).

cis-*3,6,7-Trimethylbicyclo[4.4.0]deca-3,7-diene-2,5,9-trione (10)*

The Diels–Alder adduct **9** (480 mg) was dissolved in methanol (10 mL) and trifluoroacetic acid (~10 mg) was added. The solution was stirred at room temperature for 3 h, diluted with 10% $NaHCO_3$ (20 mL), extracted with $CHCl_3$, dried (Na_2SO_4), and the solvent evaporated to give the crude **10**. Recrystallization from CCl_4 gave **10** (154 mg, 70%), mp 109–111°C; ir (neat): 1680, 1621 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.65 (1H, q (1.5 Hz), C-4 H), 5.84 (1H, q (1.5 Hz), C-8 H), 3.17 (2H) and 2.58 (1H) ((ABX 4, 6, 18 Hz), C-1, 10 H's), 2.01 (3H, d (1.5 Hz), C-3 CH_3), 1.81 (3H, d (1.5 Hz), C-7 CH_3), 1.56 (3H, s, C-6, CH_3); ^{13}C nmr ($CDCl_3$) δ: 198.6 (s) and 197.3 (s) (C-2, 5), 194.4 (s, C-9), 159.8 (s, C-7), 150.3 (s, C-3), 136.3 (d, C-4), 127.9 (d, C-8), 54.3 (s, C-6), 53.3 (d, C-1), 34.3 (t, C-10), 21.2 (q, C-6, 7 CH_3's), 16.1 (q, C-3 CH_3); ms *m/e* calcd. for $C_{13}H_{14}O_3$: 218.0942; found: 218.0938 (100), 176 (40), 123 (17), 96 (77), 68 (82). *Anal.* calcd. for $C_{13}H_{14}O_3$: C 71.54, H 6.47; found: C 70.92, H 6.38.

3,8,9-Trimethyl-5-methylene-9,11-bistrimethylsilyloxytricyclo-[6.4.0.0.^{3,6}]dodec-10-ene-2,7-dione (11a)

A solution of the adduct **10** (25 g) and excess allene (250 g) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

dry THF (500 mL) was irradiated through a Pyrex filter with a 450 W Hanovia mercury vapor lamp for 20 h while nitrogen was bubbled through the solution. The internal temperature was maintained at −40 to −50°C. The excess allene was allowed to evaporate followed by evaporation of the solvent at reduced pressure to afford the crude photoadduct **11** as an oil (27 g). Spectral data (^{1}H and ^{13}C nmr) indicate that **11** is a 4:1 mixture of the 5-methylene (**11***a*) and the 4-methylene (**11***b*) isomers. The later conversion of **11** into **5** indicates that **11***a* possesses the *cis–anti–cis* stereochemistry at the ring junctions; ir (neat): 1708, 1676 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ for major isomer **11***a*: 5.30 (1H, m) and 5.15 (1H, m) (exocyclic methylene H's), 4.96 (1H, t (1.3 Hz), C-10 H), 1.63 (3H, s), 1.52 (3H, s), and 1.37 (3H, s) (C-3, 8, 9 CH_3's), 0.42 (9H, s) and 0.28 (9H, s) (silyl CH_3's); ^{13}C nmr ($CDCl_3$) δ for major isomer **11***a*: 211.3 (s) and 206.2 (s) (C-2, 7), 148.0 (s, C-11), 140.0 (s, C-5), 112.0 (d, C-10), 110.7 (t, C-5 CH_2), 75.1 (s, C-9), 63.1 (d, C-6), 56.8 (s, C-8), 48.9 (d, C-1), 44.9 (s, C-3), 43.3 (t, C-4), 26.0 (t, C-12), 28.0 (q), 24.4 (q), 21.5 (q) (C-3, 8, 9 CH_3's), 2.28 (q) and 0.36 (q) (silyl CH_3's); ms *m/e* calcd. for $C_{21}H_{33}O_4Si_2$ ($M^+ - CH_3$): 405.1917; found: 405.1916 (18), 244 (55), 230 (22), 229 (100), 149 (27), 147 (16), 73 (59).

*3,8,9-Trimethyl-5-methylenetricyclo[6.4.0.0.^{3,6}]dodec-9-ene-2,7,11-trione (12*a)

The photoadduct **11** (27 g) was dissolved in 30% methanol in THF (150 mL) and Rexyn 101 acidic ion exchange resin (~5 g) was added. The mixture was stirred at room temperature for 30 h, poured onto 10% $NaHCO_3$ (300 mL), extracted with $CHCl_3$, washed with saturated $NaHCO_3$, dried (Na_2SO_4), and the solvent evaporated to give the crude trione **12** (17.5 g) which was used in the next step without further purification. In reactions carried out on a smaller scale (i.e., starting with 2 g of the quinone **2**) the crude trione (~3.5 g) was purified by column chromatography (Florosil, ether) to give crystalline **10** (2.2–2.6 g) which was recrystallized from CCl_4–cyclohexane (mp 120–131°C). Spectral data (^{1}H and ^{13}C nmr) indicated that **12** was an ~4:1 mixture of the 5-methylene (**12***a*) and 4-methylene (**12***b*) isomers.[4] The ultimate conversion of **12** into **5** indicates that **12***a* possesses the *cis–anti–cis* stereochemistry at the ring junctions; ir (neat): 1701, 1676, 1619 cm^{-1}; ^{1}H nmr ($CDCl_3$)[5] δ for major isomer **12***a*: 5.83 (1H, q (1.5 Hz), C-10 H), 5.16 (1H, dq (1, 2.7 Hz)) and 5.01 (1H, ddt (1.1, 2.2, 3.3 Hz)) (exocyclic methylene H's), 3.70 (1H, dq (2.2, 2.7 Hz), C-6 H), 3.41 (1H, dd (3.8, 4.5 Hz), C-1 H), 3.08 (1H, dd (3.8, 18 Hz)) and 2.53 (1H, dd (4.5, 18 Hz)) (C-11 H's), 2.86 (2H, m, C-4 H's), 1.80 (3H, d (1.5 Hz), C-9 CH_3), 1.53 (3H, s, C-8 CH_3), 1.37 (3H, s, C-3 CH_3); ^{13}C nmr ($CDCl_3$) δ for major isomer **12***a*: 209.8 (s) and 204.0 (s) (C-2, 7), 157.8 (s, C-9), 139.8 (s, C-5), 128.6 (d, C-10), 110.5 (t, C-5 CH_2), 61.1 (d, C-6), 54.9 (s, C-8), 51.5 (d, C-1), 45.1 (s, C-3), 43.1 (t, C-4), 34.3 (t, C-12), 23.6 (q, C-3, 8 CH_3's), 21.0 (q, C-9, CH_3); ms *m/e* calcd. for $C_{16}H_{18}O_3$: 258.1256; found: 258.1247 (4), 216 (40), 177 (37), 172 (27), 171 (33), 157 (25), 149 (24), 123 (45), 122 (24), 109 (22), 108 (24), 94 (26), 80 (86), 79 (100), 77 (34). *Anal.* calcd. for $C_{16}H_{18}O_3$: C 74.40, H 7.02; found: C 74.08, H 7.03.

*3,8,9-Trimethyltricyclo[6.4.0.0^{3,6}]dodec-9-ene-2,7,11-trione-5-spirooxirane 13*a

The triones **12** (1.75 g) and *m*-chloroperbenzoic acid (85%, 1.75 g) in CH_2Cl_2 (70 mL) were stirred at room temperature for 36 h. The solution was washed with 10% sodium bisulfite, water, saturated $NaHCO_3$, brine, dried (Na_2SO_4), and the solvent evaporated to give a crystalline mixture of epoxides **13** (1.58 g) after trituration with ether. Alternatively, the crude triones **12** could be oxidized as above to give the crystalline epoxides **13** in ~45% overall yield from the quinone without chromatography. Spectral data (^{1}H nmr and ^{13}C nmr) indicated that **13** was an ~4:1 mixture of the 5-spirooxirane (**13***a*) and the 4-spirooxirane (**13***b*) isomers. The conversion of **13** into **5** indicates that **13***a* possesses the *cis–anti–cis* stereochemistry at the ring junctions; ir (neat): 1706, 1674, 1616 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ for major isomer **13***a*: 5.81 (1H, q (1.5 Hz), C-10 H), 3.73 (1H, dd (3, 4 Hz)) and 3.58 (1H, br s) (oxirane CH_2), 2.82 (1H, s, C-6 H), 1.77 (3H, d (1.5 Hz), C-9 CH_3), 1.55 (3H, s, C-8 CH_3), 1.41 (3H, s, C-3 CH_3); ^{13}C nmr ($CDCl_3$) δ for major isomer **13***a*: 208.8 (s) and 204.6 (s) (C-2, 7), 195.0 (s, C-11), 157.7 (s, C-9), 129.1 (d, C-10), 63.8 (s, C-5), 54.4 (s, C-8), 53.3 (t, C-5 CH_2), 48.6 (d) and 46.0 (d) (C-1, 6), 42.2 (s, C-3), 34.1 (t) and 33.2 (t) (C-4, 12), 22.2 (q) and 20.4 (q ×2) (C-3, 8, 9 CH_3's); ms *m/e* calcd. for $C_{16}H_{18}O_4$: 274.1205; found: 274.1212 (17), 259 (14), 246 (13), 232 (39), 191 (20), 188 (22), 187 (22), 173 (21), 158 (20), 152 (27), 124 (28), 123 (49), 96 (32), 95 (28), 94 (54), 93 (24), 91 (35), 82 (51), 79 (100), 77 (59), 68 (37), 66 (38), 65 (32), 55 (26), 54 (24), 53 (44), 51 (21).

Acid Hydrolysis of the Epoxides 13

A solution of the epoxides **13** (541 mg) in THF (15 mL) and 1 *N* $HClO_4$ (5 mL) was heated under reflux overnight and poured onto saturated $NaHCO_3$ (20 mL), extracted with $CHCl_3$ and the solvents evaporated to give a highly insoluble amorphous solid after trituration with ether. The solid was dissolved in CH_2Cl_2 (15 mL) and pyridine (1 mL) and acetic anhydride (1 mL) were added. The resulting solution was stirred at room temperature for 2.5 h and the solvents were evaporated under high vacuum at 50°C to give **14** as an oil (487 mg). This was an ~3:1 mixture of **14***a* and **14***b*, respectively; ir (neat): 1740, 1710 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ for major isomer **14***a*: 5.73 (1H, br s), 4.57 (2H, m), 2.32 (2H, s), 2.12 (3H, s), 1.88 (3H, d (1.5 Hz)), 1.57 (3H, s), 0.98 (3H, s); δ for minor isomer **14***b*: 5.84 (1H, br s), 4.80 (2H, m), 2.16 (3H, s), 1.81 (3H, d (1.5 Hz)), 1.49 (3H, s), 1.10 (3H, d (6)); ms *m/e* calcd. for $C_{18}H_{22}O_6$: 334.1399; found: 334.1425 (7), 218 (37), 123 (100), 122 (42), 94 (33), 91 (20), 79 (47), 77 (25), 55 (45).

Tricyclic Alcohol 5 from the Epoxides 13

To a solution of **13** (275 mg) in dry THF (4 mL) was added 0.5 *N* 9-BBN in THF (2.2 mL). The solution was stirred at room temperature under nitrogen for 1.5 h. The solvent was evaporated at reduced pressure and the resulting oil was dissolved in ether (8 mL). Ethanolamine (70 mg) was added and the mixture was stirred at room temperature for 1 h. The precipitated 9-BBN – ethanolamine complex was removed by centrifuging and the supernatant concentrated under reduced pressure to give the crude allylic alcohol **15** as an oil. To a solution of the crude **15** in ethanol (5 mL) was added benzenethiol (120 mg) and 2 *N* KOH (25 μL). After stirring under nitrogen for 8 h at 0°C a further 25 μL of 2 *N* KOH was added and the solution heated under reflux for 1.5 h. The solution was poured onto saturated $NaHCO_3$ (20 mL), extracted with $CHCl_3$, dried ($NaSO_4$), and the solvent evaporated to give an oil which upon trituration with ether provided the crystalline **5** (200 mg), mp 209–211°C; ir (neat): 3420, 1705 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.29 (5H, br s, aromatic H's), 5.73 (1H, br s, C-12 H), 4.10 (1H, m, C-11 H), 3.62 (1H, dd (4, 11 Hz), C-5 H), 2.96 (1H, d (13 Hz)) and 2.51 (1H, d (13 Hz)) (C-8 H's), 2.56 (2H, s, C-1 H), 1.78 (3H, d (1.5 Hz), C-13 CH_3), 1.6 (3H, m, C-10, H, OH), 1.35 (3H, s) and 1.32 (3H, s) (C-6, 9 CH_3's); ms *m/e* calcd. for $C_{22}H_{24}O_3S$; 368.1449; found: 368.1444 (100), 350 (33), 335 (27), 285 (45), 284 (21), 199 (23), 198 (27), 185 (21), 175 (20), 109 (37), 91 (48), 77 (45), 65 (22); ^{13}C nmr (DMSO-d_6) δ: 209.8 (s, C-7), 201.5 (s, C-2), 184.1 (s, C-4), 135.4 (s, C-1′), 133.9 (s), and 132.7 (s) (C-3, 13), 130.6 (d, C-12), 129.1 (d ×2) and 128.1 (d ×2), C-2′, 3′), 126.3 (d, C-4′), 65.4 (d, C-11), 52.3 (t, C-8), 51.8 (s) and 49.1 (s) (C-6, 9), 47.4 (d, C-4), 46.7 (t, C-1), 35.0 (C-10), 28.6 (q), 23.9 (q), and 19.6 (q) (C-6, 9, 13 CH_3's).

[4]Compounds **12***a*, **12***b* are co-crystalline and homogeneous by tlc and thus could not be separated.

[5]Spectrum obtained at 270 MHz.

p-Bromobenzoate of Tricyclic Alcohol (6)

Tricyclic alcohol **5** (100 mg, 0.27 mmol), *p*-bromobenzoyl chloride (65.8 mg, 0.3 mmol), and 4-*N*,*N*-dimethylaminopyridine (60.7 mg, 0.4 mmol) in dry methylene chloride (10 mL) were stirred at room temperature for 1 h under nitrogen. A small amount of water was added and the organic solvent removed. The aqueous residue was extracted twice with ether. The separated ethereal solution was washed successively with 1 *N* hydrochloric acid, sodium bicarbonate, water, then dried and evaporated. The residue was crystallized from ethyl acetate and then from methylene chloride – hexane, mp 126.5–127.5°C; ir: 2990, 1713, 1590, 1280, 1110, 750 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.74 (4H, q (9 Hz)), 7.30 (5H, m), 5.70 (1H, s, C-12 H), 5.48 (1H, t (8 Hz), C-11 H), 3.78 (1H, m, C-5 H), 2.78 (2H, q (13 Hz), C-1 H), 2.58 (2H, s, C-8 H), 1.82 (3H, s, C-13 CH_3), 1.37 (6H, s, C-6, 9 CH_3); ^{13}C nmr ($CDCl_3$) δ: 209.7 (s, C-7), 201.4 (s, C-2), 184.1 (s, C-4), 135.4 (s, C-1′), 133.8 (s) and 132.7 (s) (C-3, 13), 130.5 (d, C-12), 129.0 (d ×2) and 128.1 (d ×2) (C-2′, 3′), 126.2 (d, C-4′), 65.4 (d, C-11), 52.3 (t, C-8), 51.8 (s) and 49.1 (s) (C-6, 9), 47.3 (d, C-5), 46.7 (t, C-1), 35.0 (t, C-10), 28.6 (q), 23.9 (q) and 19.6 (q), (C-6, 9, 13 CH_3's); *Anal.* calcd. for $C_{29}H_{21}O_4SBr \cdot 1/4\ CH_2Cl_2$: C 60.07, H 4.69; found: C 59.70, H 4.63.

