( )Variation in multiplicity within a row.

to cammaconine. This alkaloid (4, 5) was oxidized by permanganate to oxocammaconine (**3**). The latter was converted to a mixture of oxocammaconic acid **5** and the corresponding 14-keto acid **6** by more vigorous permanganate oxidation. Jones' reagent in acetone completed the oxidation to 14-dehydrooxocammaconic acid **6**. This decarboxylated smoothly above 210°C to give 14-dehydroaconosine (**7**). Sodium borohydride reduction of **7** gave, with the usual high stereospecificity in the reduction of the 14-carbonyl (5), oxoaconosine **8**. Finally, lithium aluminum hydride reduced the lactam carbonyl, giving **1**.

Since cammaconine has been related to talatisamine (**2***b*) (6, 7), which has been synthesized (8), this leaves no ambiguity about the structure and stereochemistry of **1**. Its melting point, rotation, and spectra (in as far as they have been reported) agree with those of aconosine.

The natural occurrence of aconosine suggests that a carbinolamine such as **9** is involved in its biosynthesis. As in lycoctonine chemistry (2, 3), **9** could lose the hydroxymethyl group in a retro-aldol reaction (via the immonium salt **10**). This implies that a biochemical mechanism exists for the reduction of the resulting carbinolamine **11** to aconosine. The problem of highly strained intermediates with bridgehead double bonds in decarboxylation of acids such as **6** and in the retro-aldol reaction has been discussed elsewhere (3, 9). For very recent work on anti-Bredt olefins see ref. 10.

Contrary to the opinion of Pelletier *et al.* (11), we consider that oxygenation of the diterpenes in vivo proceeds from a methyl group on C-4 (e.g. sachaconitine, delpheline, and deltaline) to a hydroxymethyl group (e.g. cammaconine, lycoctonine) to carbinolamines such as **9**, then to the des(oxymethylene) type (aconosine).

The mass spectra criterion, on which basis the 1β-configuration was assigned to aconosine (1), is not reliable (12), hence the mass spectrum does not conflict with structure **1** for the alkaloid.

The ^{13}C nmr assignments in Table 1 are based on predicted chemical shifts, multiplicities determined using off-resonance decoupling, correlation with values for related molecules from our own laboratory, and the extensive correlations by Jones and Benn, and Pelletier and co-workers (13).

Experimental

Preparative chromatography was on 20 × 20 cm 1000 μ silica gel plates with fluorescent indicator. Iodine vapor could also be used to detect both bases and lactams. All ^1H nmr and ^{13}C nmr spectra were for solutions in deuteriochloroform unless otherwise noted, and were obtained on a Varian EM-360 or a Bruker WP-80 spectrometer operating at 20.15 MHz in the Fourier transform mode using 16K data points and a pulse flip angle of 35°. Off-resonance decoupling used ^1H irradiation at ca. 6 ppm upfield from TMS and power of 2 watts. Infrared spectra were of methylene chloride solutions and rotations were taken in chloroform unless otherwise noted.

Oxocammaconine (3)

A solution of 304 mg of cammaconine in 15 mL of acetone and 10 mL of water was stirred in a bath held at 15°C. During 5 min a solution of 300 mg of potassium permanganate in 20 mL of 50% acetone–water (V/V) was added to this. The permanganate was reduced rapidly. The suspension was filtered through Celite, then the filtrate reduced to a volume of 10 mL on a rotating evaporator. The solution was acidified using dilute sulfuric acid, then the neutral and acidic products extracted into chloroform. An aqueous sodium carbonate wash removed the acids, leaving a solution of 195 mg of neutral product. From the aqueous layers 11 mg of acids and 62 mg of base were recovered. The neutral product crystallized from acetone–hexane. After recrystallization from the same solvent it had mp 193–195°C and ν_{max} 3500 and 1610 cm^{-1}. It had R_f 0.45 on silica gel plates with 10% methanol in chloroform for development. It had

^{1}H nmr signals at δ 1.18 (3H, t, J = 7 Hz), 3.30 (3H, s), and 3.42 (3H, s). *Anal.* calcd. for $C_{23}H_{35}NO_6$: C 65.53, H 8.37; found: C 65.26, H 8.35.

Permanganate oxidation of oxocammaconine (3)

A solution of 134 mg of oxocammaconine (**7**) was prepared in 15 mL of acetone, 1.2 mL of water, and 0.3 mL of acetic acid. To the vigorously stirred solution at 50°C was added 10 mg of manganese dioxide and 104 mg of potassium permanganate. After 5 h heating a further 200 mg of the permanganate was added. Most of the permanganate had been reduced after 16 h at 50°C. A final 52 mg of permanganate was added and heating continued for 7 h. Excess reagent was destroyed using aqueous sodium hydrogen sulfite, then the manganese dioxide removed by filtration through Celite. The solid was washed with acetone and dichloromethane. The filtrates were evaporated to dryness, then the residue distributed between dichloromethane and 5% sodium carbonate solution. The organic layer yielded 25 mg of crude 14-dehydrooxocammaconine (**4**) while the carbonate solution yielded 103 mg of acids, mainly oxocammaconic (**5**) and 14-dehydrooxocammaconic acids (**6**).

14-Dehydrooxocammaconic acid 6

The mixture of acids from permanganate oxidation of oxocammaconine (370 mg) was dissolved in 20 mL of acetone, then Jones' reagent (14) diluted with acetone was added with stirring until an excess persisted for 10 min. Excess reagent was destroyed with methanol, the solids removed by decantation and filtration, then the solvent evaporated. The residue yielded 361 mg of acids which crystallized from aqueous acetone giving 176 mg (36% from oxocammaconine) of 14-dehydrooxocammaconic acid (**6**). This had mp ca. 210°C dec.; ν_{max}: 3580, 3460, 1750, and 1595 cm^{-1}; and $[\alpha]_D$ 16° (c 0.51). Its ^{1}H nmr spectrum gave signals at δ 3.34 (3H, s), 3.33 (3H, s), and 1.28 (t, J = 7 Hz). *Anal.* calcd. for $C_{23}H_{31}NO_7$: C 63.72, H 7.21, N 3.23; found: C 63.49, H 7.45, N 3.10.

Oxidation of oxocammaconine with Jones' reagent gave **6** directly, but in poorer yield.

14-Dehydrooxoaconosine 7

14-Dehydrooxocamaconic acid (**6**, 176 mg), in a glass bulb with a long outlet tube, was decarboxylated by immersion in a bath at 220–230°C under 15 Torr for 10 min. The cooled residue was dissolved in dichloromethane (20 mL). This solution was washed with 5% sodium carbonate solution, which removed a trace of acid. The organic layers yielded 155 mg of quite pure 14-dehydrooxoaconosine which crystallized from acetone–hexane, mp 202–203°C. It had ν_{max}: 3580, 3480, 1750, and 1670 cm^{-1} and $[\alpha]_D$ −44.5° (c 0.53). Its ^{1}H nmr spectrum had signals at δ 3.34 (3H, s), 3.30 (3H, s), and 1.21 (3H, t, J = 7 Hz). *Anal.* calcd. for $C_{22}H_{31}NO_5$: C 67.84, H 8.02, N 3.60; found: C 67.80, H 8.16, N 3.53.

Oxoaconosine 8

To a solution of 216 mg of 14-dehydrooxoaconosine (**7**), in 12 mL of methanol, 230 mg of sodium borohydride was added portionwise over 5 min. The mixture was left for 15 min, then concentrated under reduced pressure. The residue was distributed between water and dichloromethane. The organic layers gave 204 mg of crude product which crystallized from acetone–hexane giving 183 mg (84%) of oxoaconosine (**8**). This had mp 208–210°C; ν_{max}: 3530, 3410, and 1630 cm^{-1}; and $[\alpha]_D$ −4.6 (c 0.69). Its ^{1}H nmr spectrum had signals at δ 4.93 (1H, d, J = 4.5 Hz, exchangeable with D_2O), 3.68 (1H, s, exchangeable with D_2O), 3.38 (3H, s), 3.24 (3H, s), and 1.18 (3H, t, J = 7 Hz). *Anal.* calcd. for $C_{22}H_{33}NO_5$: C 67.49, H 8.50, N 3.58; found: C 67.69, H 8.62, N 3.39.

Aconosine 1

Lithium aluminum hydride (170 mg) was added to a solution of 100 mg of oxoaconosine (**8**) in 5 mL of dioxane. The mixture was refluxed for 2 h under argon. Excess reagent was destroyed by addition of methanol, then saturated sodium sulfate solution. After addition of solid anhydrous sodium sulfate, the solids were removed by filtration using a bed of Celite on sintered glass. The filter cake was washed with methanol and dichloromethane, then the filtrates concentrated to small volume. The residue was diluted with water, then acidified using 5 *N* sulfuric acid. Methylene chloride extraction removed a small amount of neutral product. The aqueous layer was made strongly alkaline (NaOH), then extracted with dichloromethane, giving 82 mg of base. This crystallized from aqueous methanol giving 68 mg (71%) of aconosine with mp 150°C (Lit. (1) mp 148°C). It had ν_{max}: 3520 and 3410 cm^{-1} and $[\alpha]_D$ −25°C (c 0.57, methanol) (Lit. (1) $[\alpha]_D$ −21°). Its ^{1}H nmr spectrum in $CDCl_3$ had signals at δ 4.56 (1H, d, J = 4 Hz, exchangeable with D_2O). 4.08 (1H, d of d, J = 4 Hz), 3.56 (1H, s, exchangeable with D_2O) 3.34 (3H, s), 3.26 (3H, s), and 1.05 (3H, t, J = 7 Hz). Its ^{1}H nmr spectrum in benzene-d_6 had signals at δ 4.56 (1H, d, J = 4 Hz, exchangeable with D_2O), 4.14 (1H, d of d, J = 4 Hz), 3.89 (1H, s, exchangeable with D_2O), 3.09 (3H, s), 2.87 (3H, s), and 1.04 (3H, t, J = 7 Hz). *Anal.* calcd. for $C_{22}H_{35}NO_4$: C 69.99, H 9.35, N 3.71; found: C 69.81, H 9.21, N 3.70. The hydriodide of aconosine crystallized as rods from methanol–acetone, mp 209°C. *Anal.* calcd. for $C_{22}H_{36}INO_4$: C 52.28, H 7.18, N 2.77; found: C 52.04, H 7.35, N 2.92. Its mass spectrum had peaks at m/e: 377 (M^+) (2%), 376 (2%), 348 (4%), 347 (26%), 346 (100%), 344 (2%), 332 (2%), 330 (3%), 328 (3%), 314 (2%), and 298 (3%).

Received October 26, 1982

CLAUDE GUIMON, GENEVIÈVE PFISTER-GUILLOUZO, and MIKAEL BEGTRUP. Can. J. Chem. **61**, 1197 (1983).

Photoelectron spectra at variable temperatures demonstrate that the rate of thermal isomerization of pyrazoline-5-thione (**1***a*) into methylthiopyrazole(s) in the gaseous phase is metal catalysed. Similar isomerizations of triazolethione (**2***a* and **3***a*) are at best only slightly so.

Furthermore, photoelectron spectra and MNDO calculations show that gaseous methylthiopyrazoles (**1***b* and **1***c*) and methylthiotriazoles (**2***b* and **2***c*) exist predominantly in planar form for the *b* isomer and in nonplanar form for the *c* isomer. The ΔH^0 for the rotameric equilibria is 2.7−4.2 kJ·mol^{-1}.

CLAUDE GUIMON, GENEVIÈVE PFISTER-GUILLOUZO et MIKAEL BEGTRUP. Can. J. Chem. **61**, 1197 (1983).

L'analyse des spectres photoélectroniques enregistrés à l'aide d'une "sonde à température variable" montre que la transformation en phase vapeur de la pyrazoline-thione-5 (**1***a*) en méthylthio-pyrazole(s) est catalysée par les parois métalliques de la sonde. Cette réaction d'isomérisation est, semble-t-il, nettement plus difficile dans le cas des triazolethiones (**2***a* et **3***a*).

D'autre part les spectres expérimentaux et les calculs théoriques réalisés à l'aide de la méthode MNDO montrent que les composés S-méthylés (**1***b*, **1***c*, **2***b* et **2***c*) existent préférentiellement sous une forme plane dans le cas des isomères *b* et une forme non plane dans celui des isomères *c* et qu'ils présentent un équilibre entre rotamères (ΔH^0 compris entre 2.7 et 4.2 kJ·mol^{-1}).

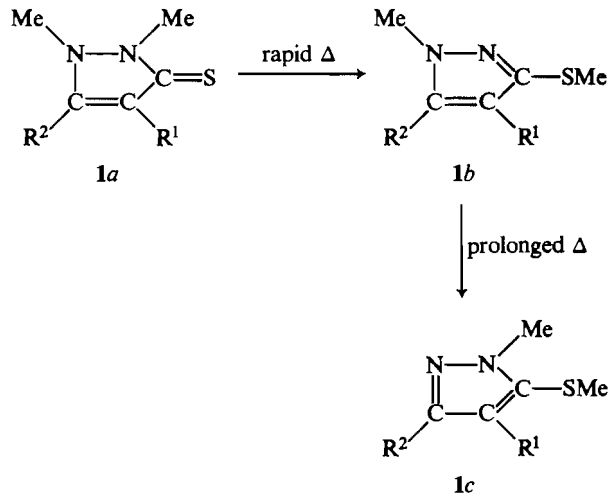
Introduction

Maquestiau *et al.* (1) recently showed that 1,2-dimethylpyrazoline-5-thione, with various substituents on the carbons (Me, ϕ) was rapidly transformed by thermal rearrangement (heating to around their melting point) into 1-methyl-3-methylthiopyrazoles and into 1-methyl-5-methylthiopyrazoles after longer periods of heating (Fig. 1).

The authors concluded from these data that form *b* is the kinetic product and that form *c* is the thermodynamic product of a reaction proceeding principally by an intermolecular mechanism.

Heating of 1,2-dimethylpyrazoline-5-thione (**1***a*, $R^1 = R^2 =$ H) suspended in benzene to 200°C for 5 h leads to its complete isomerization into a 1.04:1 mixture of 1-methyl-3-methylthiopyrazole (**1***b*) and 1-methyl-5-methylthiopyrazole (**1***c*). Similarly, 1,2-dimethyl-1,2,3-triazoline-5-thione (**2***a*) produces a 2.7:1 mixture of methylthiotriazoles (**2***b* and **2***c*) (Fig. 2) and anhydro-1,3-dimethyl-4-mercapto-1,2,3-triazolium hydroxide (**3***a*) generates a 1.6:1 mixture of methylthiotriazoles (**3***b* and **3***c*) (2) (Fig. 3). The product ratios remain unchanged by prolonging the reaction time and all single methylthio compounds are stable under the reaction conditions, indicating that the isomerizations are kinetically controlled.

In a general study of the electronic structure of thiocarbonyl compounds, we presented the photoelectron spectra of compounds **1***a*, **2***a*, and **3***a* (3). The spectrum of the first compound (**1***a*) shown here (Fig. 11-P_1) contains a minor band at around 9.15 eV. In the light of previous data, it could be due to the presence of small quantities of one or two SMe forms.



1*a* **1***b* **1***c*

FIG. 1.

Photoelectron spectroscopy has proven itself to be a good method to study equilibria in the gas phase (4). It was our desire to continue this initial work by using the variable temperature method, recently used by two of us (5). It has been previously used with success for studying conformational problems (6−10).

In order to be able to unambigously determine the existence of an equilibrium among forms *a*, *b*, and *c* in the vapor phase, however, it was necessary to record the spectra of the two SMe isomers (*b* and *c*) and to verify their structural characteristics.

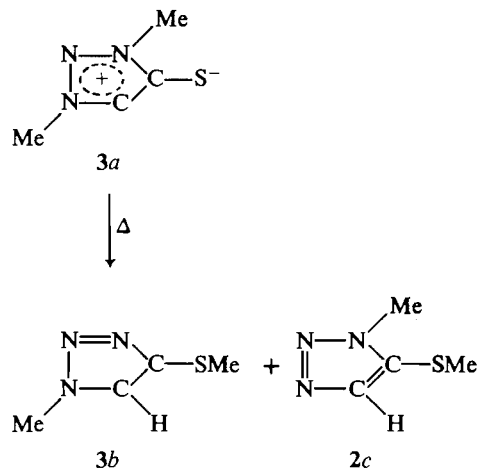

FIG. 3.

Experimental

Spectra were recorded with a Perkin–Elmer PS 18 photoelectron spectrometer with a HeI/HeII "Helectros" source. The HeI and HeII resonance lines at 21.22 eV and 40.21 eV served as the ionizing source. The spectra were calibrated with the $^2P_{1/2}$ and $^2P_{3/2}$ lines of Ar and Xe and were recorded with a resolution of 30 meV.

Results and discussion

Methylthiopyrazoles

The electronic structure of 1-methyl-3-methylthiopyrazole (**1***b*) and 1-methyl-5-methylthiopyrazole (**1***c*) derives from that of 1-methylpyrazole. According to MNDO (11) and previous *ab initio* calculations (12), the highest occupied orbitals in order of decreasing energy are π_3 and π_2, two π orbitals localized within the ring, and a σ orbital localized at N-2 (Table 1).

The introduction of a methylthio group at C-3 enables the n_S^{π} orbital to disturb the ring π-system. The π_3 orbital with a node at C-3 is hardly influenced while the π_2 orbital is disturbed to an extent depending on the angle θ between the ring plane and the C-3—S—Me plane (Fig. 4). Maximum disturbance occurs when $\theta = 0°$.

By introducing a methylthio group at C-5, the n_S^{π} orbital strongly disturbs the π_3 orbital, highly localized on C-5, while the π_2 orbital is hardly affected (Fig. 5).

The assignment of the photoelectron spectrum of 1-methyl-3-methylthiopyrazole (**1***b*) (Fig. 6) is evident from

TABLE 1. Calculated (MNDO) localization and energies of the two highest occupied MO's of 1-methylpyrazole

Localization		$-\epsilon_i$ (eV)	9.54	9.73
PI_{exp} (eV)	9.46	9.95

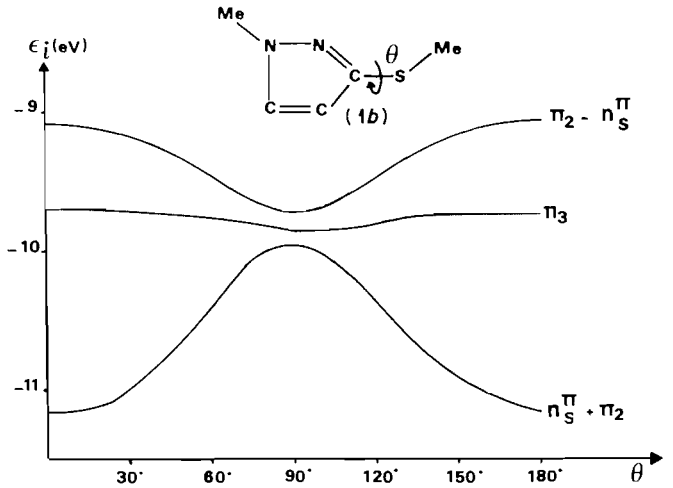

FIG. 4. Calculated (MNDO) evolution of the three π HOMO's of 1-methyl-3-methylthiopyrazole (**1***b*) as a function of the dihedral angle θ.

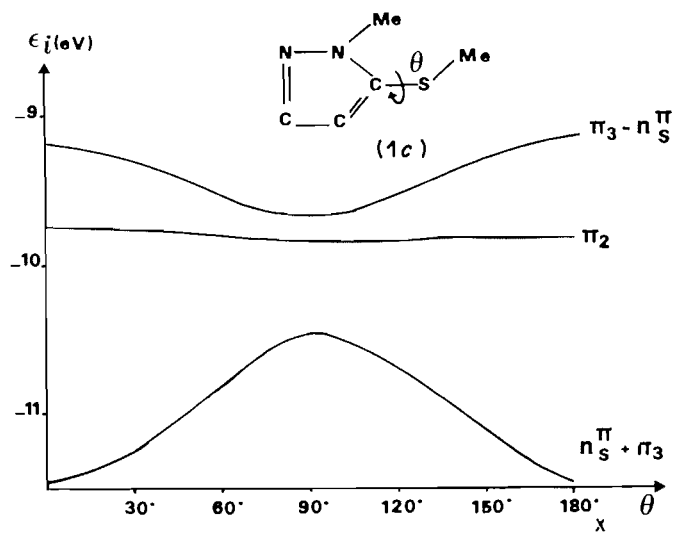

FIG. 5. Calculated (MNDO) evolution of the three π HOMO's of 1-methyl-5-methylthiopyrazole (**1***c*) as a function of the dihedral angle θ.

Table 2.The three strong and well-resolved low-energy bands are associated with the ionization of the π electrons localized within the ring. The assignment was confirmed by a spectrum recorded during HeII irradiation (40.81 eV) in which band number one, and particularly band number five, appear with reduced intensity while band number four becomes more intense. According to the empirical rules (13) successfully applied by spectrum assignment in several cases (14–18), bands number one and five would be associated with the ionization of electrons in the two orbitals highly localized on the sulfur atom,

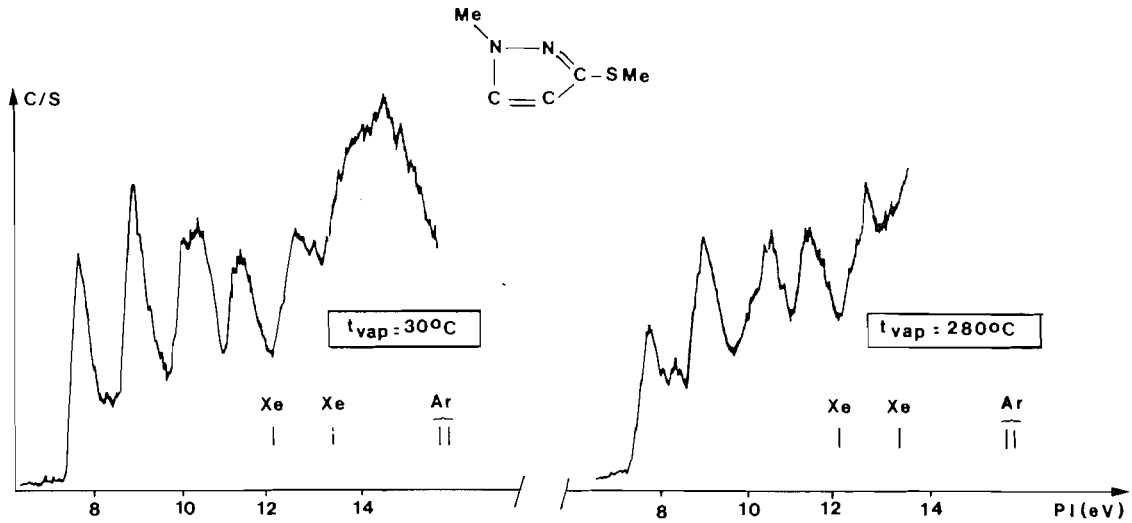

FIG. 6. Photoelectron spectra of 1-methyl-3-methylthiopyrazole (**1***b*).

[a]θ refers to the dihedral angle between the pyrazole ring plane and the C—S—Me or C—SH plane.

while band number four would be due to the ionization of electrons in an orbital localized on N-2.

A comparison between experimental and calculated ionization potentials (Table 2) indicates that 1-methyl-3-methylthiopyrazole (**1***b*) preferentially adopts a planar conformation (θ ~ 0° or 180°) in the gas phase.

This conclusion is consistent with the molecular energy calculated by the MNDO method as a function of the dihedral angle θ between the heterocycle and the S—Me fragment (this energy is minimized versus all the structural parameters). The energy minimum (Fig. 7) corresponds to an angle θ equal to 0° whereas the maximum corresponds to 180°, with a rotation barrier of 8.78 kJ·mol^{-1} (for θ = 90°, the molecular energy increases of 3.85 kJ·mol^{-1}).

In addition to the strong bands from this species, a weak band is also observed at 8.6 eV, reflecting the presence of a small quantity of a second conformer in which θ is close to 90° (Fig. 4). The proportion of the minor conformer increases with higher temperatures (Fig. 6), denoting a temperature dependent equilibrium between the two conformers in the gas phase. A calculation based on Van't Hoff's law (4) furnishes an enthalpy difference between the conformers of 4.2 kJ·mol^{-1} (Table 3). It must be emphasized that this value is approximate since its determination can lead to systematic errors as shown by Honnegger and Heilbronner (19). Nevertheless its value is consistent with the result of the MNDO calculation.

In the photoelectron spectrum of 1-methyl-5-methylthiopyrazole (**1***c*) (Fig. 8) the strong band around 9.2 eV is attributed to the ionization of electrons in the ring π orbitals and that at 10.60 eV to the ionization of n_N electrons (see Table 2). The band at 11.75 eV is unambiguously associated with the ionization of n_S^{σ} electrons, since its relative intensity decreases markedly in a spectrum recorded with HeII irradiation. The best correlation between calculated and experimental ionization potentials is obtained when θ in 1-methyl-5-methylthiopyrazole (**1***c*) is at about 90°C (see Table 2 and Fig. 5). The same MNDO calculation on this molecule indicates a stable nonplanar conformation (θ = 76.8°) and two rotation barriers (5.52 kJ·mol^{-1} for θ = 0° and 27.71 kJ·mol^{-1} for θ = 180°) (Fig. 7). A weak band at 8.3 eV whose intensity increases with increasing temperature again indicates the presence of a minor quantity of the planar conformer (θ = 0°). Calculation of the free enthalpy for the conformational equilibrium is not feasible in this case, however, due to close spacing of the bands from each conformer.

At high temperatures, the proportions of the unfavored con-

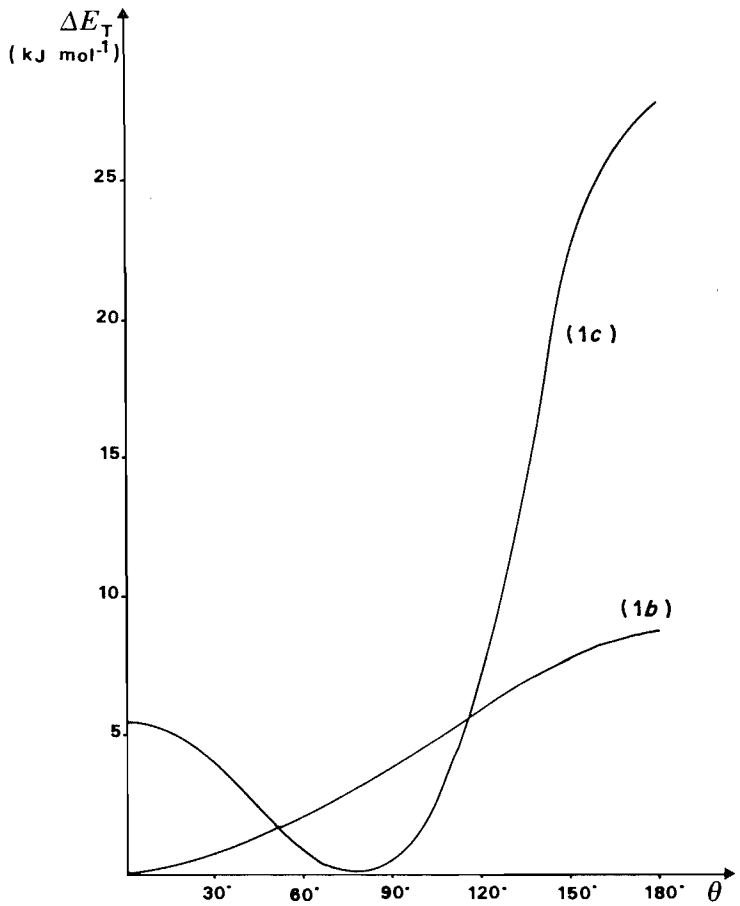

FIG. 7. Calculated (MNDO) evolution of the total energy of 1-methyl-3-methylthiopyrazole (**1***b*) and 1-methyl-5-methylthiopyrazole (**1***c*) as a function of the dihedral angle θ.

TABLE 3. Equilibrium constants K_T and differences in free enthalpy $\Delta H°$ for equilibria between planar and nonpolar conformers of methylthiopyrazoles and methylthiotriazoles

	Compounds		
Parameter	1-Methyl-3-methylthiopyrazole (**1***b*)	1-Methyl-4-methylthiotriazole (**3***b*)	1-Methyl-5-methylthiotriazole (**2***c*)
K_T[a]	0.22 (20°C) 0.42 (205°C)	0.68 (50°C) 1.02 (240°C)	4.(20°C) 2.38 (260°C)
$\Delta H°$ kJ·mol^{-1}[b]	4.2	2.9	−2.7

[a]K_T has been calculated assuming that the pair of rotamers exhibit the same cross section of ionization of the HOMO localized on the lone pair π orbital of the sulphur atom.
[b]Estimated limits of error are ±1.5 kJ·mol^{-1}.

TABLE 4. Experimental ionization potentials (eV) of methylthiotriazoles

Compounds	θ[a]	Ionization potentials (eV)					
1-Methyl-4-methylthiotriazole (**3***c*)	0°	8.33	10.	10.37	10.75	11.40	12.10
	~90°	8.75					
1-Methyl-5-methylthiotriazole (**2***c*)	0°	8.65					
	~90°	9.30	9.70	10.40	10.65	11.55	12.45

[a]Same footnote as Table 2.

formers increase. Equilibrium constants and free enthalpy differences for the conformational equilibria are given in Table 3. The parallel behavior of methylthiopyrazoles and triazoles suggests that a similar distribution of conformers is a feature of other methylthio substituted N-methylazoles.

Mercaptopyrazoles

1-Methyl-3-mercaptopyrazole (**4**) may adopt two tautomeric structures (**4***a*, *b*). In nonpolar solvents ($CDCl_3$), the SH form (**4***b*) is the sole detectable by ^1H nmr. This also obtains for other 1-substituted 3-mercaptopyrazoles (3). Comparison of the

FIG. 10.

photoelectron spectrum of 1-methyl-3-mercaptopyrazole (**4**) with the spectra of its N- and S-methyl derivatives (**1***a* and **1***b*) (Table 2) shows that only signals attributable to the SH form (**4***b*) are present. From the estimated detection limits it may be stated that the NH form (**4***a*) represents less than 5% of gaseous (**4**). Furthermore, the comparison of experimental and calculated ionization energies (Table 2) demonstrates that 1-methyl-3-mercaptopyrazole, as its S-methyl derivative (**1***b*), adopts a virtually planar conformation.

1-Methyl-5-mercaptopyrazole (**5**) may adopt three tautomeric structures (**5***a*–*c*). In nonpolar solvents, only the SH form (**5***c*) is observed by ^{1}H nmr. The addition of deuterium oxide, however, leads to the exchange of H-4 suggesting the presence of minute quantities of **5***b*. The photoelectron spectrum of **5** exhibits signals only from the SH form (**5***c*) (Table 2). Again, the NH form represents less than 5% of gaseous (**5**). The experimental ionization potentials are most consistent with those calculated for a conformer in which the angle between the ring and the C—S—H plane is close to 90°, as in the S-methyl derivative (**1***c*).

1,2-Dimethylpyrazoline-5-thione

The isomerization of 1,2-dimethylpyrazoline-5-thione (**1***a*) was studied by photoelectron spectroscopy using two probes. The first (P_1) was studied in the standard fashion (sample evaporated in ionization chamber) and the second (P_2) with the evaporation chamber separated by about 30 cm from the ionization chamber by a metallic guide in which the evaporated sample could be heated independently without affecting unvaporized material. Temperatures were measured at the two probes. The photoelectron spectra of 1,2-dimethylpyrazoline-5-thione obtained with the standard probe at a gas temperature between 100°C and 180°C corresponds to unchanged **1***a* (5) (Table 5) mixed with a minute quantity of methylthiopyrazole (**1***b*) and/or (**1***c*) giving rise to an additional weak band at 9.15 eV (Fig. 11 − P_1). The spectrum of **1***a* obtained with probe P_2 (same temperature) is devoid of pyrazolinethione bands and is similar to the spectrum of 1-methyl-3-methylthiopyrazole (**1***b*) (Fig. 6). No conclusions concerning the presence of 1-methyl-5-methylthiopyrazole (**1***c*) can be drawn, since its bands may be masked by those of the former compound (**1***b*). (In its stable conformation, **1***b* has a calculated energy 5.48 kJ·mol^{-1} lower than **1***c*). A similar spectrum is obtained by heating the gas to 360°C, the only difference being that the band at 8.7 eV, due to the nonplanar conformer of **1***b*, appears with enhanced intensity. Spectra reveal that both methylthiopyrazoles **1***b* and **1***c* are stable in the gas phase at 250°C. Hence, Fig. 11 − P_2 reflects the result of a kinetically controlled isomerization of the pyrazolinethione **1***a*.

The variable temperature experiment was terminated by recording a control spectrum of still unvaporized pyrazolinethione (**1***a*) at 80°C using probe P_1. The spectrum affirmed that the sample itself had not isomerized; neither did heating the solid sample to 160°C give rise to significant changes. Thus, isomerization of pyrazolinethione (**1***a*) into methylthiopyrazole (**1***b*) and probably **1***c* is more rapid in the gas phase than in the solid phase. Additional experiments showed that the rate of isomerization depended on dwell time in the guide rather than being a function of the temperature of the evaporated sample. This suggests a catalytic effect on isomerization brought about by contact between the metallic surfaces and the vapors.

For personal use only.

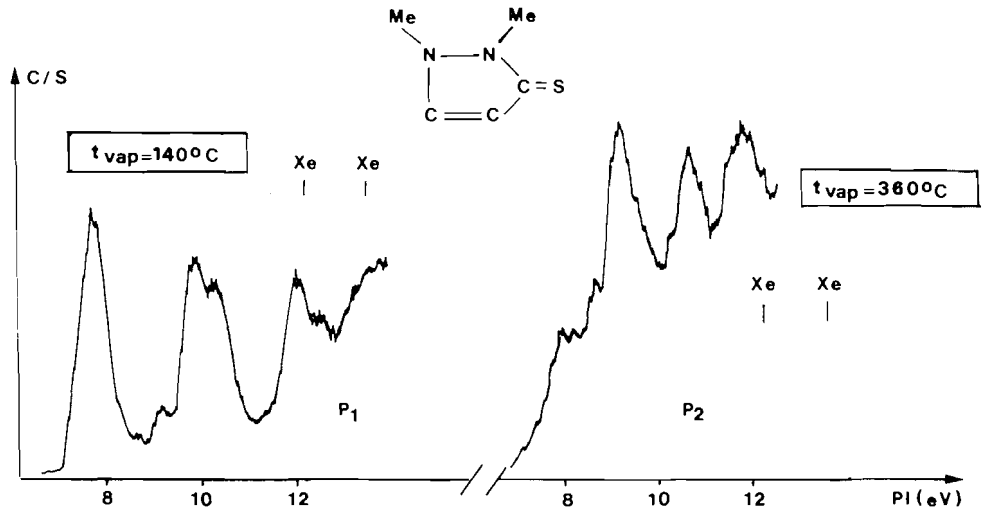

FIG. 11. Photoelectron spectra of 1,2-dimethylpyrazoline-5-thione (1*a*) using probes P_1 and P_2 (see text).

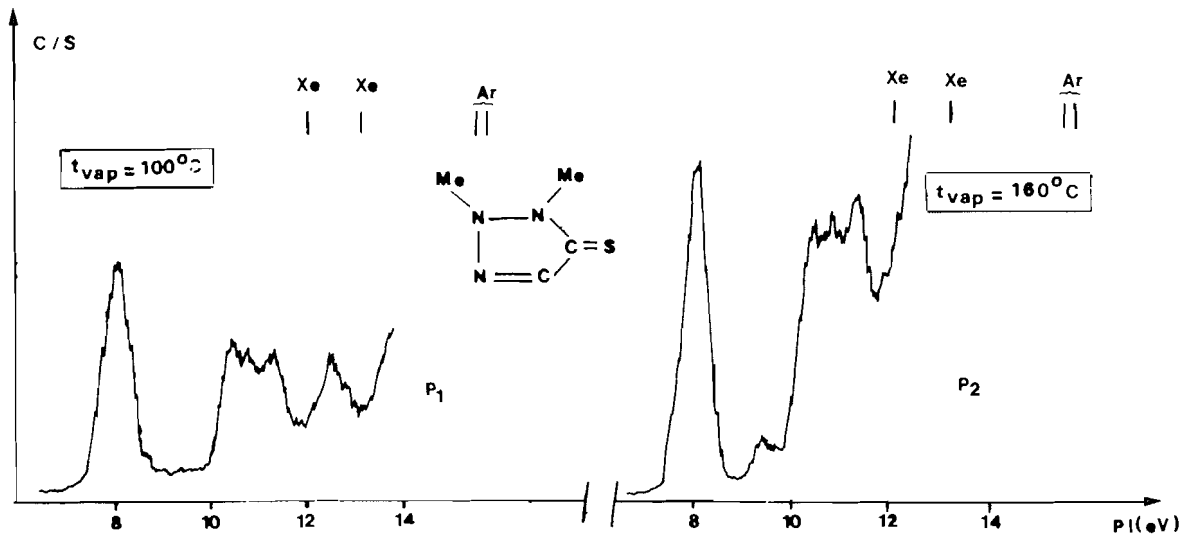

FIG. 12. Photoelectron spectra of 1,2-dimethyltriazoline-5-thione (2*a*) using probes P_1 and P_2 (see text).

TABLE 5. Calculated (MNDO) and experimental ionization potentials (eV) for 1,2-dimethylpyrazoline-5-thione (1*a*)

	Orbitals				
	$\pi_{C=S}$	n_S^{σ}	π	π	σ_{CS}
Calcd.	8.43	8.93	10.55	11.35	11.31
Expt.	7.6	7.6	9.78	10.22	11.96

The isomerization rate of gaseous 1,2-dimethyltriazoline-5-thione (2*a*) was only slightly enhanced compared to that of solid 2*a*. Thus, the spectra of just evaporated material obtained with probe P_1 indicate the presence of the unchanged thione even at 160°C (Fig. 12 − P_1). A spectrum recorded with probe P_2 after heating the evaporated sample to 160°C exhibits an additional minor band at 9.40 eV (Fig. 12 − P_2) which, according to Table 4, is most likely due to 2-methyl-4-methylthiotriazole (2*b*). The presence of 1-methyl-5-methylthiotriazole (2*c*) could not be demonstrated since its bands would be masked by those of its isomer (2*b*).

Isomerization of anhydro-1,3-dimethyl-4-mercaptotriazolium hydroxyde (3*a*) could not be detected even after heating the evaporated sample to 160°C.

Conclusion

This study indicates the power of photoelectron spectroscopy for the study of equilibria and isomerization phenomena in the gaseous phase. In our experimental conditions the isomerization of pyrazoline-5-thione and triazoline-5-thione into methylthiopyrazole seems to be a catalytic process. We have also shown that these methylthiopyrazoles exist under different rotamer forms.

Received October 28, 1982

KELVIN K. OGILVIE, DANNY P. C. MCGEE, SUZANNE M. BOISVERT, GHOLAM H. HAKIMELAHI, and ZBIGNIEW A. PROBA. Can. J. Chem. **61**, 1204 (1983).

A general procedure is described for the preparation of protected arabinonucleosides. Protection at the 5′-position involves triphenylmethyl groups (DMT and MMT) while the *tert*-butyldimethylsilyl (TBDMS) group is used to protect the 2′- or 3′-positions. The effects of novel catalysts on the position of silylation have been determined, leading to highly selective reactions at 2′- or 3′-positions.

KELVIN K. OGILVIE, DANNY P. C. MCGEE, SUZANNE M. BOISVERT, GHOLAM H. HAKIMELAHI et ZBIGNIEW A. PROBA. Can. J. Chem. **61**, 1204 (1983).

On décrit une méthode générale de préparation des arabinonucléosides protégés. On utilise le groupe triphénylméthyle (DMT et MMT) pour protéger la position 5′ tandis qu'on fait appel au groupe *tert*-butyldiméthylsilyle (TBDMS) pour protéger les positions 2′ ou 3′. On a déterminé les effets d'un nouveau catalyseur de silylation qui conduit à des réactions très sélectives au niveau des positions 2′ ou 3′.

Introduction

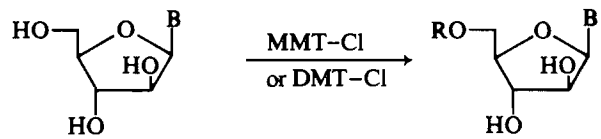
Arabinonucleosides (1−5) and arabinonucleotides (6−12) have been shown to possess a wide range of biological activities including antiviral and antitumor activity. A number of reports (13−19) have appeared which describe hydroxyl-derivatized arabinonucleosides with real or potential biological activity. However, the only literature report describing a general attempt at incorporating arabinonucleosides into nucleotide chains is the pioneering work by Wechter (20). In this latter work, the 2′- and 3′-hydroxyls were left unprotected during nucleotide coupling steps. As a result, mixtures of 2′−5′ and 3′−5′ linked nucleotides were obtained which were difficult to separate. We wish to describe the first general procedure for the preparation of protected arabinonucleosides suitable for stepwise incorporation into nucleotide chains.

The overall objective was to prepare arabinonucleosides protected at the 5′-position with monomethoxytrityl (MMT) or dimethoxytrityl (DMT) groups and protected at either the 2′- or 3′-positions with the *tert*-butyldimethylsilyl (TBDMS) group. These protecting groups have been successfully developed in the ribonucleotide area (21−23) and have allowed the synthesis of oligoribonucleotide chains both in solution (24, 25) and on a solid support (26). A preliminary report of some of these results has appeared (27).

Discussion

Tritylation of arabinonucleosides

The methoxytritylation and dimethoxytritylation of arabinonucleosides was carried out (Scheme 1) using a modification of the general procedures originally developed by Khorana and co-workers for nucleosides (28). These modifications have been described for the ribonucleosides (23). In the case of arabinonucleosides, yields (see Table 1) were generally greater than 90%. The properties of the tritylated nucleosides are collected in Table 1.



1*a* B = uracil
b B = cytosine
c B = *N*-benzoylcytosine
d B = adenine

2 R = MMT
3 R = DMT

SCHEME 1

Silylation of arabinouridine

The silylation of arabinouridine (araU, **1***a*) using the conditions developed for ribo- and deoxyribonucleosides (21, 22, 29) consisting of TBDMS-Cl and imidazole in DMF led to 51% of 3′,5′-diTBDMSaraU (**8***a*, 3′,5′-diSiaraU) and 18% of 2′,5′-diTBDMSaraU (**5***a*, 2′,5′-diSiaraU). Lesser amounts of the monosilyl derivative **4***a* and the trisilyl derivative **11***a* were obtained (Scheme 2).

The silylation of 5′-methoxytritylarabinouridine (**2***a*, 5′-MMTaraU) gave similar results (50% of **9***a*, 18% of **6***a*). One of the problems with the arabinouridine series was the difficulty of separating isomeric pairs such as **5***a* and **8***a* or **6***a* and **9***a*. Only the latter pair could be separated on a preparative scale and then with difficulty (Table 7). The isomers were generally isolated together from chromatography and the ratios determined by nmr (Table 5) as described below. Procedures were developed (below) that permit the isolation of the pure isomers.

One method that allowed the synthesis of the pure isomers was based on O^2,2′-cyclouridine (**14**). This compound is readily prepared from uridine in good yield (30). Compound **14** can be converted into 5′-methoxytrityl-3′-TBDMSarabinouridine (**9***a*) or into 3′,5′-diTBDMSaraU (**8***a*) in 70% and 80% yields respectively without the need to isolate the intermediates (e.g., **15**, **16**, and **17**). Selective acid catalyzed hydrolysis (21, 29) of either the methoxytrityl group or TBDMS group

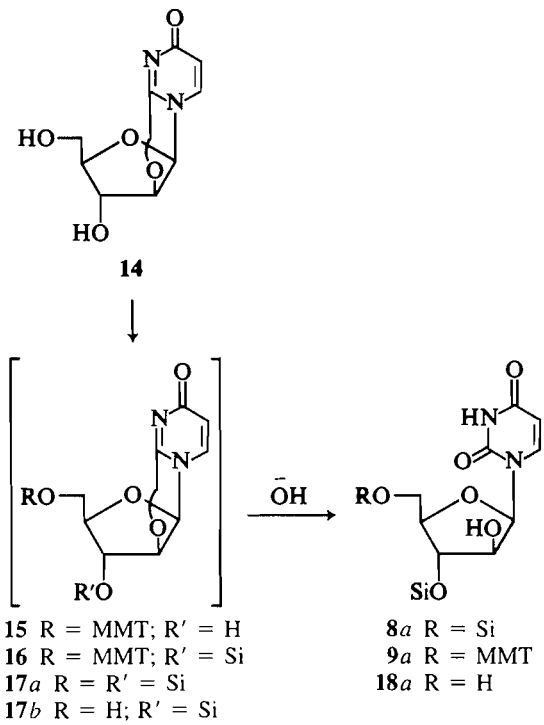

SCHEME 3

from **8***a* or **9***a* gave **18***a*.

The 5′-MMT-2′-TBDMSaraU (**6***a*) and 2′,5′-diTBDMS-araU (**5***a*) were also prepared from cyclouridine (**14**). Compound **14** was first converted to its bistetrahydropyranyl derivative (31). Base cleavage of the cyclouridine ring followed successively by silylation of the 2′-OH in DMF and the acid hydrolysis of the tetrahydropyranyl group (Scheme 4) gave 2′-TBDMSaraU (**19***a*, 31). The methoxytritylation or 5′-monosilylation of **19***a* led to the pure compounds **6***a* and **5***a*, respectively.

The cyclouridine route provided an unequivocal synthesis of the isomeric silylated arabinouridine derivatives. However, we wished to obtain a direct synthesis of these compounds. To this end we investigated the novel silylation methods that we have recently introduced in the ribo series (23, 32). The silylation of araU in THF using silver nitrate and pyridine with TBDMS-Cl gave high yields (70–80%) of the 3′,5′-diprotected derivatives (e.g., **8***a* and **10***a*). The 2′-silylated isomers (**5***a* and **7***a*) were always produced as well but in about 5% yields. If silver nitrate was omitted from this reaction only 5′-silylation occurred but in excellent yield (~90%). If pyridine was replaced by 3-methylpyridine *N*-oxide in the original reaction procedure, then the yields of 3′-silylated derivatives were nearly always above 90% (Table 2).

*Experimental conditions and abbreviations are as described in Table 4.

An amazing reversal of isomer distribution occurs on changing the solvent to dimethoxyethane (DME) containing triethylamine (Table 2). Using silver nitrate and TBDMS-Cl in this solvent gives virtually exclusive silylation at the 2′-position (e.g., **5***a* in 96% yield). High selectivity for the 2′-position is also observed in THF when DABCO and silver nitrate are used with TBDMS-Cl (Table 2, e.g., 75% of **5***a*, 5% of **8***a*). This latter result is a reversal of the situation in the ribo series where DABCO and silver ions provide a highly selective route to 3′,5′-silylation (23).

Silylation of arabinocytidine derivatives

A. *DMF and pyridine solvents*

The standard silylation procedures in DMF containing imidazole were applied to araC, *N*-benzoylaraC, and their derivatives. The results, collected in Table 3, show that using a slight excess of TBDMS-Cl led to the production of the 5′-TBDMS derivatives (**4**) in good yields. Using slightly more than two equivalents of TBDMS-Cl gave disilylated products. There was clearly a marked preference for silylation at the 3′-position relative to the 2′-position. Thus, 3′-5′-diTBDMSaraC (**8***b*) was obtained in 65% yield while the 2′-5′-isomer (**5***b*) was obtained in 11% yield. Similar results were obtained with $araC^{Bz}$ giving the 3′,5′-derivative **8***c* in 75% yield and the 2′,5′-derivative **5***c* in 15% yield. These results, along with those from araU, indicate that the 3′-hydroxyl is less sterically hindered than the 2′-hydroxyl which is in close proximity to the pyrimidine ring. The methoxytrityl derivatives **2***b* and **2***c* were

also selectively silylated at the 3′-position (Table 3). Reactions in pyridine as solvent were much slower than those in DMF but showed a clear selectivity for the 3′-hydroxyl.

B. *Dimethoxyethane as solvent*

The silylation of araC nucleosides in DME gave an isomer distribution which was the reverse of that found in the DMF system (Table 3). Thus the silylation of either araC or methoxytritylaraC using TBDMS-Cl in DME containing triethylamine gave the 2′,5′-protected derivatives **5***b* and **6***b* as the major products.

When silver nitrate was added to the DME system there was a nearly exclusive silylation at the 2′-position for araC and DMTaraC. Thus **5***b* and **7***b* were produced in 90 and 92% yields, respectively. The selectivity toward the 2′-position was lower with $araC^{Bz}$ where the yield of the 2′,5′-diTBDMS$araC^{Bz}$ (**5***c*) was 50% and that of the 3′,5′-isomer (**8***c*) was 35%.

The replacement of triethylamine by 3-methylpyridine *N*-oxide (3MPNO) gave a complete reversal of isomer distribution (Table 3). Thus araC was 90% converted to the 3′,5′-disilyl derivative (**8***b*) under these conditions.

C. *Tetrahydrofuran as solvent*

The results here were similar to those obtained for arabinouridine. Silylation occurred nearly exclusively at the 3′- and 5′-positions when pyridine or 3MPNO were present along with silver nitrate (Table 3). Further, as in the case of araU, DABCO and silver nitrate gave a high degree of selectivity for silylation at the 2′-position.

Further proof of structure of silylated arabinocytidines

Notari *et al.* (33) have reported that the 2′-hydroxyl (but not the 3′-hydroxyl) of arabinocytidine participates in the acid catalyzed deamination of araC. As a result, of the isomeric pairs **18***b* and **19***b*, only the 3′-silylated araC, **18***b*, should undergo rapid acid catalyzed deamination. In acetic acid buffer (pH 4.6) at 87°C the 3′-SiaraC (**18***b*) was 10% deaminated after 25 min (by hplc) and 66% deaminated after 5 h. Under these same conditions the 2′-SiaraC (**19***b*) was unaffected after 25 min and only 6% deaminated after 5 h.

Silylation of arabinoadenosine derivatives

A. *Dimethoxyethane as solvent*

When silylation was carried out in DME containing triethylamine and silver nitrate the results were the reverse of those found in the pyrimidine series. Thus the 3′,5′-protected derivatives **8***d* and **10***d* were each obtained in 50% yields while their 2′,5′-isomers **5***d* and **7***d* were obtained in 30 and 35% yields, respectively (Table 4). When pyridine replaced triethylamine the isomer ratios switched back to favor the 2′,5′-derivative (Table 4) but the selectivity was not very great.

B. *Tetrahydrofuran as solvent*

When THF was used as solvent, silylations in the presence of nitrate or perchlorate salts gave highly selective reactions at the 2′-position providing pyridine was used as base. In the absence of base (e.g., pyridine) reaction occurred mainly at the 5′-position. The use of picoline *N*-oxide in THF with silver nitrate and TBDMS-Cl gave highly selective silylation at the 3′-position. It is interesting to note that 4-methoxy and 4-nitropyridine *N*-oxide gave mainly 5′-silylation.

Nuclear magnetic resonance analysis of arabinocytidine derivatives

The chemical shifts for protons and carbons from the sugar ring of silylated arabinonucleosides are collected in Tables 5 and 6. The ^{13}C assignments for araC and araA derivatives were made by selectively decoupling the 2′ and 3′-protons while measuring the nuclear Overhauser effect on the C-2′ and C-3′ signals. The proton assignments were made on the basis of homonuclear decoupling experiments.

From Table 5 it can be seen that while there are small trends arising from the position of silylation, spectra are best used for comparison when the spectra of both isomers of a pair of isomers are available. The methyl groups directly attached to silicon usually appear as two singlets. The difference in chem-

*Spectra were recorded in DMSO-d_6 (ppm relative to TMS).

tion, Reese found that $J_{1',2'}$ is greater for the 3′-isomer than for the 2′-isomer. From Table 2 it can be seen that for silylated arabinonucleosides the chemical shift for H1′ is slightly greater for the 2′-isomer than for the 3′-isomer ($\Delta\delta \sim 0.05$ ppm) in agreement with the rules (34). However, it is equally clear that $J_{1',2'}$ is generally greater for the 2′-silylated isomer than for the 3′-isomer, except for 5′-tritylated derivatives.

The ^{13}C chemical shifts for the pentose carbons relative to C-5′ are collected in Table 6. It is clear that silylation of a particular oxygen leads to a deshielding of the carbon to which it is attached by ~1 ppm. This is consistent with all previous results in the ribose series (35, 36).

Experimental

General methods

Products from preparative scale reactions were isolated by short column chromatography (23) or by thick layer plates. Reactions were monitored by thin-layer chromatography (tlc) using Merck Kieselgel 60F254 analytical sheets. Solvents used on thin- and thick-layer chromatography were: (a) ethyl ether/chloroform/ethanol (5:4:1); (b) ethyl ether/xylene/chloroform (9:2:1), two developments; (c) chloroform/ethanol (9:1); (d) chloroform/ethanol (4:1); (e) ethyl acetate/ethanol (3:1); (f) chloroform/dimethylformamide (7:3); and (g) chloroform/dimethylformamide (4:1).

Ultraviolet spectra were recorded using a Cary 17 spectrometer. Nuclear magnetic resonance spectra were recorded from the following spectrometers: a Bruker WH-90, a Varian XL-200, and a Bruker WH-400.

Reagents were purified as previously described (23).

Methoxytritylation of arabinonucleosides

The nucleoside was dissolved in pyridine (5 mL/mmol) and 1.25 equiv. of monomethoxytrityl chloride were added. The solution was stirred at 50°C for 24 to 48 h. The solution was poured into vigorously-stirred ice water. The resulting solid was collected by filtration, dissolved in a small volume of acetone, and applied to silica gel thick layer plates. The thick layer plates were developed first in ether or hexane and then in chloroform–ethanol mixtures (generally 9:1 or 8:3, v/v). The properties of the products are collected in Table 1.

Dimethoxytritylation of arabinonucleosides

The nucleoside was dissolved in pyridine–DMF (1:1, 5 mL/mmol, araA, araC, and $araC^{Bz}$) or pyridine (araU). A total of 1.2 equiv. of dimethoxytrityl chloride was added in 8 equal portions (1 h betwen additions) to the solution stirred at −5°C. One hour after the final addition the solution was poured into ice water. The solid product was collected by filtration and purified by short column chromatography. The product mixture was applied to a column of silica gel (2 cm in diameter) using 13 g of silica/g of mixture. The products from araA, araC, and $araC^{Bz}$ were separated using chloroform–methanol (9:1) while $CHCl_3$–MeOH (9.5:0.5) was used in the araU reaction. Product yields and properties are collected in Table 1.

General procedure for the silylation of arabinonucleosides in N,N-dimethylformamide (DMF), pyridine, and 1,2-dimethoxyethane (DME)

The nucleoside was dissolved in the solvent (DMF, pyridine, or DME, 5 mL/mmol). DMF reactions contained 2 equiv. of

*Solvents are described in the experimental section.

imidazole/mmol of TBDMS-Cl while DME reactions contained 2 equiv. of Et_3N/mmol of TBDMS-Cl. TBDMS-Cl was added to the stirred solution. At the end of the reaction period the solution was poured into an ice/water mixture. The resulting solid was collected by filtration, dissolved in a small volume of acetone, and applied to thick layer plates. The reactions producing 5′-monosilylated nucleosides were quenched by the addition of ethanol. The solution was concentrated to a small volume and applied to thick layer plates. The results are collected in Tables 2 to 4, and physical properties are collected in Tables 7–9.

Preparation of 3′,5′-diTBDMSarabinouridine (8a) from cyclouridine

To a stirred solution containing O^2,2′-cyclouridine (250 mg, 1.1 mmol) and imidazole (6.6 mmol) in DMF (15 mL) was added TBDMS-Cl (500 mg, 3.3 mmol). The solution was stirred for 1 h and then poured into ice water. The precipitate was collected by filtration and then dissolved in 0.1 *M* ethanolic KOH ((10 mL). After 2 h, the solution was concentrated at reduced pressure to ~1/3 its original volume and poured into 100 mL of water. The solid was collected by filtration and the products were isolated from five thick layer plates developed once in chloroform/ethanol (9:1). The major band was

eluted with ethanol, which on evaporation yielded 421 mg (81%) of 3′,5′-diTBDMSarabinouridine (**8***a*, see Table 7).

*Preparation of 5′-MMT-3′-TBDMSarabinouridine (***9**a*) from cyclouridine (**14**)*

To a solution of O^2,2′-cyclouridine (200 mg, 0.88 mmol) in pyridine (5 mL) was added monomethoxytrityl chloride (380 mg, 1.2 mmol). The solution was stirred for 24 h and poured into ice water. The product (5′-MMTcyclouridine (**15**, Table 8)) can be isolated from thick layer plates (31) or, as in this case, dried overnight under vacuum. The dried material was dissolved in DMF (6 mL) and TBDMS-Cl (330 mg, 2.2 mmol) and imidazole (300 mg, 4.4 mmol) were added. The solution was stirred for 25 h and the solution was concentrated at reduced pressure. The product, 5′-MMT-3′-TBDMS-cyclouridine (**16**, Table 7) can be isolated from thick layer plates or, as in this case, dissolved in 0.5 *M* ethanolic KOH (10 mL). After 30 min the solution was concentrated at reduced pressure and poured into ice water (100 mL). The solid product was collected by filtration and the products separated by thick-layer chromatography to give 5′-MMT-3′-TBDMSarabinouridine (**9***a*, 387 mg, 70%, Table 7).

*Preparation of 2′-TBDMSarabinouridine (**19**a) from O^2,2′-cyclouridine*

O^2,2′-Cyclouridine (1 mmol) was added to a solution of dihydropyran (10 equiv.) and toluenesulfonic acid (0.1 equiv.) in acetonitrile and the solution was stirred at room temperature for 3 h. The solution was neutralized, concentrated at reduced pressure, and diluted with 0.1 *M* ethanolic KOH (10 mL). After 3 h the solution was concentrated at reduced pressure and poured into ice water. The solid, collected by filtration, was dried under vacuum and dissolved in DMF (5 mL). TBDMS-Cl (2.5 mmol) and imidazole (5 mmol) were added and the solution was stirred at room temperature for 12 h. Again the product was collected by precipitation in ice water. Treatment with 80% HOAc (in water, 15 mL) at 20°C for 24 h yielded 2′-TBDMS-arabinouridine (**19***a*) in 66% overall yield (see Table 7).

Compound **19***a* was converted into 5′-MMT-2′-TBDMSarabinouridine (**6***a*, see Table 7) by the general procedure for methoxytritylation. Monosilylation of **19***a* by the general procedure gave 2′,5′-diTBDMSaraU (**5***a*, Table 7).

Silylation of arabinonucleosides in THF silver nitrate and pyridine

General procedure

The nucleoside or its derivative was added to THF (20 mL/mmol of nucleoside) and pyridine (generally 5 equiv.) was added. To this solution was added silver nitrate (see Tables 2–4) and after stirring for 1 h at 20°C, TBDMS-Cl (Tables 2–4) was added. At the end of the reaction period the mixture was filtered into a 10% sodium bicarbonate solution (aqueous). The product was extracted into methylene chloride and products were separated by short column chromatography (~13 g of silica/g of mixture). Ethyl acetate was used to elute products in the arabinouridine series as well as the product in the preparation of 5′-TBDMSaraC and 3′,5′-diTBDMSaraA. Chloroform–methanol (9:1) was used to elute products from all of the other araC reactions. Chloroform–methanol (9.5:0.5) was used for the preparations of 5′-TBDMSaraA and 5′-DMT-3′-TBDMSaraA, while a ratio of 9.7:0.3 was used for 2′,5′-diTBDMSaraA and 5′-DMT-2′-TBDMSaraA. It is important to note that the order in which reagents are added in this reaction is critical. Yields of products are collected in Tables 2 to 4 and product descriptions are collected in Tables 7 to 10.

Silylations in dimethoxyethane–triethylamine

General procedure

The procedure is identical to that described above, except that DME replaced THF and triethylamine replaced pyridine. Yields are collected in Tables 2 to 4.

Silylations using DABCO

General procedure

DABCO (6 mmol/mmol of nucleoside) was dissolved in dry THF (25 mL/mmol of nucleoside). Silver nitrate was added and the mixture was stirred for 5 min. TBDMS-Cl was then added and after an additional 5 min the nucleoside was added and the reaction mixture was stirred at 20°C. Ratios of reagents used are listed in Tables 2 to 4. Reagents must be added in the order described above.

At the end of the reaction period the solution was collected by filtration, diluted with 50 mL of water, and the product extracted into chloroform (~100 mL). The chloroform solution was dried and concentrated and the products isolated by short column chromatography as described above. Results are collected in Tables 2 to 4.

Silylations using 3-methylpyridine N-oxide (3-MPNO)

General procedure

Silver nitrate was suspended in THF (20 mL/mmol of nucleoside). 3-MPNO was added and after 5 min TBDMS-Cl was added. This mixture was stirred at room temperature for 1.5 h. (For the dimethoxytritylated derivatives collidine was also added to this mixture in an amount equal to the amount of 3-MPNO used.) The nucleoside was then added and stirring was continued for 2 to 3 h. The solution was collected by filtration, diluted with chloroform, and extracted three times with water. The organic layer was then dried over magnesium sulfate and concentrated at reduced pressure. Products were isolated by short column chromatography. Results are collected in Tables 2 to 4.

The 1:1 adducts of 2,5-dimethyl-3,4-diphenylcyclopentadienone and dimethyl azodicarboxylate: a fourth isomer

DONALD MACKAY, DEANE DOUGLAS MCINTYRE, NICHOLAS J. TAYLOR, AND LICHIN L. WONG[1]

Guelph–Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received September 8, 1982

DONALD MACKAY, DEANE DOUGLAS MCINTYRE, NICHOLAS J. TAYLOR, and LICHIN L. WONG. Can. J. Chem. **61**, 1213 (1983).

The 1,3,4-oxadiazine **2**, one of three known 1:1 adducts of 2,5-dimethyl-3,4-diphenylcyclopentadienone and dimethyl azodicarboxylate, is converted by MeO^-–MeOH into a fourth isomer, the 1,3-oxazolidone **4**, whose structure was determined by X-ray analysis. There is evidence, however, that one of the methoxy groups of **4** comes from the solvent.

DONALD MACKAY, DEANE DOUGLAS MCINTYRE, NICHOLAS J. TAYLOR et LICHIN L. WONG. Can. J. Chem. **61**, 1213 (1983).

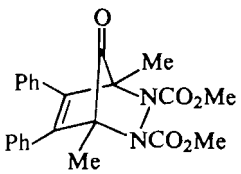
L'un des trois isomères connus des adduits 1:1 de la diméthyl-2,5 diphényl-3,4 cyclopentadiénone et de l'azodicarboxylate de méthyle, la oxadiazine-1,3,4 **2** dans le MeO^-–MeOH se transforme en un quatrième isomère, la oxazolidone-1,3 **4** dont on a déterminé la structure par cristalographie de rayons-X. Les données que l'on possède suggèrent qu'un des groupes du méthoxy **4** provient du solvant.

[Traduit par le journal]

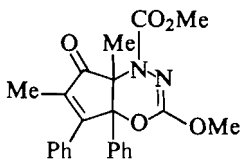
Introduction

Ten years ago we showed that the reaction of 2,5-dimethyl-3,4-diphenylcyclopentadienone with azo esters led to three structurally isomeric 1:1 adducts, formally the products of addition in a 4 + 2, 2 + 4, and 2 + 2 mode (1). Thus in the case of the dimethyl ester the initially formed bridged adduct **1** was thermally labile, giving reversibly the 1,3,4-oxadiazine **2**, and irreversibly the 1,2-diazetidine **3**; **3** was thus, remarkably, the thermodynamically most stable of the three isomers. Reversal of these reactions was also possible by photolysis, **2** or **3** being convertible into **1**.

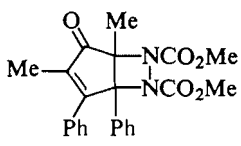
We report here on the formation of yet another isomer of these adducts.



1



2



3

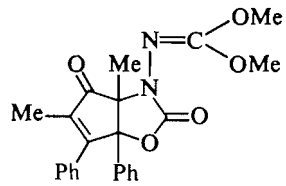
Results and discussion

Synthesis and isolation

In attempts to saponify the ester group of **2** we observed that a clean transformation took place when **2** was treated with KOH or NaOH in MeOH, satisfactory results being obtained with a 0.1 *M* solution over 5 h at reflux or a 1 *M* solution over 4 h at room temperature. Since the acidities of H_2O and MeOH are about equal, such dilute solutions of OH^- are converted nearly completely into H_2O and MeO^-. The latter is likely the catalyst since the reaction could be effected using a solution of NaOMe in dry MeOH. Inclusion of water, beyond trace amounts, led to profound decomposition of **2**.

Work-up of the reaction product by careful neutralization and ether extraction gave a good yield of a glassy solid. Its ^1H nmr spectrum ($CDCl_3$), which showed only trace impurities, had a *tert*-Me, a vinylic Me, two Ph groups, and two sharp OMe singlets (3.98, 3.74), thus resembling the spectrum of **2** rather closely (1). Strong ir peaks at 1775 and 1725 cm^{-1} implied the presence of at least one ester group, and the cyclopentenone chromophore, common to **2** and **3**, was inferred from the uv absorption at 282 nm. The mass spectrum had the parent peak at *m/e* 406 and a base peak at *m/e* 260 (cyclone). The product was thus unequivocally a fourth isomer of the adducts **1**–**3**.

All attempts to elucidate the structure of the new isomer by chemical means proved fruitless, in large measure due to its conversion with acids (hydrochloric, trifluoroacetic) into a demethylation product, $C_{23}H_{22}N_2O_5$, identical with the product obtained from any of **1**–**3** with acid (2). Its formation here was thus of little diagnostic value, other than confirming the preservation of the cyclopentenone ring system.



4

Crystallization and X-ray analysis

Sporadic efforts to crystallize the isomer since it was first prepared in 1971 were finally successful 10 years later, from a solvent mixture of ether and hexane. An X-ray analysis now shows it (Fig. 1) to be the dimethyl carbonate hydrazone, **4**, a functionality hitherto unreported in the literature.[2] The crystal

[1]MDS Health Group, Rexdale, Ont., Canada M9W 4Z9.

[2]A dimethyl carbonate azine has, however, been described (3, 4) as have phosgene hydrazones (5).

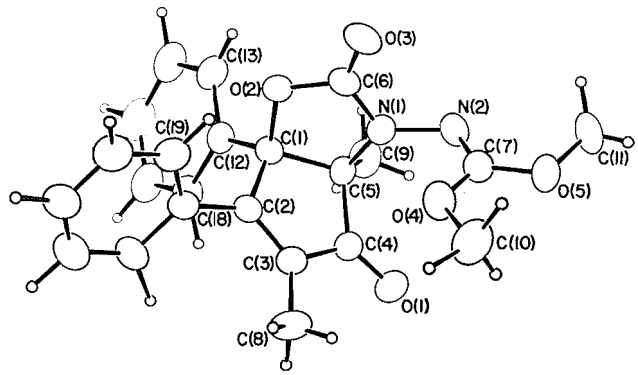

FIG. 1. ORTEP plot of compound **4**.

contained half an equivalent of solvated ether, this ratio being also confirmed by ^{1}H nmr spectroscopy. Crystals of **4** could not be obtained free of solvent, aromatic solvents being particularly easily incorporated (in preference to ether if both were present in the recrystallization medium). Thus crystals were readily obtained containing half an equivalent of any of toluene, *o*-xylene, mesitylene, or *p*-dichlorobenzene. The presence and proportion of the solvent could be determined by ^{1}H or ^{13}C nmr spectroscopy. All samples softened between 90 and 100°C and had no definable melting point.

Crystal data

$C_{23}H_{22}N_2O_5 \cdot 0.5(C_2H_5)_2O$ Mol. wt. 443.50

Monoclinic, $a = 16.522(3)$, $b = 14.062(3)$, $c = 20.761(5)$ Å, $\beta = 90.65(2)°$, $U = 4823(2)$ Å^3, space group $I2/c$ (non-standard setting of $C2/c$), $Z = 8$, $\rho_c = 1.221$ g cm^{-3}, $F(000) = 1880$, $\lambda = 0.71069$, μ (MoK$_\alpha$) = 0.936 cm^{-1}.

Data collection and reduction

A crystal (0.3 mm^3) of **4** was attached to a glass fibre and mounted on a eucentric goniometer. This was placed on a fully automated Syntex P2$_1$ diffractometer equipped with graphite monochromated molybdenum K$_\alpha$ radiation. Accurate cell dimensions were obtained from 15 well-distributed general reflections ($17 \leq 2\theta \leq 27°$). Data were collected by the $\theta-2\theta$ scan technique ($2\theta \leq 45°$) using variable scan speeds (3.9–29.3° min^{-1}), the rate being determined by a fast preliminary scan of each reflection. Of a total of 3179 unique reflections measured, 1871 with intensities $I \geq 3\sigma(I)$ were considered observed and used in the structure solution and refinement. The data were corrected for Lorentz and polarization effects.

Structure solution and refinement

The systematic absences hkl, $h + k + l = 2n + 1$ and $h0l$, h and $l = 2n + 1$ were consistent with the space groups Ic or $I2/c$. With $Z = 8$ and a centric E distribution, the latter was suggested and this choice was supported throughout the solution and refinement. The molecule was solved by direct methods (MULTAN 80) and refined by full-matrix least-squares methods. With anisotropic thermal parameters, an R of 0.13 was obtained ($R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$). This very high residual was strongly suggestive of unaccounted- for electron density. A difference Fourier map at this stage revealed the presence of a solvent molecule about the two-fold axis at $0y\frac{1}{4}$. Although exact atomic centres were unresolved, the electron density was rationalized as being an ether solvate molecule exhibiting two-fold disorder about this axis. Hydrogen atoms of the principal molecule were also located at this stage. These atoms were then included in the refinement which converged at

*Occupancy 0.5.

$R = 0.042$ with $R_w = 0.051$ ($R_w = [\Sigma w||F_o| - |F_c||^2/\Sigma w|F_o|^2]^{\frac{1}{2}}$). An empirical weighting scheme of the form $w^{-1} = 2.36 - 0.052|F_o| + 0.0018|F_o|^2$ was used in the final cycles of refinement. A final difference Fourier map revealed several residual peaks of 0.1 e Å^{-3} in the vicinity of the solvent molecule. Programs used have been described elsewhere (6). Scattering factor tables for non-hydrogen atoms were taken from the usual source (7). Scattering factors for hydrogen were those of Stewart *et al.* (8). Non-hydrogen atomic positions are listed in Table 1. Selected bond lengths and angles are given in Table 2.[3]

The bond lengths and angles in **4** are quite unexceptional. The lactam bonds to the carbonyl carbon are very similar in length to those in other lactams (9, 10), and the imino bond length is typical for hydrazones (11). The hydrazone carbon is planar, its place being almost orthogonal (85.9°) to that of the C—N—C plane in the lactam ring.

[3]Tables of (*i*) observed and calculated structure factor amplitudes, (*ii*) bond lengths and angles of phenyl groups and solvent molecules, and C—H bond lengths, and (*iii*) temperature factors are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

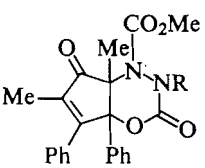
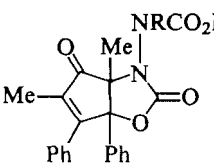
Reactions of 4

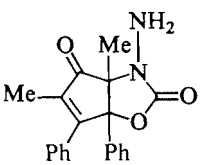
Compound **4** was slowly decomposed by prolonged treatment with MeO^- in MeOH and rapidly by aqueous alkali to a complex mixture. The acid catalyzed demethylation product formed from **4**, and from its isomers **1**–**3**, has previously been formulated as **5** (2) on the grounds that its methoxycarbonyl derivative showed two MeO singlets in its ^1H nmr spectra, as required for **6**. We assumed that the alternative formulation **7**,



5 R = H
6 R = CO_2Me



7 R = H
8 R = CO_2Me



9

otherwise acceptable on the basis of the properties of the product, could be rejected, since in its methoxycarbonyl derivative, **8**, the diastereotopic MeO groups would give one singlet, due to rapid rotation of the N—N bond. In other polyacylated hydrazines, however, there is evidence that this rotation barrier may be rather high (12). Though the two MeO singlets did not coalesce, at least up to 120°C,[4] we felt that a re-examination of this demethylation product was warranted. It has now been subjected to X-ray analysis and shown in fact to have structure **7**.[5]

Because of its sensitivity to acid or base, difficulties were encountered in trying to exchange **4** into a different hydrazone or in converting it into the free hydrazine **9**. Thus **4** was inert to refluxing acetone and inclusion of acid led only to the demethylation product **7**. Similarly the latter was produced when **4** was heated with 1,1-dimethylhydrazine, even without an acid catalyst. However, the hydrazine **9** could be obtained in a good yield when a dilute solution of **4** was refluxed with *p*-toluene sulfonic acid in MeOH. The conversion of **4** into either **7** or **9** under different solvolysis conditions can be accommodated by Scheme 1 in which the N-protonated form is attacked either by, for example, trifluoroacetate or by MeOH. Attempts to reconvert **9** into **4** with tetramethyl orthocarbonate failed, but it readily gave an oily isopropylidene derivative when refluxed in acetone.

The hydrazone was thermally very stable, surviving a three day reflux in tetrachloroethylene. Its stability allowed an examination of the MeO region in the ^1H nmr spectrum at temperatures up to 120°C (CD_3SOCD_3). No change was observed. Considerable work has been done on the rotational barriers in imino carbonates of general formula **10** (4, 13, 14), which shows that the barrier height increases with the electro-

[4]In CD_3SOCD_3. The $\Delta\nu$ value of 8.1 Hz at 80 MHz puts a lower limit to the rotation barrier of $\Delta G^{\ddagger}$ = ca. 21 kcal mol^{-1}.

[5]Crystals of $C_{22}H_{20}N_2O_5$ are orthorhombic, a = 14.263(3), b = 16.229(4), c = 16.585(3) Å, space group *Pbca*, Z = 8. The structure was solved by direct methods, using 1527 observed reflections ($3\sigma(I)$), and has been refined with isotropic thermal parameters to an R of 0.109.

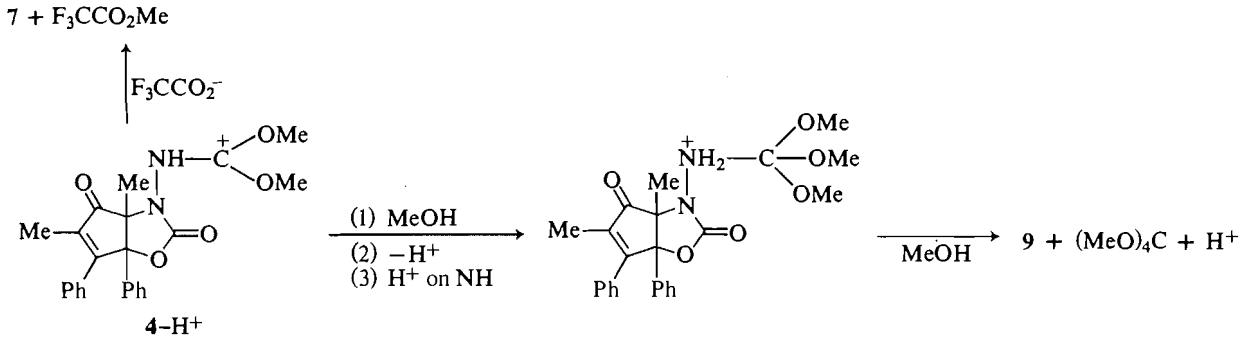
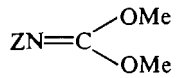
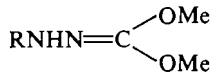


SCHEME 1

negativity of the directly bonded atom in Z (4). Thus for the anil **10** (Z = Ph) $\Delta G^{\ddagger}$ (0°C) is 14.3 kcal mol^{-1}, while for the chlorimine **10** (Z = Cl) or the azine **10** (Z = N=C(OMe)$_2$) $\Delta G^{\ddagger}$ is at least 23 kcal mol^{-1}. On this basis, rotation in **4** is expected to be too slow to affect the spectrum.



10



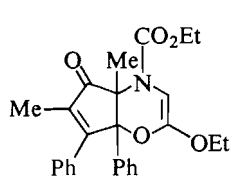
11 R = 2,4-$(NO_2)_2C_6H_3$
12 R = OEt

We found that simple hydrazone carbonates, e.g. **11** and **12**, could be routinely made from the hydrazine and tetramethyl orthocarbonate in the presence of acid. The MeO singlets in the ^{1}H nmr spectrum of each of **11** and **12** were nonequivalent. Those in **11** did not coalesce up to 150°C (CD_3SOCD_3).

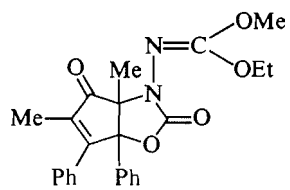
Scope of the reaction

Attempts to extend the scope of the transformation of **2** → **4** met with very limited success. The nature of both the base and the solvent was crucial. The use of OH^- or EtO^- in EtOH caused rapid degradation of **2**, as did OH^- in water-rich media, e.g. 1 : 1 aqueous MeOH. MeOH was thus uniquely necessary. In place of OH^- or MeO^- the only other suitable bases found were CN^- and CO_3^{2-}, their effectiveness being, and presumably significantly so, in the order of their base strengths: $OH^- > CN^- > CO_3^{2-}$.

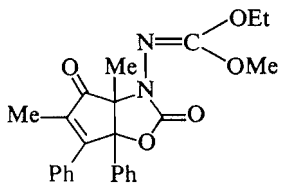
These results are strongly indicative of the incorporation of external MeOH in the hydrazone **4**. Confirmation of this was obtained by the behaviour of the oxadiazine **13**, obtained analogously from diethyl azodicarboylate. EtO^- in EtOH completely degraded **13**, but 0.2 *M* KOH in MeOH (effectively MeO^-) cleanly converted it into a mixture of two products, which resisted separation. The ^{1}H nmr spectrum was fully



13



14



15

consistent with that of an approximately equimolar mixture of the two diastereomeric hydrazones **14** and **15**, having two MeO singlets at δ 3.96 and 3.72 (cf. the MeO singlets in **4**) and two overlapping OCH_2 quartets.

These results raise more questions than they answer concerning the transformation of **2** into **4**: which MeO group in **2** is lost; which N in **2** becomes the exocyclic N in **4**; why are the MeO groups in **4** scrambled with respect to their origin, one from **2** and one from the solvent (an implication to be drawn from the reaction of **13**); why is MeOH so specific to the reaction? Work on some of these details is well underway. At this stage we can only assert that the conversion of **2** into its isomer **4** is not in fact an isomerization.

Experimental

Infrared spectra were recorded on a Beckman IR-10 and uv spectra on a Hitachi Perkin–Elmer RM-UGE spectrometer. Nuclear magnetic resonance spectra were obtained on a Perkin–Elmer R-12B (^{1}H) or a Bruker WP-80 (^{1}H, ^{13}C) spectrometer with tetramethylsilane as internal standard. Mass spectra were determined on a Varian MAT-CH7 instrument. Melting points are uncorrected.

1-(Dimethoxymethanimino)-3a,4-diphenyl-5,6a-dimethyl-2,6-dioxo-1,2,3a,6,6a-pentahydrocyclopent[d][1,3]-oxazole (4)

A solution of the oxadiazine **2** (1) (205 mg, 0.505 mmol) in 1 *M* KOH in MeOH (from solid KOH and reagent grade MeOH with no added water, 10 mL) was kept for 4 h at room temperature and then neutralized with solid CO_2. Evaporation of the solution was carried out at room temperature to near dryness and ether and water were added. The ethereal layer was twice washed with water, dried ($MgSO_4$), and evaporated. The glassy residue (202 mg) had only trace impurities as indicated by its ^{1}H nmr spectrum.

Alternatively the reaction could be carried out at reflux with a 0.2 *M* solution for 3 h or a 0.1 *M* solution for 6 h. The work-up was the same. In any of these reactions KOH could be replaced by NaOH or NaOMe.

The hydrazone could be purified by dissolving it in carbon tetrachloride and adding hexane with stirring, which caused its precipitation as an amorphous powder; ν(CCl_4): 1775 (endocyclic CO), 1725 (exocyclic and, probably, ketone CO), 1638 (probably C=N) cm^{-1}; λ_{max} (EtOH): 284 nm; ^{1}H nmr ($CDCl_3$) δ: 7.6–6.8 (10H, m, Ph), 3.98 (s, OMe), 3.74 (s, OMe), 2.12 (s, vinylic Me), 0.94 (s, *tert*-Me); ^{1}H nmr (CD_3SOCD_3) δ: 3.90 and 3.70 (OMe singlets, unchanged up to 150°C); ^{13}C nmr ($CDCl_3$) δ: 201.3 (ketone CO), 162.7, 161.4, 151.8, 138.4, 135.8, 132.6, 129.5, 128.5, 128.3, 127.7, 126.9, 126.1, 89.9 (C5), 69.1 (C1), 57.0 (OMe), 55.7 (OMe), 13.9 (vinylic Me), 10.3 (*tert*-Me); *m/e*: 406 $M^{+\cdot}$, 260 cyclone$^{+\cdot}$.

Crystallization could be achieved only with incorporation of solvent (see Discussion); from ether–hexane the crystals corresponded to $C_{23}H_{22}N_2O_5 \cdot 0.5\ Et_2O$. *Anal.* calcd.: C 67.70, H 6.13, N 6.54; found: C 67.96, H 5.89, N 6.60%.

Reactions of 2 with other basic solutions

The following solutions of **2** (typically 100 mg in 10 mL) containing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

0.2 *M* base were refluxed: (*i*) KCN in MeOH: **4** was slowly formed over about 9 h; (*ii*) Na_2CO_3 (saturated) in MeOH: **4** was very slowly formed, about 75% conversion in 17 h; (*iii*) NaOEt in EtOH: rapid decomposition; the ^{1}H nmr spectrum became very complex; (*iv*) KOH in EtOH: rapid decomposition; (*v*) KOH in 1:1 EtOH–H_2O: very rapid decomposition.

*Conversion of oxadiazine **13** into hydrazones **14** and **15***

Refluxing of **13** with 0.2 *M* KOH in EtOH, as described for the analogous reaction of **2** in MeOH, caused complete degradation.

A solution of **13** (200 mg, 0.46 mmol) in 0.2 *M* KOH in MeOH was refluxed for 4 h and then worked up as described for the synthesis of **4**. The residue (169 mg, 87%) contained only a trace of starting material, and its ^{1}H nmr spectrum was fully reconcilable with that of an approximately 1:1 mixture of **14** and **15**; ^{1}H nmr ($CDCl_3$) δ: 7.6–6.8 (10H, m, Ph), 4.40, 4.14 (two OCH_2, quartets, both J = 7.1 Hz), 3.96, 3.72 (two OMe, singlets), 2.13 (s, vinylic Me), 1.38, 1.22 (two OCH_2Me triplets), 0.94 (s, *tert*-Me).

Attempts to separate **14** and **15** by column chromatography (neutral Al_2O_3) or hplc (silica) caused degradation.

*Stability of **4***

A sample of **4** (50 mg) in tetrachloroethylene was heated at reflux (120°C) in an nmr tube. Its proton spectrum showed no change after 3 days.

*Demethylation of **4** to **7***

(*i*) *Trifluoracetic acid*

A solution of **4** (90 mg, 0.22 mmol) in carbon tetrachloride (1 mL) was made 5% v/v in trifluoroacetic acid and kept for 1 day at room temperature. After evaporating to dryness the residue was crystallized from carbon tetrachloride – hexane to give the known demethylation product **7** (50%), mp 232.5–234.5°C, undepressed in admixture with authentic material (2).

(*ii*) *Hydrochloric acid*

A solution of **4** as the hemi-etherate (30 mg, 0.068 mmol) in $CDCl_3$ (0.4 mL) in an nmr tube was shaken for 3 min with 2 drops of 12 *M* hydrochloric acid. The spectrum showed demethylation to be complete. The contents of the tube were neutralized and dried with solid Na_2CO_3, and the solution evaporated to give crude product (23 mg, 83%), which was washed with cold ether. Its ir spectrum was identical with that of an authentic sample.

*Reactions of **4** with alkali*

A solution of **4** (100 mg) in 0.2 *M* KOH in 1:1 H_2O–acetonitrile (50 mL) was refluxed for 1 h and then extracted with ether. The nmr spectrum of the residue from the ether solution showed that **4** had been completely degraded.

Attempted ketone exchange with acetone

The hydrazone **4** was recovered without change after refluxing for 12 h in acetone.

A sample of **4** (50 mg, 0.12 mmol), acetone (5 equiv.), and boron trifluoride etherate (5 equiv.) were refluxed for 2 h in chloroform (1 mL). The solution darkened and a precipitate formed. Evaporation to dryness and addition of ether gave an almost colorless solid identified as the demethylation product by its ir and ^{1}H nmr spectra.

Attempted exchange with 1,1-dimethylhydrazine

The etherate of **4** (93 mg, 0.21 mmol) and 1,1-dimethylhydrazine (38 mg, 0.63 mmol) were heated at reflux in $CDCl_3$ (0.5 mL) in an nmr tube, and the reaction monitored by proton spectroscopy. Reaction was complete after 4 days, the separation of solid being evident. Evaporation and trituration with ether gave the demethylation product, identified as before.

*The N-amino compound **9***

The hydrazone **4** (1.6 g, 0.39-mmol) and *p*-toluenesulfonic acid (1.5 g, 0.87 mmol) were refluxed together in MeOH (400 mL) for 30 min. The whole was then shaken with ether (600 mL) and water (400 mL), and the organic layer was separated, washed with water, and dried. Evaporation gave **9** as an oil (1.1 g, 80%), which slowly crystallized from ether–hexane. It was recrystallized from ether–hexane, mp 157.5–158.5°C; ν(film): 3360 (NH), 1764, 1712 (urethane, ketone CO) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.6–7.2 (10H, m, Ph), 3.93 (2H, s, NH_2, exchangeable with D_2O), 2.13 (s, vinylic Me), 0.96 (*tert*-Me). *Anal.* calcd. for $C_{20}H_{18}N_2O_3$: C 71.84, H 5.42, N 8.38; found: C 71.80, H 5.33, N 7.97%.

Refluxing of **9** in acetone for 12 h without catalyst gave a quantitative conversion into the isopropylidene derivative, obtained on evaporation as an oil; ^{1}H nmr ($CDCl_3$) δ: 7.5–7.0 (10H, m, Ph), 2.17 (6H, s, CMe_2), 1.88 (s, vinylic Me), 1.04 (s, *tert*-Me); ^{1}H nmr (C_6D_6) δ: 1.74, 1.73 (two CMe_2 singlets).

*Dimethyl carbonate 2,4-dinitrophenylhydrazone (**11**)*

2,4-Dinitrophenylhydrazine (1.84 g, 0.01 mol), tetramethyl orthocarbonate (1.36 g, 0.01 mol), and 5 drops of trifluoroacetic acid were refluxed in benzene (20 mL) for 10 min. The product obtained on cooling was collected and then crystallized from benzene as orange-red needles (1.9 g, 70%), mp 191–192°C; ν (Nujol): 3315 (NH) cm^{-1}; λ_{max} ($CHCl_3$): 3740 Å (ε 17 800); ^{1}H nmr ($CDCl_3$) δ: 10.85 (NH), 9.08 (C3-H), 8.19 (C5-H), 7.61 (C6-H), 3.99 (two coincident OMe groups); ^{1}H nmr (C_6D_6 δ: 3.38, 3.04 (two OMe singlets); *m/e*: 270 (M^+). *Anal.* calcd. for $C_9H_{10}N_4O_6$: C 40.01, H 3.73, N 20.74; found: C 40.07, H 3.80, N 20.65%.

The OMe peaks were distinguishable in CD_3SOCD_3 and did not coalesce when the nmr probe was heated to 150°C.

*Dimethyl carbonate ethoxycarbonylhydrazone (**12**)*

The preparation was similar to that of **11**, but was more efficient in MeOH as solvent with a few drops of hydrochloric acid as catalyst; ^{1}H nmr ($CDCl_3$) δ: 7.2 (1H, bs, NH), 4.20 (2H, OCH_2, q, J = 7 Hz), 3.87 (s, OMe), 3.81 (s, OMe), 1.27 (3H, OCH_2Me, t); *m/e*: 176 (M^+).

RHIANYDD M. GORDON and HOWARD B. SILVER. Can. J. Chem. **61**, 1218 (1983).

The compounds $(RCO_2)_6Zn_4O$ have not been widely reported in the literature, and in order to examine their little-known chemistry, a number of them have been synthesised by several methods. The simplest method of preparation, using the carboxylic acid and zinc oxide, was found to be restricted to branched chain acids. The reaction of these basic salts with primary and secondary amines led to a breakdown of their structures, with the formation of the amine complexes of the neutral carboxylates.

RHIANYDD M. GORDON et HOWARD B. SILVER. Can. J. Chem. **61**, 1218 (1983).

Dans la littérature on trouve peu de travaux relatifs aux composés du type $(RCO_2)_6Zn_4O$. Dans le but d'examiner leur chimie peu connue, on a synthétisé un certain nombre de ces composés selon plusieurs méthodes. On a trouvé que la méthode de préparation la plus simple qui utilise l'acide carboxylique et l'oxyde de zinc se limite aux acides ayant une chaîne secondaire. La réaction de ces sels basiques avec des amines primaires et secondaires conduit à une rupture de leurs structures avec formation de complexes d'amines de carboxylates neutres.

Introduction

Basic beryllium acetate, $(CH_3CO_2)_6Be_4O$, with its tetrahedral symmetry consisting of four beryllium atoms at the apices and an oxygen atom at the centre, has been well characterised in the literature (1). A number of reports exist on other basic beryllium carboxylates (2) and their derivatives (3). However, very little is known of the isostructural zinc compounds.

The basic acetate, $(CH_3CO_2)_6Zn_4O$, was first prepared by Auger and Robin (4) by the vacuum distillation of the normal acetate, and its structure was established by Wyart (5) and by Koyama and Saito (6). Few reports exist of any other basic zinc carboxylates. In a limited study several years ago we described the preparation and mass spectra of the 2-ethylhexanoate and 3,5,5-trimethylhexanoate (7), and Charalambous and coworkers (8) discussed the mass spectra of the acetate, *n*-propionate, and *n*-butanoate, prepared by pyrolysis of the normal carboxylate (9). Recent interest in these compounds (10) as intermediates in the formation of complexes in the gelling of crude oil spillages, has led us to examine them further, and we report here some of our findings regarding their preparation and reactions with certain amines.

Experimental

Spectroscopic analysis

Infrared spectra were recorded on a Perkin Elmer Infracord Spectrometer. Mass spectra were obtained on a Kratos MS 12 single focussing mass spectrometer at low resolution, with a direct inlet system temperature of 250°C, ion source temperature of 250°C, and with ionising electron energy of 70 eV.

AnalaR zinc oxide and the solvents employed were used as received. The carboxylic acids and amines were generally distilled, or recrystallised, to give boiling points, or melting points, consistent with those reported in the literature. Zinc 2-methylpropionate, mp 226 (Calcd. Zn 27.3; found Zn 27.3) and 2-ethylhexanoate (Calcd. Zn 18.6; found Zn 17.7) were prepared from the oxide and the free acid in stoichiometric proportions.

Preparation of $(RCO_2)_6Zn_4O$

Three methods were used to prepare the basic carboxylates. These were (*a*) by the reaction between zinc oxide and the carboxylic acid in the appropriate proportions, (*b*) by the thermal decomposition of the neutral carboxylate, $(RCO_2)_2Zn$, and (*c*) by the reaction of zinc oxide with the neutral carboxylate.

Method (a)

In a typical experiment on a 0.1 *M* scale, a mixture of the acid (6 equiv.), zinc oxide (4 equiv.), and toluene (250 mL) was placed in a round-bottomed flask fitted with a stirrer and a Dean and Stark head for the removal of water. Heating and stirring were maintained until all of the water of reaction had been collected, and then continued for a further 2 to 3 h. The product was filtered and solvent removed from the filtrate. The basic carboxylate was then purified by distillation or recrystallisation.

Method (b)

The neutral carboxylate was placed in a single-necked flask equipped with an air condenser set at right angles to the neck of the flask, which was heated for 6 h at 250 ± 5°C and at 0.2 mm. The product was isolated as the sublimate, and by toluene extraction from the residue.

Method (c)

Neutral zinc 2-ethylhexanoate (105.5 g, 0.33 mol) in toluene (350 mL) was heated and stirred for 3 h with zinc oxide (8.1 g, 0.10 mol). The product was filtered and removal of solvent afforded a viscous liquid (115 g), n_D^{25} 1.4570, whose infrared spectrum showed it to be identical to that of the spectrum of basic zinc 2-ethylhexanoate.

The physical properties of the basic carboxylates prepared are summarised in Table 1.

Reaction between basic zinc 2-methylpropionate and 2-ethylhexanoic acid

Basic zinc 2-methylpropionate (30.0 g, 0.037 mol) in xylene (400 mL) was heated with stirring for 2 h with a solution of 2-ethylhexanoic acid (32.5 g, 0.225 mol) in xylene (100 mL). Water (0.65 mL) collected in a Dean and Stark column. Distillation of the reaction mixture afforded 2-methylpropionic acid (9.47 g, 0.107 mol, bp 153–154°C). The infrared and mass spectra identified the distillation residue as a mixture of neutral zinc 2-methylpropionate and neutral zinc 2-ethylhexanoate.

Reactions of (a) basic zinc carboxylates and (b) neutral zinc carboxylates with amines

(*a*) In a typical experiment a solution of cyclohexylamine (4.0 g, 0.04 mol) in ether (10 mL) was treated with basic zinc 2-ethylhexanoate (5.7 g, 0.005 mol) in the same solvent (20 mL) at ambient temperature. The reaction was slightly exothermic and produced a clear liquid, which was kept at room temperature for 24 h. Solvent was removed to afford a waxy solid (9.55 g), which was

crystallised from 40–60°C petroleum ether to give a crystalline solid, mp 130°C (*Anal.* Calcd. for $(C_7H_{15}CO_2)_2Zn.2C_6H_{11}NH_2$: C 61.1, H 10.3, N 5.1; found: C 61.1, H 10.3, N 5.1; *Anal.* Calcd. for $(C_7H_{15}CO_2)_6Zn_4O.8C_6H_{11}NH_2$: C 59.7, H 10.1, N 5.8).

(*b*) As in the above, THF or 40–60°C petroleum ether solutions of the normal carboxylates were added to the same series of amines at 2:1 equivalent ratios and on a similar molar scale. The products, crystalline solids, were isolated and purified from hydrocarbon solvents, to yield the 2:1 complexes of the amine and neutral carboxylates.

Results and discussion

Tetrazinc μ_4-oxohexa-μ-carboxylates

The compounds prepared in the present study by one of the three methods previously described are shown in Table 1. The preferred route was to heat zinc oxide with toluene solutions of the carboxylic acid. Examination of Table 1 shows that the basic carboxylates prepared in this way are from a fairly restricted range of acids, i.e. acids with branched hydrocarbon chains. Two alternatives to the formation of the basic carboxylates were observed. Straight chain acids, of carbon number up to ten, formed only the neutral salts, leaving an excess of zinc oxide. Examples of this reaction path were seen with acetic, *n*-propionic, *n*-hexanoic, *n*-octanoic, phenylacetic, and *n*-decanoic acids. Straight chain acids greater than C_{10} did not react at all with zinc oxide, e.g. dodecanoic, hexadecanoic, and oleic acids, and this was similarly the case with 2-methyl- and 4-*t*-butyl-benzoic acids.

The reasons for these results are far from clear. Since it was shown in the case of the 2-ethylhexanoate derivative that the basic salt could be formed via the neutral, it is reasonable to assume that the neutral salt is formed as an intermediate in the reaction, thus implying reaction between the insoluble zinc oxide and the neutral salt (reactions [1] and [2]). It was also established that the neutral salt was formed from the acid, rather than the anhydride, since it was found that under the conditions of the reaction, water cannot be removed by dehydration from the acid even in the presence of a catalytic amount of zinc oxide (reaction [3]).

[1] $6RCO_2H + 3ZnO \rightarrow 3(RCO_2)_2Zn + 3H_2O$

[2] $3(RCO_2)_2Zn + ZnO \rightarrow (RCO_2)_6Zn_4O$

[3] $6RCO_2H \not\rightarrow 3(RCO)_2O + 3H_2O$

Basic zinc acetate and propionate could only be prepared by the vacuum pyrolysis of the neutral salts (reaction [4]).

[4] $4(RCO_2)_2Zn \rightarrow (RCO_2)_6Zn_4O + (RCO)_2O$

This gives further support to the hypothesis that neutral zinc carboxylates are formed as intermediates. Somewhat unexpectedly, the higher molecular weight salts, e.g. zinc di-*n*-hexanoate and *n*-octanoate, did not afford the basic compounds when treated in this way. Although it is fair to cite the insolubility of the neutral acetate and propionate in the toluene solvent as inhibiting reaction with the oxide, this cannot be said for the more oleophilic zinc *n*-octanoate and *n*-decanoate, which were soluble in the heated solvent. The reason for the lack of reactivity of the higher acids towards zinc oxide is also not immediately apparent. It is doubtful whether this is because of steric factors, since the straight chain acids would offer less hindrance of approach to zinc oxide than the lower branched-chain (e.g., trimethylacetic) acids; neither can acid strength be considered a factor in this lack of reactivity since the difference in pK_a of the acids after C_4 is negligible.

Infrared examination of the basic zinc carboxylates

Examination of the infrared spectra of the basic carboxylates shows single strong absorption bands between 1570 and 1607 cm^{-1} except for the propionate (1545 cm^{-1}), see Table 2. These bands are not seen in the infrared spectra of the nuetral salts, and confirm the findings of Beattie and Gilson (11), who reported a value of 1598 cm^{-1} for the acetate and stated this C—O stretching vibration to be characteristic of bridging or chelate carboxylate groups. In the basic beryllium carboxylates, Semenenko and Kurdyumov (12) noted an intense band at 770–80 cm^{-1}, which they ascribed to the BeO_4 tetrahedron, but a similar, consistent band was not seen by us in the zinc system.

Mass spectra

All of the basic zinc carboxylates examined showed the most intense ion to be $(RCO_2)_5Zn_3O^+$, confirming our earlier results (7) and those of Charalambous (8), Vogel and Hobrock (13), and Sipachev *et al.* (14).

Transacidification of basic zinc carboxylates

Transacidification (carboxylic acid exchange) of basic zinc carboxylates was attempted to determine whether it was possible to prepare those compounds which were not available by simple zinc oxide – carboxylic acid interaction, i.e.

[5] $(RCO_2)_6Zn_4O + 6R'CO_2H \rightarrow (R'CO_2)_6Zn_4O + 6RCO_2H$

The basic zinc carboxylate chosen was the 2-methylpropionate

*TBN from neutral zinc complex was 406.5; 411.0.

which was reacted with 2-ethylhexanoic acid. However, the above reaction did not take place. Instead, the basic structure was destroyed and water and the two neutral salts were obtained. A possible pathway is as follows:

[6] $(RCO_2)_6Zn_4O + 6R'CO_2H \rightarrow 3(R'CO_2)_2Zn + (RCO_2)_2Zn + 4RCO_2H + H_2O$

From these results it would appear that the basic carboxylate behaves as a mixture of zinc oxide and neutral carboxylate, which are both vulnerable to attack by higher molecular weight acid. These findings are consistent with those of Hardt and Stavenow (15) who reported that formic acid reacted with basic zinc acetate to afford the neutral zinc formate.

Reaction with amines

The coordination number of zinc in the basic zinc carboxylates is 4. It was therefore argued that addition compounds of the type $(RCO_2)_6Zn_4O.8RR'NH$ should be capable of existence. The reaction of the basic 2-ethylhexanoate and 2-methylpropionate with a number of primary and secondary amines proceeded smoothly to give crystalline products. Their elemental analyses were not, however, in line with compounds of the above structure, and molecular weight determinations by vapour pressure osmometry did not give consistent results. Further examination of the elemental analyses suggested that the complexes might be the addition products of the *neutral* carboxylates, $(RCO_2)_2Zn.2R'R''NH$. These compounds are well characterised in the literature (16–21) in contrast with the unknown complexes of the basic salts. In order to help clarify the situation the amine complexes of the corresponding neutral carboxylates were prepared, a full summary of the results obtained being given in Table 2. It will be noted that the melting points of the amine addition compounds from either the basic carboxylate or the corresponding neutral salt are very similar and the elemental analyses in both cases are very close and correspond with the addition product of the neutral amine. Examination of the infrared spectra of the products from the neutral and basic carboxylate with the same amine showed the same product was formed; Table 2 gives data of the carbonyl stretching frequencies.

Further evidence for the breakdown of the tetrahedral structure was provided by the determination of the Total Base Numbers (TBN) (22) of the addition compounds. This potentiometric titration of the total alkalinity of a compound proved to be a most effective way of distinguishing between the basic and neutral complexes. The breakdown by acids in the determination of the value is shown below:

[7] $(RCO_2)_2Zn.2R'R''NH + 4H^+ \rightarrow 2RCO_2H + Zn^{2+} + 2R'R''NH_2^+$

[8] $(RCO_2)_6Zn_4O.8R'R''NH + 16H^+ \rightarrow 6RCO_2H + 4Zn^{2+} + 8R'R''NH_2^+$

The results found for a representative number of complexes are shown in Table 3 from which it can be concluded that the addition compounds isolated from the interaction of the basic carboxylates with the amines are indeed the neutral salts.

Finally, the X-ray examination of the addition products from the interaction of the basic zinc 2-methylpropionate with both cyclohexylamine and 4-methyl piperidine confirmed that in both cases they were the diamino derivative of the neutral salts. This work will be reported elsewhere.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

From the evidence of the above results, it would therefore appear that nucleophilic attack of the amines on the zinc atoms destroys the basic carboxylate structure, as did the reaction with carboxylic acids.

Structure of bis(*p*-bromophenyl)tellurium(IV) dichloride

RAJ K. CHADHA, JOHN E. DRAKE, AND J. L. HENCHER
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received October 15, 1982

RAJ K. CHADHA, JOHN E. DRAKE, and J. L. HENCHER. Can. J. Chem. **61**, 1222 (1983).

The X-ray crystal structure of bis(*p*-bromophenyl)tellurium(IV) dichloride has been determined: $R = 0.025$. The crystals were triclinic, $P\bar{1}$, $a = 8.000(7)$ Å, $b = 11.811(11)$ Å, $c = 7.978(6)$ Å, $\alpha = 101.85(7)°$, $\beta = 98.73(6)°$, $\gamma = 80.95(7)°$, and $Z = 2$. The compound exhibits a ψ-trigonal bipyramidal arrangement of ligands around tellurium with weak secondary interactions between tellurium and bromine atoms in adjacent molecules.

RAJ K. CHADHA, JOHN E. DRAKE et J. L. HENCHER. Can. J. Chem. **61**, 1222 (1983).

On a déterminé la structure cristalline du dichlorure de bis(*p*-bromophényl)tellure(IV) par diffraction de rayons-X: $R = 0{,}025$. Les cristaux sont tricliniques, $P\bar{1}$, $a = 8{,}000(7)$ Å, $b = 11{,}811(11)$ Å, $c = 7{,}978(6)$ Å, $\alpha = 101{,}85(7)°$, $\beta = 98{,}73(6)°$, $\gamma = 80{,}95(7)°$ et $Z = 2$. Le composé présente un arrangement bipyramidal ψ-trigonal du ligand autour du tellure avec des interactions secondaires faibles entre les atomes de tellure et de brome des molécules adjacentes.

[Traduit par le journal]

Introduction

Crystal structures of many compounds of the type R_2TeX_2 have been determined (1–8). They all have ψ-trigonal bipyramidal stereochemistry about tellurium, but several packing arrangements arise apparently from differing secondary Te----X interactions. We have communicated the crystal structure of phenyl(*p*-bromophenyl)tellurium dichloride (1) and have shown that two independent molecules of the compound pack into discrete tetramers. This combined with a recent report on the crystal structure of diphenyltellurium dichloride (2), wherein the monomers pack into chains, has prompted us to investigate the structure of bis(*p*-bromophenyl)tellurium dichloride.

Experimental

The title compound was prepared by Bergman's method (9) followed by recrystallisation by slow-evaporation of acetonitrile solution.

A single crystal with overall dimensions 0.11 × 0.23 × 0.34 mm was mounted on a Syntex $P2_1$ diffractometer equipped with a Mo X-ray tube and a highly oriented graphite monochromator. ($\lambda = 0.71069$ Å). The crystal data at 21°C were:

$C_{12}H_8Br_2TeCl_2$ mw = 510.4
$a = 8.000(7)$ Å, $b = 11.811(11)$ Å, $c = 7.978(6)$ Å, $\alpha = 101.85(7)°$, $\beta = 98.73(6)°$, $\gamma = 80.95(7)°$, $V = 723(1)$ Å^3, $F(000) = 472$, $Z = 2$, $D_c = 2.344$ g cm^{-3}, $\mu = 7.80$ mm^{-1}.

The data were collected in $\theta/2\theta$ mode, scan width $K_{\alpha 1} - 1°$ to $K_{\alpha 2} + 1°$, variable scan rate 2–5° min^{-1} over the range $4 < 2\theta < 45°$. The intensities of three monitor reflections did not change significantly during data collection. The space group $P\bar{1}$ was used and later assumed to be correct because of successful refinement of the structure. 2127 independent reflections were recorded and reduced to 1628 ($I > 3\sigma(I)$) unique reflections. Absorption correction factors obtained by an analytical procedure ranged from 2.36 to 4.23.

The structure was solved by direct methods using the program MULTAN. Phasing was carried out for 168 E's normalised according to parity groups, with magnitude greater than 1.2. The solution with largest overall figure of merit was used to calculate the E-map from which the five atoms Te, Br(1), Br(2), Cl(1), and Cl(2) were found. The carbon atoms C(11)—C(61) and C(12)—C(62) were located by difference Fourier synthesis. Full-matrix least-squares refinement was carried out for all non-hydrogen atoms. Anomalous scattering factors were used for Te and Br throughout and all non-hydrogen atoms were refined with anisotropic temperature factors. The hydrogen atom positions were recalculated before each cycle for CH bond length of 0.97 Å and standard geometry, with isotropic temperature factors 1.1 times the isotropic equivalent for the attached carbon atoms. The final discrepancy factors were $R = 0.025$ and $R_{WF} = 0.040$.

Wayne State University versions of the programs ABSORB (10) for analytical correction, MULTAN (11), SYNCOR (for data reduction by W. Schmonsees), FORDAP (for Fourier synthesis by A. Zalkin), ORFLS (12) for structure factor and least-squares calculations, ORFEE (12) for calculation of distances and angles, ORTEP (13) and HFINDER (hydrogen atom position calculation by A. Zalkin) were used.

The final atomic coordinates for non-hydrogen atoms are given in Table 1 and important distances and angles in Table 2.[1]

TABLE 1. Atomic coordinates and equivalent isotropic thermal parameters for non-hydrogen atoms of $(p\text{-}BrC_6H_4)_2TeCl_2$[a]

Discussion

The atom labelling of the molecule, $(p\text{-}BrC_6H_4)_2TeCl_2$, is given in Fig. 1. The compound adopts a distorted trigonal bipyramidal arrangement with the chlorine atoms in axial positions and the two bromophenyl rings in the equatorial plane. The Cl—Te—Cl bond angle is close to 180° and the Cl—Te—C bond angles are close to right angles. The C—Te—C angle, 96.1(2)°, is typical of R_2TeCl_2 compounds and presumably indicates the presence of a stereochemically active non-bonding electron pair in the equatorial plane.

It is interesting to note that though Te—C and Te—Cl distances and angles are comparable to the observed distances and angles in other R_2TeCl_2 compounds (Table 3), the shortest non-bonded Te----Cl distance is considerably greater than the sum of van der Waals distances (4.0 Å). The ratio Te----Cl/Te—Cl is ~1.86, and as such, it must be presumed that the secondary Te----Cl interactions are insignificant in this compound. This is in contrast to three different kinds of secondary interactions observed in $(C_6H_5)(p\text{-}C_6H_4Br)TeCl_2$ (1) and one secondary interaction observed in $(C_6H_5)_2TeCl_2$ (2). However, the non-bonded Te----Br′ distances (3.71 Å and 3.80 Å) are comparable with the secondary Te----Br distances (3.93 Å) reported in $(C_6H_5)_2TeBr_2$ (6). This suggests that each tellurium atom may be interacting with two bromine atoms of the neighbouring molecules linking the molecules into chains (Fig. 2). The bromine atoms forming the secondary interactions are so positioned that the geometry about tellurium now appears as a distorted octahedral. Whether this indicates that the lone-pair is inactive or is still positioned, as assumed for the ψ-trigonal bipyramidal structure, between the two "secondary-bonds" is an open question.

The absence of Te----Cl interactions, which have been shown to be present in other R_2TeCl_2 compounds (1–5), could result from the availability of bromine atoms at more convenient positions for secondary interactions. Similar behaviour was observed in $(C_6H_5)_2TeF_2$ (8), where very weak Te----F interactions were attributed to the small size of the halogen atom as compared to the phenyl ring. The structure of (*p*-

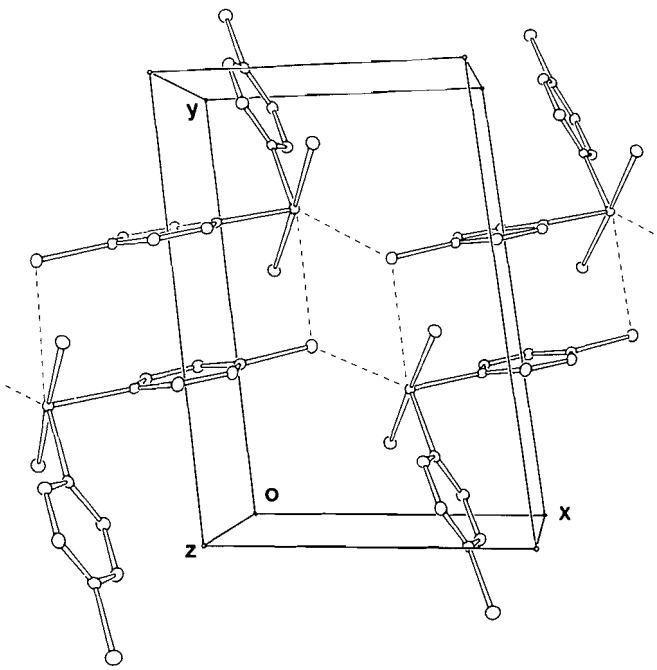

FIG. 2. Unit cell packing of $(p\text{-}C_6H_4Br)_2TeCl_2$. Hydrogen atoms are omitted for clarity.

$ClC_6H_4)_2TeI_2$ (7) which might have been assumed to be more closely related to $(p\text{-}BrC_6H_4)_2TeCl_2$ shows, an usual, Te----I′ interactions but no significant Te----Cl′ interactions (Te----Cl′ distance is 3.91 Å). This limited evidence suggests that the relationship of size and position of ligands and halides is quite subtle.

The angles between the TeCC plane and the bromophenyl rings are 51.6(5)° and 130.8(5)°, respectively, for the rings C(11)—C(61) and C(12)—C(62). The comparable angles in $(C_6H_5)(p\text{-}BrC_6H_4Br)TeCl_2$ are 41.9(10)° and 144.7(10)° for one molecule and 32.1(10)° and 129.4(10)° for the second molecule. The mean planes table[1] shows that the phenyl rings are both rotated by 140° with respect to plane C(11)TeCl(1)Cl(2) and C(12)TeCl(1)Cl(2) so that the rings are in a propeller rather than a butterfly arrangement. Neither substitution in the ring nor a change in the size or electronegativity of the halide apparently changes this arrangement. However, in $(C_6H_5)(p\text{-}BrC_6H_4)TeCl_2$ (1), the packing is such that the phenyl ring on one molecule lies parallel to the bromophenyl ring on the other, while the phenyl ring on the latter molecule lies normal to the bromophenyl ring on the former molecule. This arrangement presumably maximises the number of secondary Te----Cl interactions. By contrast, in $(C_6H_5)_2TeCl_2$ (2), the rings in adjacent molecules are parallel to one another as they are in $(p\text{-}BrC_6H_4)_2TeCl_2$. However, this present molecule is in a head-to-tail configuration in contrast to $(C_6H_5)_2TeCl_2$, where the molecules are linked in a sideways or end-on fashion.

Seven-membered ring annulation and spiro-annulation processes via preparation and thermal rearrangement of β-(2-vinylcyclopropyl) α,β-unsaturated ketones

EDWARD PIERS, HOWARD E. MORTON, ISAO NAGAKURA, AND RICHARD W. THIES[1]

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received November 8, 1982

EDWARD PIERS, HOWARD E. MORTON, ISAO NAGAKURA, and RICHARD W. THIES. Can. J. Chem. **61**, 1226 (1983).

Treatment of the β-iodo enones **4** and **26**–**28** with lithium (phenylthio)(2-vinylcyclopropyl)cuprate (**21**, mixture of epimers), followed by thermolysis (180°C, 30–45 min) of the initially formed β-(2-vinylcyclopropyl) enones, provided excellent yields of the seven-membered ring annulation products **25** and **30**–**32**, respectively. In similar fashion, the (*E*)-2-(iodomethylene)cycloalkanones **8** and **29** were transformed efficiently into the spiro-annulation products **34** and **35**, respectively. When compound **36** was treated with bromoform – sodium hydroxide in the presence of a phase-transfer catalyst, the dibromocyclopropane **37** was produced. The latter substance served as the starting material for a sequence of reactions (hydrolysis with hydrochloric acid in methanol, **37** → **38**; oxidation with pyridinium chlorochromate, **38** → **39**; Wittig reaction with methylenetriphenylphosphorane, **39** → **40**; reduction with zinc in acetic acid, **40** → **41**) culminating in the stereoselective formation of *cis*-1-bromo-2,2-dimethyl-3-vinylcyclopropane (**41**). On the other hand, treatment of compound **37** with *n*-butyllithium (ether, −90°C), followed by protonation of the presumed intermediate **43** and hydrolysis of the resultant product **44**, provided the bromo alcohol **45** in 70% yield. The latter substance was converted into *trans*-1-bromo-2,2-dimethyl-3-vinylcyclopropane (**47**). When the cuprate reagents **42** and **48** (prepared from the bromocyclopropanes **41** and **47**, respectively) were allowed to react with the iodo enones **4** and **26**, the β-(2-vinylcyclopropyl) α,β-unsaturated ketones **49**, **52**, **54**, and **56** were produced in high yields. The enone **49**, upon thermolysis in refluxing *n*-hexane, underwent facile Cope rearrangement to produce the annulation product **50** quantitatively. In contrast, the homolog **54** was notably resistant to [3,3]-sigmatropic rearrangement and, upon thermolysis in *o*-xylene, *o*-dichlorobenzene, or collidine at elevated temperatures produced, in varying ratios, the Cope rearrangement product **55** and the isomerization product **56**. Thermal rearrangement (*o*-dichlorobenzene, 220°C, sealed tube) of *trans*-3-(2,2-dimethyl-3-vinylcyclopropyl)-2-cyclohexen-1-one (**52**) provided the annulation product **51** (59% yield). In contrast, the corresponding homolog **56**, under very similar conditions, produced only a minor amount of the annulation product **55**. In this case, the major product (trienone **57**) was that resulting from a [1,5]-sigmatropic hydrogen migration (ratio of **55**/**57** ≈ 1:4).

EDWARD PIERS, HOWARD E. MORTON, ISAO NAGAKURA et RICHARD W. THIES. Can. J. Chem. **61**, 1226 (1983).

La réaction des β-iodoénones **4**, **26** et **28** avec le cuprate de (phénylthio)(vinyl-2 cyclopropyle) (**21**, mélange épimère) suivie de la thermolyse (180°C, 30–45 min) des β-(vinyl-2 cyclopropyle) énones formées initialement conduit avec d'excellents rendements à des produits d'annellation à 7 chaînons, **25**, **30** et **32** respectivement. D'une façon analogue on transforme efficacement les (*E*) (iodométhylène)-2 cycloalcanones **8** et **29** en des produits de spiro annellation **34** et **35** respectivement. Le composé **36** réagit avec un mélange de bromoforme – hydroxyde de sodium en présence d'un catalyseur de transfert de phase en donnant le dibromocyclopropane **37**. Ce dernier sert de produit de départ pour cette suite de réactions (hydrolyse avec l'acide chlorhydrique dans le méthanol, **37** → **38**; oxydation par le chlorochromate de pyridinium, **38** → **39**; réaction de Wittig avec le méthylènetriphénylphosphorane, **39** → **40**; réduction par le zinc dans l'acide acétique **40** → **41**) se terminant par la formation stéréosélective du bromo-1 diméthyl-2,2 vinyl-3 cyclopropane *cis* (**41**). D'autre part la réaction du composé **37** avec le *n*-butyllithium (éther à −90°C), suivie de la protonation de l'intermédiaire présumé **43** et de l'hydrolyse du produit résultant **44** permet d'accéder à l'alcool bromé **45** avec un rendement de 70%. On transforme cet alcool en bromo-1 diméthyl-2,2 vinyl-3 cyclopropane *trans* (**47**). Quand on fait réagir les réactifs cuprate **42** et **48** (préparés respectivement à partir des bromocyclopropanes **41** et **47**) avec les iodoénones **4** et **26** on obtient avec de bons rendements les β-(vinyl-2 cyclopropyl) cétones α,β insaturées **49**, **52**, **54** et **56**. Par thermolyse dans le *n*-hexane au reflux l'énone **49** subit facilement une transposition de Cope en donnant quantitativement le produit d'annellation **50**. L'homologue **54** au contraire résiste de façon marquée à la transposition sigmatropique [3,3] et par thermolyse dans le *o*-xylène, le *o*-dichlorobenzène où la collidine à température élevée donne dans des proportions variées le produit de transposition de Cope **55** et le produit d'isomérisation **56**. La transposition thermique (*o*-dichlorobenzène, 220°C en tube scellé) de la (diméthyl-2,2 vinyl-3 cyclopropyl)-3 cyclohexène-2 one-1 *trans* **52** conduit au produit d'annellation **51** (seulement 59%). Au contraire l'homologue correspondant **56** dans des conditions très semblables donne le produit d'annellation **55** en faible quantité seulement. Dans ce cas le produit majoritaire (la triénone **57**) provient d'une migration d'hydrogène sigmatropique [1,5] (le rapport de **55**/**57** est d'environ 1:4).

[Traduit par le journal]

Introduction

The thermal $_{\pi}2_s + _{\sigma}2_s + _{\pi}2_s$ (Cope) rearrangement of *cis*-1,2-divinylcyclopropane (**1**) to 1,4-cycloheptadiene (**2**) (eq. [1]) was first described by Vogel more than twenty years ago (1–3). This transformation is extremely facile and, in fact, in Vogel's early experiments, compound **1** was not isolated but rearranged to **2** under the conditions of its formation. Indeed, it was not until more than a decade later that **1** was isolated and shown to rearrange to **2** with a half-life of approximately 90 seconds at 35°C (4–6). In contrast to the *cis* isomer **1**, *trans*-1,2-divinylcyclopropane (**3**) is a stable, isolable compound. However, at elevated temperatures (e.g. 190°C), this substance

also rearranges cleanly and efficiently to 1,4-cycloheptadiene (**2**) (eq. [2]) (1, 3).

Since 1960, the 1,2-divinylcyclopropane → cycloheptadiene rearrangement has been studied extensively from a mechanistic point of view.[2] In general, it has been concluded that the rearrangement of **1** (and of other *cis*-1,2-divinylcyclopropanes) takes place in a concerted fashion via a boat-like transition state in which the two vinyl groups are folded back over the cyclopropane ring (see **A** in eq. [1]), thus providing cycloheptadiene systems in which the two double bonds have a (*Z*) geometry. On the other hand, thermal conversion of *trans*-1,2-divinylcyclopropanes into the corresponding 1,4-cycloheptadienes is thought to involve initial isomerization (usually rate-determining) into the *cis* isomer, followed by "normal" concerted rearrangement (e.g. **3** → **1** → [**A**] → **2**, eq. [2]).

During the first fifteen years after its discovery, the Cope rearrangement of 1,2-divinylcyclopropane systems had found only sporadic use in organic synthesis. However, more recently, this interesting transformation has been employed with increasing frequency by synthetic organic chemists, and its synthetic potential has begun to receive considerable recognition and attention (19–35).

Recently, we reported on a new five-membered ring annulation method based on the preparation and thermal vinylcyclopropane-to-cyclopentene rearrangement of β-cyclopropyl α,β-unsaturated ketones (36). For example (see eq. [3]), reaction of 3-iodo-2-cyclohexen-1-one (**4**) with lithium (phenylthio)(cyclopropyl)cuprate (**5**) provided, in 82% yield,

[3] [*c*-$C_3H_5CuSC_6H_5$]Li (**5**)

4 6

(1) 425°C
(2) basic alumina

7

3-cyclopropyl-2-cyclohexen-1-one (**6**). Thermolysis (~425°C) of the latter substance, followed by base-catalyzed isomerization of the crude product, produced the annulation product **7** in 88% yield. A subsequent paper (37) described the results of a similar study as applied to a new five-membered ring spiro-annulation procedure. Thus, for example, conversion of (*E*)-2-(iodomethylene)cyclohexanone (**8**) into the cyclopropyl enone **9** and thermolysis of the corresponding enol silyl ether

8 **5** 9

[4] (1) $LiN(i\text{-}Pr)_2$

10 gave, after acid hydrolysis of the crude thermolysate, the spiro enone **11** in ~40% overall yield (see eq. [4]).

The results summarized above, along with the fact that thermal rearrangements of 1,2-divinylcyclopropane systems are often very efficient, easily executed transformations, encouraged us to extend our studies to include the possibility of carrying out seven-membered ring annulation and spiro-annulation processes. More explicitly, it seemed eminently reasonable to propose that treatment of a cyclic β-iodo enone **12** (see eq. [5]) with a suitable (2-vinylcyclopropyl)cuprate reagent would provide the corresponding β-(2-vinylcyclopropyl) enone **13** which, upon successful subjection to Cope rearrangement, would give the annulation products **14** and/or (if R = H) **15**. A similar sequence of reactions employing a

cyclic α-(iodomethylene) ketone **16** as the starting material would produce, via the intermediate **17**, the spiroannulation product **18** (see eq. [6]). We report herein the results of some of our studies in this area.[3] In the accompanying paper (38) we describe the application of this new annulation method to a total synthesis of the bicyclic sequiterpenoid (±)-β-himachalene.

Results and discussion

(a) *Reaction of the β-iodo enones **4**, **8**, and **26–29** with lithium (phenylthio)(2-vinylcyclopropyl)cuprate (**21**). Preparation of the annulation products **25**, **30–32**, **34**, and **35** (see Scheme 1)*

Addition of a pentane solution of *tert*-butyllithium (3 mmol) to a cold (−78°C) ethereal solution of 1-bromo-2-vinylcyclopropane (**19**, 1.5 mmol, mixture of diastereomers, *cis*/*trans* 7:3),[4] followed by dilution of the resultant mixture (containing suspended lithium bromide) with tetrahydrofuran (THF), gave a solution of 2-vinylcyclopropyllithium (**20**),[5] which upon treatment with solid phenylthiocopper (44, 45) (1.5 mmol) produced a clear yellow solution of lithium (phenylthio)(2-vinylcyclopropyl)cuprate (**21**).[6] When the latter reagent was allowed to react (−78°C, 1 h; − 20°C, 1 h; 0°C, 1 h) with 1.0 mmol of 3-iodo-2-cyclohexen-1-one (**4**) (50), and the crude product was distilled (~65–90°C) under reduced pressure, a clear oil was obtained in 90% yield. Analysis of this material by gas–liquid chromatography (glc) and proton nuclear magnetic resonance (^{1}H nmr) spectroscopy indicated that it consisted of a mixture of substances which appeared to be the annulation products **24** (minor) and **25** (major), along with 3-(*trans*-2-vinylcyclopropyl)-2-cyclohexen-1-one (**23**).[7] Thus, it was clear that the initially formed *cis*-cuprate product **22** had, under the conditions of work-up and/or distillation, rearranged to the bicyclic dienone **24** which, in turn, had largely isomer-

[3]For preliminary reports, see refs. 20 and 25.

[4]This material was prepared by tri-*n*-butyltin hydride reduction (39, 40) of 1,1-dibromo-2-vinylcyclopropane (41, 42).

[5]For a coincident, independent preparation of this reagent (*cis*/*trans* = 1:4), see ref. 43.

[6]It appears that Hahn and Jones (46) were the first to report the use of a (cyclopropyl)copper reagent for the conjugate addition of a cyclopropyl group to an enone. For subsequent reports, which demonstrate the synthetic utility of these versatile reagents, see refs. 47, 48, 20, 21, 49, 25, 26, 29, and 36–38.

[7]The preparation, via a route quite different from that described herein, and thermal rearrangement of a mixture of compounds **22** and **23** had been reported previously by Marino and Kaneko (19). See also ref. 22.

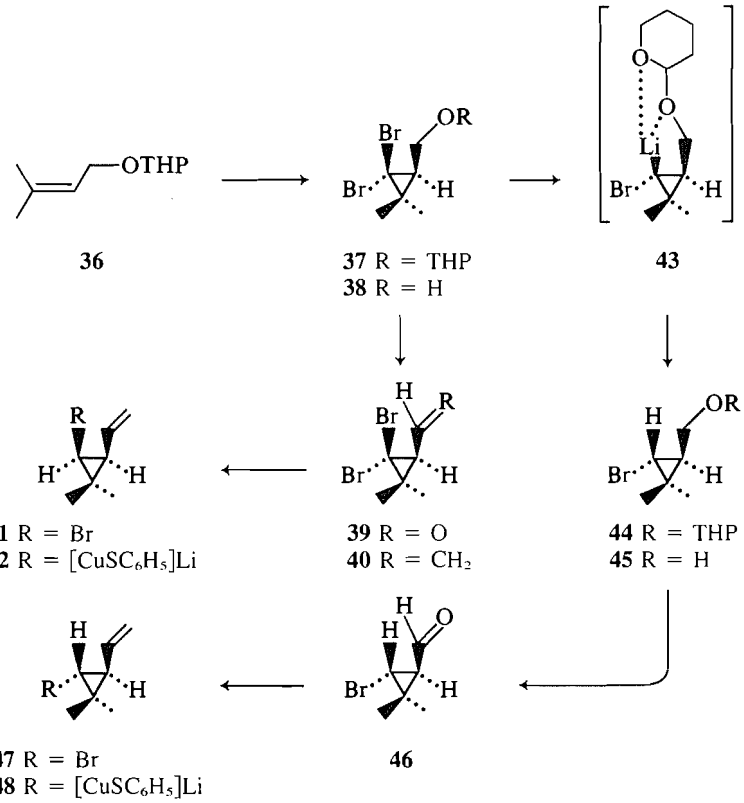

SCHEME 2

ized to the conjugated isomer **25**. In contrast, as would be expected, the product **23** derived from the *trans* cuprate reagent was stable to the work-up and distillation conditions. However, tedious separation of the mixture of products could be avoided, since the *trans* divinylcyclopropane **23** was known (19) to rearrange smoothly to the annulation product **25**. Thus, when the mixture of **23**, **24**, and **25** was heated at 180°C (neat, 30 min) and the resultant material was redistilled, the conjugated dienone **25** (19,22) was obtained in 75% overall yield.

Treatment of 3-iodo-2-methyl-2-cyclohexen-1-one (**26**) (50) with lithium (phenylthio)(2-vinylcyclopropyl)cuprate (**21**) under conditions similar to those described above for the β-iodo enone **4**, followed by direct thermolysis (180°C) of the initially formed products, provided, in 82% yield, the bicyclic dienone **30**.[8] In similar fashion, the β-iodo enones **27** and **28** could be converted smoothly and efficiently into the annulation products **31** (80%) and **32**[9] (84%), respectively.

Application of the reactions outlined above to the (*E*)-2-(iodomethylene)cycloalkanones **8** and **29** also proved successful. Thus, treatment of compound **8** with 1.5 equivalents of the cuprate reagent **21**, followed by thermal rearrangement of the resultant products **33**, produced spiro-[5.6]dodeca-7,10-dien-1-one (**34**) in 77% yield. Similarly, the (iodomethylene)cyclopentanone **29** was converted into the spiro dienone **35** in 64% yield.

It is clear from the results summarized above that the originally proposed annulation sequences (eqs. [5] and [6]) are indeed viable processes which are easily and smoothly executed. Since the β-iodo enones (**4**, **8**, **26**–**29**) are conveniently prepared from the corresponding β-dicarbonyl compounds (50) and the cuprate reagent **21** is obtained via a separate synthetic route, the overall annulation sequences are short, convergent, and efficient. Furthermore, although separation of *cis*- and *trans*-1-bromo-2-vinylcyclopropane (**19**) is possible (22, 29) and, thus, stereochemically homogeneous lithium (phenylthio)(2-vinylcyclopropyl)cuprate reagents can be prepared (29), the sequences outlined above do not require these (rather tedious) experimental operations. In each case, both the β-(*cis*-2-vinylcyclopropyl) α,β-unsaturated ketone and the corresponding *trans* isomer rearrange smoothly to provide the same annulation product.

(b) *Synthesis of* cis-*(41) and* trans-*1-bromo-2,2-dimethyl-3-vinylcyclopropane (47), and their conversion into the cuprate reagents 42 and 48, respectively (see Scheme 2)*

In order to obtain information regarding the effect of structural variations on the course of the thermal rearrangement of β-(2-vinylcyclopropyl) enones and to produce annulation products which might prove useful as synthetic precursors for natural product syntheses, we decided to extend the present study to include the preparation and use of (2-vinylcyclopropyl)cuprate reagents more highly functionalized than **21**. This section of the paper outlines the stereoselective preparation of *cis*-(**41**) and *trans*-1-bromo-2,2-dimethyl-3-vinylcyclopropane (**47**), and their transformation into the highly substituted (cyclopropyl)cuprate reagents **42** and **48**, respectively. The next section describes the reactions of the latter species with β-iodocyclohexenones and the thermal rearrangement of the resultant products.

Treatment of the tetrahydropyranyl ether of 3-methyl-2-

[8]An alternative preparation of 2-methyl-3-(2-vinylcyclopropyl)-2-cyclohexen-1-one and its rearrangement to compound **30** were reported independently by Wender and Filosa (22).

[9]For an alternative method of preparation of 2-methyl-3-(2-vinylcyclopropyl)-2-cyclopenten-1-one and its conversion into compound **32**, see refs. 21 and 22. These studies were coincident with those described herein.

buten-1-ol (**36**) with bromoform and aqueous sodium hydroxide in the presence of a phase-transfer reagent (51) provided the dibromocyclopropane **37** in 72% yield. The latter material served as a convenient starting material for the synthesis of both of the diasteromeric monobromocyclopropanes **41** and **47**. Thus, hydrolysis of **37** with hydrochloric acid in methanol, followed by oxidation of the resultant crystalline alcohol **38** with pyridinium chlorochromate in dichloromethane (52) gave, in 74% overall yield, the aldehyde **39**. When the latter substance was allowed to react with methylenetriphenylphosphorane in THF at room temperature, 1,1-dibromo-2,2-dimethyl-3-vinylcyclopropane (**40**) was obtained in 61% yield. Although this material could be distilled, it was quite unstable and tended to produce small amounts of decomposition products, especially if the distillation was carried out at temperatures above ~70°C. Therefore, a pure sample of **40** was difficult to obtain, and, typically, the undistilled product was used directly for the next synthetic step.

Reduction of compound **40** with zinc in acetic acid (53) at room temperature for 3 h afforded, in 66% yield, a mixture of *cis*-(**41**) and *trans*-1-bromo-2,2-dimethyl-3-vinylcyclopropane (**47**), in a ratio of approximately 20:1. This reaction was carried out a number of times and, in each case, compound **41** was the greatly predominant product. Presumably, since the less hindered bromine atom in **40** was preferentially removed in the reduction process, the stereoselective nature of the conversion was at least partially due to steric factors. However, it should be noted that the ratio of the two products **41** and **47** varied somewhat from one experiment to another. Although the reasons for this phenomenon were not fully delineated, it appeared that reaction time was a contributing factor. Shorter reaction times gave, in addition to some starting material,[10] a somewhat higher yield of products containing proportionately more of the *trans* product **47**, while longer reaction times produced, in decreased yields, a product which contained very little if any of compound **47**. Thus, it appears that further reductive removal of the bromine atom from **47**, to produce the highly volatile and therefore unisolated 1,1-dimethyl-2-vinylcyclopropane, occurred at a rate faster than (further) reduction of the more hindered bromine atom in **41**. In any case, the synthetically satisfying, highly stereoselective production of the *cis* monobromocyclopropane **41** could be accomplished very readily.[11]

Treatment of a cold (−90°C) ethereal solution of the tetrahydropyranyl ether **37** with 1 equivalent of *n*-butyllithium, followed by protonation of the resultant intermediate lithio carbenoid (54) and acid hydrolysis of the initially formed product **44**, provided (70% yield) a single bromo alcohol to which was assigned structure **45**. The lithium–halogen exchange reaction would be expected to involve the bromine atom which was *cis* to the group bearing the tetrahydropyranyl ether function, thus giving rise to a stabilized intermediate represented by **43**. Protonation of this species would then afford the observed product **44**.

Oxidation (pyridinium chlorochromate, dichloromethane (52)) of the alcohol **45** gave the corresponding aldehyde **46** which, upon reaction with methylenetriphenylphosphorane in THF, was converted into *trans*-1-bromo-2,2-dimethyl-3-vinylcyclopropane (**47**) (63% overall yield).

[10]The rate of this heterogeneous reduction reaction varied somewhat with the nature and source of the zinc metal.

[11]Reduction of compound **40** with tri-*n*-butyltin hydride afforded the products **41** and **47** in a ratio of approximately 3.7:1, respectively.

The ^{1}H nmr spectra of the epimeric substituted cyclopropanes **41** and **47** fully corroborated the stereochemical assignments. In the spectrum of compound **41**, the proton geminal to the bromine atom appeared as a doublet (δ 3.05) with a coupling constant of 7.5 Hz, while the corresponding proton in the epimer **47** gave rise to a doublet (δ 2.80) with J = 4 Hz. It is well known (55) that coupling constants associated with *cis* vicinal protons on cyclopropane systems are larger than those related to corresponding *trans* protons and, therefore, the stereochemical assignments appear to be secure.

Treatment of each of the bromocyclopropanes **41** and **47** with 2 equivalents of *tert*-butyllithium (ether, −78°C), followed by reaction of the resultant lithio cyclopropanes with phenylthiocopper (44, 45) (ether – THF, −20°C), afforded yellow-brown solutions of the corresponding cuprate reagents **42** and **48**, respectively. The latter species were employed in the next phase of the present study.

(c) *Reaction of the cuprate reagents **42** and **48** with the β-iodo enones **4** and **26**. Thermal rearrangement of the resultant products **49**, **52**, **54**, and **56** (see Scheme 3)*

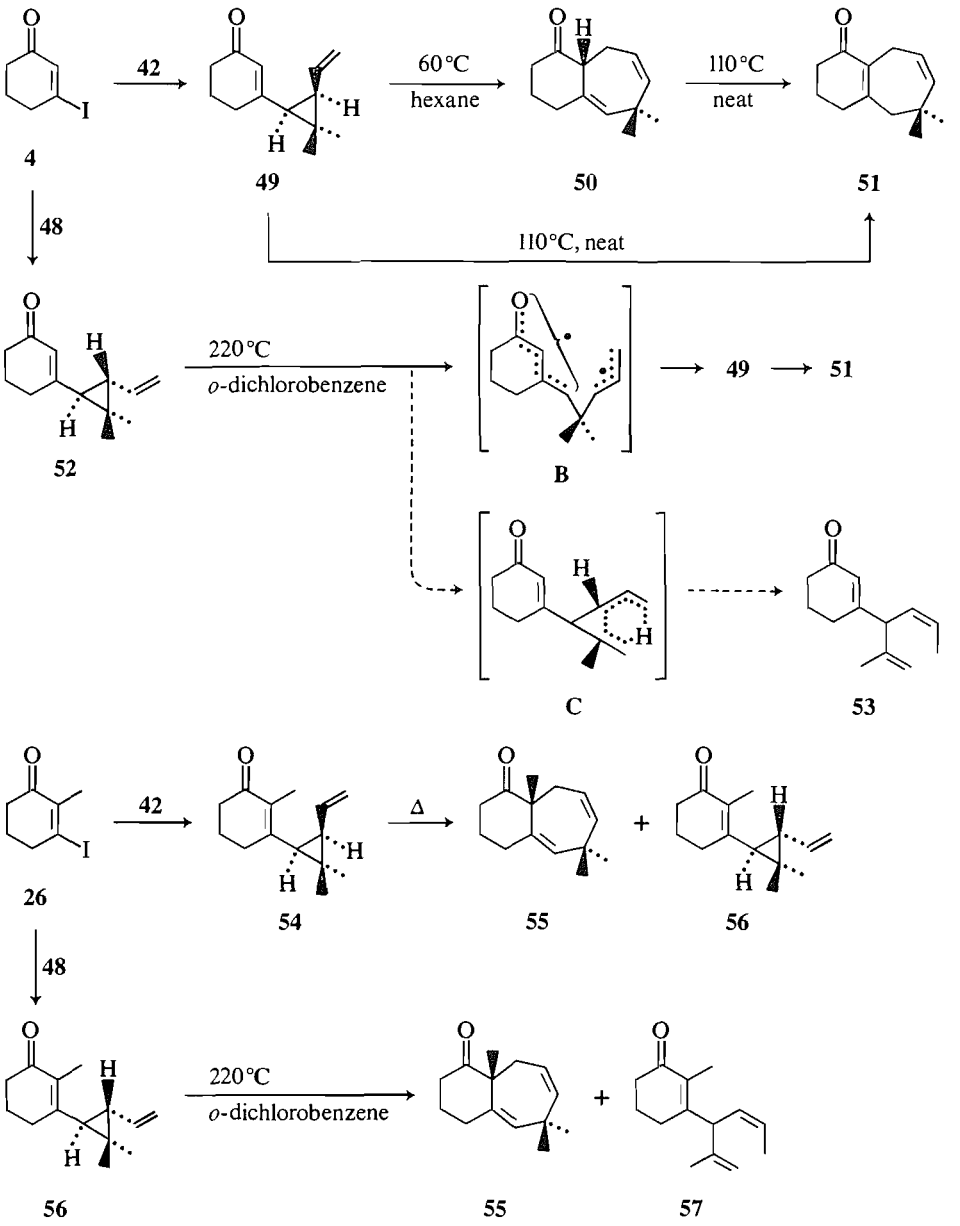
When 3-iodo-2-cyclohexen-1-one (**4**) (50) was allowed to react (−78°C → room temperature, 2.5 h) with the cuprate reagent **42**, the expected substituted cyclohexenone **49** was obtained in 88% yield. The latter substance was quite unstable and already at room temperature underwent slow bond reorganization to give the Cope rearrangement product **50** (*vide infra*). However, samples of **49** containing only small amounts of **50** could be obtained and these exhibited spectral data in full accord with those expected for the enone **49**.

Treatment of the β-iodo enone **4** with the *trans* cuprate reagent **48**, under conditions identical with those employed for the conversion of **4** into **49**, provided a nearly quantitative yield of compound **52**. In similar fashion, reaction of 3-iodo-2-methyl-2-cyclohexen-1-one (**26**) (50) with the two cuprate reagents **42** and **48** produced the highly substituted cyclohexenones **54** and **56**, respectively. It is interesting to note that even though the copper-bearing carbon atom of the *cis* cuprate reagent **42** is quite hindered, the reaction of this species with the β-iodo enone **26** to produce the sterically congested vinylcyclopropane system in **54** is smooth and efficient (76% yield).

As mentioned above, the enone **49** undergoes rearrangement slowly at room temperature to give the bicyclic dienone **50**. When a solution of **49** in *n*-hexane (bp 69°C) was refluxed for 4 h, product **50** was produced in essentially quantitative yield. Furthermore, subjection of neat samples of **49** and **50** to brief (~10–15 min) heating at 110°C provided, in each case, a high yield of the conjugated enone **51**. Thus, as one might expect, the [3,3]-sigmatropic rearrangement of **49** is a very facile process.

With respect to the thermolysis of the *trans*-divinylcyclopropane **52**, it is pertinent to note that, in theory, this substance can undergo bond reorganization via one (or both) of two alternative pathways. That is to say, "normal" Cope rearrangement could occur to provide, presumably by way of the stabilized diradical **B** and the *cis* isomer **49**, the same product (dienone **51**) as that derived from direct thermolysis of **49**. On the other hand, a [1,5]-sigmatropic hydrogen shift[12] from the appropriate cyclopropyl methyl group to the terminal carbon of

[12]For reviews regarding this type of rearrangement process, see refs. 8 and 56.



SCHEME 3

the vinyl function (via a transition state which might be represented by **C**), would produce the trienone **53**. In the event, thermolysis of compound **52** in *o*-dichlorobenzene (sealed tube, 220°C, 14 h) afforded very largely a single product, the bicyclic dienone **51** (59% yield of isolated, distilled material). Analysis of the initially obtained reaction mixture by glc and thin-layer chromatography (tlc) indicated that the product **51** was accompanied by only small amounts of unidentified compounds, along with traces of starting material. Thus, in this case, the Cope rearrangement pathway (**52** → [**B**] → **49** → **51**) is energetically favored over the alternative process involving a [1,5]-sigmatropic hydrogen shift (**52** → [**C**] → **53**).

Compared to the enone **49**, the homolog **54** was found to be remarkably stable and to exhibit notable resistance to undergoing the Cope rearrangement. In fact, when compound **54** was subjected to thermolysis at elevated temperatures, "simple" isomerization to the *trans* isomer **56** was competitive with sigmatropic rearrangement to **55**. For example, when a solution of **54** in *o*-xylene (bp 144°C) was refluxed for 48 h, the two products **55** and **56**[13] were produced in a ratio of ~2:1. On the other hand, subjection of **54** to thermolysis in a higher boiling solvent (*o*-dichlorobenzene, bp 179°C, reflux 3 h), provided compounds **55** and **56**[13] in a ratio of about 0.8:1, respectively.

A more detailed investigation of the thermolysis of enone **54** in *o*-xylene revealed that this was a frustratingly capricious reaction, since the ratio of the two products **55** and **56** varied significantly (~1.1:1 to ~2.7:1) from one experiment to another. Although the reasons underlying this difficulty have not been investigated thoroughly, it appeared that the presence of small amounts of the iodo enone **26** in the starting material **54** resulted in the production of mixtures containing relatively more of the isomerization product **56**. Perhaps the presence of trace amounts of hydrogen iodide was responsible for catalyzing the conversion of **54** into **56**. In any case, it was found that the relative amounts of the Cope rearrangement product **55**

[13]Under these conditions, the *trans*-divinylcyclopropane **56** was stable.

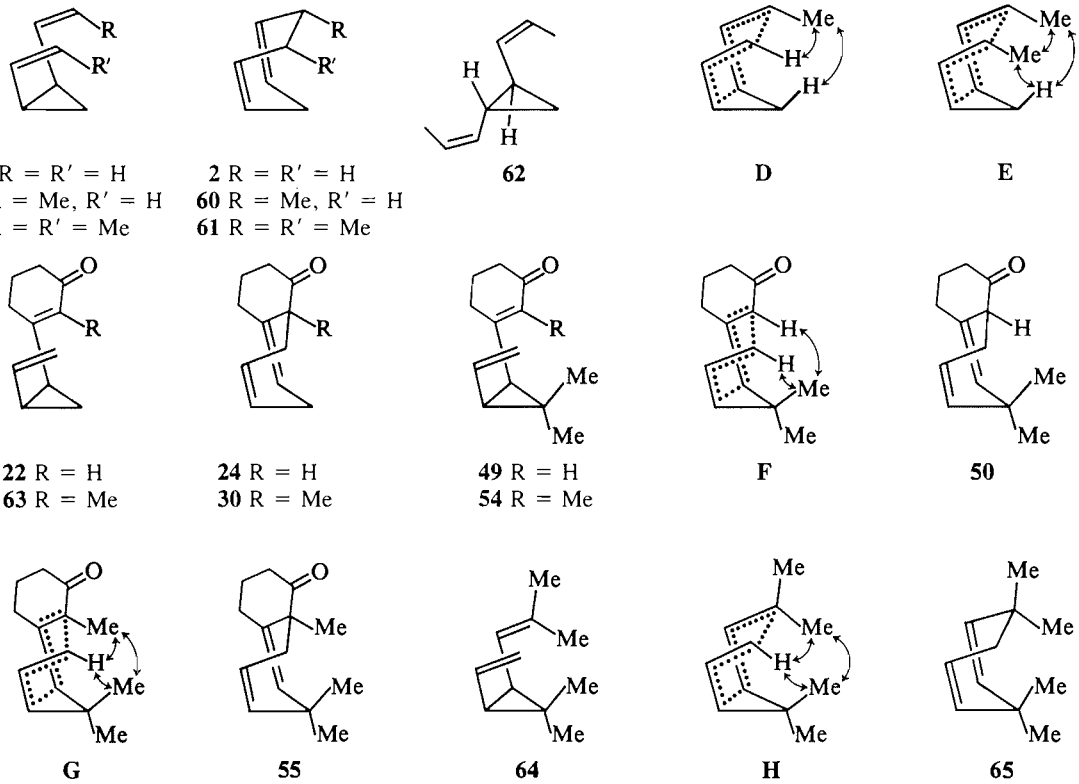

CHART 1

were greater, and the thermolysis results were somewhat more consistent, when care was taken to ensure that the starting material **54** was devoid of the iodo enone **26**, and when **54** was washed through basic alumina just prior to thermolysis.

Thermal rearrangement of the enone **54** in the weakly basic solvent collidine was also investigated. These reactions were carried out at 140–150°C for 42–44 h. Although the ratio of the two products **55** and **56** (~1.9:1 to ~2.4:1, respectively) still varied somewhat from one experiment to another, the results were more consistent than those obtained from thermolysis in *o*-xylene. Application of this procedure to the rearrangement of 10 mmol of compound **54** produced the annulation product **55** and the isomerization product **56** in isolated yields of 49 and 21%, respectively.

Subjection of the *trans*-divinylcyclopropane **56** to thermolysis (*o*-dichlorobenzene, sealed tube, 220°C, 16 h) under conditions similar to those used for the structurally similar substrate **52** produced a mixture of products which consisted largely of two components in a ratio of approximately 4:1. The minor product was shown to be the dienone **55**, while the major component was identified as the trienone **57**. Thus, in this case, the process involving a [1,5]-sigmatropic hydrogen migration is energetically more favorable than the alternative Cope rearrangement pathway.

It is appropriate to comment briefly regarding the relative ease of Cope rearrangement of the β-(*cis*-2-vinylcyclopropyl) enones **22**, **63**, **49**, and **54** and to compare these results with some related observations recorded in the literature (see Chart 1). It is known that the rate of rearrangement of *cis*-1,2-divinylcyclopropanes is affected quite dramatically by the presence of alkyl substituents on the terminal carbon atoms of the vinyl groups, particularly when these have a *cis* orientation. For example, it has been shown (16) that, at 40°C, the transformation of *cis*-2-(*cis*-1-propenyl)-1-vinylcyclopropane (**58**) into 6-methyl-1,4-cycloheptadiene (**60**) occurs at a rate ~5800 times slower than the conversion of **1** into **2**. Furthermore, the dimethyl analog **59** fails to undergo sigmatropic rearrangement to the dimethylcycloheptadiene **61**. Rather, at elevated temperatures, reversible isomerization takes place and an equilibrium mixture of **59** and **62** is produced (9, 16). These notable rate differences have been attributed to steric factors. Thus, it has been proposed (16) that the conversion of **58** into **60** proceeds by way of a transition state which is destabilized (relative to that for the transformation **1** → **2**) mainly by steric repulsion between the propenyl methyl group and the *cis* cyclopropyl proton ("methyl–ring interaction" (16), see **D**).[14] On the other hand, the transition state for the [3,3]-sigmatropic rearrangement of compound **59** would be destabilized by two such interactions, as well as by steric repulsion between the two methyl groups ("methyl–methyl interaction" (16), see **E**].[15] In this case, the combination of these deactivating features results in "simple" isomerization being energetically favored over the Cope rearrangement process.

Even though compound **58** undergoes bond reogranization at a rate considerably slower than **1**, both of these substances rearrange smoothly to produce the products **60** and **2**, respectively. Therefore, it is not surprising to find that thermolysis of the structurally analogous enones **22** and **63** results in the efficient production of the corresponding bicyclic dienones **24** and **30**, respectively.

If one assumes that [3,3]-sigmatropic rearrangement of the

[14]The deactivating energy ($\Delta\Delta G^{\ddagger}$) of the methyl-ring interaction has been estimated to be 4.55 kcal/mol. The other steric repulsion indicated in **D** ("methyl–hydrogen interaction") is, apparently, quite small, corresponding to ~0.84 kcal/mol (16).

[15]The $\Delta\Delta G^{\ddagger}$ value for the methyl–methyl interaction has been estimated to be 1.03 kcal/mol (16).

CHART 2

enone **49** proceeds via the transition state **F**, it can be seen that destabilization (relative to the transition state involved in the conversion of **22** into **24**) would be caused by steric repulsions between one of the cyclopropyl methyl groups and two of the vinyl protons (see **F**). At first sight, it would appear that these repulsions are similar to the methyl–ring interactions in transition state **E** and since the destabilizing effect of the methyl–methyl interaction (present in **E**, but absent in **F**) is quite small[15] the ease with which the enone **49** undergoes Cope rearrangement is surprising. However, it should be emphasized that in compound **49**, one of the "vinyl" groups is incorporated into a cyclohexenone ring and, thus, the substitution pattern of **49** is quite different from that of **59**. Certainly, the possibility that the conjugative effect of the carbonyl group in **49** influences the rate and/or mechanism of the reaction cannot be discounted.[16]

Again assuming a "normal" concerted mechanism, the Cope rearrangement of the highly substituted divinylcyclopropane **54** would proceed by way of the transition state **G**. Of the steric repulsions present in this species (see **G**), molecular models clearly show that the one involving the two methyl groups is particularly severe. Thus, on this basis, it is possible to rationalize, in a qualitative way, the striking difference between the relative ease of [3,3]-sigmatropic rearrangement of compounds **49** and **54** (compare **F** and **G**). However, it should be noted that the substituted divinylcyclopropane **64**, upon thermolysis at 180°C, fails to undergo Cope rearrangement to **65**. Instead, as in the case of substrate **59**, only reversible *cis* and *trans* isomerization is observed (58). Therefore, since the transition states for the conversions **54** → **55** and **64** → **65** would experience the same steric repulsions (see **G** and **H**), the fact that **54** undergoes [3,3]-sigmatropic rearrangement at all is, again, unexpected.

Conclusion

The results reported in this paper clearly demonstrate the viability of effecting seven-membered ring annulation and spiro-annulation via the preparation and thermolysis of β-(2-vinylcyclopropyl) α,β-unsaturated ketones. Indeed, it is appropriate to mention explicitly that this general method has been applied elegantly by Wender *et al.* to the synthesis of the sesquiterpenoids (±)-damsinic acid and (±)-confertin (27) and to the preparation of an intermediate containing the basic carbon skeleton found in the tigliane, daphnane, and ingenane families of diterpenoids (32). Furthermore, as mentioned previously, the accompanying paper (38) describes the details of a synthesis of the sesquiterpenoid (±)-β-himachalene via a route in which this new method played a key role.

We had mentioned earlier that one of the goals of the present study was to prepare substances which might prove useful as precursors for natural product syntheses. In this connection, the successful Cope rearrangement of the highly substituted divinylcyclopropanes **49** and **54** was particularly gratifying, since, for example, the annulation product **55** could, in theory, serve as a suitable intermediate for the synthesis of the well-known sesquiterpenoids (±)-longifolene (**67**), (±)-β-longipinene (**70**), and (±)-α-longipinene (**71**) (see Chart 2). Thus, subjection of **55** to a sequence of reactions involving at some stage bond formation between the appropriate carbon centers (* in **55**) would provide the tricyclic ketone **66**, a well-known precursor for the preparation of the natural product **67**. On the other hand, conversion of **55** into **68** (1,2-ketone transposition), followed by appropriate synthetic manipulations, including bond formation between the carbon atoms marked * in **68**, would produce the ketone **69**. The latter substance has been converted into the two longipinenes **70** and **71**.

Experimental

General[17]

Melting points and distillation temperatures are uncorrected. Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer, while infrared (ir) spectra were taken on Perkin–Elmer models 710 or 710B spectrophotometers. Proton nuclear magnetic resonance (^{1}H nmr) spectra (deuterochloroform solution) were measured using Varian Associates spectrometers, models HA-100 or XL-100. Signal positions are given in δ units, with tetramethylsilane as the internal standard. High resolution mass spectrometric measurements were recorded on a Kratos MS-50 mass spectrometer. Gas–liquid chro-

[16]It is interesting to point out that a conjugative substituent at C-1 of 1,5-hexadienes has been predicted to *decrease* the rate of Cope rearrangement of these substances (57). How this prediction relates to the work reported herein is, at least to us, unclear.

[17]This general section is applicable to the accompanying paper (38) as well as to the present paper.

matography (glc) was carried out with a Hewlett–Packard model 5832A gas chromatrograph (analytical) or with a Varian Aerograph model 90-P instrument (preparative). Thin-layer chromatography was carried out on commercial silica gel plates (Eastman Chromagram Sheet, No. 13181, analytical) or on 20 × 20 cm glass plates coated with 0.9 mm of silica gel (E. Merck, Silica Gel 60, preparative). Column chromatography was carried out on 70–230 mesh silica gel (E. Merck) while flash chromatography was accomplished using 230–400 mesh silica gel (E. Merck) according to the procedure developed by Still *et al.* (59).

Solutions of methyllithium, *n*-butyllithium, and *tert*-butyllithium, purchased from the Alfa Division of Ventron Corporation, were standardized by the method of Gilman and Cartledge (60). Bromoform and methyl iodide were passed through a short column of basic alumina (activity I) just prior to use. Tetrahydrofuran (THF) and ether were distilled under an atomsphere of nitrogen from sodium benzophenone ketyl. Diisopropylamine and hexamethylphosphoramide were distilled from calcium hydride and barium oxide, respectively, and were stored over molecular sieves. Dichloromethane was distilled from phosphorous pentoxide. *o*-Xylene was distilled, under an atmosphere of nitrogen, from sodium metal, while collidine and *o*-dichlorobenzene were freshly distilled before use.

Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver, B.C.

*Reaction of the β-iodo enones **4**, **8**, and **26–29** with lithium (phenylthio)(2-vinylcyclopropyl)cuprate (**21**). Preparation of the annulation products **25**, **30–32**, **34**, and **35***

A flame-dried 25 mL three-necked flask equipped with a bent side-arm tube containing solid phenylthiocopper (44, 45) (for the β-iodo enones **4**, **8**, **27**, and **29**: 260 mg, 1.5 mmol; for the β-iodo enones **26** and **28**: 345 mg, 2 mmol) was evacuated (vacuum pump) and filled with nitrogen (process repeated 3 times). A solution of 1-bromo-2-vinylcyclopropane (**19**, *cis*/*trans* ~7:3; for **4**, **8**, **27**, and **29**: 220 mg, 1.5 mmol; for **26** and **28**: 294 mg, 2 mmol) in anhydrous ether (3 mL) was added (syringe) to the flask via a septum cap. After the solution had been cooled to −78°C, it was treated with a solution of *tert*-butyllithium in pentane (1.2 *M*; for **4**, **8**, **27**, and **29**: 2.5 mL, 3 mmol; for **26** and **28**: 3.34 mL, 4 mmol), and the resulting mixture was stirred at −78°C under an atmosphere of nitrogen for 1 h. During this time, a white precipitate (lithium bromide) appeared. Successive addition of dry THF (10 mL, the white precipitate dissolved) and the phenylthiocopper (rotation of the bent tube) gave a yellow suspension which, when warmed to −20°C and then stirred for 10 min, produced a clear yellow solution of the cuprate reagent **21**. After this solution had been recooled to −78°C, a solution of the appropriate β-iodo enone (**4**, **28**, **29**: 222 mg, 1 mmol; **8**, **26**: 236 mg, 1 mmol; **27**: 208 mg, 1 mmol) in 2 mL of dry THF was added and the resultant reaction mixture was stirred at −78°C for 1 h, at −20°C for 1 h, and at 0°C for 1 h (**4**, **8**, **27**, and **29**) or 2 h (**26** and **28**). During this time the color of the reaction mixture changed from yellow to brown. Methanol (1 mL) and ether (10 mL) were added and the suspension thus obtained was filtered through a short column of silica gel (~10 g). The column was eluted with ether (200 mL) and the combined eluate was concentrated under reduced pressure. Distillation (~60–90°C/~0.5 Torr) of the residual material provided a clear, colorless oil which was subjected to thermolysis (neat, 180°C, 30–45 min) under an atmosphere of nitrogen. Distillation of the thermolysate provided the final product, which, in each case, consisted very largely or totally of one compound. In those cases in which the product was accompanied by small amounts of unidentified impurities, a sample of the desired annulation product was collected by preparative glc. The following products were obtained via this general procedure.

*Dienone **25*** (75% from **4**); uv (methanol) λ_{max}: 246 nm (ε 7 850); ir (film): 1665, 1638 cm^{-1}; ^1H nmr δ: 1.80–2.12 (m, 2H), 2.12–2.78 (m, 8H), 3.04–3.32 (broad s, 2H), 5.40–5.76 (m, 2H). *Exact Mass* calcd. for $C_{11}H_{14}O$: 162.1044; found: 162.1039.

*Dienone **30*** (82% from **26**); ir (film): 1710, 1665, 1635 cm^{-1}; ^1H nmr δ: 1.26 (s, 3H), 1.4–2.8 (diffuse m, 10H), 5.50 (broad t, 1H, J = 5 Hz), 5.64–6.00 (m, 2H). *Exact Mass* calcd. for $C_{12}H_{16}O$: 176.1200; found: 176.1213.

*Dienone **31*** (80% from **27**); uv (methanol) λ_{max}: 236 nm (ε 9 650); ir (film): 1700, 1645 cm^{-1}; ^1H nmr δ: 2.22–2.62 (m, 8H), 2.86–3.04 (broad s, 2H), 5.64–6.02 (m, 2H). *Exact Mass* calcd. for $C_{10}H_{12}O$: 148.0887; found 146.0886.

*Dienone **32*** (84% from **28**); ir (film): 1742, 1685 cm^{-1}; ^1H nmr δ: 1.14 (s, 3H), 2.18–2.70 (diffuse m, 6H), 2.80–2.98 (unresolved m, 2H), 5.48 (broad t, 1H, $J \approx 4$ Hz), 5.60–5.75 (m, 2H). *Exact Mass* calcd. for $C_{11}H_{14}O$: 162.1044; found: 162.1047.

*Spiro dienone **34*** (77% from **8**); ir (film): 1710, 1660, 1645 cm^{-1}; ^1H nmr δ: 1.60–2.04 (m, 6H), 2.12–2.72 (m, 4H), 2.72–2.94 (m, 2H), 5.52–5.92 (m, 4H). *Exact Mass* calcd. for $C_{12}H_{16}O$: 176.1200; found: 176.1215.

*Spiro dienone **35*** (64% from **29**); ir (film): 1738, 1640 cm^{-1}; ^1H nmr δ: 1.74–2.70 (diffuse m, 8H), 2.76–3.02 (m, 2H), 5.34–5.96 (m, 4H). *Exact Mass* calcd. for $C_{12}H_{14}O$: 162.1044; found: 162.1043.

*Tetrahydropyranyl ether of (2,2-dibromo-3,3-dimethylcyclopropyl)-methanol (**37**)*

To a mechanically stirred mixture of the tetrahydropyranyl ether of 3-methyl-2-buten-1-ol (**36**, 6.8 g, 40 mmol), benzyltriethylammonium chloride (0.16 g, 0.7 mmol), ethanol (0.32 mL, 5.5 mmol), and bromoform (21 g, 83 mmol) was added slowly 40 mL of 50% aqueous sodium hydroxide. After a period of 4 h, the dark reaction mixture was diluted with water and extracted three times with ether. The combined ether extract was washed sequentially with water, 1 *N* hydrochloric acid, water, saturated aqueous sodium bicarbonate, and brine, and then was dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 100–118°C/0.3 Torr) of the residual material gave 9.4 g of a viscous oil. Analysis of this material by spectroscopy (ir, ^1H nmr) and glc indicated that it was composed of a mixture of the desired tetrahydropyranyl ether **37**, along with some of the corresponding alcohol **38** (ratio ≈ 84:16, respectively).[18] Therefore, a mixture of this material, dihydropyran (4.5 g), and *p*-toluenesulfonic acid monohydrate (80 mg) was stirred at room temperature for 4 h. The mixture was diluted with ether and the resultant solution was passed through a short column of basic alumina (Woelm, activity III). The column was washed with additional portions of ether. Removal of the solvent from the combined eluate, followed by bulb-to-bulb distillation of the residual oil, gave 9.9 g (72%) of compound **37**; ^1H nmr δ: 1.23, 1.40 (s, s, 3H each), ~1.1–2.1 (diffuse m, 7H), 3.32–4.04 (diffuse m, 4H), 4.52–4.74 (m, 1H). *Anal.* calcd. for $C_{11}H_{18}Br_2O_2$: C 38.62, H 5.30; found: C 38.90, H 5.41.

*(2,2-Dibromo-3,3-dimethylcyclopropyl)methanol (**38**)*

To a stirred solution of the tetrahydropyranyl ether **37** (6.8 g, 19.9 mmol) in 50 mL of methanol, under an atmosphere of nitrogen, was added 10 mL of 1 *N* hydrochloric acid. After the resultant mixture had been stirred at room temperature overnight, most of the methanol was removed under reduced pressure. The remaining material was diluted with water and extracted thoroughly with ether. The combined extract was washed sequentially with water, saturated aqueous sodium bicarbonate, and brine, and then was dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 60–90°C/0.15 Torr) of the residual oil gave 4.6 g (90%) of the alcohol **38** as a viscous oil which solidified on standing (refrigerator). Recrystallization of a sample of this material from pentane containing a small amount of ether provided colorless crystals which exhibited mp 35.5°C; ir ($CHCl_3$): 3630, 3470 cm^{-1}; ^1H nmr δ: 1.29, 1.45 (s, s, 3H each), 1.62 (t, 1H, J = 7 Hz), 1.89 (s, 1H), 3.77 (d, 2H, J = 7 Hz). *Anal.* calcd. for $C_6H_{10}Br_2O$: C 27.94, H 3.91; found: C 28.07, H 3.89.

[18]The amount of alcohol **38** present in the mixture varied somewhat from one experiment to another. Clearly, if **38** was the required product (see next experiment), the dihydropyran-*p*-toluenesulfonic acid treatment was not carried out.

For personal use only.

*2,2-Dibromo-3,3-dimethylcyclopropanecarboxaldehyde (**39**)*

To a stirred suspension of pyridinium chlorochromate (8.37 g, 38.6 mmol) in 190 mL of dry dichloromethane was added rapidly a solution of the alcohol **38** (4.97 g, 19.3 mmol) in 10 mL of the same solvent. The dark mixture was stirred at room temperature for 2 h. Ether (~800 mL) was added and the resultant mixture was passed through a short column of basic alumina (Woelm, activity III). The column was washed with additional volumes of ether. Removal of the solvent from the combined eluate, followed by distillation (air-bath temperature 67–81°C/0.4 Torr) of the residual material provided 4.17 g (84%) of the aldehyde **39** as a colorless oil which crystallized on standing (refrigerator) and exhibited mp ~27.5°C; ir (film): 1705 cm^{-1}; ^1H nmr δ: 1.54, 1.61 (s, s, 3H each), 2.10 (d, 1H, J = 5.5 Hz), 9.38 (d, 1H, J = 5.5 Hz). The 2,4-dinitrophenylhydrazone derivative of the aldehyde **39** was recrystallized from methanol and exhibited mp 112–113°C (dec.). *Anal.* calcd. for $C_{12}H_{12}Br_2N_4O_4$: C 33.05, H 2.77, N 12.85; found: C 33.28, H 2.80, N 12.82.

*1,1-Dibromo-2,2-dimethyl-3-vinylcyclopropane (**40**)*

To a cold (−78°C) stirred suspension of methyltriphenylphosphonium bromide (6.24 g, 17.6 mmol) in 80 mL of dry THF under an atmosphere of nitrogen was added a solution of *n*-butyllithium in hexane (6.5 mL, 2.7 *M*, 17.5 mmol). The mixture was allowed to warm to room temperature and stirred for an additional 30 min. A solution of the aldehyde **39** (4.08 g, 16 mmol) in 5 mL of dry THF was added, the reaction mixture was stirred at room temperature for 1 h, and then was poured into 400 mL of pentane. The resultant mixture was filtered through a short column of silica gel (Woelm, activity III) and the column was eluted with further volumes of pentane. Removal of the solvents from the combined eluate, followed by distillation (air-bath temeprature 52–59°C/0.8 Torr) of the residual oil gave 2.48 g (61%) of the substituted vinylcyclopropane **40** as a colorless oil; ir (film): 3100, 1635, 905 cm^{-1}; ^1H nmr δ: 1.27, 1.45 (s, s, 3H each), 1.93–2.11 (m, 1H), 5.19–5.77 (m, 3H). This material was somewhat unstable and, therefore, it was used directly for the next step of the synthetic sequence.

cis-*1-Bromo-2,2-dimethyl-3-vinylcyclopropane (**41**)*

To a vigorously stirred solution of the substituted dibromocyclopropane **40** (5.7 g, 22.4 mmol) in 53 mL of glacial acetic acid, under an atmosphere of nitrogen, was added, in small portions over a period of 2 h, 16.0 g (24.5 mg atoms) of zinc dust. The mixture was stirred for an additional period of 1 h and then was filtered. The filtrate was diluted with brine and the resultant mixture was extracted thoroughly with a 1:10 mixture of ether and petroleum ether (bp 30–60°C). The combined extract was washed three times with 1 *N* aqueous sodium hydroxide and once with brine, and then was dried over anhydrous magnesium sulfate. Removal of the solvent by distillation at atmospheric pressure, followed by bulb-to-bulb distillation (air-bath temperature ~40°C/0.4 Torr; collecting bulb cooled with a Dry Ice – acetone bath) of the residual material gave 2.6 g (66%) of a colorless oil. Analysis (glc, ^1H nmr) of this material indicated that it consisted of a mixture of *cis*-(**41**) and *trans*-1-bromo-2,2-dimethyl-3-vinylcyclopropane (**47**) (*vide infra*), in a ratio of about 20:1. Subjection of this material to column chromatography on silica gel (elution of the column with pentane) provided the pure *cis* isomer **41**; ir (film): 3090, 1630, 900 cm^{-1}; ^1H nmr δ: 1.16, 1.18 (s, s, 3H each), 1.49 (overlapped d of d, appears as a triplet, 1H, J = 7.5 Hz), 3.05 (d, 1H, J = 7.5 Hz), 5.10–5.34 (m, 2H), 5.44–5.83 (m, 1H). *Exact Mass* calcd. for $C_7H_{11}{}^{79}Br$: 174.0044; found: 174.0031.

trans-*(2-Bromo-3,3-dimethylcyclopropyl)methanol (**45**)*

To a cold (−90°C) stirred solution of the tetrahydropyranyl ether **37** (12.31 g, 36 mmol) in 30 mL of dry ether, under an atmosphere of nitrogen, was added a solution of *n*-butyllithium in hexane (15.7 mL, 2.3 *M*, 36 mmol) and the resultant solution was stirred at −90°C for 15 min. Methanol (6 mL) was added, the mixture was allowed to warm to room temperature, and then was diluted with brine and extracted thoroughly with pentane. The combined extract was washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 58–90°C/0.6 Torr) of the crude product gave 8.42 g of a colorless oil. Analysis of this material by glc indicated that it was composed of a mixture of the tetrahydropyranyl ether **44** and the corresponding alcohol **45**, in a ratio of ~4:1. The oil was dissolved in methanol (80 mL) containing 16 mL of 1 *N* hydrochloric acid and the resultant solution was stirred overnight at room temperature under an atmosphere of nitrogen. Most of the methanol was removed under reduced pressure. The residual oil was diluted with brine and extracted thoroughly with ether. The combined extract was washed sequentially with water, saturated aqueous sodium bicarbonate, and brine, and then was dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 50–60°C/0.04 Torr) of the residual material gave 4.48 g (70%) of the desired alcohol **45** as a colorless oil; ir (film): 3400 cm^{-1}; ^1H nmr δ: ~1.1–1.45 (m, 1H), 1.14, 1.26 (s, s, 3H each), 1.96 (s, 1H), 2.69 (d, 1H, J = 4 Hz), 3.43–3.84 (m, 2H). *Anal.* calcd. for $C_6H_{11}BrO$: C 40.25, H 6.19; found: C 40.39, H 6.11.

trans-*2-Bromo-3,3-dimethylcyclopropanecarboxaldehyde (**46**)*

To a stirred suspension of pyridinium chlorochromate (7.29 g, 33.6 mmol) in 150 mL of dry dichloromethane, under an atmosphere of nitrogen, was added a solution of the alcohol **45** (3.0 g, 16.8 mmol) in 10 mL of the same solvent. After the dark reaction mixture had been stirred at room temperature for 2 h, it was poured into 800 mL of ether and the resultant mixture was filtered through a short column of basic alumina (Woelm, activity III). The column was washed with additional volumes of ether. Removal of the solvents from the combined eluate, followed by distillation (air-bath temperature 60–80°C/0.6 Torr) of the crude product, gave 2.7 g (91%) of the desired aldehyde **46** as a colorless oil; ir (film): 2850, 2750, 1705 cm^{-1}; ^1H nmr δ: 1.29, 1.44 (s, s, 3H each), 2.12 (d of d, 1H, J = 4.5, 3.5 Hz), 3.61 (d, 1H, J = 4.5 Hz), 9.67 (d, 1H, J = 3.5 Hz). *Exact Mass* calcd. for $C_6H_9{}^{79}BrO$: 175.9836; found: 175.9844.

trans-*1-Bromo-2,2-dimethyl-3-vinylcyclopropane (**47**)*

To a cold (−78°C) stirred suspension of methyltriphenylphosphonium bromide (5.5 g, 15.5 mmol) in 70 mL of dry THF, under an atmosphere of nitrogen, was added a solution of *n*-butyllithium in hexane (6.73 mL, 2.3 *M*, 15.5 mmol). The mixture was allowed to warm to room temperature and then was stirred for an additional 30 min. A solution of the aldehyde **46** (2.5 g, 14.1 mmol) in 5 mL of dry THF was added, the reaction mixture was stirred at room temperature for 1 h, and then was poured into 400 mL of pentane. The resultant mixture was filtered through a short column of Florisil, and the column was eluted with further volumes of pentane. Removal of the solvents from the combined eluate (distillation at atmospheric pressure), followed by bulb-to-bulb distillation (air-bath temperature ~40°C/0.1 Torr; collecting bulb cooled with a Dry Ice – acetone bath) of the crude product, gave 1.7 g (69%) of the substituted bromocyclopropane **47**; ir (film): 3110, 1635, 900 cm^{-1}; ^1H nmr δ: 1.10, 1.20 (s, s, 3H each), ~1.5–1.9 (m, 1H), 2.80 (d, 1H, J = 4 Hz), 4.83–5.84 (m, 3H). *Exact Mass* calcd. for $C_7H_{11}{}^{79}Br$: 174.0044; found: 177.0042.

*Reaction of the cuprate reagents **42** and **48** with the β-iodo enones **4** and **26**. Preparation of the 3-(2,2,-dimethyl-3-vinylcyclopropyl)-2-cyclohexen-1-ones **49**, **52**, **54**, and **56***

To a cold (−78°C) stirred solution of *cis*-(**41**) or *trans*-1-bromo-2,2-dimethyl-3-vinylcyclopropane (**47**) (132 mg, 0.75 mmol) in dry ether (3 mL), under an atmosphere of nitrogen, was added a solution of *tert*-butyllithium in pentane (0.71 mL, 2.1 *M*, 1.5 mmol). After the tan-colored slurry had been stirred at −78°C for 1 h, dry ether (7 mL), dry THF (2 mL), and solid phenylthiocopper (132 mg, 0.75 mmol) were added sequentially. The reaction mixture was allowed to warm to −20°C and then was stirred for an additional period of 1 h. After the resulting yellow-brown solution had been recooled to −78°C, a solution of the appropriate β-iodo enone (**4**: 111 mg, 0.5 mmol; **26**: 118 mg, 0.5 mmol) in dry ether (1 mL) was added. The reaction mixture was allowed to warm to room temperature and was stirred for an additional period of 2.5 h. Methanol (0.5 mL) and ether (10 mL)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

were added and the resultant slurry was filtered through a short column of Florisil (~10 g). The column was washed with additional volumes of ether. Removal of the solvent from the combined eluate provided the crude product. The following compounds were obtained by means of this general procedure.

cis-*3-(2,2-Dimethyl-3-vinylcyclopropyl)-2-cyclohexen-1-one (49)*

The crude product (84 mg, 88%) obtained from reaction of 3-iodo-2-cyclohexen-1-one (**4**) with the cuprate reagent **42** was not distilled, since compound **49** rearranged slowly at room temperature to afford the bicyclic enone **50**. Although a sample of **49** totally devoid of the rearrangement product **50** was not obtained, material acquired by means of a quick, careful work-up procedure exhibited the following spectral data: ir (film): 1672, 1625, 890 cm^{-1}; ^1H nmr δ: 1.06, 1.17 (s, s, 3H each), ~1.4–2.5 (diffuse m, 8H), 4.92–5.82 (m, 3H), 5.90–6.01 (m, 1H). *Exact Mass* calcd. for $C_{13}H_{18}O$: 190.1357; found: 190.1352.

trans-*3-(2,2-Dimethyl-3-vinylcyclopropyl)-2-cyclohexen-1-one (52)*

Distillation (air-bath temperature 120–130°C/0.2 Torr) of the crude product obtained from reaction of the β-iodo enone **4** with the cuprate reagent **48** provided 90 mg (95%) of compound **52**; uv (methanol) λ_{max}: 256 nm (ε 14 900); ir (film): 1670, 1622, 882 cm^{-1}; ^1H nmr δ: 1.00, 1.20 (s, s, 3H each), ~1.4–2.5 (diffuse m, 8H), 4.99–5.26 (m, 2H), 5.47–5.82 (m, 1H), 5.79–5.85 (m, 1H). *Exact Mass* calcd. for $C_{13}H_{18}O$: 190.1357; found: 190.1350.

cis-*2-Methyl-3-(2,2-dimethyl-3-vinylcyclopropyl)-2-cyclohexen-1-one (54)*

Distillation (air-bath temperature 85–100°C/0.02 Torr) of the crude product obtained from reaction of 3-iodo-2-methyl-2-cyclohexen-1-one (**26**) with the cuprate reagent **42** gave 98 mg of a viscous oil. Analysis of this material by tlc and glc indicated the presence of ~5% of the starting material **26**. Subjection of the mixture to preparative tlc (silica gel, 5:1 pentane–ether) afforded 78 mg (76%) of the enone **54** as a colorless oil; uv (methanol) λ_{max}: 257 nm (ε 10 970); ir (film): 1660, 1625, 900 cm^{-1}; ^1H nmr δ: 1.00, 1.23, 1.79 (s, s, broad s, 3H each), ~1.5–2.05 and 2.1–2.5 (diffuse multiplets, 8H), 4.95–5.70 (m, 3H). *Exact Mass* calcd. for $C_{14}H_{20}O$: 204.1514; found: 204.1522.

trans-*2-Methyl-3-(2,2-dimethyl-3-vinylcyclopropyl)-2-cyclohexen-1-one (56)*

Distillation (air-bath temperature 90–100°C/0.02 Torr) of the crude product obtained from reaction of the β-iodo enone **26** with the cuprate reagent **48** provided 100 mg of a colorless oil. Analysis of this material by tlc and glc indicated that the starting material **26** and the desired product **56** were present in a ratio of ~1:30, respectively. The mixture also contained small amounts of unidentified compounds. Purification by preparative tlc (silica gel, 5:1 pentane–ether) gave 84 mg (82%) of the enone **56** as a colorless oil; uv (methanol) λ_{max}: 257 nm (ε 12 200); ir (film): 1670, 1642, 1622, 895 cm^{-1}; ^1H nmr δ: 0.95, 1.20, 1.80 (s, s, broad s, 3H each), ~1.5–2.05 and 2.15–2.5 (diffuse multiplets, 8H), 4.98–5.26 (m, 2H), 5.48–5.90 (m, 1H). *Exact Mass* calcd. for $C_{14}H_{20}O$: 204.1514; found: 204.1494.

Thermal rearrangement of compound 49

(a) *Neat*

A sample of crude enone **49** (obtained from 111 mg, 0.5 mmol of the β-iodo enone **4**, as described above) was placed under an atmosphere of nitrogen and heated at 110°C for 10 min. Direct distillation (air-bath 110–140°C/0.3 Torr) of the resultant material gave 88 mg (93% from **4**) of the conjugated dienone **51** as a clear oil; uv (methanol) λ_{max}: 248 nm (ε 6 800); ir (film): 1665, 1635 cm^{-1}; ^1H nmr δ: 1.05 (s, 6H), 2.01 (m, 2H), 2.30–2.54 (diffuse m, 4H), 2.48 (s, 2H), 3.11 (broad d, 2H, J = 5 Hz), 5.26 (broad d, 1H, J = 12 Hz), 5.39–5.65 (d of t, 1H, J = 5, 12 Hz). *Exact Mass* calcd. for $C_{13}H_{18}O$: 190.1357; found: 190.1349.

(b) *In hexane*

A solution of the crude enone **49** (67 mg) in dry hexane (1 mL) was refluxed under an atmosphere of nitrogen for 4 h. Removal of the solvent afforded 65 mg of a light yellow oil which consisted very largely of the dienone **50**; ir (film): 1712 cm^{-1}; ^1H nmr δ: 1.14, 1.18 (s, s, 3H each), ~1.65–2.05 (m, 2H), 2.28–2.64 (m, 6H), 3.12–3.36 (m, 1H), 5.38 (m, 1H), 5.49 (d, 1H, J = 12 Hz), 5.77 (d of t, 1H, J = 6, 12 Hz). When this material was heated briefly at 110°C (neat) under an atmosphere of nitrogen, and then distilled (see above), 59 mg (88%) of the conjugated dienone **51** was obtained.

Thermal rearrangement of compound 52

A solution of the enone **52** (59 mg, 0.31 mmol) in dry *o*-dichlorobenzene (0.5 mL) was placed on a thick-walled Pyrex tube and then was thoroughly purged with a stream of dry nitrogen. After the tube had been sealed (−78°C, vacuum), it was heated at ~220°C for 14 h. Removal of the solvent from the cooled solution provided a brown oil which was purified by preparative tlc (silica gel, 1:9 ether – petroleum ether). Distillation (air-bath temperature 120–137°C/0.2 Torr) of the material thus obtained afforded 35 mg (59%) of the conjugated enone **51**, which exhibited spectral data identical with those summarized above.

Thermal rearrangement of compound 54

(a) *In o-xylene*

A solution of the enone **54** (50 mg, 0.25 mmol) in dry ether (~1.0 mL) was passed through a small column of basic alumina (~1 g, activity I). The column was eluted with dry ether (~2 mL). The oil remaining after removal of the ether from the eluate was dissolved in dry, degassed *o*-xylene (3 mL) and the resultant solution was refluxed under an atmosphere of argon for 48 h. Removal of the solvent, followed by distillation (air-bath temperature 90–110°C/0.2 Torr) of the residual material gave 42 mg (84%) of a colorless oil. Analysis of this material by glc indicated that it consisted of a small amount of starting material (~2%) along with the Cope rearrangement product **55** and the isomerization product **56**, in a ratio of ~2.7:1.[19] Separation of the two products was effected by preparative tlc (silica gel, 98:2 benzene – ethyl acetate). The dienone **55** (24 mg, 48%) exhibited ir (film): 1715 cm^{-1}; ^1H nmr δ: 1.13, 1.15, 1.26 (s, s, s, 3H each), ~1.64–2.68 (diffuse m, 8H), 5.24 (broad s, 1H), 5.42–5.80 (m, 2H). *Exact Mass* calcd. for $C_{14}H_{20}O$: 204.1514; found: 204.1516.

The enone **56** (8.5 mg, 17%) exhibited spectra identical with those obtained previously (*vide supra*).

(b) *In o-dichlorobenzene*

A sample compound **54** (68 mg, 0.33 mmol) was subjected to rearrangement in refluxing *o*-dichlorobenzene (4 mL) via a procedure identical with that described above. The reaction time was 3 h. Distillation of the crude product provided 62 mg (91%) of a colorless oil which consisted largely (glc analysis) of compounds **55** and **56** in a ratio of approximately 0.8:1, respectively.

(c) *In collidine (small scale)*

Following the procedure outlined above, a sample of the enone **54** (53 mg, 0.26 mmol) was subjected to rearrangement in refluxing collidine (1.5 mL). The reaction time was 42.5 h. The cooled solution was dissolved in 40 mL of ether and the resultant solution was washed successively with 10% aqueous sulfuric acid (4 × 10 mL), saturated aqueous sodium bicarbonate, and brine, and then was dried over anhydrous magnesum sulfate. Removal of the solvent, followed by bulb-to-bulb distillation of the residual oil, gave 39 mg (73%) of a colorless liquid. Analysis of this material by glc indicated that it

[19]As noted in the Results and discussion section of the paper, the ratio of **55**/**56** varied somewhat from one experiment to another. It ranged from ~1.1:1 to ~2.7:1 and was typically at approximately 2:1.

contained, in addition to ~15% of an unidentified compound, the rearrangement products **55** and **56** in a ratio of ~2.4:1.[20]

(d) *In collidine (larger scale)*

A solution of the enone **54** (2.04 g, 10 mmol) in 70 mL of dry, degassed collidine, under an atmosphere of argon, was refluxed for 43.5 h. The cooled reaction mixture was taken up in 1 L of ether and the resultant solution was washed successively with 10% aqueous sulfuric acid (3 × 500 mL), saturated aqueous sodium bicarbonate, and brine, and then was dried over anhydrous magnesium sulfate. Removal of the solvent gave a crude oil which was subjected to flash chromatography on silica gel (59). Elution of the column with hexanes containing 7% ethyl acetate gave 1 g (49%) of the dienone **55** and 420 mg (21%) of the enone **56**. Other substances appearing in certain fractions as mixtures with **55** and/or **56** were not identified.

Thermal rearrangement of compound ***56***

Thermolysis of the enone **56** (50 mg, 0.24 mmol) in dry *o*-dichlorobenzene (0.5 mL) at 220°C for 16 h was carried out via a procedure identical with that described for the thermolysis of compound **52** (*vide supra*). A solution of the crude product in ether (1 mL) was passed through a short column of silica gel (~1 g). The column was washed with additional ether (3 mL). Removal of the solvent from the combined eluate, followed by distillation (air-bath temperature 120–140°C/0.2 Torr) of the residual liquid gave 43.5 mg (87%) of a colorless oil. Analysis of this material by glc showed that it consisted largely of two components, **55** and **57**, in a ratio of about 1:4, respectively. Samples of each substance were obtained by preparative glc. The ir spectrum of **55** was identical with that of the same compound obtained previously, while the trienone **57** exhibited uv (methanol) λ_{max}: 245 nm (ϵ 13 000); ir (film): 1665, 1615, 895 cm^{-1}; ^1H nmr δ: 1.63 (d, 3H, J = 5 Hz), 1.69 (broad s, 3H), 1.86 (t, 3H, J = 2 Hz), 2.12–2.52 (m, 4H), 4.26 (broad d, 1H, J = 7 Hz), 4.81 (broad s, 1H), 4.92 (q, 1H, $J \approx$ 1.5 Hz), 5.38–5.86 (m, 2H). *Exact Mass* calcd. for $C_{14}H_{20}O$: 204.1514; found: 204.1510.

Preparation and thermal rearrangement of *trans*-3-[1-methyl-2-(2-methyl-1-propenyl)cyclopropyl]-2-cyclohexen-1-one. A synthesis of (±)-β-himachalene

EDWARD PIERS AND EDWARD H. RUEDIGER

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received November 8, 1982

EDWARD PIERS and EDWARD H. RUEDIGER. Can. J. Chem. **61**, 1239 (1983).

A total synthesis of the sesquiterpenoid (±)-β-himachalene (**2**) is described. Treatment of 5,5-dimethyl-2-vinyl-1,3-dioxane (**24**) with bromoform and aqueous sodium hydroxide in the presence of a phase-transfer catalyst afforded the dibromocyclopropane **25**. When the latter substance was allowed to react (tetrahydrofuran–hexamethylphosphoramide, −95°C) with *n*-butyllithium in the presence of methyl iodide, a mixture of the epimeric products **26** (87–93%) and **27** (7–13%) was produced in high yield. Compound **26** was converted via a two-step sequence (hydrolysis with 88% formic acid, **26** → **28**; Wittig reaction with isopropylidenetriphenylphosphorane, **28** → **16**) into the bromocyclopropane **16**, which was transformed into the cuprate reagent **17**. Reaction of 3-iodo-2-cyclohexen-1-one (**4**) with reagent **17**, followed by thermolysis (xylene, reflux) of the resultant product **18** (the title compound), afforded, in quantitative yield, the dienone 12. Methylation of **12** furnished compound **29** which, upon hydrogenation in the presence of tris(triphenylphosphine)chlororhodium, gave the ketone **32**. Conversion of compound **32** into the corresponding enol phosphate **33**, followed by reduction (lithium, ethylamine–tetrahydrofuran, *tert*-butyl alcohol) of the latter material, provided (±)-β-himachalene (**2**).

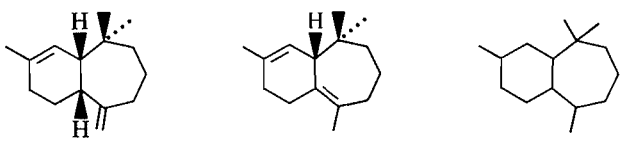
EDWARD PIERS et EDWARD H. RUEDIGER. Can. J. Chem. **61**, 1239 (1983).

On décrit une synthèse totale de sesquiterpène (±) β-himachalène (**2**). Le diméthyl-5,5 vinyl-2 dioxanne-1,3 (**24**) réagit avec le bromoforme dans l'hydroxyde de sodium aqueux en présence d'un catalyseur de transfert de phase pour donner le dibromocyclopropane **25**. Ce dernier réagit (tétrahydrofuranne–hexaméthylphosphoramide, −95°C) avec le *n*-butyllithium en présence de l'iodure de méthyle en donnant des produits épimères **26** (87–93%) et **27** (7–13%) avec un fort rendement. On a, en deux étapes, (hydrolyse par l'acide formique à 88%, **26** → **28**; réaction de Wittig avec l'isopropyllidène triphénylphosphorane, **28** → **16**) transformé le composé **26** en bromocyclopropane **16** que l'on transforme en cuprate **17**. La réaction de l'iodo-3 cyclohexène-2 one-1 (**4**) avec la réactif **17** suivie de la thermolyse (xylène, reflux) du produit résultant **18** (le composé mentionné dans le titre) donne avec un rendement quantitatif la diénone **12**. La méthylation de cette dernière conduit au composé **29** qui par hydrogénation en présence du tris(triphénylphosphine)chlororhodium donne la cétone **32**. La transformation de cette cétone en phosphate d'énol correspondant **33**, suivie d'une réduction (lithium, éthylamine–tétrahydrofuranne, alcool *tert*-butylique) permet d'accéder à la (±) β-himachalène (**2**).

[Traduit par le journal]

Introduction

The bicyclic $C_{15}H_{24}$ hydrocarbons (−)-α- and (+)-β-himachalene were first isolated some 30 years ago from the essential oil of Himalayan deodar (*Cedrus deodara* Loud.) (1). Approximately 9 years later, reports (2, 3) concerning structural elucidation work carried out independently by two research groups revealed that these two natural products possess the structures represented by formulas **1** and **2**, respectively. As such, these



1 **2** **3**

compounds represented the first two known members of a new class of sesquiterpenoids containing the himachalane carbon skeleton **3**. Later, in 1968, Joseph and Dev (4) determined that the absolute stereostructures of (−)-α- and (+)-β-himachalene are as shown in **1** and **2**, respectively.

In the accompanying paper (5) we described a new seven-membered ring annulation method based on the preparation and thermal (Cope) rearrangement of β-(2-vinylcyclopropyl) α,β-unsaturated ketones. For example, treatment of 3-iodo-2-cyclohexen-1-one (**4**) with lithium (phenylthio)(2-vinylcyclopropyl)cuprate (**5**, mixture of epimers), followed by thermolysis of the resultant products **6**, afforded, in 75% yield, the bicyclic dienone **8** (see eq. [1]). Under the conditions necessary to effect complete bond reorganization of both isomers of **6**, the initially formed Cope rearrangement product **7** isomerized to the more stable α,β-unsaturated ketone **8**. Various extensions of our study to other systems revealed that syntheses of seven-membered ring annulation products via this method are gener-

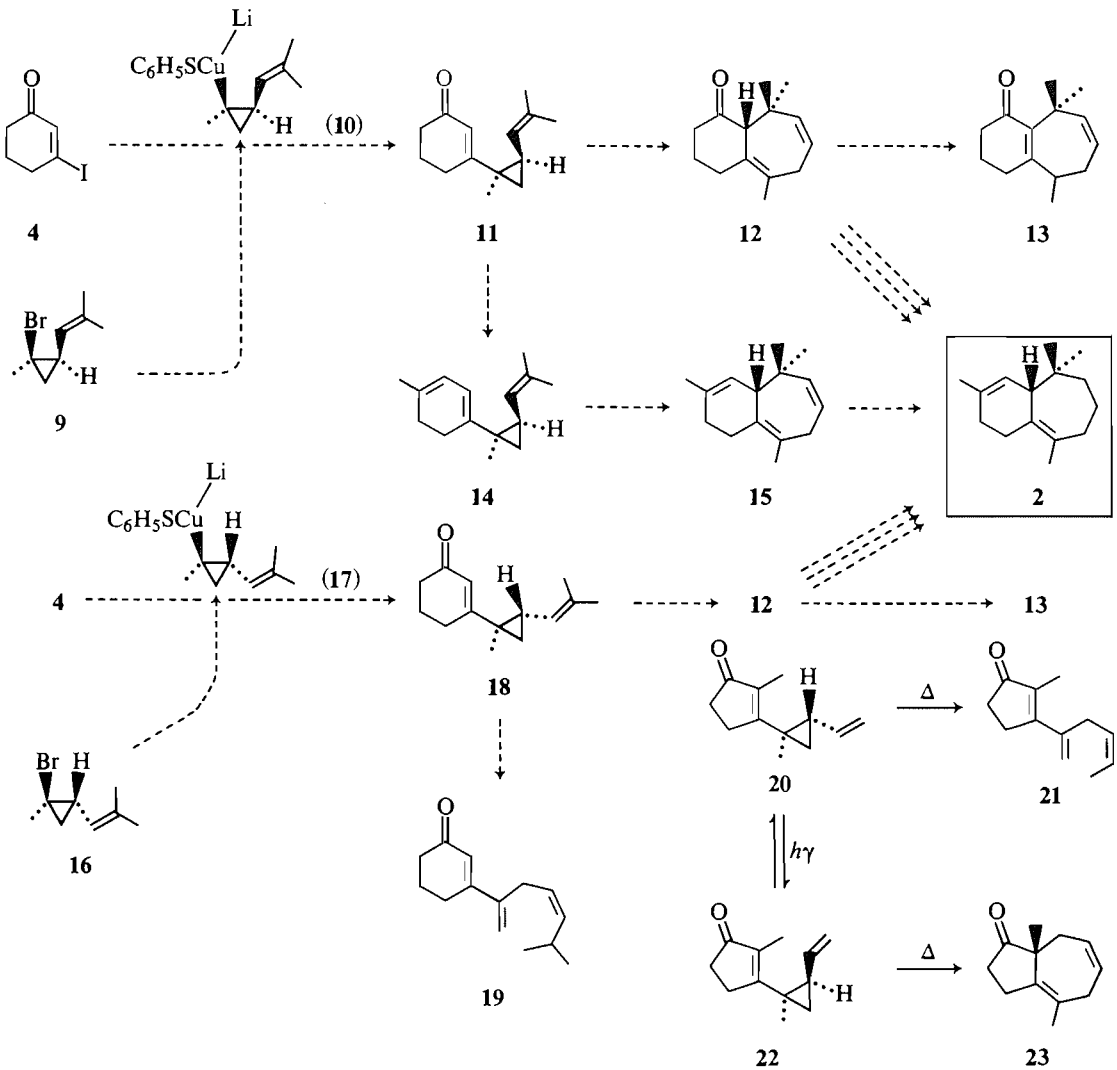

SCHEME 1

ally smooth and efficient (5). We report herein the application of this new annulation procedure to a total synthesis of racemic β-himachalene (**2**).[1,2]

Results and discussion

(a) *General considerations*

In principle, based on the work reported in the accompanying paper (5), the key step of the projected synthesis of (±)-β-himachalene (**2**) could involve thermal rearrangement of either of two possible substrates, *cis*-3-[1-methyl-2-(2-methyl-1-propenyl)cyclopropyl]-2-cyclohexen-1-one (**11**) or the corresponding *trans* isomer **18** (see Scheme 1). Thus, for example, treatement of 3-iodo-2-cyclohexen-1-one (**4**) with the substituted cyclopropylcuprate reagent **10** (presumably derived from the requisite bromide **9**) should afford the intermediate **11**. The latter substance would be expected (5) to undergo Cope rearrangement at, or slightly above, ambient temperatures to afford the required bicyclic dienone **12**. Reductive removal of the "extra" double bond in **12**, and use of the carbonyl group as a "handle" for introduction of the necessary methyl group and the alkene function would provide (±)-β-himachalene (**2**).

Alternatively, conversion of the cyclopropyl bromide **16** into the corresponding cuprate **17**, followed by reaction of this reagent with the β-iodo enone **4**, would afford the *trans* divinylcyclopropane **18**. The latter intermediate would be much more stable than the isomer **11** and, presumably, would be readily amenable to isolation at ambient temperatures. However, at elevated temperatures, compound **18** would be expected to undergo rearrangement and, if this bond reorganization were to proceed in the desired (Cope) sense, the product would again be the desired dienone **12**.

A potential problem associated with both of the sequences outlined above concerns the possibility of isomerization of the intermediate dienone **12**. Thus, in each case, the Cope rearrangement step (**11**---→**12** or **18**---→**12**), as well as some of the synthetic steps involved in the conversion of **12** into (±)-**2**, would have to be accomplished under conditions which would not effect isomerization of the tetrasubstituted double bond in **12** into conjugation with the carbonyl group (**12**---→**13**). If this isomerization, a clearly undesirable transformation, were to present a problem in either sequence, one would have to convert, prior to thermal rearrangement, the divinylcyclopropane intermediate (**11** or **18**) into a substance lacking the carbonyl group. One possibility, for example, would be to transform the intermediate **11** into the triene **14**. Cope rearrangement of the

[1]For a preliminary account of this work, see ref. 6.

[2]For other reported syntheses of (±)-β-himachalene, see refs. 7–9.

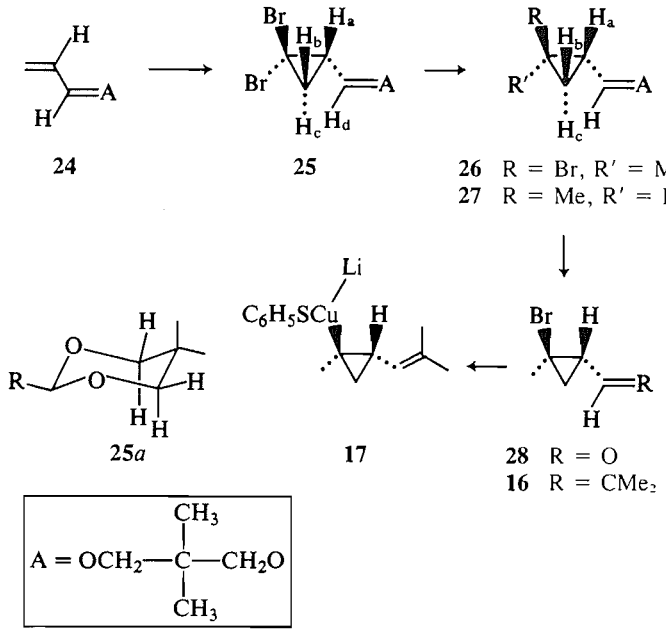

SCHEME 2

latter material would be expected to be a very facile process. Selective hydrogenation of the resultant product **15** would provide (±)-β-himachalene (**2**). It should be pointed out, however, that the anticipated ease with which the *cis*-divinylcyclopropane system in compound **11** would undergo bond reorganization could well preclude, or at least make very tricky, the possibility of transforming **11** into **14** or another suitable prerearrangement derivative. This potential difficulty could, therefore, represent a significant drawback to the synthesis of (±)-**2** via the route employing **11** as the key intermediate. On the other hand, conversion of the stable *trans*-divinylcyclopropane **18** into a suitable derivative lacking the carbonyl group should present no major difficulties.

Another potential problem attending the possible use of intermediate **18** in a synthesis of (±)-**2** should be mentioned, however. Although successful Cope rearrangement of this substance could provide the necessary bicyclic product **12**, it is clear that intermediate **18** could undergo another mode of rearrangement. That is to say, thermolysis of **18** at elevated temperatures could afford, instead of (or in addition to) the desired Cope rearrangement product **12**, a trienone **19** resulting from a [1,5]-sigmatropic hydrogen shift.[3] Indeed, it had been shown (10) that thermolysis of *trans*-2-methyl-3-(1-methyl-2-vinylcyclopropyl)-2-cyclopenten-1-one (**20**) produces nearly exclusively the trienone **21**. Subsequently, however, Wender *et al.* showed (11) that **20** could be converted cleanly into the Cope rearrangement product **23** by subjecting the former substance to simultaneous photolysis and thermolysis at 98°C. Under these conditions, a photo-induced equilibration between **20** and the isomeric material **22** occurs and, although compound **20** is *thermally* stable at 98°C, the isomer **22** readily undergoes Cope rearrangement at this temperature. This elegant procedure might also be applicable to the conversion of **18** into **12**, if high temperature thermolysis of **18** were to produce significant amounts of product **19**, resulting from a [1,5]-sigmatropic hydrogen migration.

[3]For examples of this type of rearrangement, along with appropriate citations, see ref. 5.

The analysis outlined above indicated that potential difficulties could well accompany both of the possible projected synthetic routes to (±)-β-himachalene (**2**). Therefore, the decision regarding the choice of a particular route was not straightforward. In fact, the choice as to which pathway to investigate first was made on the basis of a factor somewhat unrelated to the above discussion. More explicitly, at the outset of our work, we were not able to propose a suitable synthetic pathway which would, with a reasonable degree of certainty, result in an efficient, *stereoselective* preparation of *cis*-1-bromo-1-methyl-2-(2-methyl-1-propenyl)cyclopropane (**9**). This substance would serve as the precursor of the cuprate reagent **10**, which was to be employed to convert the β-iodo enone **4** into the possible key intermediate **11**. On the other hand, based on literature precedent (*vide infra*), it appeared that a convenient, stereoselective synthesis of the substituted bromocyclopropane **16** would be relatively straightforward. Therefore, we chose to study initially the possibility of carrying out the total synthesis of (±)-β-himachalene (**2**) via the general route **4**---→**18**---→**12**---→(±)-**2**.

(b) *Synthesis of* trans-*1-bromo-1-methyl-2-(2-methyl-1-propenyl)cyclopropane (**16**) and its converison into the cuprate **17** (see Scheme 2)*

Conversion (2,2-dimethyl-1,3-propanediol, *p*-toluenesulfonic acid, dichloromethane, anhydrous magnesium sulfate) of acrolein into the corresponding acetal **24**, followed by reaction of the latter substance with bromoform − sodium hydroxide in the presence of a phase-transfer catalyst (12), gave the crystalline dibromocyclopropane derivative **25**. Although the yield of the transformation of **24** into **25** was quite low (27%), this inefficiency was not entirely unexpected. It is well established (13) that in their reaction with alkenes dihalocarbenes behave as electrophilic reagents and, therefore, addition of these species to "electron rich" carbon−carbon double bonds is significantly faster than the corresponding process involving "electron poor" alkenes. Clearly, compound **24** belongs to the latter category and the sluggish nature of the addition of dibromocarbene to this material was shown by the observation

27	The three protons appeared as a multiplet between δ 1.04–1.18.		

that starting material remained even after a reaction time of 20 h. Furthermore, the fact that analysis of the crude product by gas–liquid chromatography (glc) showed the presence of a number of components indicated that alternative processes (e.g. insertion reactions (14)) were competing with the desired addition reaction. Fortunately, however, it was found that the required dibromocyclopropane **25** could be crystallized directly from a pentane solution of the crude reaction product, Therefore, since the acetal **24** was readily available, appreciable quantities of compound **25** could be obtained quite easily.

When a cold (−95°C) solution of compound **25** in 5:1 tetrahydrofuran–hexamethylphosphoramide containing 2 equivalents of methyl iodide was treated (dropwise) with 1 equivalent of *n*-butyllithium (hexane solution) and the resultant mixture was warmed to room temperature (15), a mixture of the diastereomeric methylated derivatives **26** and **27** was obtained in excellent yield. The relative amounts of the two products varied slightly with the scale of the reaction. For example, when the transformation was carried out on a small scale (~1 mmol), the two products were obtained in a ratio of about 93:7, respectively, while a reaction involving 25 mmol of the dibromocylopropane **25** produced the two methylated substances in a somewhat lower ratio (~87:13). However, separation of the two epimers could be achieved readily by subjection of the mixture to column chromatography on silica gel and, thus, the two crystalline products **26** and **27** were obtained in yields of 74 and 11%, respectively.

Although, on the basis of analogy (15), the major product of the methylation reaction was expected to have the newly introduced methyl group *cis* to the acetal function (compound **26**), it is pertinent to mention that this expectation was fully corroborated by a comparison of the proton nuclear magnetic resonance (^{1}H nmr) spectrum of the starting material **25** with those of the two products **26** and **27**. The data related to the ^{1}H nmr resonance of the three cyclopropyl protons (H_a, H_b, H_c) of each of the compounds **25**, **26**, and **27** is summarized in Table 1. In the spectrum of **25**, these signals are well separated and, therefore, are readily assigned.[4] Not unexpectedly, the resonances due to H_a, H_b, and H_c of the major methylation product **26** are all found upfield as compared to the corresponding signals of **25**. However, the upfield shift (0.69 ppm) of one of the protons (H_c) is significantly larger than those of the other protons (H_a, 0.16 ppm; H_b, 0.48 ppm). On the other hand, in going from the starting material **25** to the minor methylated product **27**, two of the cyclopropyl protons (H_a, H_b) experience upfield shifts (~0.9 and 0.75 ppm, respectively) significantly greater than that of the third proton (H_c, ~0.5 ppm). On the basis of these data, it seems very reasonable to conclude that the major product (see **26**) has the newly introduced methyl group *cis* to one cyclopropyl proton (H_c), while in the minor product (see **27**) the methyl group is *cis* to two protons (H_a, H_b).

Initially, hydrolysis of the acetal function of compound **26** proved to be frustratingly problematic. For example, when this substance was treated with 1 *N* hydrochloric acid in methanol (room temperature) or with hot glacial acetic acid, only starting material was recovered. On the other hand, although the acetal appeared to be hydrolyzed partially by subjection of **26** to trifluoroacetic acid or titanium tetrachloride in wet dichloromethane, these reactions were not reproducible and gave poor yields of the desired product. Therefore, it was gratifying to find (eventually) that the conversion of **26** into the aldehyde **28** could be accomplished reproducibly and efficiently (72% yield) by treatment of the former material with 88% formic acid at room temperature (18). Since the aldehyde **28** is not a very stable compound, it was characterized as the corresponding 2,4-dinitrophenylhydrazone derivative and was used directly for the next step of the synthetic sequence.

When the aldehyde **28** was allowed to react with isopropylidenetriphenylphosphorane in tetrahydrofuran at room temperature, the desired *trans*-1-bromo-1-methyl-2-(2-methyl-1-propenyl)cyclopropane (**16**) was produced in 70% yield. Treatment of compound **16** with 2 equivalents of *tert*-butyllithium in cold (−78°C) ether–tetrahydrofuran (1:1), followed by addition of solid phenylthiocopper (19, 20) and warming of the resultant mixture to −20°C, furnished a reddish-brown solution of the required cuprate reagent **17**. The latter species was employed in the next phase of the projected synthesis.

(c) *Synthesis of* trans-*3-[1-methyl-2-(2-methyl-1-propenyl)-cyclopropyl]-2-cyclohexen-1-one (18) and its conversion into (±)-β-himachalene (2) (see Scheme 3)*

When 3-iodo-2-cyclohexen-1-one (**4**) (21) was allowed to react with 1.5 equivalents of the cuprate reagent **17** in tetrahydrofuran–ether (−78°C → room temperature), the substituted cyclohexenone **18** was produced in nearly quantitative yield. When a solution of this material in xylene was heated (reflux) for 3 h, rearrangement occurred smoothly and a single product was obtained in quantitative yield. The infrared (ir)

[4]It is well known (16) that coupling constants associated with *cis* vicinal protons on cyclopropane systems are normally significantly larger than those related to corresponding *trans* protons. Thus, in the case of compound **25**, $J_{a,b}$ = 11 Hz, while $J_{a,c}$ = 6 Hz. Another feature of the ^{1}H nmr spectrum of **25** which deserves mention is the interesting pattern associated with the methylene protons of the 1,3-dioxane ring. The two axial protons (see **25***a*, R = 2,2-dibromocyclopropyl) produced a pair of doublets (δ 3.41, 3.47, J = 10 Hz in each case), while the equatorial protons gave rise to a pair of doublet of doublets (δ 3.63, 3.70, J = 10 and ~2 Hz in each case). This spectral pattern, which is not uncommon for 2-substituted 5,5-dimethyl-1,3-dioxanes, has been discussed in more detail previously (17).

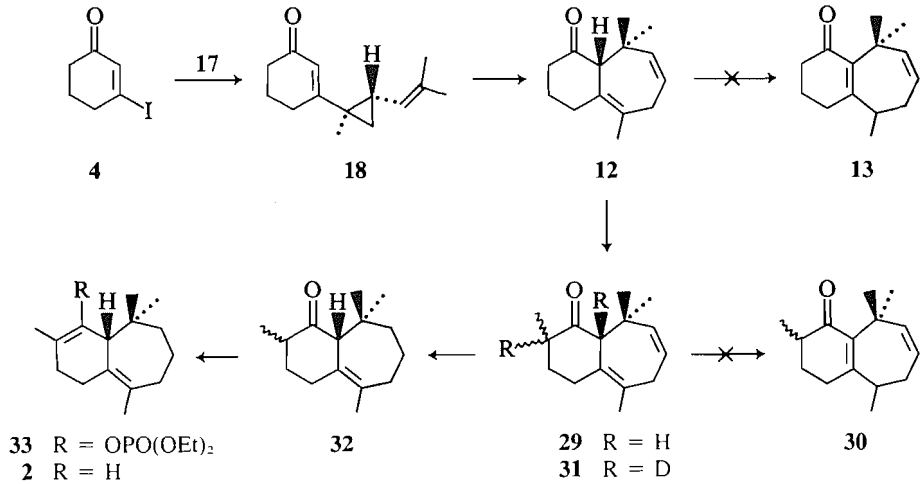

SCHEME 3

spectrum of the product exhibited a strong carbonyl absorption at 1700 cm^{-1}, while the ^1H nmr spectrum showed, along with other appropriate resonances, 3-proton singlets at δ 1.02, 1.08, and 1.80. Therefore, it was possible to draw the gratifying conclusion that the thermolysis product possessed structure **12** and, thus, both of our main misgivings with respect to the possibility of using compound **18** as a key intermediate in the projected synthesis of (±)-β-himachalene proved to be unfounded in fact.[5] Firstly, intermediate **18** underwent thermal bond reorganization exclusively in the desired Cope rearrangement sense, with no competition from the alternatively possible mode of rearrangement involving a [1,5]-sigmatropic hydrogen migration. Secondly, under the conditions of the thermolysis, the β,γ-unsaturated ketone function of the product **12** did not rearrange to the α,β-unsaturated ketone **13**.

With respect to the first point mentioned above, it is interesting to compare the thermal behaviour of compound **18** with that of 2-methyl-3-(1-methyl-2-vinylcyclopropyl)-2-cyclopenten-1-one (**20**) (10, 11). More explicitly, why does substrate **18** undergo exclusively a Cope rearrangement to furnish the bicyclic dienone **12**, while, under similar conditions, bond reorganization of compound **20** proceeds nearly entirely via a [1,5]-sigmatropic hydrogen shift pathway to afford the trienone **21**? Scheme 4 outlines the various reactions which could be involved in the thermolyses of **18** and **20**. If one assumes that the Cope rearrangement of substrate **20** would proceed by way of the corresponding *cis* isomer **22** (11),[6] and if one recalls that the latter substance undergoes Cope rearrangement very readily at relatively low temperatures (10, 11), then it is clear that the rate-determining step of the overall conversion of **20** into **23** would be the transformation (presumably by way of the diradical intermediate **A**) of **20** into **22**. Furthermore, a comparison of the transition states (see **B** and **E**) involved in the Cope rearrangement of the *cis*-divinylcyclopropanes **22** and **11**, respectively, reveals that these two states should be of very similar stability. Thus, the combined destabilizing energy associated with the steric repulsions labelled *a* and *b* in **B** should be equal (or nearly equal) to that related to the corresponding interactions in **E**, and the destabilizing energy connected with the interaction *c* (present in **E**, but absent in **B**) would be expected to be quite small.[7] Therefore, the rate-determining step of the overall conversion of **18** into **12** should also involve thermal isomerization of the *trans* isomer **18** into the *cis* isomer **11**, presumably via the diradical intermediate **D**.

The [1,5]-sigmatropic hydrogen migration associated with the thermolysis of compound **20** should, presumably, proceed by way of a transition state which can be represented by **C** (23). Since rearrangement of **20** furnishes nearly exclusively the trienone **21** (10, 11), it is clear that the hydrogen migration pathway (**20** → **C** → **21**) is energetically favored over the alternative route (**20** → **A** → **22**). Why, then, is the opposite true for substrate **18**? Based on the brief discussion given above, it is possible to propose two factors which could well contribute to the difference between the thermal behaviour of compounds **18** and **20**. Firstly, due to the presence of the two methyl groups on the 2-methyl-1-propenyl group of **18**, it seems reasonable to postulate that the diradical **D** would be more stable than the corresponding species **A**. Therefore, if this relative order of stability is reflected in the transition states giving rise to **D** and **A**, one would expect that the process **18** → **D** would be energetically favored over the conversion of **20** into **A**. Secondly, it is pertinent to compare the two transition states involved in the [1,5]-sigmatropic hydrogen migration reactions. While the transition state **C** lying between **20** and **21** has no serious steric interactions, the corresponding species **F** involved in the transformation of **18** and **19** suffers from a notable interaction between one of the vinyl methyl groups and one of the cyclopropyl protons (see *d* in **F**). Energetically speaking, these two effects are additive and it is therefore possible to rationalize, at least qualitatively, why thermolysis of **18** proceeds via the Cope rearrangement pathway.

Treatment of the ketone **12** with lithium diisopropylamide, followed by alkylation of the resultant enolate anion with methyl iodide, furnished, in 90% yield, the methylated derivative **29** (Scheme 3). The ir and ^1H nmr spectra of **29** showed unambiguously that the tetrasubstituted double bond had remained exocyclic to the six-membered ring. Indeed, experi-

[5]It is delightful to discover that, on occasion, one observes exceptions even to "Murphy's Law".

[6]For a brief discusison regarding the possible mechanism of the Cope rearrangement of *trans*-divinylcyclopropanes, see ref. 5 and citations therein.

[7]For a discussion concerning the approximate destabilizing energy values associated with steric interactions in the transition states of Cope rearrangement of *cis*-divinylcyclopropanes, see ref. 22. See also ref. 5.

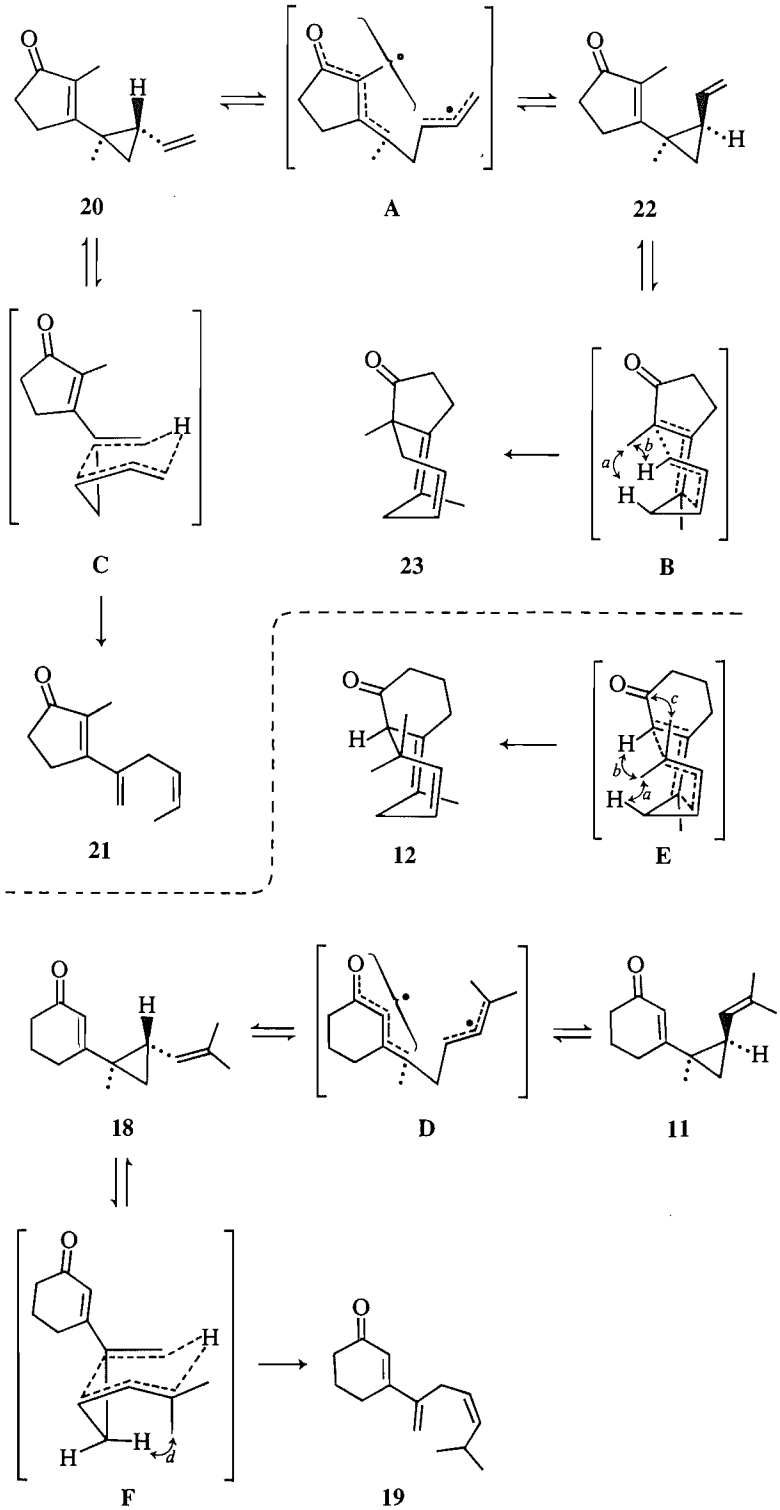

SCHEME 4

ments designed to deliberately effect iosmerization of compounds **12** and **29** into **13** and **30**, respectively, failed. Thus, both **12** and **29** were recovered essentially unchanged when solutions of these materials in methanol containing sodium methoxide were warmed for several hours. Furthermore, treatment of compound **29** with sodium methoxide in refluxing methanol-d_1 (30 h) provided, as the sole product, the dideuterio derivative **31**. The ^{1}H nmr spectrum of compound **31** showed that the broad singlet at δ 3.84 due to the bridgehead proton in **29** had disappeared, that the 3-proton doublet (δ 1.06) due to the secondary methyl group in **29** had collapsed to a singlet, and that the signal due to the vinyl methyl group (δ 1.78) had remained unchanged. It is not clear what factors underlie the fact that the β,γ-unsaturated ketones **12** and **29** are significantly more stable than their α,β-unsaturated counterparts **13** and **30**, respectively. However, an examination of molecular models suggests that in what appear to be the most stable conformations of **13** and **30** (secondary methyl group adjacent to the

carbonyl in a pseudoequatorial orientation), there exists a significant steric repulsion between one of the geminal methyl groups and the carbonyl oxygen atom. On the other hand, in the (apparently) most stable conformations of **12** and **29**, the oxygen atom is staggered between the two geminal methyl groups. In any case, the fact that compounds **12** and **29** showed no inclination to undergo isomerization was synthetically very satisfying and, presumably, made our synthetic work considerably less troublesome. In fact, the remainder of the synthetic sequence proceeded in a straightforward manner.

Hydrogenation of the dienone **29** in the presence of tris-(triphenylphosphine)chlororhodium gave, in 95% yield, the bicyclic enone **32**. Treatment of the latter substance with lithium diisopropylamide and trapping of the resultant enolate anion with diethyl bromophosphate (24)[8] afforded, in good yield, the enol phosphate **33**. Reduction of this material with lithium in ethylamine–tetrahydrofuran containing *tert*-butyl alcohol (25) furnished (±)-β-himachalene (**2**) in 38% yield.[9] The spectral and chromatographic properties of (±)-**2** were identical with those of authentic samples of the natural product.[10]

Experimental[11]

*Preparation of 5,5-dimethyl-2-vinyl-1,3-dioxane (**24**)*

To a solution of 2,2-dimethyl-1,3-propanediol (104 g, 1.0 mol) and *p*-toluenesulfonic acid (0.2 g) in 500 mL of dry dichloromethane was added successively acrolein (56 g, 1.0 mol) and anhydrous magnesium sulfate (~10 g). After the resulting mixture had been stirred at room temperature for 5 h, it was filtered through a short column of basic alumina (activity I, 100 g). The column was washed with additional dry dichloromethane (100 mL), and the solvent was removed carefully (rotary evaporator) from the combined eluate. Bulb-to-bulb distillation (air-bath 28°C/0.1 Torr, receiving bulb cooled to −78°C) of the remaining yellow liquid gave 114 g (80%) of the acetal **24** as a colorless liquid; tlc analysis: one spot; glc analysis: >99% one peak; ir(film): 2975, 2860, 1100 cm^{-1}; ^1H nmr δ: 0.74, 1.22 (s, s, 3H each), 3.52, 3.68 (d, d, 2H each, J = 11 Hz in each case), 4.86 (d, 1H, J = 5 Hz), 5.33 (broad d, 1H, J = 10 Hz), 5.48 (broad d, 1H, J = 17 Hz), 5.95 (d of d of d, 1H, J = 17, 10, 5 Hz). *Exact Mass* calcd. for $C_8H_{14}O_2$: 142.0994; found: 142.0994.

*Preparation of the dibromocyclopropane **25***

To a rapidly stirred mixture of 5,5-dimethyl-2-vinyl-1,3-dioxane (**24**) (4.26 g, 30 mmol), bromoform (15.2 g, 60 mmol), benzyltriethylammonium chloride (0.15 g), and ethanol (0.25 mL) was added dropwise 25 mL of 50% aqueous sodium hydroxide, and stirring was continued for 20 h. The resultant dark, tarry mixture was diluted with cold water (250 mL) and extracted thoroughly with pentane. The combined extract was washed with water until the aqueous phase remained neutral, and then was dried over anhydrous magnesium sulfate. Removal of the solvent and excess bromoform gave a dark brown oil. This material was taken up in pentane and the resultant solution was passed through a short column of neutral alumina (activity I). The column was washed with pentane. Removal of the solvent from the combined eluate gave a yellow oil which was subjected to crystallization from pentane at −15°C. Recrystallization from pentane provided 2.5 g (27%) of the dibromocyclopropane **25** as colorless crystals, mp 75–77°C; ir ($CHCl_3$): 2975, 2870, 1100 cm^{-1}; ^1H nmr (270 MHz) δ: 0.73, 1.23 (s, s, 3H each), 1.61 (overlapped d of d, 1H, J = 6, 6 Hz), 1.84 (d of d, 1H, J = 11, 6 Hz), 2.01 (overlapped d of d of d, 1H, J = 11, 6, 6 Hz), 3.41, 3.47 (d, d, 1H each, J = 10 Hz in each case), 3.63, 3.70 (d of d, d of d, 1H each, J = 10, ~2 Hz in each case), 4.20 (d, 1H, J = 6 Hz). *Anal.* calcd. for $C_9H_{14}Br_2O_2$: C 34.42, H 4.50; found: C 34.63, H 4.70.

*Preparation of the methylated monobromocyclopropanes **26** and **27***

To a cold (−95°C) stirred solution of the dibromocyclopropane **25** (8.00 g, 25.5 mmol) in a mixture of dry THF (125 mL), dry hexamethylphosphoramide (25 mL), and methyl iodide (7.2 g, 51 mmol), under an atmosphere of nitrogen, was added, dropwise, a solution of *n*-butyllithium (30.6 mmol) in hexane. The pale yellow solution was allowed to warm slowly to room temperature, at which time most of the volatile material was removed under reduced pressure. The remaining oil was poured into brine and the resultant mixture was extracted thoroughly with pentane. The combined extract was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave 7.1 g of a pale yellow oil which, on the basis of analysis by glc, consisted mainly of two components in a ratio of approximately 87:13. This material was subjected to column chromatography on silica gel. The column was eluted with 1:10 ether – petroleum ether. Distillation (air-bath temperature 63°C/0.1 Torr) of the major product, which was eluted from the column first, provided 4.90 g (74%) of the monobromocyclopropane **26**. Crystallization of a small amount of this material from pentane gave colorless crystals, mp 24.5–26°C; ir(film): 2975, 2870, 1100, 1020, 785 cm^{-1}; ^1H nmr (270 MHz) δ: 0.72, 1.21, 1.84 (s, s, s, 3H each), 0.92 (overlapped d of d, 1H, J = 6.5, 6.5 Hz), 1.36 (d of d, 1H, J = 10, 6.5 Hz), 1.7–2.0 (m, 1H), 3.42 (d, 2H, J = 11 Hz), 3.65, 3.68 (overlapped d of d, overlapped d of d, 1H each, J = 11, ~2 Hz in each case), 4.25 (d, 1H, J = 6.5 Hz). *Anal.* calcd. for $C_{10}H_{17}BrO_2$: C 48.21, H 6.88; found: C 48.38, H 6.86.

Recrystallization of the minor product from pentane gave 0.72 g (11%) of the monobromocyclopropane **27** as colorless crystals, mp 52–53°C; ir ($CHCl_3$): 2970, 2865, 1470, 1170, 1095 cm^{-1}; ^1H nmr (270 MHz) δ: 0.74, 1.24, 1.78 (s, s, s, 3H each), 1.04–1.18 (m, 3H), 3.49, 3.53, (d, d, 1H each, J = 11 Hz in each case), 3.68, 3.72 (overlapped d of d, overlapped d of d, 1H each, J = 11 Hz, ~2 Hz in each case), 4.29 (d, 1H, J = 6.5 Hz). *Anal.* calcd. for $C_{10}H_{17}BrO_2$: C 48.21, H 6.88; found: C 48.16, H 7.00.