Compound **6** crystallized in the monoclinic system with the following crystal data:

$C_{29}H_{27}O_4SBr \cdot \frac{1}{4}(CH_2Cl_2)$ f.w. = 551.5

$P2_1/c$, a = 14.118(2), b = 10.987(2), c = 21.534(4), β = 124.24°, V = 2761.3 Å^3, Z = 4, ρ_o = 1.36 g cm^{-3}, ρ_c = 1.33 g cm^{-3}. Radiation Ni-filtered CuK_α, λ = 1.5418 Å, θ – 2θ with scan speed 2° min^{-1} over 1.6° scan range, 10 s stationary background counts on either side of each scan. Data collected: h,k,l; $\bar{h},k,l$, with 6° ≦ 2θ ≦ 100°. Maximum applied absorption correction (15) was 1.49. $R_{sym} = \Sigma_i|\bar{I} - I_i|/\Sigma_i I_i \times 100 = 1.1\%$ for 97 reflections merged. The data set for the crystal structure analysis was limited to the 2114 reflections of the 2824 unique reflections which had net $I > 3\theta$ (I).

The solution of the structure involved examining the Patterson map to obtain the position of the bromine atom of the molecule. Least-squares refinement of the scale factor and the positional parameters of this atom produced an R of 0.497. Four additional atoms were chosen from a subsequent difference Fourier map. The positions of the remaining nonhydrogen atoms were obtained by continually phasing on larger molecular fragments and calculating difference maps. After full matrix isotropic refinement of all of the thirty-five nonhydrogen atoms of the molecule, the R index was 0.156. Further blocked anisotropic refinement produced an R index of 0.127. Twenty-seven hydrogen atoms were located from a difference Fourier map and were assigned isotropic temperature factors of 5–6 Å^2. A disordered methylene chloride molecule was located near the origin of the unit cell corresponding to an electron density peak height of one molecule/unit cell. The chlorine and carbon atoms of this solvent molecule were refined positionally and with isotropic temperature factors. The hydrogen atom positional parameters (but not the temperature factors) were also included in subsequent blocked refinement. Convergence was achieved at an R index of 0.066. These computations were carried out using the X-ray 70 system (16).[6] A perspective drawing of compound **6** is shown in Fig. 1.

Tetrahydropyranyl Ether 16 of the Tricyclic Alcohol

The tricyclic alcohol **5** (100 mg, 0.27 mmol), dihydropyran (33.6 mg, 0.40 mmol, 1.5 equiv.), and *p*-toluenesulfonic acid (0.3 mg) in dry THF (5 mL) were stirred at room temperature for 72 h. The solvent was evaporated and water and ethyl acetate were added to the residue. Extraction with ethyl acetate was repeated twice, then the organic layer was washed with sodium bicarbonate and water, dried, and evaporated to give 168 mg of the tetrahydropyranyl ester **16**. Compound **16** was purified by chromatography over Florosil (10 g). Elution with chloroform (20 × 5 mL) afforded **16** (163 mg) which was recrystallized from methylene chloride – Skellysolve B: (94.2 mg), mp 155–160°C; ir (film): 1735, 1710, 1615 cm^{-1}.

*Preparation of Tricyclic Alcohol 18*a

The THP ether **16** (350 mg, 0.77 mmol) and W-2 Raney nickel (ca. 200 mg) in ethyl acetate were heated under reflux until the starting material disappeared as shown by tlc (approximately one week). The catalyst was removed by careful filtration through Celite and the filtrate was evaporated to give 313 mg of compound **17** which was purified by chromatography over neutral alumina (activity IV) by elution with benzene–chloroform.

The THP ether **17** (100 mg, 0.29 mmol) and pyridinium-*p*-toluenesulfonate (catalytic amount) in 98% ethanol were allowed to stand at room temperature overnight, then heated at 55°C for 2.5 h. The solvent was evaporated and the residue was taken up in methylene chloride, washed with water, dried, and evaporated. The product, compound **18*a***, was purified by preparative tlc and crystallized from methylene chloride – Skelly B: mp 163–165°C; ir: 3580, 1960, 1688, 1610, 1430, 1380 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.08 (1H, s, C-3 H), 5.52 (1H, br s, C-12 H), 4.20 (1H, m ($W_{1/2}$ = 20), C-11 H), 3.09 (1H, dd (2.5, 13.5 Hz), C-5 H), 2.68 (2H, q), 2.46 (1H, s), 1.82 (2H, m, C-10 H), 1.76 (3H, s, C-13 CH_3), 1.32 (6H, s, C-6, 9 CH_3's); ms *m/e*: 242 (M^+ – 18, 93), 227 (43), 201 (18), 200 (31), 199 (18), 185 (36), 173 (18), 159 (25), 157 (32), 145 (20), 133 (36).

*Acetylation of Tricyclic Alcohol 18*a

The alcohol **18*a*** (13.1 mg, 0.05 mmol) and 4-*N*,*N*-dimethylaminopyridine (13 mg, 0.08 mmol) in dry methylene chloride (5 mL) were stirred at room temperature overnight. The mixture was diluted with water and extracted with methylene chloride. The organic layer was washed with water, 1 *N* hydrochloric acid, sodium bicarbonate and water, dried, and evaporated to give 17 mg of the acetate **19*a*** as an oil; ir (film): 3400, 1730 (sh), 1705, 1615 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.14 (1H, s, C-3 H), 5.68 (1H, s, C-12 H), 5.28 (1H, m ($W_{1/2}$ = 20), C-11 H), 3.17 (1H, dd (2.5, 13.5 Hz), C-5 H), 2.72 (2H, q), 2.52 (2H, m), 2.06 (3H, s, C-11 OCOCH_3), 1.78 (3H, s, C-13 CH_3), 1.35 (6H, s, C-6, 9 CH_3's).

*Epimerization of Tricyclic Alcohol 18*a

The alcohol **18*a*** (12.3 mg, 0.047 mmol) was heated under reflux for 3 h with sodium methoxide (prepared by dissolving sodium (3.5 mg) in dry methanol (5 mL)). The solution was cooled, neutralized with aqueous acetic acid and methanol, then concentrated. The reaction product was extracted with chloroform, washed with water, dried, and evaporated to give 13 mg of an epimeric mixture of alcohols **18*a*** and **18*b*** in the ratio 1:1.2; ^1H nmr ($CDCl_3$) δ for major isomer **18*b***: 6.02 (1H, d (2 Hz), C-3 H), 5.67 (1H, br s, C-12 H), 4.25 (1H, m ($W_{1/2}$ = 15), C-11 H), 3.22 (1H, ddd (2, 7.5, 8.5 Hz), C-5 H), 1.76 (3H, br s, C-13 CH_3), 1.17 (3H, s), 1.11 (3H, s) (C-6, 9 CH_3's).

*Epimerization of Acetate 19*a

The tricyclic acetate **19*a*** was heated with sodium methoxide (prepared by dissolving sodium (11 mg) in dry methanol (10 mL)) for 3 h. After cooling, a few drops of aqueous acetic acid were added and the solution was concentrated. The residue was extracted with methylene chloride, washed with water, dried,

[6]Tables of atomic parameters, bond lengths and angles, and structure factors are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

and evaporated to give 20 mg of a mixture. Purification by chromatography over silica gel and elution with chloroform–ether (1:1) gave a product (15.3 mg) which showed a single spot on tlc. The ^{1}H nmr spectrum showed this to be a mixture of epimeric alcohols **18***a* and **18***b*. Acetylation of this mixture by the method described above gave a mixture of epimeric acetates **19***a* and **19***b*; ^{1}H nmr ($CDCl_3$) δ for major isomer **19***b*: 5.94 (1H, d (2 Hz), C-3 H), 5.64 (1H, d (6 Hz), C-11 H), 5.58 (1H, s, C-12 H), 3.16 (1H, C-5 H), 2.04 (3H, s, C-11 $OCOCH_3$), 1.93 (3H, s, C-13 CH_3), 1.32 (3H, s), 1.22 (3H, s) (C-6, 9 CH_3's).

Pyrrole chemistry. XXIII. The cyanation of substituted pyrroles with chlorosulfonyl isocyanate (CSI). New syntheses of pyrrole-3-carbonitriles

CHARLES E. LOADER AND HUGH J. ANDERSON

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received April 14, 1981

CHARLES E. LOADER and HUGH J. ANDERSON. Can. J. Chem. **59**, 2673 (1981).

Chlorosulfonyl isocyanate (CSI) reacts not only with pyrrole itself but with pyrroles having powerful electron-withdrawing groups in the 2-position. Suitable choice of electron-withdrawing groups allows selective 4-substitution of the pyrrole ring. The *N*-chlorosulfonyl amides formed are readily converted to the corresponding nitriles. The procedure has been used to provide syntheses of pyrrole-3-carbonitrile and its 1-methyl homologue.

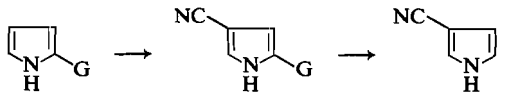
CHARLES E. LOADER et HUGH J. ANDERSON. Can. J. Chem. **59**, 2673 (1981).

L'isocyanate de chlorosulfonyle (ISC) réagit non seulement avec le pyrrole lui-même mais également avec les pyrroles ayant des groupes fortement électro-attracteurs en position 2. Un choix convenable des groupes électro-attracteurs permet une substitution sélective du cycle pyrrole en position 4. Les *N*-chlorosulfonylamides qu'on obtient se transforment facilement en nitriles correspondants. On a utilisé la méthode pour réaliser la synthèse du carbonitrile-3 pyrrole et de son analogue méthylé en position 1.

[Traduit par le journal]

Recent improvements in methods for the synthesis of pyrrole-2-carbonitrile have made this useful compound readily available (1). Although pyrrole-3-carbonitrile has been known for many years, the methods available for its preparation give poor yields or are not easily adapted to large scale work (2). In view of the versatility of the nitrile group and the limited amount known about the properties of pyrrole-3-carbonitriles we have developed a synthesis that gives good yields from pyrrole.

Using pyrrole as starting material and making use of our earlier work on the directing properties of substituents at the 2-position of the pyrrole ring (3), the most convenient route to pyrrole-3-carbonitrile appeared to be as shown in Scheme 1.



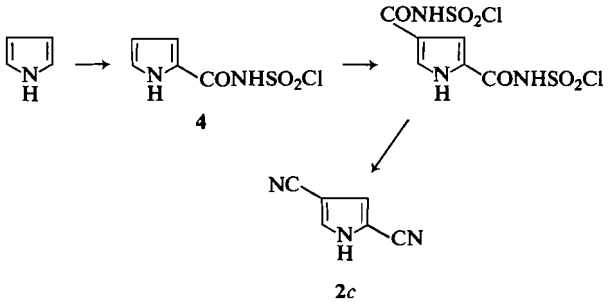
1 **2** **3**

G = suitable electron-withdrawing group directing substitution to the 4-position

a G = —COOH *c* G = —CN *e* G = —$COCCl_3$
b G = —CHO *d* G = —$COOCH_3$

SCHEME 1

Two routes appeared to be particularly attractive, one leading to the decarboxylation of 4-cyanopyrrole-2-carboxylic acid (**2***a*) and the other to the catalytic decarbonylation of 4-cyanopyrrole-2-carboxaldehyde (**2***b*). The main difficulty in this approach was the introduction of the nitrile group in good yield.



4

2*c*

SCHEME 2

Chlorosulfonyl isocyanate (CSI) has been shown to be a versatile reagent for the introduction of the nitrile group onto active aromatic ring systems (4). CSI is very reactive towards both pyrrole and 1-methylpyrrole and we have reported procedures for the preparation of both pyrrole-2-carbonitrile and 1-methylpyrrole-2-carbonitrile using the reagent (5). The yield of pyrrole-2-carbonitrile was relatively poor and our recent work has led to a modified procedure that gives a much improved yield. *N*,*N*-Dimethylformamide (DMF) does not react with CSI at low temperatures and can be used as a solvent for the reaction. CSI reacts with the pyrrole first and that product, on warming with the DMF, reacts to give the nitrile. This method avoids the formation of by-products, in particular of dicyanopyrroles, that lowered the yield obtained in the earlier procedure.

We also noted that pyrrole with excess CSI followed by treatment with DMF gave a good yield of pyrrole-2,4-dicarbonitrile (**2***c*) (containing a small

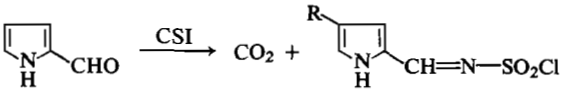
amount of the 2,5-isomer) directly from pyrrole (Scheme 2) (5), indicating that it is capable of disubstituting the pyrrole ring. Because the intermediate amide **4** has an electron-withdrawing group and is further substituted by CSI, we decided to investigate the possibility that CSI would substitute other pyrroles with electron-withdrawing groups.

The reaction between CSI and methyl pyrrole-2-carboxylate (**1***d*) gave, in a very rapid reaction, a mixture of the 4- and 5-substituted products in a ratio of about 2:1. Chromatography of the reaction product allowed the isolation of the two isomers. This poor selectivity is similar to that obtained in the Vilsmeier reaction and the non-Friedel–Crafts acylation of pyrrole-2-esters (6). In earlier unpublished work Dr. Graham H. Barnett of this university showed that in this reaction the use of aluminum chloride as catalyst lowered the yield of product. However, there was no significant change in the ratio of the two isomers in the product. Similar results were obtained for the cyanation of 2-acetylpyrrole. The cyanation of pyrrole-2-carbonitrile with CSI gave a product that was virtually pure pyrrole-2,4-dicarbonitrile (**2***c*). In this latter reaction, the proportion of 2,4-isomer was much greater than obtained from the direct disubstitution of pyrrole where the second substitution actually takes place on the amide **4** rather than the 2-nitrile (**1***c*).

The *N*-chlorosulfonyl amide thus appears to be a weaker 4-directing group than the nitrile. The unsatisfactory selectivity in the cyanation of the ester and the potential difficulties attendant to the selective hydrolysis of the 2-nitrile group in the dinitrile **2***c* (5) led us to look for an alternative, more powerful 4-directing group which could be removed selectively.

The utility of 2-trichloroacetylpyrrole as a starting material for the 4-substituted pyrrole-2-esters and carboxylic acids has been very thoroughly demonstrated by Rapoport and co-workers and by Bélanger (7). CSI reacted very slowly with 2-trichloroacetylpyrrole in acetonitrile but ultimately gave a very good yield of 2-trichloroacetylpyrrole-4-carbonitrile (**2***e*). The reaction was highly selective and no 2,5-substituted product was isolated.

The 2-trichloroacetylpyrrole-4-carbonitrile was easily converted to the 2-carboxylic acid (**2***a*) on treatment with aqueous base followed by acidification. Decarboxylation of the acid was expected to present problems because of the poor results obtained for decarboxylation of similar 4-substituted pyrrole-2-carboxylic acids (3*a*). However, moderate yields (50%) of pyrrole-3-carbonitrile were obtained using copper carbonate as catalyst,



5

a R = H
b R = —CONHSO$_2$Cl
c R = CN

while copper chromite in quinoline gave a 64% yield of the pure product **3**. This compares very well with the yield (59%) obtained by Khan *et al.* (2*a*) for the decarboxylation of 3-cyanopyrrole-2-carboxylic acid by the same method.

Several attempts were made to prepare **2***b*. Cyanation of pyrrole-2-carboxaldehyde was attempted using CSI in acetonitrile and other solvents. CSI reacts vigorously with the aldehyde and the solution becomes highly colored. The ^{1}H nmr spectrum of the reaction mixture shows changes with time that would be expected if 4-substitution was taking place. Work-up of the reaction mixture gave mostly black polymeric material. A small amount (~25%) of the desired product (**2***b*) was isolated. The reaction may involve a predominance of reaction with the aldehyde group rather than with the pyrrole ring. This type of behaviour has been observed and investigated for other aldehydes by Jensen and co-workers (8).

It appears that the CSI first reacts with the aldehyde group to give **5***a* or a precursor, this intermediate then reacts slowly with more CSI to give the 4-(*N*-chlorosulfonylcarboxamido)pyrrole (**5***b*). The conversion of **5***b* to **5***c* on the addition of DMF takes place smoothly, but extensive decomposition occurs in the final work-up. Attempts to improve the hydrolysis of **5***c* to regenerate the 2-carboxaldehyde group have so far been unsuccessful. Similar attempts at the cyanation of 1-methylpyrrole-2-carboxaldehyde gave much better yields (53%) of the desired 1-methyl-4-cyanopyrrole-2-carboxaldehyde. However, in addition to the desired product a small yield of a by-product was obtained which we have tentatively identified as **6**. The formation of **6** requires sulfonylation of the pyrrole ring by the CSI which then reacts with DMF in the work-up. Similar side reactions may be an additional factor in accounting for the poor yield obtained in the reaction of CSI with pyrrole-2-carboxaldehyde.

Decarbonylation of 4-cyanopyrrole-2-carboxaldehyde and 1-methyl-4-cyanopyrrole-2-carboxaldehyde using a palladium on carbon catalyst gave high yields of pyrrole-3-carbonitrile and 1-methylpyrrole-3-carbonitrile respectively. As this decarbonylation route appears to be superior to the decarboxylation procedure described earlier, an improved method of synthesis for 4-cyanopyrrole-2-carboxaldehyde now seems to be highly desirable. We shall pursue this problem.

The assigned structures for the new compounds obtained in this work were supported by their spectral properties and satisfactory microanalyses. In particular the coupling constants for the pyrrole ring protons in the ^1H nmr spectra usually allow the identification of the substitution pattern on the pyrrole ring (e.g. **2***a*). In other cases the compounds were converted to known compounds by simple one-step reactions (e.g., **3** was obtained from **2***a* by decarboxylation indicating that **2***a* was 4-cyano- rather than 5-cyano- pyrrole-2-carboxylic acid).

Experimental

Instruments and conditions were as described in ref. 5 except where noted below. All ir spectra are recorded as Nujol mulls unless otherwise indicated.

Pyrrole-2,4-dicarbonitrile (General Method)

Pyrrole-2-carbonitrile (2.00 g, 22 mmol) was dissolved in CH_3CN (5 mL) and cooled in a salt/ice bath. A solution of CSI (4.67 g, 33 mmol) in CH_3CN (5 mL) was added to the stirred solution over about 5 min. The solution rapidly became yellow and solid was deposited. The semi-solid mixture was allowed to warm and was held at room temperature for 2.5 h after which it was again cooled in ice and *N*,*N*-dimethylformamide (DMF) (2 mL) was added. The mixture was heated at 50°C for 15 min and then poured onto ice. Extraction of the aqueous mixture with $CHCl_3$ gave a pale yellow organic extract which was washed with aqueous $NaHCO_3$ (5%), dried ($MgSO_4$), and the solvent was removed.

The crystalline residue (2.03 g) was recrystallized from toluene/petroleum (bp 100–120°C) to give the product as colourless crystals (1.20 g, 47%), mp 181–183°C (lit. (5) mp 181–183°C); mixture mp was undepressed. Spectral properties were identical with those of an authentic sample. The mother liquors from the recrystallization contained traces of the 2,5-substituted isomer. Some material would not dissolve in toluene.

1-Methylpyrrole-2,4-dicarbonitrile

Using the same method described above for pyrrole-2,4-dicarbonitrile, except that the reaction mixture was allowed to stand overnight at room temperature before the DMF was added, 1-methylpyrrole-2-carbonitrile (2.0 g) gave the crude product (1.7 g). Chromatography of the crude product on alumina (Activity 1) and elution with ether/petroleum (bp 30–60°C) followed by sublimation gave the pure product (1.24 g, 50%), mp 108–109°C (lit. (5) mp 108–109°C); mixture mp with authentic 1-methylpyrrole-2,4-dicarbonitrile was undepressed.

Cyanation of Methyl Pyrrole-2-carboxylate

Methyl pyrrole-2-carboxylate under the conditions above gave a mixture (67% yield) of methyl 4- and 5-cyanopyrrole-2-carboxylate in a ratio of about 2:1. The mixture was separated by chromatography on an alumina column.

Methyl 4-Cyanopyrrole-2-carboxylate, mp 168–169°C (lit. (9) mp 168–169°C); ir ν: 2220 (C≡N), 1690 (C=O) cm^{-1}; nmr (acetone-d_6 + D_2O) δ: 3.83 (3H, s), 7.13 (1H, d), 7.70 (1H, d), $J_{3,5}$ = 1.6 Hz; *m/e*: 150.

Methyl 5-Cyanopyrrole-2-carboxylate, mp 173–174°C (lit. (10) mp 170–171°C); ir ν: 3251 (N—H), 2241 (C≡N), 1694 (C=O) cm^{-1}; nmr ($CDCl_3$) δ: 3.94 (3H, s), 6.83 (2H, m), $J_{1,3}$, $J_{1,4}$ = 2.4 Hz; $J_{3,4}$ = 4.4 Hz; *m/e*: 150. *Anal.* calcd. for $C_7H_6N_2O_2$: C 56.00, H 4.03; found: C 56.00, H 4.07.

Cyanation of 2-Acetylpyrrole

2-Acetylpyrrole gave a mixture (56% yield) of 2-acetylpyrrole-4-carbonitrile and 2-acetylpyrrole-5-carbonitrile 7:3. The mixture was separated by repeated crystallization from $CHCl_3$/petroleum (bp 80–100°C) mixtures.

2-Acetylpyrrole-4-carbonitrile, mp 190.5–191°C (from toluene/petroleum (bp 100–120°C)); ir ν: 3245 (N—H), 2235 (C≡N), 1657 (C=O) cm^{-1}; nmr ($CDCl_3$) δ: 2.46 (3H, s), 7.01 (1H, m), 7.36 (1H, m), $J_{3,5}$ = 1.8 Hz; *m/e*: 134. *Anal.* calcd. for $C_7H_6N_2O$: C 62.68, H 4.52, N 20.83; found: C 62.68, H 4.55, N 20.86.

2-Acetylpyrrole-5-carbonitrile, mp 152–153°C (lit. (11) mp 154.5–155.5°C). The mixture melting point with an authentic sample was undepressed; ir ν: 3227 (N—H), 2250 (C≡N), 1654 (C=O) cm^{-1}; nmr ($CDCl_3$ + D_2O) δ: 2.53 (3H, s), 6.80 (2H, s); *m/e*: 134.

Pyrrole-2-carbonitrile

Pyrrole (5.0 g) was dissolved in a mixture of DMF (25 mL) and acetonitrile (25 mL) and the solution was cooled in a solid CO_2/acetone bath. CSI (7.17 mL) in acetonitrile (30 mL) was added dropwise to the stirred solution over 10 min and the mixture formed was allowed to warm to about 5°C over about 1 h. The mixture was then poured onto aqueous NaOH (3 mol L^{-1}, 27 mL), 5% $NaHCO_3$ solution (150 mL), and ice. The aqueous mixture was extracted with dichloromethane. The organic extracts were successively washed with water, dried (anhydrous K_2CO_3), and evaporated to leave an oily residue. The residue (containing approximately equal amounts of the product and DMF) was fractionally distilled (twice) to give the product (5.0 g, 73%) bp 120–123°C/15 Torr (lit. (12) bp 112–114°C/14 Torr). The low boiling fractions contained DMF; no unchanged pyrrole was recovered. Spectral properties were identical with those of an authentic sample.

2-Trichloroacetylpyrrole-4-carbonitrile

2-Trichloroacetylpyrrole (2.0 g) was dissolved in acetonitrile (10 mL) and cooled in ice. A solution of CSI (3.2 g) in acetonitrile (3 mL) was then added dropwise to the stirred solution. When all of the CSI had been added, the ice bath was removed and the solution was stirred at room temperature for 12 h. The stirred mixture was then cooled in an ice bath, DMF (8 mL) was added, heated first to 50°C for 1 h and then stirred at room temperature for a further 3 h. The mixture was then poured onto ice (~50 g) and the aqueous mixture was extracted with $CHCl_3$. The chloroform extracts were washed successively with water and aqueous sodium hydrogen carbonate (1%), and dried ($MgSO_4$). Removal of the solvent gave an oily residue which still contained DMF. Pumping the oil under high vacuum (0.1 Torr) removed the DMF and the residue of crude material crystallized slowly. The crude product was distilled onto a cold finger (130°C/0.5 Torr) where it collected as a solid (1.6 g, 71%), mp 139–140°C; ir ν: 3302 (N—H), 2233 (C≡N), 1672 (C=O) cm^{-1}; nmr (acetone-d_6) δ: 3.07 (1H, s, N—H), 7.63, 7.93 (each 1H, m, pyrrole H), $J_{1,5}$ = 3.6, $J_{1,3}$ = 3.2, $J_{3,5}$ = 1.8 Hz; *m/e*: 236 ($^{35}Cl_3$), 238 ($^{35}Cl_2{}^{37}Cl$). *Anal.* calcd. for $C_7H_3Cl_3N_2O$: C 35.40, H 1.27, N 11.80; found: C 35.31, H 1.36, N 11.94.

4-Cyanopyrrole-2-carboxylic Acid

2-Trichloroacetylpyrrole-4-carbonitrile (1.00 g) was added to sodium hydroxide (2 mol L^{-1}, 10 mL) cooled in an ice bath. After the addition was complete, the mixture was allowed to warm to room temperature and stirred for a further 2 h during which time a cloudy solution formed. The solution was acidified with concentrated HCl and the white precipitate of product was collected by vacuum filtration, washed with cold water, and dried at 100°C. The product (0.53 g, 92%) was used without further purification for the preparation of pyrrole-3-carbonitrile.

For analysis, the acid was sublimed (130°C/0.1 Torr), mp 279°C (dec.); ir v: 3220 (N—H), 2225 (C≡N), 1670 (C=O) cm^{-1}; nmr (DMSO-d_6) δ: 7.11 (1H, m), 7.70 (1H, m), 12.6 (1H, broad), $J_{3,5}$ = 1.8 Hz; *m/e*: 136. *Anal.* calcd. for $C_6H_4N_2O_2$: C 52.95, H 2.96; found: C 52.93, H 2.98.

Pyrrole-3-carbonitrile

4-Cyanopyrrole-2-carboxylic acid (900 mg) was mixed with quinoline (6 mL) and copper chromite catalyst (600 mg) was added. The stirred mixture was heated in an oil bath to 160°C for 3 h. The resulting brown mixture was cooled, diluted with ether (100 mL), and filtered to remove insoluble material. The ether solution was washed with four portions (30 mL each) of HCl (1 mol L^{-1}) and then with sodium hydrogen carbonate solution (5% aqueous). The pale yellow ether layer was collected, dried (K_2CO_3), and evaporated to leave an oily residue which soon crystallized on cooling. The crystalline residue (486 mg) was recrystallized from a benzene/petroleum (bp 60–80°C) mixture to give pyrrole-3-carbonitrile (388 mg, 64%), mp 56–56.5°C (lit. (2) mp 55–56°C); ir v: 3275 (N—H), 2227 (C≡N) cm^{-1}; nmr ($CDCl_3$) δ: 6.43, 6.77, 7.27 (each 1H, m), 9.1 (1H, broad s, pyrrolic N—*H*); *m/e*: 92.

1-Methyl-4-cyanopyrrole-2-carboxaldehyde

1-Methylpyrrole-2-carboxaldehyde (2.0 g) was dissolved in acetonitrile (10.0 mL) and cooled in a solid CO_2/acetone bath. A solution of CSI (4.83 mL) in acetonitrile (10.0 mL) was added to the stirred solution. The mixture was allowed to warm to room temperature overnight. DMF (7.0 mL) was added to the red coloured product without cooling, and the mixture was warmed to 50°C for 1 h and then poured into a mixture of NaOH (2 mol L^{-1}, 55 mL) and ice. The brown solid that precipitated was collected by vacuum filtration and the filtrate was thoroughly extracted with ethyl ether. The ether extracts were washed with $NaHCO_3$ solution (5% aqueous), dried (K_2CO_3), and the solvent was evaporated. The crystalline residue was combined with the precipitated solid and recrystallized from petroleum (bp 100–120°C) to give the product as very pale yellow crystals (1.3 g, 53%), mp 123–124°C (lit. (9) mp 116–120°C); ir v: 2231 (C≡N), 1670 (C=O) cm^{-1}; nmr ($CDCl_3$) δ: 3.96 (3H, s), 7.09, 7.27 (each 1H, m), 9.53 (1H, s); *m/e*: 134. *Anal.* calcd. for $C_7H_6N_2O$: C 62.68, H 4.52; found: C 62.72, H 4.52.

Chloroform extraction of the aqueous layer from the above preparation gave a small amount of a by-product as a brown solid (88 mg). The solid was sublimed (160°C/0.1 Torr) to give the product **6**, mp 190–191°C; ir v: 1670, 1680 (m, C=N), 1630 (s, C=O) cm^{-1}; nmr (DMSO-d_6) δ: 2.87, 3.10, 3.84 (each 3H, s), 7.14 (1H, d) 7.60 (1H, broad), 8.07 (1H, s), 9.47 (1H, s), $J_{3,5}$ = 1.8 Hz; *m/e*: 243. *Anal.* calcd. for $C_9H_{13}N_3O_3S$: C 44.43, H 5.39, S 13.18; found: C 44.42, H 5.40, S 13.19.

4-Cyanopyrrole-2-carboxaldehyde

The same procedure was used as for the preparation of 1-methyl-4-cyanopyrrole-2-carboxaldehyde. The reaction with CSI required 48 h to reach completion and was easily followed by ^1H nmr of the reaction mixture. The crude product crystallized slowly but contained an impurity (not isolated) which turned black in air making purification difficult. Recrystallization from ether/petroleum (bp 35–60°C) gave the almost pure product as a light brown solid in 27% yield. Sublimation (110°C/0.1 Torr) gave the pure product, mp 177°C (lit. (9) mp 177–177.5°C); ir v: 3228 (N—H), 2233 (C≡N), 1646 (C=O) cm^{-1}; nmr (acetone-d_6) δ: 7.33 (1H, d), 7.82 (1H, dd), 9.58 (1H, d), $J_{3,5}$ = 1.5 Hz, $J_{CHO,5}$ = 1.1 Hz; *m/e*: 120.

1-Methylpyrrole-3-carbonitrile (by decarbonylation)

4-Cyano-1-methylpyrrole-2-carboxaldehyde (1.09 g) was mixed with palladium on charcoal (100 mg) in a pear shaped flask fitted with an air condenser, and then heated in a silicone oil bath at 210°C for 45 min. The black oily mixture formed was distilled to give the product as a colourless oil (0.72 g, 83%), bp 65–70°C/0.1 Torr (lit. (2) bp 135°C/1 Torr); ir (liquid film) v: 3127 (saturated C—H stretch), 2237 (C≡N) cm^{-1}; nmr ($CDCl_3$) δ: 3.64 (3H, s), 6.27, 6.47, 6.96 (each 1H, m); *m/e*: 106.

Pyrrole-3-carbonitrile (by decarbonylation)

Small scale decarbonylation (1) of 4-cyanopyrrole-2-carboxaldehyde (100 mg) gave the product (59 mg, 77%) which was identical to the pyrrole-3-carbonitrile prepared by decarboxylation (above).

JAMES P. KUTNEY, GARY M. HEWITT, TOSHIO KURIHARA, PHILLIP J. SALISBURY, ROBERT D. SINDELAR, KENNETH L. STUART, PHILIP M. TOWNSLEY, WILLIAM T. CHALMERS, and GIULIO G. JACOLI. Can. J. Chem. **59**, 2677 (1981).

Plant tissue cultures of *Tripterygium wilfordii* Hook F produced the cytotoxic diterpene triepoxides tripdiolide (**1**) and triptolide (**2**) in yields that were 16 and 3 times greater, respectively, than those observed in the plant itself. Other diterpenes, dehydroabietic acid (**3**) and 15-hydroxy-18-norabieta-3,8,11,13-tetraene-3-oic acid methyl ester (**4**) were also isolated. Co-occuring in these cultures were the cytotoxic quinone-methides, celastrol (**5**), compound **6**, and compound **7**. Other triterpenes produced were oleanolic acid (**8**) and polpunonic acid (**9**). β-Sitosterol (**17**) was also isolated. The proposed structure of **4** was confirmed by synthesis starting from compound **3**. Cytotoxic data are reported, and a possible biosynthetic relationship among dehydroabietic acid, compound **4**, and tripdiolide (**1**) is presented.

JAMES P. KUTNEY, GARY M. HEWITT, TOSHIO KURIHARA, PHILLIP J. SALISBURY, ROBERT D. SINDELAR, KENNETH L. STUART, PHILIP M. TOWNSLEY, WILLIAM T. CHALMERS et GIULIO G. JACOLI. Can. J. Chem. **59**, 2677 (1981).