*Preparation of the cyclopropanecarboxaldehyde **28***

To 100 mL of degassed 88% formic acid was added 10.8 g (43 mmol) of the acetal **26**. After the mixture had been stirred under an atmosphere of nitrogen for 1.5 h at room temperature, it was poured into ice and the resulting mixture was extracted thoroughly with pentane. The combined extract was washed with saturated aqueous sodium bicarbonate until neutral and dried over anhydrous magnesium sulfate. Careful removal of the solvent, followed by distillation (air-bath temperature ~25–30°C/0.1 Torr, receiving bulb cooled with liquid nitrogen) of the remaining pale yellow oil, gave 5.05 g (72%) of the aldehyde **28** as a colorless, volatile liquid. This material, which showed one peak by glc analysis and exhibited ir(film): 2875, 2780, 1710 cm^{-1}, was used directly for the next step of the reaction sequence.

The 2,4-dinitrophenylhydrazone derivative of the aldehyde **28** was recrystallized from ethanol–water, mp 160–161.5°C (dec.); ^1H nmr δ: 1.40 (overlapped d of d, 1H, J = 6.5, 6.5 Hz), 1.76 (d of d, 1H, J = 10, 6.5 Hz), 1.88 (s, 3H), 2.50 (overlapped d of d of d, 1H, J = 10, 6.5, 6.5 Hz), 7.38 (d, 1H, J = 6.5 Hz), 7.93 (d, 1H, J = 10 Hz), 8.34 (d of d, 1H, J = 10, 3 Hz), 9.12 (d, 1H, J = 3 Hz), 9.34 (broad s, 1H). *Anal.* calcd. for $C_{11}H_{11}BrN_4O_4$: C 38.50, H 3.23, N 16.33; found: C 38.58, H 3.11; N, 16.25.

[8]Use of the less reactive although more normally employed diethyl chlorophosphate failed to produce any of the desired enol phosphate **33**.

[9]Examination (glc) of the crude reduction product indicated that it consisted very largely of (±)-β-himachalene. The low yield of isolated material, obtained by purification of the crude product by preparative tlc, was probably a function of the volatility of the racemic natural product.

[10]We are very grateful to Drs. V. Lukes (Czechoslovakia) and T. Norin (Sweden) for generous samples of (+)-β-himachalene.

[11]For general information, see the preceding, accompanying paper (5).

Preparation of the alkene ***16***

To a cold (−78°C) stirred suspension of isopropyltriphenylphosphonium iodide (6.2 g, 14.4 mmol) in dry THF (50 mL), under an atmosphere of nitrogen, was added dropwise a solution of methyllithium (14.4 mmol) in ether. The mixture was warmed to room temperature and stirred until a clear, dark red solution of the phosphorane was obtained. After the solution had been recooled to −78°C, a solution of the aldehyde **28** (2.0 g, 12.3 mmol) in 5 mL of dry THF was added. The reaction mixture was warmed slowly to room temperature, was allowed to stir for 2 h, was diluted with pentane (50 mL), and then was filtered through a short column of silica gel. The column was eluted with further volumes of pentane. Careful removal of the solvent from the combined eluate, followed by distillation (air-bath temperature ~40−50°C/0.1 Torr, receiving bulb cooled with a Dry Ice − acetone bath) of the residual material, gave 1.6 g (70%) of the alkene **16** as a colorless, volatile oil; ir(film): 3010, 2960, 1440, 1385, 1150 cm^{-1}; ^1H nmr δ: 0.64 (overlapped d of d, 1H, J = 6.5, 6.5 Hz), 1.46 (d of d, 1H, J = 10, 6.5 Hz), 1.70 (s, 3H), 1.72, 1.78 (broad singlets, 3H each), 2.12 (m, 1H), 4.76 (d of septuplets, 1H, J = 7.5, 1.5 Hz). *Exact Mass* calcd. for $C_8H_{13}{}^{81}Br$: 190.0181 found: 190.0157.

Preparation of the enone ***18***

To a cold (−78°C) stirred solution of the bromocyclopropane **16** (1.03 g, 5.4 mmol) in 50 mL of dry THF−ether (1:1), under an atmosphere of nitrogen, was added dropwise a solution of *tert*-butyllithium (10.8 mmol) in pentane. After the pale yellow solution had been stirred at −78°C for 30 min, phenylthiocopper (0.93 g, 5.4 mmol) was added from a bent tube attached to the reaction flask. When the resulting suspension was warmed to −20°C and stirred at this temperature for 30 min, a dark reddish-brown solution of the cuprate reagent **17** was formed. The solution was recooled to −78°C, and then a solution of 3-iodo-2-cyclohexen-1-one (**4**) (0.80 g, 3.6 mmol) in 5 mL of dry THF was added. The reaction mixture was stirred at −78°C for 10 min, at −20°C for 15 min, and then at room temperature for 2 h. Methanol (2 mL) and ether (50 mL) were added, and the resulting orange-yellow suspension was filtered through a short column of Florisil. The column was eluted with ether. Removal of the solvents from the combined eluate, followed by distillation (air-bath temperature 110−125°C/0.3 Torr) of the residual material gave 0.73 g (99%) of the enone **18** as a pale yellow oil; ir(film): 1660, 1600 cm^{-1}; ^1H nmr (270 MHz) δ: 0.64 (overlapped d of d, 1H, J = 5, 5 Hz), 1.18 (s, 3H), 1.36 (d of d, 1H, J = 10, 5 Hz), 1.6−1.8 (m, 1H), 1.68, 1.74 (broad singlets, 3H each), 1.96 (m, 2H), 2.18 (m, 2H), 2.34 (t, 2H, J = 8 Hz), 4.92 (broad d, 1H, J = 10 Hz), 5.92 (s, 1H). *Anal.* calcd. for $C_{14}H_{20}O$: C 82.30, H 9.87; found: C 82.06, H 9.90.

Preparation of the bicyclic dienone ***12***

A solution of the enone **18** (274 mg, 1.34 mmol) in 30 mL of dry, degassed xylene was refluxed under an atmosphere of nitrogen for 3 h. After the solution had been cooled to room temperature, the solvent was removed under reduced pressure. Analysis of the remaining pale yellow oil (275 mg) by tlc and glc indicated that this material was >99% pure and, consequently, it was used directly for the next step. Distillation (air-bath temperature 87−100°C/0.1 Torr) of a small amount of the oil provided an analytically pure sample of the bicyclic dienone **12**; ir(film): 1700 cm^{-1}; ^1H nmr δ: 1.02, 1.08, 1.80 (s, s, broad s, 3H each), 1.90−2.54 (diffuse m, 6H), 2.74 (m, 1H), 3.28 (broad d, 1H, J = 18 Hz), 3.74 (broad s, 1H), 5.14 (d of d, 1H, J = 12, 3 Hz), 5.50 (d of d of d, 1H, J = 12, 8, 3 Hz). *Anal.* calcd. for $C_{14}H_{20}O$: C 82.30, H 9.87; found: C 82.06, H 9.90.

Preparation of the bicyclic dienone ***29***

To a cold (−78°C), stirred solution of lithium diisopropylamide (1.76 mmol) in 20 mL of dry THF under an atmosphere of argon was added a solution of the dienone **12** (276 mg, 1.35 mmol) in 5 mL of dry THF. After the solution had been stirred at −78°C for 30 min and at 0°C for 30 min, dry hexamethylphosphoramide (2.7 mmol) was added. The resulting orange solution was recooled to −78°C, methyl iodide (5.4 mmol) was added, and stirring was continued at −78°C for 30 min and then at room temperature for 30 min. The reaction mixture was diluted with brine and extracted thoroughly with petroleum ether. The combined organic extract was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 100−108°C/0.1 Torr) of the residual liquid gave 265 mg (90%) of the bicyclic dienone **29** as a pale yellow oil. Analysis of this material by glc − mass spectrometry indicated that it consisted of a mixture of two diastereomeric ketones, in a ratio of approximately 92:8; ir(film): 1700 cm^{-1}; ^1H nmr δ: 0.96, 1.09, 1.78 (s, s, broad s, 3H each), 1.06 (d, 3H, J = 6 Hz), 1.90−2.64 (diffuse m, 5H), 2.7−3.0 (m, 1H), 3.1−3.5 (m, 1H), 3.84 (broad s, 1H), 5.14 (d of d, 1H, J = 12, 3 Hz), 5.48 (d of d of d, 1H, J = 12, 8, 3 Hz). *Anal.* calcd. for $C_{15}H_{22}O$: C 82.52, H 10.16; found: C 82.17, H 10.20.

Treatment of the bicyclic dienone ***29*** *with NaOMe−DOMe*

To a solution of the bicyclic dienone **29** (12 mg, 92:8 mixture of diastereomers) in 2 mL of methanol-d_1 was added a small amount of dry sodium methoxide and the resulting mixture was refluxed under an atmosphere of nitrogen for 30 h. The reaction mixture was cooled to room temperature, diluted with D_2O, and then was extracted thoroughly with petroleum ether. The combined extract was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 100−110°C/0.1 Torr) of the residual material gave 8 mg of a colorless oil. Analysis of this oil by glc and by glc − mass spectrometry showed that it consisted of a mixture of two components (ratio approximately 80:20), each exhibiting a molecular ion of m/e 220. The glc retention times of the major and minor isomers corresponded to those of the major and minor components in the starting material **29**. The ir spectrum of the distilled material exhibited a strong absorption at 1700 cm^{-1}. The ^1H nmr spectrum showed that the signal (broad singlet at δ 3.84) due to the bridgehead proton in **29** had disappeared, that the 3-proton doublet (δ 1.06) had collapsed to a singlet, and that the signal (broad singlet at δ 1.78) due to the vinyl methyl group had remained unchanged. On the basis of these data, the product could be identified as the dideuterated ketone **31**.

Preparation of the bicyclic enone ***32***

To a solution of the bicyclic dienone **29** (170 mg, 0.78 mmol) in 30 mL of dry, degassed benzene was added 35 mg of tris(triphenylphosphine)chlororhodium and the resulting solution was stirred under an atmosphere of hydrogen for 22 h. The reaction mixture was diluted with petroleum ether and filtered through a short column of silica gel. The column was eluted with petroleum ether. Removal of the solvent from the combined eluate, followed by distillation (air-bath temperature 100−112°C/0.1 Torr) of the remaining brown liquid gave 163 mg (95%) of the bicyclic enone **32** as a colorless oil. Analysis of this material by glc − mass spectrometry indicated that it consisted of a mixture of two diastereomers in a ratio of about 85:15; ir(film): 1700 cm^{-1}; ^1H nmr δ: 0.86, 1.00, 1.74 (s, s, broad s, 3H each), 1.05 (d, 3H, J = 6 Hz), 1.4−1.6 (m, 4H), 1.84−2.90 (diffuse m, 7H), 3.42 (broad s, 1H). *Anal.* calcd. for $C_{15}H_{24}O$: C 81.76, H 10.98; found: C 81.67, H 11.00.

Preparation of the enol phosphate ***33***

To a cold (−78°C), stirred solution of lithium diisopropylamide (0.42 mmol) in 4 mL of dry THF under an atmosphere of nitrogen, was added dropwise a solution of the bicyclic enone **32** (61 mg, 0.28 mmol) in 2 mL of dry THF. After the solution had been stirred at −78°C for 30 min and at 0°C for 15 min, it was recooled to −78°C and dry tetramethylethylenediamine (1.5 mL) was added. Diethyl bromophosphate (200 mg, 0.56 mmol) was added dropwise, the reaction mixture was stirred at −78°C for 30 min and at room temperature for 1 h, and then was poured into brine. The resultant mixture was extracted thoroughly with ether. The combined extract was washed thrice with brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave ~100 mg of a yellow oil. This crude material, the ir spectrum of which showed no carbonyl absorption,

was used directly for the next step of the synthetic sequence. However, subjection of a small amount of this material to preparative tlc, followed by distillation (air-bath temperature 155–165°C/0.1 Torr) of the oil thus obtained, provided an analytical sample of the enol phosphate **33**; ir(film): 1450, 1275, 1040, 975 cm^{-1}; ^1H nmr δ: 0.80, 1.06, 1.70, 1.78 (s, s, broad s, broad s, 3H each), 1.34 (d of t, 6H, J = 8, 2 Hz), 1.1–1.6 (diffuse m, 6H), 1.9–2.6 (m, 4H), 3.39 (broad s, 1H), 4.17 (overlapped d of q, 4H, J = 8, 8 Hz). *Anal.* calcd. for $C_{19}H_{33}O_4P$: C 64.02, H 9.33; found: C 64.27, H 9.39.

Preparation of (±)-β-himachalene (2)

To a cold (0°C), stirred solution of lithium metal (9 mg) in ethylamine (25 mL, freshly distilled from lithium metal) under an atmosphere of nitrogen was added, dropwise, a solution of the enol phosphate **33** (46 mg, 0.13 mmol) and dry *tert*-butyl alcohol (38.5 mg, 0.52 mmol) in 2 mL of dry THF. The reaction mixture was stirred at 0°C for 20 min and then was quenched cautiously with water. The resulting mixture was extracted thoroughly with petroleum ether. The combined extract was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave 18 mg of a pale yellow oil which was subjected to purification by preparative tlc. Distillation (air-bath temperature 70–80°C/0.1 Torr) of the material thus obtained gave 10 mg (38%) of (±)-β-himachalene (**2**) as a colorless oil which was spectrally (ir, ^1H nmr) and chromatographically (tlc, glc) identical with authentic samples of natural β-himachalene kindly supplied by Drs. V. Lukes (Czechoslovakia) and T. Norin (Sweden); ir(film): 2950, 1450, 1380, 1360 cm^{-1}; ^1H nmr δ: 0.74, 0.98 (s, s, 3H each), 1.2–2.7 (diffuse m, 10H), 1.74 (broad s, 6H), 2.90 (broad s, 1H), 5.45 (m, 1H).

Received June 25, 1982

RODRIGUE SAVOIE, MARIE PIGEON-GOSSELIN, ANDRÉ RODRIGUE, and ROBERT CHÊNEVERT. Can. J. Chem. **61**, 1248 (1983).

The macrocyclic ether 18-crown-6 can form 1:1 stoichiometric complexes with $NOBF_4$ and NO_2BF_4. These complexes, which are soluble in organic media, have been isolated and studied by infrared and Raman spectroscopy. The spectra suggest that the conformation of the ether in these complexes is essentially that of the highly regular crown of D_{3d} symmetry, the NO^+ and NO_2^+ ions being stuck into the ether cavity.

RODRIGUE SAVOIE, MARIE PIGEON-GOSSELIN, ANDRÉ RODRIGUE et ROBERT CHÊNEVERT. Can. J. Chem. **61**, 1248 (1983).

L'éther macrocyclique "18-crown-6" peut former des complexes de stoéchiométrie 1:1 avec les tétrafluoroborates de nitronium et de nitrosonium. Ces complexes, qui sont solubles en milieu organique, ont été isolés et étudiés par spectroscopie infrarouge et Raman. Les données spectrales indiquent que la conformation de l'éther dans ces complexes est essentiellement celle très régulière de symétrie D_{3d}, les ions NO^+ et NO_2^+ étant localisés dans la cavité centrale de l'éther.

Introduction

Macrocyclic polyether molecules are characterized by an internal cavity lined with electronegative oxygen atoms. The accumulation of partial negative charges around this cavity explains the remarkable complexing ability of these molecules, particularly towards positive ions. Neutral polar guest compounds are also complexed, especially those which can form hydrogen bonds with the oxygen atoms of the ether (see, for example, refs. 1–3). When both conditions are simultaneously met, e.g. with cations which can form H-bonds with the ether, particularly stable complexes are obtained. We have recently reported on the synthesis and vibrational spectra of such a complex, $H_3O^+BF_4^- \cdot 18C6$[2] (4), whose crystal structure is now being examined by X-ray crystallography.[3]

In an attempt to solubilize nitronium tetrafluoroborate (NO_2BF_4) and the corresponding nitrosonium salt ($NOBF_4$), which are useful organic reagents but noteworthily insoluble in most organic solvents, we found that this could easily be achieved by complexation with 18C6, although the reactivity of the cations was then strongly modified. The complexes formed between 18C6 and the tetrafluoroborates were isolated, and we present here the results of various measurements aimed at specifying their structure.

Experimental

All of the solvents used in the preparation of the complexes were thoroughly dried, as both the starting tetrafluoroborates and the resulting complexes are highly hygroscopic and readily hydrolyzed. The $NOBF_4 \cdot 18C6$ and $NO_2BF_4 \cdot 18C6$ complexes were prepared by mixing equimolar amounts of the tetrafluoroborate salt and the ether in $CHCl_3$ or CH_2Cl_2, and shaking the resulting mixture until complete dissolution of the salt (~10 min). The synthesis was also carried out with an excess of the salt, the extra material being filtered off after the complexation was complete. The complexes were then crystallized from the chloroform solution by adding a small amount of diethyl ether. Both complexes can be hydrolyzed to the corresponding hydronium complex, $H_3O^+BF_4^- \cdot 18C6$ (4), with a >95% yield. The hydrolysis takes place readily in acetonitrile, upon addition of a small amount of water. The solvent is then evaporated under reduced pressure and the residual hydronium complex is recuperated by filtration after being washed with diethyl ether.

Characteristics of the complexes

$NOBF_4 \cdot 18C6$: slightly yellow solid (mp 113–113.5°C); yield: 93%; ^1H nmr, δ: 3.67 ppm; ^{13}C nmr: 70.327 ppm (compared to 70.755 for the free ether in $CDCl_3$). *Anal.* calcd.: C 37.81%, H 6.35%, N 3.67%; found: C 38.4%, H 6.2%, N 3.5%.

$NO_2BF_4 \cdot 18C6$: colorless solid (mp 95°C); yield 81%; ^1H nmr, δ: 3.67 ppm; ^{13}C nmr: 70.463 ppm. *Anal.* calcd.: C 36.29%, H 6.08%, N 3.52%; found: C 37.5–40.3%, H 5.9–6.6%, N 2.8–3.6%.

The elementary analysis for the nitronium complex is not very satisfactory, as large variations were obtained, even from samples from the same batch (the values given above are extremes). This reflects the instability of the complex, particularly towards moisture. Although the analysis suggests an incomplete complexation between NO_2BF_4 and 18C6, the Raman spectrum of the solid complex, which is discussed below, gives no evidence for the presence of uncomplexed 18C6, whose spectrum is very characteristic (4).

For the infrared, hexachlorobutadiene, Fluorolube, and Nujol mulls contained between Irtran-4 (ZnSe) and AgCl windows were used. The spectra were recorded on a Beckman Model IR 4250 spectrophotometer, at a slit width of 2 cm^{-1}. For the Raman measurements, the samples were contained in sealed glass capillaries. These were mounted on a motor shaft and rotated at high speed when placed in the laser beam, to prevent sample decomposition. The solids and the nitronium complex in solution in chloroform were studied at ~200 mW laser power. In the case of the nitrosonium complex solution, however, the laser power had to be kept down to ~20 mW at the sample. The slit width then had to be fixed at 5 cm^{-1} in order to get a reasonably intense spectrum, whereas the solution of the nitronium complex could be studied at 3 cm^{-1} and the solids at 1 cm^{-1} slit widths. The spectra were recorded on a microcomputer-controlled Spex Model 1400 spectrometer (5), using the 514.5 nm exciting line from a Spectra Physics Model 165 argon ion laser. Data points were gathered by steps of 1 cm^{-1}, at 1 second intervals.

The ^1H nmr spectra were taken on a Bruker HX-90 (90 MHz) with TMS as an internal standard and, for ^{13}C, on a Bruker WP-80 spectrometer working at 20 MHz.

Results and discussion

The infrared spectra of the $NOBF_4 \cdot 18C6$ and $NO_2BF_4 \cdot 18C6$ complexes are reproduced in Fig. 1, and the corresponding Raman spectra of these solids and their solutions in chloroform are compared with those of the free tetrafluoroborate salts in Figs. 2 and 3 respectively.

Among the characteristic vibrations of the tetrahedral BF_4^-

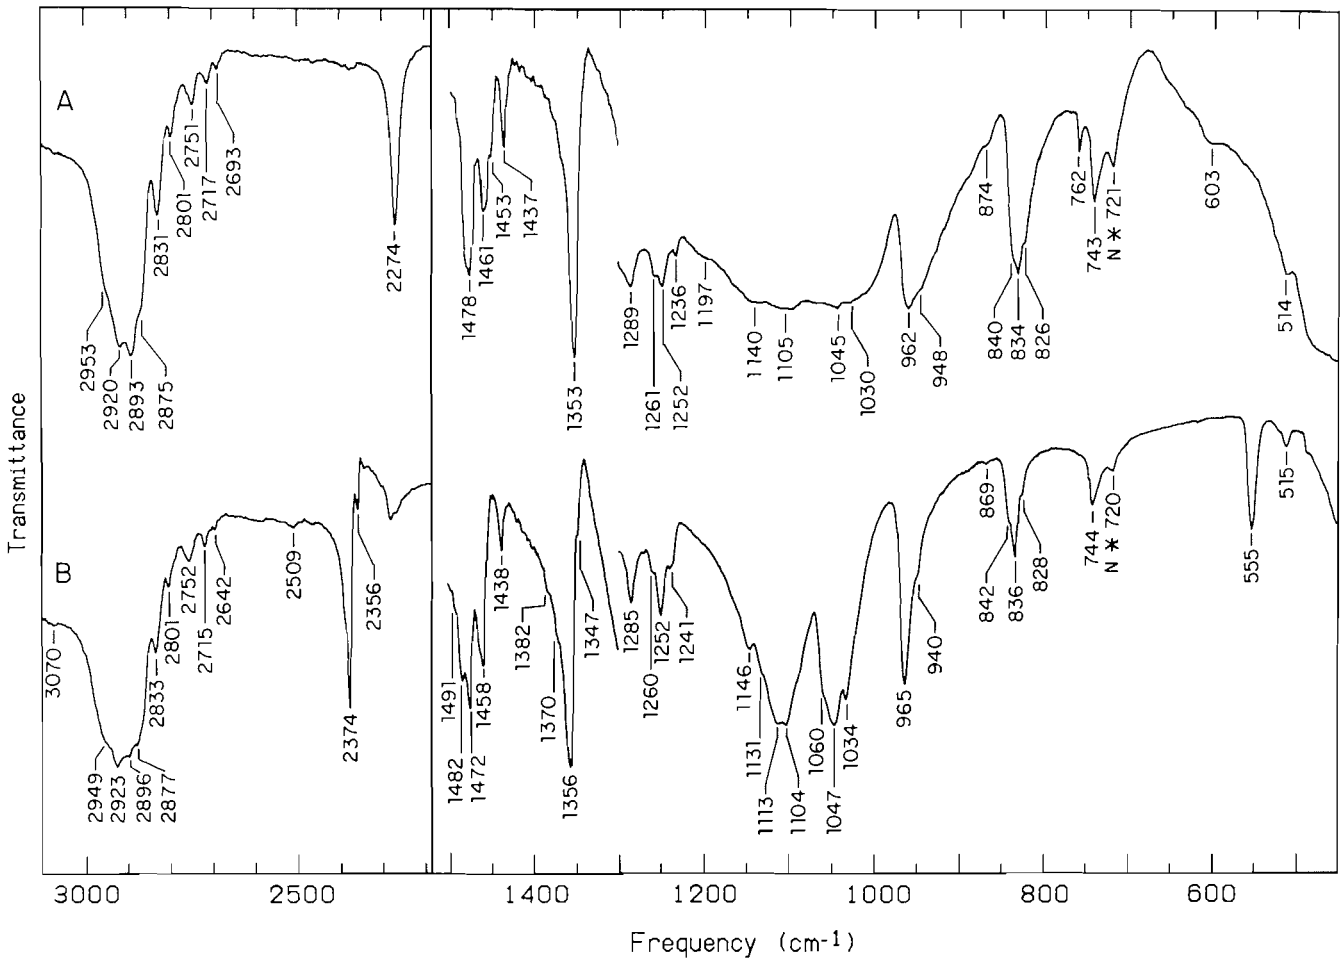

FIG. 1. Infrared spectra of hexachlorobutadiene (1300−3100 cm^{-1}) and Nujol (500−1300 cm^{-1}) mulls of the (A) $NOBF_4 \cdot 18C6$ and (B) $NO_2BF_4 \cdot 18C6$ complexes at room temperature.

ion (6−8), the totally symmetric stretching mode ν_1 gives a very sharp and strong line in the Raman spectra. From 771 and 778 cm^{-1} in the spectra of $NOBF_4$ and NO_2BF_4, respectively, this vibration is shifted to 764 cm^{-1} in the 18C6 complexes, both in $CHCl_3$ solution and in the crystalline state. The activity of this normally infrared-inactive vibration in the ir spectrum of the $NOBF_4 \cdot 18C6$ complex, where a weak band is definitely present at 762 cm^{-1} (Fig. 1A), points to some departure from tetrahedral symmetry of this ion in the nitrosonium complex. The same effect is not detected in the nitronium complex, suggesting a higher symmetry of the BF_4^- ion in the latter. It should be noted that the ν_1 band of BF_4^- is also present in the ir spectra of both free $NOBF_4$ and NO_2BF_4 (9). The decrease in the infrared intensity of this band upon complexation indicates a higher symmetry of these ions in the complexes. This is also suggested in $NOBF_4$ from the fact that the ν_4 band is split at 526/533 cm^{-1} in the salt, but not in the complex (521 cm^{-1}). The nearby band at 549 cm^{-1} in the spectrum of the complex, as well as the 368 cm^{-1} peak which is very close to the ν_2 band at 357 cm^{-1}, are most likely attributable to ether vibrations as they are also present in the spectrum of the $KBr \cdot 18C6$ complex (10).

Very little information can be obtained from the very strong infrared band near 1050 cm^{-1}, due to the asymmetric stretch (ν_3) of the BF_4^- ion. As in other tetrafluoroborate salts (6−8), this band is broadened by Fermi resonance with $2\nu_4$ and by reflection, a phenomenon often associated with transitions characterized by large $\partial\mu/\partial Q$ values. In the Raman spectrum, the corresponding band is also very broad, although extremely weak.

The stretching vibration of the NO^+ ion usually occurs in the 2300−2350 cm^{-1} frequency range, e.g. 2340 cm^{-1} in $NOBF_4$ (9), 2326 cm^{-1} in $NOAuF_6$ (11), and 2298 cm^{-1} in sulfuric acid solutions (12). The very large frequency shift, from 2342 to 2274 cm^{-1}, occurring upon complexation of $NOBF_4$ with 18C6 suggests a weakening of the N—O^+ bond in this process. This could result from a partial transfer of electronic charge from the lone pairs on the oxygen atoms of the crown ether into the vacant π^* antibonding orbitals of the nitrosonium ion. Note that if a complete transfer of the equivalent of one electron were to occur, then the N—O stretching frequency would drop to ~1875 cm^{-1}, which is the value for a neutral NO molecule isolated in an argon matrix (13).

Although the exact location of the NO^+ ion in the $NOBF_4 \cdot 18C6$ complex cannot be determined with certainty from the present results, it appears likely that it penetrates the ring of the macrocyclic ether. The cylindrical diameter of the NO^+ ion should be very similar to that of the diazonium group —N≡N^+ (~2.4 Å), and the latter has been shown by X-ray diffraction to project into the hole of the 21-crown-7 ether, the corresponding complex with 18C6 being less stable but presumably of a similar nature (14).

The N—O^+ stretching band in the Raman spectrum of the $NOBF_4 \cdot 18C6$ complex in solution in $CHCl_3$ (Fig. 2A) is rela-

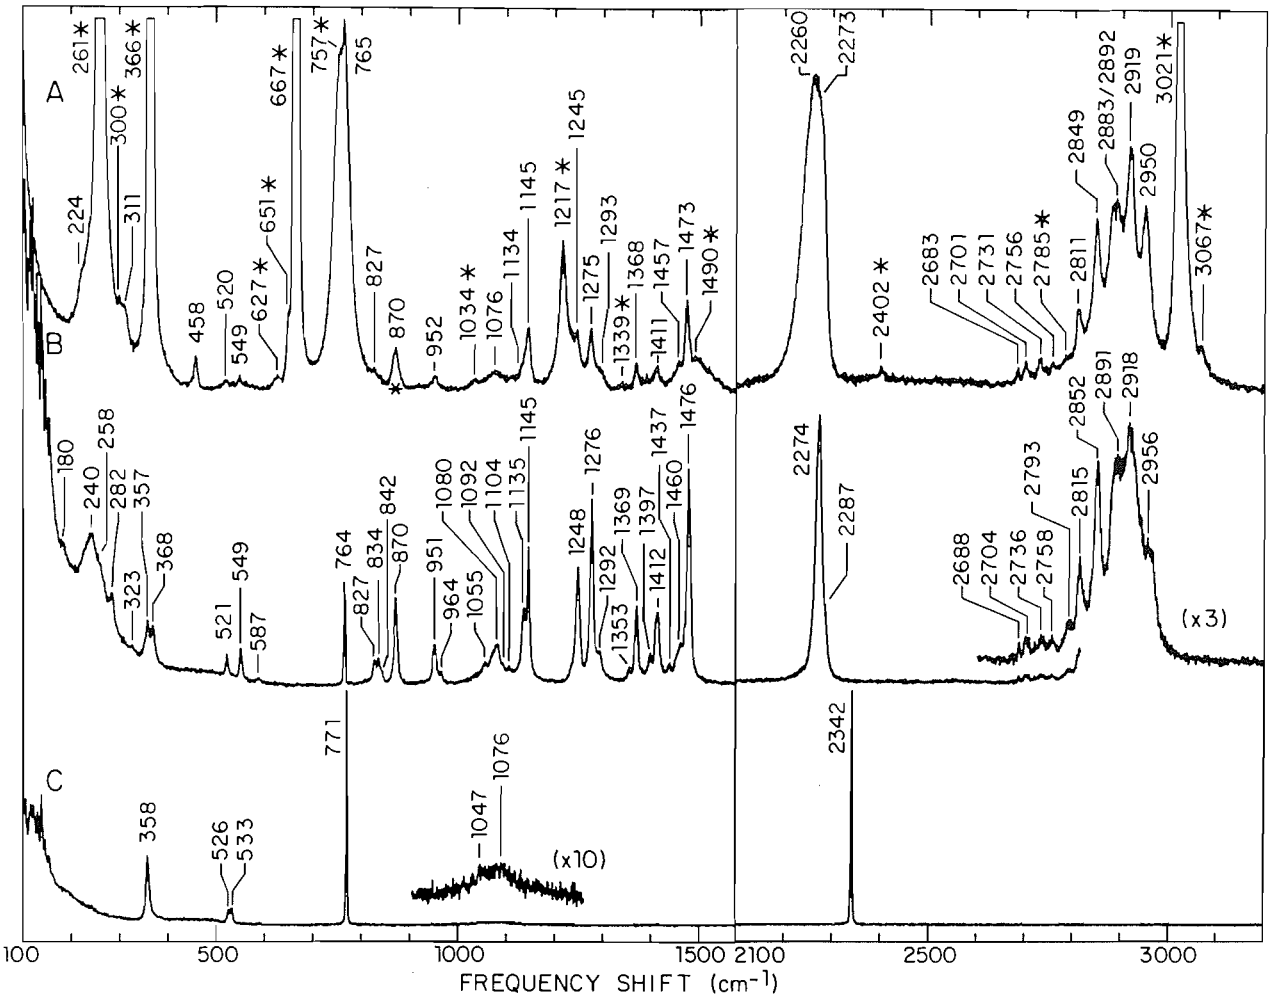

FIG. 2. Raman spectra of the $NOBF_4 \cdot 18C6$ complex (A) in solution in chloroform (solvent peaks indicated by *) and (B) in the crystalline state. The spectrum of the free $NOBF_4$ salt is shown in (C).

tively broad and appears to contain two distinct peaks separated by 15 cm^{-1}. This possibly indicates the presence in the solution of two types of complexed species. If indeed the rod-like NO^+ cation is stuck into the ether cavity, like the axle in a wheel, then it seems logical to assume that the accompanying BF_4^- counterion can be located on either side of the $NO^+ \cdot 18C6$ moiety, thus giving two different types of ion pairs: $NO^+BF_4^-$ and $ON^+BF_4^-$. In the solid complex, although the NO stretching Raman band is sharper than in the solution, it is still considerably broader than in the $NOBF_4$ salt. The main peak at 2274 cm^{-1}, with an associated low-frequency shoulder at ~2269 cm^{-1} in the spectrum at room temperature, is transformed into a well resolved doublet at 2270/2274 cm^{-1} at liquid nitrogen temperature (spectrum not shown). This splitting probably arises from intermolecular vibrational coupling, although some two-dimensional orientational disorder of the NO^+ ions, similar to that found in solid neutral NO, could be present in the solid and possibly explain the broad shoulder at ~2287 cm^{-1} on the high-frequency side of the main peak. It is noteworthy that the ν_1 vibration of the BF_4^- ion is also split, at 767/769 cm^{-1}, in the Raman spectrum at liquid nitrogen temperature. Such a fine splitting associated with very narrow vibrational components is best explained by a factor group effect, which would indicate that the primitive cell of the crystal contains at least two $NOBF_4 \cdot 18C6$ formula units.

The vibrational frequencies of the linear and centrosymmetric NO_2^+ ion are well known from its infrared and Raman spectra (9, 15–17). In the $NO_2BF_4 \cdot 18C6$ complex, the totally symmetric stretch gives a sharp Raman peak at 1397 cm^{-1}, slightly shifted from its 1407 cm^{-1} value in the free salt, whereas the corresponding asymmetric mode and the bending vibration occur at 2374 and 555 cm^{-1}, respectively, in the infrared spectrum. The mutual exclusion rule for the infrared and Raman activity of the vibrations of this ion in the complex appears to hold, which suggests that it is essentially of $D_{\infty h}$ symmetry in solid $NO_2BF_4 \cdot 18C6$. As in the case of the nitrosonium compound, it is likely that the nitronium ion is stuck into the ether cavity in the complex. Such a structure has been proposed for CdX_2 and HgX_2 adducts of 18C6 (18).

Both the infrared and Raman spectra of the crown ether in the nitronium and nitrosonium complexes are very similar to those of other complexes, such as with KSCN, RbSCN, and CsSCN (10) in which the ether has the highly symmetrical D_{3d} symmetry (19). This is also the case with the KBr complex, whose infrared (10, 20, 21) and Raman (10) spectra have been extensively studied, and with the nitromethane · 18C6 complex whose single crystal spectrum has been reported (22).

Except for the characteristic bands of the cation, the Raman spectrum of $NO_2BF_4 \cdot 18C6$ is practically identical to those of the alkaline thiocyanates (10). In the spectrum of the corre-

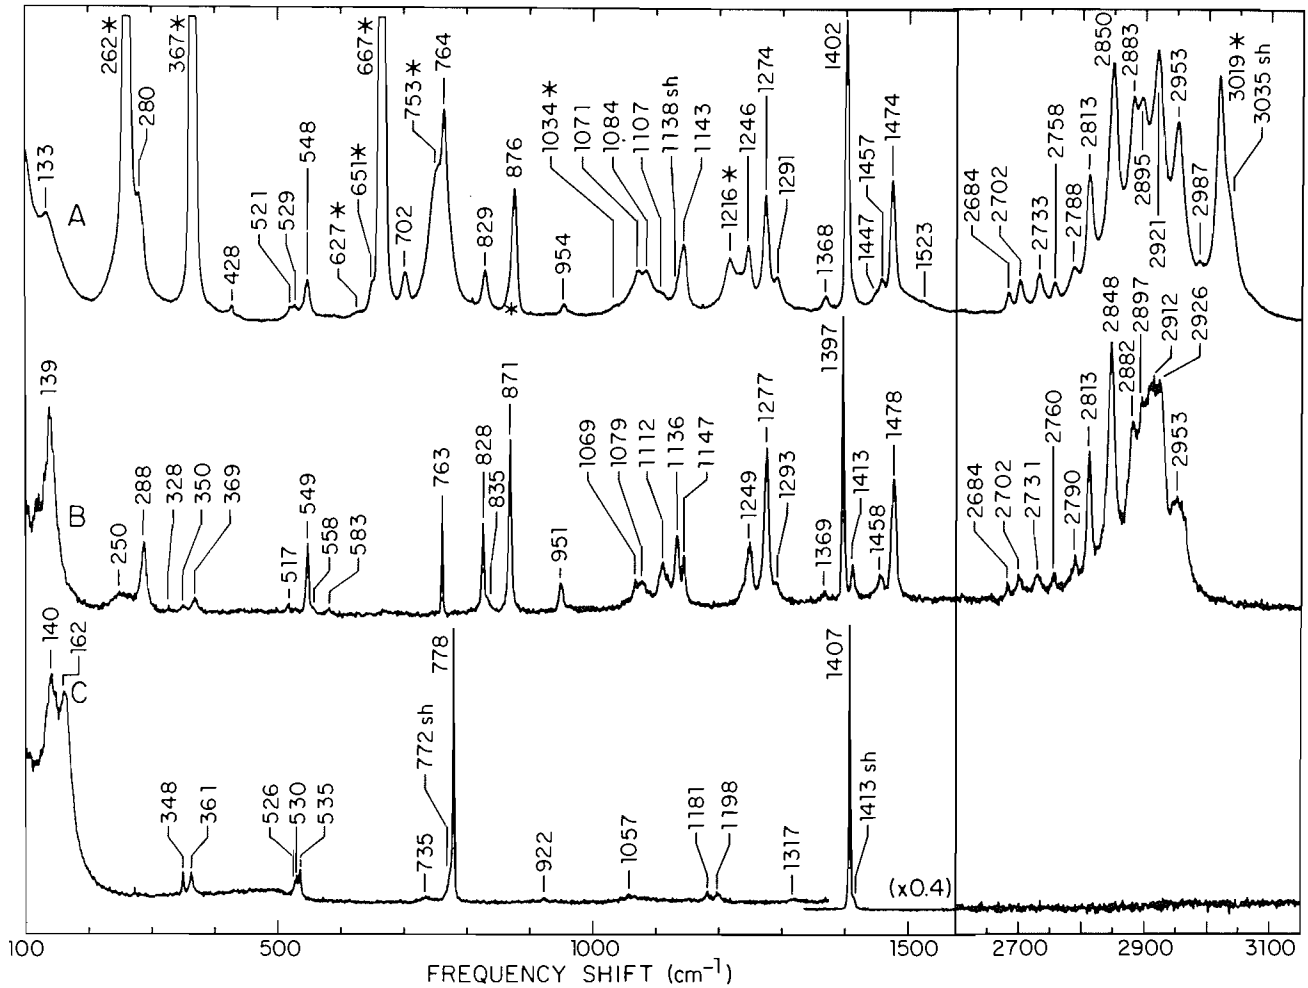

FIG. 3. Raman spectra of the $NO_2BF_4 \cdot 18C6$ complex (A) in solution in chloroform (solvent peaks indicated by *) and (B) in the crystalline state. The spectrum of the free NO_2BF_4 salt is shown in (C).

sponding nitrosonium complex, some weak extra features are present, for example at 964 cm^{-1} and in the 835 cm^{-1} region. The infrared spectra of both complexes also show weak bands, such as those at 1482 and 826 cm^{-1}, which do not appear to be present in the spectra of the KBr and alkaline thiocyanate complexes (10, 20, 21). (A stronger peak at 743 cm^{-1} in the spectra of both complexes is left unexplained as it does not belong to any of the known vibrations of the species present in these compounds.) These observations suggest that the shape of the 18C6 ether in the complexes described here is essentially that of a regular crown of symmetry D_{3d}, although some distortion is probably present, especially in the nitrosonium complex. The similarity between the Raman spectra of the solid complexes and those of the corresponding solutions also indicates that the 18C6·salt complex unit is retained upon dissolution, with little change in its basic structure.

The complexation of $NOBF_4$ and NO_2BF_4 by 18C6 strongly modifies their reactivity. For example, when the $NOBF_4 \cdot 18C6$ complex is allowed to react with benzamide in ice-cold acetonitrile, an homogeneous solution is obtained, from which no nitrogen evolution takes place and all of the starting materials can be recuperated, indicating that no reaction has occurred. This contrasts with the reaction in the absence of the crown ether: heterogeneous conditions then prevail, and the amide is transformed into the corresponding acid with a >90% yield, a behaviour consistent with the very low solubility of free $NOBF_4$ and the oxidizing nature of this salt under mild conditions (23). Similarly, free NO_2BF_4 (4 equivalents) reacts with toluene (1 equivalent) in dichloromethane, at −60°C under heterogeneous conditions, to yield 85% of a mixture of *o*- and p-nitrotoluene through a Friedel–Crafts type of reaction (24). However, when the reaction is repeated in the presence of 18C6 at a molar concentration equal to that of the salt, the nitration is completely suppressed in the resulting homogeneous solution. The reaction does, however, take place with good yield at room temperature or above, showing that the process is not completely hindered, although considerably slowed down.

On the interpretation of vibrational relaxation times

HESHEL TEITELBAUM

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received April 27, 1982

H. TEITELBAUM. Can. J. Chem. **61**, 1253 (1983).

Rate laws for the evolution of vibrational energy level populations are derived when the Bethe–Teller law is obeyed. It is assumed that a Boltzmann distribution is maintained via rapid V–V processes. A variety of different rate laws result depending on the size and direction of the perturbation, the extent from equilibrium, and how classical the oscillator is at the initial and final conditions. An earlier analysis by Breshears is shown to be a special case. A prescription is given for procedures to compare relaxation times obtained from shock tube experiments and from laser-induced fluorescence experiments, when T–V energy transfer processes are rate-determining. Corrections for thermal effects are included. Shock tube, fluorescence, and chemical activation experiments are proposed which provide meaningful conditions for testing the Bethe–Teller law and for testing the existence of a Boltzmann distribution.

H. TEITELBAUM. Can. J. Chem. **61**, 1253 (1983).

On a déduit les lois de vitesse de l'évolution des populations du niveau d'énergie vibrationnel lorsque la loi de Bethe–Teller se vérifie. On pense que la distribution de Boltzmann est maintenue par l'intermédiaire d'un processus rapide du type V–V. Il en résulte diverses lois de vitesse suivant l'amplitude et le sens de la perturbation suivant la position par rapport à l'équilibre et suivant le comportement classique ou non de l'oscillateur dans les conditions initiales et finales. On montre qu'une analyse antérieure de Breshears n'est qu'un cas spécial. On décrit la façon de procéder pour comparer les temps de relaxation obtenus à partir d'expérience en tube blindé et à partir d'expériences de fluorescence induite au laser, lorsque les processus de transfert d'énergie du type T–V sont les étapes déterminantes. On y inclut les corrections pour tenir compte des effets thermiques. On propose des expériences d'activation chimique, de fluorescence en tube blindé qui fournissent des conditions propices pour vérifier la loi de Bethe–Teller et pour vérifier l'existence d'une distribution de Boltzmann.

[Traduit par le journal]

Introduction

In an earlier study Breshears showed that the nature and extent of the departure from equilibrium determines the relative relaxation rates of vibrational level populations (1). In particular, the fluorescent intensities from vibrational levels v decay with rate coefficients proportional to v, whereas all vibrational levels in shock wave experiments decay with the same rate coefficient. These results were shown to be natural consequences of the existence of a Boltzmann vibrational distribution and a corresponding temperature T_{vib} within a single mode of a harmonic oscillator. Although not clearly stated, they are also a consequence of the vibrational levels subsequently exchanging energy ϵ_{vib} with translational energy according to the Bethe–Teller law (2) where ϵ_T is the statistical-thermodynamic vibrational energy at the translational temperature T (which in principle also varies with time).

$$[1] \qquad \frac{d\epsilon_{vib}}{dt} = \frac{1}{\tau}(\epsilon_T - \epsilon_{vib})$$

The first condition is generally supposed to be fulfilled by rapid vibration–vibration (V–V) energy transfer processes for sufficiently non-diluted gases:

$$[2] \qquad A(v) + A(v') \rightleftarrows A(v-1) + A(v'+1)$$

However the rapidity is not guaranteed if the gas A is very dilute in say Ar. The second condition (eq. [1]) is theoretically sound for small perturbations (3), i.e. near equilibrium. It is also theoretically sound for a special relaxation mechanism (harmonic oscillators subject to single quantum translation-to-vibration (T–V) Landau–Teller type transitions) (2, 4, 5). Thus [1] is by no means generally true. Nevertheless its validity is assumed by those who plot log (fluorescence intensity) or log (dE/dt) vs. time and extract single relaxation times from the slopes of such plots. That this procedure appears to work for most cases has led to its acceptance. Yet [1] has really only been confirmed experimentally for a very limited range of conditions (6, 7) based on the quasi-exponential decay of vibrational energy. Thus it is clear that without a complete theoretical base [1] must be examined more carefully.

Breshears (1) analyzed the case $\theta = h\nu/k \gg T_{vib}$ and $\theta \gg T$, where ν is the fundamental frequency. We wish to continue the analysis for other cases which are extreme but which would provide more meaningful conditions under which the Bethe–Teller law should be tested. In so doing, definitive experiments will be proposed.

Breshears' study lays the foundation for making comparisons of vibrational relaxation times as obtained from laser-induced fluorescence and from shock wave studies. We extend the analysis to give prescriptions for adjusting one or the other result, including thermal effects which are generally ignored.

Relaxation model

The fractional vibrational level population n_v/n for quantum number v of a harmonic oscillator is given by the Boltzmann distribution if processes such as [2] are rapid:

$$[3] \qquad n_v/n = \exp(-v\theta/T_{vib}) - \exp[-(v+1)\theta/T_{vib}]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

A similar expression exists at equilibrium when the translational temperature T replaces T_{vib}, and n_v^e/n represents the equilibrium fraction. As long as the translational temperature does not vary significantly, the quasi-first order rate coefficient $d \ln |n_v - n_v^e|/dt$ is (1):

$$[4] \quad \frac{d \ln |n_v - n_v^e|}{dt} = \frac{\theta}{T_{vib}^2} \frac{dT_{vib}}{dt} \times \frac{v - (v+1)\exp(-\theta/T_{vib})}{1 - \exp(-\theta/T_{vib}) - [1 - \exp(-\theta/T)]\left[\exp\left\{-v\theta\left(\frac{1}{T} - \frac{1}{T_{vib}}\right)\right\}\right]}$$

The second factor on the right hand side is denoted F, as in ref. 1. The first factor is determined by the rate law which is here assumed to be given by [1]. It was not evaluated in ref. 1. For a Boltzmann distribution of vibrational level populations of a pure gas of n harmonic oscillators at the equilibrium translational temperature T

$$[5] \quad \epsilon_T = nh\nu\,[\exp(\theta/T) - 1]^{-1}$$

Similarly

$$[6] \quad \epsilon_{vib} = nh\nu\,[\exp(\theta/T_{vib}) - 1]^{-1}$$

Substituting [5] and the derivative of ϵ_{vib} with respect to T_{vib} into [1], we obtain the rate law in terms of temperatures. τ is the vibrational energy relaxation time.

$$[7] \quad \frac{\theta}{T_{vib}^2} \frac{dT_{vib}}{dt} = \frac{1}{\tau}\left\{\exp\left[-\theta\left(\frac{1}{T} - \frac{1}{T_{vib}}\right)\right] - 1\right\} \times \left\{\frac{1 - \exp(-\theta/T_{vib})}{1 - \exp(-\theta/T)}\right\}$$

We now examine the behaviour of [4] for the special cases of shock tube experiments and fluorescence experiments. In the former $T \geq T_{vib}$, with T_{vib} varying from an initial value usually ~300 K to T; in the latter $T_{vib} \geq T$, with T_{vib} varying from an arbitrary initially high value to T. In both cases the perturbations are considered large, but shock wave experiments are usually but not always made near equilibrium, whereas fluorescence is almost always measured within the first 2 or 3 decay units i.e. $t/\tau \leqslant 3$. In both cases T varies with time according to whether vibrational energy is lost or gained. As will be seen the results depend on whether or not the molecule behaves as a classical oscillator ($\theta \ll T$) during relaxation.

Fluorescence

A. $\theta \gg T_{vib} \gg T$

$$[8] \quad \frac{\theta}{T_{vib}^2} \frac{dT_{vib}}{dt} \rightarrow -\frac{1}{\tau}$$

Furthermore $F \rightarrow v$ as shown in ref. 1, and all levels relax with rates proportional to v. If we assume a mechanism, the proportionality constant can be identified from [7]: $v = 1$ may relax by the T–V process

$$A(v = 1) + M \rightarrow A(v = 0) + M$$

with a rate constant k_{10}. Since the vibrational temperature is so high the population of $v = 0$ is much less than that at equilibrium, and the reverse process is not important. Thus $\tau = 1/k_{10}$, and

$$[9] \quad d \ln |n_v - n_v^e|/dt = -vk_{10}$$

The fluorescence intensity I_f is given by ref. 8:

$$I_f \propto \sum_{v=1} v n_v \propto \epsilon_{vib}$$

and relaxation times measured in this way are thus energy relaxation times. It is instructive to note that the solution to eq. [8] is

$$[10] \quad \frac{\theta}{T_{vib}} = \frac{\theta}{T_{vib}^0} + k_{10}t$$

Thus

$$\begin{aligned} I_f \propto \epsilon_{vib} &= nh\nu/[\exp(\theta/T_{vib}) - 1] \simeq nh\nu[\exp(-\theta/T_{vib})] \\ &= nh\nu[\exp(-\theta/T_{vib}^0)]\,[\exp(-k_{10}t)] \\ &= I_f^0 \exp(-k_{10}t) \end{aligned}$$

If the sample gas is optically thin to radiation from all levels then the effective rate constant is k_{10}. Breshears has dealt (1) with cases which are not optically thin for all v.

B. $T_{vib} \gg \theta \gg T$

The initial value of T_{vib} can be determined from

$$[11] \quad \epsilon_{vib}^0 = \frac{nh\nu}{\exp(\theta/T_{vib}^0 - 1)} \approx nkT_{vib}^0$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

It is quite clear that if all of the $v = 0$ population were laser-excited into $v = 1$, i.e. $\epsilon^0_{vib} \approx nh\nu$, then T^0_{vib} could only be as much as $\theta/\ln 2$. Thus $T_{vib} \gg \theta$ can usually be achieved realistically only as the result of a production from an exothermic chemical reaction. The population levels can be monitored by, e.g., infrared chemiluminescence. After sufficient time the situation degenerates to case *A*. Otherwise

$$\frac{\theta}{T_{vib}^2}\frac{dT_{vib}}{dt} \rightarrow -\frac{1}{\tau}\frac{\theta}{T_{vib}}$$

i.e.

[12] $$T_{vib} = T^0_{vib}\, e^{-t/\tau}$$

$T_{vib} \gg \theta$ prevails only for $t/\tau \ll \ln (T^0_{vib}/\theta)$

$$F \rightarrow \frac{-1}{\theta/T_{vib} - e^{-v\theta/T}}$$

There exists a characteristic temperature T_* which determines the sign of F, and hence the form of the relaxation rate law. T_* is given by

[13] $$T_* = \theta e^{v\theta/T} > \theta$$

For $T_{vib} \gg T_*$,

[14] $$F \rightarrow e^{v\theta/T}$$

For $T_{vib} \ll T_*$,

[15] $$F \rightarrow -T_{vib}/\theta$$

We note that a variation in T_{vib} represents a time history. If $T^0_{vib} \gg T_*$ then relaxation will proceed according to [14], but eventually ($t/\tau > \ln [T^0_{vib}/T_*]$) the relaxation will proceed according to [15]. Thus

(a) $T_{vib} \gg T_* \gg \theta \gg T$

$$d \ln |n_v - n^e_v|/dt \rightarrow -\frac{1}{\tau}\frac{\theta\, e^{v\theta/T}}{T_{vib}} = -\frac{1}{\tau}\frac{T_*}{T_{vib}}$$

Using expression [12] for the time-variation of T_{vib},

$$d \ln |n_v - n^e_v|/dt = -\frac{1}{\tau}\frac{T_*}{T^0_{vib}} e^{t/\tau}$$

which integrates to

[16] $$\ln\left\{\frac{n_v - n^e_v}{n^0_v - n^e_v}\right\} = -\frac{T_*}{T^0_{vib}} e^{t/\tau} = -\frac{T_*}{T_{vib}}$$

The relaxation amplitude is rather small, but the vibrational levels approach their equilibrium values with a stronger-than-exponential variation strongly dependent on v. If the gas sample is optically thin to radiation from all levels v, and if the chemiluminescence itself does not significantly affect the level populations, then $I_f \propto \epsilon_{vib}$. Note that $\theta \ll T_{vib}$ really means that the oscillator behaves classically during the relaxation of T_{vib} towards θ.
Therefore

$$I_f \propto kT_{vib}$$

or

[17] $$I_f = I^0_f\, e^{-t/\tau}$$

If in addition to $t/\tau \ll \ln (T^0_{vib}/T_*)$, we choose $t/\tau \ll 1 \ll \ln (T^0_{vib}/T_*)$, then [16] simplifies to

$$\ln\left\{\frac{n_v - n^e_v}{n^0_v - n^e_v}\right\} = -\frac{T_*}{T^0_{vib}} - \left(\frac{T_*}{T^0_{vib}}\right)\frac{t}{\tau}$$

and the vibrational levels relax with time constants $= \tau(T^0_{vib}/\theta)e^{-v\theta/T}$. This should serve as a good test of the Bethe–Teller law for strong departures from equilibrium. If we consider HF at $T = 300$ K, $\theta \simeq 5700$ K, $T_* = 10^{12}$ K; but for a molecule with reasonably small fundamental frequency such as the bending frequency of N_2O ($\bar{\nu}_2 = 589$ cm^{-1}), θ is reasonable. In this case $\theta = 848$ K, and $T_* = 14\,340$ K for $v = 1$ and 242 000 K for $v = 2$. Halogens are even more favourable.

(b) $T_* \gg T_{vib} \gg \theta \gg T$

T_{vib} eventually decreases below T_*, and even if the experimental conditions for case (*a*) are hard to attain (*b*) is feasible.

[18] $$F \rightarrow -\frac{T_{vib}}{\theta}$$

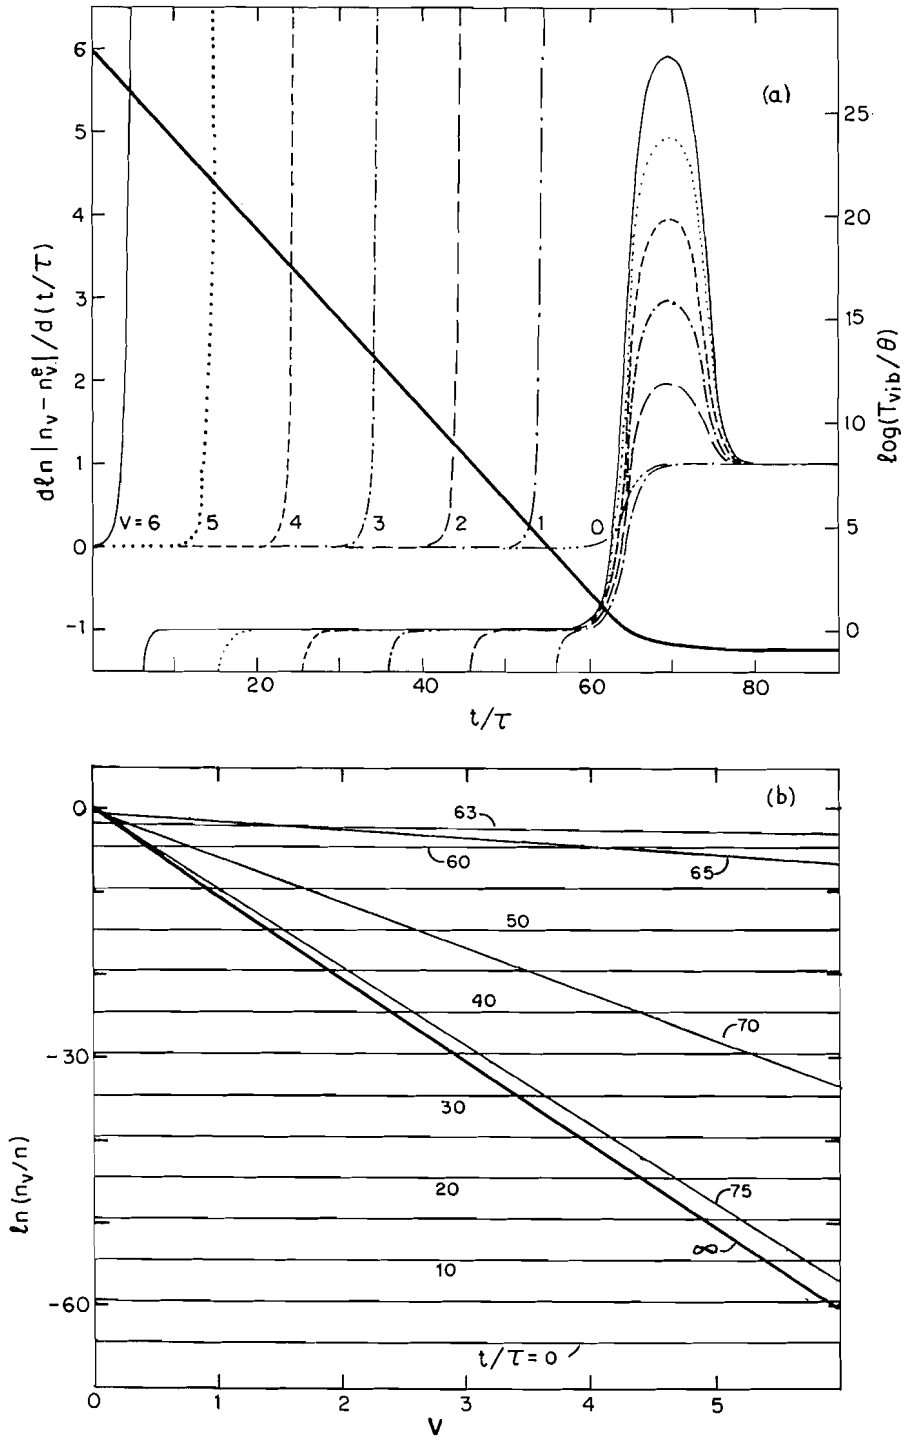

FIG. 1. Relaxation of a quantum harmonic oscillator obeying the Bethe–Teller law. Here $T^0_{vib}/\theta = 10^{28}$ K and $\theta/T = 10$. (*a*) Phenomenological rate coefficient k' as a function of reduced time and vibrational level. The thick solid curve is the variation of the vibrational temperature with time. The time origin for any real fluorescence experiment can be displaced arbitrarily to any point on the abscissa by first locating the initial vibrational temperature on the ordinate. Breshears' special case analysis (1) applies to the narrow region centred at the peaks. An ordinate of 1.0 means $k' = \tau^{-1}$. (*b*) Time evolution of the fractional level populations as a function of v (drawn as continuous curves for clarity). The thick line is the final population distribution. At the earliest time all v levels shown are underpopulated and approach equilibrium rapidly. Each level in turn becomes overpopulated, except $v = 0$, and deviate from equilibrium with a time constant τ until $t/\tau \sim 63$, whereupon the entire distribution proceeds to steepen and all level populations approach their equilibrium values at rates $\propto v$. Near equilibrium ($t/\tau > 78$) all levels relax with identical rate constants.

$$\mathrm{d}\ \ln\ |n_v - n_v^e|/\mathrm{d}t \rightarrow \frac{1}{\tau}$$

Equation [12] still expresses the time-variation of T_{vib}. The solution to [18] is

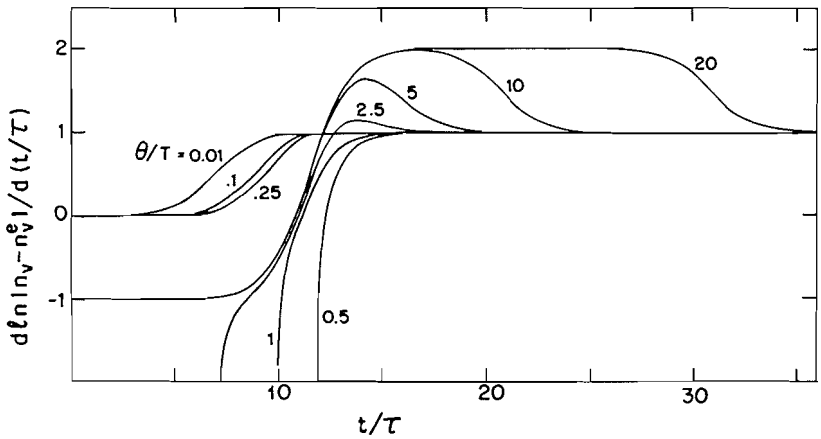

FIG. 2. Phenomenological rate coefficient for a fluorescence experiment as a function of reduced time and θ/T, which represents how close to the classical limit the relaxing molecule is. Here $v = 2$, and $T^0_{vib}/\theta = 10^5$, so that all reasonable-sized perturbations are represented by displacing the time origin. (Except near equilibrium $T_{vib} = T^0_{vib} \exp(-t/\tau)$.) Breshears' analysis applies only to $\theta/T \gg 1$, when the rate coefficient is $2\tau^{-1}$. For clarity the portions of curves for $\theta/T = 2.5, 1, 0.5$ are not drawn at times earlier than those for which the coefficients pass through $\pm\infty$. As in Fig. 1 a Boltzmann distribution is always maintained.

$$[19] \quad \ln\left|\frac{n_v - n_v^e}{n_v^0 - n_v^e}\right| = \frac{t}{\tau}$$

Evidently the level populations deviate increasingly from their equilibrium values until T_{vib} approaches θ, i.e. until t/τ approaches $\ln(T^0_{vib}/\theta)$. The fluorescence intensity and the vibrational energy both decrease exponentially with time. At first sight this might seem contradictory. Actually for most v the populations increasingly deviate from equilibrium values. They do so temporarily, only because the population distribution is essentially flat. As the vibrational temperature decreases, and the distribution steepens, the level populations increase because the number of states contributing to the partition function decrease faster yet. The same situation occurs for case (*a*); however there the population distribution is initially even flatter, and the partition function so large that all levels are almost equally populated at far below the equilibrium population of most other v and cannot help but approach n_v/n_v^e. Figures 1 and 2 display this phenomenon graphically. This behaviour is a consequence of the Bethe–Teller law, and as such lays the foundation for a test of this law. As long as $T^0_{vib} \gg \theta \gg T$, any molecule should show this behaviour, and can be used to test [1].

Shock waves

A. $\theta \gg T \geq T_{vib}$

$$F \to \frac{v}{1 - \exp\left[-v\theta\left(\frac{1}{T} - \frac{1}{T_{vib}}\right)\right]}$$

With most sensitive shock tube techniques, the relaxation zone is detected currently by measuring density gradients near equilibrium. Then $T \simeq T_{vib}$. If $(T - T_{vib}) \ll T^2/v\theta$ in addition, then as in ref. 1

$$[20] \quad F \to \theta^{-1}\left(\frac{1}{T} - \frac{1}{T_{vib}}\right)^{-1}$$

and

$$[21] \quad \frac{\theta}{T_{vib}^2}\frac{dT_{vib}}{dt} \to -\frac{\theta}{\tau}\left(\frac{1}{T} - \frac{1}{T_{vib}}\right)$$

so that $d \ln|n_v - n_v^e|/dt \to -1/\tau$, and there is a unique decay constant for all v. This constant can be identified by referring to the same model for relaxation of a harmonic oscillator by T–V processes as discussed in the fluorescence case. In the equilibration process of many levels such as

$$A(v = 0) + M \underset{10}{\overset{01}{\rightleftarrows}} A(v = 1) + M$$

the rate coefficient is $k_{10} - k_{01}$, where k_{10} is the downhill rate constant and k_{01} is the reverse uphill rate constant (4, 5). Using detailed balancing,

$$[22] \quad \tau^{-1} = k_{10}(1 - e^{-\theta/T})$$

Thus there is a basic difference between fluorescence results and shock wave results. It should be noted however that the difference exists because of the difference in perturbation sizes. It is quite feasible, for example, to measure vibrational relaxation times behind shock waves at early times, when $T \gg T_{vib}$. Then

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

$$\frac{\theta}{T_{vib}^2}\frac{dT_{vib}}{dt} \rightarrow \frac{\exp(\theta/T_{vib})}{\tau}$$

whose solution is

[23] $$\exp(-\theta/T_{vib}) = \exp(-\theta/T_{vib}^0) + t/\tau$$

T remains $\gg T_{vib}$ for times $t/\tau < e^{-\theta/T} \ll 1$.

$$F \rightarrow -v[\exp(-\theta/T_{vib})]$$

Thus

[24] $$d \ln |n_v - n_v^e|/dt \rightarrow -v/\tau$$

and each level relaxes at a rate proportional to v, just as in the fluorescence case. It is interesting to note that the Landau–Teller model (4) for T → V processes uses $k_{v-1\rightarrow v} \propto v$ on theoretical grounds in order to derive the Bethe–Teller law (2) for large perturbations, but the factor of v appearing in the above rate expression arises from the Boltzmann distribution itself. Here τ^{-1} can be identified as k_{01}, because the individual levels are subjected to generally uphill transitions at early times. A cryogenic shock tube would have to be used to achieve $\theta \gg T \gg T_{vib}$.

B. $T \gg \theta$

Here we extend the study to temperatures where the molecule behaves as a classical oscillator at equilibrium. From [4]

[25] $$F \rightarrow \frac{v - (v+1)[\exp(-\theta/T_{vib})]}{1 - \left[\exp\left(-\frac{\theta}{T_{vib}}\right)\right] - \frac{\theta}{T}\left[\exp\left\{-v\theta\left(\frac{1}{T} - \frac{1}{T_{vib}}\right)\right\}\right]}$$

and from [7]

[26] $$\frac{\theta}{T_{vib}^2}\frac{dT_{vib}}{dt} \rightarrow \frac{1}{\tau}\frac{T}{\theta}\left[1 - \exp\left(-\frac{\theta}{T_{vib}}\right)\right]\left\{\exp\left[-\theta\left(\frac{1}{T} - \frac{1}{T_{vib}}\right)\right] - 1\right\}$$

There are two special cases depending on whether the molecule behaves initially as a classical oscillator or not: (*a*) $T \gg \theta \gg T_{vib}$, (*b*) $T > T_{vib} \gg \theta$. Eventually T_{vib} approaches T, so that case (*b*) can be considered as a late time version of case (*a*). These two cases commonly occur: many molecules (excluding hydrogen-containing compounds) are nearly classical oscillators particularly at the shock tube temperatures where they relax at measurable speeds (e.g. θ = 309 K for I_2, θ = 806 K for Cl_2, etc.).

(a) $T \gg \theta \gg T_{vib}$

The rate law for vibrational temperature reduces to

$$\frac{\theta}{T_{vib}^2}\frac{dT_{vib}}{dt} = \frac{1}{\tau}\frac{T}{\theta}\exp\frac{\theta}{T_{vib}}$$

i.e.

[27] $$\exp\left(-\frac{\theta}{T_{vib}}\right) = \exp\left(-\frac{\theta}{T_{vib}^0}\right) + \frac{T}{\theta}\frac{t}{\tau}$$

and it is valid when $t/\tau < \theta/eT$.

$$F \rightarrow \frac{v}{1 - \frac{\theta}{T}\exp\frac{v\theta}{T_{vib}}}$$

and

[28] $$d \ln |n_v - n_v^e|/dt \rightarrow \frac{v}{\tau}\frac{T}{\theta}\left(1 - \frac{\theta}{T}\exp\frac{v\theta}{T_{vib}}\right)^{-1}$$

Just as in fluorescence experiments, there exists for each v a critical vibrational temperature T_c given by $T = \theta \exp v\theta/T_c$ which determines the way the level population evolves. If $T_{vib} > T_c$ the level population deviates further from its equilibrium value, i.e. overshoots it; if $T_{vib} < T_c$ the level population relaxes directly towards equilibrium. The physical explanation for this behaviour lies in the properties of the Boltzmann distribution: If the temperature is high the levels relax from a steep distribution to an essentially flat distribution wherein the populations of all levels are less than the initial population of most any level of sufficiently small v. In the flattening process most levels will first increase in population until the Boltzmann distribution approaches a classical distribution, at which point the molecule relaxes as in case *A*. In cases where the temperature is not so critically high but where the final distribution is still essentially flat, some levels of low v are overpopulated, but some at large v are underpopulated. At early times the flattening process occurs, and all level populations must approach equilibrium values. The higher v states relax most quickly, so that eventually most v states are overpopulated. The flattening process continues as in the very high temperature case with most levels increasing in population until the population distribution becomes classical. If the temperature is relatively low, but still $>\theta$, almost all levels are underpopulated. The flattening process does not result in overpopulation. These situations are

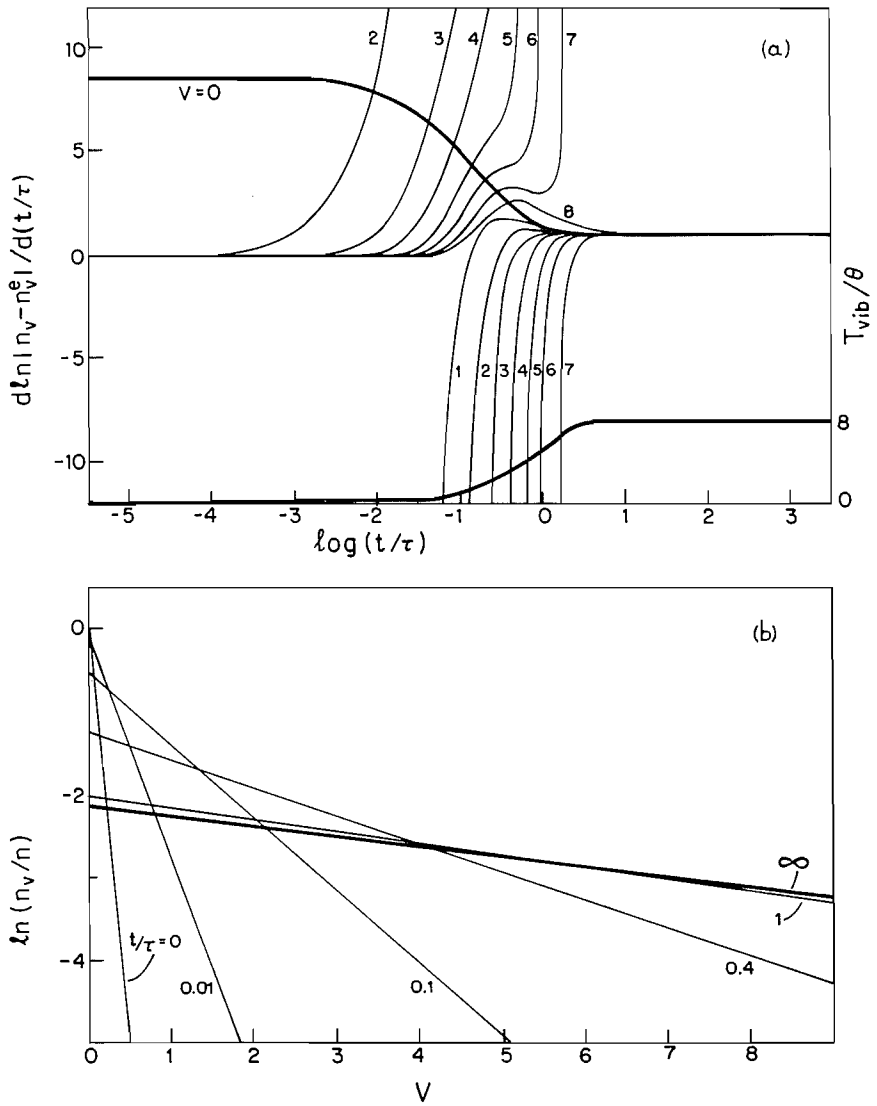

FIG. 3. Relaxation of a quantum oscillator obeying the Bethe–Teller law. Here $\theta/T^0_{vib} = 10$, $\theta/T = 0.125$. (*a*) Phenomenological rate coefficient k' as a function of reduced time and vibrational level. The thick solid curve is the vibrational temperature variation with time. In a real shock wave experiment, the vibrational temperature is within 5% of its equilibrium value T at times when most of the levels shown relax with the same rate coefficients. An ordinate of 1.0 means $k' = \tau^{-1}$. (*b*) Time evolution of the fractional level populations as a function of v (drawn as continuous lines for clarity). The thick line is the final population distribution. Note that $v \geq 8$ is never overpopulated at these conditions. By $t/\tau = 2.5$ all other levels are approaching equilibrium.

represented graphically in Figs. 3 and 4, and summarized below.

(i) $\theta\ exp\ (v\theta/T_{vib}) > T \gg \theta \gg T_{vib}$

$$F \rightarrow -\frac{vT}{\theta}\left[\exp\left(-\frac{v\theta}{T_{vib}}\right)\right]$$

i.e.

$$[29] \qquad \frac{\theta}{T_{vib}^2}\frac{dT_{vib}}{dt} = \frac{1}{\tau}\frac{T}{\theta}\exp\frac{\theta}{T_{vib}}$$

$$[30] \qquad \exp\left(-\frac{\theta}{T_{vib}}\right) = \left[\exp\left(-\frac{\theta}{T^0_{vib}}\right)\right] + \frac{T}{\theta}\frac{t}{\tau}$$

$$\frac{d\ln|n_v - n_v^e|}{dt} \rightarrow -\frac{v}{\tau}\left(\frac{T}{\theta}\right)^2 \exp\left[-\frac{(v-1)\theta}{T_{vib}}\right]$$

$$[31] \qquad \ln\left(\frac{n_v - n_v^e}{n_v^0 - n_v^e}\right) = \left(\frac{T}{\theta}\right)^{v+1}\left\{\left[\frac{\theta}{T}\exp\left(-\frac{\theta}{T^0_{vib}}\right)\right]^v - \left[\frac{t}{\tau} + \frac{\theta}{T}\exp\left(-\frac{\theta}{T^0_{vib}}\right)\right]^v\right\}$$

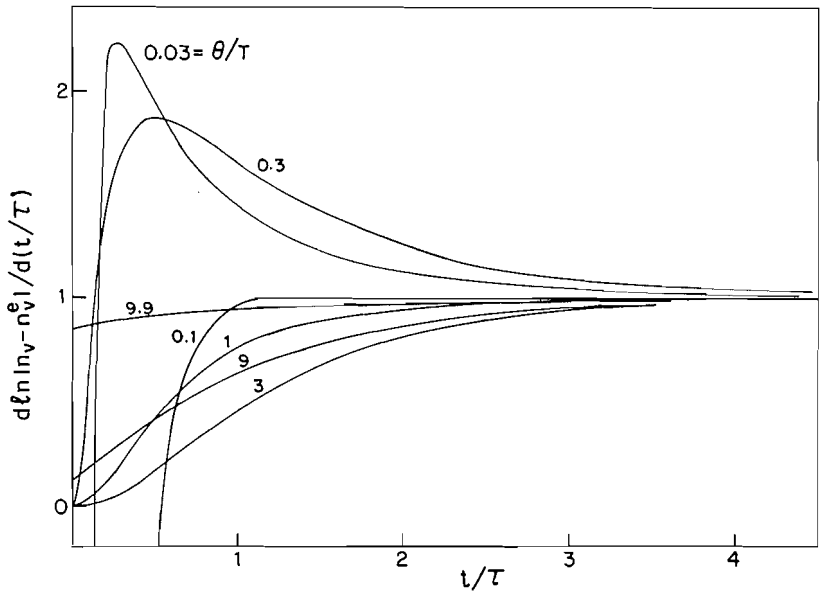

FIG. 4. Phenomenological rate coefficient k' for shock-wave experiments as a function of reduced time and θ/T. Here $\theta/T^0_{vib} = 10$ (a typical quantum oscillator). The population of $v = 4$ is shown evolving for various extents from equilibrium. It is only for a very narrow region of temperatures ($T \approx T^0_{vib}$) to which Breshears' results (1) apply, $k' = \tau^{-1}$. The figure also shows the effects of nearness to classical behaviour ($\theta/T < 1$). The early time-history related to overpopulation of $v = 4$ for $\theta/T < 0.1$ is not shown (see Fig. 3).

The levels (of large enough v) relax at rates which depend strongly on v. At the very earliest times the time-dependence approaches exponential with rate constants $\{v \exp[-(v-1)\theta/T^0_{vib}]\}(T/\theta)^2\tau^{-1}$. In terms of the critical vibrational temperature $T_c = v\theta/\ln(T/\theta)$, this situation represents $T_{vib} < T_c$ and encompasses the cases $T_c > T > \theta > T_{vib}$; $T > T_c > \theta > T_{vib}$; $T > \theta > T_c > T_{vib}$. The first two possibilities are satisfied until T_{vib} approaches θ, $t/\tau \ll e^{-1}\,\theta/T$. The third possibility is satisfied only until T_{vib} approaches T_c, i.e.

$$\frac{T}{\theta}\frac{t}{\tau} \ll \exp\left(-\frac{\theta}{T_{vib}}\right) < \exp\left(-\frac{\theta}{T_c}\right) = \left(\frac{T}{\theta}\right)^{-1/v}$$

or

$$\frac{t}{\tau} \ll \left(\frac{\theta}{T}\right)^{(1+1/v)}$$

Afterwards, $T_{vib} > T_c$, i.e. $\theta \exp(v\theta/T_{vib}) < T$.

(ii) $T > \theta\ exp\ (v\theta/T_{vib}) \gg \theta \gg T_{vib}$

$$F \to v$$

The vibrational temperature and its derivative are still given by [30] and [29], but

$$[32] \qquad \mathrm{d}\ln|n_v - n_v^e|/\mathrm{d}t \to \frac{v}{\tau}\frac{T}{\theta}\exp\frac{\theta}{T_{vib}}$$

Thus the level populations (of sufficiently small v) will deviate from their equilibrium values until T_{vib} approaches θ. This will actually occur at very early times becase $t/\tau \ll e^{-1}\,\theta/T$ and T is enormous (e.g. for $T^0_{vib} = 300$ K, $\theta = 1000$ K, T must be $>$ 28 000 K and $t/\tau \ll 0.036$). The solution of [32] is

$$[33] \qquad \frac{n_v - n_v^e}{n_v^0 - n_v^e} = \left(\frac{t}{\tau}\frac{T}{\theta}\exp\frac{\theta}{T^0_{vib}} + 1\right)^v$$

For both cases (*i*) and (*ii*) involving high and low v, a measurement of the time dependence is a good test of the Bethe–Teller law; and measurement of the v-dependence is a good test of the existence of a Boltzmann distribution. At high temperatures it is quite possible that the V–T relaxation rate approaches that of the V–V equilibration rates, and it would indeed be worthwhile testing the assumption of a Boltzmann distribution.

A feasible experiment would involve a cryogenic shock tube with $T^0_{vib} < 100$ K, $\theta \sim 300$ K, and $T \geqslant 6000$ K, for which $t/\tau < 0.050$. The molecule would have to relax slowly: N_2 would provide such an example. In such a case the level populations would have to be monitored by a Raman scattering technique.

(b) $T > T_{vib} \gg \theta$

In this case the molecule always behaves like a classical oscillator. The rate law for vibrational temperature reduces to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

[34] $$\frac{\theta}{T_{vib}^2}\frac{dT_{vib}}{dt} = -\frac{\theta}{\tau}\left(\frac{1}{T} - \frac{1}{T_{vib}}\right)\frac{T}{T_{vib}}$$

i.e.

$$\frac{dT_{vib}}{dt} = \frac{T - T_{vib}}{\tau}$$

[35] $$T - T_{vib} = (T - T_{vib}^0)\exp(-t/\tau)$$

[36] $$F \rightarrow -\left\{\theta\left(\frac{1}{T_{vib}} - \frac{1}{T}\right)\left(1 - \frac{v\theta}{T}\right)\right\}^{-1} \text{ for } v \ll (T_{vib}/\theta)T/(T - T_{vib})$$

We may be somewhat more restrictive with respect to v. If $v \ll T_{vib}/\theta$, then v is also $\ll T/\theta$, and $F \rightarrow -\theta^{-1}(1/T_{vib} - 1/T)^{-1}$.

[37] $$d \ln |n_v - n_v^e|/dt = -\frac{1}{\tau}\frac{T}{T_{vib}}$$

Thus the populations relax with rates independent of v. Unlike a quantum oscillator this conclusion does not depend on the extent of departure from equilibrium, and should be valid for $v \leqslant 10$. Nevertheless, the value of the effective rate coefficient $\tau^{-1}(T/T_{vib})$ approaches the quantum oscillator rate constant τ^{-1} as equilibrium is approached. The actual level population dependence is given by solving [36]:

[38] $$\frac{n_v - n_v^e}{n_v^0 - n_v^e} = \frac{T_{vib}^0 e^{-t/\tau}}{T - (T - T_{vib}^0)e^{-t/\tau}}$$

It should be noted that as time increases the number of levels contributing to the partition function increases dramatically. Initially, the partition function increases faster than relative level populations change. As a result the lower levels approach equilibrium while the upper levels appear to deviate even if [36] is valid for some of them. When [36] is not valid, a more general but intractable equation must be solved:

[39] $$d \ln |n_v - n_v^e|/dt = -\frac{1}{\tau}\frac{T}{T_{vib}}\frac{(T - T_{vib})}{(T - T_{vib}\exp\{v\theta[1/T_{vib} - 1/T]\}}$$

Equation [38] should be applicable to many molecules, and represents a good test of the Bethe–Teller law; e.g. for I_2 whose level populations can be monitored by uv absorption, $\theta \simeq 309$ K. It can be shock heated to attain an initial temperature of ~1500 K, and perturbed by a reflected shock wave at T ~3000 K.

It is interesting to note that [37] would also be applicable to a laser-induced fluorescence experiment. In this case $T < T_{vib}$, and the vibrational temperature would decrease according to

[40] $$T_{vib} - T = (T_{vib}^0 - T)\exp(-t/\tau)$$

and the level populations would vary according to

[41] $$\frac{n_v - n_v^e}{n_v^0 - n_v^e} = \frac{T_{vib}^0 e^{-t/\tau}}{T + (T_{vib}^0 - T)e^{-t/\tau}}$$

A particularly good test of the Bethe–Teller law would involve laser-exciting an infrared active molecule after it is shock heated and studying its fluorescence (e.g. BrCl) or its uv absorption (e.g. NO). In this way one could achieve an experimental situation for which $T_{vib} \gg T \gg \theta$.

Thermal effects

The relaxation of molecules by V ↔ T processes is always accompanied by an evolution of heat in laser-excited fluorescence or chemical activation studies, or else by translational cooling in shock tube studies. The analysis is straightforward, and it has been recognized as a problem for a very long time. It has been discussed in some detail by Hunter (9) for spectrophone or phase-lag techniques, and Yardley has given a simple expression (10) for a linearized version applicable to small perturbations. Nevertheless the correction factors are usually small in such cases, and the effect is therefore generally ignored. In practice, however, perturbations *are* large. Vibrational temperatures vary between 2000 K and 300 K in a single experiment, and correction factors can become quite significant especially if the heat content or temperature of the gas is low to start with, as in e.g. ref. 11. We present analytical expressions for these correction factors.

Four subtle but distinguishable effects can be recognized: (*a*) τ is not a constant because it depends on a time-varying temperature. Curved log-plots with respect to time indicate the presence of this effect. (*b*) If the process is a true equilibration, then the forward and reverse processes are affected differently, and a correction factor must be applied to account for the relative temperature dependence of rate coefficients. (*c*) The Boltzmann factor varies during the relaxation, so that the equilibrium level populations themselves change as equilibrium is approached. Even if a particular level population is not changing significantly, it will appear to be closer to its final equilibrium value. (*d*) Similarly, the total vibrational energy appears to relax more rapidly, since it need only relax to a value determined by a translational temperature which is less perturbed.

In the following analysis we treat only the most common experimental situations, $\theta \gg T_{vib} \gg T$ and $\theta \gg T \gtrsim T_{vib}$ in detail. The method is directly applicable to other situations. We use the Bethe–Teller law [7] for the time-dependence of the vibrational temperature:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

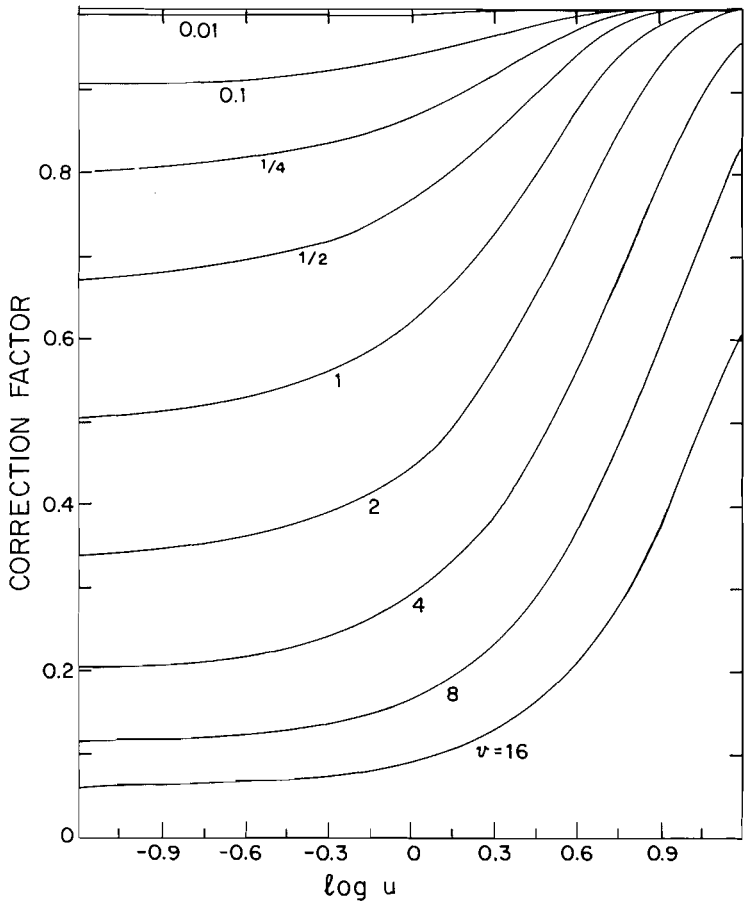

FIG. 5. Correction factor for thermal effect (b) as a function of $u = y = \theta/T_e$ and $\nu = x(T_0 - T_e)/T_e$ for shock tube studies, or alternatively as a function of $u = \theta/T_0$ and $\nu = (T_e - T_0)(1 - x)/T_0$ for fluorescence decay studies. x represents the departure from equilibrium.

$$[42] \quad \frac{\theta}{T_{vib}^2}\frac{dT_{vib}}{dt} = \frac{1}{\tau}\left[\exp\left(-\theta[1/T - 1/T_{vib}]\right) - 1\right]$$

Secondly, we consider the energy balance between the translational–rotational and the vibrational degrees of freedom. Shock tube experiments can be considered to be at constant pressure and enthalpy. This is an approximation, and indeed one analyzes data more carefully (13); however for a first-order determination of the thermal effect, the approximation is good. The gas enthalpy $H = \int_0^{T_e} C dT$ is a constant, where T_e is the true final temperature and C is the constant-pressure heat capacity $= \Sigma X_i C_i$. Here X_i is the mole fraction of species i, and C_i is the heat capacity of species i. The relaxing molecules A can release or take up heat from an inert buffer gas M. Then $C = X_A C_A + X_M C_M$, i.e. $C = X_A(C_A - C_M) + C_M$. The enthalpy is composed of translational and rotational contributions denoted by $\int(C - C_{vib})dT$ plus a vibrational term given by [6] for n molecules. On a per-molecule basis $C - C_{vib} = C_M(1 - X_A) + X_A(5k/2) + k$ for a linear molecule A; $C - C_{vib} = C_M(1 - X_A) + 3kX_A + k$ for a non-linear molecule A. If some of the A molecules' vibrational modes have already relaxed independently on a shorter time scale, then a corresponding term is added. Otherwise, and if the buffer is an atom such as Ar, then

$$[43a] \quad C - C_{vib} = k(X_A + 5/2)$$

$$[43b] \quad C - C_{vib} = k(3X_A/2 + 5/2)$$

for linear and non-linear relaxing molecules, respectively. Thus

$$H = \int(C - C_{vib})dT + X_A \epsilon_{vib}/n$$

$$X_A d\epsilon_{vib}/n dt = -(C - C_{vib})dT/dt$$

For $\theta \gg T_{vib}$ this becomes

$$[44] \quad X_A h\nu \left(\frac{\theta}{T_{vib}^2}\right)\exp\left(-\frac{\theta}{T_{vib}}\right)\frac{dT_{vib}}{dt} = -(C - C_{vib})\frac{dT}{dt}$$

This expression is also valid for laser or chemically activated systems if heat loss to the walls of the cell is not significant. In this case C is a constant-pressure heat capacity only at relatively high pressures, but is a constant volume heat capacity at low pressures where the excitation energy diffuses over the whole cell (10).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

Equations [42] and [44] must be solved simultaneously for $T(t)$ and $T_{vib}(t)$. In practice this is difficult, but one can obtain a good first-order approximation to $T(t)$ by using the Blackman procedure (12). This procedure does not linearize the problem, i.e. does not assume a weak perturbation, but does assume that C is not very temperature-dependent. It leads to

[45] $$dT/dt = (T_e - T)/\tau'$$

where

$$\tau' = \tau(C - C_{vib})/C$$

The temperature varies exponentially with time. In shock tube experiments the initial post-shock temperature T_0 is typically anywhere between 400 and 3000 K, and the final temperature can be smaller by amounts ranging up to 1000 K or more. In laser-fluorescence experiments the initial temperature T_0 is typically room temperature plus a change corresponding to the release of heat by rapidly-relaxing modes of vibration on an immeasurably shorter time scale. The final temperature T_e can be as much as 1000 K higher. In shock tube experiments large temperature changes can be correlated well with a time-varying relaxation time (effect (*a*)), but the latter must be recognized as $\tau'(T(t))$ rather than $\tau(T(t))$ if a simple log-plot analysis of gas density is used. The correction factor for this effect is most significant for pure gas A, and for high temperatures. For a diatomic molecule A it approaches 7/9; for a linear triatomic molecule it approaches 7/15, etc., if all modes relax simultaneously. In fluorescence experiments, as long as the gas is optically thin to all transitions, the light intensity is proportional to the vibrational energy, which is closely associated with τ itself.

Effect (*b*) is important for high-temperature relaxation experiments near equilibrium, when both forward and reverse reactions are important. Usually only shock tube experiments are affected. For T–V mechanisms $1/\tau$ can be identified with $k_{10}(1 - e^{-\theta/T})$. When one compares fluorescence data with shock tube data one ultimately wishes to compare their corresponding k_{10}'s. The adjustment factor depends on the portion of the relaxation zone measured. At equilibrium one has a true handle on k_{10}. Over the time range $n\tau$ to $m\tau$, the average time $(n + m)\tau/2$ corresponds to an average temperature $\bar{T}$ given by $(\bar{T} - T_e)/T_0 - T_e) = \exp[-(m + n)/2]$. Referred to equilibrium for shock tube studies, and to the intial temperature for fluorescence studies, the measured rate coefficient is always smaller by factors which depend on the parameters $y = \theta/T_e$, $z = \theta/T_0$, and $x = \exp[-(m + n)/2]$. Figure 5 summarizes the adjustment factors, and is applicable to any size perturbation or relative value of θ, or the relaxation regime studied. For classical oscillators the factor approaches $T_e/(T_e + [T_0 - T_e]x)$.

In order to examine effect (*c*), eq. [4] must be rewritten to explicitly account for the temperature variation.

[46] $$\frac{d \ln |n_v - n_v^e|}{dt} = \frac{\frac{\theta}{T_{vib}^2}\frac{dT_{vib}}{dt}\left\{v - \left[(v+1)\exp\left(-\frac{\theta}{T_{vib}}\right)\right]\right\}\left[\exp\left(-\frac{v\theta}{T_{vib}}\right)\right] - \frac{\theta}{T^2}\frac{dT}{dt}\left\{v - \left[(v+1)\exp\left(-\frac{\theta}{T}\right)\right]\right\}\left[\exp\left(-\frac{v\theta}{T}\right)\right]}{\left[\exp\left(-\frac{v\theta}{T_{vib}}\right)\right]\left[1 - \exp\left(-\frac{\theta}{T_{vib}}\right)\right] - \left[\exp\left(-\frac{v\theta}{T}\right)\right]\left[1 - \exp\left(-\frac{\theta}{T}\right)\right]}$$

In order to proceed we must specify the type of experiment.

Fluorescence

We can simplify eq. [46] by using the adiabaticity relationship [44] and dividing through with $\exp(-v\theta/T_{vib})$, and using $\theta \gg T_{vib}$, $\theta \gg T$.

[47] $$\frac{d \ln |n_v - n_v^e|}{dt} = \left\{\frac{v + v\left\{\exp\left[-v\theta\left(\frac{1}{T} - \frac{1}{T_{vib}}\right)\right]\right\}\frac{\theta^2}{T^2}\frac{kX_A\left[\exp\left(-\frac{\theta}{T_{vib}}\right)\right]}{C - C_{vib}}}{1 - \left\{\exp\left[-v\theta\left(\frac{1}{T} - \frac{1}{T_{vib}}\right)\right]\right\}}\right\}\frac{\theta}{T_{vib}^2}\frac{dT_{vib}}{dt}$$

It is clear from [44] that if the translational temperature varies with time constant τ' then so will the vibrational temperature. The solution of [45] is

[48] $$T = T_0 + (T_e - T_0)(1 - \exp[-t/\tau'])$$

which has a value $\approx T_0$ during the observation region. The final temperature depends on the amount of photon- or chemical-excitation. If e.g. each molecule had absorbed v_0 quanta of laser energy initially, then $\int_{T_0}^{T_e} C dT = v_0 h\nu X_A$.
Under the present assumption that C is constant during the relaxation process

[49] $$(T_e - T_0) = X_A v_0 h\nu/C$$

Use of [48] and [49] simplifies the adiabaticity relationship to

$$\frac{\theta}{T_{vib}^2}\frac{dT_{vib}}{dt}\left[\exp\left(-\frac{\theta}{T_{vib}}\right)\right] = -\frac{v_0}{\tau}\left[\exp\left(-\frac{t}{\tau'}\right)\right]$$

i.e.

$$\exp\left(-\frac{\theta}{T_{vib}}\right) = \exp\left(-\frac{\theta}{T_{vib}^0}\right) - \left(\frac{\tau'}{\tau}\right)v_0\left[1 - \exp\left(-\frac{t}{\tau'}\right)\right]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

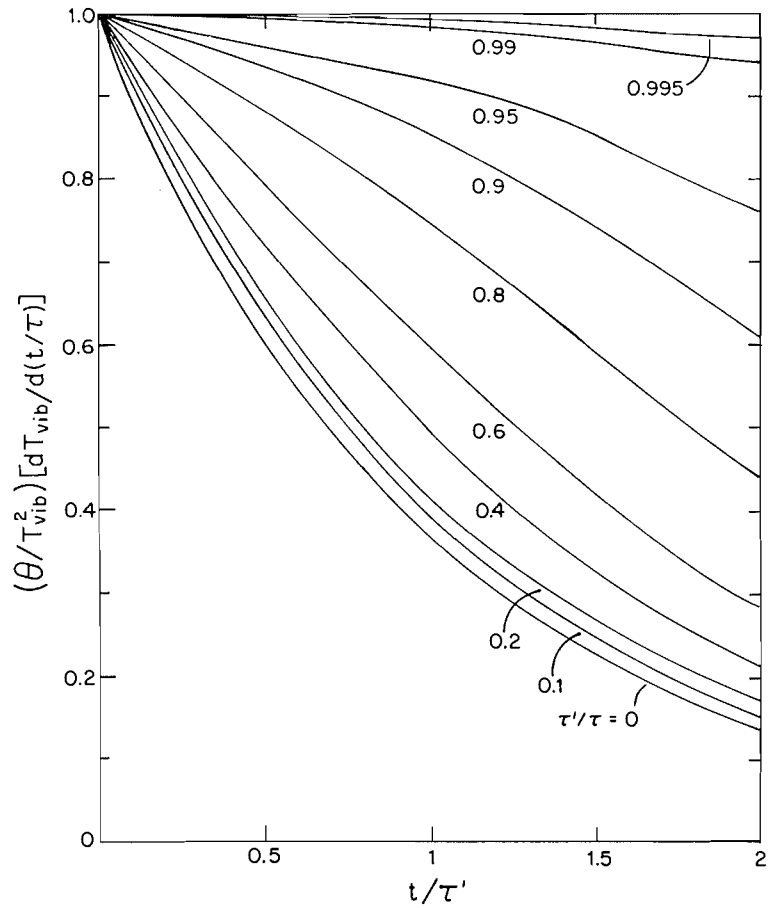

FIG. 6. Correction for thermal effect (d) as a function of reduced time t/τ' and as a function of $\tau'/\tau = (C - C_{vib})/C$. The latter depends essentially on the temperature and on the mole fraction of relaxing gas. An ordinate of 1.0 means $(\theta/T_{vib}^2)\,(dT_{vib}/dt) = \tau^{-1}$.

A more general expression allowing for other kinds of excitation can be obtained by noting that the change in vibrational energy per molecule due to the initial excitation is

$$X_A h\nu \left\{\left[\exp\frac{\theta}{T_{vib}^0} - 1\right]^{-1} - \left[\exp\frac{\theta}{T_0} - 1\right]^{-1}\right\}$$

Thus

$$T_c - T_0 \approx X_A h\nu \left[\exp\left(-\frac{\theta}{T_{vib}^0}\right) - \exp\left(-\frac{\theta}{T_0}\right)\right]\Big/C$$

and

$$\exp\left(-\frac{\theta}{T_{vib}}\right) = \exp\left(-\frac{\theta}{T_{vib}^0}\right) - \left(\frac{\tau'}{\tau}\right)\left\{\left[\exp\left(-\frac{\theta}{T_{vib}^0}\right)\right] - \left[\exp\left(-\frac{\theta}{T_0}\right)\right]\right\}\left\{1 - \left[\exp\left(-\frac{t}{\tau'}\right)\right]\right\}$$

and

$$\frac{\theta}{T_{vib}^2}\frac{dT_{vib}}{dt} = -\frac{\left\{\left[\exp\left(-\frac{\theta}{T_{vib}^0}\right)\right] - \left[\exp\left(-\frac{\theta}{T_0}\right)\right]\right\}\tau^{-1}\left[\exp\left(-\frac{t}{\tau'}\right)\right]}{\left[\exp\left(-\frac{\theta}{T_{vib}^0}\right)\right] - \left(\frac{\tau'}{\tau}\right)\left\{\left[\exp\left(-\frac{\theta}{T_{vib}^0}\right)\right] - \left[\exp\left(-\frac{\theta}{T_0}\right)\right]\right\}\left(1 - \exp\left(-\frac{t}{\tau'}\right)\right)}$$

We note that in fluorescence studies $T_{vib} \gg T > T_0$. Thus

$$[50] \qquad \frac{\theta}{T_{vib}^2}\frac{dT_{vib}}{dt} = -\frac{e^{-t/\tau'}}{\tau - \tau'(1 - e^{-t/\tau'})}$$

In the limit of no thermal effects this reduces simply to $-1/\tau$ as in [8]. Figure 6 shows that it is otherwise time-dependent. Not recognizing this can lead to significant errors! Even for modest thermal effects (i.e. $\tau' \to \tau$)

$$\frac{\theta}{T_{vib}^2}\frac{dT_{vib}}{dt} = -\frac{e^{-t/\tau'}}{(\tau - \tau') + \tau' e^{-t/\tau'}} \to -\frac{1}{\tau'}$$

We can now proceed with eq. [47]. For fluorescence studies, $\theta \gg T_{vib} > T$,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

$$[51] \quad \frac{\mathrm{d} \ln |n_v - n_v^e|}{\mathrm{d}t} \rightarrow v\left\{1 + \left[\exp\left(-\frac{v\theta}{T}\right)\right]\frac{\theta^2}{T^2}\frac{kX_A\left[\exp\left(-\frac{\theta}{T_{vib}}\right)\right]}{C - C_{vib}}\right\}\frac{\theta}{T_{vib}^2}\frac{\mathrm{d}T_{vib}}{\mathrm{d}t}$$

For a good first estimate of the adjustment factor in parentheses we set $T = T_0$, and $T_{vib} = T_{vib}^0$, which should be valid for initial rates. The factor is strongly dependent on v. For example for $\theta = 1000$ K, $T_{vib}^0 = 600$ K, $T_0 = 300$ K, $C - C_{vib} = 7/2k$, $X_A = 1$, it is 1.600 for $v = 0$, 1.021 for $v = 1$, and 1.001 for $v = 2$. It is thus not very important for moderate conditions. However in extreme cases of very low temperatures, e.g. 150 K (11), it is as large as 3.40 for $v = 0$. The linear relationship between fluorescence intensity and vibrational energy still holds approximately for gases which are optically thin to radiation from all v. Except for $v = 0$ all levels relax at rates proportional to v to a good approximation. The adjustment factor can be compared to that of Yardley and Moore (10) applicable to phase-lag measurements. Except for the dependence on v we obtain a similar adjustment factor without having to limit the analysis to small perturbations or to the phase-lag technique. More important however is the $(\theta/T_{vib}^2\ \mathrm{d}T_{vib}/\mathrm{d}t)$ factor which is time-dependent. It implies that log-plots are not all appropriate. We integrate

$$\frac{\mathrm{d} \ln |n_v - n_v^e|}{\mathrm{d}t} \approx \frac{-v\,\mathrm{e}^{-t/\tau'}}{(\tau - \tau') + \tau'\,\mathrm{e}^{-t/\tau'}} \qquad v \neq 0$$

and obtain

$$[52] \quad \left(\frac{n_v - n_v^e}{n_v^0 - n_v^e}\right)^{1/v} = \frac{(\tau - \tau') + \tau'\,\mathrm{e}^{-t/\tau'}}{\tau}$$

We note that $\tau'/\tau = (C - C_{vib})/C$. Thus a plot of $\ln\{[(n_v - n_v^e)/(n_v^0 - n_v^e)]^{1/v} - C_{vib}/C\}$ against t will give a straight line whose slope is $-1/\tau'$. For $v = 1$ this is the same as the usual procedure except for the thermal term C_{vib}/C. Not following this modified procedure will lead to the large errors noted in Fig. 4. A similar procedure applies to fluorescence intensity.

Analogous reasoning applies to more extreme, yet common situations: $T_{vib} \gg \theta \gg T$. The adiabaticity relationship is modified because the oscillator is classical. Thus

$$[53] \quad X_A k \mathrm{d}T_{vib}/\mathrm{d}t = -(C - C_{vib})\mathrm{d}T/\mathrm{d}t$$

Equation [49] for $(T_e - T_0)$ is also modified

$$[54] \quad (T_e - T_0) \simeq X_A k T_{vib}^0/C$$

However, the temperature still varies exponentially with time constant τ'. So

$$\frac{\mathrm{d}T_{vib}}{\mathrm{d}t} = -\frac{T_{vib}^0}{\tau}\,\mathrm{e}^{-t/\tau'}$$

i.e.

$$T_{vib} = T_{vib}^0 - T_{vib}^0\,(\tau'/\tau)\,(1 - \mathrm{e}^{-t/\tau'})$$

and the factor

$$\frac{\theta}{T_{vib}^2}\frac{\mathrm{d}T_{vib}}{\mathrm{d}t} = -\frac{T_{vib}^0}{\tau}\frac{\mathrm{e}^{-t/\tau'}}{T_{vib}^2}$$

is smaller than that for the limit of no thermal effects by a factor $\mathrm{e}^{-t/\tau'}\,\mathrm{e}^{-t/\tau}\,[1 - (\tau'/\tau)\,(1 - \mathrm{e}^{-t/\tau'})]^2$. Furthermore, F is reduced in magnitude by the factor $[1 - v\mathrm{e}^{-v\theta/T}\,(T_{vib}/T)^2 kX_A/(C - C_{vib})]$, which is also significant. For $T_{vib}^0 = 3000$, $\theta = 1000$ K, $T_0 = 300$ K, $X_A = 1$, $C - C_{vib} = 7k/2$, it has a value of 1.000 for $v = 0$; -0.0193 for $v = 1$; 0.927 for $v = 2$. Without thermal effects, $F > 0$ for $v = 0$; $F < 0$ for $v \geq 1$. With thermal effects $F > 0$ for $v = 0, 1$; $F < 0$ for $v \geq 2$. Thus the temporary, yet increasing deviation from equilibrium for sufficiently large v noted earlier still occurs but it affects a smaller number of levels. Since the absolute value of the correction factor is <1, the apparent rate coefficients are smaller than in the absence of thermal effects, just as in the less extreme case $\theta \gg T_{vib} \gg T$. Modified log-plots would also be necessary.

Shock waves

For the usual condition $\theta \gg T \geq T_{vib}$, $(\theta/T_{vib}^2)\ (\mathrm{d}T_{vib}/\mathrm{d}t)$ is still given by eq. [21]. Use of this equation together with the adiabaticity relationship allows one to obtain an expression for $T(t)$ and $T_{vib}(t)$ in principle. However, this is not necessary, since under shock wave conditions near equilibrium $\theta v(1/T - 1/T_{vib}) \ll 1$. Thus we directly obtain

$$F \rightarrow \frac{1 + \left(\frac{\theta}{T}\right)^2 kX_A\left[\exp\left(-\frac{\theta}{T_{vib}}\right)\right](C - C_{vib})^{-1}}{\theta\left(\frac{1}{T} - \frac{1}{T_{vib}}\right)}$$

and hence

$$[55] \quad \frac{\mathrm{d} \ln |n_v - n_v^e|}{\mathrm{d}t} = -\frac{1}{\tau}\left\{1 + \frac{\theta^2}{T^2}\frac{X_A k\left[\exp\left(-\frac{\theta}{T_{vib}}\right)\right]}{C - C_{vib}}\right\}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

without requiring an explicit expression for $T_{vib}(t)$. At or near equilibrium ($T_{vib} \simeq T \simeq T_e$), the correction factor to τ,

$$1 + \frac{\theta^2}{T_e^2}\left\{\frac{X_A k\left[\exp\left(-\frac{\theta}{T_e}\right)\right]}{C - C_{vib}}\right\}$$

is substantial. Noting that $C_{vib} = X_A h\nu(\theta/T_e^2)\exp(-\theta/T_e)$, we see that the correction factor for the population decay time is identical to that for the decay time of the measured temperature, $C/(C - C_{vib})$. For $X_A = 1$; $(C - C_{vib}) = 7/2k$; $\theta = 3000$, $T_e = 1000$, the populations of all levels decay 1.13 times faster than in the absence of thermal effects.

For the more extreme situation where the relaxing molecule always behaves like a classical oscillator, i.e. $T \gg T_{vib} \gg \theta$, $(\theta/T_{vib}^2)(dT_{vib}/dT)$ is given by eq. [34], the adiabaticity relationship by eqs. [53] and [54] and for $v < T_{vib}/\theta$.

$$F \rightarrow \frac{-\left\{1 + \frac{T_{vib}^2}{T^2}\frac{X_A k}{(C - C_{vib})}\right\}}{\theta(1/T_{vib} - 1/T)}$$

Thus

$$[56] \qquad \frac{d \ln |n_v - n_v^e|}{dt} = -\frac{1}{\tau}\left\{1 + \frac{X_A k}{C - C_{vib}}\right\}$$

Again noting that for a classical oscillator $C_{vib} = X_A k$, the decay time is just τ'. However, for a classical oscillator the correction factor can be quite substantial, e.g. if $(C - C_{vib}) = 7/2k$, $\tau' = 0.778\tau$.

Conclusions

In generalizing Breshears' analysis of the relaxation of a harmonic oscillator we have shown that the form of the rate law for the equilibration of vibrational energy level populations depends on many factors: the size and direction of the perturbation, the extent from equilibrium, and how classical the oscillator is at the initial and at the final conditions. The fluorescence decay rate coefficients are proportional to v only for a narrow range of experimental conditions. They are independent of v under shock tube conditions near equilibrium if the molecule is a quantum oscillator, but also for any size shock perturbation if the molecule is always a classical oscillator. All forms of the rate law are based on the validity of the Bethe–Teller law and on the existence of a rapid V–V energy transfer mechanism which assures a Boltzmann distribution throughout the relaxation zone. Generally, the Bethe–Teller law has been tested only under relatively mild conditions. We have proposed shock tube and laser-induced fluorescence or chemical activation experiments to test this under more extreme yet realistic conditions by observing the form of the time-dependence of the evolution of individual level populations. The rapidity of V–V processes can be tested by checking the v-dependence. (eqs. [17], [24], [32], [38], [41]).

When comparing fluorescence (fl) and shock tube (st) relaxation times, it should be noted that $\tau_{fl}/\tau_{st} = (k_{10} - k_{01})/k_{10}$ for the usual conditions, as long as a T ↔ V energy transfer mechanism prevails. Thermal effects must be accounted for, particularly in shock tube studies, where the rate coefficient $> 1/\tau$. Point-by-point analyses must be undertaken in order to obtain a true $\tau'(T(t))$, and hence a true $k_{10}(T(t))\,(1 - e^{-\theta/T(t)})$. If a relaxing gas sample is not optically thin to radiation from all levels then the rate law in fluorescence studies can be very complicated and can depend strongly on v. One must take great care in noting the extremity of the conditions. For example, for $v = 2$, if $\theta \gg T_{vib} \gg T$, $k' = 2\tau^{-1}$; if $T_{vib} \gg \theta \gg T$, $k' = \tau^{-1}(T_{vib}^0/\theta)^{-1} e^{20/T}$ when $t/\tau \ll 1$, and $k' = -\tau^{-1}$ when $\ln(T_{vib}^0/T_*) \ll t/\tau \ll \ln(T_{vib}^0/\theta)$; if $T_{vib} \gg \theta \sim T$, $k' = \tau^{-1}$. In such cases one would also have to account for thermal effects rather precisely. Simple log-plots of fluorescence intensities vs. time would not be appropriate. A proper analysis would yield τ', not τ. The ratio τ'/τ can be close to 1 if the gas is very dilute in say Ar, but the ratio can be as small as 0.78 for a single classical mode of oscillation, or even less if several modes are involved. Under some conditions, thermal effects can lead to curious ratios: e.g. −0.0193 cited above.

In summary, great care is needed in interpreting vibrational relaxation times.

Generalized rate law for vibrational relaxation of a pure diatomic gas

HESHEL TEITELBAUM

Ottawa–Carleton Institute for Research and Graduate Studies in Chemistry, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received August 3, 1982

HESHEL TEITELBAUM. Can. J. Chem. **61**, 1267 (1983).

The master equation for the vibrational relaxation of a pure gas of diatomic molecules AB is reduced to a simple analytical rate law. Anharmonicity is accounted to first order, and both T–V and near-resonant V–V energy transfer processes are included with the limitation that $\Delta v = \pm 1$. Landau–Teller type transition probabilities are used to scale the rate constants. The rate law consists of a pair of simultaneous first order non-linear differential equations — one for the mean vibrational energy, $\bar{E}$, and one for the mean squared vibrational energy $\overline{E^2}$; or equivalently a non-linear second order differential equation for $\bar{E}$ with respect to time, t, plus an algebraic equation for $\overline{E^2}$. These lead to

$$\frac{d\bar{E}}{dt} = -\frac{(\bar{E} - \overline{E^\infty})}{\tau} - \chi_e h\nu_e k_{1,1}^{2,0} N\left[2\left(\frac{\bar{E}}{h\nu'}\right)^2 - \frac{\overline{E^2}}{(h\nu')^2} + \frac{\bar{E}}{h\nu'}\right]_0 e^{-\alpha t}$$

where χ_e is the anharmonicity factor, N the molecular concentration, ν_e the spectroscopic vibrational frequency; $\nu' = \nu_e(1 - \chi_e)$; $\nu'' = \nu_e(1 - 3\chi_e)$; $\alpha = Nk_{1,1}^{2,0}/(1 - \chi_e) + 2/\tau$; $1/\tau = Nk_{1,0}(1 - e^{-h\nu''/kT})$; $k_{1,0}$ the rate constant for the process $AB(v = 1) + AB(v) \rightarrow AB(v = 0) + AB(v)$; and $k_{1,1}^{2,0}$ the rate constant for the process $2AB(v = 1) \rightarrow AB(v = 0) + AB(v = 2)$. It is shown that the Bethe–Teller law, $d\bar{E}/dt = -(E - \bar{E}^\infty)/\tau$, is valid only in the limit of zero anharmonicity or slow V–V processes, or when the initial population is Boltzmann, such as in shock tube experiments. Furthermore, a population distribution which is initially Boltzmann will remain so; whereas a non-Boltzmann distribution rapidly becomes a Boltzmann distribution on a time scale determined by the sum of T–V and V–V rate constants. The present study allows one to gauge the importance of two common assumptions: the validity of the Bethe–Teller law and the existence of a Boltzmann distribution or vibrational temperature during the relaxation.

HESHEL TEITELBAUM. Can. J. Chem. **61**, 1267 (1983).

L'équation "master" qui décrit la relaxation vibrationelle d'un gaz pur de molécules diatomiques est simplifiée afin d'obtenir une loi analytique simple. On tient compte de l'anharmonicité. Les processus T–V et les processus V–V presque-resonants sont inclus, avec la limitation $\Delta v = \pm 1$. On réduit les probabilités de transition de la sorte Landau–Teller à une échelle commune. La loi de la vitesse qui en résulte consiste en une paire simultanée d'équations différentielles non-linéaires de première ordre — l'une pour l'énergie moyenne, $\bar{E}$, et l'autre pour la moyenne des énergies carrées, $\overline{E^2}$. Cela équivaut a une équation différentielle non-linéaire de deuxième ordre pour $\bar{E}$ par rapport aux temps, t, plus une équation algébrique pour $\overline{E^2}$. Ces deux donnent

$$\frac{d\bar{E}}{dt} = -\frac{(\bar{E} - \overline{E^\infty})}{\tau} - \chi_e h\nu_e k_{1,1}^{2,0} N\left[2\left(\frac{\bar{E}}{h\nu'}\right)^2 - \frac{\overline{E^2}}{(h\nu')^2} + \frac{\bar{E}}{h\nu'}\right]_0 e^{-\alpha t}$$

ou χ_e est la facteur d'anharmonicité, N la concentration moléculaire, ν_e la fréquence vibrationelle spectroscopique; $\nu' = \nu_e(1 - \chi_e)$; $\nu'' = \nu_e(1 - 3\chi_e)$; $\alpha = Nk_{1,1}^{2,0}/(1 - \chi_e) + 2/\tau$; $1/\tau = Nk_{1,0}(1 - e^{-h\nu''/kT})$; $k_{1,0}$ est la constante de vitesse pour $AB(v = 1) + AB(v) \rightarrow AB(v = 0) + AB(v)$; et $k_{1,1}^{2,0}$ est la constante de vitesse pour $2AB(v = 1) \rightarrow AB(v = 0) + AB(v = 2)$. On montre que la loi de Bethe–Teller, $d\bar{E}/dt = -(E - \bar{E}^\infty)/\tau$, est valable seulement dans la limite de nul anharmonicité et des processus V–V extrémement lents, ou quand la répartition de la population initialle est Boltzmann, telle qui existe dans les expériences de tube de choc. En plus, une répartition de population qui est initiallement Boltzmann restera toujours Boltzmann; tandis qu'une répartition non-Boltzmann devient Boltzmann rapidement avec une échelle de temps déterminée par la somme des constantes de vitesse T–V et V–V. L'étude actuelle nous permet d'estimer l'importance de deux suppositions utilisées par les chercheurs: la validité de la loi de Bethe–Teller et l'existence d'une répartition Boltzmann ou d'une température vibrationelle.

Introduction

In the analysis of measurements of vibrational relaxation times of diatomic molecules it is often assumed that the rate of equilibration of the vibrational energy E is given by

$$[1] \quad -\frac{dE}{dt} = \frac{1}{\tau}[E - E^\infty]$$

where E^∞ is the thermodynamically expected equilibrium vibrational energy at the temperature T (which may also be a function of time). This equation is strictly valid for small departures from equilibrium (1). However, it can be shown that for special mechanisms of the relaxation process (viz. translation-to-vibration mechanisms, T–V, even large departures from equilibrium lead to eq. [1] being valid regardless of the initial distribution of vibrational level populations as long as this distribution is Boltzmann (2) initially. If the relaxing molecules can be represented by simple harmonic oscillators then τ is related simply to the rate constant k_{10} for the process

$$AB(v = 1) + M \rightleftarrows AB(v = 0) + M$$

by

$$\tau^{-1} = k_{10}[M](1 - e^{-\theta/T})$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

where $\theta = h\nu/k$, ν is the fundamental oscillator frequency, and [M] is the concentration of the vibrationally inert collision partner M. When the initial distribution is non-Boltzmann, such as can occur if the molecules are laser-exited or if they are products of an exothermic chemical reaction, it is often further additionally supposed (3) that the distribution rapidly becomes Boltzmann in form via vibration-to-vibration, V–V, energy transfer steps:

$$AB(v) + AB(v') \rightleftarrows AB(v + n) + AB(v' - n)$$

For harmonic oscillators this is a resonant process, and the resonance supposedly accounts for the rapidity of the V–V processes. Thus eq. [1] is universally used to analyze measurements of vibrational relaxation of diatomic molecules. To some extent polyatomic molecules may be included, particularly if the modes of vibration relax independently (4). Otherwise, it is generally recognized that more care is required. In fact experiments bear out the validity of eq. [1] over a limited range of conditions (5, 6). In a recent paper we discussed the consequences of the above two assumptions and thereby suggested experiments whereby they could be tested. Indeed it is clear that the above assumptions cannot always hold. For example, when the relaxing molecule encounters inert species, e.g., argon, almost exclusively, then V–V processes cannot occur. Secondly, V–V processes are second-order in [AB(v)], whereas T–V processes are first order in [AB(v)]. Thus we might expect that inclusion of only moderately rapid V–V steps into the mechanism which normally leads to eq. [1] would now lead to an analogous one which is non-linear in E. Thus by including V–V processes of finite rate, both approximations are affected: Boltzmann distributions and the validity of eq. [1]. Under most experimental conditions small non-linearities are hard to detect even if they exist. Yet they may throw light on the mechanism of vibrational relaxation. Thus it is important to know when they might be expected. In this work we examine the influence of V–V steps on the energy rate law. In so doing we determine the conditions which enable us to measure non-linearities, and which allow us to interpret vibrational relaxation measurements in more detail, and which give us an alternative rate law valid even when non-Boltzmann distributions persist.

The relaxation model

In the simplest approach we consider a set of harmonic oscillator energy levels, m. The rate of change of population of the individual levels N_m can be expressed by a master equation which includes contributions from T–V and V–V processes. For the moment we consider the V–V portion only. Then

$$[2]\quad \frac{dN_m}{dt} = -k_{m,1}^{m+1,0}N_mN_1 + k_{m+1,0}^{m,1}N_{m+1}N_0 + k_{m-1,1}^{m,0}N_{m-1}N_1 - k_{m,0}^{m-1,1}N_mN_0$$

where $k_{i,j}^{k,l}$ are the rate constants for the process

$$AB(v = i) + AB(v = j) \rightleftarrows AB(v = k) + AB(v = l)$$

In eq. [2] we have considered only those processes which are most likely, namely, resonant energy transfer ($i + j = k + l$), and $\Delta v = \pm 1$ for an individual molecule. Furthermore, a molecule will collide most likely with another which exists either in $v = 0$ or $v = 1$, particularly if a Boltzmann or near-Boltzmann distribution is applicable. This last assumption will be eliminated below. The reasoning is identical for all other possible collison partners. Equation [2] applies to all v except $v = 0$, 1:

$$[3]\quad \frac{dN_0}{dt} = k_{1,1}^{2,0}N_1^2 - k_{2,0}^{1,1}N_2N_0 + k_{2,1}^{3,0}N_2N_1 - k_{3,0}^{2,1}N_3N_0 + \ldots$$

$$[4]\quad \frac{dN_1}{dt} = 2k_{2,0}^{1,1}N_2N_0 - 2k_{1,1}^{2,0}N_1^2 + k_{3,0}^{2,1}N_3N_0 - k_{2,1}^{3,0}N_2N_1 + \ldots$$

At any given instant, the total vibrational energy is proportional to $\sum_0^\infty mN_m$. Thus we multiply eqs. [2], [3], and [4] by the appropriate value of m and perform the summation:

$$\frac{d}{dt}\sum_0^\infty mN_m\Big|_{V-V} = -\sum_1^\infty mk_{m,1}^{m+1,0}N_mN_1 + \sum_1^\infty mk_{m+1,0}^{m,1}N_{m+1}N_0 + \sum_2^\infty mk_{m-1,1}^{m,0}N_{m-1}N_1 - \sum_2^\infty mk_{m,0}^{m-1,1}N_mN_0 - \sum_1^\infty 1k_{m,1}^{m+1,0}N_mN_1 + \sum_1^\infty 1k_{m+1,0}^{m,1}N_{m+1}N_0$$

$$= -\sum_1(m+1)k_{m,1}^{m+1,0}N_mN_1 + \sum_1(m+1)k_{m+1,0}^{m,1}N_{m+1}N_0 + \sum_2 mk_{m-1,1}^{m,0}N_{m-1}N_1 - \sum_2 mk_{m,0}^{m-1,1}N_mN_0$$

which, upon relabelling in the latter two sums, gives

$$\frac{d}{dt}\sum_0^\infty mN_m\Big|_{V-V} = -\sum_1(m+1)k_{m,1}^{m+1,0}N_mN_1 + \sum_1(m+1)k_{m+1,0}^{m,1}N_{m+1}N_0 + \sum_1(m+1)k_{m,1}^{m+1,0}N_mN_1 - \sum_1(m+1)k_{m+1,0}^{m,1}N_{m+1}N_0$$

$$= 0$$

Thus, V–V processes do not contribute to the rate of change of vibrational energy. Including other collision partners in addition to those with $v = 0$ and 1 would not change this conclusion, nor would allowing $|\Delta v| > 1$. This result is to be expected for resonant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

energy transfer. If individual collisions do not change the total vibrational energy, then neither will the sum of any number of such collisions. Resonant energy transfer can at best redistribute energy among the levels but not increase or decrease it on the whole. We have ignored non-resonant processes because they can be considered as a sum of two processes — a resonant V–V process plus a non-resonant T–V process, and therefore their probabilities are much less than the product of the two components. Thus, if we wish to study the effect of V–V processes on the form of the energy rate law we must consider either these second order effects or else a more realistic model, namely, an anharmonic oscillator model. We expect the near-resonant V–V processes of anharmonic oscillators to be nearly as important as the resonant V–V processes of harmonic oscillators. Furthermore, each collision results in a small but net energy gain or loss. Thus, the near-resonant V–V processes will give a non-zero contribution to dE/dt, and we consider them to be the dominant V–V effect.

In what follows, we shall evaluate dE/dt for anharmonic oscillators using Landau–Teller type rate constants, including both T–V and "resonant" V–V processes. In a sense, this work can be considered to be an extension of the early Shuler studies (2, 7) which did not treat non-linear situations.

It should be borne in mind that while our molecules are considered anharmonic oscillators as far as energetics and detailed balancing are concerned, we retain Landau–Teller type rate constants of harmonic oscillators. We believe that this will be a reasonable representation of anharmonic oscillator transition rate constants at least with respect to their dependence on quantum number m, especially for the low-lying vibrational levels containing most of the vibrational energy.

The energy of an anharmonic oscillator in a vibrational state m referred to the ground state is given to a good approximation by

$$[5] \quad \epsilon_m = mh\nu_e(1 - \chi_e) - m^2 h\nu_e\chi_e$$

where χ_e is the anharmonicity constant. Clearly, for an anharmonic oscillator we must sum m^2N_m as well as mN_m in order to obtain $E = \sum N_m\epsilon_m$. The summation contains a finite number of terms, just as for the case of a harmonic oscillator truncated at the dissociation limit. We have shown in an earlier study (8) that this finiteness leads simply to the same result as that for a sum of infinite terms plus a truncation error or term which accounts for molecular dissociation. Under conditions where dissociation is not important to the relaxation we may ignore this term. Hence the following summations are described only by the lower limit to m.

A, T–V rates

For collisions of AB(m) with an inert species (whose vibrational energy, if any, does not change upon collision) we consider only $\Delta m = \pm 1$

$$\left.\frac{-dN_m}{dt}\right|_{T-V} = (k_{m,m+1}N_m + k_{m,m-1}N_m - k_{m+1,m}N_{m+1} - k_{m-1,m}N_{m-1})\sum_0 N_m$$

Here we have assumed that all AB(m) are equally efficient at (de-) exciting a molecule and that the collision frequencies for all AB(m) are the same. Thus, the rate of change of vibrational energy E is given by

$$[6] \quad \left.\frac{dE}{dt}\right|_{T-V} = h\nu_e(1 - \chi_e)\sum_0 m\left.\frac{dN_m}{dt}\right|_{T-V} - h\nu_e\chi_e\sum_0 m^2\left.\frac{dN_m}{dt}\right|_{T-V}$$

in which

$$[7] \quad -\sum_0 m\left.\frac{dN_m}{dt}\right|_{T-V} = N\left[\sum_0 mk_{m,m+1}N_m - \sum_1 mk_{m-1,m}N_{m-1} + \sum_1 mk_{m,m-1}N_m - \sum_0 mk_{m+1,m}N_{m+1}\right]$$

$$= N\left[\sum_0 mk_{m,m+1}N_m - \sum_0 (m+1)k_{m,m+1}N_m + \sum_0 (m+1)k_{m+1,m}N_{m+1} - \sum_0 mk_{m+1,m}N_{m+1}\right]$$

$$= -N\sum_0 k_{m,m+1}N_m + N\sum_0 k_{m+1,m}N_{m+1}$$

where $\sum_0 N_m = N$.

The V–T transition probabilities are known to some extent, namely their dependence on m. According to Landau and Teller (9, 10) both $k_{m+1,m}$ and $k_{m,m+1}$ are proportional to $(m+1)$. Note that in the derivation of these results microscopic reversibility had been neglected. The standard remedy, often called symmetrization (11), is to introduce the factor $e^{\pm\Delta\epsilon/2kT}$, where $\Delta\epsilon$ is the energy difference (constant for harmonic oscillators) between the levels m and $(m+1)$. Thus $k_{m+1,m} \propto (m+1)e^{\Delta\epsilon/2kT}$, and $k_{m,m+1} \propto (m+1)e^{-\Delta\epsilon/2kT}$. This procedure guarantees detailed balance, i.e. $k_{m,m+1}/k_{m+1,m} = e^{-\Delta\epsilon/kT}$, and hence the proper equilibrium populations. For anharmonic oscillators, $\Delta\epsilon$ can be found from eq. [5], viz.

$$\Delta\epsilon = (1 - 2\chi_e)h\nu_e - 2mh\nu_e\chi_e$$

Therefore

$$k_{m+1,m} = k_{1,0}(m+1)e^{-m\phi}$$

$$k_{m,m+1} = k_{0,1}(m+1)e^{m\phi}$$

and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

$$k_{0,1}/k_{1,0} = e^{-\theta'/T+\phi}$$

where $\theta' = h\nu_e(1 - \chi_e)/k$ and $\phi = h\nu_e\chi_e/kT$. Using these results, [7] becomes

$$-\sum_0 m\frac{dN_m}{dt}\bigg|_{T-V} = N\left[-\sum_0 k_{m,m+1}N_m + \sum_1 k_{m,m-1}N_m\right] = N\left[-k_{0,1}\sum_0(m+1)N_m e^{m\phi} + k_{1,0}\sum_0 mN_m e^{-m\phi}\right]$$

Similarly, the contribution quadratic in m becomes

$$-\sum_0 m^2\frac{dN_m}{dt}\bigg|_{T-V} = N\left[\sum_0 m^2k_{m,m+1}N_m + \sum_1 m^2k_{m,m-1}N_m - \sum_0 m^2k_{m+1,m}N_{m+1} - \sum_1 m^2k_{m-1,m}N_{m-1}\right]$$

$$= N\left[-k_{0,1}\sum_0(2m+1)(m+1)N_m e^{m\phi} + k_{1,0}\sum_0 m(2m-1)N_m e^{-m\phi}\right]$$

We can combine these two results with eq. [6] to determine the T–V contribution to dE/dt. However, it is instructive to consider first the magnitude of $m\phi$. The quantity ϕ itself is typically of the order of 0.001 to 0.03; m may be anywhere between 1 and 100. It suffices to consider the largest m which might be important, and we arbitrarily define this level p as being one whose relative population at equilibrium is less than 1% or $\sim e^{-5}$. Thus

$$e^{-p\theta'/T}(1 - e^{-\theta'/T}) \simeq e^{-5}$$

Two limiting cases may be considered, depending on the magnitude of θ/T. For $\theta/T \to \infty$ then $p\theta/T = 5$, and $e^{\pm p\phi} = e^{\pm 5\chi_e}$. At worst, then, $e^{\pm m\phi}$ is not far from unity. For $\theta/T \to 0$, $e^{-p\theta/T} = e^{-5}T/\theta$, and $e^{\pm p\phi} = Te^{\pm 5\chi_e}/\theta$. Even if θ/T is as low as 0.001, $p\phi$ is only as large as 0.12. Typically, for temperatures where vibrational relaxation times are measureable, $\theta/T \sim 1$–3. Therefore we feel justified in replacing $e^{\pm m\phi}$ by $(1 \pm m\phi)$. This approximation is certainly good for all levels $m < p$ which contribute significantly to the energy at equilibrium and therefore even more so when far from equilibrium, particularly for shock tube experiments. Using this approximation

$$\frac{dE}{dt}\bigg|_{T-V} = k\theta'\sum_0 m\frac{dN_m}{dt} - \phi kT\sum_0 m^2\frac{dN_m}{dt}$$

can be simplified:

$$\frac{dE}{dt}\bigg|_{T-V} \approx NkT\left\{k_{1,0}\left(\frac{\theta'}{T} - \phi\right)e^{-(\theta'/T-\phi)}\sum_0 N_m - \left[\frac{\theta'}{T}(k_{1,0} - e^{\phi}k_{0,1}) + \phi(3k_{0,1} + k_{1,0}) + \phi^2k_{0,1}\right]\sum_0 mN_m\right.$$
$$\left. + \phi\left[\frac{\theta'}{T}(k_{0,1} + k_{1,0}) + 2(k_{1,0} - k_{0,1}) - \phi(2k_{1,0} - 3k_{0,1})\right]\sum m^2N_m - 2\phi^2(k_{0,1} + k_{1,0})\sum m^3N_m\right\}$$

Noting that $\phi \ll 1$ and $\phi \ll \theta'/T$, and rearranging:

$$\frac{dE}{dt}\bigg|_{T-V} \approx NkT\left\{k_{1,0}\left(\frac{\theta'}{T} - \phi\right)e^{-(\theta'/T-\phi)}\sum_0 N_m - (k_{1,0} - e^{\phi}k_{0,1})[(\theta'/T)\sum_0 mN_m - \phi\sum_0 m^2N_m]\right.$$
$$\left. + \phi[(\theta'/T)(k_{0,1} + k_{1,0}) + k_{1,0}e^{-\theta'/T}]\sum_0 m^2N_m\right\}$$

Using the conservation of mass and energy, which gives $\sum_0 N_m = N$ and

[8] $$k\theta'\sum_0 mN_m - \phi kT\sum_0 m^2N_m = E$$

allows the above results to be re-expressed as

[9] $$\frac{dE}{dt}\bigg|_{T-V} = -Nk_{1,0}[1 - e^{-(\theta'/T-2\phi)}]\left[E - \frac{Nh\nu_e(1 - 2\chi_e)e^{-(\theta'/T-\phi)}}{1 - e^{-(\theta'/T-2\phi)}}\right]$$
$$+ Nk_{1,0}h\nu_e\chi_e[(\theta'/T)(1 + e^{-(\theta'/T-\phi)}) + (1 - e^{-\theta'/T})]\sum_0 m^2N_m)$$

We recognize the term subtracting from E as being, to a good approximation (12), simply the equilibrium vibrational energy of an ensemble of N anharmonic oscillators, i.e., E^{∞}_{anh}. The last term is of the order of χ_e times the first term on the right hand side, and to the same level of approximation as heretofore, it may be absorbed into E or even neglected. Thus

[10] $$\frac{dE}{dt}\bigg|_{T-V} \approx -\frac{(E - E^{\infty}_{anh})}{\tau}$$

where

[11] $$(N\tau)^{-1} = k_{10}[1 - e^{-(\theta'/T-2\phi)}]$$

Apart from the interpretation of τ, this is experimentally indistinguishable from the Bethe–Teller law (eq. [1]).

B, V–V rates

We have shown earlier that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

$$\sum_0 m \frac{dN_m}{dt}\bigg|_{V-V}$$

makes no contribution to the rate of energy change. Thus we need only evaluate

$$\sum_0 m^2 \frac{dN_m}{dt}$$

We use the same formalism as above, this time explicitly allowing for

$$AB(v = m) + AB(v = n) \rightleftarrows AB(v = m + 1) + AB(v = n - 1)$$

As pointed out by Shuler (7*d*, *e*), collisions resulting in $\Delta v \geq 2$ do not contribute significantly to the overall relaxation behaviour; thus, we need consider only $\Delta v = \pm 1$.

$$[12] \quad \frac{d}{dt}\sum_0 m^2 N_m\bigg|_{V-V} = -\sum_1 m^2 k_{m,n}^{m+1,n-1} N_m N_n + \sum_1 m^2 k_{m+1,n-1}^{m,n} N_{m+1} N_{n-1} + \sum_1 m^2 k_{m-1,n}^{m,n-1} N_{m-1} N_n - \sum_1 m^2 k_{m,n-1}^{m-1,n} N_m N_{n-1}$$

where the summation is from $n = 1$ and $m = 1$, and where we have accounted for all possible V–V transitions subject to $\Delta v = \pm 1$ with collision partners changing v in opposite directions. Formally this includes such processes as

$$AB(v = m) + AB(v = m - 1) \rightarrow AB(v = m - 1) + AB(v = m)$$

and their reverse processes whose contributions to dN_m/dt are obviously zero. Those terms as well as a large number of others in [12] cancel out. It is easily shown that

$$[13] \quad \frac{d}{dt}\sum_0 m^2 N_m\bigg|_{V-V} = \sum_{\substack{m=0 \\ n=1}} (2m + 1) k_{m,n}^{m+1,n-1} N_m N_n - \sum_{\substack{m=0 \\ n=1}} k_{m+1,n-1}^{m,n} N_{m+1} N_{n-1} (2m + 1)$$

Noting that $\sum_{\substack{m=0 \\ n=1}} k_{m,n}^{m+1,n-1} N_m N_n - \sum_{\substack{m=0 \\ n=1}} k_{m+1,n-1}^{m,n} N_{m+1} N_{n-1}$ is just $\sum_{n=0} \frac{dN_n}{dt} = 0$ when dissociation is unimportant, then

$$[14] \quad \sum_0 m^2 \frac{dN_m}{dt}\bigg|_{V-V} = 2\sum_{\substack{m=1 \\ n=1}} m k_{m,n}^{m+1,n-1} N_m N_n - 2\sum_{\substack{m=1 \\ n=1}} m k_{m+1,n-1}^{m,n} N_{m+1} N_{n-1}$$

The usual Landau–Teller probabilities for V–V transfer of energy are:

$$k_{m,n}^{m+1,n-1} = (m + 1) n k_{0,1}^{1,0}$$

$$k_{m+1,n-1}^{m,n} = (m + 1) n k_{1,0}^{0,1}$$

These rules obviously do not satisfy detailed balance. As above, we symmetrize the rate constants to account for this. Thus

$$k_{m,n}^{m+1,n-1} = (m + 1) n k_{VV} e^{(m+1-n)\phi}$$

and

$$k_{m+1,n-1}^{m,n} = (m + 1) n k_{VV} e^{-(m+1-n)\phi}$$

where $k_{VV} \equiv k_{0,1}^{1,0} = e^{-\phi} k_{1,1}^{2,0}/2$.

The exponential factor ensures the correct relative level populations at equilibrium, e.g., $k_{1,1}^{2,0}/k_{2,0}^{1,1} = (N_2 N_0/N_1^2)_{eq} = e^{2\phi}$. Using these relationships, eq. [14] becomes

$$\sum_0 m^2 \frac{dN_m}{dt}\bigg|_{V-V} = 2k_{VV}\left[\sum_{m=1} e^{\phi} m(m + 1) e^{m\phi} N_m \left(\sum_{n=1} n e^{-n\phi} N_n\right) - \sum_{m=1} m(m + 1) e^{-m\phi} N_{m+1} \left(\sum_{n=1} n e^{n\phi} N_{n-1}/e^{\phi}\right)\right]$$

Again, we expand the exponentials to two terms. Then, after considerable algebraic manipulation, and neglecting terms of the order of ϕ, we obtain

$$[15] \quad \sum_0 m^2 \frac{dN_m}{dt}\bigg|_{V-V} \approx 2k_{VV} e^{\phi}\left[2\left(\sum_0 m N_m\right)^2 - N\left(e^{\phi}\sum_0 m^2 N_m - \sum_0 m N_m\right)\right]$$

Now, since $\frac{d}{dt}\sum m N_m\Big|_{V-V} = 0$, the V–V contribution to the rate of energy change is:

$$[16] \quad \frac{dE}{dt}\bigg|_{V-V} = -2\phi k T k_{VV} e^{\phi}\left[2\left(\sum_0 m N_m\right)^2 - N\left(e^{\phi}\sum_0 m^2 N_m - \sum_0 m N_m\right)\right]$$

Rate law for vibrational relaxation

Both T–V and V–V processes contribute to the rate of change of vibrational energy. The net rate is given by the sum of eqs. [10] and [16].

$$\frac{dE}{dt} = \frac{-(E - E^{\infty})}{\tau} - 2\phi kTk_{VV}e^{\phi}\left[2\left(\sum_0 mN_m\right)^2 - N\left(e^{\phi}\sum_0 m^2N_m - \sum_0 mN_m\right)\right]$$

The term $\sum_0 mN_m$ is proportional to the vibrational energy of a set of harmonic oscillators and it forms the major portion of the vibrational energy of our set of anharmonic oscillators. It can be expressed in terms of E and $\sum_0 m^2N_m$ by using eq. [8]:

$$[17]\quad \sum_0 mN_m = [E + \phi kT\sum_0 m^2N_m]/k\theta' \approx E/k\theta'$$

Therefore

$$[18]\quad \frac{dE}{dt} \approx -\frac{(E - E^{\infty})}{\tau} - 2\phi kTk_{VV}e^{\phi}\left[2\left(\frac{E}{k\theta'}\right)^2 - N\left(\sum_0 m^2N_m - \frac{E}{k\theta'}\right)\right]$$

The second moment, $\sum_0 m^2N_m$, is more difficult to evaluate. Recourse is needed to the differential equation whose T–V and V–V components were discussed above, i.e.

$$\frac{d}{dt}\sum_0 m^2N_m = N[k_{0,1}\sum_0 (2m + 1)(m + 1)N_m e^{m\phi} - k_{1,0}\sum_0 m(2m - 1)N_m e^{-m\phi}] + 2k_{VV}e^{\phi}[2E^2/k^2\theta'^2 - N(e^{\phi}\sum_0 m^2N_m - E/k\theta')]$$

Using $e^{\pm m\phi} \approx 1 \pm m\phi$, and after some rearrangement of terms,

$$[19]\quad \frac{d}{dt}\sum_0 m^2N_m \approx Nk_{1,0}[Ne^{\phi-\theta'/T} + (1 + 3e^{\phi-\theta'/T})E/k\theta' - 2(1 - e^{\phi-\theta'/T})\sum_0 m^2N_m] + 2k_{VV}e^{\phi}[2E^2/k^2\theta'^2 + NE/k\theta' - N\sum_0 m^2N_m]$$

Together with eq. [18] this comprises the general rate law for vibrational relaxation. These equations must be solved simultaneously. Since this is not very practical for the analysis of experimental results, we attempt to combine them into a single differential equation. Before doing so, we note that $\sum_0 m^2N_m$ can be written as $N\overline{E^2}/k^2\theta'^2$, i.e., it is an average of the square of the molecular vibrational energies of harmonic oscillators and approximately so for anharmonic oscillators. Secondly, for harmonic oscillators at equilibrium

$$\frac{2\bar{E}^2}{k\theta} + \bar{E} = h\nu e^{-u}(1 + e^{-u})/(1 - e^{-u})^2$$

where $u = h\nu/kT$. Furthermore

$$\overline{E^2}/k\theta = h\nu\sum_0 m^2N_m/N = h\nu\sum_0 m^2e^{-mu}/Q \text{ at equilibrium}$$

where Q, the partition function, is $(1 - e^{-u})^{-1} = \sum_0 e^{-mu}$. Noting that $d^2Q/du^2 = \sum m^2e^{-mu}$, then at equilibrium $\overline{E^2}/k\theta$ also becomes $h\nu e^{-u}(1 + e^{-u})/(1 - e^{-u})^2$, and the second term on the right hand side of eq. [19] approaches zero at equilibrium. Taking the anharmonicity into account to first order, the first term also becomes zero. Thus, both $d\bar{E}/dt$ and $\sum m^2dN_m/dt$ approach zero at equilibrium, as is proper. We also note that $k_{VV} \gg k_{1,0}$ (V–V transition probabilities per collision are $\sim 10^{-3}$, whereas T–V transition probabilities per collision are several orders of magnitude smaller). Therefore we are tempted to ignore the first term on the right hand side of eq. [19]. However, the factor $(2E^2/k^2\theta'^2 + NE/k\theta' - N\sum m^2N_m)$ can be very small not only near equilibrium, but also at other times. In fact, any time that a Boltzmann distribution exists during the relaxation, this factor is exactly zero. Such a stituation will occur for example at $t = 0$ in a shock tube experiment; at $t = 0$ the first term $\neq 0$, and can therefore not be ignored. Thus, on a per molecule basis, eqs. [18] and [19] become:

$$[20]\quad \frac{d\bar{E}}{dt} = -\frac{(\bar{E} - \bar{E}^{\infty})}{\tau} - \chi_e'k_{1,1}^{2,0}N\left[\frac{2\bar{E}^2}{k\theta'} - \frac{\overline{E^2}}{k\theta'} + \bar{E}\right]$$

$$[21]\quad \frac{d\overline{E^2}}{dt} = Nk_{1,0}\left[e^{\phi-\theta'/T} + (1 + 3e^{\phi-\theta'/T})\frac{\bar{E}}{k\theta'} - 2(1 - e^{\phi-\theta'/T})\frac{\overline{E^2}}{k^2\theta'^2}\right]k^2\theta'^2 + k_{1,1}^{2,0}N\left[\frac{2\bar{E}^2}{k\theta'} - \frac{\overline{E^2}}{k\theta'} + \bar{E}\right]k\theta'$$

where $\chi_e' = \chi_e/(1 - \chi_e)$, and $k_{1,1}^{2,0} = 2k_{VV}e^{\phi}$ is the rate constant for the process

$$AB(v = 1) + AB(v = 1) \rightarrow AB(v = 2) + AB(v = 0)$$

We proceed to eliminate $\overline{E^2}$ by differentiating eq. [20] with respect to time and then substituting eq. [21] into the result. To simplify matters we consider τ, $k_{1,1}^{2,0}$, and $\bar{E}^{\infty}$ not to depend strongly on time, i.e. the temperature, on which each depends, does not vary significantly during the relaxation. Strictly speaking this cannot be true for gases of finite composition and of sufficient concentration for V–V processes to be important. However, these secondary matters will be discussed in subsequent papers dealing with solutions of the rate law. Here, we consider the main effects. We obtain (with $\chi_e \ll 1$)

$$[22]\quad \chi_e' N k_{1,1}^{2,0} \frac{\overline{E^2}}{k\theta'}\left[N k_{1,1}^{2,0} + \frac{2}{\tau}\right] = -\frac{d\bar{E}}{dt}\left[\chi_e' N k_{1,1}^{2,0} + \frac{1}{\tau}\right] - 4\chi_e' N k_{1,1}^{2,0} \frac{\bar{E}}{k\theta'}\frac{d\bar{E}}{dt} - \frac{d^2\bar{E}}{dt^2}$$
$$+ \chi_e' N k_{1,1}^{2,0} k\theta' \left\{N k_{1,0}\left[e^{-u} + \frac{\bar{E}}{k\theta'}(1 + 3e^{-u})\right] + N k_{1,1}^{2,0} \frac{\bar{E}}{k\theta'}\left(1 + \frac{2\bar{E}}{k\theta'}\right)\right\}$$

or

$$[23]\quad \frac{d\bar{E}}{dt}\left[\frac{N k_{1,1}^{2,0}}{1 - \chi_e} + \frac{3}{\tau}\right] = -\frac{(\bar{E} - \bar{E}^{\infty})}{\tau}\left[N k_{1,1}^{2,0} + \frac{2}{\tau}\right] - \chi_e' N k_{1,1}^{2,0}\left[\left(\frac{\bar{E} - \bar{E}^{\infty}}{\tau}\right)\left(1 + \frac{4\bar{E}}{k\theta'}\right) + \frac{4\bar{E}}{k\theta'}\frac{d\bar{E}}{dt}\right] - \frac{d^2\bar{E}}{dt^2}$$

Equation [23] is the generalized rate law for the vibrational relaxation of a pure gas of diatomic molecules. Three important conclusions are evident:

(*a*) Equation [23] is a second order differential equation. Its solution depends explicitly not only on the initial energy (or population distribution) but also on the initial *rate* of energy change. Thus, unlike the Bethe–Teller law (eq. [1]) the *form* of the expression for $d\bar{E}/dt$ will depend on the initial rate of relaxation. Physically this must be so. For example, if initially all molecules are in $v = 0$, then it is impossible for V–V processes to contribute to the relaxation mechanism: a molecule in $v = 0$ can be excited to $v = 1$ only via a T–V process. This can be seen by putting $\bar{E} = 0$, $\overline{E^2} = 0$ in eq. [20]. The initial rate will be small. Thereafter, when substantial numbers of molecules exist in $v > 1$, V–V processes will compete and possibly eventually dominate. Therefore an incubation period will exist. Such transience will not necessarily be a feature of the relaxation if, choosing a second example, half the molecules were laser-excited into $v = 1$. Then V–V processes could contribute even at $t = 0$. It is interesting to note that it is not necessary to actually specify the entire initial population distribution, but rather the initial energy, and the next higher initial moment!

(*b*) Equation [23] is non-linear in $\bar{E}$ and in $d\bar{E}/dt$. There is a term in $\bar{E}^2$ and in $\bar{E}\,d\bar{E}/dt$. This implies that in general, a quasi-first order time constant does not exist: that phenomenological time constants, τ' and τ'' defined as

$$[24]\quad \tau' = -\frac{(\bar{E} - \bar{E}^{\infty})}{d\bar{E}/dt}$$

$$[25]\quad \tau'' = -\left[\frac{d \ln (d\bar{E}/dt)}{dt}\right]^{-1}$$

are not constants, but rather vary with time, t. Actually, since eq. [23] can be written exactly in term of Nt, then $N\tau'$ and $N\tau''$ are functions of Nt (an experimentalist would write Pt where P is the gas pressure). The non-linearity in Pt gives rise to an insidious effect. For example, doubling the gas pressure ought to half the time scale, at which point τ' and τ'' would be different. This implies that τ' and τ'' are not inversely proportional to N or P. It is quite common in shock tube experiments to vary the initial gas pressure as a means of varying the temperature. It can now be seen that this is a dangerous practice, since $P\tau'$ and $P\tau''$ depend on both T and P. Spurious temperature dependences may result, particularly if some of the experiments within the temperature range sample the transient period and some beyond the transient period.

(*c*) The steady-state solution of eq. [23] corresponds to times beyond the transient period. Then $d^2E/dt^2 \approx 0$ and the vibrational energy will relax exponentially. However the time constant, if one can be said to exist, is not simply τ but is in general related to $k_{1,1}^{2,0}$ as well. Two special cases can be distinguished.

(*i*) $k_{1,1}^{2,0} \gg k_{1,0}$

The transient period is very short. After this period,

$$\frac{d\bar{E}}{dt} = -\frac{(\bar{E} - \bar{E}^{\infty})}{\tau}(1 - \chi_e) - \chi_e\left[\left(\frac{\bar{E} - \bar{E}^{\infty}}{\tau}\right)\left(1 + \frac{4\bar{E}}{k\theta'}\right) + \frac{4\bar{E}\,d\bar{E}}{k\theta'\,dt}\right]$$

It is easy to show that eq. [1] is an exact solution of this equation. Therefore, assuming that the transient period is not being probed, the rate law is identical to the Bethe–Teller law, with the rate being determined by the slowest process, T–V. The success of such a simple rate law under limited conditions (5, 6) may be due to an inability to probe into the incubation zone. The incubation zone itself will be discussed below for shock tube experiments, and in a subsequent paper for arbitrary initial population distributions.

(*ii*) $k_{1,1}^{2,0} \ll k_{1,0}$

It is unlikely that V–V transition probabilities are smaller than T–V probabilities. Yet, were this situation to exist, then the incubation period would be so long as to prevent use of the steady state assumption. Then eq. [23] reduces to

$$\frac{3\,d\bar{E}}{\tau\,dt} = -\frac{2(\bar{E} - \bar{E}^{\infty})}{\tau^2} - \frac{d^2\bar{E}}{dt^2}$$

whose solution is again exactly eq. [1], as is to be expected.

Summarizing, both for fast V–V processes beyond the transient period and for slow V–V processes during the transient period, the rate constant will be $1/\tau$. Between these limiting cases, the situation may be very different. In order to examine the form of the rate law's dependence on $k_{1,1}^{2,0}/k_{1,0}$ and to examine the conditions whereby eq. [1] is valid we must actually solve eq. [23] and obtain $\bar{E}(t/\tau)$, $\overline{E^2}(t/\tau)$, τ'/τ, and τ''/τ for various values of the parameters $k_{1,1}^{2,0}/k_{1,0}$, ϕ, and θ'/T. In general, eq. [23] can be solved numerically. However, it turns out (see below) that for all conditions of interest in shock excitation or laser excitation or chemical activation studies, exact analytical solutions are possible. These will be outlined in a subsequent paper.

To solve eq. [23] we must specify initial values of $\bar{E}$, $d\bar{E}/dt$, and $\overline{E^2}$. Equivalently instead of $\overline{E^2}(t = 0)$, we may specify the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

initial value of $[2\bar{E}^2/k\theta' - \overline{E^2}/k\theta' + \bar{E}]$. It is instructive to consider the special case of a distribution which is initially Boltzmann. As mentioned earlier, this is equivalent to setting the initial value of $[2\bar{E}^2/k\theta' - \overline{E^2}/k\theta' + \bar{E}]$ equal to 0. Shuler has shown (7*c*) that when T–V processes alone are important *and* when the population distribution is initially Boltzmann, the relaxation proceeds through a continuous series of Boltzmann distributions. We would then expect $[2\bar{E}^2/k\theta' - \overline{E^2}/k\theta' + \bar{E}]$ to remain at zero during the relaxation. However, is it not known whether this is still the case when V–V processes contribute to the relaxation of a pure gas. Nor is it known how quickly an initially non-Boltzmann distribution becomes Boltzmann. Therefore our solution for $[2\bar{E}^2/k\theta' - \overline{E^2}/k\theta' + \bar{E}]$ is an important gauge for the existence of a time-dependent vibrational temperature — a concept which is widely used. We put

$$[26]\quad \frac{d\bar{E}}{dt} = -\frac{(\bar{E} - \bar{E}^{\infty})}{\tau} + f(t)$$

and substitute into eq. [23]. The result is

$$[27]\quad \left(\frac{Nk_{1,1}^{2,0}}{1 - \chi_e} + \frac{2}{\tau}\right) = -4\chi_e' Nk_{1,1}^{2,0}\frac{\bar{E}}{k\theta'} - \frac{d\ln f}{dt}$$

Equations [26] and [27] are equivalent to and more amenable to use than eq. [23]. We examine the magnitude of $4\chi_e'\bar{E}/k\theta'$, and note that the largest vibrational energy that any molecule can have is D_e, the bond dissociation energy. In fact it would be extremely rare if *all* molecules had that much energy, even at the start of relaxation. Normally $\bar{E} \ll D_e$ regardless of the type of experiment. Thus

$$4\chi_e'\frac{\bar{E}}{k\theta'} \ll \frac{4\chi_e' D_e}{h\nu_e(1 - \chi_e)} = \frac{4\chi_e D_e}{h\nu_e(1 - \chi_e)^2}$$

The anharmonicity factor is given for a Morse oscillator, and to a good approximation for a real anharmonic oscillator, by $\chi_e \equiv h\nu_e/4D_e$. Therefore $4\chi_e' Nk_{1,1}^{2,0}\bar{E}/k\theta' \ll Nk_{1,1}^{2,0}/(1 - \chi_e)$. We conclude that for all conditions which are conceivably attainable, the term $4\chi_e' Nk_{1,1}^{2,0}\bar{E}/k\theta'$ represents a minor perturbation in eq. [27]. Thus, eq. [27] is easily integrable. We obtain

$$[28]\quad f(t) = f(0)\exp\left[-\left(\frac{Nk_{1,1}^{2,0}}{1 - \chi_e} + \frac{2}{\tau}\right)t\right]$$

The initial value of the function $f(t)$ can be seen from eq. [26] to be related to the initial rate and amplitude of the relaxation. Indeed, by comparing eq. [20] with eq. [26] we recognize that $f(t)$ is nothing more than our Boltzmann distribution gauge function, and that $f(0)$ represents the non-Boltzmann nature of the initial distribution function.

$$[29]\quad \left[\frac{2\bar{E}^2}{k\theta'} - \frac{\overline{E^2}}{k\theta'} + \bar{E}\right] = \left[\frac{2\bar{E}^2}{k\theta'} - \frac{\overline{E^2}}{k\theta'} + \bar{E}\right]_0 \exp\left[-\left(\frac{Nk_{1,1}^{2,0}}{1 - \chi_e} + \frac{2}{\tau}\right)t\right]$$

and

$$[30]\quad \frac{d\bar{E}}{dt} = -\frac{(\bar{E} - \bar{E}^{\infty})}{\tau} - \chi_e' k_{1,1}^{2,0} N\left[\frac{2\bar{E}^2}{k\theta'} - \frac{\overline{E^2}}{k\theta'} + \bar{E}\right]_0 \exp\left[-\left(\frac{Nk_{1,1}^{2,0}}{1 - \chi_e} + \frac{2}{\tau}\right)t\right]$$

We come to some very interesting conclusions:

(*a*) A population distribution which is initially Boltzmann will remain so, regardless of the importance of V–V processes!

(*b*) Furthermore, there is no incubation period in a shock tube experiment: the energy will relax exponentially with a time constant given by τ, the T–V relaxation time.

(*c*) If a non-Boltzmann distribution exists initially, it decays rapidly to a Boltzmann distribution with a rate constant = $(Nk_{1,1}^{2,0} + 2/\tau)$, i.e. *faster* than the energy itself is relaxing rather than at similar rates.

Detailed solutions of eq. [30] will be given in a subsequent paper.

Conclusions

V–V processes as well as molecular anharmonicity are responsible for deviations of the derived rate law from the now superceded Bethe–Teller law. The initial conditions applicable to any individual type of experiment are explicitly accounted for.

Our derivation involved 3 main assumptions:

(*a*) The anharmonicity is not severe. Even for H_2 ($\chi_e = 0.027$) it appears that our approximation $e^{\pm m\phi} = 1 \pm m\phi$ is valid, as explained in the text.

(*b*) The T–V and V–V transition probabilities are given by Landau–Teller harmonic oscillator probabilities. Whereas such a theory may not be totally valid (it is known, e.g., that anharmonicity strongly influences the T–V probabilities (7*e*, 13, 14) we expect that at least with respect to the dependence on vibrational quantum number, m, the assumption is realistic. Essentially the Landau–Teller theory claims that energy transfer becomes more probable the higher the energy of the molecule. For T–V this probability increases linearly with m; for V–V nearly as mn. We related ΣmN_m to $\bar{E}$ and Σm^2N_m to $\overline{E^2}$, and this resulted in a simple rate law involving only $\bar{E}$ and $\overline{E^2}$. If such data were to become available, it would perhaps be better to use empirical scaling laws, and it would be interesting to see if these would lead to substantially different rate laws.

(*c*) Changes of only ± 1 in the quantum number are considered for T–V processes. Similarly $\Delta m = \pm 1$ for V–V processes in opposite directions for each collision partner alone are considered, such that transitions are near-resonant. While this limits our

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

model, it is known that for $\Delta m \geq 2$, transition probabilities decrease dramatically (10, 11), and that as a result they contribute little to the relaxation mechanism (7*e*). However, it would be interesting to do a full numerical solution of the master equation to compare with our predictions.

(*d*) The rotational substructure has been ignored. Since V–V probabilities can be as large as 0.01, and R–T as low as 0.01, future modelling should include rotation.

Our main results are that, in general,

(*a*) Initial experimental conditions are important.

(*b*) Transient periods exist such that great care is needed in citing results of experimental measurements. Without recognizing the transient period it is possible that one would conclude τ is not inversely proportional to the pressure. It is suggested that $P\tau$ be quoted not only as a function of temperature, but also as a function of t/τ, so as to facilitate comparison between different experiments. This requirement appears to be unnecessary for shock tube studies of pure diatomic molecules for which the Bethe–Teller law applies exactly. However, the situation is not yet clear for gas mixtures or for pure polyatomic molecules, and therefore it is safest if shock tube studies were included as well.

(*c*) The present rate law permits the experimentalist to test two common assumptions — the validity of the Bethe–Teller law and the existence of a Boltzmann distribution during relaxation.

HESHEL TEITELBAUM. Can. J. Chem. **61**, 1276 (1983).

The generalized rate law for the relaxation of the vibrational energy of a pure diatomic gas, AB, derived earlier, is solved analytically for a variety of initial conditions corresponding to shock tube, laser-excited fluorescence, and chemical activation experiments. The resulting expressions can be used to easily predict whether a given system will relax according to a V–V or a T–V mechanism or both. The initial conditions and the molecular anharmonicity are shown to be as important, if not more important, for this purpose than the ratio of T–V and V–V rate constants. Behind shock waves the energy relaxes exponentially with a T–V time constant. The initial distribution remains Boltzmann. In laser or chemical activation experiments the energy does not relax exponentially, leading to phenomenological time "constants" $-(\bar{E} - \bar{E}^{\infty})/(d\bar{E}/dt)$ or $-[d \ln (d\bar{E}/dt)/dt]^{-1}$ which are not constant in time and prevent direct comparisons with shock tube data. It is only after an incubation period during which the vibrational energy is redistributed via V–V processes that the energy then exchanges with translational energy and decays. Prescriptions are given to extract T–V and V–V rate constants from such data. The initial degree of laser excitation, α, and the time regime probed, t/τ, must be known for this purpose. However, when direct overtone excitation is used, a careful choice of α can lead to extraction of the T–V constant directly. Even though the vibrational energy itself does not relax exponentially, it is shown that the mean energy, $\bar{E}/h\nu'$, and the mean squared energy, $\overline{E^2}/(h\nu')^2$, relax in such a way that the quantity $[2(\bar{E}/h\nu')^2 + \bar{E}/h\nu' - \overline{E^2}/(h\nu')^2]$ does decrease exponentially with a time constant very closely related to the V–V rate constant for $2AB(v = 1) \rightarrow AB(v = 0) + AB(v = 2)$. A short survey of various laser and chemical excitations in the literature is presented and analyzed in terms of initial conditions. In general, the larger the degree of excitation and the higher the quantum numbers of the excited levels, the more V–V character does the energy relaxation have.

The master equation for the time evolution of individual level populations is reduced to a simple form for times applicable to the early V–V redistribution of vibrational energy. This leads to a simple prescription for extrapolating measured population distributions back towards the initial distributions produced by a chemical reaction. The general features of the time–evolution profiles are found by numerical integration to show an initial broadening of the distribution simultaneous with a shift towards $v = 0$.

HESHEL TEITELBAUM. Can. J. Chem. **61**, 1276 (1983).

On résoude analytiquement la loi génerale dérivant la vitesse de la relaxation de l'énergie vibrationelle d'un gaz diatomique pur, AB — ceci pour une variété de conditions initiales correspondant aux expériences dans les tubes de choc, à la fluorescence induite par laser et à l'activation chimique. On peut utiliser les expressions qui en résultent afin de prédire facilement si un système quelconque s'équilibra selon un mécanisme V–V ou T–V. On montre que les conditions initiales et l'anharmonicité moléculaire sont aussi importantes que le rapport des constantes de vitesse T–V et V–V. Dans les ondes de choc l'énergie s'équilibre exponentiellement avec un temps de vitesse T–V. La répartition des populations des niveaux reste Boltzmann. Dans les expériences d'excitation par laser ou par réaction chimique, l'énergie ne s'équilibre pas exponentiellement — ce qui empêche que les "constantes" phénomenologiques $-(\bar{E} - \bar{E}^{\infty})/(d\bar{E}/dt)$ ou $-[d \ln (d\bar{E}/dt)/dt]^{-1}$ soient des vraies constantes par rapport au temps, et ce qui empêche une comparaison directe avec les résultats determinés par moyen de tube de choc. Il n'est qu'après une période d'incubation, pendant laquelle l'énergie vibrationelle se rédistribue via les processus V–V que l'énergie puisse se transformer en une énergie translationelle et diminuer. On donne une prescription pour tirer les constantes T–V et V–V à partir de tels mesures. Le degré d'excitation initiale, α, et le régime du temps étudié, t/τ, doivent être connus en générale pour ce but. Par contre, quand l'excitation overtone directe est utilisée une choix soigneuse de α peut mener à une extraction directe de la constante T–V. Bien que l'énergie vibrationelle même ne s'équilibre pas exponentiellement on montre que l'énergie vibrationelle moyenne, $\bar{E}/h\nu$, et l'énergie vibrationelle carrée moyenne, $\overline{E^2}/(h\nu')^2$, s'equilibrent d'une telle manière que la quantité $[2(\bar{E}/h\nu')^2 + \bar{E}/h\nu' - \overline{E^2}/(h\nu')^2]$ se décroît exponentiellement avec une constante de temps liée très étroitement à la constante de vitesse V–V pour le processus $2AB(v = 1) \rightarrow AB(v = 0) + AB(v = 2)$. Un résumé bref de plusieurs excitations par laser ou par réaction chimique décrites dans la litérature est donné. Il est analysé selon les conditions initiales des expériences individuelles. En générale on trouve que plus sévère l'excitation et que plus élevés les nombres quantiques des niveaux excités, alors plus de caractère V–V aura la relaxation.

L'équation "master" décrivant le changement des populations des niveaux vibrationels individuels par rapport au temps est simplifié pour le régime du temps qui correspond à la rédistribution rapide V–V de l'énergie. Ceci mène à une technique simple pour extrapoler les répartitions des populations observées vers la répartition initiale produite par une réaction chimique. Une intégration numérique montre qu'en générale la répartition s'applâtit simultanément avec un mouvment du pic vers $v = 0$.

A. Introduction

In a previous paper (1), we derived a rate law which describes the rate of change of the vibrational energy of pure diatomic molecules with respect to time. Both T–V and V–V processes were included, and the result was applicable to the relaxation subsequent to shock excitation, laser excitation, or chemical activation. It was shown that two common assumptions are not generally valid — the Bethe–Teller law, and the existence of a Boltzmann distribution during the relaxation. In this study we wish to demonstrate the far-reaching consequences of the unbridled use of these assumptions.

Shock tube studies of vibrational relaxation rely on measurements of the time-variation of the translational temperature of the relaxing gas. This is intimately related to the time-variation of the vibrational energy (2). The fluorescence intensity of laser-excited gases is directly proportional to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

vibrational energy (3) when the gas is optically thin to radiation from all levels (but see ref. 4). Similarly, photoacoustic detection of laser-induced relaxation is directly related to the vibrational energy. Thus the present study should be significant for enabling meaningful comparisons to be made between shock tube and laser-excitation data.

Many chemical reactions, particularly exothermic ones, produce molecules in vibrationally excited states. Infrared chemiluminescence is used to study the nascent population distributions (5–7). Yet rapid vibrational relaxation may prevent direct measurement of the initial populations. Simple extrapolation backwards in time gives a good indication of the initial distribution. It would be useful to know the relaxation rate law in order to best accomplish the extrapolation or to make checks on existing techniques. Our previous studies show (1) that the mean vibrational energy, $\bar{E}$, and the mean squared vibrational energy, $\overline{E^2}$, are constrained to relax in a certain way. This suggests the necessary guidelines for extrapolation.

We proceed by solving the generalized rate law, as applied to each of the three types of experiment. They are naturally divided into two groups: those for which the initial vibrational population distribution is Boltzmann and those which are not. To simplify matters we treat the relaxation as near-isothermal. For diatomic molecules thermal effects are not considered severe. A complete thermal analysis is presented in a subsequent study.

B. Isothermal relaxation of vibrational energy

When the translational temperature, the rate constants, and the equilibrium vibrational energy, $\bar{E}^{\infty}$, do not vary significantly with time, the generalized rate law for the relaxation of vibrational energy is given by (1)

$$[1]\quad \frac{d\bar{E}}{dt} = -\frac{(\bar{E}-\bar{E}^{\infty})}{\tau} - \chi_e h\nu_e k_{1,1}^{2,0} N[2(\bar{E}/h\nu')^2 + \bar{E}/h\nu' - \overline{E^2}/(h\nu')^2]_0 e^{-at}$$

where χ_e is the anharmonicity factor, N the molecular concentration, ν_e the spectroscopic vibrational frequency; $\nu' = \nu_e(1-\chi_e)$; $\nu'' = \nu_e(1-3\chi_e)$; $a = Nk_{1,1}^{2,0}/(1-\chi_e) + 2/\tau$; $1/\tau = Nk_{1,0}(1 - e^{-h\nu''/kT})$; $k_{1,0}$ the rate constant for the process $AB(v=1) + AB(v) \rightarrow AB(v=0) + AB(v)$; and $k_{1,1}^{2,0}$ the rate constant for the process $2AB(v=1) \rightarrow AB(v=0) + AB(v=2)$. Equation [1] applies strictly to a pure diatomic gas. The quantity $[2(\bar{E}/h\nu')^2 + (\bar{E}/h\nu') - \overline{E^2}/(h\nu')^2]$ subscripted with a zero is characteristic of the initial population distribution and thus identifies the type of experiment. At subsequent times this quantity decays to zero:

$$[2]\quad [2(\bar{E}/h\nu')^2 + \bar{E}/h\nu' - \overline{E^2}/(h\nu')^2] = [2(\bar{E}/h\nu')^2 + \bar{E}/h\nu' - \overline{E^2}/(h\nu')^2]_0 e^{-at}$$

1. Shock tubes

Using $\bar{E}_0/h\nu' = e^{-u}/(1-e^{-u})$ and $\overline{E_0^2}/(h\nu')^2 = e^{-u}(1+e^{-u})/(1-e^{-u})^2$ it is easily seen that $[2(\bar{E}/h\nu')^2 + \bar{E}/h\nu' - \overline{E^2}/(h\nu')^2]_0 = 0$. Here $u = h\nu'/kT_0$ where T_0 is the initial temperature (usually room temperature). The rate constants, $k_{1,0}$, $k_{1,1}^{2,0}$, and the equilibrium vibrational energy, $\bar{E}^{\infty}$, correspond to a final, higher temperature, T, to which the gas is exposed. Equation [1] becomes

$$[3]\quad \frac{d\bar{E}}{dt} = -\frac{(\bar{E}-\bar{E}^{\infty})}{\tau}$$

whose solution is

$$[4]\quad \bar{E} - \bar{E}^{\infty} = (\bar{E}_0 - \bar{E}^{\infty})e^{-t/\tau}$$

Clearly a single relaxation time exists. The phenomenological time constants, τ' and τ'', defined as

$$[5]\quad \tau' \equiv -\frac{(\bar{E}-\bar{E}^{\infty})}{d\bar{E}/dt}$$

and

$$[6]\quad \tau'' \equiv -\left[\frac{d\ \ln\ (d\bar{E}/dt)}{dt}\right]^{-1}$$

are both true constants and equal to τ. Therefore, shock tube studies are amenable to determining T–V rate constants exclusively. Furthermore, the Boltzmann distribution remains Boltzmann; at all times a vibrational temperature is defined, and the vibrational level populations are given by the expressions in ref. 5.

2. Non-Boltzmann initial distributions

We set

$$[7]\quad b \equiv \chi_e h\nu_e k_{1,1}^{2,0} N[2(\bar{E}/h\nu')^2 + \bar{E}/h\nu' - \overline{E^2}/(h\nu')^2]_0$$

The solution to eq. [1] is straightforward. Using the initial condition $\bar{E} = \bar{E}_0$ at $t = 0$, then

$$[8]\quad (\bar{E}-\bar{E}^{\infty}) = (\bar{E}_0 - \bar{E}^{\infty})e^{-t/\tau} + \frac{b(e^{-at} - e^{-t/\tau})}{(a - 1/\tau)}$$

Clearly this is not a simple decay process. Phenomenological time constants are not true constants in time. It is only at late times when the term e^{-at} has decayed that the apparent time constant is τ. At earlier times τ' and τ'' are given by

$$[9]\quad \frac{\tau'}{\tau} = \frac{be^{-at} + [(\bar{E}_0 - \bar{E}^{\infty})(a - 1/\tau) - b]e^{-t/\tau}}{ab\tau e^{-at} + [(\bar{E}_0 - \bar{E}^{\infty})(a - 1/\tau) - b]e^{-t/\tau}}$$

and

$$[10]\quad \frac{\tau''}{\tau} = \frac{ab\tau e^{-at} + [(\bar{E}_0 - \bar{E}^{\infty})(a - 1/\tau) - b]e^{-t/\tau}}{a^2 b\tau^2 e^{-at} + [(\bar{E}_0 - \bar{E}^{\infty})(a - 1/\tau) - b]e^{-t/\tau}}$$

These measureables are shown in Figs. 1–3 for various values of the parameters

$$\gamma = k_{1,1}^{2,0}/(k_{1,0} - k_{0,1})$$

and

$$\delta = (\bar{E}_0 - \bar{E}^{\infty})/\{h\nu_e\chi_e[2(\bar{E}/h\nu')^2 + \bar{E}/h\nu' - \overline{E^2}/(h\nu')^2]_0\}$$

as a function of the reduced time, t/τ. The first parameter represents the relative importance of V–V and T–V rate constants; the second parameter represents the relative initial deviations from equilibrium and from the Boltzmann distribution. The latter parameter can be either positive or negative; its magnitude can be $\ll 1$ or $\gg 1$, depending very sensitively on initial conditions. For example, if the initial energy is close to $\bar{E}^{\infty}$, or if the initial distribution is strongly non-Boltzmann weighted towards high vibrational levels, then $|\delta| \ll 1$; otherwise $|\delta|$ can be $\gg 1$. If the initial energy is $< \bar{E}^{\infty}$, or if the initial distribution is doubly peaked such that $\bar{E} > \bar{E}^{\infty}$ yet $[2\bar{E}^2/(h\nu')^2 + \bar{E}/h\nu' - \overline{E^2}/(h\nu')^2] < 0$, then $\delta < 0$; otherwise δ can be > 0. Thus the vibrational energy can approach equilibrium from above or below, and may overshoot or undershoot $\bar{E}^{\infty}$ before attaining $\bar{E}^{\infty}$. Overshooting (undershooting) indicates

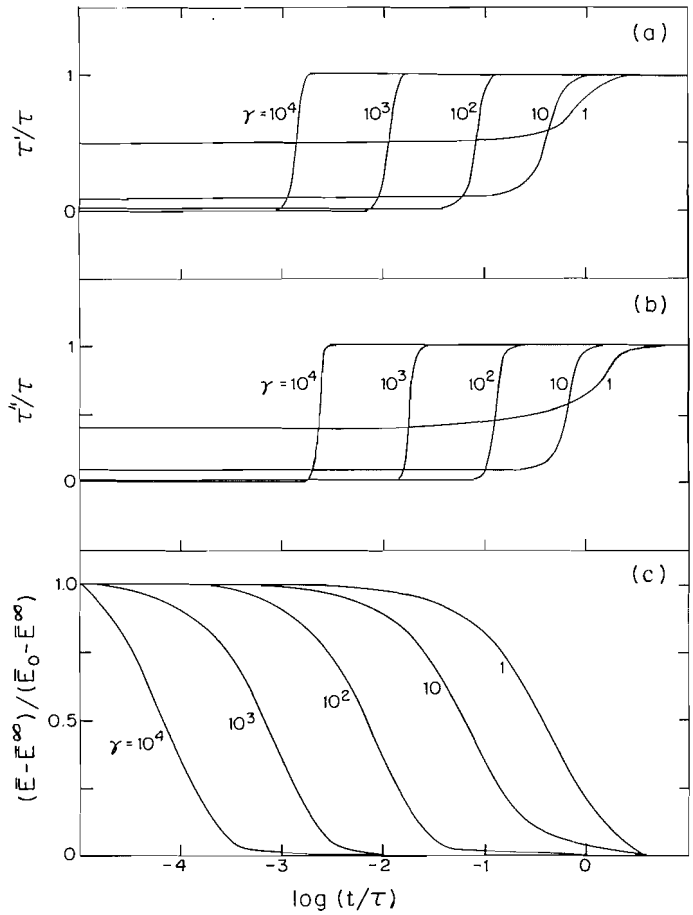

FIG. 1. Reduced phenomenological relaxation times, τ'/τ and τ''/τ, as defined by eqs. [5] and [6], and reduced vibrational energy as a function of reduced time for the relaxation of a gas of pure diatomic molecules. $\tau'/\tau = 1$ or $\tau''/\tau = 1$ mean that the time constant originates entirely from T–V processes. Here $\chi_e = 0.01$. Effect of $\gamma = k_{1,1}^{2,0}/(k_{1,0} - k_{0,1})$ on (*a*) τ'/τ, (*b*) τ''/τ, and (*c*) $(\bar{E} - \bar{E}^{\infty})/(\bar{E}_0 - \bar{E}^{\infty})$ for $\delta = 1$ where δ is given by $\delta = (\bar{E}_0 - \bar{E}^{\infty})/\{h\nu_e\chi_e[2(\bar{E}/h\nu') + (\bar{E}/h\nu') - \bar{E}^2/(h\nu')^2]_0\}$. The process which is responsible for the relaxation can be deduced by finding τ' or τ'' at a time when the energy is, say, 50% equilibrated: e.g. for $\gamma = 10$, $\tau' = 0.10\tau$, $\tau'' = 0.084\tau$, i.e. V–V is responsible; for $\gamma = 1$, $\tau' = 0.59\tau$, $\tau'' = 0.50$, i.e. V–V and T–V are roughly equally responsible.

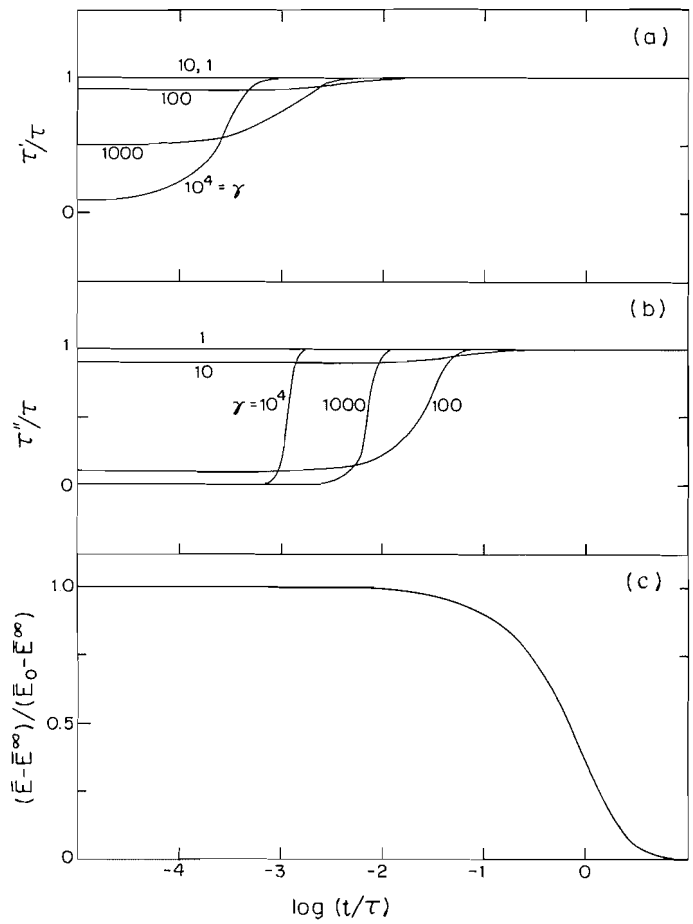

FIG. 2. Same as in Fig. 1, but with $\delta = 1000$. Note that at practically all times during which the vibrational energy changes substantially, $\tau' \simeq \tau$ and $\tau'' \simeq \tau$ for all γ. As a result, the energy relaxes almost purely exponentially at a rate determined by T–V processes.

the system's preference to readjust the population distribution without much regard to its effect on the deviation from equilibrium. A lack of overshooting (undershooting) indicates that the redistribution occurs without affecting the energy substantially. The function $(\bar{E} - \bar{E}^{\infty})/(\bar{E}_0 - \bar{E}^{\infty})$ shown in Figs. 1*c*, 2*c*, and 3*c* displays these features. Such complicated behaviour makes analysis of experimental results difficult, particularly if simple exponential behaviour is assumed, i.e. if the Bethe–Teller law, eq. [3], is assumed to be valid.

Figures 1*a*, 1*b*, 2*a*, 2*b*, 3*a*, and 3*b*, showing τ'/τ and τ''/τ as functions of the reduced time, t/τ, indicate the possible errors involved. We might expect the error in τ' and τ'' to be unimportant if γ is large, i.e. if V–V processes are dominant such that the populations redistribute themselves on a short time scale without affecting the energy much; thereafter the energy would relax on a time scale determined by T–V processes. This is indeed seen to be the case in Fig. 2. For example, by the time τ'' has reached 95% of its final value, τ, only 1% of the energy has relaxed when $\gamma = 1000$. However, it should be noted that this result corresponds to $\delta = 1000$, i.e. when the initial distribution is near-Boltzmann. Figure 1 leads to quite the opposite conclusion. Here, $\delta = 1$, i.e. the initial distribution is strongly non-Boltzmann. It is seen that regardless of the value of γ, nearly all the energy has relaxed during the transient period! In fact, τ'/τ and τ''/τ can be shown from eqs. [9] and [10] to have approximately their values at $t = 0$, i.e. $\delta/(\delta + \gamma)$ and $\delta/[\gamma(\gamma + 3)]$ respectively. Figures 1 and 2 therefore indicate that the initial conditions are far more important in determining the process responsible for relaxation than is the factor γ itself! The experimentalist should be aware of this fundamental result when interpreting his data. Indeed he can exploit this result by manipulating his conditions to give $\delta \lesssim 1$ in order to directly determine $k_{1,1}^{2,0}$. Alternatively $\delta \gg 1$ will lead to a direct determination of τ.

The influence of δ on τ' and τ'' is summarized in Fig. 3 for a typical $\gamma = 100$. We note that the smaller the value of δ, the more V–V character the energy relaxation has. For $\delta \geq 10$, only 3% of the energy or less has relaxed via V–V processes by the time $\tau' = 0.95\tau$. When $\delta < 10$, V–V relaxation becomes more important. When $0 < \delta < 1$, the energy rapidly approaches and overshoots (undershoots) equilibrium via V–V processes and then slowly reapproaches equilibrium via T–V processes. For $\delta < 0$, the energy initially deviates even further from equilibrium rapidly before finally approaching equilibrium slowly.

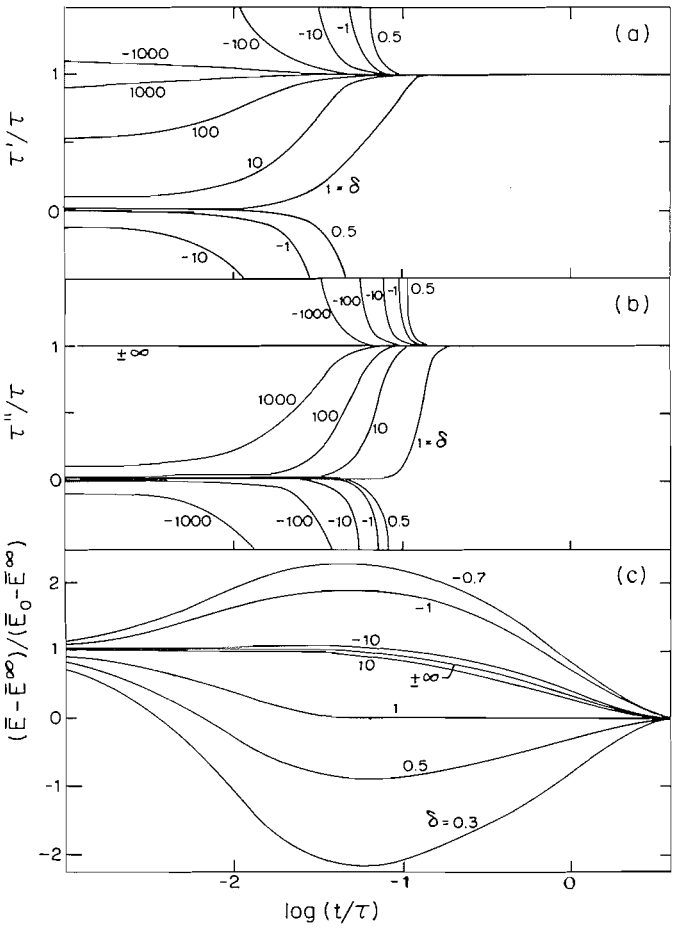

FIG. 3. Reduced phenomenological relaxation times and vibrational energy as a function of reduced time. Effect of initial conditions, i.e. of δ as defined in Fig. 1 on (*a*) τ'/τ, (*b*) τ''/τ, and (*c*) $(\bar{E} - \bar{E}^{\infty})/(\bar{E}_0 - \bar{E}^{\infty})$. Here $\chi_e = 0.01$, $\gamma = k_{1,1}^{2,0}/(k_{1,0} - k_{0,1}) = 100$. Note that only when $\delta = \pm\infty$, does the energy relax exponentially with the time constant $= \tau$. The closer δ approaches 0, i.e. the more non-Boltzmann the distribution, the larger the overshoot (undershoot) in energy.

It is also interesting to note that the transient period lasts longer for τ'' than it does for τ'.

There are several arbitrary ways to evaluate the above results. One can ask how much energy has relaxed (1%, 5%, 10%, 50% etc.) by the time t/τ has reached a certain value (0.5, 1, 2, etc.) or by the time either τ' or τ'' has reached a certain percentage of τ (50%, 90%, 95%, 99% etc.). Faced with such nonstandard criteria, an experimentalist must additionally decide with what to actually reduce his time scale (since it is not τ which he measures but rather τ' or τ''). Furthermore, the accessible range of t/τ is limited by experimental time resolution (0.1 μs for shock tubes or 1 μs for fluorescence), and transient behaviour near $t = 0$ may or may not be measurable. In other words, an experimentalist will not know unambiguously to which regime of t/τ his data correspond unless he measures τ' or τ'' over a long time scale. As an example, suppose the initial conditions are such that $\delta = 1$. Then a measurement of the phenomenological relaxation time, τ' as a function of t/τ', would result in Fig. 4, except for the scaling factor τ, rather than in Fig. 1*a*. The curves in Fig. 4 are very distinctive. By comparing both form and magnitude of experimental data with curves such as those in Fig. 4, the

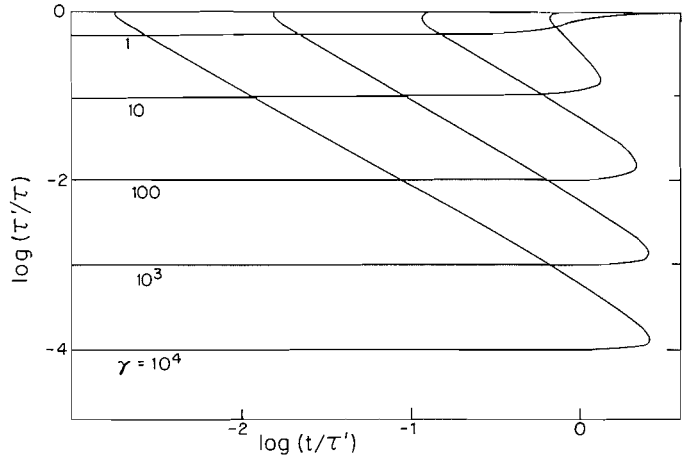

FIG. 4. Same as in Fig. 1(*a*) but with the time scale reduced by τ' instead of τ. This corresponds to what an experimentalist might plot. Note that the phenomenological relaxation time, τ', measured at a given t/τ' corresponds to three possible choices for τ. The ambiguity is cleared up when measurements are made at more than one t/τ'.

experimentalist could determine both γ and τ, as an alternative method to manipulating δ. We note that it may not be necessary to vary the time scale over many orders of magnitude: even for $\gamma = 10^4$ where the interesting region of t/τ' varies from 1.74×10^{-3} to 2.63, the absolute time scale, t, only varies by a factor of 4.7 (the region of rapid rise in Fig. 1*a*). Therefore even if the flat regions of Fig. 1*a* are not accessible by choosing δ appropriately, it is still feasible to obtain γ and τ by modest variation of the time scale, or equivalently the gas pressure (see below).

We note further that t/τ can be written at $Nt/N\tau$, where $N\tau$ is just $(k_{1,0} - k_{0,1})^{-1}$. N is the gas concentration and is proportional to the gas pressure, p. Therefore Figs. 1–3 can be considered either as functions of absolute time at a given pressure or as a function of pressure at a given absolute time. In the latter case they demonstrate an apparent deviation of the expected inverse dependence of τ' or τ'' on p. This has been observed (6).

Yet a third method to determine τ experimentally is to completely eliminate the influence of V–V processes by sufficiently diluting the relaxing gas in an inert species, such that AB–AB collisions are rare and thus negligible. This will be discussed in a subsequent article concerning mixture rules.

C. Determination of initial conditions

1. Shock waves

As mentioned above, the initial distribution is Boltzmann. Hence $\delta = \infty$, and the vibrational energy relaxes exponentially regardless of the deviation from equilibrium.

2. Fluorescence intensity measurements

Such experiments involve exciting molecules from a single vibrational level to another, v. Usually the initial level is $v = 0$. Therefore the initial values of $\bar{E}$ and $\overline{E^2}$ are larger than they would be without excitation. We note that $\bar{E}/h\nu'$ and $\overline{E^2}/(h\nu')^2$ were originally defined as $\sum_0 m(N_m/N)$ and $\sum_0 m^2(N_m/N)$. (They represent true average energies at modest temperatures when the anharmonicity does not influence the molecular energy much.) Let α be the fraction of molecules, initially in $v = 0$, which are excited into level v, then

TABLE 1. Initial conditions, δ, for vibrational relaxation of laser-excited molecules

Note: α is the fraction of molecules excited into the given indicated level v from the ground state $v = 0$. If not otherwise indicated the electronic state is the ground state. The molecules have been prepared in the specified levels by methods explained in the references cited, but their relaxation rates have not necessarily been measured, nor is α always given. δ is defined as $\delta = (\bar{E}_0 - \bar{E}^\infty)/\{h\nu_e\chi_e[2(\bar{E}/h\nu')^2 + \bar{E}/h\nu' - \overline{E^2}/(h\nu')^2]_0\}$ and is evaluated here using eq. [12].

$$[11]\quad \left[2\left(\frac{\bar{E}}{h\nu'}\right)^2 + \frac{\bar{E}}{h\nu'} - \frac{\overline{E^2}}{(h\nu')^2}\right]_0$$

$$= 2\left(\frac{\bar{E}_B}{h\nu'} + \alpha v\right)^2 + \left(\frac{\bar{E}_B}{h\nu'} + \alpha v\right) - \left(\frac{\overline{E_B^2}}{(h\nu')^2} + \alpha v^2\right)$$

$$= \left[2\left(\frac{\bar{E}}{h\nu'}\right)^2 + \frac{\bar{E}}{h\nu'} - \frac{\overline{E^2}}{(h\nu')^2}\right]_B + \alpha v\left(\frac{4\bar{E}_B}{h\nu'} + 1 + 2\alpha v - v\right)$$

where the subscript B refers to a Boltzmann distribution at the initial temperature T_0. Thus the first term on the right hand side of eq. [11] is zero. The average energy $\bar{E}_B/h\nu'$ is given to a good approximation by $e^{-u}/(1 - e^{-u})$ where $u = h\nu_e(1 - 2\chi_e)/kT_0$. The largest value α can have is the initial fraction of molecules in $v = 0$ prior to excitation, i.e. $(1 - e^{-u})$. Furthermore, the initial temperature is practically the same as the equilibrium temperature under our assumption of near-isothermal relaxation. Thus $(\bar{E}_0 - \bar{E}^\infty) = \alpha v$. (For an experiment involving simultaneous shock heating and laser excitation this is not true, and an additional term would be needed.) Combining this result with eq. [11], we obtain

$$[12]\quad \delta^{-1} \simeq \chi_e[(1 + 3e^{-u})/(1 - e^{-u}) + v(2\alpha - 1)]$$

Typically the excitation is directly into $v = 1$. Then

$$[13]\quad \delta^{-1} \simeq \chi_e[4e^{-u}/(1 - e^{-u}) + 2\alpha]$$

We can see that $\delta > (1 - e^{-u})/|2\chi_e(1 + e^{-2u})|$. For a classical oscillator ($u \to 0$), $\delta > D_e/kT$, where D_e is the Morse dissociation energy; for a quantum oscillator ($u \to \infty$) then $\delta > (2\chi_e)^{-1}$. Referring to Fig. 3 as a guide, it thus apears that the relaxation is significantly T–V in character when $v = 1$. However, when $v > 1$, eq. [12] shows that δ can be small or even negative. The relaxation then becomes V–V in character. Rabitz (7) has recently come to a similar conclusion for the special case of HD by numerically integrating the rate equations and scaling the individual rate constants in terms of $k_{1,1}^{2,0}$ and τ more elaborately than we do but using a much smaller number of V–V processes than we consider (1).

Table 1 shows the variety of values δ can have for selected molecules and therefore the special care needed in interpreting relaxation data. The molecules chosen are some which have actually been excited into the indicated levels by other workers, and whose relaxation times have either been measured or are conceivably measurable. Indeed some of these molecules exist in highly excited states in molecular lasers, and it is therefore of particular interest to understand their relaxation behaviour.

We note how sensitively the relaxation mechanism depends on initial conditions. In general, the larger the fraction of molecules initially excited into level v or the larger the value of v, the more V–V character the relaxation has (smaller $|\delta|$). Any experiment designed to measure the T–V rate constant, $k_{1,0}$, is best done by exciting few molecules into $v = 1$ and making the corrections suggested by Figs. 1–4; alternatively, any experiment designed to measure the V–V rate constant, $k_{1,1}^{2,0}$, is best done by direct excitation into the highest overtone level possible and applying the corresponding correction factors. In all cases it is crucial to measure α in order to measure δ. Yet, with rare exception (17, 20), in the experiments cited in Table 1 α has not been estimated. Certainly the need for detailed knowledge of absorption coefficients and line shapes makes this a difficult matter; however, it appears to be a necessity. For example, exciting only 1% of all HF molecules into $v = 1$ results in an essentially T–V mechanism, whereas a 50% excitation introduces V–V character. On the other hand, 1% of all HD excited into $v = 6$ results in more V–V character than does 50% excitation. If one were able to measure and control α reliably, then it would be a simple matter to arrange that the relaxation mechanism be totally T–V. Figure 5 shows the value of α necessary to make $\delta = \infty$ for this purpose.

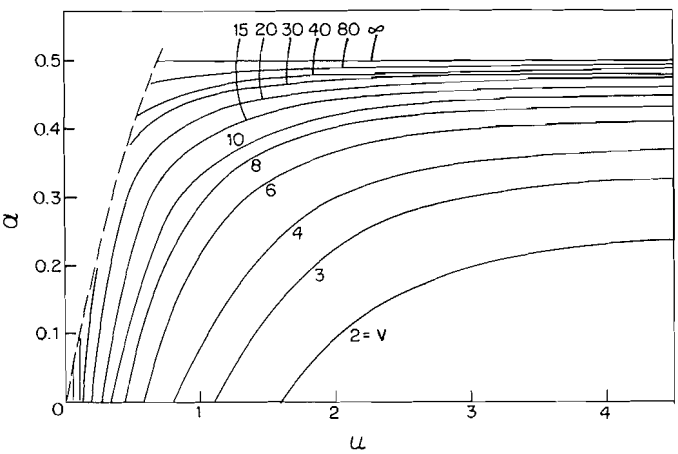

FIG. 5. The fraction of molecules, α, initially in the ground vibrational level, $v = 0$, which must be excited into level v in order to ensure pure exponential T–V relaxation, as a function of the reduced variable $u = h\nu_e(1 - 2\chi_e)/kT$. The dashed line is the function $(1 - e^{-u})$, the fraction of molecules in $v = 0$ prior to excitation, and therefore the maximum value of α physically possible.

Thermal excitation generally has little influence on δ itself (see Table 1). However, γ decreases strongly with temperature ($k_{1,0}$ increases with temperature usually according to exp $\{-cT^{-1/3}\}$, whereas $k_{1,1}^{2,0}$ is relatively temperature independent).

Initial relaxation conditions for diatomic molecules produced by a variety of techniques described in the cited references: chemical reaction, Hg-sensitization, molecular beams, photolysis, laser-induced fluorescence. All molecules are in the ground electronic state unless otherwise specified. N_v/N is the fraction of molecules produced in the indicated levels v. δ is calculated from $\delta = (\bar{E}_0 - \bar{E}^*_v)/\{h\nu_e\chi_e[2(\bar{E}/h\nu')^2 + \bar{E}/h\nu' - \overline{E^2}/(h\nu')^2]_0\}$ where $\bar{E}/h\nu' = \sum vN_v/N$, $\overline{E^2}/(h\nu')^2 = \sum v^2N_v/N$, $\bar{E}/kT = ue^{-u}(1 - e^{-u})^{-1}$ and $u = h\nu_e(1 - 2\chi_e)/kT$. The temperature, T, used is that cited in the references except for molecular beam experiments where T is calculated from the cited average collision energy, $\bar{E}_c$, using $\bar{E}_c = 3kT/2$. It is only for such high energy experiments that the equilibrium vibrational energy, $\bar{E}$, is similar to the initial product vibrational energy, $\bar{E}_0$.

[a]The fluorescence intensities for final v = 76, 78, 79, 81, and 83 of I_2 are 0.035, 0.047, 0.023, 0.0351, and 0.585 respectively. The large values of v ensure a small δ.

[b]The remaining fractional level populations of BaBr in v = 13–20 are 0.057, 0.047, 0.031, 0.021, 0.011, 0.007, 0.004, and 0.002 respectively. Those for BaI in v = 13–23 are 0.077, 0.077, 0.069, 0.060, 0.047, 0.036, 0.025, 0.018, 0.013, 0.007, and 0.005 respectively.

[c]In the Hg-sensitization of CO, H_2, D_2, O_2, and N_2 the product energy has been ascribed to vibrational energy although the data cannot distinguish between vibrational and rotational energy. Also the E–V energy transfer occurs with a background Boltzmann distribution. Thus these data are akin to those in Table 1.

[d]The remaining fractional level populations of CO in v = 13, 14, 15 are 0.18, 0.17, and 0.16 respectively.

[e]95 K is the rotational temperature for the partially relaxed rotational distribution. It is assumed here that the rotational temperature was approaching the translational temperature.

[f]The remaining fractional level populations of CO in v = 13, 14, 15 are 0.011, 0.008, and 0.007 respectively.

[g]The remaining fractional level populations of NO in v = 13–17 are 0.016, 0.011, 0.006, 0.002, and 0.001, respectively.

[h]Note the bimodal distribution for CN as well as for CO produced by 3 different methods.

Then if δ is large (Fig. 2), an essentially T–V rate acquires V–V character; if δ is small (Fig. 4), an essentially V–V rate acquires T–V character.

3. Chemical activation

Exothermic chemical reactions produce molecules in vibrationally, rotationally and, sometimes, electronically excited states. The distribution of these states is unique for each reaction, and no general mathematical relationship can as yet be written down. Therefore δ must be evaluated for each individual case, which may additionally depend on the reagents' collisional energy (or temperature) and internal energy. In Table 2 we summarize the vibrational distributions for some selected reactions. Generally, such studies are not concerned with the energy relaxation rates themselves; however, the initial product distributions relax rapidly, and it is useful to know the relaxation mechanism in order to correct for these collisional effects. Further, as shown below, the manner in which any given individual level population relaxes depends explicitly on the bulk vibrational energy and the way *it* relaxes. Thus it is crucial to determine δ. For this purpose, δ is also given in Table 2.

We see that, with a couple of exceptions, $|\delta|$ is greater than 10 for the distributions shown, implying that despite the large excursions from equilibrium the vibrational energy relaxes essentially via T–V processes if the molecules encounter only like molecules. The vibrational level populations redistribute themselves rapidly via V–V processes without significantly affecting the energy itself; subsequently the energy relaxes via T–V processes. In one case (45), CO appears to have already attained a Boltzmann distribution by the time the distribution was measured. However, the vibrational temperature, T_{vib}, is 4750 K, and $\bar{E}_0$ is still fa away from $\bar{E}^z$. Similarly the BrF distribution is almost perfectly Boltzmann. However, in this case $T_{vib} \simeq 298$ K, so the cited distribution is likely already the equilibrium distribution. The T–V character of the relaxation will also be enhanced by the presence of inert colliders. The question of mixtures will be examined in detail in a subsequent paper.

On the other hand, I_2, HF (36), and OH have been produced with very strong non-Boltzmann distributions centred at high quantum numbers, v. The departure from equilibrium, though substantial, is not sufficient to compensate this effect. Thus $|\delta|$ is small, and the relaxation has considerable V–V character. Indeed, in one case (BaF) the vibrational energy is by chance almost identical to that needed for equilibrium at 1050 K. Thus, the small energy deficit relaxes during the V–V redistribution.

One of the main aims of the experiments cited in Table 2 is to determine the nascent vibrational level populations. Subsequent relaxation masks the initial distribution. If it is not possible to arrest the relaxation by decreasing the gas pressure (and hence the collision frequency), then extrapolation techniques are required. This is particularly important for rapid V–V relaxation, which is difficult to arrest. Guidelines for extrapolation are required. The present results indicate not only how simple a matter it is to determine the mechanism of vibrational relaxation of pure diatomic molecules but also suggest a simple procedure to extract $K_{1,1}^{2,0}$ and τ. The procedure leads additionally to exact constraints on the initial population distribution:

(*a*)Evaluate $2(\sum \nu N_\nu/N)^2 + \sum \nu N_\nu/N - \sum \nu^2 N_\nu/N$ at times when the vibrational level populations are being rapidly redistributed. Equation [2] shows that this quantity decays exponentially. In the present context this is more important than the question of exponential time-evolution of energy itself.

(*b*) Plot the logarithm of this quantity as a function of time, and extrapolate back to the presumed time origin in order to give the true initial value of $[2(\bar{E}/h\nu')^2 + \bar{E}/h\nu' - \overline{E^2}/(h\nu')^2]$. This does not give the actual initial distribution, but it can be used as a constraint to ensure the reasonableness of any existing extrapolation procedure for individual level populations.

(*c*) As a bonus, the slope of such a plot gives $N[k_{1,1}^{2,0}/(1 - \chi_e) + 2/\tau]$. Conceivably, the V–T rate constant could approach the V–V rate constant at extremely high translational temperatures; however, the author knows of no physical system to which this applies, certainly not at the low temperatures found in chemiluminescence experiments. In other words, $\gamma \gg 1$ in practice, and the slope should give a direct measure of $k_{1,1}^{2,0}$. The time constant for the energy relaxation rate should give τ, and this can be used to check the above assumption. It would be interesting to re-examine the data of the experiments in Table 2 in order to obtain $k_{1,1}^{2,0}$.

In order to further expound on the power of the present formulation, we show that the time evolution of the individual levels can be expressed easily for certain conditions. We refer to the earlier paper (1) which introduces the notation for the master equation. We begin with the master equation in the form

$$[14] \quad dN_m/dt = dN_m/dt|_{T-V} + dN_m/dt|_{V-V}$$

in which the two terms on the right-hand side are expressed as

$$[15] \quad dN_m/dt|_{T-V} = -(k_{m,m+1}N_m + k_{m,m-1}N_m - k_{m+1,m}N_{m+1} - k_{m-1,m}N_{m-1})\sum_0 N_m$$

and

$$[16] \quad \left.\frac{dN_m}{dt}\right|_{V-V} = -\sum_1 k_{m,n}^{m+1,n-1}N_mN_n + \sum_1 k_{m+1,n-1}^{m,n}N_{m+1}N_{n-1} + \sum_1 k_{m-1,n}^{m,n-1}N_{m-1}N_n - \sum_1 k_{m,n-1}^{m-1,n}N_mN_{n-1}$$

where $k_{m,m+1}$ is the rate constant for the T–V process $AB(m) + AB \rightarrow AB(m + 1) + AB$, and $k_{m,n}^{m+1,n-1}$ is the rate constant for the V–V process

$$AB(m) + AB(n) \rightarrow AB(m + 1) + AB(n - 1)$$

We use the scaling relationships

$$k_{m+1,m} = k_{1,0}(m + 1)e^{-m\phi}$$

$$k_{m,m+1} = k_{0,1}(m + 1)e^{m\phi}$$

$$k_{m,n}^{m+1,n-1} = (m + 1)nk_{0,1}^{1,0}e^{(m+1-n)\phi}$$

and

$$k_{m+1,n-1}^{m,n} = (m + 1)nk_{0,1}^{1,0}e^{-(m+1-n)\phi}$$

where

$$\theta' = h\nu_e(1 - \chi_e)/k$$

and

$$\phi = h\nu_e\chi_e/kT$$

These relationships satisfy microscopic reversibility. Equations [15] and [16] become

$$[17] \quad \left.\frac{dN_m}{dt}\right|_{T-V} = -Nk_{1,0}[(m + 1)e^{-\theta'/T}e^{(m+1)\phi}N_m + me^{-(m-1)\phi}N_m - (m + 1)e^{-m\phi}N_{m+1} - me^{-\theta'/T}e^{m\phi}N_{m-1}]$$

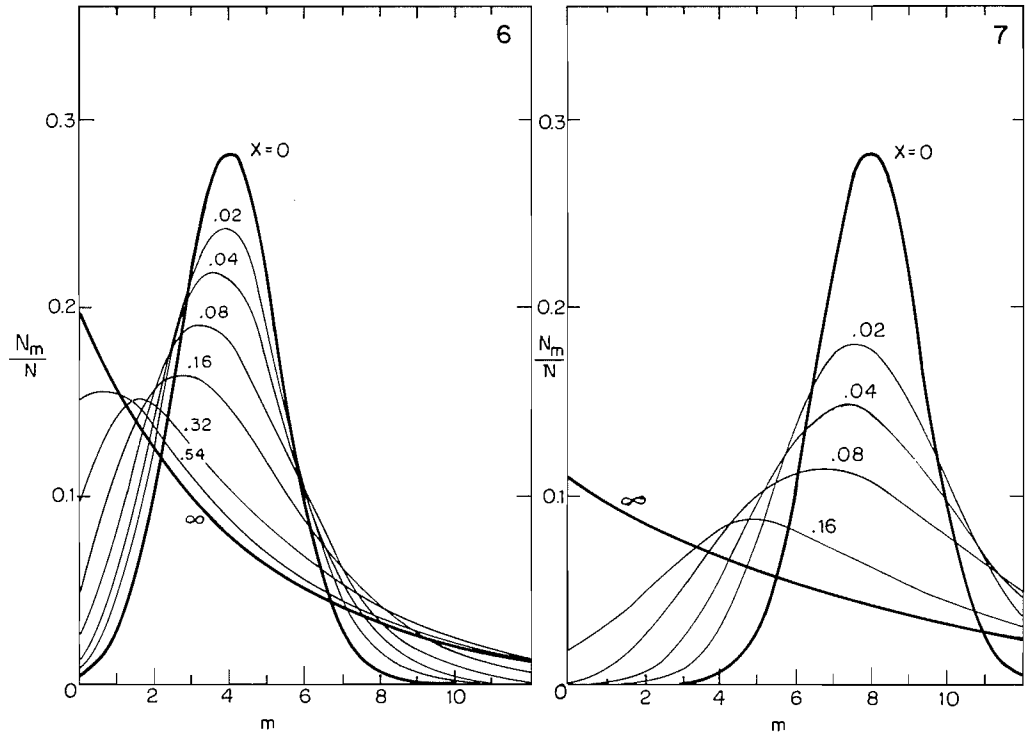

FIG. 6. Time evolution of the fractional level populations N_m/N of levels m as a function of the reduced time, $x = Nk_{1,0}^{0,1}t$. N_m/N has meaning only at integral levels of m; however, the distribution is drawn as continuous for clarity. The initial distribution ($x = 0$) and the final distribution ($x = \infty$) are indicated by thicker lines. The initial distribution is $N_m/N \propto \exp[-0.25(m - 4)^2]$, normalized so that $\sum N_m/N = 1$. At all subsequent times $\sum N_m/N$ remains at 1, and $\sum mN_m/N = 4.0025$, corresponding to a final vibrational temperature, T_{vib}, given by $h\nu/kT_{vib} = 0.2230$. The evolution is for times $\ll\tau$, and $\delta > 10$.

FIG. 7. Same as in Fig. 6, but with the initial distribution shifted to $m_0 = 8$: $N_m/N \propto \exp[-0.25(m - 8)^2]$. Here $\sum mN_m/N = 7.9992$, corresponding to a final $h\nu/kT_{vib} = 0.1178$.

$$[18]\quad \left.\frac{dN_m}{dt}\right|_{V-V} = k_{0,1}^{1,0}\{-\sum(m+1)N_m e^{(m+1-n)\phi}nN_n + \sum(m+1)N_{m+1}e^{-(m-n)\phi}nN_n + \sum mN_{m-1}e^{(m-n)\phi}nN_n - \sum mN_m e^{-(m-n-1)\phi}nN_n + \sum(m+1)N_{m+1}e^{-(m-n)\phi}N_n - \sum mN_m e^{-(m-n-1)\phi}N_n\}$$

where the summations start at $n = 0$.

Those interested in following the entire time evolution of the level populations up to equilibrium must solve the complicated set of differential equations [14], i.e. the sum eqs. [17] and [18]. In comparing eqs. [17] and [18] we note that our assumption $k_{1,1}^{2,0}(= 2e^{\phi}k_{0,1}^{1,0}) \gg k_{1,0}$ implies that we need only consider eq. [18] as the main contribution to dN_m/dt. We must be careful to recognize that this is not generally true, particularly near equilibrium, when the V–V contributions have decayed leaving T–V processes to relax the energy. However, Figs. 1–4 show that V–V processes do dominate at early times. If the experiment in question here has preserved much of the nascent distribution, then presumably not much redistribution has occurred; any modest redistribution that has occurred is V–V in character. Thus eq. [14] reduces for early times (even for $m = 0$) to

$$[19]\quad \frac{dN_m}{dt} \simeq Nk_{0,1}^{1,0}\{[(m+1)N_{m+1} - mN_m] + (\bar{E}/h\nu')[mN_{m-1} + (m+1)N_{m+1} - (2m+1)N_m]\}$$

where we have made the approximations $e^{\pm m\phi} \simeq 1$ and $e^{\pm n\phi} \simeq 1$, valid because the anharmonicity factor is so small, and where we have made use of $\sum_0 N_n = N$ and $\sum_0 nN_n \simeq N\bar{E}/h\nu'$. Whereas the vibrational energy in such experiments relaxes essentially via T–V processes ($|\delta| > 10$ in Table 2), it does so at relatively later times. At the early times in question we may consider $\bar{E}$ to be a constant and equal to the value given by the initial distribution, $\bar{E}_0$. We treat it as unknown but obtainable from an appropriate extrapolation of eq. [8] from late time measurements (the intercept of a plot of $\ln|\sum nN_n h\nu'/N - \bar{E}^{\infty}|$ vs. time, t, gives $\ln|\bar{E}_0 - \bar{E}^{\infty}|$), or else $\bar{E}/h\nu'$ can be evaluated directly from $\sum nN_n$ at each time.

The asymptotic solution ($t \to \infty$) of eq. [19] is $N_m/N = e^{-mw}(1 - e^{-w})$, as can be verified by direct substitution, with $\bar{E}/h\nu'$ given by $e^{-w}/(1 - e^{-w})$ and dN_m/dt set to zero. In other words, an arbitrary initial distribution relaxes towards a Boltzmann distribution — a particular one which is not the final equilibrium one. If $\bar{E}/h\nu'$ is considered constant (as it must be when V–V processes alone are important), then e^{-w} is determined by $\bar{E}_0/h\nu' = e^{-w}/(1 - e^{-w})$. In an example considered below, $\bar{E}_0/h\nu' = 8$; then $w = 0.1178$. For $\nu' = 4000\ cm^{-1}$ this corresponds to a vibrational temperature of 48,890 K; for $\nu' = 400\ cm^{-1}$ to 4890 K. Of course this is reached only at $t = \infty$, in principle. Before then, T–V processes will interfere and eventually dominate; $\bar{E}/h\nu'$ will change with time, and the distribution will relax according to the T–V rate law, i.e. constrained by $\bar{E} \to \bar{E}^{\infty}$. However, here we consider only the early redistribution which might be of interest for extrapolating experimental data. Equation [19] is the exact prescription nec-

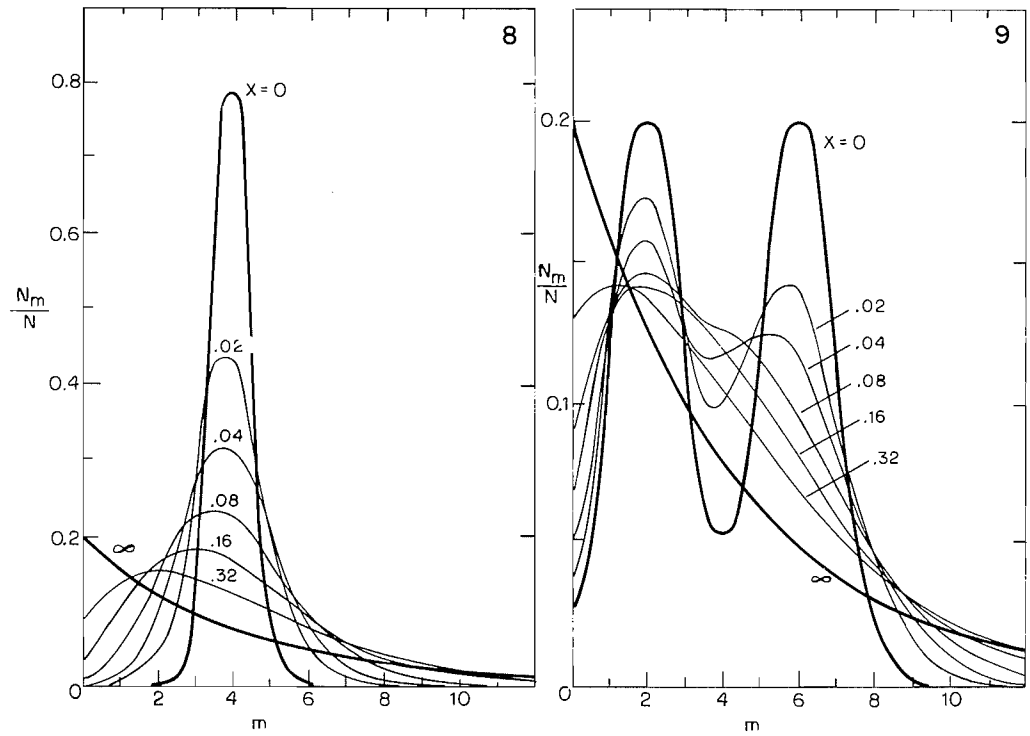

FIG. 8. Same as in Fig. 6, but with a narrower initial distribution: $N_m/N \propto \exp[-2(m-4)^2]$. Here $\sum mN_m/N = 3.9996$, corresponding to a final $h\nu/kT_{vib} = 0.2232$.

FIG. 9. Same as in Fig. 6, but with the initial distribution given by $N_m/N \propto \exp[-0.5(m-2)^2] + \exp[-0.5(m-6)^2]$. Here $-\sum mN_m/N = 4.0116$, corresponding to a final $h\nu/kT_{vib} = 0.2226$.

essary for the extrapolation. We note that any arbitrary distribution (here the first measured one) can be considered the initial distribution; and eq. [19] can be integrated backwards in time to a known time origin. The extrapolation is most conveniently carried out graphically. Equation [19], divided by N, gives the local slope of a graph of the fractional level populations vs. the reduced time, $Nk_{0,1}^{1,0}t$. (Recall that $k_{0,1}^{1,0} = e^{-\phi}k_{1,1}^{2,0}/2$ has essentially been determined in advance by the procedure described above.) Carried out in small steps of, say, 0.001 abscissa units, the initial distribution can be easily reconstructed. The slopes of such plots are, in general, not constant, underscoring the need to improve upon previous linear extrapolations. Whereas short extrapolations can be carried out in this way to correct experimental data, the entire time-evolution of the fractional level populations is best determined by numerical integration of eq. [19]. In order to proceed with examples, we must specify initial distributions. Figures 6–9 are the results of such integrations for Gaussian-like distributions peaked initially at level m_0. In these examples $\bar{E}/h\nu'$ is evaluated by direct summation, $\sum mN_m/N$, and is guaranteed by our choice of initial distributions to be substantial and thus consistent with V–V redistribution ($|\delta| \gg 1$).

As seen in Fig. 6 ($m_0 = 4$), the distribution broadens at first and develops a long exponential tail; at the same time the peak of the distribution moves towards $m = 0$. By the time the fractional level population in $m = 0$ becomes substantial most levels are overpopulated. Thereafter the populations approach their asymptotic values monotonically. It is because of the linear dependence of the V–V rate coefficients on m that the upper levels relax and spread out relatively rapidly. For this same reason the same distribution (this time peaked at $m_0 = 8$) relaxes in the same manner but more than twice as fast initially as it does when $m_0 = 4$ (see Fig. 7). We note that the reduced time scale, $Nk_{0,1}^{1,0}t$, refers to a progress variable identified as the total number of transitions. Since typical V–V collision probabilities are of the order of 0.01 transitions per collision (51), a value of 0.01 for $Nk_{0,1}^{1,0}t$ corresponds roughly to one single collision. It is therefore quite striking to see in Figs. 6–9 how the population distribution can change its character markedly even after only a few collisions!

Figure 8 compared with Fig. 6 shows that the initial width of the distribution has little or no effect on how the distribution approaches a Boltzmann one. Finally, it is interesting to see how a doubly peaked distribution (such as for the bimodal production (42–46) of CN or CO) evolves. The peak at low vibrational levels broadens but does not shift until the second peak at higher vibrational levels broadens and merges into the tail of the first one. Thereafter the resulting single peak relaxes as in Fig. 6 (See Fig. 9).

D. Summary and conclusions

We have solved analytically the rate law for the relaxation of the vibrational energy of a pure diatomic gas. We showed that it is easy to predict whether the vibrational energy in a given system will relax according to a V–V mechanism or according to a T–V mechanism or both. Surprisingly, the outcome is determined not so much by the ratio, γ, of the corresponding rate constants as it is by the specification of the initial conditions, δ (initial principal moments of the population distribution, equilibrium temperature, and anharmonicity are involved). With careful mapping out of some of the time history of the phenomenological time "constant", both the T–V constant, $k_{1,0}$, and the V–V constant, $k_{1,1}^{2,0}$, can be extracted in principle by the guidelines presented. Even time-evolution of

the individual level populations can be deduced; however, a numerical integration is required here.

Implications for comparison of shock tube results with fluorescence intensity results are clear. Whereas the former lead to $1/\tau = k_{1,0} - k_{0,1}$ directly, the latter lead to a complicated average of $k_{1,0}$ and $k_{1,1}^{2,0}$. Fluorescence data can be considered to be one of two types depending on the time resolution of the experiment: a rapid rise or drop in intensity followed by a slower decay; or else a simple decay. The former, by its nature, is usually analyzed according to a realistic V–V and T–V mechanism, and rate constants are reported. The latter type is deceptively simple and usually single time constants are reported which are often compared directly, but misguidedly, with shock tube data. In view of our results we should not be surprised at disagreement since fluorescence values of τ' are not constants in time or pressure. Using Figs. 1–4 the experimentalist could deduce τ. However, to do this the initial conditions (in this case α) and the regime of t/τ' probed must be known. These are not trivial but necessary requirements. Even then, the experimentalist will be uncertain as to which of the three choices of τ'/τ is actually appropriate, unless he measures τ' as a function of time or pressure. A survey of a variety of experiments (Table 1) suggests that fortunately many experimental conditions probably correspond to a T–V relaxation, particularly when $v = 1$ is laser-excited. However, in view of the fact that the degree of laser excitation is rarely known, this conclusion is not certain, and it would be worthwhile checking the data.

Even though they produce distinctly different initial distributions, both laser excitation and chemical activation can produce the entire range of values of δ. Particular values of α are suggested (Fig. 5) which ensure a pure T–V energy relaxation rate for fluorescence experiments involving direct overtone excitation. Of course, such external control is not possible for a chemical reaction, and it is found that the excited products of a chemical reaction ought to relax according to a mixed mechanism with the energy remaining roughly constant until the population distribution becomes essentially Boltzmann at a high vibrational temperature. Prescriptions are given for extracting rate constants simply from such data, and it would be interesting to actually carry out the analysis. A prescription is also given by extrapolating product distributions to their initial ones. Although the present technique is valuable for pure diatomic gases, the presence of relatively inert colliders in chemical activation experiments introduces an additional complexity. This will be examined in a subsequent article on mixture rules.

The present formalism should also serve as a guideline for future analysis of data from laser-assisted shock tube studies.

The autoxidation of unsaturated lipids in micelles. Synergism of inhibitors vitamins C and E

LAWRENCE ROSS COATES BARCLAY,[1] STEVEN JEFFREY LOCKE, AND JOSEPH MARK MACNEIL
Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received January 3, 1983

LAWRENCE ROSS COATES BARCLAY, STEVEN JEFFREY LOCKE, and JOSEPH MARK MACNEIL. Can. J. Chem. **61**, 1288 (1983).

The kinetics of thermally (30°C) initiated autoxidations of unsaturated lipids, linoleic acid, and methyl linoleate are studied in 0.50 *M* sodium dodecyl sulfate (SDS) micelles. The rate of chain initiation, R_i, was controlled by using known amounts of the thermal initiator, di-*tert*-butylhyponitrite (DBHN). The initiator efficiency, e, determined by the induction period method with ∝-tocopherol, was 0.30 for linoleic acid and varied (0.30 to 0.36) for methyl linoleate autoxiation as the concentration of the ester increased. The rate of autoxidation of linoleic acid follows the classical rate law since it is proportional to the substrate concentration and to the square root of chain initiation. The oxidizability of linoleic acid measured in micelles is $4.09 \times 10^{-2}\ M^{-1/2}\ s^{-1/2}$. The oxidizability of methyl linoleate varied from 2.37×10^{-2} to $6.92 \times 10^{-2}\ M^{-1/2}\ s^{-1/2}$ as the amount of solubilized ester increased. The latter results are indicative of pooling of the ester in the micellar phase. Additions of aqueous solutions of ascorbic acid to ∝-tocopherol-inhibited micellar autoxidations result in very significant extensions of the efficient inhibition period compared to that obtained with ∝-tocopherol alone. The mechanism of this synergism is briefly discussed.

LAWRENCE ROSS COATES BARCLAY, STEVEN JEFFREY LOCKE et JOSEPH MARK MACNEIL. Can. J. Chem. **61**, 1288 (1983).

On a étudié la cinétique de l'autoxydation initiée thermiquement (30°C) des lipides insaturés, l'acide linoléique et le linoléate de méthyle, dans des micelles de sulfate de dodécyl sodium (SDS) (0,50 *M*). On a contrôlé la vitesse d'initiation de la chaîne, R_i, en utilisant des quantités connues de l'initiateur thermique, le di-*tert*-butylhyponitrite (DBHN). L'efficacité de l'initiateur, e, déterminée par la méthode de la période d'induction avec l'α-tocophérol, est de 0,30 pour l'acide linoléique et varie (de 0,30 à 0,36) pour l'autoxydation du linoléate de méthyle lorsque la concentration de l'ester augmente. La vitesse d'autoxydation de l'acide linoléique obéit à la loi de vitesse classique puisqu'elle est proportionnelle à la concentration du substrat et à la racine carrée de l'initiation de la chaîne. L'oxydabilité de l'acide linoléique mesurée dans des micelles est de $4{,}09 \times 10^{-2}\ M^{-1/2}\ s^{-1/2}$. L'oxydabilité du linoléate de méthyle varie de $2{,}37 \times 10^{-2}$ à $6{,}92 \times 10^{-2}\ M^{-1/2}\ s^{-1/2}$ lorsque la quantité d'ester solubilisé augmente. Ces derniers résultats sont une indication de l'entassement de l'ester dans la phase micellaire. Des additions de solutions aqueuses d'acide ascorbique à l'autoxydation micellaire inhibée par l'α-tocophérol conduisent à une augmentation marquée de l'efficacité de la période d'induction par rapport à celle obtenue avec l'α-tocophérol seul. On discute brièvement du mécanisme de ce synergisme.

[Traduit par le journal]

The free radical autoxidation of organic molecules organized in amphiphilic microenvironments is important to various biological processes, but has been lacking in *quantitative* kinetic data. In this communication we report some results from a kinetic study of the controlled thermally initiated autoxidation of linoleic acid and of methyl linoleate in sodium dodecyl sulfate (SDS) micelles. The results show *(1) that the kinetic rate law is compatible with that well established* (1) *for the autoxidation of organic substrates in homogeneous solution; namely*

$$-\frac{d[O_2]}{dt} = \frac{k_p[RH]R_i^{1/2}}{(2k_t)^{1/2}}$$

and (2) that there is a remarkable synergistic effect in the antioxidant activity of ∝-tocopherol (∝-T) and ascorbic acid (C) when both inhibitors are present.

The apparatus and techniques employed were similar to those described (2). The mole ratio of thermal initiator, di-*tert*-butyl hyponitrite (DBHN), to SDS was varied from 0.001 to 0.01 while that of substrate to SDS ranged from 0.01 to 0.1.[2] Molar concentrations were calculated by assuming a molar volume of reaction of 0.25 liters per mole of SDS, which is the molar volume of SDS obtained from density measurements (3). The rate of chain initiation, $R_i = 2[ArOH]/\tau$ was measured by the ∝-T induction period method assuming a stoichiometric factor of 2 (4). The initiator efficiency (cage effect), $e = R_i/2k_i[DBHN]$, was calculated using $k_i = 3.2 \times 10^{-6}\ s^{-1}$ for the DBHN decomposition rate constant (2).

The experimental substrate orders obtained in 0.50 *M* SDS at 30°C are 1.02 ± 0.01 for linoleic acid in phosphate buffer (pH = 7.0) and 0.1 m*M* EDTA, and 1.34 ± 0.02 for methyl linoleate[3]. The corresponding DBHN orders are 0.53 ± 0.03 and 0.61 ± 0.05. The efficiency of DBHN in linoleic acid autoxidations was found to be 0.30 ± 0.03, independent of acid concentration, while in runs on the ester it increased measurably from 0.30 to 0.36 as the concentration of ester was increased.

These micellar autoxidations exhibited several interesting characteristics. *(1)* The initiator (DBHN) efficiency drops from 66% observed (2) in homogeneous solution to 30%. This is expected of a free radical reaction initiated in a micellar microenvironment where the higher microviscosity (5) would cause a greater extent of cage recombination (6). *(2)* The autoxidation of linoleic acid follows the classical rate law, being first order in substrate and half order in DBHN concentrations. The substrate oxidizability, $k_p/(2k_t)^{1/2} = 4.09 \pm 0.29 \times 10^{-2}\ M^{-1/2}$

[1]Author to whom correspondence should be addressed.