Les cultures des cellules de la plante *Tripterygium wilfordii* Hook F produisent les triépoxydes diterpéniques cytotoxiques, la tripdiolide (**1**) et la triptolide (**2**) avec des rendements qui sont respectivement 16 et 3 fois plus élevés que ceux que l'on obtient à partir de la plante elle-même. On a également isolé d'autres diterpènes: l'acide déhydroabiétique (**3**) et l'hydroxy-15 norabiéta-18 tétraène-3,8,11,13 oate-3 de méthyle (**4**). On obtient également à partir de ces cultures les méthylures de quinone cytotoxiques: le célastrol (**5**) et les composés **6** et **7**. On a également isolé d'autres triterpènes: l'acide oléanolique (**8**) et l'acide polpunonique (**9**) ainsi que le β-sitostérol (**17**). On a confirmé la structure proposée pour le composé **4** en le synthétisant à partir du composé **3**. On rapporte les données cytotoxiques et on propose une relation biosynthétique possible entre l'acide déhydroabiétique, le composé **4** et la tripdiolide (**1**).

[Traduit par le journal]

In a preliminary communication, we reported the production of tripdiolide (**1**), a novel cytotoxic diterpene triepoxide by tissue cultures of *Tripterygium wilfordii* Hook F (1). We now report the improved production of **1**, the isolation of cytotoxic triptolide (**2**), and the chemical analysis of secondary products obtained from shake-flask cultures.

Examination of shake-flask and stirred fermentor batch cultures (up to 60 L) of our cell line TRP 4a, showed that a modified PRL-4 medium (2) afforded the highest tripdiolide yields. Levels of **1** and **2** were respectively 16 and 3 times greater than those reported for the parent plant source (3). Multistep syntheses of some of these modified abietane-type compounds have been reported recently (4, 5). No synthesis of tripdiolide (**1**) has, however, appeared in the chemical literature.

Three procedures for the isolation of the target cytotoxic diterpenes **1** and **2** are presented in the Experimental. Method 2 proved to be the most efficient for isolating these compounds from the tissue culture broth. Two additional diterpenes, dehydroabietic acid (**3**) and the methyl ester of the novel compound, 15-hydroxy-18-norabieta-3,8,11,13-tetraene-3-oic acid (**4**), were isolated. The isolation of compound **3** and compound **4** has interesting biosynthetic implications. Scheme 1 outlines a possible biosynthetic pathway from geranylgeraniol to tripdiolide. The route from geranylgeraniol to the abietane skeleton has previously been proposed (6). We now suggest that an important step in this pathway involves the rearrange-

ment of dehydroabietic acid to a modified abietane skeleton as is depicted by compound **4**. Subsequent enzymatic oxidations would lead ultimately to tripdiolide (**1**) and triptolide (**2**). With the aid of these high yielding cultures, the possibility of obtaining pertinent biosynthetic information is now very good, and appropriate studies have been initiated.

The quinone-methide type triterpenes, celastrol (**5**), compound **6**, and compound **7** were isolated by method 1 and characterized. Celastrol (**5**) has previously been isolated from the parent plant *Tripterygium wilfordii* (7). Compound **6** had nearly identical nmr, ms, and uv data to those of celastrol, but had different R_f values on tlc. Compound **7** and tingenone had the same relationship. The stereochemistry of both compounds **6** and **7** has yet to be defined.

As a group, the quinone-methides have been of interest because of their antineoplastic activity (8). A recent study of the binding of tingenone to DNA suggests a possible mode of cellular interaction which may elicit antitumor activity (9). The cytotoxic activity of some of these compounds, as measured using the KB cancer cell tissue assay system, is summarized in Table 1.

Oleanolic acid (**8**), which has been found in a wide variety of plants (10), and polpunonic acid (**9**) have also been isolated from these cultures. Polpunonic acid, a friedelane-type triterpene, has been reported from *Plenckia polpunea* (11), and has been recently shown to be present in the tissue

TABLE 1. Cytotoxic activity of some quinone–methide compounds

Compounds (quinone-methides)	Observed ED_{40} values[a]
Celastrol (**5**)	0.55, 1.40 } Two determinations
Pristimerin (**5**, Me acid ester)	0.91
Tingenone	0.27
22-Hydroxytingenone	2.5
Compound **6**	1.8
Diazomethane product of celastrol	1.6

[a] ED_{40} expressed in μg/mL, and is the calculated effective dose which inhibits growth of 50% of control growth. Assays were done using KB cells (human epidermoid carcinoma of the nasopharynx-type 9KB-5). Cytotoxicity and *in vitro* activity were assayed as reported in ref. 18.

cultures of *Maytenus buchananii* (Loes) R. Wilezck (12).

The structure of the diterpene **4** was confirmed by a synthesis which started from dehydroabietic acid **3** (Scheme 2). The ketone **10** obtained from **3**, following the procedure of Huffman (13), was transformed to the corresponding cyanohydrin by refluxing with potassium cyanide in 18-crown-6 ether and dimethyl sulfoxide – dimethyl formamide. This latter compound was immediately dehydrated with thionyl chloride in pyridine to yield a 5:1 mixture of the α,β-unsaturated nitriles **11** and **12** (60% from **10**). Treatment of this mixture with sodium ethoxide in ethanol under reflux gave a 2:1 mixture of **11** and **12**. This mixture was reduced to the aldehydes **13** and **14** by diisobutylaluminium hydride.

Aldehydes **13** and **14** were separated by silica gel column chromatography. Compound **14** was oxidized to the acid **15** by sodium chlorite and resorcinol in acidic dioxane–water (14). This acid was treated with diazomethane to give the corresponding ester (**16**) in 72% yield from **14**. The target compound **4** was prepared by irradiating **16** as a solution in hexane with uv light for 5 h.

Experimental

The *Tripterygium wilfordii* cell line designated TRP 4a was initiated as a 2 mm × 6 mm cutting obtained from a surface-sterilized leaf (a 15 min immersion in a 0.5% sodium hypochlorite solution followed by a sterile distilled water rinse). This explant was placed on $PRD_{2.0}$ Co_{100}[2] medium containing 0.8% agar. The callus obtained through growth on solid medium was used to initiate suspension cultures which have been maintained as stock cultures by regular subculturing with 10% inoculum at 3 week intervals. This TRP 4a cell line has been maintained in stable culture for more than 2.5 years.

Tripdiolide was first detected in callus tissue by tlc. The first 28 L cultivation which was extracted, and products separated (see method 1 below), was grown in $PRD_{2.0}$ Co_{60} without casein hydrolysate. These cultures were incubated in the dark at room temperature (20–26°C) on a rotary shaker (120 rpm). The second (25 L), third (17.5 L), and fourth (22 L) cultivations of TRP 4a (separation method 2) were grown in PRL-4 medium supplemented with 0.5 mg/L of napthaleneacetic acid and 0.5 mg/L kinetin ($PRNA_{0.5}$ $K_{0.5}$). Individual cultures were 500 mL held in 1 L erlenmeyer flasks, and were incubated in the dark at 27°C (±0.5°) with 120 rpm shaking. All cultures were inoculated at 10% of the medium volume with stationary phase stock TRP 4a.

60 L Chemapec Pilot Plant Bioreactor

Fifty liters of TRP 4a were grown in a single batch, using a 60 L capacity Chemapec Inc. fermentor. The medium was $PRNA_{0.5}$ $K_{0.5}$. The incubation conditions were 120 ± 10 rpm agitation, approximately 300 mL/min aeration, and 28°C. The culture was inoculated to 3–5% with a portion of a TRP 4a culture grown in 10 L of $PRD_{2.0}$ Co_{100} in a 12 L Virtis fermentor controlled at 100 rpm agitation, and 50 mL/min aeration at 28°C (±2°), and incubated for 28 days. The Chemapec culture was harvested after 50 days. Due to periodic sampling, the reaped volume was 41 L. The broth was extracted and products separated by method 2 outlined below to give 4.0 mg of tripdiolide. This yield represented 3 times the amount reported from plant material (3).

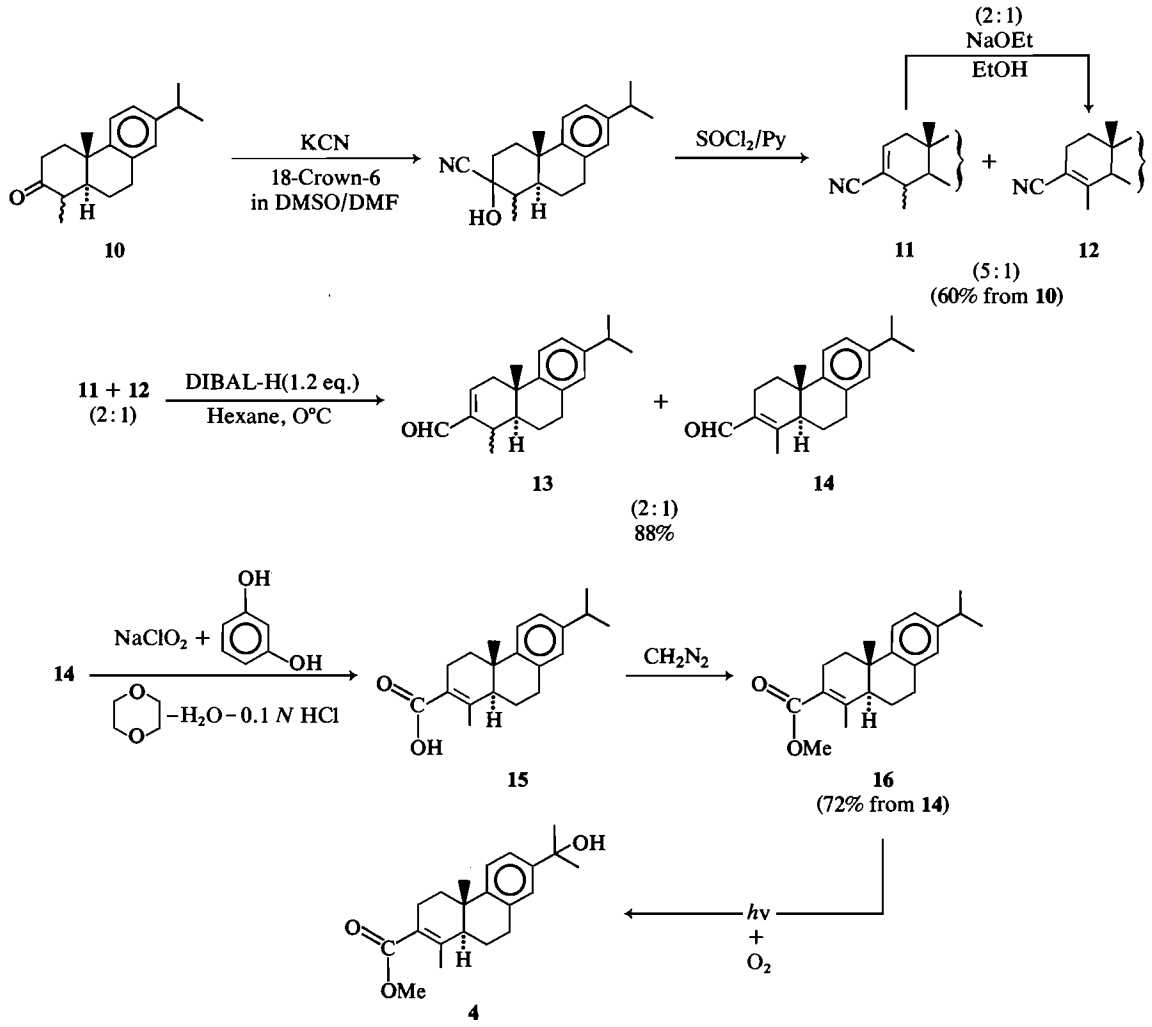
Ultraviolet spectra were recorded on a Cary 15 spectrophotometer using methanol as the solvent. Circular dichroism (cd) measurements were made on a Jasco J-20 spectropolarimeter. Infrared spectra were recorded either on a Perkin-Elmer 457 or 710 spectrophotometer. The ^{1}Hmr spectra were recorded on Bruker WH-400, Bruker WP-80, Varian XL-100, or Nicolet-Oxford H-270 instruments. Deuteriochloroform was used as the solvent with TMS as internal standard. Mass spectra were recorded on an Atlas CH-4B or AEI MS-902 instrument. Microanalyses were carried out by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia. Column chromatography utilized Merck silica gel 60 (70–230 mesh). Preparative layer chromatography utilized Merck silica gel GF 254 2 mm and 0.25 mm plates, and thin layer chromatography was carried out with Eastman silica chromagram sheets.

Separation Experimental: Method 1

A 28 L shake-flask cultivation of *Tripterygium wilfordii* cell tissue line TRP 4a grown on modified PRL-4 medium was harvested after 6 weeks. The cells (5.9 kg) were extracted with ethanol and ethyl acetate to give 10.0 g of material. The medium yielded another 7.9 g on extraction with ethyl acetate. The material from the medium was separated on a silica column (350 g) packed in benzene. The column was then eluted with benzene (fractions 1 and 2; 500 mL fractions were collected in all cases), followed by 5% benzene – ethyl acetate (fractions 3–5), then 10% benzene – ethyl acetate (fractions 6–8). The % ethyl acetate was gradually increased until the final 3 fractions (fractions 18–20) were eluted with pure ethyl acetate. The analysis showed that tripdiolide (**1**) was present in fractions 19 and 20 (0.88 g), but still was contaminated with other products. A similar column was used to separate the 10.0 g of material obtained from the tissue cells. In this case, tripdiolide was shown to be present in fraction 19 (0.31 g).

Material containing tripdiolide from both columns was absorbed on a silica column (150 g) packed in diethyl ether. Fractions 1–3 were eluted with diethyl ether; fractions 4 and 5 eluted with 1% ethanol–ether; fractions 6–8 (2% ethanol – diethyl ether); fractions 9–11 (3% ethanol – diethyl ether); fractions 12 and 13 (5% ethanol – diethyl ether); fractions 14 and 15 (10% ethanol – diethyl ether). The examination of all fractions on Eastman silica sheets in 3% methanol–chloroform showed the presence of tripdiolide in fractions 11–15.

[2] $PRD_{2.0}$ Co_{100} is the PRL-4 medium of Gamborg and Eveleigh (2) supplemented with 2.0 mg/L of 2,4-dichlorophenoxyacetic acid and 100 mL/L coconut milk.



SCHEME 2. Synthetic route to compound **4**.

Tripdiolide 1

Material from fractions 11–15 (96.6 mg) was separated on two 2 mm Merck silica plates developed in 2% ethanol – ethyl acetate to give 14.5 mg of a mixture of compounds which from tlc was mainly tripdiolide. Further purification was on 0.25 mm Merck silica plates. The plates were first developed in ethyl acetate and then four times in diethyl ether. A crystalline compound (4.5 mg) was obtained that had identical tlc behaviour as tripdiolide.

Identity was confirmed by a high resolution ms (M^+, *m/e* 377.1610; calcd. 377.1600 for $C_{20}H_{24}O_7$), mp and mixture mp 211-212°C; 270 MHz ^{1}Hmr, δ: 4.77 (2H, t, J = 1.5 Hz, 19-CH_2), 4.62 (1H, m, 2-C*H*OH), 3.93 (1H, d, J = 3 Hz, 11-CH), 3.66 (1H, dd, J = 3 and 1 Hz, 12-CH), 3.57 (1H, dd, J = 11 and 1 Hz, 14-C*H*OH), 3.55 (1H, d, J = 5 Hz, 7-CH), 2.74 (1H, d, J = 11 Hz, 14-CHO*H*), 2.65 (1H, m, 5-CH), 2.22 (1H, m, 15-CH), 2.10 (1H, 1-CH), 1.83 (1H, d, J = 1 Hz, 1-CH), 1.76 (1H, bs, exchanged with D_2O, 2-CHO*H*), 1.40 (2H, m, 6-CH_2), 1.31 (3H, s, 20-CH_3), 1.01 (3H, d, J = 7 Hz, 17-CH_3), 0.88 (3H, d, J = 7 Hz, 16-CH_3).

Celastrol 5

Fractions from the two earlier columns were pooled based on tlc analysis: fractions 1–9; fractions 10–15 (5.48 g); fractions 16–20; 0.42 g of material from fractions 10–15 was separated on two 2 mm Merck silica plates developed in 3% methanol–chloroform. Thin-layer chromatographic examination of this mixture in several solvent systems showed two major groups of orange colored compounds: group A, which ran close to the solvent front in 3% methanol–chloroform, and consisted of 7 orange compounds; group B, which in the same solvent system was located at approximately R_f 0.4, and consisted of at least 5 orange compounds. One of the orange compounds from group B was isolated in pure form (8 mg), mp 202°C (lit. (15) mp 205°C). The ^{1}Hmr (100 MHz) was characteristic of a quinone-methide type natural product, and the following data identified it as celastrol; δ: 7.09 (1H, dd, J = 7 and 1 Hz, 6-CH), 6.54 (1H, d, J = 1 Hz, 1-CH), 6.36 (1H, d, J = 7 Hz, 7-CH), 2.23 (3H, s, 4-CH_3), 1.44 (3H, s, 9-CH_3), 1.26, 1.24, 1.08 (3 × 3H, s, 13-CH_3, 14-CH_3, 17-CH_3), 0.58 (3H, s, 20-CH_3); ms: 450.2780 (M^+), $C_{29}H_{28}O_4$

(33%), 436.2682 ($C_{28}H_{36}O_4$, 8%), 267.1391 ($C_{18}H_{19}O_2$, 6%), 255.1336 ($C_{17}H_{19}O_2$, 2%), 253.1237 ($C_{17}H_{17}O_2$, 13%), 241.1231 ($C_{16}H_{17}O_2$, 38%), 227.1078 ($C_{15}H_{15}O_2$, 16%), 215.1076 ($C_{14}H_{15}O_2$, 15%), 201 ($C_{13}H_{13}O_2$, 51%). *Anal.* calcd. for $C_{29}H_{38}O_4 \cdot H_2O$: C 74.30, H 8.60; found: C 74.06, H 8.62.

Celastrol (3 mg) dissolved in ethyl acetate was treated with excess diazomethane in diethyl ether at room temperature overnight. A light orange product was obtained, mp 183–185°C; ^{1}Hmr (80 MHz), δ: 6.82 (1H, s), 6.70 (1H, d, J = 5 Hz), 6.01 (1H, d, J = 5 Hz), 3.63 (1H, s, C—COOCH_3), 1.84 (3H, s), 1.50 (9H, s), 1.16 (3H, s), 1.13 (3H, s), 1.07 (3H, s), 0.50 (3H, s); ms: 492.3241 (M^+), $C_{32}H_{44}O_4$. *Anal.* calcd. for $C_{32}H_{44}O_4 \cdot CH_3COOCH_2CH_3$: C 74.90, H 9.09; found: C 75.19, H 8.78.

Compound 6

An orange-red compound (9.9 mg), which was more polar than celastrol, was isolated from the group B compounds; mp 200–204°C. Spectral data were similar to those of celastrol; ^{1}Hmr (100 MHz), δ: 7.08 (1H, dd, J = 7 and 1 Hz, 6-CH), 6.56 (1H, d, J = 1 Hz, 1-CH), 6.36 (1H, d, J = 7 H), 2.22 (3H, s, 4-CH_3), 1.45, 1.26, 1.27, 1.12 (4 × 3CH_3, s, 9-CH_3, 13-CH_3, 14-CH_3, 17-CH_3), 0.60 (3H, s, 20-CH_3); ms: 450.2756 ($C_{29}H_{28}O_4$, M^+, 30%), 436.2602 ($C_{28}H_{26}O_4$, 3%), 267.1372 ($C_{18}H_{19}O_2$, 3%), 253.1220 ($C_{17}H_{17}O_2$, 13%), 241.1237 ($C_{16}H_{17}O_2$, 30%), 227.1078 ($C_{15}H_{15}O_2$, 8%), 215.1070 ($C_{14}H_{15}O_2$, 10%), 201.0919 ($C_{13}H_{13}O_2$, 35%), 119.0862 (C_9H_{11}, 11%).

Compound 7

Fractions 10–15 also yielded, from preparative 2 mm Merck silica separation, an orange colored compound (61 mg) in the group A series. The separation was achieved by using 10% methanol–chloroform to first give 200 mg of a mixture of compounds. These were further separated using diethyl ether – benzene (15:85), mp 145–150°C (recrystallized, hexane–benzene–methanol); 210–212°C (recrystallized, benzene); ir, ν_{max} (Nujol): 3300, 1715 cm^{-1}; λ_{max}: 250 (log ε, 4.1535), 262 sh (4.0371), 365 sh (3.2911), 412 (4.1446); cd, λ_{max} (MeOH): 257 (Δε −7.78), 263 (−8.43), 370 (+6.81), 445 (−3.56); ^{1}Hmr (100 MHz), δ: 7.06 (1H, dd, J = 7 and 1.5 Hz, 6-CH), 6.56 (1H, d, J = 2 Hz, 1-CH), 6.4 (1H, d, J = 7 Hz, 7-CH), 2.92 (2H, d, J = 14 Hz, 22-CH_2), 2.21 (3H, s, 4-CH_3), 1.52 (3H, s, 9-CH_3), 1.35 (3H, s, 14-CH_3), 1.02 (3H, s, 13- or 17-CH_3), 1.01 (3H, s, 17- or 13-CH_3), 0.96 (3H, d, J = 6 Hz, 20-CH_3); ms: 420.2666 (M^+), $C_{28}H_{36}O_3$, 405.2425 ($C_{27}H_{33}O_3$, 5.88%), 267.1390 ($C_{18}H_{19}O_2$, 2.69%), 253.1226 ($C_{17}H_{17}O_2$, 7.23%), 241.1231 ($C_{16}H_{17}O_2$, 23.7%), 227.1063 ($C_{15}H_{15}O_2$, 4.87%), 225.1288 ($C_{16}H_{17}O$, 4.54%), 202.0978 ($C_{13}H_{14}O_2$, 12.61%), 201.0910 ($C_{13}H_{13}O_2$, 11.43%), 200.0835 ($C_{13}H_{12}O_2$, 6.39%), 163.1136 ($C_{11}H_{15}O$, 2.18%), 107.0854 (C_8H_{11}, 3.53%), 78.0469 (C_6H_6, 37.65%). Direct tlc comparison with an authentic sample of tingenone, $C_{28}H_{36}O_3$, (16), showed it *not* to be identical, but had a slightly lower R_f value. For the 145–150°C mp sample. *Anal.* calcd. for $C_{28}H_{36}O_3 \cdot 0.5$ MeOH: C 78.39, H 8.77; found: C 78.30, H 8.49.

Further separation of the mixture of compounds in the fractions 10–15 gave small amounts of other orange colored compounds which have not been fully characterized. One of these had spectral properties similar to those of 20-hydroxytingenone; ^{1}Hmr (100 MHz), δ: 7.05 (1H, dd, J = 6.5 and 1.5 Hz), 6.57 (1H, d, J = 1.5 Hz), 6.38 (1H, d, J = 6.5 Hz), 3.00 (2H, d, J = 15 Hz), 2.2 (3H, s), 1.4 (3H, s), 1.35 (6H, s), 1.23 (3H, s), 0.90 (3H, s); ms: 436.2592 (M^+), $C_{28}H_{38}O_4$.

Oleanolic Acid 8

The 0.42 g of material from the fractions 10–15 also yielded 45 mg of a cream colored compound, mp 285°C (recrystallized, ethanol) from plc; ^{1}Hmr (100 MHz), δ: 5.26 (1H, t, J = 1.5 Hz, C=CH), 3.25 (dt, J = 4 and 1.5 Hz, —CHOH), 2.50 (bs, exch. D_2O, —OH), 1.20, 1.10, 0.98, 0.95, 0.92, 0.86, 0.78 (7 × 3H, singlets, 7 × CH_3); ms: 456.3622 (M^+), $C_{30}H_{48}O_3$, base peak at 248.1774 ($C_{16}H_{24}O_2$). Treatment with diazomethane gave a product, mp 193–195°C (lit. (17) mp 196–198°C); ^{1}Hmr (100 MHz), δ: 5.22 (1H, t, J = 1.5 Hz, $\diagdown$C=CH$\diagup$), 3.62 (3H, s, —COOCH_3), 3.15 (1H, dd, J = 11 and 4 Hz), 2.02 (1H, bs, exch. D_2O, —OH), 1.20, 1.15, 1.00, 0.95, 0.92, 0.82, 0.77 (7 × 3H, s, 7 × CH_3); ms: 470.3749 (M^+), $C_{31}H_{50}O_3$ (6.7%), base peak 262.1936 ($C_{17}H_{26}O_2$). *Anal.* calcd. for $C_{31}H_{50}O_3 \cdot H_2O$: C 76.16, H 10.72; found: C 76.17, H 10.72.

Polpunonic Acid 9

Separation on 2 mm Merck silica plates of the 0.42 g mentioned above from fractions 10–15 in 3% methanol–chloroform, gave a fraction which on tlc was shown to contain 5 major and 5 minor compounds. These were further separated by two successive plc runs on three 0.25 mm Merck silica plates in 3% methanol–chloroform. Three milligrams of crystals, mp 242–244°C (lit. (11) mp 246–248°C) were obtained. This was shown to be polpunonic acid by ir, ms, nmr, and mixture mp; ^{1}Hmr (80 MHz), δ: 2.30 (2H, m, CH_2 adjacent to $\diagdown$C=O$\diagup$), 1.27 (3H, s, CH_3), 1.10 (3H, s, CH_3), 1.00 (3H, s, CH_3), 0.87 (3 × 3H, some coupling evident, J = 6.5 Hz, 2 × 3° CH_3 and 1 × 2° CH_3), 0.70 (3H, s, CH_3); ms: 456.3574 (M^+), $C_{30}H_{48}O_3$, (78%).

Compound 4: 15-Hydroxy-18-norabieta-3,8,11,13-tetraene-3-oic Acid Methyl Ester

Fractions 16–19 were recombined and treated with diazomethane in diethyl ether. The product (262 mg) was separated into 29 fractions by hplc using a silica column and solvent system dichloromethane and diethylether–dichloromethane (10:1). Fraction 16 was shown to contain 8 components. Separation on 0.25 mm Merck silica plates in 3% methanol–dichloromethane gave a colorless oil (8 mg) for which structure **4** has been confirmed; ^{1}Hmr (270 MHz), δ: 7.25 (3H, m, aromatic —H), 3.75 (3H, s, $COOCH_3$), 3.0 (2H, m, 7-CH_2), 2.00 (3H, bs, 4-CH_3), 1.57 (6H, s, 17 and 16-CH_3), 1.05 (3H, s, 10-CH_3); ms: M^+ 328 (45%), 313 (65%), 310 (15%), 297 (10%), 295 (10%), 281 (8%), 278 (15%), 269 (5%), 253 (13%), 215 (51%), 197 (17%), 195 (15%), 183 (17%), 157 (19%), 149 (9%), 141 (13%), 91 (11%), 81 (5%), 59 (49%), 43 (100%).

Synthesis of Compound 4: (15-Hydroxy-18-norabieta-3,8,11,13-tetraene-3-oic Methyl Ester)

The ketone **10** was prepared from dehydroabietic acid by a procedure reported by Huffman (13). Scheme 2 outlines the synthetic route to compound **4**.

Compound 10 (18-Norabieta-8,11,13-triene-3-one)

Dehydroabietic acid (25.05 g) was converted by decarboxylation, hydroboration, and oxidation to the ketone **10** (13). The yield of **10** was 8.76 g, mp 60–63°C[3] (yield: 39%). Infrared, ν_{max}: 1705 cm^{-1}; ^{1}Hmr (80 MHz), δ: 7.23 (1H, d, J = 8 Hz), 6.99 (1H, br. d, J = 8 Hz), 6.95 (1H, br. s), 1.33 (3H, s), 1.23 (6H, d, J = 7 Hz), 1.21 (3H, d, J = 8 Hz); ms: 270 (M^+, 15%), 256 (40%), 255 (35%), 241 (100%), 223 (9%), 213 (20%), 199 (11%), 181 (25%), 171 (19%), 155 (9%), 143 (18%), 142 (15%), 141 (18%), 129 (30%), 128 (20%), 117 (14%), 91 (14%), 55 (40%). *Anal.* calcd. for $C_{19}H_{26}O$: C 84.39, H 9.69; found: C 84.01, H 9.71.

[3]The ketone reported by Huffman (13) was an oil.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

Compounds 11 (3-Cyano-18(19)-norabieta-2,8,11,13-tetraene) and 12 (3-Cyano-18(19)-norabieta-3,8,11,13-tetraene)

Potassium cyanide (1.32 g, 20.2 mmol) was added to a solution of 1.0 g (3.70 mmol) of ketone **10** and 18-crown-6 ether in 50 mL of dry dimethyl sulfoxide – acetonitrile (1:3) at room temperature. The mixture was heated at 70–80°C for 1 day.

A saturated solution of sodium chloride was added with ice, and the product extracted 3× with ether. The ether solution was washed successively with aqueous sodium carbonate, water, and brine. The crude cyanohydrin obtained after solvent removal was dissolved in 20 mL of cold pyridine, and the solution treated with 0.5 g (4.20 mmol) of thionyl chloride for 30 min at 0°C under nitrogen. The solution was stirred at room temperature for 24 h and poured into 200 mL of ice and water. The product was extracted with ether and the extract dried with anhydrous sodium sulfate. The oil which remained after solvent removal was chromatographed on silica gel using benzene–hexane (1:1). A mixture of compounds **11** and **12** was obtained. The ^{1}Hmr spectrum indicated that **11** and **12** were present in the ratio of 5:1 (0.66 g; 60% from **10**) respectively. This was changed to a 2:1 ratio (nmr analysis) by the following procedure. Compounds **11** and **12** were dissolved in 50 mL of dry ethanol and treated with excess sodium ethoxide at 80–90°C for 5 h under nitrogen; ir; λ_{max}: 2250 (C≡N) cm^{-1}; ^{1}Hmr (80 MHz), δ: 6.60 (m, C=C—*H*), 1.06 (d, J = 7.0 Hz, C_4—CH_3), 2.08 (br. s, C=C—CH_3); ms: 279 (M^+, 20%), 264 (30%), 250 (18%), 236 (10%), 222 (11%), 199 (10%), 186 (32%), 171 (23%), 159 (24%), 149 (26%), 143 (10%), 141 (9%), 129 (13%), 123 (16%), 121 (70%), 119 (98%), 117 (100%), 115 (6%), 91 (10%), 86 (34%), 84 (41%), 82 (39%). *Anal.* calcd. for $C_{20}H_{25}N$: C 85.96, H 9.01; found: C 86.01, H 8.89.

Compounds 13 (3-Formyl-18(19)-norabieta-2,8,11,13-tetraene) and 14 (3-Formyl-18(19)-norabieta-3,8,11,13-tetraene)

To a solution of 1.28 g (4.58 mmol) of the mixture of **11** and **12** in 50 mL of dry hexane at 0°C under nitrogen was added 5.5 mL (1.0 mmol in hexane) of diisobutylaluminium hydride (DIBAL-H) dropwise. The reaction mixture was allowed to warm to room temperature and stirred for 1 h. The reaction was carefully poured into 100 mL of ice and water, and extracted with ether. After drying, the solvent was removed *in vacuo*. The mixture of aldehydes was separated on a silica gel column using benzene–hexane (3:2) to give 0.71 g of compound **13** (58%) and 0.36 g (30%) of compound **14**, both as colorless oils.

Compound 13: ir, λ_{max}: 1685 cm^{-1}; ^{1}Hmr (80 MHz), δ: 9.51 (1H, s, —C(=O)—*H*), 7.25 (1H, d, J = 9 Hz), 7.07 (1H, br. d, J = 9 Hz), 6.96 (1H, br. s), 6.85 (1H, m), 1.25 (3H, s), 1.24 (6H, d, J = 7.0 Hz), 1.17 (3H, d, J = 7.3 Hz); ms: 282 (M^+, 11%), 267 (10%), 239 (8%), 186 (25%), 171 (10%), 121 (40%), 119 (100%), 117 (92%), 86 (22%), 84 (24%), 82 (30%). *Anal.* calcd. for $C_{20}H_{26}O$: C 85.05, H 9.27; found: C 85.10, H 9.30.