[2]Typically experiments were performed by adding substrate to 2 mL of 0.50 *M* SDS containing DBHN and the rate measured by a recording gas absorption apparatus (2) followed by induction periods (30 to 120 min) obtained by adding 10^{-7} to 10^{-8} mol of ∝-tocopherol in the form of a 0.50 *M* SDS solubilized ∝-T stock solution.

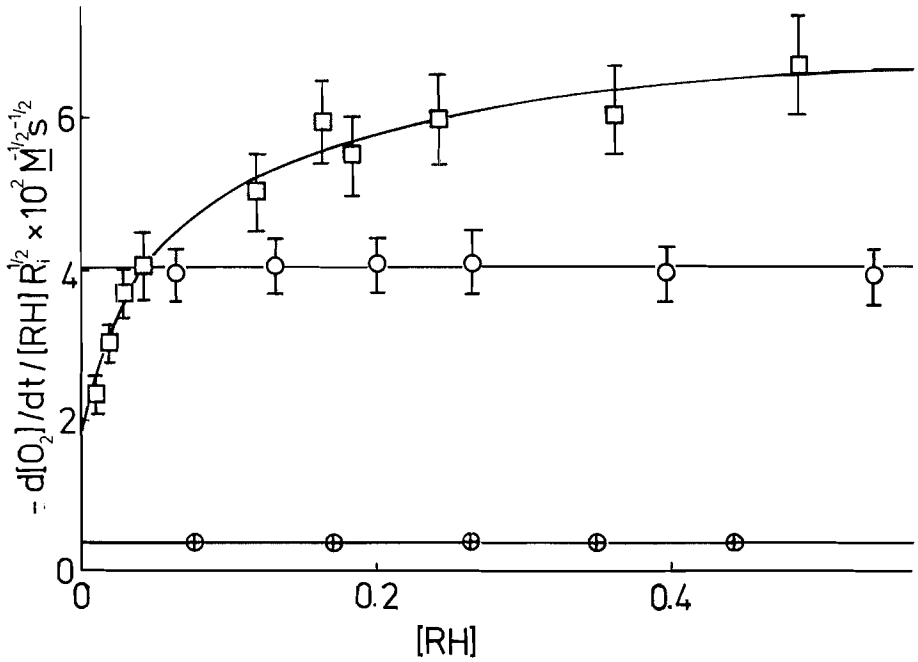

FIG. 1. Variation of the oxidizability of linoleic acid (○), pH 7.0; methyl linoleate, □; and tetralin ⊕; in 0.50 *M* SDS at 30°C. [RH] is the concentration, M L^{-1}, in the micellar phase.

$s^{-1/2}$, is constant over the concentration range used. Methyl linoleate autoxidations exhibit somewhat higher orders,[3] slightly variable *e*, and oxidizabilities which increase from 2.37×10^{-2} to 6.92×10^{-2} $M^{-1/2}$ $s^{-1/2}$ with increasing concentration (see Fig. 1).[4] We suggest that these substrates are incorporated differently in the micellar structure; the linoleate anion with its negatively charged head group is homogeneously dispersed, whereas a more complicated solubilization of the non-ionic ester, involving "pooling" at higher concentration, would decrease the volume of reaction and cause partitioning of the initiator.[4] The agreement between the limiting ester oxidizability at low concentration with the literature value of 2.1×10^{-2} $M^{-1/2}$ $s^{-1/2}$ (7) supports this viewpoint. The results contrast with trends in the oxidizability of a phosphatidylcholine which showed a marked *decrease* when dispersed in a bilayer compared to values in homogeneous solution (2). *(3)* The chain lengths exceed the number of substrate molecules per micelle, a value of 65 resulting for an average of 2.5 methyl linoleate molecules per micelle, based on a micelle aggregation number of 54 (8). This is attributed to a relatively long lifetime of *polar* (2, 9) peroxyl radicals compared to the very rapid monomer−micelle equilibrium (10), so that a peroxyl radical can propagate a chain reaction in several micelles. Thus, the chain reaction is *not* restricted by a particle size boundary that reflects the diffusing peroxyls back toward a cage encounter (11).

Finally we report a remarkable synergistic effect exerted by ascorbic acid (C), when injected into the aqueous phase, on the ∝-T-inhibited reaction in the micellar phase. ∝-T is an efficient inhibitor of micellar autoxidation when it is solubilized in SDS micelles before being injected into the reaction (Fig. 2 (C)). This is expected from the known antioxidant activity of ∝-T and the dynamic nature of micellar systems (*vide infra*). In contrast, C is a very poor inhibitor (Fig. 2 (B)). The combination of C (hydrophilic) with ∝-T (hydrophobic) results in a *very substantial extension of the efficient inhibition period observed when ∝-T is used alone* (compare Figs. 2 (D) and 2 (C)). A stoichiometric value for C as large as 0.50, relative to a value of 2 for ∝-T, was obtained at pH 4.5 and a mole ratio of C/∝-T = 4.6. The hplc analyses of samples taken from reactions inhibited with both C and ∝-T reveal that the concentration of the latter remains essentially constant throughout most of the inhibition period. Thus it appears that C in the aqueous phase serves to regenerate ∝-T in the micellar phase. Tentatively we propose the following general mechanism to account for this synergism.

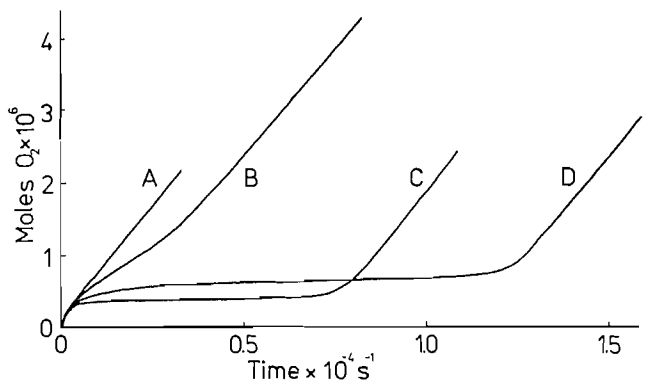

FIG. 2. Autoxiation of linoleic acid (6.4×10^{-5} mol) in 0.50 *M* SDS (2.0 mL) at pH 7.0 initiated with DBHN (7.2×10^{-6} mol): A, uninhibited reaction; B, inhibited with ascorbic acid (1.95×10^{-7} mol); C, inhibited with ∝-tocopherol (5.14×10^{-8} mol); D, inhibited with ∝-tocopherol (5.14×10^{-8} mol) and ascorbic acid (1.95×10^{-7} mol).

[3]The somewhat anomalous behaviour of methyl linoleate in this regard will be dealt with in a more complete kinetic analysis.

[4]Preliminary results shown for tetralin indicate it exhibits a constant oxidizability ($3.7 \pm 0.6 \times 10^{-3}$ $M^{-1/2}$ $s^{-1/2}$). We have no independent evidence on the *exact* location of the initiator; the lower efficiency and the approximate order, $[DBHN]^{1/2}$, indicate it is in the micellar phase.

∝-T is known to rapidly transfer H-atoms to peroxyl radicals in homogeneous solution where $k_{-H\cdot} = 2.35 \times 10^6\ M^{-1}\ s^{-1}$ (4) and the effective antioxidant activity of ∝-T observed herein indicates this is also rapid in the micellar phase. Now if the polar phenolic head group, ArOH, of ∝-T is positioned in the micelle near the aqueous phase, the derived radical, ArO·, could readily regenerate ∝-T by hydrogen atom transfer from ascorbate, $\bar{A}H$, positioned in the aqueous phase. This proposal is in agreement with the known rapid hydrogen atom transfer between ∝-T radical and C ($k = 1.55 \times 10^6\ M^{-1}\ s^{-1}$) (12) and with recent esr studies of the interaction of ∝-T radicals with C and glutathione (13). The above mechanism could lead to a higher stoichiometric factor for ascorbate (a maximum of 1 compared to our observed 0.50). However, the chemistry of ascorbic acid, ascorbate ion, and derived radical ($\dot{\bar{A}}$) is known to be rather complex (14) and other radical reactions could deplete ascorbic acid.

These results provide the first definitive evidence for the synergistic effect of vitamins C and E as inhibitors in controlled autoxidations in a microenvironment. We plan to extend this study to bilayers with the expectation of clarifying the important role of natural inhibitors in autoxidations of biological membranes.

Page 625. Due to a computational error, the ΔG_t^0(*p*NA) values for urea–water mixtures reported in Table 1 are wrong. The correct values are −1.37, −2.50, −3.49, and −4.26 kJ mol^{-1} for increasing urea concentration. As a result, the corresponding profile for urea in Fig. 1 should be increasingly negative instead of increasingly positive, as shown.

Consequently, the earlier contention that the increased destabilization of *p*NA is governed by the salting-out type interactions by the predominant zwitterionic forms of urea is not valid. Instead, the increased stabilization of *p*NA, as the corrections indicate, is chiefly governed by possible "acid–base" type interactions through $=NH_2^+$ and $—NO_2^-$ charge centres of *p*NA with zwitterionic forms of urea.

Effect of interface mass transfer on the liquid-phase oxidation of acetaldehyde

TSE-CHUAN CHOU[1] AND FWU-SHING LIN
Department of Chemical Engineering, National Chenu Kung University, Taiwan

Received May 18, 1982

TSE-CHUAN CHOU and FWU-SHING LIN. Can. J. Chem. **61**, 1295 (1983).

Partial oxidation of acetaldehyde by oxygen in the liquid phase was studied in the temperature range from −10°C to 34°C, oxygen flow rate from 90 to 100 mL/min, concentration of acetaldehyde from 3.0 to 34.0 volume percent, and at different partial pressures of oxygen. Cobalt acetate was used as catalyst. It was found that the reaction rate was governed by two types of rate equations depending on the operating conditions as well as the loading of catalyst.

In the region of higher oxygen mass transfer, the rate

[1] $r = K_1 (Co^{+++})^{0.5} (CH_3CHO)^{1.5}$

where $K_1 = 6.9 \times 10^{-3}$ L mol^{-1} s^{-1} at the temperature −10°C.

In other conditions,

[2] $r = k_2 P_{O_2}$

where $k_2 = 5.7 \times 10^{-4}$ mol L^{-1} atm^{-1} s^{-1}, and is a pseudo rate constant which depends on the dispersion of oxygen in the reactor. The experimental results appeared to support a theoretical analysis. The key reaction steps of the reaction mechanisms were also identified.

TSE-CHUAN CHOU et FWU-SHING LIN. Can. J. Chem. **61**, 1295 (1983).

On a étudié l'oxydation partielle de l'acétaldéhyde par l'oxygène en phase liquide dans l'intervalle de température allant de −10°C à 34°C, avec un débit d'oxygène de 90 à 100 mL/min, pour une concentration d'aldehyde allant de 3,0 à 34 pour cent en volume et à différentes pressions partielles d'oxygène. On a utilisé l'acétate de cobalt comme catalyseur. On a trouvé que la vitesse de réaction dépend de deux types d'équations de vitesse selon les conditions opératoires et la charge du catalyseur.

Dans la région de plus forte vitesse de transfert de masse d'oxygène

[1] $r = K_1 (Co^{+++})^{0.5} (CH_3CHO)^{1.5}$

où $K_1 = 6{,}9 \times 10^{-3}$ L mol^{-1} s^{-1} à −10°C.

Dans d'autres conditions,

[2] $r = k_2 P_{O_2}$

où $k_2 = 5{,}7 \times 10^{-4}$ mol L^{-1} atm^{-1} s^{-1}. k_2 est une constante de pseudo vitesse qui dépend de la dispersion d'oxygène dans le réacteur. Les résultats expérimentaux semblent confirmer l'analyse théorique. On a également identifié les étapes déterminantes des mécanismes de la réaction.

[Traduit par le journal]

Introduction

Peracetic acid (PAA), a very powerful organic oxidation reagent, can be prepared by many methods (1–4). However, only a few have been commercialized. One of them is the catalytic liquid-phase oxidation of acetaldehyde (2, 4).

Although catalytic liquid-phase oxidation of acetaldehyde has been investigated by several investigators (1–11), the kinetics of the oxidations, as well as the factors which affect the yield of PAA, are not adequately illustrated and past investigators proposed two different reaction mechanisms. Thus, Bawn and Williamson (12) and others (2, 13) found that the primary product of liquid-phase oxidation of acetaldehyde was peracetic acid. The secondary reaction was the reaction of peracetic acid with acetaldehyde to form another peroxide, acetaldehyde monoperoxyacetate (AMP), which was then decomposed into acetic acid or acetic acid anhydride. However, several authors (4) proposed that the primary reaction product was AMP which decomposed in acid solution to form peracetic acid and acetaldehyde.

Starcher *et al.* (14) determined the structure of AMP by ir spectroscopy. Furthermore, they indicated that both PAA and AMP in the products were peroxides. Various analytical results of these two peroxides in solution were presented by different investigators (8, 12, 14).

Backstrom and Beatty (15) first determined that the liquid-phase catalytic oxidation of acetaldehyde was a free-radical chain reaction. However, Imamura *et al.* (5) found that the secondary reaction of PAA with acetaldehyde was a series of ionic reactions. In general, ozone, ultraviolet, and metal catalysts are used as the initiator of free radical reactions (2, 8). Cobalt and iron are the most powerful metal catalysts for preparing PAA from the oxidation of acetaldehyde. By using cobalt as catalyst, Bawn and Williamson (12) found that the rate of formation of PAA was of a first order reaction with respect both to the concentration of catalyst and the concentration of acetaldehyde. They also found that the concentration or partial pressure of oxygen did not affect the reaction rate of formation of peracetic acid. On the other hand, several investigators found that the rate of reaction was 0.5 order with respect to the concentration of catalyst, 1.5 order with respect to the concentration of acetaldehyde, and zero order with respect to partial pressure of oxygen. However, Sadana (16) found that the catalyzed free-radical liquid-phase oxidation of hydrocarbons and/or oxygenated compounds might be dependent on the concentration of oxygen. Ramage and Eckert (17) indicated that mass transfer of gas-phase reactants affected

both the selectivity and the reaction rate of liquid-phase free-radical reactions. Unfortunately, there are few investigations concerning the effects of mass transfer of oxygen on the rate of acetaldehyde oxidation in the liquid phase.

In this research work, the kinetics of liquid-phase oxidation of acetaldehyde by cobalt catalyst were systematically studied. The effect of the mass transfer rate of oxygen on the rate of oxidation of acetaldehyde was explored.

Theoretical analysis

Several investigators (2, 4, 8, 11) proposed that the role of metallic catalyst is to initiate the free radical chain reactions as follows.

Initiation:

[3] $Co^{3+} + CH_3CHO \xrightarrow{k_1} CH_3\dot{C}O + H^+ + Co^{2+}$

The oxygen of the gas phase is dissolved and is absorbed in the liquid phase before it reacts with the free radicals. The process of oxygen absorption is proposed as:

O_2 absorption:

[4] $O_{2(gas)} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} O_{2(abs.)}$

The absorbed oxygen reacts with the free radicals. The chain reactions are given as follows.

Propagation:

[5] $CH_3\dot{C}O + O_{2(abs.)} \xrightarrow{k_3} CH_3CO_3^{\cdot}$

[6] $CH_3CO_3^{\cdot} + CH_3CHO \xrightarrow{k_4} CH_3CO_3H + CH_3\dot{C}O$

Formation of AMP:

[7] $CH_3CO_3H + CH_3CHO \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} AMP$

Imamura *et al.* (5) proposed and discussed step [7] in detail. Their results indicated that the formation of AMP was due to ionic reactions which are expressed as:

[8] $CH_3CO_3H \rightleftharpoons CH_3CO_3^- + H^+$

[9] $CH_3CHO + H^+ \rightleftharpoons CH_3C^+H_2O$

[10] $CH_3CO_3^- + CH_3C^+H_2O \rightarrow AMP$

Bawn and Williamson (12) and Philips *et al.* (10, 14) studied the decomposition of AMP.

[11] $AMP \rightarrow 2CH_3CO_2H$ or $(CH_3CO)_2O + H_2O$

The by-products, AMP, acetic acid, and acetic anhydride, are produced in reaction steps [7] and [11].

There are at least two main types of free radicals in the liquid phase. Thus the termination steps are expressed in [12] to [14] (18).

Termination:

[12] $2CH_3\dot{C}O \xrightarrow{k_7} (CH_3CO)_2$

[13] $CH_3\dot{C}O + CH_3CO_3^{\cdot} \xrightarrow{k_8} (CH_3CO_2)_2$

[14] $2CH_3CO_3^{\cdot} \xrightarrow{k_9}$ terminated products

In addition to steps [12] to [14], Chou and Albright (19) indicated that the termination might occur by the collision of the free radicals with a third body. Matsuzaki and Imamura (8) showed that the wall of the reactor also affected the oxidation reactions.

The regeneration of catalyst automatically occurs in the system and is expressed as

[15] $CH_3CO_3H + Co^{2+} \xrightarrow{k_{10}} CH_3CO_2^{\cdot} + OH^- + Co^{3+}$

Theoretically, free-radical reactions may include many intermediate reaction steps, which give rise to a complicated model for the reaction mechanisms. However, Chou *et al.*.(19, 20) pointed out that a simplified model could adequately express the reaction phenomena of the system by considering only the main reaction steps. The reaction model for the partial oxidation of acetaldehyde to form PAA described by the above equations could be simplified as follows.

Case i

If $(CH_3CO_3^{\cdot}) \gg (CH_3\dot{C}O)$, i.e. at high partial pressures of oxygen, the termination product concentrations can be approximately expressed by step [14]. The changes in free-radical concentrations are expressed as

$$[16]\quad \frac{d(CH_3\dot{C}O)}{dt} = k_1(Co^{3+})(CH_3CHO) - k_3(CH_3\dot{C}O)(O_{2(abs.)}) + k_4(CH_3CO_3^{\cdot})(CH_3CHO)$$

$$[17]\quad \frac{d(CH_3CO_3^{\cdot})}{dt} = k_3(CH_3\dot{C}O)(O_{2(abs.)}) - k_4(CH_3CHO)(CH_3CO_3^{\cdot}) - 2k_9(CH_3CO_3^{\cdot})^2$$

Assuming pseudo steady state conditions, we obtain from [16] and [17]

$$[18]\quad (CH_3CO_3^{\cdot}) = \left(\frac{k_1}{2k_9}\right)^{1/2}(Co^{3+})^{1/2}(CH_3CHO)^{1/2}$$

The rate of reaction is expressed as

$$[19]\quad r = \frac{d(O_{abs.})}{dt} = 2\frac{d(O_{2(abs.)})}{dt} = 2k_3(CH_3\dot{C}O)(O_{2(abs.)}) = 2k_4(CH_3CHO)(CH_3CO_3^{\cdot}) + 4k_9(CH_3CO_3^{\cdot})^2$$

Since $(CH_3CO_3^{\cdot})^2 \ll (CH_3CHO)(CH_3CO_3^{\cdot})$

$$[20]\quad r = 2k_4(CH_3CHO)(CH_3CO_3^{\cdot}) = \left(\frac{2k_1k_4^2}{k_9}\right)^{1/2}(Co^{3+})^{1/2}(CH_3CHO)^{3/2}$$

The above rate equation [20] indicates that the reaction rate is independent of the partial pressure of oxygen. The rate of mass transfer of oxygen is faster than the rate of chemical reaction.

Case ii

If $(CH_3\dot{C}O) \gg (CH_3CO_3^{\cdot})$, i.e. at moderately low partial pressures of oxygen or if the formation of $CH_3CO_3^{\cdot}$ free radical is slow, the termination can be approximately expressed by reaction step [12]. The changes of free radical concentrations are then expressed as

$$[21]\quad \frac{d(CH_3\dot{C}O)}{dt} = k_1(CH_3CHO)(Co^{3+}) - k_3(CH_3\dot{C}O)(O_{2(abs.)}) + k_4(CH_3CO_3^{\cdot})(CH_3CHO) - 2k_7(CH_3\dot{C}O)^2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

$$[22]\quad \frac{d(CH_3CO_3^{\cdot})}{dt} = k_3(CH_3\dot{C}O)\,(O_{2(abs.)}) - k_4(CH_3CO_3^{\cdot})\,(CH_3CHO)$$

At pseudo steady state, from eqs. [21] and [22], we obtain

$$[23]\quad (CH_3\dot{C}O) = \left(\frac{k_1}{2k_7}\right)^{1/2}(CH_3CHO)^{1/2}\,(Co^{3+})^{1/2}$$

By Henry's law:

$$[24]\quad (O_{2(abs.)}) = k_2 P_{O_2}$$

where $k_2 = \kappa_2 k_{-2}$ and κ_2 is the equilibrium constant of oxygen, and P_{O_2} is the partial pressure of oxygen.

If eq. [5] is assumed to be the controlling step, then the rate of reaction can be expressed as

$$[25]\quad r = 2k_3(CH_3\dot{C}O)\,(O_{2(abs.)}) = \left(\frac{2k_1k_3^2k_2^2}{k_7}\right)^{1/2}(CH_3CHO)^{1/2}\,(Co^{3+})^{1/2}\,P_{O_2}$$

Case iii

If the rate of mass transfer of oxygen is less than that of the chemical reactions, the rate of reaction can be expressed as

$$[26]\quad r = k_2 P_{O_2}$$

Experimental

The reactor consisted of a Pyrex glass tube, 34 cm in length and 3.0 cm in outside diameter. At the bottom of the tube was a porous gas disperser which contained 100/160 mesh sintered glass powder. A condenser was installed above the reactor and its temperature was maintained at about −10°C by a cooling system. Oxygen entered from the bottom of the reactor and was bubbled through the solution in the reactor. The oxygen flow rate was measured by a flowmeter with a precision of ±0.2%. The temperature of the reactor was controlled within ±0.1°C by placing the entire reactor system in a constant temperature bath.

The chemicals used were of reagent grade. The catalyst solutions were prepared by dissolving cobalt acetate in distilled water. The desired concentrations of acetaldehyde solution were obtained by mixing acetaldehyde with solvent. After the acetaldehyde solution was introduced into the reactor, the catalyst solution was added to the reactor using a syringe. Then the cooling system of the condenser was started and the flow rate of oxygen was adjusted to the desired levels. Samples were taken periodically from the reactor and analyzed using iodometry titration and gas chromatography.

The concentrations of the organic peroxides were analyzed by iodometric methods. Both peroxides, PAA and AMP, in the products were oxidation reagents of iodide ions. The titration reactions were expressed as follows.

$$[27]\quad \text{PAA: } CH_3CO_3H + 2H^+ + 2I^- \rightarrow CH_3CO_2H + H_2O + I_2$$

$$[28]\quad \text{AMP: } C_4H_8O_4 + 2H^+ + 2I^- \rightarrow CH_3CO_2H + CH_3CHO + H_2O + I_2$$

$$[29]\quad I_2 + 2S_2O_3^{2-} \rightarrow 2I^- + S_4O_6^{2-}$$

The ability of PAA and AMP to oxidize iodide ion depended on the operating conditions which included pH value, temperature, and types of solutions, etc. The concentrations of PAA and AMP could be obtained by analysis of the total peroxides (TPO, i.e. the sum of PAA and AMP) and PAA in the solution by choosing different operating conditions. The ability of PAA to oxidize iodide ion did not depend on temperature; however, the ability of AMP to oxidize iodide ion was noted to be a function of temperature (21). AMP could not be reduced by iodide ion at temperatures below −2.0°C and could be completely reduced by iodide ion at temperatures above 30°C. Accordingly, the concentrations of PAA and TPO could be obtained by idometric analysis of the samples operating at the temperatures −2.0°C and 30.0°C, respectively. The concentration of AMP was the difference between TPO and PAA.

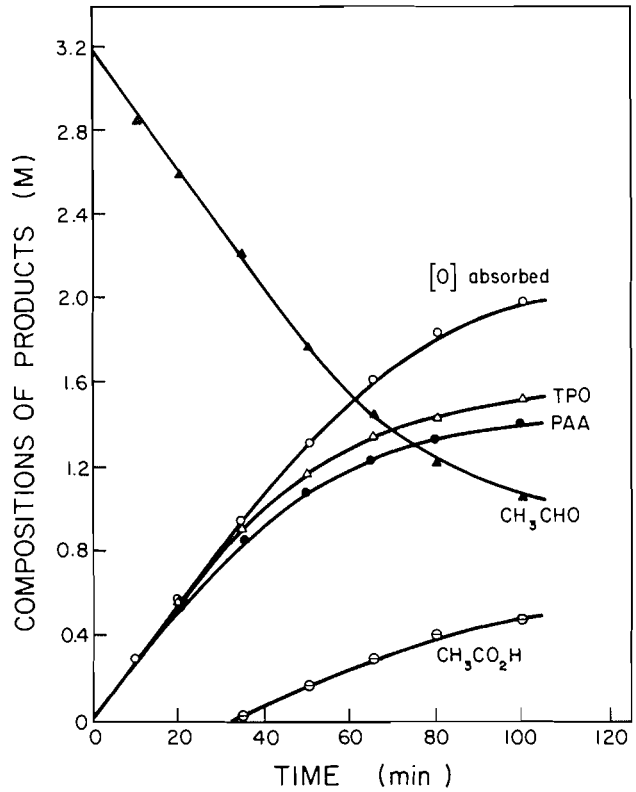

FIG. 1. The compositions of products vs. time. $[Co^{3+}] = 4 \times 10^{-4}$ M; O_2 flow rate = 100 mL/min; solvent = CH_3COCH_3; temperature = −10°C.

TABLE 1. Effect of catalyst loading on the formation of total peroxides*

12.0	0.33	0.64	0.85	1.02

* Experimental conditions: concentration of CH_3CHO, 2.65 M; oxygen flow rate, 100 mL/min; solvent, CH_3COCH_3; temperature, −10°C.

Unreacted acetaldehyde was analyzed by gas chromatography. However, acetaldehyde could be generated by the decomposition of AMP. Thus, the actual unreacted acetaldehyde was given by the difference of acetaldehyde obtained by gas chromatography and the concentration of AMP. Errors were avoided by allowing time for the complete decomposition of AMP, subsequent to TPO analysis.

The amount of oxygen reacted was equal to the amounts of TPO and acetic acid which was calculated by

$$[30]\quad [CH_3CO_2H] = [CH_3CHO]_0 - [CH_3CHO] - 2[TPO] + [PAA]$$

where $[CH_3CHO]_0$ was the initial concentration of acetaldehyde and $[CH_3CHO]$ was the concentration of the unreacted acetaldehyde.

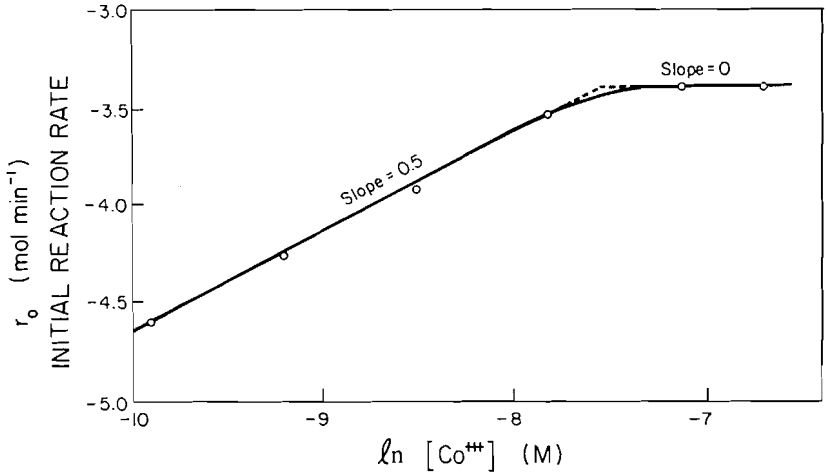

FIG. 2. Effect of the loading of catalyst on the initial reaction rate. [CH_3CHO] = 2.65 M; O_2 flow rate = 100 mL/min; solvent = CH_3COCH_3; temperature = −10°C.

* Experimental conditions: catalyst loading, 4×10^{-4} M; oxygen flow rate, 100 mL/min; solvent, CH_3COCH_3; temperature, −10°C.

Results

The compositions of products for a typical run are shown in Fig. 1. The by-product acetic acid as well as AMP was generated during an interval of 0.5 hour. As shown in the figure, the intial peroxide product was PAA only. The amounts of TPO or PAA were equal to the amounts of oxygen absorbed at the initial stage. The difference of TPO and PAA was AMP; AMP increased slightly with conversion.

The effects of catalyst loading on the initial reaction rate are shown in Table 1 and Fig. 2. The reaction rate increased with the concentration of catalyst. But the effects of catalyst loading became insignificant when the concentration of catalyst exceeded a limiting value. At the operating conditions of 2.65 M acetaldehyde, oxygen flow rate of 100.0 mL/min, temperature of −10.0°C, and acetone as the solvent, the limiting value of catalyst loading was found to be 8.0×10^{-4} mole per liter. The reaction order was shown to be 0.5 ± 0.1 and 0, below and above the limiting value of catalyst loading, respectively.

Table 2 and Fig. 3 indicate the effect of acetaldehyde concentration on the initial rate of formation of PAA. The initial reaction order was 1.4 (±0.2) with respect to the concentration of acetaldehyde in a low concentration range (1.0 M and less). Further increases in the concentration of acetaldehyde above 1.0 M did not result in further increases of PAA, and the reaction became zero order with respect to acetaldehyde.

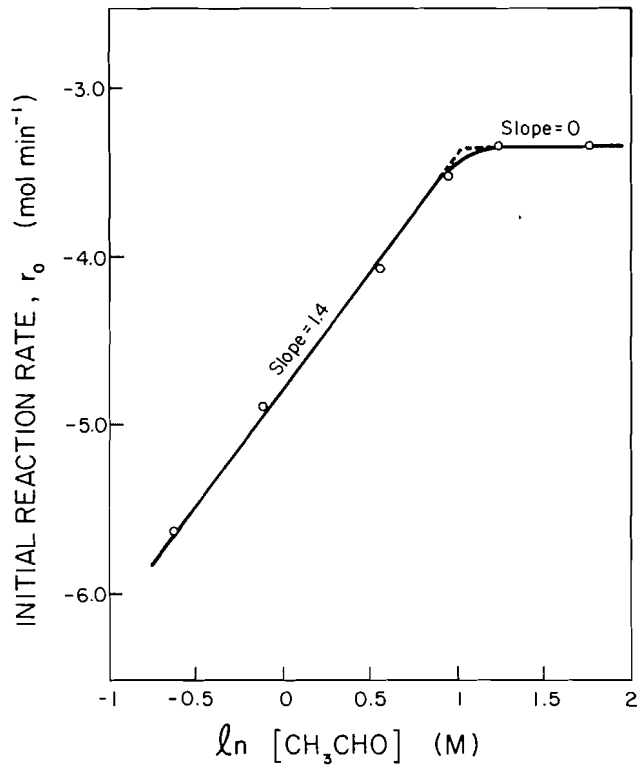

FIG. 3. Effect of the concentration of acetaldehyde on the initial reaction rate. [Co^{3+}] = 4×10^{-4} M; solvent = CH_3COCH_3; O_2 flow rate = 100 mL/min; temperature = −10°C.

At pseudo steady state, the reaction rate was equal to the rate of oxygen absorbed or reacted. At low catalyst loadings and low concentrations of acetaldehyde, the reaction rate was independent of the partial pressure of oxygen, as shown in Table 3(b) and curve I of Fig. 4. It was found that even at rather low partial pressures, the dissolved oxygen was sufficient for the oxidation reaction. The rate-determining step was reaction controlled in this case. At high catalyst loadings and high concentrations of acetaldehyde, the rate-determining step was mass-transfer controlled. In this case, the rate of reaction was a function of the partial pressure of oxygen only. However, the rate of reaction became independent of the partial pressure of oxygen at rather high partial pressures of oxygen (greater than

0.75 atm) and at fixed catalyst loadings and concentration of acetaldehyde, as shown in Table 3(a) and curve II of Fig. 4. The rate of reaction was reaction controlled again, in this case.

Accordingly, the reaction rates for the formation of peracetic acid can be expressed in two forms. When the rate-determining step is reaction controlled, the rate equation can be written as

$$r = K_1(Co^{3+})^{0.5}\,(CH_3CHO)^{1.4}$$

where K_1 was 6.9×10^{-3} L mol^{-1} s^{-1} at the temperature −10.0°C. On the other hand, when the rate-determining step was mass-transfer controlled, the rate equation can be written as

$$r = k_2 P_{O_2}$$

where k_2 is a pseudo rate constant and equal to 5.7×10^{-4} mol L^{-1} atm^{-1} s^{-1}.

Discussion and conclusion

The reaction orders of the oxidation of acetaldehyde in the liquid phase using Co catalyst depended on the reaction conditions. At higher oxygen transfer rates, the rate of reaction was dependent on the concentrations of catalyst and acetaldehyde. As shown in Table 4, the experimental results correlated well with case (*i*) of the theoretical analysis. Several investigators (4, 11) also obtained similar results, indicating that the reaction order with respect to Co catalyst was 0.5 and to acetaldehyde was 1.5. However, Bawn and Williamson (12) obtained different results which showed that the reaction order was 0.4 with respect to Co catalyst and was 1.0 to acetaldehyde.

When the oxygen transfer rate was low, the reaction rate was dependent on the partial pressure of oxygen only. As shown in Table 4, the experimental results correlated well with case (*iii*) of the theoretical analysis. In this operating range, the rate constant for mass transfer was a pseudo rate constant, depending on the dispersion of oxygen bubbles as well as the composition of the liquid phase. Ramage and Eckert (17) obtained similar results for the free-radical reactions in the liquid phase.

The theoretical analysis and the experimental results of this work both show that $CH_3CO_3^{\cdot}$ was the main free radical in the liquid phase. It was observed that the dissolved oxygen molecules combined with the free radical CH_3CO at a fast rate to

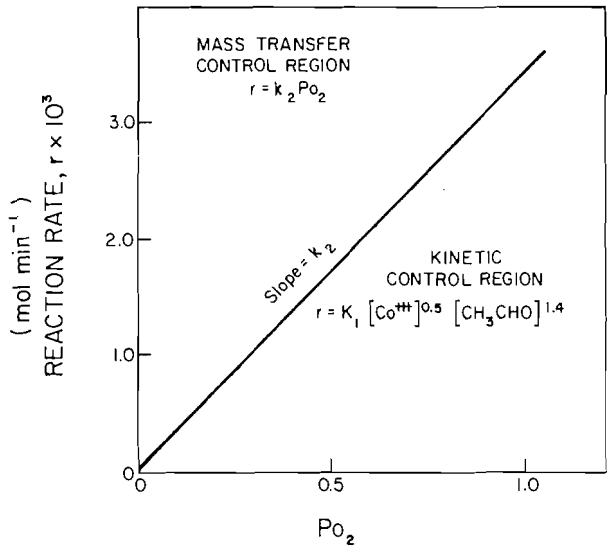

FIG. 5. The effect of the partial pressure of oxygen on the kinetics. Temperature = −10°C; solvent = CH_3COCH_3.

form the free radical $CH_3CO_3^{\cdot}$. Traylor and co-workers (18) found that several products, as well as several reaction steps, were included in the termination step involving $CH_3CO_3^{\cdot}$ free radicals.

As shown in Fig. 5, one criterion for choosing between the two rate equations might be the slope, which equals k_2 in eq. [2]. The region below the critical line represents high oxygen-transfer rates, i.e. the ratio of $(k_2P_{O_2})$ to $(K_1(Co^{3+})^{0.5}(CH_3CHO)^{1.4})$ is greater than one, and the reaction rate can be expressed by eq. [1]. The region above the same line represents low oxygen mass-transfer rates and the reaction rate can be expressed by eq. [2]. The pseudo rate constant k_2 was related to the dispersion of oxygen, the solvent used in the solution, and the flow pattern of the system.

Received July 26, 1982

E. ALLAN SYMONS, JOHN H. ROLSTON, LORRAINE A. BALDISERA, JOHN C. G. DROVER, and J. DOUGLAS BONNETT. Can. J. Chem. **61**, 1301 (1983).

Anion exchange resins like Rexyn 201(OH) and Amberlyst A-26 have been shown to be active catalysts for deuterium transfer between water and fluoroform. Under stirred slurry conditions at 50°C the Rexyn 201 is 25× more effective than NaOH on a per-hydroxide-ion basis. Addition of DMSO to the aqueous slurry produces an increase in Rexyn 201 reactivity, but the resin advantage over homogeneous ^-OH declines to zero by ~30 mol% DMSO. At 70 mol% DMSO the resin is *less* effective by a factor of ~100. Local fluoroform solubility and hydroxide ion solvation effects, including phase separation, in the pore liquid of the resin beads appear to be responsible for the observed behaviour.

E. ALLAN SYMONS, JOHN H. ROLSTON, LORRAINE A. BALDISERA, JOHN C. G. DROVER et J. DOUGLAS BONNETT. Can. J. Chem. **61**, 1301 (1983).

On a montré que les résines échangeuses d'anion du type Réxyne 201(OH) et Amberlyst A-26 sont des catalyseurs actifs pour le transfert de deutérium entre l'eau et le fluoroforme. Sous forme de pâte, agitée à 50°C, la Réxyne 201 est 25 fois plus efficace que la NaOH si on les compare sur la bases des ions hydroxydes présents. L'addition de DMSO à la pâte aqueuse provoque une augmentation de la réactivité de la Réxyne 201, mais l'avantage de la résine sur le OH^- homogène tend vers zéro lorsqu'on approche de 30 mol% de DMSO. A 70 mol% de DMSO, la résine est moins efficace par un facteur d'environ 100. La solubilité locale du fluoroforme et les effets de solvatation de l'ion hydroxyde, y compris une séparation de phase dans le liquide poreux des billes de résine, semblent être responsable du comportement observé.

[Traduit par le journal]

Introduction

Our interest in efficient catalysis of hydrogen isotope exchange between fluoroform and water was outlined previously (1). The use of dimethyl sulfoxide (DMSO) as co-solvent with water has been shown to enhance the relatively poor catalytic activity of the hydroxide ion (1) for this reaction by a factor of 10^6 (2). Such a base-catalyzed deuterium exchange step could be employed in the CF_3H redeuteration stage of a heavy water production process based on isotope-selective, infrared-laser-induced, multiphoton dissociation of CF_3D/CF_3H mixtures (3). However, on an industrial scale NaOH addition to and recovery from a large process water stream, although technically feasible, would add significantly to the overall cost of plant operation. Therefore, we have been looking for a more easily recoverable form of strongly basic catalyst.

Anion exchange resins have been used for many years as catalysts for various types of organic reactions (e.g. hydrolyses (ref. 4, Chapt. 3)), and as supports for organic reagent anions (ref. 4, Chapt. 2), but no reference has been found to their application as catalysts for hydrogen isotope exchange. In addition, although dipolar aprotic solvents like DMSO are known to increase ^-OH ion basicity in homogeneous aqueous solution (5, 6), the behaviour of *resin-bound* ^-OH ions in such mixed solvent systems has yet to be reported.

In this paper we present the results of a study of deuterium exchange between fluoroform and water catalyzed by several commercial anion exchange resins in the ^-OH form, in both water and aqueous DMSO mixtures. Some other types of heterogeneous catalyst were also tested. Unfortunately, carbon-supported metals like Pt, Pd, Ir, and Os, although quite effective for HD/H_2O exchange (7), were found to be completely inactive for CF_3D/H_2O exchange. Thus dissociation of fluoroform to give surface-adsorbed hydrogen atoms by analogy with HD/H_2O exchange (7) is an improbable route for exchange in such a weak hydrocarbon acid.

Experimental

Reagents

Deionized distilled water was used. DMSO (Fisher Certified) was distilled from 4A molecular sieves at reduced pressure, the central fraction then being stored over CaH_2. Water–DMSO solvent mixtures were prepared by weight. The resin Rexyn 201(OH) (Fisher Scientific) was used in the ^-OH form as received. The resins Amberlyst A-26 and A-27, and Amberlite 904 (BDH Chemicals) were obtained as the chlorides, and were exchanged in packed columns by treatment with NaOH solution and then water. The preparation of CF_3D from CF_3H (Matheson) has been described (2).

CF_3H gas solubility

Our general gas chromatographic method (1) was utilized, with the following modification. To prevent clogging of the syringe needle by fine resin particles in the slurries, the gas/liquid equilibration flask was equipped with an adjustable depth dip-tube assembly having a fritted disc.

Deuterium exchange runs

Essentially the same stirred gas/liquid reactor and kinetic procedure were used as before (1). The legs of the hollow stirrer shaft were changed from 1 mm capillary to 5 mm bore tubing, to prevent blockage of these gas dispersal legs by swollen resin beads. About 50–60 mL of resin slurry replaced the homogeneous catalyst solution. "Wet" resin was used to prepare the aqueous slurries, whereas vacuum-dried resin (to constant weight) was employed for the water–DMSO slurries. The Rexyn 201(OH) resin generally lost 50–51% by weight upon drying. Stirring rates up to 800 r/min were necessary to obtain rate constant data independent of stirring rate. Pseudo-first order kinetic plots were linear up to the three half-lives covered for the fastest runs, with correlation coefficients ranging from

28.9	Pure solvent	8.7	6.5	—
	Rexyn slurry[c]	8.4	6.8	−4, +5
58.1	Pure solvent	47.5	34.5	—
	Rexyn slurry[c]	45.5	36.2	−4, +5

[a]Ratio of ~15 g dry Rexyn 201(OH) resin/50 mL solvent.
[b]Moles of ^-OH in system comparable to resin slurry a.
[c]Ratio of 5 g dried resin/50 mL solvent.

0.997 to 0.9999. The experimental error for rate constants from multiple kinetic runs with the same catalyst charge was $<\pm 5\%$.

Confirmation that diffusion of CF_3D through the bulk liquid to the resin beads was not rate limiting was obtained as follows. A sample of 31 g wet (H_2O) Rexyn 201(OH) resin was suspended in a steel mesh bag in the vessel; no water, only CF_3D was added before the stirrer ws started. The "vapour" exchange rate constants measured at 47, 55, and 64°C (resin temperature by thermocouple) for the supported resin were comparable to those obtained for slurry conditions, after correction for the difference in vapour space volume.

Some of the resins, and also a sample of Ionac Chemical Company's MA-3475 anion resin membrane, were tested under countercurrent gas/liquid trickle flow conditions in a jacketed glass column of 5 cm id and 1.5 m overall height (including humidifier, catalyst, and dehumidifier sections). The resin beads were supported in fine mesh plastic or steel screen bags.

The wet (water) Rexyn resin is golden brown in colour, whereas the vacuum-dried beads are very dark brown. On contact with aqueous DMSO the dried beads remain almost black in colour, and are much more resistant to physical disintegration under the stirred slurry conditions than in pure water. The resin beads should swell in the mixed solvent, since it has been noted that the precursor resin, *p*-chloromethylstyrenedivinylbenzene co-polymer, swells readily in DMSO (8).

One batch of vacuum-dried Rexyn resin was tested for residual water, as follows. A calibration curve for water in aqueous DMSO was prepared using the H_2O peak intensity at 1942 nm in the near infrared spectrum (9) (Cary 17 spectrophotometer). A sample of the dried resin was contacted with CaH_2-dried DMSO, the slurry being gently stirred for 17 h at 21°C. The water content of the DMSO rose from 0.03 to 0.36 wt%, which corresponds to an additional ~1 wt% water in the original wet resin.

The possibility of a different solvent composition in the liquid and resin phases of a slurry was examined using the same near ir technique. Liquid samples after 22 and 88 h from a slurry of 8.9 g dried Rexyn resin in 89 g 50.94 mol% DMSO contained 51.70 and 51.90 mol% DMSO, respectively. This small *decrease* in water content of the bulk solvent reflects an in-resin solvent composition of ~43.5 mol% DMSO at equilibrium. Thus there is an "enrichment" of the water component of the solvent within the resin pores. A similar effect was reported for several types of ion exchange resin in acetone–water and dioxan–water systems (10).

Results

CF_3H gas solubility

CF_3H, only slightly soluble in water, is salted out of aqueous solution by NaOH (1). In contrast to the homogeneous distribution of ^-OH ions in NaOH solution, the ^-OH ions in a resin slurry are restricted to solvent at the surface of bead pores, so that the salting out effect in the bulk liquid for a comparable number of ions per unit volume of slurry should be reduced. As can be seen from the data in Table 1, this was found to be the case.

TABLE 2. Solvent dependence of k_{obs}(slurry) and E_a(slurry)

Mol% DMSO	k_{obs}[a] s^{-1}	E_a kJ mol^{-1}
0.0	7.4×10^{-5}	115
10.3	2.2×10^{-4}	101
30.1	1.3×10^{-3}	71
46.7	3.3×10^{-3}	63
68.2	$>8\times10^{-3}$	63

[a]For 5 g dried Rexyn 201(OH)/50 mL solvent at 49°C.

For the water–DMSO slurries a smaller ratio of resin weight to liquid volume was used (for reasons related to the kinetics of the deuterium exchange runs). As shown in Table 1, for both the 28.9 and 58.1 mol% DMSO slurry systems the CF_3H solubility is slightly lower at 25°C and slightly higher at 50°C, relative to the pure solvent mixtures. Overall, the effect of the resin on CF_3H solubility in the bulk water–DMSO solutions is slight. These small corrections were applied to the available solubility data for the pure solvent mixtures (2), to obtain the in-slurry solubilities (actually for the bulk liquid) required for calculation of in-slurry exchange rate constants (see below).

CF_3D/H_2O exchange runs

As in the case of homogeneous ^-OH catalysis of fluoroform–water exchange (1, 2), the experimental rate constants obtained are for change in CF_3D/CF_3H composition in the vapour space over the catalyst solution. The temperature- and solvent-dependent factor required for conversion of k_{obs}(vapour) to k_{obs}(slurry) is equal to the moles of fluoroform in the reaction vessel divided by the moles of gas dissolved in the bulk liquid, and ranged between about 30 and 2. In-slurry rate constants calculated on this basis do not contain a correction for any possible difference in CF_3D solubility between bulk liquid and pore liquid.

Most work was done with 5 g of dried Rexyn 201(OH) resin (average 1 mm beads) per 50 mL of solvent in the stirred reactor. In-slurry rate constant and Arrhenius activation energy data are recorded in Table 2 for the aqueous DMSO system.

For some parts of the study, the k_{obs}(vapour) data were compared directly. The dependence of k_{obs}(vapour) on weight of resin in the slurry was determined in 38 mol% DMSO. The rate

[e]Corrected to same vapour/slurry volume ratio as in stirred reactor.

constant was proportional to dried resin loading up to ~10 g per 50 mL of solvent at 49°C; above this level the slurry could not be stirred fast enough to obtain values independent of stirring rate.

Only slight increases in k_{obs}(vapour) were observed for exchange runs with 5 g of smaller diameter (sieved, ~0.5 mm) beads or crushed beads in tests done at 49°C in 38 mol% DMSO. The rate constant is therefore not significantly dependent on the surface area of these gel-type resin beads. In fact, the total $^-$OH available is the key parameter. The hydroxide ion "concentration" in each of the tested resin types was about 4 mmol g^{-1} dry resin, while the value for the membrane was somewhat lower at 0.7 mmol g^{-1}. Based on representative data given in Table 3, k_{obs}(vapour) *per mole of $^-$OH* is very similar, within experimental error (problem of resin contamination by contact with CO_2 in air) for the various resins studied in water, including gel and macroreticular types. Data are included in Table 3 for the exchange column tests; the order of magnitude lower reactivity noted for resins in the column compared to the vigorously stirred reactor most probably arises from less efficient gas/solvent/resin bead contact in the column.

In 50 mol% DMSO slurry at 49°C the catalytic activities of the Amberlite 904 resin (macroreticular type) and the Rexyn 201 resin were found to be comparable. Therefore, even in the mixed solvent there is no advantage in using the large pore size resins.

Discussion

Resin versus NaOH in water

It has been found that, on a per-hydroxide-ion basis, the Rexyn 201(OH) resin is more effective than NaOH in water for catalysis of CF_3D-H_2O exchange. The factor is ~100 at 49°C, based on the vapour phase rate constant data in the stirred reactor. The temperature dependence of this factor arises from the larger apparent Arrhenius activation energy for the NaOH case, ~115 vs. ~99 kJ mol^{-1} for the resin. The corresponding in-liquid factor is ~25 at 49°C, with E_a(liquid) values of 125 and 115 kJ mol^{-1} for NaOH and resin, respectively.

The greater reactivity of the resin compared to NaOH can arise from at least two effects, differential reactant concentrations and changes in the second order rate constants. In general, reaction rates observed for homogeneous systems tend to be higher than for the corresponding ion exchange resin catalysts (11). However, Frisch notes that adsorption of a reactant on the resin particles can sometimes lead to a reversal of the normal case, by raising the concentration of the reactant at the catalyst surface (11). In the present system, because fluoroform solubility in water is so low (ca. 2×10^{-4} mole fraction, see Table 1), any adsorption of CF_3D molecules in the resin beads would lead to an increased rate of deuterium exchange if mass transfer effects for gas transport through the solvent to and from the catalyst surface are not limiting.

The fluoroform concentration effect noted above can be expressed mathematically (12), according to the two-phase model of catalysis,[3] as the *distribution coefficient* for reactant R between the two phases, with $\lambda_R = \bar{m}_R/m_R$; $\bar{m}_R$ and m_R represent the molal concentrations of R in the resin and homogeneous phases, respectively. The term *efficiency*, q, is used to compare the observed catalytic activity of the resin and homogeneous systems. Here, q is the ratio of the rate for the anion resin-catalyzed reaction to the rate for the NaOH-catalyzed reaction with the same bulk concentration of hyroxide ion. Thus $q = (\bar{k}_{OH^-}/k_{OH^-})\lambda_{CF_3D}$ (12), where $\bar{k}_{OH^-}$ represents the second order rate constant for catalysis in the resin pores and k_{OH^-} the value for NaOH solution. In general, for reactions involving small substrate molecules and a first order dependence on the catalyst ion concentration, $\bar{k}$ and k should be similar to one another (12).[4] Therefore, in the case of base-catalyzed deuterium transfer between fluoroform and water it is probable that most of the observed enhancement for Rexyn 201(OH) resin over NaOH is due to an increased concentration of fluoroform near the active sites within the resin pores (i.e. $q \sim \lambda_{CF_3D}$).

An experimental test of this argument was carried out. A stirred Rexyn resin aqueous slurry was contacted with CF_3H gas of known volume and initial pressure at 25°C. When the pressure had dropped to a constant value, the moles of CF_3H transferred into the slurry were calculated. After correction for the moles of gas expected to be in the bulk water at the final pressure, the "concentration" of CF_3H in the resin pore water (50 wt% of the wet resin) was found to be a factor of about five higher than in the bulk water. Since most of this gas could not be contained in the pore water itself, the local CF_3H concentration in the resin structure near the catalyst sites must be

[3]These arguments were developed for *cation* exchange resin catalysis via H^+ (12), but should be equally valid for the anion resin case.

[4]It can be argued that because of a high local concentration of $^-$OH ions inside the pores some enhanced $^-$OH reactivity might be expected, which would result in $\bar{k} > k$ (see H_- basicity function data for concentrated alkaline solutions (13)). An analogous situation would exist for H^+ ions in cationic exchange resins (H_0 acidity function). However, in practice, ion exchange resins tend to be *less* effective for most reactions than the corresponding homogeneous catalysts (11). A possible explanation is that reactant molecule size is more important than currently believed (12); diffusion of larger molecules into the pores could be rate-limiting, whereas smaller molecules like fluoroform could diffuse in easily and take advantage if $\bar{k} > k$.

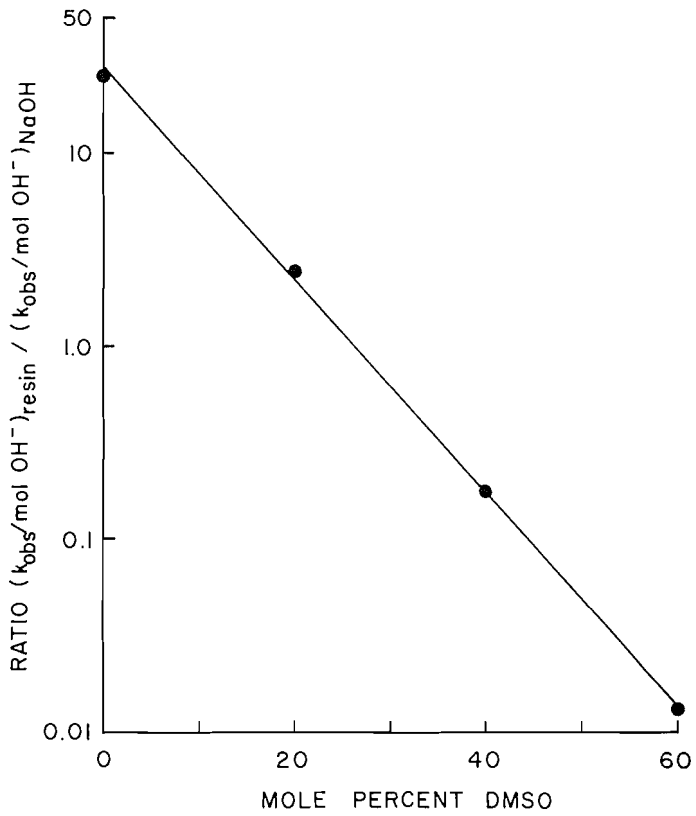

FIG. 2. Dependence of relative Rexyn 201(OH) resin ^-OH/NaOH catalytic reactivity for CF_3D/H_2O exchange on $DMSO/H_2O$ solvent composition at 49°C.

considerably higher. An observation consistent with this hypothesis is that CF_3H is ~50 times more soluble in toluene (1.06×10^{-2} mole fraction at 25°C) than in water; the similarity between the C_6H_5—CH_3 molecule and the backbone groups —C_6H_4—$CH_2\overset{+}{N}(CH_3)_4$ in the resin is clear.

Effect of DMSO addition

When DMSO is added as co-solvent, the observed in-slurry rate constant for CF_3D/H_2O exchange does increase, as shown in Fig. 1. The factor is ~100 between 0 and 70 mol% DMSO at 49°C, for 5 g dried Rexyn 201(OH) resin per 50 mL of solvent. Although this factor is significant, it falls well short of the value 10^6 measured for the homogeneous hydroxide ion case, with 0.011 mol L^{-1} ^-OH (2). As a result, the per ^-OH advantage noted above for resin over NaOH in water decreases as DMSO is added. This effect is clearly seen in Fig. 2; the resin advantage is lost by 30 mol% DMSO, and by 70 mol% DMSO the resin is *less* effective by >100×. Why?

If fluoroform adsorption in the resin particles *is* responsible for the rate enhancement over NaOH in water (see above), then the progressively greater solubility of the gas in the mixed solvent as DMSO is added (2) (Table 1) might be expected to lessen this effect. However, the ratio plotted in Fig. 2 should only gradually approach 1.0 as a result. That it falls to well below 1.0 suggests at least one other factor is also involved. It is known that for homogeneous hydroxide ion solution the addition of a dipolar aprotic solvent like DMSO to water causes reduced solvation of the ^-OH ions, and hence increased solution basicity, as measured by the H_- basicity function (5). This solvation effect is also reflected in the rapid decrease in NaOH solubility with increasing DMSO content (14). An important complication that occurs in the homogeneous system is phase separation over much of the solvent composition range (14), whereby a DMSO-poor/NaOH-rich phase forms below a DMSO-rich/NaOH-poor layer when the NaOH concentration is raised above a critical level.

The NaOH solubility (without phase separation) drops from ~29 mol L^{-1} in water to ~0.2 mol L^{-1} in 40 mol% DMSO and ~2×10^{-3} mol L^{-1} in 70 mol% DMSO (14). At 5 g dried Rexyn 201(OH) resin per 50 mL of solvent, the average ^-OH distribution in the slurry is ~0.4 mol L^{-1} and in the pore liquid itself ~4 mol L^{-1}. However, the ions are actually restricted to the even smaller liquid volume associated with the surface of the pores in the resin beads. The result will be a much higher *local* ^-OH concentration, which tends to favour a water-rich environment around the ions. If this leads to some "phase separation" at the catalyst surface in the pores, then enhanced basicity in the presence of aqueous DMSO solvent will be partially offset by a decrease in the amount of fluoroform dissolved in the region nearest the ions. The net effect would be that the calculated in-slurry rate constants would be proportionately low with increasing DMSO content, since the vapour/liquid conversion factor is based on CF_3H solubility in the bulk solvent.

It should be noted that the somewhat lower % DMSO in the resin pore liquid compared to the bulk mixed solvent (see Experimental section) will also cause a reduction in the observed in-slurry rate constant relative to the NaOH system; for example, the factor would be about four in 50 mol% DMSO at 50°C. This value is based on the reasonable assumption that the second order rate constant for ^-OH catalysis is essentially the same for the resin and NaOH solution environments. However, this factor of four is only part of the overall factor of ~20 lower reactivity for resin ^-OH versus NaOH in the 50 mol%

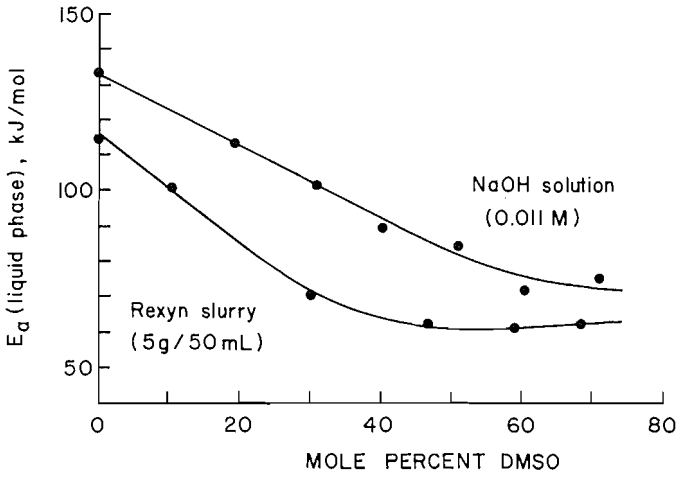

FIG. 3. Dependence of Arrhenius activation energy for Rexyn 201(OH) resin- and NaOH-catalyzed deuterium exchange between CF_3D and H_2O on DMSO/H_2O solvent composition.

DMSO case. The balance of the loss can be accounted for by the "phase separation" effect discussed above.

Mechanism of resin catalysis

By analogy with the homogeneous catalyst systems (1, 2), anion exchange resin catalysis of deuterium transfer between CF_3D and H_2O most likely involves attack by the hydroxide ion on the weak hydrocarbon acid CF_3D. However, this reaction can occur only in the solution inside the beads. Thus a better description for the resin would be a supported homogeneous, rather than hetergeneous, catalyst; homogeneous catalysis within the resin pore liquid is a common concept (12, 15).

The solvent dependence of the in-slurry Arrhenius activation energy is shown in Fig. 3; included are corresponding data for the NaOH system (2). For the slurries, k_{obs} was measured over 20–25°C within the overall range 25 to 72°C. Correlation coefficients for the Arrhenius plots were all >0.998. Although the resin and NaOH curves are similar, the resin E_a values are significantly lower. In each case E_a drops markedly as the % DMSO is raised, and then levels off by 50–60 mol% DMSO, as the $^-$OH ion becomes more reactive.

H. E. FERKUL, J. M. BERLIE, D. J. STANTON, J. D. MCCOWAN, and M. C. BAIRD. Can. J. Chem. **61**, 1306 (1983).

The catalysis of carbon monoxide hydrogenation by supported cobalt and ruthenium clusters is studied, and an unusually specific cobalt methanation catalyst is described. A variety of ruthenium carbonyl clusters catalyzes carbon monoxide methanation, irrespective of support, and $Ru_3(CO)_{12}$ on γ-alumina is found to be a potentially useful carbon dioxide methanation catalyst.

H. E. FERKUL, J. M. BERLIE, D. J. STANTON, J. D. MCCOWAN et M. C. BAIRD. Can. J. Chem. **61**, 1306 (1983).

On étudie la catalyse d'hydrogénation du monoxyde de carbone par des amas de cobalt et de ruthénium fixés sur un support et on décrit un catalyseur de méthanation à base de cobalt qui est exceptionnellement spécifique. Un certain nombre d'amas de ruthénium carboxyle catalyse la méthanation du monoxyde de carbone indépendamment du support, et on a trouvé que le $Ru_3(CO)_{12}$ fixé sur de l'alumine γ est en catalyseur de méthanation du bioxyde de carbone potentiellement utile.

The utilization of transition metals on various supports as catalysts for the hydrogenation of carbon monoxide to hydrocarbons (Fischer–Tropsch synthesis) has been well reviewed (refs. 1, 2; ref. 3, p. 29). Recently, influenced no doubt by the apparent similarities between metal carbonyl clusters and the metal particles of many heterogeneous catalysts (4–6), several attempts have been made to use cluster compounds as *homogeneous* Fischer–Tropsch catalysts, with mixed success (7). Rather more useful have been *heterogeneous* catalysts prepared by depositing metal carbonyl clusters on, for instance, oxide supports. By the late 1970's, it had been shown that cobalt (8) and rhodium (9) carbonyls can be used as very interesting precursors to a variety of Fischer–Tropsch catalysts, the product distributions from CO hydrogenation varying significantly as the supposedly inert supports were varied.

The potential for preparing novel catalysts by supporting metal carbonyl clusters on various materials seemed clear, and we have accordingly embarked on a program to investigate the use of cobalt and ruthenium carbonyl compounds in this way. The former has long been known as a versatile, low pressure catalyst (3), while the latter has been shown to be very active as a CO methanation catalyst (10) and to show interesting Fischer–Tropsch properties (11–13). We now report the results of our investigations to date; some of this work has been previously communicated (14).

Experimental

The compounds $Ru_3(CO)_{12}$ (15), $H_2Ru_4(CO)_{13}$ (16), $H_2FeRu_3(CO)_{13}$ (16), $[(Ph_3P)_2N][CoRu_3(CO)_{13}]$ (17), and $Co_4(CO)_{12}$ (18) were prepared as in the literature. The compounds $Fe(CO)_5$ and $Co_2(CO)_8$ were purchased from Strem Chemicals, as were γ-alumina (1/8 in. pellets), "large pore" silica gel (8 mesh granules), and Na–Y zeolite (1/16 in. pellets). The $RuCl_3.3H_2O$ was obtained from Johnson Matthey, Ltd.

The catalyst systems were prepared by dissolving a known amount of compound in ethyl ether ($[(Ph_3P)_2N][CoRu_3(CO)_{13}]$), *n*-pentane (other clusters), or acetone ($RuCl_3.3H_2O$). The solutions were mixed under nitrogen for several hours with a sample of the solid support (approximately 10 g) which had previously been dried at 400–500°C, the solvent was removed under reduced pressure, and the supported compounds (typically about 1–2% by weight of metal) were placed in a tubular glass reactor (length 18 cm, diameter 1 cm) under nitrogen. The catalysts were then activated by heating to 200°C in a stream of hydrogen (1 atm) for 2 h (cobalt) or 12 h (ruthenium).

Catalytic runs were carried out by passing synthesis gas mixtures through the catalysts at 1 atm. Typical reaction conditions involved H_2:CO ratios of 1.85 to 4.0, temperatures varying from 185–400°C, and space velocities of 300–600 h^{-1} for the cobalt, 1000–3750 h^{-1} for the ruthenium systems. Product water was collected by passing the reactor effluents through a water-cooled Liebig condenser; gaseous effluents were then collected and hydrocarbon distributions were determined using a Hewlett Packard 5880A gas chromatograph equipped with a 2 m column packed with Porapak Q and a flame ionization detector. Methane, H_2, CO, and CO_2 were determined using a Hewlett Packard F & M Scientific 700 gas chromatograph equipped with a 4 m Porapak Q column and a thermal conductivity detector. X-ray powder diffraction studies were carried out on Guinier-de Wolff Focussing Powder Diffraction Camera, SEM studies on a Hitachi H-450 Scanning Electron Microscope.

Results and discussion

Ruthenium catalysts

An extensive investigation of potential ruthenium catalysts was undertaken, involving two ruthenium clusters, $Ru_3(CO)_{12}$ and $H_2Ru_4(CO)_{13}$, and two mixed metal clusters, $H_2FeRu_3(CO)_{13}$ and $[(Ph_3P)_2N][CoRu_3(CO)_{13}]$, on three different supports, γ-alumina, silica gel, and Na–Y zeolite. Although quite significant differences in activity were found, the main product of CO hydrogenation was in all cases methane, formed as in reaction [1].

$$[1] \quad 3H_2 + CO \rightarrow CH_4 + H_2O$$

The oxygen-containing by-products included CO_2, however, suggesting that the water produced in reaction [1] could react further via the water gas shift reaction, [2].

$$[2] \quad H_2O + CO \rightarrow H_2 + CO_2$$

Representative data for the four clusters on the various supports are shown in Table 1. As can be seen, the best yields under these conditions were obtained using alumina as the support, but the differences between experiments were often not large. The mixed cobalt–ruthenium cluster on silica and zeolite exhibited anomalously low activities, for reasons which are not clear. It seems possible that the iminium cation decomposed during the "activation" procedure, coating the metal surface.

In an effort to better understand the effects of changing the

temperature and H_2:CO ratio, the $Ru_3(CO)_{12}/Al_2O_3$ system was studied in more detail. Representative data are shown in Table 2, and can be compared with similar data obtained under identical conditions for $RuCl_3.3H_2O$ on alumina, a recognized CO methanation catalyst (10).

Below 300°C, $Ru_3(CO)_{12}$ on alumina is not very active. As can be seen from Table 2, however, activities above 320°C are quite high, although increasing the temperature up to 400°C causes only small increases in activity. Interestingly, while the $RuCl_3.3H_2O/Al_2O_3$ system exhibited useful activity well below 300°C, there was little to choose between the two systems in the temperature range 350–400°C. In addition, while both lost activity over 8–10 h, the $Ru_3(CO)_{12}/Al_2O_3$ catalyst could be regenerated under a flow of hydrogen overnight at 300–400°C. The $RuCl_3.3H_2O/Al_2O_3$ system could not be regenerated as efficiently, and thus the catalyst life time was shorter in this case.

As mentioned above, the oxygen-containing by-products were water and CO_2; interestingly, the amounts of the latter decreased essentially to zero as the H_2:CO ratio increased to 4:1. These results suggested the possibility that the ruthenium was also behaving as a CO_2 methanation catalyst (reaction [3]),

[3] $4H_2 + CO_2 \rightarrow CH_4 + 2H_2O$

and the $Ru_3(CO)_{12}/Al_2O_3$ system was therefore investigated as a catalyst for CO_2 methanation, with typical results shown in Table 3. As can be seen, $Ru_3(CO)_{12}/Al_2O_3$ is an active CO_2 methanation catalyst at a much lower temperature than is the recognized high pressure methanation catalyst, $RuCl_3$ (11). It is to be anticipated that much higher yields of methane will be possible at higher pressures, a result which would be of great potential significance in view of current interest in the conversion of CO_2 to useful organic compounds (19).

While this work was in progress, several other groups reported the use of supported ruthenium carbonyl clusters as CO hydrogenation catalysts (20–24). In the work apparently most comparable to ours (19), it is claimed that $Ru_3(CO)_{12}$ on alumina is very active at 260°C for the hydrogenation of CO to olefins (C_2–C_6). While our system does produce small amounts of C_2–C_5 hydrocarbons below 200°C, as we have shown, methane is the sole product at higher temperatures. Indeed, we find, as have others (25), that $Ru_3(CO)_{12}$ on alumina is a very effective hydrogenolysis catalyst at 260°C, converting hexane smoothly to methane. The reasons for the different behaviour presumably involve subtle variations in the nature of the support surface. Under the conditions used here, the ruthenium exists almost certainly in the 0 oxidation state, but in aggregates of unknown size (25–27).

Cobalt catalysts

As indicated above, it is anticipated that adsorption of different clusters on different supports might give catalysts with different properties. Both $Co_2(CO)_8$ and $Co_4(CO)_{12}$ could be deposited from pentane solution onto silica and alumina, the materials so formed retaining the colouration of the carbonyls used and, presumably, their molecularity. Slow passage of hydrogen (or nitrogen) over the materials at 200°C then resulted in thermal decomposition to the metals via loss of CO. If the flow rate were too high at this point, a metallic mirror formed in the reactor tube, probably because of partial sublimation of $Co_2(CO)_8$ prior to decomposition.

On passing synthesis gas through alumina-supported systems under various conditions, a somewhat typical, for cobalt (refs. 1, 2; ref. 3, p. 29), distribution of saturated hydrocarbons was obtained. These results were similar to those reported previously (8), and work in this direction was discontinued.

Using $Co_2(CO)_8$ and $Co_4(CO)_{12}$ on the silica, however, quite different results were obtained. Using a H_2:CO ratio of 2:1 (space velocity = 482 h^{-1}), the catalyst systems were rather inactive below about 250°C and produced only small amounts of C_1–C_5 hydrocarbons. In the temperature range 300–450°C, however, the catalysts were both extremely active and selective, essentially all the CO reacting to form methane as the *sole* hydrocarbon. Interestingly carbon dioxide was also formed, in amounts equal to 60–80% of the amounts of methane, while water yields were < 5%. This behaviour, both with respect to the selectivity to methane and with respect to the formation of CO_2 as the oxygen-containing by-product, is unprecedented for cobalt-based CO hydrogenation catalysts (refs. 1, 2; ref. 3, p. 29).

It seems likely that the major reactions are as in [1] and [2], methanation of CO followed by the water gas shift reaction. Separate experiments which involved passage of water-saturated CO over fresh catalyst showed that the system does catalyze the water gas shift reaction, and the resulting increase in the concentration of H_2 may be a factor in selectivity to methane.

The unprecedented selectivity may, however, also be a result

[a]Production of CO was below the detectable limit. Water yields, based on CO_2 reacted, were about 90%.

of more subtle factors. For instance, hydrocarbon size limitation can result from shape selective catalysis if the pores in the support are sufficiently small (28), although this cannot be a factor here as the pores in the silica used are of the order of 100 Å or more in diameter.[2] A better explanation may centre around the metal particle size in the catalysts used, as there seems to exist a general relationship between particle size and molecular weight of Fischer-Tropsch products (29). We do not know the size(s) of the metal particles in the catalyst systems described here; X-ray diffraction and SEM studies on powdered samples of the catalyst were only consistent with the particles being <100 Å in diameter. However, the high selectivities to methane are certainly consistent with the formation of *small* crystallites on decomposition of the $Co_4(CO)_{12}$. The fact that the $Co_2(CO)_8$ on silica catalyst system also gives methane is not inconsistent with this hypothesis, as $Co_2(CO)_8$ is known to form $Co_4(CO)_{12}$ on mild heating (18). Furthermore, a very recent combined ir and temperature programmed decomposition study of $Co_2(CO)_8$ on silica and alumina, treated much as in this investigation, showed that $Co_2(CO)_8$ on SiO_2 formed adsorbed $Co_4(CO)_{12}$ on mild heating. This contrasted with $Co_2(CO)_8$ on γ-Al_2O_3, which seemed to form predominantly Co_2 moieties (30). While the extent of sintering at higher temperatures was not studied, it is clear that the nature of the metal species on the two supports can be quite different.

Another mode of formation of CO_2 is via the disproportion of CO (reaction [4]) (ref. 3, p. 1).

[4] $2CO \rightarrow C + CO_2$

While we have not assessed this process as a possible source of CO_2, it probably provides a route to catalyst deactivation; solid carbon was generally observed on used catalysts. Interestingly, overnight treatment of the catalyst systems with hydrogen at 400°C generally resulted in almost total renewal of catalyst activity, although no attempts have been made to ascertain the number of times a particular catalyst could be renewed. The cobalt system is unfortunately susceptible to sulphur poisoning, as the addition of 0.5% H_2S to the synthesis gas stream resulted in rapid (1 h) deactivation of the catalyst, presumably because of the formation of cobalt sulphide.

The regiospecific phase transfer catalyzed reductive carbonylation of azadienes

HOWARD ALPER[1] AND SHIYAMALIE AMARATUNGA

The Ottawa–Carleton Institute for Research and Graduate Studies in Chemistry, University of Ottawa Campus, Department of Chemistry, Ottawa, Ont., Canada K1N 9B4

Received July 30, 1982

HOWARD ALPER and SHIYAMALIE AMARATUNGA. Can. J. Chem. **61**, 1309 (1983).

Reaction of an azadiene with cobalt carbonyl, carbon monoxide, and methyl iodide under phase transfer catalysis conditions (benzene, water or aqueous NaOH, benzyltriethylammonium chloride) affords allylic amides in reasonable yields. This regiospecific reaction is sensitive to the concentration of base. One can also effect this transformation using acidic catalysis. A mechanism is proposed for the reductive carbonylation reaction.

HOWARD ALPER et SHIYAMALIE AMARATUNGA. Can. J. Chem. **61**, 1309 (1983).

La réaction de l'azadiène avec le cobalt carbonyle, le monoxyde de carbone et l'iodure de méthyle dans des conditions catalytiques de transfert de phase (benzène, eau ou NaOH aqueux, chlorure de benzyltriéthylammonium) conduit aux amides allyliques avec des rendements raisonables. Cette réaction régiospécifique est sensible à la concentration de base. On peut également effectuer cette transformation en présence d'un catalyseur acide. On propose un mécanisme pour cette réaction de carbonylation réductrice.

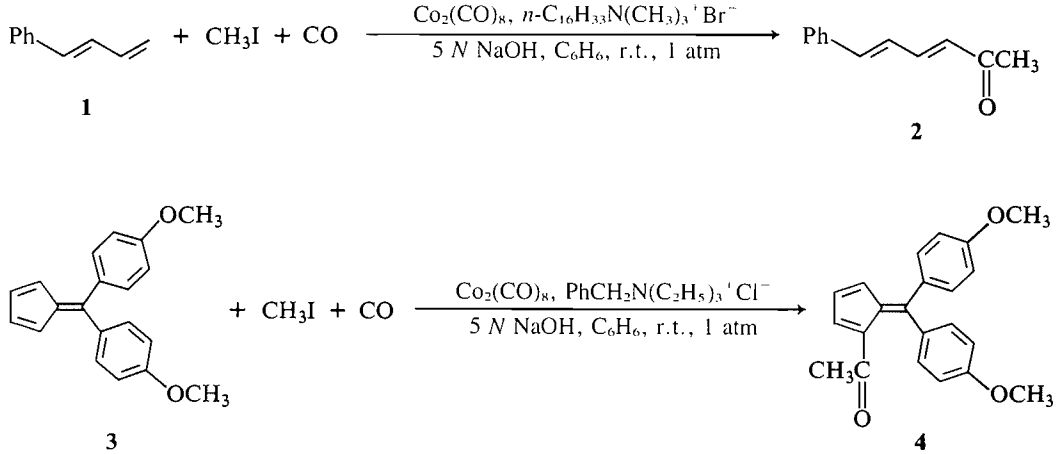
Investigations during the past six years have established phase transfer catalysis as a cheap method for the generation of anionic metal species from neutral precursors under very gentle conditions (1, 2). The formed anions, being relatively unsolvated in the organic phase, display high reactivity towards appropriate substrates. Not only can phase transfer catalysis enable one to effect reactions under much milder conditions than by conventional methods, in certain cases, the reaction course can be altered as well, leading to more useful transformations (3, 4).

A particularly valuable phase transfer process is the conversion of cobalt carbonyl to the mononuclear cobalt tetracarbonyl anion using aqueous sodium hydroxide, benzene or toluene as the organic phase, and benzyltriethylammonium chloride or cetyltrimethylammonium bromide as the phase transfer agent. Subsequent reaction of $Co(CO)_4^-$ with methyl iodide and carbon monoxide gives acetylcobalt tetracarbonyl. The latter can be intercepted by carrying out the reaction in the presence of suitable unsaturated substrates. Examples include the cobalt carbonyl catalyzed acylation of dienes (e.g. **1** → **2**), trienes (5), and fulvenes (e.g. **3** → **4**) (6). These reactions are completely regiospecific.



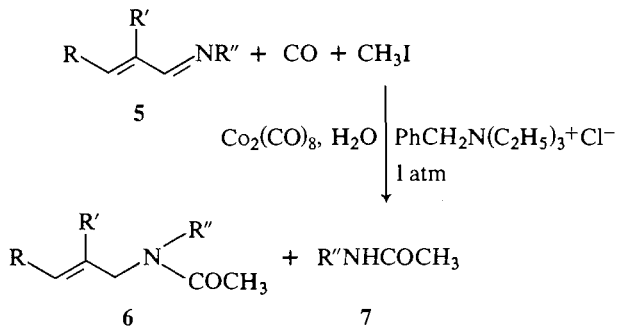
1 **2** **3** **4**

Azadienes are well known compounds, readily prepared by condensation of α,β-unsaturated carbonyls with amines (7). It was of interest to learn what effect, if any, the nitrogen heteroatom of the azadiene would have on the phase transfer catalyzed acylation reaction. We now describe the results of this investigation.

Results and discussion

Treatment of the azadiene **5**, R = Ph, R′ = H, R″ = *p*-$CH_3C_6H_4$, wih methyl iodide, carbon monoxide, benzene, water, benzyltriethylammonium chloride as the phase transfer catalyst, and cobalt carbonyl as the metal catalyst (10:1 ratio of **5**:$Co_2(CO)_8$), at room temperature for 60 h, afforded the allyl amide in 17% yield, with the remainder being recovered starting material. When the ratio of **5**/$Co_2(CO)_8$ was increased to 1:1, and the reaction time reduced to 6 h, the allylic amide (**6**) was formed in good yield (65%), and the amide **7**, R″ = *p*-$CH_3C_6H_4$, was isolated in 33% yield. Compounds **6** and **7** were obtained in the same yield when the reaction was repeated in the dark (using aluminum foil). The reaction was very fast at 60°C (2 min) but the yield of **6** decreased to 40% and **7**, R″ = *p*-$CH_3C_6H_4$ was isolated in 39% yield.

[1]E. W. R. Steacie Fellow, 1980–1982. To whom all correspondence should be addressed.



A variety of reaction conditions was used with the substrate **5**, R = Ph, R′ = H, R″ = *p*-$CH_3C_6H_4$ in order to determine the effect of the phase transfer catalyst, metal carbonyl, organic phase, and base concentration on the yield of allylic amides. In the absence of a phase transfer catalyst, the yield of allyl amide decreased from 65% to 21% (18 h reaction time), while *p*-methylacetanilide was formed in 61% yield. Benzyltriethylammonium chloride is a better phase transfer agent than Aliquat 336 (tricaprylmethylammonium chloride), since reaction using the latter was slower (18 h) and afforded the allyl amide in 41% yield. Only starting material was recovered when the reaction was run in the absence of cobalt carbonyl, but in the presence of benzyltriethylammonium chloride. Methylene chloride can be used as the organic phase in place of benzene, but the yield of **6**, R = Ph, R′ = H, R″ = *p*-$CH_3C_6H_4$ was poor (12%) while the less important **7**, R″ = *p*-$CH_3C_6H_4$ was isolated in 60% yield. When the reaction was effected for 2.5 days under homogeneous conditions (i.e. without water and a phase transfer catalyst), no allyl amide was formed. Rather, **7**, R″ = *p*-$CH_3C_6H_4$, was obtained in 35% yield with the remainder being recovered starting material. The extra hydrogen in **7** arises during work-up of the reaction mixture.

TABLE 1. Effect of base concentration on the phase transfer catalyzed reaction of **5**, R = Ph, R′ = H, R″ = *p*-$CH_3C_6H_4$ with $Co_2(CO)_8$, CH_3I, and CO

NaOH concentration *N*	Reaction time h	% Yield **6**	% Yield **7**
12.5	18	—	48[a]
5.0	3	8	88
2.0	8	22	71
0.5	8	48	36
0.1	6.5	56	38
H_2O	6	65	33

[a]50% of **5** was recovered.

The phase transfer reaction shows an interesting dependence on the base concentration of the aqueous phase (Table 1). At very high base concentration, i.e. 12.5 *N* NaOH, only **7**, R″ = *p*-$CH_3C_6H_4$ is formed. At 5 *N* NaOH, a small amount of **6** is obtained, the major product being **7**. As the concentration of base is decreased, the yield of the allylic amide increases to reasonable levels and **7**, the product of cleavage of the azadiene, is obtained in reduced yield.

Substitution of methanol for water or aqueous NaOH gives **6** in only 20% yield (and **7** in 61% yield). One can use an acid phase transfer catalyst, *p*-toluenesulfonic acid, for the conversion of **5** to **6** (water as the aqueous phase), the yield being somewhat lower (51%) than when a quarternary ammonium salt was employed as the catalyst.

On the basis of the above results, the highest yield of allylic amide **6**, R = Ph, R′ = *p*-$CH_3C_6H_4$ was realized using water as the aqueous phase, benzene as the organic phase, and benzyltriethylammonium chloride as the phase transfer catalyst. These conditions were then applied to the reactions of a series

For personal use only.

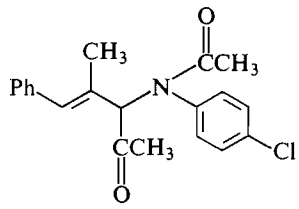
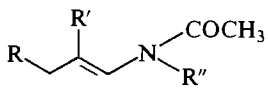
of azadienes with carbon monoxide, methyl iodide, and cobalt carbonyl. Fair to good yields (Table 2) of **6** were obtained in all but one reaction, and the products were identified on the basis of analytical and spectral data (Table 3). The exceptional case was **5**, R = Ph, R′ = CH_3, R″ = *p*-ClC_6H_4, where **8**, an unanticipated product of diacylation of the azadiene, was formed. With this one exception, the reactions were quite

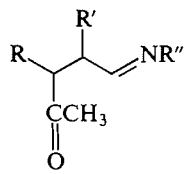


8

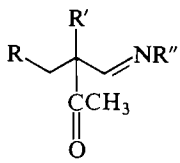
rapid, particularly at 60°C. What makes the conversion of **5** to **6** a useful one is its complete regiospecificity. Neither enamides (**9**) nor isomeric iminoketones (**10**, **11**) were detected in any of these reactions.



9

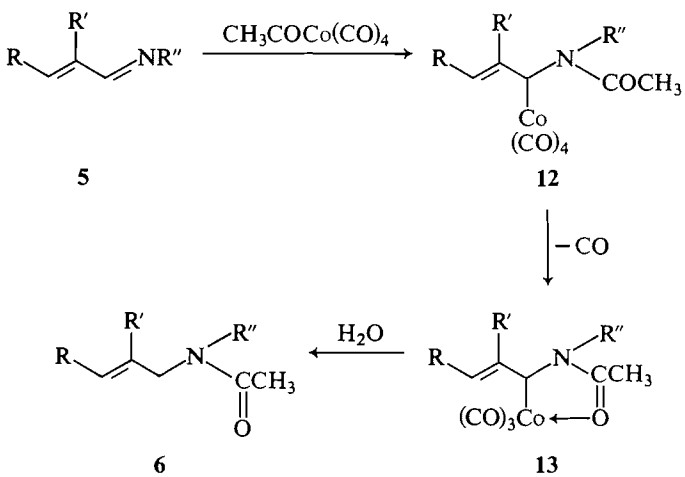


10



11

A possible mechanism for allylic amide formation is outlined in Scheme 1. 1,2-Addition of the *in situ* generated acetylcobalt



SCHEME 1

tetracarbonyl to the carbon–nitrogen double bond of **5** would give the σ-allylcobalt complex **12**. Such a 1,2-addition likely occurs at the least substituted double bond of a 1,3-diene affording a σ-allyl complex which is convertible to a π-allyl complex on subsequent loss of carbon monoxide (1). Rather than forming an analogous π-allyl complex on loss of carbon monoxide, coordination of the amide oxygen of **12** to the metal may occur to give **13**. The oxygen of an amide is more basic than that of a ketone (the intermediate σ-allyl complex formed using 1,3-dienes as substrates contains a ketone functionality). The allylic amide can then arise by hydrolytic cleavage of the carbon–cobalt bond of **13**. Although the generation of a π-allyl intermediate cannot be ruled out, one would have expected, in such an event, the enamide **9** to have been formed along with **6**.

Finally the mechanism of the cleavage and carbonylation of **5** to **7** is not known. The question, of course, arises as to the fate of the three-carbon unit of the azadiene. Repeated attempts to isolate an organic by-product (e.g. cinnamaldehyde from **5**, R = Ph, R′ = H, R″ = *p*-$CH_3C_6H_4$) failed.

In conclusion, the regiospecific phase transfer catalyzed reductive carbonylation of azadienes using $Co_2(CO)_8$ affords allylic amides in 31–65% yields. Allylic amides are valuable compounds, being precursors to a variety of acyclic and heterocyclic systems. For example, isomerization to enamides can be catalyzed by rhodium and ruthenium hydride complexes under thermal conditions (7), and by iron carbonyl under photolytic conditions (8).

Experimental section

General

Elemental analyses were carried out by Canadian Microanalytical Service Limited, Vancouver, and by Schwarzkopf Microanalytical Laboratory, Woodside, NY. The following instrumentation was used for spectral analyses: Varian T60 or HA-100 (NMR), Unicam SP-1100(IR), and VG Micromass 7070E (mass). Tetramethylsilane was the internal standard for nmr measurements. Melting points were recorded on a Fisher-Johns apparatus and are uncorrected.

The required azadienes (**5**) were synthesized by treatment of an α,β-unsaturated aldehyde with an equimolar amount of an amine, according to the procedure of Cardaci and Bellachioma (9). Cobalt carbonyl (Pressure Chemical Co.), the quarternary ammonium salts (Aldrich Chemical Co.), and methyl iodide (Eastman Kodak Co.) were commercial products and were used as received. Organic solvents were dried and distilled prior to use. All reactions were effected using dry nitrogen.

General procedure: phase transfer catalyzed reductive carbonylation of azadienes

Nitrogen gas was passed, for a period of 1 h, through a mixture of benzene (20 mL), distilled water (20 mL), and benzyltriethylammonium chloride (0.5 mmol). The gas was changed to carbon monoxide, and cobalt carbonyl (2.0 mmol) was added along with methyl iodide (1.0 mL). This mixture was stirred and then the azadiene (2.0 mmol) was added under a fast stream of carbon monoxide. The reaction mixture was stirred at room temperature or at 60°C (Table 2) until the solution became bright red, indicating completion of the reaction. The layers were separated, and the aqueous layer was extracted several times with 25 mL portions of methylene chloride. The methylene chloride extracts were combined with the organic phase (benzene), dried ($MgSO_4$), and then concentrated (rotary evaporation) to give the crude products. The products (**6** and **7**) were easily separated by column chromatography on silica gel using hexane–ether as the eluant, and recrystallized to give analytically pure materials. Product yields are given in Table 2, and melting points and spectral data for **6** (and **8**) are listed in Table 3. The acetanilide derivatives (**7**) were characterized by comparison of spectral properties with those for authentic samples.

The use of other conditions for the reductive carbonylation of azadienes

(a) Catalytic amount of $Co_2(CO)_8$

Repetition of the general procedure using 0.2 mmol of $Co_2(CO)_8$

(i.e. a 10:1 ratio of **5**, R = Ph, R′ = H, R″ = *p*-$CH_3C_6H_4$) afforded **6** in 17% yield and recovered **5**.

(b) Reaction in the absence of a quarternary ammonium salt

When the general procedure was carried out, without benzyltriethylammonium chloride, and for an extended period of time (18 h at room temperature), **6** (R = Ph, R′ = H, R″ = *p*-$CH_3C_6H_4$) was formed in 21% yield, the major product (61%) being **7**, R″ = *p*-$CH_3C_6H_4$.

(c) Using Aliquat 336 as the phase transfer agent

Substitution of 0.5 mmol of Aliquat 336 for benzyltriethylammonium chloride resulted in a more sluggish reaction (18 h) giving **6**, R = Ph, R′ = H, R″ = *p*-$CH_3C_6H_4$ in 41% yield.

(d) Reaction in the absence of $Co_2(CO)_8$

The azadiene **5**, R = Ph, R′ = H, R″ = *p*-$CH_3C_6H_4$ was completely recovered when the reaction was effected without $Co_2(CO)_8$.

(e) Using CH_2Cl_2 as the organic phase

Reaction of **5**, R = Ph, R′ = H, R″ = *p*-$CH_3C_6H_4$ at room temperature for 6 h, using methylene chloride as the organic phase, afforded **7** in 60% yield, with the desired **6** only obtained in 12% yield.

(f) At different base concentrations

The general procedure was applied to **5**, R = Ph, R′ = H, R″ = *p*-$CH_3C_6H_4$ with aqueous NaOH (0.1–12.5 *N*) used instead of water (see Table 1).

Reaction using acidic phase transfer catalysis

A degassed mixture of pentane (20 mL), water (20 mL), and *p*-toluenesulfonic acid (1.0 nmol) was treated with cobalt carbonyl (2.0 nmol) and methyl iodide (1.0 mL) under a carbon monoxide atmosphere for 4 h. Then **5**, R = Ph, R′ = H, R″ = *p*-$CH_3C_6H_4$ (2.0 nmol) was added and the reaction mixture was stirred overnight. Work-up following the general procedure gave **6** in 51% yield, and recovered starting material.

The complex, dichloro(triphenylphosphine){1-[*N*,*N*-α-dimethylaminoethyl]-2-diphenylphosphinoferrocene}ruthenium(II), prepared from $RuCl_2(PPh_3)_3$ by ligand displacement, catalyzes the hydrogenation of terminal olefins under mild conditions. The experimental rate-law for hydrogenation of hexene-1 in *n*-butanol at 40°C shows a first-order dependence on both olefin and hydrogen, and an inverse dependence to added triphenylphosphine. The dependence on ruthenium goes from first- to half-order with increasing metal concentration. The kinetic data, together with spectroscopic data, and studies on reactivity of the complex toward hydrogen, are interpreted in terms of catalysis via a ruthenium(I) complex that dissociates a phosphine ligand to generate the active species.

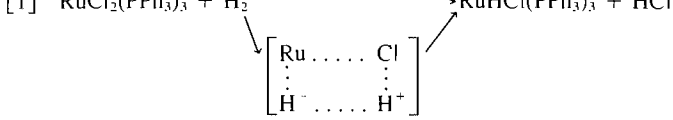
GLEN E. RODGERS, WILLIAM R. CULLEN et BRIAN R. JAMES. Can. J. Chem. **61**, 1314 (1983).

Le complexe de dichloro(triphénylphosphine){[*N*,*N*-α-diméthylaminoéthyl]-1 diphénylphosphinoferrocène-2}ruthénium(II), préparé à partir du $RuCl_2(PPh_3)_3$ par déplacement de ligand, catalyse l'hydrogénation des oléfines terminales dans des conditions douces. La loi de vitesse expérimentale d'hydrogénation de l'hexène-1, dans le *n*-butanol à 40°C, montre une dépendance d'ordre un vis-à-vis de l'oléfine et de l'hydrogène, et une dépendance inverse vis-à-vis de la triphénylphosphine ajoutée. L'influence du ruthénium va d'un ordre un à un ordre de $\frac{1}{2}$ lorsque la concentration du métal augmente. On interprète les données cinétiques ainsi que les données spectroscopiques et les études de réactivité du complexe envers l'hydrogène, en fonction de la catalyse par l'intermédiaire du complexe de ruthénium(I) qui dissocie un ligand phosphine pour produire l'espèce active.

[Traduit par le journal]

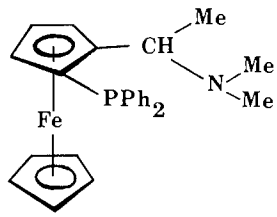
Introduction

Of all homogeneously catalyzed processes, hydrogenation has been the most intensely studied, and several systems particularly based on rhodium phosphine complexes, including some that are effective for asymmetric hydrogenation, are now understood at a remarkably sophisticated level (1–3). These rhodium systems operate via dihydride species that are formed by oxidative addition of dihydrogen at rhodium(I) centres. Catalysts based on the currently less expensive ruthenium metal are less thoroughly understood, even the well-studied and extremely active $RuHCl(PPh_3)_3$ complex (4). One unsolved problem with catalysis at ruthenium(II) centres is the accessibility of the Ru(IV) oxidation state; for example, does reaction [1], a *net* heterolytic cleavage of H_2, involve oxidative addition to give a $Ru^{IV}H_2$ intermediate followed by reductive elimination of HCl, or a transition state in which coordinated chloride stabilizes the released proton (1, 5)? Activation parameter data

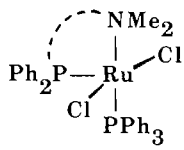


for several ruthenium(II) systems provide indirect support for a rate-determining oxidative addition (1).

Incorporation of an amino group into a phosphine, in which a coordinated nitrogen atom can play the role of proton acceptor (6), should allow for a further more direct probing of the dichotomy, and this coupled with our experience with the 1-[*N*,*N*-α-dimethylaminoethyl]-2-diphenylphosphinoferrocene ligand (**I**) (7, 8) led us to synthesize and characterize a ruthenium(II) derivative and study its reactivity toward H_2 in the absence and presence of olefinic substrates.



I



II

A range of other aminophosphine ligands has been used in catalytic hydrogenation systems, particularly with rhodium and iridium (6, 9),[2] but only qualitative rate data have been reported. There is in general a growing interest in ligand systems containing both "soft" and "hard" donor atoms (10, 11). The fact that rhodium systems such as $Rh(bipyridyl)_2^+$ can selectively catalyze hydrogenation of a ketone in ketone/olefin mixtures (12), while analogous systems with chelated diphosphines preferentially reduce olefins (13), encouraged further research into mixed PN donor systems.

Ligand **I**, abbreviated PPFA, possessing a planar element of chirality as well as chirality at the carbon substituent, is one of a range of ferrocenyl-phosphine ligands that have been used for asymmetric hydrosilylation (14) and hydrogenation (8, 15, 16). The asymmetric hydrogenation systems have used rhodium catalysts, but to our knowledge no reports on ruthenium systems have appeared. The studies reported in this present paper were carried out with the racemic ligand because of the interest noted above; they are also considered exploratory for future work using chiral systems.

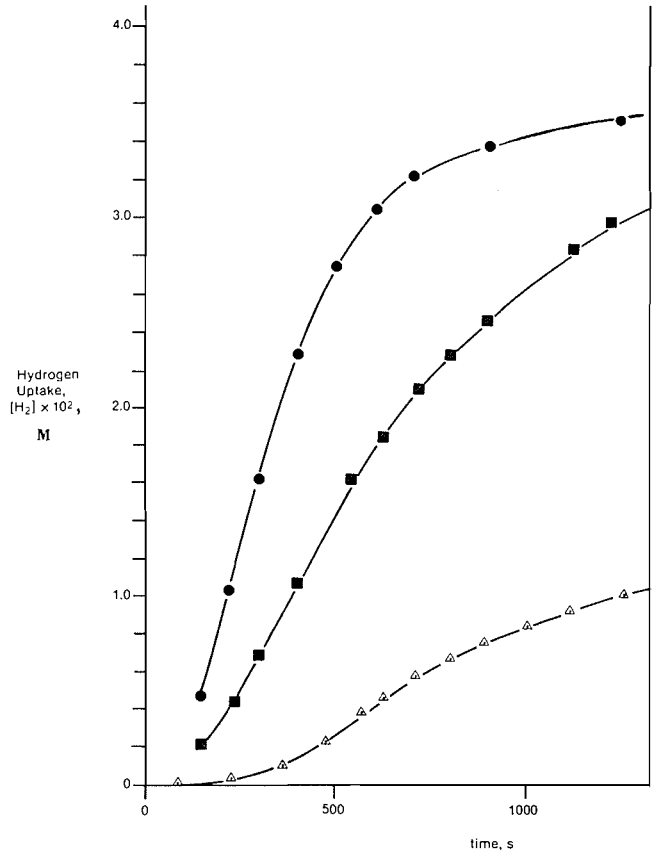

FIG. 1. Selected H_2 uptake plots for the hydrogenation of hexene-1 catalyzed by **II** in *n*-butanol at 40°C, 0.04 *M* hexene, 1 atm total pressure: ● 10×10^{-4} *M* Ru, ■ 2.47×10^{-4} *M* Ru, △ 1.23×10^{-4} *M* Ru.

vacuum system and standard Schlenk techniques. Nuclear magnetic resonance spectra were run on Varian XL100 or Bruker WM 400 instruments. Other instruments used were as follows: Perkin–Elmer 598 infrared spectrophotometer, Cary 17D uv/vis spectrophotometer, AEI-MS902 mass spectrometer, and a Hewlett Packard 5880A gas chromatograph.

Ruthenium(III) trichloride trihydrate was obtained as $RuCl_3 \cdot 3H_2O$ (40.59% Ru) from Johnson Matthey Limited. Olefinic substrates were obtained as CP grade; solids were recrystallized and liquids redistilled before use. Peroxide impurities in liquid olefins were removed by passage through an alumina column under N_2. *n*-Butanol was refluxed with magnesium metal/iodine to remove traces of water. Other materials used and the procedure used for following H_2-uptake at constant pressure have been described previously (17, 18).

*Preparation of dichloro(triphenylphosphine){1-[*N,N*-α-dimethylaminoethyl]-2-diphenylphosphinoferrocene}ruthenium(II), $RuCl_2(PPh_3)PPFA$, (II)*

Dichlorotris(triphenylphosphine)ruthenium(II) (1.24 mmol), prepared from $RuCl_3 \cdot 3H_2O$ (19), and 1-[*N*,*N*-α-dimethylaminoethyl]-2-diphenylphosphino-ferrocene (0.73 mmol), prepared from ferrocene carboxaldehyde (7), were refluxed in 75 mL of hexane for 18 h. The $RuCl_2(PPh_3)_3$ is present as a suspension in the hexane, but the slow reaction gives a resulting dark-green solid that was filtered and washed with small quantities of cold hexane. The product was dissolved in hot benzene (70°C) and, after a filtration step, the solid product was reprecipitated by adding hexane. The dark-green product, mp > 210°C dec., was isolated by filtration after the mixture had been stored at −20°C for 12 h. Infrared: 310 cm^{-1}, ν(Ru—Cl); λ_{max}, nm (ε, M^{-1} cm^{-1}) in BuOH: 628 (420), 457 (1100); ^1H nmr ($CDCl_3$) δ: 1.52 (d, 3, *J* = 7, C—CH_3), 2.44, 2.66 (2d, 6, *J* = 2.4, N—$(CH_3)_2$), 3.56 (s, 5, Fe—C_5H_5), 4.12, 4.27, 4.48 (s, t, s, 3, *J* = 2, Fe—C_5H_3), 6.23

Results

The $RuCl_2(PPh_3)$(PPFA) complex (**II**) in *n*-butanol was found to be an efficient catalyst for the hydrogenation of terminal olefins under mild conditions (30–60°C, ≤ 1 atm H_2). Under these conditions, hexene-1 as substrate gave conveniently measurable rates for kinetic studies at 40°C ([**II**] = $10^{-4} - 10^{-3}$ *M*, [hexene-1] = $(1.0–6.0) \times 10^{-2}$ *M*, added [PPh_3] = $(0.0–12.0) \times 10^{-4}$ *M*). Figure 1 shows selected uptake plots at the conditions noted using 5 mL solution volume. Hydrocarbon solvent systems gave much lower hydrogenation rates.

The total gas uptake corresponded to stoichiometric reduction of the hexene to hexane, as checked by gas chromatography. The hydrogenation rate of internal alkenes such as hexene-2, as well as of disubstituted olefins such as styrene and the prochiral substrate *N*-acetamidoacrylic acid, was negligible at 40°C. Hexene-2 was not detected at any stage during the hydrogenation, and thus there is no evidence for accompanying isomerization of the hexene-1.

The uptake plots (e.g. Fig. 1) show initially autocatalytic-type behaviour prior to reaching a maximum rate after

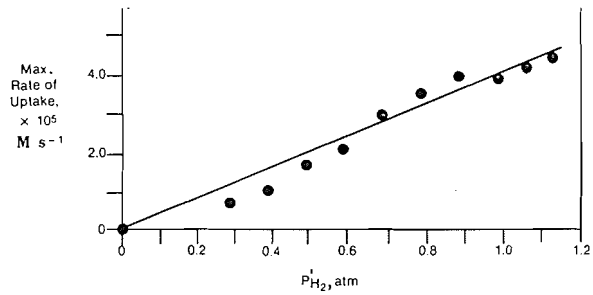

FIG. 4. Dependence of maximum hydrogenation rate on partial pressure of H_2 in *n*-butanol at 40°C, 0.04 *M* hexene, [Ru] = 2.47 × 10^{-4} *M*. Pressure reading is corrected for vapour pressure of *n*-butanol, 0.02 atm at 40°C (ref. 38*a*, p. 219).

200–800 s; the rates then gradually fall off. The "induction period" prior to the region of maximum rate increased with decreasing H_2 pressure (from 1 to 0.3 atm), and with decreasing ruthenium concentration (Fig. 1), but was largely independent of hexene-1 concentration. The maximum rates, which are readily measured, were used to determine the kinetic dependences. The data are summarized in Figs. 2–5 and reveal a complex dependence on Ru (Fig. 2A), first-order in hexene-1 (Fig. 3) and partial pressure of H_2 (Fig. 4), and an inverse dependence on added phosphine that is plotted as $(\text{rate})^{-1}$ vs. $[PPh_3]$ in Fig. 5. The dependence on Ru is first-order at low concentrations but becomes less than one with increasing concentration and, in fact, approaches half-order above 8 × 10^{-4} *M* (Fig. 2A); in the presence of excess phosphine, the dependence on Ru becomes strictly first-order (Fig. 2B).

In the absence of organic substrate, butanol solutions of **II** absorb slightly more than 0.5 mol of H_2 per Ru at several pressures. These reactions follow pseudo first-order behaviour at the constant H_2 pressure used and yield, for example, k_{obs} = 1.3 × 10^{-3} s^{-1} using 0.7 atm H_2 at 40°C. The gas uptake is accompanied by a colour change from green to orange-red. The intensity of the initial 628 nm band decreases, while increasing absorption in the 350–450 region washes out the initial 457 nm band; these spectral changes reveal isosbestic points at 435 and 530 nm. There was no evidence (ir, nmr) for the presence of a ruthenium-hydride species in the alcohol (or deuterated alcohol) solvents; reactivity toward H_2 in benzene was slow and incomplete, and again no metal hydride was detected. Of interest, the orange-red hydrogenated solutions gave no ^{31}P nmr signals, although the percursor green solutions of **II** at the same concentrations yielded a ^{13}P nmr spectrum (see Experimental and Discussion). Attempts to isolate solids from the orange-red solutions by evaporation of the solvent even under H_2 led to a slow regeneration of the green colour and partial formation of **II**; again, no metal hydride was detected in the solid residue.

Addition of hexene-1 to the orange-red solutions under H_2 caused further very slight visible spectral changes, the absorption in the 350–450 nm region decreasing somewhat; the spectrum shows only a broad shoulder from 420–450 nm ($\epsilon \sim 1000$ M^{-1} cm^{-1}), and is typical of that present during the region of maximum catalytic hydrogenation rate.

Solutions of $RuCl_2(PPh_3)$(PPFA) were unreactive toward hexene-1, although with *N*-acetamidoacrylic acid (a nonreducible substrate) a colour change from green to reddish was noted.

Suspensions of the hydridocomplex $RuHCl(PPh_3)_3$ (20) in hexane were unreactive toward the PPFA ligand (ligand/metal ratio = 2.5), even under reflux.

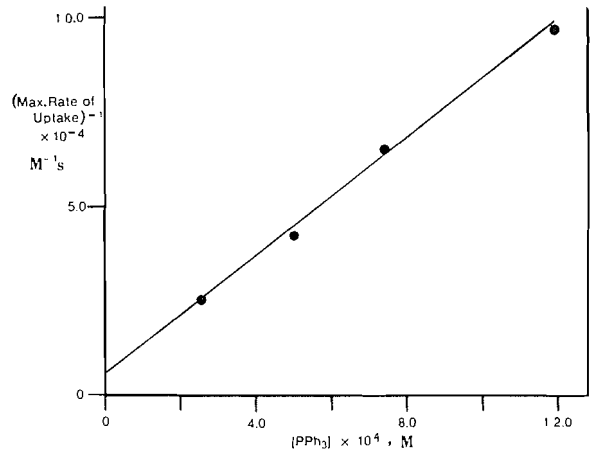

FIG. 5. Inverse dependence of maximum hydrogenation rate on added phosphine concentration in *n*-butanol at 40°C, 0.04 *M* hexene, 1 atm total pressure, [Ru] = 2.47 × 10^{-4} *M*.

Discussion

Characterization of $RuCl_2(PPh_3)$(PPFA), (II)

Complex **II** is obtained by the simple ligand exchange reaction outlined in eq. [2] using a ligand-to-complex ratio of less than one:

[2] $RuCl_2(PPh_3)_3 + PPFA \rightarrow RuCl_2(PPh_3)(PPFA) + 2P\dot{P}h_3$

Such a metathesis reaction but using excess ligand has been used previously, particularly with chelating ditertiary phosphine type ligands, to yield isolable complexes of the type $RuCl_2(\text{diphosphine})_2$, in which three or four of the phosphorus atoms are coordinated (21, 22), or of the type $Ru_2Cl_4(\text{diphosphine})_3$ containing a bridging diphosphine (22). The $CHCl_3$ solution molecular weight of **II** shows it to be a monomer, and since a visible spectrum of a Nujol sample shows the same absorption maxima as the solution spectrum (that is invariant with solvent), the same monomeric structure is indicated in the solid state; structure **II**, being either a square pyramid or distorted trigonal bipyramid, is consistent with the spectroscopic data.

The two N—CH_3 resonances in the room temperature ^1H nmr indicate that the nitrogen is coordinated as in the rhodium complex $[Rh(PPFA)(\text{norbornadiene})]^+ClO_4^-$ (7). These N—CH_3 resonances show small splittings that are field independent and are probably due to coupling to a single *trans* phosphorus. The nonproton-decoupled ^{31}P spectrum was too broad to detect this coupling. The ^1H nmr spectrum in toluene-d^8 is invariant from 0–100°C and shows the same nonequivalent methyl groups. (In a cationic rhodium complex with the arsenic analogue of PPFA, exchange between the two nonequivalent N—CH_3 groups is rapid at ambient temperatures (11).)

The ^{31}P nmr spectrum in C_6D_6 at room temperature shows two nonequivalent phosphorus atoms, the small coupling constant indicating a *cis*-geometry (22–24); the spectrum in $(CD_3)_2CO$ is invariant from −60°C to ambient temperatures.

The two-band visible spectrum with the more intense higher energy band resembles closely those of square-pyramidal $RuCl_2P_3$ species with *trans* chlorides and three phosphine (P) donors (22, 23).

Finally, the infrared spectrum shows a single band at 310 cm^{-1} that is characteristic of ν(Ru—Cl) with mutually *trans* chlorides (22, 25).

We are unaware of any studies akin to reaction [2], but using other chelating PN donor systems. A 1:1 stoichiometric reaction of $RuCl_2(PPh_3)_3$ with diop, the well-known chelating chiral diphosphine (22), has been shown to yield $RuCl_2(PPh_3)$(diop) that has an ABX pattern in the ^{31}P nmr, consistent with a structure such as **II** (26).

The nonreactivity of $RuHCl(PPh_3)_3$ toward excess PPFA is surprising in view of the success of reaction [2] and considering that chelating ditertiary-phosphines and -arsines, and chelating diamines readily yield complexes such as $RuHCl(chelate)_2$ or $RuHCl(PPh_3)_2$(chelate), under identical conditions (21, 27). The lack of reactivity may be related to solubility factors since the usual precursor and product hydrides have very low solubilities in the hexane medium (21, 26). Alternatively a hydridoruthenium(II) complex containing PPFA just may not form readily; formation of a detectable hydride via reaction of **II** with H_2 is not observed (see below), in spite of the possibility of a reaction such as [3] with the released proton being associated with a dissociated chloride or arsine donor (cf. eq. [1]).

$$[3]\quad Ru^{II} + H_2 \rightleftharpoons Ru^{II}H^- + H^+$$

Hydrogenation studies

The stoichiometry of the reaction of $RuCl_2(PPh_3)$(PPFA) with H_2, together with lack of evidence for hydride formation, is tentatively but best interpreted in terms of production of ruthenium(I) species:

$$[4]\quad Ru^{II} + \frac{1}{2}H_2 \rightleftharpoons Ru^{I} + H^+$$

The lack of ^{31}P nmr signals could be consistent with the presence of paramagnetic mononuclear Ru(I) d^7 species. No esr signal has yet been detected, but this is not uncommon for paramagnetic ruthenium species because of relatively fast relaxation rates of the quadrupolar nucleus (28). Ruthenium(I) phosphine complexes stabilized by carbonyl ligands have been known for some time (29), while evidence has been presented more recently for $[RuCl(PPh_3)_3]_n$, $[RuCl(PPh_3)_2]_2$, $[RuCl(PMe_3)_2]_2$, and $[RuCl(PPh_2(CH_2)_3PPh_2)_2]$ species (30–33).

Earlier work from this laboratory reported on the use of chlororuthenate(I) solutions for catalyzing hydrogenation of unsaturated carboxylic acids (34). Further indirect evidence against formation of a catalytically active ruthenium(II) hydride system (cf. eqs. [1], [3]) is the lack of accompanying isomerization of hexene-1 during the catalytic hydrogenation. Such monohydride catalysts are usually quite active for isomerization via the usual metal hydride addition – elimination sequence involving a metal alkyl intermediate (1, 35). Presumably, reduction to the ruthenium(I) state involves hydride formation (eq. [3]), followed by a reaction such as [5]. Such dihydrogen reduction of Ru(III) and Ru(II) species to Ru(II)

$$[5]\quad Ru^{II}H \text{ (or } Ru^0 + H^+) + Ru^{II} \rightarrow 2Ru^{I} + H^+$$

and Ru(I) species, respectively, has been studied previously (36, 37) and found to be promoted by base (cf. eqs. [1], [3], [5]). Enhanced reactivity here in butanol compared with benzene suggests solvent polarity is important, perhaps in stabilizing transition states akin to that shown in eq. [1].

The partial re-formation of complex **II**, on attempting to work up the "ruthenium(I)" solutions, implies some reversibility of reaction [4], although the gas uptake and visible spectral data show that reaction of **II** with H_2 is "complete" over the pressure range studied (0.5–1.0 atm).

The initial autocatalytic type profile of the hexene-1 hydrogenation plots is attributed to formation of the active Ru(I) catalyst, and the kinetics measured in the maximum rate region are consistent with catalysis via this species in mechanisms outlined in eqs. [6] and [7].

Pre-formation of the Ru(I) species, prior to addition of hexene-1, removed the autocatalytic region and led to initial hydrogenation rates very close to those measured in the region of maximum rate for uptake curves of the type illustrated in Fig. 1 under corresponding conditions.

$$[6]\quad Ru(I)(PPh_3) \overset{K_p}{\rightleftharpoons} Ru(I) + PPh_3$$

$$[7]\quad \begin{array}{ccc} Ru(I) + H_2 & \overset{K_1}{\rightleftharpoons} & Ru(III)H_2 \\ {\scriptstyle K_2\ \text{hexene}}\ \Big\Vert & & \Big|\ {\scriptstyle k_1\ \text{hexene}} \\ Ru(I)(\text{hexene}) & \xrightarrow[H_2]{k_2} & Ru(I) + \text{hexene} \end{array}$$

The nature of Ru(I) is uncertain but dissociation of a phosphine ligand prior to the rate-determining step is essential in order to account for the observed kinetic dependences.

If the ruthenium in solution is present as just $Ru(I)PPh_3$ and Ru(I), then the rate-law by both the K_1k_1 and K_2k_2 paths approximates to:

$$[8]\quad \frac{-d}{dt}[H_2] = \frac{(k_1K_1 + k_2K_2)K_p[Ru_T][H_2][\text{hexene}]}{K_p + [PPh_3]}$$

where subscript T refers to total concentration. This rate-law requires that K_1 and K_2 are sufficiently small such that there are no detectable hydrido or olefinic species based on the Ru(I) catalytic cycle, and this is supported by the experimental data. At sufficiently low ruthenium concentration $PPh_3 < K_p$, and rate-law [8] leads to a first-order dependence on Ru_T; at the higher ruthenium concentrations $[PPh_3] > K_p$, and in the absence of added phosphine is equated to [Ru(I)] (which is given by $[K_pRu_T]^{1/2}$). Thus the rate law then becomes:

$$[9]\quad \frac{-d}{dt}[H_2] = (k_1K_1 + k_2K_2)K_p^{1/2}[Ru_T]^{1/2}[H_2][\text{hexene}]$$

The complex dependence on Ru is thus accounted for by the K_p equilibrium, i.e. in terms of the relative magnitude of K_p and $[PPh_3]$ in the denominator of eq. [8] as Ru_T increases. In the presence of sufficient added phosphine ($[PPh_3] \gg K_p$ in eq. [8]), a first-order dependence on catalyst obtains.

The general dependence on added phosphine can by analyzed by taking the reciprocal form of eq. [8] and plotting $(\text{rate})^{-1}$ vs. $[PPh_3]$ (Fig. 5).

The mechanisms outlined in eq. [7] correspond to the well-established "hydride" (K_1k_1) and "unsaturate" (K_2k_2) routes.[3] K_1k_1 becomes zero if the k_2 unsaturate path predominates and vice versa. The very slight visible spectral change on adding hexene to the Ru(I) solutions gives some evidence for the K_2 equilibrium but the amount of Ru(I) (hexene) species present in solution is estimated to be <10% at the highest hexene concentration used (0.06 *M*). Significant amounts of this species would be evidenced kinetically by a fall-off in rate with increasing [hexene] (see Fig. 3), that is, by a less than first-order dependence as reflected in the addition of a K_2[hexene] term in the denominator of eq. [8].

The data summarized in Figs. 2–5 are internally reasonably consistent, and lead to numerical values of $(k_1K_1 + k_2K_2)$ and K_p at 40°C (the solubility of H_2 in butanol is taken as 4.0×10^{-3} M atm^{-1} at 40°C (38)). A $(k_1K_1 + k_2K_2)$ value of about 1.3×10^3 M^{-2} s^{-1} is calculated from the initial slope of Fig. 2A, while a rate vs. $[Ru_T]^{1/2}$ plot for the higher ruthenium concentrations (see eq. [9]) yields a $(k_1K_1 + k_2K_2)K_p^{1/2}$ value of about 15 $M^{-3/2}$ s^{-1}; thus K_p is estimated to be about 1.3×10^{-4} M^{-1}. The slope of Fig. 5 yields a $(k_1K_1 + k_2K_2)K_p$ value of 0.3 M^{-3} s^{-1}, although the large error in the intercept value does not allow for a reliable $(k_1K_1 + k_2K_2)$ value. The data of Figs. 3 and 4 are measured at a ruthenium concentration in which the rates are closer to first-order in catalyst (i.e. the rates approximate to $(k_1K_1 + k_2K_2)[Ru_T][H_2][hexene]$); the slopes yield $(k_1K_1 + k_2K_2)$ values of 1.1×10^3 and 1.0×10^3 M^{-2} s^{-1}. The slope of Fig. 2B at the added phosphine concentration of 11.9×10^{-4} M ($\gg K_p$) gives a $(k_1K_1 + k_2K_2)K_p$ value of 0.25 M^{-3} s^{-1}.

More detailed kinetic studies using other olefinic substrates, coupled together with isolation of the suggested Ru(I)(PPh_3) catalyst, are required to further substantiate the admittedly rather speculative mechanism outlined in eqs. [6] and [7]. Modified schemes in which phosphine dissociation occurred at the time of dihydride or olefin complex formation could satisfy the kinetics equally well. A key test for the suggested mechanism would be an independent measurement of K_p, following isolation of the Ru(I) complex; labile phosphine exchange within the K_p equilibrum could also contribute to line-broadening in the ^{31}P nmr spectrum (see above).

Catalytic hydrogenation via Ru(I) monohydride intermediates requires more elaborate reaction schemes, and would also be expected to be accompanied by some isomerization (see above).

Our initial objectives in this study, regarded as preliminary, have not been fulfilled. Apparent reduction to ruthenium(I) complicates the probing of heterolytic cleavage of H_2 by Ru(II), while the catalytic hydrogenation system discovered seems inactive, at least under mild conditions, for hydrogenation of the prochiral amino acid precursors, although this may be due to strong chelation to the $RuCl_2(PPh_3)$(PPFA) complex. Nevertheless, catalytic hydrogenation via the relatively rare ruthenium(I) state is strongly indicated, and further efforts are in hand to isolate the active complex. The activity of the system for hydrogenation of hexene-1 is comparable to that of the $RuHCl(PPh_3)_3$ catalyst, which is one of the most active known for terminal olefins.[4]

By using the isolobality principle, it is shown that the electronic structures of the 4- through 9-atom organo-transition metal clusters are closely analogous to the corresponding boranes. This parallelism is extended beyond simple structural similarities and is used to account for the high reactivity and nmr fluxionality of clusters which possess a vacant site on the polyhedral surface. Comparisons are also drawn with main group anionic and cationic clusters. Finally, it is shown that clusters containing gold atoms can, under certain circumstances, also follow the structural patterns of the boranes.

MICHAEL J. MCGLINCHEY, MICHAEL MLEKUZ, PETER BOUGEARD, BRIAN G. SAYER, ANGELA MARINETTI, JEAN-YVES SAILLARD et GÉRARD JAOUEN. Can. J. Chem. **61**, 1319 (1983).

Faisant appel au principle d'isolobalité, il est démontré que les structures électroniques des clusters organo-métalliques possédant de 4 à 9 atomes sont très analogues aux boranes correspondants. Ce parallèle est étendu au delà des similarités structurelles simples et est utilisé pour expliquer la haute réactivité et la fluxionalité en rmn des clusters qui possèdant un site vacant à la surface du polyèdre. On fait également des comparaisons avec des clusters anioniques et cationiques des éléments des groupes principaux. Finalement, il est montré que les clusters incluant des atomes d'or, peuvent dans certaines circonstances, avoir un comportement semblable à celui des boranes.

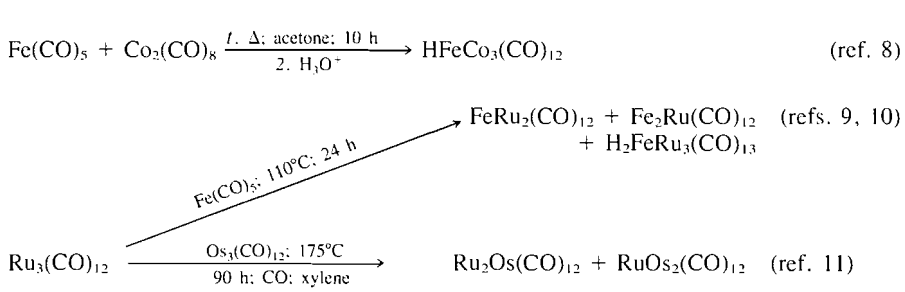
Introduction

Practitioners of industrial catalysis generally prefer to use heterogeneous systems for efficiency and ease of product separation; in contrast, academics are more likely to study homogeneous systems containing only one or two metal atoms which, while sometimes not as effective catalytically, can be more easily studied so as to yield fine details of the mechanisms involved (1–3). Over the past several years a great deal of attention has focussed on metal clusters which may be viewed as a bridge between the intensively studied monometallic systems and the less well understood reactions occurring on surfaces (4). In particular, much activity has been directed towards the search for an efficient homogeneous Fischer-Tropsch catalyst. However, such efforts have thus far met with only limited success (5).

Early cluster syntheses were, to some extent, serendipitous and involved such procedures as pyrolysis of di- or tri-metallic species to produce polymetallic clusters in a relatively uncontrolled fashion (6, 7). Some early syntheses typifying this approach are shown in Scheme 1.



SCHEME 1

The pioneering syntheses of these mixed metal clusters prompted the search for other routes which avoided the forcing conditions previously used. Indeed, it was soon realised that treatment of the readily available simple metal carbonyls with metal carbonyl anions could lead to triangular, tetrahedral, or even trigonal bipyramidal clusters as shown in Scheme 2 (12, 13).

It had long been realised by organic chemists that the dimerisation of acetylenes might yield tetrahedrane but, even though the parent molecule C_4H_4 as yet remains elusive (18), the reac-

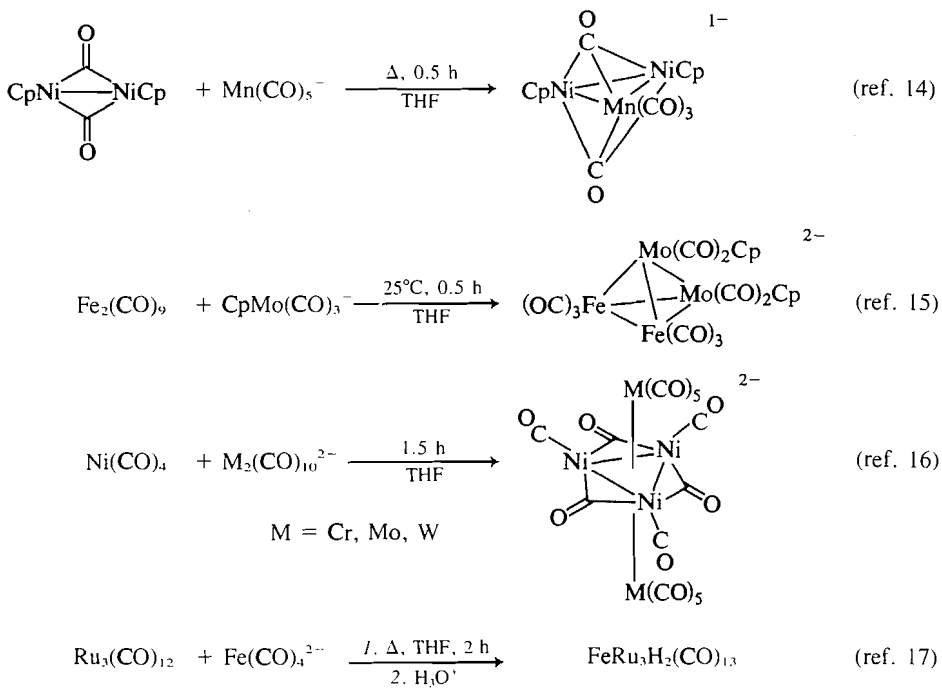
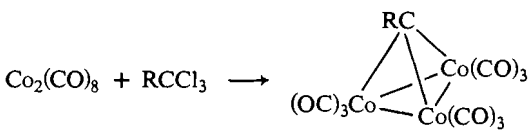


SCHEME 2

tion of alkynes with $Co_2(CO)_8$ to yield tetrahedral clusters of the type $R_2C_2Co_2(CO)_6$ was a well-established process (19) and indeed was even used to protect the alkyne linkage while another functional group in the molecule was being chemically modified (20, 21). It was, of course, realised that a metal–metal triple bond might be implicated and indeed the addition of alkynes to well-characterized metal–metal triple-bonded species provides an excellent route to a variety of tetrahedral systems (22). Scheme 3 contains several examples of this synthetic methodology in which a metal–metal multiple bond (either in an isolable molecule, or merely generated *in situ* by elimination of carbonyl groups) reacts with suitable addenda.

It has also been known for a number of years that $Co_2(CO)_8$ and $RCCl_3$ yield the tricobalt cluster complexes with a triple-bridging carbyne moiety (32), and speculation centred on the possible involvement of metal carbyne complexes, $L_nM{\equiv}CR$, which might behave analogously to alkynes. This idea has been



brilliantly exploited by Stone and colleagues (33, 34) who have characterised a tremendous variety of mixed clusters as typified by the sequences depicted in Scheme 4.

Stone's elegant work has placed this field on a firm foundation and currently provides the most logical routes to small clusters.

We next outline some underlying principles which rationalise these approaches to cluster synthesis and also account for the structures, fluxionality, and reactivity of many of these complexes. Finally, we describe some recent synthetic, structural, and spectroscopic results which support these assertions.

The Wade–Mingos bonding model

The realisation that transition metals in low oxidation states can use all nine ($1 \times s$, $3 \times p$, $5 \times d$) valence orbitals for bonding led to the widespread adoption of the "Effective Atomic Number" (E.A.N.) Rule (41). This concept has been remarkably successful in accounting for the behaviour of many catalytic intermediates, and the idea of 16-electron to 18-electron interconversions was very clearly expounded in a now classic review by Tolman (42). Thus, organo-transition metal complexes in which the central metal was assigned a 16-electron configuration could be regarded as coordinatively unsaturated; in contrast, a metal possessing an 18-electron configuration could not function as a catalytic centre without either losing or migrating a ligand or by decreasing the hapticity of a polyhapto substituent so as to generate a vacant site (43). Following this definition, complexes such as $(RC{\equiv}CR)Co_2(CO)_6$, whose structures are based on a tetrahedron, would be regarded (44) as being coordinatively saturated — a viewpoint which is belied by their surprisingly high reactivity even under mild reaction conditions. We shall return to this point presently.

Typical metal carbonyls such as **1** through **5** can all be assigned 18-electron configurations while the hexanuclear clusters **6** and **7** would, using the normal electron-counting formalism, place $18\frac{1}{3}$ electrons on each metal atom. That is, the octahedral clusters might be expected to have 84 valence elec-

trons (24 of them assigned to the 12 metal–metal bonds along the polyhedral edges) whereas in fact they have 86 valence electrons. In an apparent paradox, these seemingly *electron-rich* clusters may be conveniently rationalized as being *electron-deficient*.

We pause here a moment to clarify our nomenclature since much of one's thinking is based on the Lewis concept (45) of all bonded atoms being joined by at least one electron pair. Thus, in a system such as $B_6H_6^{2-}$ which has 26 valence electrons (12 of which are needed to form the six exo-skeletal B—H bonds) only 14 electrons, i.e., 7 electron pairs, are left with which to bond together the six borons in the cluster. Since the octahedron has 12 edges, 12 electron pairs would be required to bond the borons in a Lewis-type fashion; historically, this has been termed an electron-deficient molecule (46). Nevertheless, in molecular orbital terms no such problem exists since, from a basis set of sp_z, p_x, and p_y orbitals on each boron, one can readily construct an energy level scheme with seven strongly bonded orbitals (see Fig. 1) (47). King (48) has proposed that such systems be termed "globally delocalised" as opposed to "edge-localised". Hence, the octahedral cluster $B_6H_6^{2-}$ has seven skeletal electron pairs and is globally delocalised while the cluster C_8H_8 (cubane) has twelve skeletal electron pairs and is edge-localised.

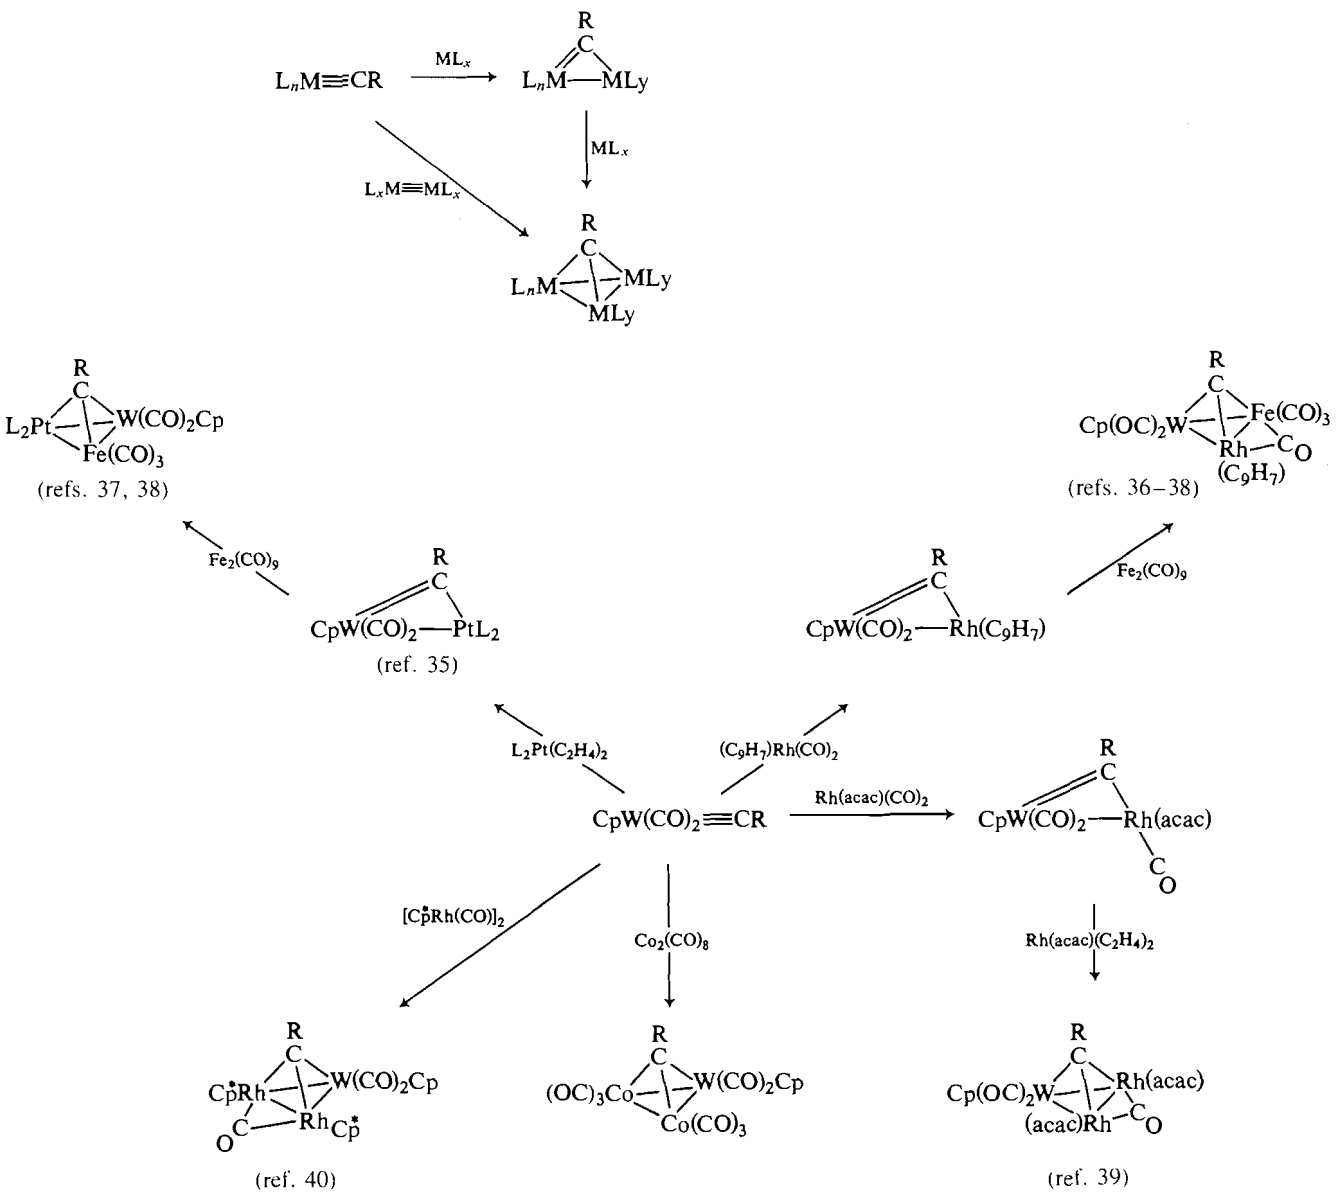

SCHEME 4

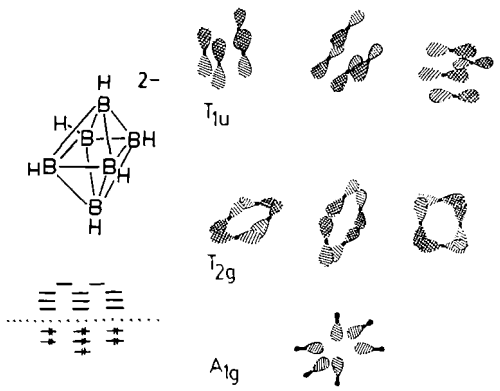

FIG. 1. The bonding molecular orbitals of $B_6H_6^{2-}$.

Returning to the case of $Ru_6(CO)_{18}^{2-}$, **6**, it has been shown in an important paper by Mingos (49) that a parallelism exists between the symmetry-adapted linear combinations of *p* and *sp*-hybridized orbitals of the boranes and those derivable from the *d* orbitals of metal carbonyl fragments. Several of these are shown in Fig. 2 and they provide a solid basis for the electron-counting schemes proposed by Wade (50) for boranes, carboranes, and transition metal clusters. The general conclusions which emerged from these considerations have a profound yet greatly simplifying effect on our view of clusters. The bonding in the six-vertex $B_6H_6^{2-}$ molecule is readily visualized as involving seven globally delocalised electron pairs. Indeed it has been shown (50, 51) that each of the $B_nH_n^{2-}$ systems gives rise to $n + 1$ bonding orbitals and some typical geometries and electron counts are shown in Fig. 3. As a corollary, one can invert this reasoning so as to state that a given number of skeletal electron pairs is associated with a particular molecular geometry. Typically, the clusters possessing 16 skeletal electrons are predicted to be based on the pentagonal bipyramid. This is indeed the case as exemplified by the boranes $B_7H_7^{2-}$, B_6H_{10} (≡ $B_6H_6^{4-}$) and B_5H_{11} (≡ $B_5H_5^{6-}$) shown in Fig. 4. These molecules may all be considered to be based on the same

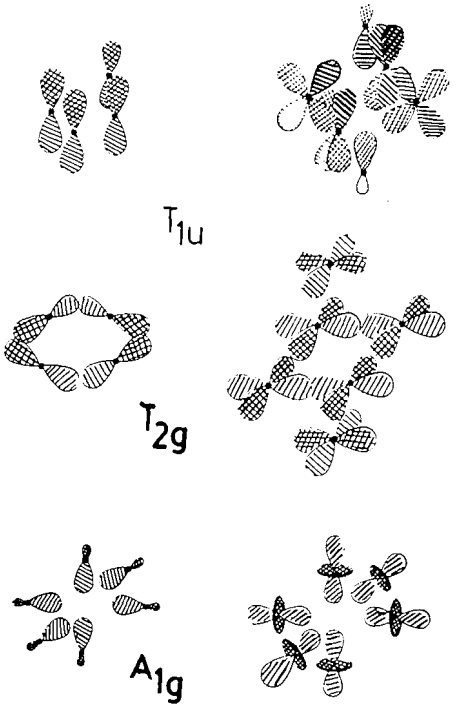

FIG. 2. Symmetry-adapted linear combinations of orbitals derived from BH and $M(CO)_3$ fragments.

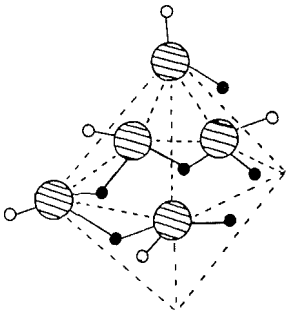
deltahedron[2] but with zero, one, and two unoccupied vertices, respectively. These have been termed *closo* (closed cage), *nido* (nest), and *arachno* (cobweb) molecules, respectively; although the more open structures would imply that electron density is being positioned in regions of space not proximate to nuclei (a physically unrealistic circumstance (52)) such is not really the case since in the neutral boranes the open faces are stitched up by bridging protons as in **8**.



8

We can now clearly draw the parallel between the HB unit which presents three orbitals and two electrons and the $(OC)_3Fe$ moiety which likewise donates three orbitals and two electrons to the cluster (see Fig. 5). Of course, the HB unit is really a 4-electron system with two *exo*-skeletal electrons in the HB bond; the $(OC)_3Fe$ moiety is a 14-electron system which uses twelve *exo*-skeletal electrons to form a σ and a π bond between the metal and each of the three carbonyl ligands. Indeed, in several important papers by Fehlner (53, 54), the interchangeability of BH and $Fe(CO)_3$ moieties has been nicely

[2]A deltahedron is a convex polyhedron of maximum compactness, i.e., all the faces are triangular.

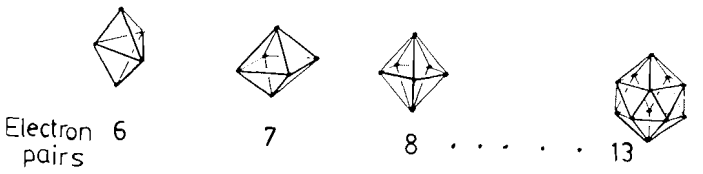


FIG. 3. Polyhedra corresponding to a particular number of skeletal electron pairs.

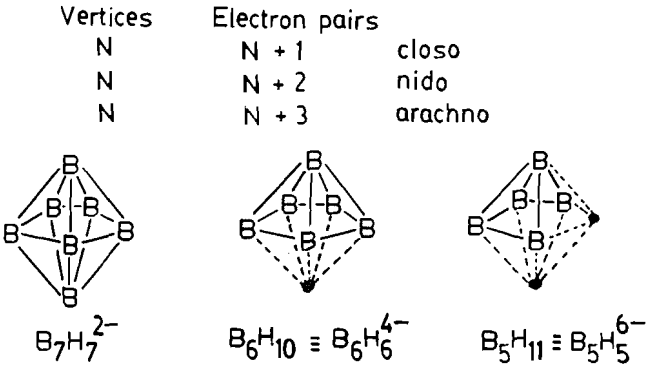

FIG. 4. Examples of boranes possessing eight skeletal electron pairs.

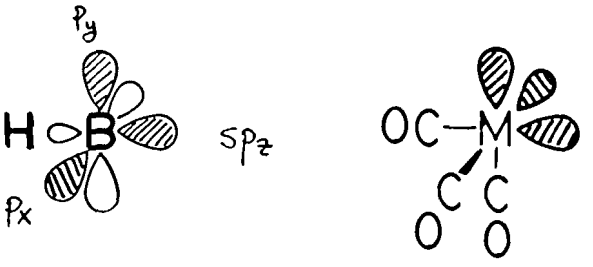

FIG. 5. The isolobal moieties BH and $M(CO)_3$.

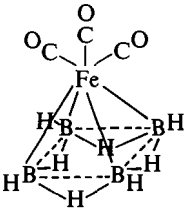
exemplified. Thus, the series $B_nH_{n+4}(Fe(CO)_3)_{5-n}$ exists for $n = 5$, 4, and 3 and they adopt the square-based pyramidal (i.e., *nido*-octahedral) geometry as typified (55) by $B_4H_8Fe(CO)_3$):



The situation in which chemically very different groups provide frontier orbitals of similar number, symmetry, extent in space, and energy has been skillfully exploited by Hoffmann (56, 57); thus one can regard the pentacarbonylmanganese and methyl radicals as being "isolobal" (58–60), each providing a single orbital containing one electron. Likewise, a parallel may be drawn between the tricarbonylcobalt moiety and the CH fragment which each provide three orbitals and three electrons to a cluster.

So, using these ideas developed by Wade (61, 62) and Mingos (63) one can classify cluster vertices as being *n*-electron donors to the cluster skeleton, as listed in Table 1.

Thus far we have for the most part summarized the ideas

TABLE 1. Some typical cluster vertices and their electron counts

Fragment	Total number of electrons	Number donated to cluster
HB	4	2
HC	5	3
$(OC)_3Cr$	12	0
$(OC)_3Fe$	14	2
$(OC)_3Co$	15	3
CpCo	14	2
CpNi	15	3
$CpMo(CO)_2$	15	3

TABLE 2. Electron counting in clusters

Cluster	Total valence electrons	=	*Exo*-skeletal electrons	+	Cluster electrons	
$B_6H_6^{2-}$	26		6×2		14	*closo*
$Ru_6(CO)_{18}^{2-}$	86		6×12		14	*closo*
$Rh_6(CO)_{16}$	86		6×12		14	*closo*
$Fe_5(CO)_{15}C^a$	74		5×12		14	*nido*
$Os_5(CO)_{15}^{2-}$	72		5×12		12	*closo*
$Co_4(CO)_{12}$	60		4×12		12	*nido*
$Fe_4(CO)_{13}^{2-}$	60		4×12		12	*nido*

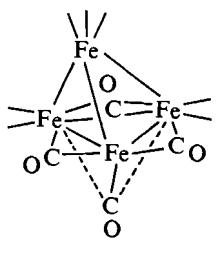
"This molecule has a square-based pyramidal arrangement of $Fe(CO)_3$ groups with the carbon atom slightly displaced below the centre of the basal plane.

developed by others; there are two reasons for this. Firstly, the transition metal chemist with a primary interest in catalysis frequently has little time to follow the intricacies of borane chemistry and the different approaches to bonding and electron-counting which derive therefrom. Secondly, we shall show that these ideas are not restricted merely to a prediction of molecular geometry but can also be used to rationalise reactivity and molecular dynamics.

Fluxionality and reactivity in clusters

Table 2 shows the application of the Wade–Mingos theory to various clusters which are then categorised as being *closo*, *nido*, or *arachno* molecules.

Now tetrahedral clusters with twelve skeletal electrons can be viewed in two ways. One could regard them as having localised bonding with one electron pair along each of the six edges of the tetrahedron. Conversely, one might regard the six electron pairs as being delocalised and hence the molecule is formally a *nido* trigonal bipyramid. Of course, such a point of view may be a purely semantic difference but photoelectron data (64) on the $RCCo_3(CO)_9$ systems support the idea of electron delocalisation. Furthermore, in $Fe_4(CO)_{13}^{2-}$, **9**, the triply bridging carbonyl (65) seems to serve the same purpose as do bridging hydrogens in *nido*-boranes.



9

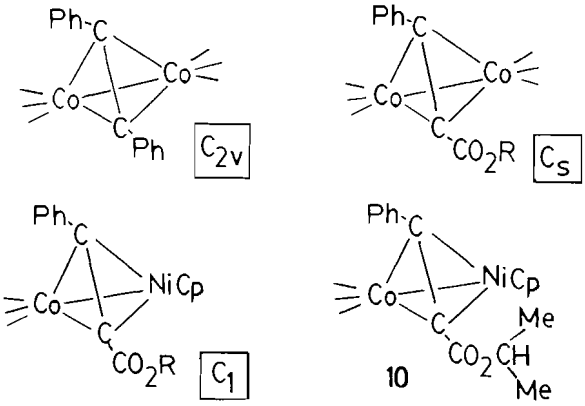


FIG. 6. Tetrahedral alkyne-bimetallic clusters.

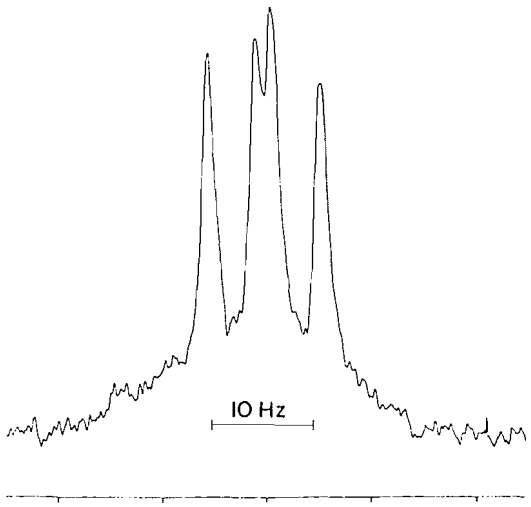

FIG. 7. 400 MHz ^1H nmr spectrum of **10**.

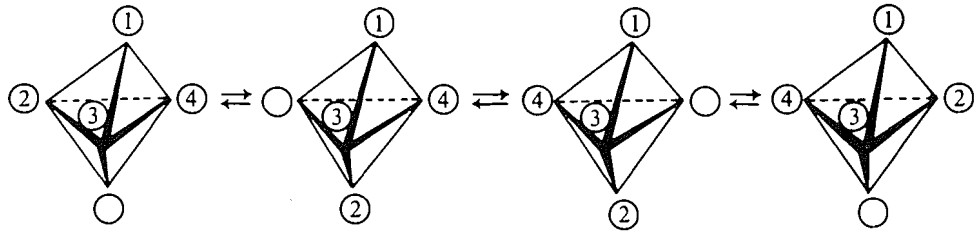
Now, if the tetrahedral clusters are viewed as *nido*-trigonal bipyramids they have a vacant coordination site on the surface of the polyhedron and may thus be regarded as being coordinatively unsaturated. The presence of a vacant site suggests that such clusters might be capable of reversibly coordinating suitable addenda and so may be of much higher reactivity than their formal 18-electron count would indicate. Furthermore, one could visualise that the vacancy might permit some structural flexibility with only a low activation energy barrier to rearrangement. A viable analogy may be drawn with SF_4 which in VSEPR terms is a trigonal bipyramid with a lone pair in an equatorial position (66). The detection of fluxionality in tetrahedral organotransition metal clusters is by no means a trivial undertaking although several previous studies (67, 68) had suggested that it might be possible. As shown in Fig. 6, one can systematically reduce the symmetry of the $(RC{\equiv}CR)Co_2(CO)_6$ (C_{2v}) to C_s by using an unsymmetrical alkyne and to C_1 by using two different metals as in $(RC{\equiv}CR')CpNiCo(CO)_3$ (69). This molecule is now chiral and so incorporation of an isopropyl group as in **10** provides a pair of diastereotopic methyl groups which can only be equilibrated via a process which racemises the chiral cluster.

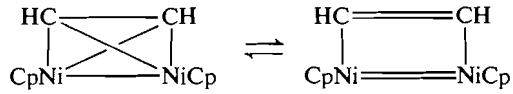
Figure 7 shows the 400 MHz ^1H nmr spectrum of the isopropyl methyl groups of **10**. At room temperature interconversion of the diastereotopic methyls is slow on the nmr time scale and so each methyl appears as a doublet. At 100°C the peaks coalesce and the activation energy for the process is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.



SCHEME 5

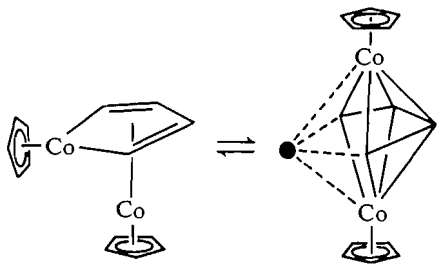
~21 kcal/mol. Hoffmann (70) has calculated a barrier of 20.5 kcal/mol for the tetrahedral–planar interconversion process shown below.



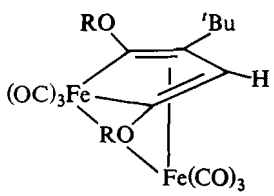
However, one could also visualise that racemisation might proceed via the mechanism in Scheme 5; this process would not involve scission of a formal bond, merely the migration of a cluster vertex into a vacant site on a surface. Nevertheless, more examples must be studied before a clear mechanistic understanding emerges.

This phenomenon of fluxionality of *vertices* is gradually gaining credence as more examples emerge; in contrast, fluxionality of peripheral *ligands*, such as carbonyls, which can migrate over cluster surfaces, is a well-established and widely-studied process (71). Nevertheless, Johnson has proposed (72, 73) that in molecules such as $Fe_3(CO)_{12}$ the fluxionality can be rationalised in terms of rotation of the metal triangle within a polyhedron of carbonyl groups. Indeed, solid state ^{13}C nmr studies by Hanson (74) and crystallographic data by Bruce (75) give some support to this proposal. Furthermore, a perusal of the literature reveals that fluxionality of vertices was observed some years ago but its potential generality was not appreciated.

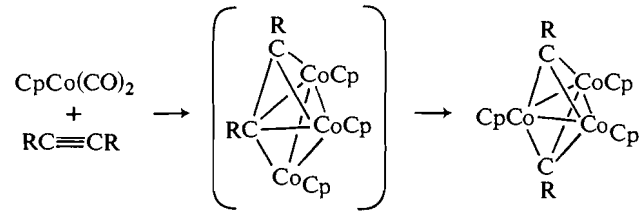
Typically, in the molecule $(CpCo)_2C_4H_4$, the two CpCo groups are equilibrated at high temperature (76). We see now that this molecule can be classified as a *nido*-pentagonal bipyramid (eight skeletal electron pairs); its nmr fluxionality is now readily explicable — perhaps via the alternative *nido*-structure shown below:



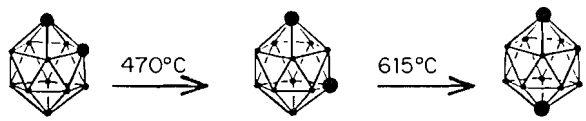
Analogous reasoning can be applied to the facile racemisation of Whiting's (77) ferro-ferradiene:



A particularly interesting reaction in this vein is that reported by Vollhardt (78), in which acetylenes and $CpCo(CO)_2$ react to furnish *closo*-clusters in which the two carbon atoms are no longer contiguous. One might speculate that in the initial product the carbon atoms are proximate but that rotation of a triangular face or reversible distortion to a square-based pyramid yields the thermodynamically favored isomer with two axial carbons; this structure also satisfies the requirements of eighteen electrons for cobalt and eight for carbon. (It has recently been suggested (79) that the rearrangement and acetylene-splitting may actually occur at the $Cp_3Co_3R_2C_2(CO)$ stage.)



Of course, rearrangements of *closo*-clusters require much higher activation energies than do those of *nido*-clusters which possess a vacancy on the polyhedral surface; this is exemplified in the icosahedral carborane series, $C_2B_{10}H_{12}$ (80):



In keeping with this view, Geoffroy (81) has shown that a *closo*-transition metal cluster can rearrange but only on the (slow) chemical time-scale rather than the much faster nmr time-scale.

Another consequence of the vacant coordination site in a formally *nido*-cluster is the expectation of high reactivity. In accord with this prediction (82) the clusters **10** through **12**, when stirred with $Fe_2(CO)_9$ in refluxing tetrahydrofuran, undergo very facile addition of an $Fe(CO)_3$ moiety as shown in Scheme 6. The products **13** through **15** have been characterised crystallographically and, as befitting their fourteen skeletal electron count, they have the square-based pyramidal geometry appropriate for a *nido*-octahedral molecule. It is noticeable, however, that in **13** and **14** the $Fe(CO)_3$ unit caps the base which is comprised of the four original vertices; furthermore the electronic configuration at each atom follows the E.A.N. formalism. In contrast, in **15** the $CpMo(CO)_2$ moiety is the capping unit and the iron, nickel, and molybdenum atoms have 17-, 18-, and 19-electron counts, respectively. This difficulty is removed and the E.A.N. rule may be disregarded when we

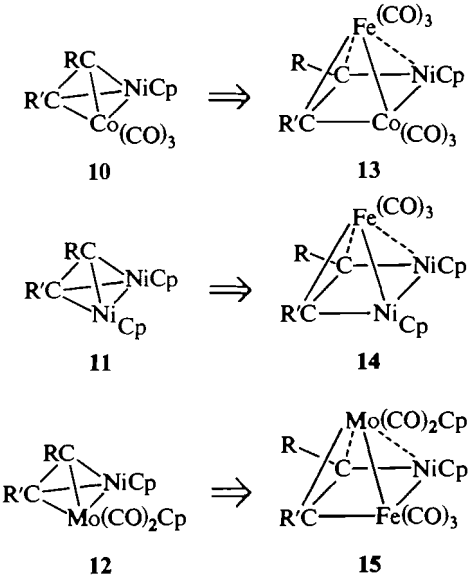

SCHEME 6

realise that the molecule has seven globally delocalised electron pairs. The particular orientation, **15***a*, *b*, or *c*, which occurs in the solid state should not particularly worry us since in solution the molecules **13** through **15** are fluxional. Typically, the variable-temperature ^{1}H nmr spectra of the cyclopentadienyl protons of **14** are shown in Fig. 8 and reveal a fluxional process with a barrier of 15 kcal/mol. Formally, one could view this rearrangement as a rotation of the alkyne moiety relative to the triangle of metal atoms. Such phenomena have been observed previously (83–88) and are usually interpreted in terms of the alkyne being σ-bonded to two atoms and π-bonded to a third. However, these are merely valence bond representations designed to satisfy the E.A.N. formalism and are unnecessary in the approach used here. Gratifyingly, other systems have been described (89) for which the 18-electron rule is inappropriate but which are well accommodated by the present model. A particularly nice example is provided by the molecule $Cp_2W_2Os(CO)_7R_2C_2$, **16**, recently studied by Stone (90); in this case the square-based pyramid (i.e., *nido*-octahedron) can have either osmium, **16***a*, or tungsten, **16***b*, as the capping atom and the crystallographic data show both rotamers to be present in the same crystal.

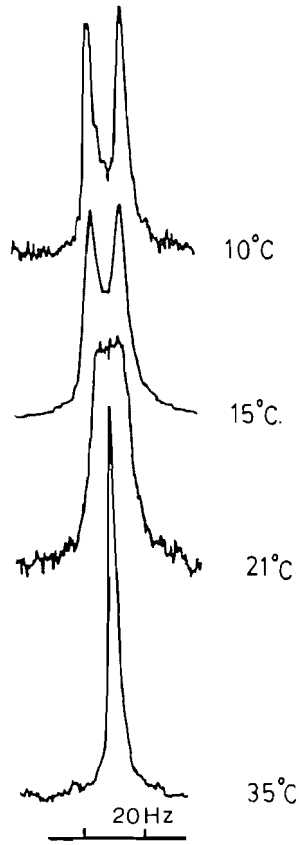

FIG. 8. Variable-temperature 80 MHz ^{1}H nmr spectra of the C_5H_5 protons of **14**.

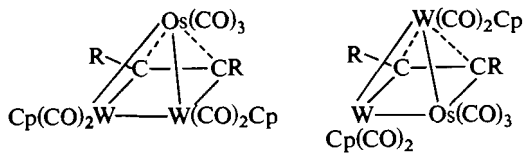
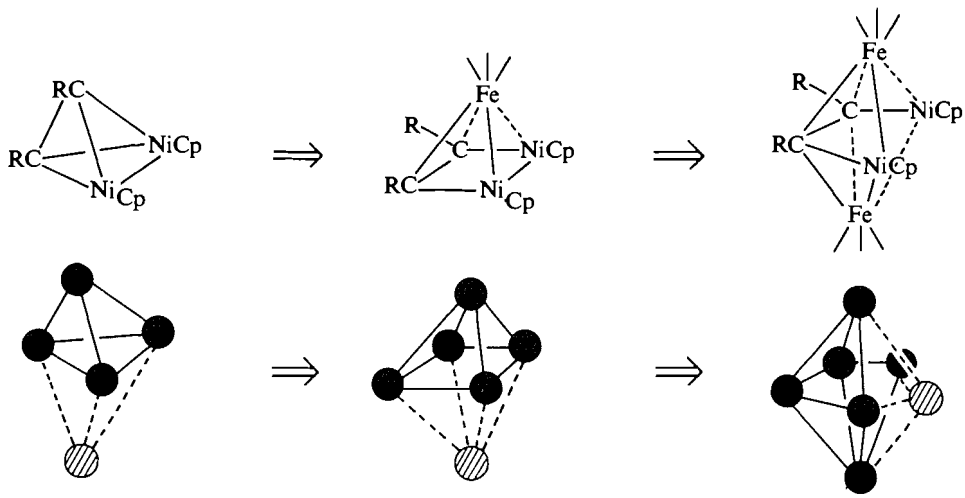


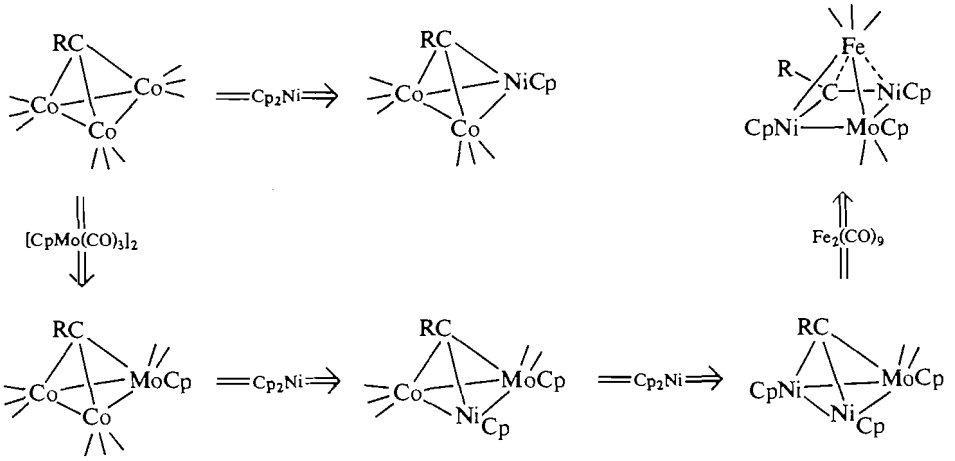
Expansion and substitution reactions in clusters

We can, therefore, summarise the reactivity patterns of *nido*-clusters by stating that they undergo addition reactions with 2-electron donors (e.g., $Fe(CO)_3$, $Os(CO)_3$, etc.) to produce the homologous *nido*-cluster with one more vertex. Scheme 7



SCHEME 7

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

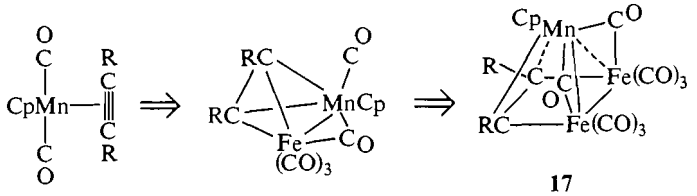


SCHEME 8

exemplifies this concept for the successive addition of $Fe(CO)_3$ moieties to the $(RC{\equiv}CR)Ni_2Cp_2$ molecule (82, 91).

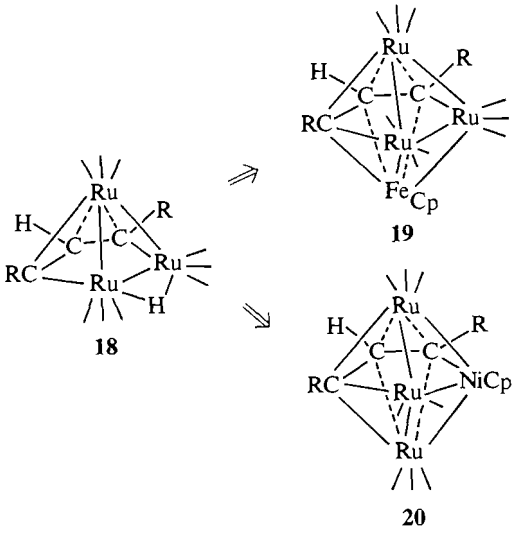
We next consider the reactions of 3-electron donor reagents with *nido*-clusters. It is apparent that addition of such a moiety, such as CpNi or $CpMo(CO)_2$, would lead initially to expansion of the cluster giving the next highest *nido*-molecule. However, the extra electron must now reside in an orbital possessing some anti-bonding character and so would destabilise the cluster. Clearly elimination of the original or another 3-electron unit would regenerate a molecule of the original *nido*-geometry. The net result would be substitution of one 3-electron donor by another. Scheme 8 gives some of our synthetic results which support this assertion. Note that the final unit added is the 2-electron donor $Fe(CO)_3$ which, of course, results in cluster expansion. The elegant work of Vahrenkamp (92–94) is also entirely consistent with this picture.

It is also possible to rationalise other synthetic results within this framework. Thus, Geoffroy has replaced a $Co(CO)_3$ unit by the isolobal $Fe(CO)_3^-$ moiety in a tetrahedral cluster (95). Furthermore, recent Russian work (96) has described the addition of $Fe_2(CO)_9$ to a $CpMn(CO)_2$ ($RC{\equiv}CR'$) complex. Formally, one could regard the starting material as being a *nido* tetrahedron;[3] now successive addition of two $Fe(CO)_3$ units leads to the 14-skeltal electron species **17** which satisfies the criteria for a *nido*-octahedral complex. The isolobal analogy relates the first reaction to Stone's synthetic pathway exemplified in Scheme 4.



17

Now, in principle, it should be possible to cap a *nido* organo-transition metal cluster by the addition of a zero-electron donor such as $Cr(CO)_3$ or CpMn. Recently, Italian workers (97) have essentially achieved this goal in an indirect manner by adding a 13-electron unit (i.e., a 1-electron donor) and eliminating a hydrogen atom. Reaction of the cluster **18** with $[CpFe(CO)_2]_2$ provides a CpFe moiety to cap the open pentagonal face while loss of the bridging hydrogen atom leaves the skeletal electron



18 **19** **20**

count at 16 but now describable as a *closo* cluster, **19**. Analogously, treatment of **18** — with $[CpNi(CO)]_2$, a source of the 3-electron donor CpNi — leads to the *closo* cluster **20** with concomitant loss of CO and a hydrogen atom.

Epilogue

It is clear from the work of numerous laboratories that the analogy between the structures of boranes and transition metal clusters is an exceedingly useful one. There are, however, some limitations which must be recognized. Thus, the gradually accumulating data on large clusters, such as those obtained in the pioneering studies by Chini and colleagues (98), are more reminiscent of close-packed metal atoms surrounded by a surface coating of ligand than of borane analogues. Molecular orbital studies by Lauher (99) have analysed the changes involved in proceeding gradually from trimetallic systems to large multi-metallic clusters. Indeed, it is of interest to find out at what point the nature of cluster bonding begins to deviate from that rationalizable using the Wade–Mingos approach.

We have discussed already the dichotomy with tetrahedral molecules which could be regarded either as having six edge-localised skeletal electron pairs or six globally-delocalised electron pairs giving rise to a *nido*-trigonal bipyramid. For 5-, 6-, and 7-vertex clusters the borane analogy seems to hold up well but inevitably with large clusters the model will tend to break down as the central core becomes more like a close-packed metal fragment.

[3]The $CpMn(CO)_2$ unit is isolobal with CH_2 and so the starting material could also be regarded as being analogous to cyclopropene.

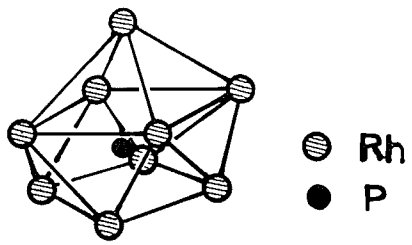
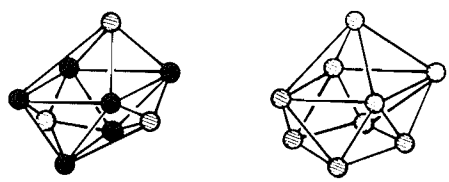
We note, however, that even a 9-vertex cluster can still behave according to the concepts described in this article. The cluster $[Rh_9P(CO)_{21}]^{2-}$, **21**, does not satisfy the E.A.N. rule but is well accounted for by the Wade–Mingos model. $[Rh_9P(CO)_{21}]^{2-}$ has 130 valence electrons and subtraction of 9 × 12 (= 108) electrons for the *exo*-skeletal ligands leaves 11 electron pairs for cluster bonding. We expect then that the molecule should adopt the shape of the 10-vertex deltahedron, viz., the bi-capped square antiprism, but with a vertex missing since this should be a *nido* molecule.



21

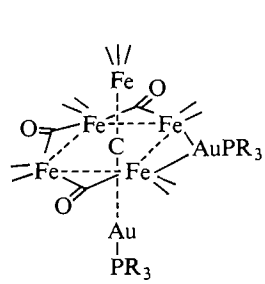
This structural prediction has been confirmed crystallographically (100) and, furthermore, our assertion that a *nido* molecule should be fluxional also has experimental support. In a very fine demonstration of the growing awareness of transition metal nmr spectroscopy, it has been shown by variable-temperature ^{103}Rh nmr that the molecule exhibits a 4:4:1 pattern of rhodium environments at low temperature but only a single line at room temperaure (101). Although no precise exchange mechanism has been elucidated for the Rh complex, we note the resemblance to another set of 9-vertex clusters, viz., Bi_9^{5+}, **22** and Sn_9^{4-}, **23** (102, 103).



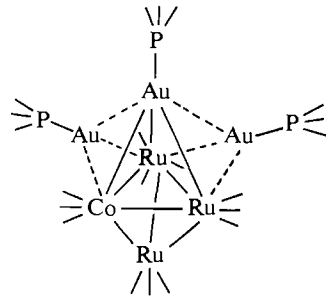
22 **23**

In **22** and **23** both clusters are classifiable as *nido* molecules[4] and it is known that the interconversion barrier for a monocapped square antiprism (C_{4v} symmetry) and the tricapped trigonal prism (D_{3h} symmetry) is rather low (103, 104). Indeed, Sn_9^{4-} has been shown to be fluxional using ^{119}Sn nmr spectroscopy (105); the analogy to the rhodium cluster **21** is thus readily apparent.

Finally, we turn to the fascinating question of the bonding modes available to the phosphine–gold moiety which has recently been incorporated into a number of systems. The simplest view of the R_3P—Au functionality is that it is isolobal with a hydrogen atom, that is, it provides a single orbital contributing only one electron to a cluster. This picture is given credence by recent work from the Lewis–Johnson group at Cambridge who have elucidated the structures of a series of Gp VIII metal clusters with phosphine–gold bridges (106, 107). Typically, in $Fe_5(CO)_{14}C(AuPPh_3)_2$, **24**, the molecule adopts essentially octahedral geometry and the 14 skeletal electron count requires only a single electron from each gold whether they be bridging or capping atoms. Similarly, Bruce (108) has developed a route to gold-containing clusters; for example, $HCoRu_3(CO)_{13}$ and $(Ph_3PAu)_3O^+$ react to give $CoRu_3(CO)_{12}(AuPPh_3)_3$, **25**, in which the Ph_3P—Au moieties have replaced bridging hydride and carbonyl units in the original cluster.

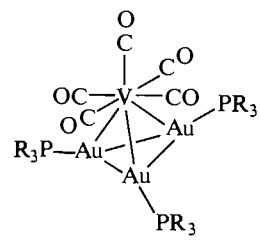


24



25

Nevertheless, other structures are extant in which this simple view is more problematical. Thus, Mingos (109) has pointed out that "although to a first approximation the $Au(PH_3)$ fragment can be considered to be isolobal with fragments such as CH_3, $Mn(CO)_5$, and $Co(CO)_4$ which have only a single frontier orbital available for bonding, it is necessary to also take into account the secondary contributions made by the $6p_x$ and $6p_y$ orbitals of gold". In spite of this, Mingos chose to describe $(Ph_3PAu)_3V(CO)_5$, **26** (110), as possessing only a single skeletal electron pair to hold together the tetrahedral cluster. However, if one were to regard the R_3P–Au unit as a three frontier orbital,[5] three-electron moiety (i.e., isolobal with CH) it can be more plausibly viewed as possessing 8 skeletal electrons, as follows: the $(R_3PAu)_3^+$ framework is an 8 electron unit isolobal with the cyclopropenium ion, $C_3H_3^+$; this can now be capped by $V(CO)_5^-$ which is isolobal with CH_3^+ (or CH_2 or CH^-) (57). In its simplest isolobal terms, $(R_3PAu)_3V(CO)_5$ corresponds to $C_4H_6^{2+}$, i.e., diprotonated tetrahedrane.



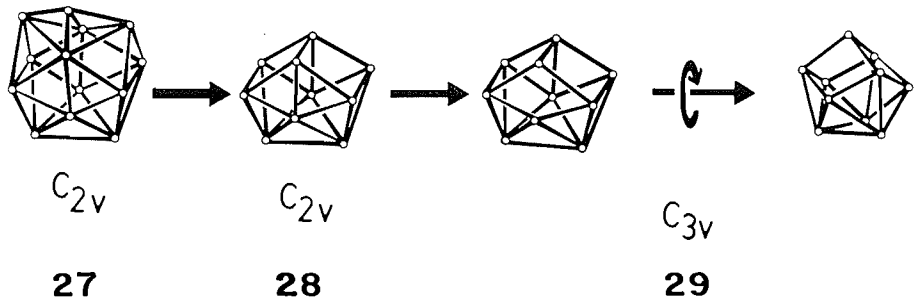
26

Indeed, to extend the analogy of gold clusters and boranes, one can consider the $Au_{11}(R_3P)_7I_3$ molecule which has a central gold atom (111). If the seven R_3P—Au fragments each contribute 3 skeletal electrons, the three Au—I vertices donate 2 skeletal electrons each and the central gold atom only 1 (i.e., it retains its d^{10} shell), we have 28 skeletal electrons and so the cluster should be based on the 13-vertex polyhedron. This polyhedron has been described by Lipscomb (112) and is produced by inserting a vertex of order 4 into any edge of the

[4]Each molecule has 40 valence electrons. Subtraction of an *exo*-skeletal lone pair for each of these main group atoms leaves 22 electrons for cluster bonding.

[5]These three orbitals are p_x, p_y, and the hybrid sd_{z^2}.

icosahedron, as in **27**. Now the Au_{11} complex must be a *hypho*-cluster and removal of three vertices yields the observed geometry **29**. However, the presence of the three iodide ligands gives the impression of threefold symmetry although, as the original authors have indicated (111), it is slightly distorted from idealised C_{3v} symmetry. One might venture a prediction that the analogous $(R_3P)_{10}Au_{11}^{3+}$ molecule would adopt the C_{2v} structure, **28**.



27 **28** **29**

Taking this analogy to its extreme, one could assign to the $(R_3P{-}Au)_6^{2+}$ molecule 16 skeletal electrons. We note that the geometry is not that of a regular octahedron but in fact the molecule is distorted along a threefold axis (113). This is somewhat reminiscent of XeF_6 (114) which in VSEPR terms (66) is an AX_6E case with two electrons too many for the regular octahedral structure.

To conclude, the current picture of metal clusters reveals that for a low nuclearity cluster with a high ligand-to-metal ratio the E.A.N. rule applies and we can assign each transition metal 18 electrons in localised bonds. As the ligand-to-metal ratio decreases we see a gradual increase in the delocalisation of electron density within the cluster framework; this behaviour parallels that observed in borane, carborane, and main group cluster chemistry. Finally, with even larger clusters of transition metal atoms, the regions of delocalised electron density are seen to merge almost into a conventional metallic structure in the centre of the cluster while the ligands merely coat the molecular periphery; the relationship to surface chemistry thus becomes more pronounced. A very nice example of the gradual transition from a cluster to a conventional metal is provided by the tetra-capped *closo*-octahedral cluster $Os_{10}C(CO)_{24}^{2-}$, for which the relationship to the face-centred cubic unit cell is readily apparent (115).

An iridium(III) hydride complex has been used in solution under a hydrogen/oxygen atmosphere at ambient temperatures to catalyze slowly the selective oxygenation of cyclooctene to cyclooctanone. The H_2 acts as a two-equivalent reducing agent in accepting the second oxygen atom of the O_2 molecule to generate water. The overall reaction shows similarities to catalytic oxygenation reactions performed by a class of P450 enzymes. Spectroscopic evidence for the iridium system indicates an oxygen atom transfer to the olefin via a hydroperoxide intermediate (IrOOH), formed by insertion of O_2 into the metal hydride bond; the hydride is thought to be regenerated, together with formation of water, by hydrogenolysis of the resulting iridium-hydroxo species. Catalytic hydrogenation of the monoene as well as hydrogenolysis of oxygen to water are observed as competing reactions. Some related rhodium systems do not give selective oxidation products.

MARK T. ATLAY, MICHAEL PREECE, GIORGIO STRUKUL et BRIAN R. JAMES. Can. J. Chem. **61**, 1332 (1983).

On a utilisé un complexe d'hydrure d'iridium(III) en solution sous atmosphère d'hydrogène/oxygène à la température ambiante pour catalyser lentement l'oxygénation sélective du cyclooctène en cyclooctanone. Le H_2 agit comme deux équivalents d'agent réducteur en acceptant le second atome d'oxygène de la molécule de O_2 pour produire de l'eau. La réaction globale montre des similitudes avec les réactions d'oxygénation catalytique réalisées par une classe d'enzymes P450. Les preuves spectroscopiques dans le cas du système iridium indiquent un transfert d'atome d'oxygène sur l'oléfine via un intermédiaire hydroperoxyde (IrOOH), formé par insertion de O_2 dans la liaison hydrure métallique. On pense que l'hydrure est regénéré de concert avec formation d'eau, par hydrogénolyse de l'espèce iridiumhydroxo résultant. On observe comme réaction de compétition une hydrogénation catalytique du monoène aussi bien qu'une hydrogénolyse de l'oxygène en eau. Quelques systèmes apparentés de rhodium ne donnent pas de produits d'oxydation sélective.

[Traduit par le journal]

Introduction

The chemical behaviour of O_2 after coordination, that is the activation of O_2, is a complex subject because of the many pathways available for O_2 reactions (1, 2). The search for more selective oxidations, especially using O_2, is a prime goal that has immense potential on an industrial scale (1–4), and is thus an important research area. The ultimate aim would be to mimic the O_2-activation properties of enzyme systems, for example, the ability of cytochrome P450 to catalyze the general reaction [1] of monooxygenases, where **S** can be a saturated or olefinic hydrocarbon (5–7). The preferred electron donor in the enzyme systems is the hydride of NADH.

$$[1] \quad \mathbf{S} + O_2 + 2c \xrightarrow{2H^+} \mathbf{SO} + H_2O \ (\mathbf{S} = \text{substrate})$$

The selective O_2-oxidation of olefins to ketones by a single oxygen atom transfer process catalyzed by rhodium complexes is well documented (7, 8); in some of these systems the second oxygen atom of the O_2 molecule is reduced concomitantly by a two-equivalent reducing agent (for example, added triphenylphosphine that is oxidized to the oxide (9), or two olefinic hydrogen atoms that are converted to water (8)), and analogies have been drawn to reaction [1].

An accidental finding in this laboratory over a decade ago (10) has led us to study the use of H_2 as the coreductant for monoxygenase-type activity. Heterolytic cleavage of the molecular hydrogen via a transition metal complex, reaction [2] (11, 12), can in principle furnish the hydride requirement of the metalloenzyme system.

$$[2] \quad M + H_2 \rightleftharpoons MH^- + H^+$$

Some aspects of the early studies (10) are presented here for they are important in terms of mechanistic considerations to be discussed later. While studying solvent effects on catalytic hydrogenation, we discovered a Rh(III)-catalyzed H_2 reduction of dimethylsulfoxide (DMSO) to the sulfide and water, and suggested a mechanism involving a hydrido-rhodium(III) intermediate containing a S-bonded sulfoxide (cf. reaction [2]). The reaction rates eventually decreased because of a buildup of inactive Rh(I), formed according to reaction [3], and stabilized by the dimethylsulfide produced.

$$[3] \quad HRh(III) \rightarrow H^+ + Rh(I)$$

In an attempt to maintain catalytic activity by reoxidation of the Rh(I), some O_2 gas was added to the H_2 atmosphere. This led to a surprising catalytic oxidation of the sulfoxide to the sulfone and water according to reaction [4] (10).

$$[4] \quad Me_2SO + O_2 + H_2 \ (\text{or } H^- + H^+) \rightarrow Me_2SO_2 + H_2O$$

Neither the Rh(III) nor Rh(I) species under O_2 alone performed the catalytic oxygenation of sulfoxide to sulfone, implying strongly that a rhodium hydride was the effective O_2 carrier. Trocha-Grimshaw and Henbest (13) also had found that isopropanol solutions of Rh(III) and Ir(III) salts carried out the same oxidation using just O_2, and such a medium is known to be effective for promoting formation of metal hydride species (14).

Our increasing interest in, and awareness of, P450 enzymes and some nonprotein model systems (15, 16), coupled with the earlier observations outlined above, encouraged us to test rhodium(III) and iridium(III) complexes as catalysts for the O_2 co-oxidation of olefins and molecular hydrogen. reports on the successful catalytic oxidation of cyclooctene to cyclooctanone according to reaction [5], using the 1,5-cyclooctadiene (cod) dimer, $[IrHCl_2(C_8H_{12})]_2$ (17).

[5] $C_8H_{14} + O_2 + H_2 \rightarrow C_8H_{14}O + H_2O$

A communication on some of the work described here has been published previously (18).

Experimental

The iridium and rhodium were obtained mainly from Johnson Matthey Ltd. as hydrated trichlorides containing 51.76% and 41.37% of the metal, respectively, while $RhBr_3 \cdot 2H_2O$ was a Platinum Chemicals product. The dimeric 1,5-cyclooctadiene (cod) and cyclooctene complexes $[IrHCl_2(C_8H_{12})]_2$, $[MCl(C_8H_{12})]_2$, and $[MCl(C_8H_{14})_2]_2$ (M = Ir, Rh) were prepared according to literature procedures (17, 19–21). The complexes $IrHCl_2(DMSO)_3$ (22) and $RhCl_3(DMSO)_3$ (23) with meridional dimethylsulfoxide ligands were also synthesized via published methods. 1,5-Cyclooctadiene, cyclooctene, cyclooctanone, and other organic compounds (Aldrich) were distilled or recrystallized before use; peroxide impurities in liquid olefins were removed by passage through an alumina column under N_2. Professor C. B. Anderson kindly provided a sample of 4-cyclooctene-1-one.

Other materials used and the procedure used for following gas-uptake at constant pressure have been described previously (24); the metal complexes could be added if necessary from a glass bucket held over the substrate solutions via use of side-arms on the reaction vessel. N,N′-Dimethylacetamide (DMA) was stirred with CaH_2 overnight and then vacuum-distilled. A convenient way of adding HCl quantitatively was in the form of the solid dimethylacetamide adduct DMA·HCl, that is readily made by bubbling HCl gas through the amide solvent (25).[3] Matheson O_2 and H_2 (99.99% grade) were used as such.

Organic products were identified by gc and ms; OV-101/chromasorb and Porapak Q were the gc column materials for the organic products and water, respectively, using 2-bromomesitylene and methanol as internal standards.

Results and discussion

Of a range of systems tested for selective oxidation of olefins (see below), the most interesting proved to be one based on iridium. Although the catalysis, the selective conversion of cyclooctene to cyclooctanone, is very slow and inefficient, it has allowed for some mechanistic studies that demonstrate, for the first time, oxygen atom transfer to an olefin from a metal hydroperoxide intermediate.

Dimethylacetamide solutions of $[IrHCl_2(C_8H_{12})]_2$ (**I**) (0.01–0.03 *M*) in the presence of at least a ten-fold excess of cyclooctene and a five-fold excess of HCl (added as DMA·HCl) absorb gas from hydrogen/oxygen mixtures at a total pressure of 1 atm and temperatures between 5–30°C to generate catalytically cyclooctanone and water as products (reaction [5]). At 5°C with 350 Torr of each gas, the turnover for cyclooctanone per iridium is about two per day based on week-long experiments. Gas-uptake measurements, that usually provide a convenient method for studying the kinetics and stoichiometry of such homogeneous catalytic reactions, proved to be of little value in studying reaction [5], because it is accompanied by a competing catalytic hydrogenolysis of the oxygen:

[6] $2H_2 + O_2 \rightarrow 2H_2O$

[3] Details on this adduct will be published later; a crystal structure reveals protonation at the oxygen atom and essential planarity at the carbonyl carbon atom [$-C(O^-)=N^+<$].

The net gas uptake is very much greater than that expected for the stoichiometry of reaction [5], as determined by the concentration of cyclooctanone (the sole organic product seen by gc). Indeed, the gas-uptake stoichiometry corresponds within experimental error to that expected for reaction [6], because the H_2O:cyclooctanone ratio at the early stages of the reaction (5°C, 350 Torr H_2, 350 Torr O_2) was about 40 and decreased to a steady value of about 10 after one day. At 30°C, the initial rate of formation of cyclooctanone is higher, but the overall turnover number after a few days is much the same as that noted at 5°C; the oxygen hydrogenolysis reaction, however, is now even more dominant and the H_2O:cyclooctanone ratio remains at about 50.

Most important observations are that radical inhibitors have no inhibitory effect on the oxidation, and that in the absence of H_2 (at 1 atm O_2, 5°C) no oxygenation of cyclooctene occurs at all. The non-selective oxidation of cyclic olefins to mixtures of epoxide, ene-one, and ene-ol (reaction [7]) via a metal-catalyzed free-radical autoxidation reaction is well-documented for iridium(I) (and rhodium(I)) complexes (1, 2, 7); the complexes initiate the reaction by decomposing an enyl hydroperoxide (reactions [8], [9]), formed *in situ* by attack of O_2 on the radical produced by allylic hydrogen abstraction (reaction [7]).

[7] 
etc.

[8] $M^{n+} + ROOH \rightarrow M^{(n+1)+} + RO^{\cdot} + OH^-$

[9] $M^{(n+1)+} + ROOH \rightarrow M^{n+} + RO_2^{\cdot} + H^+$

A possible role of the H_2, reduction of the iridium(III) to iridium(I) that then initiates the oxidation (reactions [7]–[9]), is ruled out by the radical addition experiments and the product selectivity observed.

Evidence for a plausible mechanism for the oxidation comes from reaction of the hydride dimer **I** with oxygen, but before discussing this reaction it is necessary to consider the nature of **I** in solution. The dimer dissolves only in polar aprotic solvents of high donor number (26), and the solvated monomeric species $IrHCl_2(C_8H_{12})$(DMA), **II**, is considered to be present in dimethylacetamide solution (λ_{max} 395 nm, ϵ = 1480 M^{-1} cm^{-1}); the same solvated species is formed by addition of DMA·HCl to DMA solutions of $[IrCl(C_8H_{12})]_2$ and we have established the existence of equilibrium [10] by spectrophotometry.

[10] $IrCl(C_8H_{12})(DMA) + HCl \overset{K}{\rightleftharpoons} IrHCl_2(C_8H_{12})(DMA)$
III **II**

The $[IrCl(C_8H_{12})]_2$ complex remains as a dimer in toluene solution as evidenced by molecular weight data (19), and spectrophotometric data (λ_{max}(toluene) 454 nm, ϵ = 3600 M^{-1} cm^{-1}; λ_{max} (Nujol) 454 nm), but a quite different spectrum in DMA (λ_{max} 395 nm, ϵ = 1250 M^{-1} cm^{-1}) is again attributed to a solvated monomer **III**. Although the uv/vis spectra of **II** and **III** are remarkably similar (presumably, the common 395 nm maximum is associated with a charge transfer process involving the DMA ligand), there is a sufficient difference in the extinction coefficients to approximately estimate *K* for equilibrium [10] by a standard spectrophotometric titration pro-

cedure. Knowledge of this value, about 10^4 M^{-1} at ambient temperatures, is important for it is necessary to maintain the hydride species in solution for effective catalysis of reaction [5]. The iridium(I) species **III** is not effective for the catalytic oxidation using a H_2/O_2 atmosphere, and indeed at 1 : 1 gaseous mixtures the solution tends to precipitate metal; reaction of the cyclooctene dimer $[IrCl(C_8H_{14})_2]_2$ with H_2 in DMA to give metal has been noted previously (27). One role of the excess acid in the successful catalysis using **II** is undoubtedly to shift equilibrium [10] to the right. The basicity of the DMA solvent promotes reductive elimination of HCl from **II**; Winkhaus and Singer (28) have reported on the oxidative addition of HCl to the $[IrCl(C_8H_{12})]_2$ dimer in chloroform solution with resulting precipitation of $[IrHCl_2(C_8H_{12})]_2$.

DMA solutions of **II** (1.0–5.0) 10^{-2} M at 5°C containing an equal concentration of DMA·HCl absorb 1.0 mol of O_2 per iridium at oxygen pressures from 0.3–1.0 atm, but no free oxygenated organic compound is detected. A suspension of the hydride dimer I in CH_2Cl_2 at 20°C similarly absorbs O_2 to a 1 : 1 ratio to give a deep red solution that is conveniently monitored by ir. During the dissolution process (about 20 min), the ν(Ir—H) band (at 2260 cm^{-1} in the solid) is replaced by a strong band at 3495 cm^{-1}, considered to be the ν(O—H) of hydroperoxide (29). This band decreases in intensity and disappears with time as new bands grow in at 3680 and 3605 cm^{-1} (attributed to ν(O—H) of hydroxide), and at 1692 and 1607 cm^{-1} (attributed to ν(C—O) of free (30) and coordinated 4-cyclooctene-1-one, respectively). Addition of excess triphenylphosphine replaces the coordinated ketone which is accompanied by a corresponding decrease of the 1607 cm^{-1} band. The gas uptake stoichiometry, together with the ir data, are consistent with reaction [11] written for a monomer, and showing oxygen-atom transfer to the diene from an iridium hydroperoxide intermediate.

$$[11]\quad IrHCl_2(C_8H_{12}) \xrightarrow{O_2} Ir(OOH)Cl_2(C_8H_{12}) \rightarrow \text{“}Ir(OH)Cl_2\text{”} + C_8H_{12}O$$

Figure 1 shows changes in the 3500 cm^{-1} region as a function of time following the dissolution process; the isosbestic points are considered to arise from the constant total iridium concentration of hydroperoxide and hydroxide. Insertion of O_2 into metal hydride bonds is known for $RhH(NH_3)_5^{2+}$ (31), *trans*-$RhH(OH)(en)_2^+$ (32), and $RhH(CN)_4(H_2O)^{2-}$ (33); the presence of only ligands relatively insensitive to oxidation presumably accounts for isolation of the hydroperoxides.

The inorganic iridium product of reaction [11] has not been characterized, although after the triphenylphosphine treatment, the iridium was recovered as $IrCl(PPh_3)_3$ (34), while the phosphine oxide is indicated by the presence of a strong ir band at 1200 cm^{-1} in solid residues (35); these data provide further indirect evidence for a hydroxoiridium(III) product, reaction [12].

$$[12]\quad \text{“}Ir(OH)Cl_2\text{”} + PPh_3 \rightarrow \text{“}IrCl\text{”} + OPPh_3 + HCl$$
$$\downarrow\ 3PPh_3$$
$$IrCl(PPh_3)_3$$

Such a stoichiometric two-electron reduction using tertiary phosphines in the presence of hydroxide has been demonstrated for a platinum(IV) → platinum(II) process (36).

A metal-catalyzed oxygen-atom transfer, such as that outlined in reaction [11], has been postulated (7, 8, 29), but not previously demonstrated, although transfer from alkyl peroxides (M—OOR) is well-documented, and is usually considered to go via pseudo five-membered peroxometallocyclic intermediates (2, 8, 37). A closely similar pathway for the transfer from the hydroperoxide is suggested in equation [13].

[13] 
Mimoun (8) has proposed that the nature of the products that result from decomposition of the peroxometallocycle depends on the electrophilicity of the metal and the nature of the substrate. Epoxides are formed with highly electrophilic systems such as Mo(VI) that orient the electron transfer from the O—O bond towards the alkyl carbon atom; the less electrophilic rhodium(III), and therefore iridium(III), are considered to direct the electron transfer towards the β-carbon atom, hydride transfer from which yields the ketone, as illustrated in equation [13].

Some further indirect evidence for the role of the hydride ligand in reaction [11] is that treatment of the nonhydridic iridium(I) dimer $[IrCl(C_8H_{12})_2]_2$ with dioxygen does not give any ene-one or other characterizable oxidation product. Bonnaire and Fougeroux (38) first reported on reaction of the dimer with *air* in dichloromethane or benzene and suggested formation of a hydroxo-iridium species with the diene still coordinated, while Louw and Hepner (39) noted that such dimer solutions were stable toward oxygen. Our findings are contrary to the latter workers. As a dimer in benzene or toluene solutions or as a solvated monomer in DMA, the iridium(I)-cod species is sensitive to O_2. The extent of O_2 absorption at 5°C is about 0.65 mol O_2 per iridium. A mixture of yellow and brown iridium-containing solids, as yet uncharacterized, has been isolated from the solutions; elemental analyses and ir data are variable but indicate the presence of coordinated water and a C_8 fragment (40). Further studies on the $[IrCl(C_8H_{12})_2]_2/O_2$ system are in progress.

The 4-cyclooctene-1-one product of reaction [11] is detected also in the catalytic cyclooctene oxygenation described above; presumably removal of the diene by reaction [11] provides vacant or solvated sites for subsequent coordination of the monoene. The catalysis requires regeneration of the hydride from the “$Ir(OH)Cl_2$” species, and this could involve a net heterolytic splitting of H_2 by such an iridium(III) species, either before (step *a*) or after (step *b*) a protonation step, reaction [14].

$$[14]\quad Ir(OH)Cl_2 + H_2 \xrightarrow[-H_2O]{a} IrHCl_2 \overset{d}{\rightleftharpoons} IrCl + HCl$$
$$H^+ \swarrow\!\!\!\swarrow\ b \qquad -H^+ \nearrow\!\!\!\nearrow\ +H_2,\ c$$
$$Ir(H_2O)Cl_2$$

A step such as *a* is normally favoured since the released proton in heterolytic cleavage of H_2 is often stabilized by the leaving nucleophilic ligand (11, 12), in this case, hydroxide; however,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

in the acid conditions used, the *b* equilibrium would be very much favoured towards the aquo species. The cyclooctene would then have to coordinate prior to hydride formation, that is, to the "$Ir(OH)Cl_2$" species, or to the hydride, to generate a monoene or possibly bis(monoene) intermediate corresponding to **II**. A further possible pathway to such an intermediate is reduction of the "$Ir(OH)Cl_2$" by H_2 to generate iridium(I), steps *a* and *d*, followed by coordination of monoene and then oxidative addition of HCl (cf. reaction [10]). Of interest, addition of cyclooctadiene instead of cyclooctene to the $IrHCl_2$(cod)-(DMA) system under H_2/O_2 does not result in catalytic oxidation to the cyclooctene-one. It is possible that compared to a monoene, the more strongly coordinating diene inhibits hydride regeneration. Since HCl readily adds to the iridium(I) diene complex (equilibrium [10]), this would require that the diene inhibits reactions such as step *a* or *c*.

The nature of the reactions that regenerate the hydride, reaction [14], is of critical importance, because this process is probably the rate-determining step in the overall catalysis. The kinetics of formation of the hydroxide, reaction [11], have been studied in DMA at 30°C by both a gas-uptake and more conveniently by a spectrophotometric technique (the absorption maximum at 395 nm decreases to give a continuum spectrum in the 500–300 nm region, with ϵ at 395 nm being 495 M^{-1} cm^{-1}). At about 5×10^{-4} *M* $IrHCl_2(C_8H_{12})$(DMA) and a 100-fold excess of HCl, under 0.3–1.0 atm O_2, conditions being chosen such that the $[O_2]$ is in large excess (the solubility of O_2 at 30°C was determined to be 7.6×10^{-3} *M* atm^{-1}, with Henry's Law being obeyed), the spectral changes analyzed for a standard pseudo first-order process with observed rate constants at 30°C, k_{obs}, equal to $(1.04 \pm 0.10)10^{-4}$ s^{-1} at 1.0 atm O_2. These pseudo first-order constants are proportional to the O_2 pressure from 0.3–1.0 atm, and thus the rate-law for the reaction is simply $k'[IrH][O_2]$, with k' being $(1.36 \pm 0.13) \times 10^{-2}$ M^{-1} s^{-1}. We have not been able to determine in DMA if these spectral measurements refer to production of the hydroperoxide or the hydroxide; the latter seems likely since only one set of first-order spectral changes are observed. The half-life for formation of the hydroxide following dissolution of the hydride as hydroperoxide in CH_2Cl_2 at 20°C is about 60 min (Fig. 1), comparable to that of the process measured in DMA (see below), but the coordination sphere of the iridium in the two solvents will be different. The k' rate constant is thus tentatively assigned as kK_{O_2}, where k is the rate constant for the oxygen atom transfer step, and K_{O_2} is a constant for the hydride/hydroperoxide equilibrium, that lies well to the side of hydride formation at the O_2 pressures used. Under the catalytic conditions at 30°C with 0.5 atm O_2, this would correspond to a half-life of about 3 h; some slower step appears to control the overall catalysis. A serious limitation in drawing such a conclusion, of course, is that the kinetic data determined for reaction [11] refer to the stoichiometric cyclooctadiene substrate and not the catalytic cyclooctene substrate. Nevertheless, during the cyclooctene oxidation, the visible spectrum of the solution is a continuum in the 500–350 nm region typical of that resulting from reaction [11] with no evidence for the presence of a hydride; this again implies the presence of "$Ir(OH)Cl_2$" and a process of reaction [14] being rate-determining. The monohydride formation is basically a ligand substitution process (11) (hydride for hydroxide or water) and substitution at iridium(III) is notoriously slow (41). Mechanistic aspects of reactions of O_2 with transition metal hydrides to give hydroperoxides have not been explored, and we know of no prior kinetic studies on such

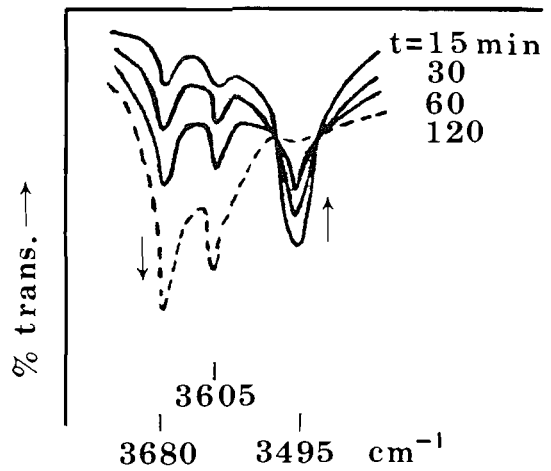

FIG. 1. Infrared changes in the 3500 cm^{-1} region in CH_2Cl_2 as a function of time (t) at 20°C, attributed to hydroperoxide to hydroxide conversion (reaction [11], see text).

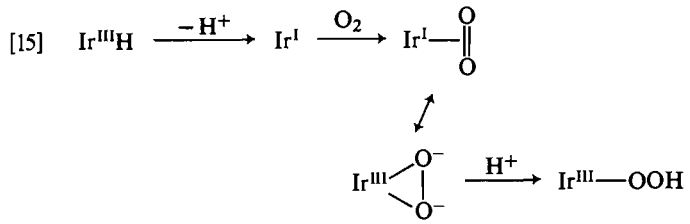
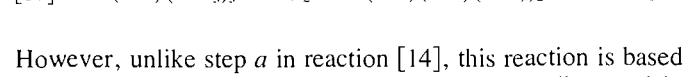
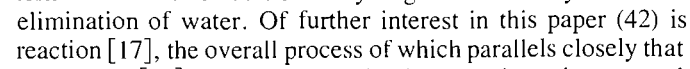
systems. The possibility of protonation of an intermediate dioxygen complex, reaction [15], cannot be ruled out (ref. 1, p. 79 and see reaction [22] below).



The net hydrogenolysis reaction shown in [16], studied by Reed and Roper (42), is of interest in that it demonstrates formation of a hydride from a hydroxo complex with liberation of water:

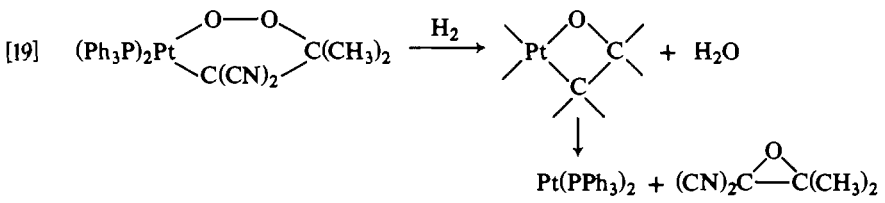


However, unlike step *a* in reaction [14], this reaction is based on a formal iridium(I) oxidation state, and was discussed in terms of oxidative addition of hydrogen followed by reductive elimination of water. Of further interest in this paper (42) is reaction [17], the overall process of which parallels closely that of reaction [11], although the oxidation state is again one, and oxidation of the phosphine was considered to proceed by way of a dioxygen species rather than a hydroperoxide, which was considered (42). Coupling of reactions [16] and [17] led to the overall catalytic hydrogenolysis of dioxygen to water with co-oxidation of triphenylphosphine (42), reaction [18],



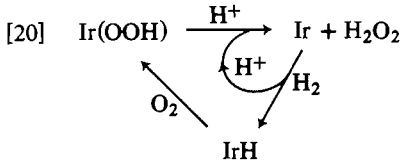
which is to be compared with reaction [5] in the present work.

The fact that molecular hydrogen can reduce cyclic peroxo complexes (43) led Sheldon and Van Doorn (44) to test reaction [19] with the known platinum(II) peroxometallocycle:



A similar hydrogenolysis process could be envisioned with the pseudo-peroxometallocycle intermediate suggested in equation [13], the reaction leading directly to epoxide (or ketone), water, and iridium(III) hydride (epoxides are readily isomerized to ketones in the presence of Lewis acids (45), but this has not been tested for in the presence of the iridium systems being studied here). However, reaction [19] did not occur under mild conditions, and the evidence for the presence of hydroxo-iridium species provides strong support for hydride regeneration via steps of reaction [14].

There is no evidence to suggest that H_2 and O_2 could produce hydrogen peroxide under the catalytic conditions, reaction [20], although the peroxide is readily formed from acid treatment of hydroperoxides.



In any case, free hydrogen peroxide under the conditions used does not oxidize unactivated monoenes such as cyclooctene.

The competing oxygen hydrogenolysis[4] reaction, [6], is poorly understood but needs to be minimized for effective olefin oxygenation. In essence, the H_2 molecule is competing with the olefin for an oxygen atom. The simplified catalytic cycle shown in Fig. 2 encompasses reactions [6], [11], and [14]; the substrate **S** may be coordinated olefin, or H_2, although we know of no precedent for reaction of H_2 with M—OOH, or OM(OH) (see below), to generate water. Attempts to study this "blank water reaction" in the absence of olefinic substrate were thwarted by the system tending to precipitate metal, particularly at higher H_2/O_2 ratios; iridium(I) under H_2, in the absence of stabilizing π-acceptor ligands (cf. reaction [14]), readily gives metal (27). An earlier study from this laboratory using a ruthenium catalyst revealed a rate-law showing a first-order dependence on H_2, and an independence of O_2 (48), which is again consistent with regeneration of an intermediate hydride being the rate-determining step. A further report using a range of platinum metal phosphine complexes as catalysts (49) noted a rate-law showing first-order in both gases but mechanisms were not considered. Use of the 1 atm H_2/O_2 mixtures at ratios ≥ 1.5 for the cyclooctene oxidation produces also some cyclooctane, in amounts comparable to the cyclooctanone; such hydrogenation must involve intermediate alkyls and reaction of these with O_2 by a net insertion to give alkylperoxides, M—OOR (ref. 1, pp. 81, 100), also could provide a pathway for the oxygenation. However, the experimental evidence for reaction [11] leads us to a working hypothesis shown in Fig. 2 for the net catalysis. Although the use of H_2/O_2 mixtures sounds alarming, we have experienced no difficulties under the mild conditions used.

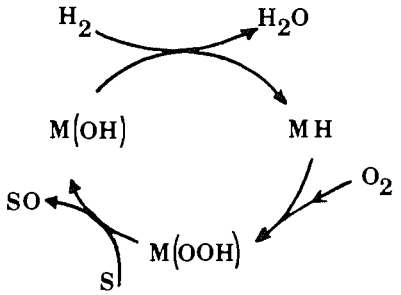


FIG. 2. Suggested catalytic cycle for selective oxygenation using H_2/O_2 mixtures; the substrate **S** may be olefin or H_2, while M represents Ir(III). MH could be written alternatively for this system as Ir(I) + H^+ (see reaction [15]).

A wide variety of related platinum metal complexes in several solvents (DMA, toluene, chlorobenzene) were tested for oxygenase-type activity with olefinic substrates. Rhodium systems in DMA included *in situ* $RhHCl_2(cod)(DMA)$ species formed from the cod dimer and HCl, $RhCl_3 \cdot 3H_2O$, $RhBr_3 \cdot 2H_2O$, $RhCl_3(DMSO)_3$, and a $[RhCl(C_8H_{14})_2]_2$/HCl mixture. Under comparable conditions (1:1 H_2/O_2 mixtures at 1 atm with cyclic olefins at 20°C), only trace amounts of several oxidation products were detected after reaction times of 2–5 days; however, extensive catalytic hydrogenation was commonly observed. Many of the above systems are known to be active hydrogenation catalysts that operate via rhodium(I) species (11, 50). Compared to iridium, the metal–hydride bond in corresponding rhodium systems is weaker (51), and hydrogen reduction to the rhodium(I) state is more likely (reactions [3], [14] step *d*); this would explain the preferred hydrogenation process, and also the formation of trace oxidation products via nonselective free-radical pathways (7), see reactions [7]–[9]. Use of the $RhCl_3(DMSO)_3$ complex in DMA, which readily generates $RhCl_3(DMSO)_2(DMA)$ containing two S-bonded DMSO ligands (23), yielded also some sulfone ($DMSO_2$) and sulfide (DMS) by oxygenation and hydrogenation, respectively. Using DMSO as solvent with olefinic substrates gave only sulphone formation according to reaction [4], presumably because the olefin is unable to compete with DMSO for a coordination site. The DMSO appears to stabilize the rhodium(III) hydride, rather than the rhodium(I) state (reaction [3]), as observed in synthetic studies (23). The oxygen atom transfer to the sulfoxide is again considered to involve a hydroperoxide intermediate rather than free hydrogen peroxide; coordination of the sulfoxide may not be essential, since the mechanism outlined in equation [21], which is exactly analogous to that suggested for the metal-catalyzed alkylhydroperoxide oxidation of sulfides to sulfoxides (52), seems plausible:

[4]The reversal of reaction [6] by photochemical means demands intense current interest (46), although catalysts were developed for disposal of the explosive 2:1 mixture of hydrogen and oxygen resulting from radiolytic decomposition of water in atomic reactors (47).

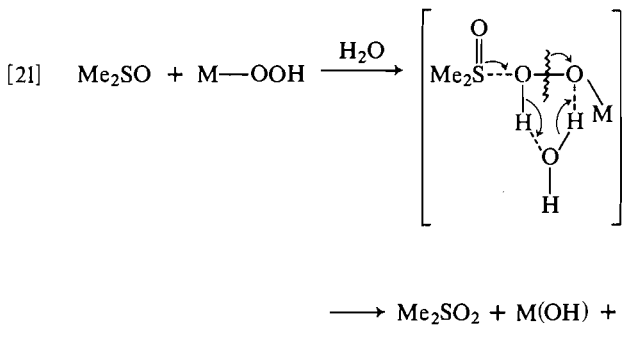
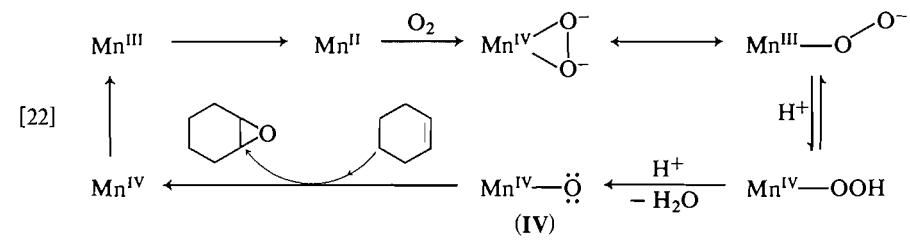
For personal use only.



A DMA solution of $IrHCl_2(DMSO)_3$ at 20°C absorbs 1.0 mol O_2 per iridium (cf. reactions [11] and [21]), but the reaction products have not yet been identified.

We have also used ethanol and isopropanol as solvents and possible sources of hydride with the iridium(III) and rhodium(III) complexes, using just an O_2 atmosphere. However, no catalytic oxygenation of olefins is observed.

Of considerable interest to the present studies are the reports from Tabushi's group on catalytic epoxidation of olefins using a manganese(III) porphyrin under O_2 with borohydride (6) or H_2/colloidal platinum (53) as co-reductant. Non free-radical pathways involving a strongly electrophilic oxygen-containing species formed via a hydroperoxide were invoked (6):[5]



The net cycle shown in equation [22] again incorporates the overall stoichiometry of the P450 system (reaction [1]), the two electrons being provided by BH_4^- or H_2/Pt. The suggested mechanism is close to that postulated for the enzyme systems that appear (16, 54) to involve an iron porphyrin intermediate analogous to **IV**, namely $[Fe^{III}—\ddot{O}]$ (or one of its resonance forms, including porphyrin cation radical formulations). The overall analogy of the postulated mechanisms for the manganese porphyrin and P450 systems, with that for our iridium system is quite striking (cf. equations [22], [11], and [13]). Both involve hydroperoxide intermediates, but formed either by protonation of coordinated reduced dioxygen species, or by insertion of dioxygen into a metal–hydride bond. The subsequent oxygen transfer to substrate, however, is pictured quite differently. The P450 systems also incorporate an oxygen atom into a saturated C—H bond and this certainly requires a strongly electrophilic oxene-type species such as $[Fe^{III}—\ddot{O}] \leftrightarrow [Fe^{V}=O]$, probably via an initial hydrogen atom abstraction (5, 16, 54). The iridium system will not oxygenate saturated hydrocarbons, and on analogy with oxygen atom transfer from coordinated alkyl peroxide, the process via the pseudo peroxometallocycle seems plausible. Protonation of $[Ir^{III}—OOH]$ to yield $[Ir^{III}—\ddot{O}] \leftrightarrow [Ir^{V}=O]$ (cf. equation [22]) seems highly unlikely; there are no known examples of oxo complexes of even iridium(III), let alone iridium(V) (or rhodium analogues).

Concluding remarks

In summary, we have discovered that catalytic selective oxygenation of a cyclic olefin to give the ketone can be effected using H_2/O_2 mixtures with an iridium complex under mild conditions. Although the reaction is very inefficient, it does prove the potential of using H_2, activated as a metal–hydride, as the coreductant in monoxygenase-type catalysis. Tabushi and Yazaki (53) have recently used colloidal platinum to catalyze the necessary two-electron transfer from H_2 in the presence of a manganese porphyrin to effect similar oxygenation to give the epoxide. The studies with the iridium systems have concentrated thus far on a single substrate (cyclooctene) and a single precursor complex $[IrHCl_2(C_8H_{12})]_2$. The rate-determining step appears to be regeneration of the hydride at a substitution-inert iridium(III) centre. Studies are in progress to investigate the scope of the present catalytic system in terms of other olefinic substrates, and also to modify and "improve" the iridium centre by variation (and removal) of the chloride ligands.

Synthesis and reactivity of iron nitrosyl hydrides substituted with triphenyl phosphine

JEAN-LOUIS A. ROUSTAN,[1] ALAIN FORGUES, JEAN-YVES MEROUR, NARINDER D. VENAYAK, AND B. A. MORROW

Ottawa–Carleton Institute for Research and Graduate Studies, University of Ottawa Campus, Ottawa, Ont., Canada K1N 9B4

Received August 17, 1982[2]

JEAN-LOUIS A. ROUSTAN, ALAIN FORGUES, JEAN-YVES MEROUR, NARINDER D. VENAYAK, and B. A. MORROW. Can. J. Chem. **61**, 1339 (1983).

Protonation of anion **1** $[Fe(CO)_3(NO)]^-$, (Na^+) in the presence of $P(C_6H_5)_3$ yielded the iron nitrosyl hydrides **3** $FeH(CO)_2(NO)(P(C_6H_5)_3)$ and **4** $FeH(CO)(NO)(P(C_6H_5)_3)_2$ or the iron nitrosyl cation **5** $[Fe(CO)_2(NO)(P(C_6H_5)_3)_2]^+$, (BF_4^-) depending upon the conditions. Anions **12** $(Li^+),[Fe(CO)(NO)(P(C_6H_5)_3)_2]^-$ and **15** $(Li^+),[Fe(CO)_2(NO)(P(C_6H_5)_3)]^-$ were formed in the reactions of $Li^+,{}^-HB(C_2H_5)_3$ **13** with hydrides **4** and **3** respectively. Anions **15** resulted also from the reaction of cation **5** with an excess (at least 6 equivalents) of boron hydride **13** and from the reaction of anion **12** with CO at atmospheric pressure. Hydrides **3** and **4** were prone to ligand exchange reactions and could be interconverted easily. This is in contrast to the reluctance of the isoelectronic cobalt hydride $CoH(CO)_3(P(C_6H_5)_3)$ to undergo further reaction with $P(C_6H_5)_3$. Another striking difference between the iron nitrosyl hydrides and the isoelectronic cobalt carbonyl hydrides was found when the reactions which normally yield bimetallic derivatives were investigated. The nature of the decomposition products formed in the thermolysis of **3** and **4**, in the reactions of **3** with olefins and dioxygen, and in the reduction reactions of cation **5** suggests that metallic dimers containing a $(Fe(NO))_2$ unit are prone to fast CO and NO exchanges triggering an irreversible fragmentation into monometallic decomposition products, comprising invariably iron dinitrosyl derivatives.

JEAN-LOUIS A. ROUSTAN, ALAIN FORGUES, JEAN-YVES MEROUR, NARINDER D. VENAYAK et B. A. MORROW. Can. J. Chem. **61**, 1339 (1983).

La protonation de l'anion **1** $[Fe(CO)_3(NO)]^-,(Na^+)$ en présence de $P(C_6H_5)_3$ conduit aux hydrures fer nitrosyles **3** $FeH(CO)_2(NO)(P(C_6H_5)_3)$ et **4** $FeH(CO)(NO)(P(C_6H_5)_3)_2$ ou au cation fer nitrosyle **5** $[Fe(CO)_2(NO)(P(C_6H_5)_3)_2]^+,(BF_4^-]$ suivant les conditions. Les anions **12** $(Li^+),[Fe(CO)(NO)(P(C_6H_5)_3)_2]^-$ et **15** $(Li^+),[Fe(CO)_2(NO)(P(C_6H_5)_3)]^-$ resultent de la réaction de $Li^+,{}^-HB(C_2H_5)_3$ **13** avec les hydrures **4** et **3** respectivement. L'anion **15** est aussi formé dans la réaction du cation **5** avec un excés (au moins 6 equivalents) du borohydrure **13**, et dans la réaction de l'anion **12** avec CO à pression atmosphérique. Les hydrures **3** et **4** se prêtent bien à des réactions d'échanges de ligandes et sont facilement interconvertibles. Par opposition l'hydrure du cobalt isoélectronique $CoH(CO)_3(P(C_6H_5)_3)$ ne réagit pas avec un excés du $P(C_6H_5)_3$. Une autre différence nette entre les hydrures fer nitrosyles et les hydrures cobalt carbonyles isoélectroniques apparait quand on s'intéresse à des réactions qui conduisent habituellement à des dérivés bimétalliques. La nature des produits de décomposition issus de la thermolyse de **3** et **4**, de la réaction de **3** avec des oléfines ou l'oxygène moléculaire, et des réactions de réduction du cation **5**, suggère que les dimères métalliques comportant un fragment $(Fe(NO))_2$ sont sujets à des échanges rapides de CO et de NO qui déclenchent une fragmentation irreversible en des produits de décomposition monométalliques, parmi lesquels figurent invariablement des dérivés du fer dinitrosyle.

Introduction

The recently discovered catalytic activity of the iron nitrosyl anion $[Fe(CO)_3(NO)]^-,Na^+$ **1** in the alkylation of allylic acetates (1) prompted us to extend the scope of our studies to other derivatives containing a $[FeNO]^x$ moiety (x = 8, 10)[3] which might serve as progenitors of other catalytically active species.

The pivotal role of transition metal hydrides, such as $CoH(CO)_4$ (3), in many reactions of current interest (4, 5) was the incentive to explore the chemistry of iron nitrosyl hydrides.

Prior to our work in this area, only one iron nitrosyl carbonyl hydride had been reported, the very thermolabile $FeH(CO)_3(NO)$ (dec. −45°C, sometimes explosively) (6). Starting with the readily available anion **1** (6), we had reported already that its protonation in the presence of an excess of triphenyl phosphine yielded the new hydride $FeH(CO)(NO)(P(C_6H_5)_3)_2$ which could be isolated easily in the solid state (7); the single crystal structure was obtained recently (8). In this paper, we report our results on protonation reactions of anion **1** in a variety of conditions, on reactions promoting the cleavage of the iron–hydrogen bond in the hydrides, and on reduction reactions of the iron nitrosyl cation $[Fe(CO)_2(NO)(P(C_6H_5)_3)_2)]^+$.

Altogether, the results provide new information useful for a better understanding of the chemistry of these nitrosyl complexes.

Experimental

All the operations were done under argon, carbon monoxide, or in vacuum. THF (tetrahydrofuran) was refluxed, then distilled from sodium/benzophenone under nitrogen and used immediately. All solvents were saturated with argon before use. Anhydrous ether (Mallinkrodt), acetic anhydride (J. T. Baker), trifluoroacetic acid (J. T. Baker or MCIB), aqueous 37% tetrafluoroboric acid (Applied Chemicals), lithium triethyl borohydride (1 *M* solution in THF), triphenyl phosphine (Aldrich), sodium nitrite (B.D.H.), iron pentacarbonyl (Pressure Chemical), and CO (Matheson, CO C.P. 99.5% min.) were used as received. The olefins (Aldrich) were passed through a short alumina column before use. SiO_2 plates for analytical chromatography were from Analtech Inc., those for preparative chromatography from Macherey Nagel; neutral alumina, activity II–III, from Merck was used for column chromatography. The ir spectra were recorded on a Unicam SP 1100 calibrated with a polystyrene film or on a Perkin–Elmer 283 (abbreviations: vs = very strong, s = strong, ν are given in cm^{-1}). The nmr spectra were recorded on a Varian HA 100 for proton (TMS internal reference) and on a Varian FT 80 operating at 32.2 MHz for phosphorus (85% H_3PO_4 external reference); a

positive chemical shift (ppm) indicates a resonance downfield from the reference. Elemental analyses were performed by M.H.W. Laboratories, Phoenix, Arizona, U.S.A. Published procedures were used to prepare authentic samples of $Fe(CO)_4(P(C_6H_5)_3)$ (10), $Fe(CO)_3(P(C_6H_5)_3)_2$ (11), and $Fe(CO)_2(NO)_2$ (12). $Fe(NO)_2(P(C_6H_5)_3)_2$ (13) was obtained from the thermal decomposition of the cation $[Fe(CO)(NO)(CH_3CN)(P(C_6H_5)_3)_2]^+,BF_4^-$ (14) in acetonitrile at 50°C, and crystallized out from the solution. $Fe(NO)_2(CO)(P(C_6H_5)_3)$ (13) was obtained from the reaction of $Fe(CO)_2(NO)_2$ with $P(C_6H_5)_3$ in hexane or ether at room temperature. Samples of (η^3-propenyl)-$Fe(CO)(NO)(P(C_6H_5)_3)$ were obtained from the reaction of (η-^{3}propenyl)$Fe(CO)_2(NO)$ with $P(C_6H_5)_3$ (9). The cation $[Fe(CO)_2(NO)(P(C_6H_5)_3)_2]^+,(BF_4^-)$ used in the reduction reactions was prepared either from the carbonylation at room temperature and atmospheric pressure of solid $[Fe(CO)(NO)(P(C_6H_5)_3)_2]^+,BF_4^-$ (14) or from the protonation of anion **1** as described below or from the direct nitrosylation of $Fe(CO)_3(P(C_6H_5)_3)$ with NO^+,BF_4^- (15). Whatever the method used for preparing the compound, the same dependency of the final distribution of the reduction products upon the excess of reductant used was observed.

Anion **1** $Fe(CO)_3(NO)^-Na^+$ was prepared by reacting $Fe(CO)_5$ with $NaNO_2$ in absolute methanol, in the presence of $NaOCH_3$, as described previously (6, 8).

*Protonation of anion **1** in THF in the presence of triphenyl phosphine*

A stock solution of anhydrous HBF_4 (17) was prepared just before use by dropwise addition of 2 mL of aqueous 37% HBF_4 (≃11 mmol of HBF_4) to 10 mL of acetic anhydride stirred and maintained at 0°C with an ice bath.

*Formation of $FeH(CO)(NO)(P(C_6H_5)_3)_2$ **4***

Anion **1** (0.7 g, 3.1 mmol) and $P(C_6H_5)_3$ (2.0 g, 7.6 mmol, ≃ 2.5 equivalents) were dissolved in 70 mL of THF cooled in an ice bath. To the stirred solution, 5 mL of the HBF_4 stock solution (≃1.5 equiv. of HBF_4) were added dropwise. Stirring was discontinued after two hours, and the homogeneous solution was brought to dryness in vacuum at room temperature. The residue was washed with 20 mL of ether, extracted with benzene, and crystallized in benzene/pentane to yield 0.66 g (30%) of hydride **4** identified by comparison with an authentic sample (7) (νCO = 1915, νNO = 1690 (THF); δ(Fe-H) = −5 pm, triplet, J_{P-H} = 79 ± 1 Hz; δP = 77.0 ppm ($CDCl_3$)).

*Formation of $[Fe(CO)_2(NO)(P(C_6H_5)_3)_2]^+,BF_4^-$ **5***

Anion **1** (0.37 g, 1.6 mmol) and $P(C_6H_5)_3$ (2.1 g, 5 equiv.) in 50 mL of THF were protonated, as described above, with 10 mL of the HBF_4 stock solution (≃5.5 equiv.) Infrared analysis of the solution, shortly after acidification, indicated complete disappearance of anion **1** and formation of an intermediate with νCO's identical to those of hydride **3**. Stirring of the solution, in the ice bath, was maintained an additional two hours, by which time a yellow precipitate had started to form. After additional stirring at room temperature for 6 hours, the solid was separated by filtration, washed with THF, dried, and extracted with $CHCl_3$. Crystallization in $CHCl_3$/pentane yielded 0.6 g (50%) of cation **5**, identical with an authentic sample prepared from the reaction of $Fe(CO)_3(P(C_6H_5)_3)_2$ with NO^+,BF_4^- (15). Infrared νCO = 2050 (s), 1990 (vs), νNO = 1790 (vs) ($CHCl_3$); reported (15): 2050 (s), 1993 (vs), 1788 (vs). *Anal.* calcd. for $C_{38}H_{30}BF_4FeNO_3P_2$: C 60.6, H 4.0, N 1.9, P 8.2; found: C 60.4, H 4.0, N 1.9, P 8.2.

*$FeH(CO)_2(NO)(P(C_6H_5)_3)$ **3***

Synthesis in solution

A typical preparation is described. Trifluoroacetic acid (0.13 mL, 1.8 mmol) was added dropwise to a stirred solution of anion **1** (0.33 g, 1.5 mmol) and $P(C_6H_5)_3$ (0.45 g, 1.7 mmol) in 35 mL of ether cooled at −15°C. An ir spectrum, recorded shortly after the addition (≃2 minutes), indicated the formation of hydride **3**. The solution was cooled to −78°C and sodium trifluoroacetate was decanted by gravity. The clear orange supernatant was used for ir, ^{1}H and ^{31}P nmr analyses (νCO = 2020, 1960; νNO = 1755; δ(Fe-H) = −3.5 ppm, doublet, J_{P-H} = 12 Hz; δP = 62.0 ppm). Heating the solution at reflux for a few minutes resulted in the decomposition of hydride **3** and precipitation of the degradation products $Fe(NO)_2(P(C_6H_5)_3)_2$ **8**, $Fe(NO)_2(CO)(P(C_6H_5)_3)$ **9**, $Fe(CO)_4(P(C_6H_5)_3)$ **10**, and $Fe(CO)_3(P(C_6H_5)_3)_2$ **11**, sparingly soluble in ether. Infrared (THF or CH_2Cl_2, numbers in parentheses correspond to literature values), **8**: νNO = 1720 (s), 1680 (vs) (1724, 1678 (13)); **9**: νCO = ~2000 (s); νNO = 1760 (s), 1720 (vs) (2009, 1764, 1722 (13)); **10**: νCO = 2060, 1975, 1945 (2059, 1978, 1938 (11)); **11** (νCO = 1890 (1887(11)). The mixtures were also analysed on tlc plates and the R_f values compared to those of authentic samples of **8**, **9**, **10**, and **11** (elution with benzene/hexane (1:4)). The same decomposition took place when ether solutions of hydride **3** were allowed to stand at room temperature for 4 hours. In that case, hydride **4** was also present in the precipitate (very likely it resulted from the reaction of hydride **3** still present with triphenyl phosphine released in solution as the decomposition was in progress). The solutions were also very air sensitive. Upon contact with air they darkened instantaneously to yield a mixture of the degradation products **8**, **9**, **10**, and **11**. The procedure given above was also used to prepare hydride **3** in toluene.

*Reaction of hydride **3** with triphenyl phosphine, formation of hydride **4***

Hydride **3** was prepared in ether, as described above, starting from 0.25 g (1.1 mmol) of anion **1**. Solid $P(C_6H_5)_3$ (1.36 g, 5.2 mmol, 5 equiv.) was added to the stirred solution. The temperature was allowed to rise to 5°C and maintained at this value with a water–ice bath. Precipitation of hydride **4** occured with gas evolution and no hydride **3** was present after 40 min (ir monitoring of the solution). The solid was filtered out, washed with 20 mL of ether, and extracted with benzene. Crystallization in benzene/pentane afforded 0.51 g of hydride **4** (64%) identified by ir and nmr.

*Reaction of hydride **4** with CO, partial conversion into hydride **3***

Hydride **4** (0.25 g)was dissolved in 10 mL of THF under argon. The orange solution darkened rapidly when CO, at atmospheric pressure, was passed into solution maintained at ~20°C with a water bath. After 20 min, there was no change in the relative intensities of the νCO's and the νNO's of **4** and **3**, which was formed in the reaction (the νNO's were in 1:1 ratio). The same experiment was done directly in an nmr tube with toluene as solvent. The ^{31}P resonance of **4** appeared at 77.4 ppm and that of **3** at 62.6 ppm.

*Stoichiometric hydrogenations with $FeH(CO)_2(NO)(P(C_6H_5)_3)$ **3***

in situ *Preparation of hydride **3** from $Fe(CO)_3(NO)^-,Na^+$*

Hydride **3** was prepared in ether as described above, starting with ~1.3 g of anion **1** for each of the reactions studied. The ir analysis of the solution was performed after the protonation step to make certain that hydride **3** was present in the solution. The stoichiometric amount of the olefin (olefin/anion **1** = 1:2) was then added, and the solution was stirred at room temperature until the disappearance of hydride **3** (15 min with 1,1-diphenyl ethylene, 2 hours with the other reactive olefins). By that time, a precipitate composed of the usual mixture of degradation products **8**, **9**, **10**, and **11** had formed. The solids were separated by filtration and the solution was concentrated to a volume of ~10 mL by distillation of the solvent at atmospheric pressure. After calibration with toluene, the solutions were subjected to vpc analysis (SE 30, 10% on Chromosorb W). In the case of 1,1-diphenyl ethylene, the organic products were separated from the metallic by-products by preparative thin-layer chromatography (elution with hexane) and analysed by ^{1}H nmr.

in situ *Generation of hydride **3** from $FeH(CO)(NO)(P(C_6H_5)_3)_2$ **4***

Hydride **4** (1 g, 1.5 mmol) was dissolved in 30 mL of THF (or benzene) under one atmosphere of CO. When ir analysis of the solution indicated the formation of hydride **3**, an excess of 1,1-diphenyl ethylene (olefin/hydride **4** = 1:1) was added at once. After 15 min, neither **4** nor **3** were detected in solution by ir. The mixture was treated as described above.

*$Li^+[Fe(CO)(NO)(P(C_6H_5)_3)_2]^-$ **12** and reaction with allyl chloride*

One mL of a 1 *M* THF solution of $LiBH(C_2H_5)_3$ (1.3 equiv.) was added to a stirred solution of hydride **4** (0.5 g, 0.78 mmol) in 5 mL of THF. Reduction into anion **12** (νCO = 1830 cm^{-1}; νNO obscured

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

by solvent absorptions; δP = 79.7 ppm) occurred within two hours at 50°C. After cooling to room temperature allyl chloride (0.1 mL, 1.24 mmol) was added dropwise. After stirring an additional 5 min the solvent was removed under reduced pressure and the residue was chromatographed on alumina (elution benzene/hexane 1:1) to afford 0.22 g (67%) of the known (η^3-propenyl)Fe(NO)(CO)($P(C_6H_5)_3$) **14** (9).

$Li^+[Fe(CO)_2(NO)(P(C_6H_5)_3)]^-$ 15 and reaction with allyl chloride

Anion **12** was prepared as described previously, starting with 1.26 g (1.97 mmol) of hydride **4** in 10 mL of THF. Conversion into anion **15** (νCO = 1920, 1885, 1850, 1820; νNO = 1600, 1530; δP = 76.7 ppm) was achieved upon passing CO at atmospheric pressure through the solution at room temperature for 15 min. Allyl chloride (0.21 mL, 2.7 mmol) was added and the solution was stirred overnight to yield a mixture of the known allyl complexes (η^3-propenyl)Fe(CO)(L)(NO) (L = CO, **16**; L = $P(C_6H_5)_3$, **14** (9)) in an approximate 2:1 ratio (based on the intensities of the νNO's).