Compound 14: ir, λ_{max}: 1685 cm^{-1}; ^{1}Hmr (80 MHz), δ: 10.19 (1H, s, —C(=O)—*H*), 7.27 (1H, d, J = 9 Hz), 7.06 (1H, br. d, J = 9 Hz), 6.93 (1H, br. s), 2.28 (3H, s), 1.27 (3H, s), 1.22 (6H, d, J = 7 Hz); ms: 282 (M^+, 18%), 267 (15%), 252 (10%), 186 (37%), 171 (10%), 159 (12%), 149 (10%), 121 (50%), 119 (100%), 117 (94%), 86 (42%), 84 (45%), 82 (50%). *Anal.* calcd. for $C_{20}H_{26}O$: C 85.05, H 9.27; found: C 85.01, H 9.30.

Compound 15: (18-Norabieta-3,8,11,13-tetraene-3-oic Acid)

To a solution of 0.36 g of the aldehyde **14** and 1.81 g of resorcinol in 20 mL of dioxane–water (1:1), 0.2 g of sodium chlorite in 5 mL of 0.1 *N* hydrochloric acid was added at room temperature (14). After 30 min stirring, the solution was extracted with ether and the ether extract dried over sodium sulfate. The solvent was removed *in vacuo* to yield compound **15**. Infrared, ν_{max} ($CHCl_3$): 3500, 1688 cm^{-1}; ^{1}Hmr (400 MHz); δ: 7.22 (1H, d, J = 9 Hz), 7.05 (1H, dd, J = 9 and 6 Hz), 6.90 (1H, d, J = 6 Hz), 2.19 (3H, bs), 1.27 (3H, s), and 1.24 (6H, d, J = 7 Hz); ms: 298 (M^+, 45%), 283 (M – CH_3, 50%), 241 (11%), 237 (10%), 223 (10%), 220 (13%), 195 (10%), 186 (100%), 171 (19%), 159 (23%), 149 (10%), 143 (14%), 129 (14%), 117 (11%), 105 (11%), 91 (11%), 87 (10%). *Anal.* calcd. for $C_{20}H_{26}O_2$: C 80.47, H 8.80; found: C 80.47, H 8.73.

Compound 16: (18-Norabieta-3,8,11,13-tetraene-3-oic Acid Methyl Ester)

Compound **15** was treated with excess diazomethane at 0°C in ether overnight. The methyl ester **16** was obtained as a colorless oil (0.28 g), 72% yield from compound **14**; ir, λ_{max}: 1720 cm^{-1}; ^{1}Hmr (80 MHz), δ: 7.25 (1H, d, J = 9.0 Hz), 7.05 (1H, br. d, J = 9.0 Hz), 6.92 (1H, br. s), 3.72 (3H, s), 2.11 (3H, br. s), 1.28 (3H, s), 1.23 (6H, d, J = 7.0 Hz); ms: 312 (M^+, 52%), 297 (27%), 283 (12%), 265 (10%), 257 (12%), 237 (32%), 199 (27%), 186 (49%), 165 (20%), 121 (40%), 119 (100%), 117 (97%), 59 (40%). *Anal.* calcd. for $C_{21}H_{28}O_2$: C 80.72, H 9.03; found: C 80.80, H 9.10.

Compound 4: (15-Hydroxy-18-norabieta-3,8,11,13-tetraene-3-oic Acid Methyl Ester)

The methyl ester **16** (98 mg; 0.298 mmol) was dissolved in 5 mL hexane–water (99:1). The solution was irradiated in a quartz cell with a 650 W Smith-Victor Corp. (Model 700) uv lamp for 5 h. The crude product (18 mg) was purified on 0.25 mm Merck silica plates (solvent: dichloromethane–methanol, 97:3) followed by hplc using a Waters silica column (dichloromethane – petroleum ether, 7:3) to give a colorless oil (8 mg). Infrared, ν_{max} ($CHCl_3$): 3590 and 1606 cm^{-1}; ^{1}Hmr (400 MHz), δ: 7.26 (3H, m, aromatic H), 3.75 (3H, s), 3.0 (2H, m, 7-CH_2), 2.00 (3H, bs, 4-CH_3), 1.57 (6H, s, 17 and 16-CH_3), 1.05 (3H, s, 10-CH_3); ms: 328 (M^+, 50%), 313 (60%), 310 (10%), 297 (12%), 295 (8%), 281 (8%), 278 (11%), 269 (9%), 253 (15%), 215 (66%), 197 (17%), 195 (13%), 183 (13%), 157 (15%), 149 (10%), 141 (12%), 91 (12%), 81 (10%), 59 (60%), 43 (100%). *Exact Mass* calcd. for $C_{21}H_{28}O_3$: 328.2039; found (M^+): 328.2038. *Anal.* calcd. for $C_{21}H_{28}O_3$: C 76.79, H 8.59; found: C 76.81, H 8.62.

β-*Sitosterol*

Material from fractions 1–9 was further fractionated on Merck 2 mm silica plates in benzene. Nine fractions were obtained. Open column chromatography on silica (180 g) of the major fraction, using carbon tetrachloride – benzene, followed by benzene – ethyl acetate, gave 8 fractions. Fraction 5 (867 mg) was further separated on a Waters Associates Prep. 500 HPLC (normal phase Porasil A) in benzene; 26 × 1 L fractions were collected. Fractions 15–18 on tlc showed one compound (116 mg), mp 137–139°C (recrystallized, methanol); nmr, tlc, mixture mp, and ms showed it to be β-sitosterol.

Separation Experimental: Method 2

A 25 L shake-flask cultivation of *T. wilfordii* cells of the TRP 4a line grown on modified PRL-4 medium was harvested after 37 days. Cells were separated from the medium by filtration through Mira cloth (Calbiochem). The broth, pH 5.9, was clarified using a CEPA model LE bench type high speed continuous centrifuge (36 000 rpm). Ethyl acetate was used as the extracting solvent (3 times) to give 2.34 g of an orange-brown solid. This was passed down a short silica column (40 g) in ethyl acetate to yield 1.85 g of a red solid; hplc separation was then performed on a normal phase Porasil A column of a Waters Associates Prep. 500 HPLC apparatus. Benzene, with increasing ethyl acetate as solvent gradient was used. Fifty fractions were collected, and were grouped based on tlc evidence; tlc

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

showed the presence of tripdiolide in fractions 25–36 (143 mg). Tripdiolide (9.1 mg) was obtained directly by treatment of these combined fractions with diethyl ether. The residue was separated on 0.25 mm Merck silica plates as outlined in method 1 to give another 12.6 mg. A total of 21.7 mg of crystalline tripdiolide was obtained. This yield represented sixteen times that reported from the plant source (3). The cells were freeze-dried to give 207 g of material. This was extracted with ethanol – ethyl acetate (1:2) and 20.1 g of a dark orange-colored solid was obtained. The open column procedure outlined in method 1 was used to separate 5 g of this extract; 2 mg of tripdiolide was obtained.

A repeat shake culture experiment (17.5 L) of TRP 4a type cells grown for 32 days was also separated by method 2 procedure to yield 18 mg of crystalline tripdiolide.

Separation Experimental Method 3

Part (5.7 g) of the material obtained from the freeze-dried cells as discussed above (20.1 g) was subjected to a solvent partition procedure. Two liters of water were added to the 5.7 g in a large mortar. Petroleum ether was added and the mixture thoroughly mixed. The mixture was next separated in a separating funnel; 0.98 g of a light orange-colored solid was recovered from the petroleum ether. The aqueous layer was successively extracted with benzene (2.11 g of a dark red material obtained), diethyl ether (yield was 0.99 g), ethyl acetate (yield was 0.34 g), and chloroform (yield was 0.20 g). The ethyl acetate fraction was shown by tlc to contain tripdiolide. A short silica column in ethyl acetate, followed by plc on 0.25 mm Merck plates gave 3.1 mg of tripdiolide. By extrapolation, the 20.1 g of extract would contain 10.9 mg or 14 times as much as that obtained by procedure 2. In summary, 32.6 mg of tripdiolide could be obtained from 22.4 g of material extracted from broth and dried cells. This represents a 0.016% yield (based on 207 g of dried cell weight) or 16 times that reported for the plant material (3).

Triptolide 2

A 22 L batch of TRP 4a cell cultures was reaped after 35 days incubation. Ethyl acetate extraction of the medium gave 1.38 g of crude material. A hplc separation procedure similar to that outlined in method 2 above was used to produce 25 fractions. From fractions 9–19. 19.7 mg of tripdiolide was obtained.

Fraction 1 (248 mg) was separated on thirteen 0.25 mm Merck silica plates in 15% acetone–benzene. This gave 9.2 mg of crude material which was further purified on three 0.25 mm Merck silica plates to yield 4.5 mg of triptolide, mp 225–227°C. This yield represented three times the yield reported for the plant material (3); ^{1}Hmr (400 MHz); δ: 4.66 (2H, m, 19-CH_2), 3.89 (1H, d, J = 4 Hz, 11-CH), 3.51 (1H, dd, J = 4 and 1 Hz, 12-CH), 3.41 (1H, dd, J = 11 and 1 Hz, 14-C*H*OH), 3.36 (1H, d, J = 5 Hz, 7-CH), 2.73 (1H, m, 5-CH), 2.32 (1H, d, J = 11 Hz, 14-CHO*H*), 2.24 (1H, m, 1-CH), 2.15 (1H, m, 15-CH), 1.98 (1H, m, 1-CH), 1.56 (2H, m, 2-CH_2), 1.10 (3H, s, 20-CH_3), 1.0 (3H, d, J = 7 Hz, 17-CH_3), 0.88 (3H, d, J = 7 Hz, 16-CH_3); ms: 360.1571 (M^+), $C_{20}H_{24}O_6$, (calcd. 360.1573). Identity was further confirmed by mixture mp, uv, and ir comparison with an authentic sample.

Isolation of Dehydroabietic Acid from TRP-4a Cultures

An aliquot (25 mL) of a 6 day old TRP 4a shake-flask culture (100 mL in a 300 mL flask) in PRL-4 medium was lyophilyzed. This was then powdered and extracted twice with 50 mL of ethyl acetate and once with 50 mL of ethanol. The extracts were combined, and removal of the solvents gave 5.3 mg of product. This was shown to contain 10 compounds by tlc (5% methanol – chloroform containing 0.1% acetic acid). The entire sample was dissolved in ethyl acetate and separated on a 0.25 mm Merck silica gel plate using the solvent system 10% methanol – chloroform with 0.2% acetic acid. The band corresponding to dehydroabietic acid (R_f 0.66) was eluted with ethyl acetate. Solvent removal yielded 1.1 mg of dehydroabietic acid (tlc, ms, methyl ester derivative comparison).

Effect of CdI_2 on electrical conductivity and phase transition behavior in AgI

MAHADEVA NATARAJAN AND ETALO A. SECCO[1]

Department of Chemistry, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received February 25, 1981

MAHADEVA NATARAJAN and ETALO A. SECCO. Can. J. Chem. **59**, 2685 (1981).

The phase transitions occurring in AgI containing dissolved CdI_2 have been examined by differential thermal analysis (DTA), electrical conductivity technique, and X-ray diffractometry. The electrical conductivity and polymorphic behavior of AgI is significantly modified by low concentrations of CdI_2. The results are interpreted in terms of substitutional Cd^{2+} and Ag^+ vacancies in AgI sublattice.

MAHADEVA NATARAJAN et ETALO A. SECCO. Can. J. Chem. **59**, 2685 (1981).

Faisant appel à l'analyse thermique différentielle (ATD), à la conductivité électrique et à la diffraction de rayons-X, on étudie la transition de phase qui se produit dans le AgI contenant du CdI_2 dissout. La conductivité électrique et le comportement polymorphique du AgI sont modifiés de façon significative par de faibles concentrations de CdI_2. On interprète les résultats en fonction de lacunes provoquées par la substitution de Ag^+ par Cd^{2+} dans le sous réseau de AgI.

[Traduit par le journal]

Introduction

AgI exists in three polymorphic forms at atmospheric pressure α, β, and γ. The high temperature α-form, first investigated by Strock (1) and later by Hoshino (2), is described as an "averaged structure" where the I atoms (ions) occupy a *bcc* arrangement with Ag atoms (ions) distributed statistically over 42 sites; it is stable between 147°C and its melting temperature. The anomalously high ionic conductivity of the α-phase was interpreted earlier in terms of highly mobile Ag^+ in a "quasi-molten" Ag^+ sublattice. Recent results from neutron scattering and microwave studies favor a jump-diffusion model for Ag^+ motion along preferential channels in the lattice as proposed by Gissler and Stump (3) (for review of electrical conductivity in AgI-type compounds see ref. 4).

The β- and γ-phases are identified as hexagonal and cubic structures, respectively. The coexistence of mixed β- and γ-phases at *RT* suggests complex phase interrelationships which are dependent on impurity content (5), thermal history, etc. While conflicting views are reported on the stability of these phases, it is accepted that the β-form is the stable phase at *RT* and the γ-form exists as a metastable phase in the range 25–136°C (6, 7).

The effects of a second component in the different solid phases can be used as a probe to clarify the phase transitions and the conductivity in AgI. CdI_2 was chosen as the component with the expectation that it will enter the AgI substitutionally at low concentrations ($r_{Cd^{2+}} < r_{Ag^+}$); the Cd^{2+} will generate Ag^+ vacancies in the Ag^+ sublattice with a resultant effect on T_t and σ–T behavior.

Experimental

Fused samples of CdI_2 in AgI were prepared by melting physical mixtures of specific compositions in porcelain crucible in air and allowing to equilibrate for an hour at temperature slightly below melting. Samples prepared in a flow of N_2 exhibited similar behavior. The observed loss of small amounts of I_2 due to CdI_2 decomposition was considered inconsequential.

The AgI used was from two sources, A. D. McKay of unspecified grade and Alfa Ventron Corp. of stated purity ≥99.9%; CdI_2 was J. T. Baker "Analyzed" Reagent, 99.9%. No discernible difference in behavior was observed in the two AgI preparations.

X-ray diffraction patterns were obtained on a Norelco diffractometer using CuK_α radiation (8). Electrical conductivity measurements (9) were done on compressed polycrystalline discs, 13 mm diameter and ~2 mm thick, under reduced pressure of 10^{-2} Torr. A thin coating of graphite (Dag #154 Acheson) ensured proper electrical contact with the two Pt disc electrodes. The heating rate was $\leq 15°\,h^{-1}$.

DTA traces were obtained on a duPont 990 Thermal Analyzer in a flowing N_2 (ultrapure) atmosphere using ignited Al_2O_3 as a reference material (10). Thermogravimetric analyses of the fused AgI–CdI_2 samples using TGA-951 accessory showed no weight loss over the temperature region investigated.

Results and Discussion

X-ray diffractogram traces of representative compositions in CdI_2 mole percentages are presented in Fig. 1. Up to 2.5% the characteristic peaks of hexagonal β-AgI remain unaffected but at 5% the (100) peak is shifted slightly to lower *d* spacing with a new peak (*) appearing at $d = 3.65$ Å between (101) and (002) peaks. Higher CdI_2 content effects an intensity drop in all peaks characteristic of AgI and intensity rise in the new peak up to 40%; the latter feature suggests compound formation, γ-

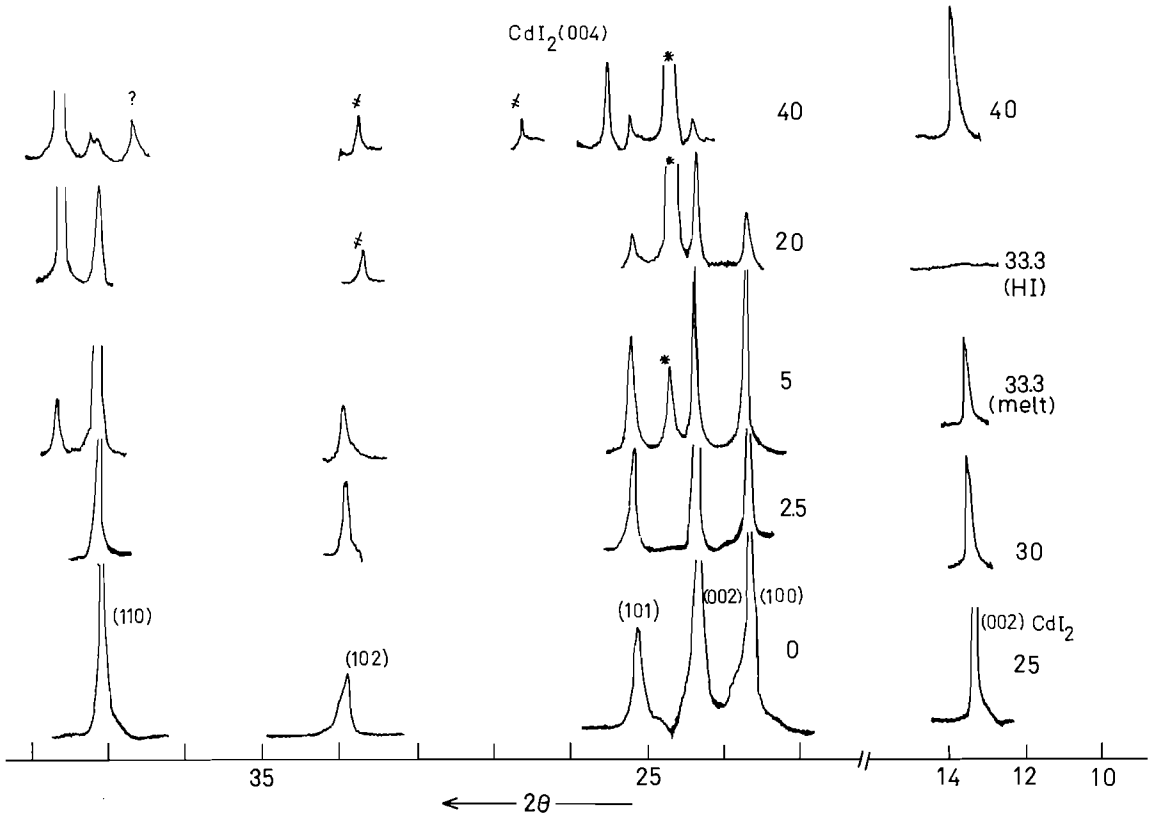

FIG. 1. X-ray diffractometry traces, peak intensity vs. 2θ, with mol% CdI_2 in AgI compositions. The peaks marked * are of possible Ag_2CdI_4 origin.

Ag_2CdI_4 (11). Our efforts to isolate and identify γ-Ag_2CdI_4 from fusion preparations were unsuccessful but γ-Ag_2CdI_4 was identified after evaporating 1:2 CdI_2–AgI in warm HI (57%) in acetic acid. Above 20% the characteristic peaks of CdI_2 intensify, e.g. $2\theta = 12.9°$.

The addition of AgI to CdI_2 effects a displacement of 12.9° peak to lower 2θ, i.e. higher *d* spacing, suggesting that AgI enters CdI_2 lattice substitutionally. Above 15% AgI no further displacement is observed while AgI peaks become evident, indicating saturation of CdI_2 plus undissolved AgI, i.e. solid solution and AgI. No evidence of γ-AgI was discernible in X-ray traces suggesting only β-AgI presence at room temperature.

DTA traces, heat and cool, of representative compositions in CdI_2 mole percentages are given in Fig. 2. The endotherm at 147 ± 1°C for pure AgI represents the β → α transition; the reverse transition reveals a slight hysteresis. However, mixed β and γ phases result on cooling AgI heated above its melting point.

CdI_2 in AgI over 5% increases the number of thermal effects; the doublet on cooling 2.5% does not reappear at higher CdI_2 compositions. The prominent endotherm at 105°C for 10% is assigned to solid–solid transition of the compound $(AgI)_{0.9}$-$(CdI_2)_{0.1}$ or $CdI_2 \cdot 9AgI$ and the broad endotherm at 150–165°C results from the overlapping of a peritectoid yielding Ag_2CdI_4 and β → α AgI transition; the clearly resolved doublet on cooling is consistent with the latter assignment. Above 10%, e.g. 30% the additional endotherm at 135°C is assigned to solid solution or disordering process of the compound in excess CdI_2 which is not reversible. The broad endotherm 225–255°C represents the slow dissolution of Ag_2CdI_4 by AgI; on cooling, the elimination or segregation gives an exotherm at 235°C with subsequent partial recombination to $(AgI)_{0.9}(CdI_2)_{0.1}$ and α → β AgI transition.

Replicate DTA traces on the same sample, heat and cool, reduce the number of thermal effects observed. Since no mass change is observed by TGA to 260°C we conclude that the sample state is determined by kinetic factors.

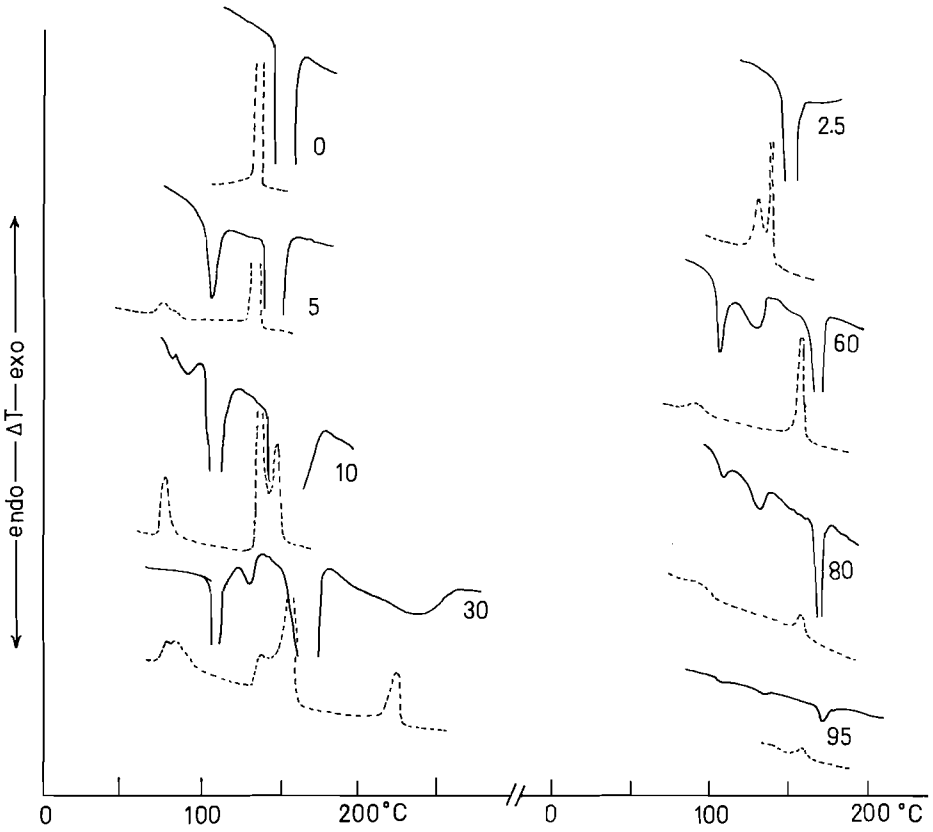

FIG. 2. DTA traces with mol% CdI_2 in AgI compositions with (full line) heat mode and (broken line) cool mode.

Alternate current electrical conductivity measurements at 1 kHz were carried out and cooling plots of representative compositions are presented in Figs. 3 and 4. Although reproducible plots, heat and cool modes, were obtained, heating plots showed non-reversible minor kinks in the unannealed disc.

Pure AgI shows a sharp break at 146°C, $\beta \rightleftarrows \alpha$ transition. 2.5% CdI_2 in AgI effects a higher relative conductivity above 50°C with the break at 125°C and the conductivity remains constant to 230°C. No physical defect in the compressed disc, such as cracking, etc., was observed after the heat–cool cycle. Our results are consistent with the conductivity results of Weiss *et al.* (12) who reported measurements on AgI below 2% CdI_2 and below 140°C. The shape and trend of the $\log\sigma - 1/T$ dependence with CdI_2 are shown by the 5, 50, and 70% plots. The breaks in the plots are consistent with the DTA thermal effects.

The presence of 5% AgI in CdI_2 (95%) has altered significantly the σ–T behavior of CdI_2 presented in Fig. 4.

The physico-chemical property measurements reported herein show a high degree of internal consistency. The AgI lattice can accommodate up to 2.5 mol% CdI_2 substitutionally where CdI_2 enters the α-AgI preferentially lowering the $\beta \rightarrow \alpha$ transition temperature. From the shift to lower d spacing for (100) planes it may be inferred that Cd^{2+} ions and Ag^+ vacancies are on lattice sites affecting (100) planes. This fact suggests that the (100) planes are critically linked to the $\beta \rightarrow \alpha$ transition energy barrier. Higher CdI_2 in AgI compositions result in compound formation and subsequent secondary effects.

The relatively constant E_a values, viz. 0.79 ± 0.07 eV, in the four samples cited, β-AgI, CdI_2, 2.5% CdI_2, 95% CdI_2, suggest a common mode of conductivity bearing in mind that conductivity for a specific charge carrier is a product of its concentration and mobility; our E_a value is consistent with the reported value of 15.4 kcal for KI in AgI (12). The higher conductivity of 2.5% CdI_2 and 5% AgI samples relative to the pure components suggest the presence of Ag^+ vacancies and I^- vacancies,

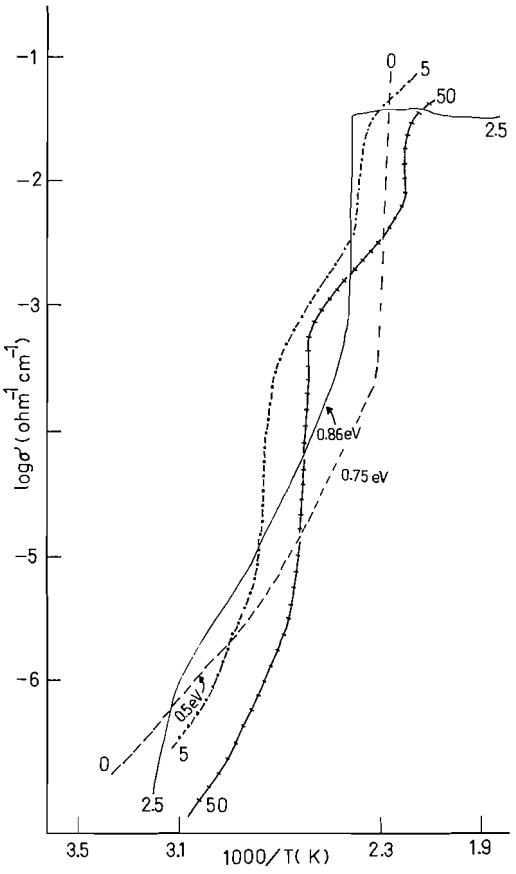

FIG. 3. Logarithm σ versus $1/T$ (K) plots of AgI-rich samples.

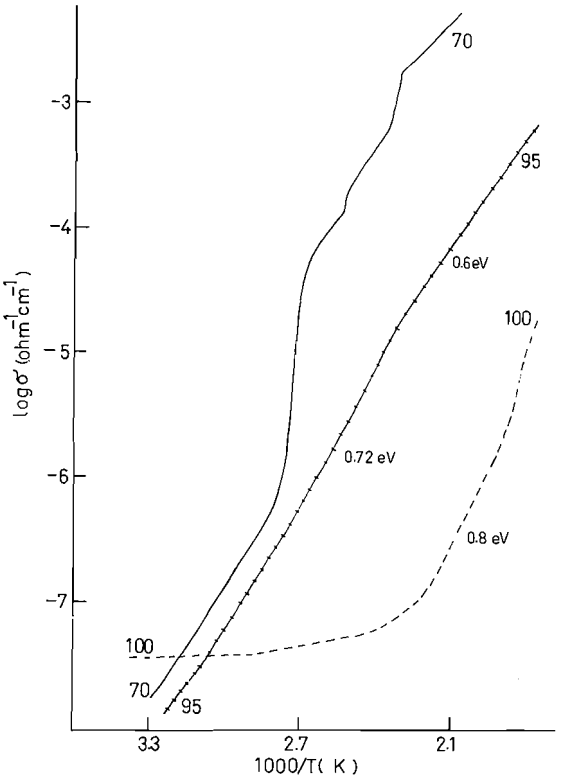

FIG. 4. Logarithm σ versus $1/T$ (K) plots of CdI_2-rich samples.

respectively, in accordance with the electroneutrality requirement.

The temperature-independent conductivity of 2.5% CdI_2 in α-AgI in the 135–230°C region resembles a fast ionic conductor. The presence of Ag^+ vacancies and Cd^{2+} in the sublattice is expected to favor the onset of high ionic conductivity of α-AgI at a lower transition temperature as observed. The jump-diffusion model for high ionic conductivity in α-AgI is consistent with our results. However, the Ag^+ vacancies and Cd^{2+} in the lattice rupture the normal periodicity for the jump-diffusion conductivity mechanism thus imposing a restriction on its simple periodic nature. In other words, the presence of Cd^{2+} in the Ag sublattice has placed a limit on the minimum energy path for Ag^+ motion along a ⟨100⟩ tunnel as proposed by Flygare and Huggins (13).

Gas phase basicities of fluorocarbonyl compounds. An ion cyclotron resonance investigation of the effects of fluorine and trifluoromethyl substituents on hydroxy carbonium ion stabilities

C. E. DOIRON AND T. B. MCMAHON

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3

Received February 23, 1981

C. E. DOIRON and T. B. MCMAHON. Can. J. Chem. **59**, 2689 (1981).

Gas phase proton affinities for a number of fluoro- and trifluoromethyl-substituted carbonyl compounds have been obtained using a combination of proton transfer equilibria and bracketing experiments. Absolute and relative substituent effects for F and CF_3 on carbonyl basicities are determined and discussed in terms of inductive, resonance, polarization, and hydrogen bonding interactions. The data are used to interpolate basicities for HCOF and CF_3CHO and are compared to theoretical *ab initio* calculations.

C. E. DOIRON et T. B. MCMAHON. Can. J. Chem. **59**, 2689 (1981).

On a obtenu les affinités pour le proton en phase gazeuse d'une série de composés carbonylés portant un fluor ou un groupement trifluorométhyle, en utilisant les équilibres de transfert de proton combinés à des expériences d'encadrement. On a déterminé les effets de substituants absolus et relatifs du F et du CF_3 sur la basicité du carbonyle et on en discute en fonction des interactions inductives, de résonance, de polarisation et de liaisons hydrogènes. On a utilisé les données pour interpoler les basicités du HCOF et du CF_3CHO et on les a comparées aux calculs *ab initio* théoriques.

[Traduit par le journal]

Introduction

Fluorine and trifluoromethyl substituents have been abundantly demonstrated to be capable of dramatically altering the stabilities of ionic species in both gas and solution phases (1–6). In the gas phase, the true intrinsic substituent effect is revealed since the ion is unencumbered by complicated solvation and ion-pair interactions (7, 8). For example, fluorine substituents are generally presumed, on the basis of solution behaviour, to destabilize positive charge centers via a strong inductive electron withdrawal brought about by the high electronegativity of fluorine (1, 2). However, recent gas phase experiments (4) and theoretical studies (9, 10) have shown that, in fact, fluorine-substituted α to carbonium ion centers gives a net stabilization interaction relative to hydrogen. This is shown to arise from the participation of fluorine 2*p* electrons in back bonding to the vacant *p* lobe of the carbonium ion center which counteracts the σ electron withdrawal (4, 9, 10). In cases where fluorine is substituted in positions other than α to a charge center, only the expected inductive destabilizing effect is observed (11).

Initial *ab initio* calculations by Csizmadia *et al.* (12) appeared to show that fluorine substituents in hydroxy methyl carbonium ions also played a stabilizing role. Their calculations revealed a greater proton affinity for formylfluoride than formaldehyde by a surprising 16 kcal/mol, roughly equal to the stabilizing effect of a methyl group (13).

A subsequent ion cyclotron resonance investigation by us (14) was in substantial disagreement with the theoretical result. Experimentally it was found that the gas phase proton affinity of acetyl fluoride was approximately 8 kcal/mol lower than that of acetaldehyde, indicating a substantial destabilization by fluorine in hydroxy carbonium ions.

More recent, *ab initio* calculations by del Bene and co-workers (15, 17) have shown a strong basis set dependence on the calculated relative basicities of formaldehyde and formyl fluoride. Using an STO-3G basis set formyl fluoride is found to have a proton affinity only 0.8 kcal/mol *lower* than that of formaldehyde (16). However, with the extended 4-31G basis set, a proton affinity difference of 20 kcal/mol was found (16). This is in general agreement with the known tendency of STO-3G calculations to overestimate π back donation (18). An analogous STO-3G study of carbonyl fluoride revealed a 6.4 kcal/mol destabilization relative to formaldehyde. No 4-31G calculation was done in this case (17).