Complex **16** was derivatized *in situ* into **14** by adding triphenyl phosphine (2.21 g, 7.9 mmol) and heating at reflux for 12 h. The η^3-allyl complex **14** was subsequently isolated as described above (0.53 g, 65%).

The reduction of hydride **4** (0.05 g, 0.08 mmol in 4.5 mL of THF) was also performed directly in a nmr tube to minimize material loss due to oxidation of the air-sensitive anions. With an excess of $LiHB(C_2H_5)_3$ (0.4 mL, 5 equiv.) the reduction into **12** took place at room temperature in less than 2 hours. After carbonylation of **12** to yield **15**, the ^{31}P nmr spectrum of the solution was composed of the peaks corresponding to anion **15** and $P(C_6H_5)_3$. They were in a 1:1 ratio, as expected for a 100% overall conversion of hydride **4** into anion **15**.

The lithium salt of anion **15** could also be formed by the fast reaction (upon mixing at 0°C) of hydride **3** in ether with one molar equivalent of the boron hydride.

Reduction of $[Fe(CO)_2(NO)(P(C_6H_5)_3)_2]^+,BF_4^-$ 5

A general procedure is given. A suspension of cation **5** (0.05 to 0.1 g) in THF (5 to 10 mL) was frozen under argon at −196°C. The required amount of boron hydride $Li^+,{}^-HB(C_2H_5)_3$ **13** (between 1 and 10 molar equivalents, depending upon the experiment) was added at once, and the temperature was raised. Stirring commenced when thawing occurred. Gas evolution began at ~−20°C and became vigorous at 0°C as the solid passed slowly into the solution. At the end of the reaction, the solutions (now homogeneous) were analyzed by ir, ^{31}P nmr, and, when anion **15** was not present, by thin-layer chromatography. In the low temperature nmr experiments, a CH_2Cl_2/THF solution of cation **5** was prepared in the nmr tube and cooled to −78°C. The required amount of reducing agent was added through the septum securing the tube, which was then transferred quickly into the probe of the spectrometer cooled at −70°C. When at least 6 equivalents of boron hydride **13** were used, anion **15** was the sole metallic product to be characterized by ^{31}P nmr and ir. For those reactions leading to anion **15**, in the absence of the degradation products, a spectroscopic yield of ≈80% was obtained when the intensity of the νCO of **15** at 1920 cm^{-1} was compared to that of calibrated solutions of anion **15** prepared from hydride **4**, as described previously. A Perkin–Elmer 283 operating in the absorbance mode was used for those mesurements.

Results

1. *Synthesis and reactions of iron nitrosyl hydrides substituted with triphenyl phosphine*

The protonation of metallic anions offers a convenient route to metallic hydrides. However, the success of the preparation might depend upon "a careful control of the reaction conditions" (18). We found this statement very appropriate in the case of the protonation reactions of the iron nitrosyl anion $[Fe(CO)_3(NO)]^-,Na^+$ **1**. In the presence of a phosphine ligand, the nature of the products formed after protonation was critically influenced by the nature of the solvent as well as the nature and the excess of both the acid and the phosphine. In the present work, triphenyl phosphine was used.

In THF, the reaction of anion **1** with ≈1.5 equiv. of anhydrous HBF_4 in the presence of 2.5 equiv. of triphenyl phosphine yielded the disubstituted nitrosyl hydride $FeH(CO)(NO)(P(C_6H_5)_3)_2$ **4** (7) (Scheme 1) in 30% yield. When 5 equiv. of both the acid and the phosphine were used, no evidence for the formation of hydride **4** was obtained. Instead, the ionic nitrosyl complex $[Fe(CO)_2(NO)(P(C_6H_5)_3)_2]^+,BF_4^-$ **5** precipitated slowly from the solution, and could be isolated in 50% yield. Shortly after acidification, ir analysis of the solution indicated the formation of an intermediate with νCO's at 2020 and 1960 cm^{-1} (solvent absorption obscured the region 1800–1700 cm^{-1} where the νNO was expected). Independently, protonation of a THF solution of the sodium salt of the anion $[Fe(CO)_2(NO)(P(C_6H_5)_3)]^-$ (7) with HBF_4 resulted in the formation of a compound with identical νCO's, and we suspected that it could be the dicarbonyl nitrosyl hydride $FeH(CO)_2(NO)(P(C_6H_5)_3)$ **3**. A cleaner synthesis of this previously unknown hydride was sought, and tri-

[a]This work.

fluoroacetic acid was selected as a more convenient reagent.

With trifluoroacetic acid, THF as a solvent was unsatisfactory. Even in the absence of phosphine, there was no significant reaction between anion **1** and one equivalent of acid. In sharp contrast to this result, in diethyl ether the anion reacted at 0°C upon mixing with the acid, and afforded the volatile dinitrosyl $Fe(CO)_2(NO)_2$ **6** (12), one of the reported decomposition products of the very thermolabile unsubstituted hydride $FeH(CO)_3(NO)$ **2** (6) (the other reported decomposition product, $FeH_2(CO)_4$ **7**, was not detected in our reaction conditions). In the presence of one molar equivalent of triphenyl phosphine, the course of the protonation reaction was dramatically altered. The new hydride $FeH(CO)_2(NO)(P(C_6H_5)_3)$ **3** was formed in yields at least equal to 70% (estimate based on the yields of products derived from **3** as shown below). This reaction could be conducted in ether as well as in toluene, under CO or argon, in the temperature range −15°C to 0°C. The solutions thus obtained were extremely reactive. Brief exposure to air, or heating for a few minutes at 35°C, induced a complete decomposition of hydride **3** into a mixture of products. The only metallic complexes which could be characterized were $Fe(NO)_2(P(C_6H_5)_3)_2$ **8** (13), $Fe(NO)_2(CO)(P(C_6H_5)_3)$ **9** (13), $Fe(CO)_4(P(C_6H_5)_3)$ **10** (11), and $Fe(CO)_3(P(C_6H_5)_3)_2$ **11** (11) (abbreviated hereafter as the degradation products). The stability of hydride **3** in solution appeared also to be affected by the presence of metallic impurities. In particular, when partially oxidized samples of anion **1** were used in the protonation reaction, the reaction afforded only the degradation products. Similarly, every attempt to isolate this hydride in a pure state was frustated by decomposition during the work-up. Therefore, the molecular structure was inferred from classical spectroscopic studies of the solutions containing the hydride. In ir, the νCO and νNO values (Table 1) compared well with those of other selected complexes containing the neutral $Fe(CO)_2(NO)(P(C_6H_5)_3)$ metallic fragment. The νNO value of 1755 cm^{-1} was indicative of a linearly bounded NO, this bonding mode was also found in the single crystal structure of a related complex, the mercuric derivative $(Fe(CO)_2(NO)(P(C_6H_5)_3)_2Hg)$ (19). In the ^{1}H nmr, the resonance of the hydride occurred at high field as a doublet ($\delta = -3.5$ ppm, $J_{P-H} = 12$ Hz), which is the best single diagnosis for its presence (20). Extensive and reversible broadening was observed upon raising the temperature from −30°C to 0°C. When freshly prepared samples of anion **1** were used in the preparation of hydride **3**, the $^{31}P\{^1H\}$ nmr spectrum was composed of a single line at $\delta = 62.0$ ppm, with no evidence for the presence of the degradation products.

Additional support for the formulation given came from observations pertaining to the chemical reactivity (Scheme 2).

Addition of an excess of triphenyl phosphine to ether solutions of hydride **3** caused gas evolution along with the precipitation of the sparingly soluble disubstituted hydride $FeH(CO)(NO)(P(C_6H_5)_3)_2$ **4** (64% yield) (7). The ligand exchange reaction took place also in the opposite direction. Exposure of THF solutions of hydride **4** to CO at atmospheric pressure resulted in the partial conversion of **4** into hydride **3**, as shown by ir and ^{31}P nmr analysis of the solutions. The maximum conversion was reached after twenty minutes of exposure to CO, the intensities of the νNO's of **3** and **4** being in a 1:1 ratio at that point. Not surprisingly, no reaction was apparent in the presence of at least a five-fold excess of triphenyl phosphine.

The monsubstituted hydride **3** was also active in the stoichiometric hydrogenation of some unsaturated molecules at room temperature. The results are summarized in Table 2. Only double bonds which were part of a conjugated system were hydrogenated successfully. No reduction of an isolated double bond such as in cyclohexene or in 1-octene was observed after two hours. 1,1-Diphenyl ethylene was the most reactive, the hydride was consumed totally in less than 15 minutes, but with the other reactive substrates, significantly longer reaction times were needed (~2 hours). At the end of each reaction the usual mixture of the degradation products was formed, with no evidence for the presence of other complexes containing CO and/or NO ligands. The disubstituted hydride **4**, which is easily handled at room temperature in the solid state with no precaution taken to exclude air, could also be used as a "stabilized" precursor of hydride **3**. For example, hydride **4**, in THF or benzene, was reacted with CO at atmospheric pressure at room temperature. When ir analysis of the solution indicated the presence of hydride **3**, 1,1-diphenyl ethylene was added. The hydrogenation of the olefin and the formation of the degradation products proceeded as in the direct reaction with hydride **3** prepared from anion **1**. Reaction with butadiene might also proceed in a similar way. Hydride **4** in THF under argon was unreactive towards one to ten equivalents of butadiene at 25°C. However, when CO was passed into the solution, rapid formation of a mixture of the degradation products occurs. No evidence for the concomitant formation of a η^3-allyl derivative was obtained. This is in contrast to the formation of a (η^3-crotyl)iron nitrosyl complex upon reaction of butadiene with the parent iron nitrosyl hydride $FeH(CO)_3(NO)$ (16).

The facile replacement of one triphenyl phosphine ligand by

[b]Hydride **3** generated from hydride **4** in benzene under CO.

CO was not limited to the neutral hydride $FeH(CO)(NO)(P(C_6H_5)_3)_2$ **4**. Its reduction product was also prone to the same facile substitution reaction.

In THF, hybride **4** was slowly reduced (2 hours at 50°C) to the lithium salt of the anion $[Fe(CO)(NO)(P(C_6H_5)_3)_2]^-$ **12** upon reaction with 1.3 molar equivalents of $LiHB(C_2H_5)_3$ **13**. The reactivity of the reduced species was very much like that of the sodium salt of the same anion, synthesized previously (7). The almost instantaneous reaction with allyl chloride at 0°C gave the allyl complex (η_3-propenyl)$Fe(CO)(NO)(P(C_6H_5)_3)$ **14** (9) in 67% yield. Furthermore, bubbling CO at atmospheric pressure through a THF solution of anion **12** at 20°C induced its irreversible conversion into the lithium salt of the dicarbonyl nitrosyl anion $[Fe(CO)_2(NO)(P(C_6H_5)_3)]^-$ **15**. Another more direct route to the same anion **15** involved the direct reduction of the dicarbonyl nitrosyl hydride **3** in ether. In that case, the reaction was fast at 0°C and occurred as soon as the reducing agent was added. The ir spectra of THF solutions of anion **15** were composed of four νCO's (1920, 1850 cm^{-1} strong and 1895, 1820 cm^{-1} weak) and two νNO's (1530 cm^{-1} strong and 1600 cm^{-1} weak). When THF was replaced by acetonitrile, only two νCO's (1895 and 1820 cm^{-1} strong) and one νNO (1600 cm^{-1}) were present. The shift towards higher wave numbers of the strong absorptions corresponding to the νNO and in the opposite direction for those corresponding to the νCO's under the influence of a good coordinating solvent was also observed with the sodium salts of the same anion **15** (7) and of the unsubstituted one $[Fe(CO)_3(NO)]^-$ **1** (21). This was taken as evidence for the occurence in THF of an equilibrium between loose and tight ion pairs, and for a specific cation...O-nitrosyl interaction in the tight ion pairs. In THF, anion **15** reacted with allyl chloride to yield a mixture of (η^3-propenyl)$Fe(CO)(NO)(P(C_6H_5)_3)$ **14** and the volatile (η^3-propenyl)$Fe(CO)_2(NO)$ **16** in a 1:2 ratio (based on the relative intensities of the NO's). The *in situ* transformation of **16** into **14** was accomplished by reaction with an excess of triphenyl phosphine, and **14** was isolated subsequently in a 65% overall yield.

2. *Reduction of the iron nitrosyl cation* $[Fe(CO)_2(NO)(P(C_6H_5)_3)_2]^+,BF_4^-$ **5**

These reactions were investigated to probe the utility of iron nitrosyl cations to serve as precursors of other iron nitrosyl derivatives. Cation **5** was already known to react with methoxide ion to yield a neutral carbomethoxy derivative (15). In the reaction with the boron hydride $LiHB(C_2H_5)_3$ **13** two competitive reactions were identified (Scheme 3).

Cation **5**, in suspension in THF, reacted with one to three molar equivalents of boron hydride **13** between −20°C and 0°C. Once the reaction reached completion (15 min), ir, ^{31}P nmr, and thin-layer chromatography revealed the formation of the degradation products **8**, **10**, and **11** (**9** was not detected) which were the only carbonyl and nitrosyl complexes to be

In **18**, $x + y \leq 4$ depending upon the coordination mode of the NO ligands

SCHEME 3 (L = $P(C_6H_5)_3$)

identified. Upon going from 3 to 6 equivalents of the reductant **13**, increasing amounts of the lithium salt of anion **15** were produced at the expense of the degradation products. With at least 6 equivalents of **13**, anion **15** was the sole metallic product to be characterized (≃80% spectroscopic yield). Although the distribution of the final reduction products was strongly affected by the amount of reducing agent used, there was no significant influence on the time required for the complete disappearance of cation **5**. Another characteristic of this reaction was the ability of one of the reduction products (anion **15**) to react rapidly with the complex subjected to the reduction (cation **5**). This was demonstrated by the following experiment. The same anion **15** (generated in two steps from an equimolar mixture of hydride **4** and reductant **13**, as described previously) reacted in THF at 0°C with the stoichiometric amount of cation **5**, added as a solid. In a few seconds, the same mixture of degradation products was produced as in the direct reduction of cation **5** with **13**. Considering previous results on related systems (22–26), an attractive route to anion **15** was to postulate the formation of the formyl complex **17** in the first step, followed by its decomposition into hydride **3** which had been found to undergo a rapid reduction upon reaction with borohydride **13**. Therefore, in an attempt to delineate the nature of the primary processes implicated in the reduction of cation **5**, its low temperature reactions in methylene chloride – THF solutions were monitored by ^1H and ^{31}P nmr. With $^{31}P\{^1H\}$ nmr, the only intermediate to be detected right after the reaction of cation **5** gave a single peak in the range δP = 61.8–62.3 ppm, depending upon the reaction conditions. Its transformation into anion **15** was fast. When an excess of reductant **13** was used, the reaction leading to **15** started at −60°C and was completed within 15 min upon raising the temperature to −40°C. In these conditions, anion **15** was the sole metallic product to be found at the end of the reaction. The nature of the intermediate remains speculative. The ^1H nmr of the solutions failed to reveal any proton resonance which could be assigned to hydride **3**. Instead, a low field triplet with 10 Hz separation between consecutive peaks was detected at δ = 13.6 ppm. The ^1H nmr data are comparable to those of the formyl complex $Ir(CO)(CHO)(P(C_6H_5)_3)_2$ (24). On that basis, the compound is tentatively formulated as the formyl derivative $Fe(CO)(NO)(CHO)(P(C_6H_5)_3)_2$ **17**. However, in the absence of low temperature ir data, the alternate formulation $Fe(CO)_2(NHO)(P(C_6H_5)_3)_2$ cannot be ruled out at present.

Discussion

In the protonation of anion **1** in THF with an excess of both the acid and the phosphine (Scheme 1), the intermediate detected by ir was likely the monosubstituted hydride **3**, on the basis of the νCO values. Probably, in those conditions, not enough free (unprotonated) phosphine was available for a rapid conversion into the disubstituted hydride **4**. The evolution towards the formation of cation **5** appears to be similar to the protonation of hydride **4** which led also to cationic complexes, and in particular to **5** when CO was present (7). In the appropriate acidic conditions, the formation of cationic derivatives indicates that the H ligand of both hydrides **3** and **4** can be removed formally as an H^-. The reductions into anions **12** and **15** demonstrate also that it can be removed easily as an H^+. Finally, the hydride ligand of hydride **3** can be transferred to an organic substrate, as shown by the stoichiometric hydrogenation reactions. The mechanisms of these reactions are not known at present, However, one should observe that, under our mild conditions, the reactive substrates were those capable of generating a resonance stabilized hydrocarbon radical. Thus, very much like the situation encountered with $MnH(CO)_5$ (27) or $CoH(CO)_4$ (3), the question of radical involvement in the hydrogenations with $FeH(CO)_2(NO)(P(C_6H_5)_3)$ should deserve further consideration.

Comparing further the reactivity of the iron nitrosyl complexes to that of the isoelectronic cobalt carbonyl hydrides reveals interesting differences; at least two are noteworthy.

The first difference resides in the substitution reactions. In particular, the substitutional lability of the monosubstituted hydride $FeH(CO)_2(NO)(P(C_6H_5)_3)$ **3**, reflected by its reaction with triphenyl phosphine to afford the disubstituted hydride $FeH(CO)(NO)(P(C_6H_5)_3)_2$, **4**, contrasts sharply with the reported lack of reaction of the isoelectronic cobalt hydride $CoH(CO)_3(P(C_6H_5)_3)$ with an excess of the same phosphine (28). This might be an indication of a greater accessibility of the metal coordination sphere in the iron complexes, possibly a consequence of the presence of the NO ligand.

The second major difference has to be found in the nature of the products resulting from thermal degradation. Decomposition of monohydrido complexes generally yields metallic dimers, as exemplified by the thermolysis of the cobalt hydrides $CoH(CO)_3(L)$ (L = CO (29), L = $P(OC_6H_5)_3$ (30), L = $P(C_6H_5)_3$ (31)). In no case could we detect the formation of metallic dimers containing a $(Fe(NO))_2$ unit in the thermolysis of the iron nitrosyl complexes $Fe(CO)_u(NO)(P(C_6H_5)_3)_v$ ($u + v = 3$, $v = 0$, 1, 2). Instead, a mixture of monometallic degradation products was formed. This difference in behavior is not restricted to thermolysis and appears to be general. For instance, metallic dimers were formed in the electrochemical one-electron oxidation of $[Co(CO)_4]^-$ (32), in the oxidation of $CpMo(CO)_3H$ (33) with molecular oxygen, in the reactions of olefins with $CpMo(CO)_3H$ (34), $MnH(CO)_5$ (27), or $CoH(CO)_4$ (3) (among others (35)), or in the reactions of a variety of cobaltates with cationic cobalt complexes (36). In contrast, $Fe(CO)_2(NO)_2$ resulted from the one-electron oxidation of the anion $[Fe(CO)_3(NO)]^-$ (37), and a mixture of the degradation products **8**, **9**, **10**, and **11** was formed in the reactions of $FeH(CO)_2(NO)(P(C_6H_5)_3)$ **3** with either molecular oxygen or olefins, and in the reaction of cation **5** with anion **15**.

All of these reactions have in common the persistent formation of monometallic dinitrosyl complexes (**2**, **8**, **9**, depending upon the reaction) which points to the occurrence of a nitrosyl exchange reaction at some stage of the reaction pathway. For such a reaction to take place, the formation of metal–metal bonded species appears to be a prerequisite (38, 39). This leads to the proposal that, in all these reactions, metallic dimers are actually formed, but they are transient intermediates because NO and CO exchange reactions promote fast and irreversible fragmentations into monometallic degradation products.[4]

This hypothesis offers an attractive and simple rationalization of the distribution of products found in the reduction of cation **5** (Scheme 3). The low temperature experiments have indicated that formation of anion **15** is a facile process at −40°C. Thus, in the temperature range −20°C to 0°C, when reduction of cation **5** in suspension in THF proceeded at a significant rate, anion **15** should have been present in solution before all of the cation had reacted with the reductant. It follows that, in parallel to the direct reduction of cation **5**, its rapid reaction with anion **15** should have occurred also to yield an unstable dimer such as **18**. Boron hydride **13** is known for its ability to reductively cleave metal–metal bonds (40). Therefore, reductive cleavage of dimer **18** back to anion **15** becomes an alternative to the irreversible evolution towards the degradation products. This model, which places the emphasis on the occurrence of a trapping reaction of the dimeric species **18** prior to its irreversible decomposition, has an obvious implication which is borne out by the results. As the excess of boron hydride **13** is increased, conversion of dimer **18** into anion **15** is expected to be favored at the expense of the degradation products, in agreement with the observations.

The question as to whether molecular hydrogen can perform also as an efficient trapping agent is then of prime importance in the context of catalytic reactions such as hydrogenation of hydroformylation. Very likely the unequivocal evaluation or the activity of the iron nitrosyl hydrides in those reactions will require conditions favoring an effective hydride regeneration step from a diiron dinitrosyl dimer, a reaction intermediate which is likely to be expected in the light of the known reactivity patterns (41, 42) of related systems. Experiments directed along those lines are underway.

[4]Extensive NO, CO, and phosphine exchanges were observed also in the reactions of halide complexes with metallates (47).

Synthesis and catalytic potential of coordinatively unsaturated rhodium hydride clusters incorporating chelating bidentate ligands

MICHAEL D. FRYZUK

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received August 20, 1982

MICHAEL D. FRYZUK. Can. J. Chem. **61**, 1347 (1983).

The synthesis of three coordinatively unsaturated clusters of the formula $[\{R_2PCH_2CH_2PR_2\}RhH]_x$ (R = OMe and OEt: $x = 4$; R = O-*i*-pr: $x = 2$) is described starting from the appropriate 2-methylallylrhodium(I) derivatives and H_2. The reaction of PMe_3 with these clusters results in the formation of mononuclear complexes of the formula $HRh(PMe_3)_2(R_2PCH_2CH_2PR_2)$. Olefins such as 1-hexene do not appear to react with the clusters although a slow isomerization to internal hexenes takes place. The tetranuclear clusters do not form a detectable adduct with H_2 up to 4 atm, although exchange with D_2 is observed. However, the dinuclear cluster adds one equivalent of H_2 per dimer to generate, in situ, $[\{(i\text{-prO})_2PCH_2CH_2P(O\text{-}i\text{-pr})_2\}_2Rh_2H_4]$. These clusters are catalytically active in the hydrogenation of 1-hexene with isomerization to internal hexenes being a competitive process. Although the evidence suggests that the dinuclear derivative does not fragment during the catalytic cycle, the catalytic activity of the tetranuclear clusters may be due to a smaller cluster present in low concentration, generated by fragmentation.

MICHAEL D. FRYZUK. Can. J. Chem. **61**, 1347 (1983).

On décrit la synthèse de trois agrégats insaturés coordonnés de formule $[\{R_2PCH_2CH_2PR_2\}RhH]_x$ (R = OMe et OEt; $x = 4$, R = O-*i*-pr: $x = 2$) à partir des dérivés appropriés du méthyl-2 allylrhodium(I) et du H_2. La réaction de PMe_3 avec ces groupes conduit à la formation des complexes mononucléaires de formule $HRh(PMe_3)_2(R_2PCH_2CH_2PR_2)$. Les oléfines, tel l'hexène-1, ne semblent pas réagir avec ces agrégats bien qu'il se produise une isomérisation lente en hexènes internes. L'agrégat tétranucléaire ne donne pas d'adduit décelable avec H_2 jusqu'à 4 atm en dépit du fait qu'on observe un échange avec D_2. Cependant l'agrégat binucléaire capte un équivalent de H_2 par dimère pour produire "in situ" le $[\{(i\text{-prO})_2PCH_2CH_2P(O\text{-}i\text{-pr})_2\}_2Rh_2H_4]$. Ces agrégats sont actifs catalytiquement lors de l'hydrogénation de l'hexène-1 avec une isomérisation en hexènes internes comme processus compétitif. Bien que les preuves suggèrent que le dérivé binucléaire ne se fragmente pas pendant le cycle catalytique, l'activité catalytique de l'agrégat tétranucléaire peut être dû à un agrégat plus petit présent à faible concentration et qui est produit par la fragmentation.

Introduction

The design of a transition metal based homogeneous catalyst for a particular chemical transformation requires the incorporation of many subtle features. Of these, coordinative unsaturation has long been recognized (1) as crucial since one must insure that the substrate molecule can coordinate to the metal complex at some point in the catalytic cycle. There are, of course, other properties that a catalyst must have, depending on the particular transformation of interest, but these can be largely overcome by a suitable choice of the metal and the ancillary ligands.

Rhodium(I) hydride complexes containing phosphorus ligands are well known (2) catalysts for olefin hydrogenation and isomerization type transformations. One of the earliest systems of this genre to be investigated (3) was P_4RhH where P = PPh_3. Using simple electron counting rules (4), P_4RhH is an 18 electron complex, and therefore coordinatively saturated, yet this particular derivative is catalytically active for the hydrogenation of olefins (5). This is not an exception to the requirement for coordinative unsaturation since it has been established (5) that phosphine dissociation occurs in solution to generate the 16 electron, coordinatively unsaturated species P_3RhH (reaction [1]) which is the active catalyst (6)

[1] $P_4RhH \rightleftharpoons P_3RhH + P$

Indeed, P_3RhH can be specifically synthesized (3, 6) and isolated and, not surprisingly, its catalytic activity was found to be greater than P_4RhH (7). It was initially believed (5) that the catalytic activity of P_3RhH also required dissociation to a 14 electron species P_2RhH (reaction [2]); however, this equilibrium was found (8, 9) to lie far to the left. Nonetheless, a

[2] $P_3RhH \rightleftharpoons P_2RhH + P$

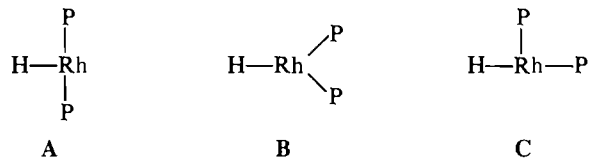
number of groups have investigated the synthesis and reactivity of 14 electron fragments of empirical formula P_2RhH. For instance (10), the use of bulky, monodentate phosphines such as tri-*tert*-butylphosphine, $P(t\text{-}Bu)_3$, and tricyclohexylphosphine, $P(C_6H_{11})_3$, generates mononuclear 14 electron fragments via dissociation of dinitrogen from $[P(t\text{-}Bu)_3]_2RhH(N_2)$ and $\{[P(C_6H_{11})_3]_2RhH\}_2\text{-}\mu\text{-}N_2$ (reaction [3]).

[3] $\frac{1}{x}[P_2RhH]_x(N_2) \xrightarrow{-N_2} P_2RhH$

$x = 1$, P = $P(t\text{-}Bu)_3$
$x = 2$, P = $P(C_6H_{11})_3$

Solution ^1H nmr studies indicate that these particular 14 electron complexes are T-shaped with *trans* disposed phosphines (Fig. 1, structure **A**); this agrees with MO calculations (11) which indicate that the Y-shaped structure (Fig. 1, **B**) is higher in energy. Interestingly, if phosphites ($P(OR)_3$) are used as ligands, a series of coordinatively unsaturated clusters of the formula $[\{P(OR)_3\}_2RhH]_x$ can be synthesized (12). Although the nuclearity of the cluster depends on the choice of $P(OR)_3$, these derivatives can be formulated, albeit simplistically, as overlapping hydride-bridged T-shaped fragments of structure **C** (Fig. 1).

Our strategy was to attempt to generate 14 electron complexes with structure **C** by the use of chelating bidentate ligands. In this manner we hoped to synthesize reactive, coordinatively unsaturated catalysts with the necessary active site *cis* to the hydride ligand by virtue of the fact that the phosphorus donors were constrained to be *cis* disposed. In fact, we were unable to isolate the proposed mononuclear fragments, but rather tetranuclear and dinuclear clusters of the formula $[\{R_2PCH_2CH_2PR_2\}RhH]_x$ (R = OMe and OEt: $x = 4$; R =



A B C

FIG. 1. Geometrical shapes available to the 14 electron fragments P_2RhH.

O-*i*-pr: $x = 2$) were generated. Fortunately, these clusters are catalytically active due to the fact that even as a cluster these derivatives are coordinatively unsaturated. We report here the syntheses of three such clusters and a portion of their reaction chemistry. A preliminary report of this work has appeared (13).

Cluster synthesis

The precursor to all the clusters of the formula $[\{R_2PCH_2CH_2PR_2\}RhH]_x$ is 2-methylallyl-1,5-cyclooctadienerhodium(I), $[\eta^3$-(2-Me-C_3H_4)Rh(COD)] (14). Substitution of the COD ligand by chelating phosphines or phosphinites is facile at room temperature (reaction [4]) to generate complexes

[4] 
R = OMe **1***a*
R = OEt **1***b*
R = O-*i*-pr **1***c*

of the type **1** which react with medium pressures of hydrogen (2–4 atm) according to reaction [5].

[5] 
R = OMe; $x = 4$ **2***a*
R = OEt; $x = 4$ **2***b*
R = O-*i*-pr; $x = 2$ **2***c*

For example, the addition of one equivalent of 1,2-bis(dimethoxyphosphino)ethane (dmope) to $[\eta^3$-(2-Me-C_3H_4)Rh(COD)] in hexane, results in the formation of $[\eta^3$-(2-Me-C_3H_4)-Rh(dmope)] (**1***a*). **1***a* can be isolated (14) and stored under nitrogen indefinitely; however, it is more convenient to immediately subject **1***a* to 2–4 atm of hydrogen in toluene solution. Over a period of a few hours, the bright yellow colour of **1***a* darkens to a deep, black–red from which dark maroon crystals of the tetranuclear cluster $[(dmope)RhH]_4$ (**2***a*) can be isolated in 60–70% yield. The nuclearity of the cluster is evident from the hydride resonance (13) which appears as an overlapping quintet of nonets due to coupling with four magnetically equivalent rhodium nuclei and eight magnetically equivalent phosphorus nuclei; a solution molecular weight determination confirms this tetrameric formulation. With the use of 1,2-bis(diethoxyphosphino)ethane (deope), a similar sequence generates the closely related tetranuclear cluster $[(deope)RhH]_4$ (**2***b*), although in this case crystalline material could not be obtained. At room temperature, the hydride resonance of **2***b* is broad, but sharpens upon heating to >40°C to an identical 23 line multiplet as is observed for **2***a*.

With the isopropyl-substituted chelating phosphinite, $(i\text{-prO})_2PCH_2CH_2P(O\text{-}i\text{-pr})_2$ (dipope), a dinuclear cluster, $[(dipope)RhH]_2$ (**2***c*), is obtained as bright red crystals from the reaction of $[\eta^3$-(2-Me-C_3H_4)Rh(dipope)] (**1***c*) with hydrogen. Once again the nuclearity of the cluster is evident from the phosphorus decoupled proton nmr wherein the hydride resonance appears as a triplet due to coupling with two magnetically equivalent rhodium nuclei.

All of these clusters are extremely air- and moisture-sensitive in solution and in the solid state. The thermal stability of these derivatives in solution appears to be quite high; at 60°C, no change is observed for **2***c* in C_6D_6 by ^1H nmr over 24 h, with similar behaviour shown for the tetranuclear derivatives **2***a* and **2***b*.

The use of infrared spectroscopy to aid in the analysis of the clusters has been rather disappointing; the Rh—H stretching frequency for the tetranuclear clusters cannot be assigned as the ir's of $[(deope)RhH]_4$ and its deuterated analogue, $[(deope)RhD]_4$, are superimposable. A medium absorption at 1180 cm^{-1} is assigned to ν_{Rh-H} for the dinuclear derivative $[(dipope)RhH]_2$ (ν_{Rh-D} = 870 cm^{-1}).

Reaction chemistry

The addition of excess trimethylphosphine, PMe_3, to **2***a* results in the slow loss of the deep red colour of the tetranuclear cluster, to generate a light yellow solution. By ^1H and $^{31}P\{^1H\}$ nmr, the species formed in quantitative yield is the mononuclear complex $[HRh(PMe_3)_2(dmope)]$ (**3***a*) (reaction [6]).

[6] 
R = OMe **3***a*
R = O-*i*-pr **3***b*

For the tetranuclear cluster, this reaction is remarkably slow, proceeding to completion over a period of 2–3 h. Monitoring the reaction by ^1H nmr indicates only the presence of the starting cluster and the mononuclear product. In contrast, the reaction of PMe_3 with the dinuclear complex **2***c* is immediate upon mixing to generate **3***c*.

The hydride resonances of **3***a* and **3***c* are virtually identical; for example, at room temperature the hydride portion of the ^1H nmr spectrum of **3***a* appears as a well resolved triplet of double triplets centered at −9.8 ppm with the following parameters: $^1J_{Rh}$ = 10.6 Hz; $^2J_{PMe_3}$ = 22.6 Hz; $^2J_{P(OMe)_2}$ = 88.5 Hz. Based on the known (15) structure of $\{P(OEt)_3\}_4RhH$, a similar pseudotetrahedral structure for **3** is reasonable with the hydride undergoing "tunneling" (15) between tetrahedral faces.[1]

A reaction which is remarkably dependent on the nuclearity of the cluster involves H_2. No reaction between the tetranuclear clusters, **2***a* and **2***b*, and H_2 is observed even up to 4 atm. Thus

[1]It is interesting to note that these mononuclear derivatives, **3**, have two types of tetrahedral faces due to the two types of ligands, unlike $\{P(OEt)_3\}_4RhH$ for which all the tetrahedral faces are identical. Based on coupling constants measured for **3***a*, it is conceivable that the hydride preferentially occupies that set of tetrahedral faces *trans* to the $P(OMe)_2$ donors since $^2J_{P(OMe)_2}$ = 88.5 Hz is typical of an "averaged" *trans* coupling (15) whereas $^2J_{PMe_3}$ = 22.6 Hz is consistent with a *cis* coupling constant.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

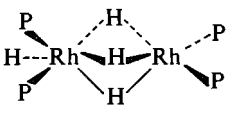
a sealed nmr tube of **2***a* under ≈4 atm of H_2 indicates only the presence of the starting tetranuclear cluster even down to −80°C. However, the hydrides of both tetranuclear clusters exchange with D_2 gas (1 atm) at room temperature over a period of 30−40 min. In contrast, the dinuclear complex **2***c* reacts immediately with H_2 to produce a new, dinuclear tetrahydride, $[(dipope)_2Rh_2H_4]$ (**4**) in quantitative yield (by ^1H nmr) (reaction [7]).

[7] 
2*c*

4

R = O-*i*-pr

Attempts to isolate **4** have so far proved unsuccessful as dehydrogenation to regenerate **2***c* appears to be facile. The structure of **4** shown is based on low temperature ^1H nmr studies (see Experimental section) wherein two hydride resonances of equal area are observed: a doublet of broad multiplets at −7.25 ppm (J_P = 148 Hz) and a broad multiplet at −12.0 ppm, at −50°C in C_7D_8. Further cooling to −90°C only results in slight broadening of these resonances. Based on other closely related dinuclear rhodium hydride complexes (12, 16), **4**, may not be the ground state structure of $[(dipope)_2Rh_2H_4]$; rather, a similar structure to that proposed (12) for $[\{P(O\text{-}i\text{-}pr)_3\}_4Rh_2H_4]$ (**5**) may be implicated.



P = P(O-*i*-pr)$_3$

5

Unfortunately, no corroborating evidence for the triply bridging hydride type structure was obtained for **4**.

Both tetranuclear clusters **2***a* and **2***b* appear inert to olefins such as 1-hexene, ethylene, butadiene, and 1,5-cyclooctadiene, although with 1-hexene, a very slow isomerization reaction is observed (vide infra). The dinuclear cluster **2***c* also appears, by ^1H nmr, indifferent to mono-olefins such as 1-hexene and ethylene whereas diolefins react quite rapidly (17).[2] Again, a very slow isomerization of 1-hexene is observed with **2***c*.

Hydrogenation of 1-hexene

The tetranuclear cluster **2***a* is an efficient catalyst for the hydrogenation of 1-hexene at 1 atm pressure and 22°C. Turnover numbers[3] are of the order of 150 h^{-1}. Concomitant with hydrogenation is an isomerization process which converts 1-hexene to *cis*- and *trans*-2-hexene in a ≈1:3 ratio; the turnover numbers for isomerization are ≈600 h^{-1} for *trans*-2-hexene formation and ≈180 h^{-1} for *cis*-2-hexene. In the absence of hydrogen, isomerization occurs with a turnover number of ≈3 h^{-1} with ratio of *trans*-2-hexene to *cis*-2-hexene being 2:1. It appears that a small amount of *cis*- and *trans*-3-hexene is also produced, but our method of analysis (see Experimental section) did not allow us to distinguish these particular stereoisomers from *cis*- and *trans*-2-hexene, respectively. It should be noted that although these turnover numbers are reproducible, extreme care must be taken to avoid oxygen contamination.

The corresponding turnover numbers for the dinuclear cluster **2***c* are higher; hydrogenation proceeds with turnover numbers of ≈700 h^{-1} while isomerization occurs with a turnover number of ≈1000 h^{-1} for *trans*-2-hexene and ≈300 h^{-1} for *cis*-2-hexene. In the absence of hydrogen, isomerization proceeds with a turnover number of ≈5 h^{-1}.

The tetranuclear cluster, **2***a*, and the dinuclear cluster, **2***c*, hydrogenate both terminal olefins and internal olefins with little or no selectivity; this is evidenced by the fact that hexane formation is relatively constant even after the disappearance of 1-hexene, leaving internal hexenes.

Discussion

Although our strategy to generate mononuclear 14 electron complexes was unsuccessful, we were able to isolate three new members of the family of coordinatively unsaturated clusters having the formula $[P_2RhH]_x$ (12, 13, 16). The nuclearity of the cluster appears to be a function of the bulkiness of the phosphorus donor ligand. The use of the bidentate ligand $(MeO)_2PCH_2CH_2P(OMe)_2$ allows for the formation of the tetranuclear cluster **2***a*, the largest member of this family of clusters; this contrasts the use of $P(OMe)_3$ as a monodentate ligand for which the trinuclear cluster $[\{(MeO)_3P\}_2RhH]_3$ is generated (12). In an attempt to generate a trinuclear cluster incorporating chelating bidentate phosphinite ligands, the use of $(EtO)_2PCH_2CH_2P(OEt)_2$ was investigated; however, only the tetranuclear cluster **2***b* was detected. The bulkier chelating phosphinite ligand $(i\text{-}prO)_2PCH_2CH_2P(O\text{-}i\text{-}pr)_2$ yields the dinuclear cluster **2***c*, analogues of which are known using monodentate phosphorus donors (12, 16).

The reactivity patterns of these clusters are beginning to take shape even though numerous reaction types other than those described are conceivable. The reaction of a strong ligand such as PMe_3 results in fragmentation of the cluster and the production of the mononuclear species **3**; the outcome of this reaction is independent of the cluster size, although the tetranuclear cluster is notably slower, and in line with these derivatives being coordinatively unsaturated (13). In contrast, mono-olefins do not form adducts which can be detected, and the cluster remains intact; however, the fact that isomerization is observed suggests either some type of weak interaction, or the generation of a reactive adduct in very small concentration.

Whereas the dinuclear cluster **2***c* oxidatively adds one equivalent of H_2 to generate the dinuclear tetrahydride **4**, no reaction with H_2 is observed with the tetranuclear clusters **2***a* and **2***b*. Yet, the hydrides of **2***a* and **2***b* exchange with D_2, again suggestive of a reactive intermediate present in very low concentration.

The differences in the reactivities of the tetranuclear clusters as compared to the dinuclear derivative are further observed

[2]For instance, 2,5-norbornadiene and 1,5-cyclooctadiene react instantaneously to generate new complexes which are under investigation.

[3]Turnover numbers for a given transformation, either hydrogenation or isomerization, are defined as: number of moles product per mole of cluster per hour.

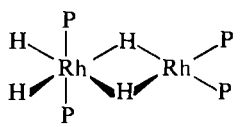
under catalytic hydrogenation conditions wherein the tetranuclear cluster exhibits lower turnover numbers for both hydrogenation and isomerization of 1-hexene.

It has been proposed (12, 16) that the mechanism of hydrogenation of olefins by dinuclear rhodium hydrides of the type $[P_2RhH]_2$, where P is a *monodentate* ligand such as $P(O\text{-}i\text{-}pr)_3$ or $P(NMe_2)_3$, proceeds without fragmentation of the binuclear framework to mononuclear species; the first step involves oxidative addition of H_2 to generate the dinuclear tetrahydride $[P_4Rh_2H_4]$, followed by olefin coordination and subsequent hydride transfers to give the alkane. The turnover numbers for hydrogenation by these dinuclear systems having monodentate ligands are approximately 10 times higher ($\approx$7200 h^{-1}) than our dinuclear cluster incorporating chelating ligands. Since the reaction conditions are comparable, it is tempting to suggest that the bidentate ligand influences the course of the reaction. Support for this comes from a recent X-ray study (16) of the dinuclear tetrahydride $[\{P(NMe_2)_3\}_4Rh_2H_4]$, wherein the phosphorus donors on one rhodium are *trans* disposed as in **6**, a stereochemistry which cannot be attained using the bidentate ligand strategy (cf. **4**).



$P = P(NMe_2)_3$

6

Although it is not clear as yet how the tetrahydride **6** could be more reactive than our tetrahydride **4**, it should be noted that, if hydrogenation and isomerization are competitive processes in the catalytic cycle, then a change in the stereochemistry of the tetrahydride intermediate may allow one process to dominate. This is in fact observed in our dinuclear system where turnover numbers for isomerization are higher than for hydrogenation.

Unfortunately, little can be deduced about the mechanism of hydrogenation of 1-hexene by the tetranuclear cluster **2***a*. It is possible that the active species, present in low concentration, is generated by fragmentation of the cluster. One possible stepwise fragmentation reaction would generate a trinuclear cluster in addition to a mononuclear fragment (reaction [8]); another possibility (reaction [9]) involves formation of dinuclear deriv-

[8] $[(dmope)RhH]_4 \rightleftharpoons [(dmope)RhH]_3 + \text{"(dmope)RhH"}$

[9] $[(dmope)RhH]_4 \rightleftharpoons 2[(dmope)RhH]_2$

atives. The presence of some undetectable reactive impurity in the tetranuclear cluster is also a possibility, although very little change in turnover numbers is observed for different batches of **2***a*. The fragmentation aspect of cluster catalysis is extremely important. For the dinuclear hydride systems, fragmentation does not appear to be a necessary component for catalysis; however, for the tetranuclear cluster, fragmentation to generate smaller clusters still remains as a possible mode of activation.

Another important facet which we are presently involved in is the following: if the cluster remains intact during the catalytic cycle, do the metal centers act synergistically (that is, substrate coordination by one metal, H_2 activation by another, and subsequent migration of the organic intermediates between metal centers), or, do the metal centers act independently within the cluster?

Experimental section

General procedures and precautions were identical to that previously described (14). Infrared spectra were recorded on a Pye-Unicam SP-1100 in matched solution cells (0.1 mm, NaCl). $[\eta^3\text{-}(2\text{-}Me\text{-}C_3H_4)Rh(dmope)]$ (**1***a*) was prepared by the literature procedure (14).

Ligand syntheses

All of the chelating phosphinite ligands were synthesized by King's method (18) from $Cl_2PCH_2CH_2PCl_2$ (19) and the appropriate alcohol, ROH (dried over $Mg(OR)_2$).

$(MeO)_2PCH_2CH_2P(OMe)_2$ (dmope): ^1H nmr (C_6D_6, ppm): PCH_2CH_2P, 1.72 (t, J_P = 6.2 Hz); $P(OCH_3)_2$, 3.32 (complex doublet, J_P = 11.0 Hz).

$(EtO)_2PCH_2CH_2P(OEt)_2$ (deope): ^1H nmr (C_6D_6, ppm): PCH_2CH_2P, 1.83 (t, J_P = 6.0 Hz); $P(OCH_2CH_3)_2$, 3.68 (m); $P(OCH_2CH_3)_2$, 1.00 (t, J_{CH_2} = 7.0 Hz).

(i-prO)$_2$PCH$_2$CH$_2$P(O-i-pr)$_2$ (dipope): ^1H nmr (C_6D_6, ppm): PCH_2CH_2P, 1.92 (t, J_P = 6.0 Hz); $P(OCH(CH_3)_2)_2$, 4.12 (m); $P(OCH(CH_3)_2)_2$, 1.22, 1.15 (d, J_{CH} = 6.0 Hz).

$[\eta^3$-(2-Me-C$_3$H$_4$)Rh(deope)] (1b): This complex was synthesized as previously described (14) for $[\eta^3\text{-}(2\text{-}Me\text{-}C_3H_4)Rh(dmope)]$. It was obtained as a yellow oil and characterized by its ^1H nmr. ^1H nmr (C_6D_6, ppm): H_{syn}, 3.83 (s, 2); H_{anti}, 2.29 (d, 2, J_P = 7.0 Hz); 2-CH_3, 1.57 (d, 3, J_{Rh} = 2.0 Hz); PCH_2CH_2P, 1.81 (m, 4); $P(OCH_2CH_3)_2$, 3.89 (m, 8); $P(OCH_2CH_3)_2$, 1.13 (t, 6, J_{CH_2} = 7.1 Hz), 1.08 (t, 6, J_{CH_2} = 7.1 Hz).

$[\eta^3$-(2-Me-C$_3$H$_4$)Rh(dipope)] (1c): This was synthesized as described above for **1***c*, and isolated as a yellow–green oil. ^1H nmr (C_6D_6, ppm): H_{syn}, 3.79 (s, 2); H_{anti}, 2.33 (br d, 2, J_P = 6.5 Hz); 2-CH_3, 1.59 (d, 3, J_{Rh} = 2.0 Hz); PCH_2CH_2P, 1.78 (m, 4); $P(OCH(CH_3)_2)_2$, 4.58 (m, 4, $J_P = J_{CH_3}$ = 6.1 Hz); $P(OCH(CH_3)_2)_2$, 1.26 (d, 12), 1.12 (d, 6), 1.03 (d, 6).

Cluster syntheses

The reaction of the 2-methylallylrhodium derivatives with hydrogen (purified by passage over MnO on vermiculite and activated 4 Å molecular sieves) was carried out in a 180 mL thick-walled glass vessel, which could be attached directly to a vacuum line, and was equipped with an 8 mm Kontes Teflon needle valve and a magnetic stirring bar.

[(dmope)RhH]$_4$ (2a): A yellow solution of **1***a* (0.700 g, 1.88 mmol) in toluene (10 mL) was degassed on the vacuum line, then cooled to −196°C and placed under 1 atm pressure of H_2. The needle valve was closed and the vessel allowed to warm to room temperature and then vigorously stirred for 24 h. The colour deepens over this time to generate a black–red solution. The excess H_2 was removed and the volume of the solution reduced to $\approx$1 mL. Hexanes (2–3 mL) was slowly added and the solution cooled at −30°C for 12 h. Large, maroon prisms formed and were filtered, washed with cold hexane, and dried under vacuum. Yield: 0.410 g (68%). mp 183°C (decomp.). Molecular weight (Signer): 1280 ± 50; theoretical: 1272. ^1H nmr (C_6D_6, ppm): $P(OCH_3)$, 3.83 (d, 48, J_P = 11.7 Hz); PCH_2CH_2P, 1.51 (br d, 16, J_P = 21.0 Hz); Rh*H*, −6.52 (q of nonets, 4, J_{Rh} = 10.7 Hz, J_P = 16.1 Hz). $^{31}P\{^1H\}$ nmr (C_6D_6, relative to $P(OMe)_3$ at +141.0 ppm): 199 (d of complex multiplets separated by $\approx$230 Hz). *Anal.* calcd. for $C_6H_{17}O_4P_2Rh$: C 22.66, H 5.39; found: C 22.91, H 5.32. ^1H nmr analysis of the filtrate from the recrystallization indicates the presence of an as yet unidentified trinuclear cluster in addition to the tetranuclear cluster: $^1H\{^{31}P\}$ nmr: (C_6D_6, ppm): Rh*H*, −6.5 (quartet, J_{Rh} = 16.5 Hz).

[(deope)RhH]$_4$ (2b): A yellow solution of **1***b* (0.900 g, 2.10 mmol) in toluene (12 mL) was treated with H_2 as described above for **2***a*. Stirring was maintained for 48 h to give a dark red–brown solution. Removal of the hydrogen and the toluene *in vacuo* gave an oily, dark red–brown solid which could not be purified further. Analysis by ^1H nmr indicates no other products are present. ^1H nmr (50°C, C_6D_6, ppm): $P(OCH_2CH_3)_2$, 4.31 (m, 32); PCH_2CH_2P, 1.56 (br d, 16); $P(OCH_2CH_3)_2$, 1.25 (t, 48, J_{CH_2} = 6.8 Hz); Rh*H*, −6.85 (q of nonets,

For personal use only.

4, J_{Rh} = 10.7 Hz, J_P = 16.1 Hz). $^{31}P\{^1H\}$ nmr (C_6D_6, relative to $P(OMe)_3$ at +141.0 ppm): 191.8 (d of complex multiplets separated by ≈230 Hz). *Anal.* calcd. for $C_{10}H_{25}O_4P_2Rh$: C 32.19, H 6.74; found: C 32.29, H 6.60.

[(dipope)RhH]$_2$ (2c): To a solution of [η^3-(2-Me-C_3H_4)Rh(COD)] (14) (0.534 g, 2.0 mmol) in hexanes (4 mL) was added dipope (0.653 g, 2.0 mmol) in hexanes (3 mL) dropwise with swirling to generate a clear olive-coloured solution. After 0.5 h, the hexanes were removed to yield an oily green–brown material which was dissolved in toluene (8 mL) and treated with H_2 as described above. After stirring for 48 h, the toluene was removed to give an oily dark-red solid which was dissolved in minimum hexanes (≈3 mL) and cooled at −30°C for 12 h. Red crystals deposited. Yield: 0.490 g (two crops, 57%). mp 153°C (decomp.). The filtrate appears to contain only the dimer contaminated by unreacted starting material. Molecular weight (Signer): 830 ± 30; theoretical: 861. ^1H nmr (C_7D_8, ppm): $P(OCH(CH_3)_2)_2$, 5.35 (m, 9, J_{CH_3} = 6.4 Hz); PCH_2CH_2P, 1.49 (br m, 8); $P(OCH(CH_3)_2)_2$, 1.45 (d, 24), 1.35 (d, 24); Rh*H*, −4.30 (br sep, 2, J_{Rh} = 34.1 Hz, J_P = 33–35 Hz). $^{31}P\{^1H\}$ nmr (C_6D_6, relative to $P(OMe)_3$ at +141.0 ppm): 196.4 (AA′A″A‴XX′, $|^1J_{Rh} + {}^3J_{Rh}|$ = 212.4 Hz). Infrared (hexane, cm^{-1}): ν_{Rh-H}, 1180 (m); ν_{Rh-D}, 870 (m). *Anal.* calcd. for $C_{14}H_{33}O_4P_2Rh$: C 39.08, H 7.73; found: C 39.01, H 7.62.

[HRh(PMe$_3$)$_2$ (dmope)] (3a): To a solution of **2***a* (0.100 g, 0.079 mmol) in toluene (3 mL) was added PMe_3 (0.100 g, 1.31 mmol) in toluene (3 mL) with swirling. The reaction mixture was allowed to stand for 2 h during which time the original deep red colour faded to give a light yellow solution. The toluene and excess PMe_3 were removed *in vacuo* to give a yellow oil which could not be crystallized. ^1H nmr (C_6D_6, ppm): $P(OCH_3)_2$, 3.44 (d, ^3J_P = 6.0 Hz); PCH_2CH_2P, 1.73 (d of m); $P(CH_3)_3$, 1.38 (br t); Rh*H*, −9.80 (t of dt, $^1J_{Rh}$ = 10.6 Hz, $^2J_{P(OMe)_2}$ = 88.5 Hz, $2J_{PMe_3}$ = 22.6 Hz). $^{31}P\{^1H\}$ nmr (C_6D_6, relative to $P(OMe)_3$, at +141.0 ppm): PMe_3, −22.6 (overlapping doublet of triplets, $^1J_{Rh}$ = 141 Hz, ^2J_P = 70.5 Hz); $P(OMe)_2$, 228.7 (d of t, $^1J_{Rh}$ = 185 Hz).

[HRh(PMe$_3$)$_2$ (dipope)] (3c): To a solution of **2***c* (0.065 g, 0.038 mmol) in hexanes (3 mL) was added PMe_3 (0.060 g, 0.790 mmol) in hexanes (3 mL) dropwise with swirling. The colour change was immediate to give a light yellow solution which was immediately pumped down under vacuum to given an off-white solid. Recrystallization from minimum hexanes gave colourless plates. Yield: 0.080 g (91%). ^1H nmr (C_6D_6, ppm): $P(OCH(CH_3)_2)_2$, 4.57 (m, $J_{CH_3} = J_P$ = 6.1 Hz); PCH_2CH_2P, 1.71 (br d., J_P = 23.0 Hz); $P(CH_3)_3$, 1.40 (br s); $P(OCH(CH_3)_2)_2$, 1.24, 1.18 (d, J_{CH} = 6.1 Hz); Rh*H*, −10.4 (t of dt, $^1J_{Rh}$ = 10.7 Hz, $^2J_{P(OMe)_2}$ = 85.4 Hz, $^2J_{PMe_3}$ = 21.1 Hz).

[(dipope)$_2$Rh$_2$H$_4$] (4): The dinuclear cluster **2***c* (0.030 g, 0.035 mmol) was dissolved in C_7D_8 (0.40 mL) and placed in an nmr tube sealed to a ground glass joint and fitted with a Teflon needle valve adapter. The nmr tube assembly was attached to a vacuum line and the solution degassed. At −196°C, H_2 (600 Torr) was introduced and the tube sealed with a toreh. After warming to room temperature, the nmr tube was cooled to −50°C in the nmr spectrometer. ^1H nmr (C_7D_8, −50°C): $P(OCH(CH_3)_2)_2$, 5.48, 5.03 (m); PCH_2CH_2P. 1.84, 1.67 (br d, J_P ≈ 20 Hz); $P(OCH(CH_3)_2)_2$, ≈1.36, 1.19 (overlapping doublets, J_{CH} = 6.0 Hz); Rh*H*, −7.25 (d of m, bridging, J_P = 148 Hz), −12.0 (br s, terminal).

Hydrogenation of 1-hexene

The hydrogenation apparatus was similar to that described for the reactor used to synthesize the clusters. A 250 mL thick-walled glass vessel fitted with a Kontes 8 mm Teflon needle valve and an efficient magnetic stirring bar was loaded with 1-hexene (Aldrich, purified by drying over activated 4 Å molecular sieves, then vacuum transferred and degassed, followed by passage through neutral alumina; the purified material was stored under N_2 in the glove box) and the cluster (ratio of substrate to cluster: ≈1500–2000:1) in the glove box and transferred to a vacuum line which had access to purified H_2. After the solution was degassed, a constant temperature bath maintained at 22.0°C was placed around the flask and hydrogen admitted to 1 atm. Samples were withdrawn periodically via the Teflon needle valve port using an argon-flushed syringe, vacuum transferred away from the catalyst, and analyzed by gas chromatography. A Varian 6000 instrument equipped with FID detectors, a 20% tri-*o*-cresylphosphate on 60/80 chromosorb-P column (20′ × 1/8″ SS) operating at 50°C was used. The identities of the gc traces were established by "spiking" with the pure materials (Aldrich).

Preparation, characterization, and some reactions of hydridobis(tri-*tert*-butyl)phosphineplatinum(II) cation containing three-coordinate platinum

RAM G. GOEL[1] AND RAMESH C. SRIVASTAVA[2]

The Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received September 7, 1982

RAM G. GOEL and RAMESH C. SRIVASTAVA. Can. J. Chem. **61**, 1352 (1983).

Removal of the chloride ligand from *trans*-PtHCl[P(*t*-Bu)$_3$]$_2$ by a noncoordinating anion affords the complexes *trans*-[PtH{P(*t*-Bu)$_3$}$_2$]X (X = PF_6, BF_4, ClO_4, SO_3CF_3), **1***a*, **1***b*, **1***c*, and **1***d* respectively, which contain the cationic hydride in which platinum is formally three-coordinate. Complexes **1** react with several σ-donor neutral ligands, L, to give the square-planar complexes *trans*-[PtHL{P(*t*-Bu)$_3$}$_2$]X. No reaction occurs with $H_2C{=}CH_2$ or $F_2C{=}CF_2$ but $(NC)_2C{=}C(CN)_2$ reacts with **1***c* to give an air-stable complex *trans*-[PtH{$(NC)_2C{=}C(CN)_2$}{P(*t*-Bu)$_3$}$_2$]ClO_4 which is indicated to contain π-bonded $(NC)_2C{=}C(CN)_2$. Neither PhC≡CPh nor $MeO_2CC{\equiv}CCO_2$ reacts with **1** but HC≡CH seems to react reversibly to form the four-coordinate species *trans*-[PtH(HC≡CH){P(*t*-Bu)$_3$}$_2$]$^+$, which could not be isolated. In marked contrast to the behaviour of previously reported cationic platinum(II) hydrides, addition of an equivalent of PCy_3 of P(*t*-Bu)$_3$ to an acetone solution of **1** results in its deprotonation and gives the platinum(0) complex Pt[P(*t*-Bu)$_3$]$_2$ quantitatively. Deprotonation of **1** also occurs upon treatment with NH_3, Me_2S, and NaOMe in acetone.

RAM G. GOEL et RAMESH C. SRIVASTAVA. Can. J. Chem. **61**, 1352 (1983).

L'élimination d'un ligand chlorure du PtHCl[P(*t*-Bu)$_3$]$_2$ par un anion coordonnant conduit aux complexes de [PtH{P(*t*-Bu)$_3$}$_2$]X *trans* (X = PF_6, BF_4, ClO_4, SO_3CF_3), **1***a*, **1***b*, **1***c* et **1***d* respectivement, qui contiennent l'hydrure cationique dans lequel le platine est formellement tricoordonné. Le complexe **1** réagit avec plusieurs ligands neutres σ-donneurs, L, en donnant des complexes carrés-plans de [PtHL{P(*t*-Bu)$_3$}$_2$]X *trans*. Il n'y a pas de réaction avec $H_2C{=}CH_2$ ou $F_2C{=}CF_2$ mais le $(NC)_2C{=}C(CN)_2$ réagit avec **1***c* en donnant un complexe de [PtH{$(NC)_2C{=}C(CN)_2$}{P(*t*-Bu)$_3$}$_2$]ClO_4 *trans* stable à l'air qui contient le $(NC)_2C{=}C(CN)_2$ lié par une liaison π. Ni le PhC≡CPh ni le $MeO_2CC{\equiv}CCO_2$ ne réagit avec le composé **1** mais le HC≡CH semble réagir de façon réversible en donnant des complexes tétracoordonnés de [PtH(HC≡CH){P(*t*-Bu)$_3$}$_2$]$^+$ *trans* que l'on ne peut isoler. Contrastant de façon marquée avec le comportement des hydrures cationiques de platine(II) rapportés antérieurement, l'addition d'un équivalent de PCy_3 ou de P(*t*-Bu)$_3$ sur le composé **1** en solution dans l'acétone conduit à sa déprotonation et donne quantitativement le complexe de platine(0): le Pt[P(*t*-Bu)$_3$]$_2$. La déprotonation du composé **1** se produit également lorsqu'on le fait réagir avec le NH_3, le Me_2S ou le NaOMe dans l'acétone.

[Traduit par le journal]

Introduction

Several cationic platinium(II) hydrides stabilized by tertiary phosphine ligands have been prepared (1) by removing the halide, X, in the complexes $PtHX(PR_3)_2$, by a poorly coordinating anion (such as ClO_4^-, BF_4^-, or PF_6^-) in the presence of either a neutral ligand or a donor solvent. Cations of the type $[PtHL(PR_3)_2]^+$, where L is a donor solvent, have often been generated and used *in situ*. All such cationic hydrides, including the complexes (1*f*) *trans*-$[PtHL(PCy_3)_2]^+$ (L = PCy_3 or P(*o*-tolyl)$_3$), invariably contain formally four-coordinate platinum(II).

As part of our continuing investigation on steric and electronic effects in platinum metal complexes of tertiary phosphines (2–7) and arsines (8–10), stabilization of platinum(II) (4, 8) and palladium(II) (9) hydrides by tri-*tert*-butylphosphine and -arsine ligands has been investigated in this laboratory. Tri-*tert*-butylphosphine has a larger steric requirement (11) than tricyclohexylphosphine as shown by the P—Pt—P angles in the two-coordinate complexes Pt{P(*t*-Bu)$_3$}$_2$ (6*a*) and Pt[PCy_3]$_2$ (12); unlike the tris(tricyclohexylphosphine)-platinum(II)$^+$ complex [PtH(PCy_3)$_3$], no metal complex containing more than two P(*t*-Bu)$_3$ ligands bonded to a metal has been isolated. The present work was undertaken to explore the possibility of stabilizing the formally three-coordinate platinum(II) hydride by tri-*tert*-butylphosphine. Coordinatively unsaturated transition metal hydrides are invariably involved in homogeneous catalytic hydrogenation and isomerization of olefins. Thus, knowledge of their chemistry is essential for a better understanding of the above-mentioned catalytic processes (13, 14). A preliminary report (15) on this work has appeared.

Results and discussion

Treatment of *trans*-PtHCl[P(*t*-Bu)$_3$]$_2$ with AgX (X = PF_6, BF_4, ClO_4, SO_3CF_3) in acetone or methanol, according to eq. [1], affords the cationic hydridoplatinum(II) complexes *trans*-[PtH{P(*t*-Bu)$_3$}$_2$]X (X = PF_6 (**1***a*), BF_4 (**1***b*), ClO_4 (**1***c*), SO_3CF_3 (**1***d*)), in almost quantitative yields.

[1] *trans*-PtHCl{P(*t*-Bu)$_3$}$_2$ + AgX → *trans*-[PtH{P(*t*-Bu)$_3$}$_2$]X + AgCl

(X = PF_6, BF_4, ClO_4, SO_3CF_3)

The compounds **1***a*–**1***d* are moisture-sensitive yellow solids which are soluble in polar solvents such as acetone, acetonitrile, and dichloromethane. Conductivity measurements on their 10^{-3} *M* solutions in dichloromethane gave Λ_M values ~50 M^{-1} ohm^{-1} cm^{-1} which are consistent with their formulation as 1:1 electrolytes (16). Analytical data and the characteristic infrared frequencies for the four compounds are given in Table 1. Their ^{1}H and ^{31}P-{^{1}H} nmr parameters are listed in Table 2.

The ^{31}P-{^{1}H} nmr spectra for all the four compounds in CH_2Cl_2 (containing 20% C_6D_6) consist of a main resonance (86.2–86.7 δ) and a pair of satellite resonances showing ^{195}Pt—^{31}P spin–spin coupling (^1J(Pt—P) = ~2625 Hz); the spectrum of **1***a* also shows a characteristic septet at −144.7 δ

[c] ^{2}H nmr data for $[PtD\{P(t\text{-}Bu)_3\}_2]PF_6$: (*a*) in CH_2Cl_2, δ(Pt—D) = −36.2 ppm, ^1J(Pt—D) = 391 Hz, (*b*) in $(CH_3)_2CO$, δ(Pt—D) = −27.9 ppm, ^1J(Pt—D) = 248 Hz.
[d] ^{2}H nmr data for $[PtD(CO)\{P(t\text{-}Bu)_3\}_2]PF_6$ in CH_2Cl_2, δ(Pt—D) = −5.6 ppm, ^1J(Pt—P) = 114 Hz.

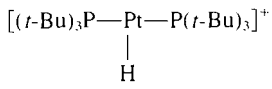

FIG. 1. T-shaped cationic hydride.

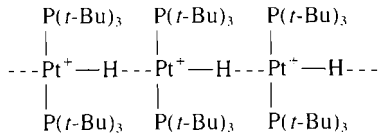

FIG. 2. Polymeric structure of cationic hydride.

(^1J(P—F) = 710 Hz) due to PF_6^-. The ^{1}H nmr spectra of **1***a*–**1***d*, in CD_2Cl_2, exhibited a 1:2:1 triplet due to the *t*-butyl protons (1.52 δ, $|^3J$(P—H) + ^5J(P—H)$|$ ≃ 13.5 Hz); a high-field triplet (~−36.2 δ, ^2J(P—H) ≃ 8.7 Hz), flanked on each side by a satellite triplet (^1J(Pt—H) ≃ 2570 Hz, ^2J(P—H) ≃ 8.7 Hz) of relative intensity 0.25, was observed due to the proton bonded to platinum. The appearance of the *t*-butyl resonance as a 1:2:1 triplet is indicative of "virtual coupling" (17) showing that the two phosphines are mutually *trans*.

The infrared spectra for **1***a*–**1***d*, in the solid state, showed characteristic bands due to the free anion (18), X, and coordinated P(*t*-Bu)$_3$ (19). It also showed a medium band at 1080 cm^{-1} which can be assigned to the Pt—H bending mode. The Pt—H stretching frequency for the three-coordinate *trans*-[PtH{P(*t*-Bu)$_3$}$_2$]$^+$ is expected to be above 2400 cm^{-1} because ν(Pt—H) for the four-coordinate *trans*-PtHX[P(*t*-Bu)$_3$]$_2$ complexes (4*a*) is in the 2400 cm^{-1} region. No band which can be assigned to ν(Pt—H) was evident in the spectra of **1***a*–**1***d*. It is very likely that ν(Pt—H) for these compounds overlaps with the C—H stretching vibrations of P(*t*-Bu)$_3$ which fall in the 2800 to 2900 cm^{-1} region. Support for this proposal is provided by the infrared spectrum of the deuterated analogue of **1***a* which shows a weak band at 2060 cm^{-1} attributable to ν(Pt—D). On this basis, ν(Pt—H) for ***1*** is expected to occur at ca. 2860 cm^{-1}.

The structure of **1***c* in the solid state was probed further by recording its high resolution ^{31}P-{^{1}H} nmr spectrum in the solid state by using magic-angle spinning technique (20). The spectrum was very similar to that observed in solution in CD_2Cl_2 and showed a main resonance at 89.08 accompanied by a pair of satellite resonances giving the ^1J(Pt—P) value of 2600 Hz which is very close to that observed in solution in CD_2Cl_2. Thus the structure of the cation *trans*-[PtH{P(*t*-Bu)$_3$}$_2$]$^+$ in the solid state cannot be markedly different than that in solution.

The δ(Pt—H), ^1J(Pt—H), and ν(Pt—H) values for **1***a*–**1***d* are the largest known for a platinum(II) hydride. Furthermore, these values are invariant of the nature of the anion X. On the basis of the spectral and conductance data and the diamagnetism[3] of the compounds, all of the four compounds are assigned an ionic structure containing the formally three-coordinate T-shaped cationic hydride as shown in Fig. 1. A polymeric structure such as shown in Fig. 2 can be ruled out on the basis of the very large values of δ(Pt—H), ^1J(Pt—H), and ν(Pt—H) as well as the absence of infrared bands attributable to ν(Pt—H—Pt). For example, the δ(Pt—H) and ^1J(Pt—H) values for the bridging hydride in the complex [Ph(PEt$_3$)$_2$Pt^a—H—Pt^b(PEt$_3$)$_2$H]$^+$ have been reported to be −9.46 δ, and ≃500 Hz [^1J(Pt^a—H) ≃ ^1J(Pt^b—H)], respectively (21).

Complexes **1** react according to eq. [2] with a variety of neutral ligands (L) to give the four-coordinate hydrides *trans*-[PtHL{P(*t*-Bu)$_3$}$_2$]X.

[2] *trans*-[PtH{P(*t*-Bu)$_3$}$_2$]X + L ⇌ *trans*-[PtH{P(*t*-Bu)$_3$}$_2$L]X

(L = H_2O, $(CH_3)_2O$, NH_3, RCN (R = Me, *t*-Bu, C_6F_5), *t*-BuNC, and CO)

*Reactions of **1** with σ-donor neutral ligands*

If either the silver salt or the solvent used for reaction [1] is not completely dry, the reaction affords the aquo complexes *trans*[PtH(OH$_2$){P(*t*-Bu)$_3$}$_2$]X, **2***a* (X = PF_6), **2***b* (X = BF_4), **2***c* (X = ClO_4), and **2***d* (X = SO_3CF_3). Complexes **2***a* and **2***c* were also obtained readily by treating Pt{P(*t*-Bu)$_3$}$_2$ with aqueous solutions of HPF_6 and $HClO_4$ as represented by eq. [3].

[3] Pt{P(*t*-Bu)$_3$}$_2$ + H_3O^+ + X^- → *trans*-[PtH{P(*t*-Bu)$_3$}$_2$OH$_2$]X

(X = PF_6, ClO_4)

The C and H analyses for complexes **2** and their anhydrous analogues, **1**, are not expected to be significantly different. Complexes **2** are, however, unequivocally characterized by their spectral data. As shown in Table 1, the infrared spectra for **2***a*–**2***c*, in the solid state, show bands at ca. 3340–3370, 3240–3230, and 1620–1640 cm^{-1} attributable to the antisymmetric and symmetric O—H stretching and H—O—H bending frequencies (18), respectively. The nmr data which are given in Table 2 show that the hydride chemical shift for the aquo complex **2***b* is 6.5 ppm downfield from that for the anhydrous analogue **1***b*; the ^1J(Pt—H) for **2***b* is 810 Hz less than that for **1***b*. The ^{31}P-{^{1}H} nmr parameters for **2** are also different than those for the anhydrous analogues.

The data given in Table 2 show that the hydride chemical shifts for **1***a*–**1***d* move ca. 8.5 ppm downfield and the ^1J(Pt—H) values decrease by ca. 1000–1100 Hz when the spectra are measured in $(CD_3)_2CO$ instead of CD_2Cl_2; the ^{31}P chemical shifts and the ^1J(Pt—P) values for the acetone and dichloromethane solutions are also different. The observed changes in the nmr spectral parameters in going from dichloromethane to acetone are best accounted for in terms of the reaction of the three-coordinate species with acetone to form the four-coordinate hydride *trans*-[PtH{P(*t*-Bu)$_3$}$_2$OC(CH$_3$)$_2$]$^+$, **3**.

The ^{1}H nmr spectra of **1** and **2** in acetone-d_6, were identical except that the spectra for **2** showed an additional resonance at ~3.0 δ which is attributable to H_2O displaced by acetone-d_6. Attempts to isolate the acetone complexes **3**, however, failed; removal of acetone afforded the starting materials **1** or **2**. It appears therefore that the equilibrium in eq. [2] lies far to the left when L = acetone and that the water is replaced only because of the high concentration of acetone when it is used as a solvent. This is presumably due to the larger steric requirement of acetone than H_2O.

The yellow colour of dichloromethane solutions of **1** was discharged completely when gaseous NH_3 was passed through them. The resulting colourless solutions afforded the ammine complexes *trans*-[PtH(NH$_3$){P(*t*-Bu)$_3$}$_2$]X, **4***a* (X = PF_6), **4***b* (X = BF_4), **4***c* (X = ClO_4) quantitatively. The infrared (Table 1)

[3]In a trigonal planar structure the *d* orbitals of platinum will split in the order d_{xz}, d_{yz} < d_{z^2} < d_{xy}, $d_{x^2-y^2}$ giving rise to two unpaired 5*d* electrons (33).

and the ^1H and ^{31}P-$\{^1H\}$ nmr spectral data (Table 2) for **4***a*–**4***c* were identical to those of authentic samples prepared by the reaction of $Pt[P(t\text{-}Bu)_3]_2$ with NH_4X (22).

Treatment of dichloromethane solutions of **1** with nitriles, *t*-butylisonitrile, and carbon monoxide gave the four-coordinate hydrides *trans*-$[PtHL\{P(t\text{-}Bu)_3\}_2]X$, **5** (L = CH_3CN, *a* (X = PF_6), *b* (X = BF_4), *c* (X = ClO_4)), **6***c* (L = (*t*-Bu)CN, X = ClO_4), **7***a* (L = C_6F_5CN, X = PF_6), **8** (L = *t*-BuNC, *a* (X = PF_6), *c* (X = ClO_4)), **9** (L = CO, *a* (X = PF_6), *b* (X = BF_4), *c* (X = ClO_4), *d* (X = SO_3CF_3)). Complexes **5**–**9** were also obtained by displacement of the aquo ligand in **2** with nitriles, *t*-butylisonitrile, and carbon monoxide. They are air-stable white solids. All of them were characterized by elemental analyses (Table 1) and by infrared and ^1H and ^{31}P nmr measurements.

The ν(Pt—H), ν(CN), ν(CO), and the anion frequencies for **5**–**9** are tabulated in Table 1. The Pt—H stretching frequency can couple with ν(CN) or ν(CO). The CO stretching frequency for the deuterated analogue of **9***a* was observed to increase by 20 cm^{-1} indicating that the perturbation of ν(CO) by ν(Pt—H) is ca. 20 cm^{-1}. The ν(CN) values for **5**–**7** are comparable to those reported for the cationic methylplatinum(II)–nitrile complexes (23) suggesting little coupling between ν(Pt—H) and ν(CN) in the former compounds. The ν(Pt—H) for the nitrile complexes **5**–**7** is very similar to that for the ammine complexes **4**. For the isonitrile and carbonyl complexes this frequency decreases by 100–130 cm^{-1}.

The ^1H and ^{31}P-$\{^1H\}$ nmr spectra for **5**–**9** show the same features as described for **1**–**4**; the spectral parameters are given in Table 2. The hydride chemical shifts for the nitrile complexes are very similar to those for the ammine complexes but the ^1J(Pt—H) values for the former complexes are higher. The isonitrile and carbonyl complexes are characterized by very low upfield hydride chemical shifts (ca. −5.0 to −9.0 δ) as well as very low ^1J(Pt—H) values (660 to 740 Hz). The ^{31}P-$\{^1H\}$ nmr parameters for **5**–**9**, like those for the other four-coordinate complexes **2**–**4** also differ from those for **1**. However, the changes are not as marked as in the ^1H nmr parameters.

Unlike the aquo complexes, the nmr parameters for the ammine, nitrile, isonitrile, and carbonyl complexes did not change significantly when solvent was changed to acetone or acetone-d_6. Thus, the ammine, nitrile, isonitrile, or CO are not displaced by acetone. The ammine and the nitrile complexes were readily converted to the corresponding carbonyl complexes when CO was bubbled through their solutions in dichloromethane.

Facile deprotonation of ***1***

In marked contrast to the formation (1) of the complexes such as *trans*-$[PtHL(PR_3)_2]^+$, where R = Et or PCy, L = a tertiary phosphine or arsine, facile deprotonation of complexes **1** according to eq. [4] occurred when an equimolar amount of either Pcy_3 or $P(t\text{-}Bu)_3$ was added to their solutions in acetone.

$$[4]\quad \textit{trans}\text{-}Pt[H\{P(t\text{-}Bu)_3\}_2]^+ + B \rightleftharpoons Pt[P(t\text{-}Bu)_3] + BH^+$$

$$(B = NH_3,\ Pcy_3,\ P(t\text{-}Bu)_3,\ SMe_2,\ OMe^-)$$

The platinum(0) complex $Pt[P(t\text{-}Bu)_3]_2$ was also obtained almost quantitatively when NH_3 was passed through acetone solutions of **1**. Complex **1***c* was also deprotonated upon adding excess dimethylsulfide to its solution in acetone. It is very unlikely that deprotonation of **1** by Pcy_3 or $P(t\text{-}Bu)_3$ proceeds via coordination of the phosphine to platinum and subsequent reductive elimination of the protonated phosphine from the resulting four-coordinate hydride. A plausible reaction pathway for the observed deprotonation seems to be attack of the nucleophile on the hydride which apparently behaves as a proton. The reaction is perhaps driven to completion due to the insolubility of $Pt[P(t\text{-}Bu)_3]_2$ in the reaction medium.

Reactions of ***1*** *with alkenes and alkynes*

^1H nmr measurements showed that no reaction occurred when $H_2C{=}CH_2$ or $F_2C{=}CF_2$ was passed through solutions of **1** in CD_2Cl_2 or $(CD_3)_2CO$ at room temperature. No reaction also occurred when dichloromethane solution of **1** was treated with PhC≡CPh or $MeO_2CC{\equiv}CCO_2Me$ for several hours. Lack of reactivity of **1** towards the above-mentioned alkenes or alkynes is in marked contrast to the facile insertion of olefins (1*d*, *e*) and acetylenes (24) into the Pt—H bond of the cationic platinum(II) hydrides *trans*-$[PtHL(PEt_3)_2]^+$. The lack of reactivity of the three-coordinate hydride is undoubtedly attributable to the steric crowding around platinum caused by the two very bulky $P(t\text{-}Bu)_3$ ligands.

Treatment of **1***c* with tetracyanoethylene in dichloromethane, however, afforded *trans*-$[PtH\{(NC)_2C{=}C(CN)_2\}\{P(t\text{-}Bu)_3\}_2]ClO_4$, **10***c*, in high yield. It is a red-brown air-stable solid, soluble in dichloromethane and acetone. Its infrared spectrum (Nujol mull) shows a medium-strong band at 2250 cm^{-1} and a medium band at 2210 cm^{-1} which are similar to the CN stretching bands observed at 2260 and 2230 cm^{-1} for the free $(NC)_2C{=}C(CN)_2$. Since coordination of nitriles (25) through the nitrogen atom usually results in an increase in the CN stretching frequency, the tetracyanoethylene in **10***c* is indicated to be bonded to platinum by a π-bond. Thus, it represents a rare and important class of compounds (1*d*, 26) which contain both olefin and hydride bonded to the metal. It has been demonstrated (13, 14, 27) that insertion of an olefin or diene into a transition metal – hydride bond proceeds via coordination of the C=C bond to the metal in a position *trans* to the hydride ligand.

The ^1H and ^{31}P-$\{^1H\}$ nmr spectra for **10***c* showed features similar to those observed for the other complexes examined in this work. The hydride chemical shift for **10***c* is 17 ppm downfield than that for the three-coordinate complex **1***c*; the ^1J(Pt—H) value is reduced by 1580 Hz. Nuclear magnetic resonance measurements showed that tetracyanoethylene in **10***c* is displaced by CH_3CN as well as by CO but not by $(CD_3)_2CO$.

The yellow solution of **1***c* in CD_2Cl_2 became colourless when HC≡CH was passed through it at room temperature. As shown in Table 2, the ^1H nmr spectrum of the resulting solution showed features similar to those seen for **1***c* except that the hydride chemical shift was 3.2 ppm downfield and the magnitude of ^1J(Pt—H) was 400 Hz less. The infrared spectrum of the solution showed a weak band at 2580 cm^{-1} and a sharp medium band at 2200 cm^{-1} attributable to ν(Pt—H) and ν(C≡C), respectively. The spectral data are thus indicative of the presence of four-coordinate species *trans*-$[PtH(HC{\equiv}CH)\{P(t\text{-}Bu)_3\}_2]^+$, **11***c*. Acetylene complexes of the type $[PtH(RC{\equiv}CR)(PR_3)_2]^+$, like their olefin analogues, have been proposed (24, 28) as intermediates in reactions involving insertion of acetylenes into Pt—H bond but direct evidence for the proposed intermediates has been lacking. Spectral characterization of **11***c* provides support for the proposed intermediates. Attempts to isolate **11***c* were, un-

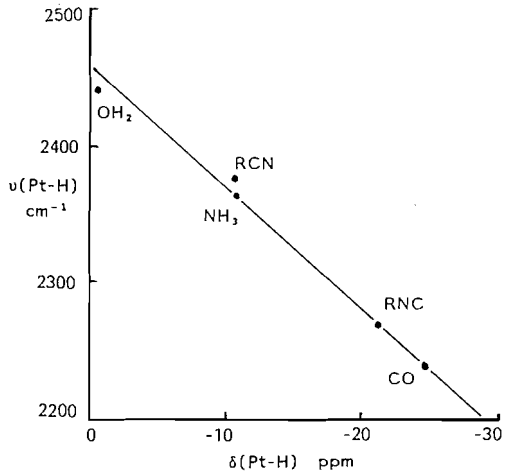

FIG. 3. A plot of ν(Pt—H), cm^{-1}, versus δ(Pt—H), ppm, for the *trans*-[PtHL{P(*t*-Bu)$_3$}$_2$]X complexes (L = H_2O, NH_3, RCN, RNC, CO).

fortunately, not successful; starting material **1***c* was recovered unchanged upon removing the volatiles. Lack of reaction of HC≡CH with the Pt—H bond in **1** is indeed remarkable and further demonstrates the extent of the kinetic stabilization provided by the steric bulk of the two P(*t*-Bu)$_3$ ligands.

The effects of the ligand *trans* to the hydride on δ(Pt—H), ^1J(Pt—H), and ν(Pt—H) have been examined (1*a*, *b*) for the series *trans*-[PtHL{E(Et)$_3$}$_2$]$^+$, where E = P or As and L = a neutral σ-donor ligand. It has been concluded that the ν(Pt—H) and ^1J(Pt—H) for the above-mentioned complexes decrease with increasing σ-donor strength of L. In the present work, ν(Pt—H) for the four-coordinate hydrides *trans*-[PtHL{P(*t*-Bu)$_3$}$_2$]$^+$ decreases in the order: H_2O > RCN > NH_3 > (*t*-Bu)NC > CO; the Pt—H coupling constants decrease in the order:

$$HC{\equiv}CH > H_2O > (CD_3)_2CO >> RCN > (NC)_2C{=}C(CN)_2 > NH_3 > CO > (t\text{-Bu})NC$$

The upfield hydride chemical shift falls in the order:

$$HC{\equiv}CH > H_2O > (CD_3)_2CO >> RCN \simeq (NC)_2C{=}C(CN)_2 \simeq NH_3 >> (t\text{-Bu})NC > CO$$

According to Buckingham and Stephens (29), the main contribution to δ(Pt—H) in platinum(II) hydrides is from the paramagnetic shielding of the proton by the platinum 5*d*-electrons. Thus, a linear correlation is expected between δ(Pt—H) and ν(Pt—H). As shown in Fig. 3, a plot of δ(Pt—H) against ν(Pt—H) for **2**, **4**–**9** gives a straight line. A linear correlation between δ(Pt—H) and ν(Pt—H) is also found (30) for the series *trans*-PtHX(PPh$_2$Me)$_2$ but there is no such correlation for the series *trans*-[PtHL{E(Et$_3$)$_3$}$_2$]$^+$ (1*a*, *b*).

Neither the ^{31}P nmr chemical shifts nor the Pt—P couplings for the *trans*-[PtHL{P(*t*-Bu)$_3$}$_2$]$^+$ complexes seem to show any systematic dependence upon the nature of L. The ammine and the nitrile complexes have the lowest chemical shifts which are upfield from those for **1**. The carbonyl complexes have the highest chemical shifts, and these are downfield from those for **1**. The spread between the lowest and the highest δ value is, however, only 10.0 ppm. The acetone complex exhibits the highest ^1J(Pt—P) value (2830 Hz) and the carbonyl complex the lowest (2408 Hz).

Experimental section

General

Tri-*tert*-butylphosphine and all other air- and moisture-sensitive materials were manipulated under an atmosphere of oxygen-free dry nitrogen or argon using a Vacuum Atmospheres Corporation glovebox and standard vacuum line techniques.

Materials

P(*t*-Bu)$_3$ (31), K_2PtCl_4 (32), Pt[P(*t*-Bu)$_3$]$_2$ (6*b*), *trans*-PtHCl[P(*t*-Bu)$_3$]$_2$ (4*b*), and *trans*-[P(*t*-Bu)$_3$]$_2$PtDCl were prepared by reported methods. Spectrograde acetone was stored over molecular sieve (3-Å) and distilled prior to use. Dichloromethane, benzene, and pentane were treated with sodium wire, distilled, and stored over molecular sieve. Reagent grade CO (Matheson) was purified by passing through a column of KOH pellets. Other chemicals were used as received.

Physical measurements

Elemental analyses were performed by Guelph Chemical Laboratory, Guelph, Ont. Melting points were determined with a Gallenkamp apparatus. Conductivity measurements were made with a Yellow Spring Instrument conductivity meter using a glass cell with platinized platinum electrodes. Infrared spectra were measured with a Perkin-Elmer 180 double-beam spectrophotometer using KRS-5 and polyethylene discs for solid samples (Nujol mull) and sealed NaCl cells for solutions. Nuclear magnetic resonance spectra in solution were recorded with a Bruker WP60 (^{1}H and ^{31}P nmr) or a Bruker WH400 spectrometer operating in the Fourier transform mode. High-resolution solid-state ^{31}P nmr spectra were obtained with a Bruker XL100 Spectrometer using a recently reported procedure (20). Hydrogen chemical shifts are relative to internal TMS. All ^{31}P chemical shifts (solution and solid state) are relative to external 85% H_3PO_4; positive δ values are downfield from 85% H_3PO_4.

Preparation of trans-*[PtH{P(t-Bu)$_3$}$_2$]X (X = PF_6, BF_4, ClO_4, SO_3CF_3)* **1**a–**1**d

To a suspension of *trans*-PtHCl[P(*t*-Bu)$_3$]$_2$ (1 mmol) in acetone (5 mL) was slowly added, with stirring, a solution of AgX (1 mmol) in acetone (2 mL). The precipitated AgCl was filtered off. The filtrate was evaporated *in vacuo* to give a yellow solid which was dissolved in dichloromethane (~3 mL). The solution was passed through a short florisil column. Pentane was added to the collected solution to give yellow [PtH{P(*t*-Bu)$_3$}$_2$]X in over 90% yield. A similar procedure was used to prepare *trans*-[PtD{P(*t*-Bu)$_3$}$_2$]PF_6.

Preparation of trans-*[PtH(H$_2$O){P(t-Bu)$_3$}$_2$]X (X = PF_6, BF_4, ClO_4, SO_3CF_3)* **2**a–**2**d

(*a*) Reaction of *trans*-PtHCl[P(*t*-Bu)$_3$]$_2$ with AgX following the above described procedure was carried out using reagent grade undried acetone.

(*b*) To a suspension of Pt[P(*t*-Bu)$_3$]$_2$ (0.5 mmol) in acetone was added equimolar amount of aqueous HPF_6 or $HClO_4$ at 0°C. Removal of volatiles under reduced pressure and recrystallization of the residue from dichloromethane/hexane gave very pale yellow crystals of **2***a* or **2***c* in 80% yield.

Reactions of ***1*** *with* NH_3

(*a*) Ammonia was bubbled through a solution of [PtH{P(*t*-Bu)$_3$}$_2$]X (0.5 mmol) in dichloromethane (10 mL) until the yellow colour disappeared. The solvent was removed under reduced pressure and the resulting solid was recrystallized with dichloromethane/pentane to give white crystalline *trans*-[PtH(NH_3){P(*t*-Bu)$_3$}$_2$]X, **4**, in >90% yield.

(*b*) Pt[P(*t*-Bu)$_3$]$_2$ was precipitated almost quantitatively when ammonia was passed through an acetone solution of **1***c* until the yellow colour was completely discharged. It was filtered, weighed, and characterized by ^{31}P-{^{1}H} nmr measurements.

Reactions of ***1*** *and* ***3*** *with nitriles*

(*a*) Excess CH_3CN (>1 mol equiv.) was added to a solution of **1** or **3** (0.5 mmol) in dichloromethane (2 mL). Removal of the volatiles *in vacuo* gave white *trans*-[PtH($NCCH_3$){P(*t*-Bu)$_3$}$_2$]X in quantitative

yields. The products were recrystallized from dichloromethane/pentane.

(*b*) A solution of (*t*-Bu)CN (0.5 mmol) in dichloromethane (1 mL) was slowly added to a solution of **1** (0.5 mmol) in the same solvent (~5 mL). The yellow colour of the solution disappeared immediately. Concentration of the colourless solution to ~1 mL, dilution of the concentrate by pentane, and cooling of the resulting solution gave colourless crystals of *trans*-[PtH{NC(*t*-Bu)}{P(*t*-Bu)$_3$}$_2$]X in ~90% yield.

(*c*) Treatment of **1***a* (0.5 mmol) with C_6F_6CN (0.5 mmol) in either methanol or dichloromethane according to the procedure (*b*) gave colourless needles of *trans*-[PtH(NCC$_6$F$_5$){P(*t*-Bu)$_3$}$_2$]PF$_6$ in ~90% yield.

Reactions of ***1*** *with (t-Bu)NC*

A solution of (*t*-Bu)NC in dichloromethane (0.5 mmol in 2 mL) was added dropwise to a stirred solution of **1***a* or **1***c* (0.5 mmol) in the same solvent at 0°C. The colourless solution was warmed to room temperature and then evaporated *in vacuo*. Recrystallization of the resulting solid from dichloromethane/pentane gave colourless crystals of *trans*-[PtH{CN(*t*-Bu)}{P(*t*-Bu)$_3$}$_2$]X (yield: ~80%).

Reactions of ***1****,* ***3****, and* ***5*** *with CO*

Carbon monoxide was passed through a solution of the platinum(II) complex in dichloromethane (0.5 mmol in 5 mL) for ~5 min at room temperature. The resulting colourless solution was concentrated *in vacuo* (to ~1 mL), diluted with pentane, and then cooled in an ice bath to give white needles of *trans*-[PtH(CO){P(*t*-Bu)$_3$}$_2$]X in over 90% yield.

Reactions of ***1*** *with P(t-Bu)$_3$, PCy$_3$, As(t-Bu)$_3$, Me$_2$S, and NaMeO*

(*a*) Dropwise addition of an acetone solution of P(*t*-Bu)$_3$, Pcy$_3$, or NaMeO (0.5 mmol in 2 mL) to a stirring solution of **1***c* (0.5 mmol) in the same solvent gave a white precipitate of Pt[P(*t*-Bu)$_3$]$_2$ which was filtered, washed with acetone, dried, and characterized by ^{1}H and ^{31}P-{^{1}H} nmr measurements in benzene (yield: >90%).

(*b*) Treatment of **1***c* with As(*t*-Bu)$_3$ in a similar manner did not result in any reaction.

(*c*) Addition of excess Me$_2$S (>1.5 mmol) to an acetone solution of **1***c* (0.5 mmol) resulted in the precipitation of Pt[P(*t*-Bu)$_3$]$_2$ in almost quantitative amount.

Reaction of ***1*** *with tetracyanoethylene*

A solution of tetracyanoethylene in dichloromethane was slowly added to an equimolar amount of **1***c* in the same solvent. Initial yellow colour changed to red–violet instantaneously. After stirring the reaction mixture for 30 min, the solvent was removed *in vacuo* to give a red–brown residue which was dissolved in minimum amount of dichloromethane. The solution was passed through a florisil column. Addition of pentane to the collected solution gave red–brown *trans*-[{P(*t*-Bu)$_3$}$_2$Pt{C$_2$(CN)$_4$}H]ClO$_4$, **10***c*, in ~85% yield.

Reactions of ***10****c with CH$_3$CN and CO*

(*a*) To a solution of **10***c* in dichloromethane was added an excess (>1 mol) of acetonitrile. The red colour of the solution disappeared. Removal of the solvent and washing of the resulting solid with benzene gave *trans*-[PtH(NCMe){P(*t*-Bu)$_3$}$_2$]ClO$_4$ which was characterized by ^{1}H and ^{31}P-{^{1}H} nmr measurements.

(*b*) Carbon monoxide was bubbled into a solution of **10***c* in dichloromethane until the red colour disappeared. Removal of the solvent and recrystallization of the resulting solid from dichloromethane/pentane gave colourless *trans*-[PtH(CO){P(*t*-Bu)$_3$}$_2$]ClO$_4$ in 90% yield.

Reactions of ***1*** *with HC≡CH*

Acetylene was bubbled through a solution of **1***a* or **1***c* in CD_2Cl_2 until the yellow colour of the solution was completely discharged. The ^{1}H nmr and infrared spectra of the resulting colourless solution were examined which indicated the formation of *trans*-[PtH(HC≡CH){P(*t*-Bu)$_3$}$_2$]ClO$_4$. Removal of the solvent, however, gave the starting material **1***c*.

Rate constants are reported for hexachloroiridate(IV) oxidation of iodide in methanol–, ethanol–, *t*-butyl alcohol–, ethylene glycol–, glycerol–, acetone–, acetonitrile–, and dimethyl sulphoxide – water solvent mixtures, and for the hexachloroiridate(IV) oxidation of catechol in methanol–water mixtures. With the aid of ancillary solubility data and measurements, solvent effects on reactivity have been analysed into initial state and transition state components. In the latter, there are probably both electron transfer and diffusion contributions since it is not possible to identify uniquely the separate kinetic steps associated with the activation process. In these redox systems, however, transition state solvation changes dominate. This conclusion is compared with initial state – transition state effects in the reaction of catechol with hexahydroxoantimonic acid, in the bromate oxidation of bromide, the peroxodisulphate oxidation of iodide, and with patterns established earlier for substitution at inorganic centres. In view of some disagreements and uncertainties in the literature concerning the number of molecules of water of crystallisation in potassium hexachloroiridate(III) and hexachloroiridate(IV), this matter, of considerable importance to hexachloroiridate transfer parameter estimation, is briefly reviewed.

MICHAEL J. BLANDAMER, JOHN BURGESS, STEPHEN J. HAMSHERE, COLIN WHITE, ROBERT I. HAINES et ALEXANDER MCAULEY. Can. J. Chem. **61**, 1361 (1983).

On rapporte les constantes de vitesse d'oxydation de l'iode par l'hexachloroiridate(IV) dans le méthanol, l'éthanol, l'alcool *tert*-butylique, l'éthylène glycol, le glycérol, l'acétone, l'acétonitrile et le diméthylsulfoxyde mélangés à l'eau comme solvants et les constantes de vitesse d'oxydation du cathécol par l'hexachloroiridate(IV) dans des mélanges méthanol–eau. Faisant appel aux mesures et aux données de solubilité secondaires, on a analysé les effets de solvant sur la réactivité des composants à l'état initial et dans l'état de transition. Dans ce dernier cas, il y a probablement à la fois un transfert d'électron et des contributions de diffusion, puisqu'il n'est pas possible d'identifier uniquement les étapes cinétiques séparées associées aux processus d'activation. Dans ces systèmes redox, cependant les changements de solvatation de l'état de transition dominent. On a comparé cette conclusion avec les effets de l'état initial et de l'état de transition dans la réaction du cathécol avec l'acide hexahydroxcantimonique, dans l'oxydation du bromure par le bromate, dans l'oxydation de l'iodure par le peroxodisulfate et avec les schémas établis antérieurement pour la substitution des centres inorganiques. Tenant compte des désaccords et des incertitudes relevés dans la littérature au sujet du nombre de molécules d'eau de cristallisation dans l'hexachloroiridate(III) et l'hexachloroiridate(IV) de potassium, on a revu brièvement cet aspect qui est d'une importance considérable pour l'évaluation du paramètre de transfert de l'hexachloroiridate.

[Traduit par le journal]

Introduction

The dissection of solvent effects on reaction rates into initial state and transition state components has been achieved for a number of inorganic and organic reactions (1). The majority of these systems have involved substitution processes. Some peroxodisulphate oxidations have been analysed in this manner but the central part played by peroxodisulphate oxygen–oxygen bond breaking in determining reactivity makes these reactions complicated to discuss. In this study, therefore, we have investigated solvent effects on reactivity for two relatively well characterised outer-sphere electron transfer reactions. With the aid of the necessary ancillary thermodynamic data and experimental results, it is possible to examine the influence of initial state and transition state solvation changes in determining overall reactivity. The electron transfer reactions chosen are the oxidations of iodide and of catechol (1,2-dihydroxybenzene) by hexachloroiridate(IV). Preliminary reports on the former reaction (2) have been followed recently by a full study (3) where the rate constant data have been rationalised in terms of the Marcus theory (4). In the catechol reaction (5), the kinetic parameters in aqueous media are consistent with a bimolecular outer-sphere redox reaction obeying straightforward second-order rate laws. Moreover, it is known that $IrCl_6^{2-}$ undergoes aquation very much more slowly (6) than it oxidises these substrates.

We have studied the $IrCl_6^{2-}/I^-$ reaction in a wide variety of binary aqueous solvent mixtures to enable us to attempt to identify the importance of solvation, dielectric, ion-pairing, and other possibly relevant factors. Organic co-solvents used ranged from monohydric alcohols[3] through such liquids as glycerol and acetone to the dipolar aprotic solvents dmso and acetonitrile. We have thus employed solvent mixtures in which co-solvent–water interactions are thermodynamically favourable and those in which such interactions are thermodynamically unfavourable. Co-solvents such as methanol, ethanol, and acetone give "typically aqueous" mixtures in which entropy effects dominate (G^E positive; $|TS^E| > |H^E|$); acetonitrile gives "typically non-aqueous positive" mixtures (G^E

positive; $|H^E| > |TS^E|$) and dmso and glycerol give "typically non-aqueous negative" mixtures (G^E negative; $|H^E| > |TS^E|$) (7). As outlined below, the $IrCl_6^{2-}$ anion neither aquates nor is reduced to any significant extent on our experimental time scales for any of the co-solvents employed.

In view of the recognised importance (8) of electrostatic effects in determining reactivities in redox reactions, it is desirable to study systems involving a variety of charge combinations. Implicit in our approach is that certain assumptions to be made regarding the extent of ion-pairing in the various solvent systems. The initial approach has been to use a ground/transition state model which although explaining our data is probably not completely adequate owing to our neglect of some of the pre-equilibria involved.[4] Also included in the present investigation, therefore, is a limited investigation of solvent effects on the corresponding oxidation of catechol where ion-pairing effects would be much less pronounced. We have also analysed solvent effects on the iodide–peroxodisulphate and catechol–antimony(V) reactions into initial state and transition state components for the purposes of comparative discussion.

Results and discussion

Oxidation of iodide by hexachloroiridate(IV)

Reaction in aqueous media

The oxidation of I^- by several complexes has been analysed recently in terms of differing kinetic pathways. In some instances ($Fe(di\text{-}imine)_3^{3+}$ and related oxidants) (3) there is evidence for two reaction sequences involving formation of either I_2^- or I·, consistent with the first- and second-order dependences on $[I^-]$ observed. A bimolecular (two-electron) transfer has also been reported in the case of a Ni(III) peptide (9). For other oxidants, however, $(Co(III)_{aq}$ (10), Cu(III) peptide (9), $Mo(CN)_8^{3-}$ (12), and 12-tungstocobaltoate(III) (11)) only a first order term in iodide is observed.

Previous studies (2, 3) on the present reaction indicate a simple second-order rate law $-d[IrCl_6^{2-}]/dt = k_2[I^-][IrCl_6^{2-}]$. These data were obtained in a reaction medium of 0.5 *M* H_2SO_4. In order to have a sufficiently documented basis in aqueous media we have re-investigated the effects of hydrogen ion and chloride ion at $I = 1.0$ *M* and confirmed at $I = 0.01$ *M*, the iodide dependence. Temperature dependence studies have also been completed. In general, measurements were made at as low an ionic strength as possible in order to minimise ion-pairing, especially in mixed solvents where the dielectric constants are markedly lower than that of water. The data agree reasonably well with those derived previously, after account is taken of the effects of ionic strength in these reactions, with $k_2 = 1.38 \times 10^3\ M^{-1}\ s^{-1}$ (0.5 *M* H_2SO_4) (3), $k_2 = 7.09 \times 10^2\ M^{-1}\ s^{-1}$ (1.0 *M* $HClO_4$), and $k_2 = 3.2 \times 10^2\ M^{-1}\ s^{-1}$ (0.01 *M* $LiClO_4$) (Table 1). Also at constant ionic strength, there is no $[H^+]$ or $[Cl^-]$ dependence observed. A similar lack of variation of rate with $[SO_4^{2-}]$ has also been observed (3). The ionic strength effects parallel those of the reactions of iodide with 12-tungstocobaltate(III) (11) and with octacyanomolybdate(V) (12). In the latter system, the study at low ionic strength ($I \leq 0.01$ *M*) has suggested that ion pairs may not play an important role in this reaction.

The temperature dependence of the rate constant yields the activation parameters $\Delta H^{\ddagger} = 27.6 \pm 0.8$ kJ mol^{-1}, $\Delta S^{\ddagger} = -105 \pm 8$ J K^{-1} mol^{-1} for the oxidation reaction. These values may be compared with those for other outer-sphere reactions, e.g. for the corresponding reaction of $Mo(CN)_8^{3-}$ which also exhibits a first order dependence on $[I^-]$, the constants are $\Delta H^{\ddagger} = 21 \pm 10$ kJ mol^{-1} and $\Delta S^{\ddagger} = -160 \pm 30$ J K^{-1} mol^{-1}. One reaction scheme proposed (3) for these reactions where rates may be rationalised in terms of the Marcus theory involves the formation of a weak ion pair ($K_{ip} = 0.3$ *M*) with a rate-determining electron transfer from the iodide ion to the metal centre, leading to formation of I·. Direct electron transfer cannot, however, be excluded.

A similar rate law could result from the rapid (pre-equilibrium) formation of an active ion-pair species which undergoes unimolecular electron transfer. Under these conditions the rate constant would be a composite k_2K_{ip}. It is interesting to note that a transient $[IrCl_6.IO_3]^{4-}$ intermediate has been suggested in the hexachloroiridate(III)–iodate reaction (13).

The detailed oxidation mechanism may thus be written in the form

$$IrCl_6^{2-} + I^- \overset{K_{os}}{\rightleftharpoons} [IrCl_6^{2-}:I^-] \underset{k_b}{\overset{k_a}{\rightleftharpoons}} [IrCl_6^{3-}.I^{\cdot}] \overset{k_c}{\rightarrow}$$

$$[IrCl_6]^{3-} + I^{\cdot} \xrightarrow[+I^-]{\text{fast}} I_3^-$$

As has been noted, the redox step is thermodynamically unfavourable. Using available $E^{\ominus}$ values[3] ($IrCl_6^{2-/3-}$, $I^-/I^{\cdot}$ 0.96 V and 1.40 V respectively) the rate k_a/k_b may be computed as $\approx 4 \times 10^{-8}\ M^{-1}$. The observed composite rate constant is of the form $k_2 = k_ak_c/(k_b + k_c)$. Also $k_bk_c/(k_b + k_c) \approx 8 \times 10^9$ s^{-1} The situation thus exists that after the initial redox reaction,

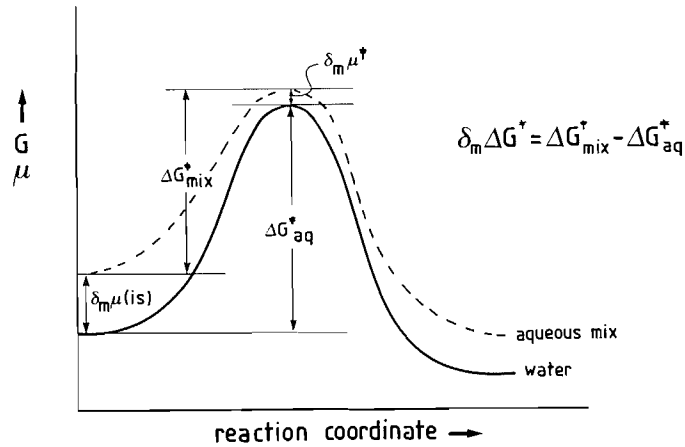

FIG. 1. Inter-relations between the kinetic and thermodynamic transfer parameters.

the recombination (k_b) within the solvent cage competes with the diffusion (k_c) of I$^{\cdot}$. It is not possible to separate the individual rate constants but since these reaction rates are close to the diffusion controlled limit, it can be shown that $k_b \approx k_c$ to within a factor of about 3. Assuming $k_b \approx k_c$ then the observed rate constant $k_2 \approx 0.5k_a$. We have, therefore, a measure of the rate of the initial redox process.

In the case of catechol reaction (*vide infra*) where $\Delta E^0 \sim -0.2$ V (69), if $k_c \approx 8 \times 10^9$ s^{-1} as above then $k_c \gg k_b$ leading to $k_{obs} = k_a$. This approach is justified since $k_a/k_b \approx 3 \times 10^{-4}$ M^{-1} leading to a value of $k_b \approx 5 \times 10^7$ s^{-1}. The rate of this outer-sphere redox recombination would be expected to be lower on Marcus theory grounds since there is a lower driving force than in the case of the iodide. Since the findings for catechol are broadly similar to those for I^- we feel that the assumptions made in the iodide reactions are tenable although inevitably in a rigorous treatment of transition state there are components of both redox recombination and diffusion.

Reaction in binary aqueous mixtures

The second order rate constants for the $[IrCl_6^{2-}]/[I^-]$ reaction are presented in Table 2. The overall pattern of reactivity is of a steady decrease in rate as the proportion of organic co-solvent is increased, e.g., k_2 (M^{-1} s^{-1}) for the reaction falls from 182 to 108 (at 298 K) in going from 24.3 to 51.9% by weight of glycerol.

Dielectric constants and ion-pairing

In this study we have assumed that direct transfer of the electron takes place when the iodide and hexachloroiridate(IV) are in "contact". This direct transfer may be contrasted with indirect transfer across intervening solvent molecules. The model is thus consistent with that of Adegite (3) and other workers (14–16) who have considered contact ion-pair precursors in such redox reactions. The dielectric properties of the solvent mixtures might be considered to have a significant effect owing to their influence on the formation of ion-paired species between the alkali metal counter ions and the negatively charged reactants. This would be true especially of the $[IrCl_6^{2-}]$ ion. It is well established that electron transfer from one anion to another may be facilitated by the role of the cation in reducing the electrostatic repulsion between the species (8, 17, 18). In general, such effects become apparent at much higher alkali metal ion concentrations than are used here. Ion association constants calculated from the standard equations (19) using the Debye–Hückel interaction potential, or estimated via known ion-pairing constants for our experimental conditions (20) suggest these effects to be sufficiently small as to contribute only slightly to the overall reactivity in the redox reaction. The relatively small specific ion effects (Table 1) and the fact that ion-pairing should lead to an increase in rate with decreasing dielectric constant (the opposite of the observed trend) substantiates our considerations in this regard. If the reactive ion-pairs are $[IrCl_6^{2-}.I^-]$ or $[M^+.IrCl_6^{2-}].I^-$, however, these species will be less favoured by increasing dielectric constant. This is consistent with the present data where the rates decrease with increasing concentrations or organic substrate in solution.

Solvation effects

The solvation and hence the chemical potentials of I^-, $IrCl_6^{2-}$ and the transition state will vary as solvent composition varies. Insofar as these determine the barriers to activation, they will determine the observed reactivity trend (Fig. 1) (1). The present data are analysed in these terms. If the Gibbs free energies of transfer of the iodide and hexachloroiridate(IV) ions, $\delta_m\mu^{\ominus}(I^-)$ and $\delta_m\mu^{\ominus}(IrCl_6^{2-})$ are known, and as the transfer function $\delta_m\Delta G^{\ddagger}$ may be derived from the rate constant variation, so the transfer function for the transition state $\delta_m\mu^{\ddagger}$ may be calculated. The transfer parameters $\delta_m\mu^{\ominus}(I^-)$ and $\delta_m\mu^{\ominus}(IrCl_6^{2-})$ must be derived from the appropriate thermodynamic data, generally coming from measurements on electrical cells or of solubilities. Unfortunately it is necessary to make assumptions in deriving the transfer parameters for individual ions. This is still an area of some discussion and concern and in this paper we have attempted to use values from consistent sources and to indicate where assumptions have been made in deriving single ion quantities.

There is a substantial body of information published on $\delta_m\mu^{\ominus}(I^-)$ values for transfer from water into binary aqueous mixtures. Two different Born-related approaches have been used (21, 22), however, and two different "large ion" assumptions employed for various ranges of mixtures by various authors, with little overlap to help in assessing consistency. We refer the reader to the sources cited (21–27) for the $\delta_m\mu^{\ominus}(I^-)$ values used below for details of calculations, conventions, and assumptions. The molar scale has also been used throughout and where necessary published values have been converted to this scale.

No transfer parameters are known for $[IrCl_6^{2-}]$, though a few are available for the closely related hexachlororhenate(IV) ion (28). Solubilities of K_2IrCl_6 have therefore been determined in

order to calculate $\delta_m\mu^{\ominus}(K_2IrCl_6)$ and hence estimate, using published values of $\delta_m\mu^{\ominus}(K^+)$ (19), values for $\delta_m\mu^{\ominus}(IrCl_6^{2-})$. In order to avoid any hydrolysis of the $IrCl_6^{2-}$ ion during solid–solution equilibrium, the measurements were made in potassium chloride solutions (29), except in 80% ethanol where K_2IrCl_6 is very sparingly soluble and the $IrCl_6^{2-}$ ion is known to hydrolyse only very slowly. Measured optical densities of suitably diluted samples of saturated solutions of K_2IrCl_6 in 0.01 *M* KCl are reported in Table 3. Data were obtained at 487 nm (ϵ = 4075 M^{-1} cm^{-1}), the extinction coefficient being in good agreement with that in the literature (30). Table 3 also includes values for the solubility product, and calculated values of $\delta_m\mu^{\ominus}(K_2IrCl_6)$ together with the transfer prameters for K^+ used (21, 25–27, 31, 33–35) and hence estimated values of $\delta_m\mu^{\ominus}(IrCl_6^{2-})$ (see also following sub-section).

The dissection of the observed reactivity variation with solvent composition is presented in Table 4, and illustrated diagrammatically in Fig. 2. The overall picture which emerges is that the transition state is more sensitive to solvent variation than the initial state. This behaviour differs from that of the majority of substitution reactions, but parallels that found recently (36) for the reaction of $S_2O_8^{2-}$ with the iron(II) complex $Fe(bipy)_2(CN)_2$, another outer-sphere electron transfer process.

One possible explanation of the greater sensitivity of the transition state to its solvent environment may be the result of its greater charge. To investigate this, we have estimated values of $\delta_m\mu^{\ominus}(IrCl_6^{3-})$ in order to compare these with $\delta_m\mu^{\ddagger}$ i.e., $\delta_m\mu^{\ominus}(I\ldots IrCl_6^{\ddagger 3-})$. Values of $\delta_m\mu^{\ominus}(IrCl_6^{3-})$ were derived as above from solubility data of K_3IrCl_6 (see below) in 0.10 *M* KCl to avoid any competing hydrolysis (37). Measurements were made in water and aqueous methanol (Table 5). The transfer parameters for $IrCl_6^{2-}$, $IrCl_6^{3-}$, and the transition state are shown in Fig. 3. It is noteworthy that the transition state is less sensitive than the $IrCl_6^{3-}$ anion; both have the same charge, but the $IrCl_6\ldots I^{3-}$ transition state is of course larger than the $IrCl_6^{3-}$ model.

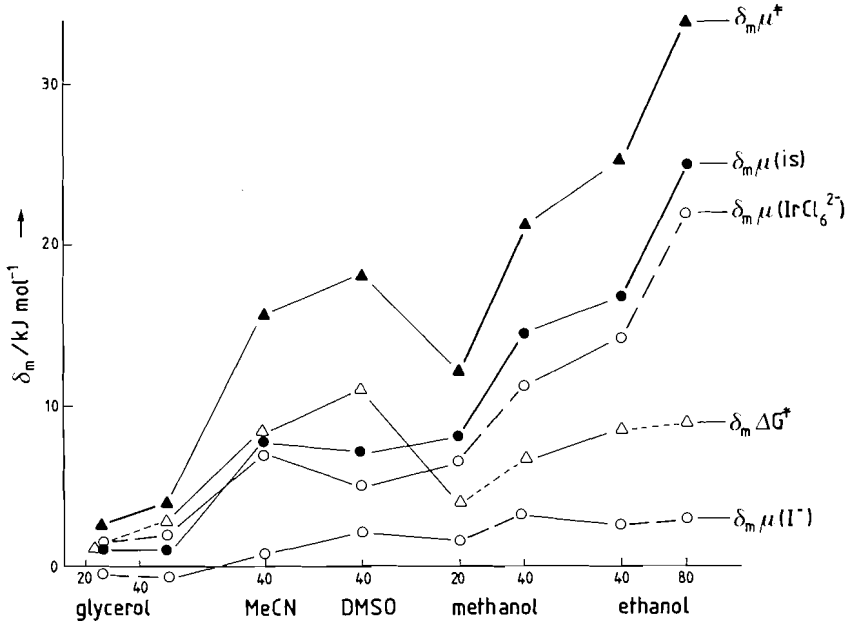

FIG. 2. Dissection of solvent effects on reactivity into initial state and transition state components for the hexachloroiridate(IV)–iodide reaction.

Hydrates of K_2IrCl_6 and K_3IrCl_6

The correct deduction of such quantities as Gibbs free energies and enthalpies of transfer of salts requires knowledge of their state of hydration. For the former it is necessary to make a correction involving the Gibbs free energy of transfer of water if the number of molecules of water of hydration in the solid in equilibrium with saturated solutions changes with solvent composition. For the latter, one has to correct for the enthalpy of transfer of the appropriate number of water molecules if one measures enthalpies of solution of a hydrate rather than of an anhydrous salt. During the present investigation we have found that there is some confusion in the literature concerning the state of hydration of both the hexachloroiridates K_2IrCl_6 and K_3IrCl_6.

In the case of the iridium(IV) salt, the confusion stems from a discussion of spectra of hexachloroiridates which includes mention of an alleged hexahydrate $K_2IrCl_6.6H_2O$ (38). The earliest papers on K_2IrCl_6 indicate that it is, like the caesium and rubidium salts but unlike the sodium and lithium salts (both have $6H_2O$), anhydrous, on the basis of chemical analysis (34, 39–41). Griffiths (42) states that K_2IrCl_6 is isomorphous with K_2PtCl_6, which is undoubtedly anhydrous. Discussions of magnetic properties (43), paramagnetic resonance (44), nqr (45), neutron diffraction (46), and vibrational spectra (47) all assume that this salt is anhydrous, as does the paper reporting its specific heat (48). We must conclude that K_2IrCl_6 is indeed anhydrous; the solitary reference (38) to the hexahydrate gives no evidence of characterisation.

Various sources imply that K_3IrCl_6 crystallises with 0, 1, or $3H_2O$. First reports of this salt described it as a trihydrate (49–51). Subsequently the separation of the monohydrate from boiling hydrochloric acid was reported (52). Delépine's extensive review of hexachloroiridates (41) recognises both tri- and mono-hydrates. X-ray diffraction data have been reported (d and I/I_0) for a powdered sample (53) but it is not apparent whether this was anhydrous or one of the hydrates. The data are indexed (54) (and referenced incorrectly) under the formula of the anhydrous salt, but the description of the solid (53) suggests the monohydrate. We believe, on the basis of appearance and of thermogravimetric experiments, that the solid in equilibrium with saturated solutions in water and in water-rich aqueous methanol at 298.2 K is the trihydrate.

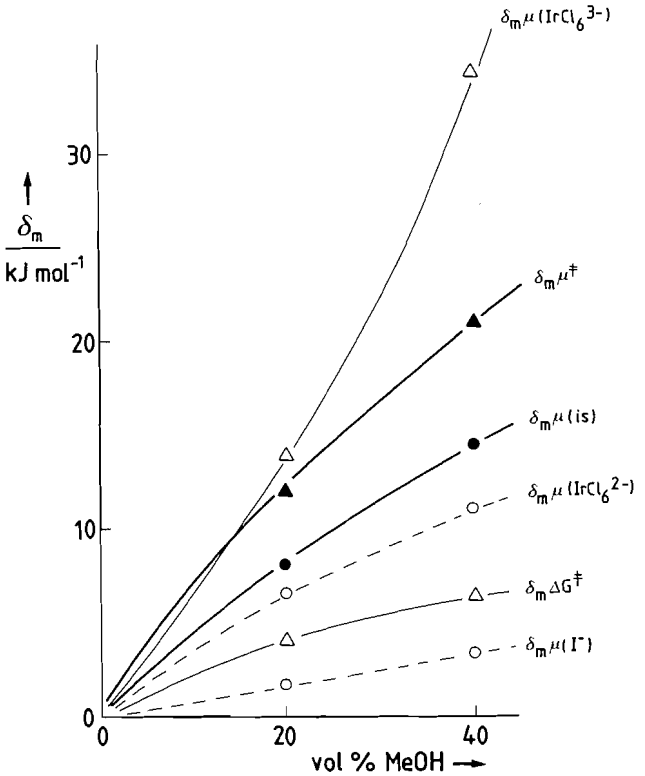

FIG. 3. Solvent effects on reactivity for the hexachloroiridate(IV)–iodate reaction in aqueous methanol; illustration of hexachloroiridate(III) as transition state model.

Oxidation of catechol by hexachloroiridate(IV)

Reaction in aqueous media

The kinetics of the oxidation have been studied under a variety of conditions in aqueous solution (5). These earlier results established a second-order rate law

$$-\mathrm{d[catechol]}/\mathrm{d}t = k_2[\mathrm{catechol}][IrCl_6^{2-}]$$

the reaction being considered as outer-sphere. These data were obtained at $I = 1.0\ M$ and a slight dependence on $[H^+]$ was observed, the reaction rate increasing with decreasing acidity. We have repeated the measurements at $I = 0$, and confirmed the second-order reaction overall. The k_2 value obtained ($1.39 \times 10^4\ M^{-1}\ s^{-1}$) at low ionic strength may be compared with an extrapolated value of $9.5 \times 10^3\ M^{-1}\ s^{-1}$ at $I = 1.0\ M$.

Reaction in binary aqueous mixtures

Rate constants (k_2) have been determined in 10, 20, and 30% methanol and solubility data on catechol has also been derived in order to calculate Gibbs free energies of transfer for this reactant. Analysis of solvents effects is shown in Table 6 with conclusions presented in Fig. 4. The pattern is similar to that for the corresponding reaction with iodide, except in that the catechol is somewhat stabilised in going from water into aqueous methanol in contrast to the de-stabilisation of the iodide ion. This finding where the extent of ion-pairing with the neutral molecule would be expected to be less than for the charged reactants may substantiate our view of the principal pathways involving only the reactants as described. Again, as with the iodide reaction the transition state for catechol is more affected by solvent than is the initial state. It would be interesting to assess how generally this pattern applies to hexachloroiridate(IV) oxidations. Several kinetic studies have been reported for this oxidant, of which a few appear attractive candidates in the present context. Thus oxidation of thiourea (55) commends itself by the availability of transfer data for the thiourea, while oxidation of the hydrazinium cation (56) would give an example of a reaction involving reactants of opposite charge, to complement the iodide and catechol systems described above. Unfortunately in these, and related reactions, the mechanisms prove not to be simple, and thus initial state – transition state dissections are hardly feasible.

We have established thus far a greater sensitivity for the transition state than for the initial state in redox reactions involving both $IrCl_6^{2-}$ and the $Fe(bipy)_2(CN)_2/S_2O_8^{2-}$ (36) system. In order to examine further the generality of this pattern[5] and the difference from the normal substitution behaviour, the hexahydroxoantimonate(IV)–catechol substitution process has been investigated and published data on other related redox reactions have been analysed. Details of experiments and calculations are presented below.

Reaction of antimony(V) with catechol

This reaction has been examined in aqueous solution (57) and the formation of 1:1 and 2:1 complexes established. The kinetics of the first stage have been investigated

the mechanism having been established as S_N1 in character.

In the present study, kinetic data for the above reaction have been obtained in several aqueous alcohol mixtures. First order rate constants were derived by monitoring the absorbance increase at 290 nm consequent on complex formation. Studies were carried out in the presence of excess catechol, and at a pH of 2.0 where the form of antimony(V) predominating is the neutral complex $HSb(OH)_6$ rather than the hexahydroxoantimonate(V) anion (57). The experimental data are presented in Table 7. The concentrations of antimony in saturated solutions containing 30% methanol and 30% *t*-butyl alcohol at pH 2 and pH 7 were determined. The results at pH 2 are included in Table 8. The solubility decreases much more dramatically on going from water to the aqueous alcohol mixtures at pH 7 than at pH 2. This is presumably attributable to the non-electrolyte form $NSb(OH)_6$ being present in more acid media. The analysis of initial state and transition state effects on the reaction are included in Table 8. The small solvent effect on reactivity contrasts with the trends in the $IrCl_6^{2-}$ reactions. The marked effects in these oxidations may be attributable to the large effects of solvent variation on the chemical potentials of the reactant ions $IrCl_6^{2-}$ and I^-. Catechol and $HSb(OH)_6$, both non-electrolytes, have small free energies of transfer from water into aqueous alcohols and there is not therefore an important contribution to reactivity variation from this source. In the catechol–antimony(V) reaction a large contribution from transition state solvation would not be expected since transition state generation does not involve charge separation or cancellation. Indeed it could be presumed that the state is reached by the stretching of an antimony to oxygen bond and the removal of water as a leaving group.

$$HSb(OH)_6 \rightarrow [(HO)_5Sb.....OH_2]^{\ddagger}$$

[5]It would be interesting to carry out an initial state-transition analysis of hexachloroiridate(IV) oxidation of oxalate, whose kinetics have recently been established in dioxan–water mixtures (70) to further examine this pattern.

t-Butyl alcohol			0.019	

Oxidation of iodide by peroxodisulphate

There is some kinetic information on this reaction in binary aqueous solvent mixtures, specifically in aqueous acetonitrile (58) and in aqueous *t*-butyl alcohol (59). Unfortunately, earlier estimates of Gibbs free energies of transfer of the peroxodisulphate anion into binary aqueous solvent mixtures included only the co-solvents methanol and acetone (60). We have therefore measured solubilities of potassium peroxodisulphate in several aqueous acetonitrile and in aqueous *t*-butyl alcohol solvent mixtures, thence estimating $\delta_m\mu^{\ominus}(S_2O_8^{2-})$ (Table 9) as before (60, 61).

Our analysis of solvent effects on the iodide–peroxodisulphate redox reaction is set out in Table 10 (58–63). Figure 5 shows the trends for the reactants and the transition state, and may be compared with Figs. 2 and 3 for the iodide–hexachloroiridate(IV) reaction. The patterns for the two similar reactions, both involving a dinegative and uninegative ion, are very similar in aqueous alcohols and in aqueous acetonitrile. Most significantly, the transition state for the iodide–peroxodisulphate reaction is again somewhat more affected by solvent composition variation, as in the other redox reactions cited earlier in this paper.

TABLE 8. Initial state and transition state solvation contributions to reactivity for the catechol–antimony(V) reaction in aqueous alcohols[a]

[a]Compositions expressed in volume % (before mixing). For reaction concentrations see Table 7.

Oxidation of bromide by bromate

The small variation in rate with solvent composition for this reaction in ethanol–water mixtures has been discussed previously (64) in terms of dielectric constant effects. The overall solvent effect pattern is markedly different here from the $S_2O_8^{2-}$ or $IrCl_6^{2-}$ reactions. Whereas for these latter oxidants the rates of oxidation decrease as the proportion of organic co-solvent increases, for the bromate(V) oxidation of bromide the rate increases slightly with the higher proportions of ethanol. The analysis of the data indicates that this small difference probably represents a balance between larger effects on the initial state and transition state. It is not possible to carry out a quantitative determination of the rate trend into the initial state and transition state components since $\delta_m\mu^{\ominus}(H_2BrO_3^+)$ cannot be estimated satisfactorily. However, it is clear that the overall solvent effect pattern must be different. Under the conditions employed the reactants (Br^- and $H_2BrO_3^+$) are ionic and it is likely that their chemical potentials will increase with the proportion of organic co-solvent. The small change observed in rate constant then requires that the chemical potential of the transition state should increase by slightly less than that of the

[d] Values for transfer to aqueous *t*-butyl alcohol obtained by a simultaneous extrapolation procedure (ref. 43) are rather larger, but their use in this dissection would not affect the general picture of relative importance of initial state and transition state solvation (cf. also ref. 63).
[e] Estimated from values in Table 9.

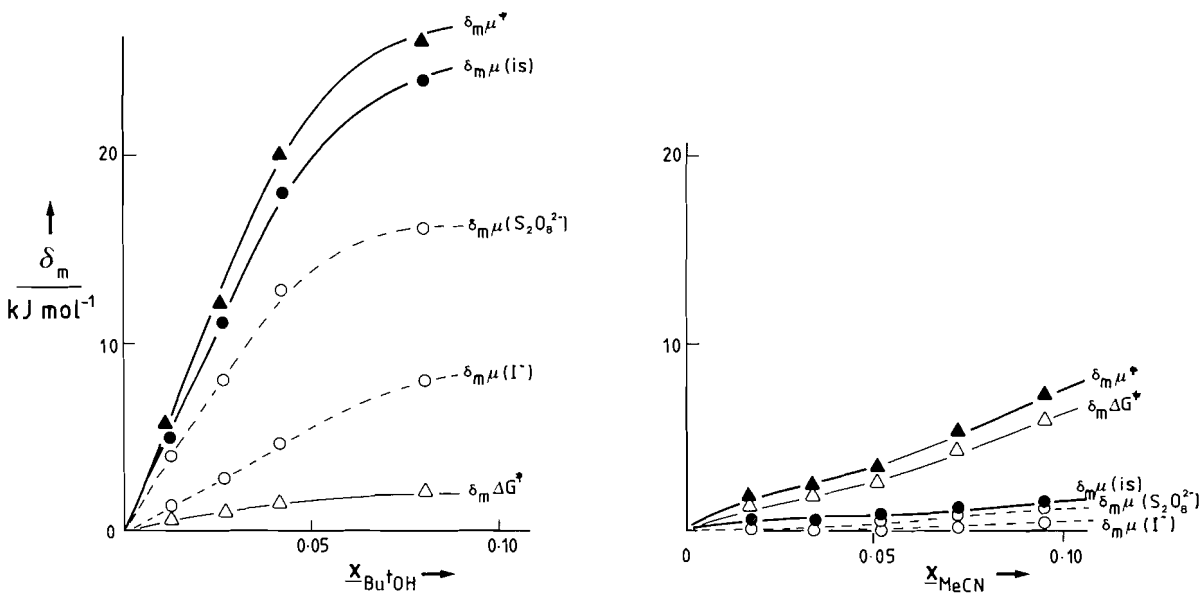

FIG. 5. Dissection of solvent effects on reactivity into initial state and transition state components for the peroxodisulphate–iodide reaction.

initial state. The pattern contrasts with that for $IrCl_6^{2-}$ oxidations. One difference, however, is that the charges of the reactant ions are now opposite in sign and this may be reflected in a transformation of solvation as a result of charge neutralisation in the transition state, a feature not present in the systems described above. In this way the behaviour is more reminiscent of substitution process such as those involving mercury(II) (65). There is an interest in establishing whether redox and substitution reactions behave in a similar manner and comparison of the mercury(II)-catalysed aquation and chromium(II) reduction of chlorotransition metal complexes (66) may be fruitful areas of study in this regard.

Oxidation of iodide by 12-tungstocobaltate(III)

We have recently shown that, in methanol–, acetonitrile–, and dimethyl sulphoxide–water mixtures, solvent effects on reactivity are dominated by destabilisation of the transition state on adding organic co-solvent, just as in the hexachloroiridate(IV) oxidations dealt with in the present paper (67).

Experimental

For experiments in aqueous solution, all solutions were prepared with water de-ionised then distilled from an all-glass apparatus. K_2IrCl_6 (Aldrich) was used without further purification. Potassium and sodium iodide were AnalaR grade. Acetonitrile (Anachem) was treated with calcium hydride, and distilled over P_2O_5. Acetone (Anachem), dimethylsulphoxide (Eastman), glycerol (Fisher), and ethylene glycol (Fisher) were reagent grade and used without further purification.

Spectra were recorded on a Varian Techtron Model 635 uv–visible instrument which when thermostatted was also used for monitoring the slower kinetic runs. The stopped-flow apparatus used has been described previously (68). Rate data were derived either from photographic analysis of oscilloscope traces or from the output of a PCM computer coupled to the photomultiplier tube of the instrument. Under pseudo-first order conditions, plots were linear to the greater than 80% reaction. Reproducibility between runs was ±3%.

Reçu le 29 octobre, 1982

D. GONBEAU, G. PFISTER-GUILLOUZO et J. BARRANS. Can. J. Chem. **61**, 1371 (1983).

Nous avons réalisé en base *ab initio* double zeta de valence une approche quantochimique sur des entités modèles HP=NH et HP=CH_2. Un processus de minimisation à métrique variable a été utilisé pour la détermination des paramètres géométriques.

Les "forces" des liaisons $2p_\pi-3p_\pi$ pour P=N et P=C ont été estimées par évaluation des barrières obtenues en réalisant une rotation de 90° d'une partie de la molécule vis à vis de l'autre. L'essentiel des effets de corrélation a été pris en compte et pour la détermination des états à 90° de plus basse énergie un formalisme rigoureux RHF a été utilisé.

Nous avons ainsi mis en évidence des caractéristiques électroniques différentes pour les deux motifs et à partir de ces résultats nous avons interprété leur comportement réactionnel: dimérisation, addition de réactifs polaires et site de protonation dans le cas de HP=NH.

D. GONBEAU, G. PFISTER-GUILLOUZO, and J. BARRANS. Can. J. Chem. **61**, 1371 (1983).

Using *ab initio* valence double zeta as a basis, a quantum-chemical approach was developed for the models HP=NH and PH=CH_2. The geometric parameters were determined by a variable metrics minimization process.

The $2p_\pi-3p_\pi$ bond forces for P=N and P=C were estimated by evaluating the barriers obtained by a 90° rotation of one part of the molecule with respect to the other. The essential correlation effect was considered and a rigourous RHF formalism was used to determine the state at 90° of lower energy.

Different electronic characteristics were found for both motives and according to these results, their reaction behaviour was interpreted: dimerization, addition of polar reactants, and protonation site for HP=NH.

1. Introduction

La synthèse et la caractérisation de composés du phosphore à coordinence 2 est un domaine actuellement en plein développement (1–8). A notre connaissance, seules deux approches théoriques parallèles à la notre (9, 10) sur la structure électronique d'intermédiaires phosphorés présentant une liaison $p_\pi-p_\pi$ ont été réalisées contrairement aux nombreux travaux existants sur le silaéthylène (11). Le présent travail a pour but d'analyser la nature et la stabilité des doubles liaisons P=C et P=N dans les systèmes acycliques par une approche quantochimique. Dans ce but, nous avons choisi comme modèle d'une part la molécule HP=CH_2 détectée par pyrolyse de la diméthylphosphine (12)

$$(CH_3)_2PH \xrightarrow[1000°C]{} H_2C{=}PH + CH_4 \xrightarrow[-H_2]{} H{-}C{\equiv}P$$

et plus récemment de $Me_3SiCH_2PH_2$ (13), d'autre part le motif HP=NH qui bien qu'actuellement non isolé représente le plus simple des composés présentant la double liaison P=N.

2. Conditions de calcul

Tous les calculs ont été réalisés à l'aide du programme MONSTERGAUSS 80 (14*a*).

Une base double zeta de valence 4-31G (15) avec orbitales de polarisation de type *d* sur tous les hétéroatomes a été utilisée (une orbitale gaussienne de type *d* $\xi^d_P = 0{,}57$, $\xi^d_N = 0{,}8$, $\xi^d_O = 0{,}8$).

Nous avons vérifié que nos résultats essentiels n'étaient pas modifiés par introduction de fonction de polarisation de type *p* sur les hydrogènes.

Les paramètres géométriques ont été optimisés grâce à un processus de minimisation à métrique variable avec évaluation du gradient selon la méthode de Broyden–Fletcher–Goldfarb–Shanno (14*b*).

Tous les calculs sur les états couches ouvertes ont été menés à l'aide du formalisme RHF.

De plus afin de tenir compte des effets essentiels de corrélation et disposer de grandeurs comparables entre les deux systèmes examinés une IC 6x6 a été autorisée sur les états fondamentaux à 0° et les singulets couches fermées à 90°. En effet l'influence notable de la corrélation au niveau du fondamental provient essentiellement du mélange important avec la configuration doublement excitée ψ ($\pi^2 \rightarrow \pi^{*2}$) où l'orbitale liante π est remplacée par l'antiliante π^* alors qu'une configuration correspondante n'existe évidemment plus à 90°.

De plus étant donné la position de cette orbitale π dans les deux composés examinés (dernière occupée ou avant dernière occupée) nous avons été amenés à envisager toutes les mono et diexcitations possibles entre les deux dernières orbitales occupées et la première vacante.

3. Analyse des résultats

3.1 *Etats fondamentaux. Structures géométriques, orbitales moléculaires, populations de Mulliken*

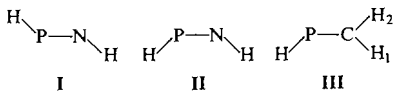
3.11 *Structures géométriques*

Pour les deux composés la structure énergétiquement privilégiée à l'état fondamental a été trouvée plane, l'isomère *trans* étant légèrement favorisé par rapport au *cis* dans le cas de HPNH ($\Delta E \simeq 0{,}22$ kcal/mol).

Tous les paramètres géométriques (longueurs et angles) ont été minimisés; les valeurs obtenues ont été reportées dans le tableau 1.

Nous constatons en premier lieu un bon accord d'ensemble

TABLEAU 1. Paramètres géométriques minimisés pour HPNH (*cis* et *trans*) et $HPCH_2$[a]



I II III

Paramètre	I	II	III	Exp
P—{N / C	1,5485	1,5402	1,6403	1,670 (1)

N^PH	99,18	104,49	98,29	100 (1)
C				97,5 (2)

[a]Les longueurs sont exprimées en angstroms et les angles en degrés.
[b]Valeurs obtenues pour $H_2C{=}NH$.

entre les données théoriques et celles des structures microondes réalisées pour $HPCH_2$ (12, 13). La deuxième structure qui correspond à une obtention de $HPCH_2$ à partir de $Me_3SiCH_2PH_2$ paraît plus précise mais seules les valeurs de l'angle CPH et du moment dipolaire sont indiquées; leur comparaison avec les résultats de nos calculs est tout à fait satisfaisante.

La liaison P=C (1,64 Å) présente bien un caractère de double liaison puisque trouvée intermédiaire entre une triple liaison (P≡C: 1,54 Å) (16, 17) et une simple liaison (P—C ≃ 1,85 Å) (18*a*).

Il en est de même pour la liaison P=N de 1,55 Å environ nettement plus courte que la simple liaison à 1,72 Å (18*b*) et tout à fait comparable à celle obtenue en rayons X pour $(Me_3Si)_2N$—P=N—SiMe (1,545 Å) (7) et $Me_3Si(tBu)N$—P=N—*t*Bu (1,544 Å) (6).

Par ailleurs, nous remarquons un angle de valence au phosphore du même ordre pour HPNH *trans* et $HPCH_2$ (99°) alors qu'il apparaît pour l'isomère *cis* de 104°.

Cette différence reste toutefois moins grande que celle observée sur l'azote 112°–120°. Ces remarques mettent bien en évidence une certaine rigidité du groupement PH à phosphore dicoordiné.

3.12 *Orbitales moléculaires*

Dans le tableau 2 nous avons reporté les valeurs des énergies obtenues pour les dernières orbitales moléculaires occupées de HPNH (*cis* et *trans*) et de $HPCH_2$ et leurs natures respectives précisées grâce au procédé de localisation de Boys (19) et à un mode d'analyse que nous avons mis au point (20). Nous observons ainsi pour $HPCH_2$ que la dernière orbitale occupée à 9,625 eV correspond à la liaison π_{P-C} avec une nette localisation sur le carbone, l'orbitale à 10,427 eV est associée à la paire σ du phosphore.

Dans le cas de HPNH par contre étant donné la forte interaction entre les paires du phosphore et de l'azote, l'orbitale moléculaire correspondant à la liaison $\pi_{P=N}$ et très fortement localisée sur l'azote à 11,404 eV (isomère *trans*) et 11,468 eV (isomère *cis*) n'est plus la dernière occupée; elle apparaît entre les deux combinaisons des paires σ en opposition de phase et en phase, la première avec un fort poids sur le phosphore et la deuxième sur l'azote. Nous observons également le phénomène bien connu d'une interaction des paires en *trans* nettement plus importante qu'en *cis* respectivement d'environ 4,5 et 2,2 eV.

La première virtuelle pour tous les dérivés correspond à la $\pi^*_{P=X}$ (X = N, C) légèrement plus haute pour $HPCH_2$ que pour HPNH avec une localisation plus importante sur le phosphore particulièrement dans le cas de HPNH.

3.13 *Populations de Mulliken*

Afin de préciser les caractéristiques électroniques des liaisons dans les deux composés HPNH *trans* et $HPCH_2$, nous avons procédé à une analyse de population selon Mulliken et parallèlement à un tracé des orbitales moléculaires essentielles.

Comme il est bien connu que les charges totales sur les atomes et les populations de recouvrement sont des données sensibles au choix de la base sans aucun caractère quantitatif nous les examinons donc en comparatif pour les deux dérivés (figure 1).

En premier lieu, l'examen des charges nettes totales sur les atomes révèle un caractère polaire nettement plus marqué pour P—N que pour P—C avec une accumulation de charge plus grande sur l'azote que sur le carbone reflétant ainsi les électronégativités respectives de ces trois atomes P: 2,1; C: 2,5; N: 3.

Le transfert de charge du groupement PH vers le groupement NH est de 0,45 e^- environ et seulement de 0,19 e^- du groupement PH vers le groupement CH_2.

Bien qu'elle ne soit pas très importante la participation des orbitales *d* au niveau des atomes de phosphore n'est pas négligeable: 0,32 e^- pour HPNH et 0,27 e^- pour $HPCH_2$; dans les deux cas ce sont essentiellement les orbitales *d* de symétrie σ dans le plan de la molécule qui interviennent.

Les populations de recouvrement paraissent voisines pour les deux dérivés aussi bien en total qu'en π légèrement plus faibles pour HPNH que pour $HPCH_2$ mais révèlent dans les deux cas un caractère réel de liaison π.

Le point le plus intéressant concerne la distribution électronique π qui présente toujours en charge nette un caractère asymétrique pour P—N et au contraire une quasi symétrie dans le cas de P—C.

Des conclusions similaires peuvent être déduites de l'examen des contours des orbitales moléculaires π tracés pour les deux dérivés (figures 2 et 3). Dans le cas de HPNH, l'accumulation de charge électronique sur l'azote conduit à une augmentation de l'effet d'écran de la charge nucléaire et en conséquence à une extension de l'orbitale atomique $2p\pi_N$ comparée à celle d'un atome isolé, l'effet inverse intervenant pour le phosphore. Les contours tracés visualisent cet ajustement des orbitales atomiques. Celui réalisé pour $HPCH_2$ bien que du même type met parfaitement en évidence une densité électronique sur le carbone nettement moins importante en π que sur l'azote.

3.14 *Force de liaison π. Etats à 90°*

Pour compléter notre approche nous avons cherché à atteindre pour chaque dérivé un autre "indice" que l'on qualifie habituellement de "force de liaison π".

En effet, en réalisant une rotation de 90° d'une partie de la molécule vis à vis de l'autre la barrière obtenue ΔE_r qui correspond à la rupture de la liaison π est considérée comme représentative de la force de cette liaison puisqu'en première approximation les liaisons σ demeurent inchangées par rotation autour de leur axe $\Delta E_r \simeq \Delta E_\pi$. Il faut donc pour l'évaluation de ΔE_r outre l'état fondamental à 0° déterminer celui à 90° de plus basse énergie.

Des remarques contradictoires (21, 22) ont été faites dans la littérature sur la détermination de cet état à 90° mais deux

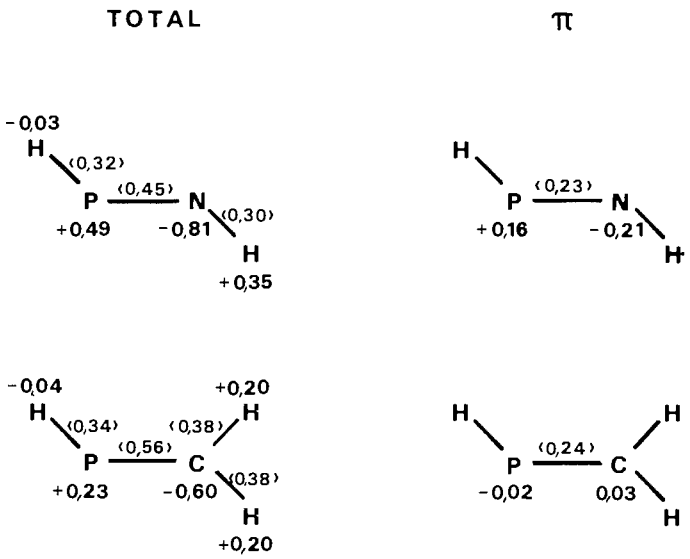

FIG. 1. Analyses de population selon Mulliken pour les états fondamentaux. Charges nettes et populations de recouvrement entre parenthèses.

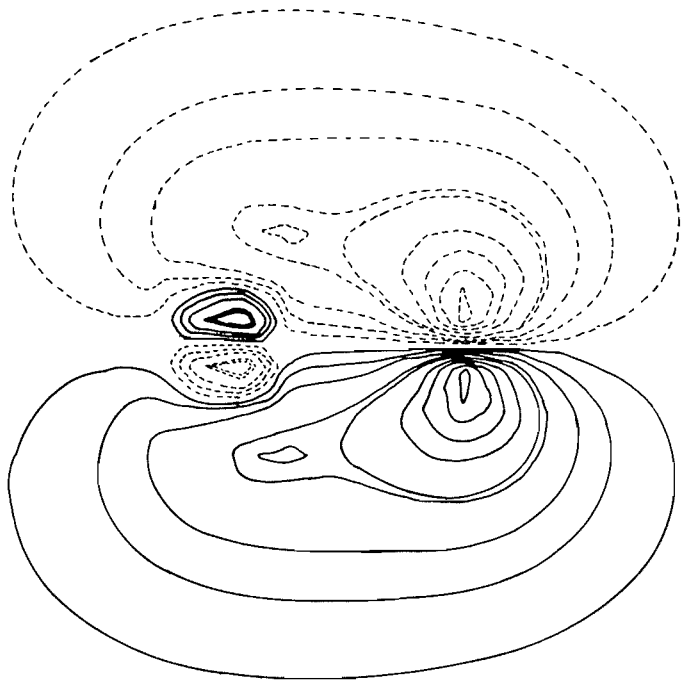

FIG. 2. Contours de l'orbitale $\pi_{P=N}$ dans HPNH *trans*. Les lignes tracées correspondent aux valeurs suivantes de ψ = ±0,02, ±0,05, ±0,08, ±0,13, ±0,14, −0,2, ±0,25, ±0,3, ±0,35.

points semblent bien établis.

D'une part pour une molécule plane du type HXYH avec X = Y, la rotation à 90° conduit à un éclatement de l'orbitale moléculaire doublement occupée à 0° en deux orbitales mono occupées dégénérées. L'état à 90° de plus basse énergie de nature radicalaire (répartition symétrique des électrons de la liaison π sur chaque atome) est atteint par un formalisme couches ouvertes; différents calculs réalisés sur C_2H_4, Si_2H_4 (21, 22) l'ont parfaitement montré.

D'autre part la non identité de X et Y conduit à une levée de dégénérescence d'autant plus importante qu'est grande la différence d'électronégativité entre X et Y; la rotation à 90° conduit alors à un état plus ou moins zwitterionique; on observe en effet une tendance à la localisation des électrons de la liaison π sur l'atome le plus électronégatif et ceci d'autant plus que la liaison π à 0° était polaire. L'état le plus stable à 90° est alors généralement atteint comme l'a remarqué Salem (23) par le calcul du singulet couches fermées; c'est ce que Curtis (22) a également observé dans le cas du silaéthylène H_2CSiH_2.

Pour notre part étant donné l'ambiguïté existant au niveau de $HPCH_2$: X ≠ Y, mais liaison π non polaire à 0°, nous avons, pour être assuré d'obtenir l'état à 90° de plus basse énergie, procédé pour les deux dérivés aux calculs des états couches ouvertes et du singulet couches fermées.

En ce qui concerne les états couches ouvertes un formalisme rigoureux RHF a été utilisé; les paramètres géométriques optimisés à 0° ont été conservés pour le calcul des états à 90°.

S'il nous a été possible d'atteindre sans problème les triplets (tableau 3), il n'en a pas été de même pour les singulets couches ouvertes que nous n'avons pu mener à convergence en dépit de nombreux essais; leur énergie est cependant généralement plus haute que celle du triplet correspondant.

Les énergies obtenues pour les singulets couches fermées ont été reportées dans le tableau 3.

Afin d'obtenir des grandeurs tout à fait comparables pour les deux composés examinés nous avons réalisé comme précisé auparavant une interaction de configurations sur les états fondamentaux et les singulets couches fermées correspondants. Nous sommes ainsi conduits à une évaluation de $\Delta E_r = E_{IC}(\theta = 0°) - E_{IC}(\theta = 90°)$; les valeurs obtenues de 48,1 kcal/mol et 105,4 kcal/mol respectivement pour HPNH et $HPCH_2$ révèlent une liaison π beaucoup plus faible pour HPNH que pour $HPCH_2$.

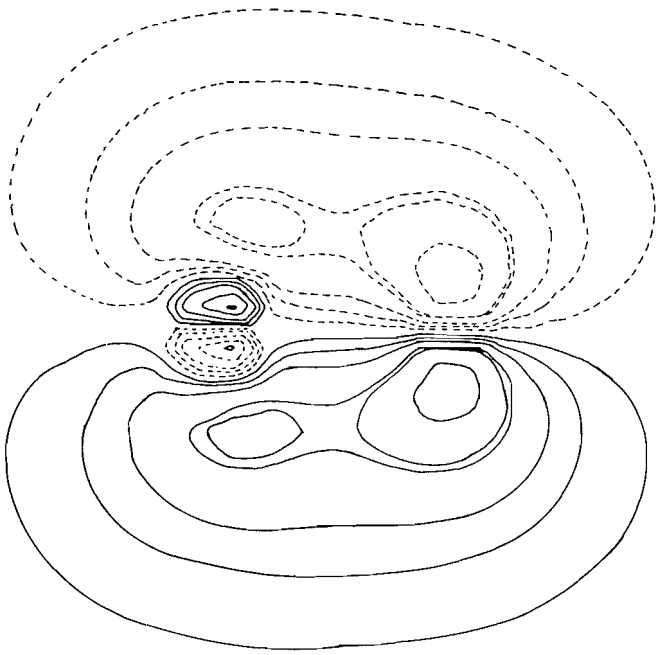

FIG. 3. Contours de l'orbitale $\pi_{P=C}$ dans $HPCH_2$. Les lignes tracées correspondent aux valeurs suivantes de ψ = ±0,02, ±0,05, ±0,08, ±0,13, ±0,14, ±0,2.

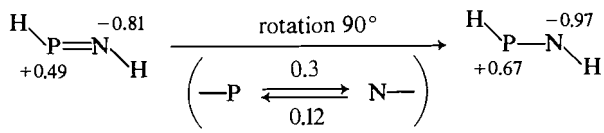
Par ailleurs, nous observons conformément aux remarques précédentes une très nette différence énergétique entre le triplet couches ouvertes et le singulet couches fermées dans le cas de HPNH alors que des valeurs énergétiques proches ont été obtenues pour $HPCH_2$.

Nous avons ensuite cherché à mieux cerner les caractéristiques électroniques de l'état à 90° qui correspond à la rupture de la liaison π et qu'il était par la même intéressant d'analyser plus en détail.

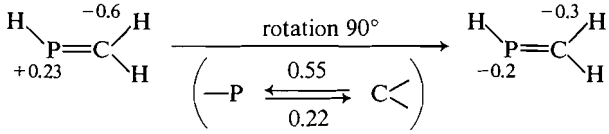
L'examen des populations de Mulliken (figure 4) révèle dans le cas de HPNH comme pressenti précédemment une polarité accrue P^+N^- et au contraire dans le cas de $HPCH_2$ un caractère type radicalaire de la liaison P—C dans l'état à 90°.

En analysant de façon plus approfondie les variations de population des diverses orbitales p_y (perpendiculaire au plan moléculaire à 0°) p_x dans le plan moléculaire et p_z selon l'axe de la liaison nous sommes conduits aux remarques suivantes en ce qui concerne la rupture de la liaison π.

Dans le cas de HPNH l'essentiel des mouvements électroniques lors de la rotation réside dans la perte en π du phosphore au profit de l'azote et à l'inverse nous notons un gain léger en σ au niveau du phosphore ce qui correspond au schéma suivant:



Un comportement tout á fait différent est observé pour $HPCH_2$; un transfert et π très notable du carbone vers le phosphore intervient et conjointement un mouvement apparaît en σ du phosphore vers le carbone ce qui conduit au schéma:



3.15 *Evolution thermique de chaque dérivé sur la nappe du fondamental*

Nous avons également tenté d'examiner l'évolution thermique de chaque dérivé sur la nappe du fondamental par le biais d'une minimisation des états à 90°.

Ceci nous a permis de pressentir qu'un mécanisme de rotation n'était envisageable que dans l'hypothèse d'un changement de multiplicité de la fonction d'onde puisqu'aucun extremum n'a pu être atteint aux environs de 90° pour un état singulet.

Le procédé de minimisation nous amène en effet à envisager sur la nappe du fondamental un processus d'évolution thermique bien différencié pour chaque composé.

Dans le cas de HPNH nous sommes conduits à un extremum plan l'hydrogène porté par l'azote étant situé dans le prolongement de la liaison P—N, le processus mis en jeu est celui de l'inversion de l'azote dans le plan de la molécule, la barrière obtenue étant de l'ordre de 15 kcal/mol environ. Ce comportement est à rapprocher de celui généralement invoqué pour l'isomérisation *cis–trans* aussi bien dans le cas de la formaldoxime (24) que de la diimide (25).

Pour $HPCH_2$, par minimisation, l'état à 90° se transforme rapidement en un intermédiaire  Etant donné la détection expérimentale lors de la pyrolyse de la phosphapropyne P≡CH nous sommes naturellement amenés à envisager une évolution de l'intermédiaire par abstraction d'hydrogène vers P≡CH, la barrière cette fois nettement plus importante se situe aux environs de 75 kcal/mol. Les géométries respectives de ces deux états de transition ont été reportées dans le tableau 4.

3.2 *Réactivité des phospha alkènes et iminophosphanes*

A partir de l'ensemble de ces données nous avons tenté d'interpréter la réactivité de ces deux composés.

A priori la très forte polarisation de la liaison P—N aussi bien en total qu'en π et la faible "force de liaison π" implique que HPNH soit une molécule extrémement réactive. De plus, l'atome de phosphore tout en présentant un caractère électrophile marquée (système π) garde sa nucléophilie: la dernière orbitale moléculaire occupée de ce système étant de type σ nettement localisée sur le phosphore comme le montre le contour de cette orbitale reporté dans la figure 5.

Par contre $HP{=}CH_2$ se caractérise par une force de liaison π nettement plus élevée et une polarité nettement moins marquée particulièrement en π où un caractère radicalaire apparaît.

De plus comme nous l'avons vu l'orbitale moléculaire localisée sur la paire libre du phosphore est énergétiquement plus profonde que dans HP—NH ce qui laisse pressentir une nucléophilie moins marquée.

Cette différence dans la structure électronique reflète bien le comportement chimique de ces molécules.

3.21 *Réaction d'addition*

Une des caractéristiques essentielles de ces deux systèmes est leur facilité de self-addition. Les monomères ne sont

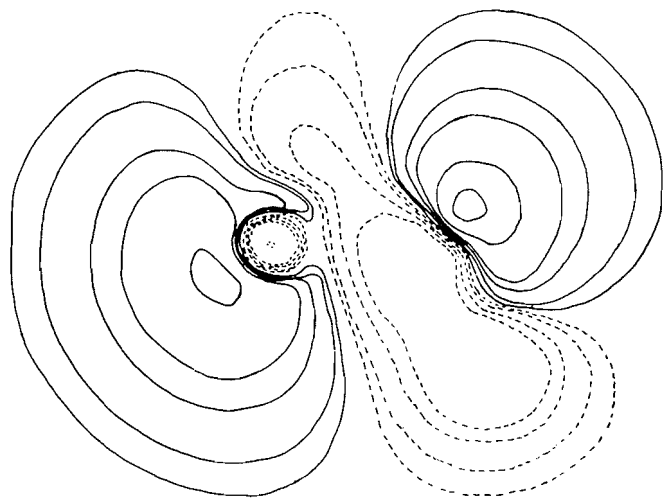

FIG. 5. Contours de la dernière orbitale occupée dans HPNH. Les lignes tracées correspondent aux valeurs suivantes de $\psi = \pm 0{,}01$, $\pm 0{,}02$, $\pm 0{,}05$, $\pm 0{,}08$, $\pm 0{,}18$, $\pm 0{,}3$.

obtenus notamment pour les iminophosphanes que dans des conditions bien particulières l'encombrement sur l'atome de phosphore paraissant un des facteurs importants (7).

Si l'on examine les contours des $\pi^*_{P=X}$ reportés dans les figures 6 et 7, on conçoit que pour une dimérisation (2 + 2) l'étape déterminante correspondra à la formation d'une liaison P—X (recouvrement maximal entre le contour observé sur l'atome X dans l'orbitale π occupée et celui sur P dans l'orbitale π^*) et donc à l'obtention de dimères tête–queue. Il faut toutefois noter que dans le cas de $\pi^*_{P=C}$, la forme de la π^* ne permet pas de rejeter l'hypothèse d'une dimérisation tête–tête fait observé expérimentalement notamment lorsque le carbone porte un substituant donneur (26). Par contre, dans le cas des iminophosphanes si la dimérisation tête–queue est bien observée (27) la réaction de cycloaddition (2 + 1) a été également mise en évidence (28) ce qui s'interprète en effet pour ce motif par une compétition avec l'attaque électrophile sur la paire libre du phosphore qui comme nous l'avons observé a une nette localisation dans la dernière orbitale moléculaire occupée.

Cette réactivité différente est également observée pour l'addition des réactifs polaires. Dans le cas de la double liaison P=C, l'addition 1,2 a été observée pour ROH (29) avec toutefois des conditions drastiques puisque catalysée par le méthylate de sodium.

Cette réaction apparaît également comme compétitive avec celle de substitution sur le phosphore et préservation de la double liaison (30).

Afin de mieux appréhender ce comportement nous avons examiné pour les phospha alkènes l'intermédiaire correspondant à une attaque anionique et pour cela procédé à la minimisation de l'entité $(\overset{HO}{H}\!\!>\!P—CH_2)^-$. Nous avons cependant conservé pour les longueurs C—H et les angles $P\hat{C}H$ les

valeurs obtenues lors de leur minimisation dans $PHCH_2$. Les valeurs optimisées ont été reportées dans le tableau 5.

Nous remarquons tout d'abord une pyramidalisation très nette au niveau de l'atome de phosphore qui s'accompagne d'un allongement de la longueur P—C avec simultanément un très net accroissement de la longueur P—H et une ouverture de l'angle $\widehat{HPC}$.

L'analyse de population selon Mulliken (figure 8) fait

apparaître une accumulation de charge négative importante sur l'hydrogène porté par le phosphore.

L'observation simultanée d'un allongement de la longueur P—H et d'une forte charge négative sur l'hydrogène traduit bien la possibilité d'une substitution sur le phosphore avec préservation de la double liaison et départ de H^-.

Parallèlement nous notons un caractère fortement négatif du carbone. Vis à vis de $HPCH_2$ nous observons un net accroissement de densité électronique dans la direction perpendiculaire au groupement CH_2 (1,003 dans $HPCH_2$, 1,82 dans $(\begin{smallmatrix}HO\\H\end{smallmatrix}\!>\!P—CH_2)^-$) la dernière orbitale occupée du système de symétrie π présentant une localisation très importante sur l'atome de carbone.

E_t (Hartree)	−396,230574	−396,15606
	ΔE = 46,7 kcal/mol	

Ces observations traduisent raisonablement la compétition pour ce système d'une réaction de substitution nucléophile avec préservation de la double liaison et d'une réaction d'addition 1,2.

Dans le cas de la double liaison P=N expérimentalement la seule addition 1,1 a été constatée (27, 31) les conditions opératoires étant toutefois particulièrement douces: il semble que comme pour la dimérisation (2 + 1) il faille invoquer les caractères nucléophile et électrophile de l'atome de phosphore. Nous avons comme précédemment examiné l'intermédiaire résultant d'une attaque anionique par OH^- sur le phosphore.

On constate (tableau 5, figure 8) un comportement légèrement différent puisque l'allongement de la liaison PH et l'accumulation de charge sur l'atome d'hydrogène sont moins importants. De plus, pour cet intermédiaire, la dernière orbitale moléculaire occupée reste une orbitale localisée sur la paire libre du phosphore traduisant ainsi la possibilité pour cet atome d'être le site d'attaque nucléophile et électrophile.

Si donc le caractère nucléophile de l'atome de phosphore dans les iminophosphanes est évident, il nous a semblé utile de compléter notre approche par l'examen du site de protonation sur ce système.

3.22 *Basicité de HP=NH*

Pour définer un site de protonation préférentiel on peut procéder à une détermination de l'énergie d'interaction électrostatique entre une charge ponctuelle (proton) et le potentiel du à la distribution de charge moléculaire; différents travaux ont toutefois mis en évidence la déficience de ce seul mode d'approche (32). En effet, la protonation induit une réorganisation totale des nuages électroniques au voisinage du site concerné et il faut également prendre en compte la relaxation au niveau des structures géométriques. Ceci nécessite la minimisation de tous les paramètres longueurs et angles des différentes espèces protonées possibles.

Pour notre part, en première approche du problème nous avons entrepris la minimisation des deux motifs $(HPNH_2)^+$ et $(H_2PNH)^+$.

Tous les paramètres ont été optimisés à l'exception des longueurs PH et NH, définies a priori à l'aide des résultats d'un travail précédent (33). Les valeurs obtenues ont été reportées dans le tableau 6.

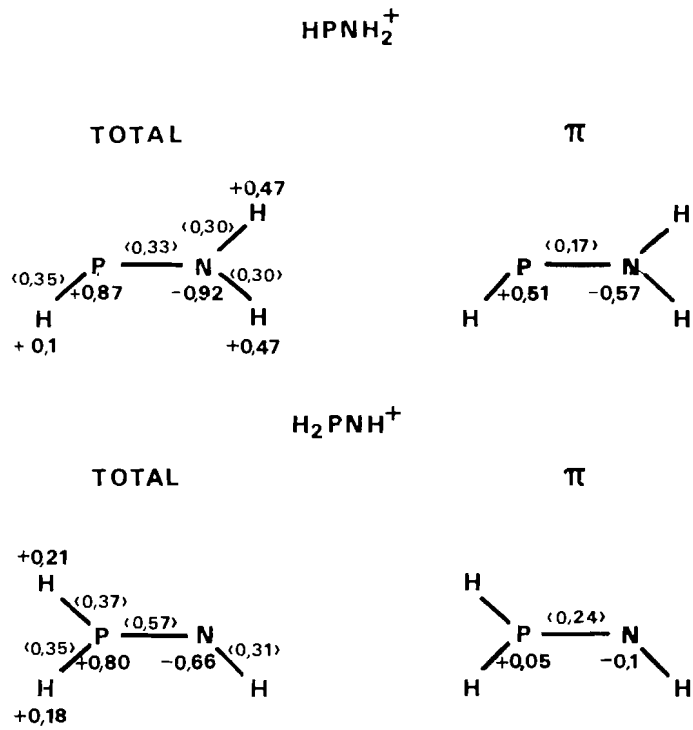

FIG. 9. Analyses de population selon Mulliken pour $HPNH_2^+$ et H_2PNH^+. Charges nettes et populations de recouvrement entre parenthèses.

Par rapport à HPNH nous observons un allongement de la longueur PN dans $(HPNH_2)^+$ et par contre un très net raccourcissement dans $(H_2PNH)^+$.

Il est également intéressant de remarquer la planéité des deux systèmes ainsi que la structure trigonale plan de l'atome protoné.

Si ce résultat pouvait être pressenti en ce qui concerne l'azote on aurait pu penser obtenir une pyramidalisation du phosphore or c'est une structure parfaitement plane qui a été déterminée.

L'examen des énergies obtenus (tableau 6) après une interaction de configurations du même type que celles précédemment réalisées, font apparaître un motif $(HPNH_2)^+$ nettement plus stable que $(H_2PNH)^+$.

Si dans certains cas on peut pressentir une dualité entre le site préférentiel à longue distance et celui réellement favorisé à l'accrochage ceci est peu vraisemblable dans le cas considéré étant donné la forte charge négative de l'azote dans HPNH et l'importante différence énergétique obtenue entre les deux formes protonées (46,7 kcal/mol). Les résultats de l'analyse de population selon Mulliken ont été reportés dans la figure 9 pour les deux composés.

Nous remarquons dans les deux cas une polarité $P^+—N^-$, l'atome de phosphore étant toujours nettement plus positif au total que dans HPNH; par contre, l'atome d'azote dans $(HPNH_2)^+$ apparaît plus négatif que dans HPNH l'inverse étant observé pour $(H_2PNH)^+$.

Un examen plus détaillé nous montre dans le cas de $(HPNH_2)^+$ que l'atome d'azote ayant perdu des électrons au niveau σ en draine en retour fortement en π, ce qui lui confère une charge nette négative importante en π; le phosphore par contre devient fortement positif essentiellement de par le trans-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

fert en π sur l'azote. Nous remarquons également un caractère renforcé de la "paire du phosphore" (accroissement de densité électronique dans la direction correspondante), enfin la population de recouvrement reflète une très forte diminution du caractère de double liaison (0,17 au lieu de 0,23 dans HPNH). Tout ceci révèle nettement dans le cas d'une protonation sur l'azote une structure ion phosphenium $HP^+—NH_2$ (figure 9) et en aucune façon du type $H—P=N^+H_2$ comme on aurait pu l'envisager a priori. Une telle entitée vient d'être récemment mise en évidence (34).

Contrairement à ce qui a été observé précédemment nous ne constatons lors d'une protonation sur le phosphore $(H_2PNH)^+$ qu'un très faible retour en π; par contre, une analyse plus approfondie révèle un transfert type $p \rightarrow d$ dans le plan de la molécule de l'azote vers le phosphore et qui se traduit par l'accroissement notable de l'indice de population total (0,45 dans HPNH → 0,57 dans $(H_2PNH)^+$) cette possibilité de transfert est peut-être l'un des facteurs à l'origine de la planéité observée au niveau du phosphore.

La protonation sur le phosphore ne conduit pas à une structure d'ion nitrenium mais à une entité iminophosphenium $H_2P^+=NH$ avec renforcement de la double liaison vis à vis de HPNH. De telles espèces viennent d'être isolées et caractérisées (35).

4. Conclusion

En conclusion cette étude quantochimique nous a permis de mieux appréhender les caractéristiques des deux motifs P=N et P=C.

Les iminophosphanes sont des molécules très polaires susceptibles de réactions d'addition (2 + 1) ou 1,1, le phosphore présentant pour cette entité une nucléophilie certaine, le site basique étant toutefois l'atome d'azote.

Dans le cas de $HPCH_2$ la force de la liaison π nettement plus grande et la polarité plus atténuée révèlent une molécule plus stable et moins réactive.

Remerciements

Synthesis of Mannich bases from electrochemically generated iminium salts in the presence of silyl enol ethers[1]

ROGER N. RENAUD,[2] DENIS BÉRUBÉ, AND CAMPBELL J. STEPHENS
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received October 26, 1982

ROGER N. RENAUD, DENIS BÉRUBÉ, and CAMPBELL J. STEPHENS. Can. J. Chem. **61**, 1379 (1983).

The formation of Mannich bases from the reaction of silyl enol ethers with *N*-methyl-*N*-mesitylmethyleniminium salt, generated by the electrochemical oxidation of *N*,*N*-dimethylmesidine, was studied. Important factors influencing the reaction are: (a) the silyl enol ether must be nucleophilic enough to react with the iminium salt and, at the same time, must be more difficult to oxidize than the tertiary amine, (b) the product of the reaction must not be oxidized at the operating potential. Examples are presented in this paper illustrating the successes and limitations of this reaction.

ROGER N. RENAUD, DENIS BÉRUBÉ et CAMPBELL J. STEPHENS. Can. J. Chem. **61**, 1379 (1983).

La formation de bases de Mannich a été étudiée en faisant réagir des éthers silyl énoliques sur le sel *N*-méthyl-*N*-mésitylméthyleniminium préparé par oxydation électrochimique de la *N*,*N*-diméthylmésidine. Les facteurs pouvant influencer la réaction sont: (a) l'éther silyl énolique doit être assez nucléophilique pour réagir avec le sel iminium et, en même temps, doit être plus difficile à oxyder que l'amine tertiaire, (b) le produit de la réaction ne doit être oxydé au potentiel employé. Des exemples montrant le succès et la limitation de cette réaction sont présentés dans cette étude.

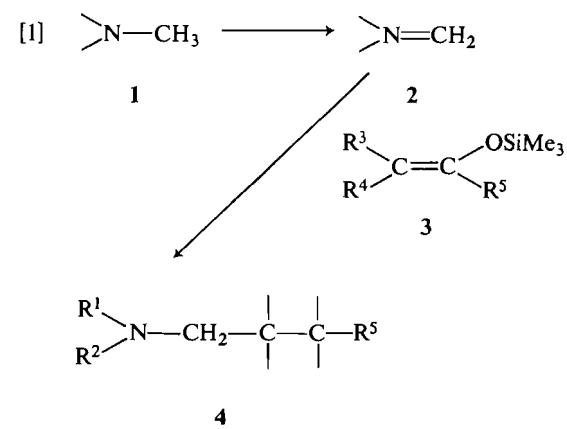
Many methods describing the aminomethylation of ketones are reported in the literature. The classical Mannich reaction is a typical example (1). Recently, aminomethylation was achieved successfully by the nucleophilic attack of silyl enol ethers on *N*,*N*-dimethylmethyleniminium salts (2, 3), chloromethyl methylurethan (4), and aminomethyl ethers (5).

The electrochemical formation of iminium cations from tertiary amines has been extensively studied (6–9). Recently, it was shown that the iminium cation, obtained from the electrochemical oxidation of *N*,*N*-dimethylanilines, gave good yields of addition products with nucleophiles such as diethyl phosphate and dialkylmalonates (7, 8). It seemed to be interesting for us to study the preparation of Mannich bases **4** by the nucleophilic attack of silyl enol ethers **3** on electrochemically prepared iminium cations **2**, according to Scheme 1. Only a selection of silyl enol ethers in the presence of the iminium salt of *N*,*N*-dimethylmesidine **1** are reported in this paper in order to present the scope of the potential of this preparative method.



SCHEME 1

Results and discussion

Controlled potential electrolyses were performed at a platinum electrode in acetonitrile containing 0.1 *M* lithium perchlorate. By using a one-compartment cell, a dark solution and an electrode passivation were obtained. The current was reversed for 2 s every minute in order to regenerate the surface of the electrode. A two-compartment cell eliminated these problems and simplified the purification of the products. Nevertheless, the yield of products increased only slightly by using a divided cell. Good yields (Table 1) of **4***a*–**4***d* were obtained[3] for the electrolysis of *N*,*N*-dimethylmesidine in the presence of the silyl enol ethers **3***a*–**3***d*, respectively. However, the Mannich base **4***e* was obtained in low yield from **3***e* while **4***f* was not detected from **3***f*.

Examination of the oxidation potentials of the reactants and the products gave some light on the electrolysis results. The current–potential curve of *N*,*N*-dimethylmesidine in $CH_3CN-LiClO_4$ (0.1 *M*) at a platinum rotating disc electrode showed a half-wave potential ($E_{1/2}$) of 0.55 V. As a result of this experimental condition, the $E_{1/2}$ of the silyl enol ethers and the products have to be considered. Figure 1 illustrates the current–potential curves of the electrochemical oxidation of *N*,*N*-dimethylmesidine, the silyl enol ether **3***a*, and the Mannich base product **4***a*. At 0.45 V, only a small quantity of the product **4***a* is oxidized while the current for the oxidation of *N*,*N*-dimethylmesidine is still reasonable (100–150 mA). Acceptable yields of **4***a*–**4***d* ($E_{1/2} \approx 0.6$ V) were obtained from the silyl enol ethers **3***a*–**3***d* respectively ($E_{1/2} > 1.2$ V) (Table 1). For O-methyl-O-trimethyl silyl isobutylketene acetal (**3***f*) ($E_{1/2} = 0.4$ V), the electrolysis has to be conducted at a potential higher than its own oxidation potential. On the other hand, even if ethyl 3-trimethylsiloxy-2-butenoate (**3***e*) has an oxidation potential ($E_{1/2} = 1.95$ V) high enough, a large quantity of the silyl enol ether **3***e* was recovered and the product **4***e* was obtained in only a very low yield. Further studies are in progress with other silyl enol ethers in order to obtain an explanation for this observation.

[1]NRCC No. 20111.

[2]Author to whom correspondence should be addressed.

[3]No aminomethylated product **4***a* was observed when the electrolysis was conducted in the presence of acetophenone. The formation of the Mannich base ω-[*N*-*tert*-butyl-*N*-methylamino]-propiophenone has been obtained, however, from *N*-methyl-*N*-*tert* methyleniminium perchlorate in the presence of acetophenone in methylene chloride (10).

[b]Ar =  .

[c]Isolated yields and current yields.

[d]A mixture of axial and equatorial stereoisomers in a ratio 1:3 respectively.

Besides the major products **4***b* and **4***d*, some compounds **5***b* and **5***d* were also isolated.[4] These compounds were determined to be the result of the oxidation of **4***b* and **4***d* to give a new iminium cation which reacted with another molecule of silyl enol ether to give **5** (Scheme 2). The same observation was noticed by Shono *et al.* (11) for the oxidation of dimethyl aniline in the presence of methanol as the nucleophile. For **4***a* and **4***c*, the compounds **5***a* and **5***c* are probably formed but could not be obtained pure enough for identification.

The product **4***c* is actually a mixture of two stereoisomers, the axial and the equatorial 2-substituted-4-butyl cyclohexanone in a ratio of 1:3. This ratio was determined by a current–potential curve on the mixture. The axial substituted product has a $E_{1/2}$ of 0.57 V while the equatorial equivalent is at 0.68 V. The stereochemistry was assigned by comparing the wideband proton decoupled, the proton undecoupled, and the spin echo spectra. The methylene carbon at C-2 is adjacent to a nitrogen and most likely appears at 58.05 ppm for the equatorial isomer and at 55.38 ppm for the axial isomer. Also, C-6 for the axial 2-substitution (33.84 ppm) has an upfield shift compared with the equatorial 2-substitution (38.30 ppm). This δ-effect of 4.9 ppm is comparable with the δ-effect of 5 ppm observed for 2-methyl cyclohexane (12). The carbonyl carbon appears at 214.68 ppm and 212.97 ppm for the axial and the equatorial isomers, respectively. Therefore, this downfield shift (208.8 ppm for cyclohexanone and 210.3 ppm for 2-methyl cyclohexanone) is due to the aromatic amino group attached to the methylene group at C-2.

[4]A complete study on the electrochemical oxidation of *N*,*N*-dimethylmesidine in the presence of nucleophiles has been published (7, 8).

Experimental

Reagents

N,*N*-dimethylmesidine was prepared by the Eschweider–Clarke reaction (13). The silyl enol ethers and the O-methyl-O-trimethylsilyl-isobutylketene acetal were obtained by reported methods (14). The acetonitrile was purified as reported in the literature (15).

Analytical methods

Infrared spectra were recorded on a Perkin–Elmer Model 267 spectrophotometer. Proton magnetic resonance spectra were taken in deuteriochloroform on a Varian Associates spectrometer model E.M. 360 and are reported in the δ scale. The ^{13}C magnetic resonance spectra were taken on a Bruker WP-80 apparatus. The mass spectra were obtained from a Finnigan 400 gc–ms spectrometer. The moleculear weight determinations were done on a Mechrolab vapor pressure osmometer model 301A.

Electrochemical instrumentation

All potentials were referred to Ag/0.01 *M* $AgNO_3$ in acetonitrile–$LiClO_4$ (0.1 *M*). Current–potential measurements were obtained using a conventional three-electrode cell equipped with a programmer PAR 175, a potentiostat PAR 173, a coulometer PAR 379, a rotating disc electrode from Tacussel, and a Hewlett–Packard 7045B X–Y recorder. The controlled potential electrolyses for the preparative scale synthesis were carried out in a H-type cell. This cell has a glass frit diaphragm separating the two compartments. The

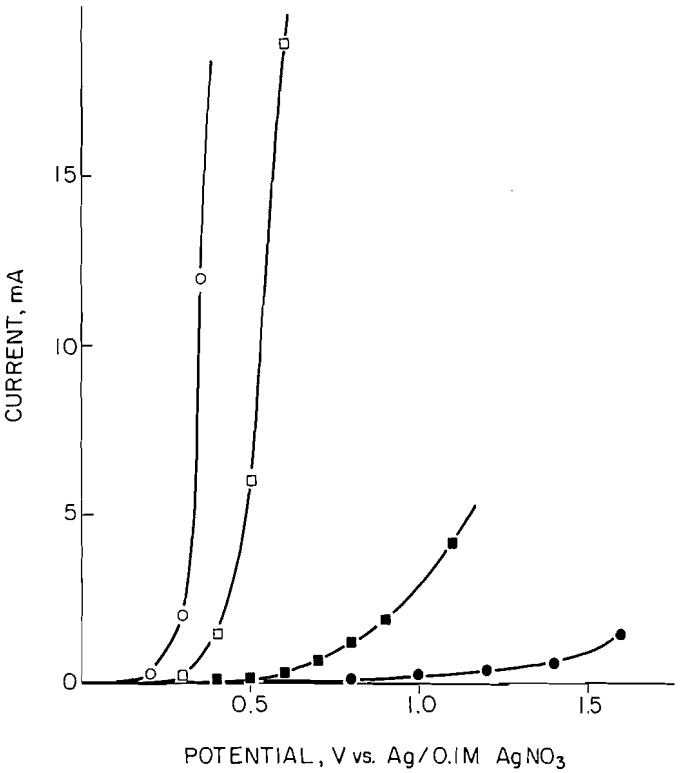

FIG. 1. Current–potential curves. Curve ●: acetonitrile–$LiClO_4$ (0.1 *M*). Curve ■: 1-phenyl-1-trimethylsilyloxyethylene (**3***a*) (0.1 *M*). Curve ○: *N*,*N*-dimethylmesidine (0.1 *M*). Curve □: *N*-methyl-*N*-3-phenylpropanone-3 mesidine **4***a* (0.1 *M*).

anodic compartment (150 mL) contained a semi-circular platinum screen (4 cm × 9 cm). A platinum screen (1 cm × 1 cm) was used as the cathode. The source of energy was obtained from a 300 V Lambda power supply model LB-706-FM, and the potential was controlled manually by means of a high resistance voltmeter.

General procedure

A mixture of $LiClO_4$ (1.34 g), Na_2CO_3 (2.12 g), silyl compound (≈5 mol excess), and *N*,*N*-dimethylmesidine (1.63 g; 0.01 mol) in acetonitrile (125 mL) was placed in the anodic compartment. The cathodic solution was $LiClO_4$ (0.1 *M*) in acetonitrile. The potential of the anodic solution was controlled at ≈0.45 V until 2.0 F/mol has been passed. The anodic solution was filtered and concentrated on a rotary vacuum evaporator. The oily residue was extracted with three 50-mL portions of n-pentane. The pentane was removed on a rotary evaporator. The residue was pumped under a pressure of 10^{-2} Torr for 24 h at room temperature. The volatiles, which were collected in a trap cooled in liquid nitrogen, consisted of unreacted starting materials. The remaining low vapor pressure oil was fractionated by flash chromatography (16) using a column of 2 cm diameter by 40 cm long and the main fraction was further purified by fractional distillation in a bulb-to-bulb apparatus under reduced pressure.

Physical properties of the products

(A) *From 1-phenyl-1-trimethylsilyloxy-ethylene* **3**a

The crude product showed only one important spot on the tlc plate. Purification by flash chromatography using hexane – ethyl acetate (6:1) and by a bulb-to-bulb distillation at 100°C (10^{-2} Torr) gave 1.2 g (42.7%) of a yellow oild (**4***a*) which crystallized on standing (mp 59–60°C); ir ($CHCl_3$): 1680 cm^{-1}; ^1H nmr: 2.18 (s, 9H), 2.61 (s, 3H), 3.22 (q, AB, 4H), 6.72 (s, 2H), 7.42 (m, 3H) 7.78 (m, 2H); ms *m*/*e*: 281 (M^+, 14), 162 ($M^+ - C_8H_7O$, 100). *Anal.* calcd. for $C_{19}H_{23}NO$: C 81.14, H 8.19, N 4.98; found: C 81.18, H 8.26, N 4.84.

X = the ketonic substituent

SCHEME 2

The residue obtained after removal of the high vapor pressure fraction at 10^{-2} Torr showed two important spots on the tlc plate. The crude product was fractionated by flash chromatography using hexane – ethyl acetate (6:1) as the eluent. Two fractions were obtained. The first one was purified further by bulf-to-bulb distillation at 85°C (10^{-2} Torr) to give 1.5 g (57.9%) of a yellow oil (**4***b*); ir (film): 1710 cm^{-1}; ^1H nmr: 1.9 (broad m, 9H), 2.09 (s, 9H), 2.64 (s, 3H), 3.28 (m, 2H), 6.71 (s, 2H); ms *m*/*e*: 259 (M^+, 7), 162 ($M^+ - C_6H_9O$, 100). *Anal.* calcd. for $C_{17}H_{25}NO$: C 78.76, H 9.65, N 5.41; found: C 78.35, H 9.76, N 5.34. The second fraction amounted to 0.41 g (11.5%) of slightly impure **5***b*; ir (film): 1700 cm^{-1}; ^1H nmr: 1.4–2.6 (broad m including the aromatic CH_3 groups, 29H), 3.2 (m, 4H), 6.80 (s, 2H). Mol. Wt. calcd.: 355; found: 348.

(C) *From 1-trimethylsilyloxy-4-*tert*-butyl-1-cyclohexen* **3**c

The oily product obtained was shown by tlc to contain one major compound and 5 minor ones. The main product **4***c* (1.24 g; 39.4%) was separated by flash chromatography using hexane – ethyl acetate 8:1 as the eluent. A sample of the purified product was distilled in a Späth bulb under a pressure of 10^{-2} Torr at 120°C. A very slight decomposition was noticed at that temperature. Infrared (film): 1703 cm^{-1}; ^1H nmr: 0.89 (s, 9H), 1.68 (m, 8H), 2.28 (broad s, 9H), 2.70 (s, 3H), 3.28 (m, 2H), 6.80 (s, 2H); ms *m*/*e*: 315 (M^+, 6), 162 ($M^+ - C_{10}H_{17}O$, 100). *Anal.* calcd. for $C_{21}H_{33}NO$: C 80.00, H 10.48, N 4.44; found: C 80.06, H 10.37, N 4.40.

(D) *From 1-trimethylsilyloxy-1-cyclopentene* **3**d

The crude mixture contained two important spots on the tlc plate. It was purified by flash chromatography (hexane – ethyl acetate 6:1). The first fraction (**4***d*) was purified further by bulb-to-bulb distillation under a pressure of 10^{-2} Torr at 70°C to give a nearly colorless oil (1.40 g; 57.1%); ir (film): 1725 cm^{-1}; ^1H nmr: 1.92 (m, 7H), 2.24 (s, 9H), 2.72 (s, 3H), 2.90–3.82 (m, 2H), 6.80 (s, 2H); ms *m*/*e*: 245 (M^+, 37), 162 ($M^+ - C_5H_7O$, 100). *Anal.* calcd. for $C_{16}H_{23}NO$: C 78.37, H 9.38, N 5.71; found: C 78.15, H 9.43, N 5.63. The second fraction which corresponded to **5***d* (0.24 g; 7.3%) always contained a slight impurity; ir (film): 1720 cm^{-1}; ^1H nmr: 1.60–2.60 (broad m including the aromatic methyl groups at 2.30, 16H), 2.70–3.70 (m, 4H), 6.80 (s, 2H). Mol. Wt. calcd.: 327; found: 332.

(E) *From ethyl 3-trimethylsilyloxy-2-butenoate* **3**e

A dark brown product was obtained from the electrolytic reaction. The gummy residue, obtained after the removal of the volatile fraction at room temperature under reduced pressure (10^{-2} Torr), was a mixture of at least ten compounds by tlc. After separation by flash chromatography, one of the compounds seemed to correspond to **4***e* (0.02 g; 1.4%) but it was still slightly impure. Infrared (film): 1740 and 1715 cm^{-1}; ^1H nmr: 1.20 (t, 3H), 2.22 (broad s, 12 H), 2.71 (s, 3H) 2.80–3.82 (m, 3H), 4.20 (q, 2H), 6.86 (s, 2H). *Anal.* calcd. for $C_{17}H_{25}NO_3$: C 70.10, H 8.59, N 4.81; found: C 68.64, H 7.82, N 5.07.

(F) *From* O-*methyl*-O-*trimethylsilyl*-*isobutylketene acetal* (**3f**)

The crude product after removal of the volatile fraction at room temperautre (10^{-2} Torr) amounted to only 0.1 g from which no Mannich base could be obtained.

Syntheses of optically active 2-tetrahydrofuran derivatives

PATRICE C. BÉLANGER AND HAYDN W. R. WILLIAMS
Merck Frosst Canada Inc., P.O. Box 1005, Pointe-Claire/Dorval, Québec, Canada H9R 4P8

Received July 2, 1982[1]

PATRICE C. BÉLANGER and HAYDN W. R. WILLIAMS. Can. J. Chem. **61**, 1383 (1983).

The resolution of 2-tetrahydrofuran-carboxylic acid and assignment of configuration to the enantiomers are reported. New syntheses of the enantiomers of 2-tetrahydrofurancarboxaldehyde are also described.

PATRICE C. BÉLANGER et HAYDN W. R. WILLIAMS. Can. J. Chem. **61**, 1383 (1983).

La résolution de l'acide tétrahydrofuran-2-carboxylique et la détermination de la configuration des énantiomères y sont rapportées. On décrit aussi de nouvelles synthèses des énantiomères de la tétrahydrofuran-2-carboxaldéhyde.

Introduction

The availabilities of 2-tetrahydrofuranyl derivatives of defined stereochemistry are of current interest because of the introduction of this moiety into compounds with pharmaceutical applications. Thus the 2-tetrahydrofuranylmethyl group has been introduced into saluretics (1), diuretics (2), and more recently into potent analgesics which are claimed to lack some of the undesirable side effects that are observed with the classical opiates (3). Another aspect of the stereochemistry of tetrahydrofuran derivatives which may become important is their use as chiral ligands for metal ions such as lithium (4).

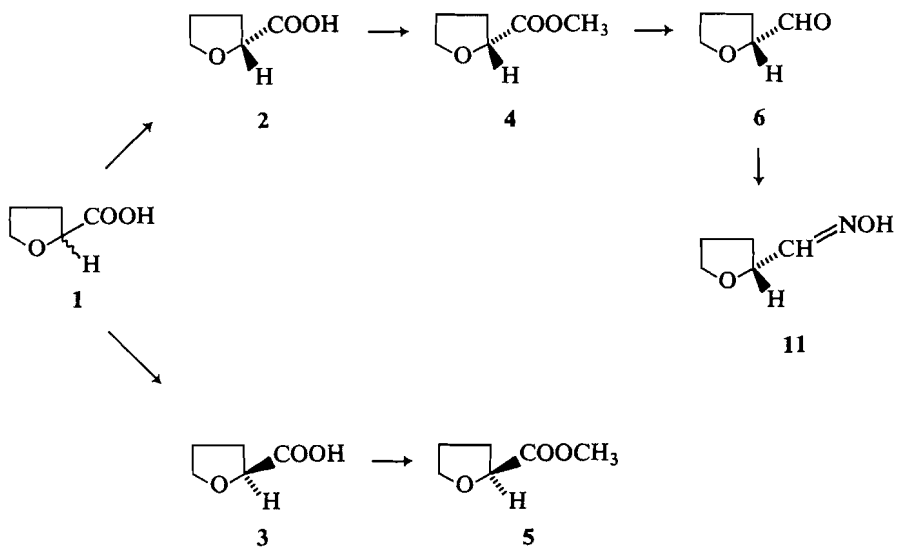
When the tetrahydrofuranylmethyl group can be introduced into a molecule by way of tetrahydrofurfurylamine, this is an attractive approach because of the ease of obtaining both enantiomers from the commercially available racemic amine (2).

Another way that has been used to introduce this functionality is by alkylation of a nucleophilic centre with a 2-tetrahydrofurylmethyl halide (3, 5) or sulphonate (3*b*). This approach is less convenient because of the multistep syntheses of these chiral reagents (some of which are liquids and consequently difficult to obtain optically pure). Furthermore, they are somewhat unreactive alkylating agents (see for example, ref. 6 and ref. 3*b*, p. 1482), and therefore not attractive to use when synthetic strategy dictates the introduction of the group at a late stage in a long sequence.

Accordingly we began a study on the preparations of the enantiomers of 2-tetrahydrofuroic acid, and also investigated more facile preparations of the enantiomers of 2-tetrahydrofurancarboxaldehyde which have been made previously from D-ribose (or D-xylose) and D-lyxose (7). Either of these pairs of chiral tetrahydrofuran derivatives might be convenient alternatives to the reagents mentioned above in an appropriate alkylation procedure.

Results and discussion

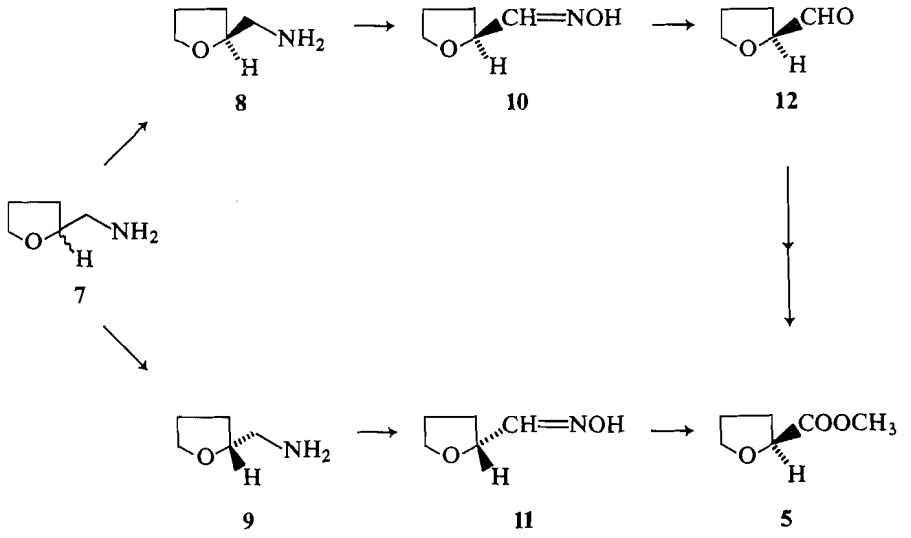
The enantiomers of 2-methyltetrahydrofuran-2-carboxylic acid have been described in a German patent (8) but tetrahydrofuran-2-carboxylic acid seems not to have been resolved previously. Thus, treatment of racemic carboxylic acid **1** with half an equivalent of brucine dihydrate in ethyl acetate gave an 81% yield of a salt, which upon recrystallization twice from acetonitrile afforded 51% of the brucine salt of (+)-tetrahydrofuran-2-carboxylic acid **2**. Recovery of (−)-enriched carboxylic acid from the mother liquors and recrystallization of its salt with (+)-ephedrine provided (−)-tetrahydrofuran-2-carboxylic acid **3**. Esterification of the enantiomeric acids with diazomethane gave the corresponding methyl esters and the latter were examined by nmr in the presence of an optical shift reagent to assess their chiral purity. This was greater than or equal to 94% e.e. in the case of



1 **2** **3** **4** **5** **6** **11**

SCHEME 1

[1]Revision received December 29, 1982.



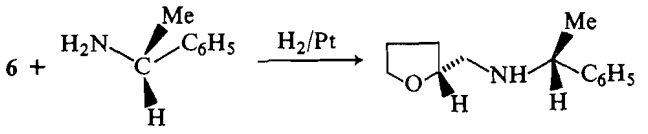
SCHEME 2

(−)-ester **4** derived from (+)-carboxylic acid **2**, and the other ester did not contain a detectable amount of its enantiomer.

The absolute configuration of (+)-tetrahydrofuran-2-carboxylic acid was determined to be *R* by reduction of the corresponding methyl ester with DIBAH to the known *R*-tetrahydrofuran-2-carboxaldehyde **6** (7). However, comparison of the physical properties of **6** prepared in this way with data in the literature (7) was not completely satisfactory. The boiling point was reported to be 75–80°C/2 × 10^{-2} Torr which seemed inordinately high compared to boiling points of 50°C/20 Torr for tetrahydrofurfurylamine and 45°C/2 × 10^{-1} Torr for methyl tetrahydrofuran-2-carboxylate. Our product distilled at 60°C/20 Torr and, by comparing the integration of the aldehydic proton with that for the protons at C-2 and C-5, it was judged to be over 80% monomer (but the spectrum still showed traces of impurity from the reagent). The reported rotation for *R*-tetrahydrofuran-2-carboxaldehyde synthesized from D-ribose (or D-xylose) (7) is −3.4° (*c* 1.2, MeOH). Measurement of the rotation of **6** in methanol gave an initial value of $[\alpha]_D$ −4.3° (*c* = 1.00, MeOH) but this was found to change to −3.3° in about 5 min and to +1.5° in 45 min. After 24 h the reading was +0.9°. A possible explanation of these changes might be a rapid formation of a hemiacetal on dissolving the aldehyde in methanol, followed by a slower formation of acetal and perhaps a much slower concomitant racemization. Measurements of the rotations of these enantiomeric aldehydes in tetrahydrofuran give much higher values than, but of opposite sign to, those determined in methanol, and they correlated well with determinations of optical purity by another method, as will appear later.

The absolute configurations of the tetrahydrofuran-2-carboxylic acid enantiomers do not rest solely on the rather unsatisfactory comparison of the rotation of **6** with the literature value. *S*-Tetrahydrofuran-2-carboxaldehyde **12** was synthesized by another route starting from tetrahydrofurfurylamine, as outlined in Scheme 2.

The latter was resolved by a slight modification of the method of Cragoe (2) which provided both optical isomers by way of their salts with L-tartaric acid, instead of using the more expensive D-tartaric acid for one isomer. The absolute configurations of these amines are known (9). Oxidation of the *S*-isomer with hydrogen peroxide and sodium tungstate (10) afforded the oxime in about 60% yield with little or no racemization as determined by nmr spectrometry in the presence of an optical shift reagent. Unfortunately, reductive hydrolysis of the oxime to the *S*-aldehyde with titanium trichloride (11) afforded the product in only 40% yield, and measurement of the rotation (in THF) suggested that this material had undergone more racemization than the product derived from DIBAH reduction of the ester. However, the optical rotation in solution in tetrahydrofuran showed unequivocally that this aldehyde had the opposite chirality to that obtained from (+)-tetrahydrofuran-2-carboxylic acid and confirmed the assignment of *R* configuration for the latter.



SCHEME 3

Conversion of these aldehydes **6** and **12** to their oximes **10** and **11** provided a means of estimating their optical purity by the nmr method, which was 80% e.e. for **6** and 66% e.e. for **12**.

R-Tetrahydrofuran-2-carboxaldehyde has been used for synthesizing chiral products (5), but it is difficult to assess the optical purity of the aldehyde made from D-ribose compared to that made by the procedure described herein. When **6** was used to alkylate *S*-α-methylbenzylamine by reduction, it gave a mixture of diastereoisomeric secondary amines in a ratio of 9:1 (by hplc analysis), that is, with no significant racemization during the reaction (Scheme 3).

Experimental

Melting points were determined using a Thomas–Hoover melting-point apparatus and are uncorrected. The 90-MHz ^{1}H nmr spectra were recorded with a Varian Associates EM-390 spectrometer using Me_4Si as internal standard. The optically selective nmr shift reagent used was tris [3-(heptafluoropropylhydroxymethylene)-*d*-camphorato] europium(III) derivative. Rotations were recorded with a Perkin–Elmer 241 polarimeter.

R-*Tetrahydrofuran-2-carboxylic acid* **2**

A hot solution of racemic tetrahydrofuran-2-carboxylic acid (51.35 g, 0.443 mol) in ethyl acetate (513 mL) was treated with brucine dihydrate (95.2 g, 0.221 mol) in small portions with stirring. The suspension was allowed to cool and the solid was collected, 97.5 g (81%); mp 192–195°C; $[\alpha]_D$ −6.95° (*c* 1.025, MeOH).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

The solid was recrystallized twice from acctonitrilc (1.2 L), with evaporation to approximately 500 mL before collecting the product each time; 62.0 g (51%) of the brucine salt of **2**, mp 200.5–201°C; $[\alpha]_D$ −5.8° (*c* 1.00, MeOH) was obtained.

The brucine salt (63.5 g, 0.1165 mol) was treated with *N*-hydrochloric acid (128 mL) and 1:1 ethyl acetate/ether (500 mL). After stirring the mixture for 30 min, sodium chloride (30 g) was added. This resulted in the precipitation of brucine hydrochloride which was filtered off and washed with 1:1 solvent mixture. The aqueous phase was separated and extracted with solvent mixture (5 × 250 mL). After washing the combined extract with saturated sodium chloride solution (500 mL) to which had been added 6 *N* hydrochloric acid (5 mL), the extract was dried (Na_2SO_4) and evaporated. Bulb-to-bulb distillation of the residual oil yielded 13.2 g of **2**, bp approximately 90°C/0.07 Torr; $[\alpha]_D$ +30.4 (*c* 1.01, $CHCl_3$).

S-*Tetrahydrofuran-2-carboxylic acid* ***3***

The mother liquors from the first stage of the resolution were combined and evaporated, and the tetrahydrofuran-2-carboxylic acid enriched in the *S*-isomer was recovered by acidification, extraction, and distillation as described for the *R*-isomer.

A hot solution of the recovered acid (20.2 g, 174 mmol) in ethyl acetate (150 mL) was treated with (+)-ephedrine (28.7 g, 174 mmol) slowly with stirring. The solution was allowed to cool a little and was seeded and cooled to room temperature, giving 28.7 g (59%) of solid, mp 108–112°C; $[\alpha]_D$ +20.0° (*c* 1.00, MeOH).

The solid was recrystallized twice from ethyl acetate (420 mL, then 220 mL) to afford the (+)-ephedrine salt of **10**, 18.8 g (38%); mp 116–116.5°C; $[\alpha]_D$ +13.8° (*c* 1.00, MeOH).

Conversion of this salt to the free acid by the procedure described for **2** gave **3**, $[\alpha]_D$ −30.1° (*c* 1.21, $CHCl_3$).

Methyl R-*tetrahydrofuran-2-carboxylate* ***4***

Treatment of a solution of **2** (2.00 g, 17.2 mmol) in methanol with etheral diazomethane, followed by distillation in a kugelrohr apparatus, provided **4**, 1.96 g (87.7%); oven temperature approximately 50°C/0.1 Torr; $[\alpha]_D$ −8.0° (*c* 0.92, MeOH); nmr δ($CDCl_3$): 4.45 (m, 1H, H at C-1), 3.9 (m, 2H, H at C-4), 3.75 (s, 3H, CH_3), 1.95 (m, 4H, H at C-2 and C-3).

Methyl S-*tetrahydrofuran-2-carboxylate* ***5***

The ester of *S*-chirality was made by esterification of **3** with diazomethane, $[\alpha]_D$ +8.1° (*c* 1.05, MeOH).

In the presence of the optical shift reagent the methyl groups of the two esters can be distinguished, and the relative heights of the two signals can be used as a measure of optical purity. The *S*-ester did not contain a detectable amount of the enantiomer while the *R*-ester had at least 94% e.e. In the latter case the "ringing" of the signal is likely to result in an overestimation of the *S*-methyl ester group which is the upfield signal.

Resolution of tetrahydrofurfurylamine

The procedure supplied by Dr. E. J. Cragoe Jr. (2) and Mr. C. M. Robb was modified slightly to obtain both enatiomers from their salts with L-tartaric acid. The 1:1 salt of tetrahydrofurfurylamine and natural tartaric acid prepared on a molar scale in methanol (1 L) was recrystallized three times from this solvent to give (*R*)-tetrahydrofurfurylammonium hydrogen L-tartrate, 96.9 g, mp 96–97°C dec.; $[\alpha]_D$ −0.56° (*c* 2.00, H_2O).

Crude (*S*)-tetrahydrofurfurylammonium hydrogen L-tartrate (117 g), recovered from the mother liquors of the above recrystallizations, was suspended in boiling ethanol (≈450 mL) and the solid was collected after the suspension had cooled to about 45°C. Repetition of this procedure in hot ethanol (465 mL) gave *S*-tetrahydrofurfurylammonium hydrogen L-tartrate, 96.1 g; mp 126–127°C; $[\alpha]_D$ +36.1° (*c* 2.00, H_2O).

S-*Tetrahydrofuran-2-carboxaldehyde oxime* ***10***

S-Tetrahydrofurfurylamine **8** was liberated from its salt with L-tartrate salt (50.0 g) by treatment with potassium hydroxide (2); 16.25 g (81%); bp 49–52°C/17 Torr; $[\alpha]_D$ + 14.6° (*c* 2.035, MeOH).

A solution of **8** (5.05 g, 50 mmol) in water (50 mL) was treated with sodium tungstate (500 mg), and then at 10–15°C over a period of 3 h with 50% hydrogen peroxide (7.2 mL, 125 mmol). After stirring the mixture a further 30 min, it was saturated with NaCl and extracted with ethyl acetate (5 × 100 mL). The extract was dried ($MgSO_4$) and evaporated to an oil. On distillation, the latter afforded 3.53 g (61%) of pure **10**, bp 100–110°C/0.08 Torr; $[\alpha]_D$ −41.3° (*c* 1.975, MeOH); nmr δ ($CDCl_3$): 7.32 (d, 0.7H, *J* = 7 Hz, *syn* CH=N), 6.84 (d, 0.3H, *J* = 5 Hz, *anti* CH=N), 4.90 (m, 0.3H, H-2 of the *anti*-isomer), 4.33 (m, 0.7H, H-2 of the *syn*-isomer), 3.88 (m, 2H, CH_2O), 1.95 (m, 4H, 2 × CH_2).[2]

R-*Tetrahydrofuran-2-carboxaldehyde oxime* ***11***

The title compound was made from **9**, of rotation $[\alpha]_D$ −14.1 (*c* 2.085, MeOH) by the method described above. The product had bp 85–95°C/0.04 Torr; $[\alpha]_D$ +40.2° (*c* 2.00, MeOH).

The addition of the optical shift reagent to a solution of the racemic oxime in deuterochloroform results in the splitting of the doublet in the nmr spectrum, due to the *syn* CH=N group, into a pair of doublets of almost equal height. The amount of optical shift reagent added is fairly critical because the downfield shift produced on this signal is small relative to the shifts produced on signals upfield of it, and further addition of reagent results in overlap. The doublet of the *R*-isomer is downfield of the *S*-isomer.

The products **10** and **11** above were optically pure within the limits of this procedure.

S-*Tetrahydrofuran-2-carboxaldehyde* ***12***

Method A

The *S*-oxime **10** (2.30 g, 20 mmol) was added to a solution of citric acid monohydrate (6.10 g, 30 mmol) and concentrated ammonium hydroxide (2 mL) in water (40 mL) at −2°C under argon. Titanium trichloride (7.4 g, 48 mmol) was added in small portions. Stirring was continued at room temperature for 2 h and then sodium chloride (6 g) was added before extraction with methylene chloride (10 × 50 mL). The dried (Na_2SO_4) extract was evaporated to yield crude **12**, 795 mg (40%); $[\alpha]_D$ −16.6° (*c* 1.115, THF); nmr δ($CDCl_3$): 9.68 (d, *J* = 1.5 Hz, CHO), 4.25 (m, H at C-2), 3.9 (m, H's at C-5), 1.9 (m, H's at C-3 and C-4). The protons at 9.68 and 4.25 always integrate 1:1 but are low with respect to the other multiplets, probably due to the formation of trioxane or other polymers.

The yield can be increased to about 60% by continuous extraction with methylene chloride but with a slight drop in the specific rotation of the product.

R-*Tetrahydrofuran-2-carboxaldehyde* ***6***

Method B (13)

To a solution of the *R*-ester **4** (464 mg, 4.0 mmol) in a mixture of hexane (20 mL) and ether (8 mL) at −60°C was added 1.0 *M* diisobutylaluminium hydride (10 mL) slowly over 20 min. The mixture was stirred in the cooling bath for 30 min and then it was quenched with saturated NH_4Cl solution. The upper layer was decanted and the lower layer was extracted with methylene chloride (7 × 10 mL). Filtration was necessary to obtain a good separation. The combined extract was dried (Na_2SO_4) and evaporated to give crude **6**, 285 mg (71%); $[\alpha]_D$ +32.7° (*c* 0.995, THF).

The crude product was distilled in a semi-micro climbing-film apparatus (bath temperature ≈60°C/20 Torr) to give a distillate containing about 82% monomeric **6** (by nmr), $[\alpha]_D$ +60.1°C (*c* 0.885, THF). The variation with time of the specific rotation of this product in methanol is described in the discussion.

Examination of the enantiomeric purities of aldehydes ***6*** *and* ***12***

1. *By way of the oximes*

Each of the above aldehydes **6** or **12** (100 mg, 1 mmol) in water (1.5 mL) was treated with sodium acetate trihydrate (136mg) and hydroxylamine hydrochloride (70 mg). The solution was allowed to stand

[2]The ^1H nmr spectrum of the racemic oxime has been described previously (12).

overnight, then sodium chloride (0.5 g) was added and the mixture was extracted several times with ethyl acetate. The product was purified by kugelrohr distillation to afford the oximes in ≈63% yield.

The oxime from **12**, $[\alpha]_D$ −27.3° (*c* 0.97, MeOH), was found to have 66% e.e. by an optical shift nmr method, while that from undistilled **6** had $[\alpha]_D$ +33.3 (*c* 1.675, MeOH) and 80% e.e. by nmr.

In neither of the methods of preparation of the aldehydes were the reaction conditions optimized to reduce racemization, but clearly Method B is the more promising procedure in this regard.

2. *By way of the corresponding ester*

Sodium hydroxide (1 *N*, 2 mL) was added to a solution of silver nitrate (340 mg, 2 mmol) in water (3 mL) and to the stirred suspension of silver oxide was added **12** (100 mg, 1 mmol). The reaction mixture was titrated to pH 6.5 with NaOH and filtered. The filtrate was acidified to pH 6 and extracted several times with ether to provide 2-tetrahydrofurancarboxylic acid (39 mg). The latter was esterified with diazomethane and the ester was purified by chromatography (silica gel, 1:1 ether/hexane) before an nmr optishift study. This showed the ester **5** to have 60% e.e., in fair agreement with the estimated optical purity of the oxime regenerated from this sample of aldehyde, by rotation and nmr. Details of the mr shift reagent results are described in the discussion.

Reductive alkylation of S-α-*methylbenzylamine*[3] *with (2R)-tetrahydrofuran-2-carboxaldehyde*

Crude **6** (265 mg, 2.65 mmol) prepared by DIBAH reduction of ester **4** in methanol (10 mL) was treated with *S*-α-methylbenzylamine (322 mg, 2.65 mmol) and a few drops of acetic acid were added before stirring the mixture at room temperature for 15 min. Platinum oxide (30 mg) was added and the mixture was hydrogenated at room temperature and pressure. The product was purified by column chromatography (Merck silica gel eluted with 0.25:2.5:100 ammonium hydroxide/methanol/chloroform) and the diastereoisomeric products were collected in one fraction, 283 mg; nmr δ($CDCl_3$):7.34 (m, 5H, ArH), 4.1–3.6 (m, 4H, CH_2—O—CH & N—CH), 2.7–2.3 (m, 2H, CH_2N), 2.0–1.5 (m, 4H, CH_2—CH_2), 1.38 (d, 3H, J = 6 Hz, CH_3).

There was no evidence for different shifts for the methyl group in the two diastereoisomers in this product, nor in that made from racemic 2-tetrahydrofurancarboxaldehyde. The latter was made for reference purposes for the estimation of the two diastereoisomeric amines by hplc. Using a μ Bondapak C18 column, 40:60 water/methanol buffered at pH 5.5 with acetic acid/sodium acetate, and flow rate of 1.8 mL/min, the retention time of the (2*R*)-tetrahydrofuran-2-ylmethylamine derivative was 3.1 min and that of the (2*S*)-diastereomer was 2.2 min. By this means the amount of *R*,*S*-diastereoisomer was estimated to be 91.06 ± 0.43% (mean of 5 results). This result is in good agreement with the estimated optical purity of the aldehyde and suggests that no racemization occurred during the reductive alkylation.

[3]1-(−)-α-Methylbenzylamine 99 + % from Aldrich Chemical Co. which has *S* absolute configuration (14).

Synthesis and conformational studies of phosphate esters of 1,2-*O*-isopropylidene-α-D-ribo- and xylo- pentofuranoses[1,2]

JEAN-RICHARD NEESER,[3] JEAN M. J. TRONCHET, AND ETIENNE J. CHAROLLAIS

Institut de Chimie Pharmaceutique et Pavillon des Isotopes de l'Université, 30 quai Ernest Ansermet, CH 1211 Genève 4

Received November 22, 1982

JEAN-RICHARD NEESER, JEAN M. J. TRONCHET, and ETIENNE J. CHAROLLAIS. Can. J. Chem. **61**, 1387 (1983).

The synthesis and properties, particularly ^{1}H, ^{31}P, and ^{13}C nmr, of new phosphate esters of 1,2-*O*-isopropylidene-α-D-ribo- and xylo-furanoses are described. For the cyclic phosphates the configuration at the asymmetric phosphorus atom is determined and for all derivatives the preferred conformation of the furanose and dioxaphosphorinane rings and the conformation around the phosphoester bonds are presented. The dependency of $^3J_{POCC}$ coupling constants on factors other than dihedral angles is reported and discussed.

JEAN-RICHARD NEESER, JEAN M. J. TRONCHET et ETIENNE J. CHAROLLAIS. Can. J. Chem. **61**, 1387 (1983).

Nous décrivons la synthèse et les propriétés spectroscopiques (en particulier de rmn ^{1}H, ^{31}P et ^{13}C) de nouveaux esters phosphoriques de *O*-isopropylidène-1,2-α-D-ribo- et xylo-furannoses. Pour les dérivés phosphate cyclique, la configuration au niveau de l'atome de phosphore asymétrique a été attribuée, et pour tous nos composés, la conformation préférentielle des cycles furannosique et dioxaphosphorinanne, ainsi que la conformation autour des liaisons phosphoester, sont déterminées. Nous observons également une variation des constantes de couplage $^3J_{POCC}$ en fonction d'autres facteurs que les angles dièdres et discutons de la signification de tels résultats.

Considering the importance of pentose phosphates, either by themselves, as structural units of nucleotides, or in metabolic biochemical systems, we were prompted to study derivatives of two important naturally occurring pentoses, namely D-xylose and D-ribose. The observations made on these model compounds might prove useful in the understanding of the conformational properties of biologically important nucleotide derivatives.

Syntheses of derivatives **1** to **12** were carried out from 1,2-*O*-isopropylidene-α-D-xylofuranose (**A**) or 1,2-*O*-isopropylidene-α-D-ribofuranose (**B**), as depicted in Fig. 1.

Results and discussion

1. *Infrared and nuclear magnetic resonance spectroscopy. Configurational assignment of asymmetrical phosphorus atoms in compounds 1 to 4*

As previously reported (6–9), the values of the P=O stretching frequency (around 1300 cm^{-1}) can be used successfully to assign the configuration of phosphorus atoms of a pair of asymmetrical phosphorus-containing epimeric dioxaphosphorinane rings. Such an assignment is dependent on the orientation of the P=O bond, resulting from the conformation of the heterocycles. For example, in compound **1**: ν P=O (equatorial) = 1295 cm^{-1}, and in compound **2**: ν P=O (axial) = 1285 cm^{-1}.

Tables 1–4 summarize the nmr data for compounds **1** to **12**. As previously reported (7–9), ^{31}P chemical shifts of derivatives **1** and **2** show a dependence similar to that of ν P=O, as a function of the orientation of the phosphoryl bond: in compound **1**, δ ^{31}P = +16.80 (P=O equatorial) and in compound **2**, δ ^{31}P = +14.10 (P=O axial). Configurational assignment of the phosphorus atom for **3** was deduced from a comparison of the ^{1}H and ^{13}C nmr spectra of **1** and **3**. The phosphorus atom configuration for **4** was established from the X-ray diffraction data in the crystalline state.

2. *Conformational analysis*

For molecular conformational analysis, nmr coupling constants have been widely used. The most critical aspect of such studies is the choice of vicinal correlations for translating the observed ^3J values into dihedral angles.

As will be discussed in detail later in the text, the $^3J_{HH}$ vs. θ_{HH} and $^3J_{PH}$ vs. θ_{PH} relationships previously proposed by many authors are well-established and widely applicable. On the other hand, the $^3J_{PC}$ vs. θ_{PC} correlation seems less well-documented and poses a more difficult problem for its rationalization. In this study, because of the wide range of nmr data available, it has been possible to translate the observed ^3J coupling constants from the ^{1}H nmr spectra into dihedral angles, using only well-established correlations for conformational assignments, and to use those angles to interpret the $^3J_{PC}$ vs. θ_{PC} relationship derived from the ^3J couplings observed in the ^{13}C nmr spectra.

2.1 *Conformations of furanose rings*

The furanose ring conformations are defined here using the terminology introduced by Altona and Sundaralingam (10). These conformations were determined with the aid of the widely used Karplus relationship (11), modified by Abraham *et al.* (12*a*) for the 1,2-*O*-isopropylidene-furanose bicyclic systems. These authors had proposed the $^3T_2$ conformation for the sugar ring of their molecules, from the following observations: for a *xylo* configuration, for example, $J_{1,2} \simeq J_{3,4}$ (3.5–3.9 Hz) and $J_{2,3} \leq 0.5$ Hz. These facts imply a symmetrical conformation with $\theta_{2,3} \simeq 90°$, and this is compatible only with the $^3T_2$ conformation.

Examination of the data in Tables 2 and 4 warrants some comments: the furanose rings in **1**, **2**, and **3** (α-D-*xylo* configuration) exhibit $J_{2,3} = 0$ in each case. However, $J_{3,4}$ (≃2 Hz) is always smaller than $J_{1,2}$ (≃3.6 Hz). The furanose rings of compounds **4** and **7** to **12** (α-D-*ribo* configuration) are characterized by a similar value for $J_{1,2}$ (3.3–3.6 Hz), and by a large coupling constant $J_{3,4}$ (6.8–9.2 Hz) which suggests an *anti*-orientation of the H—C_3 and H—C_4 bonds.

Using a technique previously developed in our laboratory (12*b*), we have calculated from the coupling constants $J_{1,2}$, $J_{2,3}$, and $J_{3,4}$ the predominant furanose ring conformations for all

[1]Phosphorated sugars: V; for Part IV, see ref. 1; III, ref. 2; II, ref. 3; I, ref. 4.

[3]Present address: Research Department, Nestlé Products Technical Assistance Co. Ltd., 1000 Lausanne, Switzerland.

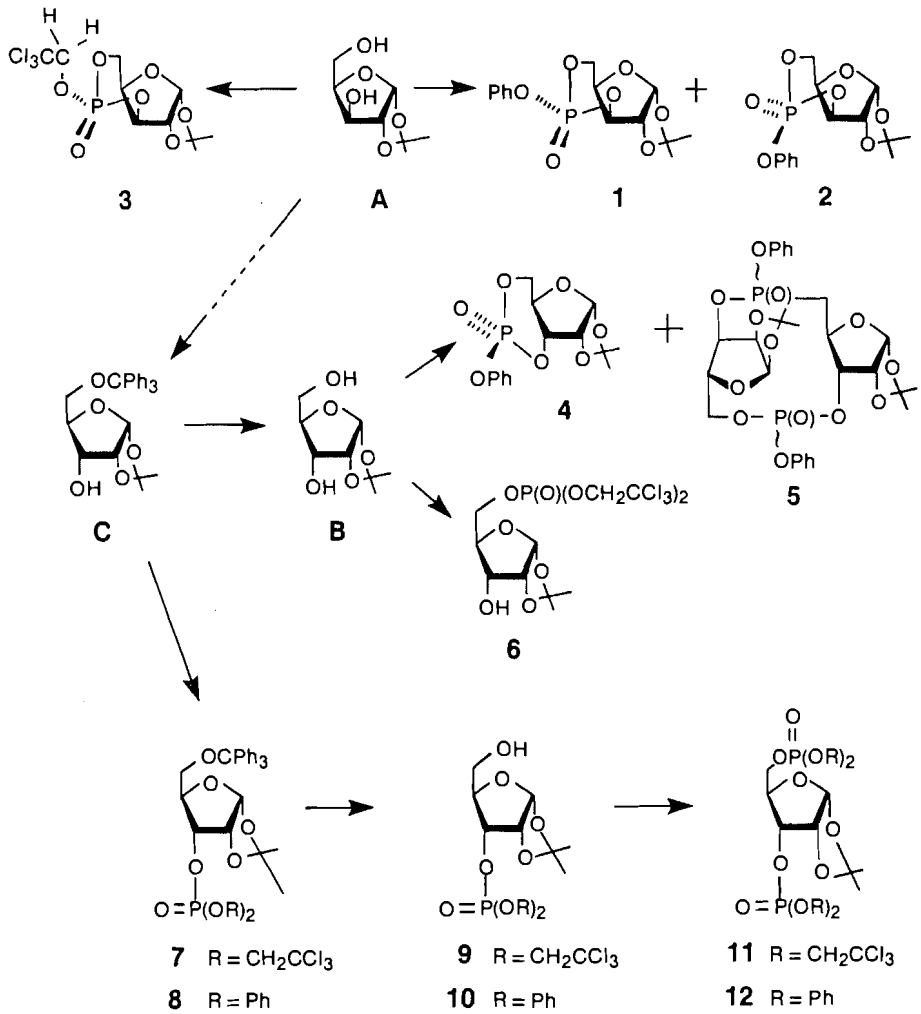

FIG. 1

our compounds. The results of these calculations allow unambiguous assignment of the $^3T_2$ twist form as being the predominant furanose ring conformation for **1**, **2**, and **3**. In the same way, it was found that sugar rings of compounds **7** to **10** adopt the $_2T^3$ twist form; this is very close to the $^3T_2$ conformation and allows equatorial and quasi-equatorial orientations for the substituents on C_3 and C_4 respectively. Due to the complexity of the ^{1}H nmr spectrum of **4** even at 360 MHz, the $^3T_4$ ribofuranose ring conformation for this compound had to be deduced from the X-ray crystal structure determination. This twist form is in accord with that expected for a five-membered sugar ring *trans*-fused to a six-membered phosphate ring (13*a*). Compounds **11** and **12** are characterized by a smaller $J_{3,4}$ value (6.8 and 7.3 Hz respectively) in comparison with the same constant for compounds **7** to **10** (8.6 to 9.2 Hz). Calculations suggest, in both cases, a very unusual $_2T^1$ twist form for the 1,2-*O*-isopropylidene-furanose rings, which probably arises as a result of the particular arrangement between the bulky 3-*O*-phosphoryl and 4-*C*-phosphorylhydroxymethyl groups.

2.2 *Conformational assignment of dioxaphosphorinane rings using $^3J_{HCCH}$ and $^3J_{POCH}$ coupling constants for 1, 2, and 3 and X-ray diffraction data for 4*

In studies of pentose-5-*O*-phosphate derivatives, the $^3J_{HH}$ vs. θ_{HH} correlation proposed by Lee and Sarma (13*a*) (eq. [1]) has been extensively used for determination around the C_4—C_5 bond:

$$[1] \quad {}^3J_{HH} = 10.5 \cos^2 \theta - 1.2 \cos \theta$$

Similarly, a convenient $^3J_{POCH}$ vs. θ_{PH} correlation can be easily deduced from many previous works (13–26), including studies of cyclic phosphates. This relationship has been shown to be susceptible to the coordination number of the phosphorus atom (27), ring-strain, and bond angle distortions (13*b*, 15, 28). However, the $^3J_{POCH}$ vs. θ_{PH} relationship proposed by Lee and Sarma (13*a*) (eq. [2]) has been used extensively and successfully for conformational assignment of various dioxaphosphorinane rings previously studied, including conformationally "free" six-membered rings (19, 20), six-membered phosphate rings fused *cis* to five-membered sugar rings (13*b*, 15), and similar *trans*-fused bicyclic systems (13*a*). The relevant function is:

$$[2] \quad {}^3J_{POCH} = 18.1 \cos^2 \theta - 4.8 \cos \theta$$

In the discussion which follows, we will use both the above relationships together with the well-known dependence of $^4J_{POCCH}$ values on the geometry of the coupling-route bonds (13*a*, 15, 19, 29*a*).

As shown in Table 2, the phosphate rings of **1** and **3** exhibit the following typical constants:

(a) $J_{4,5pro\text{-}R} \simeq J_{4,5pro\text{-}S} \simeq 1.5$–$2$ Hz

(b) small $J_{5pro\text{-}R,P}$ ($\simeq$1.9 Hz) and large $J_{5pro\text{-}S,P}$ (22.3–22.7 Hz) values

(c) $J_{3,P} = 0$
(d) a long range coupling $^4J_{4,P} = 2$–2.5 Hz.

Inspection of Dreiding models clearly shows the limitations of the conformational mobility of these *cis*-fused bicyclic systems. With respect to the previously assigned $^3T_2$ conformation for the sugar rings in **1** and **3**, the use of the Lee and Sarma relationships (13*a*) (eq. [1] and [2]) immediately shows that criteria (a), (b), and (c) lead to the unambiguous assignment of the chair conformation depicted in Fig. 2 as being the only form adopted by the dioxaphosphorinane rings of **1** and **3**. The bicyclic *cis*-fusion between the six-membered phosphate ring and the five-membered sugar ring implies a chair conformation flattened at the C_4 atom, which is intermediate between the ideally expected $^{C4}C_P$ chair and the $^{O3,O5}F$ form (see Tronchet *et al.* (29*b*)). The specific dihedral angles measured on Dreiding models ($\theta_{P,H5pro\text{-}S} = 175°$; $\theta_{P,H5pro\text{-}R} = 65°$, $\theta_{P,H3} = 75°$) are in complete agreement with the observed values for the coupling constants. It is of interest to note that two routes are responsible for the long range coupling $^4J_{4,P}$, each of them implying three coplanar bonds.

Table 2 shows that most of the constants for compound **2** are of the same order of magnitude as the ones observed for **1** and **3**. On the other hand, the observed $J_{3,P} = 5.1$ Hz coupling constant rules out a single stable form for the six-membered phosphate ring of **2**. A variable temperature nmr study on **2** shows that the $^3J_{3,P}$ value decreases with temperature, suggesting that the flattened chair form ($^{C4}C_P/^{O3,O5}F$) previously described for **1** and **3** is favoured at low temperature. Inspection of a Dreiding model indicates that the dioxaphosphorinane ring of **2** can adopt an intermediate conformation between the twist-boat $^PS_{C5}$ and the boat $^{P,C4}B$ (see Fig. 2). Again using the Lee and Sarma equations, the typical dihedral angles of this form can be translated into coupling constants, and the participation of this new form in the conformational equilibrium of **2** can be

$^{2}J_{CH_2,P}$ (CCl_3)	?	—	3.9	—	3.7	—
$^{3}J_{CCl_3,P}$	11.1	—	11.0	—	11.3	—

finally estimated. The J values deduced from the dihedral angles of this $^{P}S_{C5}/^{P,C4}B$ form ($\theta_{P,H3}$ = 150°; $\theta_{P,H5pro\text{-}R}$ = 110°; $\theta_{P,H5pro\text{-}S}$ = 130°) imply as much as 30% of this conformer in the dioxaphosphorinane equilibrium of **2**. The remaining 70% is attributed to the previously described $^{C4}C_P/^{O3,O5}F$ form.

It is interesting to note that both these conformational assignments for the phosphate rings of epimers **1** and **2** can be correlated with the previous configurational assignments on phosphorus. It is well known (19) that axially oriented alkoxy and aryloxy phosphorus substituents lead to more stable dioxaphosphorinane chair forms than the equatorially oriented ones. In this regard it is not surprising that the phosphoester ring of **1** (axially substituted with a phenoxy group) adopts a pure stable flattened chair form, whereas the same ring in **2** (equatorially substituted) is in equilibrium between two forms in which the chair one is favoured.

Inspection of a Dreiding model clearly shows the rigidity of the *trans*-fused bicyclic system in the case of compound **4**. The X-ray diffraction data of **4** unambiguously show the adoption of a flattened chair form for the phosphorated heterocycle of this compound. The *trans* bicyclic fusion between both the sugar and phosphate rings is responsible for the flattened form, which in fact is intermediate between the $^{P}C_{C4}$ chair and the $F_{C4,O3}$ form (see Fig. 2).

2.3 *Contribution of the coupling constants* $^{3}J_{POCC}$ *to the conformational analysis of dioxaphosphorinane rings of* ***1*** *to* ***4***

Different $^{3}J_{POCC}$ vs. θ_{PC} correlations have already been proposed, but this relationship is dependent on the phosphorus coordination number (30) and, perhaps, on the stereochemistry of the phosphorus atom (31, 32). In addition, studies of different series of compounds suggest different correlation equations. For example, ribonucleotide cyclic phosphate rings give coupling constant values in accord with the relation:

$$[3] \quad ^{3}J_{POCC} = 8-8.6\cos^2\theta \qquad (17, 33-35)$$

However, dioxaphosphorinane ring derivatives of phosphorochloridates or phosphoramidates *cis*-fused to a glucofuranose ring suggest another "Karplus-like" curve (36). More recent

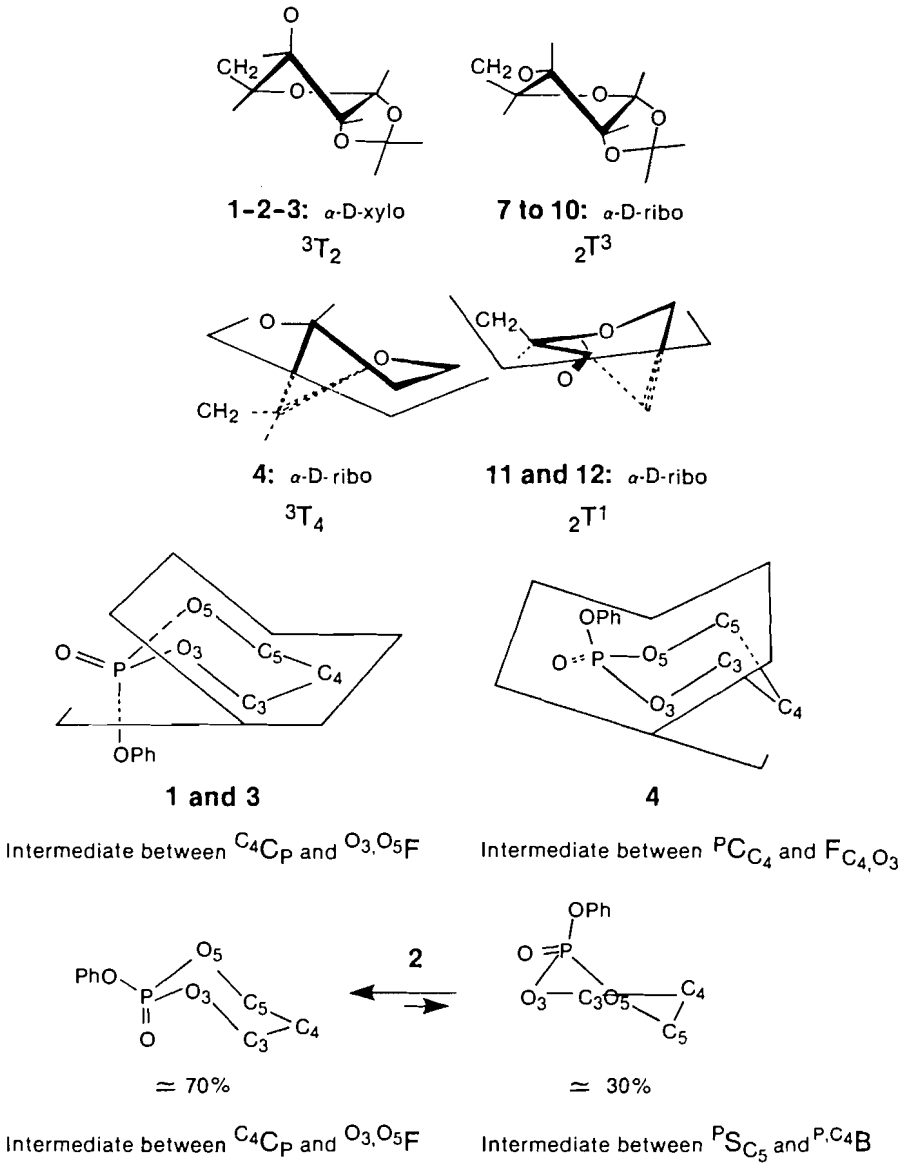

FIG. 2. Conformations of furanose and dioxaphosphorinane rings.

studies of ribonucleotides (37–40) confirm the values of $J_{P,C2'}$ = 8–8.5 Hz ($\theta \simeq 175°$) and $J_{P,C4'}$ = 3–4 Hz ($2 \times \theta = 65°$). On the other hand, studies of cyclic phosphate derivatives of carbohydrate pyranoses led O'Connor *et al.* (41) to propose the use of the extrapolated value of 14 Hz ($\theta = 180°$) to rationalize their assignment of coupling constants of 10.8 to 11.7 Hz, to correspond to dihedral angles ≃ 160°.

The above conformational assignments can be used to study the $^3J_{POCC}$ vs. $\theta_{P,C}$ relationships in our compounds. For this purpose, ^{13}C nmr spectra were recorded in the same solvents as these used for the ^1H measurements. The fact that the conformation of **4** was deduced from its crystal structure requires some careful considerations. Previous studies on similar ribonucleotides (13*a*, 16) have shown in each case the adoption of the same flattened chair, by the ribonucleotides in solution, as that assigned to **4** in the crystalline state. In addition, the rigidity associated with the *trans*-fused bicyclic system of the phosphorated heterocycle of **4** rules out any other conformational contribution in this case. Finally, the axial orientation of the phenoxy substituent on phosphorus is an additional stabilizing factor for the flattened chair in **4**. For all these reasons, we can assume that the observed $^3J_{P,C}$ coupling constants are as significant for the $^PC_{C4}/F_{C4,O3}$ conformation of **4** as they are for the $^{C4}C_P/^{O3,O5}F$ conformation of **1** and **3**.

When a coupling takes place via two routes, the well-established practice is to consider the ^3J correlated value as the sum of both the contributions (17, 33–36); with this assumption, we derive the following correlations (see Table 2).

Compounds **1** and **3**: $\theta_{P,C2} = 160°$ (J = 10.9–11 Hz)
$\theta_{P-O3,C3-C4} = 50°$, $\theta_{P-O5,C5-C4} = 65°$ (J = 7.6–7.7 Hz)

Compound **4**: $\theta_{P,C2} = 174°$ (J = 7.6 Hz)
$\theta_{P-O3,C3-C4} = 59°$, $\theta_{P-O5,C5-C4} = 52°$ (J = 5.3 Hz)

Such values clearly show that the "Karplus-like" approach cannot be used as a unique factor for rationalization of the $^3J_{POCC}$ coupling constants. The $^3J_{P,C2}$ value for **1** and **3** is larger than the one for **4** even though it corresponds to a smaller

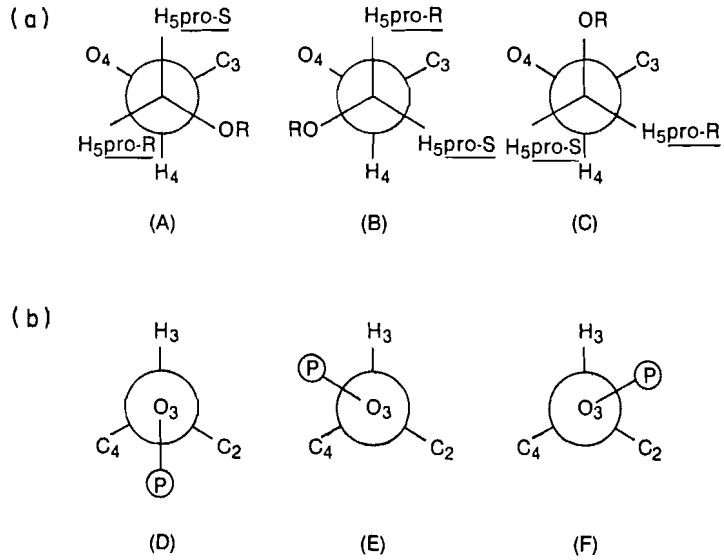

FIG. 3. (a) Possible conformations around C_4—C_5 bond: **7** to **12**, (b) possible conformations around C_3—O_3 bond: **7** to **12**.

dihedral angle. In fact, assuming that the expected $^3J_{POCC}$ vs. $\theta_{P,C}$ relationship has the approximate form:

$$[4] \quad {}^3J_{POCC} = A \cos^2 \theta$$

the observed constants in **1** and **3** lead to the relation:

$$[5] \quad {}^3J_{POCC} = 12.5 \cos^2 \theta$$

whereas those observed for **4** lead to the relation:

$$[6] \quad {}^3J_{POCC} = 8 \cos^2 \theta$$

It is of interest to note that the correlation deduced from **4** (eq. [6]) is in complete agreement with previous results for ribonucleotides (17, 33–35, 37–40). In the same way, the correlation for compounds **1** and **3** (eq. [5]) is in agreement with previous results on different cyclic phosphoesters (41).

The conformational equilibrium previously assigned for the dioxaphosphorinane ring of **2** involves a 30% participation of the $^PS_{C5}/^{P,C4}B$ form, which implies $\theta_{P,C2} = 90°$. The zero value of ^3J generally corresponds to the same dihedral angle and this leads to the conclusion that only 70% (the flattened chair) of the equilibrium contributes to the $^3J_{P,C2}$ in **2** [i.e. 8 Hz $\simeq 0.7 \times 11$ Hz]. This observation suggests a minimal dependence of $^3J_{P,C}$ constants on the stereochemistry of phosphorus. Furthermore, since the phosphoryl P=O and C_3—C_2 bonds are *cis* in compounds **1**, **3**, and **4**, the difference between the relationships (eqs. [5] and [6]) again cannot be attributed to stereochemical factors on phosphorus.

However, two differences between **1** (**3**) and **4** have to be emphasized. First, the fact that both the chair forms are not flattened at the same atom certainly produces important changes in the torsional angles and the ring strain. In this regard, the important differences observed for the $^2J_{POC}$ constants are significant. Secondly, change between the *xylo*- (**1**, **2**, **3**) and the *ribo*-configuration (**4**) produces an inversion in the orientation of the O_3—C_3 bond (the median bond of the coupling route for $^3J_{P,C2}$) with respect to the orientation of the electronegative substituent $-O_2$ on C_2.

In conclusion, *the* $^3J_{POCC}$ *vs.* $\theta_{P,C}$ *"Karplus-like" relationship appears to be drastically more susceptible to ring strain, bond angle distorsions, and epimeric orientation of the electronegative substituents than is the* $^3J_{POCH}$ *vs.* $\theta_{P,H}$ *relationship.*

2.4 *Conformation around the* C_4—C_5 *bond for the acyclic phosphoesters 7 to 12*

In the following analysis we will assume that $^3J_{HCCH}$ constants have values which are the average between *gauche* and *trans*-periplanar ^3J values related to the three possible low-energy rotamers around the C_4—C_5 bond, as shown in Fig. 3. Inspection of Dreiding models precludes (A) from all of the equilibria, for steric reasons. Using the Karplus relationship (11), it immediately appears that in **9** and **10** (where $J_{4,5}$ coupling constants are very small) (C) is the only populated conformation, whereas in **7** and **8** a small participation of (B) in the equilibria has to be considered ($J_{4,5pro\text{-}R}$ = 3.9–4.3 Hz).

The Lee and Sarma relation (13*a*) (eq. [1]) indicates that (B) is the only populated conformation around C_4—C_5 in **11** and **12**. The large couplings ($J_{4,5pro\text{-}R}$ = 11.7–12 Hz) are significant for this *trans*-periplanar orientation of both the protons. Conformation (B) permits a maximum distance between both the phosphoester groups of **11** and **12**.

2.5 *Assignment of conformations around* C_5—O_5 *and* C_3—O_3 *for acyclic phosphoesters 7 to 12, using the* $^3J_{POCH}$ *coupling constants*

Conformational equilibria around the phosphoester bonds C_3—O_3 (compounds **7** to **12**) and C_5—O_5 (**11** and **12**) will be discussed on the basis of previous results (20, 23, 25, 42–45), and assuming that populations of three low-energy rotamers exist in solution. As a result, the observed $^3J_{POCH}$ value will therefore be averaged as follows:

$$[7] \quad {}^3J_{POCH} = (N_1 + N_2)\,{}^3J^g + N_3\,{}^3J^t$$

where N_i is the molar fraction of conformer i and $\sum_i N_i = 1$.

Starting from the successfully used values, $^3J^g_{POCH} = 2.1$ Hz and $^3J^t_{POCH} = 22.9$ Hz (41), study of the conformational equilibrium around the C_5—O_5 bond in **11** and **12** shows unequivocally the large predominance of the rotamer with C_4,P *trans*-periplanar. It is relevant to note that the two $^3J_{5,P}$ constants are small enough to justify such an orientation.

A similar approach to the rotameric composition around the C_3—O_3 bond of **7** to **12** (see Fig. 3) only allows one to min-

For personal use only.

imize the participation of (D) to the equilibrium around this phosphoester bond ($J_{3,P}$ being relatively small). Further study of the $^3J_{POCC}$ coupling constants is necessary to complete this approach, the phosphorus atom being coupled in this case to one proton and two carbons.

2.6 *Contribution of the coupling constants $^3J_{POCC}$ to the conformational analysis of the phosphoester bonds of acyclic derivatives 7 to 12*

Use of $^3J_{POCC}$ coupling constant values to calculate the rotameric compositions of phosphate groups have already been reported. For the phosphate and the phosphonate derivatives, these constants do not seem susceptible to phosphorus substituents (32, 46). Previous studies (41, 47–52) have generally proposed the value $^3J^g_{POCC} = 2–3$ Hz but are very divergent in the choice of the $^3J^t_{POCC}$ value, which has been assumed by different groups to be 8.5 Hz (47), 10 Hz (48–50), 11 Hz (51), or 14 Hz (41, 52).

In this study, we have had an opportunity to evaluate the effect of the coupled carbon substituents on the $^3J_{POCC}$ values. The compounds available present three very different P—O—CH_2—C phosphoester fragments, namely:

(a) P—O—CH_2—CCl_3 (compounds **7**, **9**, **11**)

(b) P—O—C(5)H_2—C(H)(O)(C) (compounds **11** and **12**)

(c) P—O—CH_2—CH_3 (compounds of refs. 1 and 53)

Again, starting with the $^3J^g_{POCH} = 2.1$ Hz and $^3J^t_{POCH} = 22.9$ Hz values, the rotameric compositions of these fragments can be determined and the $^3J_{P,C}$ values rationalized. The appropriate equations are:

[8] $^3J_{POCH_A} = 22.9\,N_1 + 2.1\,(1 - N_1)$

[9] $^3J_{POCH_B} = 22.9\,N_2 + 2.1\,(1 - N_2)$

[10] $N_3 = 1 - (N_1 + N_2)$

[11] $^3J_{POCC} = {}^3J^t_{POCC}\,N_3 + {}^3J^g_{POCC}\,(1 - N_3)$

Assuming that the possible variaiton of the $^3J^g_{POCC}$ value has to be drastically smaller than the variation of the $^3J^t_{POCC}$ one, the last equation can be solved using the approximate $^3J^g_{POCC} = 2–3$ Hz value. Then from Table 4 we get:

(a) fragment P—O—CH_2—CCl_3
$^3J^t_{POCC} \simeq 17$ Hz (compounds **7** and **9**)

(b) fragment P—O—C(5)H_2—C(4)(O)(C)—H
$^3J^t_{POCC} \simeq 12$ Hz (compounds **11** and **12**)

(c) fragment P—O—CH_2—CH_3
$^3J^t_{POCC} \simeq 8–9$ Hz (compounds of refs. 1 and 53)

These results show unequivocally the very large susceptibility of the $^3J_{POCC}$ constants to the electronegativity of the coupled carbon substituents.

Considering now the C_3—O_3 phosphoester bond of compounds **7** to **12**, similar equation systems lead to a $^3J^t_{POCC}$ value which is not consistent with the values observed for the $^3J_{C4,P3}$ and $^3J_{C2,P3}$ vicinal coupling constants (see Table 4). A variation of 10 to 15 Hz appears in the estimated value of $^3J^t_{POCC}$.

In fact, repulsion between the very bulky substituents in some of these compounds can lead to important variations in bond angles, and changes in furanose ring conformations (see 2.1) can produce important variations in the orientation of the oxygenated electronegative substituents. Again these observations show the large susceptibility of the $^3J_{POCC}$ coupling constants to factors other than dihedral angles. In addition, it is of interest to note that, in studies of 3′-ribonucleotides, the validity of the symmetrical two-state model (which considers that the P—O bond can make two equal angles with the $C_{3'}$—$H_{3'}$ bond) is still under discussion, regarding its applicability to the interpretation of nmr data (50).

Even if a quantitative estimation is not possible, careful inspection of the $^3J_{C4,P3}$ constant (Table 4) seems to show that in **8** to **10**, the (F) conformation depicted in Fig. 3 is predominant for the C_3—O_3 bond, whereas the previously assigned *trans*-periplanar arrangements of both the O_5 and C_3 atoms, and P_5 and C_4 atoms, seem to restore a larger conformational mobility around C_3—O_3 in **11** and **12**.

NOTE ADDED IN PROOF: Since the submission of this work to the journal, an article has appeared (54) on the "Karplus relation" for $^3J_{POCC}$ of nucleotides. Even if the relationship proposed by these authors is not appropriate for most of the compounds of the present study, this report reaches essentially the same conclusions regarding the dependency of $^3J_{POCC}$ on electronegativity of the coupled carbon substituents.

Experimental

Thick and thin layer chromatographic measurements were carried out on HF 254 Merck silica and dry column chromatography on 60F 254 Merck silica. The ir spectra were run on a Perkin–Elmer 357 and uv spectra on a Unicam SP 800 or a Beckman 25 spectrometer. Melting points were determined with a Mettler FP 52 apparatus. The ^{1}H nmr spectra were run at 360 MHz on a Bruker WH 360, at 250 MHz on a Cameca, or at 90 MHz on a Perkin–Elmer R32 instrument; ^{13}C nmr spectra were recorded at 25.2 MHz on a Varian XL 100 and ^{31}P nmr spectra at 40.5 MHz on a Bruker instrument. All chemical shifts (δ) are reported in parts per million. The specific optical rotation $[\alpha]_D$ values were obtained with a Schmidt and Haensch polarimeter and the mass spectra were recorded on a Varian SM-1B at 70 eV (m/z, relative abundance in %).

(S_P)-1,2-O-Isopropylidene-3,5-O-phenoxyphosphoryl-α-D-xylofuranose (1)

Phenylphosphorodichloridate (2.6 mL, 17.3 mmol) was added dropwise to a stirred solution of **A** (2.84 g, 15 mmol) in pyridine (17 mL) at 0°C and the mixture was stirred for 16 h at 20°C. After removing the pyridine, the resultant mixture was dissolved in $CHCl_3$ (50 mL), washed (saturated solution $NaHCO_3$, 2 × 25 mL; H_2O, 4 × 25 mL), dried ($MgSO_4$), and the $CHCl_3$ was removed under reduced pressure. A mixture (4.68 g) of **1** and **2** (21:29, nmr) was obtained and thick layer chromatography with EtOAc/hexane (1:1) as eluant yielded 1.72 g (35%) of **1** and 2.41 g (49%) of **2**. Characterization of **1**: R_f 0.72 (EtOAc/hexane 1:1, 2 developments); mp 101.2–104.3°C; $[\alpha]_D^{22}$ +15.0° (c 0.9, $CHCl_3$); uv (EtOH): 210 nm (ε = 2640); ir (KBr): 1385 and 1375 (CMe_2), 1295 (P=O) cm^{-1}; nmr: see Tables 1 and 2; m/z: 328 (34, M^+), 313 (22, M^+ − Me), 235 (10), 175 (12), 156 (10), 140 (9), 139 (100), 97 (42), 94 (11), 77 (11). *Anal.* calcd. for $C_{14}H_{17}O_7P$: C 51.22, H 5.22, P 9.44; found: C 51.42, H 5.25, P 9.49.

(R_P)-1,2-O-Isopropylidene-3,5-O-phenoxyphosphoryl-α-D-xylofuranose (2)

Obtained as above; R_f 0.40 (EtOAc/hexane 1:1, 2 developments); mp 71.0–72.5°C; $[\alpha]_D^{21}$ +25.6° (c 0.8, $CHCl_3$); uv (EtOH): 208.5 nm (ε = 2210); ir (KBr): 1390 and 1375 (CMe_2), 1285 (P=O) cm^{-1}; nmr: see Tables 1 and 2; m/z: 328 (64, M^+), 313 (77, M^+ − Me), 235 (16), 212 (20), 175 (32), 156 (21), 139 (100), 97 (39), 94 (20), 77 (14). *Anal.* calcd. for $C_{14}H_{17}O_7P$: C 51.22, H 5.22, P 9.44; found: C 51.33, H 5.40, P 9.35.

*(R_P)-1,2-O-Isopropylidene-3,5-O-(2,2,2-trichloroethoxy)phosphoryl-α-D-xylofuranose (**3**)*

A solution of bis(2,2,2-trichloroethyl)phosphorochloridate (1 g, 2.63 mmol) in pyridine (1.75 mL) was added to a stirred solution of **A** (500 mg, 2.63 mmol) in pyridine (4.25 mL) at 0°C and the mixture was stirred for 2 h at 20°C. After removing the pyridine, the resultant mixture was dissolved in $CHCl_3$ (40 mL), washed (saturated solution $NaHCO_3$, 2 × 20 mL; H_2O, 2 × 20 mL), and the $CHCl_3$ was removed under reduced pressure. The crude compound was crystallized from ether to yield 855 mg of **3** (85%); R_f 0.32 (EtOAc/hexane 1:1); mp 184.9–187.3°C; $[\alpha]_D^{23}$ +8.9° (*c* 1, $CHCl_3$); ir (KBr): 1390 and 1380 (CMe_2), 1300 (P=O) cm^{-1}; nmr: see Tables 1 and 2; *m/z*: 371, 369, and 367 (3, 7, and 7, M^+ − Me), 235 (18), 140 (9), 139 (100), 137 (5), 99 (7), 97 (44), 68 (5), 59 (4), 43 (11). *Anal.* calcd. for $C_{10}H_{14}Cl_3O_7P$: C 31.32, H 3.68, Cl 27.73; found: C 31.52, H 3.89, Cl 27.85.

*(R_P)-1,2-O-Isopropylidene-3,5-O-phenoxyphosphoryl-α-D-ribofuranose (**4**)*

Procedure (a)

Phenylphosphorodichloridate (1.2 mL, 8.04 mmol) was added dropwise to a stirred solution of **B** (1.5 g, 7.95 mmol) in pyridine (30 mL) at 0°C and the mixture was stirred for 16 h at 20°C. After removing the pyridine, the resultant mixture was dissolved in $CHCl_3$ (80 mL), washed (saturated solution $NaHCO_3$, 2 × 40 mL; H_2O, 4 × 40 mL), and concentrated. Thick layer chromatography with EtOAc/hexane (1:1) as eluant (2 developments) yielded 740 mg (28.5%) of **4** and 820 mg (31.5%) of a fraction containing **5**.

Procedure (b)

A suspension of Me_3COK (638 mg, 5.7 mmol) in anhydrous DMSO (11 mL) was prepared in a glove-box under rigourously anhydrous conditions. In the same atmosphere, this suspension was added to a solution of **10** (800 mg, 1.9 mmol) in anhydrous DMSO (9 mL), the resultant mixture was stirred 5 min at 20°C, and a suspension of Dowex 50 pyridinium resin (10 g) in anhydrous pyridine was added. Out of the glove-box, the resultant suspension was filtered, the resin washed with MeOH (10 mL), and the combined filtrates were concentrated under reduced pressure (10^{-2} Torr). Thick layer chromatography with EtOAc/hexane (1:1) as eluant yielded 312 mg (50.3%) of **4**; R_f 0.63 (EtOAc/hexane 1:1, 2 developments); mp 158.6–159.1°C; $[\alpha]_D^{27}$ +36.3° (*c* 1, $CHCl_3$); uv (EtOH): 210 nm (ε = 2300); ir (KBr): 1385 and 1375 (CMe_2), 1300 (P=O) cm^{-1}; ^1H nmr, δ ($CDCl_3$, 360 MHz): 1.38 and 1.64 (2s, 2 × 3H, CMe_2), 4.26 (d × d × d, 1H, H—C_3, $J_{2,3}$ = 4.0), 4.32–4.41 (m, 2H, H—C_4 and H_A—C_5), 4.67 (m, 1H, H_B—C_5), 4.77 (t, 1H, H—C_2, $J_{1,2}$ = 3.5), 5.89 (d, 1H, H—C_1), 7.19–7.39 (m, 5H, Ph); ^{13}C and ^{31}P nmr: see Tables 1 and 2; *m/z*: 328 (42, M^+), 313 (100, M^+ − Me), 177 (12), 175 (52), 149 (21), 117 (10), 97 (10), 94 (15), 77 (21), 57 (12). *Anal.* calcd. for $C_{14}H_{17}O_7P$: C 51.22, H 5.22, P 9.44; found: C 51.26, H 5.48, P 9.25.

*Dimer **5***

Obtained from the above *Procedure (a)*, the fraction of R_f 0.45 yielded, after hplc (EtOAc/hexane 3:2), 495 mg (19%) of **5**: R_f 0.45 (AcOEt/hexane 1:1, 2 developments); mp 190–200°C (dec.); $[\alpha]_D^{26}$ +85.1° (*c* 1, $CHCl_3$); ir (KBr): 1385 and 1375 (CMe_2), 1295 (P=O) cm^{-1}; ^1H nmr δ ($CDCl_3$, 90 MHz): 1.27, 1.33, 1.51 and 1.55 (4s, 4 × 3H, 2 × CMe_2), 4.01–4.80 (m, 10H, 2 × H—C_2, 2 × H—C_3, 2 × H—C_4, 2 × H_2—C_5), 5.70 and 5.81 (2d, 2 × H—C_1, $J_{1,2}$ = 3.6), 7.11–7.44 (m, 10H, 2 × Ph); *m/z*: 641 (19, M^+ − Me), 564 (24), 563 (100), 541 (8), 313 (13), 176 (10), 139 (16), 105 (12), 97 (11), 77 (14), 43 (8). *Anal.* calcd. for $C_{28}H_{34}O_{14}P_2$: C 51.22, H 5.22, P 9.44; found: C 51.17, H 5.32, P 9.36.

*1,2-O-Isopropylidene-5-O-bis(2,2,2-trichloroethoxy)phosphoryl-α-D-ribofuranose (**6**)*

A solution of bis(2,2,2-trichloroethyl)phosphorochloridate (1 g, 2.63 mmol) in pyridine (1.75 mL) was added to a stirred solution of **B** (500 mg, 2.63 mmol) in pyridine (4.25 mL) at 0°C and the mixture was stirred for 2 h at 20°C. After the usual work-up, the reactional mixture yielded 1.07 g (76.5%) of **6**; R_f 0.21 (EtOAc/hexane 1:2); mp 89.8–91.6°C; $[\alpha]_D^{22}$ + 18.4° (*c* 1, $CHCl_3$); ir (KBr): 3470 (OH), 1385 and 1380 (CMe_2), 1290 (P=O) cm^{-1}; ^1H nmr, δ (90 MHz, CD_3OD): 1.35 and 1.54 (2s, 2 × 3H, CMe_2), 3.91 (m, 1H, H_A—C_5, $J_{4,5A}$ = 4.0, $J_{5A,5B}$ = 9.0), 3.99–4.53 (m, 3H, H—C_3, H—C_4, H_B—C_5), 4.58 (d × d, 1H, H—C_2, $J_{1,2}$ = 3.2, $J_{2,3}$ = 4.2), 4.76 (m, 4H, 2 × CH_2CCl_3), 5.77 (d, 1H, H—C_1); *m/z*: 407, 405, 403, and 401 (5, 11, 14, and 7), 367, 365, 363, 361, and 359 (3, 11, 21, 29, and 14), 233, 231, 229 (8, 17, and 18), 139 (100), 129 (75), 100 (66), 99 (61), 97 (80), 85 (37), 59 (78), 43 (57). *Anal.* calcd. for $C_{12}H_{17}Cl_6O_8P$: C 27.04, H 3.22, Cl 39.91; found: C 27.20, H 3.42, Cl 40.10.

*1,2-O-Isopropylidene-3-O-bis(2,2,2-trichloroethoxy)phosphoryl-5-O-trityl-α-D-ribofuranose (**7**)*

A solution of bis(2,2,2-trichloroethyl)phosphorochloridate (7.76 g, 20.4 mmol) in pyridine (40 mL) was added to a stirred solution of **C** (4 g, 9.26 mmol) in pyridine (40 mL) at 0°C and the mixture was stirred for 24 h at 20°C. After the destruction of the excess of reagent with cold water and the usual work-up, dry column chromatography with EtOAc/hexane (1:2) as eluant yielded 6 g (84%) of **7**; R_f 0.81 (EtOAc/hexane 1:2); mp 108.5–109.5°C; $[\alpha]_D^{24}$ +44.7° (*c* 1, $CHCl_3$); uv (EtOH): 211 nm (ε = 14 560); ir (KBr): 1390 and 1380 (CMe_2), 1300 (P=O) cm^{-1}; nmr: see Tables 3 and 4; *m/z*: 521, 519, 517, 515, and 513 (1, 2, 3, 2, and 1), 477, 475, 473, and 471 (3, 5, 7, and 4), 244 (24), 243 (100), 241 (10), 166 (9), 165 (50), 141 (11), 127 (8), 105 (13), 99 (11), 43 (8). *Anal.* calcd. for $C_{31}H_{31}Cl_6O_8P$: C 48.03, H 4.03, Cl 27.44; found: C 48.00, H 4.19, Cl 27.40.

*3-O-Diphenoxyphosphoryl-1,2-O-isopropylidene-5-O-trityl-α-D-ribofuranose (**8**)*

Diphenylphosphorochloridate (3.45 mL, 23.14 mmol) was added dropwise to a stirred solution of **C** (4 g, 9.26 mmol) in pyridine (40 mL) at 0°C and the mixture was stirred for 24 h at 20°C. After the destruction of the excess of reagent with cold water and the usual work-up, dry column chromatography with EtOAc/hexane (1:2) as eluant yielded 5.35 g (87%) of **8**; R_f 0.71 (EtOAc/hexane 1:2); mp 122.0–124.1°C; $[\alpha]_D^{24}$ +57.1° (*c* 1, $CHCl_3$); uv (EtOH): 210.5 nm (ε = 19 820); ir (KBr): 1385 and 1375 (CMe_2), 1295 (P=O) cm^{-1}; nmr: see Tables 3 and 4; *m/z*: 421 (25), 407 (10), 405 (23), 364 (22), 363 (100), 333 (8), 277 (8), 251 (27), 244 (27), 243 (52), 165 (12). *Anal.* calcd. for $C_{39}H_{37}O_8P$: C 70.47, H 5.61; found: C 70.54, H 5.73.

*1,2-O-Isopropylidene-3-O-bis(2,2,2-trichloroethoxy)phosphoryl-α-D-ribofuranose (**9**)*

A suspension of **7** (5.5 g, 7.1 mmol) in aqueous 80% AcOH (750 mL) was heated (45°C) until dissolution (1 h) and the mixture was stirred for 18 h at 20°C. After concentration to 50 mL, addition of water (200 mL), filtration, and again concentration to dryness, dry column chromatography yielded 2.6 g (69%) of **9**; R_f 0.21 (EtOAc/hexane 1:2); mp 96.8–97.6°C; $[\alpha]_D^{23}$ +40.1° (*c* 1, $CHCl_3$); ir (KBr): 1390 and 1385 (CMe_2), 1305 (P=O) cm^{-1}; nmr: see Tables 3 and 4; *m/z*: 523, 521, 519, 517, and 515 (6, 21, 49, 55, and 26, M^+ − Me), 405, 403, and 401 (2, 12, and 12), 369, 367, 365, 363, 361, and 359 (4, 13, 32, 38, 21, and 11), 359, 357, and 355 (6, 17, and 17), 329, 327, and 325 (2, 13, and 17), 233, 231, and 229 (6, 17, and 21), 141 (100), 139 (43), 127 (83), 113 (28), 99 (49), 85 (38). *Anal.* calcd. for $C_{12}H_{17}Cl_6O_8P$: C 27.04, H 3.22, Cl 39.91, P 5.81; found: C 27.24, H 3.24, Cl 39.85, P 5.96.

*3-O-Diphenoxyphosphoryl-1,2-O-isopropylidene-α-D-ribofuranose (**10**)*

The same treatment (see preparation of **9**) from **8** (4.8 g, 7.2 mmol) for 8 1/2 h at 20°C yielded 2.58 g (85%) of **10**; R_f 0.13 (EtOAc/hexane 1:2); mp 90.0–90.8°C; $[\alpha]_D^{23}$ +39.2° (*c* 1, $CHCl_3$); uv (EtOH): 209 nm (ε = 6500); ir (KBr): 1380 and 1370 (CMe_2), 1285 (P=O) cm^{-1}; nmr: see Tables 3 and 4; *m/z*: 271 (56), 252 (13), 251 (100), 250 (12), 175 (27), 142 (24), 141 (26), 113 (29), 94 (40), 85 (11), 69 (11), 43 (15). *Anal.* calcd. for $C_{20}H_{23}O_8P$: C 56.87, H. 5.49; found: C 56.73, H 5.60.

*1,2-O-Isopropylidene-3,5-di-O-[bis(2,2,2-trichloroethoxy)phosphoryl]-α-D-ribofuranose (**11**)*

A solution of bis(2,2,2-trichloroethyl)phosphorochloridate (270 mg, 0.7 mmol) in pyridine (1 mL) was added to a stirred solution of **9** (300 mg, 0.56 mmol) in pyridine (4 mL) at 0°C and the mixture was stirred for 2 h at 20°C. After the usual work-up (see preparation of **6**), the reactional mixture yielded 445 mg (91%) of **11**; R_f 0.48 (EtOAc/hexane 1:2); mp 78.7–79.3°C; $[\alpha]_D^{23}$ +31.1° (*c* 1, $CHCl_3$); ir (KBr): 1385 and 1375 (CMe_2), 1290 (P=O) cm^{-1}; nmr: see Tables 3 and 4; *m/z*: 863, 861, 859, 857, and 855 (1, 1, 2, 2 and 1, M^+ − Me), 763, 761, 759, 757, 755, and 753 (1, 2, 2, 2, 1, and 1), 407, 405, 403, and 401 (1, 1, 2, and 2), 367, 365, 363, 361, and 359 (2, 2, 2, 2, and 1), 341, 339, and 337 (1, 3, and 3), 311, 309, and 307 (1, 2, and 3), 141 (7), 140 (8), 139 (100), 99 (7), 97 (20). *Anal.* calcd. for $C_{16}H_{20}Cl_{12}O_{11}P_2$: C 21.95, H 2.30, Cl 48.58; found: C 22.11, H 2.33, Cl 48.77.

3,5-Di-O-diphenoxyphosphoryl-1,2-O-isopropylidene-α-D-ribofuranose (12)

Reaction of **10** (400 mg, 0.95 mmol) with diphenylphosphorochloridate (0.2 mL, 1.34 mmol), as described in the preparation of **8**, yielded 510 mg (82%) of **12**; R_f 0.29 (EtOAc/hexane 1:2); syrup; $[\alpha]_D^{21}$ +35.2° (*c* 0.9, $CHCl_3$); uv (EtOH): 210.5 nm (ϵ = 9600); ir (film): 1390 and 1380 (CMe_2), 1300 (P=O) cm^{-1}; nmr: see Tables 3 and 4; *m/z*: 564 (7), 563 (29), 562 (100), 503 (5), 408 (14), 390 (4), 254 (15), 252 (23), 251 (7), 139 (14), 137 (8), 97 (4). *Anal.* calcd. for $C_{32}H_{32}O_{11}P_2$: C 58.72, H 4.93, P 9.46; found: C 58.63, H 5.03, P 9.63.

Acknowledgements

This work was supported by the Fonds National Suisse de la Recherche Scientifique (subsides no. 2.781.77 and 2.277.79). The authors would like to thank Professor A. Buchs and Miss O. Clerc for recording the mass spectra, Dr. U. Bürger and Mr. J. P. Saulnier for the 25.2 MHz ^{13}C nmr spectra, Mr. Reutenauer (Centre Grenoblois de Résonance Magnétique, France) for the 250 MHz ^1H nmr spectra, Professor B. Gross, Miss F. Chrétien, and Mr. P. Simon (Université de Nancy, France) for the ^{31}P nmr spectra, Dr. B. Willhalm and Mr. W. Thommen (Firmenich & Co. S.A., Genève) for the 360 MHz ^1H nmr spectra, and Dr. K. Eder for the microanalysis. It is a pleasure to thank Dr. G. Rihs and co-workers (Ciba-Geigy & Co. S.A., Bâle) for the X-ray diffraction study of **4**, and Mrs. C. Baud for technical assistance in the synthesis of some compounds. One of us (J.R.N.) is grateful to Professors R. Barker, L. D. Hall, and G. Pouzard for helpful discussions.

Synthesis of piperazine-2,5-diones related to bicyclomycin: 1,4-dibenzyl-3-hydroxy-3-[1-(2-methoxyethyl)ethenyl]piperazine-2,5-dione. 2. Route via cyclic intermediates[1]

PETER YATES AND JOHN HAROLD HOARE

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received November 9, 1982

PETER YATES and JOHN HAROLD HOARE. Can. J. Chem. **61**, 1397 (1983).

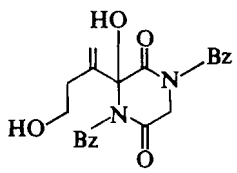
1,4-Dibenzyl-3-hydroxy-3-[1-(2-methoxyethyl)ethenyl]piperazine-2,5-dione (**43**), which incorporates several of the structural features of the antibiotic bicyclomycin, has been synthesized via a reaction sequence involving early construction of the piperazine-2,5-dione ring. In model studies 3-isopropylidenepiperazine-2,5-dione was di-*N*-benzylated and epoxidized to give 4,7-dibenzyl-2,2-dimethyl-1-oxa-4,7-diazaspiro[2.5]octane-5,8-dione (**10**). The opening of the epoxide ring of **10** by several reagents was investigated and it was found that treatment with magnesium isopropylcyclohexylamide (MICA) gives 1,4-dibenzyl-3-hydroxy-3-(1-methylethenyl)piperazine-2,5-dione (**23**). Treatment of ethyl 3-(2-methoxyethyl)-3-methylglycidate (**28**) with *p*-toluenesulfonic acid followed by hydrogenation and oxidation gives ethyl 5-methoxy-3-methyl-2-oxopentanoate, which on reaction with chloroacetamide and sulfuric acid followed by treatment of the resulting enamide with ammonia gives (*Z*)- and (*E*)-3-(4-methoxybut-2-ylidene)piperazine-2,5-dione. Di-*N*-benzylation of these followed by epoxidation gives (*Z*)- and (*E*)-4,7-dibenzyl-2-(2-methoxyethyl)-2-methyl-1-oxa-4,7-diazaspiro[2.5]octane-5,8-dione (**41** and **42**). Treatment of **41** with MICA converts it to compound **43**. Chromatography of **43** on silica converts it in part to *N*-benzyl-*N*-(2-benzylamino-2-oxoethyl)-3-(2-methoxyethyl)-2-oxo-3-butenamide, which on treatment with MICA regenerates **43**.

PETER YATES et JOHN HAROLD HOARE. Can. J. Chem. **61**, 1397 (1983).

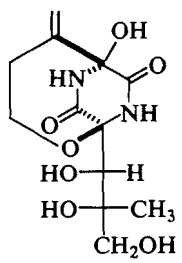
On a synthétisé la dibenzyl-1,4 hydroxy-3 [(méthoxy-2 éthyl)-1 éthényl]-3 pipérazinedione-2,5 (**43**), qui contient plusieurs des caractéristiques structurales de l'antibiotique bicyclomycine, en faisant appel à une suite de réactions qui font intervenir l'élaboration du cycle pipérazinedione-2,5 dès le début. Dans une étude type on a di-*N*-benzilé l'isopropylidène-3 pipérazinedione-2,5 et on l'a époxydé pour obtenir la dibenzyl-4,7 diméthyl-2,2 oxa-1 diaza-4,7 spiro[2,5] octadione-5,8 (**10**). On a étudié l'ouverture du cycle de l'époxyde du composé **10** par plusieurs réactifs, et on a trouvé que le traitement avec l'isopropylcyclohexylamide de magnésium (ICAM) donne la dibenzyl-1,4 hydroxy-3 (méthyl-1 éthényl)-3 pipérazinedione-2,5 (**23**). Le traitement de la (méthoxy-2 éthyl)-3 méthyl-3 glycidate d'éthyle (**28**) avec l'acide *p*-toluènesulfonique suivi d'une hydrogénation et d'une oxydation donne le méthoxy-5 méthyl-3 oxo-2 pentanoate d'éthyle qui par réaction avec le chloroacétamide et l'acide sulfurique suivie du traitement de l'énamide résultant avec l'ammoniac donne la (méthoxy-4 butylidène-2) pipérazinedione-2,5 (*Z*) et (*E*). La di-*N*-benzylation de ces composés suivie d'une époxydation conduit à la dibenzyl-4,7 (méthoxy-2 éthyl)-2 méthyl-2 oxa-1 diaza-4,7 spiro[2,5] octadione-5,8 (*Z*) et (*E*) (**41** et **42**). Le composé **41** réagit avec le ICAM en donnant le produit **43**. Ce dernier par chromatographie sur de la silice se transforme en partie en *N*-benzyl *N*-(benzylamino-2 oxo-2 éthyl) (méthoxy-2 éthyl)-3 oxo-2 butène-3 amide qui traité avec le ICAM regénère le composé **43**.

[Traduit par le journal]

We have discussed in the previous paper in this series (2) the synthesis of the piperazine-2,5-dione **1** (Bz = benzyl), which is related to the antibiotic bicyclomycin (**2**). This was prepared by a reaction sequence, which we have designated as a route via acyclic intermediates, wherein an intermediate of type **3**

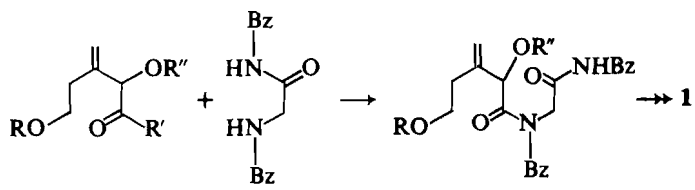


1



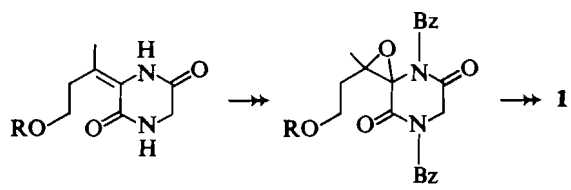
2

was first constructed and then treated with *N*,*N*′-dibenzylglycinamide (**4**) to give a diamide **5**, which was converted to **1** with closure of the piperazine-2,5-dione ring at a late stage in the sequence (Scheme 1). We now describe an alternative synthetic strategy for the synthesis of **1**, which we designate as a route via cyclic intermediates, in which the piperazine-2,5-dione ring is constructed at an early stage of the synthesis in the form of a 3-alkylidene derivative of type **6** which is converted to an epoxide of type **7**, which in turn is manipulated to introduce the desired functionality (Scheme 2).



3 **4** **5**

SCHEME 1



6 **7**

SCHEME 2

Since the preparation of an epoxypiperazine-2,5-dione of type **7** had not been reported previously, we decided to begin

[1]For a preliminary account of part of this work, see ref. 1; for paper 1 in this series, see ref. 2.

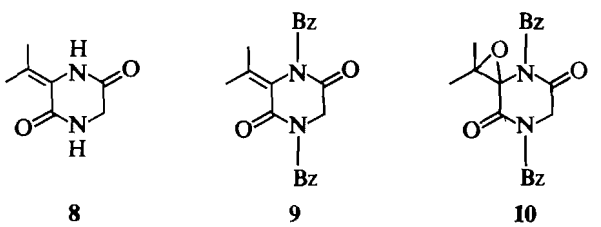
our investigation with the preparation of the known 3-isopropylidenepiperazine-2,5-dione (**8**) in order to study its *N*-benzylation to **9** and the epoxidation of this to **10**, and to investigate the reactions of the epoxide.



Two routes have been reported for the synthesis of **8**. In the first (3) ethyl 3-methyl-2-nitro-2-butenoate (**11**), prepared by nitration of ethyl 3,3-dimethylacrylate,[2] was reduced with aluminum amalgam to the ene amino ester **12**,[3] which was converted with chloroacetyl chloride to the amide **13**, which in turn was treated with ammonia to give the piperazine-2,5-dione **8** (Scheme 3). On repetition of this reaction sequence we obtained **8**, which was dibenzylated to give **9**. We also investigated the reaction of **13** with benzylamine and found that although it gave the desired mono-*N*-benzyl derivative **14** of **8**, which could be benzylated to give **9**, the yields were low, and **9** is preferably prepared via dibenzylation of **8**.

However, we were unable to improve the poor yield previously reported (3) for the reduction of **11**; furthermore we later encountered difficulties in applying this method to the synthesis of piperazine-2,5-diones of type **6** in the main series

[2]Cf., also, ref. 4.

[3]It is of interest that the α-imino isomer of **12** was not observed to tautomerize to the latter (3).

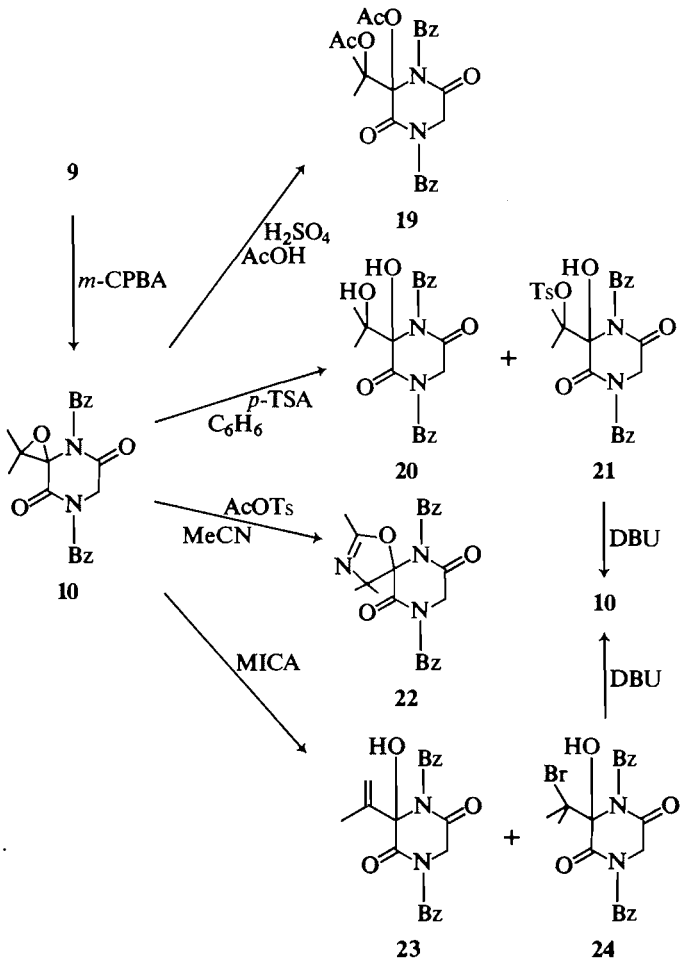

SCHEME 6

(*vide infra*). We therefore turned to the second route (5) for the synthesis of **8**. This involved the synthesis of ethyl α-oxoisovalerate (**15**) by the route shown in Scheme 4 (6) and condensation of this with chloroacetamide in benzene and sulfuric acid[4] to give the amide **13** which, as in the first sequence, was converted to the piperazine-2,5-dione **8** with ammonia.

We considered the synthesis of **15** by this route to be too long and too low yielding to be viable. We therefore investigated the report (8) that **15** could be prepared from the readily available ethyl 3,3-dimethylglycidate (**16**) by treatment with *p*-toluenesulfonic acid in toluene at 80–85°C. The exact details of this work were not available to us, and we carried out the reaction in boiling benzene. Under these conditions we obtained the unsaturated hydroxy ester **17** as the major product and a small amount of **15** (Scheme 5). We were able, however, to utilize this route since hydrogenation of **17** to **18** followed by oxidation gave **15** in good yield. Condensation of this with chloroacetamide and sulfuric acid to give **13** as in Scheme 4 and treatment of this with alcoholic ammonia gave the piperazine-2,5-dione **8** in satisfactory yields and this is undoubtedly the best route to the latter compound. As already noted, this could be dibenzylated to give the desired intermediate **9**.

We next turned our attention to the epoxidation of **9** to **10** (cf., **7**) and the opening of the epoxide ring in the latter. We found that **9** could be converted to **10** by treatment with *m*-chloroperoxybenzoic acid in boiling methylene chloride for 18 hours. It is of interest that in the ^{1}H nmr spectrum of **10** the three sets of methylene proton signals appear as AB systems in contrast with their signals in the spectrum of **9**, where they appear as singlets; this is attributable to the presence of a chiral centre in **10**, but not **9**, which renders diastereotopic each pair of methylene protons. In our initial attempts to open the epoxide ring of **10** we used reagents that we had used successfully previously for the conversion of the epoxide rings of 3-methylglycidic esters to allylic alcohols (ref. 2 and Scheme **5**). However, treatment of the epoxide **10** with acetic anhydride and sulfuric acid gave only the diacetate **19** and none of the desired product **23** (Scheme 6), while treatment with *p*-toluenesulfonic acid in benzene gave a mixture of the diol **20** and the hydroxy tosylate **21**; the latter on reaction with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) regenerated the epoxide **10**. Treatment of **10** with acetyl tosylate (9) in acetonitrile gave a product that is considered to be **22** and to arise by intervention of the solvent. During this work Corey *et al.* (10) reported the use of magnesium isopropylcyclohexylamide (MICA) for the opening of epoxide rings and we found that this reagent would bring about the desired cleavage of the epoxide **10** to the allylic alcohol **23**, which was accompanied by the bromohydrin **24**. The preparation of MICA (10) involves treatment of isopropylcyclohexylamine with methylmagnesium bromide; the magnesium bromide produced in this reaction must be responsible for the opening of the epoxide ring of **10** to give **24**. Treatment of the bromohydrin **24** with DBU regenerated the epoxide **10**.

Having carried out these model studies, we returned to the series proper. As mentioned previously, use of an α-nitro α,β-unsaturated ester for the synthesis of the desired 3-alkylidenepiperazine-2,5-dione derivative encountered difficulties. These stemmed from the circumstance that the reaction of 4-methoxy-2-butanone (**25**) (11) with methyl nitroacetate and ammonium acetate gave, instead of the expected α-nitro α,β-unsaturated ester **26**, the saturated nitro keto ester **27**, which must arise via elimination of methanol from **25** followed by Michael addition of methyl nitroacetate (Scheme 7). We therefore adopted a route analogous to that in Scheme 5. In the present case (Scheme 8) treatment of a diastereomeric mixture of the glycidic esters **28**, prepared from the reaction of **25** with ethyl chloroacetate and sodium ethoxide (2), with *p*-toluenesulfonic acid in boiling benzene gave the allylic alcohols **29** and **30** together with a small amount of the α-oxo ester **31**; the desired allylic alcohol **29** was the major reaction product. Catalytic hydrogenation of the product mixture gave a 1:2 mixture of the saturated hydroxy esters **32** and **33**. The latter must result from hydrogenolysis of the CH_3O—C bond, presumably via the allylic ether **30**. Since this was a minor component of the initial mixture, double bond migration must have occurred prior to hydrogenolysis and hydrogenation. Platinum is known to cause less migration of ethylenic double bonds and less hydrogenolysis of allylic alcohols than does palladium (12); we therefore turned to the use of platinum as catalyst, when we obtained a 2:1 mixture of **32** and **33**. This mixture was not separated but was oxidized directly with Jones reagent to give a mixture of the α-oxo esters **31** and **34** which were separated by fractional distillation.

[4]It was originally reported (5) that the best yields for this reaction were obtained by the use of sulfuric acid; however, in later publications from the same laboratory (7) phosphoryl chloride is used exclusively.

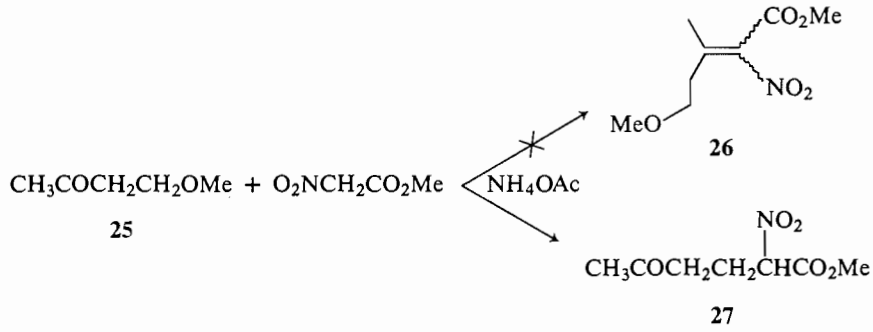
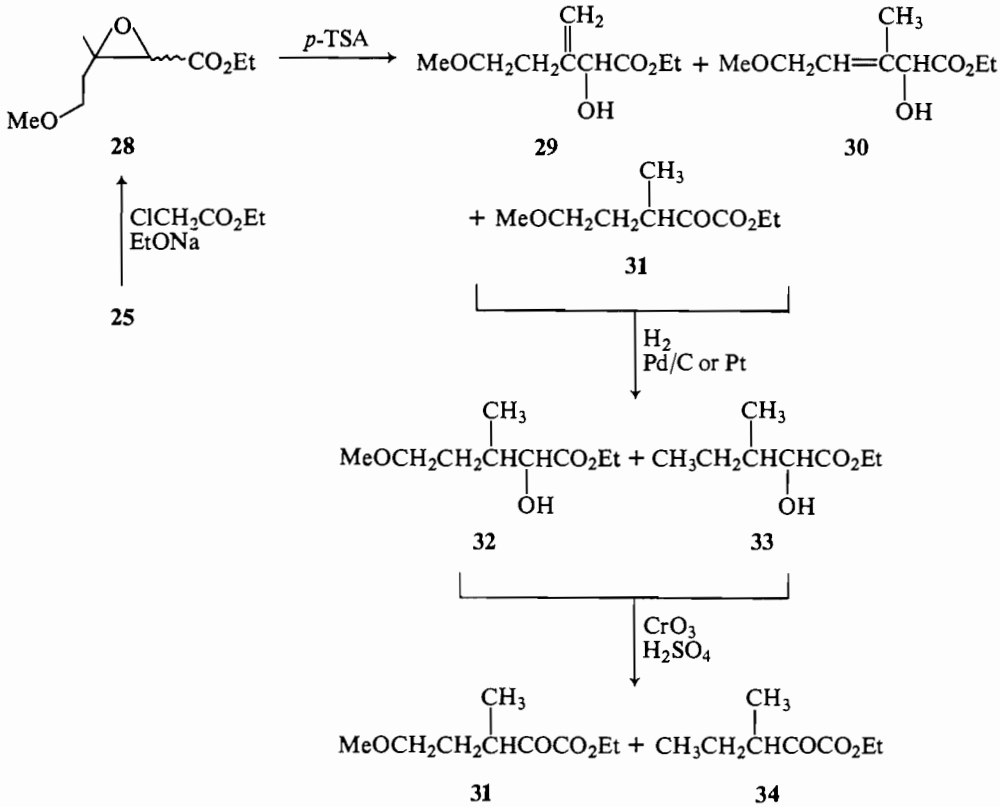


SCHEME 7



SCHEME 8

Treatment of **31** with chloroacetamide and sulfuric acid in benzene (5) gave a mixture of the *Z* and *E* amides **35** and **36** in a 3:1 ratio (Scheme 9). The configurational assignments to the products were made by the use of ^{1}H nmr spectroscopy, signals at δ 2.05 (s) and 2.37 (t) ppm being assigned to **35** and signals at δ 1.87 (s) and 2.80 (t) ppm to **36**, based on the expected greater deshielding of allylic protons by a carboxylic ester group that bears a *cis* relationship to them (13). This mixture was treated with ethanolic ammonia to give the piperazine-2,5-diones **37** and **38**, also in a 3:1 ratio. This mixture was separated by crystallization and chromatography and the individual stereoisomers were again identified by ^{1}H nmr spectroscopy (**37**: δ 2.27 (s), 1.90 (t) ppm; **38**: δ 1.62 (s), 2.78 (t) ppm), based on the expected similar effect of the carbonyl group of the α,β-unsaturated amide moiety to that of the ester group in **35** and **36** (*cf.* refs 5 and 7). Attempted benzylation of **37** and **38** with two equivalents of benzyl bromide and sodium hydride was unsuccessful, but each isomer could be converted to its *N*,*N*′-dibenzyl derivative, **39** and **40**, respectively, by treatment with silver oxide and benzyl bromide in dimethylformamide, a procedure modeled on a method previously used for the *N*-methylation of piperazine-2,5-dione (14); in each case a mono-*N*-benzylated product was also isolated. Again the dibenzyl isomers could be readily distinguished by ^{1}H nmr spectroscopy: **39**: δ 2.13 (s), 2.48 (t) ppm; **40**: δ 1.80 (t), 2.93 (t) ppm.

Epoxidation of each of **39** and **40** with *m*-chloroperoxybenzoic acid in boiling methylene chloride gave the *Z* and *E* epoxides **41** and **42**, respectively (Scheme 10). It is of interest that differential deshielding effects by the carbonyl group of the α,β-epoxy amide moiety are observable in the ^{1}H nmr spectra of the epoxides that are related to those in the α,β-unsaturated carbonyl compounds discussed above; the effects are smaller (**41**: δ 1.45 (s), 1.80 (m) ppm; **42**: δ 1.35 (s), 1.98 (m) ppm), as expected for the changed spatial relationship of the protons in question and the carbonyl group. As in the model series, the

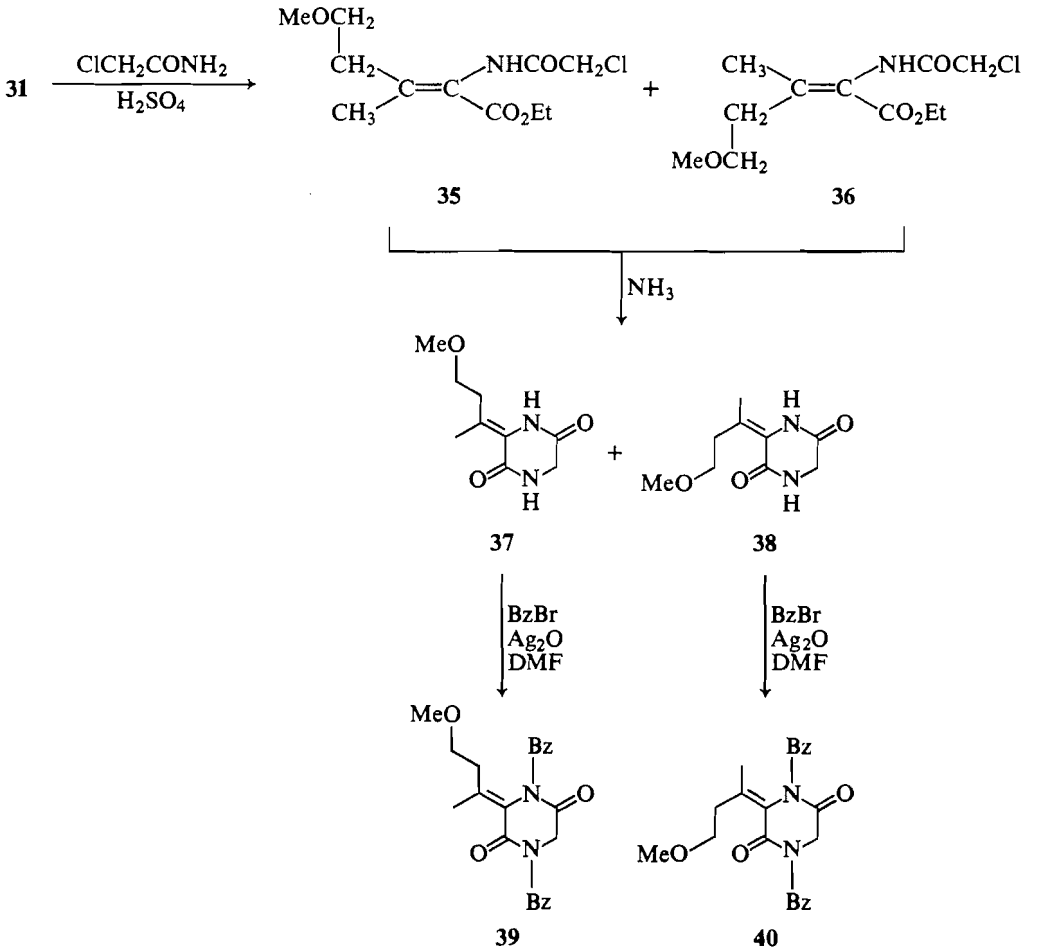
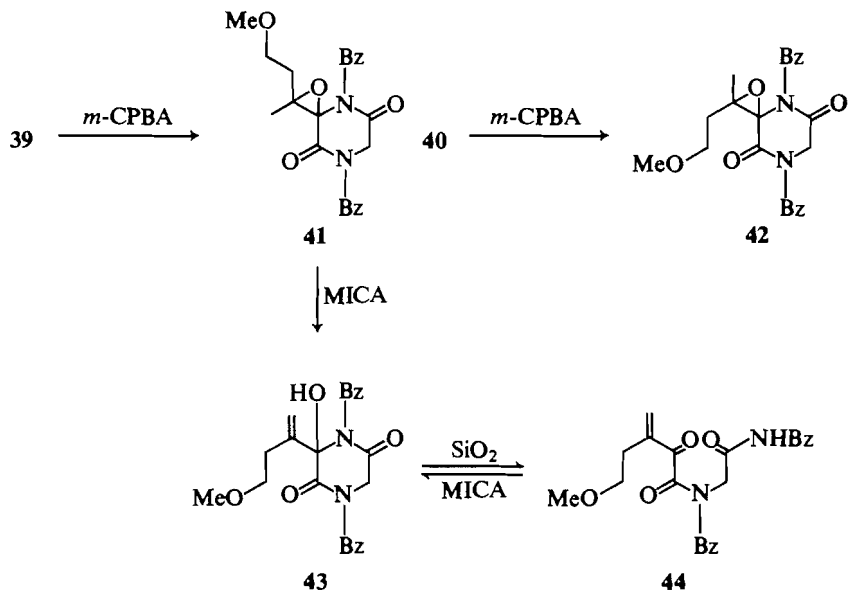


SCHEME 9



SCHEME 10

introduction of chiral centres in going from **39** and **40** to **41** and **42** resulted in the appearance of the benzylic and ring methylene proton signals in the ^{1}H nmr spectra as AB systems rather than singlets. Treatment of **41** with MICA opened the epoxide ring to give the desired allylic alcohol **43** (this reaction was not investigated with the *E* isomer **42**). Attempted purification of **43** by chromatography on silica returned a 1:1 mixture of **43** and its acyclic isomer **44**, which we had previously indepen-

dently synthesized as a key intermediate in our route to **43** via acyclic intermediates (2). The fact that the crude product from the treatment of **41** with MICA was obtained as the cyclic isomer **43** led us to investigate the reaction of MICA with the acyclic isomer **44**. We were happy to find that this reagent brought about efficient closure of **44** to **43**, a transformation that had hitherto eluded us despite the application of a variety of other reagents (2). We consider that the efficacy of MICA relates to the ability of magnesium in the magnesio derivative of **44** to coordinate efficiently with the oxygen atom of the ketonic carbonyl group, thus facilitating attack by nitrogen at the carbon atom of that group.

Of the two routes to the piperazine-2,5-dione **43**, we chose subsequently to use the acyclic route since the MICA reaction with the acyclic intermediate **44** gave a cleaner product than it did with the cyclic epoxide intermediate **42**. We have therefore described our further investigations of piperazine-2,5-diones related to **43** in connection with our discussion of its synthesis by the acyclic route (2).

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Unless otherwise specified, the ir spectra were recorded for $CHCl_3$ solutions and the ^1H and ^{13}C nmr spectra for $CDCl_3$ solutions. Mass spectra were recorded at 70 eV and peak positions (*m/e*) are followed by relative abundances in parentheses. Chromatographic separations were carried out by liquid column chromatography except where otherwise indicated. All R_f values were determined on analytical thin-layer chromatographic silica gel plates. Preparative thin-layer chromatography was carried out on 20 × 20 × 1-mm or 20 × 20 × 2-mm silica gel plates containing a fluorescent indicator. The bands were extracted with methanol and the residue obtained after filtration and evaporation was triturated with chloroform or dichloromethane; filtration and evaporation yielded the product; iodine or uv visualization was employed. Apparatus for the experiments that were carried out under nitrogen was flame dried immediately prior to use under a dry nitrogen flow. All organic extracts were dried over anhydrous $MgSO_4$ and evaporated by means of a rotary evaporator at water aspirator pressure.

*Ethyl 3-methyl-2-oxobutanoate (**15**)*

A solution of *p*-toluenesulfonic acid (prepared from the monohydrate predried in benzene by azeotropic removal of water; 5.4 g, 28 mmol *p*-TSA) and ethyl 3,3-dimethylglycidate (**16**) (2) in benzene (100 mL) was boiled under reflux for 4 h. The benzene solution was washed with water (10 mL), dried, filtered, and concentrated giving an 86% yield of crude ethyl 2-hydroxy-3-methyl-3-butenoate (**17**).

Compound **17** (71.62 g, 0.497 mol) was reduced quantitatively to ethyl 2-hydroxy-3-methylbutanoate (**18**) by catalytic hydrogenation over 5% Pd/C (100 mg) in ethanol at a pressure of 50 psi.

The alcohol **18** (24.0 g, 0.169 mol) in acetone (200 mL) was stirred in an ice bath while Jones reagent (CrO_3 (16.5 g), H_2SO_4 (14 mL), H_2O (40 mL)) was added dropwise with stirring. After addition of the reagent was complete, the ice bath was removed and stirring was continued for 30 min at room temperature. The acetone solution was decanted from the deposited chromium salts, which were washed well with methylene chloride. The combined acetone solution and methylene chloride washings were dried, filtered, and concentrated giving a quantitative yield of **15**.

*4,7-Dibenzyl-2,2-dimethyl-1-oxa-4,7-diazaspiro[2.5]octane-5,8-dione (**10**)*

3-Isopropylidenepiperazine-2,5-dione (**8**) was found to be best prepared by condensation of **15** (7.21 g, 50 mmol) with 2-chlorocetamide (9.35 g, 100 mmol) in benzene (50 mL) containing conc. H_2SO_4 (1 mL) (5). This solution was boiled under reflux for 18 h with azeotropic removal of the water formed. This gave a 70% yield of ethyl 2-[(chloroacetyl)amino]-3-methyl-2-butenoate (**13**), which was cyclized in 90% yield to **8** by treatment with saturated ethanolic ammonia (5).

A solution of **8** (2.00 g, 13 mmol) in dry dimethylformamide (12 mL) was added dropwise with stirring to a suspension of sodium hydride (50% oil dispersion; 1.24 g, 26 mmol) in benzene (15 mL) and benzyl bromide (5.56 g, 32.5 mmol) under nitrogen. The mixture was stirred overnight at room temperature and poured into water (10 mL). The benzene layer was separated and washed with water (3 × 10 mL), dried, filtered, and concentrated. The residue was chromatographed on silica with 1:1 ethyl acetate – hexanes as eluent. The band with R_f = 0.35 was found to give 1,4-dibenzyl-3-isopropylidene-2,5-piperazinedione (**9**) (2.52 g, 58%); ir λ_{max}: 5.90, 6.04 μm; ^1H nmr δ: 6.9–7.4 (m, 10H), 4.72 (s, 2H), 4.55 (s, 2H), 3.72 (s, 2H), 2.15 (s, 3H), 1.90 (s, 3H).

A solution of **9** (1.63 g, 4.87 mmol) and 85% *m*-chloroperoxybenzoic acid (2.00 g, 9.9 mmol) in methylene chloride (90 mL) was boiled under reflux for 20 h. The mixture was washed with aqueous saturated Na_2SO_3 (20 mL) and aqueous 10% $NaHCO_3$ (20 mL) and dried, filtered, and concentrated. The residual oil crystallized on standing and the product was recrystallized from ether to give **10** (1.54 g, 90%) as white feathery crystals, mp 122–123°C; ir λ_{max}: 5.90 μm; ^1H nmr δ: 6.9–7.4 (m, 10H), 4.91 (d, *J* = 15 Hz, 1H), 4.16 (d, *J* = 15 Hz, 1H), 4.71 (d, *J* = 15 Hz, 1H), 4.46 (d, *J* = 15 Hz, 1H), 3.88 (d, *J* = 17 Hz, 1H), 3.75 (d, *J* = 17 Hz, 1H), 1.43 (s, 3H), 1.33 (s, 3H); ^{13}C nmr δ: 166.0 (s), 163.8 (s), 136.9 (s), 135.4 (s), 129.0–127.7 (d), 73.6 (s), 65.3 (s), 50.3 (t), 49.6 (t), 45.0 (t), 19.2 (q), 18.3 (q); *m/e*: 350(6), 259(20), 201(13), 91(100). *Anal.* calcd. for $C_{21}H_{22}N_2O_3$: C 71.98, H 6.33, N 7.99; found: C 71.59, H 6.30, N 8.00.

*Reaction of **10** with acetic anhydride and sulfuric acid. Formation of 3-acetoxy-3-(1-acetoxy-1-methylethyl)-1,4-dibenzylpiperazine-2,5-dione (**19**)*

Compound **10** (253 mg, 0.722 mmol) was dissolved in acetic anhydride (7 mL) and 3 drops of conc. H_2SO_4 were added. The mixture was stirred for 20 min at room temperature and added to benzene (30 mL) and the benzene solution was washed with water (5 × 10 mL). It was then dried, filtered, and concentrated. The residue was dissolved in methylene chloride and hexanes were added dropwise to effect crystallization of **19** (174 mg, 53%); ir λ_{max}: 5.73, 5.95 μm; ^1H nmr δ: 7.13 (m, 10H), 4.00–5.30 (m, 6H), 1.93 (s, 3H), 1.75 (s, 3H), 1.73 (s, 3H), 1.57 (s, 3H).

*Reaction of **10** with p-toluenesulfonic acid. Formation of 1,4-dibenzyl-3-hydroxy-3-(1-hydroxy-1-methylethyl)piperazine-2,5-dione (**20**) and 1,4-dibenzyl-3-hydroxy-3-(1-p-toluenesulfonoxy-1-methylethyl)piperazine-2,5-dione (**21**)*

A solution of *p*-toluenesulfonic acid (prepared from the hydrate, dried in benzene by azeotropic removal of water; 178 mg, 0.936 mmol) and **10** (252 mg, 0.719 mmol) in benzene was stirred at room temperature for 10 min, washed with water (2 mL), dried, filtered, and concentrated. The residue was found to contain a 1:1 mixture of diol **20** and tosylate **21**, as indicated by its ^1H nmr spectrum. It was dissolved in ether and **20** crystallized (60 mg). Concentration of the mother liquor led to the crystallization of **21** (130 mg), leaving a mother liquor containing **21** contaminated with **20**. Diol **20**, mp 182–185°C; ir λ_{max}: 2.98, 5.98 μm; ^{1} nmr δ (acetone-d_6): 7.18 (m, 10H, 3.4–5.1 (m, 6H), 2.07 (m, 2H), 1.33 (s, 3H), 1.27 (s, 3H); *m/e*: 368(6), 310(9), 282(9), 219(8), 149(20), 91(100). Tosylate **21**, mp 174–175°C; ir λ_{max}: 2.93, 2.95 μm; ^1H nmr δ: 7.30 (m, 14H), 5.28 (s, 1H), 4.78 (d, *J* = 15 Hz, 1H), 4.71 (d, *J* = 15 Hz, 1H), 4.42 (d, *J* = 15 Hz, 2H), 3.87 (d, *J* = 18 Hz, 1H), 3.54 (d, *J* = 18 Hz, 1H), 2.40 (s, 3H) 1.70 (s, 3H), 1.60 (s, 3H).

*Reaction of **21** with DBU. Formation of **10***

The tosylate **21** (33 mg, 0.063 mmol) and 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU) (10 mg, 0.066 mmol) in methylene chloride (5 mL) were stirred at room temperature overnight. The mixture was washed with 3 *M* hydrochloric acid (2 mL), dried, filtered, and concentrated. A quantitative yield of epoxide **10** was obtained.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

*Reaction of **10** with acetyl* p-*toluenesulfonate and acetonitrile. Formation of 6,9-dibenzyl-2,4,4-trimethyl-1-oxa-3,6,9-triazaspiro[4.5]dec-2-ene-7,10-dione (**22**)*

A solution of **10** (223 mg, 0.629 mmol) and acetyl *p*-toluenesulfonate (9) (194 mg, 0.906 mmol) in acetonitrile (5 mL) was stirred at room temperature for 1 h. The mixture was dissolved in methylene chloride (25 mL) and the solution was washed with water (10 mL), aqueous 10% $NaHCO_3$ (10 mL), and saturated aqueous NaCl (10 mL), dried, filtered, and concentrated. The residue was chromatographed on a preparative silica gel plate with 20% ethyl acetate–hexanes (R_f = 0.40) as eluent. This gave 61 mg of an orange oil considered to be crude **22**; ir λ_{max}: 6.00 μm; ^{1}H nmr δ: 7.2–7.3 (m, 10H), 3.6–5.0 (m, 6H), 2.13 (s, 3H), 1.33 (s, 3H), 1.27 (s, 3H); *m/e*: 391, 334(26), 243(40), 91(100).

*1,4-Dibenzyl-3-hydroxy-3-(1-methylethenyl)piperazine-2,5-dione (**23**) and 1,4-dibenzyl-3-(1-bromo-1-methylethyl)-3-hydroxypiperazine-2,5-dione (**24**)*

A solution of magnesium isopropylcyclohexylamide (MICA) (10) was prepared by syringing neat cold methyl bromide into a mixture of magnesium turnings (50 mg, 2.1 mmol) and dry tetrahydrofuran (4 mL) under nitrogen with stirring and mild warming until all of the magnesium was consumed. Additional tetrahydrofuran (7 mL) was added and excess isopropylyclohexylamine (0.5 mL) was syringed into the methylmagnesium bromide – tetrahydrofuran solution with stirring to form MICA after the solution had been stirred at room temperature for 20 min.

A solution of **10** (184 mg, 0.525 mmol) in dry tetrahydrofuran (4 mL) was syringed dropwise with stirring over a period of 1 h into the MICA solution under nitrogen at room temperature. The mixture was stirred overnight at room temperature during which time it assumed a cloudy yellow color. The solution was cooled in an ice bath and 4 *N* hydrochloric acid (3 mL) was added with stirring. The acidified mixture was extracted with methylene chloride (3 × 20 mL). The combined extracts were dried, filtered, and concentrated. The residual gum was dissolved in ether (~5 mL) and **23** crystallized in 40–50% yield. Compound **23** crystallized from chloroform–hexanes as white needles, mp 147–148°C; ir λ_{max}: 2.85, 5.95 μm; ^{1}H nmr δ: 6.9–7.4 (m, 10H), 5.03 (m, 2H), 4.88 (s, 1H), 4.88 (dd, *J* = 15 Hz, 1H), 4.81 (d, *J* = 14 Hz, 1H), 4.34 (d, *J* = 14 Hz, 2H), 3.83 (s, 2H), 1.75 (s, 3H); *m/e*: 350(1), 333(1), 309(2), 281(4), 253(17), 91(100). *Anal.* calcd. for $C_{21}H_{22}N_2O_3$: C 71.98, H 6.33, N 7.99; found: C 71.92, H 6.38, N 8.00.

The mother liquor from the original crystallization of **23** yielded impure **24** as a gum which resisted crystallization; ir λ_{max}: 2.95, 5.93 μm; ^{1}H nmr δ: 7.20 (m, 10H), 3.50–5.23 (m, 7H), 1.88 (s, 6H). This was reconverted to epoxide **10** on treatment with excess DBU (5 equiv.) in methylene chloride.

*Reaction of 4-methoxy-2-butanone (**25**) with methyl nitroacetate. Formation of methyl 2-nitro-5-oxohexanoate (**27**)*

A solution of **25** (11) (2.14 g, 21.0 mol), methyl nitroacetate (15) (2.54 g, 21.3 mmol), and ammonium acetate (1.81 g, 23.5 mmol) in benzene or methanol (75 mL) was boiled under reflux for 2h. In the case of methanol, the methanolic solution was added to methylene chloride (75 mL) and the methylene chloride solution was washed with water (3 × 20 mL), dried, filtered, and concentrated. In the benzene case, the benzene solution was washed with water (3 × 20 mL), dried, filtered, and concentrated. In either case the residue was molecularly distilled at 100°C (0.015 Torr) to give **27** (2.89 g, 73%); ir λ_{max}: 5.53, 5.82 μm; ^{1}H nmr δ: 5.22 (n, 1H), 3.85 (s, 3H), 2.2–2.8 (m, 4H), 2.18 (s, 3H).

*Ethyl 5-methoxy-3-methyl-2-oxopentanoate (**31**)*

A solution of ethyl 3-(2-methoxyethyl)-3-methyglycidate (**28**) (2) (100 g, 0.531 mol) and *p*-toluenesulfonic acid (prepared from the hydrate, dried in benzene by azeotropic removal of water; 3.5 g, 18 mmol) in benzene (100 mL) was boiled under reflux for 5 h, during which time the solution assumed a dark red-brown color. The solution was washed with water (20 mL), dried, filtered, and concentrated and the residue was distilled at 75–85°C (0.025 Torr). The distillate (75 g) contained a 3:1 mixture of ethyl 2-hydroxy-3-(2-methoxyethyl)-3-butenoate (**29**) and ethyl 2-hydroxy-5-methoxy-3-methyl-3-pentenoate (**30**) and a small amount of α-oxo ester **31** as indicated by its ^{1}H nmr spectrum.

This mixture (73 g, 0.39 mol) in ethanol (150 mL) was hydrogenated over PtO_2 (100 mg) in a Parr hydrogenation apparatus at 50 psi pressure of hydrogen. The catalyst was filtered and the filtrate was concentrated to give a 2:1 mixture of ethyl 2-hydroxy-5-methoxy-3-methylpentanoate (**32**) and ethyl 2-hydroxy-3-methylpentanoate (**33**), as indicated by ^{1}H nmr spectroscopy. (The use of 5% Pd/C as catalyst gave a 1:2 mixture of **32** and **33**.) The mixture was used without separation in the next step.

The mixture of **32** and **33** (70 g) in acetone (500 mL) was oxidized with Jones reagent (CrO_3 (29.8 g), conc. H_2SO_4 (25 mL), water (72 mL)) in analogous fashion to the preparation of **15**. The crude product was fractionally distilled through an 8-in. column packed with glass helices. Ethyl methyl-2-oxopentanoate (**34**) (15.8 g) distilled at 0–31°C (0.015 Torr) followed by ethyl 5-methoxy-3-methyl-2-oxopentanoate (**31**) (47.5 g, 68%), bp 55–57°C (0.015 Torr); ir λ_{max}: 5.80 μm; ^{1}H nmr δ: 4.37 (q, *J* = 7 Hz, 2H), 3.40 (m, 2H), 3.23 (s, 3H), 1.87 (m, 3H), 1.33 (t, *J* = 7 Hz, 3H), 1.12 (d, *J* = 7 Hz, 3H); *m/e*: 189, 188, 157(2), 129(8), 115(100), 101(10). *Anal.* calcd. for $C_9H_{16}O_4$: C 57.43, H 8.57; found: C 57.36, H 8.55.

(Z)- *and* (E)-*3-(4-Methoxybut-2-ylidene)piperazine-2,5-dione (**37** and **38**)*

A solution of compound **31** (51.0 g, 0.270 mol) and chloroacetamide (37.0 g, 0.400 mol) in benzene (325 mL) and conc. H_2SO_4 (5.5 mL) was boiled under reflux for 10 h with azeotropic removal of water by means of a Dean–Stark apparatus. The benzene solution was washed well with water, dried, filtered, and concentrated. Unconsumed **31** (19.4 g) was distilled from the residue at 55°C (0.015 Torr) leaving a 3:1 mixture (44.3 g, 62%) of ethyl (*Z*)- and (*E*)-2-[(chloroacetyl)amino]-5-methoxy-3-methyl-2-pentenoate (**35** and **36**) as indicated by its ^{1}H nmr spectrum: δ: 9.17 (br s, 0.7H), 8.00 (br s, 0.3H), 4.13 (m, 4H), 3.53 (m, 5H), 2.80 (t, *J* = 6 Hz, 0.5H), 2.37 (t, *J* = 6 Hz, 1.5H), 2.05 (s, 2H), 1.87 (s, 1H), 1.10 (t, *J* = 7 Hz, 3H).

A solution of this mixture of **35** and **36** (60.0 g, 0.228 mol) in cold saturated alcoholic ammonia (500 mL) was stirred for 2 days at room temperature. The ethanolic solution was concentrated and the residue was dissolved in 2 *N* hydrochloric acid (50 mL). The aqueous solution was extracted several times with methylene chloride (10 × 25 mL). The combined methylene chloride extracts were dried, filtered, and concentrated, leaving a white solid (27.5 g, 61%). The solid was dissolved in chloroform and **38** crystallized as a white solid. The mother liquor contained a mixture of **37** and **38**, which could not be further purified by crystallization. The mixture was chromatographed on silica with 5% methanol – chloroform as eluent. The *Z* isomer **37** (R_f = 0.43) (20.4 g, 45%) was thus separated from the *E* isomer **38** (R_f = 0.24) (3.05 g; total 6.49 g, 14%).

Compound **37** was recrystallized from acetone as white needles, mp 157–158°C; ir λ_{max}: 2.89, 5.91 μm, ^{1}H nmr δ: 8.85 (br s, 1H), 7.23 (br s, 1H), 3.93 (m, 2H), 3.55 (t, *J* = 6 Hz, 2H), 3.37 (s, 3H), 1.90 (t, *J* = 6 Hz, 2H), 2.27 (s, 3H); *m/e*: 198(19), 166(100), 153(24), 138(9), 125(14), 45(65). *Anal.* calcd. for $C_9H_{14}N_2O_3$: C 54.54, H 7.12, N 14.13; found: C 54.72, H 7.16, N 14.10.

Compound **38** was recrystallized from dimethylformamide as white needles, mp 211–212°C; ir λ_{max}: 3.90, 5.91 μm; ^{1}H nmr δ(DMSO-d_6): 9.05 (br s, 1H), 7.80 (br s, 1H), 3.73 (m, 2H), 3.38 (t, *J* = 6 Hz, 2H), 3.20 (s, 3H), 2.78 (t, *J* = 6 Hz, 2H), 1.62 (s, 3H); *m/e*: 198(6), 166(100), 153(20), 138(6), 125(9), 45(35). *Anal.* calcd. for $C_9H_{14}N_2O_3$: C 54.54, H 7.12, N 14.13; found: C 54.51, H 7.18, N 14.16.

*(Z)-1,4-Dibenzyl-3-(4-methoxybut-2-ylidene)piperazine-2,5-dione (**39**)*

A solution of **37** (1.00 g, 5.04 mmol), silver oxide (1.75 g, 7.57 mmol), and benzyl bromide (6.90 g, 40.4 mmol) in dimethyl-

formamide (40 mL) was stirred at room temperature for 8 h. Benzene (100 mL) was added and the solution was filtered through Celite to remove the silver salts. The filtrate was washed with water (3 × 25 mL), dried, filtered, and concentrated. Excess benzyl bromide was removed by molecular distillation at 90°C (0.015 Torr). This residue was chromatographed on silica with 20% ethyl acetate – chloroform as eluent. Compound **39** was eluted (R_f = 0.49) as a yellow gum (578 mg, 30%); ir λ_{max}: 5.78 (sh), 5.96, 6.09 (sh) μm; ^{1}H nmr δ: 7.20 (m, 10H), 4.78 (s, 2H), 4.47 (s, 2H), 3.67 (s, 2H), 3.57 (t, J = 6 Hz, 2H), 3.30 (s, 3H), 2.48 (t, J = 6 Hz, 2H), 2.13 (s, 3H); *m/e*: 378(7), 347(9), 256(33), 91(100). *Acurate Mass* calcd. for $C_{23}H_{26}N_2O_3$: 378.1943; found: 378.1940.

From later chromatographic fractions an *N*-benzyl-3-(4-methoxybut-2-ylidene)piperazine-2,5-dione (R_f = 0.25) (233 mg) was obtained. This was recrystallized from chloroform–hexanes as white needles, mp 88–89°C; ir λ_{max}: 2.91, 5.95 μm; ^{1}H nmr δ: 7.27 (s, 5H), 7.08 (br s, 1H), 5.15 (s, 2H), 4.02 (s, 2H), 3.42 (t, J = 6 Hz, 2H), 3.30 (s, 3H), 2.72 (t, J = 6 Hz, 2H), 2.28 (s, 3H); *m/e*: 288(13), 256(6), 197(35), 165(34), 137(11), 91(100). *Anal.* calcd. for $C_{16}H_{20}N_2O_3$: C 66.55, H 6.99, N 9.71; found: C 66.35, H 6.98, N 9.70.

The above reaction was repeated for 6 h at room temperature. A 39% yield of **39** was obtained after chromatographic separation from uncharacterized polybenzylated products with higher R_f values.

(E)-*1,4-Dibenzyl-3-(4-methoxybut-2-ylidene)piperazine-2,5-dione* (***40***)

A solution of **38** (3.51 g, 17.2 mmol), silver oxide (6.0 g, 26 mmol), and benzyl bromide (24.5 g, 143 mmol) in dimethylformamide (100 mL) was stirred at room temperature for 15 h and worked up as in the preparation of the *Z* isomer **39**. The residue was chromatographed on silica with 20% ethyl acetate – chloroform as eluent. After elution of polybenzylated material of higher R_f, **40** was eluted (R_f = 0.40) as a yellow gum (2.38 g, 37%); ir λ_{max}: 5.93, 6.01 (sh), 6.08 (sh) μm; ^{1}H nmr δ: 7.18 (m, 10H), 4.70 (s, 2H), 4.50 (s, 2H), 3.40 (s, 2H), 3.48 (t, J = 6 Hz, 2H), 3.30 (s, 3H), 2.93 (t, J = 6 Hz, 2H), 1.80 (s, 3H); *m/e*: 378(8), 347(9), 256(31), 91(100). *Accurate Mass* calcd. for $C_{23}H_{26}N_2O_3$: 378.1943; found: 378.1956.

Stripping of the chromatographic column with methanol gave an *N*-benzyl-3-(4-methoxy-2-ylidene)-piperazine-2,5-dione (R_f = 0.08) (248 mg, 5%) as an orange gum which resisted crystallization; ir λ_{max}: 2.93, 5.98 μm; ^{1}H nmr δ: 7.28 (s, 5H), 7.25 (br s, 1H), 5.18 (s, 2H), 4.00 (s, 2H), 3.53 (t, J = 6 Hz, 2H), 3.32 (s, 3H), 3.03 (t, J = 6 Hz, 2H), 2.07 (s, 3H).

(Z)-*4,7-Dibenzyl-2-(2-methoxyethyl)-2-methyl-1-oxa-4,7-diazaspiro[2.5]octane-5,8-dione* (***41***)

A solution of compound **39** (4.76 g, 12.6 mol) and 85% *m*-chloroperoxybenzoic acid (5.25 g, 25.8 mmol) in methylene chloride (225 mL) was boiled under reflux for 18 h. The mixture was washed with saturated aqueous Na_2SO_3(50 mL), water (50 mL), and aqueous 10% $NaHCO_3$ (50 mL), dried, filtered, and concentrated. The residual oil was dissolved in ether and the epoxide **41** crystallized as a white solid (4.49 g, 91%). It was recrystallized from chloroform–cyclohexane as white cubes, mp 148–149°C; ir λ_{max}: 5.91 μm; ^{1}H nmr δ: 7.25 (m, 10H), 3.70–5.02 (3 ABdd, 6H), 3.43 (m, 2H), 3.20 (s, 3H), 1.80 (m, 2H), 1.45 (3, 3H); *m/e*: 394(16), 303(12), 272(6), 219(15), 201(18), 131(12), 91(100). *Anal.* calcd. for $C_{23}H_{26}N_2O_4$: C 70.03, H 6.64, N 7.10; found: C 70.00, H 6.68, N 7.11.

(E)-*4,7-Dibenzyl-2-(2-methoxyethyl)-2-methyl-1-oxa-4,7-diazaspiro[2.5]octane-5,8-dione* (***42***)

The epoxidation of **40** (2.38 g, 6.26 mmol) with 85% *m*-chloroperoxybenzoic acid (3.00 g, 14.8 mmol) in methylene chloride (125 mL) was carried out analogously to the epoxidation of **39**, giving the *E* epoxide **42** (2.05 g, 83%), which was recrystallized from ether as white feathery needles, mp 112–113°C; ir λ_{max}: 5.93 μm; ^{1}H nmr δ: 7.30 (m, 10H), 3.75–5.05 (3 ABdd, 6H), 3.38 (m, 2H), 3.12 (s, 3H), 1.98 (m, 2H), 1.35 (s, 3H); *m/e*: 394(12), 303(5), 272(5), 256(8), 219(11), 201(15), 131(9), 91(100). *Anal.* calcd. for $C_{23}H_{26}N_2O_4$: C 70.03, H 6.64, N 7.10; found: C 69.84, H 6.60, N 7.08.

1,4-Dibenzyl-3-hydroxy-3(1-(2-methoxyethyl)ethenyl)piperazine-2,5-dione (***43***)

A solution of MICA in dry tetrahydrofuran (7 mL) was prepared as in the preparation of **23** from magnesium turnings (0.0296 g, 1.22 mmol), methyl bromide, and isopropylcyclohexylamine (0.30 mL, 1.8 mmol). Epoxide **41** (96 mg, 0.24 mmol) in dry tetrahydrofuran (2 mL) was syringed with stirring into the MICA solution under nitrogen cooled in a Dry Ice – acetone bath. After addition was complete the Dry Ice bath was replaced by an ice bath and the solution was stirred for an additional 2 h. The ice bath was removed and the mixture was stirred overnight at room temperature and poured into 2 *N* hydrochloric acid (2 mL). The acidified solution was extracted with methylene chloride (3 × 20 mL). The combined methylene chloride extracts were dried, filtered, and concentrated giving ~100 mg of crude **43** as a viscous pale yellow gum, with ir and ^{1}H nmr spectra corresponding to those of **43** prepared by treatment of *N*-benzyl-*N*-(2-benzylamino-2-oxoethyl)-3-(2-methylethyl)-2-oxo-3-butenamide (**44**) with MICA (2). It was chromatographed on a preparative silica plate with 20% ethyl acetate – chloroform as eluent. The eluted product (R_f = 0.53) was a 1:1 mixture of **43** and **44** as shown by its ^{1}H nmr spectrum.

The monoblocking of symmetrical diketones on insoluble polymer supports[1,2]

ZHANG-HUANG XU,[3] COLIN R. MCARTHUR, AND CLIFFORD C. LEZNOFF
Department of Chemistry, York University, Downsview (Toronto), Ont., Canada M3J 1P3

Received September 1, 1982

ZHANG-HUANG XU, COLIN R. MCARTHUR, and CLIFFORD C. LEZNOFF. Can. J. Chem. **61**, 1405 (1983).

A 1% crosslinked divinylbenzene–styrene copolymer, incorporating vicinal diol groups or their isopropylidene precursors, was used to form the monoacetals of the symmetrical diketones, *p*-diacetylbenzene, 1,2-cyclohexanedione, 1,3-cyclohexanedione, 1,4-cyclohexanedione, and 2,5-hexanedione. The free ketone groups reacted with phenylmagnesium bromide to give, in high yield, after acid hydrolysis from the polymer, the expected products such as 3-phenyl-2-cyclohexen-1-one from 1,3-cyclohexanedione. The ^{13}C nmr spectra of some polymer-bound substrates and simple analogs are described.

ZHANG-HUANG XU, COLIN R. MCARTHUR et CLIFFORD C. LEZNOFF. Can. J. Chem. **61**, 1405 (1983).

On a utilisé un copolymère de divinylbenzène–styrène réticulé à 1%, incorporant un groupe diol vicinal ou son précurseur isopropylidène pour former le monoacétal des dicétones symétriques, *p*-diacétylbenzène, cyclohexanedione-1,2, cyclohexanedione-1,3, cyclohexanedione-1,4 et hexanedione-2,5. Les groupes cétone libres réagissent avec le bromure de phénylmagnésium pour donner avec un fort rendement, les produits attendus tels: la phényl-3 cyclohexen-2 one-1 à partir de la cyclohexanedione-1,3 après clivage de la résine par hydrolyse acide. On décrit les spectres de rmn du ^{13}C de quelques substrats fixés sur le polymère ainsi que ceux des analogues simples.

Acetal formation of ketones represents one of the most common uses of blocking groups in organic synthesis (4). A wide variety of symmetrical diketones have the potential of being used as inexpensive starting materials in the synthesis of complex organic structures, but first it would be necessary to monoprotect *one* of the two identical ketone groups. In fact, the monoprotection of symmetrical diketones has been addressed many times. For example, 1,4-cyclohexanedione ethylene monoacetal (5, 6), other 1,4-dione monoacetals (7), and 1,3-cyclohexanedione ethylene monoacetal (8) have been prepared, but only by circuitous routes or in low yield. Although the most common synthons derived from 1,3-cyclohexanedione are 3-ethoxy-2-cyclohexen-1-one (9, 10) and the 3-halo-2-cyclohexen-1-ones (11, 12), reactions on the former have sometimes proved difficult to perform (13). Monoacetals of *aromatic* 1,2-diketones have been prepared by alkylation procedures (14), but this method cannot be generalized to include all classes of symmetrical diketones.

Insoluble polymer supports (15, 16) can be used to monoblock symmetrical diols (17, 18), aromatic dials (19–21),[4] dihydroxyaromatic compounds (22), diamines (23), and diacid chlorides (24). A solid phase resin incorporating an appropriate functional group can react with a large excess of symmetrical difunctional compound to give the monoprotected derivative, which can be removed from the excess symmetrical difunctional compound by simple filtration. This "fishhook" principle (17, 23, 25) does *not* depend on site-isolation (26) of the polymer-bound functional groups, as these groups are likely to react with only one molecule each of large excesses of the symmetrical difunctional compounds in the solution phase.

In earlier work we have used polymer-bound 1-*O*-benzyl-2,3-*O*-isopropylideneglycerol (**1**) to prepare polymer-bound 3-benzyloxypropan-1,2-diol (**2**). Subsequent use of **2** as a monoacetalization reagent of aromatic dialdehydes has been reported (19–21), but the use of **2** and related polymer-bound 1,3-diols as monoblocking agents for *symmetrical diones* either failed or exhibited low loading capacities for the diones (20).[5] We have recently shown (27) that ^{13}C nmr spectroscopy can be used to characterize polymer-bound substrates and hence we prepared (19) new samples of **1** and **2** for possible use as monoacetalization agents. The ^{13}C nmr of **1** and **2** exhibited the normal broad absorptions due to the aliphatic and aromatic carbons of the cross-linked polystyrene and, for **1**, distinct absorptions for the 2,3-*O*-isopropylideneglyceryl appendage (Table 1). Much to our surprise, the ^{13}C nmr of polymer **2** showed that polymer **2** contained a major amount of polymer **1** resulting from incomplete acid hydrolysis of **1** to **2**. Thus our early work on the use of polymer **2** for the monoacetylation of symmetrical aromatic dials involved the use of a mixture of mostly **1**, admixed with some of **2**, and hence we had done a *transacetalization* as opposed to an *acetalization*.[6] Indeed, reaction of terephthalaldehyde with **1** (instead of **2**) *or* new pure **2**, prepared by hydrolysis of **1** under more vigorous conditions (Experimental), gave us results identical to those previously reported (19). The ^{13}C nmr of pure **2** (Table 1), as prepared herein, did not exhibit the characteristic absorptions of the isopropylidene group in **1**.

The assignments of the ^{13}C absorption peaks in Table 1 are based on coupled and decoupled (Table 1) spectra of **1**, **2**, 1-*O*-benzyl-2,3-*O*-isopropylidene glycerol (**2***a*) (28), and L-1-*O*-benzylglycerol (**2***b*) (Sigma Chem. Co.) (Fig. 1). Polymers **1** and **2** exhibited low intensity peaks for C-1, medium

[3]Visiting Fellow, Wuhan Teacher's College, Wuhan, China, 1981–1982.

[4]A non-polystyrene based polymer has been used recently (37) in the preparation of monoblocked symmetrical aromatic dialdehydes but extensive double-binding occurred, undoubtedly due to their much higher capacities and the nature of the polymer. This polymer was not used to monoblock symmetrical diketones.

[5]At a recent symposium a report has appeared on using polymer-bound diols as blocking agents of symmetrical diones (38).

[6]Only 5–10 mg of the original samples were still available but 500 mg of sample is required for the ^{13}C nmr of these polymers and hence old polymer **2**, prepared by the old method, yielded **2** containing significant amounts of residual **1** as shown by ^{13}C nmr.

TABLE 1. ^{13}C chemical shifts of some polymer-bound substrates and their monomeric analogs

Compound	Carbon Position[a] 1	2	3[b]	4[b]	5	6, 7	Aromatic
1	73.12	70.62	74.38	66.90	108.8	26.40,25.01	Broad
2	73.56	71.78	70.87	64.21			Broad
2*a*	73.51	71.15	74.78	66.91	109.36	26.79,25.41	138.1 128.4 127.7
2*b*	73.34	71.53	70.95	63.87			137.9 128.4,127.8

[a]Aliphatic carbons numbered from the phenyl group, δ ppm with respect to TMS.
[b]^{13}C chemical shifts of glycerol, δ 62.95 and 72.30 ppm for C-1 and C-2 respectively (DMSO), and 2,3-*O*-isopropylidene glycerol (2,2-dimethyl-1,3-dioxolane-4-methanol), δ 63.11, 76.44, 66.07, 109.41 and 26.74, 26.05 ppm respectively, for the C-1 to C-7 carbons numbered from the alcohol end were used in assigning the absorption peaks.

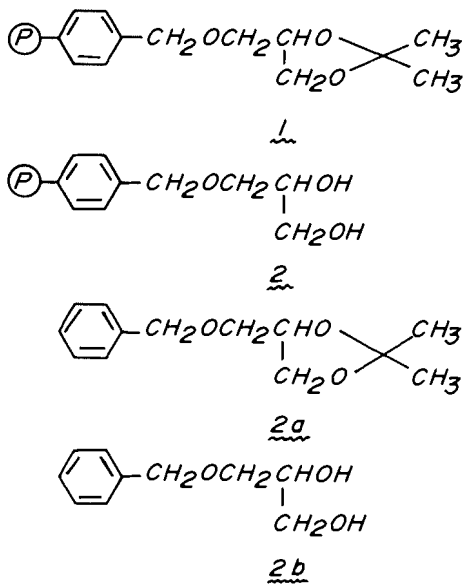

FIG. 1

intensity peaks for C-2, and sharp, high intensity peaks for other carbons, consistent with our earlier observations (27) of reduced mobility of carbons close to the polymer backbone.

Monoprotection of p-*diacetylbenzene (3) and its reaction with Grignard reagent*

Treatment of the polymer-bound isopropylidene derivative (**1**) or the polymer-bound 1,2-diol (**2**) with excess *p*-diacetylbenzene (**3**) gave the polymer-bound *p*-diacetylbenzene monoacetal (**4**) in high yield using *p*-toluenesulfonic acid and triethylorthoformate as a catalyst (29). Standard conditions (30) or the use of the boron trifluoride – ether complex (31) as catalysts afforded **4** in lower yield. The loading capacities of various preparations of **4** were determined by acid hydrolysis of **4** and recovery of the starting dione **3** (Table 2).

The infrared (ir) spectrum of **4** exhibited a characteristic carbonyl absorption at 1690 cm^{-1}. When **4** (prepared from **2**) reacted with phenylmagnesium bromide (**5**) in tetrahydrofuran (THF) polymer **6** was obtained. Polymer **6** no longer exhibited absorptions at 1690 cm^{-1} and a strong O—H absorption at 3400 cm^{-1} indicated that reaction had occurred and was essentially complete. Acid cleavage of **6** liberated 1-(4′-acetylphenyl)-1-phenylethene (**7**), the expected product in 99% yield resulting from the Grignard reaction and dehydration of the labile tertiary benzylic alcohol present in **6** (Scheme 1).

Monoprotection of 1,2-cyclohexanedione (8), 1-3-cyclohexanedione (9), and 1,4-cyclohexanedione (10) and their reactions with phenylmagnesium bromide (5)

Treatment of **1** or **2** with **8**, **9**, or **10** as above yielded the polymer-bound monoblocked acetals **11**, **12**, and **13** respectively. Polymers **11**–**13** exhibited strong absorptions at 1720 cm^{-1} supporting the assigned structures. The ^{13}C nmr spectrum of **12** exhibited a characteristic absorption at 110.7 ppm due to the quaternary carbon of the 5-membered ring acetal. This can be compared to similar absorption peaks for **1** and **2***a* (Table 1). The loading capacities of **11**–**13** prepared under various conditions were determined as for **4** above (Table 2). When the polymer-bound monacetals **12** and **13** were treated with phenylmagnesium bromide (**5**) as before, the polymer-bound tertiary alcohols **14** and **15** were obtained. The ir spectra of **14** and **15** exhibited broad peaks at 3400 cm^{-1}, typical of O—H vibrations, and the carbonyl absorptions had disappeared. Acid hydrolysis of **15** gave the expected 3-phenyl-2-cyclohexen-1-one (**16**) in 90% yield based on the amount of **9** bound to **12**. Similarly, **15** gave a mixture of 4-phenyl-3-cyclohexen-1-one (**17***a*) and 4-phenyl-2-cyclohexen-1-one (**17***b*) in 79% yield. Predictably, the acid cleavage conditions caused elimination of the tertiary alcohol groups and some isomerization to the α,β-unsaturated ketone (**17***b*) (Scheme 2).[7]

Acyclic diketones such as 2,5-hexanedione (**18**) can be monoblocked by the above methods using **2** to give the polymer-bound monacetal (**19**) (Table 2) (Fig. 2). Treatment of other ketones such as 2,3-butanedione (**20**), acetophenone (**21**), and cyclododecanone (**22**) gave the polymer-bound acetals (**23**–**25**) respectively. Only *p*-benzoquinone (**26**) proved unreactive to **2** under the standard conditions.

As shown in Table 2, a used polymer **2** showed no diminution in its capacity to prepare 3-phenyl-2-cyclohexen-1-one (**16**) (32). As mentioned recently, 4-substituted-2-cyclohexen-

[7]The high yields of the Grignard adducts show that double-binding of the symmetrical diones to the polymers is not significant at these capacities.

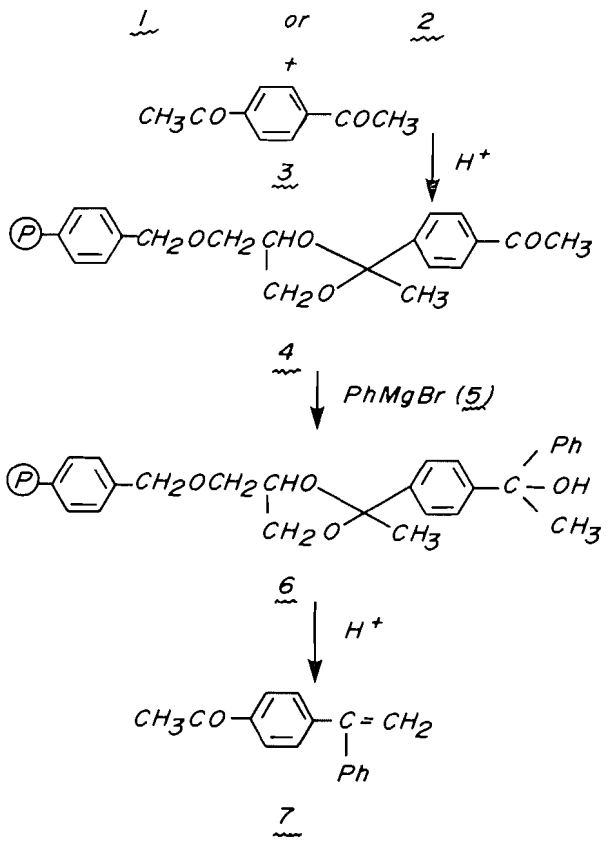
2	**21**	A	**24**	0.66	3.1	0.26
2	**22**	A	**25**	0.19	2.3	0.73
2	**26**	A	—	—		

[a]Reaction conditions; A = *p*-toluenesulfonic acid, 80°C, 48 h; B = *p*-toluenesulfonic acid, triethylorthoformate, 80°C, 48 h; C = boron trifluoride – ether complex, room temperature, 24 h.

[b]Determined by liberation from the polymer with 4 *M* HCl at 80°C and purification by preparative tlc.

[c]This value was obtained indirectly from *used* polymer **2**. At least 0.62 mmol/g of **16** was obtained using recycled **2**. This yield is greater than using fresh **2** and hence recycled **2** shows no reduced capacity.

[d]By analysis of residual chloride in **1**, polymers **1** and **2** contain 0.92 mmol/g of vicinal diol moieties and hence the percentage of *reactive* polymer-bound diol groups can be recorded.



SCHEME 1

1-ones and -3-enones have great synthetic potential (33) and the procedure outlined herein represents the first general method of monoprotecting symmetrical diketones. The free ketone group can be used for synthetic elaboration in multistep synthesis of polycyclic and acyclic compounds.

Experimental

Nuclear magnetic resonance (nmr) spectra for carbon were recorded on a Varian FT-80A spectrometer at 20 MHz using deuterochloroform ($CDCl_3$) as solvent and tetramethylsilane as the internal standard. Parameters used for polymers swollen in $CDCl_3$ were similar to those previously described.[27] Mass spectra (ms) were recorded at 70 eV on a VG Micromass 16F mass spectrometer in the EI mode. Microanalyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ont. All other instrumentation and general procedures were the same as described previously (34).

Preparation of polymer-bound 1-O-benzyl-2,3-isopropylidene glycerol (1)

A Merrifield resin (Sigma Chemical Col.) containing 1.04 mmol of —CH_2Cl groups per g of resin was treated as previously described (19), except that the mixture was stirred for *48 h instead of 24 h*, to give polymer **1**. A modified Volhard analysis (35) of **1** prepared after 24 h stirring showed 0.33 mmol of residual chloride per g of polymer, while stirring for 48 h or longer resulted in analyses showing only 0.12 mmol of residual chloride. The ^{13}C nmr spectrum of **1** is described in Table 1.

Preparation of polymer-bound 3-benzyloxypropan-1,2-diol (2)

Polymer **1** was treated as previously described (19), except that the mixture of 1.5 *M* aqueous HCl in dioxane (1:1) or 1 *M* H_2SO_4 in dioxane (1:1) was stirred *at 80°C for 72 h* to give polymer **2**. Hydrolysis of the ketal group of **1** was shown to be complete by examination of the ^{13}C nmr of **2** (Table 1).

Polymer-bound p-*diacetylbenzene monoacetal (4)*

As shown in Table 2, the preparation of **4** occurred almost equally as well from polymer **1** as polymer **2** in all three methods, A, B, or C. The procedures are identical using **1** or **2** and hence we describe the preparation of **4** using **1** or **2** as representative.

Method A. Using p-*toluenesulfonic acid*

To 15.91 g of polymer **1** in 100 mL of dry benzene was added 3.07 g of *p*-diacetylbenzene (**3**), 0.20 g of *p*-toluenesulfonic acid, and 9.47 g of anhydrous sodium sulphate. The mixture was heated for 48 h at 80°C. The mixture was filtered, washed twice with pyridine, twice with pyridine–water (1:1), ten times with water, three times

FIG. 2

with ethanol, and three times with dry ether, and dried under vacuum to give 16.8 g of polymer (**4**). In general, higher loadings are obtained with greater excesses of symmetrical difunctional compounds (16).

The loading capacity of polymer **4** for **3** was determined as follows. A mixture of 4.50 g of **4** in 10 mL of dioxane and 10 mL of 4 *M* aqueous HCl was stirred at 80°C for at least 48 h. The mixture was filtered and recovered **1** was washed six times with water, once with acetone, three times with ethanol, and three times with ether. The aqueous filtrate was extracted three times with ether. The combined ether extracts were dried over Na_2SO_4, filtered, and evaporated to crude **3**. Purification of **3** by column chromatography or silica yielded 0.176 g of pure **3** in the ether–hexane (1:1) fractions, showing that **4** contained at least 0.39 mmol per g of **3** (Table 2).

Method B. Using p-*toluenesulfonic acid and triethyl orthoformate*

To 2.68 g of polymer **2** in 30 mL of dry benzene was added 1.02 g of **3**, 0.12 g of *p*-toluenesulfonic acid, 0.5 mL of triethyl orthoformate, and 4.1 g of anhydrous sodium sulphate. The mixture was stirred at 80°C for 48 h and worked up as described for method A to give 2.8 g of **4**. The loading capacity (Table 2) of this polymer **4** was determined as for method A.

Method C. Use of boron trifluoride – ether complex

To 2.66 g of **2** in 30 mL of dry benzene was added 1.07 g of **3**, 1.0 mL of boron trifluoride – diethyl ether, and 3.44 g of anhydrous sodium sulphate. The mixture was stirred at room temperature for 24 h and worked up as described for method A to give 2.8 g of **4**. The loading capacity (Table 2) of this polymer **4** was determined as for method A.

The ir spectra of **4** from methods A, B, and C all showed significant C=O stretching vibrations, at 1690 cm^{-1}, of varying intensities depending on the loading capacities (Table 2).

Preparation of the polymer-bound Grignard adduct ***6***

To 6.2 g of **4** (containing 0.39 mmol of **3** per g of **4**) in 70 mL of dry THF was added 0.1 mol of phenylmagnesium bromide (**5**) in 50 mL of dry THF. The mixture was stirred at room temperature for 43 h and at 80°C for 2 h. The mixture was filtered and washed three times each with dry THF, anhydrous ethanol, and dry ether to give 7.0 g of polymer **6**. Polymer **6** showed a broad absorption band at 3400 cm^{-1} and no absorption band at 1690 cm^{-1} in the ir spectrum.

Hydrolysis of ***6*** *to give 1-(4′-acetylphenyl)-1-phenylethene (7)*

A mixture of 5.56 g of **6** in 60 mL of 4 *M* aqueous HCl in dioxane (1:1) was stirred and heated at 80°C for at least 48 h. The mixture was filtered and washed six times with water, twice with hot water, and three times each with acetone, ethanol, and ether. The aqueous filtrate was extracted three times with ether, washed twice with water, and dried over magnesium sulphate. The combined acetone and ether extracts yielded 0.8 g of a yellow oil. Column chromatography on silica gel yielded, in the 1:1 ether–hexane fractions, 0.48 g of 1-(4′-acetylphenyl)-1-phenylethene (**7**) in 99% yield based on the amount of **3** bound to **4**; mp 44–46°C; ir ($CDCl_3$): 1690, 1608, 1275; ^1H nmr δ: 2.61 (s, 3H), 5.52 (s, 2H), 7.42 (s, 5H), 7.7 (A_2B_2, q, 4H); *m/e*: (M^+) 222 (100), ($M^+ - 15$) 207 (100), 176 (82). *Anal.* calcd. for $C_{16}H_{14}O$:C 86.44, H 6.36; found: C 86.53, H 6.40.

*Preparation of polymer-bound aliphatic symmetrical dione monoacetals (****11****–****13****, ****19****, ****23****–****25****)*

The preparations of **11**–**13**, **19**, and **23**–**25** were identical to those described for **4** above by Method A and in one example by Method B (Table 2). All polymer-bound monoacetals showed strong carbonyl absorption at 1710–1730 cm^{-1} in their ir spectra. The loading capacities (Table 2) were determined as above for **4**.

Preparation of the polymer-bound Grignard adducts ***14*** *and* ***15***

Polymer-bound 1,3-cyclohexanedione monoacetal (**12**) (4.8 g), containing 0.65 mmol of **9** per g, reacted with **5** as described for **6** above to give 5.5 g of the polymer-bound adduct **14**.

Similarly, polymer-bound 1,4-cyclohexanedione monoacetal (**13**) (4.8 g), containing 0.39 mmol of **10** per g of **13**, gave 5.5 g of the polymer-bound adduct **15**.

Hydrolysis of ***14*** *to give 3-phenyl-2-cyclohexen-1-one*

A mixture of 4.8 g of **12** was hydrolyzed as described above in the preparation of **7** to give a yellow oil. Chromatography on silica gel using hexane–ether (1:1) gave, in 90% yield, 0.51 g of 3-phenyl-2-cyclohexen-1-one (**16**); mp 62–63°C (lit. (32) mp 64°C); ir: 1668, 1610, 775; ^1H nmr δ: 1.7–2.8 (m, 6H), 6.28 (s, 1H), 7.32 (m, 5H); *m/e*: (M^+) 172 (56), 144 (100), 115 (58).

Hydrolysis of ***15*** *to give a mixture of 4-phenyl-3-cyclohexen-1-one (****17****a) and 4-phenyl-2-cyclohexen-1-one (****17****b)*

A mixture of 4.8 g of **13** was hydrolyzed as above for the preparation of **7** to give a yellow oil. Purification as for **16** gave, in 79% yield, 0.35 g of a mixture of 4-phenyl-3-cyclohexen-1-one (**17***a*) and 4-phenyl-2-cyclohexen-1-one (**17***b*) (36); ir: 1720, 1690. Vapor phase

chromatography – mass spectroscopy of the mixture of **17***a* and **17***b* exhibited only two peaks in the ratio of 42:58. The mass spectra of the two peaks were consistent with the assigned structures, the first eluting peak showing *m/e* at (M^+) 172 (62), 144 (20), 130 (100), 129 (48), 115 (55) and the latter at (M^+) 172 (65), 130 (100), 129 (66), 115 (45).

Symmetry in N—H···N bonding, the structure of β-iminoamines and their salts[1]

SYDNEY BROWNSTEIN, ERIC J. GABE, AND LATA PRASAD
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received November 10, 1982

SYDNEY BROWNSTEIN, ERIC J. GABE, and LATA PRASAD. Can. J. Chem. **61**, 1410 (1983).

Crystals of 2-*N*-phenylamino-4-*N*-phenylimino-2-pentene are orthorhombic, a = 8.7283(6), b = 8.8369(5), c = 18.8798(8) Å, Z = 4, space group $P2_1ab$. It is resolved to R_F = 0.053 for 684 observed reflections. Crystals of 2-*N*-phenylamino-4-*N*-phenylimino-2-pentene hydrochloride are monoclinic, a = 14.6120(9), b = 5.2736(7), c = 20.708(1) Å, β = 102.287(5)°, Z = 4, space group $P2_1/c$. The final residual is 0.054 for 1255 reflections. Crystals of 2-*N*-methylamino-4-*N*-methylimino-2-pentene hydrochloride are trigonal, a = 7.1666(7), c = 15.3299(8) Å, Z = 3, space group $P3_121$. The final residual is 0.044 for 343 observed reflections. The free base exists, in the solid, as the amino-imino form and not as a symmetrical structure. The N—H bond distances in the six-membered ring of the free base are equal as are the N—H bond distances in the infinite chains of the hydrochloride salts. The compounds are fluxional in solution.

SYDNEY BROWNSTEIN, ERIC J. GABE et LATA PRASAD. Can. J. Chem. **61**, 1410 (1983).

Les cristaux de *N*-phénylamino-2 *N*-phénylimino-4 pentène-2 sont orthorhombiques et appartiennent au groupe d'espace $P2_1ab$ avec a = 8,7283(6), b = 8,8369(5), c = 18,8798(8) Å, Z = 4. On a résolu la structure jusqu'à une valeur de R_F = 0,053 pour 684 réflexions observées. Les cristaux du chlorhydrate de *N*-phénylamino-2 *N*-phénylimino-4 pentène-2 sont monocliniques avec a = 14,6120(9), b = 5,2736(7), c = 20,708(1) Å, β = 102,287(5)°, Z = 4, groupe d'espace $P2_1/c$. On obtient une valeur finale de R = 0,054 pour 1255 réflexions. Les cristaux du chlorhydrate de *N*-méthylamino-2 *N*-méthylimino-4 pentène-2 sont trigonaux avec a = 7,1666(7), c = 15,3299(8) Å, Z = 3, groupe d'espace $P3_121$. La valeur résiduelle finale est de 0,044 pour 343 réflexions observées. La base libre existe, dans le solide, sous forme de amino-imino et non comme une structure symétrique. Les longueurs de la liaison N—H des cycles à 6 chaînons de la base libre sont égales comme le sont les longueurs de liaison N—H dans les chaînes sans fin des chlorhydrates. Les composés en solutions sont fluxionnaires.

[Traduit par le journal]

Introduction

It is well known that β-diketones often exist primarily in the enolic form with an intramolecular hydrogen bond. Exchange between the keto and enol forms is sufficiently slow that the relative concentrations and structures of each tautomer can be determined by proton magnetic resonance (1). The chemical shifts of the carbon atoms 2 and 4 in the hydrogen-bonded enolic form are identical. This may arise via rapid exchange between structures **A** and **B** or because the molecule has the symmetrical structure **C** as shown in Scheme 1.

From the variation in chemical shift with changing substituents on carbon atoms 2 and 4, it was concluded that only form **C** is present in solution (2). Direct measurements of such structures in the solid have been made by X-ray and neutron diffraction. The earliest studies reported symmetrical O···H···O bonding as in structure **C** (3, 4). The consensus of more recent studies is that the bonding is asymmetric as in structures **A** and **B** (5–8).

A similar ambiguity exists for β-iminoamines as shown in Scheme 2. Proton resonance spectroscopy shows single lines which cannot distinguish between a rapid averaging of species **D** and **E**, or the existence of structure **F** (9). An X-ray crystal structure determination was undertaken to resolve this ambiguity.

The eneamines are much more basic than the corresponding β-diketones and form salts with mineral acids. The position of protonation in the salts and its effect upon the molecular symmetry and hydrogen bonding are also of interest. The situation is nominally similar to that in 1,8-bis(dimethylamino)-napthalene, a much stronger base than one might expect (10), with a slow rate of proton removal due to the presence of a strong intramolecular hydrogen bond (11).

Experimental

2-*N*-methylamino-4-*N*-methylimino-2-pentene hydrochloride (MMPH) and the corresponding phenylamino compound (PPPH) were prepared according to the literature procedure and recrystallised from absolute ethanol. The phenylamino compound (PPP) was prepared from the hydrochloride by reaction with triethylamine and was recrystallised from petroleum ether (9).

Intensity data for all the compounds were measured on a Picker 4-circle automatic diffractometer using graphite monochromatised CuKα radiation by θ/2θ scan methods with line profile analysis (12). The unit cell constants were obtained by least-squares refinement of the setting angles of reflections with $2\theta > 75°$ (λCuKα = 1.5406 Å). The relevant experimental details are given in Table 1. The intensities were corrected for Lorentz and polarization effects, using measured values for direct beam polarization (13). Absorption corrections were not considered to be justified because the effects are small and the crystals irregular. For PPP, the space group $P2_1ab$ with equivalent positions (x, y, z; $\frac{1}{2}+x$, $\bar{y}$, $\bar{z}$; $\frac{1}{2}+x$, $\frac{1}{2}-y$, z; x, $\frac{1}{2}+y$, $\bar{z}$), is a non-standard setting of the space group $Pca2_1$. For MMPH the space group $P3_121$ was selected arbitrarily over the enantiomorphic group $P3_221$.

All three structures were solved by the application of MULTAN (14). After several cycles of refinement with isotropic temperature factors, the hydrogen atoms were located in a difference map. The

structures were refined further by block-diagonal least-squares method with anisotropic temperature factors for the non-hydrogen atoms. Hydrogen atoms were included in all structure factor calculations, but only in PPP were H(1) and H(2) refined with isotropic temperature factors. Counting statistics weights were used throughout ($w = (1/\sigma^2)|F_o|$). The final R-values are given in Table 1. The scattering factors for neutral atoms were taken from International tables for X-ray crystallography (1974). The final positional and equivalent isotropic temperature factors are given in Tables 2, 3, and 4. All calculations were performed using the NRC PDP8-E system of programs (15).

*B_{eq} is the arithmetic mean of the principal axes of the thermal ellipsoid.

Discussion

The atom numbering, bond lengths and angles for the three structures are shown in Figs. 1, 2, and 3.

In the structure of PPP there is an intramolecular N—H···N bond (Fig. 1). Within the limits of accuracy of the structure determination, H(1) has refined close to a symmetrical position between N(1) and N(2). The fragment N(1)C(1)C(2)C(3)N(2)

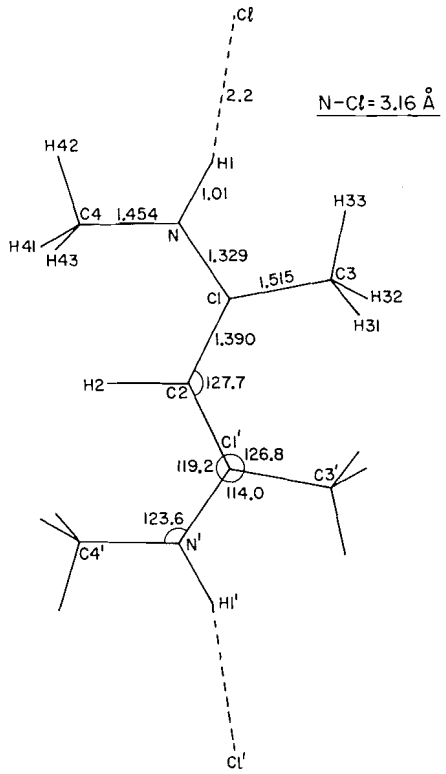

FIG. 3. Atom numbering, bond lengths (σ = 0.008 Å), and bond angles (σ = 0.5°) for MMPH.

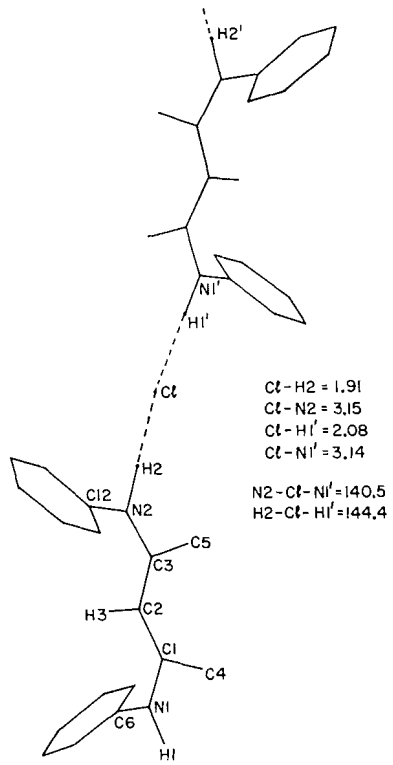

FIG. 4. The relationship between PPPH units.

is not symmetric (Fig. 1) and the molecule does not possess any symmetry as in bisbromobenzoylmethane (3) and bischlorobenzoylmethane (4) where there is a two-fold axis. The only other related structure with an intramolecular N—H···N bond is that of 3,5-dimethyl-1,7-diphenyl-4-(2,4,6-trinitrophenyl)-2,6-diazahepta-2,4-diene in which the N—H···N bond is not symmetric (16). In view of this it seems unlikely that the N—H···N bond in PPP really is symmetric. The molecule may exist in the crystal as a combination of the species **D** and **E**, but the difference in the lengths of the N(1)—C(1) (1.376 Å) and N(2)—C(3) (1.314 Å) bonds strongly suggests that H(1) is really attached to N(1) even though the refined position does not agree with this.

In PPPH, both N(1) and N(2) are protonated. The molecule, though not situated in a position of crystallographic symmetry, appears to possess a plane of symmetry passing through C(2) and perpendicular to the plane C(1)C(2)C(3). The molecules are linked together by N—H···Cl bonds forming zig-zag chains along the (001) direction (Fig. 4).

In MMPH the atoms C(2) and Cl are situated on a crystallographic two-fold axis (Table 3 and Fig. 3). The structure is similar to the phenyl analogue.

Conclusion

Electron density maps suggests that PPP exists in the solid as a combination of the species **D** and **E**, with the convolution of the two H(1) positions producing a diffuse maximum at the symmetrical position. However the N—C bond lengths indicate more strongly that H(1) is attached to N(1). The occurrence of the electron density maximum is probably an artifact of the data and should not be given too much significance.

Partial molal volumes of some halobenzenes in carbon tetrachloride

FEREIDOON SHAHIDI

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received September 17, 1982

FEREIDOON SHAHIDI. Can. J. Chem. **61**, 1414 (1983).

The partial molal volumes at infinite dilution $\bar{V}^0$ for a number of halobenzenes are measured and related to their van der Waals volumes. Results indicate larger volume increments for halogen atoms in halobenzenes than those in alkyl halides. Possible explanations are forwarded. The effect of steric overcrowding in *ortho*-substituted benzenes on the $\bar{V}^0$ values are evaluated.

FEREIDOON SHAHIDI. Can. J. Chem. **61**, 1414 (1983).

On a mesuré les volumes molaires partiels à dilution infinie $\bar{V}^0$ d'un certain nombre d'halobenzènes et on les a rapportés à leurs volumes de van der Waals. Les résultats indiquent que les atomes d'halogènes des halobenzènes subissent une plus forte augmentation de volume que ceux des halogénures d'alkyles. On fournit des explications possibles de ce phénomène. On évalue l'effet d'un encombrement stérique des benzènes substitués en position *ortho* sur les valeurs de $\bar{V}^0$.

[Traduit par le journal]

Introduction

The partial molal volumes, $\bar{V}^0$, of aromatic hydrocarbons and their alkyl derivatives in carbon tetrachloride (1) at 25°C may be calculated using the equation

$$[1] \quad \bar{V}^0 = 11.61 + \sum_1^m n_i I_i - \sum_1^k p_j \delta_j$$

where n_i is the number of groups (methyl, methylene, aromatic $=C<$ or $=C<^{H}$ etc.) of type i and I_i is the volume increment of such a group; δ_j represents the decrement due to the overlap feature j and p_j is the number of such features present in the molecule. The value of 11.61 mL mol^{-1} serves as the covolume factor (2) or the volume of the solvent cavity required to accommodate a point kinetic particle of no intrinsic volume.

In the present paper we test the applicability of eq. [1] to a number of halobenzenes listed in Table 1.

Experimental

The compounds given in Table 1 are commercial products obtained from Aldrich Chemical Co. They were purified by conventional methods of recrystallization and distillation. Carbon tetrachloride was purified as described elsewhere (2).

Densities were measured at 25.00 ± 0.01°C using a Paar digital precision density meter, model DMA 02C, and the apparent molal values were then calculated using eq. [2]

$$[2] \quad \phi_v = \frac{M_2}{W_2}(1/d - W_1/d^0)$$

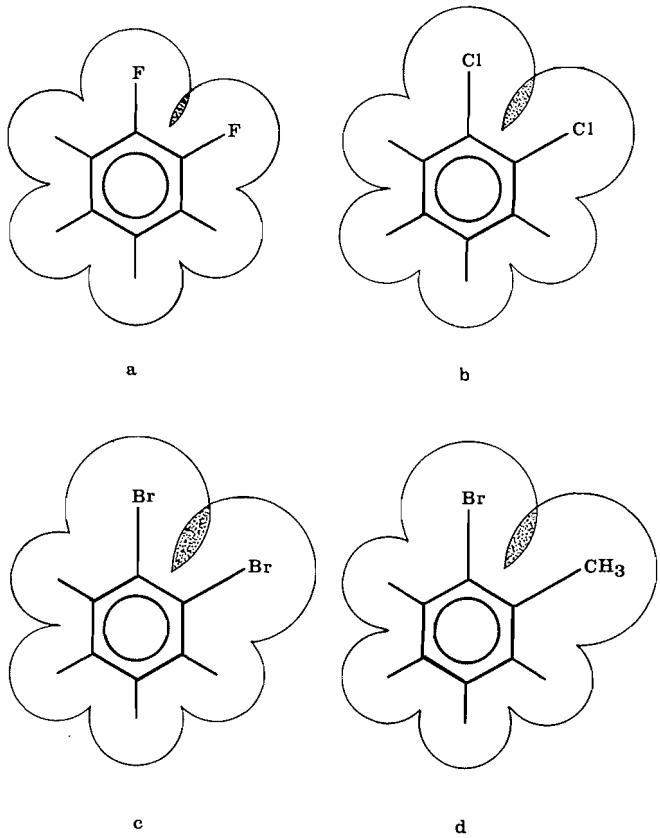

FIG. 1. Scale drawings of *ortho*-disubstituted halobenzene molecules: van der Waals radii of 1.2 Å for hydrogen, 1.47 Å for fluorine, 1.75 Å for chlorine, 1.85 Å for bromine, and 2.0 Å for methyl indicated.

where M_2 is the solute molecular weight, W_2 its weight fraction, W_1 the weight fraction of solvent, and d and d^0 are the densities of the solution and solvent respectively. The partial molal volumes at infinite dilution, $\bar{V}^0$, were then obtained from a least-squares fit of the apparent molal volumes, ϕ_v, to zero concentration. The errors quoted are standard deviations.

Results and discussion

In Table 1, the partial molal volumes, $\bar{V}^0$, obtained experimentally together with those calculated using eq. [1] are tabulated.

Group contributions to the partial molal volumes, I, and volume decrements, δ, caused by steric compression due to the overlap of the van der Waals volumes of *ortho*-substituted groups (features $a-d$ in Fig. 1) are listed in Table 2. The group contributions for the halogen atoms attached to aromatic rings are considerably larger than those obtained for haloalkanes.

The halogen atoms in haloalkanes behaved as if their volumes were smaller than those indicated by their van der Waals volumes V_w (3). The partial molal volume of a solute is made up of V_w plus the void or "empty" volume V^e (4), which depends on the closeness of packing of the solvent molecules about solute molecules. A bromine atom has about the same V_w as a methyl group (5) and if the packing of carbon tetrachloride molecules about it is similar, would be expected to have the same volume increment I.

The volume increment, I, of 24.95 mL mol^{-1} for bromine in benzene bromides is fairly close to that of 26.85 mL mol^{-1} for a methyl group. Furthermore, the *ortho* effect of bromine atoms (feature c) in $\bar{V}^0$ of bromobenzenes is similar to that of a methyl group in methylbenzenes, i.e., 2.20 versus 2.35 mL mol^{-1}. Thus the geometrical size of the groups is reflected in the measured values of $\bar{V}^0$.

The calculated group contributions, I_{calcd}, to the partial molal volumes based on the equation

$$[3] \quad I = V_w + 5.9 \times 10^{-9}A$$

developed elsewhere (5), are much closer to the values obtained experimentally for aryl halides than those found for haloalkanes (3) (see Table 2). It has been shown that the halogen atoms in aryl halides have larger van der Waals volumes than those attached to alkyl chains (4). However, these differences may not fully account for the observed variations in $\bar{V}^0$ values; factors related to the surface area and packing efficiency of solvent molecules about the molecules of solute are important contributors.

Partial molal volumes, $\bar{V}^0$, for cyclohexylbromide (122.6 ± 0.4 mL mol^{-1}) and 1,4-dibromocyclohexane (134.1 ± 0.5 mL mol^{-1}) as well as those for 1- and 2-bromoadamentenes (6) agree well with the calculated $\bar{V}^0$ values using the volume increment of 19.53 mL mol^{-1} for the bromine atom, hence excluding the involvement of conformational effects (7).

In halobenzenes, due to the electron-withdrawing effect of halogen atoms, the π-electron cloud of the benzene rings is made less available towards donor–acceptor complexation (8–11) with the solvent as comapred with unsubstituted aromatic hydrocarbons and their alkyl derivatives. This results in

[b]In aryl halides.

larger $\bar{V}^0$ values than those expected on the basis of the latter two classes of compounds. Since the contributions of aromatic $=C<$ and $=C<^{H}$ are fixed, this "apparent" volume increase will be reflected in the I values for the halogen atoms in aryl halides. Furthermore, the approach of carbon tetrachloride molecules on the π-surfaces of these halobenzenes may be restricted due to unfavorable dipole − induced dipole interactions and this also results in an "apparent" increase in the volume contribution, I, for halogens in these compounds.

Therefore, a combination of the effects considered above may account for the observed differences between the I values of the halogens in aliphatic and aromatic halocompounds. However, these speculations (*vide supra*) must only be considered as "tentative" at this stage.

Magnetic shielding constants, calculated for C-13 and N-15 nuclei in the finite perturbation method using INDO and London's approximations, are analyzed in terms of mono-, di-, and tricentric contributions, thus permitting an assessment of the relative importance of local vs. nonlocal contributions. For both C-13 and N-15, it appears that the changes in total shielding are almost entirely dictated by those of the local paramagnetic contribution, i.e., $\Delta\sigma_{total} \simeq \Delta\sigma^{P}_{local}$.

E. C. VAUTHIER, S. FLISZÁR, F. TONNARD et S. ODIOT. Can. J. Chem. **61**, 1417 (1983).

Des constantes d'écran magnétique, calculées par la méthode des perturbations finies au niveau INDO avec l'approximation de London pour des noyaux C-13 et N-15, sont analysées en termes de contributions mono-, di- et triatomiques en permettant ainsi une évaluation de l'importance relative des contributions locales et non-locales. Il ressort que les variations totales des constantes d'écran sont pratiquement entièrement dictées par celles de la contribution paramagnétique locale, c.-à-d., $\Delta\sigma_{total} \simeq \Delta\sigma^{P}_{local}$.

Introduction

The rigorous theory of magnetic shielding, which is now clearly described (1), is practically unmanageable for any compound of chemical interest. Reasonable compromises between theoretical rigor and practical feasibility have been offered (2–12) with the result that realistic shielding constants can now be calculated. For a representative collection of carbon-13 shieldings, for example, an average deviation of ~5 ppm between calculated and experimental results covering a range of ~145 ppm is indicative for the sort of precision which can now be obtained (12) and suggests that reasonable confidence can be put in the approximations involved in this type of calculations.

The present study covers carbon-13 and nitrogen-15 nuclei of a diversified group of molecules. Of course, shielding constants are calculated and compared with experimental data. Primarily, however, it appears interesting to gain an insight into the role of electron densities associated (admittedly in a somewhat loose fashion) with the various atoms of a molecule as regards the shielding of any given nucleus. From within the formalism describing the magnetic shielding, this type of insight is offered by numerical analyses of the individual contributing terms and by an evaluation of the relative weights of local vs. nonlocal contributions.

While the results obtained in this manner are obviously not rigorous and should, therefore, not be unduly generalized to other systems without appropriate verifications, it becomes possible to assess the prevailing role of local paramagnetic contributions with a reasonable degree of confidence.

Outline of calculations

The average diamagnetic and paramagnetic contributions, σ^d and σ^p, respectively, to the total average magnetic shielding

$$\sigma = \sigma^d + \sigma^p$$

are calculated using the formalism described earlier (12). This approach is rooted in Pople's finite perturbation theory (3). It involves the INDO approximations (11) on a gauge invariant atomic orbital (GIAO) basis (7) and London's approximation. Moreover, it satisfies the Hermitian requirement for the first-order perturbation matrix reflecting the effect of an applied external magnetic field. The latter condition results in a significant improvement of calculated ^{13}C magnetic shieldings, the average precision being of the order of ~5 ppm (12). The point is that this formalism for σ permits a separation into mono-, di-, and triatomic contributions, thus revealing the relative importance of "local" and "distant" electron densities on the magnetic shielding of a given nucleus. The various contributions making up the total shielding $\sigma(M)$ of nucleus M are: $\sigma^d(M)$ = local diamagnetic shielding, from AO's centered on M; $\sigma^d(K)$ = diamagnetic contribution of all atoms but M, from AO's centered on K; $\sigma^p(M)$ = local paramagnetic shielding, from AO's centered on M; and $\sigma^p(K)$ = paramagnetic contribution of all atoms but M, from AO's centered on K. In addition, we must consider the following sums which have physical meanings although this is not the case for the individual terms, i.e., $\sigma(MK) = \sigma^d(MK) + \sigma^d_0(MK) + \sigma^p_0(MK)$ = total (dia- plus paramagnetic) contribution of all the MK pairs

of atoms involving M, from AO's centered on M and K; $\sigma(M, AB) = \sigma^d(M, AB) + \sigma_0^d(M, AB) + \sigma_0^p(M, AB)$ = contribution of all pairs AB but those involving atom M, from AO's centered on atoms A and B. Finally, the total shielding of atom M is expressed by the sum

$$\sigma = \sigma^d(M) + \sigma^d(K) + \sigma^p(M) + \sigma^p(K) + \sigma(MK) + \sigma(M, AB)$$

which is readily calculated from the appropriate expressions indicated in eq. [9] of ref. 12.

It is clear that the INDO approximations are only there in order to keep the calculations at a manageable level. The quality of the London and INDO approximations involved can be evaluated from the results obtained in this fashion, in comparisons with experimental data. While certainly plagued by occasional lack of precision, the results deduced within the framework of INDO theory still enable a balanced assessment of the major relevant trends governing magnetic shielding.

Results

The calculations were carried out by means of the program NMR C INDO-80[1] which optimizes the Slater exponents in order to account for the molecular environment. Anticipated errors arising from London's approximation are tentatively compensated, at least in part, with the use of the modified INDO parameters $\beta_H^0 = -14.31$ and $\beta_C^0 = -16.57$ eV as determined in an earlier study (12), and $\beta_N^0 = -21.38$ eV. While obviously not free from possible criticisms, namely, as regards the choice of a single β_C^0 parameter for describing all *sp*, sp^2, and sp^3 carbon atoms, the fact remains that this simple parameterization leads to acceptable results considering the large range in shielding which is investigated. Standard geometries were assumed throughout.

The results obtained for carbon nuclei are indicated in Table 1. While there is clearly room for improvements, it appears fair to conclude that the comparison with experimental data supports the general validity of the approximations involved in the present semiempirical approach, namely London's approximation as well as those of INDO theory, including the INDO parameters β^0.

Similarly, Table 2 describes the analysis of the individual contributions to the shielding of nitrogen-15 nuclei. The results are compared with their experimental counterparts and suggest that the approximations involved in these calculations are (under the present conditions) acceptable and justify a reasonable confidence in the individual contributions. The latter are analyzed as follows.

Discussion

To begin with, it appears that the *local* diamagnetic shielding, $\sigma^d(M)$, is virtually constant for a given nucleus, i.e., ~57.1 ± 1.2 ppm for C-13 and ~88.2 ± 1.2 ppm for N-15. This result, which is in line with current views, plays a role in the forthcoming evaluation of the total (dia- and paramagnetic) *local* contributions to the shielding of a nucleus. Moreover, the present calculations illustrate the minor role played by distant atoms on the shielding of heavy nuclei like C-13 and N-15. This point is, indeed, revealed by the contributions of the tricentric integrals, $\sigma(M, AB)$, which are both small and fairly

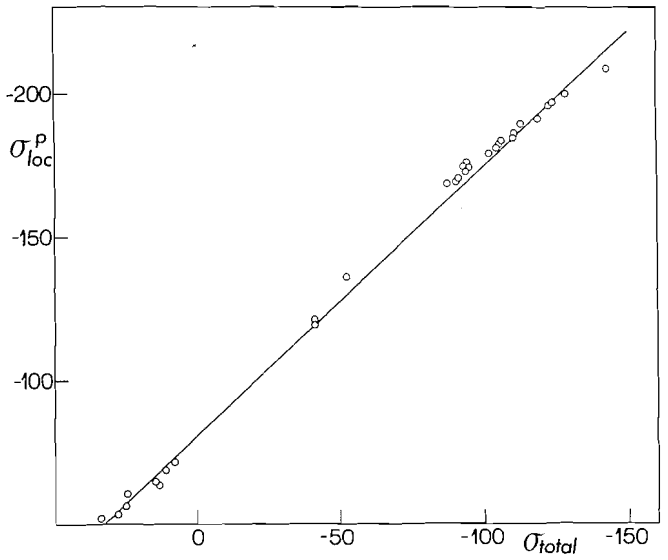

FIG. 1. A comparison of calculated local paramagnetic with total shielding constants of C-13 nuclei (ppm). The results are extracted from Table 1 and ref. 12.

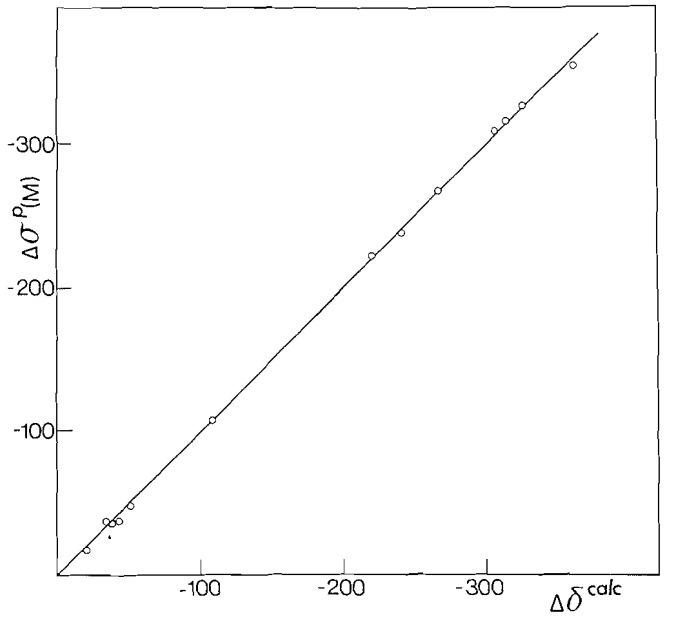

FIG. 2. A comparison between local paramagnetic and total shielding constants (ppm, from Table 2).

constant, particularly in comparison with closely related compound, i.e.,

$$\sigma(M, AB) \simeq 2.8 \pm 2 \text{ ppm (C-13)}$$
$$\simeq 2.5 \pm 3 \text{ ppm (N-15)}$$

The fact that "distant" atoms have only a minor, if any, effect on the shielding of heavy nuclei justifies in part the solvaton model (13) discussed by Jallah-Heravi and Webb (14). For hydrogen, however, the situation is different, as revealed by the relative importance of tricentric integrals in the calculation of σ (12), thus suggesting a possible explanation for solvent effects affecting proton magnetic shielding constants.

On the other hand, the total dia- and paramagnetic contributions of all atoms but M, from AO's centered on K, i.e., $\sigma^{d}(K) + \sigma^{p}(K) + \sigma(MK)$, also appear to be relatively invariant although this is not the case for the individual terms. For N-15 nuclei this sum is 30.6 ± 6 ppm, this average being taken for all the compounds indicated in Table 2. However, the results suggest slightly different values in comparisons involving only atoms of similar nature, namely, 27.9 ± 3 ppm in amines, 35.1 ± 1.5 ppm in nitriles, and 29.3 ± 3 ppm in cyclic compounds. Similarly, the sum $\sigma^{d}(K) + \sigma^{p}(K) + \sigma(MK)$ is ~19.6 ± 4 ppm for the carbon nuclei of the noncyclic molecules and ~13.8 ± 4 ppm for the cyclic molecules indicated in Table 1. Of course, it would be difficult and premature to evaluate how real are the differences between nuclei belonging to different series of compounds; it seems fair, however, to assume that there is some truth in the similarities within a series of closely related molecules.

With these reservations in mind regarding the precise meaning of "constancy" when speaking about the terms examined so far, it appears from the present calculations that the sum of all the contributions other than the local (dia- and paramagnetic) ones is nearly invariant, namely, 20.5 ± 5.5 ppm for C-13 nuclei and 33.1 ± 4 ppm for N-15 nuclei. Of course, this is the result of a number of compensations because the individual terms entering the sum occasionally exhibit significant variations. Turning now to the local paramagnetic term, $\sigma^{p}_{local} = \sigma^{p}(M)$, calculated from AO's centered on M and, moreover, remembering that the local diamagnetic part, $\sigma^{d}(M)$, is virtually constant, it appears that the total variation in shielding, $\Delta\sigma_{total}$, is almost entirely determined by that of the local paramagnetic term, i.e.,

$$\Delta\sigma_{total} \simeq \Delta\sigma^{p}_{local}$$

This result is expressed in Fig. 1 for carbon-13, and in Fig. 2 for nitrogen-15 nuclei.

The results given in Figs. 1 and 2 are self-explanatory. They are significant because they cover an important range of shielding (~160 ppm for ^{13}C and ~400 ppm for ^{15}N) for nuclei belonging to a well diversified group of molecules. Of course, these results are not free from relatively minor uncertainties linked to the necessity of using approximations in order to keep the computations at a manageable level.

Within the precision of the present type of analysis, it seems nonetheless reasonable to retain the essentially local character of the main factors governing the magnetic shielding of heavy nuclei, thus offering a justification for correlations between nmr shifts and atomic charges which, of course, are strictly local properties. Indeed, accurate correlations of this type are occasionally observed in well-defined series of compounds (15), suggesting, in agreement with the present results, that the local charge density determines the major part, by far, of the differences in shielding between nuclei in comparable situations.

The structure and conformation of *cis*-2-phenylcyclobutanecarboxylic acid and *cis*-3-(*p*-fluorophenyl)cyclobutanecarboxylic acid

GEORGE M. REISNER, JAMES D. KORP, IVAN BERNAL, AND RICHARD FUCHS
Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.

Received October 20, 1982

GEORGE M. REISNER, JAMES D. KORP, IVAN BERNAL, and RICHARD FUCHS. Can. J. Chem. **61**, 1422 (1983).

The structure of *cis*-2-phenylcyclobutanecarboxylic acid (**1**) and *cis*-3-(*p*-fluorophenyl)cyclobutanecarboxylic acid (**2**) have been determined by X-ray diffraction methods. Crystals of **1** are monoclinic, space group $C2/c$ with a = 15.420(8), b = 11.687(6), c = 11.226(5) Å, β = 112.45(4)°, and eight molecules in the unit cell. Crystals of **2** are monoclinic, space group $P2_1/n$, a = 8.038(5), b = 5.405(4), c = 22.69(1) Å, and β = 97.30(4)°, with four molecules in the unit cell. In both compounds the cyclobutane ring is puckered, with dihedral angles of 27° and 31°. The bond joining the substituted ring atoms in **1** is significantly longer (1.581(2) Å) than the other three (average 1.535(2) Å), due to crowding of substituents. In **2** both the carboxyl and phenyl substituents are close to the bisecting geometry, whereas in **1** both substituents deviate from this conformation, the carboxyl more than the phenyl.

GEORGE M. REISNER, JAMES D. KORP, IVAN BERNAL et RICHARD FUCHS. Can. J. Chem. **61**, 1422 (1983).

On a déterminé par diffraction de rayons-X la structure de l'acide phényl-2 cyclobutanecarboxylique *cis* (**1**) et de l'acide (*p*-fluorophényl)-3 cyclobutanecarboxylique *cis* (**2**). Les cristaux du composé **1** sont monocliniques et appartiennent au groupe d'espace $C2/c$ avec a = 15,420(8), b = 11,687(6), c = 11,226(5) Å, β = 112,45(4)° et possèdent 8 molécules par maille. Les cristaux du composé **2** sont monocliniques et appartiennent au groupe d'espace $P2_1/n$ avec a = 8,038(5), b = 5,405(4), c = 22,69(1) Å et β = 97,30(4)° avec 4 molécules par maille. Dans les deux composés le cycle cyclobutane est gauche avec des angles dièdres de 27° et de 31°. La liaison reliant les atomes substitués du cycle dans le composé **1** est nettement plus longue (1,581(2) Å) que celle des trois autres (moyenne: 1,535(2) Å) à cause de l'encombrement des substituants. Les substituants carboxyles et phényle du composé **2** adoptent une conformation qui s'approche d'une géométrie bisectrice tandis que les substituants du composé **1** dévient de cette conformation, le carboxyle déviant d'avantage que le phényle.

[Traduit par le journal]

Recent thermochemical studies of simple cyclobutane derivatives (cyclobutyl cyanide, ethylcyclobutane cyclobutylamine) (1, 2) indicate that all three are stabilized by 2.0 ± 0.4 kcal/mol relative to cyclobutane. This is surprising, because other data (3) demonstrate that these substituents do not stabilize the cyclopropane ring, where substituent-ring π interactions should be more favorable. Also, it is not clear from previous crystal studies (4–8) whether ring bond lengths in cyclobutane derivatives are affected mainly by the electronic properties of substituents (π donors and acceptors, σ donors and acceptors), or by crowding of adjacent substituents. Furthermore, we are unaware of any previous studies on similarly unhindered substituted cyclobutanes which establish whether substituents such as phenyl and carboxyl preferentially assume a ring-bisecting conformation most favorable for π interaction. Since the accuracy of the thermochemical data on cyclobutane (2), and the existence of stabilization in substituted cyclobutanes have been questioned (1), we wished to look for structural evidence of cyclobutane–substituent conjugation. The existence of conjugation (in cyclopropane derivatives, for example ref. 9), is not necessarily reflected in thermochemical stabilization, but stabilization is unlikely in the absence of conjugation.

With this question in mind we have undertaken an X-ray study of two comparably substituted cyclobutane derivatives, *cis*-2-phenylcyclobutanecarboxylic acid (**1**) and *cis*-3-(*p*-fluorophenyl)cyclobutanecarboxylic acid (**2**). As shown in a previous structural determination (9), both the phenyl and the carboxyl group are capable of conjugation with small ring systems.

It is anticipated that the two substituents will be sterically crowded in **1** but not in **2**, and this should permit a distinction to be drawn between steric and electronic effects.

Experimental

Syntheses

cis-2-Phenylcyclobutanecarboxylic acid was synthesized by the method of Burger and Beard (10), and recrystallized from hexane (mp 83.5–85.0°C). A crystal for X-ray study was formed by slow partial evaporation of a hexane solution at room temperature.

cis-3-(*p*-Fluorophenyl)cyclobutanecarboxylic acid (**2**) was synthesized by the low temperature addition of *p*-fluorophenylmagnesium bromide to ethyl 3-ketocyclobutane-1-carboxylate, hydrogenolysis of the resulting hydroxyl group, and ester hydrolysis (11). The material recrystallized from hexane melted at 81.5–83.5°C. A crystal was grown from a heptane solution by partial evaporation at room temperature.

X-ray structure determinations

Data collection methods for the two compounds were similar. Intensity measurements were carried out with an ENRAF-NONIUS CAD-4 computer-controlled diffractometer. A summary of the crystallographically important parameters for data collection and processing is given in Table 1. Accurate cell constants were determined from 25 strong high angle reflections. The intensities were measured using the θ–2θ scan technique, with the scan rate depending on the net count obtained in rapid pre-scans of each reflection. The standard reflections, monitored every 2 h, did not show any significant deviations from the initial measurements. In reducing the data, Lorentz and polarization factors were applied, but no absorption corrections were made.

Both structures were solved using MULTAN (12). All subsequent calculations were carried out using the SHELX-76 (13) system of programs. All the hydrogen atoms were located in difference density Fourier maps. After all shift/esd ratios were less than 1.0, the refinements converged to the agreement factors given in Table 1. No unusually high correlations were noted in either refinement. The atomic scattering factors for C, O, and F were computed from numerical Hartree–Fock wave functions (14); for hydrogen those of Stewart

Results and discussion

Figures 1 and 2 depict stereoscopically related pairs of compounds **1** and **2**, respectively, and also show the atomic nomenclature used.

In both compounds the cyclobutane ring was found to be puckered, with dihedral angles of about 27° and 31°. These values are typical of non-fused, substituted cyclobutane rings.

Of the four independent carbon−carbon bonds of the cyclobutane ring in compound **2**, two are significantly longer (1.552(4) and 1.550(5) Å) than the other two (1.532(5) and 1.533(5) Å). This pattern of somewhat unequal bonds occurs in a wide variety of compounds, some of which appear in Cotton's review. Additional examples were recently reported also by Busetti *et al.* (5). The four independent bonds average 1.542(4) Å which is virtually identical to the value of 1.544(3) Å found by Cotton and Frenz (4).

The pattern of the carbon−carbon bonds in the four-membered ring of compound **1** is different. One, C3−C4, is significantly longer (1.581(2) Å) than the other three (1.536(3), 1.538(2), 1.532(2) Å). Carr *et al.* (6) who studied the crystal and molecular structure of *cis*-1,2-dimethoxycarbonyl-1,2-bis(4-nitrophenyl)cyclobutane observed a similar but somewhat larger lengthening of the bond between the two disubstituted atoms (1.606(3) Å). It was suggested that steric hindrance may be responsible for this additional lengthening. Since *cis* substitution of adjacent carbon atoms sometimes results in no significant lengthening of the corresponding ring bond (*cis*-1,2-cyclobutanedicarboxylic acid, C—C = 1.546(3) Å) (7) the possibility that this lengthening may originate in the electron-withdrawing properties of the substituent groups was proposed (6). However, Bock (8) found that in octahydroxycyclobutane, the ring bond lengths are only 1.562(4) and 1.564(2) Å despite the strong electron-withdrawing properties of the hydroxyl groups. But perhaps the σ acceptor quality of the hydroxyl group was in this case balanced by π back donation. In view of the fact that in our case a lengthening of one of the ring bonds occurs only in compound **1** for which the two substituents are in *cis* conformation bonded to adjacent carbons and not for compound **2** which has the same *cis* substituents but on non-adjacent carbons, it seems reasonable to assume that this increase in the C3—C4 bond in compound **1** is mainly due to steric hindrance.

It was found (5) that puckering of the cyclobutane ring decreases the average C—C—C angle from 90° by about 1.6° (4), although values as low as 86.3(2)° and 86(1)° (7, 16) were reported. The angles found for compounds **1** and **2** range between 86.4(3)° and 89.9(3)°.

The six phenyl ring distances average 1.376 Å and 1.377 Å for compounds **1** and **2**, respectively. The variation observed among the individual phenyl bond lengths is probably due to the higher thermal motion of the more distant carbons. The C3—C6 bond of attachment observed for compound **1** (1.502(2) Å) is virtually identical to that of a pure C_{sp^2}—C_{sp^3} bond (1.505 Å) (18), which is indicative of the absence of any conjugation between the phenyl and cyclobutane rings. The somewhat shorter bond of attachment found in compound **2** (1.484(4) Å) might be due to a very slight conjugation between the phenyl and the four-membered ring.

The carboxyl group of compound **2** shows a much smaller difference between the two C—O bond lengths (1.239(4) and 1.284(4) Å) than those observed for compound **1** (1.228(2) and 1.311(2) Å). Also, hydrogen H13 of the OH group has a much

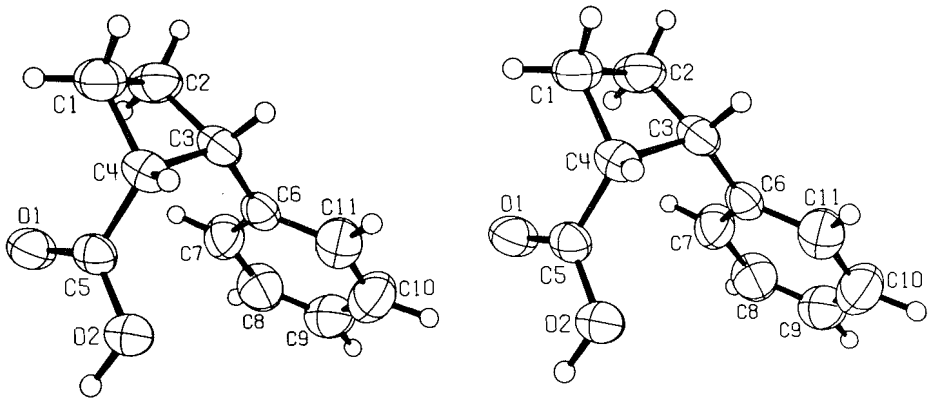

FIG. 1. Stereoscopic view of the atom-labelling scheme for *cis*-2-phenylcyclobutanecarboxylic acid (compound **1**).

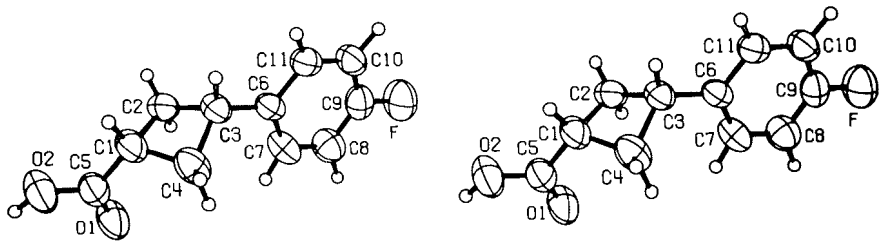

FIG. 2. Stereoscopic view of the atom-labelling scheme for *cis*-3-(*p*-fluorophenyl)cyclobutanecarboxylic acid (compound **2**).

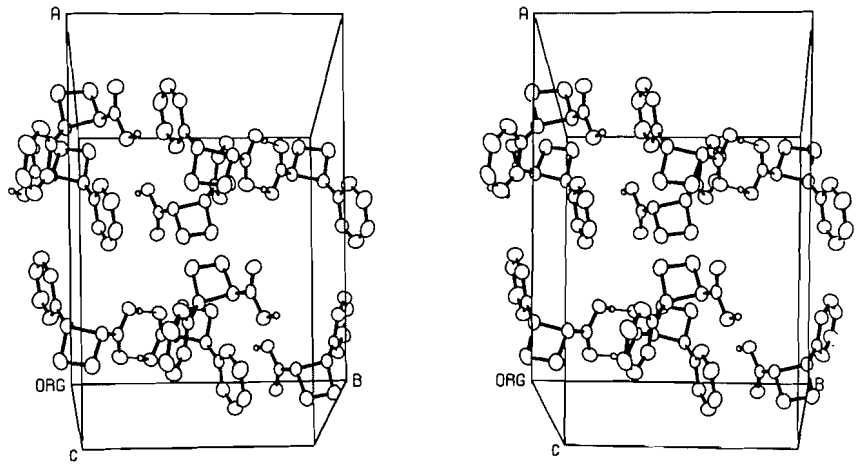

FIG. 3. Stereoscopic view of the molecular packing of **1**. Hydrogens (except H13) are omitted for clarity and the hydrogen bonds between pairs of molecules are included.

higher temperature factor in **2** than in **1**. The bonds of attachment are normal for C_{sp^2}—C_{sp^3} and virtually identical for both compounds (1.494(2) and 1.490(4) Å), again showing no tendency towards conjugation.

The phenyl groups of both compounds are, of course, planar within experimental error. As expected, the carbonyl carbons lie within the plane defined by the three neighboring atoms.

The conformation of the sterically hindered compound **1** differs to a great extent from that observed for compound **2**. Thus, for compound **1** the dihedral angles between the planes of the two substituent groups (phenyl and carboxyl) and the planes defined by those three carbons of the four-membered ring closest to the substituent groups are both about 69°. The dihedral angle between the two substituent groups is 128.2°. In compound **2** the phenyl and carboxyl groups are almost normal to the respective planes of the cyclobutane ring (95.9° and 90.9°). The two substituents are close to being parallel, the dihedral angle between them being 12.8°.

As may be seen from the torsion angles (Table 7) of the unhindered compound **2**, both substituents approach the bisecting conformation with the carbonyl group being somewhat closer to that ideal position than the phenyl. The conformation of the carboxyl group is such that the carboxyl oxygen is nearer to the four-membered ring center with the hydrogen being *syn*-planar positioned. By contrast, the substituents in compound **1** are inhibited by steric problems from achieving the bisecting geometry, the carbonyl group deviating more from the ideal conformation than the phenyl substituent (see torsion

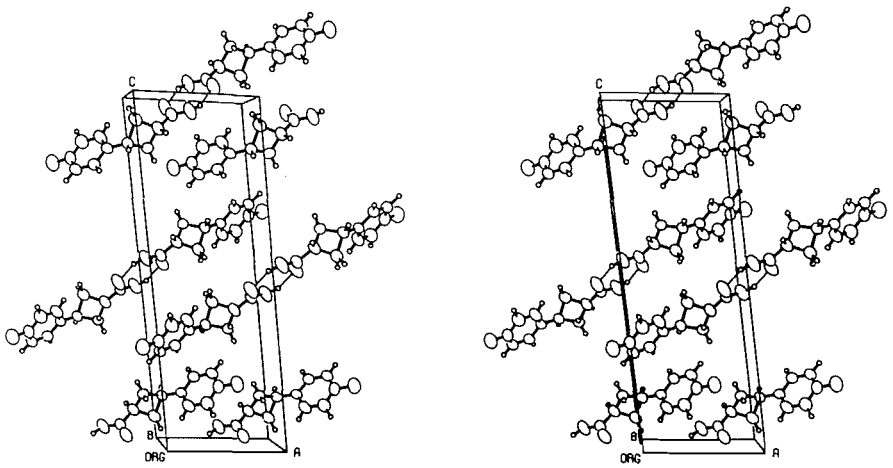

FIG. 4. Stereoscopic view of the molecular packing of **2**. Hydrogen bonds between pairs of molecules are included.

angles, Table 7). The carbonyl oxygen of the carboxyl group is still nearer to the four-membered ring. This situation is in sharp contrast to that recently found by us in *cis*-2(*m*-nitrophenyl)cyclopropanecarboxylic acid (9) where both phenyl and carboxyl groups are far from the bisecting positions with the *phenyl ring* deviating more than the carboxyl group.

The packing of the molecules in the unit cells is shown in Figs. 3 and 4 for compounds **1** and **2**, respectively. Pairs of molecules are mutually hydrogen bonded across crystallographic inversion centers, the bonding being of the "dimer" type found in most carboxylic acids (17). The hydrogen bonding parameters are: **1**: O1...O2 = 2.65(1) Å, H13...O1 = 1.67(2) Å, O2—H13...O1 = 174(2)°; **2**: O1...O2 = 2.65(1) Å, H13...O1 = 1.71(2) Å, O2—H13...O1 = 157(2)°.

Methylmercury(II) sulfhydryl interactions. Potentiometric determination of the formation constants for complexation of methylmercury(II) by sulfhydryl containing amino acids and related molecules, including glutathione

ALAN P. ARNOLD AND ALLAN J. CANTY[1]

Chemistry Department, University of Tasmania, Hobart, Tasmania, Australia 7001

Received May 5, 1982

ALAN P. ARNOLD and ALLAN J. CANTY. Can. J. Chem. **61**, 1428 (1983).

Formation constants for the interaction of methylmercury(II) with 2-mercaptoethanol, mercaptoacetic acid, *O*-methylmercaptoacetate, 2-mercaptosuccinic acid, L-cysteine, D,L-penicillamine, *N*-acetyl-D,L-penicillamine, glutathione, thiocholine, and 4-mercapto-*N*-methylpiperidine have been determined by potentiometric titration. For the equilibrium $MeHg^+ + RS^{n-} \rightleftharpoons [MeHgSR]^{1-n}$, log β occurs in the range 14.60(1)−17.14(1), with the lowest value obtained for the cationic complex of thiocholine, $MeHgSCH_2CH_2\overset{+}{N}Me_3$. Acid dissociation constants for the ligands are reported. Formation constants for the addition of both one and two equivalents of MeHg(II) to L-cysteine have been determined, giving log *K* ca. 4.1 for the reaction

$$MeHgSCH_2CH(\overset{+}{N}H_3)(CO_2H) + MeHg^+ \rightleftharpoons (MeHg)_2\overset{+}{S}CH_2CH(\overset{+}{N}H_3)(CO_2H)$$

occurring at low pH, and log *K* 8.8 for the reaction

$$MeHgSCH_2CH(NH_2)CO_2^- + MeHg^+ \rightleftharpoons MeHgSCH_2CH(\overset{+}{N}H_2HgMe)CO_2^-$$

occurring at higher pH.

ALAN P. ARNOLD et ALLAN J. CANTY. Can. J. Chem. **61**, 1428 (1983).

On a déterminé par titrage potentiométrique les constantes de formation pour l'interaction du méthylmercure(II) avec le mercapto-2 éthanol, l'acide mercaptoacétique, le *O*-méthylmercaptoacétate, l'acide mercapto-2 succinique, la L-cystéine, la D,L-pénicillamine, la *N*-acétyl-D,L-pénicillamine, la glutathione, la thiocholine et la mercapto-4 *N*-méthylpipéridine. Dans le cas de l'équilibre $MeHg^+ + RS^{n-} \rightleftharpoons [MeHgSR]^{1-n}$, log β est de l'ordre de 14,60(1) à 17,14(1), le complexe cationique de thiocholine, $MeHgSCH_2CH_2\overset{+}{N}Me_3$ donne la plus faible valeur. On rapporte les constantes de dissociation acide des ligands. On a déterminé les constantes de formation dans le cas de l'addition d'un et de deux équivalents de MeHg(II) sur la L-cystéine qui donne log *K* = 4,1 environ pour la réaction

$$MeHgSCH_2CH(\overset{+}{N}H_3)(CO_2H) + MeHg^+ \rightleftharpoons (MeHg)_2\overset{+}{S}CH_2CH(\overset{+}{N}H_3)(CO_2H)$$

se produisant à faible pH et log *K* = 8,8 pour la réaction

$$MeHgSCH_2CH(NH_2)CO_2^- + MeHg^+ \rightleftharpoons MeHgSCH_2CH(\overset{+}{N}H_2HgMe)CO_2^-$$

se produisant à un pH plus élevé.

[Traduit par le journal]

Introduction

The interaction of methylmercury(II) with thiols to form complexes MeHgSR is believed to be important in both the toxicology of MeHg(II) and the use of antidotes containing thiol groups (1). Thus, a fundamental requirement in studying the biological behaviour of MeHg(II) is accurate values of β_{110} for equilibria [1], where RSH are thiols that occur *in vivo*.

[1] $MeHg^+ + RS^- \rightleftharpoons MeHgSR$

[2] $\log \beta_{110} = [MeHgSR]/[MeHg^+][RS^-]$

Early determinations of log β_{110} with mercaptoalbumin (distribution method) (2, 3), cysteine and glutathione (distribution) (3), and 2-mercaptoethanol (potentiometric) (4) gave values in the range 15.7−16.9. Some recent determinations agree well with these values. Thus, Jawaid and Ingman (5) obtained log β_{110} 15.7 ± 0.12 for L-cysteine (potentiometric); and it has been reported that substituted thiophenols form complexes with log β_{110} in the range 10.48−15.60 (potentiometric) (6, 7) to give the relationship log $\beta_{110} = 0.798pK(RSH) + 8.77$, which is also obeyed by the early values (2−4) of log β_{110} within 0.5p*K* units.

However, Hojo *et al.* (8) in a recent potentiometric study obtained values for several thiols, including L-cysteine and glutathione, which are well below the values reported by other workers (log β_{110} 7.19−9.03). Jawaid and Ingman (5), and Reid and Rabenstein (9), have commented on these results and the latter workers have reported log β_{110} for mercaptoacetic acid, mercaptoethanol, mercaptosuccinic acid, cysteine, penicillamine, homocysteine, and *N*-acetylpenicillamine. Reid and Rabenstein obtained values consistent with the early workers and Jawaid and Ingman, but not Hojo *et al.*

The results of Reid and Rabenstein were obtained using novel ^1H nuclear magnetic resonance competition experiments involving determination of K_d for the equilibrium [3], from which β_{110} for MeHgSR can be evaluated from β_{110} for $MeHgSCH_2CO_2^-$ [4] (9).

[3] $MeHgSCH_2CO_2^- + RS^- \rightleftharpoons MeHgSR + {}^-SCH_2CO_2^-$

[4] $$K_d = \frac{[MeHgSR][{}^-SCH_2CO_2^-]}{[MeHgSCH_2CO_2^-][RS^-]} = \frac{\beta_{110} \text{ for MeHgSR}}{\beta_{110} \text{ for } MeHgSCH_2CO_2^-}$$

Swarzenbach and Schellenberg's value of β_{110} for the 2-mercaptoethanol complex was used to calculate β_{110} for $MeHgSCH_2CO_2^-$ after measurement of K_d for mercaptoacetate/2-mercaptoethanol competition.

However, discrepancies between reported values for MeHg(II) thiolate formation constants, and reliance of the nmr method on the single determination of β_{110} for 2-mercaptoethanol, indicate that further measurement of β_{110} for a range of thiols is desirable. In addition, MeHg(II) binds to glutathione in red blood cells (10), and thus competitive equilibria between MeHg(II), glutathione, and sulfhydryl containing antidotes for MeHg(II) poisoning (e.g. D-penicillamine (11) and *N*-acetyl-D,L-penicillamine (11, 12)) are important, but the formation constant for interaction of MeHg(II) with glutathione has only been determined in one of the early investigations (distribution method) (3). We report here a potentiometric study of the interaction of MeHg(II) with all of the ligands studied by the nmr method (except for homocysteine), glutathione, *O*-methylmercaptoacetic acid, and the cationic thiols thiocholine and *N*-methyl-4-mercaptopiperidine. Our potentiometric results confirm early values for glutathione and 2-mercaptoethanol, are in complete agreement with constants determined using the nmr method and provide values for the formation constants for addition of a second MeHg(II) group to L-cysteine to form $(MeHg)_2\overset{+}{S}CH_2CH(\overset{+}{N}H_3)(CO_2H)$ and $MeHgSCH_2CH(\overset{+}{N}H_2HgMe)CO_2^-$.

Experimental

Chemicals

The thiols 2-mercaptoethanol (Koch-Light) and mercaptoacetic acid (Aldrich) were fractionally distilled under reduced nitrogen pressure and stored under nitrogen at −20°C. The crystalline thiols L-cysteine, *N*-acetyl-D,L-penicillamine (Koch-Light), D,L-penicillamine (Ega-Chemie), 2-mercaptosuccinic acid (Aldrich), and glutathione (Sigma) were used as received and stored under nitrogen over P_2O_5. Thiocholine perchlorate was a gift from P. Guerney (University of New South Wales). The thiol *O*-methylmercaptoacetic acid was prepared by acid catalysed *O*-alkylation of mercaptoacetic acid in refluxing methanol (bp 46−47.5°C (4 mm), lit. (13) 42−43°C (10 mm)), and 4-mercapto-*N*-methylpiperidine was prepared as described (13) (bp 31−32°C (1 mm), lit. (14) 62°C (0.8 mm)).

A solution of methylmercury(II) hydroxide was obtained by stirring MeHgI (20 mmol, purified as described elsewhere (15, 16)) with freshly prepared silver oxide (ca. 20 mmol) for 12 h under nitrogen in 50 mL of freshly boiled water. The resultant suspension was filtered (Whatman No. 54), in a nitrogen-flushed glovebox, directly into a 1 L volumetric flask containing a slight excess of nitric acid (20 mmol) to give a $MeHg^+/H^+/NO_3^-$ solution with $[MeHg^+]$ and $[H^+]$ nominally 0.02 *M* and 0.005 *M*, respectively. The solution was stored under nitrogen. Values of $[H^+]$ were determined by alkalimetric titration, monitored potentiometrically, after addition of excess KI to remove $MeHg^+$ as insoluble MeHgI. Values of $[MeHg^+]$ were determined as described elsewhere (15, 16), involving titration with thiosulfate in 50% aqueous methanol with Michlers thioketone as an indicator. The composite concentration, $[H^+] + [MeHg^+]$, was also determined by alkalimetric titration in the absence of iodide, and was in agreement with values for $[H^+]$ and $[MeHg^+]$. Concentration of H^+ and $MeHg^+$ remained constant for 15 months.

The 0.1 *M* potassium hydroxide titrant (Merck Titrisol®) was stored in leached borosilicate glass and was protected by Carbasorb®. The alkali was frequently standardised by potentiometric titration against primary standard grade potassium hydrogen phthalate. The equivalent points of these titrations were determined by the program TITRAT, and produced identical titrant concentrations to alternate titrations against borax standardised 0.1 *M* nitric acid in 0.1 *M* potassium nitrate when equivalent points were found by Gran type 1 or type 2 methods (17). These latter titrations also provided estimates of pK_w^c (see below) and indicated the presence of less than 0.1% weakly acidic impurities, e.g. carbonate, silicate.

Water used for preparation of all titration solutions was deionised by mixed bed ion exchange to a specific resistance greater than 4×10^6 ohm cm, then boiled and cooled under nitrogen prior to use.

The ionic strength of potentiometric titration solutions was adjusted to 0.1 *M* with twice recrystallised potassium nitrate or potassium iodide. The latter also serves as a competitive ligand for MeHg(II) in the formation constant titrations (see below).

Potentiometric measurements

All pH measurements were performed in a thermostatted double walled cell based on that of Perrin and Sayce (18), in which the entire assembly was maintained at 25.00 ± 0.02°C to minimise thermal gradients within the electrodes. An Orion Model 7010 digital pH meter was equipped with a standard glass electrode (Philips GA 110) or low resistance glass electrode (Philips GAT 130), together with a glass sleeve double junction saturated calomel reference electrode (Philips R44/2-SD/1) in which the outer bridge solution was 1 *M* potassium nitrate. The inner (reference) half cell of this electrode was vented outside of the titration vessel to preclude contamination by volatile thiols. The electrode pair was standardised before each titration with thermostatted NBS standard solutions (19) (pH 4.008, 6.865, and 10.012).

Solutions for thiol pK determination

Immediately following standardisation of the electrode assembly, 50.0 mL of thiol solution were transferred to the dried purged titration vessel. For thiols containing carboxylic acid groups 0.1 *M* nitric acid was then added to given an initial pH in the range 2.5−3. Titrant (0.1 *M* potassium hydroxide) was delivered by a motorised 5 mL piston burette (Metrohm D535) through a finely drawn glass capillary placed just beneath the solution surface. The solution was purged with high purity nitrogen which has been passed through a column of Carbasorb® (to remove CO_2) and a thermostatted solution of 0.1 *M* potassium nitrate. Magnetic stirring was stopped and nitrogen redirected over the solution surface during pH measurement. The pH readings were recorded when drift was less than 0.001 units per min. Equilibrium was obtained within 1−5 min in at least moderately buffered regions.

Using this procedure 30−60 titration points were collected over periods of 1−3 h. The electrode standardisation was then verified with the pH 6.865 NBS buffer. On the rare occasions that the electrode standardisation had drifted by more than 0.002 pH, the titration was repeated. Early attempts to use combination electrodes, particularly with solutions of some vicinal dithiols, resulted in restandardisation discrepancies of up to 1 pH unit after such titrations, forcing the use of separate glass and reference electrodes.

Solutions for formation constant determination

An aliquot of $MeHg^+/H^+/NO_3^-$ stock solution was added to 50.0 mL of vigorously stirred thiol solution (containing 0.1 *M* potassium iodide) in order to achieve 1:1 or 2:1 $MeHg^+$:thiol stoichiometry. If precipitation of MeHgI was evident during MeHg(II) addition potassium hydroxide titrant was simultaneously added to achieve the minimum pH consistent with a clear solution. The titration procedure was then identical to that for p*K* determinations. It was often convenient to combine the two procedures by titrating the thiol ligand in 0.1 *M* potassium iodide, then adding $MeHg^+/H^+/NO_3^-$ solution and retitrating after readjustment of the ionic strength with potassium nitrate.

Calculation of equilibrium constants

Calibration of the glass electrode in terms of $[H]^+$

The equilibrium constants recorded in this work are concentration constants, requiring that the electrode assembly be calibrated in terms of log $[H^+]$ rather than log $\{H^+\}$. The approach to this problem advocated by Irving *et al.* (20), and expanded by McBryde (21), and Hedwig and Powell (22) was used in this work, where $[H^+]$ is derived from the measured pH by the relationship

$$-\log [H^+] = pH + pH_{cal}$$

where pH_{cal} includes activity coefficient corrections and accounts for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

systematic errors inherent in transferring electrodes from buffers to titration solutions.

Initially pH_{cal} was measured in a series of titrations of strong acid (0.01 *M* HNO_3 in 0.1 *M* KNO_3) with 0.1 *M* potassium hydroxide. However, it is more convenient to treat pH_{cal} as an unknown parameter in the multiparametric curve fitting procedures used to calculate thiol acid dissociation constants or MeHg(II) complex formation constants. In this way pH_{cal} can be estimated from data below pH 4 for the actual titration under study, rather than from separate preliminary titrations. Values of pH_{cal} calculated in this way over many titrations were always in the range −0.08 to −0.05, in agreement with similar values found elsewhere (22, 23) or in this work by separate strong acid – strong base titrations. It should be emphasised that extraction of low p*K*'s (less than 3) from titration data by any calculation or method requires accurate values of $[H^+]$ in this low pH region (20).

For solutions of moderately strong acids in the multimolar level (p*K* less than 3) small errors in $[H^+]$ result in large *systematic* errors in the estimated p*K* value which are not reflected by the usual error estimates produced by least squares procedures.

A related problem is that of accurate values of K_w^c, which equals $[H^+][OH^-]$ in the ionic medium of interest. Estimates of p*K* values greater than 10−11 are highly correlated to errors in K_w^c and to electrode calibration above pH ~ 11, e.g. it can be shown that the uncertainty in pK_w^c produces 10 times this error in the acid dissociation constant of a weak monoprotic acid with pK_w^c approximately 11.5 (20). Values of pK_w^c were obtained from the difference in $E°$ of the electrode assembly in acid and alkaline regions of strong acid/strong base titrations (24), giving $pK_w^c = 13.74 \pm 0.02$ at 25°C in 0.1 *M* potassium nitrate, which agrees favourably with $pK_w^c = 13.784 \pm 0.006$ calculated from the molal value of 0.1 molal KCl at this temperature (25). However, it was found that the thiol p*K* titration data could not be adequately fitted in the region above pH 10 using pK_w^c 13.74. Multiparametric refinement by TITRAT or MINIQUAD 81 (see below) over many titrations produced values of pK_w^c in the range of 13.86 ± 0.04. This value probably includes a small term due to electrode non-linearity above pH 10. It should be noted that there seem to be many reported instances of equilibrium constants calculated at high pH, e.g. thiol p*K*, in which the value of pK_w^c is either not recorded or has been taken from sources using different experimental conditions. Difficulties in this area are reflected by the general lack of agreement between such constants.

Acid dissociation constants of the thiol ligands were obtained together with values of the proton purity of the ligands with the computer program TITRAT. This program is a generalised version of the interactive rigorously weighted non-linear least-squares programs used by Schwartz and Gelb to evaluate two simultaneous acid dissociation constants (26). TITRAT can refine any combination of the parameters applicable to the titration of a polyprotic acid or base mixture by a stock monoprotic acid or base.[2] The running time of the original program was decreased by an order of magnitude by the use of analytical expressions for condition function derivatives, and the convergence properties improved by quadratic optimisation of the parameter shifts during the refinement.

In this work the acid dissociation constants in the concentration form were refined simultaneously with the number of millimoles of ligand and electrode calibration parameters pH_{cal} and pK_w^c.

Protons do not compete effectively in aqueous solutions with MeHg(II) for the thiolate ligands studied here. One means of overcoming this limitation to the use of pH titrations is to reduce the effective MeHg(II) thiolate constant by competition with another ligand. Iodide is particularly well suited in this regard, e.g. solutions of MeHg(II) and 2-mercaptoethanol exhibit buffer regions in the pH range 3−5 in the presence of 0.1 *M* KI, due to the equilibrium

$$MeHgI + HSCH_2CH_2OH \rightleftharpoons MeHgSCH_2CH_2OH + I^- + H^+$$

The formation constant of MeHgI was obtained by pH titration of MeHg(II) in the presence of 0.1 *M* KI, giving log *K* 8.500(1) (lit. 8.60 (ref. 4), 8.7 (ref. 28)). Above pH 8 the equilibrium

$$MeHgI + H_2O \rightleftharpoons MeHgOH + I^- + H^+$$

is established. Similarly, formation constants for MeHgOH and $(MeHg)_2OH^+$ were evaluated by titration in 0.1 *M* KNO_3, giving log β_{10-1} −4.607 (9) (lit. −4.50 (ref. 29), −4.59 (ref. 4), −4.67(3) (ref. 30), −4.70 (ref. 31), −4.40(2) (ref. 32), −4.686(15) (ref. 33)) and log β_{20-1} −2.234 (18) (lit. −2.22 (constant calculated using values of K_w^c recorded in ref. 4), −2.53 (quoted (refs. 32, 33)), −1.725(30) (ref. 33), −2.33 (quoted (refs. 32, 33))).

The ternary MeHg(II)/thiolate/iodide/proton (or hydroxide) systems were treated using a recent version (34) of the program MINIQUAD 75 (35), which allows simultaneous refinement of formation constants and pH calibration parameters pH_{cal} and the analytical proton excess (H_{tot}) for each titration fit. Refinement of H_{tot} simultaneously with the formation constants by MINIQUAD 81 consistently indicated values 1−2 μmol greater than those calculated from anal-

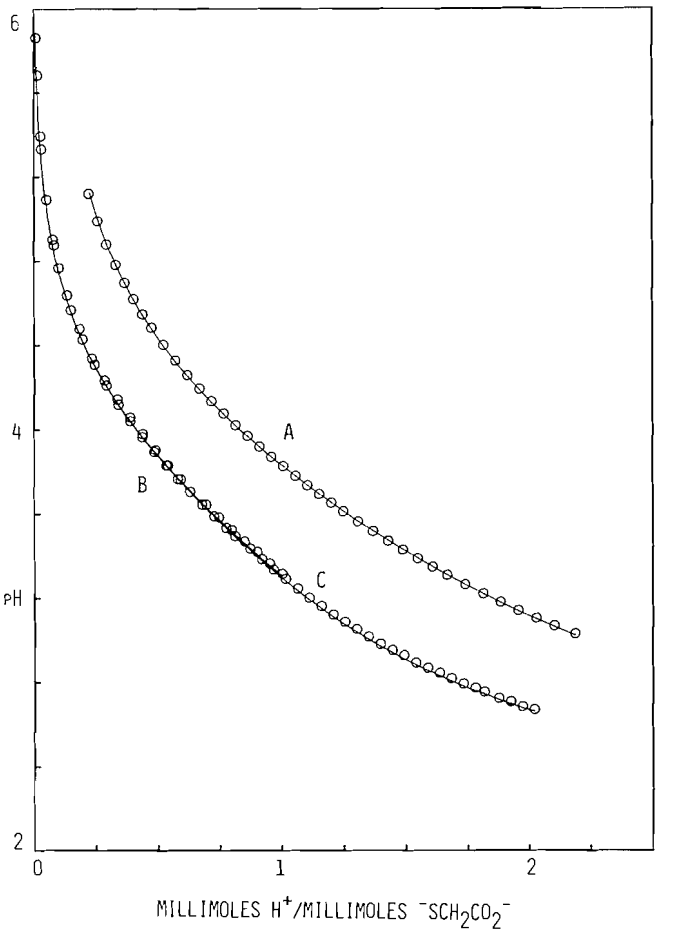

FIG. 1. Titration data for MeHg(II) and mercaptoacetic acid. Data for *A* were obtained with iodide competition, for *B* and *C* without iodide competition. For each titration initial amounts of MeHg(II), $^-SCH_2CO_2^-$, and H^+ are given in mmol followed by molarity of KOH and initial volume; *A*: 0.07703, 0.08244, 0.17977, 0.09947 *M*, 54.97 mL; *B*: 0.1895, 0.1895, 0.1895, 0.09649 *M*, 100.00 mL; *C*: 0.2051, 0.2051, 0.4144, 0.09837 *M*, 102.00 mL. For titration *A* 5.482 mmol of I^- were present.

[2]During this work the programs ACBA (27) and MUPROT (28) were reported. These serve the same purpose as TITRAT, but do not use the statistically rigorous weighting scheme necessary for titrations in which titrant volumes and pH have comparable uncertainties (26). TITRAT is written in OS/8 BASIC for implementation on a Dec PDC/8E minicomputer and uses 12 K core for 60 titration points and up to 6 parameters refined simultaneously. Listings of the program are available on request.

	log β_{111}	25.33(3)	

[a]At 25°C and 0.3 *M* ionic strength. Mixed constants involving protons have been converted to concentration constants using $-\log \gamma_{H^+} = 0.15$ from the Davies equation (61).

[b]Literature value 16.12 at 20°C and 0.1 *M* ionic strength (4).

[c]Values in italics have been derived from measurement of p*K*'s, e.g. for the acid $MeHgSCH_2CO_2H$, log β_{111} = log β_{110} + (p*K* of $MeHgSCH_2CO_2H$).

[d]Jawaid and Ingman obtained log β_{110} 15.70 ± 0.12 and log β_{111} 24.96 ± 0.08 at 25°C and 1 *M* ionic strength (5).

ytical proton concentrations of the thiol and $MeHg^+/H^+/NO_3^-$ solutions. This may reflect the presence of minute quantities of weakly acid silicate or carbonate impurities in the ionic strength adjustment salt or water, or slow leaching of the borosilicate titration vessel, as has been noted elsewhere (36). Such impurities produce slight buffer action for solutions between pH 5 and 8 but do not significantly affect values outside this range. However, neglect of their presence, but not refining H_{tot}, leads to high values of *U* (residual sum of squares, $\sim 10^{-7}$ to 10^{-6}) and *R* (Hamilton *R* factor, ~0.003 to 0.010). Refinement of H_{tot} often improved the degree of fit indicators, e.g. $U \sim 10^{-12}$ to 10^{-9}, $R \sim 0.0003$ to 0.001, and formation constant error estimates, without significantly altering the constants themselves.

Formation constants of the species MeHgI, MeHgOH, and $(MeHg)_2OH^+$ and protonated forms of thiol were fixed in MINIQUAD 81 refinements of MeHg(II) thiolate formation constants. Ternary complexes of the type MeHgI(SR) were rejected by MINIQUAD 81.

A typical example of fit between experimental and calculated titration curves is shown in Fig. 1.

Results and discussion

Acid dissociation and formation constants

Acid dissociation constants (p*K*) for the ligands are given in Table 1, and agree well with previously reported values. Dissociation constants for the thiol groups are given in italics, but since the potentiometric method yields macroscopic constants the two highest values for L-cysteine, D,L-penicillamine, and glutathione are composite macroscopic constants due to simultaneous dissociation of NH_3^+ and SH groups over the same pH region.

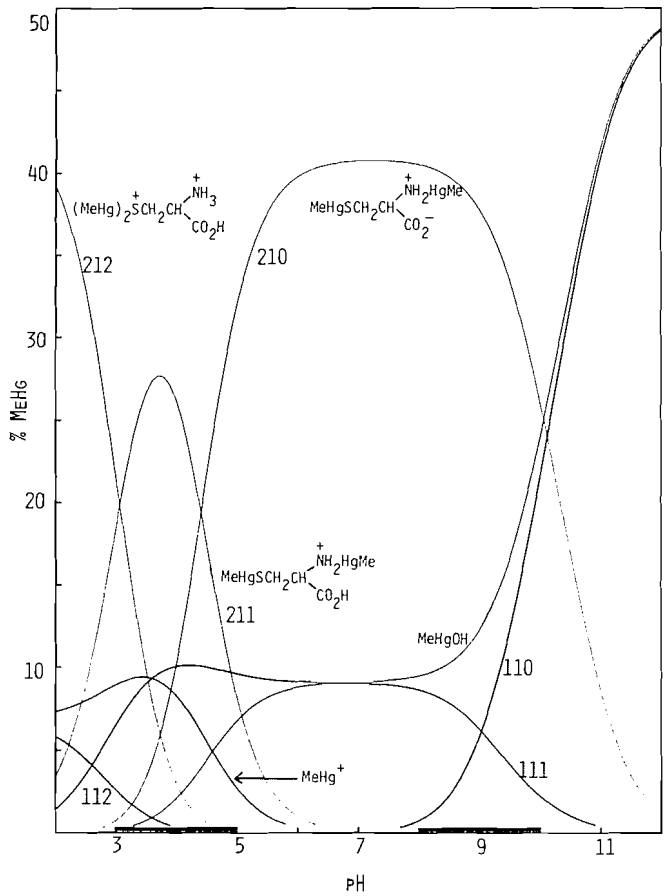

FIG. 2. Species distribution for 0.002 *M* MeHg(II) and 0.001 *M* L-cysteine. The heavy line indicates the pH range of MINIQUAD 81 data. Complex 112: $MeHgSCH_2CH(\overset{+}{N}H_3)(CO_2H)$; 111: $MeHgSCH_2CH(NH_3^+)CO_2^-$; 110: $MeHgSCH_2CH(NH_2)CO_2^-$.

Formation constants for the complexes are given in Table 2, and are in the form log β_{mlh} for equilibria [5], where RS^{n-} represents the fully deprotonated form of the thiol ligand (at pH ca. 12), e.g. 2-mercaptoethanol $^-SCH_2CH_2OH$, L-cysteine $^-SCH_2CH(NH_2)CO_2^-$, and glutathione $^-O_2C(NH_2)CHCH_2CH_2CONHCH(CH_2S^-)CONHCH_2CO_2^-$.

$$[5]\quad m\mathrm{MeHg}^+ + l\mathrm{RS}^{n-} + h\mathrm{H}^+ \rightleftharpoons (\mathrm{MeHg})_m(\mathrm{RS})_l(\mathrm{H})_h^{m+h-nl}$$

$$[6]\quad \beta_{mlh} = \frac{[(\mathrm{MeHg})_m(\mathrm{RS})_l(\mathrm{H})_h^{m+h-nl}]}{[\mathrm{MeHg}^+]^m[\mathrm{RS}^-]^l[\mathrm{H}^+]^h}$$

Thus, the equilibrium constant for equation [1] is described by β_{110}. Dissociation of a proton from a coordinated ligand is usually represented as p*K* of the protonated form of the complex, and may be expressed in terms of β_{mlh}, e.g. for the 2-mercaptoacetic acid complex the dissociation

$$MeHgSCH_2CO_2H \rightleftharpoons MeHgSCH_2CO_2^- + H^+$$

is described by $pK_{111} = \log \beta_{111} - \log \beta_{110}$. Values of log β_{110} are in excellent agreement with the results of Reid and Rabenstein (9), Schwarzenbach and Schellenberg (4), and Jawaid and Ingman (5); and thus support early determinations, involving other biological thiols, by Hughes (2) and Simpson (3).

Sulfhydryl-containing amino acids and peptides

Proton nmr spectroscopic studies indicate that the deprotonated sulfhydryl group of *N*-acetyl-L-cysteine, when coor-

dinated to MeHg(II), is able to coordinate to an additional MeHg(II) group (62); and Rabenstein and Fairhurst (63) obtained ^{1}H nmr evidence for similar binding by glutathione in the pH range 0–4. For glutathione at higher pH nmr spectra suggest binding of the second MeHg(II) group to the amine group (63). Several MeHg(II) and PhHg(II) complexes of L-cysteine and D,L-penicillamine with two organomercury groups have been isolated (8, 64, 65) and a MeHg(II) D,L-penicillamine complex isolated from an aqueous solution has been found from an X-ray crystallographic study to have sulfur and amine bound MeHg(II) groups, $MeHgSCMe_2CH(\overset{+}{N}H_2HgMe)CO_2^-$ (64).

Since the ^{1}H nmr and crystallographic results indicate that complexes of 2:1 stoichiometry have structures that differ with pH, evidence was sought for complexes of these stoichiometries with a representative sulfhydryl containing amino acid, L-cysteine, using the potentiometric approach. Solutions containing L-cysteine with more than one equivalent of MeHg(II) were investigated by titration in the absence of iodide. Under these conditions, the sulfur atom may be regarded as "always coordinated", and equilibria were treated assuming a "ligand" of the form $MeHgSCH_2CH(NH_2)CO_2^-$. The data could be satisfactorily refined to give pK_{110} 8.936 (6) (c.f. 9.01 derived from log β_{110} and log β_{111} (Table 2)), pK_{111} 11.60 (2); and for log $\beta'_{ml'h}$ where $l' = MeHgSCH_2CH(NH_2)CO_2^-$ log β'_{110} 8.800 (7), log β'_{111} 13.221 (13), log β'_{112} 15.67 (12), giving derived values of log β_{210} 25.26 (2), log β_{211} 29.69 (3), and log β_{212} 32.13 (13). Thus, for the equilibrium of interest at low pH

$$MeHgSCH_2CH(\overset{+}{N}H_3)(CO_2H) + MeHg^+ \rightleftharpoons (MeHg)_2\overset{+}{S}CH_2CH(\overset{+}{N}H_3)(CO_2H)$$

$$\log K = \log \beta_{212} - \log \beta_{112} \approx 4.1$$

and at higher pH

$$MeHgSCH_2CH(NH_2)CO_2^- + MeHg^+ \rightleftharpoons MeHgSCH_2CH(\overset{+}{N}H_2HgMe)CO_2^-$$

$$\log K = \log \beta_{210} - \log \beta_{110} = 8.8$$

Formation constants for complexes of the type $(MeHg)_2\overset{+}{S}R$ have not been previously reported, but for the proposed equilibrium at higher pH the value of 8.8 compares well with those of 7.88 (ref. 66) and 7.55 (ref. 33) for interaction of MeHg(II) with glycine to form $^-O_2CCH\overset{+}{N}H_2HgMe$. A species distribution diagram (Fig. 2) calculated for a 2:1 ratio of MeHg(II):L-cysteine at 0.002 *M* MeHg(II) illustrates occurrence of these complexes in different pH ranges and, depending on pH, presence of appreciable proportions of the complexes of 1:1 stoichiometry.

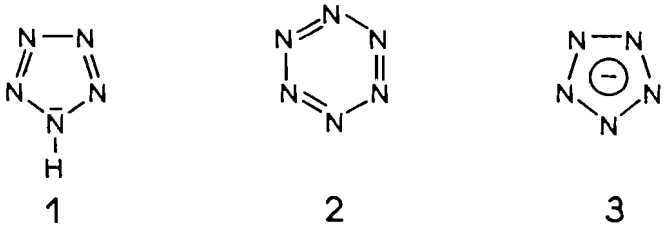
La méthode "*ab initio*" LCAO-SCF-MO avec la base 4-31G a été utilisée pour étudier le supersystème N_5^-. Les trois structures possibles (ion azoture + azote moléculaire, ion pentazène et ion pentazole) et leurs chemins de réaction ont été calculés. L'anion du pentazole est moins stable que les réactifs N_3^- + N_2, mais beaucoup plus stable que l'anion du pentazène; il pourrait constituer un objectif synthétique raisonnable. Les énergies d'activation des différents chemins ont été comparées à celles du supersystème neutre N_5H.

MINH-THO NGUYEN, MICHEL SANA, GEORGES LEROY, and JOSE ELGUERO. Can. J. Chem. **61**, 1435 (1983).

"*Ab initio*" LCAO-SCF-MO calculations using the 4-31G basis set were carried out in order to study the supersystem N_5^-. The three possible stable structures (azide ion + molecular nitrogen, pentazene ion, and pentazole ion) and their reactions paths were calculated. The pentazole anion is less stable than the reagents N_3^- + N_2, but much more stable than the pentazene anion; it could constitute a reasonable synthetic target. The activation energies of the different paths were compared with those of the neutral supersystem N_5H.

Introduction

Au cours de deux précédents travaux nous avons examiné théoriquement le cas de deux molécules aromatiques situées à la frontière de la chimie inorganique et de la chimie organique: le pentazole N_5H **1** (1) et l'héxazine N_6 **2** (2).



1 2 3

L'objet du présent travail est double: d'une part, étudier théoriquement la structure de l'anion pentazole **3**; d'autre part, examiner sa réactivité en vue de déterminer si l'anion **3** est un objectif synthétique plus réaliste que le pentazole **1**. Parallèlement, nous voulions établir si l'anion pentazole était susceptible d'intervenir dans un mécanisme de fixation de l'azote moléculaire.

Méthode

Tous les calculs ont été effectués par la méthode "*ab initio*" LCAO-SCF-MO. Etant donné le caractère d'ions négatifs des molécules à étudier, la base 4-31G a été choisie (3). Elle permet dans le cas présent d'obtenir des orbitales HOMO d'énergie négative. Les optimisations des géométries ont été effectuées de façon itérative; la précision obtenue est estimée à 0,03 Å sur les distances et 3° sur les angles. Dans ce travail, nous ne tiendrons pas compte des erreurs de superposition dont l'existence est souvent admise dans de tels calculs, en base limitée. En effet, les procédés utilisés pour évaluer ces erreurs de superposition sont sujets à caution lorsque la géométrie du supersystème est fort différente de celle des espèces isolées, ce qui est précisément le cas ici.

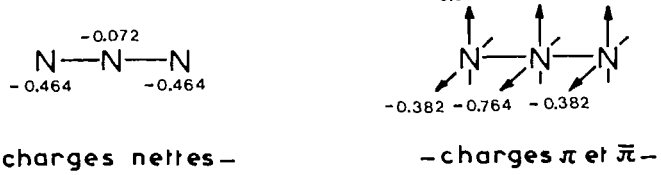
Discussion

1. *Les molécules isolées*

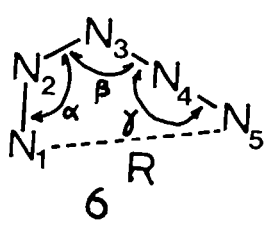
La figure 1 représente les trois formes de la supermolécule N_5^-: ion azoture **4** + azote moléculaire **5**, ion pentazène **6** et ion pentazole **3**.

Le tableau 1 confronte, pour la géométrie de l'ion azoture, les résultats du calcul avec l'expérience. Sa structure électronique est celle d'un dipôle-1,3 de type propargyle, selon la classification d'Huisgen (6). Cependant, les centroïdes de



charge (7) indiquent que chaque liaison NN est de nature triple et la formule de structure correspondante suggère l'existence de deux liaisons adjacentes à 6 électrons. En fait, comme certains d'entre nous l'ont démontré (8), une intégration de la densité électronique dans le domaine compris entre deux plans passant par les atomes d'azote terminaux indique la présence de 10 électrons, au lieu de 12, autour de l'atome d'azote central.

La structure de la molécule d'azote **5** a été discutée dans notre travail sur le pentazole (1). Quant à l'anion pentazène **6**, nous donnons ci-dessous sa géométrie optimisée.

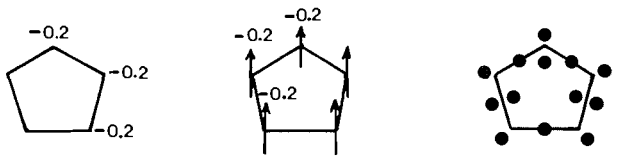


R = 2,87 Å
N_1N_2 = 1,23 Å
N_2N_3 = 1,41 Å
N_3N_4 = 1,25 Å
N_4N_5 = 1,13 Å

α = 110°
β = 107°
γ = 185°

Nous constatons que la liaison N_3N_4 dans l'anion **6** (1,25 Å) a un caractère double plus marqué que dans la pentazène, où elle est quasi simple (1,32 Å (1)); cette différence de structure est due à la délocalisation de la charge négative de l'anion N_5^- sur le squelette moléculaire. Ceci mis à part, la distribution des centroïdes de charge est semblable dans le pentazène et dans son ion négatif.

Finalement, l'anion pentazole **3**, de symétrie D_{5h}, a une distance NN de 1,32 Å et un angle interne de 108° dans sa géométrie d'énergie minimum. Sa structure électronique peut se résumer comme suit :



2. *Les chemins réactionnels*

a. Cycloaddition de l'anion azoture sur l'azote moléculaire (**4** + **5** → **3**)

L'ion azoture intervient dans des réactions de cycloaddition dipolaire-1,3 face à des dipolarophiles conventionnels, tels les nitriles (formation de tétrazoles (9)). La réaction avec l'azote moléculaire n'a pas été signalée. Etant donné la parfaite symétrie des réactifs, nous avons imposé la symétrie C_s à la supermolécule. Les paramètres de structure calculés le long du chemin de réaction sont reunis dans le tableau 2.

L'approche des réactifs est coplanaire (τ = 0°) et l'état de transition se situe aux alentours de R = 1,85 Å le long de la coordonnée de réaction comme dans le cas du supersystème neutre "acide hydrazoïque + azote moléculaire" (1). Dans le complèxe activé, le transfert de charge vers le dipolarophile atteint une valeur de 0,38 électrons en base 4-31G. La réaction est endothermique, les réactifs isolés sont plus stables de 15,6 kcal mol^{-1} que l'anion du pentazole. La barrière d'activation est égale à 55,9 kcal mol^{-1} (dans le sens **4** + **5** → **3**). Même si la base 4-31G a tendance à augmenter la barrière d'activation par rapport à celle obtenue en base minimale STO-3G, la valeur trouvée pour le système N_3^- + N_2 est notablement plus haute que celle calculée pour d'autres cycloadditions dipolaires-1,3 (moins de 35 kcal mol^{-1} (10)).

b. Décomposition des dipoles-1,5 : cas de l'anion pentazène (**6** → **4** + **5**)

Cette réaction fait partie d'un vaste ensemble, dans lequel on peut inclure les transpositions de Curtius et de Wolff (11). Sur la figure 3 sont représentés les paramètres de structure retenus dans le calcul du chemin de réaction. Dans le sens inverse *b'* (**4** + **5** → **6**) il correspond à l'addition nucléophile du dipole-1,3 sur la molécule d'azote.

La distance r est choisie comme coordonnée de réaction. Nous n'avons imposé aucune contrainte sur la distance R', en fait, cette distance n'est pas directement optimisée car elle est dépendante des autres paramètres de structure. Pour tous les

points du chemin de réaction, l'optimisation de la géométrie conduit à des valeurs nulles pour les angles δ et σ ; tous les atomes restent dans un même plan. Les résultats obtenus sont reportés dans le tableau 3.

Etant donné la taille importante de la supermolécule, les paramètres du tableau 3 ne sont que partiellement optimisés en base 4-31G. Notons que les angles α et γ diminuent (le dernier restant toujours supérieur à 180°), tandis que l'angle β et les longueurs des liaisons augmentent. Energétiquement, l'anion du pentazène se décompose exothermiquement (~84 kcal mol^{-1}) à une distance r = 1,60 Å avec une barrière d'activation de l'ordre de 17 kcal mol^{-1}. En vue de comparer ce résultat à celui du pentazène (STO-3G : ΔH_R = 43,1 kcal mol^{-1}, $\Delta E^{\neq}$ = 2,5 kcal mol^{-1} (1)), nous avons recalculé en base 4-31G quelques points du chemin de décomposition de ce dernier. Les résultats en base étendue confirment ceux obtenus en base minimale : la barrière à la décomposition du pentazène reste d'environ 1 kcal mol^{-1}. Bien que les chaleurs de décomposition en base 4-31G pour le pentazène et son anion sont proches (−78 et −84 kcal mol^{-1}) en raison de la différence importante entre les deux barrières d'activation nous pouvons admettre que l'anion pentazène est beaucoup plus stable que le composé neutre.

L'analyse des mouvements électroniques en termes de centroïdes de charge est voisine de celle décrite pour la molécule neutre (1). La principale différence est que dans la réaction $HN_3 + N_2 \rightarrow N_5H$, l'analyse de population de Mulliken montre qu'en tout point du chemin de réaction le transfert de

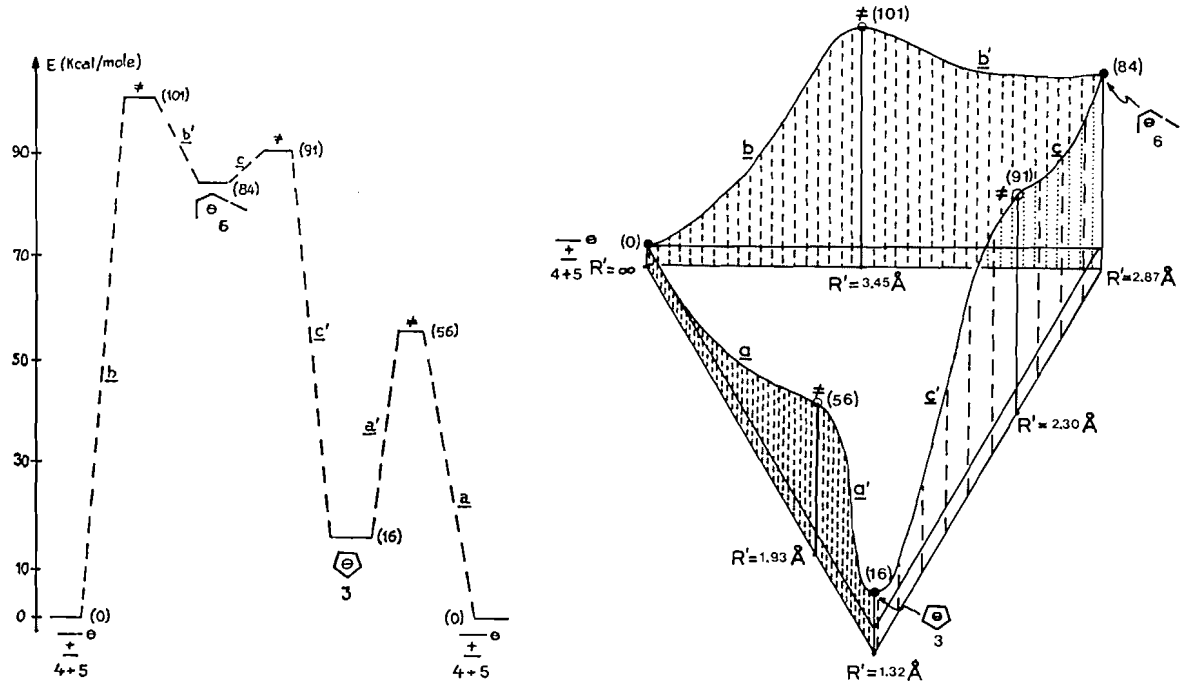

FIG. 5. Energies relatives des points caractéristiques des chemins de réaction du système N_5^- (kcal mol^{-1}, valeurs entre parenthèses).

charge s'effectue de la molécule neutre vers le dipôle-1,3 (le transfert est maximum à l'état de transition, r = 1,34 Å, et vaut, en base 4-31G, 0,15 électrons), tandis que dans le système $N_3^- + N_2 \rightarrow N_5^-$, le transfert de charge se fait de l'anion azoture **4** vers la molécule d'azote **5** et vaut 0,04 électrons à l'état de transition. Cette différence de comportement entre HN_3 et N_3^- est une conséquence de la charge négative de l'ion azoture. En langage chimique usuel, *dans le supersystème neutre, l'entité nucléophile est l'azote moléculaire tandis que dans le supersystème anionique c'est l'ion azoture qui joue ce rôle.*

La différence entre les voies "concertée" *a* et "non concertée" *b* est que dans la première il y a formation de deux liaisons σ distinctes N_1N_5 et N_3N_4 et dans la seconde d'une liaison σ et d'une liaison π entre les deux centres N_3 et N_4.

c. Cyclisation des dipôles-1,5 : cas de l'anion pentazène (**6** → **3**)

Dès les travaux pionniers de Reimlinger en 1970 (12), les cyclisations électrocycliques-1,5 ont reçu une attention considérable comme source d'hétérocycles pentagonaux (13, 14). Dans le cas particulier des anions des dipôles-1,5 on doit citer, par exemple, l'obtention d'anions tétrazoliques par cyclisation d'anions d'azidoimines (15, 16);[4] plusieurs de ces travaux signalent qu'en milieu neutre la forme dipôle-1,5 est stable tandis qu'en milieu basique la forme tétrazole est largement favorisée.

Le chemin de réaction correspondant à la fermeture de l'anion pentazène N_5^- en anion pentazole a été partiellement optimisée en base double 4-31G ; les paramètres de structure et les énergies associées sont reportés dans le tableau 4. Nous avons utilisé le jeu de paramètres défini sur la figure 4. L'optimisation montre que les atomes d'azote restent dans un même plan tout le long du chemin de réaction ($\sigma \cong 0$), le processus d'électrocyclisation est donc planaire.

L'état de transition se situe à R' = 2,30 Å; la barrière d'activation et la chaleur de réaction valent respectivement 7,5 et −68,4 kcal mol^{-1} par rapport à l'ion pentazène. Si nous comparons ces valeurs à celles de la réaction "pentazène → pentazole" calculées en base 4-31G avec la géométrie optimisée en base STO-3G (1): 9,6 kcal mol^{-1} pour $\Delta E^{\neq}$ et −24,8 kcal mol^{-1} pour ΔH_R, nous remarquons que si les barrières d'activation sont du même ordre de grandeur, par contre la différence entre les chaleurs de réaction est énorme. La stabilisation de la forme cyclique par rapport à la forme ouverte est de 43,6 kcal mol^{-1} en passant de la molécule neutre à son anion. Cette stabilisation nous suggère que la délocalisation de la charge négative sur le cycle rend l'anion plus "aromatique" que la molécule neutre.

Au total, ces résultats sont en accord avec l'expérience qui montre que sous forme anionique l'équilibre forme ouverte/forme fermée se déplace vers la forme cyclique (15, 16).[4]

3. *Le bilan énergétique de la supermolécule* N_5^-

Sur la figure 5, nous donnons le profil énergétique de différentes réactions de la supermolécule N_5^- calculée en base double 4-31G.

Les réactifs ($N_3^- + N_2$) restent le système le plus stable, mais la différence d'énergie entre ce dernier en l'anion pentazole **3** n'est que de 16 kcal mol^{-1} au lieu de 54 kcal mol^{-1} dans le système neutre (1). Contrairement au cas du pentazène (1), la décomposition de l'ion pentazène **6** via l'ion pentazole **3** (voie $c-a'$) est favorisé par rapport à sa décomposition directe (voie b'). L'anion pentazole **3** se décompose à son tour en suivant le chemin de cycloreversion a' et la barrière d'activation est nettement plus grande (40 kcal mol^{-1}) que celle de la molécule de pentazole (6 kcal mol^{-1} (1)). Ces résultats nous montrent que l'anion pentazole **3** est plus stable que la molécule neutre, comme il arrive pour d'autres anions cycliques ; ainsi les aza[13] annulènes ont une structure polyènique tandis que l'anion aza[13] annulenyl possède toutes les caractéristiques d'une molécule aromatique (17). Selon nos calculs, il est raisonnable d'admettre que les cycles pentagonaux sont suffisamment grands pour que cette règle soit valable. Signalons

[4]Voir aussi ref. 9, p. 402.

pour terminer que la différence de stabilité entre le pentazole **1** et son anion **3** indique que le premier doit être un composé très acide en solution davantage même que le tétrazole (pK_a = 4,90 (18)).

Conclusion

Les résultats obtenus par le calcul montrent que si l'anion du pentazole **3** n'est pas une entité moléculaire suffisamment stable pour être utilisée pour la fixation de l'azote moléculaire, elle constitue néanmoins un objectif synthétique réaliste. Sa mise en évidence pourrait se faire par échange isotopique, en traitant l'ion azoture marquée à l'azote 15 par un grand excès d'azote moléculaire $^{14}N-^{14}N$ à très haute pression. La formation d'un intermédiaire pentazolique **3** se traduirait par l'échange $^{15}N/^{14}N$ au niveau de l'ion azoture :

$$^{15}N_3^- + {}^{14}N_2 \rightleftharpoons [\mathbf{3}] \rightleftharpoons {}^{14}N_3^- + {}^{15}N_2$$

Ce type d'expériences a été utilisée avec succès par Zollinger (19) pour démontrer l'existence d'un équilibre reversible $PhN_2^+ \rightleftharpoons Ph^+ + N_2$. Une autre possibilité sérait de pieger l'anion **3** sous forme de complèxe π, par exemple, avec du manganèse-tricarbonyle **7** ou avec du fer-cyclopentadienyle **8**. Dans les deux cas, les analogues monoazotés (dérivés de l'anion du pyrrole) sont connus (20).

An investigation of the biphasic kinetics observed during the hydroxide ion-catalyzed hydrolysis of alkyl dithioesters[1]

A. C. STORER

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received October 4, 1982

A. C. STORER. Can. J. Chem. **61**, 1440 (1983).

Kinetic evidence is presented for the establishment of an equilibrium, in dilute aqueous alkaline solutions, between alkyl dithioesters and a species **I**. The species **I** is formed either by the extraction of a proton from, or by the addition of an hydroxide ion to, the dithioester. In the former case **I** would be an anion (probably an enethiolate) formed by the removal of a proton from the α-carbon atom, and in the latter case **I** would be a stabilized tetrahedral intermediate formed by the addition of an hydroxide ion to the thiocarbonyl carbon atom. It has not been possible, using kinetic evidence alone, to distinguish conclusively between these two possibilities. However, using the available evidence, arguments are presented in favor of **I** being an enethiolate anion.

A. C. STORER. Can. J. Chem. **61**, 1440 (1983).

On présente des preuves cinétiques de l'équilibre qui s'établit entre des dithioesters d'alkyle et une espèce **I** en solution alcaline aqueuse diluée. L'espèce **I** se forme soit par élimination d'un proton du dithioester, soit par addition d'un ion hydroxyde sur la dithioester. Dans le premier cas, l'espèce **I** serait un anion (probablement un enethiolate) formé par l'élimination d'un proton de l'atome de carbone en position α et dans le deuxième cas, l'espèce **I** serait un intermédiaire tétraédrique stabilisé formé par l'addition d'un ion hydroxyde sur l'atome de carbone du thiocarbonyle. A partir de cette preuve cinétique uniquement il n'est pas possible d'établir une distinction entre ces deux possibilités. Cependant, à partir des preuves disponibles, on présente des faits qui tendent à prouver que l'espèce **I** est un anion enethiolate.

[Traduit par le journal]

Introduction

In this laboratory extensive studies are underway on the cysteine protease catalysed hydrolysis of thionoesters (1–3). The reaction pathway for these enzymes and substrates involves a dithioacyl enzyme intermediate, the hydrolysis of which can be followed spectrophotometrically (1). In order to compare the hydrolysis of these intermediates with that of the more normal thioacyl enzyme intermediates it is first necessary to compare the base catalysed hydrolysis of simple alkyl dithio- and thiolesters.

Extensive reports have appeared in the literature concerning the base catalysed hydrolysis of esters and thiolesters (e.g. refs. 4–16) and a limited amount of work using thionoesters has been reported (17–20). However, only three reports, none of which contain kinetic analyses, could be found concerning the base catalysed hydrolysis of dithioesters (21–23). According to Sakurada (21), the action of aqueous alkali on ethyl dithioacetate leads to the production of dithioacetic acid, however, two other studies (22, 23) report that thiol acids are produced by dithioester hydrolysis. The conflicting nature of these studies is most probably a reflection of their limited nature and also the high acidity of the α-CH protons of alkyl dithioesters. This acidity is responsible for side reactions at high concentrations of the dithioester (see below).

Nucleophilic displacement reactions involving esters, thiolesters, or thionoesters and hydroxide ions are thought to proceed via the formation of tetrahedral intermediates. However, few examples are available, in the literature, that provide evidence for the existence of such intermediates (13). Concurrent hydrolysis and isotopic oxygen-exchange reactions have been shown to occur in alkaline solutions of esters enriched in carbonyl-^{18}O (10–12, 15), and sulfur–oxygen exchange has been observed during thionoester hydrolysis (17, 18). These observations are consistent with a mechanism involving the formation of a tetrahedral intermediate. Evidence for the existence of such intermediates can also be inferred from the existence of stable salts formed by the addition of sodium methoxide to ethyl trifluoroacetate in di-n-butyl ether (24) and to methyl trifluoroacetate in methanol (25).

The α-CH acidity of the various oxygen and sulfur esters is in the order dithioester > thiolester > ester (26–32). Due to the small amount of information available on the α-CH acidity of thionoesters, they are not included in this comparison (33). The rate constant for the abstraction of an α-hydrogen atom by an hydroxide ion from ethyl thiolacetate has been determined to be 0.0067 $M^{-1} s^{-1}$ and the equivalent rate for methyl acetate has been estimated to be $\simeq 0.0005\ M^{-1} s^{-1}$ (30). Thus, the rate for the thiolester is approximately an order of magnitude greater than that for the oxygen ester. No such measurements have been made for thiono- or dithioesters.

Thiocarbonyl compounds are generally less stable than their oxygen analogues because sulfur does not easily form a double bond to a carbon atom. Stabilization of thiocarbonyls can occur by enethiolization if there is at least one α-hydrogen atom. This mechanism for stabilization is commonly found among simple thiones, e.g. thioketones. In contrast to this, dithioesters at neutral pH are generally quite stable in the thione form, as confirmed by spectroscopic methods (34, 35). However, dithioesters with relatively acidic α-CH protons, i.e. $CH_3CH_2OCOCH_2CSSCH_2CH_3$ (34–37) and CH_3COCH_2-$CSSCH_2CH_3$ which has a pK of 6.85 (28), are readily decolorized by bases and this is thought to be due to the formation of enethiolate anions (36–38).

This communication contains the results of a kinetic study of the reaction of hydroxide ions with several alkyl dithioesters. The results can be explained by the rapid attainment of an equilibrium between the dithioesters and a species (**I**) formed either by the extraction of a proton from, or by the addition of an hydroxide ion to, the dithioester. This equilibration is then followed by a slower hydrolysis of the dithioester and/or the species **I**. The study was facilitated by the fact that dithioesters have a strong absorption peak at around 305 nm and they are sufficiently soluble in aqueous solution.

TABLE 1. The dithioesters used in this study

Compound	Structure
1 Methyl dithioacetate	$CH_3-C(=S)-S-CH_3$
2 Ethyl dithioacetate	$CH_3-C(=S)-S-CH_2CH_3$
3 Methyl dithiopropionate	$CH_3-CH_2-C(=S)-S-CH_3$
4 Ethyl dithio-isobutyrate	$(CH_3)_2CH-C(=S)-S-CH_2CH_3$
5 Ethyl dithiotrimethylacetate	$(CH_3)_3C-C(=S)-S-CH_2CH_3$

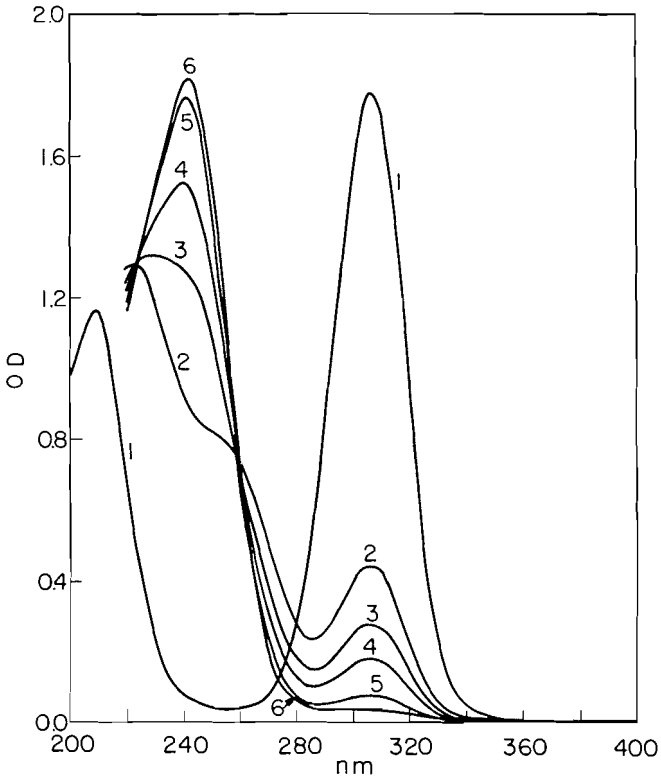

FIG. 1. Absorption spectra of (1) 140 μ*M* ethyl dithioacetate in aqueous solution; and in the presence of 0.1 *M* NaOH at various times after mixing (2) 2 min, (3) 30 min, (4) 60 min, (5) 90 min, and (6) 120 min.

Experimental

The dithioesters listed in Table 1 were synthesized as described by Marvel *et al.* (39) and were obtained as orange-colored oils. The results of elemental analysis agreed with the expected values to within acceptable limits (±0.02 × expected value). All aqueous solutions were prepared using distilled, deionized, boiled water. Base solutions were prepared by diluting the desired quantity of a carbonate-free standard sodium hydroxide solution. Stock solutions of the dithioester were prepared using acetonitrile as solvent such that the final concentration of the nitrile in the reaction mixture was less than 0.5%. Saturated aqueous solutions of dithioester **2** (Table 1) were also used as stock solutions and gave the same results as the acetonitrile solutions, however, the aqueous stock solutions were less stable. The hydrolytic reaction was monitored at 308 nm using a Cary 219 spectrophotometer with the sample compartment thermostated at 20°C.

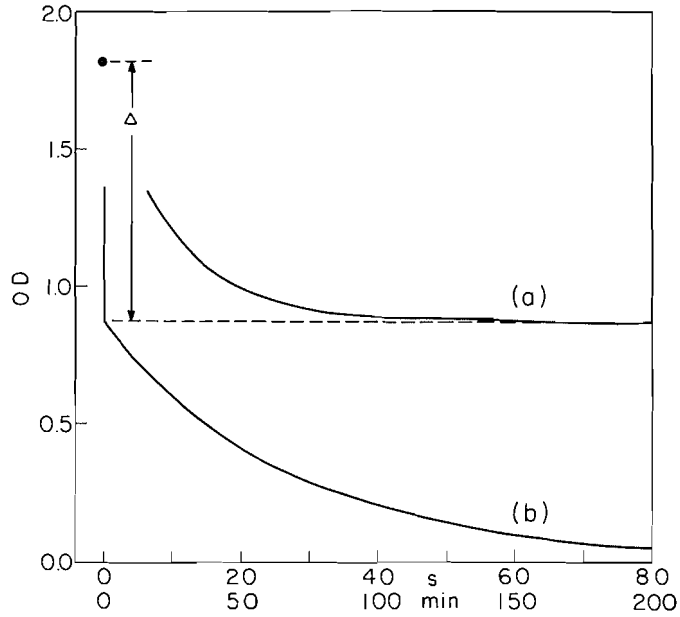

FIG. 2. The variation with the time after mixing of the optical density at 308 nm of an aqueous mixture of 0.032 *M* NaOH and 140 μ*M* ethyl dithioacetate, showing (a) the fast exponential decay and (b) the slow exponential decay.

Due to the small range of hydroxide ion concentrations used, no attempt was made to keep the ionic strength constant as the hydroxide concentration was varied. Papoff and Zambonin (16) have shown that the rates of hydrolysis of methyl and ethyl acetate are not significantly influenced by varying the ionic strength up to 0.5 *M*. The measured rate constants were obtained from plots of log OD against time after correcting for the residual OD after the completion of the reaction. When present, the two kinetic phases were sufficiently separated (Fig. 2) i.e. $k^f_{meas} > 500 \times k^s_{meas}$, that the rate constants were obtained graphically. The straight lines through the data points were obtained by linear least-squares analysis. Acetonitrile (40) and dimethyl sulphoxide (41) were purified before use.

Results

The reactions of the dithioesters with hydroxide ions were carried out at low concentrations of the dithioester, i.e. <1 m*M*. At higher concentrations the reaction mixture became darker in color due to an unwanted side reaction, presumably a Claisen type condensation of the dithioesters (42). On mixing dithioesters **1**, **2**, and **3** with a large excess of sodium hydroxide in aqueous solution a rapid drop is observed in the 308 nm absorption peak of the dithioester (i.e. Figs. 1, 2). This initial drop is complete within two minutes of mixing. The residual absorption at 308 nm then decays away at a much slower rate, being replaced by a product peak at 242 nm. Because of the large difference in the time dependencies of the fast initial drop and the slower decay of the residual absorption peak, both processes can be analysed separately. Rate constants[2] were measured for both the fast decay (k^f_{meas}) and the slow decay (k^s_{meas}) over a range of hydroxide concentrations (e.g. Fig. 3). The constants were obtained from plots of log $(I_t - I_\infty)$ against time (t), where I_t and I_∞ are the OD's, measured at 308 nm, at time t and at the end of the decay, respectively. The plots were linear for more than 90% completion of each process, thus both

[2]The primary pseudo-first-order rate constants, k^f_{meas} and k^s_{meas}, are available, at a nominal charge, from the Depository for Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

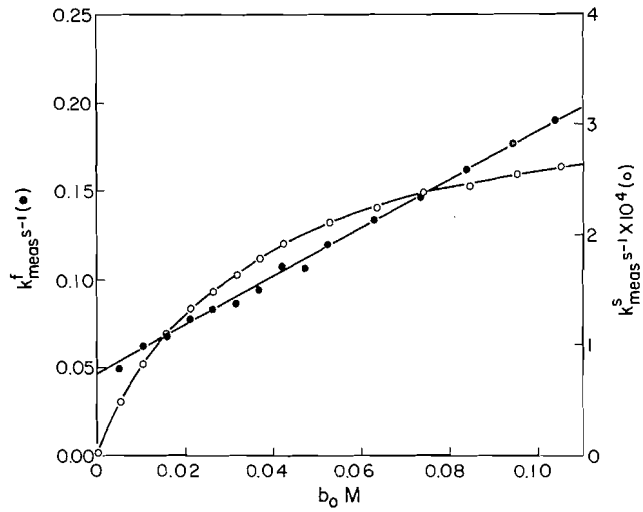

FIG. 3. Plots of k^f_{meas} and k^s_{meas} against the NaOH concentration. The dithioester concentration was 140 μM.

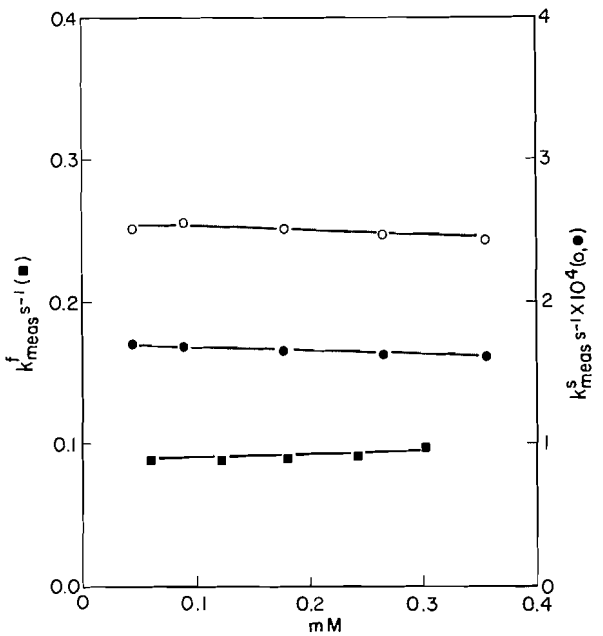

FIG. 4. Plots of (■) k^f_{meas} at 0.032 M NaOH, (•) k^s_{meas} at 0.032 M NaOH, and (○) k^s_{meas} at 0.11 M NaOH as a function of the ethyl dithioacetate concentration.

processes can be defined by single exponential functions. As a check, for some of the reaction mixtures k^s_{meas} values were also obtained by monitoring the appearance of the product peak at 242 nm; in all cases the value of k^s_{meas} obtained was the same as that obtained for the disappearance of the residual dithioester absorption at 308 nm.

From Fig. 3 it can be seen clearly that the magnitude of k^f_{meas} is proportional to the hydroxide ion concentration (b_0) whereas the magnitude of k^s_{meas} is not. At high values of b_0, k^s_{meas} approaches a limiting value that is independent of b_0. Both k^f_{meas} and k^s_{meas} are independent of the dithioester concentration over a modest range (Fig. 4). The reversibility of the first fast step but not of the second slower step can be readily shown by the partial reestablishment of the intensity of the 308 nm absorption peak on neutralization of the base in mixtures of the dithioester and hydroxide ions shortly after mixing (Fig. 5b). The absorption spectra obtained within 2 min of mixing (e.g.