The effects of trifluoromethyl substituents on amine and alcohol basicities have been previously investigated experimentally in the gas phase (19). The CF_3 substituent effect has been shown to be separable into contributions from inductively destabilizing and through space-polarization stabilizing interactions (19), with the destabilizing component dominating in protonated alcohols and amines. A recent *ab initio* investigation has similarly shown a strong destabilizing effect of CF_3 substituents on carbonium ion centers with $CF_3CH_2^+$ predicted to

be destabilized by 37 kcal/mol relative to CH_3^+ (18).

In order to clarify and quantify the dual role of both fluorine and trifluoromethyl substituents on carbonium ion centers, we have undertaken the present investigation of gas phase basicities of carbonyl fluoride, trifluoroacetyl fluoride, hexafluoroacetone, 1,1,1-trifluoroacetone, and acetyl fluoride. By comparison of the basicities of fluorinated and non-fluorinated analogues, it is hoped that a resolution of fluorine- and trifluoromethyl-substituent effects into contributions from inductive, resonance, polarization, and hydrogen bonding interactions may be obtained.

Experimental

All experiments were conducted at ambient temperature (20°C) using an ICR spectrometer of basic Varian V-5900 design extensively modified to permit trapped-ion experiments according to the method of McMahon and Beauchamp (20). Details of the design and operation of the trapped-ion ICR technique and conventional ICR single and double resonance experiments have been described in detail previously (21, 22).

All compounds used were commercially available chemicals of the highest purity obtainable. Carbonyl fluoride, trifluoroacetyl fluoride, and acetyl fluoride were obtained from PCR Inc. Hexafluoroacetone and 1,1,1-trifluoroacetone were purchased from ICN Pharmaceuticals Inc.

A typical relative proton affinity determination involved preparation of a mixture of bases of accurately known partial pressures using a Validyne AP-10 absolute pressure gauge attached to a monel vacuum line. This mixture was leaked into the ICR cell region via a high vacuum leak valve. In cases in which no hydrogens were present in either base, methane was also added to generate CH_5^+ to act as a protonation reagent (23). Usually three mixtures of ratios varying by a factor of 10 were examined to make a single relative proton affinity determination.

Equilibrium constants for each proton transfer reaction were calculated from the constant steady state ratio of ionic intensities and the known neutral pressure ratio. A typical example is that shown in Fig. 1 for the proton transfer equilibrium involving CF_2O and CF_3CFO, reaction [1].

[1] $CF_3CFOH^+ + CF_2O \rightleftharpoons CF_2OH^+ + CF_3CFO$

The ΔG^0 values calculated from the equilibrium constants determined were then converted to approximate ΔH^0 values by estimating the entropy changes for each of the proton transfer reactions based solely on changes in rotational entropies due to symmetry changes (24).

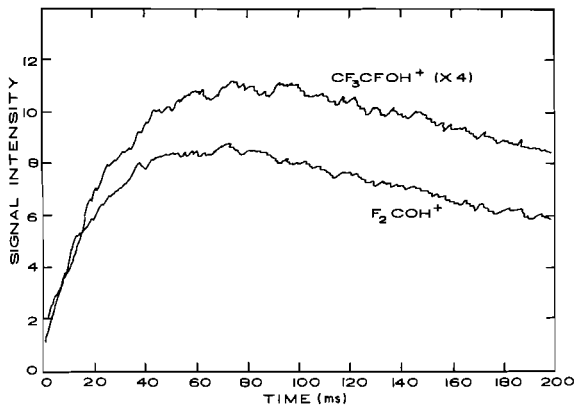

FIG. 1. Variation of relative abundances of F_2COH^+ and CF_3CFOH^+ with time in the CH_4 chemical ionization of a 4:1 mixture of F_2CO:CF_3CFO following a 5 ms, 70 eV electron beam pulse. Methane pressure is 2×10^{-7} Torr and carbonyl mixture pressure is 1.6×10^{-6} Torr. Only the protonated bases are shown.

Results

The equilibrium constants obtained for all proton transfer equilibria examined are summarized in Table 1, together with the ΔG^0 values derived from them, the estimated ΔS^0 values and the resulting ΔH^0 values. The relative proton affinities thus obtained may be placed on an approximate absolute proton affinity scale by a combination of appropriate double resonance experiments with reference bases of accurately known basicity in the gas phase.

The proton affinity of ethylene has recently been redetermined to be 163 ± 2 kcal/mol by two independent investigations (25, 26). Using photoionization and photoion-photoelectron coincidence (PIPECO) experiments, Baer has accurately identified the threshold for production of $C_2H_5^+$ from

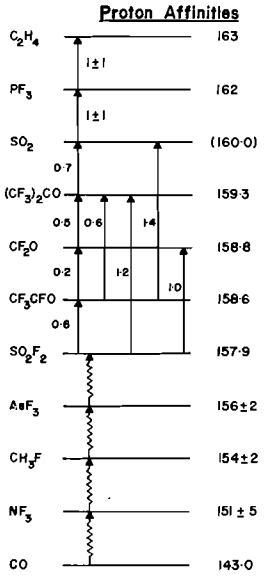

FIG. 2. Proton affinities for fluoro- and trifluoromethyl-substituted carbonyl compounds and various reference bases. A wavy arrow indicates the exothermic direction of proton transfer was identified by double resonance experiment. Numbers beside straight arrows are values of ΔH_{rxn}^0 taken from Table 1 or the text.

C_2H_5I while simultaneously measuring the kinetic energy release, reaction [2] (25).

[2] $C_2H_5I \xrightarrow{h\nu} C_2H_5^+ + I$

This measurement allows a calculation of 215.3 ± 1 kcal/mol for $\Delta H_f^0(298)$ for $C_2H_5^+$ using the known $\Delta H_f^0(298)$ for C_2H_5I and I (27). From the values of $\Delta H_f^0(298)$ for C_2H_4 and H^+ (28) a proton affinity for ethylene of 164.4 ± 1 kcal/mol may be calculated.

This value for the proton affinity of ethylene is in excellent agreement with another that may be derived from a combination of equilibrium experiments (26, 29). Bohme has recently determined the proton affinity of ethane to be 142.1 ± 1.4 kcal/mol from the measurement of the equilibrium constant for reaction [3] (26).

[3] $N_2OH^+ + C_2H_6 \rightleftharpoons C_2H_7^+ + N_2O$

The value of ΔH_f^0 (298) for $C_2H_7^+$ derived from this experiment may be combined with the value of ΔH^0 of −11.8 ± 0.5 kcal/mol determined by Kebarle for reaction [4] (29) to yield a value of $\Delta H_f^0(298)$ for $C_2H_5^+$ of 216.7 ± 2 kcal/mol. This allows a calculation of the proton affinity of ethylene of 163 ± 2 kcal/mol. Since Baer's determination lies within these error limits, we have chosen the reference standard for our absolute proton affinity scale as C_2H_4 with a value of 163 ± 2 kcal/mol.

[4] $C_2H_5^+ + H_2 \rightleftharpoons C_2H_7^+$

Double resonance experiments have shown that the proton affinity of PF_3 is less than that of C_2H_4, but at the same time sufficiently close to it to give an endothermic double resonance response for reaction [5] (23).

[5] $C_2H_5^+ + PF_3 \rightarrow HPF_3^+ + C_2H_4$

Equilibrium could not be established due to the reactivity of $C_2H_5^+$ with C_2H_4 (30).

[6] $HPF_3^+ + SO_2 \rightarrow SO_2H^+ + PF_3$

Similarly, reaction [6] was found to be endothermic to a sufficiently small extent to observe a positive double resonance signal. We have thus arbitrarily assigned a value for the proton affinity of SO_2 as 160 kcal/mol relative to an ethylene value of 163 kcal/mol. This proton affinity for SO_2 is consistent with a prediction by Munson based on a correlation of valence ionization potentials and proton affinities for oxygen-containing species (31).

The fluorocarbonyl compound proton affinities may all be related to that of SO_2 via the equilibrium data summarized in Table 1. The proton affinity scale thus derived from these compounds is given in Fig. 2. It is of interest to note that the value of 159 kcal/mol derived for the proton affinity of hexafluoroacetone is in excellent agreement with predictions based on empirical correlations of fluorinated acetone proton affinities with both the number of fluorine substituents and with vertical ionization potentials of the fluorinated acetones (32).[1]

At the lower end of the proton affinity scale given in Fig. 2, the fluorocarbonyl compounds may be seen to be more basic than AsF_3 with a proton affinity of 156 ± 2 kcal/mol (33).

The basicities of acetyl fluoride and 1,1,1-trifluoroacetone have been previously determined by us (14, 32). Acetyl fluoride may be assigned a proton affinity of 178 ± 2 kcal/mol based on the exothermicity of reactions [7] and [8].

[7] $H_3S^+ + CH_3CFO \rightarrow CH_3CFOH^+ + H_2S$

[8] $CH_3CFOH^+ + HCO_2H \rightarrow HCO_2H_2^+ + CH_3CFO$

As discussed previously, no equilibrium involving CH_3CFO could be obtained due to competing reaction channels. The proton affinity of 1,1,1-trifluoroacetone has been established as 178 kcal/mol based on a value of ΔH^0 of −0.6 ± 0.2 kcal/mol

[1]Reference data are taken to be those of ref. 13 with a $PA(NH_3)$ of 202.3 kcal mol^{-1}.

determined for the equilibrium in reaction [9] (32).

[9] $(CF_3COCH_3)H^+ + CH_2(CN)_2 \rightleftharpoons CH_2(CN)_2H^+ + CF_3COCH_3$

Discussion

It is of interest to examine the results obtained for the basicities of fluorocarbonyl compounds both in terms of absolute magnitudes of the fluorine and trifluoromethyl substituents effects, and in terms of the relative magnitudes of the two group effects.

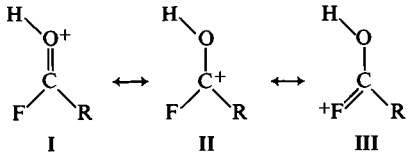
From the results above and those in Table 1, it may be seen that replacement of hydrogen by fluorine at a carbonyl carbon results in a lowering of the carbonyl oxygen basicity of roughly 8 kcal/mol. This may be inferred from the 8 kcal/mol difference in basicity between CH_3CFO and CH_3CHO and from the 16 kcal/mol difference in basicity between F_2CO and H_2CO. This order of substituent effect for fluorine at carbonyl carbon is supported by observations by Taft, who reports a difference of 8.5 kcal/mol between the basicities of $FCO_2C_2H_5$ and $HCO_2C_2H_5$ (34). This magnitude for the fluorine substituent effect allows a prediction of 167 kcal/mol for the proton affinity of formyl fluoride which disagrees with predictions using both the STO-3G and 4-31G basis sets. Thus, the STO-3G basis set appears to overestimate the importance of π back donation from fluorine to the hydroxy carbonium ion center, while the 4-31G basis set must underestimate this contribution.

A comparison of the basicities of acetaldehyde and 1,1,1-trifluoroacetone reveals a difference of 8 $\pm$ 2 kcal/mol in the substitution of a CF_3 group for hydrogen at carbonyl carbon. Alternatively, comparison of 1,1,1-trifluoroacetone with acetone shows a reduction of 17 kcal/mol in proton affinity by substitution of CF_3 for CH_3. These relative data can thus be used to predict a value of the proton affinity of trifluoroacetaldehyde (CF_3CHO) of either 8 kcal/mol less than formaldehyde (167 kcal/mol), or 17 kcal/mol less than acetaldehyde (169 kcal/mol). Thus, the proton affinity of CF_3CHO is expected to be 168 $\pm$ 2 kcal/mol. Similarly, the difference in proton affinity between $(CF_3)_2CO$ and $(CH_3)_2CO$ (36 kcal/mol) is seen to be roughly twice that between CH_3COCF_3 and $(CH_3)_2CO$. In addition, the difference between the basicity of $(CF_3)_2CO$ and the predicted basicity of CF_3CHO is equal to the predicted difference between CF_3CHO and CH_2O.

These comparisons above reveal a remarkable similarity in the effects of F and CF_3 substituents on carbonyl basicities. It may be seen that within the experimental uncertainties, the proton affinities of CH_3CFO and CH_3COCF_3 are equal. The equilibrium experiments carried out in the present study also unambiguously show nearly identical basicities for the disubstituted carbonyls F_2CO, CF_3CFO, and $(CF_3)_2CO$. In addition, as a consequence of these similarities, the basicities of the elusive compounds HCOF and CF_3CHO are predicted to be nearly equal. This rather surprising similarity is not expected from the known substituent behaviour of fluorine and trifluoromethyl groups in solution studies of ionic species. For example, the substituent constant scale developed for electrophilic species by Brown and Okamoto gives a σ^+ value for *m*-CF_3 of 0.52 while that for *m*-F is only 0.35 (35). Thus in solution CF_3, substituents are expected to inductively destabilize positive charge centers more than F. Similarly, the Hammet σ scale gives values of 0.43 and 0.34 for *m*-CF_3 and *m*-F respectively (35). The greater electron-withdrawing effect of CF_3 relative to F is also borne out in both solution and gas phase studies of anionic species. For example, the pK_a's of *meta*- and *para*-substituted benzoic acids and phenols are lower for CF_3 substituents than for F substituents (35). In addition, gas phase acidity data have also shown that *meta*- and *para*-CF_3-substituted phenols are 5 and 9 kcal/mol more acidic than the corresponding F-substituted phenols (36). Obviously then, in the gas phase cationic species investigated in the present work, substituent effects either not present or not important in solution cationic species or gas phase anionic species must be considered to explain the similarity of CF_3 and F effects on carbonyl basicities.

Four distinct types of effect may be identified to operate in the protonated fluorocarbonyl species. The first of these is the normal electron-withdrawing inductive effect which removes electron density from the cationic center through the σ framework, destabilizing the ion. On the basis of the evidence discussed above it is to be expected that CF_3 substituents will exert the greater σ electron-withdrawing effect and inductively destabilize the protonated carbonyl group to a greater extent.

As discussed in the Introduction, in compounds in which fluorine is substituted directly at the carbonyl carbon, a resonance stabilization of the positively charged carbonium ion center may occur via a π interaction between the fluorine 2*p* orbital and the vacant 2*p* lobe on the carbonium ion center typified by the valence bond structures **I–III**. No similar resonance stabilization of CF_3-substituted carbonyls is possible.



I II III

Both of the above types of interaction should contribute to an enhanced basicity of fluorine-substituted carbonyls relative to the analogous trifluoromethyl-substituted compounds. Since it is experimentally observed that both groups of carbonyls have nearly equal proton affinities, there must be one or more interactions giving rise to a preferential stabilization of the CF_3 substituted systems. One such interaction which immediately suggests itself is a through-space polarization interaction between the substituent and the charge center. This type of stabilization, originally suggested by Braumann (37), depends upon the group polarizability of the substituent and the distance between the substituent and the charge center. The polarizability of the CF_3 group may be estimated to be 2.12 Å^3 while that for a fluorine atom roughly is 0.45 Å^3 compared to a hydrogen atom polarizability of 0.40 Å^3 (38). In charge-delocalized systems such as the protonated carbonyl bases, there is no single site which may be identified as the charge center, although Mulliken population analyses from *ab initio* calculations indicate significant positive charge should reside on the hydrogen (12, 15–17). If such is the case, the distance between hydrogen and substituent would be less for CF_3 than F. These two factors would thus combine to give a significantly greater stabilization for the CF_3-substituted carbonyl via a through-space polarization interaction.

A further interaction likely giving rise to preferential stabilization of protonated CF_3-substituted carbonyls is intramolecular hydrogen bonding. Del Bene has shown that the *cis* form of protonated formylfluoride, **IV**, is more stable than the *trans* form, **V**, by roughly 2.5 kcal/mol (15, 16) due to the formation of a weak intramolecular hydrogen bond. In protonated CF_3 substituted carbonyls intramolecular hydrogen bond formation between the methyl fluorine and hydrogen should be even more facile since the geometry of these species brings the substituent fluorine very close to hydrogen, as in **VI**. This situation is very similar to that found in β-fluoroalcohols and amines where relatively strong intramolecular hydrogen bonds are found (39, 40). In this case, the hydrogen bond interaction should be significantly stronger due to the increased positive charge on the hydrogen and, in addition, should be substantially greater than that found in fluoro-substituted carbonyls.