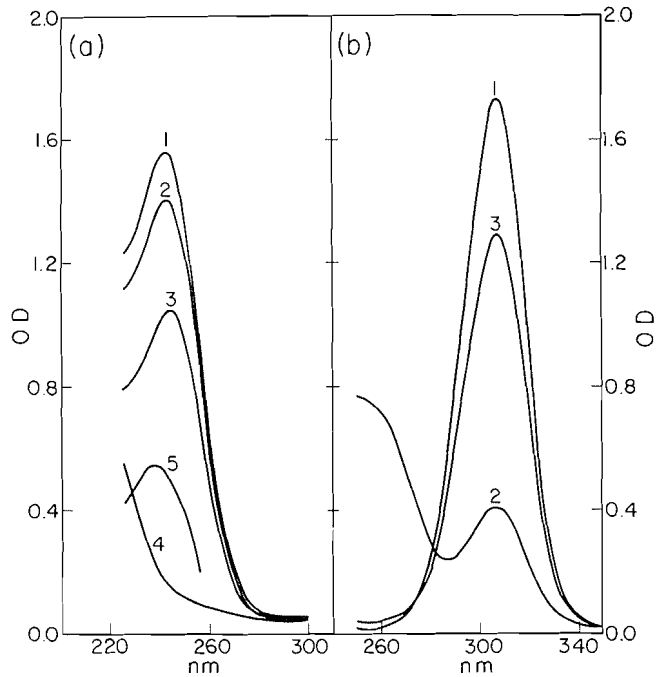

FIG. 5. (a) (1) An absorption spectrum of the products produced in a mixture of 137 μM ethyl dithioacetate and 0.1 M NaOH taken 120 min after mixing; (2) the same spectra after titrating the mixture with concentrated hydrochloric acid to about pH 10, (3) pH 7, and (4) pH 2; (5) the difference spectrum obtained by substracting (3) from (1). (b) (1) The absorption spectrum of a 137 μM aqueous solution of ethyl dithioacetate; (2) the same solution plus 0.1 M NaOH, 2 min after mixing; (3) and after neutralizing the NaOH with hydrochloric acid 10 min after the addition of the NaOH.

Fig. 1) contain mainly features due both to the residual dithioester, i.e. the peak at 308 nm, and to an intermediate, i.e. the peak in Fig. 1 at 223 nm and the shoulder at 258 nm. Because of the slower rate of formation of the final products no significant contributions from them are observed at this time. The peak due to the products at 242 nm is more obvious in spectra obtained at longer times after mixing and is seen to increase in intensity with time. The products were identified as ethyl mercaptan and thiolacetic acid by allowing the reaction to go to completion and then titrating with hydrochloric acid while monitoring the peak at 242 nm (Fig. 5a). At approximately pH 10 there is a drop in the intensity of the products peak and a shift in the λ_{max} to 244 nm. From pH 9 down to pH 4 there is no further change in the absorption spectrum. The peak eventually disappears below pH 4. On subtracting the product spectrum at pH 7 from that obtained prior to any addition of acid, a difference spectrum is obtained (Fig. 5a) which has a λ_{max} at 238 nm. Ethyl mercaptan has a pK of 10.5 (43) and an absorption peak at 238 nm measured for the ionized form, with an extinction coefficient of "approximately 4,000" (44). The predicted absorption at 238 nm for a stoichiometric production of ethyl mercaptide ion from the ethyl dithioacetate in the experiment depicted in Fig. 5a is 0.55; the measured value in the difference spectrum is 0.55. The value of ϵ_{max} for ethyl dithioacetate used in these calculations was $10^{4.1}$ (45). The residual peak at pH 7.0 is very similar to that expected for a stoichiometric production of thiolacetic acid which has a pK of 3.33. The ionized acid has an absorption maximum at 244 nm with an extinct coefficient of $10^{3.9}$. This ϵ_{max} was determined by measuring the OD's of serial dilutions of a stock solution of thiolacetic acid. The predicted optical density at pH 7 in Fig.

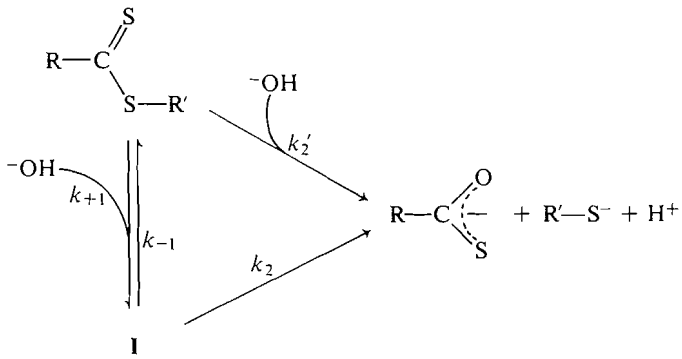
5a is 1.08 and the measured value is 1.05.

The simplest model consistent with an analysis of the results described above is one in which the initial rapid decrease in absorption at 308 nm is due to the establishment of an equilibrium. This equilibrium would be between the dithioester and another species (**I**) formed by the action of hydroxide ion on the dithioester. The equilibrium is coupled with the slower hydrolysis of the dithioester and/or breakdown of **I**, to give mercaptide and thiolacid anions, i.e.



SCHEME 1

The rapid establishment of the equilibrium between the dithioester and **I**, provided that the concentration of hydroxide ion is far in excess of the dithioester and $k^f_{meas} \gg k^s_{meas}$, is given by the equation:

$$[1] \quad \frac{\chi}{\chi_0} = \frac{k_{-1} + k_{+1}b_0 e^{-(k_{-1}+k_{+1}b_0)t}}{k_{-1} + k_{+1}b_0}$$

where χ and χ_0 are the optical densities at 308 nm of the dithioester solution at times t and 0 min respectively, and b_0 is the concentration of hydroxide ions. From eq. [1] the measured rate constant for the fast exponential decay, k^f_{meas}, is given by:

$$[2] \quad k^f_{meas} = (k_{-1} + k_{+1}b_0)$$

Thus Scheme 1 predicts that plots of k^f_{meas} against b_0 for the dithioesters should be linear and yield values for k_{-1} and k_{+1} (Fig. 3, and Tables 2–4). The amplitude of the fast decay, Δ, can be measured directly from the recorder traces (Fig. 2). From eq. [1] it can be shown that:

$$[3] \quad \frac{\chi_0 - \Delta}{\chi_0} = \frac{k_{-1}}{k_{-1} + k_{+1}b_0}$$

Therefore a plot of $(\chi_0 - \Delta)^{-1}$ against b_0 gives a straight line with intercept $1/\chi_0$ and slope K_{eq}/χ_0 where $K_{eq} = k_{+1}/k_{-1}$ (Fig. 6). An equation based on Scheme 1 can also be derived for the rate, k^s_{meas}, of the slow exponential decay. Since the establishment of the equilibrium between the dithioester and **I** is very fast compared with k^s_{meas}, it is not unreasonable to assume that the dithioester and **I** are in equilibrium throughout the course of the slow decay in absorption. This being the case, the desired equation is:

$$[4] \quad \frac{\chi}{\chi_0} = \left\{\exp\left[\frac{-(k_2K_{eq} + k_2')b_0t}{(1 + K_{eq}\cdot b_0)}\right]\right\} \Big/ (1 + K_{eq}\cdot b_0)$$

and k^s_{meas} is therefore given by:

$$[5] \quad k^s_{meas} = \frac{(k_2K_{eq} + k_2')b_0}{(1 + K_{eq}b_0)}$$

The equations show that k^s_{meas} is not expected to be linearly dependent upon b_0 but, as b_0 increases, k^s_{meas} reaches a maximum value that is independent of b_0 (Fig. 3). A plot of b_0/k^s_{meas}

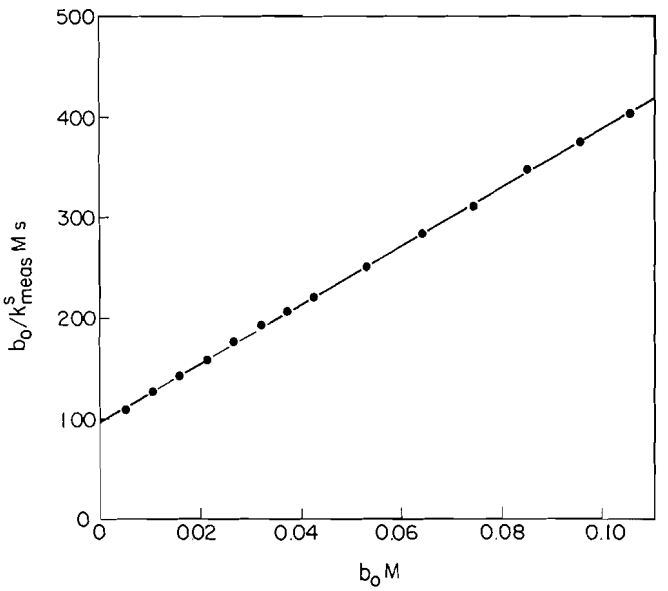

FIG. 7. A plot of b_0/k^s_{meas} against the NaOH concentration. The dithioester concentration was 140 μM.

against b_0 should give a straight line, Fig. 7, from which values for K_{eq} and $(k_2K_{eq} + k_2')$ can be obtained. In order to simplify the discussion of the data only the two limiting cases $k_2 = k_2^0$, $k_2' = 0$ and $k_2 = 0$, $k_2' = k_2^{0'}$ will be considered. Hence the values of k_2^0 and $k_2^{0'}$ given in Tables 2–4 were obtained by alternately applying these assumptions.

Table 2 lists the values of k_{+1}, k_{-1}, k_2^0, $k_2^{0'}$, and K_{eq} obtained in aqueous sodium hydroxide solution for dithioesters **1**, **2**, and **3**. Dithioesters **4** and **5** are insoluble in aqueous solution. A problem arose with measuring k^s_{meas} values for methyl dithioacetate, **1**, in that, due to the high volatility of this dithioester, some is lost from solution by escape from the surface of the liquid, and thus the measured values of k^s_{meas} were too high. To partially overcome this problem and allow for estimates of k_2^0 and $k_2^{0'}$ to be made, an alternative plotting procedure was used to analyse the k^s_{meas} data of **1**. The average of K_{eq} obtained for **1** using k^f_{meas} and Δ (see Table 2) was substituted into eq. [5] and b_0/k^s_{meas} was plotted against $(1 + K_{eq}b_0)$; k_2^0 and $k_2^{0'}$ were then obtained by drawing the asymptote to the plotted line. The amplitude of the fast decay of dithioester **3** was such that in order to determine k_{+1}, k_{-1}, and K_{eq} a lower range of hydroxide ion concentration had to be used. At these lower concentrations of base k^s_{meas} was too slow to be measured accurately, thus no values of k_2^0 and $k_2^{0'}$ were obtained for this dithioester. Table 3 lists the results obtained for dithioesters **2**, **4**, and **5** using a 60% v/v acetonitrile–water mixture in which all three are soluble. For dithioester **4** it was not possible to completely separate k^f_{meas} and k^s_{meas} and so the measured rate constants represent some combination of the two. Immediately after mixing dithioester **4** with base in CH_3CN/H_2O a spectrum similar to that for the intermediate formed from **1** is obtained; however, this is soon lost under a product peak. For dithioester **5** in CH_3CN/H_2O there was no significant decrease in the dithioester absorption over a period of two hours. Table 4 contains the constants obtained for the alkaline hydrolysis of **2** in various DMSO–water mixtures and for **4** and **5** in 60% v/v

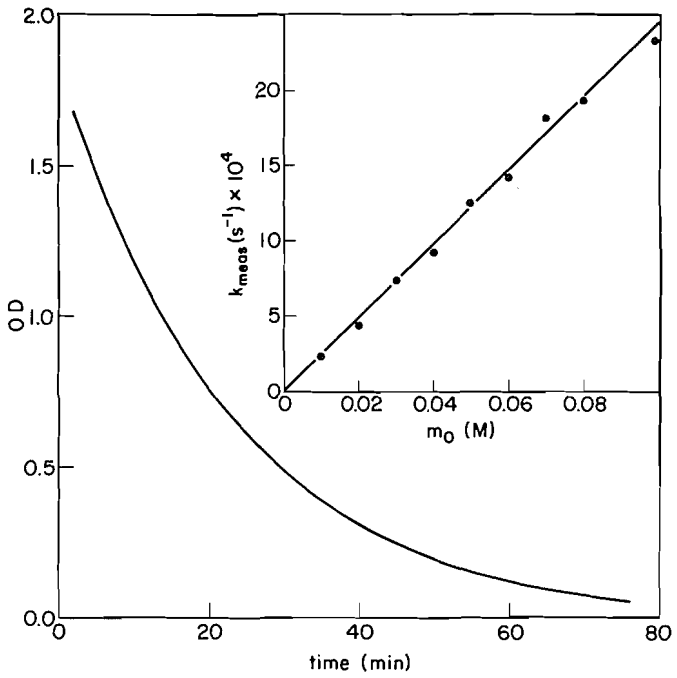

FIG. 8. The variation with the time after mixing of the optical density at 306 nm of a methanolic solution of 0.03 *M* CH_3ONa and 140 μM ethyl dithioacetate. The insert shows a plot of the measured rate constant for this reaction as a function of the methoxide concentration.

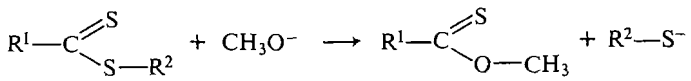
DMSO–water. At above 40% v/v DMSO it becomes impossible to measure k^s_{meas} for dithioester **2** because of the increased amplitude of k^f_{meas}. Eventually k^f_{meas} becomes too fast to be measured by the techniques used in this study (i.e. at >70% DMSO). Log–log plots of the kinetic constants for **2** against the % v/v of water give straight lines with slopes −3.96, 1.25, 4.07, and −4.06 for k_{+1}, k_{-1}, k_2^0, and $k_2^{0'}$ respectively. The significance, if any, of these values is unknown; however, using the plots it is possible to predict values for k_{-1}, k_2^0, and $k_2^{0'}$ for dithioester **2**, in 60% v/v DMSO. These values are included in Table 4. For dithioesters **4** and **5** in 60% v/v DMSO, only single exponential processes were involved in the disappearance of their absorbance at 308 nm. The rate constants for these processes are also given in Table 4. For dithioester **2** in H_2O, CH_3CN/H_2O, and $DMSO/H_2O$, it was possible to demonstrate the reversibility of the initial fast phase of the reaction by neutralizing the base with hydrochloric acid. For dithioester **2** in all solvent systems this reversion was rapid. For dithioester **4**, since k^f_{meas} and k^s_{meas} have similar values in CH_3CN/H_2O, only a partial reversion was observed. This reversion was more extensive in $DMSO/H_2O$. However, in both solvent systems the reversion was much slower than for dithioester **2**. In $DMSO/H_2O$, for dithioester **4**, the slow reversion appeared to be independent of excess HCl (up to 0.3 *M*) and had a rate of 0.0024 s^{-1}. The reaction of dithioester **5** with hydroxide ions in $DMSO/H_2O$ was not perceptibly reversed by the addition of HCl. Due to the uv absorbance of DMSO it was not possible to detect any intermediate formation by absorption spectroscopy. However, in CH_3CN/H_2O, features were observed for dithioesters **2** and **4** that correspond to those observed for the intermediates formed from dithioesters **1**, **2**, and **3** in aqueous solution.

The reaction of the dithioesters with sodium methoxide in methanol proceeds with a single exponential decay (Fig. 8) of the dithioester absorption coupled with an increase in absorption of a product peak at 235 nm. For dithioester **2**, after the completion of the reaction the product peak was titrated with aqueous HCl. A partial decrease in intensity of the peak was observed, presumably corresponding to the titration of ethyl thiolate anions. The residual peak which remained even at very low pH had a λ_{max} of 238 nm and corresponded both in position and intensity to that expected for a stoichiometric production of methyl thionoacetate (λ_{max} 238 nm, ϵ_{max} $10^{3.9}$ in CH_3OH). The scheme for the reaction of the dithioesters with methoxide ions in methanol is therefore:



No evidence was obtained for either an intermediate or a reversible step in the reaction. The rate constants obtained for all five dithioesters are given in Table 5. The reaction of **5** with methoxide ions is extremely slow and only an estimate of the upper limit for the rate constant was obtained.

TABLE 5. Reaction with sodium methoxide in methanol at 20°C

Discussion

The consistency of the results presented above with those predicted by Scheme 1 and eqs. [1] and [4] provides ample evidence for the existence, in basic solutions, of at least one anionic species in equilibrium with the dithioesters. Rate constants have been obtained for both the formation and breakdown of this anion and values for the equilibrium constant (K_{eq}) for several of the dithioesters have been obtained by different routes. The similarity in the values of K_{eq} and the consistency of the kinetic behaviour with that predicted by Scheme 1 does not exclude the possibility that more than one anion is in equilibrium with the dithioester. However, since no evidence is available for more than one anion, Scheme 1 is the simplest that is fully consistent with the available data.

The kinetic constants (k_2^0 and $k_2^{0'}$) defining the slow exponential decay in Tables 2–4 were obtained by alternately applying limiting conditions to eq. [5], i.e. $k_2 = k_2^0$, $k_2' = 0$ and $k_2 = 0$, $k_2' = k_2^{0'}$. These limiting conditions correspond to two possible explanations for the nature of the anionic species **I**. In the first **I** would be a stabilized tetrahedral intermediate and in the second it would be an enethiolate ion. The two possibilities will be discussed separately.

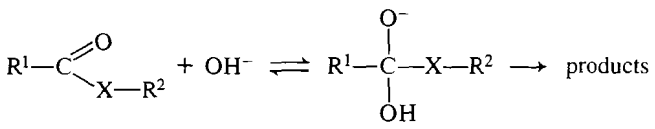
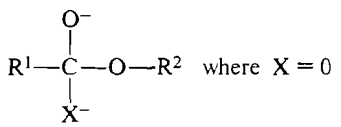
Tetrahedral intermediate

By analogy with esters (7, 10–13, 15, 24, 25), thiol esters (14, 15), and thionoesters (17–19) it seems reasonable to assume that dithioesters hydrolyse via a tetrahedral intermediate. The tetrahedral intermediate for esters and thiolesters is generally thought to be a monoanion:

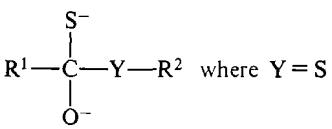


where X = O or S. The base catalysed carbonyl oxygen exchange observed for esters (7, 10–12, 15) and thiol esters (15) is explained by the reversible nature of the addition of the base to the ester coupled with a prototropic shift between the two oxygen atoms. At high concentrations of base it has been proposed that the tetrahedral intermediate formed during ester hydrolysis deprotonates to give a dianion (16):



A similar dianion (X = S) has been proposed to account for the pH dependent changes in the O/S exchange observed during the base catalysed hydrolysis of thionoesters (17–19). For ethyl thionobenzoate a value of 12.5 has been proposed for the pK_a for the formation of the dianion from the monoanionic tetrahedral intermediate. It has been pointed out (46) that the assignment of this pK_a value may be in error since it relies on the assumption that the rates of product formation from the monoanion and the dianion are equal. Plots of the product distribution patterns, which depend upon the degree of O/S exchange, for benzoylthionocholine and its dimethylamino analog have midpoints at approximately pH 10 (19). For some thionoesters the extent of O/S exchange is only diminished at the higher pH's (17–19). This is because their alkoxide anions (CH_3CH_2OH, pK 15.9 (18); $(CH_3)_2N\,CH_2CH_2OH$, pK 15 (19)) have similar leaving group abilities to the sulfur dianion (S^{2-}, p$K \simeq 15$). No O/S exchange is observed at high pH for benzoyl thionocholine since the choline anion (pK 13.9) is a better leaving group than the sulfur dianion. It is believed therefore that the lack of any observed O/S exchange for the dithioesters is explained by the formation of a dianionic tetrahedral intermediate in the pH range (>11) used in this study coupled with the leaving group ability of the mercaptide anions (p$K \simeq 10.5$).

Although it is highly probable that the hydrolysis of dithioesters proceeds via a dianionic tetrahedral intermediate, there is some evidence that suggests that **I** is not such a species. This evidence is as follows. For esters, thiolesters, and thionoesters the stability of the tetrahedral intermediates formed, monoanionic or dianionic, is such that no accumulation of this intermediate is possible. Therefore if the anionic species, **I**, that accumulates during the hydroxide ion catalysed hydrolysis of dithioesters is a tetrahedral intermediate, this intermediate must possess some stabilizing property that is unique to the structure:



It seems unlikely that this stabilizing property would be absent from the same structure with Y = O. Also if **I** is a tetratrahedral intermediate and if, as seems likely, this intermediate is dianionic for dithioesters, then two equivalents of base would be consumed in the production of **I** and hence plots of k'_{meas} against b_0 should be nonlinear. This is clearly not the case (Fig. 3). The difference in the stability of **I** formed from dithioesters **1** and **3** (Table 2) is difficult to explain if **I** is a tetrahedral intermediate since the change from acetyl to propionyl is only expected to have a small effect on the stability and rates of formation and breakdown of the tetrahedral intermediates formed from these compounds.

Enethiolate ion

The α-CH protons of dithioesters are more acidic than those of the corresponding esters and thiolesters, e.g. the pK_a of $CH_3COCH_2CXYCH_2CH_3$ is 11.0, 9.11, and 6.85 for X = O, Y = O; X = O, Y = S; and X = S, Y = S respectively (28, 32). The contribution of the acetyl group to these pK_a values is quite large, i.e. the pK_a of acetone is ≈20 whereas that of acetylacetone is 9.0 (47). Thus the pK_a of the α-CH protons of simple alkyl dithioesters must be considerably higher than the value of 6.85 given above for $CH_3COCH_2CSSCH_2CH_3$ (28). This latter compound and other relatively acidic dithioesters are readily decolorized by base (34–37), e.g. asymmetric ethyl dithiomalonate is decolorized in sodium acetate solution. The simple alkyl dithioesters studied here are less readily decolorized by base, ie. higher pH's are required to bring about decolorization. However, it is not unreasonable to assume that the mechanism of decolorization is the same for all the dithioesters and that the difference in ease of decolorization is merely a reflection of the differing pK_a's of the dithioesters.

The identification of **I** as an enethiolate anion is supported by the observation that a variation in the nature of the R group in Scheme 1 markedly affects not only the rate but also the extent of production of the enethiolate (Tables 2–4). Substitution of a methyl group for a proton increases the stablility of the double bond and this could account for the increase in the value of the equilibrium constant on going from dithioester **1** to **3**, Table 2. The relative rates of proton abstraction (k_{+1}), normalized for the number of α-CH protons, for dithioesters **1**, **3**, and **4** are 1, 0.64, and 0.02, Tables 2–4 (the value for **4** is an upper limit) and the relative rates for the reverse step (k_{-1}) for dithioesters **1** and **3** are 1.0 and 0.028. The decrease in k_{+1} can possibly be accounted for by an increase in steric hindrance to proton abstraction in the series **1**, **3**, and **4**, whereas the decrease in k_{-1} may be due to an increase in both the steric hindrance and the stability of alkyl substituted double bonds.

Unfortunately the fact that no species **I** was detected for dithioester **5**, which lacks α-CH protons, cannot be used as unequivocal evidence for the identification of **I** as an enethiolate anion. As can be seen from Tables 2–4, as the degree of substitution on the α-C increases, it becomes more difficult to detect **I** because the rate of hydrolysis and the rate of formation of **I** converge. Thus the lack of any detectable species **I** for dithioester **5** could merely be an extension of this convergence to the point where the rate of hydrolysis exceeds the rate of formation of **I**.

From the equilibrium constants in Table 2 it is possible to calculate apparent pK_a's of 12.5 for dithioesters **1** and **2** and of 11.4 for dithioester **3**. These values can be compared with the published value of 6.85 reported for acetyl ethyl dithioacetate (28), the difference of 4.5–5.6 pK units being accounted for by the acetyl group substitution.

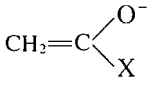
It was not possible to detect any equilibration process in CH_3O^-/CH_3OH mixtures (Table 5, Fig. 8). If a direct ionization of the dithioester is involved, then it can possibly be expected that an equilibrium should be observed in methanol solution. However, on changing solvent a reversal in the relative rates of hydrolysis and formation of **I** may be occurring such that the equilibration process is not observed. The production of thionoesters from dithioesters by the action of methoxide ions in methanol has been reported previously (31).

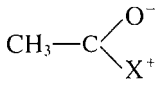
Comparison between dithioesters, esters, and thiolesters

From the arguments presented above it seems that the most probable nature of **I** is that of an enethiolate anion. The subsequent comparisons will be made on the assumption that, in Scheme 1, **I** is an enethiolate anion, $k_2 = 0$, and $k_2^{0\prime}$ represents the hydrolysis of the residual dithioester.

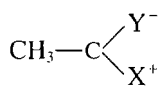
The rate of proton abstraction by hydroxide ions from ethyl dithioacetate in aqueous solution (k_{+1}; Table 2) is 1.36 M^{-1} s^{-1} and the comparable rates for ethyl thiolacetate and methyl acetate are 0.0067 M^{-1} s^{-1} and ≃0.0005 M^{-1} s^{-1} respectively (30). The approximately 10-fold difference in the rates for ethyl thiolacetate and methyl acetate is explained by the increased contribution of the resonance form



in the carbanions produced from thiolesters (30). It is suggested that the difference in the relative contributions of this resonance form is a result of the greater extent of stabilization of oxygen esters by the resonance form (30).



That this resonance form contributes more to the structure of esters than thiolesters can be shown by dipole moment measurements, i.e. oxygen esters have larger dipole moments than their corresponding thiol esters (48). However, similar dipole measurements with dithioesters (48) place their dipole moments between those of the corresponding oxygen and thiolesters. Therefore, although the differences in the rates of proton abstraction from esters, thiolesters, and dithioesters most probably reflects differences in the relative stabilities of the anions formed, no clear correlation can be made to the relative contribution of the form



to the structure of the ester, thiolester, or dithioester. It is felt, however, that the greater polarizability of the thiocarbonyl group over the carbonyl group (49) is an important factor in the increased rate of proton abstraction from dithioesters compared to esters and thiolesters.

The rate constants for the alkaline hydrolysis of the dithioesters are given by the $k_2^{0\prime}$ values in Tables 2–4. In aqueous solution only the rates for methyl and ethyl dithioacetates could be obtained and these rates are very similar. The ratio of the corresponding rates for methyl and ethyl acetate is 0.601 (50). If the assumption is made that dithioester **5** cannot form a species **I**, then the measured rate constant for this compound in Table 4 is $k_2^{0\prime}$ (its hydrolytic rate constant). Therefore the ratio of the base catalysed rates of hydrolysis of dithioesters **2** and **5** in 60% aqueous DMSO is 0.0014 and the ratio for the corresponding oxygen esters in 88% aqueous ethanol is 0.0105 (50). The effects of solvent–water mixtures on the rates measured for ethyl dithioacetate (Tables 3 and 4) are those to be expected based on the solvent effects on the hydrolysis of ethyl acetate (41).

The rate constants for the alkaline hydrolysis of ethyl acetate and ethyl thiolacetate, at 20°C in 62% aqueous acetone solution, are very similar, i.e. 0.029 M^{-1} s^{-1} (5) and 0.026 M^{-1} s^{-1} (4) respectively. The thiolacetate study (4) was conducted at several acetone concentrations, thus allowing an extrapolation of the data to 0% acetone to give a rate constant of approximately 0.06 M^{-1} s^{-1} in aqueous solution. This value compares favourably with that of 0.055 M^{-1} s^{-1} (obtained by extrapolation of rates obtained at higher temperatures in ref. 8) for the alkaline hydrolysis of n-butyl thiolacetate in dilute aqueous solution at 20°C. By interpolating data in ref. 41 it has been possible to obtain a value of 0.08 M^{-1} s^{-1} for the alkaline hydrolysis of ethyl acetate in aqueous solution at 20°C. Therefore the comparable rates for the alkaline hydrolysis of ethyl acetate, ethyl thiolacetate, and ethyl dithioacetate in aqueous solution at 20°C are 0.08, 0.06, and 0.0103 M^{-1} s^{-1} respectively. From these data it appears that there is little difference in the rates of alkaline hydrolysis of ethyl acetate and thiol acetate whereas the dithioester is marginally less readily hydrolysed. The alkaline hydrolysis of the ester and thiolester is thought to proceed via a monoanionic tetrahedral intermediate, whereas in the pH range of this study the dithioester hydrolysis is thought to proceed predominantly via a dianionic tetrahedral intermediate, i.e. in this pH range $k_4 \cdot [OH^-] \gg k_5$. The involvement of this dianionic tetrahedral intermediate in dithioester hydrolysis is not inconsistent with a linear dependence of the rate of hydrolysis on the base concentration. It is stated above that **I** cannot be the dianionic tetrahedral intermediate since $k^{f}_{meas} \propto [OH^-]$, not $[OH^-]^2$; however, the formation of **I** is an equilibrium process and, provided $k_4 \gg k_{-3}$ in the scheme above, then $k_{hydrolysis} = [OH^-] \cdot k_3$.

MAREK J. WÓJCIK and CZESŁAWA PALUSZKIEWICZ. Can. J. Chem. **61**, 1449 (1983).

Infrared spectra of hydrogen-bonded methyl salicylate have been studied in the temperature range 173–293 K, in solutions of various concentrations (in CCl_4) and in the gaseous state. Results show that the molecules form monomeric intramolecular hydrogen bonds in the solid, liquid, and gaseous state. Far-infrared spectra were recorded which give the wavenumber of low-frequency O . . . O mode used in theoretical reconstruction of the band connected with the O—H stretching vibration. The position and especially the width of this band are determined to a large extent by the influence of the environment.

MAREK J. WÓJCIK et CZESŁAWA PALUSZKIEWICZ. Can. J. Chem. **61**, 1449 (1983).

On a étudié les spectres infrarouges du salicylate de méthyle comportant des liaisons hydrogènes en solutions de différentes concentrations (dans le CCl_4) et à l'état gazeux dans un intervalle de température allant de 173 à 293 K. Les résultats révèlent que les molécules forment des liaisons hydrogènes intramoléculaires monomères dans l'état solide, liquide et gazeux. On a enregistré les spectres dans l'infrarouge lointain qui donnent la longueur d'un mode O . . . O de faible fréquence utilisé pour la reconstruction théorique de la raie reliée à la vibration d'élongation du O—H. La position et spécialement la largeur de cette raie sont déterminées dans une large mesure par l'influence de l'environnement.

[Traduit par le journal]

1. Introduction

In a previous paper (1) we have studied infrared spectra of hydrogen-bonded crystalline salicylic acid, acetylsalicylic acid, and deuterium-bonded D-salicylic acid. There are common features in the spectra of closely related salicylic and acetylsalicylic acids. The first has both intra- and intermolecular hydrogen bonds (2, 3) whereas in acetylsalicylic acid (aspirin) intramolecular H-bonds are absent and intermolecular are similar to those in salicylic acid (4).

It was tempting to study another compound derived from salicylic acid in which only intramolecular hydrogen bonds can be formed and intermolecular hydrogen bonds are absent. We were interested to find out whether infrared band of this compound, connected with the O—H stretching vibration (ν_s) would be similar to the band located at 3233 cm^{-1} in the infrared spectrum of the crystalline salicylic acid (1).[2]

We have chosen methyl salicylate which has relatively simple infrared ν_s band. Methyl salicylate is liquid at room temperature and its freezing point is 264.6 K.

To make a direct comparison between ν_s bands of methyl salicylate (liquid) and salicylic acid (crystal), it was necessary to look into changes brought by the change of state and temperature variation. We have recorded infrared spectra of methyl salicylate in the temperature range 173–293 K, both in liquid and solid state. The main question was whether these spectra are due to intra-or intermolecular hydrogen bonds or a mixture of them. We were looking for an answer to this question by investigating spectra of solutions of methyl salicylate in CCl_4, changing concentrations, and by recording spectrum of the gaseous methyl salicylate.

Far-infrared spectra were also recorded to determine the wavenumber of a O . . . O mode necessary for theoretical calculation based on the Witkowski–Maréchal model (5, 6).

2. Experimental

Infrared spectra of the liquid and solid methyl salicylate and its solutions in CCl_4 were recorded on a Digilab model 14 Fourier transform spectrophotometer in the Regional Laboratory of Physico-Chemical Analyses and Structural Research in Cracow.

Samples were placed in cells of variable optical path lengths, with the KRS-5 windows for the medium- and high-frequency region and the polyethylene windows for the low-frequency region. Spacers used varied between 0.025 and 3.0 mm. Empty cells or cells with the solvent were used as a reference. Liquid nitrogen was a coolant. Methyl salicylate was cooled slowly below the freezing point down to the liquid nitrogen temperature and then slowly heated. Figure 1 presents the spectra recorded when temperature was increasing.

Infrared spectrum of the gaseous methyl salicylate was recorded on a Perkin–Elmer model 580B spectrophotometer in the Institute of Physics Polish Academy of Sciences in Warsaw by Mr. M. Szcześniak. The length of the cell was 8 cm.

3. Results and discussion

Infrared spectra of methyl salicylate are presented in Fig. I at temperatures varying from 173 to 293 K. The most significant changes in the spectra accompany the temperature interval 264 to 273 K where the phase transition occurs (solid–liquid).

The high-frequency region 2600–3800 cm^{-1} (Fig 1*a*) representing the O—H stretching vibration is more structured on the low-frequency side of the maximum peak (at 3187 cm^{-1} at room temperature) and has a prominent narrow band at

[1]To whom all correspondence should be addressed. Present address: Division of Physical Chemistry, Faculty of Pharmaceutical Sciences, Hongo, Bunkyo-ku, Tokyo 113, Japan.

[2]The band at 3233 cm^{-1} seen in the spectrum of salicylic acid (Fig. 2 of ref. 1) but absent in the spectrum of acetylsalicylic acid (Fig. 1 of ref. 1) was theoretically ascribed to the internal hydrogen bond — compare theoretical lines in both figures.

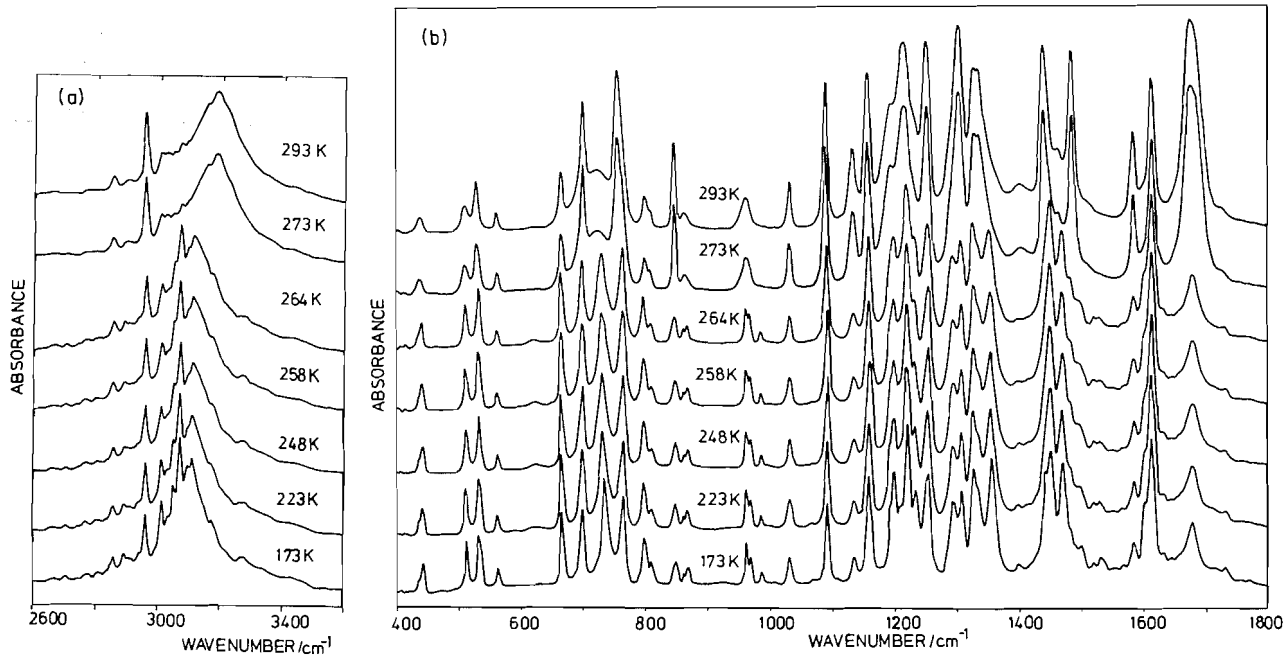

FIG. 1. (*a*) Infrared spectra of methyl salicylate in the region 2600−3800 cm^{-1} at different temperatures; (*b*) infrared spectra of methyl salicylate in the region 400−1800 cm^{-1} at different temperatures.

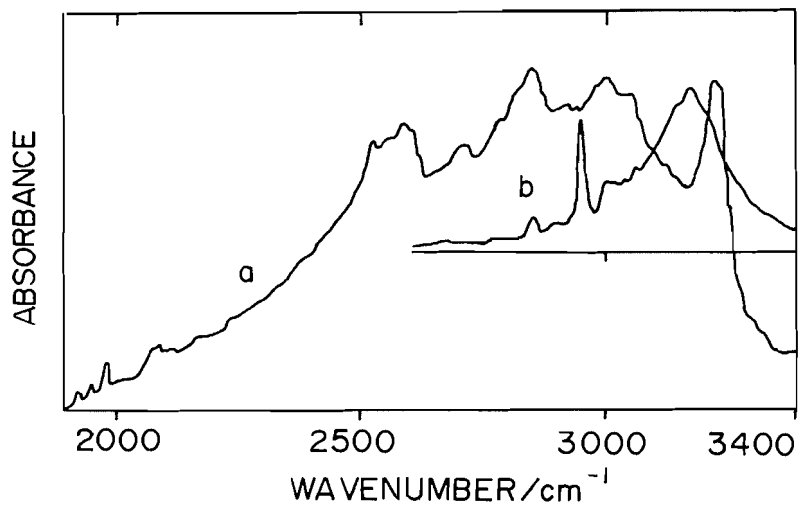

FIG. 2. Infrared spectra of solutions of methyl salicylate in carbon tetrachloride at different concentrations at room temperature. Solid line means the spectrum of the pure methyl salicylate and broken line spectra of solutions.

2955 cm^{-1} due to the CH_3 group. The position of this band remains almost unchanged during the phase transition and variation of temperature though its relative weight becomes smaller when temperature goes down.

The most striking changes accompanying the phase transition are those concerning the position of the central peak. The central peak shifts down to 3111 cm^{-1} and is no longer the most prominent peak. There are two characteristic bands at 3071 and 3012 cm^{-1}, the band at 3071 cm^{-1} being now the strongest with its relative importance increasing with decreasing temperature. These bands are visible in the spectrum of the liquid, in solutions (Fig. 2) and in the gas phase (Fig. 3). Moreover, recently we have observed a prominent peak in this region in the spectrum of O-deuterated salicylaldehyde (7), therefore we think that they are due to C—H vibrations of the benzene ring.

The overall half-width of the ν_s band is not very sensitive to the phase transition nor temperature decrease in the investigated interval (it changes from about 200 cm^{-1} at 293 K to 195 cm^{-1} at 264 K and 170 cm^{-1} at 173 K). It is, however, roughly twice as large as the half-width of the related band in crystalline salicylic acid (the half-width of this band is approximately 90 cm^{-1}). Figure 4 shows the overlay of spectra of salicylic acid and methyl salicylate at room temperature. One observes differences between the ν_s band of methyl salicylate and the band ascribed previously to the internal hydrogen bond both in the position (3187 cm^{-1} and 3233 cm^{-1}) and the width.

The medium-frequency region 400−1800 cm^{-1} (Fig. 1*b*) also shows characteristic changes accompanying the phase transition. The changes below and over the freezing point are not very significant.

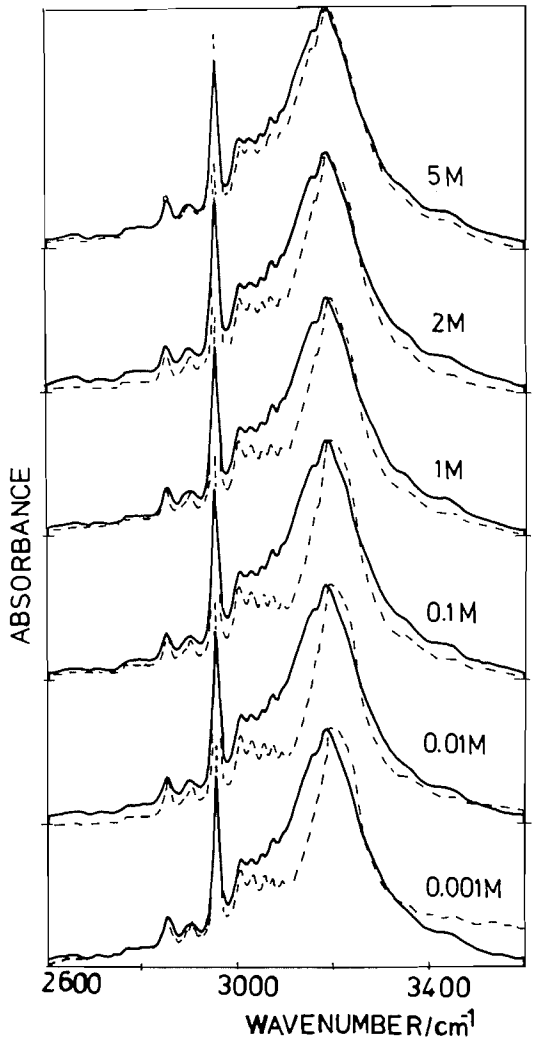

FIG. 3. Infrared spectrum of the gaseous methyl salicylate at 343 K.

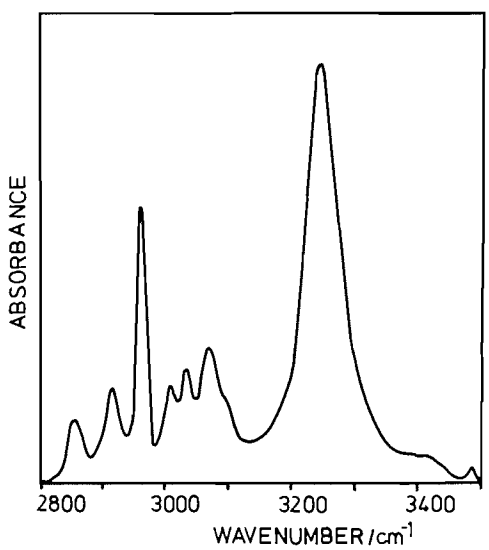

FIG. 4. Comparison between the spectrum of salicylic acid (*a*) and methyl salicylate (*b*) at room temperature.

The experimental facts gathered above show the difference between the ν_s band of methyl salicylate both in the liquid and solid state and the band ascribed to the intramolecular hydrogen bond in salicylic acid. The difference is both in the position and more striking in the width. Also the ν_s band of methyl salicylate seems to be more structured especially in the solid state. The question is whether this band is due to an internal hydrogen bond of a different strength than in salicylic acid or to an intermolecular one, or to a mixture of them.

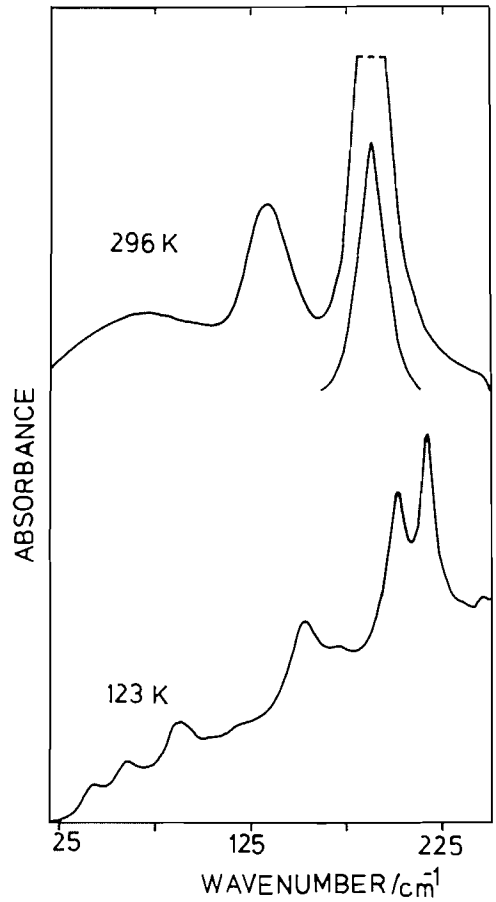

FIG. 5. Far-infrared spectra of methyl salicylate.

To solve this problem we have recorded high-frequency infrared spectra of methyl salicylate in solutions with an inert solvent carbon tetrachloride. Concentrations of methyl salicylate varied from 5 to 0.001 *M*. Results are presented in Fig. 2. One can see that dilution causes narrowing of the ν_s band but does not significantly change positions of the peaks nor the fine structure of the band. The half-width diminishes to 112 cm^{-1} at 0.001 *M*. The structure of the ν_s band of the isolated molecules of methyl salicylate in carbon tetrachloride is essentially the same as the structure of the pure liquid and solid methyl salicylate which indicates that the OH group of this molecule forms an internal hydrogen bond. External perturbations in the liquid (and to smaller extent in the solid) state cause additional broadening of the band.

Figure 3 presents an infrared spectrum of the gaseous methyl salicylate in the region 2800–3500 cm^{-1} at 343 K. The central peak is located at 3255 cm^{-1} and the half-width of the ν_s band is about 60 cm^{-1}. The position of the CH_3 band and secondary features of the spectrum are similar to those observed in the spectra of methyl salicylate in the liquid and solid state and in the solutions. This evidences that molecules of methyl salicylate form intramolecular hydrogen bonds also in the gaseous state.

The position of the ν_s band is now at the higher wavenumber

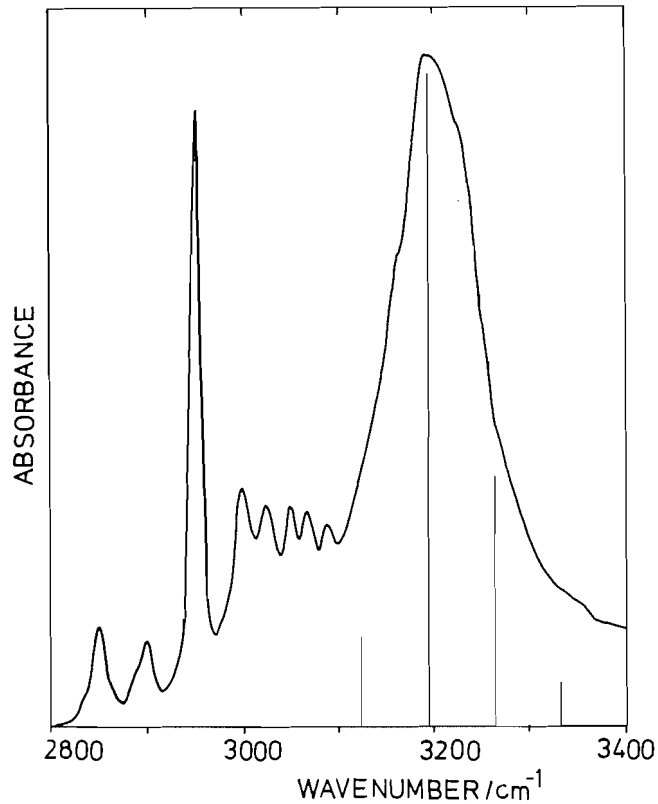

FIG. 6. Comparison between the experimental and calculated infrared spectrum of the 0.001 *M* methyl salicylate in CCl_4 at room temperature. The distortion parameter *b* (6) equals 0.5.

(but not very different) than the position of the ν_s band of the intramolecular hydrogen bond in salicylic acid (3255 cm^{-1} and 3233 cm^{-1}). The half-width is smaller (60 cm^{-1} and 90 cm^{-1}), contrary to the situation in the spectra of the liquid and solid methyl salicylate.[3] The ν_s band in the gaseous state is smooth and is the most similar to the band associated with the intramolecular hydrogen bond in the crystalline salicylic acid.

The experimental facts presented above show that the position of the ν_s band of methyl salicylate and especially its half-width are determined to a large extent by an influence of the environment. We note also that the half-width of this band is much smaller in the gaseous state than in the liquid and solid state which is not always the case (see, e.g., spectra of acetic acid (8, 9) or formic acid (10) in different phases).

[3]But not in solutions with low concentrations of methyl salicylate where the half-width approaches the value found in salicylic acid.

Far-infrared spectra of methyl salicylate in the liquid and solid state in the region 20–250 cm^{-1} are presented in Fig. 5. There are three main peaks in the spectrum at 296 K: 69, 132, and 187 cm^{-1}. These peaks shift upwards to 87, 152, and a doublet 202 and 217 cm^{-1} at 123 K. The value 70 cm^{-1} was used in a theoretical reconstruction of the ν_s band of the 0.001 *M* methyl salicylate in CCl_4 presented in Fig. 6. The calculation was based on the Witkowski–Maréchal model (5, 6) assuming an adiabatic coupling between the O—H stretching vibration and a low-frequency intramolecular O . . . O mode.

The value 70 cm^{-1} is also close to the wavenumber observed in the Raman spectrum of the crystalline salicylic acid (63 cm^{-1}) and used in theoretical reconstruction of infrared spectra of salicylic acid and O-deuterated salicylic acid (65 cm^{-1}) (1). It is probably connected with the low-frequency O . . . O bending vibration in strongly distorted intramolecular hydrogen bond. Two other observed wavenumbers 132 and 187 cm^{-1} were also used in calculations but did not give an agreement with the experimental spectrum.

4. Conclusions

Experimental results reported in this paper evidence that molecules of methyl salicylate form intramolecular hydrogen bonds in the gaseous, liquid, and solid state. Width and position of the ν_s band depend to a large extent on intermolecular interactions. The O—H stretching vibration in methyl salicylate couples with an intramolecular O . . . O mode of the wavenumber close to 70 cm^{-1}, lower than typical values for the O . . . O stretching vibrations in intermolecular hydrogen bonds.

On the positional reactivity order in the sulfuric acid sulfonation of the two naphthalenesulfonic acids[1]

PETER DE WIT AND HANS CERFONTAIN[2]

Laboratory for Organic Chemistry, University of Amsterdam, Nieuwe Achtergracht 129, 1018 WS Amsterdam, The Netherlands

Received November 8, 1982

PETER DE WIT and HANS CERFONTAIN. Can. J. Chem. **61**, 1453 (1983).

The sulfonation in 98.5% H_2SO_4 at 25.0°C of naphthalene-1-sulfonic acid yields 58% 1,5-, 32% 1,6-, and 10% 1,7-disulfonic acids and that of the 2-sulfonic acid 4% 1,3-, 74% 1,6-, 18% 1,7-, and 4% 2,6- + 2,7-disulfonic acids. Further sulfonation of the latter disulfonic acid mixture in 105.2% H_2SO_4 at 25.0°C yields 78% 1,3,6- and 12% 1,3,5- + 1,3,7-trisulfonic acids. Reaction of naphthalene-1,5-disulfonic acid with 105.2% H_2SO_4 at 25°C yields 5-sulfonaphthalene-1-sulfonic anhydride.

Partial rate factors for the sulfonation of naphthalene-1- and -2-sulfonate in highly concentrated aqueous sulfuric acid (where the sulfonating entity is $H_2S_2O_7$) are reported. They are discussed in terms of the difference in the reactivity of the α- and β-positions of the naphthalene skeleton and the electronic and steric effects of the sulfonate substituent already present.

PETER DE WIT et HANS CERFONTAIN. Can. J. Chem. **61**, 1453 (1983).

La sulfonation de l'acide naphtalènesulfonique-1 à 25,0°C dans du H_2SO_4 à 98,5% conduit aux acides disulfoniques-1,5, -1,6 et -1,7 avec des rendements respectifs de 58%, de 32% et de 10%. Dans les mêmes conditions la sulfonation de l'acide naphtalènesulfonique-2 conduit aux acides disulfoniques-1,3 (4%), -1,6 (74%), -1,7 (18%) et à 4% d'acides-2,6 et -2,7. Une sulfonation plus poussée du dernier mélange d'acides à 25,0°C dans du H_2SO_4 à 105,2% donne 78% d'acide trisulfonique-1,3,6 et à 12% d'acide trisulfonique-1,3,5 et -1,3,7. La réaction de l'acide naphtalènedisulfonique-1,5 avec du H_2SO_4 à 105,2% à 25°C conduit à l'anhydride sulfo-5 naphtalènesulfonique-1.

On rapporte les facteurs de vitesse partielle de sulfonations des naphtalènesulfonate-1 et naphtalènesulfonate-2 dans de l'acide sulfurique fortement concentré (ou l'entité sulfonante est $H_2S_2O_7$). On en discute en fonction de la différence de réactivité des positions α et β du squelette naphtalène et des effets électroniques et stériques du substituant sulfonate déjà présent.

For personal use only.

The sulfuric acid sulfonation of naphthalene yields a mixture of the 1- and 2-sulfonic acids (1, 2). At room temperature the reaction is kinetically controlled and the 1- and 2-sulfonic acid isomer ratio varies at 25.0°C from 5.9 to 4.3 on increasing the sulfuric acid concentration from 75 to 95% H_2SO_4 (3). At temperatures >150°C the main product of sulfonation is the 2-sulfonic acid which is the thermodynamically more stable product in view of the significant degree of *peri* strain in the 1-sulfonic acid. In fact, there is some steric hindrance for the introduction of a sulfo group *peri* to hydrogen, as appears from the small, but significant, kinetic isotope effect of hydrogen for the sulfonation of the 1-position of naphthalene: for reaction with SO_3 in nitromethane at 0°C, $k_H/k_D = 1.8 \pm 0.1$ (4).

We now report the isomer distribution of disulfonic acids formed in the sulfonation of the two naphthalenesulfonic acids occurring in 98.5% H_2SO_4 at 25.0°C at low substrate concentration (0.25 *M*). The ratio of the disulfonic acid components in the sulfuric acid reaction mixtures was determined after complete substrate conversion by multicomponent ^1H nmr analysis (5) on the basis of the specific absorptions of the disulfonic acid components. As to the sulfonation mixture resulting from the 2-sulfonic acid, the singlet at 9.12 ppm was assigned to the 8-H of the 1,7-disulfonic acid, the triplet at 7.86 ppm to the 3-H of both the 1,6- and 1,7-isomers, and the low intensity absorption in between 7.85 and 7.50 ppm to the 6- and 7-H of the 1,3-isomer. The absorption in between 8.0 and 8.9 ppm not accounted for by these isomers is due to the 2,6- and 2,7-isomers which, as appears from the spectra of authentic samples, do absorb only in between 8.0 and 8.9 ppm. As to the sulfonation mixture of the 1-sulfonic acid, the non-overlapping $\frac{1}{2}$AB absorption at 8.95 and the singlet at 9.14 ppm were assigned to the 4- and 8-H of the 1,5-disulfonic acid and the 8-H of the 1,7-isomer respectively; the remaining absorptions are due to the 1,6-isomer. The absence of absorption below 7.75 ppm sets an upper limit of 2% to the content of the 1,3-isomer of which the 6- and 7-H would absorb in that region.

The isomer distribution for the sulfonation of naphthalene-1-sulfonic acid was thus determined to be 58% 1,5-, 32% 1,6-, and 10% 1,7-disulfonic acids and that of the 2-sulfonic acid 4% 1,3-, 74% 1,6-, 18% 1,7-, and 4% 2,6- + 2,7-disulfonic acids. These data differ significantly from those for the sulfonation at 57°C reported by Spryskov and Karavaev (6) (for the 1-SO_3H with 104% H_2SO_4 75% 1,5-, 15% 1,3- + 1,7-, and 10% 1,6-disulfonic acids and for the 2-SO_3H with 99% H_2SO_4 67% 1,6-, 21% 1,3- + 1,7-, 1% 2,6- and 11% 2,7-disulfonic acids). The present data are preferred in view of the method of analysis (^1H nmr versus derivatization). Moreover, the data of Spryskov and Karavaev for reaction at 57°C may not be strictly thermodynamically controlled, the main high temperature products being the 2,6- and 2,7-disulfonic acids (7). The present data are in line with the observation that the disulfonation of naphthalene with 107% H_2SO_4 at 40°C yields about 70% of the 1,5- and 25% of the 1,6-disulfonic acids (8) and, as to the 2-sulfonic acid, agree with those reported earlier (9).

The sulfonation of aromatic substrates in sulfuric acid in the range of 88−100% sulfuric acid proceeds by a three-step mechanism via σ-complex intermediates in which the electrophilic sulfonating entity is $H_2S_2O_7$ (10). The partial rate factors for that mechanism (determined from the sulfonation rate constants of benzene (11) and the two naphthalenesulfonic acids

[1]Aromatic sulfonation, part 87. Preceding paper: see ref. 25.

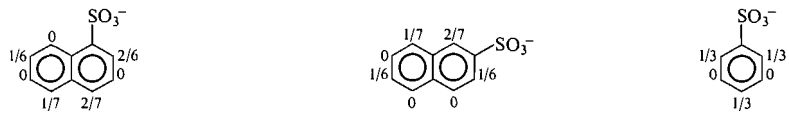
$f_6 + f_7 = 0.007$

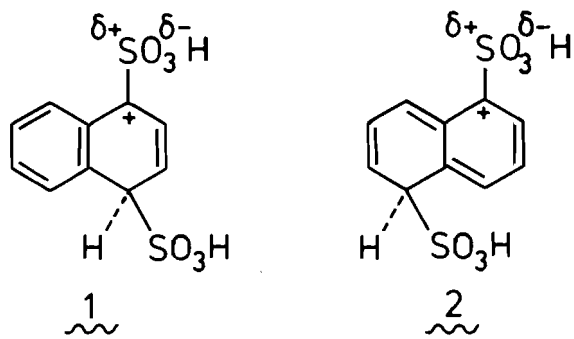
TABLE 2. Fractions of mesomeric structures of the various σ-complexes for the sulfonation of the two naphthalenesulfonic acids and benzenesulfonic acid, which are notably destabilized by the positive charge on the sulfur of the sulfo substituent, together with the derived positional reactivity orders



2<4<7<5<3 = 6 = 8 1<3 = 6<8<4 = 5 = 7 2 = 4<3

(3) and the presently reported isomer distribution data) are given in Table 1, together with those of naphthalene (determined from the (extrapolated) rate constant ratio of naphthalene (3) and benzene (11) (=90 ± 20) and the naphthalenesulfonic acid isomer distribution data (3)) and benzenesulfonic acid (12). It should be recalled that the substrate species undergoing electrophilic substitution in concentrated aqueous sulfuric acid is the arenesulfonate anion rather than the uncharged arenesulfonic acid (12, 13).

The partial rate factor order for the sulfonation of an arenesulfonic acid is governed by three factors, viz. (*i*) the differences in the cation localization energies of the positions under scrutiny of the parent arene, (*ii*) the difference in steric hindrance for the introduction of the sulfonic acid group, and (*iii*) the electronic directing effect of the sulfonate substituent already present in the substrate in destabilizing the σ-complexes under comparison (14). An estimate of the substituent effect of the $-SO_3^-$ group in destabilizing the σ-complexes can be obtained by counting the fractions of the mesomeric structures of the various σ-complexes for the introduction of the second sulfo group which are notably destabilized as the result



of repulsion between the positive charges on the mutually adjacent aromatic carbon and the S of the sulfonate substituent (sulfur being electropositive relative to oxygen) already present (14, 15). Typical examples of such destabilized mesomeric structures are **1** and **2**. The thus obtained data and the derived positional reactivity orders are given in Table 2.

As to the steric factors, sulfonation *peri* to a sulfonate group is fully impeded (16, 17) and the degree of steric hindrance for sulfonation *ortho* to that substituent is substantial (17, 18). As far as the third factor is concerned, the cation localization energies of benzene and naphthalene (19) predict the positional reactivity order for electrophilic substitution to be: 1-naphthalene > 2-naphthalene > 1-benzene.

Upon introducing a sulfonate substituent, the rate reduction for naphthalene of the positions in the ring containing the sulfonate substituent is $108 : <0.0004 = >3 \times 10^5$ for naphthalene-1-sulfonate and $108 : \leq 0.007 = \geq 2 \times 10^4$ for the 2-isomer, compared with a rate reduction of 4×10^8 for benzenesulfonic acid. The rate reduction in the other ring of the naphthalenesulfonic acids is far less. The observed partial rate factor orders for the sterically accessible α-positions (${}^{2\text{-S}}f_5 > {}^{2\text{-S}}f_8 > {}^{1\text{-S}}f_5 > {}^{2\text{-S}}f_4 > {}^{2\text{-S}}f_1$ and ${}^{1\text{-S}}f_4$) and the β-positions (${}^{2\text{-S}}f_7 \simeq {}^{1\text{-S}}f_6 > {}^{1\text{-S}}f_7 \geq {}^{2\text{-S}}f_6 \simeq {}^{2\text{-S}}f_3 > {}^{1\text{-S}}f_2$ and ${}^{1\text{-S}}f_3$) both compare satisfactorily with the predicted positional reactivity orders (cf. Table 2), except for ${}^{2\text{-S}}f_4$ and ${}^{1\text{-S}}f_3$. The observed values of these two partial rate factors are substantially smaller than predicted on the basis of counting the fraction of mesomeric structures of the σ-complexes which are destabilized as the result of repulsion of the positive charges on the adjacent aromatic C and sulfonate S. This approach unjustly presumes, however, that all the mesomeric structures describing the σ-complex for sulfonation at a given position are equivalent. In fact the structures are of two types, viz. benzenoid and quinoid, of which the latter are higher in energy and thus far less contributing than the former. On the basis of this starting point it can be argued (14) that the positional reactivity orders for the sterically assessible α- and β-positions of naphthalene-1-sulfonic acid will be $4 < 5$ and $3 < 7 < 6$, respectively, and for naphthalene-2-sulfonic acid $4 < 8 < 5$ and $3 \simeq 6 < 7$, respectively, which are in fact the observed positional reactivity orders.[3]

The further reaction of the naphthalenedisulfonic acid mix-

[3]The low values of ${}^{2\text{-S}}f_4$ and ${}^{1\text{-S}}f_3$ may in part be due to the negative inductive effect exerted by the $-SO_3^-$ substituent in addition to the significant $-M$ effect (12, 20).

tures obtained in 98.5% H_2SO_4 was affected by addition of neat sulfur trioxide so as to raise the sulfuric acid concentration to 105.2% H_2SO_4 at 25.0°C. After 30 h, the reaction mixture starting originally from naphthalene-2-sulfonic acid was found to contain 78% 1,3,6-trisulfonic acid (^{1}H nmr (105% H_2SO_4), δ(ppm): 9.15 (s, 2-H), 8.45 and 8.92 (AB, J = 8−9 Hz, 7- and 8-H), 8.94 and 8.97 (overlapping singlets, 5- and 4-H[4]), 12% 1,3,5- + 1,3,7-isomers (assigned on the basis of the 9.26 singlet to both the 4-H of the 1,3,5- and the 8-H of the 1,3,7-isomer), and 10% unreacted disulfonic acid. Apparently both the 1,3- and the 1,6-disulfonic acids are fully converted into the 1,3,6-trisulfonic acid. The 1,3,5- and 1,3,7-trisulfonic acids thus originate very predominantly from the 1,7-disulfonic acid which, based on the effects of the two sulfo substituents, will be less reactive than the 1,3- and 1,6-disulfonic acids.

Reaction of the disulfonic acid mixture resulting from naphthalene-1-sulfonic acid with 105.2% H_2SO_4 at 25°C led to the formation of a white precipitate which proved to be insoluble in the numerous carefully dried organic solvents tested.[5] The precipitate "dissolved" very slowly in both water and concentrated aqueous sulfuric acid.[6] The ^{1}H nmr and uv spectral data of these two solutions are identical with those of naphthalene-1,5-disulfonic acid. The precipitate is therefore assigned to be the anhydride of two molecules of naphthalene-1,5-disulfonic acid: 5-sulfonaphthalene-1-sulfonic anhydride.[7] In fact the ir spectrum (KBr) shows absorptions at 1406, 1390, and 716 cm^{-1} which are characteristic for the sulfonic anhydride group (22) and at 1180 and 1030 cm^{-1}, which bands are also observed with disodium naphthalene-1,5-disulfonate and are characteristic for the sulfonate group (23).

Experimental

The ^{1}H nmr spectra were recorded with a Varian XL 100 spectrometer. The chemical shifts are relative to neat tetramethylsilane as external reference (concentric capillary). Potassium naphthalene-1- and sodium napthalene-2-sulfonate and the disodium salts of 1,5-, 2,6- and 2,7-disulfonic acids were commercial products which were purified by successive recrystallization from ethanol−water. The sulfonation procedures were as described before (24).

[4]Compare ref. 21.

[5]The turbidity of the reaction mixture of naphthalene with an excess of weak oleum at ≤25°C at the later stages of the reaction was noticed before (8, 21), but it appears that no isolation was attempted.

[6]Naphthalene-1,5-disulfonic acid dissolves rapidly in these two solvents.

[7]Upon shaking in an excess of 105% H_2SO_4, naphthalene-1,5-disulfonate was found to convert slowly into the same white precipitate.

Conformation of purine mononucleotides by H{H} and P{H} nuclear Overhauser effects

H. SANTOS AND A. V. XAVIER
Centro de Química Estrutural, U.N.L., 1200 Lisboa, Portugal

AND

C. F. G. C. GERALDES[1]
Chemistry Department, University of Coimbra, 3000 Coimbra, Portugal

Received October 21, 1982

H. SANTOS, A. V. XAVIER, and C. F. G. C. GERALDES. Can. J. Chem. **61**, 1456 (1983).

The proton–proton and phosphorus–proton nuclear Overhauser effect (nOe) of guanosine 5′-monophosphate (5′-GMP) was measured in aqueous solution at different pH values and in the presence of excess La^{III} at acid pH. These data and nOe data from the literature for other mononucleotides were used together with vicinal proton–proton coupling constants to investigate the conformations of mononucleotides in aqueous solution, especially their rotational state about the glycosidic bond. Comparison of observed and calculated enhancements using various conformational models for the glycosidic bond gave predominantly *anti* conformations for 5′-AMP and 5′-GMP and a mixture of *syn* and *anti* conformations for 2′-AMP, 2′-GMP, 3′-AMP, and 3′-GMP. Protonation of 5′-GMP at N-7 of the guanine base alters the amplitude of its torsion angle within the *anti* range. The agreement between the glycosidic nucleotide conformations defined by nOe and by the lanthanide probe method is good but not perfect. As complexation of 5′-GMP with La^{III} through the phosphate group has only a small effect on the conformation of its exocyclic group, a comparison of the two methods is justified.

H. SANTOS, A. V. XAVIER et C. F. G. C. GERALDES. Can. J. Chem. **61**, 1456 (1983).

On a mesuré l'effet Overhauser nucléaire (eOn) proton–proton et phosphore–proton du monophosphate-5′ de guanosine (MPG-5′) en solution aqueuse à différents pH et en présence d'un excès de La^{III} à un pH acide. On a utilisé ces données ainsi que celles de eOn, relevées dans la littérature, conjointement avec les constantes de couplage vicinal proton–proton pour étudier les conformations des mononucléotides en solution aqueuse et plus spécialement leur état rotationnel autour de la liaison glycosidique. La comparaison des exaltations observées et calculées en utilisant divers modèles conformationnelles pour le lien glycosidique a donné de façon prédominante des conformations *anti* pour le MPA-5′ et le MPG-5′ et un mélange de conformations *syn* et *anti* pour le MPA-2′, le MPG-2′, le MPA-3′ et le MPG-3′. La protonation du MPG-5′ au niveau N-7 de la base guanine modifie l'amplitude de son angle de torsion dans le domaine *anti*. L'accord entre la conformation glycosidique du nucléotide définie par le eOn et par la méthode d'essai du lanthane est bon mais non parfait. Une comparaison des deux méthodes se justifie puisque la complexation du MPG-5′ avec La^{III} via le groupe phosphate n'a qu'un effet faible sur la conformation de son groupe exocyclique.

Introduction

Extensive studies of the solution conformation of nucleosides and nucleotides have been carried out with the aim of relating molecular geometry to biological function. The conformation of nucleosides and mononucleotides may be described in terms of the three dihedral angles χ, ψ, and ϕ in the nomenclature of Sundaralingam (1) (Fig. 1) and the pseudorotational state of the furanose ring (2). Nuclear magnetic resonance (nmr) spectroscopy provides a very convenient experimental technique for the solution conformational analysis of nucleosides and mononucleotides in terms of these parameters (3). Torsion about the glycosidic bond may be studied through nuclear Overhauser effect (nOe) methods (4) and the remaining parameters by analysis of measured spin–spin coupling constants (3). The lanthanide probe method (5) has also been widely used in conformational studies of these molecules.

Most of the early applications of homonuclear nOe to the study of the conformations of nucleosides and nucleotides about the glycosidic bond (6–8) have been of a qualitative nature. Quantitative conformational studies, at first restricted to rigid molecules (9), have more recently been applied to flexible molecules using approximate methods (12–15) or the full theory (10, 11, 16, 17). Recently the phosphorus–proton nuclear Overhauser effect has also been used in a conformational study of the sugar–phosphate moiety of various mononucleotides (18).

This study is concerned with a full conformational analysis of guanosine 5′-monophosphate (5′-GMP) in aqueous solution using homonuclear and phosphorus–proton nOe values. The nOe values for other mononucleotides, available in the literature, are also analysed using the same procedure.

Another major aim of this study is the investigation of the effect of La^{III} binding upon the conformation of 5′-GMP in aqueous solution, using nOe and coupling constants data for the 5′-GMP/La^{III} complex, because the possibility of a conformational change induced by probe binding constitutes a major limitation of the lanthanide probe method.

Experimental

The mononucleotides, purchased from Sigma Chemical Company, were lyophilized as frozen solutions in 99.8% D_2O (from Norsk Hydro). The final dry residues were taken up in ~1 mL of 99.8% D_2O and the resultant solutions at pH 7 were passed through columns of Chelex 100 (Bio-Rad Laboratories, Richmond, CA) previously equilibrated with 99.8% D_2O. This procedure frees the nucleotide solutions of cations with charge higher than one. The solutions were then lyophilized at least twice from 99.8% D_2O, and the final solutions were prepared by dissolution in 99.8% D_2O of the required quantity of nucleotide obtained by weighting. pH adjustments were made with DCl or NaOD using a Radiometer PHM63 Digital pH Meter equipped with an Ingold F 3434 electrode. Residual paramagnetic impurities were removed by addition of 1 m*M* EDTA. Residual oxygen was

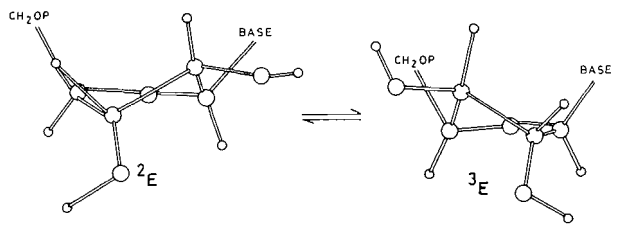

FIG. 2. Diagram of $N(C_{3'}$ *endo*) and $S(C_{2'}$ *endo*) conformations of the furanose ring.

removed by at least four freeze–pump–thaw cycles at less than 10^{-5} Torr.

The lanthanum^{III}/5'-GMP solutions were obtained by dissolution of the nucleotide in a 0.5 *M* lanthanum chloride solution. At pH 1.2 it was not possible to obtain solutions of concentrations higher than 0.015 *M* in 5'-GMP, due to its easy jellification. In these conditions, the percentage of complex formed was about 80%.

The lanthanum chloride solutions were obtained by dissolution in DCl of 99.999% La_2O_3 (from Koch–Light).

All glassware that was to contact the samples, after Chelex treatment, was rinsed with basic EDTA, deionized water, and acetone and then blown dry.

All nmr measurements were made with a JEOL JNM-PF-100 spectrometer, equipped with a JEOL EC100 computer for Fourier transformation. Proton resonance was observed at 100 MHz and phosphorus resonance at 40.49 MHz. Probe temperature was 28°C.

The samples were placed in Wilmad No 507-PP precision tubes and, in the measurements in which benzene was used as standard for area integrations, a 1 mm capillary tube containing benzene was placed concentrically in the main nmr tube.

In order to allow for full relaxation of the observed nuclei, in the proton spectra the time interval between two consecutive pulses was 12 s, and in the ^{31}P spectra a repetition interval of 20 s and a pulse width corresponding to a 45° flip angle were used.

The nOe effects were obtained using a gated decoupling technique which allowed the separation of decoupling and nOe effects (19). An unperturbed spectrum was first collected; then the perturbed spectrum was measured with the proton decoupler at a single frequency (low power) or a broad band of frequencies (high power). Signal areas were measured on expanded spectra via planimetry, and area differences between the perturbed and the unperturbed spectra were recorded as positive or negative nOe's expressed as percentage change. Each value was obtained from at least ten measurements in similar conditions. Experimental precision was 3%. The decoupling power used was the minimum necessary to saturate the spin considered.

Spin-lattice relaxation times were measured by application of a

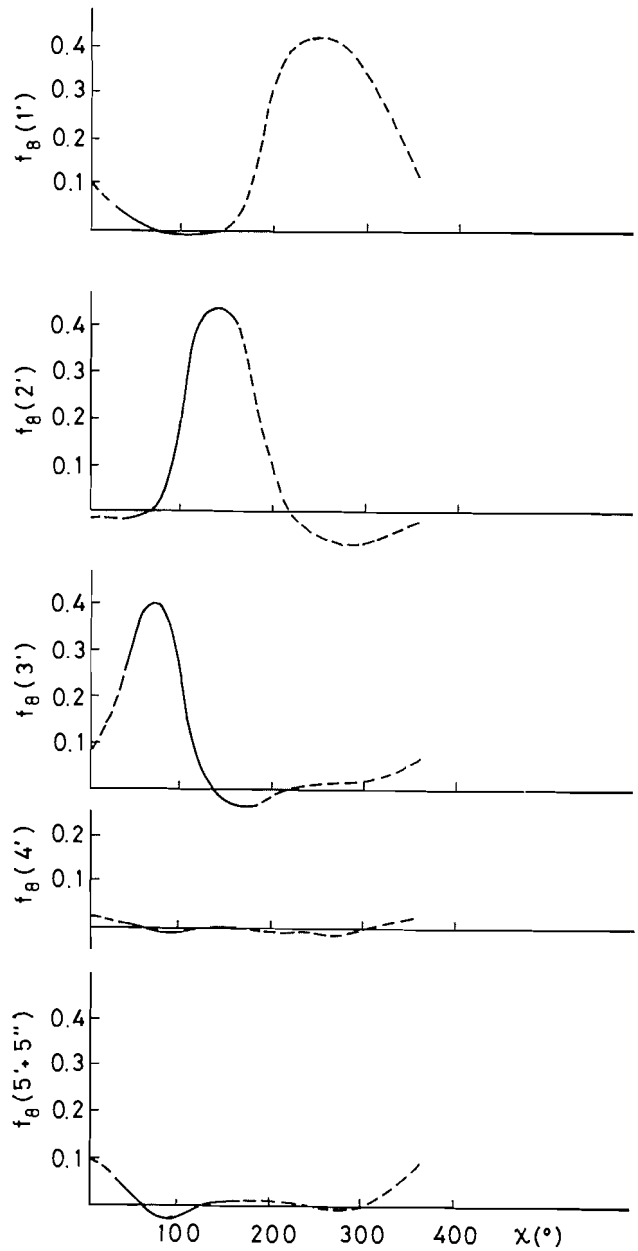

FIG. 3. Plots of various calculated nOe values for H_8 of 5'-GMP vs. glycosidic torsion angle χ, for a $N(C_{3'}$ *endo*) furanose ring conformation and $\psi = 60°$.

180°–τ–90° pulse sequence repeated at time intervals longer than $5T_1$.

The proton spectra of all the nucleotides considered in the present work have been thoroughly studied (20, 21).

The theoretical nOe enhancements $f_8(i)$, for H_8 due to irradiation of the ribose protons, as a function of the torsion angles, were calculated directly from eq. [2], using for this purpose the computer program BURLESK (22) modified to give interproton distances r_{ij} from atom coordinates for various molecular conformations obtained by variation of the ψ and χ angles with increments of 30° and 20° respectively. Two starting conformations were used differing in the geometries adopted for the furanose rings: the $N(C_{3'}$ *endo*) geometry was obtained from the crystal structure coordinates of 5'-GMP (23) and the $S(C_{2'}$ *endo*) geometry was obtained from those coordinates by use of a computer program for model building (Fig. 2). The calculation of the nOe enhancements was carried out in the following way: from the r_{ij} distances, ρ_{ij} values and R_d values were calculated using eqs. [3] and [4]; then $f_8(i)$ values were calculated by a successive approximations

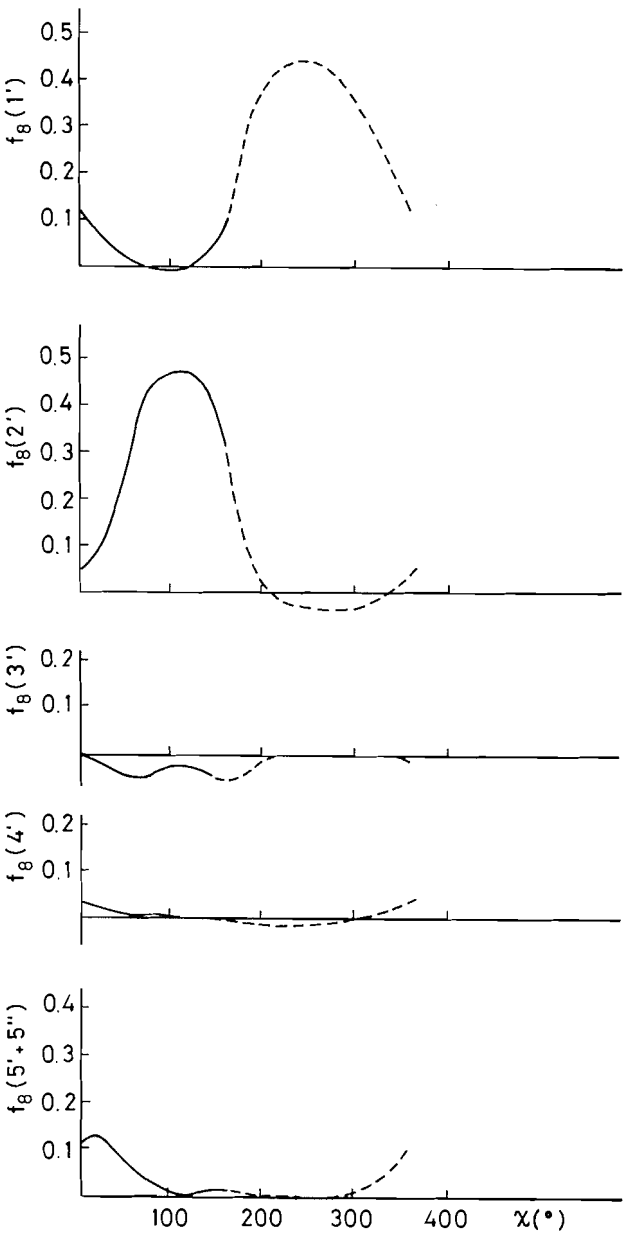

FIG. 4. Plots of various calculated nOe values for H_8 of 5′-GMP vs. glycosidic torsion angle χ, for a $S(C_{2'}$ *endo*) furanose ring conformation and $\psi = 60°$.

method (4) using as a starting point the first term of eq. [2]. A τ_c value of 6×10^{-11}s was used for all i,j pairs, a value calculated for 5′-GMP by Guéron and co-workers (12) using Stokes law. A value of ρ^* of 0.017, estimated for 2′,3′-isopropylideneinosine (10), was used for all protons.

Calculated nOe $f_8(i)$ values vs. glycosidic torsion angle, χ, are represented in Figs. 3 and 4. The full parts of the curves represent the regions where there are no van der Waals contacts between atoms (24).

Results, calculations, and discussion

The nuclear Overhauser effect is defined as the fractional enhancement in the integrated intensity of spin d which occurs upon saturation of spin s as:

$$[1]\quad f_d(s) = \frac{\text{area of } d \text{ when } s \text{ is saturated} - \text{equilibrium area of } d}{\text{equilibrium area of } d}$$

For a given molecular geometry defined by internal variables Ω, subject to certain conditions and approximations (all nuclei are under the extreme narrowing condition, relaxation is exclusively dipole–dipole, cross-correlation effects are negligible, and a single correlation time τ_c can be used for all interaction vectors, $\tau_c(ij)$), which are generally satisfied by small organic systems, it can be shown that (4, 9)

$$[2]\quad f_d(s,\Omega) = \sum_s \frac{\gamma_s \rho_{ds}(\Omega)}{2\gamma_d R_d(\Omega)} - \frac{1}{2\gamma_d R_d(\Omega)} \times \sum_{n \neq d,\, s} \gamma_n \rho_{dn}(\Omega) f_n(s,\Omega)$$

where

$$[3]\quad R_d = \sum_i \rho_{di} + \rho_d^*$$

and

$$[4]\quad \rho_{ij} = \gamma^2_i \gamma^2_j \tau_c / r^6_{ij}$$

where γ_i is the gyromagnetic ratio of nucleus i, r_{ij} is the distance between nucleus i and j, ρ_d^* is the direct relaxation rate of spin i due to "other" relaxation paths, and τ_c is the molecular reorientational correlation time. Because $f_d(s)$ is a function of internuclear distances, comparison of theoretically calculated with observed enhancements can give information about molecular geometry.

H{H}nOe values

The experimental homonuclear nOe's for 5′-GMP and other mononucleotides are given in Table 1. It should be noted that the present nOe data for 5′-GMP are slightly different from previously reported values (12). In the interpretation of these nOe data in terms of conformations of the mononucleotides studied, we will need to use conformer populations derived by an independent method, namely the analysis of vicinal coupling constants. These populations, obtained from the literature, are summarized in Table 3. The most interesting feature of the data is the strong pH dependence of the ribose conformer population in 5′-GMP, which is monitored by the pH dependence of its $J_{2'1'}$ coupling constant (12), see Fig. 5.

Attempts were first made to interpret the observed enhancements in terms of a single torsional conformer about the $C_{1'}$—N bond. Comparison of the theoretical enhancements as a function of χ for each ribose conformation with the observed enhancements led to the conclusion that no single conformer accounts for the observed homonuclear nOe data. Therefore in order to explain the nOe's it is necessary to allow for pseudorotational equilibria in the furanose ring using the $N(C_{3'}$ *endo*) percentage populations of Table 3 and exchange between torsional conformers about the glycosidic bond.

The calculation of theoretical nOe's for molecules with internal motions depends on the exchange conditions as defined by Schirmer *et al.* (10) on the basis of the relative values of the rate constants k for internal motions, the proton relaxation rates $R_d \simeq 1\ s^{-1}$, and the molecular rotational rate $\tau_c^{-1} \equiv \tau_R^{-1} \simeq 2 \times 10^{10}\ s^{-1}$. Ultrasonic relaxation studies (26) and ^1H and ^{13}C spin-lattice relaxation studies (27, 28) allow us to conclude that the rate constants for all internal motions are $k < 10^9\ s^{-1} << \tau_c^{-1}$, so case I (slow, $k << R_d$) or case II (intermediate, $R_d << k << \tau_c^{-1}$) exchange conditions may apply. Although it is extremely improbable that case I conditions prevail, i.e. that $k << 1\ s^{-1}$, in this work the nOe's were calculated for case I exchange conditions, as previous work on

similar systems has shown that the results of the conformational analysis are essentially the same using case I or case II exchange conditions (17).

In the slow exchange region (case I), the nOe enhancement is described by a generalization of eq. [2] to a discrete set of conformations

$$[5]\quad f_d(s) = \sum_{\Omega} P_\Omega f_d(s, \Omega)$$

where P_Ω is the fraction of molecules in conformation Ω, or to a continuous path described by internal variables Ω

$$[6]\quad f_d(s) = \int f_d(s, \Omega)\, P(\Omega)\, d\Omega$$

where $P(\Omega)$ is the distribution function for the variable Ω. Therefore two variables are necessary to describe the sugar–base torsion: the allowed angles and the probabilities at these angles. The populations of the *N* and *S* furanose ring conformations used are given in Table 3. The *gauche–gauche* conformation about the $C_{4'}$—$C_{5'}$ bond was chosen as it has been shown to dominate the equilibrium about this bond (Table 3).

Various conformational models for the mononucleotides were used. Calculations were started using discrete two-site χ angle distributions (χ_N, χ_S), where χ_N and χ_S are glycosidic angles associated with the *N* and *S* furanose ring conformations. On the basis of an observed correlation of furanose and base conformations (14), the χ_N and χ_S populations P_N and P_S were assumed to be equal to the populations of the *N* and *S* furanose puckered conformations (Table 3). The (χ_N, χ_S) conformations which give the minimum variance between experimental and calculated homonuclear proton nOe values for various purine mononucleotides, shown in Table 4, indicate that in the case of the adenine mononucleotides, 5′-AMP has an *anti* conformation of the base, but 3′-AMP and 2′-AMP have high populations of both *anti* and *syn* base conformations. The guanine mononucleotides show a pH-dependent conforma-

tional change of both furanose and base moieties, associated with base protonation at N-7 with a pK_a of 2.7 (31). A similar pH effect is not observed on the conformations of adenine mononucleotides, although adenine is protonated at N-1 with a pK_a of 3.9 (31). 3′-GMP and 2′-GMP at high and low pH have large populations of both *anti* and *syn* base conformations, whereas 5′-GMP has mainly *anti* base conformations, with a larger glycosidic angle amplitude at high pH. Very good fits of experimental nOe's were obtained in all cases using the discrete two-site conformational model, as expressed by *R* factors (41) smaller than 0.05 (see Table 4). The higher value for the 5′-GMP data at pH 1.2 is a consequence of the very small observed nOe's in this case.

The nOe values observed for the La^{III}/5′-GMP complex solutions are very similar to those obtained for the free ligand at the same pH, therefore indicating no significant change of the furanose ring and base conformation induced by the binding of the lanthanide ions. This was confirmed at low pH by identical values obtained for $J_{2'1'}$ coupling constants of the free and La^{III} bound ligand (Fig. 5). A similar observation was found for ribosyl-adenosine 5′,5″-biphosphate (40). The $f_8(5' + 5'')$ value is significantly higher for the La^{III} complex, thus suggesting that, at least in part, the corresponding decreased H_8—$H_{5',5''}$ distance is a consequence of complexation, through an increase of the gt and tg conformer populations about the $C_{4'}$—$C_{5'}$ bond. Of course glycosidic angle values closer to zero for 5′-GMP/La^{III} at pH 1.2 (Table 4) would also decrease the H_8—$H_{5',5''}$ distance and increase $f_8(5' + 5'')$. This conformational change of the exocyclic group of 5′-GMP due to La^{III} complexation was also detected by a decrease of the long-

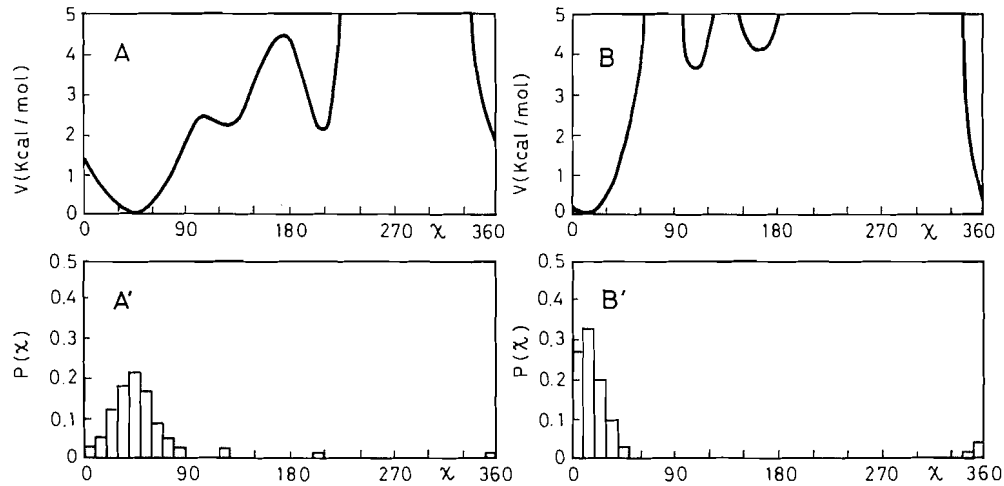

FIG. 8. Calculated potential energy curves for 5′-AMP from the literature (37) (A, B) and χ angle distributions derived from them by Boltzmmans's statistics (A′, B′) (all gg); A, A′ (*N* pucker); B, B′ (*S* pucker).

range $^4J_{PH_{4'}}$ coupling constant in the complex when compared to the value of 1.2 Hz for the free ligand at the same pH (32).

The effect of pH on the base conformation of 5′-GMP was also studied by following the variation with pH of the long range coupling constant between the H_8 base proton and the furanose $H_{1'}$ proton. In a very restricted pH zone, about pH 1.8, a $^4J_{H_8H_{1'}}$ of about 0.5 Hz was observed, as confirmed by $H_{1'}$ irradiation (Fig. 6). A study of the variation of ^4J with pH (Fig. 7) showed that it decreased for pH values lower or higher than about 1.8. Due to its small value, the variation of ^4J was followed through the difference of the half-height width of the H_8 resonance, in the absence and in the presence of $H_{1'}$ irradiation.

Theoretical and experimental studies of $^4J_{HH}$ and $^4J_{PH}$ coupling constants through saturated bonds (32, 33) have shown that they have maximum values for a planar *W* atom arrangement. These studies are applicable to 5′-GMP at low pH (pH < 2) as, when the guanine base is saturated, the bond order C_8—N_9 is about one. The results obtained suggest a variation of the base orientation with pH, through rotation about the glycosidic bond, with a passage through an intermediate position close to a planar arrangement of the bonds involved. As the nOe data point to an *anti* base conformation, this planar–*anti* configuration of the base corresponds to $\chi \simeq 40°$. Comparison with the interpretation of the nOe data (Table 4) suggests that at very low pH (<1.8) χ is smaller than 40°, and base deprotonation at N-7 would cause a base rotation to higher χ values (at least in the *N* furanose conformation). Base protonation at N-7 increases its effective charge from zero to one, changing the electrostatic interactions with other parts of the molecule, namely with the phosphate group. A minimum conformational energy will be obtained for $\chi > 40°$ and for $\chi < 40°$. The $\chi = 40°$ value corresponding to a maximum ^4J value is obtained for an effective charge of the base of about +0.77.

A comparison of the base conformations of the mononucleotides defined, within the discrete two-site conformational model, by nOe and by the lanthanide probe method (29, 30) was carried out through a comparison of the corresponding best fit (χ_N, χ_S) values and of the calculated nOe data for those glycosidic angle values (Tables 4 and 5). In the case of 5′-GMP the two methods agree very well and the best fit (χ_N, χ_S) value obtained by the lanthanide probe method gives calculated nOe data in very good agreement with the experimental nOe data for the 5′-GMP/La^{III} complex. The other mononucleotides do not give such a good agreement of both glycosidic angles and calculated nOe values defined by the two methods.

Another very simple torsional model for mononucleotides was considered, namely the free-rotational model in which all angles have equal probability. According to this model $f_8(1')$ is 0.18 (pure *N*) and 0.19 (pure *S*), $f_8(2')$ is 0.06 (pure *N*) and 0.16 (pure *S*), and $f_8(3')$ is 0.09 (pure *N*) and 0.02 (pure *S*). A comparison of the calculated $f_8(i)$ values for the *N* pucker populations given in Table 3 with the observed values (Table 1) shows that this model is not acceptable.

The experimental data could in principle also be fitted to gaussian distributions (16), but due to theoretical uncertainties (17) such a refinement was not undertaken. This is related to the problem of solution degeneracy: although more complete solutions than those presented in Table 4 exist, they would result in conformational models which in essence do not differ from them.

The nOe values presented in Table 1 were also used to test published potential energy curves for the conformations of mononucleotides about the glycosidic bond (34–37). Angular distributions of χ_N and χ_S values were derived from these potential energy curves by Boltzmann's statistics (Fig. 8) and, with overall weights given by the populations of the furanose *N* and *S* puckers (Table 3), were used to calculate proton nOe's for various combinations of ribose puckers and intramolecular hydrogen bonds (distributions 1 to 34 in Table 6). A comparison of experimental (Table 1) and calculated data (Table 6) indicates that for 5′-AMP the potential energy minimum at $\chi \sim 120°$ is lower than implied by Fig. 8, giving a higher population at $\chi \sim 120°$ and a higher $f_8(2')$ value. The data for 5′-GMP at pH 8.0 suggest that its χ angle conformer population distribution is very similar to 5′-AMP, while at pH 1.2 it is compatible with distribution 9 (Table 6) which assumes no POH...N_3 intramolecular hydrogen bond and consists of χ angles in the *anti* range ($\chi \sim 300°-70°$). The data for 3′-AMP and for 3′-GMP are incompatible with a $O_{5'}H...N_3$ intramolecular hydrogen bond and are best represented respectively by distributions 26 and 32, which consist of χ angles in the mainly *anti* ranges of 220°–320° and 20°–140°.

3′-AMP and 3′-GMP at neutral pH have higher populations at $\chi \sim 90°-120°$ than 3′-GMP at acid pH, giving larger $f_8(2' + 3')$ nOe values (Table 1). The data for 2′-AMP and 2′-GMP at neutral pH are very similar and differ considerably from the data for 2′-GMP at acid pH. The 2′-GMP data are incompatible with all theoretical distributions (Table 6) and no 2′-AMP distribution was tested as it is unavailable in the literature. However, the χ angle distributions for 3′-AMP and 3′-GMP should not be very different respectively from 2′-AMP and 2′-GMP at similar pH conditions.

As a whole there is no improvement of the fit of nOe data to the calculated values using distributions derived from potential energy curves when compared to the best fit distributions within the discrete two-state model. Some conclusions about the validity in solution of those potential energy calculations are possible, namely about the details of their shape, the relative depths of their minima, and the existence or not of some intramolecular hydrogen bonds.

P{H} nOe values

Phosphorous–proton nOe data for 5′-GMP and other mononucleotides are recorded in Table 2. A phosphorous spin-lattice relaxation defined entirely by a dipole–dipole interaction would give a phosphorous–proton nOe value of up to 124% (4). The fact that the nOe's are not the theoretical value indicates other modes of relaxation, such as residual impurities or different relaxation mechanisms. The single frequency irradiation nOe's illustrate the potential of P{H} nOe for conformational analysis of mononucleotides (18). Although no quantitative analysis was undertaken, the similar values for irradiation of the $H_{5'} + H_{5''}$ and $H_{4'}$ sugar protons in the three mononucleotides studied (see Table 2) reflect similar joint ψ,ϕ distributions about the $C_{4'}$—$C_{5'}$ and $C_{5'}$—$O_{5'}$ bonds, namely about 0.72 gg, g′g′ (18), in good agreement with $^4J_{PH_{4'}}$ coupling constant values. The low nOe values for $H_{2'}$, $H_{1'}$, and H_8 irradiation in all mononucleotides does not allow any conclusion about the ribose ring and base conformations, as the large internuclear distance renders the P{H} nOe very insensitive to the conformations of these moieties. In particular, a predominant *anti* base conformation, detected by other methods (29, 39), is not precluded as it is entirely compatible with a low $P\{H_8\}$ nOe value.

Conclusions

The present work demonstrates that proton–proton and phosphorus–proton nuclear Overhauser effect measurements are useful methods of nucleotide conformational analysis. Comparison of observed and calculated enhancements allowed a test of various conformational models for these systems to be carried out. For instance, the conformational state about the glycosidic bond cannot be described by any single conformation or by free rotational distributions. The χ angle distributions described by potential energy calculations for the mononucleotides studied give generally good agreement between calculated and experimental nOe's.

Calculations using discrete two-site χ angle distributions (χ_N, χ_S) give predominant *anti* conformations for 5′-AMP and a mixture of *syn* and *anti* conformations for 3′-AMP and 2′-AMP. 3′-GMP and 2′-GMP give a mixture of *syn* and *anti* conformations. In opposition to all these cases, where no pH-dependent conformational change is observed, protonation of 5′-GMP at N-7 of the guanine base induces a conformational change within the *anti* range with a wider glycosidic angle amplitude at high pH. This effect was also monitored by a pH dependence of the $^4J_{H_8H_{1'}}$ coupling constant. La^{III} binding to the phosphate group of 5′-GMP slightly increases the gt + tg conformer populations about the $C_{4'}$—$C_{5'}$ bond in relation to gg, a fact also monitored by a change of the value of the $^4J_{PH_{4'}}$ coupling constant.

The agreement between the glycosidic nucleotide conformations defined by nOe and by the lanthanide probe method (29, 30) is very good for the more rigid mononucleotides 5′-GMP and 5′-AMP and reasonably good for the other mononucleotides studied. The better agreement of the two methods for the more rigid mononucleotides is a consequence of a smaller extent of averaging of very different conformationally dependent geometric functions associated with the two methods.

The use of χ angle distributions described by potential energy calculations for the mononucleotides did not generally improve the fit of the nOe data, but allowed conclusions about their validity in solution. It should be borne in mind that significant nOe may occur from states which do not correspond to minimum energy conformations (15), showing therefore the limitations of earlier approaches (12, 13).

Introduction

Since Yamanouchi's pioneering studies on sea cucumber saponins (holothurins) (2), several species of various families of this class of echinoderms have been shown to possess these bioactive substances (3). Their molecular structures have been determined to be glycosides of triterpenes of the lanosterol type with a distinctive D-ring fused γ-lactone.

We wish to report the structure of psoluthurin A (**1**), the major triterpene glycoside of *Psolus fabricii* (order Dendrochirota), an arctic–subarctic species collected off the north shore of the St. Lawrence estuary at Les Escoumins, Québec. Our findings constitute the first report of the presence of these holothurins in a species of the family Psolidae. This compound appears to be the first reported example of a saponin of either plant or animal origin containing two sulfate groups. In addition, *P. fabricii* is only the second species so far shown to possess a saponin in which its aglycone is distinguished by a C(16) ketone function; the other species, of a different order, is *Stichopus japonicus* (order Aspidochirota, family Stichopodidae) (3). Isolation and purification procedures are detailed and physico-chemical evidence is presented in support of the assigned structure **1**.

Results and discussion

Isolation and purification procedures

The bright red sea cucumbers, *Psolus fabricii*, were collected slightly downstream from the pilot's wharf close to the village of Les Escoumins on the north coast of the St. Lawrence at a depth of 8–15 m (low tide). Live specimens were kept in low temperature sea water aquaria prior to use.

Preliminary work by our group[4] showed that the use of previously published isolation and purification procedures for a variety of holothurins (4–6) were difficult to apply in our case, as they appear to be tailored to the properties of the particular glycosides. The lack of versatility of these methods led us to develop a more general procedure which is shown in Fig. 1. Soaking the body walls in acetone removed most of the pigments (7) and permitted facile air-drying thereafter. The dried material was ground to a powder and extracted successively with benzene and methanol. An aqueous solution of the crude extract obtained from ethanol (75%) extractions was placed on

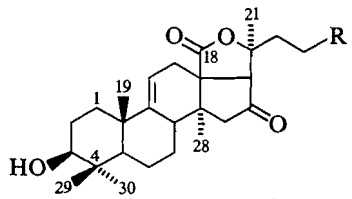
a column of Amberlite XAD-2. Washing the column with water removed the inorganic salts and subsequent elution with increasing amounts of methanol resulted in a partial separation of the mixture of glycosides. The polymeric resin XAD-2 of the reversed phase type had been successfully used by Gilgan *et al.* in the isolation of steroid glycosides obtained from starfish (8). Psoluthurin A (**1**) was finally separated from the minor psoluthurins by low-pressure liquid chromatography on silica gel (37–53 μ) using $CHCl_3$–MeOH–H_2O (see experimental) as eluant.

The homogeneity of **1**, a problem frequently encountered with holothurins (9), was verified by reversed-phase thin-layer chromatography (rptlc). The presence of an impurity (<5%) was detected and the physico-chemical data given below were obtained with the slightly impure **1** except for the atomic absorption result. In this latter case, a small amount of the pure substance obtained by reversed-phase hplc was used.

Structural elucidation of psoluthurin A (1)

Psoluthurin A (**1**) was obtained as a white solid, mp 259–263°C (dec.), $[\alpha]_D^{23}$ −32.6° (pyr.), with no uv absorption maximum above 210 nm. The ir spectrum (KBr) showed strong hydroxyl absorption at 3400 cm^{-1} as well as two carbonyl bands at 1765 cm^{-1} and 1745 cm^{-1} indicating a γ-lactone, characteristic of holothurins, and a cyclopentanone respectively. The two bands at 1240 cm^{-1} and 820 cm^{-1} suggest the presence of a sulfate moiety. This latter observation was further substantiated by a positive rhodizonate test (10), the presence of 2.47 atoms of sodium by atomic absorption spectroscopy, and a comparison of ^{13}C nmr data with desulfated psoluthurin A **2** (DS-PSOL-A) (see below). Absorptions at 1650 cm^{-1} (νC=C) and 900 cm^{-1} (νC=CH_2) are indicative of a vinylidene group. The cd spectrum (MeOH), $[\theta]_{235}$ −10 000



4 (Genin-1) R: CH=

5 (Genin-2) R: CH_2–OH

6 (Genin-3) R: CH_2–OCH_3

and $[\theta]_{300}$ −16 300, confirmed the presence of a γ-lactone (11) and a cyclopentanone (12) respectively.

Aqueous acid hydrolysis (2 *N* HCl) of **1** led to the formation of genin-1 (**4**, major) and genin-2 (**5**, minor) as well as the four usual holothurin monosaccharides, xylose, glucose, quinovose, and 3-*O*-methylglucose (identical R_f values by gc with the anomers of the authentic D-sugars). The high resolution mass spectrum of **4**, mp 219–221°C, established the molecular formula of $C_{30}H_{44}O_4$ for the parent ion m/z 468.3239 (calcd.: 468.3241) and the infrared spectrum (CCl_4) showed absorption at 3600 cm^{-1} (OH), 1760 cm^{-1} (γ-lactone), 1740 cm^{-1} (cyclopentanone). Its ultraviolet spectrum in methanol was transparent above 210 nm. The characteristic holothurinogenin mass spectral fragmentation (12) was noted, in particular, a fragment of m/z 423 supports the C(16) ketone function and the m/z 381 ($M^+ - 87$) indicates the C(3)—OH (13). Ions of m/z 109 and 69 are characteristic of side chain fragmentations with a Δ^{24} double bond (11). The physico-chemical data are similar to those reported for stichopogenin-A_2, isolated under identical conditions from holotoxin A (11). Their structural identity was further substantiated by a direct comparison with an authentic sample by tlc.[5] The identification of **5** as stichopogenin-A_4, an aglycone artifact obtained under identical conditions from holotoxin A (14), follows from the similarity of the ir spectra of **5** and **4**, the transparency of the uv spectrum, the lack of formation of **5** under anhydrous methanolysis conditions, and identical tlc behavior when compared with an authentic sample of stichopogenin-A_4.[5] Thus the structure of the triterpene moiety of **1** is identical to that of holotoxin A, as further demonstrated to be the case by the ^{13}C nmr and mass spectral data given below.

Methanolysis of **1** under anhydrous conditions (1% HCl) led to the formation of genin-3 (**6**, major) and **4** (minor) as well as equimolecular quantities of methyl xylopyranoside, methyl quinovopyranoside, methyl glucopyranoside, and methyl 3-*O*-Me-glucopyranoside. The concordance of the behavior of **1** and holotoxin A under identical conditions, the similarity of the ir spectra of **4**, **5**, and **6** and the transparency of the uv spectra, indicate **6** to be 25-methoxystichopogenin-A_4. Confirmation of this structure was obtained by an analysis of its ^{13}C nmr spectrum and a comparison with the spectrum of stichopogenin-A_4 (15*a*) and the spectra of **1** and **2** (Table 1). The signals at 110.6 and 151.6 ppm in the spectrum of **6** indicate the endocyclic double bond to be at 9:11 (14, 16).

Previous studies of holothurins have shown that double bond migration may occur under acidic solvolysis conditions (17, 18). In order to determine the authentic structure of the aglycone of **1**, a ^{13}C nmr spectral study of the latter was carried out (Table 1). The signals at 36.0, 26.8, 88.7, 39.4, 52.7, 26.6, and 17.4 were assigned to carbons C(1), C(2), C(3), C(4), C(5), C(29), and C(30) respectively taking into account the influence of C(3) glycosidation (19). The similar chemical shifts observed for quaternary carbons C(10) and C(14) of **1** and **6** as well as the signals at 151.9 and 111.0 observed in the spectrum of these and other similar substances (14, 16, 18) confirm the 9:11 position for the endocyclic double bond in **1**. The signals at 145.3 and 110.4 were assigned to the side chain double bond at Δ^{25} based on a comparison with the theoretical values (20) showing 145.4 (C(25)) and 109.7 (C(26)) in contrast to 126.3 (C(24)) and 131.5 (C(25)) for Δ^{24}. This then indicates that isomerization of the double bond from Δ^{25} to Δ^{24} occurred on acid hydrolysis of **1** to **4**. The signals at 213.9, 176.5, 83.4, and 55.7 ppm were respectively assigned to the four remaining quarternary carbons C(16), C(18), C(20), and C(13) in agreement with the results reported by Elyakov and co-workers (15). The remaining signals were assigned by comparison with similar compounds (14, 16, 21). These results confirm the structural identity of the triterpene aglycone of **1** with that of holotoxin A and B (14).

TABLE 2. Fast atom bombardment mass spectral data

m/z	Ion
Positive ions	
1327	(Na-K-disulfate) + Na^+ and/or (Na Na disulfate) + K^+
1313	((Na,Na disulfate) + Na^+) + 2
1311	(Na,Na disulfate) + Na^+
1305	(Na,K disulfate) + H^+
1289	(Na,Na disulfate) + H^+
1283	(K,H disulfate) + H^+
1267	(Na,H disulfate) + H^+
1209	(Na monosulfate) + Na^+
1107	(Na sulfate) + Na^+
Negative ions (complementary)	
1281	(Na,K disulfate) − Na^+
1265	(Na,Na disulfate) − Na^+ and/or (Na,K disulfate) − K^+
1163	(Na monosulfate) − Na^+

Information on the oligosaccharide chain of **1** was obtained from the ^{13}C nmr studies. Particularly important was a comparison with the ^{13}C nmr spectrum of **2** (Table 1). The latter was formed by a mild anhydrous acid methanolysis (0.06 *N* HCl – MeOH) at room temperature and gave a negative rhodizonate test as well as a satisfactory elemental analysis. In the case of **1** the chemical shifts of the C(6) carbons of glucose and 3-*O*-Me-glucose as well as that of the methyl carbon of the latter are only very slightly affected by glycosidation sites (22) and hence corresponding signals should be observed in the 60–63 ppm region. However, only two signals appear in this part of the spectrum at 61.1 and 60.5 ppm, assigned to the C(17) of the aglycone and the methyl of 3-*O*-Me-glucose respectively. The signals at 67.0 and 67.4 ppm are indicative of the two C(6) sugar carbons attached to sulfate groups. This is borne out by the disappearance of these two signals in **2** and the appearance of two new signals at 62.3 and 62.4 pm. The deshielding effect observed (≃5 ppm) is in agreement with the results reported by Kitagawa *et al.* (21) for holothurin A and by Archbald *et al.* (23) for monosaccharide sulfates. In addition the ir absorption at 820 cm^{-1} of **1** is characteristic of C(6) sulfates (24).[6] The signals in the range 104–106 ppm assigned to the C(1) carbons of the two psoluthurins are indicative of a β configuration (25). The remaining signals were assigned as shown in Table 1, based partly on relaxation times (T_1), and are in good agreement with previous studies (21, 26). Also in accord with these latter studies were the NT_1 values obtained for the sugars of **2**, 0.20 (xylose), 0.23 (glucose and quinovose), and 0.29 (3-*O*-Me-glucose). These NT_1 values show 3-*O*-Me-glucose to be the terminal sugar (in agreement with the gc–ms and FAB-ms (fast atom bombardment) results presented below) and xylose to be attached to the aglycone. This latter fact was confirmed by the isolation of a xyloside from **2** under mild anhydrous acid (0.25 *N* HCl) methanolysis.

[5]An authentic sample was kindly provided by professor Isao Kitagawa of Osaka University, Japan.

[6]This absorption is absent in the ir spectrum of **2**.

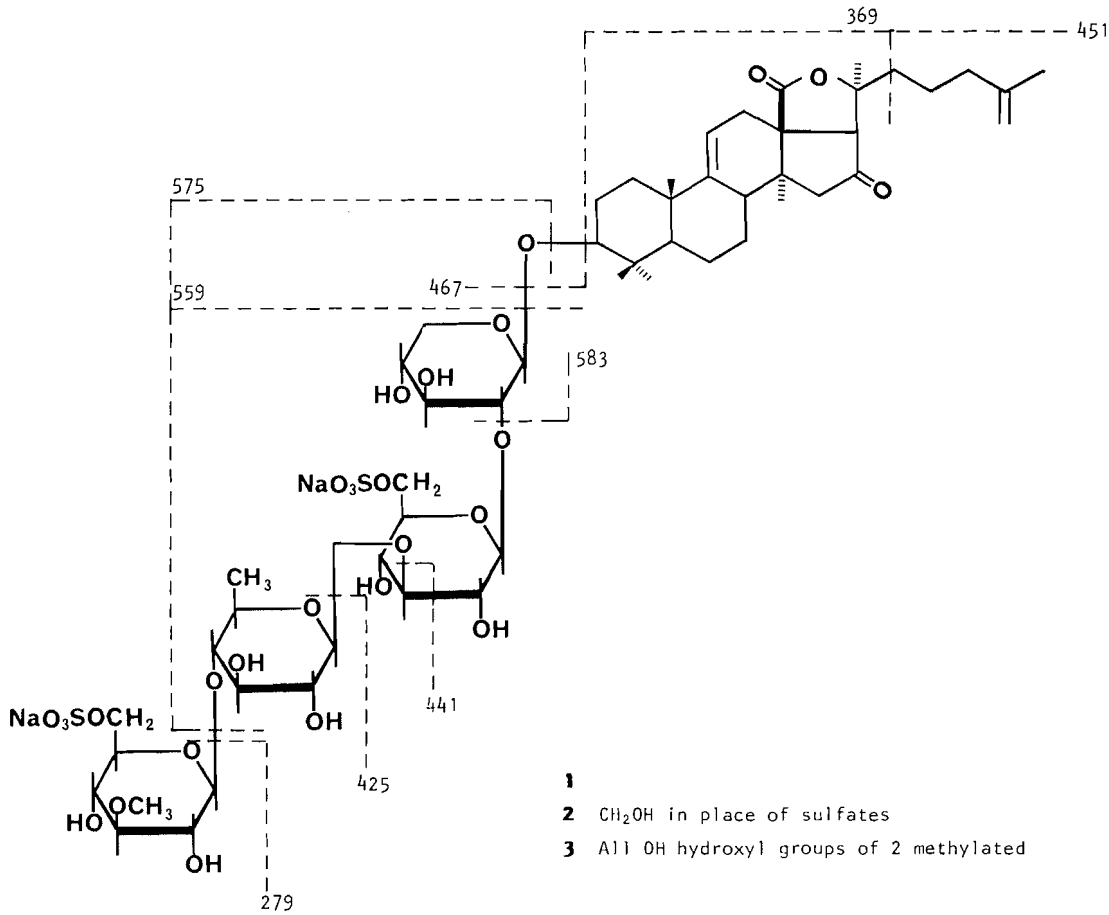

FIG. 2. FAB mass-spectral fragmentation pattern of psoluthurin A (**1**).

The complete sugar sequence as well as further confirmation of the structure of **1** was obtained by FAB mass spectrometry (27, 28). The positive- and negative-ion FAB-mass spectra data for **1** are presented in Table 2 demonstrating the power of FAB-ms for ascertaining the sugar sequence of a glycoside. The structural information this technique provided for **1** is in good agreement with other spectroscopic data. Spectra were recorded on a glycerol support in the positive and negative modes using a ZAB-2f instrument.

Molecular weight information was obtained from the region m/z 1267 through 1327. In particular, the ion m/z 1289 represents the $(M + H)^+$ ion of the di-sodium-disulfate form of the molecule. Other ions are the result of the various combinations possible for the molecular ion, when a trace of potassium salt is present (27, 28). The presence of potassium can be accounted for in two ways: the presence of a potassium-sodium-disulfate analog (m/z 1283, 1305, and 1327) or more simply a trace of an impurity such as KCl or KBr. The former is thought to be more probable due to the presence of a complementary counterpart in the negative spectrum at m/z 1281.

The sequencing of the sugars was also evident from the FAB-mass spectra, as well as the location of the sulfates (Fig. 2). In fact, a peak at m/z 583 indicates that xylose is directly attached to the aglycone moiety and that it does not bear a sulfate group.[7] Peaks at m/z 279 and 575 indicate that 3-*O*-Me-glucose is terminal and that it bears a sulfate moiety. Finally, peaks at m/z 441 and 425 confirmed that quinovose is directly attached to 3-*O*-Me-glucose and that it does not bear a sulfate group.[7] Deduction leaves the glucose unit between quinovose and xylose, and bearing the second sulfate group.

Methylation of **2** resulted in the formation of one major product, permethylated DS-PSOL-A (**3**) (tlc behavior and subsequent methanolysis results). The purified (lplc) permethylated product was methanolysed under anhydrous conditions (2 *N* HCl, 55°C, 3 h) and the following partially methylated monosaccharides of the mixture obtained were identified by gc–ms. Permethylated methyl glucopyranoside (R_f 6.7 (β), 7.4 (α)) gave a mass spectrum identical to that of an authentic sample of the α anomer (R_f 7.4) and was in agreement with the published data (29). The following characteristic ions are of particular note: m/z 187 (A_2;[8] $M^+ - (MeO + MeOH)$), 101 (F_1, G_1), 75 (J_1), and 88 (H_1, base peak). Similarly, methyl-2,3-di-*O*-methylquinovopyranoside (R_f 4.5 (β), 5.0 (α)) gave the same mass spectrum as an authentic sample (R_f 5.0 (α)) and the following ions of particularly important diagnostic value were in accord with the published data (30): m/z 175 (A_1; $M^+ - OMe$), 130 ($B_1 - MeOH$), 88 (H_1, base peak), the very weak 102 ($B_1 - HCO_2Me$), and the absence of 72 (K_1). Further confirmation was obtained from the mass spectrum of methyl-2,3-di-*O*-methyl-4-*O*-trimethylsilylquinovopyranoside[9] showing the following characteristic ions: m/z 247 (A_1; $M^+ -$

[7]These assertions come from the fact that the formation of a *singly charged* ion from the loss of two sulfate groups, or a sulfate +aglycone unit, is not possible.

[8]The symbols used are those found in ref. 29.

OMe), 159 (F_1), 146 (H_1^1 or H_1^3), 130 (K_1), and 88 (H_1^2; base peak). The following characteristic ions of the mass spectrum of methyl-2,4,6-tri-*O*-methylglucopyranoside were the same as those reported for the β anomer (31) (the relative intensities were also of the same order): *m/z* 173 (A_2; M^+ − (MeO + MeOH)), 102 (r), 101 ($s_1s_3s_4$), 88 (t_1), 87 ($s_2s_5s_6$), 75 (v_2), 74 (t_2t_3), and 71 (base peak). The identification was further confirmed by the following ions of the mass spectrum of methyl-2,4,6-tri-*O*-methyl-3-*O*-trimethylsilylglucopyanoside[9]: *m/z* 245 [M^+ − (MeO + MeOH)], 187 [M^+ − (MeO + Me_3SiOH)], 173 (E_2), 146 (H_1^2; base peak), 131 (H_1 − Me), 102 (K_1), 75 (J_1), 73 (H_2), and the absence of 159 (F_1). The fourth partially methylated monosaccharide, methyl-3,4-di-*O*-methylxylopyranoside, was identified by a comparison of the mass spectrum of its trimethylsilyl derivative with data previously published.[9] The following ions are characteristic of this compound: *m/z* 233 (A_1; M^+ − MeO), 159 (F_1^2; base peak), 146 (H_1^2), 143 [A_2; M^+ − (MeO + Me_3SiOH)], 131 (H_1 − Me), 101 (F_1^1), 88 (H_1), 75 (J_1), and 58 (K_1). These results indicate the following positions of attachment of the four monosaccharides (see Fig. 2): aglycone (C(3)) – xylose (1 → 2) – glucose (1 → 3) – quinovose (1 → 4) – 3-*O*-Me-glucose. The same mass spectra were obtained from the methylated trimethylsilylated monosaccharides from a second methylation–methanolysis experiment of **2**. In this instance the separation was carried out on a SE-30 capillary column (30 m) and the mass spectrum of a disaccharide separated from the mixture showed a signal at *m/z* 363 attributed to the ion MeO^+=CH—CH=CH—O—(2,4,6-tri-*O*-methyl-3-*O*-trimethylsilylglucopyranoside). The presence of this ion, resulting from the characteristic fragmentation of a disaccharide and the presence of fragment ions from the methylated 3-*O*-TMS glucoside as well as the absence of the ion of *m/z* 161 indicates the disaccharide to be composed of 3-*O*-TMS glucose and xylose linked 1–2 (29). This result further confirms the sugar sequence of **2** and accordingly the complete structure of psoluthurin A (**1**) is that proposed in Fig. 2.

Experimental

Melting points were determined on a Fisher–Johns hot stage melting point apparatus or on a Buchi SMP-20 using capillary tubes and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 237-B grating spectrophotometer. Ultraviolet spectra were recorded on a Perkin–Elmer Coleman 124 "double beam" uv–visible spectrophotometer in 95% ethanol solutions. Optical rotations were measured on a Perkin–Elmer 141 polarimeter using a sodium lamp at a 589 nm wavelength. Carbon-13 nuclear magnetic resonance spectra were recorded on Bruker CXP-300 and WH-400 spectrometers operating at 75.46 MHz and 100.62 MHz respectively or on a CFT-20 spectrometer operating at 25.2 MHz. The spin-lattice relaxation times (T_1) were measured by the inversion recovery method at Université de Montréal. Chemical shifts are expressed in ppm downfield from tetramethylsilane (δ scale). Low resolution mass spectra were obtained on a AEI-MS 12 spectrometer using an ionization energy of 70 eV. Fast atom bombardment mass spectra (FAB-ms) were recorded on a glycerol support in the positive and negative modes using a ZAB-2f instrument (VG Analytical Limited, England). The gc–ms analyses were carried out on a Perkin–Elmer Sigma-3 using columns of 3% OV-17 (2 m) and a SE-30 capillary (30 m) interfaced with a Kratos-AEI M-25 and equipped with a DS-55S (NOVA 3 computer) data processor. Circular dichroism spectra were recorded on a mcd apparatus at Carleton University. Gas–liquid chromatography experiments were accomplished on a Hewlett–Packard 5730-A gas chromatograph equipped with a flame ionization detector. Stainless steel columns (1.8 m long) packed with 3% OV-17 support were used. Thin-layer chromatographic analyses were carried out on precoated silica gel GF-254 (E.M. Reagents) and Kc18 (Whatman) glass plates. Glycoside fractions were developed in the solvent systems $CHCl_3$–MeOH–H_2O 60:42:10 (solvent A) or 65:35:10 (lower layer, solvent B) while the solvent system EtOAc–hexane 50:50 (solvent C) was used for the aglycone fractions. Preparative tlc were performed on precoated silica gel G glass plates (20 × 20 cm, 0.5 mm thickness, E.M. Reagents). Detection was accomplished by spraying a 1% ceric ammonium nitrate in 50% sulfuric acid solution followed by heating at 100–120°C. Low pressure column chromatography separations were carried out on silica gel 60 H (E. Merck, B.D.C.), on Whatman silica gel LPS-1 (13–24 μ), and LPS-2 (37–53 μ). Columns were prepared as a slurry in $CHCl_3$. The hplc separations were carried out on a column (1 × 25 cm) of Spherisorb ODS, 10 μm (C_{18}), using a Waters-244 chromatograph linked to a Kratos SF-770 UV detector. The atomic absorption analysis was carried out on a Perkin–Elmer model 610 using an acetylene–oxygen flame. All solvents used were "reagent grade" and were distilled prior to use.

Isolation and purification of psoluthurin A (1)

The body walls from 177 specimens of the sea cucumber *Psolus fabricii* collected at Les Escoumins, Québec, were treated with 4 L of acetone (residue after evaporation: 99.5 g) and ground to a fine powder (4.21 kg) which was successively extracted several times with benzene and methanol to remove the residual pigments and lipids. The 75% ethanol extracts were combined and evaporated under reduced pressure using a roto-evaporator to give the crude psoluthurin mixture (66.0 g). The mixture was then subjected to an Amberlite XAD-2 resin (Mallinekrodt, 20–50 mesh) column chromatography. In a typical run, a fine suspension of the mixture (3.94 g) in water (50 mL) was placed on a prewashed[10] resin column (4.5 × 54 cm) and eluted with water (1 L), 25% MeOH in water (500 mL), 50% MeOH in water (1.8 L), and methanol (700 mL) to afford a salt-free partially purified glycoside mixture (450 mg). Low pressure column chromatography (silica gel-LPS-2 199 g; 4 × 30 cm; bed volume 390 mL; elution at 12 psi; flow rate 6 mL/min; developing solvent $CHCl_3$–MeOH–H_2O, 60:15:2.1 (525 mL) → 60:20:3.5 (2,750 mL) → 60:25:4.5 (900 mL) of the mixture (228 mg) furnished **1** (167 mg) homogeneous by tlc (solvents A and B), as well as several other glycosides obtained in minute amounts. Psolothurin A (**1**) (2.3 mg) was further purified for the atomic absorption analysis using reversed-phase hplc on a column of Spherisorb ODS eluting with MeOH–H_2O 70:30 followed by recrystallization from 85% aqueous ethanol. The sodium analysis was carried out on an aqueous acidic solution of **1**.

Psoluthurin A (**1**), mp 259–263°C (dec.); $[\alpha]_D^{23}$ −32.6 (*c* 0.45, pyr.); uv λ_{max} (EtOH) (nm): transparent above 210; ir ν_{max} (KBr) (cm^{-1}): 3400 (OH, Br), 1765 (γ-lactone), 1745 (5-memb. ketone), 1240 (S=O), 900 (C=CH_2), 820 (C—O—S); cd (*C* 0.17 *M*, MeOH): $[\theta]_{400}$ 0, $[\theta]_{300}$ −16 000 (neg. max), $[\theta]_{260}$ −1000 (neg. min.), $[\theta]_{235}$ − 10 000, $[\theta]_{220}$ 0, $[\theta]_{210}$ +2000!; FAB-ms: see Table 2; ^{13}C nmr (pyr. $-d_5$): see Table 1; potassium rhodizonate test: positive (yellow coloration); atomic absorption 2.47 ± 0.13 sodium atoms per molecule of **1**.

Aqueous acid hydrolysis of psoluthurin A (1)

1. Carbohydrate constituents

A solution of **1** (50 mg) in 2 *N* HCl (10 mL) was heated under reflux for a period of 4 h. After cooling, the aqueous solution was extracted with $CHCl_3$ (3 × 10 mL) and neutralized with Ag_2CO_3, the AgCl precipitate being removed by filtration on a thin pad of Celite. The solution was then evaporated to dryness under reduced pressure to afford a mixture of carbohydrates (25 mg). The mixture was subjected to trimethylsilylation (32) and the resulting TMS derivatives were analysed by gc (isotherm at 120°C for the initial 4 minutes, then increasing temperature by 1°C/min to 160°C; injection port and detector at 250°C). The retention times of the mixture of sugars were identical to those of the α and β anomers of authentic D-xylose (18.2,

[10]The resin was washed successively with water (300 mL), MeOH (2 L), $CHCl_3$ (2 L), MeOH (2 L), and water (3 L) to eliminate any organic residue present on the resin.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

21.7), D-quinovose (20.2, 23.3), 3-*O*-Me-D-glucose (23.4, 28.3), and D-glucose (31.3, 39.1).

2. Aglycone constituents

The $CHCl_3$ extract were successively washed with $NaHCO_3$ saturated solution (10 mL), NaCl saturated solution (10 mL), and dried over $MgSO_4$. The mixture obtained after evaporation (14 mg) was subjected to preparative tlc (solvent C) to afford **4** (7.2 mg) and **5** (1.0 mg). Genin-1 (**4**) recrystallized from MeOH to give thin white needles, mp 219–221°C; uv λ_{max} (EtOH) (nm): transparent above 210; ir ν_{max} (CCl_4) (cm^{-1}): 3400 (OH), 1760 (γ-lactone), 1740 (5-memb. ketone); ms *m/z* (%): 468.3239 (M^+, calcd. for $C_{30}H_{44}O_4$: 468.3241; 98), 453 ($M^+ - CH_3$; 20), 450 ($M^+ - H_2O$; 9), 435 ($M^+ - CH_3 - H_2O$; 24), 423 (15), 381 (15), 109 (84), 69 (85), 43 (100); R_f (solvent C) 0.37, identical to stichopogenin-A_2 (11). Genin-2 (**5**), mp undetermined; uv λ_{max} (EtOH) (nm): transparent above 210; ir ν_{max} (CCl_4) (cm^{-1}): 3400 (OH), 1750 (γ-lactone and 5-memb. ketone); R_f (solvent C) 0.10, identical to stichopogenin-A_4 (14).

Methanolysis of psoluthurin A (1)

1. Carbohydrate constituents

A solution of **1** (33 mg) in anhydrous 1% HCl – MeOH (10 mL) was refluxed for 3 h. After cooling, the solution was evaporated to dryness and water was added and extracted with $CHCl_3$ (3 × 10 mL). The aqueous solution was treated as before to afford a mixture of methyl glycosides (19 mg) quantitatively analysed by gc (same conditions as in hydrolysis analyses) of the TMS derivatives. (The retention times were identical to those of the authentic methyl D-glycosides of the following sugars: xylose (14.5), quinovose (16.5), 3-*O*-Me-glucose (18.3, 19.5), and glucose (29.5). The relative quantities were determined to be equimolecular by gas-phase chromatography (peak area/mass of TMS derivative).

2. Aglycone constituents

The $CHCl_3$ extracts were treated as before and the residual mixture separated by preparative tlc (solvent C) to give **4** (4 mg), identified by tlc and **6** (6 mg), mp 231–233°C; $[\alpha]_D^{23}$ −113° (*c* 0.11, MeOH), uv λ_{max} (EtOH) (nm): transparent above 210; ir ν_{max} (CCl_4) (cm^{-1}): 3600 (OH), 1745 (γ-lactone and 5-memb. ketone); ^{13}C nmr ($CDCl_3$): see Table 1; R_f (solvent C) 0.28.

Desulfation of psoluthurine A (1)

A solution of **1** (66 mg) in anhydrous 0.08 *M* HCl – MeOH (10 mL) was stirred at room temperature for 24 h. After neutralization with Ag_2CO_3 and evaporation, the residue was subjected to low pressure column chromatography (CH_2Cl_2–MeOH–H_2O, 60:13:2) to afford the desulfated psoluthurin A (**2**, 36 mg), mp 258–259°C (dec.); $[\alpha]_D^{22}$ −80.4° (*c* 1.11, pyridine); uv λ_{max} (EtOH) (nm): transparent above 210; ir ν_{max} (KBr) (cm^{-1}): 3400 (OH), 1745 (5-memb. ketone), 1755 (sh), and 1765 (sh, γ-lactone); ^{13}C nmr (pyr. $-d_5$): see Table 1; potassium rhodizonate test: negative. *Anal.* calcd. for $C_{54}H_{84}O_{22} \cdot 2H_2O$: C 57.84, H 7.9; found: C 57.98, H 7.62.

Methanolysis of desulfated psoluthurin A (2)

A solution of **2** (22 mg) in anhydrous 0.25 *N* HCl – MeOH (5 mL) was stirred at room temperature for 2 h. The mixture of products obtained (presumably prosapogenols by tlc behavior) was partly separated by lplc and afforded a substance (R_f 0.75, CH_2Cl_2–MeOH–H_2O, 60:25:5.4) which was subjected to anhydrous methanolysis (2 *N* HCl – MeOH) at 60°C for 5 h. The solution was evaporated under vacuum and gc analysis (same conditions as the anlysis of the methanolysis of psoluthurin A) of the TMS derivative showed methyl xylopyranoside as the only sugar present.

Permethylation of desulfated psoluthurin A (2)

A solution of the dimsyl carbanion (prepared from NaH (50 mg) and DMSO (1.5 mL) with heating at 65°C for 45 min under N_2) was added to a solution of **2** (14.7 mg) in DMSO (0.5 mL) and stirred for an additional hour. The resulting solution was poured into an ice–water mixture and extracted several times with hexane, washed with water, dried over $MgSO_4$, and evaporated. Low pressure column chromatography (benzene–acetone, 10:1) of the residue afforded the permethylated desulfated psoluthurin A (3.9 mg), as a viscous oil (R_f 0.22, benzene–acetone, 5:1).

Methanolysis of permethylated desulfated psoluthurin A (3)

A solution of **3** (1.4 mg) in anhydrous 2 *N* HCl – MeOH (1.0 mL) was heated under reflux for 3 h. After cooling, the solution was neutralized with Ag_2CO_3, centrifuged, filtered on a 2 μ membrane, evaporated and analysed by gc–ms (3% OV-17: 100 → 180°C, 8°/min; SE-30: 3 min at 80°C then 80 → 180°C, 5°/min); permethylated methyl glucopyranoside: R_f 6.7, 7.5 (3% OV-17); ms *m/z* (%): 187 (2), 176 (2), 131 (3), 111 (4), 102 (6), 101 (45), 88 (100), 75 (52), 73 (21); methyl 2,3-di-*O*-methylquinovopyranoside: R_f 4.5, 5.0 (3% OV-17); ms *m/z* (%): 175 (2), 130 (16), 102 (15), 101 (12), 88 (100); methyl 2,3-di-*O*-methyl-4-*O*-trimethylsilylquinovopyranoside: R_f 15.3, 16.2 (SE-30); ms *m/z* (%): 247 (2), 159 (29), 146 (27), 130 (21), 101 (27), 88 (100), 75 (32), 73 (33); methyl-2,4,6-tri-*O*-methylglucopyranoside: R_f 8.5 (3% OV-17); ms *m/z* (%): 173 (2), 102 (33), 101 (73), 88 (30), 87 (20), 75 (23), 74 (74), 71 (100); methyl-2,4,6-tri-*O*-methyl-3-*O*-trimethylsilylglucopyranoside: R_f 7.8, 8.4 (3% OV-17); ms *m/z* (%): 245 (1), 187 (7), 185 (2), 173 (1), 146 (100), 131 (25), 111 (8), 102 (5), 101 (19), 88 (12), 75 (19), 73 (38); methyl-3,4-di-*O*-methyl-2-*O*-trimethylsilylxylopyranoside: R_f 14.4, 14.5 (SE-30); ms *m/z* (%): 233 (3), 173 (2), 159 (100), 146 (42), 143 (3), 131 (2), 101 (7), 88 (23), 75 (25), 73 (35), 58 (8); methyl-3,4-di-*O*-methyl-2-*O*-(2,4,6-tri-*O*-methyl-3-*O*-trimethylsilyl-glucopyranosyl)-xylopyranoside: R_f 35.0 (SE-30); ms *m/z* (%): 363 (2), 277 (5), 245 (6), 187 (10), 159 (5), 146 (100), 131 (6), 111 (7), 102 (5), 101 (40), 88 (63), 75 (47), 73 (40).

Acknowledgments

We thank the following agencies for financial support of this research: the Natural Sciences and Engineering Research Council of Canada (J.W.A.), the Québec–Ontario exchange projects (J.W.A., F.X.G.), the Government of Québec via the F.C.A.C. program (F.X.G.), and the Fondation de l'Université du Québec à Chicoutimi (F.X.G.). We are grateful to J. R. J. Paré and J. Bélanger (Carleton University) for advice on the FAB/ms interpretation; V.G. Analytical for the FAB/ms spectrum, and I.C.P. Smith of N.R.C. for the ^{13}C nmr (75.46 MHz) spectrum.

Regiochemistry and reactivity in the chlorination of sulfides

JAMES REID HANCOCK, WILLIAM RAYNE HARDSTAFF, PAUL ALAN JOHNS, RICHARD FRANCIS LANGLER,[1] AND WILLIAM STANLEY MANTLE

Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received July 5, 1982[2]

JAMES REID HANCOCK, WILLIAM RAYNE HARDSTAFF, PAUL ALAN JOHNS, RICHARD FRANCIS LANGLER, and WILLIAM STANLEY MANTLE. Can. J. Chem. **61**, 1472 (1983).

Huheey's original method for the calculation of substituent electronegativities is modified so that isomeric groups have different electronegativities. The modified form of Huheey's method is then employed to show that our previously published method for anticipating regiochemistry in asymmetric sulfide chlorinations, i.e., ΔX_P calculations for the α and α′ substituents in the sulfide substrates, is successful in all fifty known cases. A new reactivity function (R_P) is defined, for the sulfenium ion intermediates, which permits one to anticipate when substrates become inert to chlorine in exhaustive chlorinations conducted in aprotic media.

JAMES REID HANCOCK, WILLIAM RAYNE HARDSTAFF, PAUL ALAN JOHNS, RICHARD FRANCIS LANGLER et WILLIAM STANLEY MANTLE. Can. J. Chem. **61**, 1472 (1983).

On a modifié la méthode originale de Huheey relative au calcul de l'électronégativité du substituant de telle sorte que les groupes isomères ont des électronégativités différentes. On a alors utilisé la forme modifiée de la méthode de Huheey pour montrer que notre méthode, de prévision de la régiochimie des chlorations asymétriques des sulfures i.e. les calculs de ΔX_P pour les substituants en positions α et α′ des sulfures, publiée antérieurement s'applique parfaitement à tous les 50 cas connus. On définit une nouvelle fonction de réactivité (R_P), pour les ions sulfenium intermédiaires, qui permet de prévoir le moment où les substrats ne réagissent plus avec le chlore dans les chlorations exhaustives réalisées en milieu aprotique.

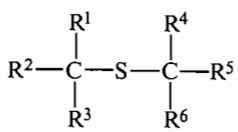
[Traduit par le journal]

Introduction

As part of our continuing studies on the chlorinolyses of organosulfur compounds, we have reported a study of regiochemistry in asymmetric sulfide chlorinations (1). The currently accepted mechanism for these reactions (*vide* Scheme 1) is due to Wilson and Huang (2).

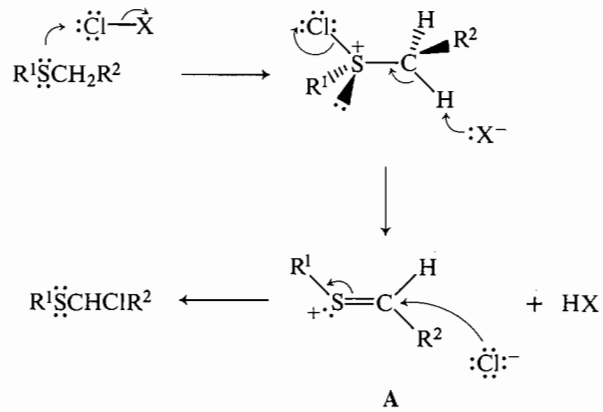
Our previous discussion (1) considered the nature of the CSπ bonding in the intermediate sulfenium ions[3] (**A**, Scheme 1). The old view that CSπ bonding in sulfenium ions is inferior to the corresponding COπ bonding due to "the more diffused nature of the sulfur orbital" (4) is inconsistent with recent MO computations (5). We have learned of a much earlier suggestion (6) that CSπ bonding in related systems is superior to CNπ bonding.

As a result of our bonding arguments, we have suggested that the preferred sulfenium ion will be the one which has the most electronegative substituents on the sp^2 carbon (1). To determine which side chain will be preferentially chlorinated, (*i*) sum the electronegativities of the substituents on the α carbon of the starting sulfide and (*ii*) subtract the sum of the substituent electronegativities for the α′ carbon, i.e. for **1**:



1

$$[1] \quad \Delta X_P = [X_P(R^1) + X_P(R^2) + X_P(R^3)] - [X_P(R^4) + X_P(R^5) + X_P(R^6)]$$



SCHEME 1

If $\Delta X_P < 0$, then reaction goes preferentially into the side chain bearing R^4, R^5, and R^6 but if $X_P > 0$, then reaction goes preferentially into the side chain bearing R^1, R^2, and R^3. A semiquantitative correlation was found between the yield of major regioisomer and ΔX_P for the thirty known asymmetric sulfide chlorinations (1, 7) with essential regiospecificity observed for all cases where $\Delta X_P \geq 0.20$.

Substituent electronegativities were determined using Huheey's method and the parameters which he provided (8, 9). Since that time, we have completed a study comparing net group charges obtained by Huheey's group electronegativity method with those obtained by *ab initio* and semi-empirical molecular orbital calculations (10). One of the conclusions of this study was that Huheey's parameters for the phenyl group ($a = 8.03$, $b = 1.21$, and $X_P = 2.49$) (9) required revision to those parameters shown in Table 1. Revision of the phenyl parameters requires the revision of electronegativity parameters for the phenyl substituted groups shown as entries 2–4 in Table 1. These new parameters furnish new values for some of our previously tabulated ΔX_P's. The cases affected are presented in Table 2. These revisions produce no net change in

the performance of our approach to the prediction of regiochemistry in asymmetric sulfide chlorinations.

Results and discussion

Our first concern in the present study was that isomeric groups may not have the same directing ability in these reactions. Should that be the case, then Huheey's original method, for which "isomeric groups will yield identical electronegativities" (8), has an inherent feature that constitutes a limitation for our approach to regiochemical predictions in asymmetric sulfide chlorinations.

Fundamental to Huheey's original approach to the calculation of group electronegativities (8) is the assumption that all atoms in a group equalize their electronegativities. Thus, two substituents in the same group will have the same electronegativity whether they are remote from or immediately adjacent to each other. Since inductive effects fall off rapidly with distance and are generally thought to be exhausted within three bonds, this assumption is clearly untenable for remote substituents. Such sets of isomeric groups require more than one set of electronegativity parameters. The series of sulfide chlorinations shown in Table 3 presents the problem as it applies to ΔX_P calculations and regiochemistry. With the shift of chlorine ($\alpha \rightarrow \beta \rightarrow \gamma$) in cases $1 \rightarrow 3$, regioselectivity declines, as expected, on the basis of diminishing ΔX_P. However, previous experience (1) suggests that a ΔX_P value of 0.19 (case 3) should indicate essential regiospecificity. Indeed, case 4, for which ΔX_P is 0.19, is regiospecific.

We suggest that (*i*) Huheey's original X_P of 2.39 for chloroethyl groups is best viewed as intermediate between the values appropriate for the 1-chloroethyl and the 2-chloroethyl groups, (*ii*) the 1-chloroethyl group is unlikely to have a X_P value

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

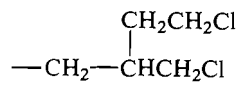
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

significantly different from that for the chloromethyl group (X_P = 2.47), and (*iii*) the 2-chloroethyl group should have a X_P value much closer to that for the ethyl group (X_P = 2.29). The preceding points are compatible with Huheey's earlier suggestion that the origin of the problem of obtaining different X_P values for different isomeric groups is the failure of his original approach to account for the "dilution of polar effects" (8).

Given that asymmetric sulfide chlorinations have been found to exhibit regioselectivities which correlate with substituent ΔX_P values, the chlorinations (cases 3 and 4, Table 3) permit one to obtain reasonable estimates for the two X_P values in question, i.e., $ClCH_2CH_2$, 2.33 and CH_3CHCl, 2.45. Assuming that (*i*) it is satisfactory for all isomeric groups in the same set to have the same "*b*" values, (*ii*) each group has a X_P value intermediate between the X_P values for its component groups e.g., for $ClCH_2CH_2$, X_P should fall between 2.29 (X_P for CH_2) and 2.47 (X_P for $ClCH_2$), and (*iii*) the X_P value for the central atom directly attached to the group of interest is weighted more heavily than its nearest central atom and so on, the following formula may be obtained for group electronegativity which varies with isomeric structure *and* furnishes the appropriate values for the isomeric chloroethyl groups.

$$[2] \quad a_1 = \frac{3^{n-1}a_1 + 3^{n-2}a_2 + 3^{n-3}a_3 + \ldots + 3^{n-n}a_n}{3^{n-1} + 3^{n-2} + 3^{n-3} + \ldots + 3^{n-n}}$$

Thus a_1 is the Mulliken electronegativity[4] for an isomeric group where a_1, a_2 ..... a_n are the Mulliken electronegativities for each component group containing one central atom. Equation [2] will also afford unique answers for chains which have side chains capable of existing in isomeric form. All component groups which are equidistant from the point of contact must have equal weights. Thus a unique electronegativity for **8** can be obtained readily as shown in eq. [3].



8

$$[3] \quad a_8 = \frac{3^3a_{CH_2} + 3^2a_{CH} + 3^1a_{CH_2Cl} + 3^1a_{CH_2} + 3^0a_{CH_2Cl}}{3^3 + 3^2 + 3^1 + 3^1 + 3^0}$$

Table 1 (entries 5–12) presents revised electronegativity parameters for some isomeric ethyl groups. Table 4 presents the results of reactions between a selection of asymmetric sulfides and molecular chlorine or sulfuryl chloride. The ΔX_P values tabulated reflect our modifications to Huheey's electronegativity parameters. As was the case previously (1), the substituent electronegativity difference (ΔX_P) correctly anticipates the observed regioselectivity in every case.

Two previous proposals for the prediction of regiochemistry in these reactions had been advanced i.e. (*i*) reaction will go into the side chain bearing the most acidic α-H atoms (13) and (*ii*) reaction will go into the side chain which is best able to support positive charge (14). We have argued (1) that the first proposal is inconsistent with the reaction shown in eq. [5] and the second proposal is inconsistent with the results shown in eq. [6].

[4]In keeping with Huheey's approach, we use Mulliken electronegativities ($X_M \equiv a$) to carry out calculations. The relationship between Mulliken and Pauling electronegativities is X_P = 0.336 (X_M − 0.615).

[5] 
(60%) (40%)

[6] $PhCH_2SCH_2Cl \xrightarrow{SO_2Cl_2} PhCH_2SCHCl_2$ (100%)

We wished to find a single substrate which would have a common regiochemical outcome predicted by both previous approaches and a different outcome predicted by our approach based on ΔX_P. 4-Chloro-1-phenyl-2-thiabutane **9** is such a system. The α-phenyl group would be expected to (*i*) acidify the α-protons substantially more than an α-chloromethyl group and (*ii*) stabilize an incipient carbonium ion substantially more than an α-chloromethyl group. Thus both of these views lead to the conclusion that chlorination should occur nearly exclusively at the benzylic carbon. However, a consideration of the ΔX_P value for this system (X_P $ClCH_2$, 2.47 (11); X_P Ph, 2.41 (Table 1)) leads to the conclusion that reaction should produce similar amounts of both regioisomers with a modest predominance of the dichloroethyl benzyl sulfide. Equation [7] presents the results of this chlorination:

[7] $ClCH_2CH_2SCH_2Ph \xrightarrow[CCl_4]{SO_2Cl_2}$

9

$ClCH_2CHClSCH_2Ph$ (65%) + $ClCH_2CH_2SCHClPh$ (35%)

The reaction in eq. [7] along with those in Table 4 and our previous results (1) bring the total to fifty asymmetric sulfide chlorinations for which ΔX_P predictions of regioselectivity are successful.

Our initial report (1) failed to discuss only one asymmetric sulfide chlorinolysis known at that time. Paquette (15) had reported the chlorinolysis of the novel dibenzothiepins shown in Scheme 2.

These results provide a contrast to the chlorinolysis of dibenzyl sulfide which affords the α,α-dichlorosulfide cleanly. Paquette has suggested that formation of the cross-chlorinated systems **3** and **6** is due to steric compression between the second chlorine and the nearest R group in **4** and **7**. We would like to suggest that the origin of **3** and **6** more likely lies with bimolecular elimination (*vide* Scheme 1) occurring from chlorosulfonium cation conformations which have the initial α-chlorine in a pseudoaxial position, thereby forcing reaction into the opposite side.[5] Such a proposal has been frequently advanced to rationalize the regiochemistry of thiane-1-oxide chlorinations (7). Formation of cross-chlorinated sulfides might well be a hallmark of chlorinolyses of medium-ring sulfides.

In our previous study (1), virtually all of the substituents affecting the regiochemical outcome of sulfide chlorinations were situated on a carbon attached to sulfur. We hoped, for this

[5]This proposal presupposes that the elimination step requires a transdiaxial relationship between α-H and Cl, a possibility suggested earlier (16).

1. CH_3SCH_3	13.20	CH_3SCH_3(0)	$ClCH_2SCH_3$(100)
2. $PhCH_2SCH_3$[b]	13.41	$PhCH_2SCH_3$(0)	$PhCHClSCH_3$(100)
3. $CH_3SO_2CH_2SCH_2Ph$[b]	14.31	$CH_3SO_2CH_2SCH_2Ph$(25)	$CH_3SO_2CHClSCH_2Ph$(75)
4. CH_3SCH_2CN	14.84	CH_3SCH_2CN(20)	$CH_3SCHClCN$(80)
5. $NCCH_2SCH_2CO_2CH_3$	15.58	$NCCH_2SCH_2CO_2CH_3$(61)	$NCCHClSCH_2CO_2CH_3$(39)

[a]Chlorinations were carried out with sulfuryl chloride in carbon tetrachloride at room temperature.
[b]ΣX_P for this sytem was calculated using the phenyl parameters shown in Table 1.

$ZCH_2CH_2SCH_3$

10*a* Z = CH_3O_2C—
10*b* Z = $PhCH_2SO_2$—
10*c* Z = CH_3SO_2—

Our approach to the synthesis of these systems goes through the corresponding β-chloro intermediate (—SCH_3 is introduced in the last step). Base-catalyzed elimination of HCl produces the corresponding vinyl systems which have a pronounced tendency to polymerize. We have, consequently, telescoped the procedure so that the vinyl systems are prepared *in situ* and the Michael addition of the appropriate mercaptan carried out without isolation of the vinyl intermediates (see, for example, ref. 17).

Chlorination of the substrates **10***a* → **10***c* furnished crude products in which the dominant product(s) was/were not the simple regioisomeric α-chlorosulfide(s). We have chosen to investigate the chlorination of **10***c* in more detail. Column chromatography of the crude product afforded a moderate yield of a colorless oil whose spectra were consistent with a vinyl sulfone-sulfide structure. In the nmr, the vinyl protons appeared as a pair of doublets (δ 7.70 and 6.15, J_{AC} ~ 15 Hz). Table 5 presents some appropriate spectral parameters which clearly implicate the *trans* structure for **11** as shown in eq. [8].

[8] $CH_3SO_2CH_2CH_2SCH_3 \xrightarrow[CHCl_3]{SO_2Cl_2}$

11

Thus, an assessment of the directing ability of substituents situated on β-carbons in asymmetric sulfide chlorinations is only possible when those substituents have a relatively weak acidifying effect on the protons attached to the β-carbon (see eq. [7] for an example).

No results have been published indicating that any feature of these reactions is sensitive to the polarity of the aprotic solvent employed. In particular, we have been unable to find any examples of a shift in regioselectivity attributable to a change in solvent polarity. Table 6 presents results which indicate that these reactions proceed more rapidly in polar aprotic solvents than in nonpolar aprotic solvents. Since these reactions were all

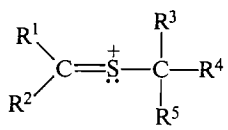
conducted at reflux in the appropriate chlorocarbon solvent, the salutory effect of higher polarity (lower boiling) methylene chloride is firmly established. These results are consistent with the ionic mechanism established for these reactions (see Scheme 1).

In our previous paper (1), we suggested that reactivity for sulfides in these reactions is dependent upon (*i*) the sum of the electronegativities of the substituents (ΣX_P) on the α and α′ carbon atoms and (*ii*) the substituent electronegativity difference (ΔX_P). From the reactions considered at that time, it was clear that ΣX_P is the more important factor. The results shown in Table 7 show that ΣX_P alone can be a useful guide to reactivity for some sulfide chlorinations. We have found that systems for which $\Sigma X_P \leq 14.91$ will monochlorinate readily.

For systems where $\Sigma X_P > 14.91$, the substitution pattern becomes important and ΣX_P alone is not a reliable guide to reactivity. We have been unable to find a correlation between reactivity and any function with ΣX_P and ΔX_P as variables. This difficulty is not surprising, in that these parameters are applicable to the ground state sulfide which is clearly a poor representation of the transition state giving rise to the key sulfenium ion intermediate. In fact, the correlation between ΔX_P and observed regiochemistry in asymmetric sulfide chlorinations must be fortuitous since it also represents an extrapolation of ground state properties to transition state properties. We have found that a useful reactivity function can be obtained using electronegativity parameters for sulfenium ion substituents, i.e., X_P is obtained for R^1R^2C— and $R^3R^4R^5C$— in **12** and the resultant values summed to furnish ΣX_P^*. When chlorination proceeds



12

into the disfavored side chain, as indicated by ΔX_P, then ΣX_P^* correlates with the gross reactivity of the system in question; viz. ΣX_P^* will indicate whether or not the substrate is inert to Cl_2. Since ΔX_P loses its definition for sulfenium ions, we have accounted for the enhanced reactivity of molecules which can chlorinate in the favored side chain by reducing ΣX_P^* by 1. Thus a systematic approach to anticipating gross reactivity of sulfide substrates for which $\Sigma X_P > 14.91$ is now available: (*i*) determine ΔX_P for reaction into the side chain under consideration; for reaction into the favored side $r = -1$; for reaction into the disfavored side $r = 0$, (*ii*) determine ΣX_P^* for the requisite sulfenium ion intermediate, and (*iii*) evaluate R_P', which is defined in eq. [9].

$$[9] \quad R_P' = \Sigma X_P^* + r$$

A more convenient scale of values is obtained with R_P which is defined in eq. [10].

$$[10] \quad R_P = R_P' - 5.22$$

The final form of our reactivity function (R_P) gives values <0 for molecules which are still able to react with Cl_2 at a useful rate and values >0 for molecules which are inert.[6] Since R_P does not account for a number of important factors, notably the nature of the solvent, these numbers should not be taken to indicate relative reactivities, but simply to indicate whether further reaction is likely (e.g., it is futile to attempt to obtain 1,1,1,3,3-pentachloro-2-thiapropane by chlorinating 1,1,1,3-tetrachloro-2-thiapropane (entry 5, Table 8)). When the fifty sulfide chlorinations of regiochemical interest are supplemented with those substrates for which the regiochemistry is trivial, there are some sixty-seven sulfide chlorinations to which R_P calculations potentially apply. For thirty-seven of these reactions $\Sigma X_P \leq 14.91$. R_P values for the remaining thirty cases are presented in Table 8.

In attempting to apply ΔX_P and R_P predictions to the outcome of sulfide chlorinations, one should bear in mind that α-chlorination is *not* expected to occur when (*i*) one of the substituents on sulfur is unusually susceptible to external nucleophilic attack (S_N1 or S_N2) which will lead to the cleavage af a CS bond (7), (*ii*) a β-carbon bears a strongly acidifying group, and (*iii*) the substrate contains a substituent capable of neighboring group participation (12).

In conclusion, we have (*i*) further modified Huheey's method for the calculation of group electronegativity parameters, (*ii*) extended the number of asymmetric sulfide chlorinations for which ΔX_P correctly anticipates the regiochemical outcome, and (*iii*) defined a new function R_P which permits an assessment of the gross reactivity of sulfide substrates in reactions with Cl_2.

Experimental

General

Details have been provided previously (1).

Chlorinations with sulfuryl chloride

The following procedure was employed for the chlorination of those new substrates listed under "*Reagent*: SO_2Cl_2" in Table 4. The desired sulfide (0.5 g) was dissolved in carbon tetrachloride (10 mL) and a solution of sulfuryl chloride (1 equivalent) in carbon tetrachloride (10 mL) added dropwise over 5 minutes. The reaction mixture was stirred at ambient temperature for 0.5 h and the solvent evaporated. The product mixture in most cases was analyzed by integrated nmr. The outcome of the following cases could not be determined by nmr alone.

Chlorination of 2-oxo-5-phenyl-4-thiapentane

$PhCH_2SCH_2C(O)CH_3$ (entry 15, Table 4) which had ir ($CHCl_3$) 1701 cm^{-1} was subjected to the procedure outlined under "Chlorinations with sulfuryl chloride". The homogeneous product, $PhCH_2SCHClC(O)CH_3$, had ir[7] ($CHCl_3$): 1740 cm^{-1}; nmr ($CDCl_3$) δ: 2.33 (3H, s), 4.00 (2H, s), 5.30 (1H, 2), and 7.4 (5H, s).

Chlorination of 2-oxo-5-p-bromophenyl-4-thiapentane

p-$BrPhCH_2SCH_2C(O)CH_3$ (entry 16, Table 4) which had ir ($CHCl_3$) 1710 cm^{-1} was subjected to the procedure outlined under "Chlorination with sulfuryl chloride". The homogeneous product, *p*-$BrPhCH_2SCHClC(O)CH_3$, had ir[7] ($CHCl_3$): 1738 cm^{-1}; nmr ($CDCl_3$) δ: 2.33 (3H, s), 3.90 (2H, s), 5.33 (1H, s), 7.26 (2H, d), and 7.53 (2H, d).

Chlorination of methyl 4-cyano-3-thiabutyrate

$NCCH_2SCH_2CO_2CH_3$ (entry 20, Table 4) which had ir (CCl_4) 1748 cm^{-1} was subjected to the procedure outlined under "Chlorinations with sulfuryl chloride". Since reaction was incomplete, the reaction was repeated on the crude product. The homogeneous product, $NCCHClSCH_2CO_2CH_3$, had ir (CCl_4): 1750 cm^{-1}; nmr ($CDCl_3$) δ: 3.86 (5H, m) and 5.96 (1H, s).

[6]By "inert" we mean that there is no observable formation of the α-chlorosulfide (by nmr) after chlorination of 0.5 g for 4 h at ambient temperature.

[7]A shift to higher νCO is associated with a field effect for α-halocarbonyl compounds (20).

[a] $R_P > 0$ implies sulfide is inert to Cl_2 and $R_P < 0$ implies sulfide will react with Cl_2.
[b] New chlorinations were carried out with Cl_2.

Chlorinations with Cl_2

The following procedure was employed for the chlorination of the new substrates listed in Table 8. The desired sulfide (0.5 g) was dissolved in carbon tetrachloride[8] (5 mL) and Cl_2 bubbled (ca. 200 mL/min) into the solution. The chlorinations were interrupted after 5, 15, and 50 min and the crude product checked by nmr at each stage. When two nmr's were the same, chlorination was carried out for a further 4 h and the final product checked by nmr.

Preparation of 1-chloro-2-thiabutane

Ethanethiol (4.993 g) and p-formaldehyde (2.466 g) were added to methylene chloride (25 mL) and the mixture cooled with an ice/water bath. HCl (ca. 200 mL/min) was bubbled into the reaction mixture for 50 min. Methylene chloride (100 mL) was added and the resultant solution dried ($MgSO_4$) and concentrated. The residue was rectified at ambient pressure affording clean chlorosulfide (5.225 g, bp 128−131°C). The product had ir (CCl_4): 2950 and 1250 cm^{-1}; nmr ($CDCl_3$) δ: 1.36 (3H, t), 2.86 (2H, q), and 4.86 (2H, s).

Preparation of 1-cyano-2-thiapropane

Four preparative runs were carried out as described below and the crude products from each run combined. Sodium cyanide (5.077 g) was dissolved in dry DMSO (200 mL) and 1-chloro-2-thiapropane (10.008 g) added dropwise over 5 min. The reaction mixture was stirred at ambient temperature for 1 h. Water (300 mL) was added and the resultant solution washed with diethyl ether (three 200-mL portions). The combined organic layers were washed with 5% HCl (two 200-mL aliquots) and water (200 mL). The organic layer was dried ($MgSO_4$) and concentrated. The combined material from four runs was distilled at reduced pressure affording impure cyanosulfide (4.528 g, bp 100−120°C/100 Torr). The distilled cyanosulfide was chromatographed on silica gel (400 g) employing chloroform elution (100 mL fractions). Fractions 12−19 were combined and distilled affording clean cyanosulfide (2.190 g, bp 98−100°C/100 Torr). The cyanosulfide had ir ($CHCl_3$): 2245 cm^{-1}; nmr ($CDCl_3$) δ: 2.33 (3H, s) and 3.33 (2H, s); ms m/e: 87 (M^+, 70%), 61 (80%), and 47 (100%).

Preparation of 1,3-dicyano-2-thiapropane

Sodium sulfide nonahydrate (8.67 g) was added to 95% ethanol (50 mL) and the mixture brought to gentle reflux. Chloroacetonitrile (5.02 g) in 95% ethanol (50 mL) was added dropwise over 50 min. Upon completion of the addition the reaction mixture was refluxed for an additional 0.5 h. Norite (ca. 5 g) was added and the resultant hot mixture filtered through Celite. Water (100 mL) was added and the resultant mixture washed with chloroform (three 100-mL aliquots). The combined chloroform layers were concentrated, affording a black oil. The crude oil was chromatographed on silica gel (100 g) employing chloroform elution (100 mL fractions). Fractions 4−6 were combined and concentrated affording a yellow solid. The chromatographed product was recrystallized (2×) from 95% ethanol affording clean dicyanosulfide (0.702 g, mp 39−41°C). The dicyanosulfide had ir ($CHCl_3$): 2290 cm^{-1}; nmr ($CDCl_3$) δ: 3.60 (s); ms m/e: 112 (M^+, 37.5%), 72 (40.6%), 45 (59.3%), and 41 (100%).

Preparation of 4-chloro-2-thiabutane

The preparation and properties of 4-chloro-2-thiabutane have been detailed previously (17).

Preparation of 5-chloro-2-thiapentane

The preparation and properties of 5-chloro-2-thiapentane have been detailed previously (11).

[8] For cases where the sulfide was not soluble in CCl_4, chloroform was used.

Preparation of 2-thia-4-pentanone

Sodium metal (3.803 g) was dissolved in methanol (250 mL) and the solution cooled with an ice/water bath. Methanethiol (25 mL) was slowly bubbled into the solution. Chloroacetone (14.999 g) in methanol (50 mL) was added dropwise over 10 min and the reaction mixture stirred at ambient temperature overnight. Water (250 mL) was added and the resultant mixture washed with methylene chloride (four 100-mL portions). The combined organic layers were dried ($MgSO_4$) and concentrated. The residue was rectified at reduced pressure affording the ketosulfide (12.730 g, bp 90−92°C/100 Torr). The ketosulfide had ir ($CHCl_3$): 1705 cm^{-1}; nmr ($CDCl_3$) δ: 2.10 (3H, s), 2.30 (3H, s), and 3.23 (2H, s): ms *m/e*: 104 ($M^{+\cdot}$, 38.7%), 61 (80.0%), and 43 (100%).

Preparation of 2-thia-4-pentanol

Lithium aluminum hydride (4.792 g) was covered with dry diethyl ether (300 mL) and the mixture refluxed 0.5 h. The mixture was cooled to room temperature and a solution of 2-thia-4-pentanone (12.70 g) in diethyl ether (100 mL) added dropwise over 1 h. The reaction mixture was refluxed for 1 h. Ethyl acetate (25 mL) was added dropwise. 1% HCl (100 mL) was added slowly. Water (300 mL) was added and the layers separated. The aqueous layer was washed with methylene chloride (five 100-mL aliquots). The organic layers were combined and concentrated. The residue was rectified at reduced pressure affording the sulfide-alcohol (9.059 g, bp 103−105°C/100 Torr). The sulfide-alcohol had ir ($CHCl_3$): 3475 cm^{-1}; nmr ($CDCl_3$) δ: 1.26 (3H, d), 2.16 (3H, s), 2.70 (3H, m), and 3.93 (1H, m); ms *m/e*: 106 ($M^{+\cdot}$, 55%), 62 (100%), and 45 (68%).

Preparation of 4-chloro-2-thiapentane

A solution of 2-thia-4-pentanol (9.059 g) in chloroform (30 mL) was brought to gentle reflux. A solution of thionyl chloride (10.116 g) in chloroform (15 mL) was added dropwise over 10 min. The reaction mixture was refluxed for 6 h and the solvent evaporated. The residue was distilled twice at reduced pressure yielding clean chlorosulfide (3.503 g, bp 82−84°C/100 Torr). The chlorosulfide had ir ($CHCl_3$): 3000 cm^{-1}; nmr ($CDCl_3$) δ: 1.63 (3H, d), 2.20 (3H, s), 2.86 (2H, m) and 4.10 (1H, m); ms *m/e*: 126 (8.7%), 124 ($M^{+\cdot}$, 26.2%), and 61 (100%).

Preparation of 1-phenyl-2-thia-4-pentanone

Sodium metal (3.781 g) was dissolved in absolute ethanol (250 mL) and benzylthiol (20 mL) added. Chloroacetone (14.800 g) was added and the reaction mixture stirred at ambient temperature for 48 h. Water (250 mL) was added and the resultant mixture washed with chloroform (five 100-mL aliquots). The combined organic layers were dried ($MgSO_4$) and concentrated. The residue was distilled at reduced pressure yielding the ketosulfide (23.857 g, bp 138−140°C/1.4 Torr). The product had ir ($CHCl_3$): 1701 cm^{-1}; nmr ($CDCl_3$) δ: 2.16 (3H, s), 3.06 (2H, s), 3.63 (2H, s), and 7.26 (5H, s); ms *m/e*: 180 ($M^{+\cdot}$, 14.2%), 123 (37.8%), and 91 (100%).

Preparation of p-*bromobenzyl chloride*

p-Bromobenzyl alcohol (50 g) was dissolved in chloroform (100 mL) and the solution brought to gentle reflux. A solution of thionyl chloride (32 g) in chloroform (30 mL) was added dropwise over 20 min. The reflux was continued for four hours and the solvent evaporated. The crude product was rectified at reduced pressure affording the bromochloride (32.69 g, bp 115°C/6 Torr). The product had ir ($CHCl_3$): 1600 and 1590 cm^{-1}; nmr ($CDCl_3$) δ: 4.53 (2H, s), 7.23 (2H, d), and 7.50 (2H, d); ms *m/e*: 208 (7.4%), 206 (29.7%), 204 ($M^{+\cdot}$, 23.4%), 171 (97.8%), and 169 (100%).

Preparation of p-*bromobenzyl thiol*

A solution of *p*-bromobenzyl chloride (32.70 g) and thiourea (12.11 g) in 95% ethanol (80 mL) was refluxed for 26 h. Water (95 mL) and sodium hydroxide (9.6 g) were added and the resultant solution refluxed for 2 h. Water (100 mL) was added and the resultant mixture washed with methylene chloride (four 100-mL aliquots). The combined organic layers were dried ($MgSO_4$) and concentrated. The residue was distilled at reduced pressure affording *p*-bromobenzylthiol (22.96 g, bp 115−117°C/2.8 Torr). The mercaptan had ir ($CHCl_3$): 1595 cm^{-1}; nmr ($CDCl_3$) δ: 1.73 (1H, t), 3.63 (2H, d), 7.06 (2H, d), and 7.36 (2H, d); ms *m/e*: 204 (30.6%), 202 ($M^{+\cdot}$, 29.7%), 171 (100%), and 169 (100%).

*Preparation of 1-*p*-bromophenyl-2-thia-4-pentanone*

Sodium metal (0.566 g) was dissolved in methanol (100 mL) and *p*-bromobenzylthiol (5.000 g) added. Chloroacetone (2.277 g) was added dropwise and the reaction mixture stirred at ambient temperatre for 24 h. Water (100 mL) was added and the resultant mixture washed with methylene chloride (four 100-mL aliquots). The combined organic layers were dried ($MgSO_4$) and concentrated. The residue was chromatographed on silica gel (400 g) employing chloroform elution (100-mL fractions). Fractions 10−20 were combined and concentrated. The chromatographed product was dissolved in hot 95% ethanol and treated with charcoal. After concentration and drying the ketosulfide was obtained as a colorless waxy solid (0.770 g). The product had ir ($CHCl_3$): 1710 cm^{-1}; nmr ($CDCl_3$) δ: 2.16 (3H, s), 3.06 (2H, s), 3.60 (2H, s), 7.18 (2H, d), and 7.46 (2H, d); ms *m/e*: 260 (11%), 258 ($M^{+\cdot}$, 11%), 171 (78%), 169 (80%), and 43 (100%).

Preparation of 5-phenyl-2-thiapentane

A mixture of magnesium metal (2.016 g) and benzylchloride (10.293 g) in diethyl ether (300 mL) was refluxed for 3 h. A solution of 4-chloro-2-thiabutane (3.008 g) (17) in diethyl ether (60 mL) was added dropwise over 10 min and reflux continued for 1.5 h.

The cooled reaction mixture was poured into saturated aqueous ammonium chloride (500 mL) and the layers separated. The aqueous layer was washed with diethyl ether (two 200-mL aliquots). The combined organic layers were dried ($MgSO_4$) and concentrated. The crude residue was applied to five preparative tlc plates which were developed with carbon tetrachloride. The middle bands (R_f, ca. 0.7) were scraped, combined, and washed with chloroform. Upon concentration and distillation of the residue, 5-phenyl-2-thiabutane (0.185 g, bp 97°C/1.4 Torr) was obtained. The sulfide had ir ($CHCl_3$): 2940 and 1610 cm^{-1}; nmr ($CDCl_3$) δ: 1.87 (2H, m), 2.07 (3H, s), 2.54 (4H, m), and 7.24 (5H, s); ms *m/e*: 166 ($M^{+\cdot}$, 63.3%), 118 (100%), 117 (70%), and 91 (56.6%). This sample was identical in all respects with one obtained by the base-catalyzed reaction of methanethiol with the tosylate derived from 3-phenyl-1-propanol.

Preparation of 1-chloro-3-thiapentane

The preparation and properties of 1-chloro-3-thiapentane have been detailed previously (17).

Preparation of methyl 3-thiapentanoate

The preparation and properties of methyl 3-thiapentanoate have been detailed previously (11).

Preparation of methyl 4-chloro-2-thiabutanoate

The methyl ester of thioglycolic acid (4.925 g) and paraformaldehyde (1.418 g) were added to methylene chloride (25 mL) and the mixture cooled with an ice/water bath. HCl was bubbled (ca. 200 mL/min) into the reaction mixture for 1 h. The reaction mixture was diluted to 100 mL with methylene chloride, dried ($MgSO_4$), and concentrated. The residue was rectified at reduced pressure affording the sulfide-ester (3.846 g, bp 89−91°C/6 Torr). The sulfide-ester had ir ($CHCl_3$): 1740 cm^{-1}; nmr ($CDCl_3$) δ: 3.56 (2H, s), 3.86 (3H, s), and 4.93 (2H, s); ms *m/e*: 156 (8.3%), 154 ($M^{+\cdot}$, 23.3%), 97 (13.3%), 95 (41.6%), and 74 (100%).

Preparation of methyl 4-cyano-2-thiabutanoate

Sodium cyanide (1.580 g) was added to anhydrous DMSO (200 mL). Methyl 4-chloro-2-thiabutanoate (5.025 g) was added dropwise to the reaction mixture. Upon completion of the addition the reaction was stirred at ambient temperature for 1 h. Water (300 mL) was added and the resultant solution washed with diethyl ether (three 200-mL aliquots). The combined ether layers were washed with 5% HCl (two 200-mL portions) and water (200 mL). The organic layer was dried ($MgSO_4$) and concentrated. The crude residue was distilled at reduced pressure affording clean cyanosulfide-ester (1.200 g, bp 138−140°C/5 Torr). The cyanosulfide-ester had ir (CCl_4): 2250 (very

For personal use only.

weak) and 1750 cm^{-1}; nmr ($CDCl_3$) δ: 3.56 (2H, s), 3.63 (2H, s), and 3.86 (3H, s); ms *m/e*: 145 ($M^{+\cdot}$, 43.1%), 86 (75%), and 74 (100%).

Preparation of ***9***

The preparation and properties of 4-chloro-1-phenyl-2-thiabutane have been reported previously (17).

Preparation of ***10***a

The preparation and properties of methyl 2-thiapentanoate have been reported previously (11).

Preparation of ***10***b

Sodium (0.632 g) was dissolved in absolute ethanol (100 mL). 2-Chloroethyl benzyl sulfone (3.000 g) (17) was added and the reaction mixture stirred at ambient temperature for 15 min. Methanethiol (5 mL) was slowly bubbled into the solution and the reaction mixture refluxed for 1 h. Water (100 mL) was added and the resultant mixture washed with chloroform (three 100-mL aliquots). The combined chloroform layers were dried ($MgSO_4$) and concentrated. The residue was recrystallized from 95% ethanol yielding colorless flakes of ***10b*** (1.840 g, mp 106.5–109°C). The sulfone-sulfide had ir ($CHCl_3$): 1320 and 1120 cm^{-1}; nmr ($CDCl_3$) δ: 2.10 (3H, s), 3.04 (4H, m), 4.30 (2H, s), and 7.44 (5H, s); ms *m/e*: 230 ($M^{+\cdot}$, 1.8%), 91 (100%), 75 (32.7%), and 74 (29.0%). *Anal.* calcd. for $C_{10}H_{14}O_2S_2$: C 52.10, H 6.10; found: C 52.35, H 6.14.

Preparation of ***10***c

2-Chloroethyl methyl sulfone (4.999 g) (17) was added to a solution of pyridine (60 mL) and triethylamine (7.083 g) and the reaction stirred at ambient temperature for 5 min. The reaction mixture was cooled with an ice/water bath and methanethiol (5 mL) slowly distilled into the reaction mixture. The reaction mixture was stirred at ambient temperature overnight. Chloroform (150 mL) was added and the resultant solution washed with 5% HCl (50-mL portions) until the aqueous pH remained acidic. The organic phase was dried ($MgSO_4$) and concentrated. The residue was rectified at reduced pressure affording a crystalline distillate (1.602 g, bp 114°C/0.3 Torr, mp 31–34°C). The sulfone-sulfide had ir ($CHCl_3$): 1325 and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 2.16 (3H, s), 3.00 (5H, s and m), and 3.30 (2H, m); ^{13}C nmr ($CDCl_3$)[9] δ: 14.74, 25.52, 40.47, and 53.58; ms *m/e*: 154 ($M^{+\cdot}$, 25%), 75 (89.5%), and 74 (100%).

Chlorinolysis of ***10***c

The sulfone-sulfide ***10c*** (0.437 g) was chlorinated as described under "Chlorinations with sulfuryl chloride". The crude was chromatographed on silica gel (50 g) employing chloroform elution (50-mL aliquots). Fractions 6 and 7 were combined affording clean vinylogous thiosulfonate **11** (0.245 g) as a colorless oil. The vinylogous thiolsulfonate had ir ($CHCl_3$): 1315 and 1130 cm^{-1}; nmr ($CDCl_3$) δ: 2.35 (3H, s), 3.00 (3H, s), 6.15 (1H, d, $J \sim 15$ Hz), and 7.70 (1H, d, $J \sim 15$ Hz).

Hydrogen fluoride laser induced multiphoton decomposition of 2,2,2-trifluoroethanol[1]

ROBERT D. MCALPINE, D. K. EVANS, AND J. W. GOODALE

Physical Chemistry Branch, Atomic Energy of Canada Limited, Research Company, Chalk River Nuclear Laboratories, Chalk River, Ont., Canada K0J 1J0

Received November 9, 1982

ROBERT D. MCALPINE, D. K. EVANS, and J. W. GOODALE. Can. J. Chem. **61**, 1481 (1983).

The HF laser-induced multiphoton decomposition (MPD) of 2,2,2-trifluoroethanol (TFE) was studied for two different "dog-bone" irradiation geometries using TFE pressures from 0.134 to 3.82 kPa. The depletion kinetics of TFE are first order in TFE pressure and the formation kinetics for several of the large number of products display pseudo-first order kinetics with pressure dependent stoichiometric ratios.

Three different theoretical models for decomposition probability versus fluence were tested. All were integrated over a complex irradiation geometry and were found to predict equally well the number of decomposed TFE molecules to within a factor of 3 or 4 of the experimental result.

ROBERT D. MCALPINE, D. K. EVANS et J. W. GOODALE. Can. J. Chem. **61**, 1481 (1983).

On a étudié la décomposition par multiphotons (DMP) du trifluoro-2,2,2 éthanol (TFE) induite par un laser au HF en utilisant deux géométries différentes d'irradiation du type "dog-bone" à des pressions de TFE allant de 0,134 à 3,82 kPa. La cinétique de la diminution du TFE est d'ordre un dans l'échelle de pression du TFE et la cinétique de la formation de plusieurs des nombreux produits est de pseudo ordre un lorsque la pression dépend des rapports stoechiométriques.

On a vérifié trois différents modèles théoriques de probabilité de décomposition en fonction de la fluence. On les a tous intégrés dans une géométrie d'irradiation complexe et on a trouvé qu'ils prédisent bien et de façon égale le nombre de molécules de TFE décomposées à un facteur qui représente de 3 ou 4 fois les résultats expérimentaux.

[Traduit par le journal]

1. Introduction

Comparison studies (1, 2) of pulsed HF laser-induced multiphoton absorption (MPA) and decomposition (MPD) of hydroxyl-containing molecules have demonstrated the relative ease of MPA and MPD for molecules having the onset of the "quasi-continuum" (3) occurring for excitation of one or two photons. This onset occurs earlier for "large" molecules, such as 2,2,2-trifluoroethanol (TFE) than for "small" molecules. Consequently, at low pressures, HF laser-induced MPA and MPD for TFE are considerably easier than for the "small" molecule methanol. For methanol, excitation to the "quasi-continuum" requires absorption of 4−5 HF laser photons (1, 2). This, and the large anharmonicity of the mode initially pumped, is what distinguishes "large" from "small" molecules (1, 2).

For the preliminary studies of the HF laser-induced MPD of TFE reported in ref. 2, kinetics were obscured by the pressure dependence of the stoichiometric ratios (the number of product molecules per TFE decomposed). This variation has now been clarified and consistent kinetic results are reported.

In ref. 2 the probability of decomposition as a function of laser fluence, $f(E)$, was measured and an exponential form first suggested by Fuss (4) was fitted to the results. Two other functional forms for $f(E)$ have been suggested: a Cumulative Log-Normal Distribution Function (CLNDF), which arises from the energy grained master equation description of collisionless MPD (5−7), and an empirical form which was used to describe the MPD yields of CDF_3 (8). To further the understanding of MPD, it is important to develop and test predictive descriptions for MPD yields. Two focussed beam (dog-bone type (9)) geometries were chosen and the data for $f(E)$ from ref. 2 were used to predict the decomposition yields for the two irradiation geometries for each of the three models. We have done the appropriate decomposition experiments in the two geometries to allow the comparison of the predictions of these models with experimental results.

2. Experimental

2.1 *Irradiation source and geometry*

The P_1 (7) line ($\bar{\nu}$ = 3644.16 cm^{-1} (10); radiant energy, E = 170 ± 20 mJ; divergence, θ = 0.5 mrad, pulse width (FWHM) 270 ns) of a Lumonics Model 212A pulsed HF laser, equipped with an unstable resonator front optic, was used for all irradiations. A cylindrical cell of length 7.5 cm, outside diameter 2.5 cm, and volume 39.9 cm^3 was fitted with sapphire windows. The centre of the focal region was located 4.25 cm behind the front window.

Two irradiation geometries (see Fig. 1) were obtained by use of two different focal length (F) lenses. A germanium lens, antireflection coated for 2.6−3.1 μm of F = 20 cm, was used for Geometry A and an uncoated CaF_2 lens, F = 122 cm, was used for Geometry B.

2.2 *Analytical procedures*

Products not condensable at −196°C (H_2, CO, and CH_4) were analyzed by mass spectrometry as previously described (11, 12). Condensable products were analyzed with a Hewlett−Packard model 5700 A gas chromatograph using dual 3.05 m long, 3.18 mm od stainless steel columns packed with 80−100 mesh Poropak-Q. Quantitative analysis was obtained by comparison of peak area with calibration curves obtained from samples for each of the pure compounds: CF_2=CF_2, CF_2=CH_2, CF_2=CHF, and TFE. If H_2O or HF are products, they would not be detected by this system.

A Finnigan model 1020B computerized gas chromatograph/mass spectrometer was used to identify the following additional products: CO_2, C_2F_6, CHF_3, $CF_3CF_2CF_3$, CF_3CF_2H, CHF=CHF (*trans*), CF_2HCl (impurity), CF_2=CH—CF_3, and CF_3CF_2CHO. There are at least eight additional minor products which were detected but not identified.

3. Results and discussion

3.1 *MPD Kinetics and pressure dependence*

For Geometry A, the amount of TFE consumed and of products obtained were measured as a function of both the number of laser pulses, m, and the TFE initial pressure, P. These results are given in Table 1, and their fit to a single first order rate law (2), for the decomposition of TFE with $k_1(A)$ = (4.8 ± 1.3) × 10^{-5} $(pulse)^{-1}$, is shown in Fig. 2. A similar, though less extensive, study for Geometry B (Table 1) also follows a

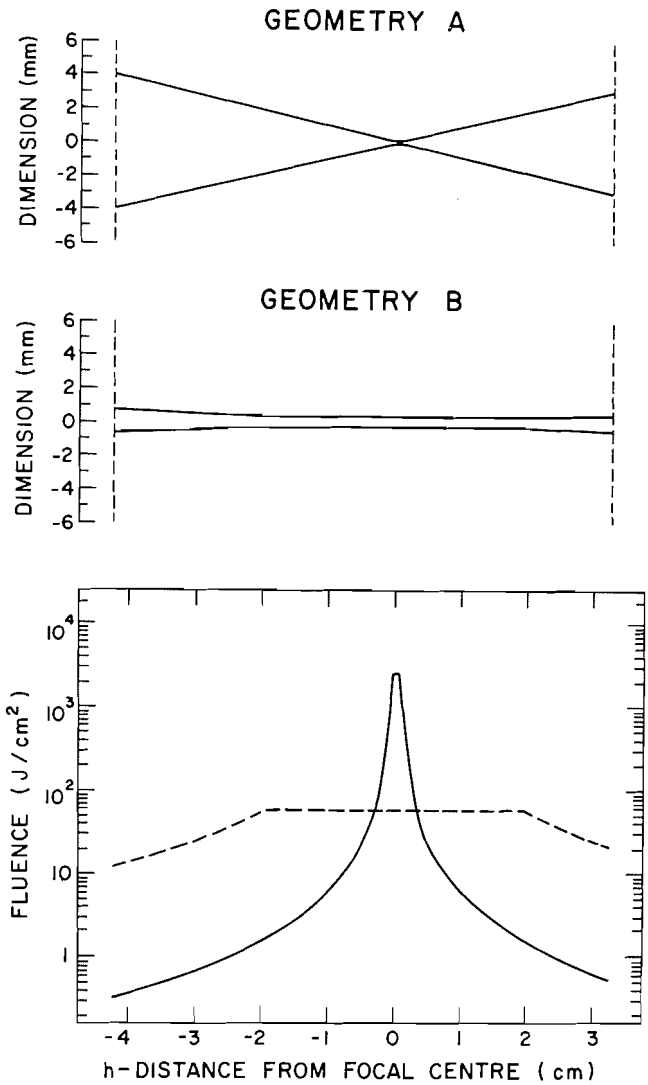

FIG. 1. The irradiation geometries used in this study, and the corresponding spatial dependence of fluence (bottom graph). The solid line (——) corresponds to Geometry A and the dashed line (----) to Geometry B.

first order rate law, with $k_1(B) = (2 \pm 1) \times 10^{-4}$ pulse^{-1}. The difference between $k_1(A)$ and $k_1(B)$ reflects the fact that both a different fraction of the TFE molecules is in the photolysis zone in each case, and, because of the different distribution of E, different fractions of the "illuminated" molecules decompose.

MPD of TFE to give various products can be represented by eq. [1].

$$[1] \quad q_0\, CF_3CH_2OH \rightarrow q_1\, CO + q_2\, C_2F_4 + q_3\, H_2 + q_4\, CF_2CH_2 + q_5\, CF_2CHF + q_6\, CH_4 + \ldots$$

The stoichiometric ratio of each product, η_i, which may be pressure dependent (2), is defined by [2].

$$[2] \quad \eta_i = q_i/q_o$$

The array of products which was observed indicates a complex decomposition chemistry. The major products observed do not account for all the atoms from the measured decomposition of TFE (see Table 1). The discrepancy can largely be accounted for by assuming H_2O and HF are products which would not be detected by our analytical technique. As the pressure or the number of pulses increases, the products observed tend to account for most of the C and F atoms from the decomposed TFE. Quite possibly, as product concentrations build up, they react with primary products from later pulses to give the observed molecules. We must still assume H_2O is a product to get an atom balance for the high pressure, long irradiation experiments. In such a complex system it is unlikely that product formation (except for primary products) would be simple first order. The formation of products such as C_2F_4 and the pressure dependence of some of the stoichiometric ratios (2) in the MPD and TFE demonstrate that the chemistry is complex in this system. We have tested to what extent first order (or more correctly, pseudo-first order) kinetics can fit the dependence of the amount of various products on the number of laser pulses.

In Fig. 3 is shown a fit of the data to a pseudo-first order form of the type given in eq. [3].

$$[3] \quad M^i_m/N_o = \eta_i[1 - \exp(-k_1 m)]$$

where N_o is the number of TFE molecules before photolysis and M^i_m is the number of the i'th product molecules present after m laser pulses. Values of η_i, the slopes from Fig. 3, are given in Table 2. These confirm that the stoichiometric ratios are, indeed, pressure dependent. Further, these results show that, for a fixed pressure, and for up to 50% TFE conversion, pseudo-first order forms provide a reasonable approximation of the quantities of products formed in the MPD of TFE.

The stoichiometry results for the products CO and H_2 differ from those reported earlier (2) by ~2-fold. The earlier results (2) were obtained using cylindrical rather than dog-bone geometry. For the former geometry, cell windows terminate the photolysis zone, and this suggests that wall effects (which are unlikely for Geometry A) in the formation of H_2 and CO may be responsible for the ~2-fold difference in the stoichiometric ratios.

From the photolysis results reported above, we are not able to elucidate the primary photochemical decomposition mechanism. The products observed are typical of a complex, free-radical scheme.

3.2 *Comparisons of theories and experiments*

The decomposition probability of TFE as a function of average fluence, $f(E)$, was previously measured for a cylindrical excitation geometry (2). Several models (4–8) have appeared which allow us to predict the total number of TFE molecules decomposed per pulse (D) for complex geometries such as the "dog-bone" shape (9), if $f(E)$ is known. We have used the data from ref. 2 in these models to calculate D for each of Geometries A and B. These are compared with the results of MPD experiments for these geometries.

For the "dog-bone" Geometries A or B, the differential decomposition of TFE is given by eq. [4]

$$[4] \quad \frac{dD}{dh} = f_i(E) N \frac{dV}{dh}$$

where h is the longitudinal distance (as in Fig. 1) from focal center, N is the TFE number density, and $V(h)$ describes the "dog-bone" photolysis geometry. Integration of [4], which depends on the choice of $f_i(E)$, will give the decomposition yield, D.

The three different models used for $f_i(E)$ are given by eqs.

TABLE 1. The number of TFE molecules decomposed and of several product molecules formed after m HF laser pulses. N_0 and N_m are respectively the number of TFE molecules in the cell before and after m pulses

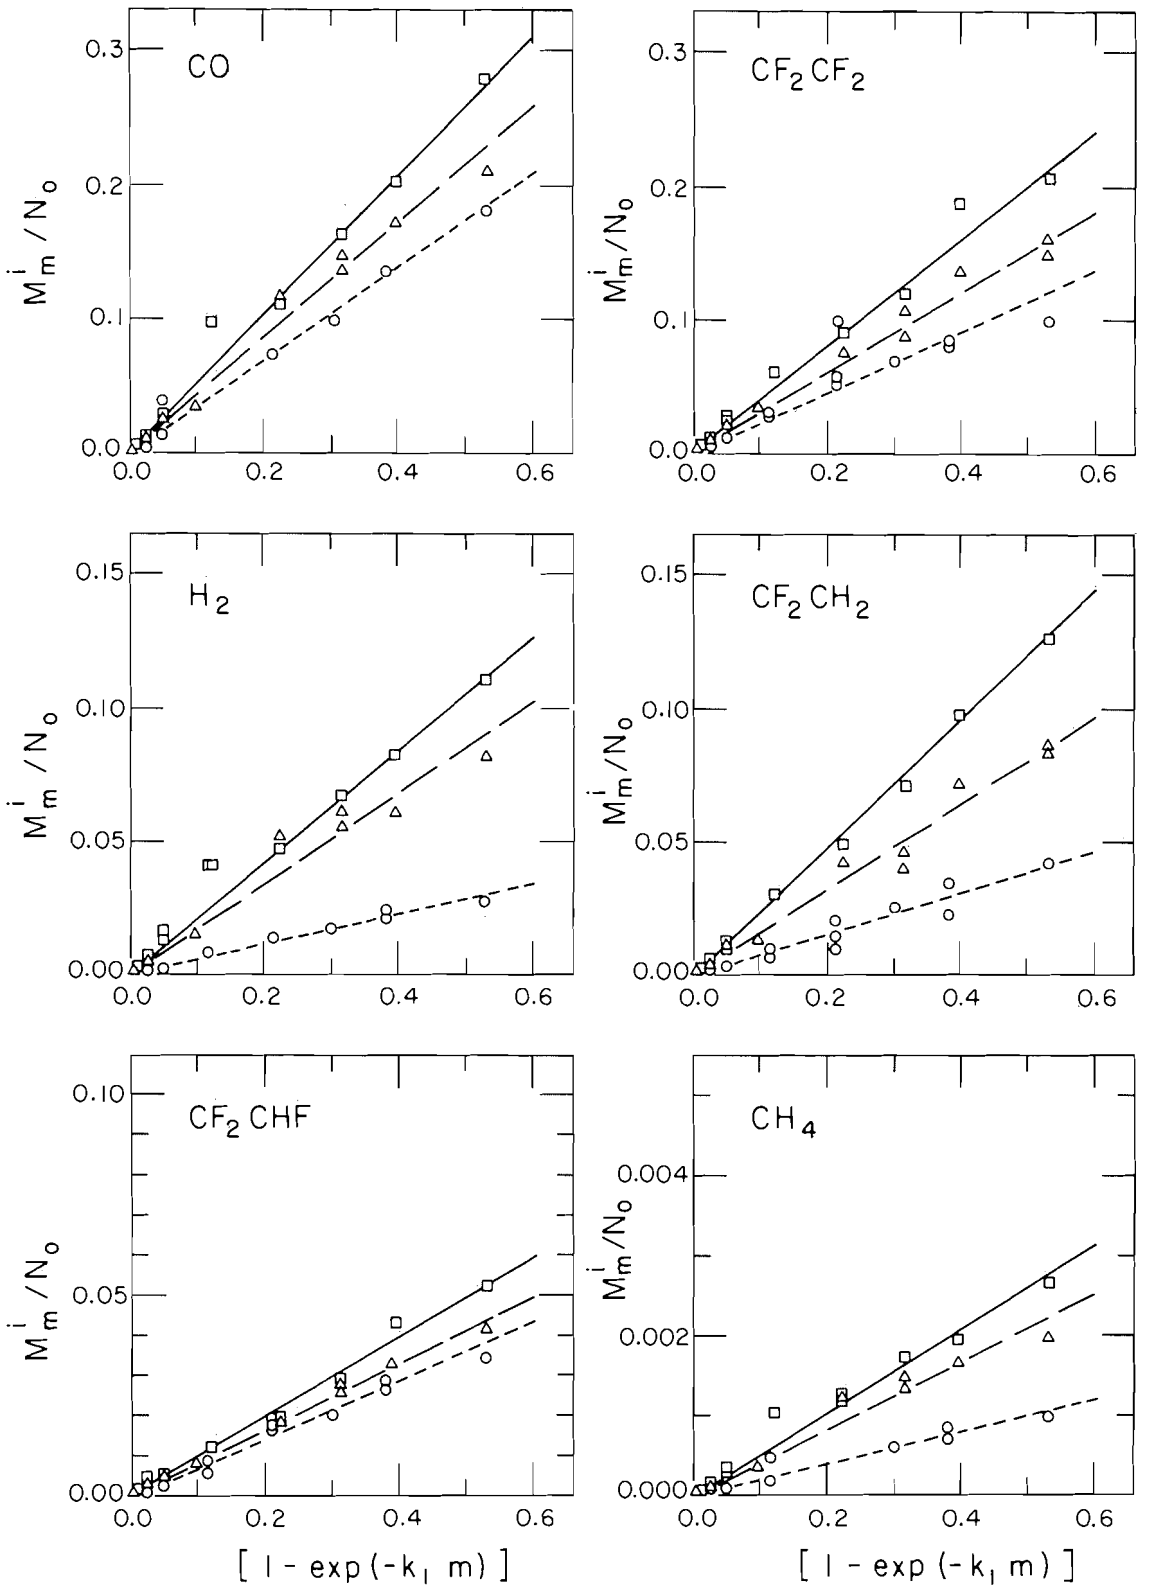

FIG. 3. A fit of various products indicated to pseudo-first order kinetics (see ref. 2) for three initial TFE pressures. The initial TFE pressures are represented as follows: (○), (....) 0.134 kPa; (△), (----) 0.823 kPa; (□) (——) 1.34 kPa. The slopes of the lines give the stoichiometric ratios, η_i.

[7] $f_3(E) = (E/125)^3$, $E < 125$ J/cm^2

$= 1 \qquad E \geq 125$ J/cm^2

The first form, $f_1(E)$ was discussed by Fuss (4). The second form is the CLNDF (5–7) and the parameters, $\mu = 4.7$ and $\sigma = 0.7$ (the standard deviation), were obtained by plotting the measured values of f versus $\log_e E$ as is described in refs. 5–7. The third form was used to describe the MPD of CDF_3 (8).

Plots of the form of $f_i(E)$ for these models are shown in Fig.

TABLE 3. A comparison of measured and calculated values of the total number of TFE molecules decomposed (D) for two different geometries. The TFE pressure was 1.33 kPa

	Measured	Calculated Model 1	Calculated Model 2	Calculated Model 3
Geometry A	$(6.3\pm1.7) \times 10^{14}$	1.4×10^{14}	1.4×10^{14}	1.3×10^{14}
Geometry B	$(2.6\pm1.3) \times 10^{15}$	1.1×10^{15}	8.9×10^{14}	5.0×10^{14}

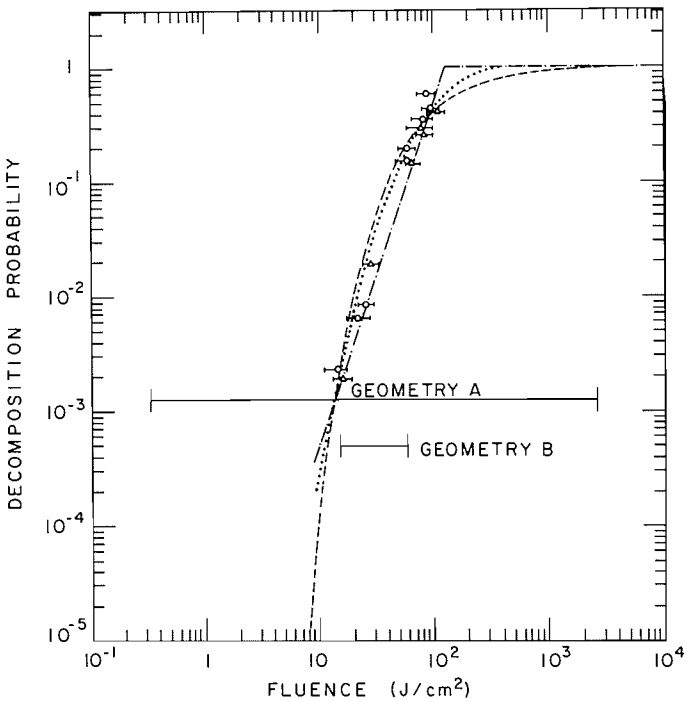

FIG. 4. Plots of $f_i(E)$ versus fluence for the MPD of TFE according to the three models discussed in the text. The various models, eqs. [5] to [7] respectively, are shown as follows: (----). Model 1; (....), Model 2; (-·-·-), Model 3. Also shown are the experimental points from ref. 2 for the following TFE initial pressures: (○), 1.00 kPa; (△), 1.33 kPa. The solid horizontal lines show the range of fluences for each of Geometries A and B.

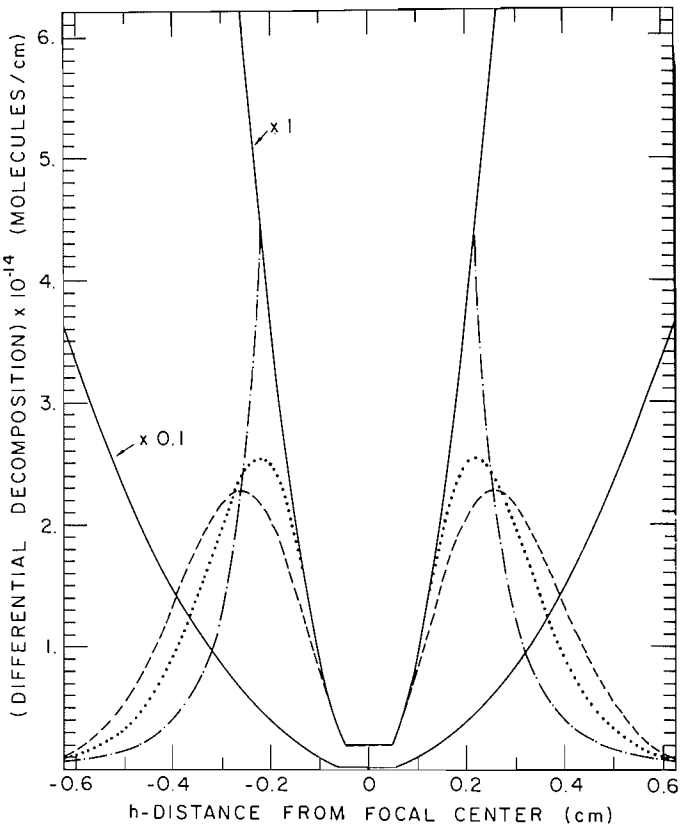

FIG. 5. Plots of the differential decomposition (eq. [4]) (TFE pressure = 1.33 kPa) versus h for Geometry A acording to the three models discussed in the text. The various models are shown as follows: (----), Model 1; (....), Model 2; (-·-·-), Model 3. The solid line shows the differential decomposition as it would appear if all of the irradiated molecules decomposed (that is $f_i \equiv 1$). A second solid line shows the first one reduced by a factor of 10 and is included since the first line goes off scale.

4 along with the data of ref. 2. All three models provide a reasonable fit to these data, and it is not possible to choose one over the others.

Plots of the differential decomposition (eq. [4]) for the three models are given in Fig. 5 for Geometry A. All three models demonstrate clearly that MPD occurs in the region within 6 mm of focal centre and well away from the cell walls. For Geometry B a similar plot shows the MPD is confined mainly to the region within about 3 cm of focal centre. Cell walls and windows would not play a significant role in either of these geometries according to all the models.

A numerical evaluation of the values of D for each model (TFE pressure 1.33 kPa) is given in Table 3, with experimental results for comparison. Models 1 and 2 agree very closely with each other and all the models correctly predict decomposition to within a factor of 3 or 4 for each geometry. This agreement is, perhaps, as good as can be expected considering the experimental uncertainties (the errors in k_1, the wider range of irradiation fluences than was used to determine the parameters for each model, and the errors associated with measuring f) encountered in these types of experiments. All three of these models provide a crude prediction of D, and currently, one cannot be judged as yielding results superior to the others.

4. Conclusions

The previously reported (2) pressure dependence of the H_2 and CO yields for TFE was complicated by the effect of pressure dependent stoichiometric ratios. This effect has now been measured and the depletion kinetics for the HF laser-induced MPD of TFE (an example of a large OH-containing molecule) are shown to follow first order behavior.

The three models for decomposition probability versus fluence predicted decomposition yields equally well for the complex geometries used in these experiments to within a factor of 3 or 4 of experimental results.

The products of the MPD of TFE are a complex array typical of free-radical reactions with possibly more than one primary decomposition channel. A selection of these products was shown to follow pseudo-first order kinetics even to the point at

which almost half of the available TFE had been decomposed. The results of this study did not allow the primary decomposition channels to be identified.

Hétérobicycles sulfurés dérivés de l'α-thioglycérol. Synthèse d'alkyl-2,8-dioxa-6-thiabicyclo[3.2.1]octanes[1]

JACQUES GELAS ET MARC TEPPAZ-MISSON

Université de Clermont-Ferrand, École Nationale Supérieure de Chimie, Ensemble Scientifique des Cézeaux, Boite Postale 45, 63170 Aubière, France

Reçu le 25 octobre, 1982

JACQUES GELAS et MARC TEPPAZ-MISSON. Can. J. Chem. **61**, 1487 (1983).

La synthèse de 2,8-dioxa-6-thiabicyclo[3.2.1]octanes, substitués en position 1, 4 ou 7 par des groupements alkyle ou phényle, est décrite. Quatre méthodes de préparation sont comparées: (*i*) action du sulfure de sodium sur les 2,4-dichloroalkyl-1,3-dioxolannes; (*ii*) action du sulfure de sodium sur les ditosylates de 2,4-di(hydroxyalkyl)-1,3-dioxolannes; (*iii*) action des cétones α-halogénées sur l'α-thioglycérol; (*iv*) action des cétones α-hydroxylées sur l'α-thioglycérol. Les structures des dioxathiabicyclooctanes ont été établies par spectrographie de rmn ^{1}H (les spectres de masse ont été décrits par ailleurs) et confirmée chimiquement par désulfuration par le nickel Raney.

JACQUES GELAS and MARC TEPPAZ-MISSON. Can. J. Chem. **61**, 1487 (1983).

The synthesis of 2,8-dioxa-6-thiobicyclo[3.2.1]octanes, substituted by alkyl or phenyl groups in positions 1, 4, or 7, is described. Four synthetic routes are compared: (*i*) action of sodium sulfide on 2,4-dichloro-1,3-dialkyldioxolanes; (*ii*) action of sodium sulfide on the ditosylates of 2,4-dihydroxyalkyl-1,3-dioxolanes; (*iii*) action of α-haloketones on α-thioglycerol; and (*iv*) action of α-hydroxyketones on α-thioglycerol. The structures of the dioxathiabicyclooctanes have been established by proton nmr (mass spectra have already been described) and chemically confirmed by desulfurization by Raney Nickel.

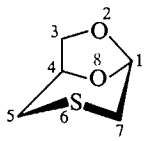
Un grand intérêt est porté depuis longtemps vers l'étude d'analogues oxygénés, azotés et sulfurés du système bicyclo-[3.2.1]octane en raison notamment des éventuelles applications biologiques ou pharmacologiques de tels composés. Nous avons dans ce but mis au point diverses voies d'accès à des hétérobicycles obtenus à partir d'un acétal cyclique fonctionnalisé du type 1,3-dioxolanne (voir publications citées dans la référence 1). Le présent mémoire décrit une série de (±)-alkyl-2,8-dioxa-6-thiabicyclo[3.2.1]octanes.[2]



De tels bicycles présentent en particulier l'intérêt de se prêter à une étude de leur fragmentation sous impact électronique (2) susceptible d'être comparée à celle de ses homologues oxygénés (3); ils permettent également l'accès aux sulfoxydes et sulfones correspondants (4) ainsi qu'à des 1,4-oxathiannes fonctionnalisés par un groupement hydroxyméthyle obtenus par hydrogénolyse des bicycles (4, 5).

A notre connaissance, la première mention dans la littérature du dioxathiabicyclooctane date de 1965 et est due à Foster et coll. (6) qui avaient obtenu le 1(*R*),4(*R*)-dioxathiabicyclooctane à partir du 1,6-anhydro-β-D-glucopyranose; l'hydrolyse de la fonction acétal permettait alors l'accès à une classe nouvelle de "sucres" contenant un hétéroatome supplémentaire (dérivé du 2-hydroxy-1,4-oxathianne). Nous comparons ici quatre voies d'accès possibles aux alkyl-dioxathiabicyclooctanes.

[1]Recherches dans la série des acétals cycliques: Partie XXV; Partie XXIV: voir réf.1.

[2]Nous indiquerons simplement "dioxathiabicyclooctane" dans la suite du mémoire.

Synthèse des dioxathiabicyclo[3.2.1]octanes

Action du sulfure de sodium sur les 2,4-dichloroalkyl-1,3-dioxolannes (Méthode A)

La cyclisation de composés dihalogénés sous l'action du sulfure de sodium est une méthode connue pour permettre l'accès à des cycles sulfurés. Citons simplement la synthèse du thiophanne dans le diméthylsulfoxyde (7) et celle du dioxathiabicyclooctane dans le méthanol en présence d'iodure de potassium (8). Dans notre cas cette méthode présente l'inconvénient du point de vue de son rendement de n'utiliser que le seul stéréoisomère *cis* (Schéma 1) du mélange *cis*−*trans* des dioxolannes obtenus par acétalisation classique d'une chlorhydrine avec une cétone halogénée (9). L'isomère *trans* reste inattaqué ou subit des dégradations sans intérêt ici.

Le rendement ne dépasse guère de ce fait 30 à 35% et est sujet à des variations inattendues.

Dans le cas du bicycle **3** les deux diastéréoisomères **3**a (Me-7 axial) et **3**e (Me-7 équatorial) sont obtenus dans la proportion 75:25.

Action du sulfure de sodium sur les ditosylates de dioxolannes-diols (Méthode B)

Les 2,4-di(hydroxyalkyl)-1,3-dioxolannes ont été préparés (10) par action de cétones α-hydroxylées sur le glycérol (reflux dans le benzène en présence d'acide et dans un appareil de Dean−Stark). Les diols sont ensuite traités de façon classique par le chlorure de *para*-toluènesulfonyle et immédiatement soumis à l'action du sulfure de sodium (Schéma 2). Cette méthode présente, comme la précédente, l'inconvénient de ne faire intervenir que les dioxolannes *cis*. Elle est de plus inapplicable à la synthèse d'un dérivé disubsitué en 5 ou en 7 qui nécessiterait la préparation d'un tosylate d'alcool tertiaire.

Action des cétones α-halogénées sur l'α-thioglycérol (Méthode C)

Dans une note (11) l'un d'entre nous avait décrit l'obtention *directe* du bicycle 2 par action de la chloropropanone sur l'α-thioglycérol (Schéma 3). Dans ce cas la totalité des réactifs est utilisée. On opère au sein de pyridine et de benzène: la

réaction d'acétalisation est catalysée par le chlorure de pyridinium formé par l'élimination d'acide chlorhydrique (lequel se dégage spontanément en l'absence de pyridine dès que l'on mélange les réactifs); le benzène permet (piège de Dean–Stark) d'éliminer l'eau au fur et à mesure de sa formation. Nous montrons ici par la synthèse des dérivés **3** (mélange de stéréoisomères) et **5** avec un excellent rendement que la méthode semble généralisable à toute cétone α-halogénée.

Il n'en reste pas moins que la formation d'acide chlorhydrique (même "neutralisé" presqu'instantanément par la pyridine) peut être préjudiciable à l'utilisation de composés carbonylés très fragiles. De plus, les cétones α-chlorés tertiaires ne sont pas très courantes. C'est pourquoi nous avons pensé compléter cette méthode par une réaction similaire mais utilisant des cétones α-hydroxylées entraînant uniquement l'élimination d'eau.

Action des cétones α-hydroxylées sur l'α-thioglycérol (Méthode C′)

Dans ce cas les dioxathiabicyclooctanes sont obtenus direc-

[a]Solvant: tétrachlorure de carbone sauf pour les composés **7** et **8** (chloroforme). Les déplacements chimiques sont indiqués en ppm par rapport au tétraméthylsilane (multiplicité: s, singulet; d, doublet; q, quadruplet; m, multiplet). Les constantes de couplage indiquées en valeur absolue sont les espacements de signaux mesurés sur les agrandissements et sont exprimées en Hz.

[b]Le spectre du composé **8**a, en mélange avec son isomère **8**e, est nettement caractérisé seulement par la présence de deux singulets larges à 5,58 (H-1) et à 3,61 (H-7éq).

tement par chauffage des matières premières (reflux dans le xylène) en présence d'acide *para*-toluènesulfonique et dans un appareil de Dean−Stark (Schéma 3). Il est nécessaire d'ajouter lentement le composé carbonylé dans le milieu afin d'éviter de provoquer une réaction de dimérisation des α-cétols suivis d'une cyclodéshydratation en trioxabicyclo[2.2.1]heptanes (12). Le rendement est excellent au départ des cétols secondaires (obtention de **3**a (Me-7-axial) et **3**e (Me-7 équatorial) dans la proportion 25:75 inverse de celle observée pour la méthode A) et tertiaire (obtention de **6**), mais reste médiocre pour les cétols primaires (obtention de **2** et **5**). Par ailleurs, pour ces derniers (action de l'hydroxypropanone et action de l'hydroxyméthylphénylcétone) on observe (Schéma 4) la formation secondaire des deux stéréoisomères des bicycles **7** et **8**. Celle-ci résulte vraisemblablement d'une isomérisation partielle des cétoalcools respectivement en aldéhyde lactique et phényl-2 hydroxy-2 éthanal. Une telle isomérisation est tout à fait comparable à la transformation de Lobry de Bruyn et Alberda van Ekenstein, classique en série glucidique (13) et possible aussi bien en milieu acide que basique. On peut donc

SCHÉMA 5. Désulfuration des dioxathiabicyclooctanes.

invoquer (13) le passage par la forme *ènediol* des produits de départ (Schéma 4). On peut rapprocher cette observation de l'interprétation qui avait été proposée (14) pour expliquer la présence de 2,6-diméthylpyrazine au sein de la 2,5-diméthylpyrazine préparée par pyrolyse du glycérol en présence de sels d'ammonium: dégradation du glycérol en hydroxypropanone que s'isomérise partiellement en aldéhyde lactique avant l'intervention de l'ammoniac. Il est à noter enfin que la présence d'eau dans le thioglycérol de départ accroît la faible tendance à former les bicycles résultant d'une transposition de la cétone hydroxylée.

Identification des dioxathiabicyclooctanes

Elle repose essentiellement sur l'étude de leurs spectres de rmn (Tableau 1). Leurs spectres de masse ont été étudiés par ailleurs (2).

Lorsqu'on compare les trioxabicyclooctanes (1) (homologues uniquement oxygénés) aux dioxathiabicyclooctanes, on constate que l'introduction d'un atome de soufre entraîne un déplacement très important du signal des protons équatoriaux vers les champs forts. Cet effet, beaucoup moins marqué pour les protons axiaux a pour conséquence: (*i*) d'étaler assez largement en fréquence les spectres pour permettre d'approcher une analyse au premier ordre correcte; (*ii*) de différencier nettement les protons en α de l'atome de soufre selon leur stéréochimie. L'ordre proton axial−proton équatorial respectivement à *champ faible* et *champ fort* est l'inverse de celui observé pour un cyclohexane ou un tétrahydropyranne (15). Il est à noter que la différence $\delta_{Hax} - \delta_{Héq}$ est de l'ordre de 0,6 à 1,2 ppm et est donc nettement plus élevée que celle qui est observée pour le thiacyclohexane (15) ($\Delta\delta \simeq 0{,}2$ ppm) ou pour les oxathiannes (16) ($\Delta\delta \simeq 0{,}1$ à 0,7 ppm). Ceci peut vraisemblablement être attribué à l'anisotropie du pont méthylènoxy dans les dioxathiabicyclooctanes. L'attribution des différents signaux à tel ou tel proton a été confirmée par double-irradiation des protons en cause. L'intensité de la constante de couplage pour les protons géminés H-3 *exo* et H-3 *endo* est du même ordre de grandeur que celle déterminée pour les protons en même position dans les trioxabicyclooctanes (1) et conforme à celle attendue pour un cycle oxygéné à cinq maillons (17). En revanche, pour les protons géminés en α de l'atome de soufre la constante est sensiblement plus élevée (de 1 à 2 Hz) que celle observée dans les homologues oxygénés (pour une discussion des effets d'un hétéroatome sur les constantes J_{gem} voir la mise au point de Cahill *et al.* (17)).

Compte-tenu du recouvrement des valeurs du couplage vicinal $J_{4,5}$ que H-5 soit axial ou équatorial, il serait dangereux d'attribuer la stéréochimie de H-5 sur la seule indication d'un couplage ax−éq plus élevé que le couplage éq−éq. Une attribution plus sûre de cette stéréochimie repose sur l'observation d'un couplage à longue distance mettant en jeu H-5 axial et H-3 *endo* selon un chemin de couplage en *W*. On peut constater que l'existence de ce couplage (de valeur peu différente de celle relevée pour les trioxabicyclooctanes (1)) est en faveur d'une conformation chaise peu déformée pour le cycle 1,4-oxathianne des dioxathiabicyclooctanes. L'absence d'une déformation importante paraît confirmée par le faible (sinon nul) couplage vicinal entre H-3 *endo* et H-4 qui de ce fait forment dans l'espace un angle dièdre proche de 90°. Le couplage ^4J observé ici est le seul qui soit facilement et nettement attribué; cependant, une analyse plus fine permettrait vraisemblablement de mettre en évidence d'autres types de couplages (notamment $^4J_{1,4}$ et $^5J_{1,5éq}$) décelés précédemment dans les trioxabicyclooctanes (1, 18).

Ainsi que nous le discutons dans le paragraphe suivant, le problème de la localisation de l'atome de soufre dans la molécule bicyclique s'est posé pour les composés obtenus directement à partir du thioglycérol et des dérivés carbonylés. Il a été résolu par l'analyse spectrographique (rmn); le résultat a été confirmé chimiquement:

(*i*) Le déplacement à champ fort des protons en α de l'atome de soufre permet une attribution aisée de ces protons sur le spectre. Lorsqu'il s'agit d'un groupement méthylène on constate que la constante de couplage géminé (12−13 Hz) est celle attendue pour un cycle à six chaînons (1,4-oxathianne) et non celle (6−7 Hz) qui serait observée (17) pour un cycle à cinq chaînons (1,3-oxathiolanne). Ceci est confirmé par la valeur de la constante de couplage (6−7 Hz) pour les protons géminés situés à champ plus faible (CH_2 en α de O-2).

(*ii*) La structure des composés est confirmée par la réaction de désulfuration par le nickel Raney (19) effectuée sur un certain nombre d'entre eux (Schéma 5). La position de l'atome de soufre dans les dioxathiabicyclooctanes est attribuée grâce à l'identification aisée des alkyl-1,3-dioxolannes obtenus par comparaison (rmn) avec les couples de diastéréoisomères authentiques préparés par acétalisation du 1,2-propanediol et parfaitement identifiés par Eliel et coll. (8).

Mécanisme de formation

L'acétalisation de l'α-thioglycérol par une cétone

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

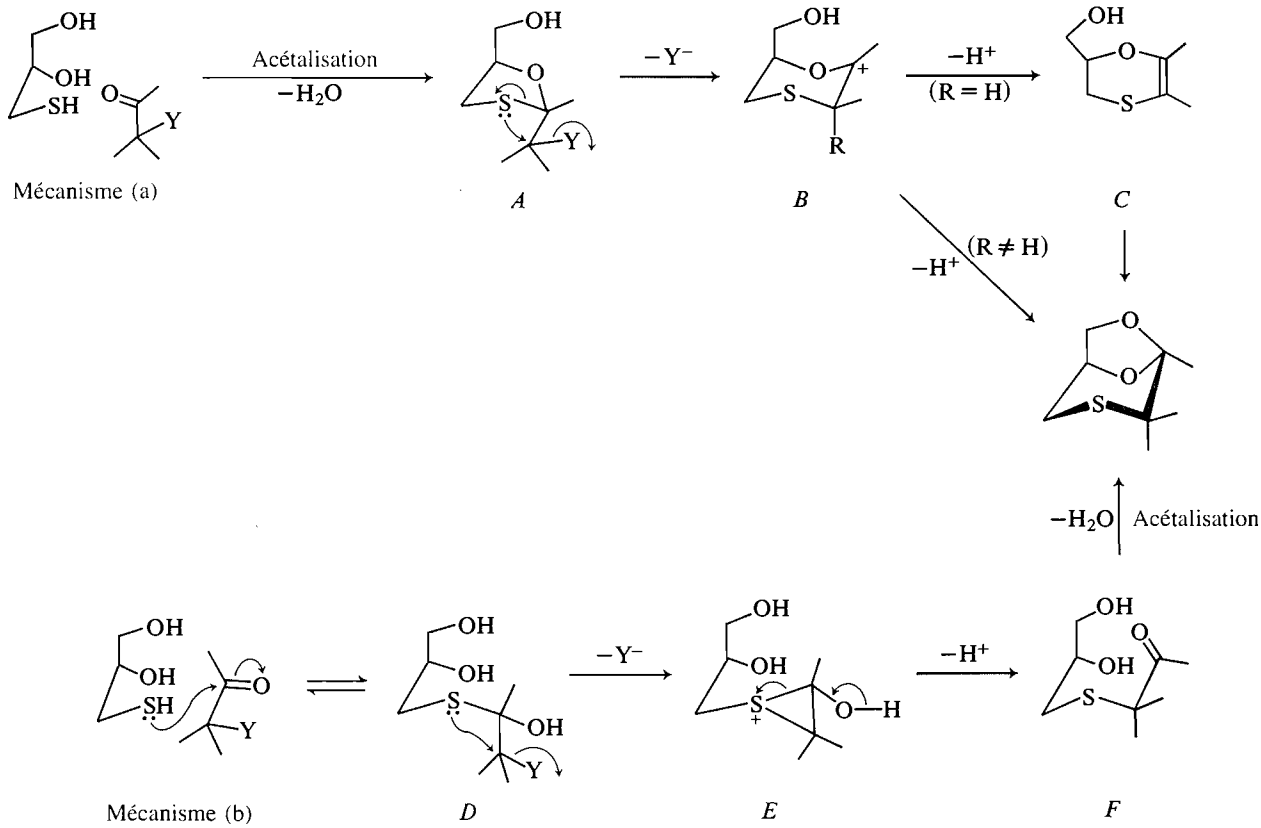

SCHÉMA 6. Mécanisme de formation des dioxathiabicyclooctanes.

α-halogénée ou α-hydroxylée peut théoriquement conduire à trois types d'hétérocycles: 1,3-dioxolanne, 1,3-oxathiolanne et 1,3-oxathianne. En fait, pour des raisons d'interaction *syn*-axiales existant dans le cycle à six chaînons (20) la formation du dernier type d'hétérocycle peut être écartée (contrôle thermodynamique en milieu acide). Pour des cétones aliphatiques il est connu (21) que l'acétalisation de l'α-thioglycérol conduit exclusivement à des 1,3-oxathiolannes (confirmant ainsi la plus grande réactivité de la fonction thiol vis à vis du groupement carbonyle comparée à celle de la fonction alcool). Compte-tenu de la structure des bicycles que nous obtenons (1,3-dioxolannes pontés) nous pouvons proposer: (*i*) soit l'évolution très rapide d'un 1,3-oxathiolanne du type *A* (Schéma 6, mécanisme (a)), produit cinétique de la réaction; (*ii*) soit la formation du bicycle sans passage par un oxathiolanne (mécanisme (b)).

Une transformation comparable avait été proposée par Parham *et al.* (22) pour expliquer la formation d'oxathiène (type *C*) à partir de l'oxathiolanne formé par la réaction du thioglycol et du chloracétaldéhyde diméthylacétal.

L'évolution des intermédiaires *A* ou *D* peut se produire selon le mécanisme de type S_N2 suggéré sur le schéma 6 ou par un autre processus; il n'est pas exclu qu'un carbocation puisse intervenir, particulièrement lorsque l'atome de carbone porteur de Y est quaternaire. La formation des bicycles par addition de la fonction alcool sur la double-liaison de l'oxathiène *C* paraît en revanche peu vraisemblable pour au moins deux raisons: (*i*) le bicycle **6** (R = R′ = Me) ne peut donner un tel intermédiaire *D*; (*ii*) pour des réactions proches (action de cétones α-halogénées ou α-hydroxylées sur le 1,2-dithioglycérol) nous avons isolé (23)[3] des dithiènes (composés du type *D* où l'atome d'oxygène est remplacé par un second atome de soufre) qui ne subissent pas de cyclisation dans les conditions de la réaction. Il n'en reste pas moins que plusieurs mécanismes peuvent entrer en concurrence. Le caractère de meilleur groupe partant de l'atome d'halogène par rapport à la fonction alcool peut favoriser un mécanisme prévoyant l'expulsion rapide d'hydracide préalablement à toute autre réaction. Lorsque la réaction des cétones halogénées est menée en l'absence de pyridine c'est effectivement ce que l'on constate expérimentalement.

Cette étude est actuellement étendue aux séries des 1,2- et 1,3-dithioglycérols ainsi qu'à celle du trithioglycérol. Les résultats ainsi obtenus dans ces séries modèles sont également appliqués en série glucidique pour leur intérêt synthétique et biologique.

Partie expérimentale

Les analyses par chromatographie en phase gazeuse ont été réalisées sur un appareil Hewlett–Packard 5750 équipé d'une colonne Carbowax 20 M. Les séparations d'échantillons par chromatographie en phase gazeuse ont été effectuées sur un appareil Varian–Aerograph 750 N (colonne Carbowax 20 M, 9 mm × 6 m). Les spectres de rmn ^1H ont été réalisées sur un appareil Varian T 60. Les analyses centésimales ont été faites au Service Central de Microanalyse du CNRS.

Synthèse des dioxathiabicyclooctanes

Méthode A: Action du sulfure de sodium sur les 2,4-dichloroalkyl-1,3-dioxolannes

Une solution de sulfure de sodium nonahydrate (48 g, 0.2 mol) dans 100 mL de méthanol est additionnée de 0.1 mol d'un dichloroalkyldioxolanne (cf. Schéma 1) préparé selon les réfs. 9 et 24 et de 2 g d'iodure de potassium. On porte à reflux durant quatre à cinq jours. Après refroidissement on ajoute 250 mL d'eau, extrait au dichlorométhane, sèche (sulfate de sodium) et évapore le solvant sous vide. Le résidu est distillé. Le dioxathiabicyclooctane correspondant

distille en tête (rendement 30 à 35%), suivi du dichloroalkyldioxolanne *trans* inattaqué (le rendement calculé en tenant compte de la réaction du seul dérivé *cis* est de 45 à 50%).

De nombreux autres composés minoritaires sont détectés par chromatographie en phase gazeuse. Un rendement légèrement supérieur est obtenu en remplaçant le méthanol par le diméthylsulfoxyde et en portant le mélange réactionnel vers 100°C durant environ trois jours.

Méthode B: Action du sulfure de sodium sur les ditosylates de 2,4-dihydroxyalkyl-1,3-dioxolannes

Une solution de 0.1 mol d'un dihydroxyalkyldioxolanne (cf. Schéma 2), préparé selon la réf. 10, dans 100 mL de pyridine anhydre est refroidie à 0°C. On ajoute par petites portions du chlorure de *para*-toluènesulfonyle (41.8 g, 0.22 mol) sous une forte agitation. On laisse revenir à température ambiante et on maintient l'agitation durant 24 h. On verse sur un mélange de glace et de carbonate de sodium, extrait au dichloromethane. L'extrait est lavé plusieurs fois par une solution aqueuse saturée de bicarbonate de potassium. On sèche et évapore les solvants sous vide. On reprend par 20 mL de toluène anhydre et chasse le solvant sous vide, l'opération étant répétée trois fois afin d'éliminer totalement la pyridine. Le résidu (le plus souvent amorphe) est immédiatement placé en solution dans 100 mL de diméthylsulfoxyde. On ajoute 0.2 mol de sulfure de sodium nonahydrate et porte à 80−100°C durant 24 h. Après refroidissement, on ajoute 200 mL d'eau et extrait au dichlorométhane. L'extrait est lavé plusieurs fois par 50 mL d'eau. On sèche, évapore le solvant et distille rapidement hors du résidu le dioxathiabicyclooctane qui peut ensuite être rectifié (rendement environ 40%, 60% si l'on tient compte du fait que seul le dérivé *cis* réagit).

Méthode C: Action des cétones α-halogénées sur l'α-thioglycérol

Une solution de 3-mercapto-1,2-propanediol (α-thioglycérol, 21.6 g, 0.2 mol) dans un mélange de 400 mL de benzène et de 400 mL de pyridine est placée dans un ballon bicol de 1 L surmonté d'une boule à brome et d'un piège de Dean−Stark. On ajoute à température ambiante par la boule à brome, 0.22 mol de cétone α-chlorée (cf. Schéma 3, composés commerciaux) et on porte à reflux de benzène qui élimine progressivement l'eau formée au cours de la réaction.

Lorsque 3 à 4 mL d'eau (0.2 mol environ) ont été recueillis, le ballon est refroidi et les solvants sont évaporés sous vide. Le résidu est dissous dans du dichlorométhane qui est lavé à l'eau, séché et évaporé. Le dioxathiabicyclooctane formé est distillé (rendement 80 à 85%).

Méthode C': Action des cétones α-hydroxylées sur l'α-thioglycérol

Un mélange de xylène (700 mL environ), d'α-thioglycérol (21.6 g, 0.2 mol) et d'acide *para*-toluènesulfonique (2 g) est vigoureusement agité dans un Erlenmeyer de 1 L placé sur un agitateur magnétique chauffant et surmonté d'une dérivation munie d'une part d'un piège de Dean−Stark et d'autre part d'une boule à brome. On porte à reflux et on ajoute goutte à goutte l'α-hydroxycétone choisie (cf. Schéma 3, composés commerciaux). La réaction est arrêtée lorsque deux équivalents d'eau ont été recueillis (environ 0.4 mol, 7 à 8 mL). On ajoute environ 5 g de carbonate de sodium et on agite durant une heure. On filtre et évapore le xylène sous pression réduite. On distille le résidu sous vide. Dans le cas du composé **5** (et parfois également pour le composé **6**) le résidu cristallise; le dioxabicyclooctane est alors recristallisé directement (dans le méthanol pour **5** et un mélange méthanol − éther de pétrole 40−65°C pour **6**) (rendements respectifs: composés **2** et **5**: 20−25%; composé **3**: 85%; composé **6**: 90%).

Dans le cas de la préparation des composés **2** et **5** à partir de cétols primaires, on isole par chromatographie en phase gazeuse préparative respectivement les composés **7**a et **7**e séparément (rendement: 5%) et les composés **8**a et **8**e en mélange (rendement 8%).

Désulfuration des dioxathiabicyclooctanes

Une suspension de nickel Raney fraîchement préparée selon la réf. 25 (10 mL de suspension agitée et lavée plusieurs fois par du méthanol anhydre) est additionnée d'une solution du dioxathiabicyclooctane (cf. Schéma 5) dans l'éthanol (5 mL d'éthanol pour 1 mmol de substrat). On ajoute une solution de soude (40 mg, 1 mmol) dans l'éthanol (2 mL) et on porte à reflux jusqu'à ce que tout le bicycle de départ ait disparu (contrôle par chromatographie, durée 15 à 30 min).

On filtre et distille l'éthanol avec précaution (les dioxolannes obtenus sont volatils); le résidu est repris par du tétrachlorure de carbone et analysé par chromatographie en phase gazeuse et par rmn ^{1}H. L'identification est confirmée par comparaison avec des échantillons authentiques préparés par acétalation classique du 1,2-propanediol avec respectivement l'acétone (cas du dérivé **2**), la méthyléthylcétone (cas de **3**) et la méthylisopropylcétone (cas de **4**). Dans les deux derniers exemples, l'acétalation conduit au mélange des deux isomères *cis* et *trans*, alors que le seul isomère *cis* est obtenu par désulfuration.

Diffusion with hydrolysis equilibria: transport coefficients of aqueous SO_2, NH_3, and Na_2CO_3 [1]

D. G. LEAIST[2]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received June 4, 1982

D. G. LEAIST. Can. J. Chem. **61**, 1494 (1983).

Practical equations are derived for estimating diffusion coefficients and Onsager transport coefficients of aqueous solutes subject to hydrolysis. The derivation is based on the Nernst–Hartley method which is extended to include chemical reaction of solute with solvent. The derived equations and existing mobility data are used to estimate transport coefficients of aqueous SO_2 (20°C), NH_3 (15°C), and Na_2CO_3 (25°C). In dilute solution where hydrolysis is extensive, rates of diffusion of SO_2 and NH_3 are increased by about 50% and 25%, respectively, relative to unhydrolyzed solute. Because of the carbonate–bicarbonate equilibrium, diffusion in aqueous Na_2CO_3 is a ternary process characterized by coupled transport of NaOH. In dilute solution the NaOH flux may exceed the flux of Na_2CO_3.

D. G. LEAIST. Can. J. Chem. **61**, 1494 (1983).

On a dérivé des équations pratiques pour évaluer les coefficients de diffusion et les coefficients de transport de Onsager des solutés aqueux soumis à l'hydrolyse. La dérivation se base sur la méthode de Nernst–Hartley que l'on a élargie afin d'inclure la réaction chimique du soluté avec le solvant. On a utilisé l'équation dérivée ainsi que les données de mobilité existantes pour évaluer les coefficients de transport des solutions aqueuses de SO_2 (20°C), de NH_3 (15°C) et de Na_2CO_3 (25°C). En solution diluée où l'hydrolyse est importante, les vitesses de diffusion du SO_2 et du NH_3 augmentent d'environ de 50% et de 25% respectivement par rapport au soluté non hydrolysé. A cause de l'équilibre carbonate–bicarbonate, la diffusion dans du Na_2CO_3 aqueux est un processus ternaire caractérisé par un transport couplé de NaOH. En solution diluée le flux de NaOH doit excéder celui du Na_2CO_3.

1. Introduction

Our objective in this paper is to determine the effects of hydrolysis on the diffusional properties of aqueous solutes. Because highly mobile hydrogen or hydroxide ions are produced, such effects require careful attention in cases of extensive hydrolysis.

Ammonia, carbon dioxide, chlorine, and sulfur dioxide are important examples of molecular solutes which hydrolyze. Among hydrolyzing electrolytes are those which contain carbonate, phosphate, sulfide, and cyanide as well as iron, zinc, aluminum, uranium, and numerous other metal ions (1). Diffusion of these solutes in aqueous media occurs in a variety of technological and biological processes; particular applications involve gas absorption, transport of corrosion products, and migration of minerals in groundwater.

By extending the well-known Nernst–Hartley (2, 3) method (thoroughly discussed by Robinson and Stokes in ref. 4) to include chemical reaction of solute with solvent, we develop practical equations for predicting transport coefficients of hydrolyzing solutes. Molecular solutes are considered first, followed by treatment of electrolytes. To illustrate the main points we discuss diffusion in dilute aqueous SO_2, NH_3, and Na_2CO_3. We confine our attention to isothermal, isobaric systems free of externally applied forces. Furthermore, the rate of hydrolysis is assumed to be rapid compared to diffusion so that local chemical equilibrium exists (refs. 5, 22; ref. 28, p. 296).[3]

2. Molecular solutes

Theory

Consider molecular solute M in aqueous solution with equilibria

$$M + H_2O \overset{K_h}{\rightleftharpoons} M\cdot H_2O \overset{K_1}{\rightleftharpoons} H^+ + (MOH)^-$$

The diffusional flux of solute comprises four chemical species numbered as follows: 1, unhydrated molecular M; 2, the hydrate $M\cdot H_2O$; 3, $(MOH)^-$; and 4, H^+. Because diffusion is characterized by zero flow of electric current, fluxes of $(MOH)^-$ and H^+ are equal. Local chemical equilibrium of the above reactions places two additional constraints on the fluxes of species. Therefore, diffusion of aqueous M is a binary process.

Fick's equation

$$[1] \quad J = -D\nabla c$$

and the Onsager equation

$$[2] \quad J = -L\nabla\mu$$

relate the total molar flux of solute to gradients in solute concentration and chemical potential (6, 7). Flow equations for the chemical species may also be written (8)

$$[3] \quad \hat{j}_i = -\sum_{k=1}^{4} \hat{l}_{ik}\nabla\hat{\mu}_k \qquad i = 1, 2, 3, 4$$

where molar fluxes, transport coefficients, and gradients in electrochemical potentials of the species are denoted by $\hat{j}_i$, $\hat{l}_{ik}$, and $\nabla\hat{\mu}_k$, respectively. The constraints imposed on the species fluxes by zero flow of electric current and by chemical equilibrium are expressed as

$$[4] \quad \hat{j}_3 = \hat{j}_4$$

---

[2]Present address: Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7.

[3]Although rapid hydrolysis is usually an accurate approximation, the slow hydrolysis of carbon dioxide is a notable exception to this rule: the formation of carbonic acid $CO_2 + H_2O \rightarrow H_2CO_3$ is the rate-limiting step.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

[5][4] $\nabla\hat{\mu}_1 = \nabla\hat{\mu}_2$

[6] $\nabla\hat{\mu}_2 = \nabla\hat{\mu}_3 + \nabla\hat{\mu}_4$

Equations [2] and [3] are closely related. For example, the total solute flux equals the sum of fluxes of M, $M\cdot H_2O$, and $(MOH)^-$ species and is expressed as

[7] $J = \hat{j}_1 + \hat{j}_2 + \hat{j}_3$

Also, the solute chemical potential gradient equals the sum of the electrochemical potential gradients of the ions.[3]

[8] $\nabla\mu = \nabla\hat{\mu}_3 + \nabla\hat{\mu}_4$

To estimate the transport coefficients, we make the dilute solution approximations, as others (2–4, 8, 9–17) have done, that (*i*) all off-diagonal $\hat{l}_{ik}$ coefficients are zero

[9] $-\hat{j}_i = \hat{l}_{ii}\nabla\hat{\mu}_i$

and that (*ii*) the mobility of each species is constant.

[10] $\hat{l}_{ii} = \hat{c}_i\hat{u}_i = \hat{c}_i\hat{D}_i/RT$

$\hat{c}_i$, $\hat{u}_i$, and $\hat{D}_i$ denote the concentration (in moles per unit volume), mobility, and diffusivity of the *i*th species.

Substituting eqs. [3]–[10] into eq. [2], we obtain after some algebra (17) the following expression for the Onsager coefficient

[11] $$L = \frac{c}{RT}\left[(1-\beta)\frac{\hat{D}_1 + K_h\hat{D}_2}{1+K_h} + \beta\frac{\hat{D}_3\hat{D}_4}{\hat{D}_3+\hat{D}_4}\right]$$

The apparent degree of hydrolysis defined by

[12] $$\beta = \frac{[(MOH)^-]}{[M] + [M\cdot H_2O] + [MOH^-]} = \frac{\hat{c}_3}{c}$$

is obtained[4] from the formula

[13] $$K_a = \frac{\beta^2 c}{1-\beta}\frac{y_\pm^2}{y}$$

where K_a is the apparent hydrolysis constant (measured by conductivity or by electromotive force cells), $y_\pm$ $(= (\hat{y}_3\hat{y}_4)^{1/2})$ and y are activity coefficients, and c is the formal concentration of solute. The term $(\hat{D}_1 + K_h\hat{D}_2)/(1 + K_h)RT$ in eq. [11] is interpreted as the number-average mobility of molecular species M and $M\cdot H_2O$; $\hat{D}_3\hat{D}_4/(\hat{D}_3 + \hat{D}_4)RT$ represents the mobility of fully ionized $M\cdot H_2O$. In practice, $\hat{D}_i$ values are obtained from binary data, and, for charged species, from molar ionic conductivities by use of the relation $\hat{D}_i = RT\hat{\lambda}_i/F^2\hat{z}_i^2$.

The derivative of the solute chemical potential with respect to concentration is required to obtain the expression for D (6, 7)

[14] $D = L\partial\mu/\partial c$

Following the usual hydrate convention (18, 19), we have

[15] $\mu = \mu^0 + RT\ln[(1-\beta)cy]$

Differentiation of eqs. [13] and [15] gives

[16] $$\frac{\partial\mu}{\partial c} = \frac{RT}{c}\left[1 + \frac{\beta}{2-\beta}\left(1 + \frac{\mathrm{d}\ln(y_\pm^2/y)}{\mathrm{d}\ln c}\right) + \frac{\mathrm{d}\ln y}{\mathrm{d}\ln c}\right]$$

In the limiting cases of no hydrolysis ($\beta = 0$) and complete hydrolysis ($\beta = 1$), $\partial\mu/\partial c$ is approximately RT/c and $2RT/c$, respectively. Thus for a given concentration gradient, hydrolysis increases the chemical potential gradient (the virtual force driving the diffusional process).

Equations [11] and [16] are combined to give

[17] $$D = \left[(1-\beta)D_0 + \beta D_\pm/2\right] \times \left[1 + \frac{\beta}{2-\beta}\left(1 + \frac{\mathrm{d}\ln(y_\pm^2/y)}{\mathrm{d}\ln c}\right) + \frac{\mathrm{d}\ln y}{\mathrm{d}\ln c}\right]$$

The term $D_0 = (\hat{D}_1 + K_h\hat{D}_2)/(1 + K_h)$ represents the number-average diffusivity of molecular species M and $M\cdot H_2O$. $D_\pm = 2\hat{D}_3\hat{D}_4/(\hat{D}_3 + \hat{D}_4)$ is the Nernst diffusion coefficient for fully ionized $M\cdot H_2O$.

Omission of activity coefficient terms in eq. [17] may lead to larger errors in the estimated value of D than errors arising from approximations by eqs. [9]–[10] (4). If the activity coefficient terms are neglected, however, the expression for D simplifies considerably to

[18] $D = 2[(1-\beta)D_0 + \beta D_\pm/2]/(2-\beta)$

which emphasizes that D is not a simple number-weighted average of the diffusivities of molecular and ionized forms of solute.

It is often convenient to define diffusional fluxes of solute relative to the solvent component (6, 7). Strictly speaking, the equations derived here refer to solute fluxes relative to *unreacted* solvent. Since the flux of hydrolyzing solute is accompanied by a flux equal to $[(1-\beta)K_h + \beta]J$ of reacted solvent (as $M\cdot H_2O$, $(MOH)^-$, and H^+), diffusion coefficients in the true solvent-fixed frame are smaller by a factor of $1 - [(1-\beta)K_h + \beta]c/c_0$ where c_0 is the concentration of the solvent. In most cases, however, this distinction is negligible because of the high concentration of solvent relative to solute.

In the preceding discussion, hydrolysis of the solute was presumed to liberate H^+. By interchanging H^+ and OH^- the same analysis can of course be applied to alkaline hydrolysis reactions such as $M + H_2O \rightleftarrows (HM)^+ + OH^-$.

To illustrate the magnitude of effect of hydrolysis on diffusion of molecular solutes we shall use the equations which were developed together with experimental mobility data to estimate the transport coefficients of dilute aqueous SO_2 and NH_3.

SO_2–H_2O (20°C)

Sulfur dioxide hydrolyzes rapidly (20) to give bisulfite and hydrogen ions (21, 23)

$$SO_2 + H_2O \rightleftarrows H^+ + HSO_3^-$$

$$K_a = 0.0146 \text{ mol dm}^{-3}$$

The hydrate H_2SO_3 is also present, but in negligible proportion ($K_h \approx 0$) (24–26). Diffusivities of the ions in dilute solution are accurately known from their conductivities (ref. 4, Appendix 6.2; refs. 21, 22): $\hat{D}_3(HSO_3^-) = 1.21 \times 10^{-9}$ and $\hat{D}_4(H^+) = 8.45 \times 10^{-9}$ m^2 s^{-1}. While the diffusivity of molecular SO_2 is more uncertain, both self-diffusion data (25) and extensive gas absorption studies (27–31) suggest $\hat{D}_1(SO_2) = 1.45$ $(\pm 0.05) \times 10^{-9}$ m^2 s^{-1} as a reasonable value. Based on these data, calculated values of the degree of hydrolysis, mobility (L/c), and diffusion coefficient of aqueous SO_2 at various concentrations are listed in Table 1. In the calculations the activity coefficient of molecular SO_2 was set equal to unity

[4]It is tacitly assumed that the solution is dilute enough so that the activity of water is very nearly unity.

TABLE 1. Transport coefficients of dilute aqueous SO_2 (20°C)

$10^3 \times c$ (mol dm^{-3})	β	$10^{12} \times L/c$ (mol m s^{-1} N^{-1})	$10^9 \times D$ (m^2 s^{-1})
0.01	1.00	0.43	2.12
0.1	0.99	0.43	2.10
1.0	0.94	0.44	2.02
5.0	0.81	0.47	1.86
10.0	0.71	0.48	1.78
50.0	0.46	0.52	1.62
100.0	0.37	0.54	1.57

(23). For the charged species, the semi-empirical relation (ref. 20, Chapt. 23; ref. 32)

$$[19] \quad \hat{y}_i = \exp\left[-A\hat{z}_i^2 I^{1/2}/(1 + I^{1/2})\right]$$

was used with A (20°C) = 1.17. For this system, the ionic strength I equals βc.

Although hydrolysis of SO_2 produces highly mobile H^+, we see in Table 1 that complete hydrolysis actually reduces the mobility of the solute relative to unhydrolyzed solute by about 25% — motion of molecular SO_2 together with its hydrolysis products through the solvent experiences more frictional resistance than in the absence of hydrolysis. On the other hand, hydrolysis increases the diffusivity by about 50%, primarily as a result of the increased free energy gradient.

At extremely low concentrations (less than about 10^{-5} mol dm^{-3}) both dissociation of bisulfite to form sulfite ions ($pK_a = 6.9$) (1, 25) and production of OH^- by self-ionization of water (15, 33) must be taken into account. We shall neglect these complications here.

NH_3–H_2O (15°C)

Hydrolysis products of ammonia include ammonium and hydroxide ions (34, 35)

$$NH_3 + H_2O \rightleftarrows NH_4^+ + OH^-$$

$$K_a = 1.64 \times 10^{-5} \text{ mol dm}^{-3}$$

Significant amounts of the hydrate NH_4OH are also present (36, 37). The ionic diffusivities (ref. 4, Appendix 6.2) are: $\hat{D}_3(NH_4^+) = 1.54 \times 10^{-9}$ and $\hat{D}_4(OH)^- = 4.09 \times 10^{-9}$ m^2 s^{-1}. For the number-average diffusivity of hydrated and unhydrated ammonia, $D_0 = (\hat{D}_1(NH_3) + K_h\hat{D}_2(NH_4OH))/(1 + K_h)$, we use the experimental value (38–41) 1.77 ($\pm$0.10) $\times 10^{-9}$ m^2 s^{-1} determined for the binary diffusion coefficient of aqueous ammonia at concentrations large compared to K_a where the degree of hydrolysis is negligible. It is worth emphasizing that because NH_3 and NH_4OH species are present in constant proportion (9, 36, 37) $[NH_4OH]/[NH_3] = K_h$, separate values of their diffusivities are not required for our purposes.

Calculated transport coefficients of aqueous ammonia are listed in Table 2. Equation [19] was used to compute ionic activity coefficients with A (15°C) = 1.16 (ref. 20, chapt. 23, 32). Again, the activity coefficients of the molecular species were set equal to unity. The results suggest that hydrolysis reduces the mobility of the solute by about 35% while increasing its diffusivity by about 25%. Because the hydrolysis constant is relatively small, hydrolysis has an appreciable effect on the diffusional properties of ammonia solutions only at very low concentrations.

3. Electrolytes

Theory

Compared to hydrolyzing molecular solutes, the diffusional behaviour of hydrolyzing electrolytes is more complex. Consider aqueous electrolyte $C_{\nu_c}A_{\nu_a}$. Let anion A^{z_a} hydrolyze as follows

$$A^{z_a} + H_2O \rightleftarrows (HA)^{z_a+1} + OH^-$$

Relative to undissociated solvent, four chemical species diffuse: C^{z_c}, A^{z_a}, $(HA)^{z_a+1}$, and OH^-. Because fluxes of species are constrained by local chemical equilibrium of the hydrolysis reaction and by zero flow of electric current, two diffusional fluxes are linearly independent. Diffusion of the electrolyte is a *ternary* process.

That aqueous $C_{\nu_c}A_{\nu_a}$ is a binary system for equilibrium thermodynamic properties yet its diffusional properties are ternary is interpreted as follows. At thermodynamic equilibrium the requirements of electroneutrality, equilibrium of the hydrolysis reaction, and stoichiometry serve to fix the concentrations of all species for a given concentration of electrolyte. Along an electrolyte concentration gradient, however, there are non-equilibrium fluxes of ions. Because more than two ions are present, they diffuse at different rates. In particular, highly mobile OH^- diffuses more rapidly than $(HA)^{z_a+1}$. Hence the stoichiometry requirement $[(HA)^{z_a+1}] = [OH^-]$ valid at thermodynamic equilibrium does not apply to the diffusing electrolyte. It follows that diffusion cannot be described by a flux of $C_{\nu_c}A_{\nu_a}$ alone — a second flux, say of electrolyte $C(OH)_{\nu_{OH}}$, must also be specified.

In the event of further hydrolysis reactions such as

$$(HA)^{z_a+1} + H_2O \rightleftarrows (H_2A)^{z_a+2} + OH^-$$

diffusion of the electrolyte would remain a ternary process: although each additional reaction produces one additional chemical species, there is also one additional chemical equilibrium to be satisfied and therefore no additional independent fluxes.

How does hydrolysis influence the rate of diffusion of the electrolyte? As mentioned earlier, there are opposing tendencies to increase the free energy gradient of the electrolyte and to decrease its mobility. Furthermore, so that zero flow of electric current is maintained, the flux of rapidly diffusing OH^- tends to increase the flux of C^{z_c} counterions at the expense of reduced fluxes of coions $(HA)^{z_a+1}$ and A^{z_a}. To illustrate these points in greater detail, we shall consider diffusion in aqueous sodium carbonate. A specific example is chosen rather than the general case for the sake of clarity.

Na_2CO_3–H_2O (25°C)

Hydrolysis of the carbonate ion in aqueous Na_2CO_3 produces bicarbonate and hydroxide ions (20, 42)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

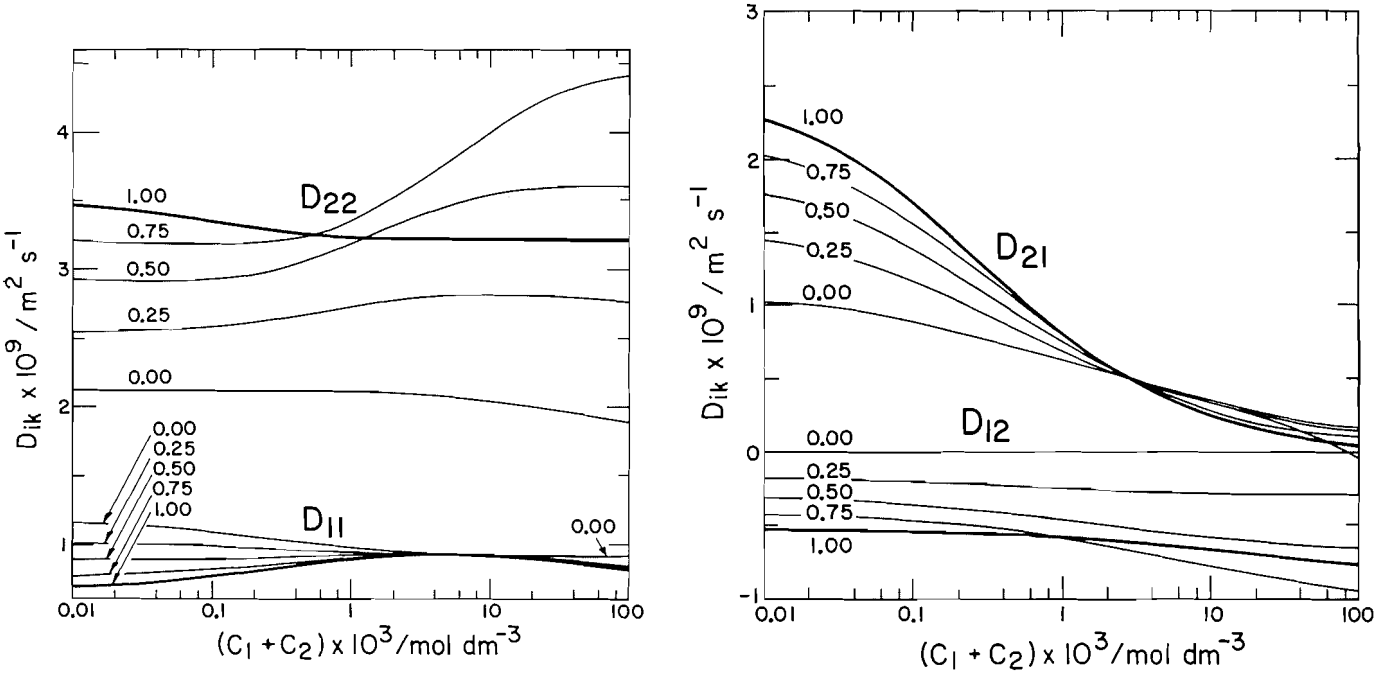

FIG. 1. Calculated diffusion coefficients of $Na_2CO_3(c_1)$–$NaOH(c_2)$–H_2O (25°C) plotted against the total electrolyte concentration $c_1 + c_2$ for different values of $c_1/(c_1 + c_2)$. The heavy curves labelled "1.00" refer to aqueous Na_2CO_3 without added NaOH.

[20] $CO_3^{2-} + H_2O \rightleftarrows HCO_3^- + OH^-$

$K_a = 2.15 \times 10^{-4}$ mol dm^{-3}

Ternary diffusion of the salt is conveniently described (6, 7) in terms of molar fluxes of the neutral components 1, Na_2CO_3 (both hydrolyzed and unhydrolyzed forms); and 2, NaOH.

$$[21]\quad -J_i = \sum_{k=1}^{2} L_{ik}\nabla\mu_k \qquad i = 1, 2$$

$$[22]\quad -J_i = \sum_{k=1}^{2} D_{ik}\nabla c_k \qquad i = 1, 2$$

This representation has the advantage that one of the fluxes (J_1 here) accounts for the entire flux of carbonate and bicarbonate ions. We number the various species as follows: 1, CO_3^{2-}; 2, OH^-; 3, Na^+; and 4, HCO_3^-. Flow equations for the species are identical to eq. [3]. Constraints imposed on the species fluxes by zero flow of electric current and by chemical equilibrium are expressed as

$$[23]\quad \hat{j}_3 = 2\hat{j}_1 + \hat{j}_2 + \hat{j}_4$$

$$[24]^4\quad \nabla\hat{\mu}_1 = \nabla\hat{\mu}_2 + \nabla\hat{\mu}_4$$

Equations [21] and [3] for electrolyte and species fluxes are related as follows: the flux of Na_2CO_3 component equals the sum of CO_3^{2-} and HCO_3^- fluxes;

$$[25]\quad J_1 = \hat{j}_1 + \hat{j}_4$$

the flux of NaOH component equals the flux of OH^- in excess of HCO_3^-;

$$[26]\quad J_2 = \hat{j}_2 - \hat{j}_4$$

and the electrolyte chemical potential gradients equal the sum of the electrochemical potential gradients of the constituent ions

$$[27]\quad \nabla\mu_1 = \nabla\hat{\mu}_1 + 2\nabla\hat{\mu}_3$$

$$[28]\quad \nabla\mu_2 = \nabla\hat{\mu}_2 + \nabla\hat{\mu}_3$$

Proceeding as in Section 2, we obtain (17)

$$[29]\quad L_{11} = \frac{\hat{l}_{11}(\hat{l}_{22} + \hat{l}_{33} + \hat{l}_{44}) + \hat{l}_{44}(\hat{l}_{22} + \hat{l}_{33})}{4\hat{l}_{11} + \hat{l}_{22} + \hat{l}_{33} + \hat{l}_{44}}$$

$$[30]\quad L_{12} = L_{21} = -\frac{\hat{l}_{33}\hat{l}_{44} + 2(\hat{l}_{11}\hat{l}_{22} + \hat{l}_{11}\hat{l}_{44} + \hat{l}_{22}\hat{l}_{44})}{4\hat{l}_{11} + \hat{l}_{22} + \hat{l}_{33} + \hat{l}_{44}}$$

$$[31]\quad L_{22} = \frac{\hat{l}_{33}(\hat{l}_{22} + \hat{l}_{44}) + 4(\hat{l}_{11}\hat{l}_{22} + \hat{l}_{11}\hat{l}_{44} + \hat{l}_{22}\hat{l}_{44})}{4\hat{l}_{11} + \hat{l}_{22} + \hat{l}_{33} + \hat{l}_{44}}$$

with $\hat{l}_{ii} = \hat{c}_i\hat{D}_i/RT$. Diffusivities of the ions in dilute solution are accurately known from conductivity data (ref. 4, Appendix 6.2): $\hat{D}_1(CO_3^{2-}) = 0.92 \times 10^{-9}$; $\hat{D}_2(OH^-) = 5.28 \times 10^{-9}$; $\hat{D}_3(Na^+) = 1.33 \times 10^{-9}$; and $\hat{D}_4(HCO_3^-) = 1.18 \times 10^{-9}$ m^2 s^{-1}.

Solute chemical potentials are expressed as

$$[32]\quad \mu_1 = \mu_1^0 + RT \ln [(2c_1 + c_2)^2(1 - \beta)c_1\hat{y}_1\hat{y}_3^2]$$

$$[33]\quad \mu_2 = \mu_2^0 + RT \ln [(2c_1 + c_2)(\beta c_1 + c_2)\hat{y}_2\hat{y}_3]$$

Concentrations of Na_2CO_3 and NaOH components are denoted by c_1 and c_2, respectively. The degree of hydrolysis of Na_2CO_3 defined by

$$[34]\quad \beta = \frac{[HCO_3^-]}{[CO_3^{2-}] + [HCO_3^-]}$$

is obtained[4] from the formula

$$[35]\quad K_a = \frac{\beta c_1(\beta c_1 + c_2)}{(1 - \beta)c_1}\frac{\hat{y}_2\hat{y}_4}{\hat{y}_1}$$

Following differentiation of eqs. [32], [33], and [35], expressions for the diffusion coefficients are obtained by use of the relation (6, 7)

$$[36]\quad D_{ik} = \sum_{m=1}^{2} L_{im}\partial\mu_m/\partial c_k$$

In Fig. 1, calculated values of the four diffusion coefficients of $Na_2CO_3(c_1)-NaOH(c_2)-H_2O$ (25°C) are plotted against the total solute concentration $c_1 + c_2$ for several values of the ratio $c_1/(c_1 + c_2)$. Activity coefficients were computed using eq. [9] with A (25°C) = 1.18 (ref. 20, chapt. 23; ref. 32). First we shall discuss diffusion coefficients of aqueous Na_2CO_3 without added NaOH ($c_2 = 0$, heavy lines labelled "1.00").

D_{11} determines the flux of Na_2CO_3 produced per unit concentration gradient in that component. At concentrations large compared to K_a so that the degree of hydrolysis is negligible, yet dilute enough so that the Nernst–Hartley approximations are accurate, the expression for D_{11} simplifies to

$$[37]\quad D_{11}(\beta = 0) = \frac{3\hat{D}_{CO_3^{2-}}\hat{D}_{Na^+}}{\hat{D}_{CO_3^{2-}} + 2\hat{D}_{Na^+}}\left(1 + \frac{d\ln y_{\pm 1}}{d\ln c_1}\right)$$

where $y_{\pm 1} = (\hat{y}_1\hat{y}_3^2)^{1/3}$. At lower concentrations hydrolysis increases the proportion of HCO_3^- relative to CO_3^{2-}. In the limit of infinite dilution hydrolysis is complete and we have

$$[38]\quad D_{11}(\beta = 1) = \frac{4\hat{D}_{Na^+}\hat{D}_{HCO_3^-}}{\hat{D}_{OH^-} + 2\hat{D}_{Na^+} + \hat{D}_{HCO_3^-}} = 0.69 \times 10^{-9}\ m^2\ s^{-1}$$

In ternary diffusion studies it is usually taken for granted that solute 1 is unable to produce coupled flow of solute 2 in solutions free of solute 2: $D_{21} \rightarrow 0$ as $c_2/c_1 \rightarrow 0$ (10, 16, 43, 44). It is remarkable that in aqueous Na_2CO_3 without added NaOH the cross-diffusion coefficient D_{21} (which determines the flux of NaOH produced per unit Na_2CO_3 gradient) is very large and positive. In fact, D_{21} is more than three times as large as D_{11} at high dilution (refer to the curve for D_{21} labelled "1.00"). This means that the Na_2CO_3 gradient produces an initial flux of NaOH more than three times larger than the Na_2CO_3 flux, even though the solution is free of added NaOH! In effect, as OH^- diffuses more rapidly than either CO_3^{2-} or HCO_3^-, the Na_2CO_3 gradient generates "its own" NaOH flux. In the limit of infinite dilution the expression for D_{21} simplifies to

$$[39]\quad D_{21}(\beta = 1) = \frac{4\hat{D}_{Na^+}(\hat{D}_{OH^-} - \hat{D}_{HCO_3^-})}{\hat{D}_{OH^-} + 2\hat{D}_{Na^+} + \hat{D}_{HCO_3^-}} = 2.39 \times 10^{-9}\ m^2\ s^{-1}$$

That the limiting value of D_{21} is proportional to the difference in diffusivity between hydrolysis products OH^- and HCO_3^- is noteworthy; this difference is the source of the multicomponent nature of the diffusional properties of aqueous Na_2CO_3.

The cross-diffusion coefficient D_{12} measures the ability of the NaOH flux to produce coupled flow of Na_2CO_3. As mentioned earlier, the flux of rapidly diffusing OH^- reduces the flux of coions CO_3^{2-} and HCO_3^-. This accounts for both the negative sign of D_{12} as well as the reduction in the main diffusion coefficient of Na_2CO_3 by hydrolysis.

The curve for D_{22} labelled "1.00" gives the diffusion coefficient of trace amounts of NaOH in aqueous Na_2CO_3 as a function of Na_2CO_3 concentration. In dilute mixtures of strong electrolytes (10, 43, 44) (NaCl–NaOH–H_2O for example) its value is approximately equal to the diffusivity of OH^-, about $5.3 \times 10^{-9}\ m^2\ s^{-1}$. In aqueous Na_2CO_3, however, its value is considerably lower: 3.2 to $3.5 \times 10^{-9}\ m^2\ s^{-1}$. This discrepancy arises because in aqueous Na_2CO_3, not all hydroxide is transported as the OH^- species. Instead, some hydroxide reacts with bicarbonate (eq. [20]) and is transported as CO_3^{2-} plus H_2O with countercurrent flux of HCO_3^-.

$Na_2CO_3(c_1)-NaOH(c_2)-H_2O$ (25°C)

Also plotted in Fig. 1 are ternary diffusion coefficients of aqueous Na_2CO_3 with added NaOH. These curves are plotted against the total electrolyte concentration $c_1 + c_2$ for values of $c_1/(c_1 + c_2)$ equal to 0.00, 0.25, 0.50, and 0.75. The curve for D_{22} labelled "0.00", for example, gives the binary diffusion coefficient of aqueous NaOH as a function of concentration.

To first approximation, multicomponent diffusion coefficients in dilute mixtures of strong electrolytes are constant for fixed electrolyte ratios. This behaviour is primarily a result of electrostatic nature of the coupling between ionic fluxes (10, 43, 44). Because there are chemical as well as electrostatic interactions between the fluxes, the diffusion coefficients plotted in Fig. 1 for fixed ratios of Na_2CO_3 to NaOH do not follow this simple pattern. The diffusion coefficient for trace amounts of Na_2CO_3 in aqueous NaOH (curve for D_{11} labelled "0.00") illustrates this point nicely. Neglecting minor activity coefficient terms, we have

$$[40]\quad D_{11}(c_1/c_2 = 0) = (1 - \beta)\hat{D}_{CO_3^{2-}} + \beta\hat{D}_{HCO_3^-}$$

At very low NaOH concentrations where hydrolysis of CO_3^{2-} is essentially complete, trace amounts of Na_2CO_3 diffuse as HCO_3^-, while at higher NaOH concentrations the carbonate–bicarbonate equilibrium is shifted in favor of CO_3^{2-} and transport as CO_3^{2-} predominates.

$Na_2CO_3(c_1')-NaHCO_3(c_2')-H_2O$

Although convenient, the description of diffusion of aqueous Na_2CO_3 in terms of fluxes J_1 and J_2 of components Na_2CO_3 and NaOH is not unique. Another description would be in terms of fluxes J_1' and J_2' of Na_2CO_3 and $NaHCO_3$. Since $J_1 = J_1' + J_2'$, $J_2 = -J_2'$; $c_1 = c_1' + c_2'$; and $c_2 = -c_2'$, eq. [22] may be transformed from the Na_2CO_3–NaOH representation into the Na_2CO_3–$NaHCO_3$ representation. The two sets of diffusion coefficients are related by $D_{11}' = D_{11} + D_{21}$, $D_{12}' = D_{11} + D_{12} - D_{21} - D_{22}$, $D_{21}' = D_{21}$, and $D_{22}' = D_{22} - D_{21}$.

4. Conclusions

A procedure based on the Nernst–Hartley method has been developed to estimate diffusion coefficients of aqueous solutes which hydrolyze.[5] The procedure allows detailed interpretation of the concentration dependence of the diffusion coefficients in terms of (*i*) changes in the solute free energy gradient caused by hydrolysis and (*ii*) changes in the mobility of the solute arising from changes in the proportion of unhydrolyzed solute and hydrolysis products. At low concentrations where the procedure may be used with confidence, diffusion coefficients have been estimated for several systems. Typically, hydrolysis may either increase or decrease the rate of diffusion by several tens of per cent. The diffusion coefficients are most sensitive to concentration at solute concentrations of the same order of magnitude as the hydrolysis constant where similar amounts of unhydrolyzed solute and hydrolysis products are present in solution. In the case of a hydrolyzing salt, diffusion is a ternary process (four diffusion coefficients must be specified) pro-

[5]Although we have dealt only with estimating diffusion coefficients of hydrolyzing solutes, the same procedure is applicable to diffusion with solvolysis in nonaqueous solvents.

ducing coupled fluxes of acid or hydroxide hydrolysis products which may exceed the flux of salt itself.

Investigation of the possible pathways for magnetic exchange interactions in homobinuclear chelates of naphthazarin

CONSTANTINOS A. TSIPIS AND MICHAEL P. SIGALAS
Laboratory of Inorganic Chemistry, University of Thessaloniki, Thessaloniki, Greece

AND

VASILIOS P. PAPAGEORGIOU AND MARIA N. BAKOLA-CHRISTIANOPOULOU[1]
Department of Chemical Engineering, College of Engineering, University of Thessaloniki, Thessaloniki, Greece

Received March 15, 1982

CONSTANTINOS A. TSIPIS, MICHAEL P. SIGALAS, VASILIOS P. PAPAGEORGIOU, and MARIA N. BAKOLA-CHRISTIANOPOULOU. Can. J. Chem. **61**, 1500 (1983).

Homobinuclear complexes of the binucleating naphthazarinato ligand of the general formula $[M_2(C_{10}H_4O_4)(C_{10}H_8N_2)_2]^{2+}$-$(PF_6^-)_2$, where M = Cu, Ni, and Zn, $C_{10}H_4O_4$ = naphthazarinato ligand, and $C_{10}H_8N_2$ = 2,2′-bipyridyl, have been prepared and studied. In these complexes the naphthazarinato ligand, acting as a bridging unit between the two metal centers, supports the propagation of magnetic exchange interactions through its extensive π-electron system. The spectroscopic and magnetic data of the compounds showed that each metal ion is surrounded by two oxygen and two nitrogen donor atoms in a nearly tetrahedral configuration (C_{2v} point group) with the naphthazarinato ligand adopting a centrosymmetrical structure of C_{2h} symmetry. The room-temperature magnetic data of the copper(II) and nickel(II) homobinuclear chelates (1.32 and 1.73 BM per metal ion at 8000 G, respectively), as well as the slight decrease of the magnetic moments as the magnetic field strength decreases are indicative of the operation of antiferromagnetism in these chelates. Quantum mechanical calculations of the Hückel LCAO-MO type improved by ω-technique have been used to provide a qualitative guide to the possible pathways for the superexchange processes observed in the tetrahedral copper(II) and nickel(II) chelates, as well as to explain qualitatively why there is no antiferromagnetic interactions propagated by the bridging naphthazarinato ligand in analogous homobinuclear chelates with other coordination geometries such as square planar, square-pyramidal, trigonal bipyramidal, and octahedral.

CONSTANTINOS A. TSIPIS, MICHAEL P. SIGALAS, VASILIOS P. PAPAGEORGIOU et MARIA N. BAKOLA-CHRISTIANOPOULOU. Can. J. Chem. **61**, 1500 (1983).

On a préparé et étudié les complexes homobinucléaires du ligand naphthazarinato binucléant de formule générale $[M_2(C_{10}H_4O_4)(C_{10}H_8N_2)_2]^{2+}(PF_6^-)_2$ où M = Cu, Ni et Zn, $C_{10}H_4O_4$ = ligand naphthazarinato et $C_{10}H_8N_2$ = bipyridyl-2,2′. Dans ces complexes le ligand naphthazarinato agit comme unité de pont entre les deux centres métalliques et est responsable, au moyen de son système accentué d'électrons π, de la propagation des interactions d'échange magnétique. Les données spectroscopiques et magnétiques relatives à ces composés révèlent que chaque ion métallique est entouré de deux atomes donneurs d'oxygène et d'azote dans une configuration quasi tétraédrique (point de group C_{2v}) avec le ligand naphthazarinato adoptant une structure centrosymétrique de symétrie C_{2h}. Les données magnétiques à la température ambiante se rapportant aux chélates homobinucléaires du cuivre(II) et du nickel(II) (1,32 et 1,73 BM) par ion métallique à 8000 G respectivement) aussi bien que la légère diminution des moments magnétiques avec la force du champ magnétique sont une indication de la présence d'un antiferromagnétisme dans ces chélates. On a utilisé les calculs de mécanique quantique du type Hückel LCAO-MC améliorés par la technique-ω pour obtenir un guide qualitatif des schémas possibles des processus de superéchange observés dans les chélates tétraédriques du cuivre(II) et du nickel(II) aussi bien pour expliquer qualitativement l'absence d'interactions antiferromagnétiques propagées par le ligand naphthazarinato en position de pont dans les chélates homobinucléaires analogues avec d'autres géométries de coordination tel le carré plan, la pyramide carrée, la bipyramide trigonale et octaédrique.

[Traduit par le journal]

Introduction

The dianion of 5,8-dihydroxy-1,4-naphthoquinone (commonly knwon as naphthazarin) is a potential binucleating ligand, which forms stable polynuclear or binuclear chelates with bivalent metal ions (1, 2). Due to its extensive π-electron system, the naphthazarinato binucleating ligand would be expected to support the propagation of magnetic exchange interactions (superexchange interactions) between two paramagnetic metal ions. However, in a recent study of the magnetic exchange interactions in some five- and six-coordinated binuclear complexes of copper(II) and nickel(II) containing a bridging naphthazarinato ligand no antiferromagnetic exchange interactions were detected (2). This is not surprising, since it is now well-established (2–5) that the strength and mechanism of such magnetic exchange interactions are primarily depended upon the symmetry and energy of the orbitals of both the metal ions and the binucleating ligand. In other words, the coordination geometry about the central paramagnetic metal ions, as well as the structure of the bridging unit are the most important factors determining the operation of magnetic exchange interactions. In this regard it will be important the study of the ability of the naphthazarinato binucleating ligand to support magnetic exchange interactions in binuclear complexes with other coordination geometries about the central paramagnetic metal ions.

In the present paper we report on our results concerning: (*i*) the synthesis and characterization of some new four-coordinated homobinuclear chelates of the binucleating naphthazarinato ligand of the general formula $[M_2(C_{10}H_4O_4)$-$(C_{10}H_8N_2)_2]^{2+}$ $(PF_6^-)_2$, where M = Cu, Ni, and Zn, $C_{10}H_4O_4$ = naphthazarinato ligand, and $C_{10}H_8N_2$ = 2,2′-bipyridyl; (*ii*) the study of their structural and magnetic properties; and (*iii*) the theoretical prediction, on the basis of HMO quantum chemical calculations improved by ω-technique, of the possible pathways for the superexchange processes observed in the copper(II) and nickel(II) chelates. The quantum chemical calculations

also have been used to confirm the structure of the naphthazarinato ligand, as well as to interpret the electronic spectra of the new compounds.

Experimental

Physical measurements

Infrared spectra were recorded, in the region of 4000–250 cm^{-1}, on a Perkin-Elmer 467 spectrophotometer using KBr discs or Nujol mulls. Electronic spectra were obtained on a Perkin-Elmer Hitachi 200 spectrophotometer and on a Cary 17D spectrophotometer, using freshly prepared solutions in DMF. Magnetic susceptibility measurements were done by the Faraday technique at different magnetic field strengths using $Hg[Co(SCN)_4]$ as the calibrant. Diamagnetic corrections were made using Pascal's constants. Conductivity measurements were done in a Wheatstone bridge Model RC 216 B_2 using 10^{-3} *M* solutions in DMF. Carbon, hydrogen, and nitrogen were determined using a Perkin-Elmer 240 Elemental Analyzer.

Starting materials

All solvents were of reagent grade and were used without further purification in synthetic work. All the other reagents were obtained commercially.

Preparation of the chelates

The investigated homobinuclear chelates were of the general formula $[M_2(C_{10}H_4O_4)(C_{10}H_8N_2)_2](PF_6^-)_2$ (where M = Cu, Ni, and Zn, and $C_{10}H_8N_2$ = 2,2′-bipyridyl). The 2,2′-bipyridyl ligand was selected as the nonbridging ligand because it prevents the formation of polynuclear chelates. The new chelates were prepared according to the following general method:

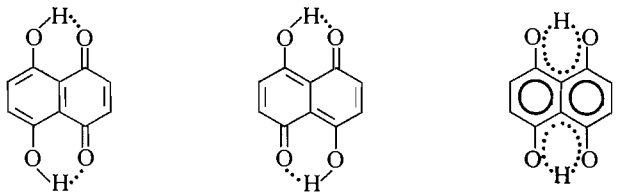
Into a three-necked flask equipped with a magnetic stirrer, a reflux condenser, and a separatory funnel, were charged 0.475 g (2.4 mmol) of naphthazarin and 100 cm^3 of methylene chloride as a solvent. To the resulting solution, a solution containing 5.0 mmol of the metal acetate, 0.78 g (5.0 mmol) of 2,2′-bipyridyl, and 2.00 g (12.3 mmol) of NH_4PF_6 in 100 cm^3 of ethanol was added slowly under continuous magnetic stirring. The reaction mixture was left for 1 h at room temperature and then was refluxed for 4 h. After cooling, the mixture was filtered and the precipitate was washed several times with small portions of water, ethanol, and methylene chloride and dried under vacuum over P_2O_5. The isolated chelates are soluble in DMF and DMSO, but insoluble in water and in all common organic solvents. The yields of the reactions were almost quantitative (more than 80%). All the chelates are deep blue in color and do not melt up to 300°C. Their analytical data are as follows: *Anal.* calcd. for $[Cu_2(C_{10}H_4O_4)(C_{10}H_8N_2)_2](PF_6)_2$: C 39.27, H 2.19, N 6.10; found: C 39.54, H 2.29, N 6.15; *Anal.* calcd. for $[Ni_2(C_{10}H_4O_4)(C_{10}H_8N_2)_2](PF_6)_2$: C 39.69, H 2.22, N 6.17; found: C 40.01, H 2.16, N 5.98; *Anal.* calcd. for $[Zn_2(C_{10}H_4O_4)(C_{10}H_8N_2)_2](PF_6)_2$: C 39.11, H 2.18, N 6.08; found: C 39.41, H 2.28, N 6.18.

Calculations

Quantum chemical calculations were performed using the Hückel LCAO-MO method improved by ω-technique (6, 7). In the course of the HMO calculations the following parameters were adopted: for the quinonic oxygen atoms $h = 1.00$ and $k = 1.20$ and for the phenolic oxygen atoms $h = 1.50$ and $k = 0.70$. The value of ω was chosen as 0.9. The self-consistent charge (SCC) process was applied simultaneously to both the quinonic and phenolic oxygen atoms. The 14 × 14 secular determinants were factorized by taking advantage of the symmetry of the molecules and standard methods of group theory.

Results and discussion

The structure of naphthazarin has been a matter of considerable controversy in a number of papers published up to date (8–15). The following three different possible structures have been proposed:



I **II** **III**

Schmand and Boldt (13) showed, by spectroscopic studies, that the naphthazarin molecule exists in solution as 5,8-dihydroxy-1,4-naphthoquinone (structure **I**, C_{2v} point group), which according to the authors must be more stable than the centrosymmetrical 1,5-quinoid structure (structure **II**, C_{2h} point group). On the contrary, very recently Bratan and Strohbusch (15) showed, by ir and ^1H nmr spectroscopy, that the molecular structure of naphthazarin in solution is that of a centrosymmetrical structure with highly mobile protons in intramolecular hydrogen bonds. The fast tunnelling of the two protons interconvert the two equivalent centrosymmetrical 1,5-quinoid structures giving their average structure **III** which belongs to the D_{2h} point group. According to these authors the 1,5-quinoid structure must be more stable than the 1,4-quinoid structure. The crystal structure determination of the free naphthazarin (12) showed a nearly D_{2h} symmetry for the molecule. Strictly speaking, the symmetry of the naphthazarin molecule refering in this paper is C_{2h}, since the shortest C···O bonds were those at 1- and 5-positions. Thus the X-ray structure determination of the naphthazarin molecule supports the idea of Bratan and Strohbusch that the 1,5-quinoid structure is the more stable one.

An analogous situation exists also in the case of naphthazarin diacetate, where some studies showed that the 1,5-quinoid structure is the more stable one (11) in solution, while the X-ray structure determination (14) showed that in solid state naphthazarin diacetate exists as 5,8-diacetoxy-1,4-naphthoquinone.

With the foregoing ambiguous aspects about the structure of naphthazarin in mind and the fact that the knowledge of its structure is of crucial importance in our attempts to gain an insight on the possible pathways for the magnetic exchange interactions, we calculated by the HMO method and the total π-electron energies for all the three possible structures of naphthazarin. According to the HMO calculations, the electron configurations of the three possible structures of naphthazarin in their ground states are written:

structure **I**: $1b_1^2, 1a_2^2, 2b_1^2, 2a_2^2, 3b_1^2, 4b_1^2, 5b_1^2$

structure **II**: $1a_u^2, 1b_g^2, 2b_g^2, 2a_u^2, 3a_u^2, 3b_g^2, 4a_u^2$

structure **III**: $1b_{3u}^2, 1b_{2g}^2, 1b_{1g}^2, 1a_u^2, 2b_{3u}^2, 2b_{1g}^2, 3b_{3u}^2$

For these electron configurations one could easily obtain the following total π-electron energies:

$$E_\pi(C_{2v}) = 14\alpha + 24.486\beta$$

$$E_\pi(C_{2h}) = 14\alpha + 24.814\beta$$

and

$$E_\pi(D_{2h}) = 14\alpha + 24.566\beta$$

These values of the π-electron energies clearly indicate that structure **II** is the more stable one for the naphthazarin molecule. The energy difference between structures **I** and **II** is equal

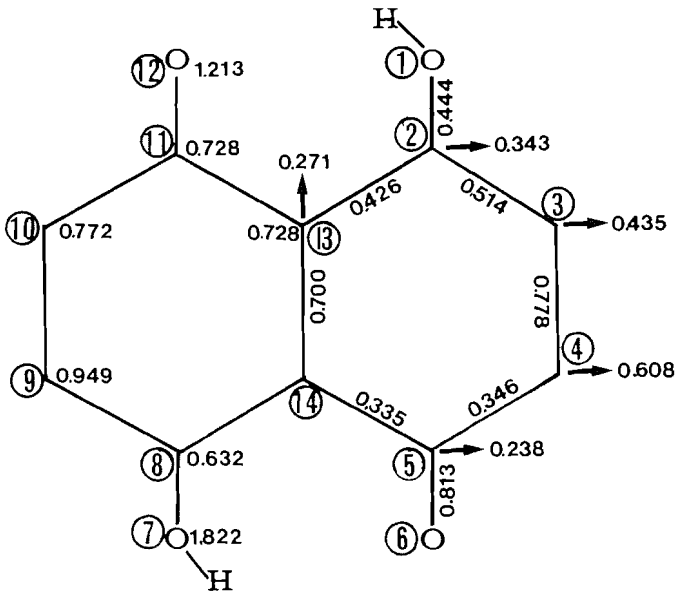


FIG. 1. Homobinuclear chelates of naphthazarin.

to 0.328β which corresponds to about 5.576 kcal. The present quantum chemical results justify both the assumption made by Bratan and Strohbusch (15) that the 1,4-quinoid structure must have a higher energy than the 1,5-quinoid structure and the results of the X-ray structure determination (12). The calculated bond orders (Fig. 1) for the more stable C_{2h} structure of naphthazarin are in accordance with the bond lengths calculated by X-ray structure determination (12). Also in Fig. 1 are shown the charge densities q_i on each atom i and the free valence number F_i. Both HOMO and LUMO in the centrosymmetrical 1,5-quinoid structure are localized on the benzenoid system of the molecule.

The D_{2h} structure of naphthazarin is an average of two equivalent centrosymmetrical C_{2h} structures which are interconverted by fast tunneling of the two protons (15). However, since the tunneling rates decrease exponentially with increasing mass of the tunneling particle, the D_{2h} structure could not be adopted in metal chelates where the hydrogen atoms of naphthazarin are substituted from the heavier metal ions. Thus in metal chelates we would expect structure **II** to predominate over the other structures. In fact, this assumption was justified by the examination of the electronic and ir spectra of the chelates under investigation.

In Table 1 the obtained singlet electronic transition energies for the 1,5-quinoid structure are compared with the experimental ones. A brief description of the MO's involved in the reported transitions and their symmetry and polarization are given. It must be noted that for the metal chelates only the intraligand transitions are reported in Table 1. From the results presented in Table 1 it is evident that the electronic spectra of naphthazarin and those of its metal chelates are well interpreted in terms of the C_{2h} symmetry for the naphthazarinato moiety. Although we did not take into consideration configuration interaction, a good agreement is found between theoretical and experimental data.

The C_{2h} structure of the naphthazarinato ligand in its metal chelates was further supported from the examination of the ir spectra. The most relevant absorption bands in the ir spectra of the investigated chelates together with their tentative assignments are listed in Table 2. All the chelates showed a number of intense bands in the region of 1200–1700 cm^{-1}. In naphthazarin the stretching frequency of the carbonyl groups occurs at 1621 cm^{-1}, while that of the coordinated carbonyl groups in the metal chelates is shifted to lower wavenumbers. The shifts amount to some 65 cm^{-1}. The $\nu(C\cdots O)_1$ band in naphthazarin is broader than in the metal chelates, a fact which can be ascribed to a superposition of two absorptions at almost the same frequency for the naphthazarin molecule (15). The bands which are superimposed were the expected B_{1u} and B_{2u} normal modes of the carbonyl groups for a D_{2h} structure of naphthazarin. On the other hand, the narrow $\nu(C\cdots O)_1$ band of the studied chelates is indicative of a C_{2h} structure for the naphthazarinato ligand, since only one band of B_{1u} symmetry is expected for a C_{2h} structure. Of considerable importance are also the bands which occur in the region of about 1280 cm^{-1}. These bands were attributed to the $\nu(C\cdots O)_2$ stretching frequencies (16–18) and show the same pattern as the $\nu(C\cdots O)_1$ bands. These bands are thus again narrow and sharp in the case of the metal chelates, indicative for the C_{2h} structure of the naphthazarinato ligand. The position of the $\nu(C\cdots O)_2$ bands indicates that the C—O bond has a significant fractional double bond character as would be expected from the extension of the π-electron system of the ligand. Finally, in the ir spectra of the chelates studied were observed all the bands, which are characteristic of the 2,2′-bipyridyl ligand (19–21) and the PF_6^- anion (22), as well as of the MO_2N_2 moiety (23, 24).

Conductivity measurements in the case of the copper(II) chelate in DMF solutions gave Λ_μ = 159 mho cm^2 mol^{-1}, a value which is in the range of the values observed for 1:2 electrolytes in the same solvent (25). Unfortunately, the low solubility of the nickel(II) and zinc(II) chelates in DMF prevented the conductivity measurements for these chelates, although very dilute solutions showed that these compounds are also electrolytes. The above data clearly show that the investigated chelates are homobinuclear dicationic compounds containing the binucleating naphthazarinato ligand as a bridging unit with the C_{2h} structure. The excess positive charge is balanced by PF_6^-. It must be noted that the X-ray structure determination on an analogous five-coordinated dicopper complex (2) showed that the bridging naphthazarinato unit adopts the C_{2h} symmetry. This fact further supports our results on the structure of the bridging naphthazarinato ligand in the four-coordinated homobinuclear chelates under investigation.

We have next attempted to explore the possible pathways for the magnetic exchange interactions observed in the investigated homobinuclear chelates of copper(II) and nickel(II), in terms of pairwise interactions of dimeric molecular orbitals. For this purpose we need to know, apart from the symmetry properties of the π-molecular orbitals of the naphthazarinato ligand, the symmetry properties of the orbitals of the metal ions which are occupied by the unpaired electron(s) as well. Therefore, we must first know the structure and symmetry of the MO_2N_2 moiety contained in these chelates. The magnetic data of the investigated chelates can be used for this purpose. Unfortunately, the crystal-field bands in the electronic spectra of the studied chelates correlated to their structures was impossible to be observed, since they are masked from the very intense intraligand and charge transfer transitions.

For the diamagnetic zinc(II) chelate, each metal ion is surrounded by two oxygen and two nitrogen donor atoms in a nearly tetrahedral geometry with C_{2v} symmetry, since it is well known that zinc(II) four-coordinated complexes adopt the tetrahedral structure. The paramagnetic nature of the four-

coordinated nickel(II) chelate (μ_{eff} = 1.69 BM, 1.73 BM, and 1.73 BM at 4000 G, 8000 G, and 11700 G, respectively) excludes the square-planar configuration and hence we can also accept the tetrahedral structure around the central atoms with C_{2v} symmetry for this chelate. For the copper(II) chelate the room temperature magnetic moment (μ_{eff} = 0.91 BM, 1.32 BM, and 1.29 BM at 4000 G, 8000 G, and 11700 G, respectively) does not give us any strong support for the square-planar or tetrahedral geometry, although in analogy with the other two chelates we have reason to believe that the copper(II) chelate probably also adopts the tetrahedral structure around the central atoms with C_{2v} symmetry. Nevertheless, as we shall see later, the magnetic exchange interactions observed exclude the square-planar structure for the copper(II) chelate. According to the above aspects all the homobinuclear chelates under investigation must have a centrosymmetric structure of C_{2h} symmetry with tetrahedral coordination geometry of the central atoms.

The room temperature magnetic data of the copper(II) and nickel(II) homobinuclear chelates reflect a considerable spin–spin interaction between the unpaired electrons on the two metal centers. The low magnetic moments observed both at low and high field strengths are indicative of the operation of antiferromagnetism in these compounds. Also the slight decrease of the magnetic moments as the magnetic field strength decreases is indicative of the operation of antiferromagnetism. These observations show that our binuclear d^9–d^9 system displays the singlet (antiferromagnetism) ground state. The same happens also in the binuclear d^8–d^8 system.

For the copper(II) binuclear chelate (d^9–d^9 system), if we assume the tetrahedral structure about the central atoms with local C_{2v} symmetry the unpaired electron at each copper(II) center will be located in one of the d_{xy}, d_{xz}, and d_{yz} atomic orbitals. All these three AO's are nondegenerate in the C_{2v} point group and belong to the A_2, B_1, and B_2 irreducible representations, respectively. Depending on the type of the AO in which the unpaired electron(s) reside, the magnitude of the magnetic exchange interactions will be gauged by the energy separation between the bonding and antibonding dimeric MO's, whose nature and symmetry in C_{2h} point group are:

$$\varphi_1 \sim d_{xy}(A) + d_{xy}(B) \qquad B_u$$
$$\varphi_2 \sim d_{xy}(A) - d_{xy}(B) \qquad A_g$$
$$\varphi_3 \sim d_{xz}(A) + d_{xz}(B) \qquad A_u$$
$$\varphi_4 \sim d_{xz}(A) - d_{xz}(B) \qquad B_g$$
$$\varphi_5 \sim d_{yz}(A) + d_{yz}(B) \qquad B_g$$
$$\varphi_6 \sim d_{yz}(A) - d_{yz}(B) \qquad A_u$$

On the bridging naphthazarinato unit there are π-molecular orbitals which belong to A_u and B_g irreducible representations. Hence, only the symmetry adapted combinations φ_3,φ_4 and φ_5,φ_6 resulting from the d_{xz} and d_{yz} AO's, respectively, can interact with the a_u and b_g π MO's of the ligand. The symmetry adapted combination $\varphi_3(a_u)$ can be combined with the $1a_u$, $3a_u$, and $6a_u$ π MO's of the ligand and the $\varphi_4(b_g)$ with the $1b_g$, $4b_g$, and $7b_g$ π MO's. On the other hand, the symmetry adapted combination $\varphi_5(b_g)$ can be combined with the $2b_g$, $3b_g$, and $5b_g$ π MO's and the $\varphi_6(a_u)$ with the $2a_u$, $5a_u$, and $7a_u$ π MO's. However, among the a_u and b_g π MO's of the ligand only those which do not contain any nodal plane between the two copper(II) centers will be able to support the propagation of the magnetic exchange interactions. Thus, only the $1a_u$, $2a_u$, and $2b_g$ π MO's of the ligand combined with the φ_3, φ_6, and φ_5 symmetry adapted combinations, respectively, will support the observed magnetic exchange processes. These possible combinations are depicted schematically in Fig. 2. The same situation is also expected to exist in the case of the nickel(II) chelate (d^8–d^8 system) where the two unpaired electrons on each nickel(II) center occupy the d_{xz} and d_{yz} AO's.

If now we assume for the copper(II) chelate the square-planar configuration (point group C_{2v}) the unpaired electron will be located in the $d_{x^2-y^2}$ AO which belongs to A_1 irreducible representation in the C_{2v} point group. In this case the magnetic exchange interactions will be gauged by the energy separation of the following bonding φ_1 and antibonding φ_2 MO's:

$$\varphi_1 \sim d_{x^2-y^2}(A) + d_{x^2-y^2}(B) \qquad A_g$$

$$\varphi_2 \sim d_{x^2-y^2}(A) - d_{x^2-y^2}(B) \qquad B_u$$

Since in the bridging naphthazarinato unit there are no π MO's of A_g and B_u symmetry any magnetic exchange interaction will not be allowed in this case. Hence, the observed magnetic exchange interactions in the copper(II) chelate is in support of the tetrahedral structure adopted also from this chelate as in the case of the nickel(II) and zinc(II) chelates.

In the previous discussion on the possible pathways for the magnetic exchange interactions supported by the π-electron system of the bridging naphthazarinato ligand we ignored its σ-electron system. CNDO/2 calculations on the naphthazarinato ligand in its C_{2h} structure showed (2) that there are σ-MO's pertaining to a_g and b_u symmetry species. Hence one would expect these MO's to interact with the φ_1 and φ_2 dimeric MO's in the case of the tetrahedral and square-planar homobinuclear chelates discussed above, since they pertain to the same symmetry species. However, the energies and the overlap characteristics of these MO's do not allow such interactions and therefore could not be possible pathways for magnetic exchange interactions (2). It is obvious then that the magnetic exchange interactions observed in our complexes are mainly supported by the π-electron system of the bridging naphthazarinato unit.

Finally, it is worthwhile to note that previous studies of the magnetic exchange interactions in analogous five- and six-coordinated homobinuclear complexes of copper(II) and nickel(II) showed that the naphthazarinato bridging unit does not have the ability to support such interactions (2). This is not surprising, since according to our results the ability of the bridging naphthazarinato ligand (C_{2h} symmetry) to support superexchange interactions through its extensive π-electron system depends on the coordination geometry about the central atoms which determines the nature of the d AO's where the unpaired electron(s) reside. Thus, for the five-coordinated dicopper complex, $[Cu_2(dien)_2(DHNQ)](BPh_4)_2$, the unpaired electron resides on the $d_{x^2-y^2}$ AO whose bonding and antibonding combinations pertain to a_g and b_u symmetry species, respectively. However, in the bridging naphthazarinato unit there are no π MO's of a_g and b_u symmetry and therefore no magnetic exchange interactions will expected for this complex. For the six-coordinated dinickel complex, $[Ni_2(tren)_2(DHNQ)](BPh_4)_2$, the two unpaired electrons will be located on the $d_{x^2-y^2}$ and d_{z^2} AO's whose bonding and antibonding combinations pertain to a_g and b_u symmetry species, respectively. It is obvious then that no magnetic interactions will be expected for this complex because of the lack of the suitable symmetry molecular orbitals in the bridging unit. Any magnetic exchange interaction supported by the σ MO's of the bridging ligand pertaining to a_g and b_u symmetry species is excluded on the basis of their energy and overlap characteristics (2).

We can conclude from our results that the naphthazarinato binucleating ligand in its C_{2h} structure could support magnetic superexchange interactions through its extensive π-electron system only in the case of four-coordinated homobinuclear chelates of copper(II) and nickel(II) with tetrahedral geometry. For other geometries, such as square-planar, square-pyramidal, trigonal bipyramidal, and octahedral naphthazarinato bridging unit could not support such phenomena, because of the lack of any possible pairwise orbital interaction between dimeric molecular orbitals in such coordination geometries.

DAVID K. RYAN, CARL P. THOMPSON, and JAMES H. WEBER. Can. J. Chem. **61**, 1505 (1983).

The binding of Cu^{2+} to soil-derived fulvic acid (SFA) measured by fluorescence quenching titration is much stronger than Co^{2+} and Mn^{2+} which are similar. The conditional stability constants from curve fitting at pH 6 are 1.1×10^5 for Cu^{2+}, 5.1×10^3 for Co^{2+}, and 4.2×10^3 for Mn^{2+}. The slight advantage in strength for Co^{2+} over Mn^{2+} is also demonstrated by the binding curves at pH 6 and 7. These two metal ions not only tend to bind more weakly but also bind to fewer sites, giving complexing capacity values of about 1.5×10^{-6} *M* compared to 2.0×10^{-5} for Cu^{2+} at pH 6. This lower binding capacity may be due to outer sphere complexation that does not allow access to some sites complexed by inner sphere binding Cu^{2+}. Scattering experiments demonstrate that Cu^{2+} is more effective at precipitating and aggregating SFA than Co^{2+} and Mn^{2+}. Cu^{2+} probably neutralizes the negative charges on SFA molecules allowing larger hydrophobic aggregates to form and precipitate.

DAVID K. RYAN, CARL P. THOMPSON et JAMES H. WEBER. Can. J. Chem. **61**, 1505 (1983).

La liaison du Cu^{2+} à l'acide fulvique provenant de la terre (AFT) mesurée par titration d'extinction de la fluorescence est plus forte que celle du Co^{2+} et du Mn^{2+} qui sont très semblables. Les constantes de stabilité conditionnelle tirées des courbes d'ajustement à un pH de 6 sont de $1{,}1 \times 10^5$ pour le Cu^{2+}, de $5{,}1 \times 10^3$ pour le Co^{2+} et de $4{,}2 \times 10^3$ pour le Mn^{2+}. On démontre également le léger avantage, du point de vue de la force, du Co^{2+} sur le Mn^{2+} à l'aide des courbes de liaison à des pH de 6 et 7. Ces deux ions métalliques non seulement tendent à se lier plus faiblement mais également se lient à un plus petit nombre de sites en donnant des valeurs de capacité de complexation d'environ $1{,}5 \times 10^{-6}$ *M* comparé à $2{,}0 \times 10^{-5}$ pour le Cu^{2+} à un pH de 6. Cette faible capacité de liaison peut être due à une complexation hors sphère qui ne permet pas l'accès à quelques sites complexés par la liaison du Cu^{2+} à l'intérieure de la sphère. Des expériences de dispersion démontrent que le Cu^{2+} est plus efficace pour précipiter et agglutiner le AFT que le Co^{2+} et le Mn^{2+}. Le Cu^{2+} neutralise probablement les charges négatives des molécules de AFT permettant ainsi à des agrégats hydrophobes plus volumineux de se former et de précipiter.

[Traduit par le journal]

Introduction

The transport, toxicity, and removal of trace metal ions in aquatic systems is intimately related to their speciation (1, 2). Under certain conditions naturally occurring humic and fulvic acids can play a major role in determining the forms of certain trace elements present in natural waters (3, 4). The ability to predict speciation of various metal ions in a given system relies heavily on the stability of metal complexes of organic matter and inorganic ligands. Only the latter complexes are relatively well understood. In order to obtain reliable information on the extremely complex trace metal – humic material interactions, existing data must be supported and confirmed using alternate methods. This is especially true for the challenging analytical problems that natural systems provide.

In this study the natural fluorescence of soil-derived fulvic acid (SFA) is used as a probe to compare the complexation of Mn^{2+}, Co^{2+}, and Cu^{2+} and to demonstrate the effect of pH. Binding of these paramagnetic metal ions to natural organic matter results in quenching of its fluorescence (5–9), and we have related this effect to the fraction of this natural ligand that is bound (5). This type of information is completely analogous to Scatchard's (10) $\bar{\nu}$ ([bound metal ion]/[total ligand]) which is usually calculated from free and total metal ion concentrations (7, 11, 12). However, fluorescence measures free ligand concentration and provides data that is complementary to ion-selective electrode (ISE) experiments or other methods that measure free metal ion in equilibrium with fulvic acid (7).

Our results have implications for the nature and strength of binding of Mn^{2+}, Co^{2+}, and Cu^{2+} to humic matter in natural waters. In addition, Rayleigh scattering experiments conducted simultaneously with fluorescence give valuable solubility information about SFA – metal ion complexes. We use scattering polarization measurements to determine whether or not aggregation of precipitate particles is significant.

Experimental

The apparatus and procedures used for fluorescence quenching titrations have been described in detail elsewhere (5, 6). All solutions used in this study were 10 mg/L SFA in 0.1 *M* KNO_3 and filtered through 0.4 nm filters. In all experiments the SFA solutions were titrated at constant pH with 1000 mg/L Mn^{2+}, Co^{2+}, or Cu^{2+} atomic absorption standards (Fisher, 50-M-81, 50-C-193, and 50-C-194). The fluorescence excitation wavelength was 350 nm with emission measured at 445 nm. Rayleigh scattering measurements were made with both excitation and emission monochromators set at 500 nm. Scattering polarization experiments were done at 400 nm with a SLM Instruments model 8000/8000S spectrofluorometer with data aquisition system. No wavelength filters were used between the sample and detector.

Results and discussion

Titrating a solution of SFA with a paramagnetic metal ion causes its fluorescence to be quenched (5, 7). The degree of quenching is related to two factors; the quenching ability of the metal ion and the extent of complexation. Figure 1 shows the decrease in fluorescence intensity of 10 mg/L SFA in 0.1 *M* KNO_3 as Mn^{2+} is added at pH 5, 6, 7, and 8. At least duplicate titrations were conducted for each pH and the reproducibility is fairly good. A trend of increased fluorescence quenching with increasing pH is clearly evident. This same trend is demonstrated for Co^{2+} in Fig. 2. These results are directly comparable to our previous work with Cu^{2+} (5) done under identical conditions and analogous to initial studies with these systems (7).

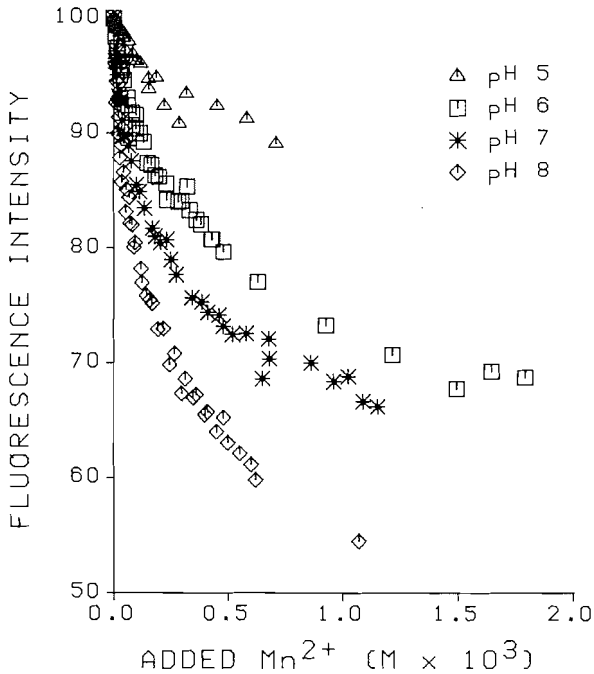

FIG. 1. Fluorescence quenching curves for 10 mg/L soil fulvic acid (SFA) with Mn^{2+} in 0.1 *M* KNO_3 at four pH values. Duplicate titrations are shown for pH 5 and 8, triplicates for pH 6 and 7.

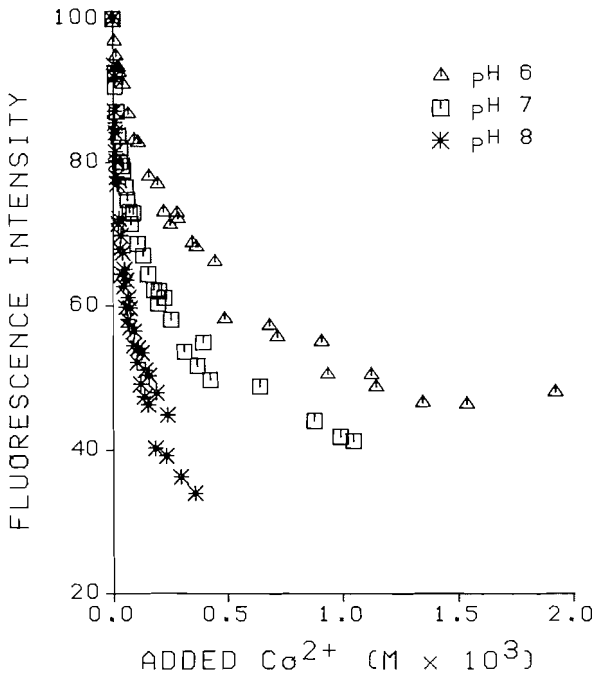

FIG. 2. Fluorescence quenching curves with Co^{2+} under the same conditions as in Fig. 1. Duplicate titrations are shown for pH 8, triplicates for pH 6 and 7.

We explain these data by noting that as pH increases conditional stability constants for weak acid ligands increase (13). At higher pH there is less competition from protons for potential metal ion binding sites. For a fixed ratio of total metal ion concentration (C_M) to total ligand concentration (C_L) the fraction of the ligand complexed will be greater at higher pH. The quenching ability of a given metal ion is assumed to be constant as pH is varied and the overall quenching effect is related to the extent of complexation. Changes in SFA fluorescence with pH

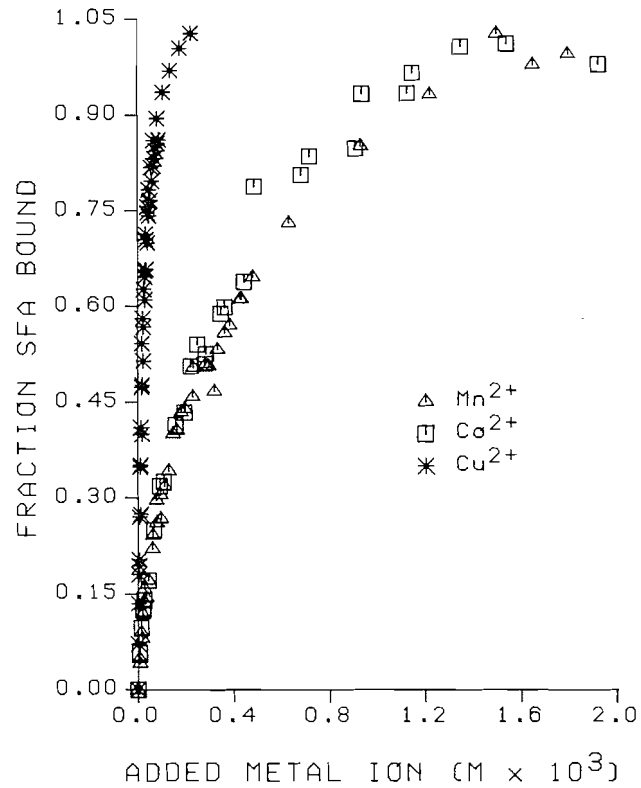

FIG. 3. Binding curves of total added metal ion concentration vs. fraction of soil fulvic acid bound ($[ML]/C_L$) for Mn^{2+}, Co^{2+}, and Cu^{2+} at pH 6. Results for Co^{2+} and Mn^{2+} and experimental conditions are the same as in Figs. 1 and 2. Dashed line indicates theoretical maximum where all SFA is bound.

in the absence of metal ion have been shown to be small in the pH range of these experiments (7). Therefore the trends observed in Figs. 1 and 2 show the effect of pH on the conditional stability constant.

We did not correct the data for metal ion hydrolysis. The general effect of hydrolysis is to reduce the amount of metal ion available to complex with SFA and quench its fluorescence. The fraction of the free metal ion hydrolyzed is constant at constant pH and is therefore easily accounted for. A more quantitative treatment has been given previously (6).

The relationship between the measured fluorescence intensity and complexation can be described mathematically by eq. [1].

$$[1] \quad [ML]/C_L = (I_L - I)/(I_L - I_{ML})$$

C_L is the total concentration of binding sites for the ligand, [ML] is the concentration of complex regardless of stoichiometry, and $[ML]/C_L$ is the fraction of ligand bound to the metal ion. The fluorescence intensity I is the measured value at any point in the titration and I_L and I_{ML} are the limiting intensities when all the ligand is free and bound, respectively. For convenience in making comparisons I_L is set to 100% in Figs. 1 and 2. The right side of eq. [1] describes fluorescence quenching as the ratio of the decrease in the initial fluorescence intensity observed at any point in the titration to the difference between the maximum and minimum values.

Equation [1] allows construction of binding curves (total added metal ion vs. fraction of SFA bound) from fluorescence titration data. Figures 3 (pH 6) and 4 (pH 7) show comparisons of this type for Mn^{2+}, Co^{2+}, and Cu^{2+}. Triplicate curves for

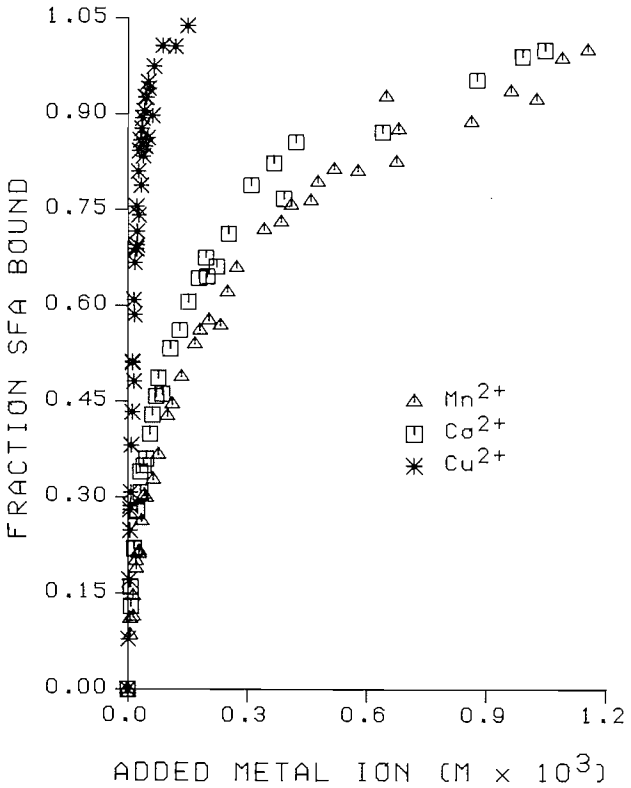

FIG. 4. Binding curve for pH 7, all other conditions are the same as in Fig. 3.

each metal ion are given at both pH values. Cu^{2+} binds very strongly at both pH's, and is at or near complete saturation of the ligand at about 1×10^{-4} *M* Cu^{2+} added. The curves for Mn^{2+} and Co^{2+} are quite similar to each other, but show much weaker binding than Cu^{2+}. In both Figs. 3 and 4 the curves for Mn^{2+} fall just below that for Co^{2+}, indicating that the conditional stability constant (K) for Mn^{2+}–SFA is slightly lower. Curve fitting analysis described previously (5, 6) substantiates this to some extent. Pooled replicate experiments at pH 6 gave conditional K values of 4.2×10^3 for Mn^{2+} and 5.1×10^3 for Co^{2+}. The C_L values were 1.5×10^{-6} *M* for both metal ions. These values compare with a K of 1.1×10^5 and C_L of 2.0×10^{-5} for Cu^{2+} at pH 6 (5). Experiments with Co^{2+} and Mn^{2+} at pH 7 did not converge on meaningful results for the constants; the fitted C_L values were negative. The most likely reason for this is that the pH 7 experiments were not carried far enough for curve fitting to be effective. From Fig. 4 it is evident that the Mn^{2+} and Co^{2+} curves do not quite level off at the end as they did for pH 6 (Fig. 3).

Various K values for complexation of these metal ions with different organic ligands also indicate that Cu^{2+} binds much more strongly than Co^{2+} and Mn^{2+}, whose binding strengths are similar. For example salicylic acid, a reasonable model ligand for fulvic acid, forms complexes of these metal ions with log K values of 5.9 for Mn^{2+}, 6.7 for Co^{2+}, and 10.6 for Cu^{2+} at 25°C and 0.1 *M* ionic strength (14). This trend is predominantly rationalized on the basis of "effective nuclear charge" (15). In addition Co^{2+} should have a slight advantage in binding strength over Mn^{2+} due to ligand field stabilization energy upon complex formation. The binding of Cu^{2+}, Co^{2+}, and Mn^{2+} to fulvic acid follows the relationships expected from inorganic considerations. In the large amount of literature on Cu^{2+} – fulvic acid complexation it is accepted that Cu^{2+} is among the strongest binding of the divalent cations (16). Co^{2+} and Mn^{2+} are generally considered to be much weaker than Cu^{2+} and often indistinguishable in binding strength.

To distinguish the type of binding of Mn^{2+} and Cu^{2+} to SFA Deczky and Langford (17) used nmr. Their results indicate that Mn^{2+} binds to SFA with its hydration shell intact. This outer sphere binding is opposite to the behavior of Cu^{2+} which loses its associated water molecules and shows inner sphere behavior. Although their work was done at pH 2 and 4, the interpretation can probably be extended to the higher pH values used in this study due to the very low hydrolysis constant of $10^{-10.5}$ for Mn^{2+} (18). Because of the outer sphere binding in Mn^{2+}–SFA, and by analogy in Co^{2+}–SFA, the attraction may be primarily electrostatic in nature, resulting in weaker binding.

The strength of metal ion – SFA binding can also affect the shapes of the relatively large molecules of SFA. Strong inner sphere complexation may cause conformational changes to make available binding sites that weaker outer sphere complexation of Mn^{2+} cannot induce. In the absence of metal ion the shapes of SFA molecules are probably mainly controlled by hydrogen bonding and electrostatic forces. In the pH 5 to 8 range of these studies the carboxyl groups are predominantly ionized and phenolic groups are partially ionized or essentially unionized. The repulsion between ionized carboxyls and possible hydrogen bonding between ionized carboxylate and unionized phenolic groups probably controls the shape of SFA molecules. A flat molecule may be folded over and held in a particular configuration in this way.

The same functional groups that determine conformation are also involved in binding metal ions. An ion such as Mn^{2+} that binds weakly is not effective at competing with protons for weakly acidic phenolic sites. It can therefore only bind to certain carboxyls. In addition many sites may be occluded in a microenvironment internal to a folded molecule of SFA. The strong binding of Cu^{2+}, however, can probably break up the majority of the existing hydrogen bonds by forming a very stable coordination complex with several sites. Bresnahan *et al.* (19) previously observed a large increase in Cu^{2+}–SFA binding between pH 5 and 6. The Cu^{2+} binding may alter the shape of the molecule and give it a new configuration. This new conformation is controlled by the Cu^{2+} ion and could consist of the molecule being fully or partially wrapped around one or more metal ion center. This type of conformational change may expose sites that were internal to the molecule, thus making them available for binding to additional Cu^{2+} ions. Mn^{2+} cannot induce the conformational changes so the internal sites remain unavailable, giving lower binding capacities for this metal ion.

The discussion of the type of binding of Mn^{2+} and Cu^{2+} to SFA may have implications for their fluorescence quenching ability. In the absence of conclusive structural and spectral information concerning the binding sites and fluorophors of fulvic acid it is impossible to determine the exact mechanism of quenching (20). However, any process will probably contribute to the quenching to a greater or lesser extent, depending on the distance of the metal ion center from the binding site. Mn^{2+} is insulated from the binding site by its hydration sphere. Thus it is probably farther from the fluorophore and may not perturb the orbitals of SFA to such a large degree. Therefore its quenching ability as well as its binding ability may be impaired. Co^{2+} may behave like Mn^{2+} as evidenced by similar binding ability.

TABLE 1. I_{ML} values at various pH values

	I_{ML}		
M^{2+}	pH 5	pH 6	pH 7
Mn^{2+}	—	68.6	66.2
Co^{2+}	—	46.9	41.2
Cu^{2+} [a]	40.2[b]	22.4	20.7

[a]Determined by curve fitting.
[b]Less reliable value (see ref. 5).

A direct comparison of the relative fluorescence quenching effects of Mn^{2+}, Co^{2+}, and Cu^{2+} on SFA can be made using I_{ML} values. Table 1 lists the experimentally determined values for Co^{2+} and Mn^{2+} from this work, and those determined from curve fitting for Cu^{2+} (5). These values represent the limit of quenching ability since they are the residual fluorescence, reported as percent of total, when $[ML]/C_L$ (eq. [1]) is unity. Some generalizations can be made from these data. Copper ion quenches to the greatest extent. For example, at pH 6 and 7 Cu^{2+} quenches nearly 80% of SFA fluorescence, Co^{2+} is less than half as effective, and Mn^{2+} is the poorest quencher by far. Cu^{2+} binds to many more sites than either Mn^{2+} or Co^{2+} and this is the reason for its greater quenching ability. However, these other ions are not capable of binding to the extent that Cu^{2+} does and therefore cannot quench as much. It is also evident from Table 1 that I_{ML} values decrease with increasing pH. The additional value for Cu^{2+} at pH 5 also supports this. The reason for the observed trend may be related to the variation of SFA fluorescence with pH (7). It must be noted that the values in Table 1 are reported as percentage of the maximum value at that pH. All fluorescence intensities in the absence of metal ion are normalized to 100% as discussed above.

Another marked difference was noted for Co^{2+} and Mn^{2+} compared with Cu^{2+} in titrations of SFA. Previous studies have shown that Cu^{2+} causes an increase in solution scattering and eventually effects the precipitation of fulvic acid (5, 12, 21) and natural water organic matter (6) while Co^{2+} and Mn^{2+} do not. In these titrations the maximum Co^{2+} and Mn^{2+} concentration attained was about five to ten times that of Cu^{2+}. We observed no scattering increase for Mn^{2+}, a relatively small increase for Co^{2+}, and a large increase for Cu^{2+}. Sholkovitz and Copeland (22) obtained similar results for the coagulation of river organic matter by Cu^{2+}, Co^{2+}, and Mn^{2+}. They found Co^{2+} gave no measurable precipitation and Mn^{2+} very little, while Cu^{2+} and Fe^{3+} were extremely effective. Their conclusion is that cation-induced coagulation is less for Mn^{2+} and Co^{2+} because of their weaker association to humic materials. In this study, since Co^{2+} and Mn^{2+} did not cause a great deal of scattering, it was possible to conduct the titrations well into the region where fluorescence leveled off. This allowed direct experimental determination of I_{ML} values which was not possible for Cu^{2+} (5).

We previously proposed (5, 23) that Cu^{2+} induces aggregation of SFA as well as precipitation. Figure 5 curve *A* is a Rayleigh scattering titration curve for 10 ppm SFA in 0.1 *M* KNO_3 with Cu^{2+} at pH 7. As Cu^{2+} is added, the number of precipitate particles formed increases and scattering increases. Of particular interest in Fig. 5 is the region of curve *A* near 1.5×10^{-4} *M* added Cu^{2+} where the slope decreases defining a break in the curve. Our previous work using centrifugation as well as scattering showed that precipitation did not cease in this region and we concluded that aggregation may be taking place

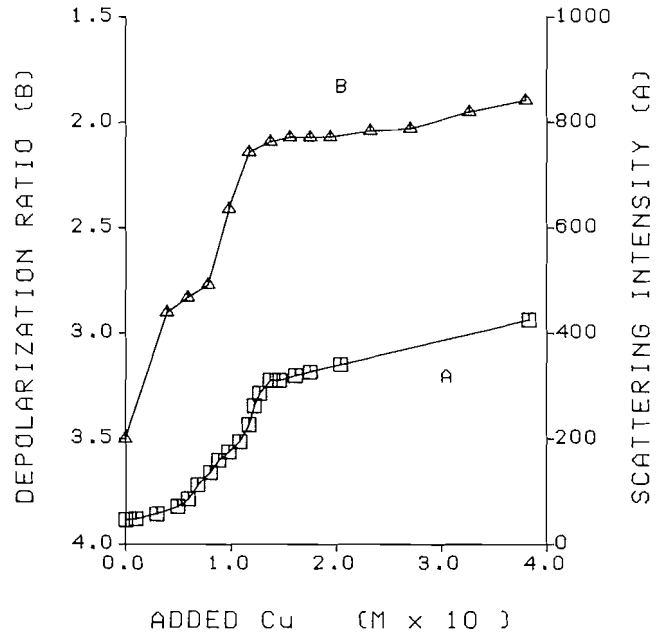

FIG. 5. Total added Cu^{2+} concentration vs. Rayleigh scattering intensity (arbitrary units) measured at 500 nm (curve A, right axis) and depolarization ratio ($I_\perp/I_\parallel$) measured at 400 nm (curve B, left axis) at pH 7. All other conditions are the same as in Figs. 1–4.

(5). The formation of large aggregates may explain why precipitation occurs with a simultaneous loss in sensitivity of scattering. The larger aggregates are less efficient at scattering light of a given wavelength than smaller particles (24). Thus, once aggregation becomes significant above 1.5×10^{-4} *M* Cu^{2+} the rate at which scattering increases is less.

To support this conclusion we conducted a scattering polarization experiment. Using a plane-polarized source, allowed measurement of the intensity of Rayleigh scattering for both parallel ($I_\parallel$) and perpendicular ($I_\perp$) components. The scattering polarization of a Cu^{2+}–SFA solution also changes as Cu^{2+} is added and binds to SFA. From Fig. 5 (curve *B*) it is evident that the depolarization ratio ($p = I_\perp/I_\parallel$) decreases rapidly at first and then seems to level off, decreasing slowly after that. This behavior is inversely related to the Rayleigh scattering in curve *A*.

The decrease in the depolarization ratio indicates that the scattering particles are becoming more isotropic (25). That is to say the initial Cu^{2+}–SFA particles formed are probably somewhat anisotropic (possibly pancake shaped (26)), but may become more isotropic due to aggregate formation. The aggregates may more closely approach a spherical shape giving rise to isotropic scattering and lower depolarization ratios. Although the evidence presented does not conclusively prove the proposed theory of aggregate formation, it is presented as a possible explanation. This phenomenon also explains why the Rayleigh scattering curve undergoes a "break" or drastic change in slope at the same total Cu^{2+} concentrations as the depolarization curve. The scattering intensity of unpolarized light measured at 90° may have some extra components of polarization due to anisotropy (25). As aggregates form and the scattering particles become more isotropic, the added component due to anisotropic scattering becomes less. Thus the scattering does not increase as rapidly once the polarization has leveled off. The effect of anisotropy on scattering can be written

For personal use only.

[2] $I_s = I_R + I_a$

where I_s is the measured scattering intensity, I_R the Rayleigh component, and I_a the anisotropic component. This effect may be rather large due to the size of p. An equation has been derived to calculate the additional scattering due to anisotropy (I_a) from polarization data (25). For SFA with no Cu^{2+} added this is 1.08. At the end of the titration it is 1.03. Thus corrections of scattering intensity for anisotropy may be important for SFA and have bearing on molecular weight calculated from light scattering (21).

Photoisomerization of gaseous tetramethylethylene in the far ultraviolet

GUY J. COLLIN[1] AND HÉLÈNE DESLAURIERS

Département des Sciences Fondamentales, Université du Québec à Chicoutimi, Chicoutimi (Qué.), Canada G7H 2B1

Received November 12, 1982

GUY J. COLLIN and HÉLÈNE DESLAURIERS. Can. J. Chem. **61**, 1510 (1983).

We have studied the gaseous photoisomerization of tetramethylethylene at 184.9 nm in the presence of various quenchers. The quantum yield of isomers is a function of the pressure, such that $[\Phi(\text{isomer})]^{-1} = a + b[P]^{-1}$. It is shown that the isomerization efficiency of a quencher M correlates with the intermolecular well depth between the photoexcited molecule A* and the quencher M, $\epsilon_{A^*,M}$. The log of the efficiency of isomerization is a linear function of this well depth.

Moreover, molecular oxygen, nitric oxide, and temperature have distinctive effects on the photoisomerization quantum yield measured at 213.8 nm: oxygen has a reverse effect, whereas nitric oxide induces a very strong isomerization.

GUY J. COLLIN et HÉLÈNE DESLAURIERS. Can. J. Chem. **61**, 1510 (1983).

La photoisomérisation du tétraméthyléthylène gazeux a été systématiquement étudiée à 184.9 nm en présence de plusieurs intercepteurs. L'inverse du rendement quantique des isomères croît linéairement avec l'inverse de la pression du stabilisant. Les efficacités du stabilisant semble corréler l'importance du puits de potentiel, $\epsilon_{A^*,M}$, entre la molécule excitée et la molécule ou l'atome stabilisant, de telle sorte que le log de l'efficacité de l'isomérisation est une fonction linéaire de ce puits de potentiel.

En outre l'oxygène moléculaire, l'oxyde nitrique et la température ont un effet très particulier sur la photoisomérisation à 213,8 nm: l'oxyde nitrique induit une très forte isomérisation tandis que l'oxygène a un effet contraire.

Introduction

In a recent paper, we reported the photolytic study of tetramethylethylene (TME) at 184.9 nm and in the region very close to the absorption threshold, i.e. at 213.8 and 228.8 nm. At low pressure, between 1 and 30 Torr, two families of products have been observed. In the first one, there are products such as 3-methyl-1,2-butadiene, 2,3-dimethyl-1,3-butadiene, 2-butyne, and isoprene. They are formed in the fragmentation processes of the photoexcited molecule; their quantum yield decreases with an increase in the pressure of the reaction chamber. Isomers are products of the second one: they are 2,3-dimethyl-1-butene (2,3-DM-1-B), 3,3-dimethyl-1-butene (3,3-DM-1-B), and 1,1,2-trimethylcyclopropane (1,1,2-TMCP). The quantum yield of these compounds increases with an increase in the total pressure (1).

In this report we intend to focus our attention on the isomerization processes in order to improve, if possible, the knowledge of the relationship between these processes and the nature of the available excited electronic states formed in the photoabsorption process.

Experimental

The experimental methods and details have already been described (1). Tetramethylethylene and cyclohexane are API products (impurity 0.08 ± 0.2 and 0.007 ± 0.004 mol%, respectively). All other additives are from Matheson of Canada. They have a purity stated as being more than 99.99%, except CH_3Cl (99.5%), n-C_4H_{10} (99.9%), and NO (99.0%). They are used as received. All these materials and the photolytic mixtures were analyzed by gas-chromatography using a squalane column and a double flame ionization detector (1).

In the temperature effect study at 213.8 nm, the reaction chamber was built with a double wall containing a water circulating system. Thus, the inside wall of the reaction chamber has the desired temperature, except for the quartz window, which is at room temperature. The shape and volume of the reaction chamber are similar to those of the already described photolytic cell (1).

Results

The results are shown in tables and graphs. They are presented as quantum yields. At this point, a correction to the previous quantum yields reported at 184.9 nm should be made. In the data processing, a factor of 2.0 was forgotten, so that all the previous quantum yields reported in ref. 1 must be divided by this factor.

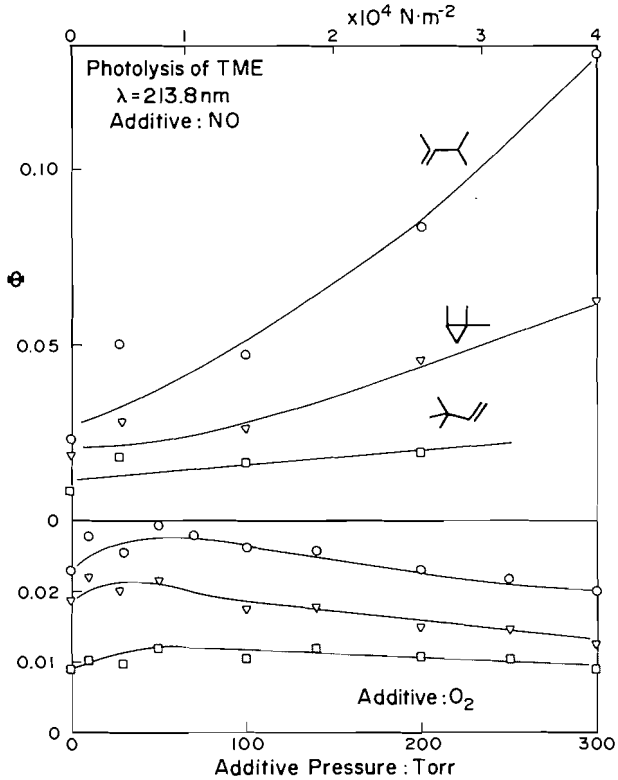

FIG. 2. Photolysis of TME (10 Torr) at 213.8 nm in the presence of either NO (upper part) or O_2 (lower part).

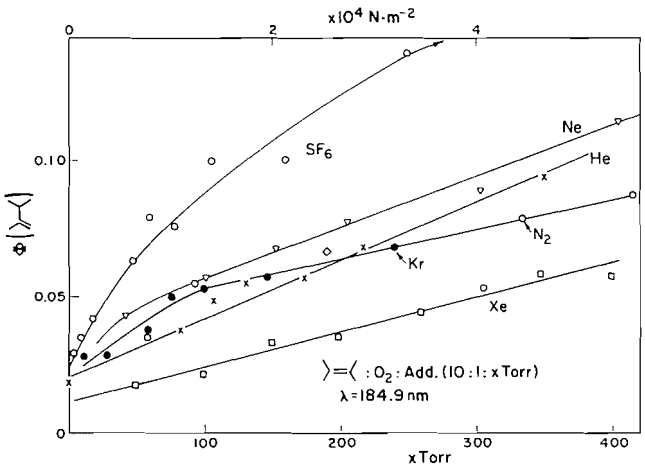

FIG. 3. Photolysis of TME:O_2:M (10:1:x Torr) mixtures at 184.9 nm: the quantum yield of 2,3-DM-1-B versus the pressure of quencher, x.

rather small effect on the 3,3-DM-1-B and 1,1,2-TMCP quantum yields and a more pronounced one on that of 2,3-DM-1-B: Table 1.

(*3*) The addition of NO results in a very strong increase of the isomer quantum yields: compare the effects of NO and SF_6 in Figs. 1 and 2.

(*4*) The addition of O_2 has a reverse effect on the isomer quantum yields: a small increase may be observed at low oxygen content ($P \leq 50$ Torr). At higher oxygen pressure, the three isomer quantum yields decrease: Fig. 2.

(b) At 184.9 nm

(*1*) Figures 3–5 show the general increase in the quantum

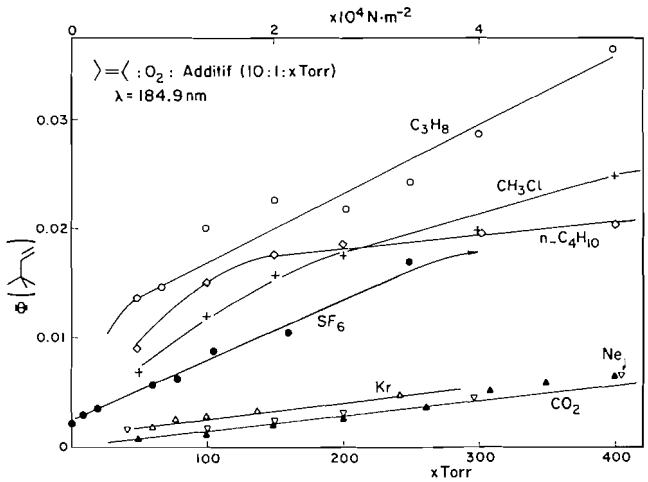

FIG. 4. Photolysis of TME:O_2:M (10:1:x Torr) mixtures at 184.9 nm: the quantum yield of 3,3-DM-1-B versus the pressure of quencher, x.

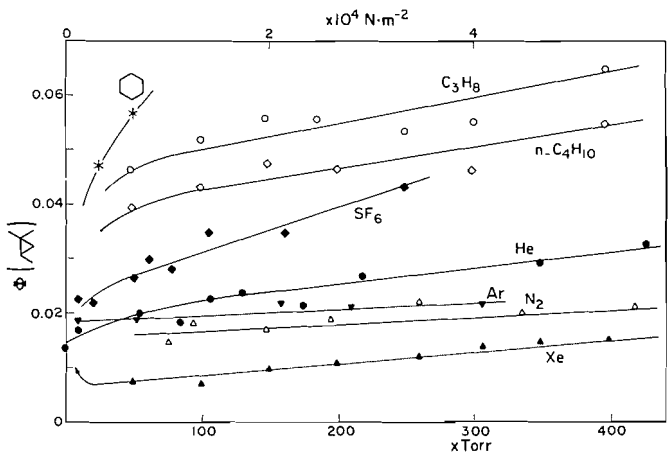

FIG. 5. Photolysis of TME:O_2:M (10:1:x Torr) mixtures at 184.9 nm: the quantum yield of 1,1,2-TMCP versus the pressure of quencher, x.

yield of each of the three isomers with an increase in the pressure of the chosen additive. At first glance, it can be stated that an increase in the pressure results in an increase of the isomerization. However, a comment must be made for the xenon and CO_2 cases. Although they follow the above stated rule, the addition of a few Torr of one of them decreases the isomer quantum yields. At high pressures, they are among the worst additive as far as efficiency in isomerization is concerned.

(*2*) The addition of 10 or 100 Torr of NO to 10 Torr of TME does not change the 1,1,2-TMCP quantum yield and multiplies by ca. 4.0 the 2,3-DM-1-B quantum yield: $\Phi_{NO}(1,1,2\text{-TMCP}) = 0.02$ and $\Phi_{NO}(2,3\text{-DM-1-B}) = 0.08_5$.

Discussion

(a) At 184.9 nm

In the previous paper from this laboratory, a mechanism was proposed in order to explain such an isomerization (1);

[1] TME + $h\nu \rightarrow$ TME* ($I\phi^*$)

[2] TME* $\rightarrow$ TME (+ $h\nu_0$ or I.C.)

[3] TME* + TME $\rightarrow$ 2 TME

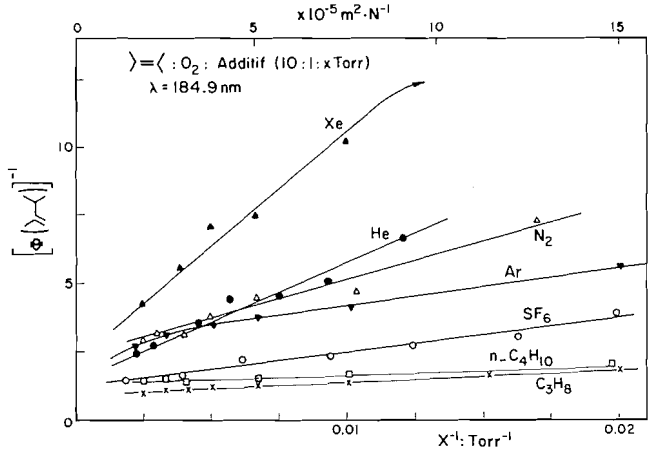

FIG. 6. The reverse of Φ(2,3-DM-1-B) versus the reverse of the additive pressure.

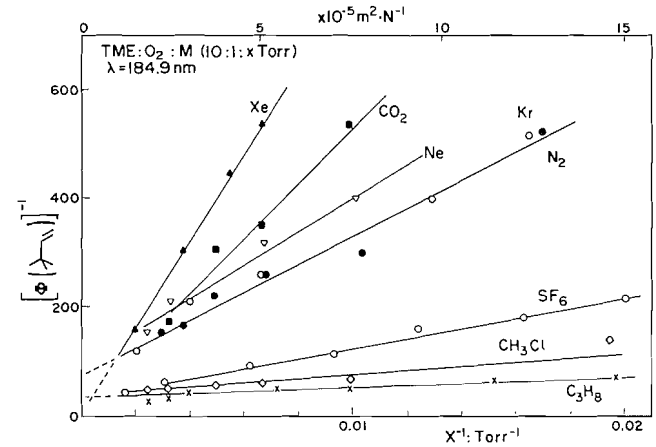

FIG. 7. The reverse of Φ(3,3-DM-1-B) versus the reverse of the additive pressure.

[4] $TME^* + TME \rightarrow P^* + TME$ (→ isomer P)

[5] $TME^* + M \rightarrow TME + M$

[6] $TME^* + M \rightarrow P^* + M$ (→ isomer P)

Process [2] contains very low fluorescence: $\Phi(h\nu_0) \simeq 2 \times 10^{-5}$ (2) and also fragmentation processes at low pressure following the internal conversion of the electronic energy of the photoexcited molecule. Processes [3] and [5] are deactivation processes brought about by physical collisions and processes [4] and [6] are of the induced preisomerization kind. A simple kinetic treatment of this mechanism leads to the following expression:

$$[A] \quad \frac{\phi^*}{\Phi(P)} = \frac{k_2 + [TME](k_3 + k_4) + [M](k_5 + k_6)}{k_4[TME] + k_6[M]}$$

Two interesting limiting cases are obvious. If [M] = 0, [A] becomes

$$[A'] \quad \frac{1}{\Phi(P)} = \frac{k_2}{k_4[TME]\phi^*} + \frac{k_3 + k_4}{k_4\phi^*}$$

and if [M] ≫ TME, it becomes

$$[A''] \quad \frac{1}{\Phi(P)} = \frac{k_2}{k_6[M]\phi^*} + \frac{k_5 + k_6}{k_6\phi^*}$$

Thus, in both cases, the inverse of the isomer quantum yields is a linear function of the inverse of the pressure either of TME (1) or M. Figures 6 and 7 are examples of this behavior. Table 2 gives a systematic report for expressions [A'] or [A'']. It includes all data measured at M pressure above 100 Torr: [M] ≥ 10[TME]: and $[\Phi(\text{isomer})]^{-1} = a + b[M]^{-1}$. The a value, taken at $[M]^{-1} = 0$, is the inverse of the quantum yield of the pertinent isomer formed in the presence of a very high amount of the additive M. Table 3 shows these quantum yields at "infinite" pressure. Thus additives are more or less efficient as far as isomerization is concerned. The rare monoatomic gasses are among the least efficient. On the other hand, CH_3Cl and propane are very good.

At this "infinite" pressure all processes included in process [2] may be ignored in a first approximation: $\phi^* = 1.0$. In any case, fluorescence has a very low quantum yield and the fragmentation processes are negligible at 100 Torr and higher pressures. Thus, in the presence of TME alone, the total efficiency for isomerization is 0.29, and the deactivation process [3] accounts for 71% of the TME* + TME colliding process. It can likewise be assumed that the ratio $k_3/(k_3 + k_4)$ for propane is 0.33_8 and, of course, $k_4/(k_3 + k_4)$ is 0.66_2 or less. Thus, one third of the TME* + C_3H_8 efficient collisions lead to isomerization.

At this point, it is relevant to come back to the expression [A'']. By using helium as a reference, the following expression may be deduced.

$$[B] \quad \frac{b(He)}{b(M)} = \frac{k_2}{\phi^* k_{6,He}} \times \frac{\phi^* k_{6,M}}{k_2}$$

or

$$\frac{b(He)}{b(M)} = \frac{k_{6,M}}{k_{6,He}}$$

where b(He) and b(M) are the slope of the plot $[\Phi(\text{isomer})]^{-1}$ versus $[M]^{-1}$ (Table 2), and $k_{6,M}$ and $k_{6,He}$ are the second order rate constants for the M or He induced preisomerization processes. By correcting each k value by the square of the collision diameter and by the reduced mass of the colliding partners, such that

$$k_{x,y} = A_{x,y}(\sigma_x + \sigma_y)^2 \mu_{x,y}^{-1/2}$$

one may calculate the $A_{6,M}/A_{6,He}$ ratios (Table 4). The same kind of calculations may be done with the zero intercepts, ($[M]^{-1} = 0$) of the same plots.

$$[C] \quad \frac{a(He)}{a(M)} = \frac{k_{5,He} + k_{6,He}}{\phi^* k_{6,He}} \times \frac{k_{6,M}\phi^*}{k_{5,M} + k_{6,M}}$$

or

$$\frac{a(M)}{a(He)} \times \frac{A_{6,M}}{A_{6,He}} = \frac{A_{5,M} + A_{6,M}}{A_{5,He} + A_{6,He}}$$

The results are shown in Table 5. Thus, both Tables 4 and 5 indicate the relative efficiencies of processes [5] and processes [5] + [6] for each quencher and isomer. Lin *et al.* (3) have developed a relationship "to correlate the rate constants k_M or cross-sections σ_M for a series of added gasses M which collisionally induce a state formation A* → B" (3). The relation is

$$[D] \quad \ln k_M = \ln C + \beta(\epsilon_{MM}/k)^{1/2}$$

where C and β are constants and ϵ_{MM} is the well depth between pairs of M molecules. Figures 8 and 9 are the plots of ln $A_{6,M}$ and ln $(A_{5,M} + A_{6,M})$ versus $(\epsilon_{MM}/k)^{1/2}$ and show such correlations. In Fig. 8, the three lines represent the best sets of data points ($r^2 = 0.93$). In the 2,3-DM-1-B case, the Ne, Xe, C_3H_8, and n-C_4H_{10} data have not been included. It is obvious that neon gives a very high efficiency; the same seems also true for the two alkanes, whereas Xe has very low efficiency. In the 3,3-DM-1-B and 1,1,2-TMCP cases, the same set of data has been included in the linear regressions. Again, Ne and Xe have been ignored as well as CO_2 and Ar, but now propane and n-butane are included. Figure 9 shows a much less obvious interpretation. The 3,3-DM-1-B line gives a good correlation coefficient provided that the Ne, CH_3Cl, Xe, and CO_2 cases are discarded. The 2,3-BM-1-B case gives two possible answers: either the He and CH_3Cl points or the C_3H_8 and n-C_4H_{10} points are included ($r^2 = 0.90$); Ne, Ar, and Xe are obviously discarded. Finally, the 1,1,2-TMCP coefficient of determination is poor: $r^2 = 0.88$. At this point, it should be recalled that the (ϵ_{MM}/k) values may be derived through several methods giving rise to various results. Thus, uncertainties are associated with these values (3, 4). However, it is obvious that CO_2 and Xe have very low efficiency. As noted by Lin *et al.*, there are several exceptions and many quenchers present a large deviation from the correlation. For example, Ne was noted as a "special case", and the "heavy atom effect of Xe" is well known (3). From the ratio given in Fig. 9, it appears that if xenon reacts with TME* at a rate higher or much higher than does helium, it gives rise to products different from those formed in the processes [5] and [6]. Resonance specific to some M partners may be present, and their data do not fit in with the above correlations. This may be the case for TME itself, where the agreement is not good (Fig. 9). However, it is beyond the scope of this paper to speculate deeply on these exceptions.

(b) At 213.8 nm

As has been said above the isomerization quantum yields are lower at this wavelength compared to what they are at 184.9 nm. In order to avoid absorption of light by O_2 at 184.9 nm, the effect of this quencher was made at 213.8 nm. Although there is a small increase of the isomer quantum yields at low pressure, these quantum yields decrease smoothly with high oxygen content: the pressure effect is the reverse. Thus, oxygen does not promote the isomerization; it reacts slowly with the photoexcited molecule; when it does so, isomers are not among the products. The effect of molecular oxygen in a photochemical system is rather complex (5). Some electronic S_1-T mixings may be present in this system.

On the other hand, the nitric oxide effect is rather important. Although the well depth for SF_6 is greater than the NO one by a factor of 1.33 (3), NO has a much higher efficiency as far as isomerization is concerned. Again, the effect of nitric oxide in a photochemical system may be complex (6), and possible

intersystem crossing channels are open in the presence of NO.

In a recent study of the trimethylamine photolysis, Obi *et al.* observed that O_2 and NO quenched quite efficiently the fluorescence of trimethylamine (7). They suggested that the quenching effect of O_2 may be attributed to a charge transfer process occurring from the photoexcited molecule. In the present case, the process would be

[7] $\quad TME + O_2 \rightarrow [TME^+ \ldots O_2^-]^*$

Obviously, the NO quenching process and the O_2 one do not produce the same products.

At this wavelength the pressure of the additive was insufficient to be very far from the "infinite" limit. At this point, it is worthwhile to recall the relative yield of isomers measured in the neat liquid TME (8). Although in this report there was no indication of the incident wavelength used, it is likely that a continuum photolyzed the liquid sample from the cut-off of the quartz cell to the absorption threshold of TME. With these conditions, Kropp *et al.* found similar quantities of 2,3-DM-1-B and 3,3-DM-1-B and smaller quantities of TMCP (Table 6). These observations seem to suggest a strong wavelength dependence of the products as it was noted in the gas phase (1): Table 6. Moreover, it is interesting to note that the temperature effect was more pronounced on the 2,3-DM-I-B quantum yield than the one observed with the two other isomers.

Finally, it is worthwhile to recall some interesting observations made at 184.9 nm (Table 6). The 2,3-DM-1-B quantum yield is proportional to the total pressure: $\Phi(2,3\text{-DM-1-B}) = \alpha P$. The 3,3-DM-1-B and 1,1,2-TMCP quantum yields are such that $\Phi(x) = \delta + \lambda P$. Moreover, the ratio $\Phi(1,1,2\text{-TMCP})/\Phi(3,3\text{-DM-I-B})$ is closed to 4. Thus these last two products may be formed from the same intermediate, which is different from the one involved in the 2,3-DM-1-B

The phenyl selenolates of tin(II), lead(II), arsenic(III), antimony(III), and bismuth(III), $M(SePh)_n$ (M = Sn(II) or Pb(II), $n = 2$; M = As(III), Sb(III), or Bi(III), $n = 3$), have been synthesized by acid–base reaction of the appropriate metal acetate (for M = Sn(II) or Pb(II)) or thiophenolate (for all five elements) with PhSeH, and characterized by elemental analysis and, for the Group V elements, ^{77}Se and ^{13}C nmr spectroscopy.

$M(SPh)_2$ and $M(SePh)_2$ (M = Sn(II) or Pb(II)) are poorly soluble in MeOH but dissolve in the presence of an equimolar or greater amount of PhS^- or $PhSe^-$. The soluble stannate(II) complexes are triligated as shown by the slow exchange ^{119}Sn and, where appropriate, ^{77}Se nmr spectra of the series $[Sn(SPh)_x(SePh)_{3-x}]^-$ ($x = 0-3$) measured for the supernatant liquor of mixtures in which $\{Sn(EPh)_2\}_{total}/PhE^-_{total} > 1$. The corresponding plumbate(II) complexes are probably triligated also, but are labile on the nmr timescale; the parent complexes $Pb(EPh)_3^-$ have been characterized in solution by ^{207}Pb and ^{13}C (E = S and Se) and ^{77}Se (E = Se) nmr spectroscopy. For both Pb(II) and Sn(II), the order of chemical shifts in the metal nmr spectra is $\delta(MSe_3) > \delta(MS_3)$. The metal nmr spectra of the mixtures $M(SePh)_2:PhSe^-:PhS^- \approx 1:2:4$ (M = Sn(II) or Pb(II)) show that the coordination of $PhSe^-$ occurs in preference to coordination of PhS^- for both tin(II) and lead(II).

Thiolatoplumbates(II) might be formed during some antidotal treatments for lead poisoning, so "fingerprint" ^{207}Pb nmr spectra have been measured for a range of model soluble species formed in $Pb(SR)_2$–(excess)RS^- mixtures in MeOH, including some mixtures containing newly synthesized and characterized lead thiolates derived from dithiolate anions. For RS^- = MeS^-, EtS^-, PhS^-, $C_6H_{11}S^-$ (for which "$Pb(SR)_2$" has been shown to be $Pb(SC_6H_{11})(OAc)$), $^-S(CH_2)_2S^-/2$, $^-SCH_2CHS^-Me/2$, and $^-SCH_2CHS^-CH_2OH^2$, δ_{Pb} (from $PbMe_4$ in toluene as reference) falls in the comparatively short range 2518–2999 ppm.

The redistribution of ligands between $M(SPh)_3$ and $M(SePh)_3$ in chloroform to give equilibrium mixtures of $M(SPh)_x(SePh)_{3-x}$ occurs slowly on the preparative timescale for M = As, rapidly on the preparative timescale but slowly on the ^{13}C and ^{77}Se nmr timescales for M = Sb, and rapidly on the ^{13}C and ^{77}Se nmr timescales for M = Bi. Thus ^{13}C and, where appropriate, ^{77}Se nmr data are reported for $M(SPh)_x(SePh)_{3-x}$ (M = As or Sb) and $Bi(EPh)_3$ (E = S or Se). In addition, it has been possible, using ^{13}C nmr assessment of species distribution in the systems $Sb(SPh)_3$–$As(SePh)_3$ and $Bi(SPh)_3$–$As(SePh)_3$, to deduce that for the trivalent Group V elements the order of preference for $PhSe^-$ over PhS^- as ligands is Bi > Sb > As.

Trends in the ^{13}C nmr data for $M(SPh)_x(SePh)_{3-x}$ (M = As or Sb) and ^{77}Se nmr data for a range of metal complexes of $PhSe^-$ have been discussed. The selenium chemical shifts are influenced primarily by the acceptor atom and are in the order Cd(II) < Zn(II) < Pb(II) < Sn(II) < As(III) < Bi(III) < Sb(III).

J. J. Ivan Arsenault et Philip A. W. Dean. Can. J. Chem. **61**, 1516 (1983).

On a synthétisé les sélénolates de phénylétain(II), arsenic(III), antimoine(III) et bismuth(III), $M(SePh)_n$ (M = Sn(II) ou Pb(II), $n = 2$; M = As(III), Sb(III) ou Bi(III), $n = 3$) en utilisant une réaction acide–base de l'acétate métallique approprié (pour M = Sn(II) ou Pb(II) ou du thiophénolate (de tous les 5 éléments) avec le PhSeH et on les a caractérisés par l'analyse élémentaire et, dans le cas des éléments du groupe V, par le spectroscopie de rmn du ^{77}Se et du ^{13}C.

Le $M(SPh)_2$ et le $M(SePh)_2$ (M = Sn(II) ou Pb(II) sont faiblement solubles dans le MeOH mais ils se disolvent en présence d'une quantité équimolaire ou plus de PhS^- ou de $PhSe^-$. Les complexes de stannate(II) solubles sont tricoordonnés comme le montrent les spectres rmn d'échange lent du ^{119}Sn et lorsque le cas se présente, ceux du ^{77}Se des séries $[Sn(SPh)_x(SePh)_{3-x}]^-$ ($x = 0-3$), des mélanges de liqueur surnageante dans lesquelles le rapport $[Sn(EPh)_2]_{total}/PhE^-_{total} > 1$. Les complexes correspondants de plumbate(II) sont probablement tricoordonnés également, mais ils sont labiles dans l'échelle de temps de la rmn. On a caractérisé les complexes apparentés de $Ph(EPh)_3^-$ en solution par la spectroscopie de rmn du ^{207}Pb et du ^{13}C (E = S et Se) et du ^{77}Se (E = Se). L'ordre de grandeur des déplacements chimiques dans les spectres rmn du métal est de: $\delta(MSe_3) > \delta(MS_3)$ pour le Pb(II) et le Sn(II). Les spectres de rmn du métal des mélanges de $M(SePh)_2:PhSe^-:PhS^-$ 1:2:4 (M = Sn(II) ou Pb(II)) montrent que la coordination du $PhSe^-$ est privilégiée par rapport à celle du PhS^- dans le cas de l'étain(II) et du plomb(II).

Les thiolatoplombates(II) peuvent se former lorsqu'on utilise certains antidotes contre l'empoisonnement par le plomb. Ainsi on mesure les spectres de rmn du ^{207}Pb "empreintes digitales" d'un certain nombre d'espèces solubles modèles formées dans les mélanges de $Pb(SR)_2$–RS(excès) dans le méthanol incluant quelques mélanges contenant les nouveaux thiolates de plomb, dérivés des anions dithiolates, que l'on a synthétisés et caractérisés. Dans le cas où RS^- = MeS^-, EtS^-, PhS^-, $C_6H_{11}S^-$ (pour lesquels on a montré que le "$Pb(SR)_2$" est du $Pb(SC_6H_{11})(AcO)$), $^-S(CH_2)_2S^-/2$, $^-SCH_2CHS^-Me/2$ et $^-SCH_2CHS^-CH_2OH^2$, le δ_{Pb} (à partir du $PbMe_4$ dans le toluène comme référence) tombe dans l'intervalle comparativement courte de 2518–2999 ppm.

La redistribution des ligands entre $M(SPh)_3$ et $M(SePh)_3$ dans le chloroforme pour donner des mélanges à l'équilibre de $M(SPh)_x(SePh)_{3-x}$ se fait lentement à l'échelle préparative pour M = As, rapidement à l'échelle préparative mais lentement dans les échelles de temps de la rmn du ^{13}C et du ^{77}Se pour M = Sb, et rapidement dans l'échelle de temps de la rmn du ^{13}C

et du Se pour M = Br. Ainsi on rapporte les données de la rmn du ^{13}C et de la rmn du ^{77}Se, lorsque le cas se présente, relatives au complexe $M(SPh)_x(SePh)_{3-x}$ (M = As ou Sb) et $Bi(EPh)_3$ (E = S ou Se). De plus en utilisant les estimations, en rmn du ^{13}C, de la distribution des espèces dans les systèmes $Sb(SPh)_3-As(SePh)_3$ et $Bi(SPh)_3-As(SePh)_3$, il est possible de conclure que dans le cas des éléments trivalents du groupe V l'ordre de préférence pour $PhSe^-$ par rapport à PhS^- comme ligands est Bi > Sb > As.

On discute des tendances des données de la rmn du ^{13}C relatives au $M(SPh)_x(SePh)_{3-x}$ (M = As ou Sb et des données de la rmn du ^{77}Se se rapportant à un certain nombre de complexes métalliques du $PhSe^-$. Les déplacements chimiques du sélénium sont influencés en premier lieu par l'atome accepteur et sont dans l'ordre: Cd(II) < Zn(II) < Pb(II) < Sn(II) < As(III) < Bi(III) < Sb(III).

[Traduit par le journal]

Introduction

Recent publications from this laboratory have reported multinuclear nmr data for thiolato- and selenolato-zincates, -cadmates, and -mercurates(II) (1, 2). In addition, combined ^{113}Cd and ^{31}P nmr spectroscopic scrutiny of cadmium complexes of phosphine oxides, sulfides, and selenides (3–5) has shown these to be useful models for the ^{113}Cd nmr chemical shifts of the CdE_4 (E = O, S, or Se) kernels, among others. More lately, a ^{31}P and metal nmr investigation has been made of complexes of tin(II) and lead(II) with $EP(chx)_3$[2] (E = O, S, or Se), or mixtures of the sulfide and selenide, as ligands, and ^{119}Sn and ^{207}Pb chemical shift data (as appropriate) measured for the MO_3, MS_3, MSe_3, and MS_xSe_{3-x} (M = ^{119}Sn or ^{207}Pb) kernels (6). The last-mentioned results were intended to provide a basis for the metal nmr component of the multinuclear nmr study of thiolato- and selenolato-stannates(II) and -plumbates(II), which we now describe. As our work on the tin(II) and lead(II) species progressed, it became evident that a knowledge of the chemical and ^{77}Se and ^{13}C nmr spectroscopic behaviour of $M(SPh)_3$, $M(SePh)_3$ and, if possible, $M(SPh)_x(SePh)_{3-x}$ (M = As, Sb, or Bi), would be a useful complement, and details of our study of these species are provided here too.

Lead(II) thiolates, $Pb(SR)_2$, generally of poor solubility, have been extensively investigated (e.g. refs. 7–10), and in recent years their tin(II) analogs, which have similar solubility properties, have been a subject of interest also (e.g. refs. 9–12). We could find no previous mention of dissolution of these thiolates in the presence of excess thiolate ion or of characterization of the soluble species so formed.

The phenylthiolates of trivalent arsenic, antimony, and bismuth are known compounds (e.g. refs. 7, 9, 13, 14). In contrast the phenylselenolates of these elements have received little attention; as part of a brief study of $As(SePh)_3$ (prepared from $AsCl_3$ and $Me_3SiSePh$), ^1H nmr and low frequency infrared and Raman data but not analytical data were presented (15), and attempts to prepare $M(SePh)_3$ (M = As or Sb) from MCl_3 and NaSePh yielded only PhSeSePh (13). The arsenic–selenium bond is of particular interest because arsenic and selenium compounds may interact *in vivo* (e.g. refs. 16–19).

A vicinal dithiol, sodium 2,3-dimercaptopropane-1-sulfonate (DMPS), is now being used as a therapeutic chelator in cases of lead poisoning (20), and it seems possible soluble thiolatoplumbates might be formed during treatment. Therefore we have looked at a wider range of thiolate complexes in the case of lead(II) than in the cases of the other elements, for which only phenylthiolate has been used as a model thiolate ligand.

[2]Abbreviations used: chx = cyclohexyl (C_6H_{11}); BAL = $HSCH_2CH(SH)CH_2OH$; DMPS = $HSCH_2CH(SH)CH_2SO_3^-Na^+$.

Experimental

Materials

Reagent grade arsenic trichloride and lead methanethiolate and certified grade antimony trichloride, bismuth(III) and tin(II) oxides, and lead acetate, all from Fisher Scientific Co. Ltd., were used as received.

Proton nmr revealed no significant impurities in ethanethiol, cyclohexylthiol, ethanedithiol, 1,3-propanedithiol, 2,3-dimercapto-1-propanol (BAL), sodium 2,3-dimercapto-1-propanesulfonate (DMPS), bis(2-mercaptoethyl) ether or sulfide (all from Aldrich Chemical Co.), 1-mercapto-2-propanol (from K & K), 2-mercaptoethanol (from Eastman Kodak Co.), 1,2-propanedithiol, 1,2- or 1,4-butanedithiol or 1,5-pentanedithiol (all from Chemical Procurement Labs. Inc.), while ^{13}C nmr showed phenylthiol (Eastman Kodak Co.) and phenylselenol (Strem Chemicals, Inc.) to be satisfactorily pure; all these compounds were used without further purification.

The literature routes to bismuth(III) acetate (21), tin(II) acetate (22), $Pb(SPh)_2$ and $Pb(SEt)_2$ (8), $Bi(SPh)_3$ (9), and $As(SPh)_3$ and $Sb(SPh)_3$ (13) were used, except that $Sb(SPh)_3$ was prepared in ethanol, not benzene.

General manipulative procedure

All preparations and other manipulations involving thiols or phenylselenol or their anions were carried out using deoxygenated solvents under nitrogen or argon. All solid products were dried under vacuum. Solids known or suspected to be air-sensitive ($Sn(OAc)_2$, $Sn(SPh)_2$, and the Group IV and V phenylselenolates) were stored and weighed in a nitrogen-filled glovebox.

Preparation of lead(II) thiolates

Shaw and Woods (8) reported the synthesis of a range of compounds $Pb(SR)_2$ from simple monothiolates by addition of a stoichiometric amount of the thiol in ethanol to a solution of lead(II) acetate in aqueous ethanol. No dithiols were studied in this earlier work. We have investigated the applicability of the method of Shaw and Woods as a route to 1:1 compounds of Pb(II) with a variety of dithiolates, and have prepared in pure form[3] the compounds containing the dithiolates of ethanedithiol, propane-1,2- and -1,3-dithiols, butane-1,2- and -1,4-dithiols, pentane-1,5-dithiol, BAL, DMPS, and bis(2-mercaptoethyl) ether and sulfide, by combination of stoichiometric amounts of the dithiol in ethanol (or aqueous ethanol for DMPS) and lead acetate in aqueous ethanol at approximately 65°C. (The exact stoichiometry does not seem to be critical: 1:1, 2:1, and 1:2 mixtures of $Pb(OAc)_2$ and $HS(CH_2)_2SH$ all yielded the 1:1 product.) For comparison with the BAL complex, the compounds $Pb(SR)_2$ derived from 2-mercaptoethanol and 1-mercapto-2-propanol have also been made. Earlier, the 1:1 compound of lead(II) and the 2,3-dimercapto-1-propanesulfonate trianion has been synthesized from PbO and the parent acid of DMPS in water (25). Also, a compound $(\overline{S.Pb.S.CH_2.CHCH_2SO_3})_2Pb$ is said to be formed from $Pb(OAc)_2$ and DMPS (26).

In the earlier work (8), $Pb(OAc)_2$ and chxSH gave a product that could not be obtained analytically pure but which contained only about

[3]Several lead dithiolates have been prepared for use as synthetic intermediates in a route to cyclic disulfides (23, 24), but no evidence of purity was reported.

half of the theoretical amount of sulfur. We find this compound to be Pb(Schx)(OAc).

Our results demonstrate that the method of Shaw and Woods (8) is of wide applicability. Analytical data for new lead thiolates, and those which have not been obtained previously from $Pb(OAc)_2$, are given in Table 1.

Preparation of $Sn(SPh)_2$ from $Sn(OAc)_2$

$Sn(SPh)_2$ was made from $Sn(OAc)_2$ and PhSH in essentially the same manner used for $Pb(SPh)_2$ (8): the stoichiometric amount of PhSH in ethanol was added to a well-stirred slurry of $Sn(OAc)_2$ in aqueous ethanol at 50°C, forming pale yellow insoluble $Sn(SPh)_2$. (Higher temperatures caused decomposition of the $Sn(OAc)_2$.) *Anal.* calcd. for $C_{12}H_{10}S_2Sn$: C 42.78, H 2.99; found: C 42.96, H 2.86.

As noted above, $Sn(SPh)_2$ has been prepared previously by a variety of routes (9–12) but not, apparently, by the one used here.

Preparation of $Sn(SePh)_2$ and $Pb(SePh)_2$

In a straightforward extension of the method used to prepare the phenylthiolates (ref. 8 and see above), the phenylselenolates formed when the stoichiometric amount of PhSeH in ethanol was added to a well stirred slurry of the appropriate metal(II) acetate in aqueous ethanol at room temperature. In both cases, stirring was continued for ca. 30 min before filtering off the product, which was yellow for tin(II) and orange for lead(II). Analytical data for the new compounds are given in Table 2.

These compounds could also be prepared by addition of a stoichiometric amount of PhSeH to a stirred slurry of the appropriate $M(SPh)_2$ at room temperature. The colours of the (insoluble) phenylselenolates are immediately apparent. If a slight excess of $M(SPh)_2$ is used, the supernatant liquor after 30 min stirring shows only PhSH by ^{13}C nmr, demonstrating the completeness of the selenol–thiol exchange.

Preparation of $As(SePh)_3$, $Sb(SePh)_3$, and $Bi(SePh)_3$

Preliminary ^{13}C nmr experiments showed that $M(SPh)_3$ (M = As, Sb, or Bi) in $CDCl_3$ underwent complete selenol–thiol exchange with PhSeH at a rate that was fast on the preparative timescale for Sb and Bi but slow for As. The synthesis of the metal(III) phenylselenolates took advantage of this behaviour. To a solution ($As(SPh)_3$) or slurry ($Sb(SPh)_3$ and $Bi(SPh)_3$) of the metal(III) phenylthiolate (5 mmol) in $CHCl_3$ at room temperature, PhSeH (slight excess over 15 mmol) was added. This addition resulted in a colour change (colourless to yellow) in the case of As(III), and a colour change (pale yellow to bright yellow for Sb(III); orange to deep red for Bi(III)) and solubilization for the other two elements. After stirring for an appropriate time (ca. 1 h for Bi or Sb; ca. 12 h for As) the solvent was removed *in vacuo*. The solids which remained were triturated with several aliquots of degassed methanol to remove possible contaminants (PhSH, PhSeH, or PhSeSePh), and finally dried *in vacuo*, to yield pale and bright yellow powders for $As(SePh)_3$ and $Sb(SePh)_3$, respectively, and dark red needles for $Bi(SePh)_3$. Analytical data for the new compounds are given in Table 2.

Nuclear magnetic resonance sample preparation

Solutions of $PhSe^-$ or PhS^- or other thiolates in methanol or CD_3OD were produced by stoichiometric acid–base reaction with $CH_3O^-Na^+$ or $CD_3O^-Na^+$, itself formed *in situ* from metallic sodium.

$M(SPh)_2$–$M(SePh)_2$–(PhS^- or $PhSe^-$) and $M(SPh)_2$–PhSeH mix-

tures for M = Sn or Pb were shaken or stirred for several minutes at room temperature, and then filtered into the nmr tube through a 10 mm fine sinter if necessary (as it was, for instance, in cases where excess $M(SPh)_2$ or $M(SePh)_2$ was used). The stoichiometry was chosen to ensure that in solution $[M]_{total} \approx 0.25$ *M*. Solutions were prepared from other $Pb(SR)_2-RS^-$ mixtures in the same manner.

$M(SPh)_3-PhSeH$ (M = As, Sb, or Bi), $M(SPh)_3-M(SePh)_3$ (M = As, Sb, or Bi), and $M(SPh)_3-M'(SePh)_3$ (M = Sb, M′ = As; M = Bi, M′ = As or Sb) mixtures, and samples of $M(SPh)_3$ and $M(SePh)_3$ alone, in $CHCl_3$ or $CDCl_3$, were made up from appropriate masses (volume for PhSeH) of the components, and filtered into the nmr tube through a 10 F sinter if necessary. Normally $[M]_{total}$ was kept at 0.25 *M*. However, a saturated solution of relatively poorly soluble $Bi(SPh)_3$ was used. Thorough flushing of nmr tubes, sinters, pipettes, etc. with N_2 or argon was *essential* for the preparation of stable solutions containing the phenylselenolates.

Nuclear magnetic resonance spectra were measured on freshly prepared samples if possible; if this was not possible, the samples were flame-sealed and stored in liquid nitrogen until the spectra could be obtained.

Nuclear magnetic resonance samples to be used for metal and ^{77}Se nmr studies of the stannous and plumbous complexes on the WH-400 were made up in flame-sealed 9 mm od hand made nmr tubes that were a sliding fit in standard 10 mm nmr tubes. For ^{77}Se nmr studies of $M(SePh)_3$ and $M(SePh)_3-M(SPh)_3$ mixtures on the WH-400, samples were kept in capped argon-filled standard 10 mm nmr tubes; similarly, samples for ^{13}C nmr scrutiny using the XL-200 were kept in capped, argon-filled standard 5 mm nmr tubes. Flame-sealed hand made 10 mm od nmr tubes were used to hold samples for preliminary ^{13}C and ^{207}Pb nmr study on the XL-100.

Nuclear magnetic resonance spectra

Preliminary ^{13}C and ^{207}Pb nmr spectra (with and without proton decoupling, respectively) were measured on spinning samples using a Varian XL-100-12 spectrometer system operating at 25.2 and 20.9 MHz, respectively. The 10 mm od sample tubes were held coaxially in a standard 12 mm od tube, and D_2O (at 308 K) or, for variable temperature, $(CD_3)_2CO$, in the outer annulus provided a ^2D lock, as described previously (e.g. ref. 1). The ^{207}Pb nmr spectra were referenced by sample interchange with 1.0 *M* $Pb(NO_3)_2$, for which δ_{Pb}(1.0 *M* $Pb(NO_3)_2$(aq)) = $\delta_{Pb}(PbMe_4$(toluene)) + 2961 ppm (27). The ^{13}C nmr spectra were referenced to external dioxane in D_2O for 308 K measurements or the CD_3 signal of external $(CD_3)_2CO$ for reduced temperature measurements; at 308 K δ_C(external dioxane in D_2O) $\approx \delta_C$(internal TMS) − 67.8 ppm while δ_C(external $(CD_3)_2CO$) $\approx \delta_C$(internal TMS) − 29.4 ppm but is slightly temperature sensitive. Typically, satisfactory ^{207}Pb nmr spectra of 0.25 *M* solutions required aequisition of several thousand transients using a 12.5 kHz spectral window, a 45° (40 μs) pulse width, a 1 s acquisition time, and a 4.3 s cycle time. On the XL-100 the 20.9 MHz region contains many "glitches" so that comparison with spectra of samples containing no lead is an essential. Carbon-13 nmr spectra were obtained using conditions reported previously (1). Proton-decoupled 50.3 MHz ^{13}C nmr spectra were measured with a Varian XL-200 spectrometer system, using spinning samples, a ^2D lock and, typically, a 10 kHz spectral window, 3 μs (45°) pulse width, a 1.6 s acquisition time, and a 2 s cycle time. Samples with $[Ph]_{total} \approx 0.75$ *M* gave acceptable spectra in several hundred to several thousand transients depending whether they contained one or several species. The solvent signal was used as internal reference and converted to the TMS scale using δ_C(TMS, int) = $\delta_C(CDCl_3$, int) + 77.05 = $\delta_C(CD_3OD$, int) + 49.00 ppm.

A Bruker WH-400 spectrometer system was used to obtain 295 K and variable temperature ^{77}Se, ^{119}Sn, and ^{207}Pb nmr spectra at 76.4, 149.2, and 83.4 MHz, respectively (the last after preliminary measurement at 20.9 MHz as described above). The primary references, used externally, were saturated H_2SeO_3(aq), neat $SnMe_4$, and 1.0 *M* $Pb(NO_3)_2$(aq), respectively. The ^{77}Se data were converted to neat Me_2Se as reference using $\delta_{Se}(Me_2Se$(neat)) = $\delta_{Se}(H_2SeO_3$(aq)) + 1326 ppm; the ^{207}Pb data were converted to $PbMe_4$ (in toluene) as reference as indicated above. In obtaining these spectra, neither proton decoupling nor a ^2D lock was normally used, and only those samples in standard 10 mm tubes were spun (i.e. only the samples containing Group V elements); samples in 9 mm od nmr tubes would not always spin satisfactorily, so for consistency all were kept stationary. After initial location of the signals using a 50 kHz spectral window, smaller spectral windows were normally used. Typical operating conditions were: for ^{77}Se, 10 kHz spectral window, 38 μs (90°) pulse width and 0.8 s acquisition and 1.8 s cycle time; for ^{119}Sn, 20 kHz spectral window, 25 μs (60°) pulse width, 0.4 s acquisition and cycle time; for ^{207}Pb, 10 kHz spectral window, 38 μs (90°) pulse width and 0.8 s acquisition and cycle time. (The larger spectral window was used for ^{119}Sn to accommodate the spectra of mixtures where several signals were present (see below).)

Elemental microanalyses

Analyses were performed by Guelph Chemical Laboratories Ltd.

Results and discussion

Tin(II) complexes

Tin(II) thiophenolate, $Sn(SPh)_2$, is poorly soluble in MeOH at room temperature, but becomes completely soluble in the presence of an equimolar or greater amount of SPh^- or $SePh^-$. The corresponding tin(II) selenophenolate, $Sn(SePh)_2$, exhibits the same behaviour. Evidently, soluble stannate(II) complexes are formed in solution, and we have characterized these by a combination of ^{119}Sn, ^{77}Se, and ^{13}C nmr.

A solution in which $Sn(SPh)_2/SPh^- = 1/2$ gives, at 295 K, a single ^{119}Sn nmr line, with $\delta_{Sn} = 136$ ppm, essentially the same chemical shift found for the supernatant liquor from a mixture in which $Sn(SPh)_2/SPh^- > 1$ (Table 3). These two results show that only a single tin(II) complex exists in the $Sn(SPh)_2-SPh^-$ system. Similarly, the system $Sn(SePh)_2-SePh^-$ gives a single ^{119}Sn nmr signal with a shift quite insensitive to composition, showing that only a single soluble phenylselenolate complex is formed in this system. At 295 K neither the ^{119}Sn resonance of the mother liquor from $Sn(SePh)_2/SePh^- > 1$ nor the ^{119}Sn resonance from the solution with $Sn(SePh)_2/SePh^- < 1$ shows satellites from those isotopomers containing ^{77}Se (natural abundance 7.6%, spin $I = 1/2$). At reduced temperature the spectrum of the solution containing excess $PhSe^-$ still shows no ^{77}Se satellites, but if $Sn(SePh)_2/PhSe^- > 1$ the expected one bond $^{77}Se—^{119}Sn$ coupling can be observed, and is 710 Hz at 198 K, similar in magnitude to the 570 Hz found for $Sn(SeP(chx)_3)_3^{2+}$ at 213 K (6). The presence of excess free $PhSe^-$ must induce rapid free−bound ligand exchange, a conclusion supported by the observation of only a single phenyl pattern in the reduced temperature 50.3 MHz ^{13}C nmr spectra of mixtures with $Sn(SePh)_2/SePh^- < 1$. As rapid ligand exchange requires excess free ligand, the exchange process at the tin(II) centre must be associative, a conclusion also reached from nmr data for $Sn(SeP(chx)_3)_3^{2+}-SeP(chx)_3$ mixtures in SO_2 (6). It is not possible to tell from the ^{119}Sn nmr spectra of $Sn(SPh)_2-SPh^-$ mixtures whether free−bound ligand exchange is rapid. However, partial resolution of free and bound PhS^- resonances occurs at temperatures below ca. 223 K in the 50.3 MHz ^{13}C nmr spectra (though not the 25.2 MHz ^{13}C nmr spectra) of mixtures with $Sn(SPh)_2/SPh^- < 1$, so it seems that the rate of associative ligand exchange on tin(II) is less for PhS^- than for $PhSe^-$.

The triligated nature of the soluble stannate(II) complexes was confirmed by the ^{119}Sn and ^{77}Se nmr spectra of mixed ligand systems prepared from appropriate combinations of

[a]For the tin complexes M = ^{119}Sn; chemical shifts were measured relative to external neat $SnMe_4$ at 295 K. For the lead complexes M = ^{207}Pb; chemical shifts are given relative to $PbMe_4$ in toluene after measurement relative to external 1 *M* $Pb(NO_3)_2$(aq) at 295 K and conversion using $\delta_{Pb(NO_3)_2} = \delta_{PbMe_4} + 2961$ ppm (27). Estimated error for both δ_{Sn} and δ_{Pb} is ±1 ppm.

[b]Relative to external neat Me_2Se; measured initially relative to external saturated H_2SeO_3(aq) at 295 K and converted using $\delta_{Me_2Se} = \delta_{H_2SeO_3} + 1326$ ppm. Estimated error ±1 ppm.

[c]Relative to TMS, at 294 K; measured initially relative to the solvent ^{13}C signal and converted using $\delta_{TMS} = \delta_{CD_3OD} + 49.00 = \delta_{CDCl_3} + 77.05$ ppm; estimated error ±0.02 ppm.

[d]In the supernatant liquid from mixtures where $\{M(EPh)_2\}_{total}/EPh^-_{total} > 1$ (see text).

[e]At 198 K in mixtures of $[Sn(SPh)_x(SePh)_{3-x}]^-$.

[f]At 295 K.

[g]For the supernatant from $Sn(SPh)_2/SPh^- > 1$.

[h]At 195 K, $\delta_{Sn} = 125$ ppm, $\nu_{1/2} \approx 30$ Hz.

[i]At 213 K.

[j]Separate ^{13}C spectra of mixed ligand species could not be observed at reduced temperature (see text).

[k]For the supernatant from $Sn(SePh)_2/SePh^- > 1$.

[l]At 195 K, $\delta_{Sn} = 184$ ppm, $\nu_{1/2} \approx 50$ Hz, $^1J(^{77}Se—^{119}Sn) = 710 \pm 10$ Hz.

[m]Ligand exchange is fast on the nmr timescale at all accessible temperatures; separate spectra from mixed ligand species could not be observed.

[n]No ^{77}Se satellites observed.

$Sn(EPh)_2$ and PhE^- (E = S, Se) such that $\{Sn(EPh)_2\}_{total}/PhE^-_{total} > 1$ (to reduce the free−bound ligand exchange rate). The 198 K ^{119}Sn nmr spectra show, as the S/Se ratio of the mixture is changed, a total of four resonances which can readily be attributed to $[Sn(SPh)_x(SePh)_{3-x}]^-$ with chemical shifts covering the ^{119}Sn chemical shift range from 123 ($x = 3$) to 185 ppm ($x = 0$) and increasing monotonically but not linearly with x (Table 3).[4] These ^{119}Sn nmr chemical shifts and their span are quite similar to those found for $[Sn(SP(chx)_3)_x(SeP(chx)_3)_{3-x}]^{2+}$ for which δ_{Sn} (from $SnMe_4$) ≈ 181, 161, 133, and 94 ppm for $x = 0$, 1, 2, and 3, respectively (6). Of the three $PhSe^-$-containing species, only for $Sn(SePh)_3^-$ could the ^{77}Se satellites be observed with certainty in the 198 K spectra; they should be most intense for this species. (Statistically, the Sn $^{77}SeSe_2$ kernel should be 19.4% of all $SnSe_3$.) As noted above, these satellites are absent at 295 K showing that intermolecular $PhSe^-$ exchange is rapid at this temperature. Consistent with intermediate-to-fast ligand exchange, at 295 K a single very broad resonance with composition-dependent chemical shift, is observed for mixtures of various $[Sn(SPh)_x(SePh)_{3-x}]^-$. A single much sharper ^{119}Sn resonance is found when mixtures with $Sn(EPh)_2/EPh^- < 1$ are studied at 295 K, and this behaviour allows an assessment of the preference of Sn(II) for SPh^- or $SePh^-$ in these systems. A mixture of composition $Sn(SePh)_2/SePh^-/SPh^- \approx 1/2/4$ gave a resonance with a ^{119}Sn nmr chemical shift of 194 ppm, much closer to that of $Sn(SePh)_3^-$ (205 ppm when $Sn(SePh)_2/SePh^- \approx 1/2$) than to that of $Sn(SPh)_3^-$ (136 ppm when $Sn(SPh)_2/SPh^- \approx 1/2$). Hence we conclude that tin(II) has marked, though perhaps not complete, preference for $PhSe^-$ over PhS^-.

In agreement with the ^{119}Sn nmr results, a total of three ^{77}Se resonances are found for the supernatant liquor from

[4]The incremental chemical shifts from $\delta(Sn(SPh)_3^-)$ can be accommodated in terms of pairwise additivity parameters (28), $\Delta\delta_{S-Se}$ and $\Delta\delta_{Se-Se}$ are approximately 14 and 18 ppm for $[Sn(SPh)_x(SePh)_{3-x}]^-$; the corresponding values for $[Sn(SP(chx)_3)_x(SeP(chx)_3)_{3-x}]^{2+}$ are 19 and 29 ppm (6).

$Sn(EPh)_2-PhE^-$ mixtures with $\{Sn(EPh)_2\}_{total}/PhE^-_{total} > 1$. By following intensity variation as a function of $(S/Se)_{bound}$, these resonances can be assigned to $[Sn(SPh)_x(SePh)_{3-x}]^-$ ($x = 0-2$), as shown in Table 3.

In the reduced temperature 50.3 MHz ^{13}C nmr spectra of solutions which gave slow exchange ^{119}Sn and/or ^{77}Se nmr spectra we were unable to resolve separate signals for the various species $[Sn(SPh)_x(SePh)_{3-x}]^-$ that were known to be present. There is no inconsistency here, for the signal separations in the 76.4 MHz ^{77}Se nmr spectra are 920 Hz minimum, and those in the 149.2 MHz ^{119}Sn nmr spectra are 360 Hz minimum (i.e. $^1J(^{77}Se—^{119}Sn)/2$), whereas by comparison with the ^{13}C nmr data for the isoelectronic species $Sb(SPh)_x(SePh)_{3-x}$ (see below), signal separations of 50 Hz or less could be expected for the various resonances in the 50.3 MHz ^{13}C spectra. The linewidths in the reduced temperature ^{77}Se and ^{119}Sn nmr spectra are quite large (Table 3) and almost certainly contain a contribution from lifetime broadening; i.e. these are slow-exchange but not limiting spectra. The exchange rate which only broadens the ^{77}Se and ^{119}Sn lines is, apparently, sufficient to collapse the ^{13}C nmr spectra with their smaller chemical shift differences. In short, exchange seems to be slow (but existent) on the 76.4 MHz ^{77}Se and 149.2 MHz ^{119}Sn nmr timescales but fast on the 50.3 MHz ^{13}C nmr timescale.

Lead complexes

Like their stannous analogs, $Pb(SPh)_2$ and $Pb(SePh)_2$ are poorly soluble in MeOH but dissolve in the presence of equimolar or greater amounts of PhS^- or $PhSe^-$. The soluble components of $Pb(SPh)_2-PhS^-$ or $Pb(SePh)_2-PhSe^-$ mixtures give, at 295 K, ^{207}Pb nmr chemical shifts that are barely dependent on the $Pb(EPh)_2/PhE^-$ ratio, e.g. at 295 K for solutions in which $Pb(EPh)_2/EPh^- \approx 1/2$, $\delta_{Pb} = 2808$ and 3173 ppm for E = S and Se respectively, close to the values found for the corresponding mixtures with $Pb(EPh)_2/EPh^- > 1$ (Table 3). Thus each of the systems $Pb(EPh)_2-EPh^-$ contains only a single species $Pb(EPh)_x^{(x-2)-}$. The value of x could not be determined from our ^{207}Pb, ^{77}Se, or ^{13}C nmr studies of $Pb(SPh)_x^{(x-2)-}:Pb(SePh)_x^{(x-2)-}$ mixtures because no slow exchange spectra could be obtained. Thus, for instance, the supernatant liquor from a mixture with $Pb(SePh)_2/PhS^- \approx 1.1$ gave a single broad ^{207}Pb nmr resonance ($\delta_{Pb} \approx 3036$ ppm; $\nu_{1/2} \approx 600$ Hz) at 295 K but at 213 K no observable signal in the range 2690–3289 ppm. The exchange rate must be in the intermediate region relative to frequency separation of the expected lines in the 83.4 MHz ^{207}Pb nmr spectrum at 213 K, and in the intermediate-to-fast region at 295 K. Also, for the solution component of $Pb(SePh)_2/SePh^- > 1$ at reduced temperature, we could observe neither ^{77}Se satellites in the ^{207}Pb nmr spectrum nor ^{207}Pb (natural abundance 22.6%; spin $I = 1/2$) satellites in the ^{77}Se nmr spectrum, showing that the rate of intermolecular ligand exchange is fast relative to the (unknown) magnitude of $^1J(^{77}Se—^{207}Pb(II))$.

The chemical behaviour of the plumbous systems mirrors that of the stannous systems discussed above, and this suggests that x is three. The 295 K ^{207}Pb nmr chemical shifts of $Pb(SPh)_3^-$ and $Pb(SePh)_3^-$ (Table 3) are reasonably close to those found for $Pb(SP(chx)_3)_3^{2+}$ and $Pb(SeP(chx)_3)_3^{2+}$ (approximately 2457 and 3011 ppm, respectively, in SO_2 at 213 K (6)), allowing for the existence of sizeable solvent and temperature effects in ^{207}Pb nmr spectra. Indeed a prior knowledge of the ^{207}Pb nmr chemical shifts of the $EP(chx)_3$ complexes shortened considerably the time needed to find the ^{207}Pb resonances of the PhE^- complexes.

To compare the competitiveness of $PhSe^-$ and PhS^- for coordination to lead(II), the ^{207}Pb nmr spectrum of a solution of composition $Pb(SePh)_2/PhSe^-/PhS^- \approx 1/2/4$ was examined at 295 K. The single quite sharp ($\nu_{1/2} \approx 30$ Hz) exchange averaged resonance had a chemical shift of 3151 ppm, much closer to the shift of $Ph(SePh)_3^-$ than to that of $Pb(SPh)_3^-$ (Table 3). It can be concluded that coordination of $PhSe^-$ to lead(II) is strongly preferred over coordination of PhS^-.

As discussed in the Introduction, thiolatoplumbates may be formed during treatment with thiol-containing therapeutic chelators in cases of lead intoxication. Therefore we thought it desirable to establish the range of ^{207}Pb chemical shifts for lead(II) complexes with a wider selection of thiolates as ligands. The dissolution of $Pb(SR)_2$ in MeOH in the presence of excess SR^- appears to be fairly general: of the thiolates examined only the 1:1 lead(II) thiolates with $^-S(CH_2)_2S^-$ and $^-SCH_2CHS^-CH_2SO_3^-Na^+$ were poorly soluble in the presence of excess of the corresponding thiolate. In methanol solutions containing $Pb(SR)_2/RS^- \approx 1/6$ ($Pb(SR)(OAc)/RS^- \approx 1/5$ for R = chx), δ_{Pb} was found to be 2999, 2941, 2814, 2965, 2518, and 2551 ppm for RS^- = MeS^- (at 295 K), EtS^- (at 295 K; $\delta_{Pb} = 2772$ ppm in water at 305 K), $chxS^-$ (at 305 K), $^-S(CH_2)_3S^-/2$ (at 305 K), $^-SCH_2CHS^-Me/2$ (at 305 K), and $^-SCH_2CHS^-CH_2OH/2$ (at 305 K). From this preliminary screening we conclude that the ^{207}Pb chemical shifts of thiolatoplumbates(II) fall into a comparatively narrow region of the total ^{207}Pb nmr chemical shift range so that ^{207}Pb nmr may be a useful technique in detecting the presence of this type of complex. A possible complication is the lability of these complexes, which can cause extensive line broadening if intermediate-to-fast exchange between multiple sites can occur. It is interesting that a cyclohexylthiolato complex, probably $Pb(Schx)_3^-$ from the ^{207}Pb nmr chemical shift, is formed even though $Pb(Schx)_2$ could not be synthesized via $Pb(OAc)_2$ (see Experimental section). Also noteworthy are the somewhat different values of δ_{Pb} found for the two vicinal dithiolates studied. Because of the lability of the complexes we were unable to establish with certainty that chelation occurs in these cases, though this seems probable. The stoichiometries of the lead(II) thiolates with the dianion of BAL, $^-S(CH_2)_2OH$, and $^-SCH_2CHOHMe$, 1:1 with the dithiolate and 2:1 with the monothiolates (see Experimental section), argues against involvement of the hydroxy group of BAL in coordination to lead.

Arsenic, antimony, and bismuth complexes

We have studied the chemical and ^{77}Se and ^{13}C nmr spectroscopic behaviour of $M(SPh)_3$, $M(SePh)_3$, and $M(SPh)_x(SePh)_{3-x}$ (M = As, Sb, or Bi) for comparison with the tin(II) and lead(II) complexes described above. Details of the ^{77}Se and ^{13}C nmr spectra obtained are included in Table 3.

In $CDCl_3$ as solvent, a redistribution of ligands between $As(SPh)_3$ and $As(SePh)_3$ occurs over a period of several hours at room temperature, as indicated by the time dependence of the ^{13}C nmr spectra. By variation of the $As(SPh)_3/As(SePh)_3$ ratio, equilibrium mixtures of various species $As(SPh)_x(SePh)_{3-x}$ can be formed, as expected for an apparently near statistical redistribution, and their separate ^{77}Se and ^{13}C spectra measured. The behaviour of $Sb(SPh)_3-Sb(SePh)_3$ mixtures is similar except that the ligand redistribution is fast on the chemical timescale though not on the nmr timescale. In this case, the redistribution is complete within approximately the time

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

needed to mix the components: no time dependence of the ^{13}C nmr spectra was noted. At ambient probe temperature, separate ^{13}C and, when expected, ^{77}Se nmr spectra are observed for $Sb(SPh)_x(SePh)_{3-x}$.

In contrast to the nmr spectral behaviour of the arsenic- or antimony-containing systems, ^{13}C and ^{77}Se nmr spectra characteristic of fast intermolecular exchange are found at all accessible temperatures for $Bi(SPh)_3-Bi(SePh)_3$ mixtures. There is no doubt, however, that mixed ligand systems do form, for both the ^{77}Se and the ^{13}C nmr chemical shifts vary as the $Bi(SPh)_3/Bi(SePh)_3$ ratio is changed, and in addition there are obvious colour changes in the mixtures. Because of the lability of $Bi(SPh)_x(SePh)_{3-x}$, only data for $Bi(SPh)_3$ and $Bi(SePh)_3$ are included in Table 3. Overall, the trend in the lability of the Group V species, i.e. lability increasing with atomic number, is the same as found for the analogous Group IV complexes (see above).

The occurrence of slow exchange nmr spectra for the arsenic and antimony complexes allowed a study of the distribution of SPh^- and $SePh^-$ competitively between pairs of the Group V elements. Accordingly, we measured the ^{13}C nmr spectra of equilibrated mixtures $M(SPh)_3-M'(SePh)_3$ where M = Sb and M′ = As, and where M = Bi and M′ = As or Sb. The As–Sb mixtures gave slow exchange ^{13}C spectra for both $As(SPh)_x(SePh)_{3-x}$ and $Sb(SPh)_x(SePh)_{3-x}$, and from the overall stoichiometry and the distribution of the various species it was apparent that the preference for $PhSe^-$ over PhS^- was Sb > As. Similarly the As–Bi mixtures gave slow exchange spectra for $As(SPh)_x(SePh)_{3-x}$ along with fast exchange spectra for $Bi(SPh)_x(SePh)_{3-x}$, and it was possible to conclude that the preference for $PhSe^-$ over PhS^- was Bi $\gg$ As. The order of preference Bi > Sb could not be confirmed directly because Sb–Bi mixtures gave fast exchange ^{13}C nmr spectra at 294 K and slow exchange spectra could not be obtained even for $Sb(SPh)_x(SePh)_{3-x}$ by reducing the temperature. Nevertheless, it is evident that within the series of Group V elements the overall order of preference for $PhSe^-$ over PhS^- is Bi > Sb > As. We could not measure the preference of individual elements for $PhSe^-$ vs. PhS^-, but our results for the isoelectronic species $Sn(EPh)_3^-$ and $Pb(EPh)_3^-$ (see above) suggest that it should be $PhSe^- > PhS^-$ for Sb and Bi at least.

A number of empirical correlations are evident from the data in Table 3. In the ^{77}Se nmr spectra of both $As(SPh)_x(SePh)_{3-x}$ and $Sb(SPh)_x(SePh)_{3-x}$ there is a linear or near-linear increase in shielding as x increases. The trend to increasing shielding with increasing x is found for the ^{13}C resonances of C_2, C_3, and C_4 of both PhS^- and $PhSe^-$ bound to As or Sb also, albeit on a much smaller scale and not always linearly, while the corresponding C_1 resonances show a near-linear decrease in shielding with increase in x. In the case of δ_{C_4} the changes observed appear to reflect slight shifting of electrons throughout the molecules as sulfur is replaced by less electronegative selenium: considering one —SPh or —SePh, change of the attached group from $(PhS)_2M-$ to $(PhSe)_2M-$ should result in electron release into the phenyl ring of interest and this is known to cause increased shielding (29), as is observed. The same effect can account for the observed changes in δ_{C_3}; however, δ_{C_1} and δ_{C_2} are known to be sensitive to other factors as well, because of their closer proximity to the atom which is being varied, and similarly the factors affecting δ_{Se} may include through-space as well as through-bond effects.

The data in Table 3 and elsewhere (2*a*, 30) show that the biggest influence on δ_{Se} of $PhSe^-$ is the atom to which the selenium is attached. The known variation of δ_{Se} with metal atom is Cd(II) < Zn(II) < Pb(II) < Sn(II) < As(III) < Bi(III) < Sb(III). Because of its sensitivity to acceptor atom, δ_{Se} should prove a useful probe for specific metal–selenolate bonds once a sufficient library of model data is available.

Acknowledgments

This work was made possible by an Operating Grant (to P.A.W.D.) and a Strategic Grant in Environmental Toxicology (to P.A.W.D. jointly with Drs. M. J. Stillman and G. M. Cherian of the Departments of Chemistry and Pathology, respectively, U.W.O.), both from the Natural Sciences and Engineering Research Council of Canada (N.S.E.R.C.). N.S.E.R.C. also provided a Major Installation Grant to the Southwestern Ontario NMR Centre where the high field ^{77}Se, ^{119}Sn, and ^{207}Pb nmr spectra were obtained with the expert technical help of Mr. Bruce MacDonald. Dr. J. B. Stothers and Mrs. V. Richardson of this Department measured the high field ^{13}C nmr spectra, while Mrs. H. M. Schroeder, previously of this Department, ably assisted in obtaining initial low field ^{13}C and ^{207}Pb nmr spectra.

Second sphere coordination of phenols, anilines, and benzoic acids to the hexacyanocobaltate(III) anion

DONALD R. EATON,[1] RICHARD J. BUIST, AND CAROL V. ROGERSON
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 19, 1982

DONALD R. EATON, RICHARD J. BUIST, and CAROL V. ROGERSON. Can. J. Chem. **61**, 1524 (1983).

Complexing between the hexacyanocobaltate(III) anion and ten substituted phenols, eight substituted anilines, and eight substituted benzoic acids has been studied in dimethyl sulfoxide solutions by means of ^{59}Co nmr. For the phenols substantial changes in the chemical shifts and in the line widths are observed and are attributed to hydrogen bonding interactions. Effective equilibrium constants and chemical shifts for the hydrogen bonded species have been calculated. The equilibrium constants vary with the phenol substituent, being largest for electron withdrawing substituents and smallest for electron donating substituents. The chemical shifts are virtually independent of substituent. The data show that the lifetimes of the hydrogen bonded complexes are long compared to the rotational correlation time. The complex with *para*-nitrophenol has also been studied by measuring ^{1}H and ^{13}C spin–lattice relaxation times. These measurements allow the separation of the increase in ^{59}Co line width due to increase in correlation time and that due to increase in quadrupole coupling constant. From the ^{13}C measurements a value of the correlation time for the complex of 2.8 10^{-10} s is obtained together with a ^{59}Co quadrupole coupling constant of 8.34 MHz. The equilibrium constants for complex formation with the anilines are small and only the products of the equilibrium constant and the chemical shift of the hydrogen bonded complex can be derived from the experimental data. The benzoic acids show evidence of dimerization in solution and this again prevents the calculation of absolute equilibrium constants. The data, however, do indicate that the ability to form hydrogen bond complexes does not vary dramatically with the acid strength of the hydrogen donor. With phenols and benzoic acids there is considerable line broadening on complex formation but with anilines only a small line broadening is observed. This is consistent with very short hydrogen bond lifetimes for the aniline complexes.

DONALD R. EATON, RICHARD J. BUIST et CAROL V. ROGERSON. Can. J. Chem. **61**, 1524 (1983).

Faisant appel à la rmn du ^{59}Co, on a étudié la complexation de l'anion hexacyano cobaltate(III) avec dix phénols substitués, huit anilines substituées et huit acides benzoïques substituées dans des solutions de diméthylsulfoxide. Dans le cas des phénols on observe des changements importants dans les déplacements chimiques et dans la largeur des raies et on les attribue à des interactions de liaison hydrogène. On a calculé les constantes effectives d'équilibre et les déplacements chimiques des espèces liées par des liaisons hydrogènes. Les constantes d'équilibre varient avec le substituant du phénol, cette constante est plus élevée dans le cas des substituants électro-attracteurs et plus faible dans le cas des substituants électro-donneurs. Les déplacements chimiques sont virtuellement indépendants du substituant. Les données montrent que les temps de vie des complexes liés par des liaisons hydrogènes sont longs par rapport au temps de corrélation rotationnelle. On a également étudié le complexe avec le *para*-nitrophénol en mesurant les temps de relaxation spin réseau du ^{1}H et du ^{13}C. Ces mesures permettent de séparer l'augmentation de largeur de la raie du ^{59}Co due à l'augmentation du temps de corrélation et celle due à l'augmentation de la constante de couplage quadrupolaire. A partir des mesures de ^{13}C on obtient une valeur de 2,8 × 10^{-10} pour le temps de relaxation du complexe ainsi qu'une valeur de constante de couplage quadrupolaire du ^{59}Co de 8,34 MHz. Les constantes d'équilibre de formation du complexe avec les anilines sont faibles et on ne peut déduire que les produits de la constante d'équilibre et du déplacement chimique, du complexe lié par des liaisons hydrogènes, à partir des données expérimentales. Les acides benzoïques se dimérisent en solution et ceci empêche de calculer les constantes absolues d'équilibre. Les données cependant indiquent que la capacité des complexes à former des liaisons hydrogènes ne varient pas de façon marquée avec l'acidité du donneur d'hydrogène. Dans le cas des phénols et des acides benzoïques il y a un élargissement considérable de la raie lors de la formation des complexes mais dans le cas des anilines on observe qu'un faible élargissement de la raie. Ces résultats sont en accord avec des temps de vie très courts des liaisons hydrogènes des complexes de l'aniline.

Introduction

Ligands held in the second coordination sphere of metal complexes potentially play an important role as intermediates in a variety of reactions. Ligand exchange (1), electron transfer (2), and catalytic mechanisms (3) involving second sphere intermediates have all been discussed. A major barrier to the evaluation of the importance of these ideas is the lack of quantitative information on the stabilities and labilities of second sphere complexes. It is essential to be able to estimate the equilibrium constant for complex formation and the lifetime of the intermediate to adequately assess its possible role in a given mechanism. This information is often difficult to obtain. Hydrogen bonding is probably one of the more important interactions responsible for the binding of second sphere ligands. There have been a number of studies (4–6) leading to equilibrium constant information on such complexes but very little rate data is available. The present paper reports the results of a study of hydrogen bonding interactions between the hexacyanocobaltate(III) anion and phenols, anilines, and benzoic acids.

^{59}Co nmr provides an attractive approach to the study of second coordination sphere equilibria and kinetics (7). The chemical shifts are very large and therefore provide a sensitive probe for second sphere interactions. Chemical shift data can be used to obtain equilibrium constants for the formation of second sphere complexes. We have reported previously (8) that there is also considerable broadening of the lines on hydrogen bond formation. The extent of this broadening varies considerably with the nature of the hydrogen donor. The broadening results from a decrease in the relaxation time of the ^{59}Co nucleus. The details depend on the relative values of the lifetime of

the hydrogen bonded complex and the rotational correlation time of the molecule. On the basis of nmr (8) and infrared studies (9) it has been deduced that for strong hydrogen bonds the former is greater and for weak hydrogen bonds the latter is greater. The line width studies therefore have the potential to provide information on the hydrogen bond lifetimes. The ^{59}Co relaxation times depend on both a correlation time and a quadrupole coupling constant. The ^{59}Co studies by themselves do not provide sufficient information to separate changes in relaxation time produced by changes in correlation time and changes produced by increased quadrupole coupling. The ^{59}Co nmr studies have therefore been supplemented by measurements of ^{1}H and ^{13}C relaxation times of complexing phenols. The strategy for the analysis of the phenol data is therefore to use ^{59}Co chemical shifts to obtain second sphere equilibrium constants. The way these equilibrium constants vary with the substituent on the phenyl ring is of particular interest. Proton T_1 measurements on the phenol provide additional information of the relative values of the hydrogen bond lifetime and the rotational correlation time and indicate the relative importance of changes in correlation time and quadrupolar coupling. Calculation of the ^{59}Co relaxation times for the second sphere complexes is accomplished by combining the equilibrium data from the chemical shifts with the line broadening data. Finally ^{13}C T_1 measurements on the phenol lead to the calculation of a correlation time for the complex and hence to effective ^{59}Co quadrupole coupling constants for the hydrogen bonded molecules. The range of acidities covered by the phenols is limited. The study has therefore been extended by considering substituted benzoic acids and anilines. Benzoic acids are considerably stronger acids than phenols — the pK_a of benzoic acid is 4.19 and that of phenol 9.89. Anilines show primarily basic properties. The NH_2 protons are only very weakly acidic so that the three series of benzoic acids, phenols, and anilines span a very wide range of acidities.

Experimental

^{59}Co nmr spectra were obtained using a Bruker WH90 FT NMR spectrometer at a frequency of 21.36 MHz. Proton and ^{13}C spectra were obtained using a Bruker WP80 FT spectrometer. Spin–lattice relaxation times (T_1) were measured by the inversion recovery technique (180–τ–90 pulse sequence). Deuterated dimethyl sulphoxide (Norrell Chem. Co.) was used as a solvent throughout. This avoids competition from the solvent for hydrogen bonding sites on the cobalticyanide ion. The solubility of potassium cobalticyanide in dimethyl sulfoxide is limited. The addition of cyclohexyl-18-crown-6-ether increases the solubility by complexing the potassium ions allowing a concentration of 0.05 *M* to be obtained easily. This concentration was used throughout. We have shown previously (8) that the crown ether does not affect the chemical shifts or line widths of the ^{59}Co resonances. It does, however, effect the T_1's of the phenol as described below. ^{59}Co line widths are reported as the full width at half intensity. The chemical shifts are reported relative to $K_3Co(CN)_6$ in Me_2SO_4-d_6. This resonance occurs at a chemical shift of +283 ppm from the usual reference of $K_3Co(CN)_6$ in water. All phenols were of analytical quality and used without further purification. The temperature of the nmr probe was 25 ± 0.5°C for both instruments. The deuterated solvent was used to provide a deuterium lock. Equilibrium constant calculations were carried out on an Osborne 1 microcomputer using BASIC programming.

The ^{59}Co line widths are sensitive to small amounts of water in the Me_2SO_4-d_6. The amount of water tends to vary a little from sample to sample. It was shown that this variation does not affect the increase in line width caused by the addition of the organic compound and that errors in the reported parameters from this source are negligible.

Results

A. ^{59}Co chemical shifts and line widths — phenols

It has been shown previously (7, 8) that the cobalticyanide ion will form hydrogen bonds with suitable proton donating molecules and this leads to a high field shift in the ^{59}Co nmr resonance. This is consistent with an increased ligand field strength for the hydrogen bonded CN^- ion resulting from additional π backbonding placing additional negative charge on the nitrogen adjacent to the electropositive hydrogen. Such hydrogen bonding is not likely to occur with dimethyl sulfoxide and hence its choice as a solvent. Phenols possess an acidic hydroxyl group well suited to hydrogen bond formation. It has been well documented (10–12) that phenols hydrogen bond to dimethylsulfoxide and hence the observed ^{59}Co shifts will be the outcome of a competition between the solvent and the cobalticyanide for the phenolic hydrogen bond. The choice of a range of phenols with both electron withdrawing and electron donating substituents allows a systematic study of this competition. It is also anticipated that hydrogen bond formation will lead to an electric field gradient at the Co nucleus leading to more rapid quadrupolar relaxation and hence an increase in line width.

Tables of the chemical shifts and line widths at different phenol concentrations are available from the Depository of Unpublished Data.[2] Ten substituted phenols have been examined with substituents ranging from the electron withdrawing nitro group to the electron donating amino and methoxy groups. Changes of around 100 ppm in chemical shift and up to more than 1 kHz in line width are observed. They range from a chemical shift of 50.0 ppm and a line width increase of 544 Hz for 1.249 *M* *p*-aminophenol to a chemical shift of 128.9 ppm and a linewidth increase of 1185 Hz for 1.103 *M* *p*-nitrophenol.

B. Relaxation measurements

The ^{59}Co line widths reported above depend upon the relaxation times of both hydrogen bonded and non-hydrogen bonded species. The nature of this dependence is a function of the relationship between the lifetime of the hydrogen bonded complex and its rotational correlation time. Rotational correlation times for metal complexes are usually $\sim 10^{-11}$ s. Less is known of hydrogen bond lifetimes but for amine–water hydrogen bonds Emerson *et al.* (13) have derived values in the range 10^{-10}–10^{-12} s, i.e., comparable to the rotational correlation times. In previous studies (8, 9) we have deduced that for the cobalticyanide ion the hydrogen bond lifetimes can be either longer or shorter than the correlation time depending on the strength of the hydrogen bond. The theory of nmr relaxation under conditions of very rapid chemical exchange has been reviewed by Laszlo (14) who has designated studies in this area "dynamic NMR II". Anderson and Fryer (15) have shown that although the general formulation is complex there are two simple limiting cases. If the chemical exchange lifetime is $\gg \tau_2$ (the rotational correlation time) relaxation rates are averaged, i.e.,

$$[1] \quad \frac{1}{T_2} = \frac{P_A}{T_{2A}} + \frac{P_B}{T_{2B}}$$

If the converse is true relaxation times are averaged, i.e.,

$$[2] \quad T_2 = P_A T_{2A} + P_B T_{2B}$$

In both bases P_A and P_B are the fractional populations of the two chemically distinct sites which can be obtained from the ^{59}Co chemical shifts. In the extreme narrowing case ($\omega^2\tau^2 \ll 1$) $T_1 = T_2$ and the above equations are equally applicable to T_1. The ^{59}Co line widths can be used to determine which (if either) of these limiting conditions is applicable. This information has been supplemented with ^1H and ^{13}C T_1 measurements on *para*-nitrophenol in the presence and absence of cobalticyanide ions. The results of these measurements are reported in Tables 1 and 2. If T_1, T_{1A}, P_A, and P_B are known T_{1B} can be calculated using either eq. [1] or [2]. The use of the correct equation should lead to constant values for T_{1B} at all concentrations of phenol and cobalticyanide. It is apparent from the data in Tables 1 and 2 that the T_1's are also dependent on the concentrations of *para*-nitrophenol and of crown ether. Comparisons between relaxation times with and without cobalticyanide must therefore be made at constant *p*-nitrophenol and crown ether concentrations. In the presence of potassium cobalticyanide the crown ether is present as a potassium complex. The measurements in the absence of cobalticyanide were therefore carried out with the addition of an equivalent amount of potassium chloride to complex the crown ether. The line broadening mechanism for the ^{59}Co is not completely certain (we have recently demonstrated substantial field dependences of line widths for Co complexes which are not anticipated for quadrupolar broadening). We have previously shown (8) that both T_1 and T_2 are decreased on hydrogen bond formation eliminating "chemical exchange" as a line broadening mechanism. There remains the problem of separating the effect due to a change in quadrupole coupling constant (or chemical shift anisotropy if this is important) and that due to a change in correlation time. This difficulty is not present in the ^1H and ^{13}C T_1 measurements. In both cases dipolar relaxation is dominant and the change in T_1 on hydrogen bond formation can be ascribed to a change in correlation time. In the case of the aromatic carbons bonded to hydrogen dipolar relaxation due to the directly bonded hydrogen is expected to dominate. This is confirmed by measurement of the nuclear Overhausser enhancement (16). A value of 1.83 ±

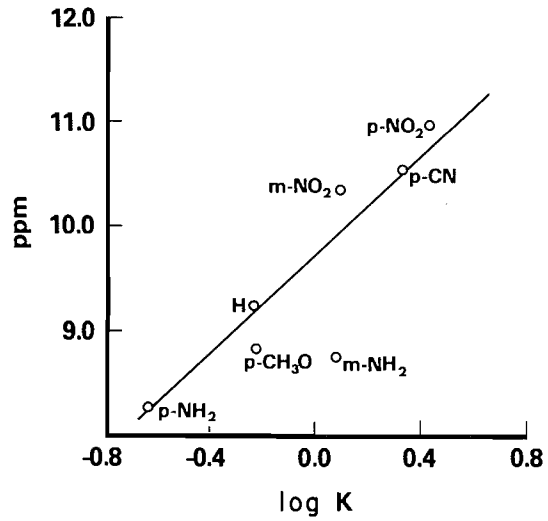

FIG. 1. Correlation of equilibrium constants with hydroxyl proton chemical shifts (ref. 12).

0.20 was obtained comparable with the theoretical value of 2.0 for complete intramolecular dipolar relaxation. From the ^{13}C measurements we can therefore calculate an absolute value of the correlation time of the hydrogen bonded complex and use this to obtain an effective quadrupole coupling constant.

C. Chemical shifts and line widths — anilines and benzoic acids

^{59}Co chemical shifts and line widths for $Co(CN)_6^{3-}$ in the presence of various anilines and benzoic acids are available from the Depository of Unpublished Data. The changes in chemical shift and the increases in line width for anilines are both considerably smaller than the corresponding changes for phenols. A similar set of measurements using *N,N*-dimethyl aniline showed no shifts or line broadening confirming the necessary presence of an NH_2 group for second sphere bonding. Thus 0.862 *M p*-anisidine produces a chemical shift of 5.7 ppm and an additional broadening of only 11 Hz. At the other extreme 1.219 *M p*-nitroaniline gives a chemical shift of 43.1 ppm and a broadening of 84 Hz. Both the chemical shifts and increases in line widths for the benzoic acids are greater than for corresponding anilines, but in spite of the greater pK_a's are smaller than those for the phenols. Thus 1.057 *M p*-aminobenzoic acid gives a shift of 44.6 ppm and a broadening of 692 Hz whereas 0.632 *M p*-nitrobenzoic acid produces a shift of 54.3 ppm and a broadening of 1429 Hz.

Discussion

A. Chemical shifts of phenols

The initial objective of the present study is to determine how the equilibrium constants for the formation of hydrogen bonded second sphere complexes and the chemical shifts of these complexes vary with phenol substituent. The chemical shift is a measure of the change in the electronic properties of the cyanide ligand and hence of the strength of the hydrogen bond formed. The simplest model is to assume the formation of a 1:1 complex between the cobalticyanide and the phenol, i.e.,

$$Co(CN)_6^{3-} + P \rightleftarrows Co(CN)_6^{3-}P$$

It is implied that both the "free" phenol and the cobalticyanide are solvated by the dimethylsulfoxide. It may be readily shown that the concentration of free phenol (P) and the observed chemical shift ($\Delta\nu$) are related by the equation:

$$[3] \quad \frac{P}{\Delta\nu} = \frac{1}{K\Delta\nu_\infty} + \frac{P}{\Delta\nu_\infty}$$

where K is the equilibrium constant for the above reaction and $\Delta\nu_\infty$ is the chemical shift of the hydrogen bonded adduct. A plot of $P/\Delta\nu$ versus P should therefore be linear with a slope of $1/\Delta\nu_\infty$ and an intercept of $1/K\Delta\nu_\infty$. This equation is readily solved by successive approximation with the initial assumption that the concentration of free phenol equals the total phenol concentration. Table 3 gives the values of K and $\Delta\nu_\infty$ obtained on the assumption of a 1:1 complex. The correlation coefficients for the final fit to eq. [3] are also given. They are generally greater than 0.99, indicating that this model gives a satisfactory fit to the data. The degree of association of the cobalticyanide for a given concentration of phenol is readily obtained as $\Delta\nu/\Delta\nu_\infty$. Plots of this function versus the observed line width are also satisfactorily linear and give the line widths of the cobalticyanide/phenol complexes shown in Table 3.

The above model is overly simplified in two respects. It neglects possible association of the phenol molecules in solution and it neglects the formation of second sphere complexes of stoichiometries other than 1:1. Covington *et al.* (17–19) and more recently Kitaigorodskii, Nakipelov, and Zamaraev (20) have derived expressions for the equilibria which remove these limitations. Tsuno *et al.* (11) and Fujio *et al.* (12) have demonstrated that the self association of phenols in dimethyl sulfoxide is negligible at concentrations below 0.5 *M*. Presumably the strength of the hydrogen bond formed with the solvent is greater than that formed by a phenol dimer. The linearity of the fit to eq. [3] indicates that self-association is not important. This fit does not, however, prove that only a 1:1 complex is formed. We have carried out calculations assuming other stoichiometries and obtain equally good fits. These calculations assumed that the equilibrium constant for binding the second phenol was equal to that for the first phenol. From previous mixed solvent studies it is clear that the equilibrium constants for successive addition of second sphere ligands become progressively smaller. The analysis of Kitaigorodski *et al.* (20) demonstrates that data of the type reported in the present paper cannot be unambiguously fitted to a unique set of equilibrium constants. However, these authors concluded that the equilibrium constant K_{eff} found by assuming a 1:1 complex provides a true measure of the stability of the outer sphere complex. Numerical analysis showed that the values of K_1, the true equilibrium constant, were only slightly larger than K_{eff}, the value obtained by neglecting complexes of higher stoichiometries. We take therefore the K_{eff} values of Table 3 as a measure of the stability of the hydrogen bonded complexes. Errors in this equilibrium constant will of course lead to errors of a similar magnitude in the chemical shift and line width parameters of Table 3.

An alternative method of analysing this data is provided by the Scratchard Plot (21):

$$\Delta\nu/P = K\Delta\nu_\infty - K\Delta\nu$$

which is eq. [3] cast in a different form. A number of data sets have been analysed in this manner. The values of K and $\Delta\nu_\infty$ obtained are very similar to those given in Table 3. The Scratchard Plot is useful in enzyme studies to distinguish different complexing sites but it does not appear suitable for deciding the stoichiometry in a case with several identical complexing sites.

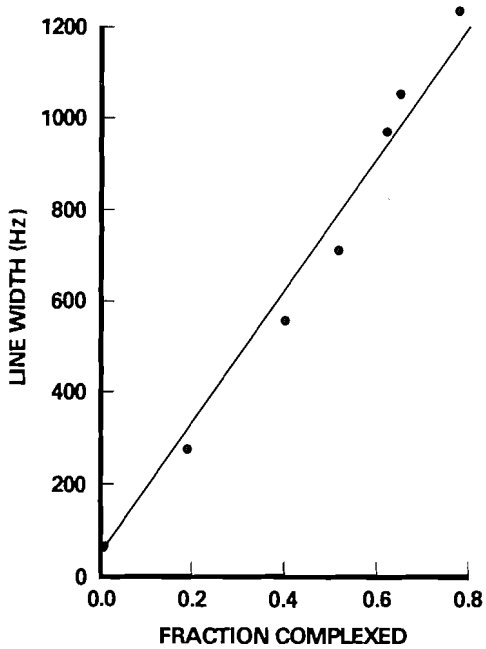

FIG. 2. Variation of line width with degree of association for *para*-nitrophenol.

The most notable feature of the results of Table 3 is that the differences in the effects of the different phenols arise almost entirely from differences in equilibrium constants. With the exception of the amino phenols, the chemical shifts and line widths of the hydrogen bonded complexes are almost independent of substituent. The amino phenols can hydrogen bond either through the OH group or the NH_2 group and this is a likely source of their anomalous behaviour. The equilibrium constants are largest for the most electron withdrawing substituents and smallest for the most electron donating substituents. They can be correlated with a variety of other measures of electron withdrawing ability such as pK_a's and Hammett and other forms of substituent parameters. Shown in Fig. 1 is a plot of ln K_{eff} versus the chemical shift of the hydroxyl proton in DMSO. Fujio *et al.* (12) have used these proton chemical shifts to derive substituent parameters and have discussed their relationship to the electronic structure of the phenols in some detail. Eymen and Drago (10) have related the proton chemical shifts to hydrogen bond strengths. The values of K_{eff} can be equally well correlated with any of these parameters.

B. Relaxation times of phenol complexes

The increases in line width of the ^{59}Co resonance on addition of phenol reflect a decrease in T_2. It is usually considered that the dominant relaxation mechanism for ^{59}Co is quadrupolar. In this case:

$$\frac{1}{T_2} = \frac{3}{40}\frac{2I+3}{I^2(2I-1)}\left(\frac{e^2Qq}{h}\right)^2\left(1+\frac{\eta^2}{3}\right)\tau_2$$

A decrease in T_2 can be the result of either an increase in the quadrupole coupling constant e^2Qq or an increase in the correlation time τ_2 or both. It is not possible to separate these two effects on the basis of ^{59}Co data alone. The proton and ^{13}C relaxation data of Tables 1 and 2 have been used for this purpose. It is assumed that the T_1's for the protons and carbons result entirely from dipolar relaxation which is unaffected by complexation so that any change in relaxation time reflects a change in correlation time.

The observed relaxation times are an average of the relaxation properties of the complexed and uncomplexed molecules which are in rapid chemical exchange and it is first necessary to decide how to carry out the averaging. As pointed out above, depending on whether the chemical exchange lifetime is long or short relative to the correlation time, either the relaxation rates or the relaxation times should be averaged. In the former case a plot of line width versus degree of association (obtained from the chemical shift data) should be linear. In the latter case a plot of 1/line width versus degree of association should be linear. Figure 2 shows the plot versus line width for *para*-nitrophenol. It is clearly linear, showing that the exchange lifetimes are greater than the correlation times. The line widths of Table 3 have been evaluated on this basis.

The proton T_1's of Table 1 confirm this conclusion and allow us to estimate the contribution of the change in correlation time to the line width increase. We note first that the T_1's are dependent on the concentration of the phenol. This most probably reflects viscosity changes. There is also a decrease on adding crown ether. Complexing between crown ether and *para*-nitrophenol has indeed been reported by Virtanen and Viirret (22) in carbon tetrachloride. A weaker complex would be expected in dimethyl sulphoxide but significant interaction is obviously occurring. It is therefore necessary to compare the T_1's at equal concentrations of both phenol and crown ether in the presence and absence of cobalticyanide. The data of Table 2 shows decreases of from 50–100% on the addition of cobalticyanide. This analysis neglects the change in viscosity resulting from the relatively low concentration (0.05 *M*) of cobalticyanide.

These changes are much smaller than the changes in the ^{59}Co line width produced by similar concentrations of *para*-nitrophenol — more than an order of magnitude increase is observed. We deduce that the major contribution to the increased line widths of the ^{59}Co is the electric field gradient induced by the hydrogen bond leading to a greatly increased quadrupole coupling constant. The proton T_1's can also be used to check the form of the averaging of the relaxation. Values of T_1 complexed can be calculated based on either of eqs. [1] and [2]. Averaging of the relaxation times leads to negative values for T_1 complexed which is clearly inadmissible. Averaging of the relaxation rates gives reasonably consistent values of T_1 complexed as shown by the data in Table 4.

The ^{13}C relaxation times in Table 2 allow us to carry this analysis a little further. Qualitatively, the ^{13}C T_1's behave quite similarly to the ^1H T_1's. They decrease with increasing *para*-nitrophenol concentration, with increasing crown ether concentration, and with the addition of cobalticyanide. It is assumed that the ^{13}C relaxation of the aromatic carbons directly bonded to hydrogen is determined by dipole–dipole interaction with the neighbouring hydrogen, i.e. (24),

$$\frac{1}{T_1} = \frac{\mu_0^2\gamma_H^2\gamma_C^2h^2}{12\pi^2}\frac{I(I+1)}{r^6}\tau_2$$

This assumption is confirmed by the Overhauser effect measurement and is consistent with results reported for nitrobenzene and other aromatic molecules (16). Using the equilibrium constant of Table 3 and assuming averaging of the free phenol and complexed phenol relaxation rates, we obtain values of T_1 for the complex of 0.16 s and 0.14 s from the two aromatic carbons bearing protons. Using an average value of 0.15 s this leads to a correlation time of 2.8×10^{-10} s for the *para*-nitrophenol complex. The corresponding value for "free"

[d]Correlation coefficients for aniline plots.

para-nitrophenol is 2.2×10^{-11} s. Ader and Loewenstein (23) have reported a correlation time of 1.8×10^{-11} s for "free" cobalticyanide ion. This was obtained by combining the ^{14}N line width with the ^{14}N quadrupole coupling constant from solid state data. The complexed cobalticyanide should have the same correlation time as the complexed *para*-nitrophenol since both refer to the same molecule. The correlation time is proportional to the cube of the molecular radius. The radius for $Co(CN)_6^{3-}$ is given as 3.9 Å. The increase of correlation time from 1.8×10^{-11} s to 2.8×10^{-10} s requires an increase of the radius to 9.75 Å. A model assuming normal bond lengths and a phenolic hydrogen bond with an H—O—C angle of 105° gives a separation between the Co atom and the average position of the oxygen atoms of the nitro group of 9.8 Å. This indicates that the correlation time obtained from the ^{13}C results is reasonable for a hydrogen bonded adduct between $Co(CN)_6^{3-}$ and *para*-nitrophenol. This correlation time can now be used to obtain an effective ^{59}Co quadrupole coupling constant for the adduct. Using the line width from Table 3 (2408 Hz) gives a quadrupole coupling constant of 8.34 MHz. This is fairly small compared with the quadrupole coupling constants of complexes with different first sphere ligands but not unreasonable for a second sphere effect.

C. *Complexing with anilines and benzoic acids*

Analysis of the chemical shift data for anilines and benzoic acids is more restricted than that for phenols. Equation [3] may be rewritten:

$$\Delta\nu = \frac{K[\mathrm{An}]}{1 + K[\mathrm{An}]}\Delta\nu_\infty$$

If $K[\mathrm{An}] \ll 1$, a linear relationship between $\Delta\nu$ and [An] is anticipated. The slope of such a plot gives the product $K\Delta\nu_\infty$ but it is not possible to obtain K and $\Delta\nu_\infty$ independently. This is the case for the present data for anilines. Table 5 gives the slopes, and correlation coefficients for these plots. The correlation coefficients are generally greater than 0.99, indicating a satisfactory fit.

The behaviour of the benzoic acids is somewhat different. Plots of eq. [3] are not linear. Figure 3 shows two examples of such plots for benzoic acids. They show a pronounced upward curvature. The probable explanation involves the formation of benzoic acid dimers. Dimers of carboxylic acids have been extensively studied in many solvents (25–27). It would be anticipated that the monomer would be favoured in a solvent such as dimethylsulphoxide, which is capable of forming hydrogen bonds, compared to nonpolar solvents such as benzene. The formation of dimers in dimethylsulphoxide is demonstrated by the observation that the proton resonance of the carboxylic acid hydrogen shows a concentration dependence of its chemical shift and line width. It differs in this respect from the hydroxyl resonance of phenols (11, 12). The effect of dimer formation on the ^{59}Co chemical shifts will be to cause a smaller shift at high concentrations of acid, since less monomer is available to complex with the $Co(CN)_6^{3-}$. The curvature of Fig. 3 is consistent with this interpretation. K and $\Delta\nu_\infty$ cannot therefore be obtained independently from the slope and intercept. However, the intercept at zero concentration can be estimated fairly reliably and according to eq. [3] this provides a value of $K\Delta\nu_\infty$ at extreme dilution, i.e. under conditions where the effects of dimerization are minimal. These values are also given in Table 5. This table also contains the corresponding quantities for the phenols for the purpose of comparison. The variation of $K\Delta\nu_\infty$ with substituent is similar for all three sets of data as is illustrated for anilines and phenols in Fig. 4. In all cases electron withdrawing substituents produce the larger shifts and electron donating substituents the smaller shifts. In the case of phenols it was shown that the equilibrium constants rather than the chemical shifts of the hydrogen bonded complex provided

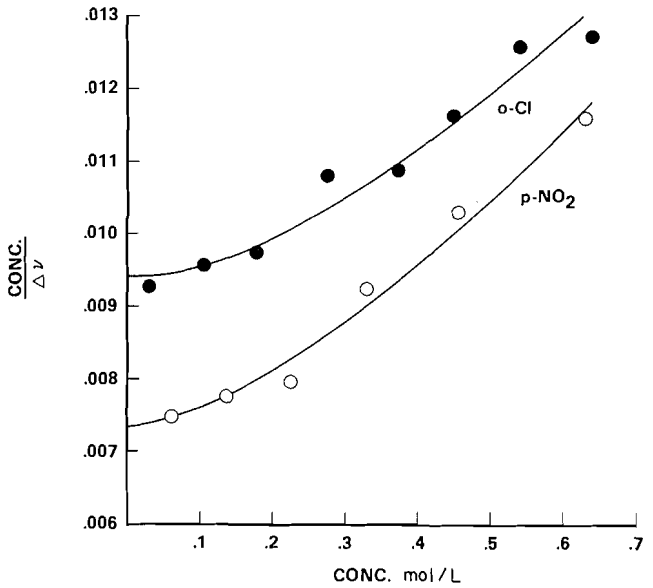

FIG. 3. Plots of $[B]/\Delta\nu$ versus [B] for benzoic acids.

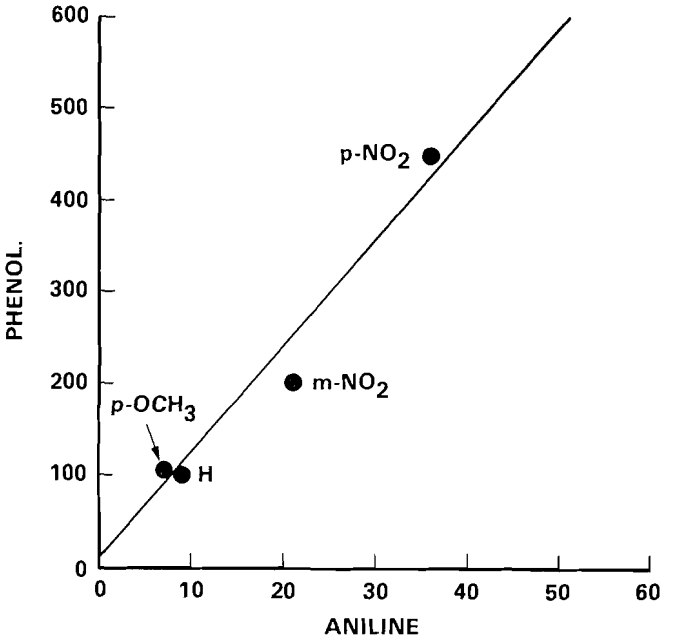

FIG. 4. Correlation of $K\Delta\nu_\infty$ for phenols and anilines.

the major sources of variation. In fact, the chemical shifts for a wide range of hydrogen bonded complexes are remarkably constant. They range (8) from ~350 ppm for the fully hydrogen bonded complex in formic acid, to 280 ppm in pure water, 200 ppm in methanol, and around 150 ppm estimated for the 1:1 complex with phenols. If this trend is followed it seems reasonable that the shift for an aniline complex would be rather less than that for a phenol complex and certainly not greater. This leads to the conclusion that the equilibrium constants for the anilines are no more than one order of magnitude smaller than those for the phenols since the products $K\Delta\nu_\infty$ are smaller by this amount.

A similar estimate for the benzoic acids can be obtained. It can be argued that the values of $\Delta\nu_\infty$ for the benzoic acids will be not less than those for the phenols and probably somewhat larger. It follows that the equilibrium constants are less than those of the phenols by a factor of no more than 2 or 3.

The most notable feature of these results is the relatively modest variation in hydrogen bonding ability over a very wide range of pK_a's. This most probably reflects the competitive nature of the hydrogen bonding process. If a molecule will form stronger hydrogen bonds with the cobalticyanide it will also form stronger hydrogen bonds with the solvent dimethylsulfoxide so that the fraction hydrogen bonded to the metal complex is relatively insensitive to hydrogen bonding ability. For the carboxylic acids hydrogen bonding leading to dimerization also becomes competitive and the net result is a smaller fraction of molecules bonded to the cobalticyanide than in the case of the weaker phenolic acids. The implication of this result is that second sphere hydrogen bonded complexes could be of importance as reaction intermediates for a wide range of acid strengths.

D. The lifetimes of the hydrogen bonds

It has been noted above that if the hydrogen bonds have long lifetimes ($\gg$ the correlation time) and relaxation rates are averaged and if they have short lifetimes ($<$ the correlation time) the relaxation times are averaged (14). The choice of averaging conditions has a large effect on the extent of line broadening. This point may be illustrated with a numerical example. If there is rapid exchange between two species one with a line width of 100 Hz and one with a line width of 1 Hz and 50% of each is present, the resulting line will have a width of 50.5 Hz if the line widths are averaged. Averaging of relaxation times gives a line width of 1.98 Hz, i.e., in one case there is an increase in line width of a factor of 50 on complex formation and in the other case of a factor of 2 for the same degree of complex formation.

In the case of the phenols it is clear that the rates are averaged, indicating that the lifetime is greater than 10^{-10} s. An upper limit of 10^{-6} s can be inferred from the lack of chemical shift broadening ($T_1 = T_2$) in spite of the 150 ppm (equivalent to 3200 Hz at the field of the present experiments) chemical shift difference of the complexed and free forms. In the case of the anilines and benzoic acids we cannot obtain absolute values for the dependence of line width on complex concentration since the absolute values of the equilibrium constants are not known. Relative values can, however, be obtained. The fraction of cobalticyanide complexed is proportional to the chemical shift. The line widths should therefore be proportional to chemical shifts if relaxation rates rather than relaxation times are averaged.

In the converse case a plot of line width versus the reciprocal of chemical shift would be appropriate. For the phenols and benzoic acids plots of line widths versus chemical shifts are linear with correlation coefficients always greater than 0.98 and in most cases greater than 0.99. The slopes of such plots are given in Table 6. The increases in line widths for the anilines are very small. In fact with the exception of the *p*-nitroaniline they are comparable to the increases which would be anticipated from the larger viscosities of the more concentrated solutions. The rate of increase in line width with increase in chemical shift is much smaller than observed for the phenols and benzoic acids as shown by the data in Table 6. The correlation of line width with chemical shift for the anilines is poor. It should be noted that the figures in the three columns of Table 6 are only directly comparable if the chemical shifts for the aniline, phenol, and benzoic acid complexes were identical. If, as anticipated, the aniline shifts are rather smaller than the phenol shifts and the benzoic acid shifts rather larger, the

[a]Increase in line width/chemical shift Hz/ppm.

differences between the three sets of data would be more pronounced. The implication of these data is that the stronger hydrogen bond formed by the benzoic acid produces a larger electric field gradient at the Co and hence a large quadrupole coupling constant and a broader line. These data also indicate that p-hydroxybenzoic acid and p-aminobenzoic acid interact primarily through the carboxylic acid group and p-aminophenol primarily through the phenolic hydroxide. The very small broadening and its poor correlation with chemical shift caused by the anilines is consistent with the hypothesis that weak hydrogen bonds have lifetimes less than the rotational correlation time of the complexes. Unfortunately the very small broadening and the consequent large percentage errors in the line width increases prevent a quantitative test of this possibility. If, however, this is the case, it is the lifetime of the complex, rather than the equilibrium constant, which limits the mechanistic importance of second sphere hydrogen bonded complexes.

Molecular rearrangements. Part XX.[1] Thermolysis of carboxylic acid esters[2]

M. M. ALY, M. Z. A. BADR, A. M. FAHMY, AND S. A. MAHGOUB
Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt, A.R.E.

Received November 25, 1982

M. M. ALY, M. Z. A. BADR, A. M. FAHMY, and S. A. MAHGOUB. Can. J. Chem. **61**, 1532 (1983).

Thermolysis of phenyl benzoate on heating under reflux for ca. 10 days in a nitrogen atmosphere gives phenol, *o*- and *p*-hydroxybiphenyl, biphenyl, and carbon monoxide. Phenyl phenylacetate under the same conditions gives toluene, bibenzyl, stilbene, phenol, *o*- and *p*-benzylphenol, 9-phenylxanthene, water, and carbon monoxide. Thermolysis of benzyl benzoate is accompanied by decarboxylation and the formation of toluene, diphenylmethane, bibenzyl, stilbene, and biphenyl. Thermolysis of benzyl phenylacetate proceeds smoothly, affording carbon dioxide, toluene, bibenzyl, and stilbene. It was concluded that thermolyses of esters proceeds through a free radical mechanism involving homolytic fission of either the O—CO or O–alkyl bond with subsequent decomposition of the radicals so formed.

M. M. ALY, M. Z. A. BADR, A. M. FAHMY et S. A. MAHGOUB. Can. J. Chem. **61**, 1532 (1983).

Le benzoate de phényle chauffé au reflux sous atmosphère d'azote pendant 10 jours environ donne le phénol, les *o*- et *p*-hydroxybiphényle, le biphényle et le monoxyde de carbone. Dans les mêmes conditions la thermolyse du phénylacétate de phényle donne le toluène, le bibenzyle, le stilbène, le phénol, les *o*- et *p*-benzylphénol, le phényl-9 xanthène, l'eau et le monoxyde de carbone. La thermolyse du benzoate de benzyle s'accompagne d'une décarboxylation avec formation de toluène, de diphénylméthane, de bibenzyle, de stilbène et de biphényle. La thermolyse du phénylacétate de benzyle donne le bioxyde de carbone, le toluène, le bibenzyle et le stilbène. On conclut que la thermolyse des esters se fait selon un mécanisme de radical libre qui implique la fission homolytique de la liaison O—CO ou O–alkyle suivie de la décomposition des radicaux formés.
[Traduit par le journal]

The isomeric change of phenolic esters to hydroxyketones under the influence of Lewis acid catalysts, known as the Fries rearrangement, has long been used for its synthetic value (1).

Recently, the photo-Fries rearrangement has been a subject of extensive study (2) and it is now well established that the process involves fragmentation into free radicals which undergo extensive geminate recombinations.

Similarly the noncatalysed thermal rearrangement of esters became of increasingly great importance, since esters can be used as additives for lube oils (3) although the mechanism is still subjudice that it may involve ketene formation or homolysis of the ester molecule at different sites, according to the stability of the radicals so formed.

The present work describes the behaviour of some carboxylic acid esters when heated at their reflux temperatures, ca. 320°C.

Thermolysis of phenyl benzoate was found to give rise to phenol, *o*- and *p*-hydroxybenzophenone, *o*- and *p*-hydroxybiphenyl, biphenyl, and carbon monoxide. Such results can be accounted for in terms of a free radical mechanism involving benzoyl–oxygen bond homolysis (route (*a*)) forming phenoxyl and benzoyl radical pairs that can undergo C—C coupling, forming the isomeric *o*- and *p*-hydroxybenzophenones. Moreover, the benzoyl radicals may undergo decarbonylation forming phenyl radicals that subsequently attack the phenol molecule to give *o*- and *p*-hydroxybiphenyl or dimerize into biphenyl (cf. Scheme 1).

However, it may be assumed that biphenyl can be obtained from dimerization of phenyl radicals formed through homolysis of the O—Ph bond of the ester (route (*b*)), yet such a suggestion was ruled out by the absence of benzoic acid or carbon dioxide, even in trace amounts. Furthermore, on pyrolysis of *p*-cresylbenzoate, no methyl-substituted biphenyls were detected among the pyrolysates.

The absence of the carbon–oxygen dimer of the phenoxyl radicals, namely, *o*- and *p*-phenoxyphenols (as proved by glc), emphasizes the results obtained from spin resonance work (4) where it is possible to deduce that ca. 80% of the unpaired spin density resides on the *ortho* and *para*-ring carbon atoms.

Moreover, the oxygen–oxygen dimer, namely, diphenylperoxide, would probably be unstable under such conditions and need not be considered (5).

Replacement of the phenyl with the benzyl group in the acid moiety of phenyl benzoate resulted in extensive decarbonylation. Thus, thermolysis of phenyl phenylacetate leads to the formation of toluene, bibenzyl, stilbene, 9-phenylxanthene, and water as neutral products together with carbon monoxide, phenol, and *o*- and *p*-benzylphenol. The formation of these products necessitates the homolysis of the CO—O bond as for phenyl benzoate, forming phenoxyl and phenylacetyl radical pairs. The phenylacetyl free radicals eventually decarbonylate to give benzyl free radicals which participate in the formation of toluene, bibenzyl, and stilbene as mentioned in previous work (6). The normal fate of phenoxyl radicals is to form phenol, through H abstraction, and isomeric *o*- and *p*-benzylphenols, through coupling with benzyl radicals. The formation of 9-phenylxanthene can be rationalized as proceeding by the mechanism suggested by Hickinbottom and El-Kobaisi (7*a*), cf. Scheme 2.

It may be assumed that the phenylacetyl free radicals may give rise to phenyl ketene (8). However, this suggestion was ruled out by the absence of phenylacetic acid among the products. Moreover, no significant amounts of *o*- and/or *p*-hydroxyphenylacetophenone were detected in such ester pyrolysis which would be exptected if the phenylacetyl free radicals survived long enough to couple with phenoxyl radicals.

On the other hand, replacement of the phenyl with the benzyl group in the phenolic moiety of phenyl benzoate gave a quite different result, where the thermolysis of benzyl benzoate gives rise to toluene, diphenylmethane, bibenzyl, stilbene, biphenyl, tetraphenylethane, and carbon dioxide. Such results imply the preliminary homolysis of the benzyl–O bond (a) rather than the benzyl–O bond (b) into benzyl and benzoate radical pairs. The

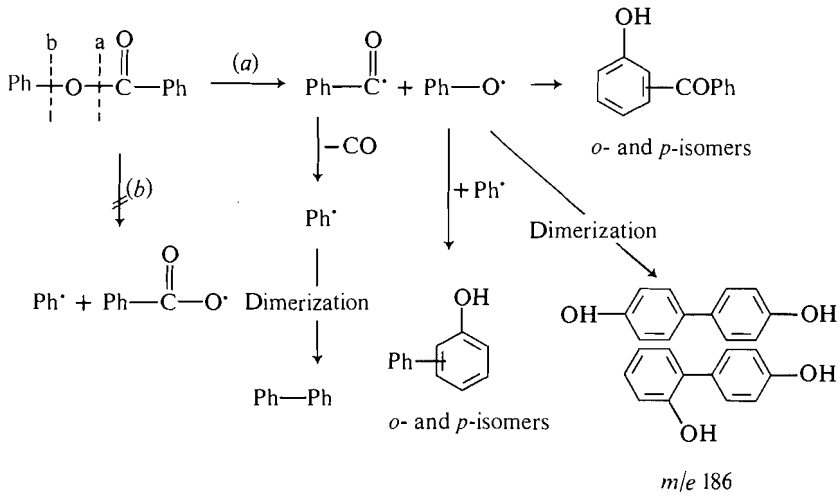
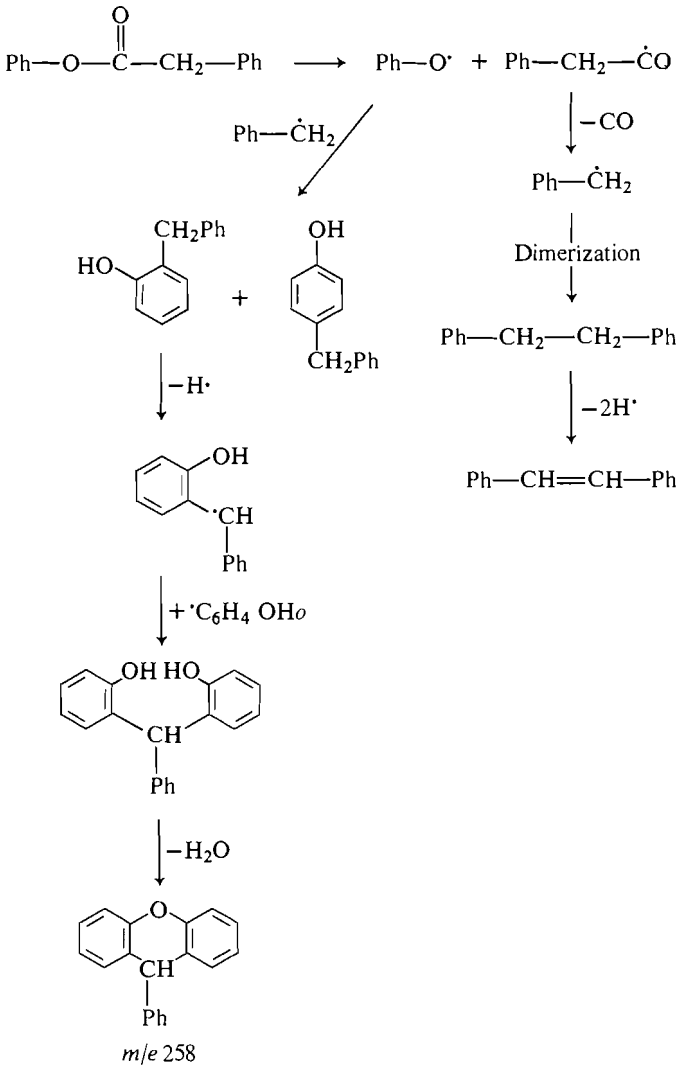


SCHEME 1



SCHEME 2

ease of rupture parallels the decrease in bond dissociation energy values, being 83 and 69 kcal mol^{-1} for (b) and (a) bonds, respectively (9). The normal fate of benzyl radicals is to form toluene, bibenzyl, and stilbene, whereas the benzoate radicals decarboxylate into carbon dioxide and phenyl radicals. Coupling of benzyl and phenyl radicals leads to the formation of diphenylmethane, while addition of phenyl radicals to the olefinic double bond of stilbene leads to the formation of tetraphenylethane (cf. Scheme 3).

The secondary attack of the free radicals on some undecomposed ester molecules need not be considered since the bulk of the products is reasonably explained on the basis of the suggested mechanism.

Homolysis of benzylic hydrogen in benzyl benzoate and phenyl phenylacetate needs higher bond dissociation energy (98.3–100.2 kcal mol^{-1}) (9) as compared with that required for the CO—O bond.

Benzyl phenylacetate undergoes facile decomposition on heating, evolving CO_2 and furnishing mainly toluene, bibenzyl, and stilbene together with an unidentified resinous material.

Experimental

All melting points are uncorrected. The ir spectroscopic analyses were carried out on a Pye–Unicam ir spectrophotometer, Model SP 200 G. The glc measurements were carried out on a Pye–Unicam gas chromatograph, "Series 104", equipped with a dual flame ionization detector, Model 24. The columns used were 4 ft × 5 mm packed with 20% SE on Chromosorb W (35–80 mesh) or 10% SE 30 on Celite (60–80 mesh). Thin-layer chromatography was carried out on glass plates covered with silica gel (25–40 mesh) and eluted with benzene–cyclohexane (3:1 v/v) or ether – petroleum ether (40–60°) (1:7 v/v). Molecular weight determinations of some reaction products were carried out by mass spectrophotometer, Model A.E.I. M.S. 902.

General procedure

The appropriate ester (20 g) was pyrolyzed by reflux under a nitrogen atmosphere for ca. 10 days (except for benzyl phenylacetate where pyrolysis was complete after 20 h reflux). The carbon monoxide formed was detected by platinum chloride test paper and absorbed in a trap containing ammoniacal cuprous chloride, whereas carbon dioxide was detected by lime water or baryta solution. The products were separated as indicated in previous work (10) and identified by tlc, glc, ir, or mixture melting point with authentic samples whenever possible. The results are shown in Tables 1 and 2.

Received October 12, 1982

ALBERT R. NORRIS, SPENCER E. TAYLOR, ERWIN BUNCEL, FRANCINE BÉLANGER-GARIÉPY, and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **61**, 1536 (1983).

$[CH_3Hg(C_4H_6N_2S)]NO_3$ belongs to space group $P\bar{1}$, $a = 7.146(2)$, $b = 7.783(3)$, $c = 10.184(5)$ Å, $\alpha = 72.95(3)$, $\beta = 71.09(3)$, $\gamma = 81.83(2)°$, and $Z = 2$. The structure was refined to $R = 0.039$ (1850 nonzero reflections). The crystal contains complex cations in which the CH_3Hg^+ ion is bonded to the exocyclic sulfur atom by a Hg—S bond of 2.382(2) Å. The nitrate ions form secondary bonds to mercury and hydrogen bonds to the acidic proton attached to N(3). $[CH_3Hg(C_4H_5N_2S)]$ is monoclinic, space group Cc, $a = 7.734(1)$, $b = 17.125(3)$, $c = 6.061(3)$ Å, $\beta = 99.66(3)°$, and $Z = 4$. Refinement converged to $R = 0.039$ (678 nonzero reflections). The crystal consists of individual monomeric molecules in which the CH_3Hg^+ ion forms a Hg—S bond of 2.338(7) Å. The molecular packing is considered as unusual, since Hg forms no intermolecular secondary bonds in the equatorial plane, even though N(3) has an available lone pair. This lone pair on N(3) is completely free, owing to the absence of H-bond donors in the structure. The applicability of HSAB theory to the present results (S- versus N-binding) is considered.

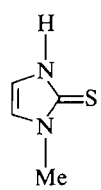
ALBERT R. NORRIS, SPENCER E. TAYLOR, ERWIN BUNCEL, FRANCINE BÉLANGER-GARIÉPY et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **61**, 1536 (1983).

Le $[CH_3Hg(C_4H_6N_2S)]NO_3$ appartient au groupe d'espace $P\bar{1}$ avec $a = 7,146(2)$, $b = 7,783(3)$, $c = 10,184(5)$ Å, $\alpha = 72,95(3)$, $\beta = 71,09(3)$, $\gamma = 81,23(2)°$ et $Z = 2$. On a affiné la structure jusqu'à une valeur de $R = 0,039$ (1850 réflexions observées). Le cristal contient des cations complexes dans lesquels l'ion CH_3Hg^+ est lié à l'atome de soufre exocyclique par une liaison Hg—S de 2,382(2) Å. Les ions nitrates forment des liaisons secondaires avec le mercure et des liaisons hydrogène avec le proton acide attaché à N(3). Le $[CH_3Hg(C_4H_5N_2S)]$ est monoclinique et appartient au groupe d'espace Cc avec $a = 7,734(1)$, $b = 17,125(3)$, $c = 6,061(3)$ Å, $\beta = 99,66(3)°$ et $Z = 4$. On a affiné la structure jusqu'à une valeur de $R = 0,039$ (678 réflexions observées). Les cristaux sont des molécules monomères individuelles dans lesquelles l'ion CH_3Hg^+ forme une liaison Hg—S de 2,338(7) Å. L'empilement moléculaire est inhabituel puisque le Hg ne forme pas de liaisons secondaires intramoléculaires dans le plan équatorial bien que le N(3) ait un doublet libre disponible. Ce doublet libre sur N(3) est complètement libre à cause de l'absence de donneurs de liaison hydrogène dans la structure. On discute des résultats en relation avec la théorie HSAB.

[Traduit par le journal]

Introduction

Structural studies of the interaction of metal ions with 1-methylimidazoline-2-thione (**1**), hereafter referred to by its trivial name methimazole, are of interest, in part because of the possible application of the resulting complexes as antitumour drugs (1). Complexes of **1** with Pt(II), Pd(II) (2), as well as Co(II) and Zn(II) (3), have been structurally characterized. It



1

has also been reported (4) that the use of methimazole (and other sulfur-containing thyroid hormone inhibitors) affords a significant degree of protection against the effects of dimethylmercury and diphenylmercury intoxication in laboratory animals. An investigation of the complexes formed by methimazole with $CH_3Hg(II)$ hence appeared to be of interest, as an extension of our studies dealing with interactions of $CH_3Hg(II)$ with imidazole derivatives (5) and various nucleic bases (6–12).

Structural identification of metal ion complexes in the imidazole and methimazole series has in the past relied heavily on spectroscopic methods such as ir and nmr and it is only recently that X-ray crystallographic studies have been used for this purpose. In this regard, the crystal structure of the free ligand is not known, but the 1,3-dimethyl analog has been studied by Ansell (13) and a number of derivatives with sugar groups as substituents have been examined by Marquez and co-workers (14, 15). Some of the molecules investigated by the latter group are analogs of 1-methylimidazoline-2-thione, since only one of the ring nitrogen atoms is blocked by an alkyl or aryl group (15). Thus, these compounds also raise the problem concerning the position of the acidic proton. This was not explicitly discussed by the authors, who assumed that the proton was attached to N(3) rather than to the exocyclic sulfur atom. We are inclined to consider this assumption as correct, because if N(3) were free (16), the C(2)—N(3)—C(4) angle should be appreciably smaller than C(2)—N(1)—C(5), which is not the case.

Complexes of 1,3-dimethylimidazoline-2-thione with $AsCl_3$ (17) and with Co(II) (18) were studied by X-ray diffraction. As expected, the metal atoms interact with sulfur, which is the only available donor atom. Blocking the sulfur atom, as in 1-methyl-2-(methylthio)imidazole results in binding to N(3), which bears no proton in this ligand (19). The problem is not so simple with 1-methylimidazoline-2-thione (methimazole), because the proton on N(3) is not an efficient blocking group.

Coordination may take place at sulfur leaving the hydrogen on N(3), but the opposite distribution cannot be ruled out. The former pattern had been found in the 2:1 adduct with $CdCl_2$ (20), and while this work was in progress, two crystallographic studies showed the same type of binding in 4:1 compounds with $Co(ClO_4)_2$ (21) and $Zn(NO_3)_2$ (22).

The two crystal structures reported here were determined in connection with preparative and solution work (8) aimed at establishing the mode of interaction of the heavy CH_3Hg^+ ion with methimazole. The ^1H nmr results favored CH_3Hg^+ binding to the exocyclic sulfur atom of these compounds in DMSO solution. However, infrared bands used by other workers to determine the binding site pointed to the opposite conclusion. Therefore, unambiguous structural information from X-ray diffraction appeared desirable.

Experimental section

$[CH_3Hg(C_4H_6N_2S)]NO_3$

$C_5H_9HgN_3O_3S$ fw = 391.80

Triclinic, space group $P\bar{1}$, a = 7.146(2), b = 7.783(3), c = 10.184(5) Å, α = 72.95(3), β = 71.09(3), γ = 81.83(2)°, V = 511.6 Å^3, D_o = 2.52 g cm^{-3} (flotation in bromoform – ethylene dichloride), D_c = 2.543 g cm^{-3}, Z = 2 formula units per cell, μ(CuKα) = 307.7 cm^{-1}, λ(CuK$\bar{\alpha}$) = 1.54178 Å, t = 23°C.

Crystals suitable for X-ray diffraction work were obtained as described elsewhere (8). The specimen used for data collection had the following distances between the indicated pairs of faces: 0.24 mm (001 and 00$\bar{1}$), 0.043 mm (100 and $\bar{1}$00), and 0.063 mm (010 and 0$\bar{1}$0).

Triclinic Laue symmetry (space groups $P1$ or $P\bar{1}$) was deduced from a set of precession and cone axis photographs. The reduced cell obtained from the films was confirmed by the autoindexing procedure carried out on 25 reflections found by the SEARCH routine and centered on an Enraf-Nonius CAD4 diffractometer. The Niggli parameters clearly indicated that the crystal could not be described in a space group of higher symmetry. The final cell parameters were obtained by least-squares refinement on the setting angles of the 25 reflections.

The intensity data were collected in the $\omega/2\theta$ scan mode. A fixed slit of 4.0 mm was used and the scan range (ω) was (1.00 + 0.14 tan θ)° extended 25% on each side for background measurements. Prescans at 10° min^{-1} were done and all weak reflections ($I < \sigma(I)$) were not remeasured at low speed. Their F_o and $\sigma(F_o)$ values were taken from the prescan counts. For stronger reflections, scan speed S between 10 and 1° min^{-1} was selected to make the $I/\sigma(I)$ ratio = 100, but a maximum scan time of 90 s was imposed. Three standard reflections were monitored every hour. They showed random fluctuations of $<\pm 4\%$ about their respective means. Crystal orientation was checked every 100 reflections by recentering three reflections. Misorientation was always <0.1° and no crystal recentering was done during data collection.

A set of 2274 independent reflections (hkl, $h\bar{k}l$, $hk\bar{l}$, and $h\bar{k}\bar{l}$, $2\theta \leq 140°$) was measured. The net intensity I was obtained from $I = (P - B/0.50)S$, where P is the total scan count and B is the total background count measured during one half of the scanning time. The standard deviation was calculated from $\sigma^2(I) = (P + B/0.25)S^2 + (0.02I)^2$. A total of 1850 reflections with $I > 2.5\sigma(I)$ was retained for structure determination. An absorption correction was applied at a later stage in the refinement (Gaussian integration, grid 10 × 10 × 10, transmission coefficient = 0.030–0.180). The data were finally corrected for the Lorentz and polarization effects.

The structure was solved by the heavy-atom method and refined by full-matrix least-squares. The centrosymmetric $P\bar{1}$ space group was assumed first. Mercury was positioned from a three-dimensional Patterson synthesis and all nonhydrogen atoms were located from a subsequent difference Fourier synthesis (ΔF) phased on Hg. Isotropic refinement led to the R index $\Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.132$. Anisotropic refinement reduced R to 0.069. At this point, the absorption correction was applied and the R factor reduced to 0.039. The hydrogens attached to C(4), C(5), and N(3) were fixed at their ideal positions (C—H = 0.95, N—H = 0.85 Å, B_{iso} = 6.0 Å^2). Their parameters were not refined, but their coordinates were recalculated after each cycle of refinement. The hydrogens of the methyl groups could not be clearly distinguished from the general background in the ΔF map. Individual weights based on counting statistics were applied in the last least-squares cycles. Anisotropic refinement converged to R = 0.039 and $R_w = [\Sigma_w(|F_o| - |F_c|)^2/\Sigma_w|F_o|^2]^{1/2} = 0.055$. The goodness-of-fit ratio was 2.41 (118 parameters varied). There were no indications in the final ΔF map that the space group could be $P1$ instead of $P\bar{1}$. The map contained a few peaks of 1.0–1.5 e/Å^3 within 1.4 Å from Hg and the general background was $<\pm 0.66$ e/Å^3.

TABLE 1. Refined fractional coordinates

$[CH_3Hg(C_4H_5N_2S)]$

$C_5H_8HgN_2S$ fw = 328.79

Monoclinic, Cc, a = 7.734(1), b = 17.125(3), c = 6.061(3) Å, β = 99.66(3)°, Z = 4, D_o = 2.74(2) g cm^{-3}, D_c = 2.759 g cm^{-3}, λ(MoK$\bar{\alpha}$) = 0.71069 (graphite monochromator), μ(MoKα) = 196.1 cm^{-1}, t = 23°C.

The specimen used had the following dimensions: 0.068 mm (1$\bar{1}$0 and $\bar{1}$10) × 0.112 mm (110 and $\bar{1}\bar{1}$0) × 0.48 mm (001 and 00$\bar{1}$). Space group Cc or $C2/c$ were deduced from a set of precession and cone axis photographs (systematic absences: hkl, $h + k \neq 2n$; $h0l$, $l \neq 2n$). The data were collected as described above, with a scan range of ω = (1.0 + 0.35 tan θ)°. A set of 908 independent hkl and $hk\bar{l}$ reflections was collected ($2\theta \leq 55°$), of which 678 had an $I/\sigma(I)$ ratio >3.0. An absorption correction was applied (transmission factor = 0.08–0.35).

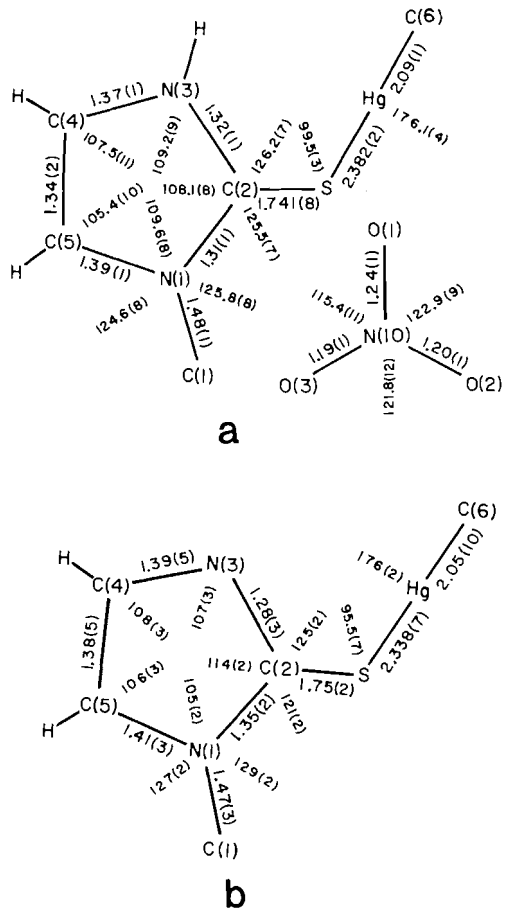

FIG. 1. Numbering scheme and intramolecular interatomic distances and bond angles. *a* = $[CH_3Hg(C_4H_6N_2S)]NO_3$; *b* = $[CH_3Hg(C_4H_5N_2S)]$.

In space group $C2/c$ (general equipoint of order 8), the molecule would have to sit on a symmetry element. The Patterson map showed no peaks that could be assigned to vectors between Hg atoms occupying equipoints $4a$ to $4d$. Equipoint $4e$ (two-fold axis) could not be ruled out at this stage. However, the four S atoms would have to lie on a symmetry element as well. This would introduce specialization in the Hg—S vectors (u and w = 0, 1/4 or 1/2). No peaks corresponding to such vectors could be found, even though their heights should have been just below those of the Hg—Hg vectors. These considerations, as well as the fact that a structure in which Hg would lie on a two-fold axis appeared unlikely, led us to solve the structure in space group Cc. The Hg atom was positioned on a general equipoint. Its y coordinate was determined from the Patterson map, whereas the x and z coordinates were arbitrarily chosen to fix the origin. Since the Hg atoms defined a centrosymmetric set, the resulting ΔF map was expected to contain a pair of overlapping images related by the pseudo-inversion center. The pair of strong peaks corresponding to the S atoms in these images was easily recognized in the map. One of them was arbitrarily used to fix the enantiomorph. A ΔF map phased on Hg and S revealed the positions of the atoms in the five-membered ring.

Isotropic refinement led to R = 0.089. Anisotropic refinement of all nonhydrogen atoms (H(4) and H(5) fixed with B = 6.0 Å^2 and methyl hydrogens not found) converged to R = 0.039 and R_w = 0.043. The goodness-of-fit ratio was 1.31 (78 parameters varied). The final ΔF map had a general background $<\pm 0.35$ e/Å^3, with some peaks of 0.9–1.2 e/Å^3 near Hg.

A few extra cycles of refinement were calculated after changing the signs of all coordinates, in order to determine whether anomalous dispersion could distinguish between the two enantiomorphic structures. The parameters changed by $\leq 0.8\sigma$ and the R factor remained the same. This is not surprising, since the Hg atoms, which are the only significant contributors to anomalous dispersion (f'_{Hg} = −2.7, f''_{Hg} = 9.3, f'_S = 0.13, f''_S = 0.16), define a centrosymmetric arrangement.

The refined coordinates for both structures are listed in Table 1. Lists of structure factors and thermal parameters are available upon request.[2] The scattering curves were those of Cromer and Waber (23) except for hydrogen (24). Anomalous dispersion terms f' and f'' for Hg and S were taken from Cromer (25).

Description of the structure and discussion

The structures are schematically represented in Fig. 1, with interatomic distances and bond angles.

$[CH_3Hg(C_4H_6N_2S)]NO_3$

The ligand in the $[CH_3Hg(C_4H_6N_2S)]^+$ cation behaves as observed in the Cd(II) (20), Co(II) (21), and Zn(II) complexes (22): the acidic hydrogen is bound to N(3) and the metal is attached to sulfur. Mercury exhibits its common linear coordination (S—Hg—C(6) = 176.1(4)°). It forms a Hg—C bond of normal length (2.09(1) Å) (26) and the bond to the exocyclic sulfur atom (Hg—S = 2.382(2) Å) is typical of two-coordinated mercury forming a number of extra secondary bonds (27). The metal–sulfur bond is not coplanar with the ring (Hg—S—C(2)—N(1) = −134°) and the angle at sulfur is ~100°.

Crystal structures on seven imidazoline-2-thione moieties having a free thione group give an average value of 1.691 Å for the C(2)=S bond length (see supplementary material). This bond is lengthened to 1.741(8) Å upon CH_3Hg^+ coordination and a similar lengthening was observed in the $AsCl_3$ complex with the dimethyl derivative (17). Metal coordination, as well as methylation, to sulfur is likely to reduce the double bond character of C(2)=S and it appears to be reasonable that the C—S distances in the complexes approach the value found in the S-methylated compound (1.74 Å) (19). It is not clear, however, why the lighter elements seem to affect the C(2)=S bond to a much smaller extent: Zn (21), 1.708 Å; Co (22), 1.717 Å; Co (18), 1.696 Å.

Within the experimental error of the present study, the geometry of the five-membered ring is not significantly modified by complexation to sulfur (21). The ring, including the N(1)-methyl group, is planar within 2.5σ (0.028 Å), but the sulfur-to-plane distance is large (0.130(2) Å). The almost identical internal C—N—C angles at N(1) and N(3) confirm the presence of a hydrogen atom attached to N(3), since an angle 4–5° smaller is expected for a free lone pair on nitrogen (16).

The nitrate ion shows the expected trigonal structure and it is planar within 0.5σ (0.005 Å).

As is usually the case in the solid state, two-coordinate mercury expands its coordination number by forming weak bonds in the equatorial plane (assuming C—Hg—S as the axial direction) (Table 2). Oxygens O(1) of two nitrate ions bridge a pair of mercury atoms (Fig. 2), thus leading to a centrosymmetric dimeric unit. Each of these oxygens is much more strongly bonded to one mercury (2.833 Å) than to the other (3.153 Å). On the same side as the weaker contact, O(1)

[2]Tables of observed and calculated structure factor amplitudes, anisotropic temperature factors, and least-squares plane calculations are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0S2.

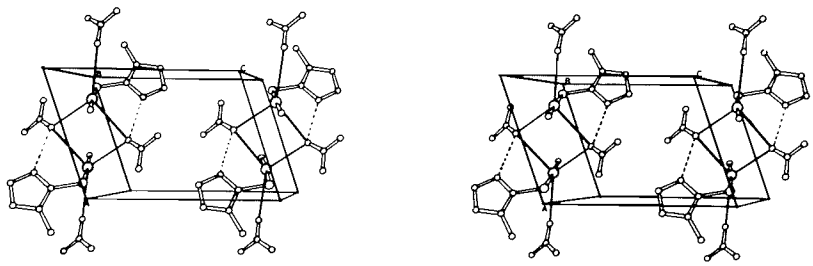

FIG. 2. Stereo view of the unit cell of $[CH_3Hg(C_4H_6N_2S)]O_3$ down the b^* axis. The origin is at the top left corner of the cell, a and c are in the plane of the figure (a down, c to the right). Mercury is shown as a larger sphere and O(1) is the bridging oxygen of the nitrate ions. The remaining atoms can be identified by reference to Fig. 1. Hydrogens are omitted.

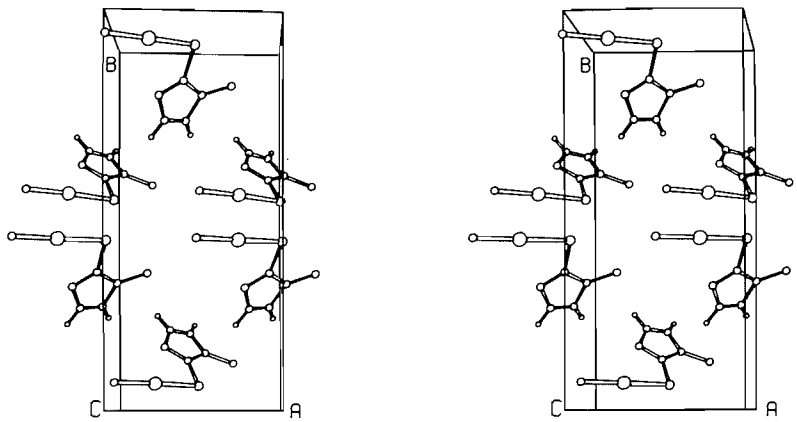

FIG. 3. Stereo view of the unit cell of $[CH_3Hg(C_4H_5N_2S)]$. Mercury is shown as a larger sphere and hydrogens are omitted. The atoms can be identified by reference to Fig. 1.

acts as the acceptor in a strong H-bond involving N(3)—H(3): N(3)—O(1) = 2.79(1) Å, C(2)—N(3)—O(1) = 116.9(6)°, C(4)—N(3)—O(1) = 133.9(8)°, N(10)—O(1)—N(3) = 115.1(6)°. Each Hg atom completes a (2+3)-coordination by interacting weakly with O(2) of a nitrate ion belonging to another dimer (Hg...O(2) = 3.10 Å).

$[CH_3Hg(C_4H_5N_2S)]$

The structure consists of individual monomeric molecules in which the CH_3Hg^+ ion is coordinated to the sulfur atom of the ligand in its anionic form (Fig. 1*b*). Mercury is linearly coordinated as usual and the Hg—CH_3 bond length is normal. The angle at sulfur (95.5(7)°), although smaller than in the previous compound, is still in the normal range. The lengthening of the C2=S bond, discussed above, is again observed but in this case, the large standard deviations make the effect barely significant. The CH_3Hg^+ lies in the plane of the ring, with a

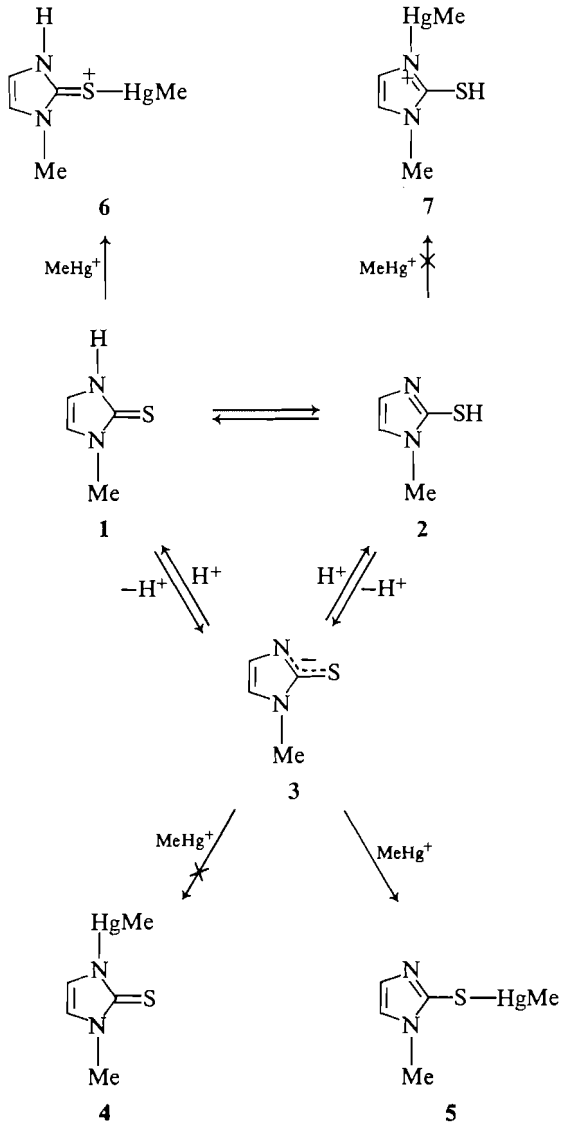

SCHEME 1

Hg—S—C(2)—N(1) torsion angle of 182(2)°. It is noteworthy that the Hg—S bond (2.338(7) Å) is significantly shorter than in the cationic complex (2.382(2) Å). As shown in the packing diagram in Fig. 3, mercury does not form the usual intermolecular contacts with donor atoms on adjacent molecules, in spite of the fact that lone pairs are available on N(3) and S. The absence of such intermolecular contacts may provide the explanation for the reduction in the Hg—S bond length.

The light-atom coordinates have high esd's and the large resulting errors on the geometry of the ring preclude any comparisons with other structures.

Discussion

In both of these compounds, the CH_3Hg^+ ion exhibits its usual behavior, forming only one additional short bond and showing linear two-coordination. The absence of any secondary bonds by intermolecular contacts with N(3) or S in $[CH_3Hg(C_4H_5N_2S)]$ is somewhat surprising, however.

The lengthening of the C=S bond observed upon coordination suggests that it is close to a single bond in the complexes. As further support for this assumption, one can point out that the metal–sulfur bond is not forced into a particular orientation with respect to the ring: the CH_3Hg^+ group lies in the plane of the ring in $[CH_3Hg(C_4H_5N_2S)]$, but it makes an angle of −134° in $[CH_3Hg(C_4H_6N_2S)]NO_3$. A wide range of orientations has also been found in other complexes (15, 21, 22). Thus, it seems that the metal—S—C(2)—N(3) torsion angle is not imposed by electronic effects, but by crystal packing. It is likely that the CH_3Hg^+ group can rotate unhindered in the free molecule.

Since the X-ray crystallographic studies here reported have confirmed our previous conclusions based on chemical and spectroscopic studies (8), some observations can be made as to the applicability of HSAB theory (28, 29) concerning reactivity in these systems.

The neutral complex $[CH_3Hg(C_4H_5N_2S)]$ (**5**) is derived by the action of CH_3Hg^+ on the deprotonated species **3**, in aqueous solution under basic conditions. Interestingly, the tautomeric equilibrium between **1** and **2** (Scheme 1) has been found to favor predominantly **1** in several solvents (8) (see, however, ref. 6). These results, i.e. coordination of CH_3Hg^+ to the sulfur atom of **3** while H^+ coordinates to the nitrogen, are readily accommodated on the basis of HSAB theory. Thus the soft Hg atom prefers the soft sulfur site, the harder N3 atom being used to accept the hard H^+ cation.

Formation of the cationic complex $[CH_3Hg(C_4H_6N_2S)]NO_3$ (**6**) can also be discussed on the basis of Scheme 1, which considers coordination of CH_3Hg^+ to either of the neutral tautomeric species **1** or **2**. That **6** is favored exclusively over **7** is again in complete accord with expectations on the basis of HSAB theory.

Motional behavior of 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose in solution. A ^{13}C spin-lattice relaxation study

PHOTIS DAIS AND ARTHUR S. PERLIN
Department of Chemistry, McGill University, Montreal (Que.), Canada H3C 3G1

Received December 1, 1982

PHOTIS DAIS and ARTHUR S. PERLIN. Can. J. Chem. **61**, 1542 (1983).

^{13}C nuclear magnetic resonance spin-lattice relaxation times (T_1) have been used to probe the motional behavior of 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose (**1**) in dimethyl sulfoxide solution. This system offers structural features well suited to the study of a variety of internal motions, i.e., ring oscillation, ring puckering interconversion, and methyl internal rotation, all of which are superimposed on an isotropic overall reorientation. Among various models examined to evaluate internal rotations, a two-sites jump model was found satisfactory for interpreting the oscillation and puckering motions of the flexible 5,6-*O*-isopropylidene ring, whereas a diffusional model described hindered rotation of the geminal methyl groups of the rigid 2,3-*O*-isopropylidene ring from 15° to 80°C. The activation energy associated with the temperature dependence of the rate of overall molecular tumbling was found to agree with the hydrodynamical prediction of 4.57 kcal/mol associated with the temperature dependence of the ratio (η/T). In addition, an explicit treatment of the relaxation data vs. solution viscosities, as a function of temperature, indicated that **1** reorients under the "slip" boundary conditions.

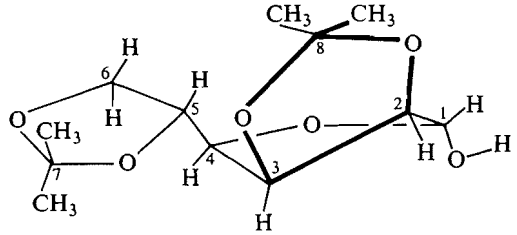
PHOTIS DAIS et ARTHUR S. PERLIN. Can. J. Chem. **61**, 1542 (1983).

On a fait appel aux temps de relaxation spin réseau (T_1) en rmn du ^{13}C pour étudier le mouvement du di-*O* isopropylidène 2,3:5,6-α-D mannofurannose (**1**) en solution dans le diméthylsulfoxyde. Ce système présente des caractéristiques structurales qui conviennent parfaitement à l'étude de divers mouvements internes, i.e. l'oscillation du cycle, l'interconversion gauche du cycle et la rotation interne du méthyle, qui se superposent tous à une réorientation globale isotropique. Parmi les divers modèles étudiés pour évaluer les rotations internes, on a trouvé un modèle discontinu à deux sites satisfaisant pour interpréter les mouvements d'oscillation et de gauchissement du cycle flexible de *O*-isopropylidène-5,6 tandis qu'un modèle de diffusion décrit la rotation des groupes méthyles géminés du cycle rigide de *O*-isopropylidène-2,3 entre 15° et 80°C. On a trouvé que l'énergie d'activation associée à l'influence de la température sur la vitesse du mouvement moléculaire global s'accorde avec la prédiction hydrodynamique de 4,5 kcal/mol associée à l'influence de la température sur le rapport (η/T). De plus un traitement explicite des données de relaxation versus la viscosité de la solution, en fonction de la température indique que le composé **1** se réoriente dans des conditions limites de "glissement".

[Traduit par le journal]

Introduction

Measurements of ^{13}C nmr spin-lattice relaxation provide (1–5) valuable information about the molecular dynamics of compounds in solution. Relaxation data are utilized in the present study to describe the motional behaviour of a carbohydrate acetal derivative, namely 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose (**1**). Some conformational properties of **1** were described recently (6), in particular, the favoured orientation of its anomeric hydroxyl group in methylsulfoxide. More generally, however, compound **1** is a useful model for the examination of multiple internal rotations of differing angular amplitudes. Here, attention is focused on motional features of the two *O*-isopropylidene substituents of the molecule, i.e., internal barriers to rotation of the *C*-methyl groups, librational motions of the rings, and interconversions between their puckered conformations.



1

Precise details about the dynamics of such a molecule as **1** are not likely to be readily accessible (7, 8), since several degrees of freedom exist for contributions to the relaxation of C—H vectors within its flexible segments, as well as because of difficulty in partitioning observed relaxation times (or rates) into individual contributions from different origins. However, the examination of **1** was facilitated by the fact that one or more of the motional components proved to influence the relaxation of some nuclei but not others, and that **1** exhibits (6) overall isotropic molecular tumbling. Moreover, a relatively broad approach was taken, through the application of different motional models that allow for both internal motion and overall isotropic diffusion. As will be shown, interpretations of the relaxation measurements carried out with **1** over the temperature range 15–80°C are strongly dependent on the models adopted. Also, internal jump models suggested by theoretical calculations proved to be the most satisfactory in accounting for the effects of temperature on the spin-lattice relaxation of ^{13}C nuclei of the *O*-isopropylidene substituents. Finally, viscosity as well as nmr data suggest that **1** reorients according to the "slip" hydrodynamic model.

Experimental

^{13}C nuclear magnetic resonance relaxation experiments were conducted at 50.3 MHz under conditions of full ^1H-noise decoupling with a Varian XL-200 spectrometer, equipped with a variable temperature probe. The temperature was controlled to within ±0.3°C by the computer of the spectrometer, by means of a precalibrated copper–constantan thermocouple in the probe insert. The spin-lattice relaxation times were measured by the standard two-pulse inversion recovery technique. The pulse duration for a 180° flip angle, checked periodically by producing a null in the amplitude of the fid, was 28 μs, whereas the acquisition time was 1.023 s with an 8 kHz spectral window and 16 384 data points. The waiting time between sequences was 5× the estimated value of the longest T_1 at each temperature and

[a] By employing the two states puckering model as expressed by eq. [2].
[b] $\tau_A = \tau_B = 10^{-12}$ s.
[c] The values within parentheses are the angles θ which reproduce the experimental data.
[d] $\tau_A = 10^{-12}$ s, $\tau_B = 2 \times 10^{-12}$ s.
[e] $\tau_A = \tau_B = 10^{-11}$ s and θ equal the values in the 6th column; see footnote (*b*).
[f] $\tau_A = \tau_B = 10^{-10}$ s and θ values as in footnote (*e*).

a total of 100 scans was accumulated for each spectrum. Typically, 15–20 equispaced τ values were used, covering approximately a 2.0 s T_1 range, and the τ values were "arrayed" in each run by utilizing the XL-200 program. To minimize systematic errors, and factor out time as a variable in long experiments, the interleaving procedure available with the spectrometer was used. Values of T_1 were determined by a two-parameter fit using an equilibrium magnetization value (M_0) that was the average of at least four separate determinations. The probable error in the two-parameter fit in the T_1 calculations was ±5% or better at each temperature whereas, in general, the reproducibility was 5–10%, the upper limit pertaining at high temperatures. Samples of 1.0 *M* of **1** in DMSO-d_6 were degassed by three freeze–pump–thaw cycles before use. The ^{13}C nOe measurements were carried out on the same spectrometer by "gated decoupling" (9), three experiments being performed for each nOe value. Delays of at least 10× the longest T_1 were used between the 90° pulses.

Viscosity measurements were performed with a precalibrated Ubbelohde viscometer immersed in a silicone bath, at temperatures varying by not more than ±0.1°. Density measurements were made with a bicapillary pycnometer at the same temperatures in the same bath. Solutions of 1.0 *M* 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose in DMSO-d_6 were employed for all of the measurements.

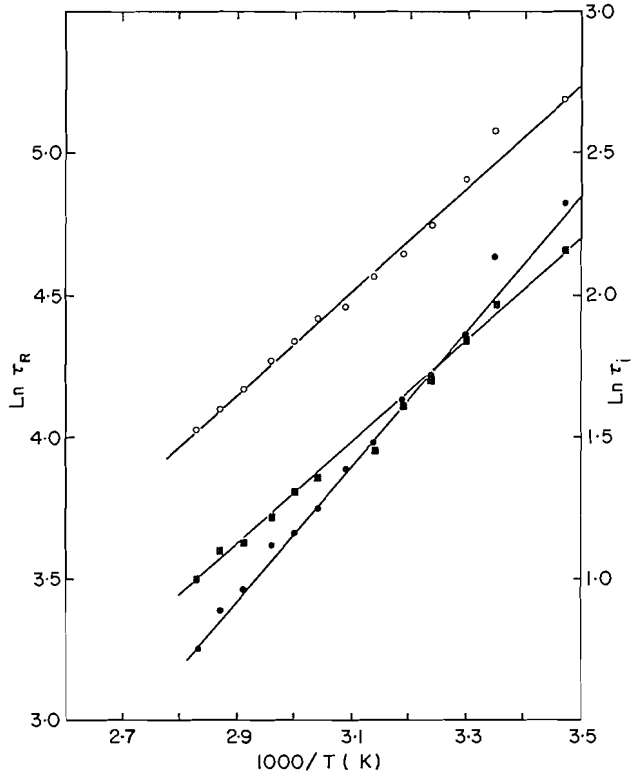

FIG. 1. Temperature dependence of the overall (τ_R) and methyl internal rotation rates (τ_i) of **1** in DMSO-d_6 solution. (●) Overall molecular motion; (○) *exo* methyl group; (■) *endo* methyl group.

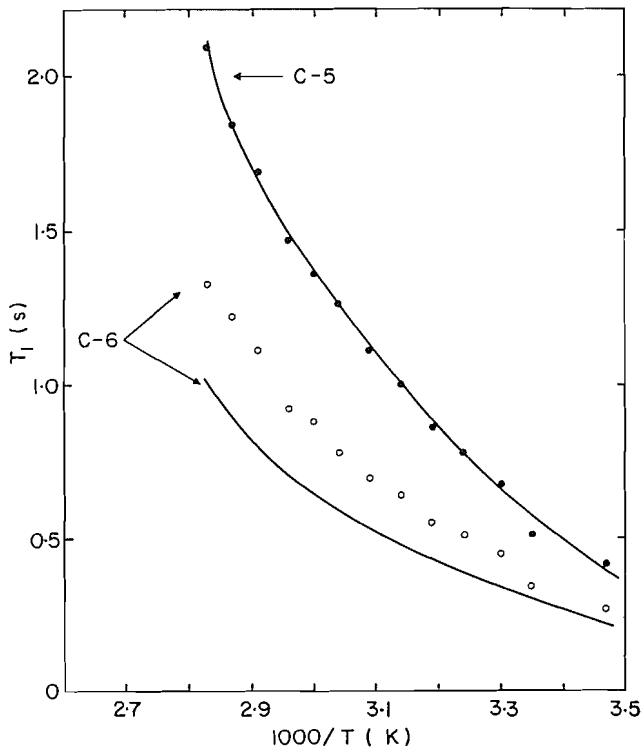

FIG. 2. Simulation of $1/T$ dependence of T_1 of C-5 and C-6 of **1**. The theoretical curves (solid lines) have been calculated with τ_R values from Table 2, taking $\tau_G = 0.8 \times 10^{-14}$ s, $E_G = 6.41$ kcal/mol.

Results and approximate analysis

Overall molecular motion

Carbon-13 T_1 values obtained from 15°C to 80°C for the protonated carbons of **1** are summarized in Table 1. The nOe factors for several sets of measurements (Table 1) indicate that the protonated carbons of **1** relax at all temperatures predominantly via the dipole–dipole interaction. T_1 values of carbons 1 to 4 of the mannose ring increase with increasing temperature in accord with the dipole relaxation theory (3, 4) and as these values are equal within experimental error at each temperature, it is clear that **1** reorients isotropically as a whole. Table 2 lists the numerical average of the T_1 values ($T_{1,R}$) for each temperature or, better, the average of the correlation times, (τ_R) calculated by means of eq. [1], which reflects the rate of the overall orientation of the molecule about its center of mass

$$[1] \quad \frac{1}{T_1} = \frac{N\gamma_H^2\gamma_C^2\hbar}{r_{C-H}^6}\tau_R$$

Equation [1] holds for isotropic motion and in the extreme narrowing approximation of a dipolar process, which is met in the present study as confirmed by the maximum values of the nOe factors (Table 1). γ_H and γ_C are the gyromagnetic ratios of ^1H and ^{13}C nuclei respectively, $2\pi\hbar$ is Planck's constant, N is the number of protons directly attached to the carbon of interest, and r_{C-H} is the C—H bond length (equal to 1.08 Å).

An Arrhenius plot of τ_R on a logarithmic scale vs. reciprocal temperature (K^{-1}) (Fig. 1) yields an activation energy of 4.88 ± 0.64 kcal/mol with a pre-exponential factor $\tau_R = 2.5 \pm 1.5 \times 10^{-14}$ s.

5,6-O-Isopropylidene ring

As seen in Table 1, the relaxation times of carbon-5 and, particularly, carbon-6 of the flexible 5,6-*O*-isopropylidene ring are longer than predicted by eq. [1] assuming that these carbons relax only via the overall motion of the molecule. This lack of agreement suggests that additional degrees of freedom influence the relaxation of the C-5—H-5 and C-6—H-6, C-6—H-6′ vectors.

Stereochemical models suggest that rotation of the ring about the C-4—C-5 axis is severely hindered mainly by nonbonded interactions involving the methyl groups. Therefore, the motion of the ring about this axis may be regarded as an oscillation with a certain angular amplitude. In attempting to simulate the experimental T_1 data in terms of molecular motional characteristics, possible models were evaluated. Some theoretical expressions (10–14) describe internal motion as a jump between several stable conformations. According to these models, the rates of jumping or, equivalently, the lifetimes of the various conformations, determine the relaxation rates. However, the fact that low-amplitude diffusion is ineffective (12, 13) in causing relaxation suggests that a jump model involving relatively few conformations should be generally suitable for describing relaxation. Consequently, a model consisting of two alternate conformational states is taken to be an appropriate description of oscillation in the flexible 5,6-*O*-propylidene ring of **1**. This leads to an evaluation of T_1 in terms of the overall diffusion rate, the internal diffusion rates (or, equivalently, the lifetimes of the two states), the angle between a particular C—H vector and the axis about which it rotates due to the jump, and the range through which the C—H vector jumps. When τ_R is the molecular correlation time for overall isotropic motion, τ_A and τ_B are the life times of the two stable states, the angle β is defined by the relaxation vector and the axis about which the vector jumps, and θ is one-half of the jump range (i.e., the jumps in between $-\theta$ and $+\theta$), the spin-lattice relaxation time is given by (12, 13)

$$[2]\quad \frac{1}{T_1} = \frac{N\gamma_H^2\gamma_C^2\hbar^2}{r_{C-H}^6}\left[(1-C)\frac{\tau_R}{1+\omega^2\tau_R^2} + C\frac{\tau_N}{1+\omega^2\tau_N^2}\right]$$

where

$$[3]\quad \tau_N^{-1} = \tau_R^{-1} + \tau_C^{-1},\ \tau_C^{-1} = \tau_A^{-1} + \tau_B^{-1}$$

and

$$[4]\quad C = \frac{3\tau_A\cdot\tau_B}{(\tau_A+\tau_B)^2}[\sin^2\beta(1-\cos 2\theta)][2-\sin^2\beta(1-\cos 2\theta)]$$

In a model corresponding to the limit $\tau_A = \tau_B$, which was derived by Ghesquiere *et al.* (11) to interpret the dynamic behaviour of the pyridyl ring in poly(4-vinyl pyridine), which is adopted here, the relation obtained for the dipolar relaxation rate of ^{13}C is given (11) by

$$[5]\quad \frac{1}{T_1} = \frac{3}{80}\frac{N\gamma_H^2\gamma_C^2\hbar^2}{r_{C-H}^6}\left\{A_1\left[\frac{\tau_R}{1+(\omega_H-\omega_C)^2\tau_R^2} + \frac{3\tau_R}{1+\omega_C^2\tau_R^2} + \frac{6\tau_t}{1+(\omega_H+\omega_C)^2\tau_R^2}\right] + A_2\left[\frac{\tau_t}{1+(\omega_H-\omega_C)^2\tau_t} + \frac{3\tau_t}{1+\omega_C^2\tau_t^2} + \frac{6\tau_t}{1+(\omega_H+\omega_C)^2\tau_t^2}\right]\right\}$$

where

$$[6]\quad A_1 = \frac{2}{3}(1-3\cos^2\beta)^2 + \sin^2 2\beta(1+\cos\theta) + \sin^4\beta(1+\cos 2\theta)$$

$$A_2 = \sin^2 2\beta(1-\cos\theta) + \sin^4\beta(1-\cos 2\theta)$$

τ_t is the correlation time defined as

$$[7]\quad \tau_t^{-1} = \tau_R^{-1} + \tau_G^{-1}$$

τ_G being the correlation time of the oscillation. The other parameters in eqs. [5] and [6] have their usual meaning, as before. In the limit $\tau_A = \tau_B = \tau_G$ eqs [2] and [5] become identical, with coefficients $C = 3/8\,A_1$ and $(1-C) = 3/8\,A_2$.

In molecular system **1**, the fixed axis of the oscillation is the C-4—C-5 axis, $\beta = 111.5°$, and $\omega_H = 5.65\times10^8$ rad/s and $\omega_C = 1.42\times10^8$ rad/s, for the 200.1 and 50.3 MHz observed frequencies of ^1H- and ^{13}C-nuclei, respectively. When eq. [5] is used for fitting the theoretical $T_1 = f(1/T)$ curves to experimental data for C-5 and C-6, therefore, the other parameters needed are θ, τ_R, $\tau_G°$, E_G the pre-exponential factor, and the activation energy of the oscillation. Parameter τ_R for the isotropic motion of **1** for each temperature is given in Table 2. Therefore, the best fit of the T_1 vs. $1/T$ curve was obtained by choosing the smallest possible value of θ corresponding to the experimental T_1 for each value of τ_G, the procedure being repeated to obtain optimal agreement over the whole temperature range. Figure 2 shows the simulation of the $1/T$ dependence of T_1 for C-5, obtained by taking $\tau_G° = 0.80\times10^{-14}$ s, $E_G = 6.41$ kcal/mol, and an oscillation amplitude varying from 30° – 70° and increasing with temperature between 15°C and 80°C. It was then found that the application of eq. [2] with the condition that $\tau_A = \tau_B = \tau_G = 10^{-10}$ s, led to the same conclusion for C-5 as far as the angular amplitude of oscillation is concerned. Hence the 5,6-*O*-isopropylidene ring

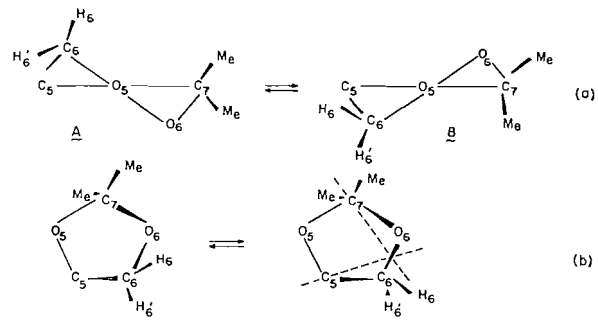

FIG. 3. Dynamic models for the flexible 5,6-*O*-isopropylidene ring in **1**. (a) Interconversion between two antisymmetric C_2 forms; (b) Same, as viewed perpendicular to the C_5—O_5—C_7 plane. The two effective internal jump axes are indicated by dotted lines.

oscillates between two stable states with a rather high activation energy. Also, the slow internal correlation times relative to the correlation time of the overall motion indicate that ring oscillation does not significantly affect the relaxation of C-5, despite the increase in the oscillation amplitude with increasing temperature.

It may be noted that several sets of parameters fit the relaxation data in both models. At a given temperature, a combination of low 2θ amplitudes (10° – 15°) and fast jump rate (10^{-11} – 10^{-12} s) leads to the same experimental T_1 value as a larger amplitude and slow jump rate. However, the number of possible solutions is drastically reduced by reference to coupling constants (6). Hence, $^3J_{H\text{-}4,H\text{-}5}$ coupling (6.38 Hz) indicates that the equilibrium orientation of the C-5—H-5 vector with respect to the C-4—H-4 vector is intermediate between *gauche* and *trans*; i.e., the ring performs an oscillational motion with an amplitude of about 60°.

A final result worth noting is related to the different stabilities of the two states characterized by the τ_A and τ_B lifetimes. If, for instance, $\tau_A \gg \tau_B$, then no relaxation effect would be observed even if $\tau_A \ll \tau_R$. However, this is not true for the present system, as indicated by the relaxation data, at high temperatures especially, where T_1, C-5 > $T_{1,R}$ (Tables 1 and 2). Calculations of T_1 performed using $\tau_A = 10^{-10}$ s, $\tau_B = 2\times10^{-10}$ s and $\tau_A = 10^{-10}$ s, $\tau_B = 3\times10^{-10}$ s resulted in small increases (2° – 3°) in the values of θ. Although the resulting range of motion does not change appreciably, it is not unreasonable that the lifetimes of the states could differ by a factor of 2 or 3. The set of parameters used to evaluate T_1 of C-5 does not also fit for T_1 of C-6 (Fig. 2). This discrepancy, which increases with temperature, is a consequence of the different β angles formed by the C-6—H-6 (−58°) and C-6—H-6′ (43°) vectors with respect to the oscillation axis, and results in an average T_1 value for C-6. However, a second source of the large deviation observed between theoretical and experimental T_1's (Fig. 2) may be found in the puckering motion of the flexible *O*-isopropylidene ring. Not only can this motion be justified by the relaxation data but also from C—H and H—H coupling constants, which demonstrated (6) the existence of a conformational equilibrium between two sites characterized by the *gauche* or *trans* orientation of O-6 with respect to H-5. Puckering motion of this kind has been treated quantitatively for other systems, particularly for the tetrahydropyrrole ring of proline, either when the amino acid was free or was incorporated into various peptides (12).

From the foregoing discussion it is seen that the C-6—H-6, H-6′ vectors relax via three types of motion: (1) librational

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

reorientation of the isopropylidene ring about the C-4—C-5 axis, (2) puckering motion of the ring, and (3) isotropic overall reorientation. However, the derivation of a theoretical expression of relaxation time that partitions these three motional components is not straightforward, even if these motions are considered to be independent.

A comparison between the relaxation times of C-5 and $T_{1,R}$ (Tables 1 and 2) shows only a small difference, which ranges from 8% at 15°C to 16% at 80°C. Consequently, the terms containing the τ_G correlation time in the general equation may be omitted, and the equation simplified to eq. [5] or to the more general eq. [2]. Now τ_A and τ_B represent the lifetimes of the isopropylidene ring in the two stable states A and B, defined in Fig. 3a, which depicts the interconversion between two antisymmetric twisted forms. This model assumes that atoms C-5—O-5—C-7 are nearly coplanar, and that C-6 occupies an *endo* or *exo* position relative to the C-4—C-5 axis. Angle β is formed by the C-6—H-6, H-6′ vectors and the two effective internal jump axes (12), represented by dotted lines in Fig. 3b, where the ring is viewed perpendicular to the C-5—O-5—C-7 plane; 2θ is the total range through which the C-6—H-6 and/or C-6—H-6′ vectors move from $-\theta$ to $+\theta$. A value of 77.7° for angle β was calculated by taking bond lengths of C-5—C-6 = 1.55 Å, C-5—O-5 = C-6—O-6 = C-7—O-7 = 1.43 Å, and bond angles for O-5—C-5—C-6 = O-5—C-6—O-6 = O-5—C-7—O-6 = 104°, and C-7—O-5—C-5 = C-7—O-6—C-6 = 108°. This geometry of the isopropylidene ring was based on several crystallographic data for *O*-isopropylidene aldofuranose derivatives (ref. 26 in ref. 8). T_1 values calculated for C-6 using different τ_A and τ_B lifetimes are summarized in Table 2 for comparison with experimental data. The best fit was obtained with $\tau_A = 10^{-12}$ s and $\tau_B = 2 \times 10^{-12}$ s and a range of $2\theta = 40° - 48°$. Good results also were obtained by the use of $\tau_A = \tau_B = 10^{-12}$ s, although these lifetimes resulted in small decreases in the values of 2θ, i.e., 40° – 42°. Overall, the range through which the C-6—H-6, H-6′ vectors move is within the range of motion found (12, 13) for most proline derivatives studied. The calculated ratios of NT_1, C-6/NT_1, C-5 fall significantly below 2, suggesting that the stabilities of the two twisted forms of the isopropylidene ring (Fig. 3a) may differ. This is also consistent with the indication (6) from coupling constants that conformation B is preponderant. Therefore, the lifetimes of the two conformations may differ by a factor of 2 to 3.

The experimental data can be reproduced as well by using $\tau_A = \tau_B = 10^{-11}$ s and $\tau_A = \tau_B = 10^{-10}$ s, together with a substantial increase in the range of motion, i.e., $2\theta \sim 60°$ and 80°, respectively. However, as this alternative corresponds to a slow puckering motion approximating the low rate of oscillation of the ring and, therefore, should have little influence on the relaxation of C-6, it is not in agreement with the experimental data.

Methyl groups

Two pairs of geminal *C*-methyl groups are attached to the molecular frame of **1**. That the internal rotation of these groups is hindered can be verified by the negligible contribution of the spin-rotation mechanism to the relaxation of the four symmetric tops at all temperatures (Table 1). Furthermore, the maximum values of the nOe factors (Table 1) suggest an explicit relationship between the dipolar T_1's and the methyl barrier to rotation, which reflects the magnitude of steric interference experienced by the methyl tops. The internal reorientation rate of a methyl group rotation can be expressed by eq.

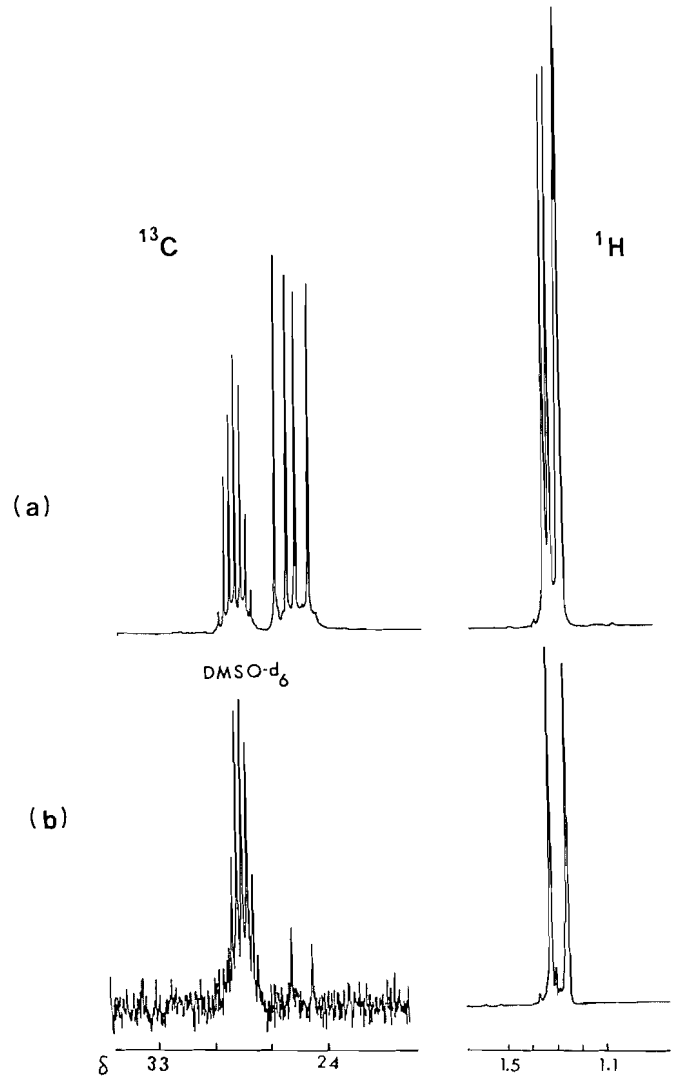

FIG. 4. Partial ^{13}C and ^{1}H nmr spectra of the methyl groups of **1** in acetone-d_6. (a) Nondeuterated compound; (b) deuterated compound.

[8], which represents the stochastic diffusion model (15)

$$[8] \quad \frac{1}{T_{1,\,CH_3}} = \frac{3\gamma_H^2\gamma_H^2\hbar^2}{r_{C-H}^6}\tau_R\left[A + B\frac{6\tau_i}{6\tau_i + \tau_R} + C\frac{3\tau_i}{3\tau_i + 2\tau_R}\right]$$

where τ_i is the correlation time for the internal motion, τ_R is the correlation time for the overall isotropic reorientation, and *A*, *B*, *C* are geometric terms defined previously (15). If jumps between three equivalent positions separated by 120° are assumed, the last term becomes $C(6\tau_i/6\tau_i + \tau_R)$ (15).

The pair of methyl groups of the 5,6-*O*-isopropylidene ring of **1** is not amenable to a rigorous quantitative treatment in terms of internal motion about C—CH_3, due to the multiple internal motions of the ring itself. However, this limitation does not apply to the geminal methyl groups of the 2,3-*O*-isopropylidene ring. Being fused to the mannofuranose moiety, this ring is clearly far more rigid, as can be verified from the analysis of ^{1}H—^{1}H couplings and ^{1}H-relaxation data for **1** (6). Before proceeding with an analysis of the internal rotation of these latter methyl groups, it is necessary to identify their signals in the ^{13}C nmr spectrum of **1**.

The four methyl groups absorb at δ 26.97, 26.17, 25.57, 24.65 and δ 1.36, 1.33, 1.27, 1.26 in ^{13}C and ^{1}H nmr spectra, respectively, in acetone-d_6 solution (Fig. 4a). To distinguish

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

between the two geminal pairs we selectively deuterated the methyls of the 5,6-*O*-isopropylidene ring. That is, acid-catalysed exchange between **1** and the acetone-d_6 solvent resulted in the elimination of two of the methyl resonances in either the ^{13}C or ^{1}H nmr spectrum (Fig. 4b). Because of the marked lability of the 5,6-*O*-isopropylidene substituent relative to that at C-2—C-3, the peaks remaining at δ 26.17, 24.65 and 1.35, 1.25 must have been due to the geminal pair of the 2,3-*O*-isopropylidene substituent. A further distinction within each pair of methyls was based on ^{1}H-nOe measurements. Irradiation of the methyl proton resonating at δ 1.25 caused a strong enhancement of the spatially proximate H-2 (7.8 ± 1.2%) and H-3 (10.0 ± 2.3%) of the mannose ring. Therefore, the peak at δ 1.26 (and corresponding ^{13}C peak at 24.65) is assigned to the *exo* methyl group of the fused ring, whereas the *endo* methyl group of the same ring accounts for the signals at δ 1.36 and 26.17. Analogously, irradiation of the methyl proton resonating at δ 1.27 led to enhancement of the H-5 resonance by 5.5 ± 0.8%. This result confirms the assignment of the signals at δ 1.27 and 25.57 to the *endo* methyl group of the 5,6-*O*-isopropylidene substituent, whereas those of the *exo* group are assigned by difference.

The motional characteristics of the methyl rotors attached to the rigid 2,3-*O*-isopropylidene ring can be described either by diffusion or jump models, although a diffusion process (jumps < 10°) may be anticipated in the DMSO used as solvent, due to its relatively high viscosity. An appropriate test as to whether or not reorientation is diffusional, is to compare the correlation times, τ_i, with the mean period of the free rotor (χ-test) (16).

If τ_i is much larger than τ_f (the time the free rotor takes to reorient through one rad), i.e. when $x = \tau_i/\tau_f \gg 1$, then the process is diffusional. Accordingly, the experimental T_1's lead to χ-values of 163.9 (15°C) and 57.2 (80°C) for the *exo* methyl group, and 64.3 (15°C) and 24.4 (80°C) for the *endo* methyl. These values, which are far greater than unity, indicate that the diffusion limit offers a good approximation for describing the motion of the methyl groups. Figure 1 shows the temperature dependence of the calculated relaxation rates, τ_i, for the two methyl groups, assuming C—C—H angles of 109.47°. From these plots, the activation energies for methyl group rotation were found to be 3.7 ± 0.6 and 3.3 ± 0.7 kcal/mol for the *exo* and *endo* methyls, respectively. Blunt and Stothers (17) have shown that in systems characterized by moderate steric interference for the methyl group, average C—C—H angles of 112° to 113° may reasonably be expected, and that these values should be considered for calculations using eq. [8]. By using a C—C—H angle of 112°, the respective activation energies were found to be 3.8 ± 0.6 (*exo*) and 3.4 ± 0.6 (*endo*) kcal/mol. However, the effect of angle on the calculated energies depends on the ratio $T_{1,CH_3}/T_{1,R}$ and is more important the larger this ratio becomes. The limit of rapid rotation for an angle of 109.47° is $T_{1,CH_3}/T_{1,R} = 3$, whereas that for an angle of 112° is $T_{1,CH_3}/T_{1,R} = 4$. In the present study, the relaxation time ratios range from 1.03 (15°C) to 0.86 (80°C) for the *exo* methyl group, and 1.55 (15°C) to 1.26 (80°C) for the *endo* methyl. Nevertheless, as already shown, the higher values of these ratios for the *endo* group do not also correspond to a greater increase in activation energy relative to the *exo* group, when the C—C—H angle is increased. In summary, the calculated τ_i and E_α values are fairly insensitive to variations in the C—C—H angle, due to the small increase of the $T_{1,CH_3}/T_{1,R}$ ratio with temperature.

It is of interest to assess possible sources of the hindrance to methyl group rotation. Assuming that viscosity effects on internal motion are of the same magnitude for both the *exo* and *endo* methyl groups of the fused 2,3-*O*-isopropylidene ring, then any difference observed in activation energies should reflect a difference between the two groups in nonbonded interactions they experience in the molecular frame. In this event, a simple expression of the activation energy would be an energy barrier separating two rotamers, one with minimum and the other with maximum interactions between the appropriate groups. Because the CH_3—C—CH_3 bond angle in fused *O*-isopropylidene rings of systems analogous to **1** is close to 113.7° (see ref. 26 in ref. 8), significantly higher than the idealized value of 109.47°, methyl–methyl interactions in the eclipsed conformations are probably not so important. Similarly, the O-2—C-8—O-3 angle is reduced to 106° from 109.47°, which does not favor interactions within the isopropylidene skeleton. In this respect, it is worth noting that the barriers to internal rotation of geminal methyl groups in camphor derivatives are lower than those in adamantanes (18) due, undoubtedly, to the smaller C-1—C-7—C-4 angle (significantly less than 109.47°) in the former molecules.

Molecular models indicate that the energy differences between the staggered and eclipsed conformations of the methyl groups are accounted for mainly by interactions with H-2, H-3, and H-5. Owing to the twist conformation ($^2T_3$) of the mannose ring (6) and the associated distortion of the *O*-isopropylidene ring, there are nonequivalent interactions between the *exo* methyl and H-2 and H-3 (principally H-2), thereby inducing a preferred conformation for this group and increasing its activation energy relative to the *endo* methyl. The energy barrier to internal rotation of the latter must be due mainly to interactions with H-5 since all other protons of the mannose moiety are too remote (>4.8 Å). However, because of the librational motion of the C-5—H-5 vector described previously, the methyl H-5 interactions are relaxed somewhat when the C-5—H-5 vector is in the extreme opposite site with respect to the *endo* methyl group. This situation is reflected in the lower activation energy of the *endo* relative to the *exo* methyl group.

The hydrodynamic behavior of ***1***

Simple hydrodynamic theory (19, 20) shows that the reorientation of a solute particle in a viscous medium can be described by the equation

$$[9] \quad \tau_R = C(\eta/T)$$

where η is the shear viscosity of the solution, T the absolute temperature of the liquid, and C a parameter which depends on the molecular shape, the solvent, the concentration, and the specific solute–solvent interactions. In a process activated by rotational diffusion the activation energy of the overall molecular motion, as calculated earlier from the nmr data, can be equated with the activation energy associated with the ratio η/T. This prediction is upheld by measurements of the solution viscosity (Table 2) as a function of temperature. These data, when plotted as ln (η/T) vs. $1/T$, gave a very good straight line (correlation coefficient = 0.9994) with a slope corresponding to an E_α = 4.57 kcal/mol, i.e., very close to the value of 4.88 kcal/mol derived from the nmr data.

Although the activation energy of the overall molecular reorientation is related to the viscous properties of the solution, molecular geometry and the specific nature of solute–solvent interactions also play an important role in rotational relaxation. Short range interactions or intermolecular collisions between

molecules of the solute and solvent create torques which alter the angular momentum, and hence the reorientational properties, of the probe molecule. In other words, the molecular reorientation may be hydrodynamic, depending on the nature of the coupling of the probe solute molecule to the solvent. One way to account for hydrodynamic effects on rotational relaxation in an explicit form is by the use of eq. [9], according to the Debye–Stokes–Einstein hydrodynamic model (19)

$$[10] \quad \tau_R = \frac{V_S}{k}\frac{\eta}{T}$$

where V_S is the volume of the solute and k is Boltzmann's constant. This equation holds for spherical solute molecules which are much larger than those of the solvent, and when the latter rotate at the surface of the solute particles (with the particle), i.e., under the "stick boundary condition". Equations [9] and [10] predict that a plot of τ_R vs. η/T should be a straight line,[1] with slope $C = V_S/k$, which proved to be true for the present experimental data (correlation coefficient = 0.9934). The experimental slope was found to be 7.8 (deg.ns/cP), which is far smaller than the calculated slope of 1593 (deg.ns/cP) given by eq. [10], assuming the stick boundary conditions. A volume (V_S) of 219.9 Å^3 was calculated from van der Waals' increments (21), which agrees well with volumes estimated from molecular models.

Hu and Zwanzig (22) have considered a rotating spheroid under the "slip boundary conditions", where the rotating particle displaces the surrounding fluid, which, in contrast to the stick case, exerts no drag force on the particle. Under slip boundary conditions, C_{slip} is zero for a sphere, and approaches unity for increasingly nonspherical spheroids.

To fit the experimental slope using the slip boundary conditions, one must assume that molecule **1** is a prolate ellipsoid with a ratio of ~0.92 for the lengths of the shorter and longer axes, that is, an almost spherical molecule. This result is in good agreement with the nmr data, which are clearly consistent with a nearly spherical particle reorienting isotropically. However, the "slip" model predicts (20, 22, 23) that the overall reorientation of a spherical molecule must be viscosity independent provided that the molecule reorients within its "own volume". This behavior may be excluded for the present system, particularly as the value of activation energy of the overall motion is about 5 kcal/mol. The viscosity dependence of the overall motion of **1** may be explained by a relatively weak coupling of translational and rotational motion, promoted by association of DMSO molecules with the OH group and possibly also with various ring oxygens of **1** (24). Despite their extremely short lifetimes, these possible dipole complexes may significantly influence the reorientational motion, because even these relatively weak interactions could reduce the coefficient C in eq. [8] decisively (20, 25).

[1]It is often convenient to express eq. [9] by $\tau_R = C(\eta/T) + \tau_R^\circ$ where τ_R° is an experimentally determined parameter, which appears to be of the order of the free-rotor correlation time (20). However, our data are not precise enough to determine such small additive terms. Equations [9] and [10] seem adequate for an analysis of our data.

Acknowledgments

The authors express their gratitude to Dr. Françoise Sauriol for kind assistance, and to McGill University and the Natural Sciences and Engineering Research Council of Canada for generous support. Viscosity measurements were carried out by Alison Burgess and Dr. R. Brown.

KIM M. BAINES, KEITH VAUGHAN, DONALD L. HOOPER, and LORNE F. LEVECK. Can. J. Chem. **61**, 1549 (1983).

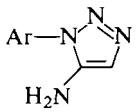
A series of triazenes of type ArN=N—NH—CH_2CO_2Et, *N*-arylazoglycine ethyl esters, have been prepared by coupling the arene diazonium salt, $ArN_2^+ \cdot X^-$, with ethyl glycinate, $NH_2CH_2CO_2Et$; an electron-withdrawing substituent, e.g. NO_2, CN, CO_2R, and Cl, in the *ortho* or *para* position of the aryl group is essential for efficient coupling. The *p*-substituted arylazoglycine ethyl esters cyclize when treated with alcoholic potassium hydroxide to afford the potassium salts of the 1-aryl-5-hydroxy-1,2,3-triazoles, which can be obtained free by acidification of the potassium salt solution with acetic acid. Reaction of the potassium salts with acetic anhydride yields the 1-aryl-5-acetoxy-1,2,3-triazoles. The 5-hydroxytriazoles, when heated in ethanol, rearrange to α-diazoacetanilides, $ArNH \cdot COCHN_2$. The diazoamides can be obtained in low yield directly from the triazenes by prolonged refluxing in ethanol. *o*-Substituted aryltriazenes do not cyclize under the same conditions but fragment to the arylamine.

KIM M. BAINES, KEITH VAUGHAN, DONALD L. HOOPER et LORNE F. LEVECK. Can. J. Chem. **61**, 1549 (1983).

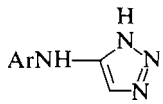
On a préparé une série de triazènes du type ArN=N—NH—CH_2CO_2Et, esters *N*-arylazoglycinate d'éthyle, en couplant le sel diazionium de l'arène $ArN_2^+ \cdot X^-$ avec le glycinate d'éthyle, $NH_2CH_2CO_2Et$. Un substituant électro-attracteur, par exemple: NO_2, CN, CO_2R et Cl, en position *ortho* ou *para* du groupe aryle est essentiel pour un couplage efficace. L'ester arylazoglycinate d'éthyle substitué en position *para* se cyclise dans l'hydroxyde de potassium alcoolique en donnant les sels de potassium des aryl-1 hydroxy-5 triazoles-1,2,3 que l'on peut obtenir à l'état libre en acidifiant la solution de sel de potassium avec l'acide acétique. La réaction du sel de potassium avec l'anhydride acétique conduit aux aryl-1 acétoxy-5 triazoles-1,3,5. Par chauffage dans l'éthanol les hydroxy-5 triazoles se transposent en α-diazoacétanilides, $ArNH \cdot COCHN_2$. On peut obtenir les diazoamides avec un faible rendement en partant directement des triazènes que l'on porte longuement au reflux dans l'éthanol. Dans les mêmes conditions les aryltriazènes substitués en position *ortho* ne se cyclisent pas mais se fragmentent pour donner des arylamines.

[Traduit par le journal]

In Part III (1) of this series, the synthesis and characterization of a number of α-substituted 1-aryl-3-alkyltriazenes (ArN=N·NH·CH_2Y, e.g. Y = CN and CO_2R) was described. In a further study (2), the α-cyanomethyl triazenes were found to undergo cyclization to afford 5-amino-1-aryl-1,2,3-triazoles (**1**) which in turn undergo rearrangement in



1



2

protic media to give the isomeric 5-(arylamino)-1,2,3-triazoles (**2**). The results reported in this paper originate from the logical extension of the amino-triazole synthesis to the synthesis of the 5-hydroxy-1,2,3-triazole system (**4**) via the analogous 1-aryl-3-(ethoxycarbonylmethyl)triazenes (**3**). Triazenes of type **3** do indeed give rise to 5-hydroxytriazoles (**4**), which show a facility to undergo rearrangement to the α-diazoacetamides (**5**). This study describes (a) the general reaction conditions required to achieve the synthesis of the 5-hydroxytriazoles, (b) the optimal conditions for a general synthesis of the α-diazoacetamides (**5**), (c) the characterization of a series of compounds of both types **4** and **5**. In addition, the spectroscopic properties of the triazenes of type **3** are explored in order to explain their degradation in solution.

5

5-Hydroxytriazoles are available through a limited number of routes, the most general being the reaction between an organic azide and an activated methylene compound (e.g. malonic ester) (3). Open-chain triazene intermediates in these reactions have been postulated (4, 5), but the hypothesis has not been experimentally verified. Indeed, the potential use of triazenes of type **3** as triazole synthons has been largely ignored; a close analogy is the recently reported synthesis of

[a]The *p*-substituted aromatic patterns are nearly first order AA'BB' systems. Apparent chemical shifts and coupling constants are reported.

5-ethoxy-1*H*-1,2,3-triazoles by coupling of alkenediazonium salts with primary alkylamines (6). Previous studies of triazenes of type **3**, otherwise named *N*-arylazoglycine ethyl esters, have been directed at their degradation to α-diazocarboxylic esters (eq. [1]):

[1] $ArN{=}N{-}NH{-}CH_2CO_2Et \rightarrow ArNH_2 + N_2CHCO_2Et$

Conversion of *N*-(*p*-nitrophenylazo)-glycine ethyl ester (**3***a*) to *p*-nitroaniline and ethyl diazoacetate proceeds smoothly in a two-phase system of methylene chloride and 6% aqueous acetic acid (7). The diazoacetate can be formed quantitatively, without isolation of the intermediate triazene (**3***a*), by coupling the *p*-nitrobenzenediazonium salt and ethyl glycinate in dry dimethylformamide with a slight molar excess of triethylamine (8). Clearly, the tendency of triazenes of type **3** towards degradation necessitates careful control of reaction conditions to achieve cyclization.

Experimental

Melting points were determined with a Kofler hot stage apparatus and are uncorrected. Infrared spectra were recorded with liquid paraffin mulls on a Perkin–Elmer model 299 spectrophotometer. The uv spectra were recorded on a Varian/Cary 219 spectrophotometer. The ^1H nmr spectra were recorded on Varian Em-360 and CFT-20 spectrometers and the ^{13}C nmr spectra were obtained on the CFT-20 spectrometer. Microanalyses were carried out by the Canadian Microanalytical Laboratory, Vancouver, B.C.

1-Aryl-3-(ethoxycarbonylmethyl)triazenes (3)

General procedure

The arylamine ($ArNH_2$) (0.013 mol) was dissolved in 2 *M* hydrochloric acid (30 mL), diluted with water (40 mL), and diazotized at 0°C over a period of 1–2 h with sodium nitrite (0.013 mol) dissolved in water (10 mL). The diazonium salt solution was filtered and the clear filtrate treated with a solution of glycine ethyl ester hydrochloride (0.013 mol). After stirring the cold mixture for 15 min, a ten-fold molar excess of sodium acetate trihydrate (20 g) was added and the triazene precipitated slowly (over 2 h) from the reaction mixture. The product was filtered, dried, and recrystallized from a suitable solvent. The yields and physical data of the triazenes are given in Table 1.

The *p*-nitro- (**3***a*) and *p*-chloro- (**3***c*) phenyl triazenes recrystallize from nonpolar aprotic solvents without complication. However, heating the *p*-cyano- (**3***b*) or *p*-ethoxycarbonyl- (**3***d*) phenyltriazenes in a similar solvent results in the formation of oils. In the case of the *p*-cyano derivative (**3***b*) the oil was removed by charcoal treatment of the hot solution, but in the recrystallization of **3***d* from hexane the oil persists even after several charcoal treatments and two solid forms of **3***d* were obtained. A yellow amorphous solid forms when the oil cools; a different form of **3***d* crystallizes from the solution as fine white needles. The yellow and white forms of **3***d* have the same melting points and give identical elemental analyses. Solutions of the two forms of **3***d* give identical ir, uv, and nmr spectra, whereas ir spectra of the solids in Nujol mulls are substantially different.

The uv spectra of the two forms of **3***d* in ethanol or hexane have identical absorption maxima; λ_{max} (EtOH): 223(16 000), 310(19 050) nm; λ_{max} (hexane): 221(9950), 289(19 250) nm. The ^1H and ^{13}C nmr spectra in deuteriochloroform are identical. In the ^{13}C spectra of freshly prepared solutions, both yellow and white forms show two methyl signals at 13.9 and 14.07 ppm, two methylene carbons at 60.5 and 61.2 ppm, coincident aromatic peaks at 130.5 ppm, and a broad signal at 118 ppm representing the carbons *ortho* to the tautomeric system $-N{=}N{-}NH- \rightleftharpoons -NH{-}N{=}N-$. The unprotonated carbons of the aromatic ring were not resolved from the noise before decomposition of the triazene became the dominant phenomenon. The methylene carbon between N and carbonyl groups in the glycine moiety was not observed; this is common for rapid tautomerism in triazene systems (9).

The ir spectra of the yellow and white forms of **3***d* as Nujol mulls are strikingly different. The white form has a single broad carbonyl band at 1720 cm^{-1}, presumably the overlapping bands of the ester carbonyl groups, and NH absorption at 3320 cm^{-1}; the yellow form has two carbonyl bands well separated at 1750 and 1685 cm^{-1} and NH absorption at 3230 cm^{-1}. Chloroform solution ir spectra of the yellow and white forms are identical, showing carbonyl bands at 1740 and 1710 cm^{-1} and NH bands at 3430 and 3330 cm^{-1}.

*1-Aryl-5-hydroxy-1,2,3-triazoles (**4**)*

An alcoholic solution of potassium hydroxide (1.0 g, 0.018 mol) was added dropwise with continuous stirring to a solution of the appropriate triazene (0.009 mol) (**3**) in absolute ethanol (25–100 mL). The resulting deep red solution was stirred at room temperature and the reaction followed by tlc to completion. The time required varied with the substituent in the aryl group as follows: *p*-nitro-, 1h; *p*-cyano-, 1.5 h; *p*-chloro-, 10 min; *p*-ethoxycarbonyl-, 40 min. In the case of the *p*-cyanophenyltriazene (**3***b*), a precipitate formed during the reaction and was removed by filtration before continuing. The ethanolic solution was evaporated to dryness under vacuum and the residue dissolved in the minimum volume of distilled water (20–50 m). In the case of *p*-nitrophenyltriazene (**3***a*), a water-insoluble product was removed by filtration and identified (mp and ir spectrum) as *p*-nitroaniline (yield 18%). The aqueous solution was acidified with glacial acetic acid (~5 mL), whereupon the hydroxytriazole (**4**) precipitated from solution and was filtered, washed with distilled water, and dried. Owing to the solubility characteristics of the hydroxytriazoles, appropriate solvents for recrystallization could not be found. When a suitable solvent was found, e.g. nitromethane, the triazoles invariably were found to undergo the rearrangement to the diazoacetamide spontaneously in the hot solvent. Purification of each triazole was achieved as follows.

4*a* (*p*-Nitrophenyl-), the yellow triazole, resisted all attempts at purification by recrystallization or chromatography but was ob-

tained as a single component (tlc analysis) by two successive acetone triturations.

4*b* (*p*-Cyanophenyl-) was obtained as a single yellow component (tlc analysis) after two triturations with chloroform.

4*c* (*p*-Chlorophenyl-) (pale orange) was of sufficient purity for analysis without further treatment.

4*d* (*p*-Ethoxycarbonylphenyl-) (pale yellow) was the major component of a two-compound mixture (tlc analysis) obtained from the crude product by two triturations with acetone, followed by trituration with benzene. The second component was unidentified. Physical data of the triazoles are detailed in Table 2.

Potassium salts of **4**a *and* **4**b

(a) The potassium salt of 1-(*p*-nitrophenyl)-5-hydroxy-1,2,3-triazole (**4***a*) was isolated from the red alcoholic solution by slow evaporation of the solvent; long lustrous brown needles of the salt resulted, mp > 300°C, yield 86%; ir (Nujol): 3380 (very broad), 1670 (weak), and 1600 cm^{-1}; nmr (DMSO-d_6): 8.48, 8.18 (AA′BB′ pattern, 4H), and 6.1 (s, 1H, =CH) ppm).

(b) Similarly, the potassium salt of **4***b* precipitated in the basic alcoholic solution of the triazene (**3***b*). The salt had mp 286–289°C, yield 27%; ir (Nujol): 3550 (sharp), 3270 (broad), 2225 (sharp), 1664 (w), and 1610 cm^{-1}; nmr (DMSO-d_6): 8.33, 7.69 (AA′BB′ pattern, 4H), and 6.08 (s, 1H, =CH) ppm.

1-Aryl-5-acetoxy-1,2,3-triazoles (8)

The potassium salt of the 5-hydroxytriazole was prepared as described above by reaction of the appropriate triazene (**3**) (0.004 mol) with alcoholic potassium hydroxide (0.008 mol). The potassium salt was dissolved in water (50 mL), mixed with ice (~10 g), and treated with acetic anhydride (0.75 g) with vigorous stirring. The red colour of the potassium salt disappeared within 5 minutes and a yellow or white precipitate of the acetoxytriazole was formed. The solid was filtered, washed, dried, and recrystallized from hexane or benzene to afford the acetoxytriazoles (**8**). Physical data are given in Tables 3 and 4.

N-*Aryl-α-diazoacetamides (5)*

General procedure

Method A

The 1-aryl-5-hydroxytriazole (**4**) (0.005 mol) was dissolved in absolute ethanol (~50 mL) and refluxed for 1.5–2 h. The solvent was removed under vacuum and the residue purified by recrystallization to afford the diazoacetamides (**5***a*, *b*, *c*, and *d*).

Method B

The 1-aryl-3-(ethoxycarbonylmethyl)triazene (**3**) (0.008 mol) was dissolved in absolute ethanol (125 mL) and the mixture refluxed for several hours. The progress of the reaction was followed by tlc until successive chromatograms showed no change in the composition of the mixture; in none of the examples followed by this method could a single component be obtained. The reaction time varied from 2–6.5 h. The solvent was removed under vacuum to afford a gummy residue which was purified by successive triturations and recrystallizations to yield the diazoacetamides (**5***a* and *e*). Analogous reaction with the *p*-chlorophenyl- (**3***c*) and *p*-ethoxycarbonylphenyl- (**3***d*) triazenes gave mixtures of products with the spectroscopic properties expected of the diazoacetamide, but the pure material could not be isolated.

Table 5 gives the yields obtained by methods A and B and the physical data of the diazoacetamides.

*Degradation of 1-(*p*-nitrophenyl)-3-(ethoxycarbonylmethyl)triazene (3*a*)*

(a) Triazene **3***a* (0.30 g) was dissolved in absolute ethanol (20 mL) and mixed with triethylamine (13.9 mL, 0.1 mol). The solution, which changed colour to bright orange immediately, was refluxed for 1 h. The solvent was removed under vacuum and the residue washed with water and filtered to yield crude *p*-nitroaniline (0.150 g, 90%), which was identified by comparison of the ir spectrum with an authentic sample.

(b) Triazene **3***a* (0.30 g) was dissolved in absolute ethanol (20 mL) and mixed with concentrated hydrochloric acid (4.0 mL, 0.05 mol).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

The mixture was left at ambient temperature for 36 h and the solvent removed under vacuum. The residue was washed with water and filtered to yield *p*-nitroaniline (0.1 g, 60%).

(c) Triazene (**3***a*) (0.30 g) was dissolved in absolute ethanol (20 mL), then mixed with acetic acid (20 mL) and the mixture refluxed for 1 h. The solvent mixture was removed under vacuum to yield a gummy residue; the presence of *p*-nitroaniline in the residue was confirmed by tlc.

(d) A small quantity (~50 mg) of triazene **3***a* was dissolved in chloroform and left to stand. Small aliquots of the solution were examined by tlc over a period of several days. After 24 h at room temperature, there was detectable degradation of the triazene into two products, in addition to the spot of unchanged triazene on the tlc. One of the products has identical R_f to *p*-nitroaniline. Spectroscopic analysis of the residue in the chloroform solution shows that the second product is ethyl diazoacetate (see eq. [1]). The solution ir spectrum in chloroform shows absorption at 2100 cm^{-1} and the structure is confirmed by the ^1H nmr spectrum in $CdCl_3$: 4.72 (singlet, N_2CH). 4.22 (quartet, J = 7.1 Hz, O—CH_2), and 1.27 (triplet, J = 7.1 Hz, CH_3) ppm.

*Reaction of 1-(o-nitrophenyl)-3-ethoxycarbonylmethyltriazene (**3**f) with potassium hydroxide*

The *o*-nitrophenyltriazene (**3***f*) (3.2 g) and potassium hydroxide (0.76 g) were dissolved in a minimum volume of ethanol and the solution left to stir for 4 hours. The solvent was removed under vacuum and the residue treated with water. The insoluble fraction was removed by filtration and identified, by ir spectroscopy and tlc, as *o*-nitroaniline (1.0 g, 42%). The filtrate was divided into two equal portions. The first portion was acidified with glacial acetic acid (2 mL) and stirred for several hours; no precipitation was evident. The second portion was treated with acetic anhydride and stirred for several hours, but again no reaction occurred.

Discussion

The method (1) of preparation of 1-aryl-3-(ethoxycarbonylmethyl)triazenes (**3**) by reaction of the arenediazonium salt with ethyl glycinate has been extended to include several new examples. Each of the compounds **3***a*–*e* includes an electron-withdrawing substituent in the aryl moiety. The presence of such a substituent in the arenediazonium ion appears essential to efficient diazo-coupling with ethyl glycinate. Attempted reaction with benzenediazonium ion gave an intractable mixture, while the triazene product from *p*-toluene diazonium ion showed the spectroscopic properties expected, but could not be isolated.

Compounds **3***a*–*e* were obtained in high yield, could be recrystallized from nonpolar solvents, and were stable for reasonable storage periods. Compound **3***c*, the *p*-chloro derivative, was noticeably less stable than others, completely decomposing to a black tar after 2 months at room temperature. Compound **3***d*, the *p*-ethoxycarbonyl derivative, is unique in this series in that recrystallization leads to two different solid forms, which become identical in solution. The reasonable explanation of this result is that these forms differ only in arrangement of molecules in the solid.

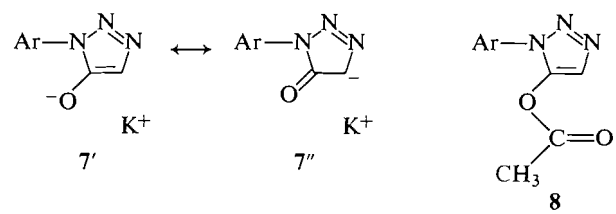
By analogy with the easy cyclization of 3-cyanomethyltriazenes (2), the 3-ethoxycarbonylmethyltriazenes might be expected to be readily converted to the hydroxytriazoles (**4**) on refluxing in ethanol. When this was attempted, thin-layer chromatography indicated that reaction did occur, but not a single reaction. When the solvent was removed from each such reaction mixture, the residue showed intense infrared absorption at 2100 cm^{-1}. After several careful triturations and successive recrystallizations small yields (<5%) of the α-diazoacetamides **5***a* and **5***e* were obtained. These compounds show the 2100 cm^{-1} absorption as a dominant feature of their infrared spectra.

Hence we may conclude that the reaction **3** → **5** is one of the reactions of the triazenes **3** in hot ethanol; presumably **4** is an intermediate that rearranges to the α-diazoacetamide in the protic solvent. The poor yields of the diazoamides led us to investigate other reactions of the triazenes **3** in order to improve yields and to isolate the hydroxytriazoles **4**. Ethanolic triethylamine, ethanolic acetic acid, and ethanolic hydrochloric acid each result in decomposition of the triazene as evidenced by high yields of the corresponding aniline. No such decomposition occurs when the triazenes are allowed to react with alcoholic potassium hydroxide at room temperature.

With alcoholic KOH a single product, the potassium triazolate (**7**) is formed in high yield within 1 hour. The reaction is general for all triazenes (**3***a*–*d*) treated in this way; the potassium salts of the *p*-nitrophenyl (**4***a*) and *p*-cyanophenyl (**4***b*) triazoles were isolated in crystalline form and characterized spectroscopically. Acidification of aqueous solutions of the salts with acetic acid precipitates the hydroxytriazoles (**4***a*–*d*) in high yield. Only the *p*-nitrophenyltriazene **3***a* showed any decomposition to the aniline in this reaction.

The *p*-chlorophenyltriazole **4***c* precipitated with glacial acetic acid was pure enough for analysis. The other three triazoles were particularly resistant to purification, rearranging to the diazoacetamide when recrystallization was attempted, and decomposing when subjected to either column or preparative thin-layer chromatography. Trituration with appropriate solvents yielded sufficiently pure material for spectroscopic study.

The most distinctive feature of the infrared spectra of the hydroxytriazoles is the broad band in the region 2300–2600 cm^{-1}, a region where absorption of a strongly hydrogen-bonded enolic hydroxyl group might be expected. The enol structure **4** is evidently the preferred tautomer of the triazoles, rather than a keto-form such as **6**; the ir spectra are blank in the region of carbonyl absorption. The ^1H nmr shows the singlet absorption of the CH of the aromatic triazole ring at 7.1 ppm. In the potassium salt (**7**) this peak is shifted to 6.1 ppm, most likely as a result of the resonance **7′** ↔ **7″**. The OH signal is



7′ **7″** **8**

clearly distinguished from the aromatic protons at 7.73 ppm in the spectrum of the *p*-cyanophenyl triazole (**4***b*).

Further unequivocal characterisation of the hydroxytriazoles was provided by reaction of the potassium salts (**7**), in aqueous solution, with acetic anhydride to afford the 5-acetoxytriazoles (**8**) in high yield. Unlike the hydroxytriazoles, the acetate derivatives recrystallized without change from nonpolar solvents so that analytically pure materials were obtained. The acetates show strong absorption in the ir at 1800–1810 cm^{-1}, which is unusually high frequency for an ester carbonyl group and may indicate that the triazole moiety is strongly electron withdrawing. The ^1H nmr spectra exhibit an acetyl Me resonance at ~2.4 ppm and an aromatic, one-proton singlet at 7.8–7.9 ppm, assigned to the hydrogen attached to C-4 of the triazole ring; the latter is shifted significantly downfield compared to the corresponding resonance in the hydroxytriazole.

Although 1-*p*-chlorophenyl-5-acetoxy-1,2,3-triazole (**8***c*) survives recrystallization without degradation or rearrangement, it, like the triazene (**3***c*), has quite a short shelf life at room temperature. After only a few weeks of storage, samples of **8***c* were found to contain acetic acid, which was definitely not present when the samples were fresh. Further investigation showed that **8***c* had undergone hydrolysis to the hydroxytriazole (**4***c*), presumably by nucleophilic acyl substitution following absorption of ambient moisture. The other acetates (**8***a*, *b*, and *d*) have not shown any tendency to decompose.[3]

[3]NOTE ADDED IN PROOF: Acetate **8***d* also shows signs of decomposition after storage for 8–10 months.

Degradation of the *p*-chlorophenyl-5-acetoxytriazole (**8***c*) was also observed when attempts were made to record its ^{13}C nmr spectrum in DMSO-d_6. Many of the signals in the spectrum of **8***c* were doubled, suggesting that hydrolysis to the hydroxytriazole in the nmr tube had occurred during the 10–12 hours required to record a spectrum. Decomposition may also explain why the signals from the quaternary aromatic carbons, C-1 and C-4, were not detected. The other acetoxytriazoles were sufficiently soluble in deuteriochloroform to give full ^{13}C spectra, which are summarized in Table 4. All carbons in compounds **8***a*, **8***b*, and **8***d* were detected and assigned to their respective signals, so that the structure of these acetates have been unequivocally confirmed by the ^{13}C nmr data, thus removing any doubt that might exist regarding the structure-proof of the parent 5-hydroxytriazoles (**4**).

The *N*-aryl-α-diazoacetemides (**5**) were obtained in high yield by refluxing the triazoles (**4**) for short periods in absolute ethanol. The products obtained in this way were much purer than the mixtures obtained by refluxing the triazenes. All of **5***a*–*d* were satisfactorily recrystallized, albeit in some cases only with extreme care, from nitromethane. The spectroscopic properties of these compounds include the distinctive 2100 cm^{-1} infrared absorption and, in the ^1H nmr, the NH signals between 9.8 and 10.4 ppm, with the diazo CH at 5.6 ppm.

The ^{13}C nmr spectra of one triazole, one triazolate, and one diazoacetamide were obtained to help verify the structure assigned. In the fully decoupled spectrum of 1-(*p*-ethoxycarbonylphenyl)-5-hydroxy-1,2,3-triazole (**4***d*) eight signals are apparent. The assignments of these signals are listed in Table 6. The ^{13}C spectrum of *N*-(*p*-nitrophenyl)-α-diazoacetamide (**5***a*) also confirmed the structure proposed; the signals are assigned in Table 7. The chemical shift of the CH in the diazo group is much smaller than initially expected; however, Albright and Freeman have observed (10) that the diazo carbon is shielded by an extraordinary amount, compared with normal sp^2 hybridized carbons. The ^{13}C spectrum of **7***a* (Table 8) is consistent with the resonance, **7′** ↔ **7″**; the chemical shift of the oxygen-bearing carbon in the triazole ring at 161.05 ppm accords with the carbonyl character of this group.

The application of this synthesis to *ortho*-substituted phenyl triazoles of type **4** was unsuccessful. Coupling *o*-nitrobenzene diazonium ion with ethyl glycinate gave a moderate yield of the triazene (**3***f*), which was obtained as an oil and characterized by ^1H nmr (Table 1). This triazene decomposes on storage; a crystalline material growing in the oil was identified from its ir spectrum as *o*-nitroaniline and the presence of ethyl diazoacetate (eq. [1]) in the residual oil was evident from the band at 2100 cm^{-1}. Degradation of **3***f* to *o*-nitroaniline was also observed in reaction with alcoholic KOH; there was no evidence of cyclization of **3***f* to a triazole in the KOH-catalysed reaction or when **3***f* was refluxed in ethanol.

Although *p*-acetylbenzenediazonium salt does not couple readily with primary alkylamines, the isomeric *o*-acetylbenzenediazonium ion couples with ethyl glycinate, neutralized with sodium acetate, to give a good yield of the *o*-acetylphenyltriazene (**3***g*). Compound **3***g* is a bright, orange solid with spectroscopic features mostly consistent with the triazene structure. The nmr spectrum shows all the expected ^1H signals and the ir spectrum has carbonyl absorption at 1750 (ester) and 1680 (ketone) cm^{-1}. The only inconsistent feature is the non-observation of NH ir absorption. Triazene **3***g* does not recrystallize unchanged from ethanol or benzene; a complex mixture of products results when **3***g* is heated in ethanol but

conversion to a diazomide is not evident.

In conclusion, the results reported here describe a convenient and unequivocal route to the 1-aryl-5-hydroxytriazole system without substituents at the 4-position of triazole ring. Other general methods of synthesis, e.g. the reaction of azides with reactive methylene compounds (3), afford triazoles substituted at C-4. This paper also describes conditions for the rearrangement of the hydroxytriazoles to α-diazoacetamides, which are not readily available by other routes. These results confirm the predictions made by Olsen (5), who postulated that 5-hydroxytriazoles should rearrange to the diazoacetamide. Whereas Olsen suggested the rearrangement might be reversible, the equilibrium **4** $\rightleftharpoons$ **5** appears to lie in favour of the diazoamide under the conditions used here. This ring-opening reaction is very similar to the Dimroth rearrangement of aminotriazoles via an α-diazoacetamidine intermediate (11), which is the imino-analogue of the α-diazoacetanilide. Whereas the diazoacetamidines are unstable and recyclize spontaneously, the diazoamides cannot follow the Dimroth pathway any further and, as we have shown here, are sufficiently stable to permit isolation.

Analytical data for the reported compounds are given in Table 9.

Electrical and thermal properties of Na_2SO_4 doped with $NaVO_3$, $Ln_2(SO_4)_3$ (Ln = Eu, Pr)

NOBUHITO IMANAKA, GIN-YA ADACHI,[1] AND JIRO SHIOKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka Suita, Osaka, 565, Japan

Received July 7, 1982[2]

NOBUHITO IMANAKA, GIN-YA ADACHI, and JIRO SHIOKAWA. Can. J. Chem. **61**, 1557 (1983).

In order to develop useful solid electrolytes for SO_2 detectors, Na_2SO_4, Na_2SO_4–$Eu_2(SO_4)_3$, Na_2SO_4–$NaVO_3$, and Na_2SO_4–$NaVO_3$–$Ln_2(SO_4)_3$ (Ln = Eu, Pr) systems have been prepared, and their electrical and thermal properties have been measured. By doping Na_2SO_4 with $Eu_2(SO_4)_3$, the electrical conductivity increases and the apparent activation energy of the Na_2SO_4–$Eu_2(SO_4)_3$ system shows a value between those of Na_2SO_4-III and Na_2SO_4-I. Addition of $NaVO_3$ and $Ln_2(SO_4)_3$ (Ln = Eu, Pr) to Na_2SO_4 suppressed the phase transformation, by stabilizing the structure of the Na_2SO_4-I phase even at a relatively low temperature.

NOBUHITO IMANAKA, GIN-YA ADACHI et JIRO SHIOKAWA. Can. J. Chem. **61**, 1557 (1983).

Dans le but de mettre au point des électrolytes solides utiles pour les détecteurs au SO_2, on a préparé des systèmes de Na_2SO_4, Na_2SO_4–$Eu_2(SO_4)_3$, Na_2SO_4–$NaVO_3$ et Na_2SO_4–$NaVO_3$–$Ln_2(SO_4)_3$ (Ln = Eu, Pr) et on a mesuré leurs propriétés électriques et thermiques. En dopant le Na_2SO_4 avec du $Eu_2(SO_4)_3$, la conductivité électrique augmente et l'énergie d'activation apparente du système Na_2SO_4–$Eu_2(SO_4)_3$ atteint une valeur qui se situe entre celles du Na_2SO_4-III et du Na_2SO_4-I. L'addition de $NaVO_3$ et de $Ln(SO_4)_3$ (Ln = Eu, Pr) à du Na_2SO_4 supprime la transformation de phase en stabilisant la structure de la phase Na_2SO_4-I même à une température relativement faible.

[Traduit par le journal]

Introduction

Polymorphism and electrical conductivity of Na_2SO_4 have been studied by many investigators (1–18). It has been known that Na_2SO_4 has five polymorphisms and that it exhibits Na^+ ion conduction at an elevated temperature. Sodium sulfate exhibits the Na_2SO_4-V phase at room temperature. On heating, the Na_2SO_4-V phase transforms firstly to a metastable phase, Na_2SO_4-III, and then to Na_2SO_4-I, a high temperature phase. On the other hand, the Na_2SO_4-I phase transforms to Na_2SO_4-III, a low temperature phase, which takes several months before its transformation to the Na_2SO_4-V phase. The existence of phase IV is still questioned.

Recently, attempts have been made to utilize $(Na, K)_2SO_4$ as molten (19, 20) or solid electrolytes (21–23) for detecting SO_2 or SO_3 in gases. However, a disadvantage in using Na_2SO_4 or K_2SO_4 (24) as a solid electrolyte is the presence of a phase transformation and the lack of sufficient electrical conductivity at low temperatures. Furthermore, it is difficult to establish the SO_2–SO_3 equilibrium rapidly at the surface of solid electrolytes. Attempts have often been made to increase the electrical conductivity of Na_2SO_4 by doping with divalent or trivalent cations (25–30). However, phase transformations still remain. In this paper, $Ln_2(SO_4)_3$ (Ln = Eu, Pr) is used as a dopant to increase the electrical conductivity and $NaVO_3$ is added to establish the SO_2–SO_3 equilibrium quickly.

Experimental

Anhydrous Na_2SO_4 and $NaVO_3$ were purchased from Wako pure Chemical Industries Ltd. $Eu_2(SO_4)_3$ and $Pr_2(SO_4)_3$ were prepared by adding concentrated sulfuric acid to Eu_2O_3 and Pr_6O_{11}, respectively. Two-component systems, Na_2SO_4–$Eu_2(SO_4)_3$ and Na_2SO_4–$NaVO_3$, and three-component systems, Na_2SO_4–$NaVO_3$–$Ln_2(SO_4)_3$ (Ln = Eu, Pr) were prepared, firstly by mixing the appropriate amount of Na_2SO_4, $NaVO_3$, and $Ln_2(SO_4)_3$ (Ln = Eu, Pr) and then by sintering the mixtures for 3 h at 1073 K.

Electrical conductivities were measured by means of the complex impedance method (30, 31) with a Hewlett Packard vector impedance meter 4800A using the apparatus shown in Fig. 1. Reproducibility of the results, log (σT), was within $\pm 0.3\ \Omega^{-1}\ cm^{-1}\ K$. σ and T represent electrical conductivity and absolute temperature, respectively. A Chromel–Alumel thermocouple was used to measure temperature. X-ray diffraction analyses were performed by using a Rigaku Rotaflex diffractometer with CuKα radiation. DTA measurements were done with a Rigaku Thermoflex.

Results and discussion

The two-component systems

The Na_2SO_4–$Eu_2(SO_4)_3$ system

In the Na_2SO_4–$Eu_2(SO_4)_3$ system, samples of Na_2SO_4 doped with 0.7 mol% $Eu_2(SO_4)_3$, 4.1 mol% $Eu_2(SO_4)_3$, and 8.2 mol% $Eu_2(SO_4)_3$ were prepared. Temperature dependences of Na_2SO_4 and their electrical conductivities are shown in Fig. 2. Na_2SO_4 and Na_2SO_4 doped with 0.7 mol% $Eu_2(SO_4)_3$ exhibited a discontinuity due to the phase transformation of Na_2SO_4-III to Na_2SO_4-I. On the other hand, the samples doped with more than 0.7 mol% $Eu_2(SO_4)_3$ exhibited no change in slope. By doping $Eu_2(SO_4)_3$ into Na_2SO_4, cation vacancies were produced to increase the electrical conductivity and described as $(Na_{(2-3x)/2}Eu_{x/2}\square_x)_2SO_4$, where $\square$ is a cation vacancy. FIG. 2. Temperature dependences of electrical conductivities for the $Na_2SO_4-Eu_2(SO_4)_3$ system. -○- $Na_2SO_4-Eu_2(SO_4)_3$ = 91.8:8.2; -△- $Na_2SO_4-Eu_2(SO_4)_3$ = 95.9:4.1; -●- $Na_2SO_4-Eu_2(SO_4)_3$ = 99.3:0.7; -▲- Na_2SO_4.

TABLE 1. The phases and thermal properties of the $Na_2SO_4-Eu_2(SO_4)_3$ system

Na_2SO_4 (mol%)	$Eu_2(SO_4)_3$ (mol%)	Phases[a]	DTA peaks[b] (K)
99.3	0.7	α + Na_2SO_4-V	493
95.9	4.1	γ + Na_2SO_4-V	553
91.8	8.2	γ + Na_2SO_4-V	563, 573, 818, 1003

[a]The α phase is similar to the Na_2SO_4-III phase (15, 16); the γ phase is different from any Na_2SO_4 phase; Na_2SO_4-V is the initial raw material. X-ray analyses were done at room temperature.
[b]Reproducibility of DTA temperature is within 2 K.

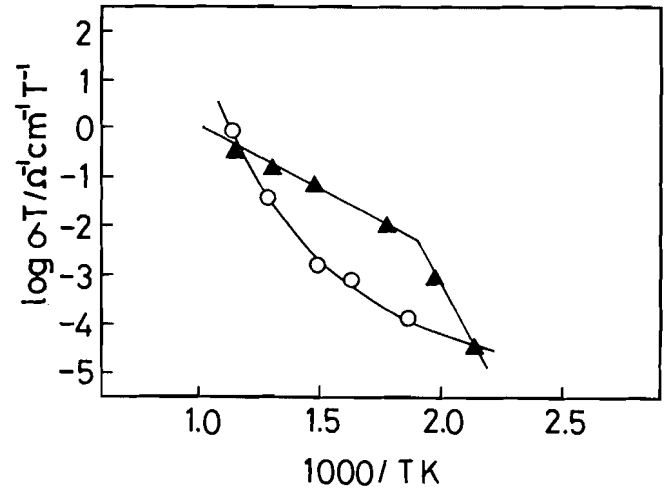

FIG. 3. Temperature dependences of electrical conductivities for $Na_2SO_4-NaVO_3$ = 95:5. -○- $Na_2SO_4-NaVO_3$ = 95:5; -▲- Na_2SO_4.

cases of Na_2SO_4 doped with 4.1 mol% $Eu_2(SO_4)_3$ and 8.2 mol% $Eu_2(SO_4)_3$, $(Na_{0.89}Eu_{0.04}\square_{0.08})_2SO_4$ and $(Na_{0.79}Eu_{0.07}\square_{0.14})_2SO_4$ were formed. In the $Na_2SO_4-Eu_2(SO_4)_3$ system, Na_2SO_4 doped with 4.1 mol% $Eu_2(SO_4)_3$ exhibited the highest electrical conductivity. By doping 8.2 mol% $Eu_2(SO_4)_3$ into Na_2SO_4, its electrical conductivity is about one-tenth that for Na_2SO_4 doped with 4.1 mol% $Eu_2(SO_4)_3$. The reason why Na_2SO_4 doped with 4.1 mol% $Eu_2(SO_4)_3$ exhibited the highest electrical conductivity in the $Na_2SO_4-Eu_2(SO_4)_3$ system may be attributed to the fact that the vacancies produced by doping of Eu^{3+} have a tendency to make clusters when $Eu_2(SO_4)_3$ is dissolved to more than 4.1 mol%.

TABLE 2. The phases and thermal properties of the $Na_2SO_4-NaVO_3$ system

Na_2SO_4 (mol%)	$NaVO_3$ (mol%)	Phases[a]	DTA peaks[b] (K)
98	2	α + Na_2SO_4-V	533, 888
95	5	α + Na_2SO_4-V + trace $NaVO_3$	528, 888
93	7	α + trace Na_2SO_4-V + trace $NaVO_3$	528, 878
90	10	α + trace Na_2SO_4-V + trace $NaVO_3$	523, 873

[a]The α phase is similar to Na_2SO_4-III (15, 16); Na_2SO_4-V and $NaVO_3$ are the initial raw materials. X-ray analyses were done at room temperature.
[b]Reproducibility of DTA temperature is within 5 K.

The apparent activation energies for Na_2SO_4-III and Na_2SO_4-I calculated from the logarithm of electrical conductivity multiplied by absolute temperature vs. the reciprocal absolute temperature curve are 73 kJ/mol and 20 kJ/mol, respectively. The apparent activation energy for Na_2SO_4 doped with 4.1 mol% $Eu_2(SO_4)_3$, 40 kJ/mol, is between 73 kJ/mol for Na_2SO_4-III and 20 kJ/mol for Na_2SO_4-I.

The phases and thermal properties of the $Na_2SO_4-Eu_2(SO_4)_3$ system are summarized in Table 1. From X-ray analysis, some of the original Na_2SO_4-V still remained in all samples. Formation of a $Na_2SO_4-Eu_2(SO_4)_3$ solid solution does not seem to be a facile process. By a DTA measurement, some peaks are detected with no weight change, hence phase transformations were considered to occur. Therefore the two component system, $Na_2SO_4-Eu_2(SO_4)_3$, is not suitable for solid electrolytes.

The $Na_2SO_4-NaVO_3$ system

In the $Na_2SO_4-NaVO_3$ system, Na_2SO_4 doped with 2 mol% $NaVO_3$, 5 mol% $NaVO_3$, 7 mol% $NaVO_3$, and 10 mol% $NaVO_3$, where these mol% are initial concentrations of the dopant, were prepared. In all samples of Na_2SO_4 doped with $NaVO_3$, electrical conductivities are greatly lowered by the doping. A representative behavior is shown in Fig. 3. The structure of Na_2SO_4 is partially destroyed by doping of $NaVO_3$ because the volume of the VO_3^- anion is larger than that of SO_4^{2-}. Doping by $NaVO_3$ does not affect the electrical charge balance. The phases and thermal properties of $Na_2SO_4-NaVO_3$ are summarized in Table 2. From X-ray analysis, Na_2SO_4-V still remained in all samples and $NaVO_3$ remained in most samples except Na_2SO_4 doped with 2 mol% $NaVO_3$. These results are probably due to the low solubility of $NaVO_3$ in solid Na_2SO_4. By a DTA measurement, some peaks due to phase transformations are observed in all samples listed in Table 2. Electrical conductivities of the two-component system $Na_2SO_4-NaVO_3$ are very low. Doping of a third component to the $Na_2SO_4-NaVO_3$ system is necessary in order to improve electrical conductivities.

The three-component systems

The $Na_2SO_4-NaVO_3-Eu_2(SO_4)_3$ system

In the $Na_2SO_4-NaVO_3-Eu_2(SO_4)_3$ system, samples of Na_2SO_4 doped with 0.9 mol% $NaVO_3$ and 1.0 mol% $Eu_2(SO_4)_3$, 1.7 mol% $NaVO_3$ and 2.0 mol% $Eu_2(SO_4)_3$, 2.4 mol% $NaVO_3$

[a] The α and β phases are similar to the Na_2SO_4-III and Na_2SO_4-I phases, respectively (15, 16). X-ray analyses were done at room temperature.
[b] Reproducibility of DTA temperature is within 8 K.

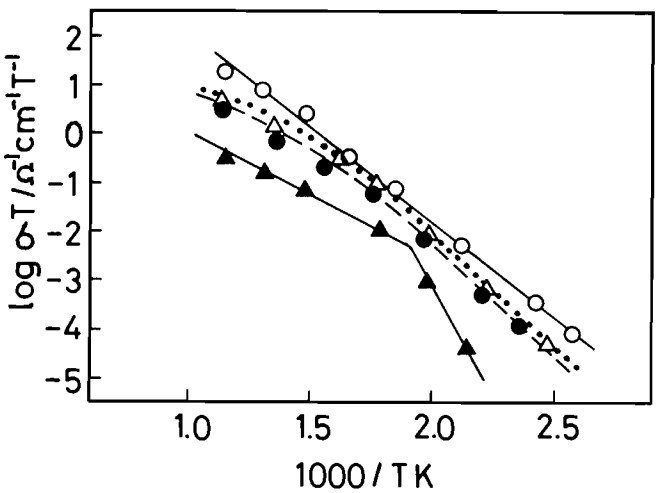

FIG. 4. Temperature dependences of electrical conductivities for the Na_2SO_4–$NaVO_3$–$Eu_2(SO_4)_3$ system which exhibit the β phase. –○– Na_2SO_4–$NaVO_3$–$Eu_2(SO_4)_3$ = 91.0:4.0:5.0; ·△· Na_2SO_4–$NaVO_3$–$Eu_2(SO_4)_3$ = 93.2:2.8:4.0; –●– Na_2SO_4–$NaVO_3$–$Eu_2(SO_4)_3$ = 94.6:2.4:3.0; –▲– Na_2SO_4.

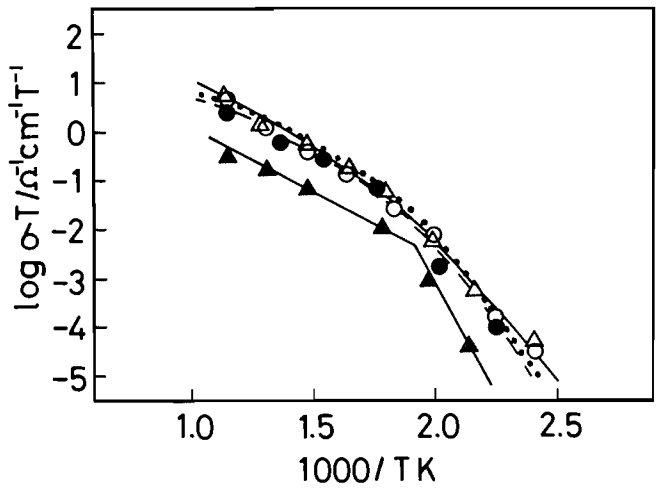

FIG. 5. Temperature dependences of electrical conductivities for the Na_2SO_4–$NaVO_3$–$Pr_2(SO_4)_3$ system which exhibit the β phase. –○– Na_2SO_4–$NaVO_3$–$Pr_2(SO_4)_3$ = 91.1:3.9:5.0; ·△· Na_2SO_4–$NaVO_3$–$Pr_2(SO_4)_3$ = 92.8:3.2:4.0; –●– Na_2SO_4–$NaVO_3$–$Pr_2(SO_4)_3$ = 94.4:2.6:3.0; –▲– Na_2SO_4.

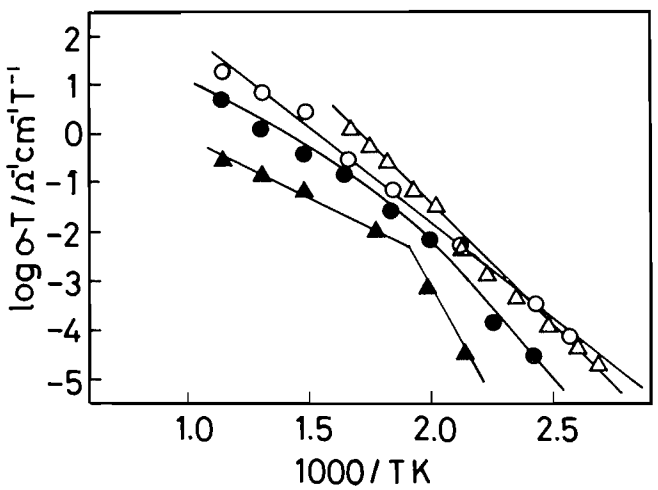

FIG. 6. Temperature dependences of electrical conductivities for Na_2SO_4, Na_2SO_4–$Eu_2(SO_4)_3$, and Na_2SO_4–$NaVO_3$–$Ln_2(SO_4)_3$ (Ln = Eu, Pr). –○– Na_2SO_4–$NaVO_3$–$Eu_2(SO_4)_3$ = 91.0:4.0:5.0; –●– Na_2SO_4–$NaVO_3$–$Pr_2(SO_4)_3$ = 91.1:3.9:5.0; –△– Na_2SO_4–$Eu_2(SO_4)_3$ = 95.9:4.1; –▲– Na_2SO_4.

and 3.0 mol% $Eu_2(SO_4)_3$, 2.8 mol% $NaVO_3$ and 4.0 mol% $Eu_2(SO_4)_3$, and 4.0 mol% $NaVO_3$ and 5.0 mol% $Eu_2(SO_4)_3$ were prepared. The phases and thermal properties are summarized in Table 3. From X-ray analysis, peaks due to the raw materials, $NaVO_3$ and $Eu_2(SO_4)_3$, have disappeared in all samples. The samples that showed the α phase are Na_2SO_4 doped with 0.9 mol% $NaVO_3$ and 1.0 mol% $Eu_2(SO_4)_3$, and 1.7 mol% $NaVO_3$ and 2.0 mol% $Eu_2(SO_4)_3$. The samples that exhibited the β phase are Na_2SO_4 doped with 2.4 mol% $NaVO_3$ and 3.0 mol% $Eu_2(SO_4)_3$, 2.8 mol% $NaVO_3$ and 4.0 mol% $Eu_2(SO_4)_3$, and 4.0 mol% $NaVO_3$ and 5.0 mol% $Eu_2(SO_4)_3$. The α and β phases are similar to the Na_2SO_4-III phase (15, 16) (a low temperature phase) and the Na_2SO_4-I phase (15, 16) (a high temperature phase), respectively. In a DTA measurement, the samples that exhibited the α phase show some endothermal peaks, due to phase transformations. On the other hand, the samples that exhibited the β phase show no endothermal peak, which means no phase transformation occurred. Therefore, the samples that exhibited the β phase in the Na_2SO_4–$NaVO_3$–$Eu_2(SO_4)_3$ system have potential as solid electrolytes for a SO_2 detector concentration cell. Electrical conductivities of the Na_2SO_4–$NaVO_3$–$Eu_2(SO_4)_3$ samples which exhibit the β phase are shown in Fig. 4. Compared with Na_2SO_4, the electrical conductivities increased about 1.0–2.0 orders of magnitude and the break in the log (σT) vs. $10^3/T$ relation disappeared. Electrical conductivities increased with increasing concentration of the dopants $NaVO_3$ and $Eu_2(SO_4)_3$, that is, the doping of $NaVO_3$ hardly influences the conductivity of the samples. The samples of Na_2SO_4–$NaVO_3$–$Eu_2(SO_4)_3$ which exhibited the β phase maintain the structure of the Na_2SO_4-I phase even at a relatively low temperature. Therefore, the electrical conductivities of this system at a low temperature are

much greater than those of Na_2SO_4.

The apparent activation energy for a sample of Na_2SO_4 doped with 4.0 mol% $NaVO_3$ and 5.0 mol% $Eu_2(SO_4)_3$, which is expected to be the best one of the five samples considered because its conductivity curve is almost linear without discontinuities, is 32 kJ/mol. This apparent activation energy, 32 kJ/mol, is smaller than 40 kJ/mol for Na_2SO_4 doped with 4.1 mol% $Eu_2(SO_4)_3$. The sample of Na_2SO_4 doped with 4.0 mol% $NaVO_3$ and 5.0 mol% $Eu_2(SO_4)_3$ having the Na_2SO_4-I (a high temperature phase) structure and a low apparent activation energy is considered to be a good solid electrolyte for a SO_2 detector concentration cell.

The Na_2SO_4–$NaVO_3$–$Pr_2(SO_4)_3$ system

In the system Na_2SO_4–$NaVO_3$–$Pr_2(SO_4)_3$, Na_2SO_4 doped with 1.0 mol% $NaVO_3$ and 1.0 mol% $Pr_2(SO_4)_3$, 2.0 mol% $NaVO_3$ and 2.0 mol% $Pr_2(SO_4)_3$, 2.6 mol% $NaVO_3$ and 3.0 mol% $Pr_2(SO_4)_3$, 3.2 mol% $NaVO_3$ and 4.0 mol% $Pr_2(SO_4)_3$, and 3.9 mol% $NaVO_3$ and 5.0 mol% $Pr_2(SO_4)_3$ were prepared. The phases and thermal properties are summarized in Table 4. From X-ray analysis, the raw materials $NaVO_3$ and $Pr_2(SO_4)_3$ were not detected in all samples. The samples doped with 1.0 mol% $NaVO_3$ and 1.0 mol% $Pr_2(SO_4)_3$, and 2.0 mol% $NaVO_3$ and 2.0 mol% $Pr_2(SO_4)_3$ showed the α phase. On the other hand, the samples doped with 2.6 mol% $NaVO_3$ and 3.0 mol% $Pr_2(SO_4)_3$, 3.2 mol% $NaVO_3$ and 4.0 mol% $Pr_2(SO_4)_3$, and 3.9 mol% $NaVO_3$ and 5.0 mol% $Pr_2(SO_4)_3$ exhibited the β phase. In a DTA measurement, the samples that exhibited the β phase show no endothermal peak (the sample Na_2SO_4 doped with 3.9 mol% $NaVO_3$ and 5.0 mol% $Pr_2(SO_4)_3$ shows a peak at 587 K, but very small), due to the fact that no phase transformation occurred. Therefore, the samples that exhibited the β phase in Na_2SO_4–$NaVO_3$–$Pr_2(SO_4)_3$ are also good ones for solid electrolytes. The electrical conductivities of Na_2SO_4–$NaVO_3$–$Pr_2(SO_4)_3$ samples which exhibit the β phase are shown in Fig. 5. Electrical conductivities increase about 1.5 orders of magnitude in comparison with Na_2SO_4 and there is no break in the conductivity curve. Cation vacancies increase by doping more $Pr_2(SO_4)_3$. On the other hand, electrical conductivities decrease by doping more $NaVO_3$. These effects cancel each other, the electrical conductivities having almost the same curve in these three samples. The samples of Na_2SO_4–$NaVO_3$–$Pr_2(SO_4)_3$ which exhibit the β phase also keep the structure of the Na_2SO_4-I phase even at a relatively low temperature. Therefore, the electrical conductivities at low temperature are much higher than those of Na_2SO_4.

The apparent activation energy for the sample of Na_2SO_4 doped with 3.9 mol% $NaVO_3$ and 5.0 mol% $Pr_2(SO_4)_3$ is 34 kJ/mol; this sample is considered to be the best one of the five considered, because its electrical conductivity curve is almost linear without discontinuities over the temperature range between 445 K and 769 K. The apparent activation energy, 34 kJ/mol, is smaller than 40 kJ/mol for Na_2SO_4 doped with 4.1 mol% $Eu_2(SO_4)_3$.

Electrical conductivities of Na_2SO_4–$NaVO_3$–$Ln_2(SO_4)_3$ (Ln = Eu, Pr) compared with Na_2SO_4–$Eu_2(SO_4)_3$ and Na_2SO_4 are shown in Fig. 6. By doping Na_2SO_4 with $Eu_2(SO_4)_3$, or $NaVO_3$ with $Ln_2(SO_4)_3$ (Ln = Eu, Pr) the log (σT) vs. $10^3/T$ plot shows an almost linear relationship although phase transformations still occur in the Na_2SO_4–$Eu_2(SO_4)_3$ system. Doping Na_2SO_4 prevents Na_2SO_4 from forming the Na_2SO_4-I phase because the volume of the VO_3^- anion is greater than that of SO_4^{2-}. On the other hand, by adding $Ln_2(SO_4)_3$ (Ln = Eu, Pr) to the Na_2SO_4–$NaVO_3$ system, the disadvantage that the volume of the VO_3^- anion is larger than that of the SO_4^{2-} is cancelled because the Ln^{3+} cation (Ln = Eu, Pr) radius is greater than that of the Na^+. As a result, the Na_2SO_4–$NaVO_3$–$Ln_2(SO_4)_3$ (Ln = Eu, Pr) system easily forms the high temperature Na_2SO_4-I phase. Lattice defects are increased by doping with Ln^{3+} (Ln = Eu, Pr). Therefore the electrical conductivities of Na_2SO_4–$NaVO_3$–$Ln_2(SO_4)_3$ (Ln = Eu, Pr) at relatively low temperatures increase compared with those of Na_2SO_4 and Na_2SO_4–$Eu_2(SO_4)_3$.

In the three-component systems, the apparent activation energy of Na_2SO_4 doped with 4.0 mol% $NaVO_3$ and 5.0 mol% $Eu_2(SO_4)_3$, $(Na_{0.86}Eu_{0.05}\square_{0.09})_2SO_4$ – 0.04 $NaVO_3$, 32 kJ/mol, is slightly smaller than that of Na_2SO_4 doped with 3.9 mol% $NaVO_3$ and 5.0 mol% $Pr_2(SO_4)_3$, $(Na_{0.86}Pr_{0.05}\square_{0.09})_2SO_4$ – 0.04 $NaVO_3$, 34 kJ/mol. Electrical conductivities of Na_2SO_4–$NaVO_3$–$Eu_2(SO_4)_3$ are higher than those of Na_2SO_4–$NaVO_3$–$Pr_2(SO_4)_3$. In both three-component systems, the concentration of cation vacancies is 0.09 and very close to 0.08 for Na_2SO_4 doped with 4.1 mol% $Eu_2(SO_4)_3$, which means that most of cation vacancies are able to act as sites for Na^+ ion migration. Therefore the concentration of cation vacancies is not a main factor for the difference in electrical properties. One reason for the difference in electrical conductivities and apparent activation energies for Na_2SO_4–$NaVO_3$–$Eu_2(SO_4)_3$ and Na_2SO_4–$NaVO_3$–$Pr_2(SO_4)_3$ comes from the difference of ionic radius between Eu^{3+} (0.126 nm) (32) and Pr^{3+} (0.132 nm) (32). Because the ionic radius of Na^+ (0.126 nm) (32) is closer to that of Eu^{3+} (0.126 nm) (32) rather than to that of Pr^{3+} (0.132 nm) (32), the Na_2SO_4–$NaVO_3$–$Eu_2(SO_4)_3$ system maintains the structure of the Na_2SO_4-I phase better than the Na_2SO_4–$NaVO_3$–$Pr_2(SO_4)_3$ system.

In the three-component systems, electrical conductivities are the highest and the apparent activation energies are the lowest of the present systems. The three-component systems of Na_2SO_4–$NaVO_3$–$Ln_2(SO_4)_3$ (Ln = Eu, Pr) are considered to be good solid electrolytes as a SO_2 detector concentration cell, especially at relatively low temperatures.

Received October 25, 1982

PENELOPE W. CODDING, HANS KOENIG, and RICHARD T. OAKLEY. Can. J. Chem. **61**, 1562 (1983).

The crystal and molecular structures of 1,2,7,9-tetrathia-3,6,8,10-tetra-aza-cyclophept(*e*)indene, a novel carbon–sulphur–nitrogen heterocycle based on the phenazulene ring system, are reported. Crystals of the compound are orthorhombic, space group *Pbca*, a = 7.1334(8), b = 14.761(2), c = 16.677(2) Å, V = 1756.0(3) Å^3, Z = 8. The structure was solved by direct methods and refined by full-matrix least-squares procedures to a final R = 0.044 and R_w = 0.027. Molecules of the title compound consist of a five-membered C—S—S—N—C ring and a seven-membered C—N—S—N—S—N—C ring fused to a benzene ring. Internal structural parameters and the cell packing pattern suggest a dipolar charge distribution. The molecules are stacked in parallel planes in a head-to-tail fashion; the interplanar separation is 3.39 Å and the angle between the molecular planes and the *a* axis is 18°. The electronic spectrum of the molecule is discussed in relation to the perimeter model.

PENELOPE W. CODDING, HANS KOENIG et RICHARD T. OAKLEY. Can. J. Chem. **61**, 1562 (1983).

On rapporte la structure moléculaire et la structure cristalline du tétrathia-1,2,7,9 tétra-aza-3,6,8,10 cyclohept(*e*)indène, un nouvel hétérocycle, contenant le carbone, le soufre et l'azote, basé sur le système cyclique phénazulène. Les cristaux de ce composé sont orthorhombiques et appartiennent au groupe d'espace *Pbca* avec a = 7,1334(8), b = 14,761(2), c = 16,677(2) Å, V = 1756,0(3) Å^3, Z = 8. On a résolu la structure par les méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs de R = 0,044 et de R_w = 0,027. Les molécules du composé mentionné dans le titre comprennent un cycle à cinq chainons C—S—S—N—C et un cycle à sept chainons C—N—S—N—S—N—C condensés sur le cycle benzène. Les paramètres structuraux internes et le dessin de l'entassement moléculaire suggèrent une distribution de charge bipolaire. Les molécules sont entassées dans des plans parallèles en positions tête contre queue; la séparation des plans est de 3,39 Å et l'angle entre les plans moléculaires et l'axe *a* est de 18°. On discute du spectre électronique de la molécule en fonction du modèle du périmètre.

Introduction

The unique electrical properties of $(CH)_x$ and $(SN)_x$ polymers (1) have demonstrated the potential applications of nonmetallic chemistry in the development of new conducting materials. The design and preparation of polymers and macrocycles featuring a combination of carbon–carbon and sulphur–nitrogen linkages thus represent an appealing challenge to synthetic chemists. Recently several such systems have been reported (2–6). In the course of our own work on the construction of heterocycles containing conjugated sulphur–nitrogen bonds (7) we have discovered the novel tricyclic molecule 1,2,7,9-tetrathia-3,6,8,10-tetra-aza-cyclohept(*e*)indene **1**, an inorganic analogue of the recently reported phenazulene ring system **2** (8). In the present paper we describe the crystal and molecular structures of **1**.

2

Experimental

Starting materials and general procedures

The bifunctional sulphur diimide $Me_3SiNSN(C_6H_4)NSNSiMe_3$ was prepared as recently described (4). Sulphur dichloride (Fisher) was distilled from phosphorus trichloride prior to use. Ultraviolet–visible spectra were recorded on a Cary 219 spectrophotometer. Chemical analyses were performed by MHW laboratories, Phoenix, Arizona.

Unique reflections	1548
No. with $I > 3\sigma(I)$	775
μ (cm^{-1})	9.98

Preparation of $C_6H_2S_4N_4$, 1

A solution of $Me_3SiNSN(C_6H_4)NSNSiMe_3$ (1.00 g, 2.9 mmol) in 200 mL of methylene chloride was added dropwise over a 5 h period to a stirred solution of sulphur dichloride (0.30 g, 2.9 mmol) in 1200 mL of methylene chloride. After 24 h the mixture was filtered and the filtrate concentrated on a rotary evaporator to ~50 mL. This dark green/blue solution was eluted through a short 50-mm plug of silica and the dark blue solution so obtained evaporated to dryness. The bronze coloured residue was recrystallized from hot toluene to give metallic golden needles of $C_6H_2S_4N_4$, **1** (12 mg, 0.4 mmol, 1%), mp 254–257°C. Ultraviolet–visible (CH_2Cl_2) λ_{max} (log ε): 625(4.0), 582(4.0), 366(4.0), 342(4.0). *Anal.* calcd. for $C_6H_2S_4N_4$: C 27.91, H 0.78, N 21.71, S 49.61; found: C 28.13, H 1.06, N 21.43, S 49.36. *Mol. wt.* calcd. for $C_6H_2S_4N_4$: 257.9162; found: 257.9159.

*The hydrogen atom parameters were not refined. U_{iso} was set to 1.2 × the U_{iso} of the atom to which they are bonded.

X-ray analysis

A needle shaped crystal of **1** was used for data collection on an Enraf Nonius CAD4F diffractometer. The crystallographic data are summarized in Table 1. After alignment of the crystal, 25 reflections were centered and indexed using the automatic routines of the instrument. The cell was identified as orthorhombic; this lattice assignment was confirmed and the space group determined by examination of the intensities measured during the data collection. Systematic absences of $(0kl)$, $k = 2n + 1$, $(h0l)$, $l = 2n + 1$, and $(hk0)$, $k = 2n + 1$ identified the space group as *Pbca*. Data were collected at room temperature using an $\omega/2\theta$ scan of 96 steps, of which the central 64 steps were taken as the peak, P, and the first and last 16 steps were taken as backgrounds, $B1$ and $B2$ so that $I = [P - 2(B1 + B2)]Q$, where Q was the scan rate. Lorentz and polarization corrections were applied and E values were calculated by applying a K-curve. No absorption correction was made.

Initial coordinates for all the sulphur, carbon, and nitrogen atoms of the molecule were obtained by direct methods (MULTAN 78 (9)) and refined by full-matrix least-squares techniques using isotropic thermal parameters to give residual indices of $R = \Sigma(||F_o| - |F_c||)/\Sigma|F_o| = 0.082$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)^{1/2} = 0.087$. After a refinement of anisotropic thermal parameters and coordinates, a difference Fourier synthesis revealed the positions of the two unique hydrogen atoms. They were included in the model at idealized positions (d(C—H) = 0.95 Å) with thermal parameters 20% greater than the isotropic thermal parameters of the C atoms to which they were bonded. The hydrogen atom parameters were not refined. The reflections included in the final refinement were observed reflections plus those unobserved data with I_c values greater than $3\sigma(I_o)$, i.e. a total of 1203 data. After convergence of the least-squares refinement with a maximum shift/error = 0.004, the residual indices for the 1203 reflections and the 127 variables were $R = 0.044$ and $R_w = 0.027$. The weights were defined as $(\sigma^2(F))^{-1}$ and the standard deviation of an observation of unit weight was 0.90. Atomic coordinates for the structure are given in Table 2. Table 3 provides intramolecular bond length and intervalence angle information.[2] All computations were done using the XRAY 76 system of programs (10) implemented on a Honeywell computer with a Multics operating system. Scattering factors were those of Cromer and Mann (11).

[2]The anisotropic thermal parameters (Table 4) and the table of observed and calculated structure amplitudes (Table 5) are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and discussion

Preparation of $C_6H_2S_4N_4$, 1

We have recently reported the reaction between *N*-phenyl-*N'*-trimethylsilyl sulphur diimide $PhNSNSiMe_3$ and sulphur dichloride, which yields the novel anti-aromatic 12π-electron heterocycle **3** (eq. [1]) (7). As a continuation of this work we have explored the reaction of the bifunctional *p*-phenylene derivative $Me_3SiNSN(C_6H_4)NSNSiMe_3$, **4**, with sulphur di-

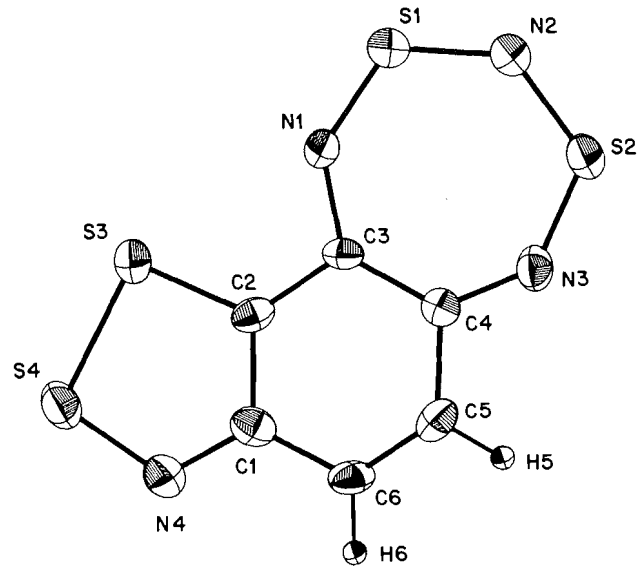

FIG. 1. An ORTEP drawing (50% probability ellipsoids) of the molecule, showing the atom numbering scheme. The hydrogen atoms are drawn as an arbitrary spheroid of 0.1 Å radius.

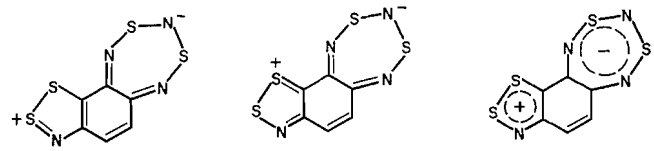
chloride (eq. [2]) with the intent of producing the tricyclic anthracene-like molecule **5**. It has already been shown that the principal product of this reaction (albeit with a different stoichiometry) is the polymer $(—SNSNC_6H_4NSN—)_x$ (4), but small amounts of a tractable compound are also formed. Chromatography of the reaction mixture reveals an intense blue component which, upon subsequent separation and crystallization, can be isolated as metallic gold needles with the empirical formula $C_6H_2S_4N_4$. Although this analysis is consistent with the anticipated product **5**, an X-ray crystal structure determination of the compound has revealed the novel phenazulene-like framework **1**. We have no immediate explanation for the formation of **1** rather than **5**; further studies on related electrophilic annelations may provide an answer.

Crystal, molecular, and electronic structures of 1

An ORTEP drawing of the molecule indicating the atom numbering scheme is shown in Fig. 1. As a whole the molecule is essentially planar (σ = 0.001 Å), the two largest deviations from the mean molecular plane occurring at S3(0.030 Å) and N1(0.027 Å). The slight buckling of the perimeter at these two sites probably reflects the rather short nonbonded contact S3---N1 (2.850(4) Å), which is considerably shorter than the sum of the van der Waals' radii for sulphur and nitrogen (3.35 Å) (12). The structural parameters within the rings (Table 3) point to a delocalized π-system whose ground state cannot be adequately represented by a single valence bond structure such as **1**. Other likely resonance contributors are **6** and **7**. Indeed the dipolar formulation **8** provides perhaps the most useful basis for describing the principal features of the molecular and crystal structures.



6 **7** **8**

According to **8** the molecule consists of a cyclic 5-atom

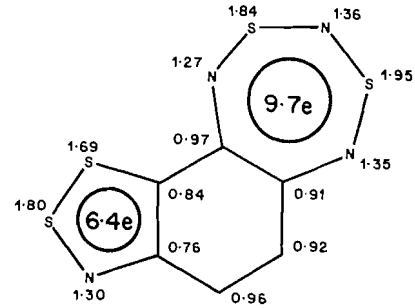


FIG. 2. Extended Hückel π-charge densities. Circled numbers represent total π-charge densities in the different rings.

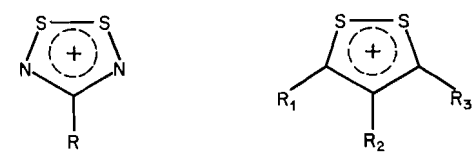
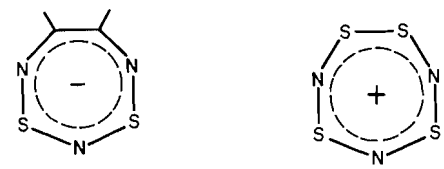
6π-electron dithiazolium cation fused to a cyclic 7-atom 10π-electron $C_2S_2N_3^-$ anion by means of the C2—C3 bond. The strongly localized nature of the C5—C6 π-bond is reflected by its shortness (1.326 Å) relative to the other C—C bonds (range 1.403−1.425 Å) and the C—C distance in benzene (1.39 Å) (13). While the 5-membered C_2S_2N ring can be considered as a simple hybrid of the better-known dithiadiazolium **9** (14) and dithiolium **10** (15) cations, the latter 7-membered $C_2S_2N_3$ ring represents a novel structural unit in SN heterocyclic chemistry. If treated in isolation, e.g. **11**, the π-system of this anion can be viewed as isoelectronic with the thiotrithiazyl cation **12** (16). Consistently the mean SN distances in the $C_2S_2N_3$ ring of **1** closely resemble those found in $S_4N_3^+$ salts (17).



9 **10**



11 **12**

Extended Hückel (EH) molecular orbital calculations on a planar projection of **1** refine the valence bond picture and substantiate the charge distribution suggested by **8**. Thus, a summation of the EH π-charge densities over the nine occupied π-orbitals (Fig. 2) reveals a total π-charge density on the C_2S_2N and $C_2S_2N_3$ rings of 6.4 and 9.7 π-electrons respectively, i.e. there is a net π-charge transfer of about 0.6 electrons from the small to the large ring.

The arrangement of the molecules in the unit cell provides further evidence in favour of the dipolar representations **6**, **7**, and **8**. The molecules form stacks in the *a* direction, the packing being such that the five-membered C_2S_2N ring of one molecule lies approximately over the seven-membered ring of the molecule below it (see Fig. 3). This pattern repeats itself throughout the stack, producing an alternating sequence of molecules, i.e. the positively charged end of one molecule is

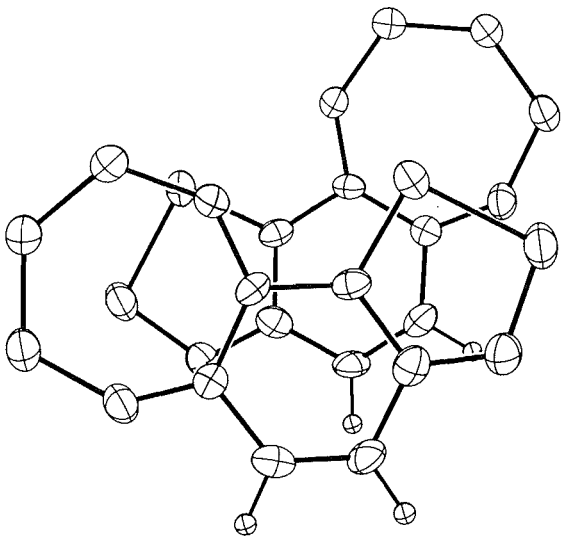


FIG. 3. Heat-to-tail packing of two molecules, viewed from a direction perpendicular to their mean planes.

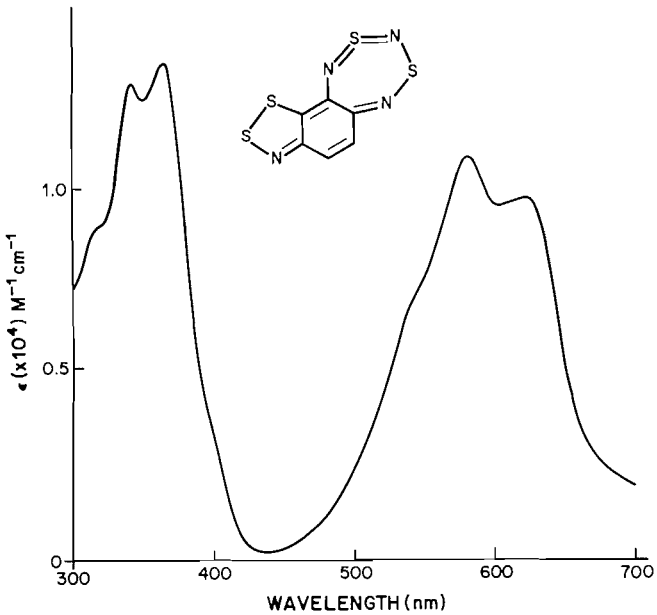

FIG. 4. Ultraviolet–visible spectrum of $C_6H_2S_4N_4$ (in CH_2Cl_2).

sandwiched between the negative ends of its two nearest neighbours, and vice versa. This head-to-tail mode of packing is typical of many $\pi-\pi^*$ donor–acceptor complexes (18); in the present case the structure represents a novel example of a self-complexing molecule (18, 19). The planes of consecutive molecules in the stack are parallel and make an angle of 18° with the *a* axis. The interplanar separation is uniformly 3.39 Å, i.e. there is no pairing of the molecules. The observed spacing is reminiscent of that found in naptho[1,8-*cd*:4,5-*c'd'*]bis-[1,2,6]thiadiazine (3.40 Å) (2*a*) and graphite (3.35–3.37 Å) (20).

While the structural evidence points to the possibility of intermolecular charge transfer interactions in the solid state, there are no indications of such phenomena in dilute solution. The colour of the compound in solution (deep blue) differs markedly from that in the solid state (metallic bronze), and the visible spectrum shows no deviations from the Beer–Lambert law. Indeed the appearance of the spectrum (Fig. 4) finds an appealing explanation through the use of the perimeter model (21, 22). Within the confines of this approximation, those cyclic π-electron systems which possess $4n + 2$ electrons inside their perimeters (regardless of cross-links or heteroatoms) will be characterized by four electronic transitions, generally referred to as L_1, L_2, B_1, and B_2 in order of increasing energy. In essence the four bands correspond to excitations from the two highest occupied π-levels of the perimeter to the two lowest unoccupied orbitals. In phenazulene, which is a 14π-electron perimeter, there appears to be a reasonable correlation between theory (23) and experiment (8). In the present case, where we have an 18π-electron system with low symmetry, all four transitions are expected to be allowed. It is therefore tempting to assign the observed bands to these four transitions. The absorptions visible as shoulders on the main bands may be evidence of vibronic coupling or second order excitations not dealt with by the simple theory. Detailed analysis of the MCD spectrum of the molecule would undoubtedly clarify the assignments.

Nonadditive effects of polysubstitution in CH_4 and CH_3: a test of *ab initio* and semiempirical MO methods

N. COLIN BAIRD

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received November 18, 1982

N. COLIN BAIRD. Can. J. Chem. **61**, 1567 (1983).

The effects to the bond lengths and molecular energy of making multiple substitutions at the same carbon atom in methane and the methyl free radical are studied using various molecular orbital methods. All *ab initio* calculations were based upon the Hartree–Fock formalism (unrestricted in the case of free radicals) and employed the STO-3G (with *d* orbitals on chlorine), 3-21G, and 4-31G bases, the last both with and without a set of Gaussian *d* orbitals on the carbon. The semiempirical methods used were the MINDO/3 and MNDO methods of Dewar and co-workers; computations for polysubstituted ethanes by these two methods also are reported. The *ab inito* methods which use a split valence shell basis set account very well for the trends in bond lengths and heats of formation, at least when the polysubstituent is fluorine or hydroxyl. In contrast, the semiempirical calculations and the *ab initio* STO-3G results gave very poor results. Finally, the role of interactions between the AH bonds in a variety of hydrides AH_n is illustrated using experimental energetics.

N. COLIN BAIRD. Can. J. Chem. **61**, 1567 (1983).

Faisant appel à différentes méthodes de calcul d'orbitales moléculaires, on a étudié les effets des substitutions multiples au niveau du même atome de carbone du méthane et du radical libre méthyle, sur les longueurs de liaison et sur l'énergie moléculaire. Les calculs *ab initio* reposent tous sur le formalisme de Hartree–Fock (sans restriction dans le cas des radicaux libres) et utilisent les bases: STO-3G (avec les orbitales *d* du chlore), 3-21G et 4-31G. Les deux dernières sont utilisées avec ou sans l'ensemble d'orbitales *d* de gauss du carbone. On a utilisé les méthodes semi-empiriques telles le MINDO/3 et le MNDO de Dewar et de ses collaborateurs. On rapporte également les calculs effectués par ces deux méthodes sur les éthanes polysubstitués. Les méthodes *ab inito* qui impliquent l'ensemble de base de la couche de valence dédoublée rendent très bien compte des tendances des longueurs de liaison et des chaleurs de formation lorsque le polysubstituant est au moins le fluor ou l'hydroxyle. Les calculs semi-empiriques et les résultats *ab initio* du STO-3G donnent au contraire de très faibles résultats. Finalement on illustre le rôle des interactions entre les liaisons AH de divers hydrures AH_n en utilisant l'énergétique expérimentale.

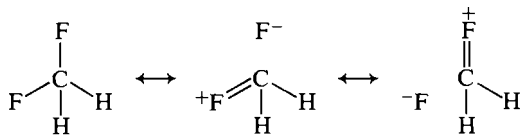
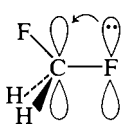
Introduction

For many purposes, polyatomic molecules can be profitably considered to be systems containing noninteracting two-centre bonds. However, the interaction between bonds, especially if they are equivalent, can have important ramifications to physical properties (e.g. the stability and geometry of conjugated hydrocarbons) and to chemical behavior (e.g. in reactions subject to orbital symmetry control).

The rather peculiar behavior of hydrocarbons which contain multiple substitution at the same carbon by highly-electronegative substituents has been long recognized. The most famous examples are the various fluorinated methanes, whose unusual characteristics have traditionally been attributed to resonance among valence-bond structures involving doubly-bonded fluorine; e.g.





From an analysis using molecular oribtal theory (1) of disubstituted molecules XCH_2Y, it has been suggested that one of the principal stabilizing interactions in such systems is back-bonding from fluorine to carbon via donation of electron density from a p_π lone pair on one fluorine into the antibonding σ^*_{CF} orbital associated with the second fluorine and which lies in the same plane as the lone pair. The other stabilizing factor, which evidently is more important with weak π donors and strong σ acceptors such as fluorine, is the bond strengthening which results from a depletion of electron density about the carbon.

Our interest in the present report is not so much to investigate the origin of the polysubstitution effects; rather it is to survey common calculational procedures in order to discover which are reliable in quantitatively reproducing the nonadditive energetic and geometric effects associated with multiple substitution. For the *ab initio* methods, we wish to determine whether these effects lie within the Hartree–Fock framework, and if so what is the minimum size of basis set that should be used. Some testing of *ab initio* MO methods in their handling of the energetic effects of polysubstitution has been reported by Pople and by Radom and their co-workers (1*a*–*d*). Here we extend and generalize their analysis, making use of published and archival results (1) as well as some new calculations. Similarly Dewar and co-workers have already made some comments regarding the behavior of the MNDO and MINDO/3 methods in reproducing nonadditive effects in the fluoromethanes (2), and here we incorporate and extend their analysis.

Method of calculation

All new *ab initio* MO calculations reported herein were obtained using the GAUSSIAN-76 program (3) on a CDC Cyber 73 computer. The basis sets for the *s* and *p* orbitals correspond to the expansions of Pople and co-workers and use their standard molecular scaling factors (4*a*, *b*, *c*). In some of the 4-31G calculations (as noted in text) a set of six Gaussian *d* orbitals, each of exponent 0.80 (4*d*), was added to the central

TABLE 1. CF bond lengths (Å) in fluoromethanes (relative to CH_3F)

Species	Experimental[a]	*Ab initio* calculation[b] via STO-3G	3-21G	4-31G	4-31G*(C)	Semi-empirical calculations MNDO	MINDO/3

carbon atom; this basis set is denoted in the text as 4-31G*(C). The STO-3G* basis for chlorine employs five *d* orbitals,[1] with standard exponent (3*c*). All results were obtained using the Hartree–Fock procedure, unrestricted in the case of open shell species. The conformations assumed in $CH_2(OH)_2$ and $CH(OH)_3$ were the idealizations found optimum in previous calculations for these molecules (1*b*, *c*). Fuller details concerning the results of the calculations reported here for the first time are given in Tables D-1 to D-5.[2]

All new MINDO/3 (5*a*) and MNDO calculations were obtained using the MINDO/3 (5*a*) and MNDOC (5*b*) computer programs on a CDC Cyber 170-835 computer.

Results and discussion

One striking effect of multiple fluorine substitution at the same carbon is the progressive contraction of the CF bond lengths. Each substitution of F for H in methane shortens all the carbon–fluorine bonds. The overall effect amounts to 0.06 Å in going from CH_3F to CF_4, i.e. about one-third the difference between single and double bonds formed by carbon with other elements of the same row.

The changes in the CF bond lengths in the polyfluoromethanes, relative to that computed for CH_3F, are given in Table 1 for *ab initio* calculations by the STO-3G, 3-21G, 4-31G, and 4-31G*(C) (i.e., with *d* orbitals on carbon) basis sets, for semiempirical MO calculations by the MNDO and MINDO/3 methods (2, 6) as are experimental values.

All *ab initio* calculations predict the correct qualitative trend, i.e. that CF distances progressively decrease with each additional substitution of fluorine for hydrogen, from CH_3F to CF_4. However, the STO-3G basis greatly underestimates the magnitude of the contractions, the overall decrease being only 0.018 Å compared to the observed 0.06 Å. The split valence-shell orbital bases, with or without *d* orbitals on carbon, account very well for the contractions, the overall decreases being 0.079 Å, 0.06_3 Å, and 0.06_7 Å by 3-21G, 4-31G, and 4-31G*(C), respectively. (The effect of the *d* orbitals is to contract all the CF lengths by about the same amount, $0.03_5 \pm 0.00_3$ Å.)

The MINDO/3 method also reproduces very well the experimental trend in CF bond lengths. However, the MNDO method fails completely in this regard, since it predicts small *increases* in CF length from CH_3F to CH_2F_2 and to CHF_3. (Both results were noted by Dewar and co-workers (2).) To investigate the generality of these trends, we have obtained optimum MNDO and MINDO/3 geometries for the various polyfluoroethane series, i.e. $CH_3CH_{3-n}F_n$, $CH_2FCH_{3-n}F_n$, $CHF_2CH_{3-n}F_n$, and $CF_3CH_{3-n}F_n$. For the CH_2F—R units, a decrease of 0.004 Å is predicted to occur whenever the number of F atoms within the R group is increased by one. Similar, though somewhat less constant, increases occur within the CHF_2—R and CF_3—R groups (see Table 2). Clearly, then, the MNDO method predicts that CF lengths undergo some contraction due to changes in the inductive effect of the groups bonded to the carbon. However, if the results in Table 2 are reconsidered from the viewpoint of variations in R_{CF} due to a change in the number of fluorine atoms bonded to that same carbon, virtually no changes (within ±0.002) occur. This experience is consistent with the behavior of the fluoromethane series. Experimentally, few results are available but it is clear that large contractions, of the order of 0.06–0.07 Å do occur in going from CH_2FCH_2F to CF_3CH_3 and CF_3CF_3 respectively (2), in contrast to the small MNDO predicted changes of −0.002 Å and 0.010 Å, respectively.

Interestingly, the MNDO calculations predict large changes in the CC bond length in the polyfluoromethanes as the number

[1]As a referee has pointed out, such a basis for chlorine is unsaturated with respect to *s* and *p* orbitals, and the *d* orbitals will not act exclusively as polarization functions. However Pople and co-workers have successfully used this basis (3*c*).

[2]Complete set of data is available at a nominal charge, upon request, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[b]From ref. 1e.

of fluorines is varied (Table 2). Elongations of about 0.03, 0.03, 0.02, and 0.02 Å within the CF_3—R, CHF_2—R, CH_2F—R, and CH_3—R series, respectively, occur for each substitution of H by F within the R group. Overall, from CH_3CH_3 to CF_3CF_3, a total elongation of 0.16 Å is predicted; experimentally (2) the increase is much smaller ($\sim 0.02_4$ Å). Presumably the increase is due to increasing population of the C—C antibonding MO by electron donation from the fluorines.

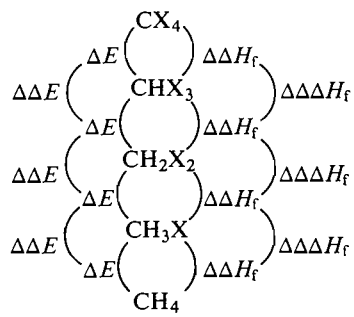
Comparisons of bond lengths predicted by MINDO/3 were hampered by the tendency, previously noted by Dewar *et al.* (2) for the method to predict (incorrectly) π-complexes of F_2 with ethylenes for polyfluorinated ethanes. In the present case, this occurred for staggered conformations of CF_3CH_2F, CF_3CHF_2, and CHF_2CHF_2. In the only remaining complete series, i.e. $CH_3CH_{3-n}F_n$, decreases of 0.03_1 Å and 0.02_7 Å are predicted by going from $n = 1-2$, and $n = 2-3$, respectively.

The CF bond is predicted by all split valence-shell *ab initio* calculations to undergo contraction in the fluoromethyl free radical series (Table 3). Again the minimal STO-3G basis set predicts essentially no effect, as does the semiempirical MNDO method. The MINDO/3 results predict a contraction from CH_2F to CHF_2, but no change from the latter to CF_3.

A contraction in the carbon−chlorine bond lengths is found experimentally to occur in going from CH_3Cl to CH_2Cl_2 and again from CH_2Cl_2 to $CHCl_3$; these changes, however, are much smaller than those in the corresponding fluorocarbons. Again contractions in the carbon−halogen distance are not predicted by STO-3G calculations, even with the addition of *d* orbitals on chlorine (Table 4). However, the 4-31G basis set calculations again reproduces the changes very well, whereas 3-21G predicts as large values as are obtained for the fluoromethanes. Experimentally, the C—Cl length does not change significantly from $CHCl_3$ to CCl_4 (see Table 4); this is correctly predicted by the split valence shell calculations. Curiously the MNDO method, which failed completely for fluoromethanes, does very well in accounting for the C—Cl bond length changes in the chloromethanes (Table 4). It also predicts a contraction of −0.008 (−0.022 Å experimental) in going from CH_3CH_2Cl to CH_3CHCl_2, and −0.003 (+0.005 Å) from the latter to CH_3CCl_3. The bond length changes predicted for the chloromethyl radicals are small (Table 4).

The carbon−oxygen and oxygen−hydrogen bond lengths, and the COH angles, in methanol and in methanediol also were optimized using the 4-31G basis with *d* orbitals on carbon. A contraction in R_{CO} of 0.01_6 Å is predicted from CH_3OH to $CH_2(OH)_2$, which is somewhat less than the decrease of 0.021 Å obtained in 4-31G calculations (7).

The nonadditive energetic effects of multiple substitution have traditionally been gleaned from experimental thermochemical heats of formation, ΔH_f, of a series of molecules, e.g. CH_4, CH_3X, ... CX_4. If the bond energies in such molecules remain exactly constant from one member to another, the increment $\Delta\Delta H_f$ in the heat of formation upon substitution of H by X will be a constant. Conversely, any changes $\Delta\Delta\Delta H_f$ to the increment are a direct measure of the nonadditivity of bond energies. The same information can be obtained from $\Delta\Delta E$, the change to the increment in total energy E computed for a molecule.



We have computed $\Delta\Delta\Delta H_f$ and $\Delta\Delta E$ values for the fluorinated, chlorinated, and hydroxylated methanes and for the fluorinated and chlorinated methyl radicals from experimental heats of formation (where available), calculated ΔH_f's for the MNDO and MINDO/3 methods, and calculated *ab initio* E's for the various basis sets; the results are listed in Table 5. To save space, the $\Delta\Delta\Delta H_f$ or $\Delta\Delta E$ value is listed for the common member of the two series concerned; e.g. the $\Delta\Delta\Delta H_f$ calcu-

[a]The $\Delta\Delta E$ value for a species CH_nX_{m-n} is the ΔE for the reaction

$$2\ CH_nX_{m-n} \rightarrow CH_{n+1}X_{m-n-1} + CH_{n-1}X_{m-n+1}$$

where $m = 4$ for closed-shells and $m = 3$ for free radicals. The $\Delta\Delta\Delta H_f$ value for a species CH_nX_{m-n} is $-\Delta H°$ (at 298 K) for the same reaction.

[b]Calculated from data in ref. 9 unless indicated otherwise.

[c]Calculated from data in ref. 11.

[d]Calculated from data in ref. 8; see also Discussion in text.

[e]Calculated using ΔH_f of −19.6 and −22.8 kcal for CH_3Cl and CH_2Cl_2 respectively from ref. 8, and of −24.7 and −22.4 for $CHCl_3$ and CCl_4 respectively both from ref. 18.

[f]Calculated using non-optimized geometry for $CH(OH)_3$; see Table D-3 for details.

lated from the $\Delta\Delta H_f$ values for CH_2X_2 and CH_3X and for CH_3X and CH_4 is listed as the entry for CH_3X. For this particular case, our $\Delta\Delta E$ parameter is identical to the bond separation energy term defined by Pople and co-workers (1).

In each of the series of substituted methanes and methyl radicals, the experimental $\Delta\Delta\Delta H_f$ values are positive for CH_3X or CH_2X and decrease continuously with successive substitution for X = F or OH. This behavior implies that although the interaction of such C—X bonds with each other is more stabilizing than those of C—H bonds with each other, the magnitude of each bond−bond interaction decreases with increasing substitution. Qualitatively, this behavior is reproduced by *ab initio* calculations using any of the basis sets. Those computed using STO-3G, however, clearly are unreliable (Table 5). The results from the 3-21G and 4-31G basis sets are very good for the fluoromethanes, and give some hope that with minor improvement essentially quantitative results can be obtained. It was for this reason that we tried adding *d* orbitals to the central carbon with the 4-31G basis. These results, labelled 4-31G*(C) for the fluoromethanes, the fluoromethyl radicals, and for the hydroxymethanes (where available) agree almost exactly with experiment (rms error = 1.6 kcal). From these results it can be concluded that changes in correlation energy must make only negligible contributions to energy nonadditivity in such molecules.

Since the $\Delta\Delta E$ values using the 4-31G*(C) basis appear reliable, they can be combined with experimental heats of formation for lesser-substituted compounds to obtain ΔH_f values for more highly-substituted members of the same series. Thus the $\Delta\Delta E$ of +16.1 kcal can be combined with the known heats of formation of −17.9 and −48.1 for methane and methanol to yield an extrapolated ΔH_f of −94.4 kcal for methanediol, in good agreement with the estimate (?) of −93.5 given by Benson (8). Similarly the ΔH_f of methanetriol is estimated to be −145.1 kcal mol^{-1}. Interestingly, the $\Delta\Delta H_f$ values (9) for the $CH_n(OCH_3)_{4-n}$ series are 13.1, 7.8, and −1.4 kcal mol^{-1}. If the $\Delta\Delta E$ value for $CH(OH)_3$ is indeed approximately +2 kcal, the extrapolated ΔH_f for $C(OH)_4$ is about −198 kcal.

The $\Delta\Delta E$ (and $\Delta\Delta\Delta H_f$) values can be combined to yield the total stabilization energy due to all bond interactions and the energy per bond−bond interaction. For CH_2F_2, CHF_3, and CF_4 the totals are 12.7 (14.2), 33.6 (34.4), and 53.7 (53.6) kcal mol^{-1} respectively from the 413-G*(C) (and experimental) results; the energy per interaction decreases along the series, from 12.7 (14.2) to 11.2 (11.5) to 8.9 (8.9) kcal. The 4-31G*(C) interaction per bond pair decreases from 16.1 in $CH_2(OH)_2$ to 12.2 kcal in $CH(OH)_3$. A decrease in the effectiveness of each interaction as the number of participating substituents increases is expected to the extent that hyperconjugation and simple delocalization contribute significantly to the overall change.

In the case of the methane molecule, multiple substitution of hydrogen by chlorine is predicted to involve nonadditive energy effects which are slightly destabilizing, rather than stabilizing as in the case for multiple F or OH substitution; the effect amounts to about 5 kcal per substitution. In other words, the interaction of C—H bonds with C—Cl and with other C—Hs is predicted to be slightly more powerful than of C—Cl bonds with each other. Experimentally the destabilizing effects of multiple substitution are observed in the transition from CH_2Cl_2 to $CHCl_3$ to CCl_4, but not earlier in the series (see $\Delta\Delta\Delta H_f$ values in Table 5). If the $\Delta\Delta E$ values for the chloromethanes behave as do those for the fluoromethanes and fluoromethyl radicals, addition of *d* orbitals to the carbon atom will make the 4-31G results less negative by approximately 2.5 kcal each. Even so, the theoretical calculations predict some destabilization upon each multiple chlorine substitution. In-

[a]Unless indicated otherwise, from ref. 11.
[b]With *d* orbitals on chlorine (i.e. STO-3G*) for H—CH_2Cl and H—$CHCl_2$.
[c]From ref. 19.
[d]Deduced from data given in ref. 1*e* and 12.
[e]From ref. 12*a*; the 4-31G energy was evaluated at the geometry optimum for the STO-3G basis set.

spection of the 4-31G Mulliken population analysis for the *ab initio* calculations for the mono- and disubstituted methanes indicates that the rather significant π bonding between carbon and halogen which occurs in difluoromethane (via back donation of electron density from F to C (1*a*) occurs to a much lesser extent (about one-third as much) in dichloromethane as measured by the increase in CX bond overlap population. Interestingly, the electron transfer from halogen is almost as large with chlorine as with fluorine (0.018 e versus 0.023 e) but the effect is less, reflecting perhaps the usual inability of atoms in the chlorine row to form π bonds as well as do atoms in the fluorine row of the Periodic Table. The total CX bond overlap populations increase continuously from CH_3F to CH_4 whereas they decrease continuously from CH_3Cl to CCl_4.

Experimental thermochemistry for other chlorinated hydrocarbons supports the contention that the interaction of C—Cl bonds with C—H bonds is slightly less stabilizing than that of C—H bonds with each other, and is greater than that of C—Cl bonds with each other. In particular, the isomerization of 1,1-dichloroethane to the 1,2 isomer is a thermoneutral process (10). Further, the change in ΔH_f upon symmetrical chlorination of ethane is 10.5 kcal for the first pair of chlorines, 5.2 for the second, and −1.4 for the third, i.e. the $\Delta\Delta\Delta H_f$ values become *less* negative as the extent of substitution increases (10).

For the various chloroethane series, i.e. CH_3—R, CH_2Cl—R, $CHCl_2$—R, and CCl_3—R where R varies from CH_3 to CCl_3, the MNDO and MINDO/3 methods predict $\Delta\Delta E$ values all of which are negative and in the range from −3.7 to −6.0 kcal (MNDO) and −2.5 to −6.1 kcal (MINDO/3). Very little variation in the CCl or CC bond lengths is observed. (Detailed values are available from Tables D-4 and D-5.)

As with fluoroethanes, the MNDO method predicts that some lengthening of the carbon−carbon bond occurs for each substitution of chlorine for hydrogen; however, the total elongation from ethane to hexachloroethane amounts to only 0.05 Å. The MINDO/3 results for chloroethanes also predict elongation with substitution, but only to about half the extent predicted by MNDO.

It is well known that MO theory, even at the Hartree−Fock limit, yields very inaccurate results for the dissociation energies for individual bonds and for all bonds in a molecule, since the change in correlation energy upon dissociation is often of the same order of magnitude as the change in Hartree−Fock energy. Thus for example, the present 4-31G*[(C)] calculations predict the CH_3—H bond dissociation energy to be 86.4 kcal mol^{-1} (uncorrected for vibrational effects) compared to the experimental value of 105 ± 1 kcal mol^{-1}, and the $CH_4 \rightarrow C + 4H$ energy to be 324.6 kcal mol^{-1}, compared to 397.2 experimentally. However, much of chemistry is concerned not simply with the magnitude of the dissociation energy of a particular bond AB in polyatomic molecules XX′X″ABYY′Y″ but rather with the effect on this quantity of varying the groups X and Y bonded to atoms A and B respectively. One could imagine that the change in correlation energy upon AB bond scission is small compared to the change in Hartree−Fock energy when the substituted groups X and Y are varied. The present results offer some hope in this regard. In Table 6 we have listed the C—H bond dissociation energies, relative to that in methane, for XX′X″CH molecules, where the groups X are drawn from hydrogen, fluorine, chlorine, hydroxyl, amino, and methyl (results for the latter three groups being obtained, where available, from the literature). In general, the STO-3G basis overestimates the effect of the groups X in lowering the C—H bond dissociation energies, at least when the effect experimentally is small or of opposite sign. In contrast, the 4-31G basis generally underestimates the stabilization. The 4-31G basis with *d* orbitals on carbon does quite well, successfully predicting that the H—CH_2F and H—CHF_2 dissociation energies are equal and a few kilocalories below that for H—CH_3, and that the energy for H—CF_3 *exceeds* the value for methane.

The total energies for the fluoromethanes and fluoromethyl radicals can be combined to obtain C—F bond dissociation energies; these are listed in Table 6 relative to the values for CH_3—F. Each substitution of hydrogen by fluorine raises substantially the C—F energy, and this trend is reproduced very well by the 4-31G calculations when *d* orbitals are included.

Hydride formula	Bond energy			
	Al	Si	P	S
AH	68	71.3	73.5[b]	82±3
AH_2	—	—	75.3	87.6
AH_3	—	71.4	77.9[b]	—
AH_4	—	77.1[b]	—	—

[a]Calculated from data in ref. 11 unless indicated otherwise.
[b]Calculated from data in ref. 8.
[c]Calculated from data in ref. 20.

The effects are underestimated grossly by the STO-3G basis set, and to some extent by 4-31G.

The C—F bond energies in the fluoromethanes vary significantly, but the C—H energies do not, because the favourable interactions between the different carbon–fluorine bonds occur to almost equal extents in the radical and molecule which have equal numbers of fluorines. Removal of a fluorine eliminates the interaction of this C—F bond with all remaining C—F linkages; thus D(C—F) increases with the number of fluorines in the free radical left behind.

It is not generally realized that interaction among bonds greatly stabilizes polyatomic molecules. The clearest evidence of this effect is provided by the progression in the average A—H bond energy in a series of hydrides AH_n as n increases from unity. The available experimental data on these trends is summarized in Table 7. For each series in which data are available, i.e. A = boron, carbon, nitrogen, oxygen, silicon, phosphorus, and sulphur, the average A—H bond energy invariably increases with n. Usually the biggest increase occurs from AH to AH_2, the succeeding increases decreasing with n (see especially the carbon hydrides). The simplest interpretation of this data is that interaction of C—H bonds with each other, i.e. delocalization of the MOs over as many equivalent hydrogen nuclei as possible, is greatly stabilizing. The total stabilization of all four bonds in CH_4 amounts to 75 kcal mol^{-1}, of the three bonds in NH_3 and PH_3 amounts to ~55 and ~13, and of the two bonds in H_2O and H_2S amounts to 17 and 11 respectively. The total stabilization of the two bonds in AH_2 species is approximately constant at ~19 ± 2 kcal in C, N, O and that of the three in AH_3 amounts to ~53 kcal. The corresponding stabilization energies all are considerably smaller in the hydrides of silicon, phosphorus, and sulphur.

It would be of interest also to display average bond energy terms in other AX_n molecules as a function of n for other atoms and groups X. In most cases, however, π bonding between X and unused atomic orbitals of the central atom A in molecules where n has not reached its normal maximum complicates the analysis (not to mention a scarcity of experimental data).

The nature of bonding in hexahalothorates and hexahalouranates(IV)

ALAN D. WESTLAND AND M. T. H. TARAFDER
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received September 30, 1982

ALAN D. WESTLAND and M. T. H. TARAFDER. Can. J. Chem. **61**, 1573 (1983).

Enthalpies of reaction have been determined by solution calorimetry for the process $2AX(c) + ThX_4(c) = A_2ThX_6(c)$ where A = K, Cs and X = Cl, Br. The measurements afforded the following values of standard enthalpies of formation ΔH_f^0 (298 K), in kJ mol^{-1}: K_2ThCl_6, −2108; Cs_2ThCl_6, −2151; K_2ThBr_6, −1774; Cs_2ThBr_6, −1826. The standard enthalpies of formation of $ThCl_6^{2-}$ (g), $ThBr_6^{2-}$ (g), UCl_6^{2-} (g), and UBr_6^{2-} (g) and the two-halide ion affinities of $ThCl_4$, $ThBr_4$, UCl_4, and UBr_4 were compared by assuming semi-empirical (Kapustinskii) values of the lattice energies of the complexes. Homolytic and heterolytic bond energies were also calculated.

ALAN D. WESTLAND et M. T. H. TARAFDER. Can. J. Chem. **61**, 1573 (1983).

On a déterminé par calorimétrie de solution, les enthalpies de réaction du processus: $2AX(c) = ThX_4(c) = A_2ThX_6(c)$ où A = K, Cs et X = Cl, Br. Les mesures fournissent les valeurs suivantes des enthalpies normales de formation ΔH_f^0 (298 K) en kJ mol^{-1}: K_2ThCl_6, −2108; Cs_2ThCl_6, −2151; K_2ThBr_6, −1774; Cs_2ThBr_6, −1826. On a comparé les enthalpies normales de formation du $ThCl_6^{2-}$ (g), du $ThBr_6^{2-}$ (g), du UCl_6^{2-} (g), du UBr_6^{2-} (g) et les affinités de deux ions halogénures du $ThCl_4$, du $ThBr_4$, du UCl_4 et du UBr_4 en se servant des valeurs semi-empiriques (Kapustinskii) des énergies de réseau des complexes. On a également calculé les énergies de liaison homolytique et hétérolytique.

[Traduit par le journal]

Introduction

There have been no reports of thermochemical measurements on ternary salts of thorium tetrabromide. An early calorimetric investigation of A_2ThCl_6 salts (1) shows a lack of internal consistency and the value, −62.3 kJ, obtained for the process $2CsCl + ThCl_4 = Cs_2ThCl_6$ disagrees with the value −73.6 kJ obtained by Fuger and Brown (2). In the earlier work, the ternary salts were prepared by fusing a mixture of the component chlorides, while the later workers obtained Cs_2ThCl_6 by crystallization from ethanolic hydrochloric acid. In a previous research (3), one of us found that Cs_2NbCl_6 prepared by crystallization from solution provided an enthalpy of solution which was several kJ mol^{-1} less negative than that of a sample prepared in the dry way. A redetermination of the heats of solution of complexes prepared in the dry way appeared to be desirable as well as the study of bromothorates.

Vdovenko *et al.* (4, 5) have studied the thermochemistry of the A_2UCl_6 and A_2UBr_6 salts. Also, Fuger and Brown determined the enthalpy of formation of Cs_2UCl_6 and obtained a result in fairly good agreement with that in ref. 4.

Results and discussion

Enthalpies of reaction [1] were determined by measuring the heats of solution of each of the substances participating in the reaction:

$$[1] \quad 2AX(c) + ThX_4(c) \overset{\Delta H_1}{=} A_2ThX_6(c)$$

The combination of reaction enthalpies, $2\Delta H_2 + \Delta H_3 - \Delta H_4$, which is derived from processes [2] to [4], is very nearly equivalent to ΔH_1. This has been shown previously for analogous systems (6, 7). The braces denote solutions of

$$[2] \quad AX(c) + \{HCl, ThX_4\} \overset{\Delta H_2}{=} \text{solution}$$

$$[3] \quad ThX_4(c) + \{HCl, AX\} \overset{\Delta H_3}{=} \text{solution}$$

$$[4] \quad A_2ThX_6(c) + \{HCl\} \overset{\Delta H_4}{=} \text{solution}$$

4.0 molar hydrochloric acid containing the appropriate quantities of the solutes indicated. It was assumed that the thorium compounds are labile and that the complexes therefore gave the same dissolved species as were formed when AX and ThX_4 were dissolved separately. At any rate, the complex, Cs_2ThCl_6, may be crystallized from a solution of the component chlorides in concentrated acid (2).

TABLE 1. Enthalphy of solution, ΔH_2, for alkali halides in 4.02 molar hydrochloric acid. Values taken from ref. 6 and 7

Compound	ΔH_2 (kJ mol^{-1})
KCl	18.39±0.11
CsCl	13.70±0.24
KBr	19.87±0.04
CsBr	23.25±0.15

Acid was used in the calorimeter in order to suppress in part the hydrolysis of dissolved thorium compounds. When water was used in the calorimeter, as in Chauvenet's work (1), hydrolysis caused undue evolution of heat, and the calculation of enthalpies of complex formation involved taking differences of large numbers.

The heats of solution, ΔH_2, ΔH_3, and ΔH_4, are recorded in Tables 1 to 3, respectively. In our work with the tetrahalides of various elements, the measured enthalpies were essentially independent of sample size. Thus, the solutes behaved as though they were at infinite dilution. We believe this condition to have obtained in the present study as well.

The heats of solutions of the alkali halides at infinite dilution in 4 *M* hydrochloric acid are not measurably influenced by the presence of small quantities of the solutes, MX_4. Therefore, values of ΔH_2 obtained in previous researches (6, 7) were used in the present work. Equivalent amounts of alkali halide were added to the calorimeter liquid when the enthalpies of solution of $ThCl_4$ and $ThBr_4$ were measured, although there was no evidence that such additions had any influence on the measurements.

As a check on the purity of the $ThCl_4$, we obtained the value

	2.3357	−142.8	−143.3±1.0

−186.2 kJ mol^{-1} for the enthalpy of solution in 6.0 *M* hydrochloric acid. This compares well with the value −185.3 kJ mol^{-1} obtained by Eyring and Westrum (8).

The uncertainty limits given in Tables 1−3 are the standard deviations of the measurements. These limits do not include an estimate of accuracy as influenced by purity of materials, etc. An additional uncertainty pertains to the potassium complexes. It has been the practice in this laboratory to investigate two or three alkali salts of a given haloanion in order to examine the results for self-consistency. In the case of the alkali halothorates, however, the phase diagrams of the ACl−$ThCl_4$ systems reveal that the salts of Na, K, and Rb melt incongruently (9, 10). There is some disagreement about this, as other groups of workers claim that K_2ThCl_6 melts congruently (11, 12), but an examination of the various phase diagrams leads us to believe that a too-rapid cooling of the melt produced the compound in some cases by a nonequilibrium process. We therefore sought to obtain the potassium salt by rapid air-cooling of a melt of the stoichiometric composition. Also, melts with the compositions $KThCl_5$ and K_3ThCl_7 were cooled in a similar way to produce these reported compounds. Debye−Scherrer patterns of each of the three solids so obtained were distinct from one another. The potassium salts, K_2ThCl_6 and K_2ThBr_6, gave patterns which were indexed as tetragonal while the caesium salts were trigonal (13).

TABLE 4. Enthalpy of complexing, ΔH_1, of the alkali-metal hexahalothorates

Compound	ΔH_1 (kJ mol^{-1})
K_2ThCl_6	−50.66±2
Cs_2ThCl_6	−81.1 ±2
K_2ThBr_6	−23.3 ±3
Cs_2ThBr_6	−73.1 ±3

A line with $\sin^2\theta = 0.0149$ appeared strongly in the patterns of $KThCl_5$ and K_3ThCl_7 and weakly in the pattern of K_2ThCl_6. It is therefore likely that a small quantity of the 1:1 and/or the 3:1 compound occurred in the preparation of K_2ThCl_6. The heat of solution of an equimolar mixture of $KThCl_5$ and K_3ThCl_7 would differ from the heat of solution of $2K_2ThCl_6$ by the enthalpy of the process [5]:

$$[5] \quad 2K_2ThCl_6 = KThCl_5 + K_3ThCl_7$$

This may be a small quantity as in the case of the analogous process: $3CaB_2O_4 = CaB_4O_7 + Ca_2B_2O_5$ for which $\Delta H_{reaction}$ is −2.1 kJ (14). If the K_2ThCl_6 contained as much as 10 mole percent impurities and the enthalpy of reaction [5] were as much as ±20 kJ, the error in the measured value of ΔH_4 would be only ±1 kJ mol^{-1}. The thermal data for the potassium salts are thus the subject of some uncertainty in this way, but it will be seen below that the data for the various salts are reasonably self-consistent.

The enthalpies of formation of the complexes relative to the component halides are listed in Table 4 and the standard enthalpies of formation from the elements are given in Table 5. The enthalpies of formation of the gaseous ions, ThX_6^{2-} and UX_6^{2-}, are also presented. The values for the gaseous anions depend upon a calculation of lattice energies of the ternary salts. These calculations followed the method of Kapustinskii and Yatsimirskii (15) and the ancillary data used are also included in Table 5. In addition, the following enthalpies of formation were used (all values in kJ mol^{-1}): KCl(c), −436.7 (16); CsCl(c), −442.8 (16); KBr(c), −393.8 (16); CsBr(c), −394.5 (17); $ThCl_4$(c), −1184.4 (18); $ThBr_4$(c), −963.4 (18); UCl_4(c), −1018.4 (4); UBr_4(c), −802.5 (18). Enthalpies of formation of Cs_2UCl_6 and K_2UBr_6 from the component halides have been reported as −100.8 and −43.5 kJ mol^{-1}, respectively (4, 5).

The lattice energies calculated by the Kapustinskii−Yatsimirskii method are not accurate because the anionic groups are treated as mere point charges. A superior approach is that of Jenkins and Pratt but their procedure requires a knowledge of the metal−halogen distances and the partial charges on the atoms (19). The cruder calculations are presented here in the belief that they lead to valid qualitative comparisons between closely related compounds.

Scheme 1 embodies the cycles from which the relations [6]

$$\begin{array}{ccc} 2A^+(g) + 2X^-(g) + MX_4(g) & \xrightarrow{\overline{\Delta H}_s(g)} & 2A^+(g) + [MX_6]^{2-}(g) \\ \uparrow U_{AX} \quad \uparrow \Delta H_{subl.} & & \uparrow U_{A_2MX_6} \\ 2AX(c) + MX_4(c) & \xrightarrow{\Delta H_1} & A_2[MX_6](c) \end{array}$$

Ta	−35	+38

and [7] may be derived (ss = standard state).

[6] $\Delta H_f^0(A_2MX_6,c) = \Delta H_1 + 2\Delta H_f^0(AX,c) + \Delta H_f^0(MX_4,c)$

[7] $\Delta H_f^0(MX_6^{2-},g) = U(A_2MX_6) - 2\Delta H_f^0(A^+,g) + \Delta H_f^0(A_2MX_6,c)$

ΔH_f^0 for $K^+(g)$ and $Cs^+(g)$ were taken to be 514.2 and 452.3 kJ mol^{-1} respectively (16).

The two-halide ion affinities, $\Delta H_x(g)$ are of interest as they refer to the process of forming the complex anion in the gas phase in which the effects of crystal forces do not play a role. The values of $\overline{\Delta H_x}(g)$ are given by [8]:

[8] $\overline{\Delta H_x}(g) = \Delta H_f^0(MX_6^{2-},g) - 2\Delta H_f^0(X^-,g) - \Delta H_f^0(MX_4,g)$

The energy of reorganizing sp^3 hydridization of the MX_4 molecule to sp^3d^2 hybrids is involved in $\underline{\Delta H_x}(g)$ but it is difficult to evaluate this factor. Values of $\overline{\Delta H_x}(g)$ are listed in Table 6(a).

As expected for a class a type ion such as Th^{4+}, the chloride ion affinity of $ThCl_4(g)$ is very much more negative than the bromide ion affinity of $ThBr_4(g)$. However, the situation is reversed for $UCl_4(g)$ and $UBr_4(g)$. This reversal of the expected result was found also with hafnium chloride and bromide (6, 7). It can be concluded that U^{IV} has incipient class b character, or in Pearson's terminology, U^{IV} is a softer acid than Th^{IV}. We believe that the tendency toward class b character shown by certain high-valent elements may be attributed to their power to polarize atoms bonded to them. Indeed, U^{IV} has a greater effective nuclear charge than has Th^{IV} owing to the poor shielding of the $5f$ electrons. Uranium would thus be better able to accept the charge density inherent in $p_\pi \rightarrow d_\pi$ bonding. The argument should apply to both MX_6^{2-} and the tetrahalides, but π-bonding is presumably weaker for the latter because of their tetrahedral geometry. Strong π-bonding should therefore favour the anions.

By referring to Table 6(b), the two-halide ion affinities of MX_4 (M = Th, U) may be compared with those of MX_4 (M = Zr, Hf, Nb, Ta, Sn), a group of compounds studied previously in this laboratory.

The chloride ion affinity of $ThCl_4(g)$ and the bromide ion affinity of $UBr_4(g)$ are the greatest of all the values listed. This is remarkable in view of the large size of the actinide ions for which $M^{4+} - X^-$ coulombic interaction is not strong. However, $X^- - X^-$ repulsions in the MX_6^{2-} groups would be smaller for the actinide ions also. The order of the acceptor strength towards Cl^- is $ThCl_4 > UCl_4 > HfCl_4 > TaCl_4 > ZrCl_4 > NbCl_4 > SnCl_4$. The order of bromide affinities is similar except that the thorium compound follows that of hafnium.

Jenkins and Pratt have shown that the chloride ion affinities of various other transition element tetrachlorides follow the same trend of diminishing in magnitude toward the right in a period (20, 21). They found the same to be true for the homolytic M—Cl bond energies as well. Rather paradoxically, Brown *et al.* found that the stretching force constant increases in the series $HfCl_6^{2-}$ through $PtCl_6^{2-}$ and they related this to trends in σ- and π-bonding and optical electronegativities (22).

However, the two-halide ion affinities represent differences between the thermodynamic states of reactants and products and, therefore, may not relate in a simple fashion to bond order and force constants of product species alone.

The calculations that led to the foregoing results made use of data taken from the literature. The enthalpies of sublimation at the indicated temperatures were (values in kJ mol^{-1}): $ThCl_4$

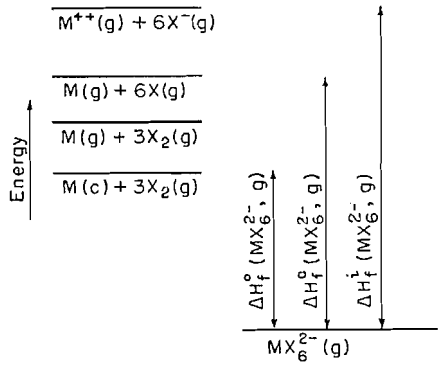

FIG. 1

(1131 K), 247.0 (23); $ThBr_4$ (1088 K), 184.0 (23); UCl_4 (863 K), 193.7 (17); UBr_4 (792 K), 175.3 (17). Use of the heat capacities (14, 24) gave the following room temperature values: 269.0; 204.8; 207.4; 189.5 kJ mol^{-1} respectively. The standard enthalpies of formation of $Cl^-(g)$ and $Br^-(g)$ were taken to be −246.0 and −233.9 kJ mol^{-1} respectively (25).

Jenkins and Pratt have defined bond energies in two ways (20) that involve the quantities shown in Fig. 1. One definition refers to the process [9]:

$$[9] \quad MX_6^{2-}(g) \xrightarrow{\Delta H_f^a} M(g) + 6X(g) + 2e$$

in which case the average (homolytic) bond energy, $E(M—X)_{hom}$, is defined as

$$[10] \quad E(M—X)_{hom} = -\frac{1}{6}\Delta H_f^a(MX_6^{2-},g)$$

Alternatively, by referring to the heterolytic fission of the bond [11]:

$$[11] \quad MX_6^{2-}(g) \xrightarrow{\Delta H_f^i} M^{4+}(g) + 6X^-(g)$$

the average (heterolytic) bond energy, $E(M—X)_{het}$ is given as:

$$[12] \quad E(M—X)_{het} = -\frac{1}{6}\Delta H_f^i(MX_6^{2-},g)$$

Pearson and Mawby (26) have maintained that the heterolytic bond energy represents the coordinate bond energy and is more informative. From Fig. 1 it is evident that

$$[13] \quad -\Delta H_f^a(MX_6^{2-},g) = \Delta H_f^0(M,g) + 6\Delta H_f^0(X,g) - \Delta H_f^0(MX_6^{2-},g)$$

and

$$[14] \quad -\Delta H_f^i(MX_6^{2-},g) = \Delta H_f^0(M^{4+},g) + 6\Delta H_f^0(X^-,g) - \Delta H_f^0(MX_6^{2-},g)$$

We used the following data from the sources cited:

Data		Reference
$\Delta H_f^0(Th,g)$	= 598.3 kJ mol^{-1}	27

TABLE 8. Raman spectral data of ThX_4 and $(Alk)_2ThX_6$

Compound	Th—X Stretching frequency (cm^{-1})
$ThCl_4$	300 s
K_2ThCl_6	282 vs*
Cs_2ThCl_6	310 s
$ThBr_4$	195 s
K_2ThBr_6	175 s
Cs_2ThBr_6	198 vs

*s = strong; vs = very strong.

Bond energy data (Table 7) indicate that the energy of the Th—X bond is essentially the same in K_2ThX_6 and Cs_2ThX_6 despite the differences in structure and the attendant uncertainties in the calculation of lattice energies. The agreement affords some assurance about the validity of the methodology. Thus when we compare M—Cl and M—Br bonds, the difference, significant although not large, is presumed to be meaningful. Also, the Th—X and U—X bonds have almost the same heterolytic energy within experimental error. The slight differences that are discernable are responsible for the class *a* and class *b* distinctions referred to earlier. Thus, small differences in bond energies can be quite significant when there are as many as six bonds in the molecule.

The homolytic bond energies for the Th—X bonds are significantly greater than those for the U—X bonds. The difference for the chlorides, 38 kJ per bond, agrees well with the difference, 39 kJ per bond, between the values quoted by Jenkins and Pratt (34). The absolute values given by these authors differ from ours because of the different method of calculating lattice energies.

Solid state Raman spectra of $ThCl_4$, $ThBr_4$, and the alkali complexes were recorded from 800 to 100 cm^{-1} (Table 8). The very strong band at 300 cm^{-1} for $ThCl_4$ is assigned to the totally symmetric Th—Cl stretch (35–37). This is shifted to 282 cm^{-1} and 310 cm^{-1} in K_2ThCl_6 and Cs_2ThCl_6, respectively. The corresponding mode gives a band at 195 cm^{-1} in the spectrum of $ThBr_4$ (36) and this also is seen to be shifted upon complexation. Woodward and Ware obtained spectra for $ThCl_6^{2-}$ and UCl_6^{2-} in methyl cyanide solution and derived the stretching force constants (a_{1g} mode), 1.51 and 1.40 mdyn/Å, respectively (38). These values conform to the relative bond energies. Unfortunately, the vibrational spectra of the solid compounds do not reveal the various modes required for a force field calculation.

Experimental

Preparation of compounds

Thorium tetrachloride was obtained by passing CCl_4 vapour, entrained in a stream of dry nitrogen, over ThO_2 at 600°C. The product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

so obtained was purified by repeated vacuum sublimation in a platinum tube heated to 760°C. The final product was handled in a dry nitrogen atmosphere and was stored in sealed ampoules. *Anal.* calcd. for $ThCl_4$: Cl 37.93; found: Cl 37.84%.

Thorium tetrabromide was prepared by a published method (39) with little modification. Bromine (25 mL) was added dropwise to thorium powder (4.18 g, Alpha Ventron, purity 99.9%) in 5 mL of methyl cyanide. The mixture was refluxed under N_2 for 12 h. The solid product was heated for 4 h at 180°C and was subsequently sublimed under vacuum in a platinum tube heated to 550°C. The product was handled in a dry nitrogen atmosphere and was stored in sealed ampoules. *Anal.* calcd. for $ThBr_4$: Br 57.93; found: Br 57.70%.

Preparation of ternary salts

The preparation of K_2ThCl_6 is typical. Potassium chloride was dried at 500°C *in vacuo* and mixed with the stoichiometric amount of $ThCl_4$. The mixture, with a weight of about 7 g, was sealed *in vacuo* in a quartz tube and this was heated in a tube furnace. Once a clear liquid had been formed, the tube was agitated to bring about thorough mixing. The melt was quenched in air and the solidified mass was ground in a dry nitrogen atmosphere.

X-ray diffraction patterns were obtained by the Debye–Scherrer technique. Line spacings were determined by the Straumanis technique and the lattice constants were obtained from extrapolated Nelson–Riley plots.

Calorimetric measurements

The calorimeter and its calibration have been described previously (3). In the present study, it contained 300 cm^3 of 4.02 molar hydrochloric acid and was operated at 25°C. The compound under study was contained in a thin-walled glass bulb which was crushed under the acid at the appropriate moment. Dissolution was complete in 4 min or less. The calorimeter was calibrated electrically before and after each sample run and the mean of the two calibrations was used. The temperature of the calorimeter liquid was restored to 25°C after each series of readings by means of allowing a few drops of liquid nitrogen to evaporate in a well which extended down into the calorimeter liquid. The temperature data were treated by the numerical method described by Kubaschewski *et al.* in order to correct for heat loss or gain (14).

Spectra

Raman spectra of the solids were obtained with a Control Laser Model 552A argon laser (5145 Å) operated at 2.0 watts. The finely ground samples were held in sealed Pyrex capillary tubes.

The radiolysis at room temperature and 118°C of aqueous solutions containing sodium nitrate and either sodium formate or 2-propanol

ALLEN JOHN ELLIOT AND FREDERICK CHARLES SOPCHYSHYN

Atomic Energy of Canada Limited Research Company, Chalk River Nuclear Laboratories, Physical Chemistry Branch, Chalk River, Ont., Canada K0J 1J0

Received November 19, 1982

ALLEN JOHN ELLIOT and FREDERICK CHARLES SOPCHYSHYN. Can. J. Chem. **61**, 1578 (1983).

Deoxygenated sodium nitrate solutions ($\leq 2.5 \times 10^{-2}$ *M*) containing sodium formate (≤ 0.5 *M*) have been irradiated at room temperature and 118°C. With formate concentrations $\leq 5 \times 10^{-2}$ *M*, $G(NO_2^-)$ increased ~25% over the temperature range. Calculations suggest part of this increase in $G(NO_2^-)$ may arise from an increase in the overall solvated electron yield. With 0.5 *M* sodium formate solutions containing 2.5×10^{-2} *M* sodium nitrate, $G(NO_2^-)$ rose from 3.6 at room temperature to ~14 at 118°C, suggesting the occurrence of a chain reaction at higher formate concentrations. $G(H_2O_2)$ and $G(H_2)$ were not functions of temperature for all the above solutions.

The pH dependence of $G(NO_2^-)$ was determined at room temperature for sodium nitrate solutions containing either sodium formate or 2-propanol. The $G(NO_2^-)$ as a function of pH could only be modelled satisfactorily with rate constants from the literature in the sodium formate case.

It is concluded that the solvated electron yield in irradiated aqueous solutions at elevated temperatures cannot be confidently deduced from measurements made with nitrate as an electron scavenger in the presence of formate ions or alcohols.

ALLEN JOHN ELLIOT et FREDERICK CHARLES SOPCHYSHYN. Can. J. Chem. **61**, 1578 (1983).

On a irradié des solutions désoxygénées de nitrate de sodium ($\leq 2{,}5 \times 10^{-2}$ *M*) contenant du formiate de sodium ($\leq 0{,}5$ *M*) à la température de la pièce et à 118°C. Dans cet intervalle de température et pour des concentrations en formiate $\leq 5 \times 10^{-2}$ *M*, $G(NO_2^-)$ augmente de 25% environ. Les calculs suggèrent qu'une partie de cette augmentation de $G(NO_2^-)$ peut être due à l'augmentation du rendement global en électrons solvatés. Pour des solutions de formiate de sodium 0,5 *M* contenant du nitrate de sodium à une concentration de $2{,}5 \times 10^{-2}$ *M*, $G(NO_2^-)$ passe de 3,6 à la température de la pièce à 14 environ à 118°C ce qui suggère la présence de réaction en chaîne lorsque les concentrations en formiate sont élevées. Dans toutes les solutions étudiées $G(H_2O_2)$ et $G(H_2)$ ne dépendent pas de la température.

On a déterminé l'influence du pH sur $G(NO_2^-)$ pour des solutions de nitrate de sodium contenant soit du formiate de sodium, soit du propanol-2 à la température de la pièce. Les constantes de vitesse relevées dans la littérature, dans le cas du formiate de sodium, permettent d'établir un modèle satisfaisant uniquement pour $G(NO_2^-)$ en fonction du pH.

On conclut donc qu'on ne peut déduire avec exactitude le rendement en électron solvaté dans les solutions aqueuses irradiées à des températures élevées à partir des mesures prises avec les nitrates comme pièges à électrons en présence d'ions formiates ou d'alcools.

Introduction

In nuclear reactors, water, which can be used as a moderator (70–120°C) or a heat transfer medium (~300°C), is subjected to intense fields of ionizing radiation. While the radiation chemistry of aqueous solutions at room temperature is, in general, well understood (1), the very little data published (2–4) on water-radiolysis at higher temperatures is often confusing. As an example, Freeman and co-workers (3) report that the *G*-value (number of species formed per 100 eV of radiation energy absorbed) of the solvated electron, e^-_{aq}, increases from 2.7 at room temperatures to 4.8 at 300°C yet Burns and Marsh (4) report a $G(e^-_{aq})$ of 0.4 at 400°C.

The yields of e^-_{aq}, hydroxyl radicals, hydrogen atoms, molecular hydrogen, and hydrogen peroxide in radiolysed water are measured by adding chemical scavengers and analyzing for products (1–4). The measured yield is dependent on the reactivity (R) of the scavenger (5) present, where R is defined in eq. [1],

$$[1] \quad R = k_{X+S}[S]$$

and k_{X+S} is the rate constant for reaction of a primary radical (X = e^-_{aq}, $\dot{O}H$, $\dot{H}$) with the scavenger (5). For small values of R ($<10^7$ s^{-1}), only those primary radicals which escape the spur will be scavenged but as R increases, primary radicals will be scavenged from the spur itself (1, 5). Draganić and Draganić (5) have systematically documented this effect at room temperature. The effect of a moderate rise in temperature (<150°C) will reflect the change in k_{X+S} relative to geminate recombination and diffusion out of the spur for the primary species plus any increase or decrease in overall radical yield.

Interpretation of scavenger experiments require an understanding of the underlying chemistry. In this paper we report results obtained from the radiolysis of solutions at room temperature and 118°C which contain the nitrate ion, which is often used as an electron scavenger, and the formate ion or 2-propanol molecule, both of which are used as hydroxyl radical scavengers.

Experimental

The solute chemicals (purchased from Fisher Scientific Ltd. or Anachem Chemicals Ltd.) were used as supplied. The water was triply distilled. In experiments where the yields at room temperature were compared to those at 118°C, the solutions were irradiated in cylindrical Pyrex cells. The samples were degassed, and ~10 mL of solution transferred to the ~13 mL cell which was then sealed with a flame. The samples were irradiated in a thermostated oil bath in an AECL Gammacell, the dose rate of which was $\sim 2 \times 10^{19}$ eV kg^{-1} s^{-1}. Samples irradiated at 118 ± 3°C were rapidly cooled immediately after irradiation to room temperature (25 ± 3°C). In other room temperature experiments, solutions were irradiated in syringes after being saturated with the appropriate UHP gas. Nitrous oxide (Matheson) was first passed through a RIDOX (Fisher) column to remove oxygen.

The nitrite ion concentration was determined by the diazo-method (6) using an extinction coefficient at 540 nm of 52 860 M^{-1} cm^{-1}. Hydrogen peroxide yields were assayed by the tri-iodide ion method

(7) utilizing an extinction coefficient at 350 nm of 25 500 M^{-1} cm $^{-1}$. A McLeod gauge was used to measure the gas yields volumetrically and the fraction of the gas in the sample was determined on a CEC-21-610 mass spectrometer.

Since hydrogen peroxide was to be assayed from solutions irradiated at 118°C, the thermal stability of $\sim 2 \times 10^{-4}$ M hydrogen peroxide solutions was followed at 25, 70, 100, and 118°C. These samples which were prepared from a 30% hydrogen peroxide solution (unstabilized) were degassed and sealed in Pyrex cells as used for the irradiations. The hydrogen peroxide and oxygen concentrations were followed with time. The peroxide decomposed at measurable rates only at 100°C and 118°C and here the half-lives were 5–6 h and 0.75–1 h, respectively. The sum of the peroxide concentration plus twice the oxygen concentration equalled the initial peroxide concentration. As no irradiation was longer than 60 s and since the solutions were cooled immediately, the thermal decomposition of peroxide will not be a source of error in the experiments at 118°C.

Results

The G-values of nitrite, hydrogen peroxide, and hydrogen are summarized in Figs. 1 and 2 and Table 1 for degassed sodium nitrate solutions containing sodium formate irradiated at room temperature and 118°C. The hydrogen peroxide and hydrogen concentrations were linearly dependent on the dose received; the G-values given in Table 1 are the mean of at least five determinations and the errors are one standard deviation.

As can be seen in Fig. 1, $G(NO_2^-)$ decreased with increased dose and when extrapolated to zero dose, $G(NO_2^-)$ obtained at room temperature agreed with those previously reported by Draganić and Draganić (5) whose results are given by the triangles in this figure. At 118°C, $G(NO_2^-)$ was always greater than the room temperature results; however, for 0.5 M sodium formate solutions, $G(NO_2^-)$ (Fig. 2) was higher than expected (see later) so a number of further experiments were carried out. Firstly, to see if ionic strength was a factor, a 2.5×10^{-3} M sodium nitrate, 5×10^{-3} M sodium formate solution was irradiated with and without 0.2 M sodium sulphate present. At best, $G(NO_2^-)$ was marginally higher for the solution containing the sodium sulphate as can be seen in Fig. 1 for both irradiation temperatures. Secondly, to see if a stable end-product formed during the irradiation was capable of reducing nitrate ions to nitrite at 118°C, solutions containing sodium nitrate and 0.5 M sodium formate were first irradiated at room temperature and then heated at 118°C for longer than 10 min. There was always a small increase in $G(NO_2^-)$, as shown by the diamond symbols in Fig. 2, but the increases were probably within experimental error and therefore not considered to be significant.

Solutions of sodium nitrate with the 0.5 M sodium formate replaced by 0.5 M 2-propanol were also irradiated. For a nitrate concentration of 2.5×10^{-2} M $G(NO_2^-)$ was 3.0 and 3.4 at room temperature and 118°C respectively, while for a nitrate concentration of 2.5×10^{-3} M, the corresponding $G(NO_2^-)$ were 2.6 and 2.8. As with the formate samples, the $G(NO_2^-)$ decreased with increasing dose so the quoted values are those extrapolated to zero dose.

No nitrite was detectable in an unirradiated sodium nitrate solution containing either formate or 2-propanol which had been preheated to 118°C. However, care had to be taken in sealing the cells during sample preparation to ensure no nitrate was left in the constriction as this thermally decomposed to form nitrite.

The effect of pH on $G(NO_2^-)$ is shown in Fig. 3*a* for N_2-saturated 5.0×10^{-2} M sodium formate solutions containing

either 2.5×10^{-3} M or 2.5×10^{-2} M sodium nitrate irradiated at room temperature. Shown in Fig. 3*b* are the results when the formate was replaced by 5×10^{-2} M 2-propanol.

To investigate the decrease of $G(NO_2^-)$ with dose for both formate ion and 2-propanol solutions, the reactions of $CO_2^{\cdot-}$ and $(CH_3)_2\dot{C}OH$ with nitrite ions were followed at room temperature. Firstly, nitrous oxide saturated solutions containing

0.5 M sodium formate and $3-20\times10^{-5}$ M sodium nitrite and, secondly, nitrogen saturated solution containing 0.26 M acetone, 0.26 M 2-propanol, and $3-20\times10^{-5}$ M sodium nitrite were irradiated in syringes. In both cases $G(NO_2^-$ loss) was ~1.9.

Discussion

One of the most widely used methods to determine the scavengable yield of e^-_{aq} has been to measure $G(NO_2^-)$ in deoxygenated solutions containing nitrate ions as an electron scavenger and either formate (5, 9, 10), 2-propanol (5, 11–13), ethanol (5, 8, 14), or methanol (13) as a hydroxyl radical scavenger.

Reaction [2] indicates the species present in irradiated neutral water.

[2] $H_2O \rightsquigarrow e^-_{aq}, \dot{O}H, \dot{H}, H_2O_2, H_2$

When nitrate ions and one of the above hydroxyl radical scavengers are present, the generally accepted mechanism is reactions [3] and [4] followed by [9]–[11] in the case of formate and [17]–[19] for 2-propanol (5, 9–13) (see Table 2). The other alcohols react in a manner similar to 2-propanol. Provided the formate or 2-propanol concentration is twice the nitrate concentration so that reaction [10] or [18] scavenges greater than 95% of the hydrogen atoms in competition with [4] then $G(NO_2^-)$ can be equated to $G(e^-_{aq})$ scavenged. However, for this last relationship to hold it must be assumed that reactions [11] and [19] are sufficiently fast so that no nitrogen dioxide is converted to nitrite via reactions [5]–[7].

The pH dependence of $G(NO_2^-)$ at room temperature

In the present study, $G(NO_2^-)$ was used as a measure of $G(e^-_{aq})$ scavenged for irradiations at room temperature and 118°C. The choice of which hydroxyl radical scavenger, formate or 2-propanol, was based on how well the pH dependence, at room temperature, of $G(NO_2^-)$ (Fig. 3) could be modelled since the only rate constants not known are [11] and [10] (Table 2).

By comparing Fig. 3*a* to 3*b*, it is obvious that for similar reactivity (eq. [1]) of solutes, $G(NO_2^-)$ for the 2-propanol solutions was lower than that of the corresponding formate solutions for pH > 5.5 where reaction [8] does not compete significantly. In fact, this is generally true of all nitrate solutions where alcohols are used as a hydroxyl scavenger (5, 9–14). This suggests that [19] is either too slow to compete with [5]–[7] and [20] or that reaction of the alcohol-radicals with nitrogen dioxide does not form nitrite exclusively. A possible reaction could be [21].

[21] $(CH_3)_2COH + \dot{N}O_2 \rightarrow (CH_3)_2C(NO_2)(OH)$

The pH dependence of $G(NO_2^-)$ for nitrate–formate solutions can be satisfactorily modelled (using the computer program MACKSIMA CHEMIST (22)) with the reactions and rate

constants in Table 2 provided the rate constant k_{11} was equal to or greater than $6 \times 10^9 M^{-1} s^{-1}$. This value of k_{11} is greater than $(2k_5 \times 2k_{12})^{1/2}$ as would be expected for a redox reaction (23). The initial G-values for the species formed in reaction [2] were taken from the reactivity plots in ref. 5. Although both reactions [3] and [8] are ionic strength dependent, the actual magnitude of the dependence is ambiguous from the literature (24–27). The values used (Table 2) were a conservative attempt to correct for ionic strength and the calculated results are given by the solid lines in Fig. 3*a*.

The pH dependences of $G(NO_2^-)$ for the nitrate–2-propanol solutions (Fig. 3*b*) are similar to those reported by Sawai (11). As noted earlier, $G(NO_2^-)$ for this system is lower than that for the corresponding formate solution of the same reactivity. A fit between the experimental results and those calculated using the rate constants in Table 2 could not be obtained using G-values for the products in [2] calculated from reactivities (5) (solid line – Fig. 3*b*). An attempt to fit the data with the scavenged $G(e^-_{aq})$ equated to $G(NO_2^-)$ for pH > 5.5 (and the G-values for the other species formed in [6] scaled down to ensure a mass balance) was also unsuccessful as shown by the dashed lines in Fig. 3*b*. The rate constant k_{19} was fixed at $6 \times 10^9 M^{-1} s^{-1}$ for these calculations. From this it was apparent that the chemistry in irradiated nitrate–2-propanol is not well understood, so for the majority of the high temperature studies the nitrate–formate system was used.

Comparison of the radiolyses of nitrate solutions at room temperature and 118°C

At room temperature, the results for $G(NO_2^-)$ when extrapolated to zero dose agree reasonably with those of Draganić and Draganić (5) (Fig. 1); however, the decrease of $G(NO_2^-)$ with dose cannot be due to depletion of the initial solutes. Since it was found that both $CO_2^{\cdot-}$ and $(CH_3)_2\dot{C}OH$ could react with nitrite ions in sodium nitrite solutions, the same reaction [22]

[22] $NO_2^- + CO_2^{\cdot-}$ or $(CH_3)_2\dot{C}OH \rightarrow$ products

might be occurring in the nitrate solutions in competition with [11] or [19] as the nitrite concentration builds up during the irradiation.

When the nitrate–formate solutions were irradiated at 118°C, $G(NO_2^-)$ was always greater than that at room temperature (Fig. 1). For formate concentrations of $5 \times 10^{-3} M$ and $5 \times 10^{-2} M$, the increase in $G(NO_2^-)$ of 25% over the room temperature value is compatible with most of the published $G(e^-_{aq})$ data. Freeman and co-workers (3) used sulphur hexafluoride (SF_6) and nitrous oxide (N_2O) as electron scavengers and found for SF_6 over the temperature range 23°C to 106°C a 20% increase in $G(F^-/6)$ while for N_2O, $G(N_2)$ increased 19% over the range 23°C to 80°C. Kalecinski (8) who irradiated deoxygenated 0.1 M potassium nitrate and 0.1 M ethanol solutions found $G(NO_2^-)$ increased 16% over the temperature range 20°C to 130°C. However, above 130°C, Kalecinski found $G(NO_2^-)$ decreased to zero by ~195°C.

When the formate was replaced by 0.5 M 2-propanol (which has ÒH reactivity similar to the formate) in our experiments, the increases in $G(NO_2^-)$ were 8% and 15% for the 2.5×10^{-3} M and $2.5 \times 10^{-2} M$ sodium nitrate respectively. Again these results are consistent with earlier published results (3, 8) and the present results with formate concentrations less than 0.5 M. However, with the 0.5 M formate solutions, when extrapolated to zero dose, the increase in $G(NO_2^-)$ of 55% and 280% for $G(NO_2^-)$ from $2.5 \times 10^{-3} M$ and $2.5 \times 10^{-2} M$ nitrate concentrations respectively appears high when compared to the above results.

Figure 1*c* shows that raising the ionic strength from $7.5 \times 10^{-3} M$ to $3 \times 10^{-1} M$ with 0.2 M Na_2SO_4 did not affect $G(NO_2^-)$ significantly. The hydrogen and hydrogen peroxide yields for all the nitrate–formate solutions were temperature independent within experimental error (Table 1). Heating to 118°C, solutions previously irradiated at room temperature did not affect $G(NO_2^-)$ (Fig. 2). Taking these results in total indicates that for the 0.5 M formate solutions, nitrate is not being reduced to nitrite by a stable end product of the radiation at 118°C, and it is not high ionic strength giving rise to the increase in $G(NO_2^-)$. The results suggest that the high nitrite

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

yields in 0.5 *M* formate solutions arise from a chain reaction, possibly initiated by the direct action of the radiation on the formate ion, which reduces nitrate to nitrite.

Calculation of $G(e^-_{aq})$ *from* $G(NO_2^-)$ *at 118°C*

Leaving aside the 0.5 *M* formate solutions, the question arises as to whether the increase of 25% in $G(NO_2^-)$ found for the solutions with lower formate concentrations reflects a real increase in the overall e^-_{aq} yield; an increase in the reactivity of the nitrate; or simply a chain reaction as postulated in the 0.5 *M* formate case. Based on an activation energy of 2–4 kcal/mol for reaction [3] (24), the reactivity of the nitrate ion will increase by a factor of two to five. Presumably the reactivity of formate (reaction [9]) will increase by a similar amount. This should lead to an increase in e^-_{aq} scavenged for the low solute concentrations and, hence, an increased $G(NO_2^-)$ (5).

One approach to determine whether, in addition to the increased reactivity of the solutions at 118°C, there is an increase in the overall $G(e^-_{aq})$ is the following. With the nitrate – 5×10^{-2} *M* formate solution, assume in going from 25°C to 118°C that: the yield of the products in [6] do not change; the reactivity plots in ref. 5 are still valid; and the rate constants for [3] and [9] increase a factor of five. The predicted increases in $G(NO_2^-)$ for 2.9×10^{-4} *M*, 2.5×10^{-3} *M*, and 2.5×10^{-2} *M* nitrate solutions are 10%, 17%, and 20%, respectively. The corresponding calculated decreases in $G(H_2O_2)$ are 19%, 17%, and 14%. However, $G(H_2O_2)$ is not a function of temperature in the current experiments (Table 1). The predicted decrease in $G(H_2)$ of ~10% is within the experimental error of our experiments (Table 1). Furthermore, the predicted increases in $G(NO_2^-)$ do not account for the observed 25% increase observed at *all* nitrate concentrations. This indicates that reactivity alone under these conditions cannot account for the results. However, if the reactivity increase is coupled with an increase in the yield of the products of reaction [6] at 118°C then this may account for the results.

The constancy of the 25% increase in $G(NO_2^-)$ for all solutions with formate less than 0.5 *M* suggests that the processes occurring in the 0.5 *M* formate solutions are not occurring in the dilute solutions. In the 0.5 *M* formate case the percentage increase in $G(NO_2^-)$ was nitrate concentration dependent (Fig. 2).

Conclusions

The use of nitrate as an electron scavenger in the presence of formate or 2-propanol is not a good method to use in evaluating $G(e^-_{aq})$ at temperatures above room temperature. The chemistry of the solutions is complex and not completely understood. The weakness of the scheme lies, in part, in expecting 100% efficiency from reactions [11] and [19]. In principle, the best scavengers are those which are converted by the e^-_{aq} (or $\dot{O}H$) directly into a stable product or to an intermediate which decays by a first order process to a stable product. Studies towards this end are under way in these laboratories now.

Organic sulfur mechanisms. 24. Preparation and reactions of 2-hydroxyethanesulfonyl chloride, the first hydroxyalkanesulfonyl chloride[1]

JAMES FREDERICK KING AND JOHN HENRY HILLHOUSE
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 21, 1982

JAMES FREDERICK KING and JOHN HENRY HILLHOUSE. Can. J. Chem. **61**, 1583 (1983).

2-Hydroxyethanesulfonyl chloride (**1***a*) is readily made by reaction of an aqueous solution of 2-mercaptoethanol (**4***a*) with chlorine. This is the first clearly proved preparation of a compound which is both an alcohol and a sulfonyl chloride. Reactions of **1***a* with water and alcohols evidently proceed largely by intramolecular cyclization to the transient β-sultone (**2***a*), which then undergoes nucleophilic ring opening to form the products. In the presence of tertiary amines a minor but significant part of the reaction is shown by deuterium labelling to proceed via hydroxymethylsulfene (**14**), the principal reaction of which is simply to add the alcohol or water; only a small part, if any, of the sulfene (**14**) loses the hydroxyl group to give the ethenesulfonate derivatives (**13** or **22**). Aqueous chlorination of 3-mercapto-1-propanol gave 3-chloro-1-propanesulfonyl chloride (**5***a*) and 1,3-propane sultone (**2***b*) with no sign of any 3-hydroxy-1-propanesulfonyl chloride (**1***b*). A mechanism for the aqueous chlorination process invoking a cyclic chlorooxasulfoxonium ion (**27**) is discussed.

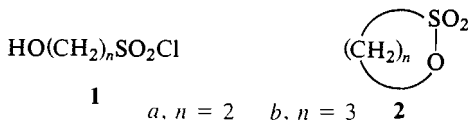
JAMES FREDERICK KING et JOHN HENRY HILLHOUSE. Can. J. Chem. **61**, 1583 (1983).

On prépare facilement le chlorure d'hydroxy-2 éthanesulfonyle (**1***a*) en faisant réagir une solution aqueuse de mercapto-2 éthanol (**4***a*) avec le chlore. C'est la première fois qu'on prépare un composé qui est à la fois un alcool et un chlorure de sulfonyle. Le composé **1***a* réagit avec l'eau et l'alcool principalement par cyclisation intramoléculaire en donnant le β-sultone (**2***a*) qui par ouverture nucléophile du cycle conduit aux produits désirés. Le marquage au deutérium permet d'établir qu'en présence d'amines tertiaires il se produit une réaction secondaire importante par l'intermédiaire d'un hydroxyméthylsulfène (**14**) qui s'additionne principalement sur l'eau ou l'alcool; seule une faible partie, s'il y en a, du sulfène (**14**) perd le groupe hydroxyle pour donner les dérivés éthènesulfonates (**13** ou **22**). La chloration aqueuse du mercapto-3 propanol-1 donne le chlorure de chloro-3 propane-1 sulfonyle (**5***a*) et le propane-1,3 sultone (**2***b*) sans aucune trace de chlorure d'hydroxy-3 propane-1 sulfonyle (**1***b*). On discute un mécanisme de chloration aqueuse qui fait intervenir un ion chlorooxasulfoxonium cyclique (**27**).

[Traduit par le journal]

Introduction

In connection with our study of the pyridine-promoted hydrolysis of ethenesulfonyl chloride (1), the question arose as to whether 2-hydroxyethanesulfonyl chloride (**1***a*) – or indeed any compound with both alcohol and sulfonyl chloride groups – was capable of being prepared in pure form. An alcohol, of course, normally reacts with a sulfonyl chloride to give the



1 *a*, $n = 2$ *b*, $n = 3$ **2**

sulfonic ester as the initial product, but the reaction in the absence of catalysis is not, in fact, particularly fast at room temperature. Geiseler and Laue's estimate for the rate of reaction of 1-propanesulfonyl chloride in 1-butanol at 25°C corresponds to a half reaction time of 27 hours (2). Scott and Lutz, presumably to obtain a conveniently rapid rate for kinetic studies, used as their medium refluxing ethanol, in which 1-octanesulfonyl chloride showed a half-life of 8 min (3). These bimolecular reactions give, of course, only a rough lower limit to the rate of reaction of the analogous bifunctional species (**1**), since **1** is capable of cyclization to form **2**, and for certain ring sizes this will be much faster than the corresponding bimolecular process. Such a reaction of **1***a*, however, would lead to the four-membered ring sultone **2***a*, and the formation of four-membered sulfur-containing rings is typically not much faster than the bimolecular reaction at ordinary concentrations (4, 5). In addition, the electron-withdrawing influence of the nearby chlorosulfonyl group might be expected to lower the nucleophilicity of the hydroxyl function, thereby enhancing the stability of **1***a*.

Preparation of compounds with both chlorosulfonyl and *phenolic* hydroxyl groups has been reported on occasion (6–10), the first being the synthesis of **3***b* seventy-five years ago (6). Although the presence of the two substituents *ortho*

to the hydroxyl in **3***b* appears to lead to easier preparation and lower reactivity, the simplest member of the series (**3***a*) has been obtained in crystalline form and is not especially fragile (9). The hydroxyl group of an alcohol is more nucleophilic than that of a phenol, however, and we were not surprised that a search of the chemical literature turned up no properly authenticated examples of a compound with both an alcoholic hydroxyl and a chlorosulfonyl function.[2]

The most frequently used routes to alkanesulfonyl chlorides involve either (*i*) reactions of the sulfonic acid (or salt) with an inorganic acid chloride like thionyl chloride or phosphorus pentachloride, or else (*ii*) aqueous chlorination of a thiol or like material with the sulfur at a low oxidation level (17). Obviously the inorganic acid chloride route is a poor candidate for the synthesis of **1** since any reagent likely to convert a sulfo group to a chlorosulfonyl might also be expected to transform an alcohol to the chloride, and, in fact, the reaction of sodium 2-hydroxyethanesulfonate ("isethionate") with either $POCl_3$–PCl_5 or $SOCl_2$–dimethylformamide is a good preparative route to 2-chloroethanesulfonyl chloride (**5***a*) (18).

More surprising, perhaps, are the reports that chlorination of mercaptoalkanols also proceeds with replacement of the hydroxyl by chlorine according to the general equation **4** → **5**.

$$HO(CH_2)_nSH \xrightarrow{Cl_2/H_2O} Cl(CH_2)_nSO_2Cl$$

4 **5**

a, *n* = 2 *d*, *n* = 5
b, *n* = 3 *e*, *n* = 6
c, *n* = 4

Gilbert, for example, describes a procedure involving chlorination followed by careful addition of water in which **5***a* is prepared from **4***a* in 94% yield (19). Goethals and Verzele (20) report that chlorination of aqueous suspensions of **4***b*, **4***c*, **4***d*, or **4***e* yields the corresponding ω-chloro-1-alkanesulfonyl chloride (**5**) as the major, or only, identified product.

Although these results were obviously not directly encouraging, they were indirectly helpful. Upon consideration of possible mechanisms for these processes (which are discussed in detail in the Results and discussion section), we were led to try simple chlorination of an aqueous solution of **4***a*, and found that the major isolated product was, indeed, **1***a*, along with a smaller amount of **5***a*. This preparation, together with the proof of structure and the reactions of **1***a* with water and alcohols, make up the substance of this paper. To our knowledge, **1***a* is the first characterized compound which is both an alcohol and an alkanesulfonyl chloride. It is also probably the simplest such compound capable of isolation at room temperature.[3] Part of this work has been described in preliminary form (24).

Results and discussion

*Preparation and proof of structure of 2-hydroxyethanesulfonyl chloride (**1**a)*

In our hands best preparative yields (~30%) of **1***a* were obtained by very rapid chlorination of an ice-cooled solution of **4***a*, followed by rapid work-up. The latter involved extraction of the reaction mixture first with benzene, then with methylene chloride, and then saturation of the aqueous layer with sodium chloride followed by further extraction with methylene chloride. The benzene extracts contained all of the 2-chloroethanesulfonyl chloride (**5***a*) (10% yield) mixed with some **1***a* (7%), the methylene chloride extracts on removal of solvent gave essentially clean 2-hydroxyethanesulfonyl chloride (**1***a*) in 28% yield, as a slightly syrupy liquid which gave appropriate elemental analyses and showed peaks characteristic of the hydroxyl and chlorosulfonyl groups at 3590, 3460, 1375, 1168, and 1058 cm^{-1} in the infrared. The ^{13}Cmr spectrum, which showed only peaks at 56.9 and 67.6 ppm, and the ^{1}Hmr spectrum with two perturbed triplets centred at 3.98 and 4.28 and a singlet at 2.8 ppm are clearly in excellent agreement with the assigned structure.[4] A solution of **1***a* in $CDCl_3$ (0.1 *M*) was stable for at least six months at room temperature, whereas the neat compound, though stable at −20°C, was approximately half decomposed after three weeks at room temperature.

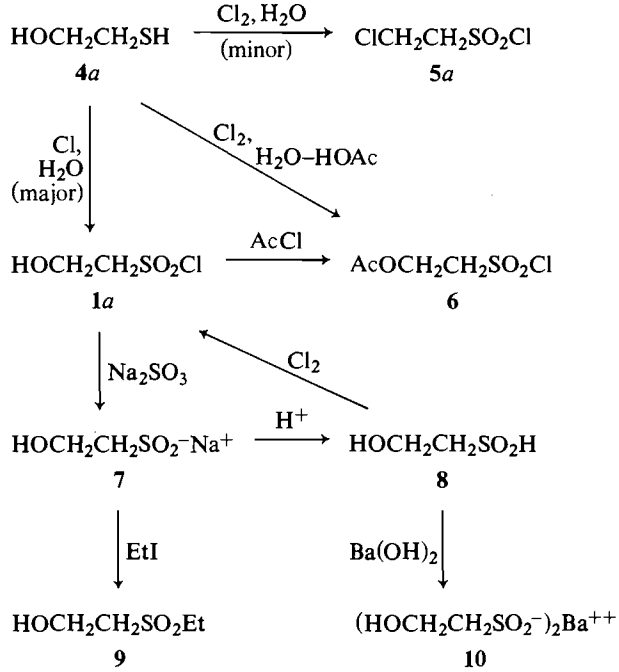
A number of runs on a preparative scale (i.e. 10 to 30 g of **4***a*) carried out more or less as described above gave yields of **1***a* varying from about 10 to 35%. We have not systematically attempted to maximize the yield but we can offer a few pointers. (*i*) A large excess of chlorine seems to be necessary; smaller amounts lead to incompletely oxidized products characterized by a bad smell and relatively high-field peaks in the ^{1}Hmr spectrum. (*ii*) Rapid work-up appears to help minimize hydrolysis of **1***a*. (*iii*) Most of the **5***a* can be removed from a mixture of **1***a* and **5***a* by washing the neat liquid with cyclohexane; the work-up described above, however, is preferable when a sample of **1***a* without any **5***a* is desired.

These reactions, together with a number of transformations carried out to provide further evidence for the assigned structure (**1***a*), are summarized in Scheme 1. Reaction of **1a** with acetyl chloride gave a good yield of 2-acetoxyethanesulfonyl

[2]A hydroxyalkanesulfonyl chloride structure (**iii**), had, in fact, been suggested by Schroeter and Sulzbacher in 1928 (11) for a material obtained by reaction of PCl_5 with a substance assigned structure (**ii**), which in turn had been made by the action of strong base on **i**. In 1918, when Schroeter first proposed (12) structure **ii** for the product from **i**, the then accepted structure for the adduct of acetone and bisulfite was not **ii** but rather the α-hydroxysulfite formulation, $Me_2C(OH)OSO_2^-$ (Fig. 1). In 1926 Raschig and Prahl (13, 14) presented a formidable case for the α-hydroxy-sulfonate structure for aldehyde- and ketone-bisulfite adducts, and Schroeter and Sulzbacher attempted to refute the Raschig and Prahl revision by the following argument: they felt they had proved **ii** to be the structure of the product from **i**, this product was different from the acetone-bisulfite adduct, and therefore the acetone-bisulfite adduct could not have structure **ii**. Subsequent extensive work including two X-ray crystallographic structure determinations (15, 16, and references cited) has fully confirmed the α-hydroxy-sulfonate structure for the bisulfite adducts, however, and hence the compound from **i** cannot have structure **ii**, and there is thus no basis for assigning stucture **iii** to the product of its reaction with PCl_5. To the best of our knowledge neither of these materials has been studied since 1928, and their chemical natures are unknown.

[3]The simplest number of the series is, of course, hydroxymethanesulfonyl chloride, but it seems unlikely that this, or any other geminal hydroxy-sulfonyl chloride (including **iii** in footnote 2), can be isolated at room temperature. As we have noted (21), it is difficult to prepare and keep any compound of the general structure RSO_2Z when Z is a good nucleofuge and R a group capable of forming a reasonably stable cation, R^+; see also refs. 22 and 23. Except under the mildest conditions, any reaction capable of giving $HOCH_2SO_2Cl$ would thus be expected to give CH_2O, SO_2, and HCl, or products of their further reaction.

[4]NOTE ADDED IN PROOF: Very recent experiments by Mr. K. C. Khemani in this laboratory have (a) led to improved yields of **1***a* (>80% on a 25 mmol scale), and (b) enabled unambiguous assignment of the 56.9 ppm peak to C-2 and that at 67.6 ppm to C-1.



SCHEME 1

chloride (**6**), identical with a specimen prepared by Anschütz' method (7); the acetoxysulfonyl chloride (**6**) was also obtained as the product of chlorination of 2-mercaptoethanol (**4***a*) in a 1:1 mixture of water and acetic acid. Reduction of **1***a* with sodium sulfite gave the sodium sulfinate (**7**); the sulfinic acid **8** was obtained by acidification and continuous extraction of a solution of **7**, and was readily converted back to **1***a* by brief chlorination. Reaction of the sodium sulfinate **7** with ethyl iodide gave a modest yield of ethyl 2-hydroxyethyl sulfone (**9**), identical to a sample prepared from sodium ethanesulfinate and ethylene chlorohydrin (25). These observations clearly establish the structure **1***a* beyond reasonable doubt.

The barium sulfinate (**10**) in Scheme 1 is of interest in connection with the report by Hesse *et al.* (26) that this compound is the chief product of the reaction of ethylene sulfone with barium hydroxide. As our first route to the synthesis of **1***a* we had, in fact, attempted to make **10**, expecting that it would be easily converted to **1***a*. As we shall describe in detail in a separate paper, in our hands the major product of the reaction of ethylene sulfone with barium hydroxide was, in fact, the ethanesulfonate salt. After preparing authentic **10** as shown in Scheme 1 we were able to show that the product obtained from ethylene sulfone contained less than 5% of **10**.

Hydrolysis of 2-hydroxyethanesulfonyl chloride (1a)

Our original interest in preparing **1***a* stemmed from its possible use as a source of hydroxymethylsulfene (**14**), the chemistry of which we wished to examine to determine if it played any part in the hydrolysis of ethenesulfonyl chloride. Since sulfenes are most commonly generated from an alkanesulfonyl chloride by the action of a tertiary amine, we have accordingly looked at the reaction of **1***a* with tertiary amines and water. Prior to discussing the hydrolysis in the presence of amines, however, it is appropriate to look at the reaction with water alone.

Hydrolysis of **1***a* at pH 4.0 (in the pH-stat apparatus using sodium hydroxide as the titrant to maintain constant pH) gave, in addition to (*i*) the expected sodium 2-hydroxyethanesulfonate (**11**), (*ii*) a small amount of sodium 2-chloroethanesulfonate (12), and (*iii*) an unidentified product in what appears to be a somewhat larger amount (see Table 1 and the top line of Scheme 2). At pH 11.0 the same products plus a trace of sodium ethenesulfonate (**13**) were observed. As indicated in Table 1, addition of potassium chloride increased the yield of **12**. Compounds **11** and **12**, along with a trace of **13**, were found also in the product of reaction in D_2O (apparent pH 3.0 and 11.0); the spectra showed no sign of any deuterium incorporation.[5]

In the presence of pyridine, the reaction in D_2O (at apparent pH 6.0) showed two changes as indicated in the bottom line of Scheme 2: (*i*) the betaine **16** was formed as the major product, and (*ii*) about half of the 2-hydroxyethanesulfonate salt was the monodeuterated material (**15**). As indicated in Scheme 2, the latter product presumably arises from trapping of the sulfene (**14**) which is formed as a minor intermediate (ca. 15 to 20%) in the reaction of **1***a* with pyridine. Even this minor proportion of hydroxymethylsulfene (**14**) formation serves, however, to answer the question which prompted this study in the first place, viz. how does hydroxymethylsulfene (**14**) react in aqueous pyridine? The yield of the monodeuterated 2-hydroxyethanesulfonate (**15**), compared with the very small yield of ethenesulfonate (**13**), shows clearly that virtually all of the sulfene (**14**) goes to 2-hydroxyethanesulfonate and little, if any, loses OH^- to form the ethenesulfonate (**13**).

The sulfene (**14**) is, of course, but a minor contributor in the reactions of 2-hydroxyethanesulfonyl in water and all or most of the other products that we have identified may be easily explained by postulating that they are formed by way of β-sultone (**2***a*) (see Scheme 2, dotted lines radiating from **2***a*). The unsubstituted β-sultone (**2***a*) has never been isolated, though it has been postulated as an intermediate (27) and a number of substituted analogues have been prepared, either by cycloaddition of sulfur trioxide onto alkenes (28–32) or by the reaction of perhalogenated aldehydes or ketones with alkanesulfonyl chlorides and tertiary amines (33–37). β-Sultones lacking halogen substituents react readily with such nucleophiles as water, methanol, pyridine, and aniline to give the products derived from substitution with C—O cleavage (28, 38), and it is therefore reasonable to propose, as in Scheme 2, that the betaine (**16**) and the 2-chloroethanesulfonate (**12**) arise from the sultone (**2***a*). Clearly, with aqueous 0.54 *M* KCl at pH 4.0 (see Table 1), this means that at least half of the product is formed from **2***a*, and one may make a reasonable case that most, and perhaps all, of the **11** also comes from **2***a*. To do this we make use of the Swain–Scott equation, $\log k/k_0 = sn$, which is known to work reasonably well for alkyl transfer processes (39). Taking $n = 3.04$ for chloride ion (39) and assigning $s = 0.65$ as a typical value for a primary alkyl sulfonate ester,[6] we then obtain $\log k_{Cl}/k_0 = 2$, or $k_{Cl}/k_0 = 100$, where k_{Cl} and k_0 are the second-order rate constants for the reaction of **2***a* with chloride ion and water, respectively. If **12** and **11** are formed only from **2***a*, the product ratio will therefore be given by $k_{Cl}[Cl^-]/k_0[H_2O]$. Hence for a reaction in which the initial value of $[Cl^-]$ is 0.54 *M* and $[H_2O] = 55$ *M*, the

[5] For simplicity in this discussion we ignore the deuteration of the hydroxyl hydrogen, which will, of course, have roughly the deuterium content of the active hydrogen of the particular medium.

[6] Cf. Ethyl tosylate, $s = 0.66$ (39), ethyl mesylate, $s = 0.64$, butyl mesylate, $s = 0.65$, etc. (40).

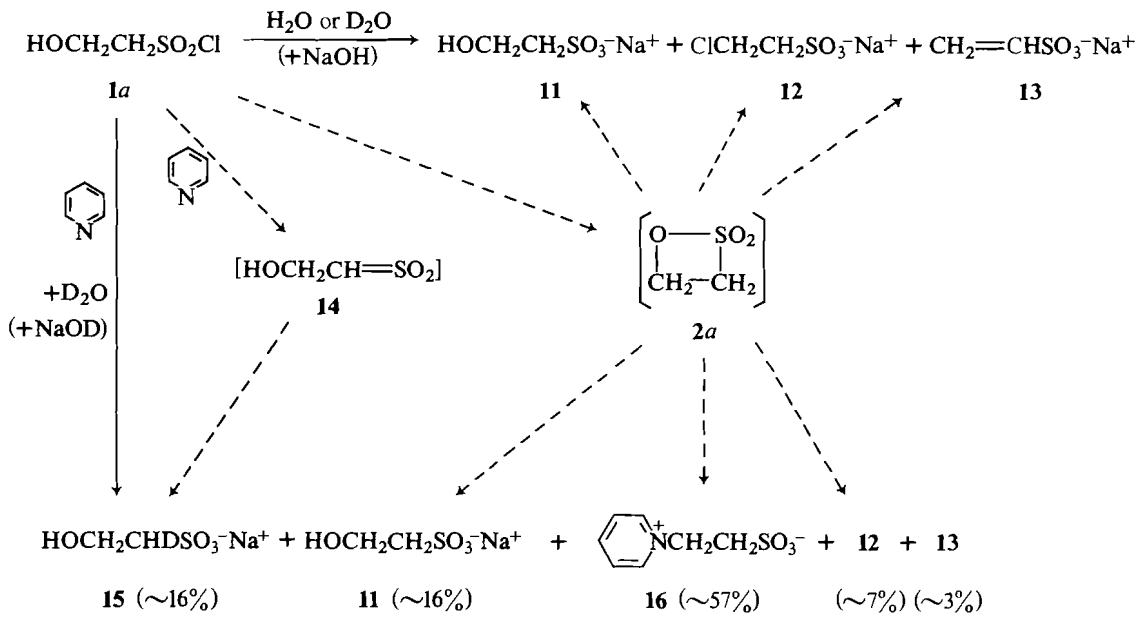

SCHEME 2

product ratio, **12**/**11**, would be predicted to be ~1, which is, within experimental error, that found under these conditions (0.9 ± 0.1, see Table 1). Similarly the hydrolysis in 0.1 *M* KCl is predicted to give a product ratio around 0.2; the observed value is 0.24 ± 0.07. The assignment of $s = 0.65$ for **2***a* is, of course, only a guess for illustrative purposes, but it should perhaps be noted that a value significantly smaller than 0.65 would predict a smaller yield of **12**, i.e. would make it impossible for Scheme 2 to account for the amount of **12** actually formed. On the other hand, a value much larger than 0.65 would imply that **2***a* is distinctly more selective than ethyl tosylate or ethyl or butyl mesylate. We find it difficult to quantify the effects of (a) the presence of the sulfonyl group β to the reacting carbon, and (b) the release of ring strain in this reaction, but if, as seems quite possible, these two effects are opposed then the combined effect may well be small and hence *s* may, in fact, be close to 0.65. This line of reasoning would indicate that most, and perhaps all, of the **11** and **12** formed in the simple hydrolyses at pH 4.0 and 11.0 and similarly most of the product not derived from the sulfene (**14**) in the pyridine-promoted reaction, are formed by way of β-sultone.[7] It is clear, however, that the point is by no means proved, and, recalling that some of these hydrolyses give a material as yet unidentified, further experiments are required to give a clear picture of the hydrolysis of **1***a*.

The very small amount of **13** produced in these reactions warrants brief mention. Of the various ways in which it might arise, perhaps the simplest is by hydrolysis of a small amount of **5***a* present as impurity in the **1***a*; **13** is the exclusive (>98%) product of hydrolysis of **5***a* at pH 6.0, and, in fact, the yield of **13** places an upper limit on the amount of **5***a* present in these samples of **1***a*. Formation of the "dimer", $HOCH_2CH_2SO_2$-

[7]Safety note: Since 1,3-propane sultone (**2***b*) has been identified as a strong carcinogen (Org. Synth. **58**, 168 (1978)) it would seem prudent to suspect β-sultone (**2***a*) also. We therefore recommend that until future experiments show this to be unnecessary, such likely sources of β-sultone as 2-hydroxyethanesulfonyl chloride (**1***a*) be handled with all precautions appropriate to a potentially highly hazardous material.

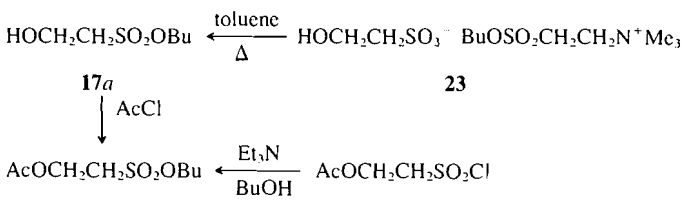
$OCH_2CH_2SO_2Cl$, by the conventional reaction of the alcohol and chlorosulfonyl groups of two molecules of **1***a*, could also lead to **13** since, by analogy with **5***a*, hydrolysis of the "dimer" might well give equivalent quantities of **13** and **11**. Finally, for the pyridine-promoted reaction, some of the **13** could arise from the sulfene by loss of hydroxide on trapping, as mentioned above.

Reactions of 2-hydroxyethanesulfonyl chloride with an alcohol and a tertiary amine

Although carried out under somewhat different conditions, the reactions of **1***a* with alcohols and tertiary amines in methylene chloride are quite similar to the pyridine-promoted hydrolysis. The most prominent products are the ester (**17**), the betaine (**19**), and the 2-chlorosulfonate salt (**20**) (See Table 2 and Scheme 3). Except for a brief, century-old paper describing the formation in very low yield of ethyl 2-hydroxyethanesulfonate by a silver salt procedure (41*a*),[8] alkyl hydroxyalkanesulfonates were to our knowledge previously unknown compounds and rigorous evidence for these structures (**17***a* and **17***b*) was therefore required. The neopentyl ester (**17***b*) gave correct elemental analyses and showed appropriate infrared and ^{1}Hmr spectra (see Experimental). The butyl ester (**17***a*) was identical to a fully characterized specimen prepared by a substrate–reagent ion-pair (SRIP) reaction of butyl [2]betylate 2-hydroxyethanesulfonate (**23**), a procedure developed simultaneously in this laboratory as part of our work on the chemistry of betylates (42, 43). In addition, acetylation of **17***a* gave butyl 2-acetoxyethanesulfonate (**24**), characterized by elemental analyses and spectra, and by the observation of identical ^{1}Hmr peaks in the spectrum of the product from the reaction of 2-acetoxyethanesulfonyl chloride (**6**) with 1-butanol and triethylamine; this spectrum also showed the presence of an almost equivalent amount of butyl ethenesulfonate (**22**, R = Bu).



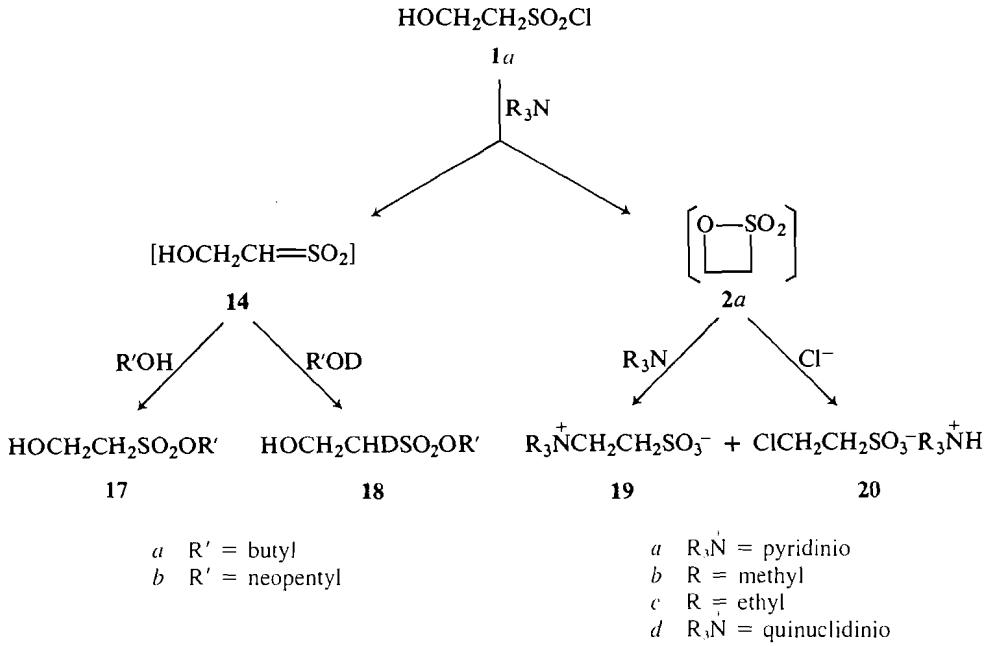
The mechanism of formation of the ester (**17**) follows from the reaction with 1-butanol-*d* which gives mostly the monodeuterated ester (**18**), clearly pointing to the intermediacy of the sulfene (**14**) as indicated in Scheme 3. The other major products, **19** and **20**, and probably at least some of 2-hydroxyethanesulfonate salt (**21**) very likely come from β-sultone (**2***a*) by reaction with the amine, chloride ion, and adventitious water, respectively. It is possible that a little of the 2-hydroxysulfonate salt (**21**) is formed from the ester (**17***a*) by transfer of the butyl group to the amine or some other nucleophile, but the lack of deuterium in the salt (**21**) formed in the presence of butanol-*d* shows this reaction to be unimportant. Such a pathway also does not account for the **21** formed in the reactions with neopentyl alcohol, since control experiments show the neopentyl ester to be completely stable to these conditions. The ethenesulfonate esters (**22**) could arise (a) from small amounts of 2-chloroethanesulfonyl chloride (**5***a*) present

TABLE 2. Tertiary-amine promoted reactions of 2-hydroxyethanesulfonyl chloride (**1***a*) with alcohols[a]

		Percentage yields of products[b]				
Alcohol (R′OH)	Amine (R_3N)	$HOCH_2CH_2SO_2OR'$ (**17**) (or $HOCH_2CHDSO_2OR'$ (**18**))	$R_3\overset{+}{N}CH_2CH_2SO_3^-$ (**19**)	$ClCH_2CH_2SO_3^-$ $R_3\overset{+}{N}H$ (**20**)	$HOCH_2CH_2SO_3^-$ $R_3\overset{+}{N}H$ (**21**)	$CH_2{=}CHSO_2OR$ (**22**)
1-Butanol	Pyridine	7	57	28	<1	3
1-Butanol	Trimethylamine	33	38	20	7	3
1-Butanol-*d*[c]	Trimethylamine	40[c]	40[c]	14[c]	3[c]	3[c]
1-Butanol	Triethylamine	27	22	43	<1	3
1-Butanol	Quinuclidine	30	29	21	10	<1
Neopentyl alcohol	Pyridine	8	35	40	8	2
Neopentyl alcohol	Trimethylamine	25	51	5	10	6

[a]In CH_2Cl_2 at room temperature with excess amine (1.5 to 10 equiv.) and alcohol (~10 equiv.).
[b]The product was analyzed by a combination of extraction and ion exchange procedures with the relative composition of binary mixtures (e.g. **17** and **22**) obtained from ^{1}Hmr spectra (see Experimental).
[c]The 2-hydroxyethanesulfonic ester from the reaction with 1-butanol-*d* was estimated from its ^{1}Hmr spectrum to consist of >80% of **18** and <20% of **17**. The other products from this reaction showed no sign of deuterium incorporation.

[8] Cf. Reference 41*b* and also ref. 41*c*.



SCHEME 3

as impurity in the starting material, or (b) as secondary products from the trapping of the sulfene (**14**). The comparatively small amount of ethenesulfonate salt (**13**) already noted in the hydrolysis experiments (Table 1) indicates that the amount of **5***a* in these samples of **1***a* does not exceed 1%, and hence that at least some of the **22** comes by way of the sulfene (**14**). This latter reaction is perhaps most simply visualized in a generalized form as follows:

$$XCH_2CH_2{=}SO_2 \xrightarrow{HZ} [XCH_2\bar{C}HSO_2Z] \begin{cases} \xrightarrow{H^+} XCH_2CH_2SO_2Z \\ \rightarrow CH_2{=}CHSO_2Z + X^- \end{cases}$$

(Somewhat more complex schemes involving, for example, concerted addition to different conformers of the sulfene, are not, however, rigorously excluded.) A specific example of the above general scheme has been proposed (44) to account for the formation of both ethenesulfonate and betylate esters from the sulfene $R_3N^+CH_2CH{=}SO_2$. In addition, the observation of both **24** and **22** (R = butyl) from the acetoxysulfonyl chloride (**6**) (see above) also points to the operation of such a pathway. The small proportion of ethenesulfonate ester when X = OH, as compared to $X = R_3N^+$ or OAc, is in good agreement with the relatively poor, but not totally neglible, leaving group reactivity, or nucleofugality (45), of the hydroxyl group.

It should be noted that the reaction with 1-butanol-*d* provides evidence not only for the sulfene route to the hydroxy-ester (**17**), but also, since all of the other products lack deuterium, specifically against the intermediacy of the sulfene (**14**) in the formation of **19** and **20**. This means that if **19** and **20** arise from β-sultone (**2***a*), it cannot have been formed from the sulfene (**14**). This is not very surprising since such a cyclization is in Baldwin's terminology a 4-*endo-trig* process, which, with first-row elements at least, is strongly "disfavoured" (46). β-Sultone formation is, in our view, most probably a general-base assisted direct cyclization of **1***a*, a respectable 4-*exo-tet* reaction.

One feature apparent from Table 2 is the difference in the yield of the hydroxy-ester (**17**) with different amines. The saturated tertiary amines give 25–40% of **17** whereas pyridine leads to <10% of **17** and correspondingly larger amounts of the products formed from β-sultone (**2***a*). This recalls earlier observations in this laboratory (47) on the reaction of methanesulfonyl chloride with *p*-toluidine-d_2 and a tertiary amine; the predominant product with triethylamine (after work-up) was the monodeuterated amide, $CH_2DSO_2NHC_6H_4CH_3$, but with pyridine was the undeuterated amide $CH_3SO_2NHC_6H_4CH_3$. Also related are the recent findings of Farng and Kice (48) in the reactions of 1-butanesulfonyl chloride with piperidine-*d* and morpholine-*d*; the piperidide and morpholide were α-monodeuterated to the extent of 72% and 15% respectively. These results are consistent with competing elimination–addition (sulfene) and direct substitution mechanisms in which the elimination is more sensitive to change in base strength than the substitution (48), a picture that is in itself consistent with the high sensitivity to base change shown by the rate of sulfene formation from methanesulfonyl chloride (49).

The mechanism of the aqueous chlorination of mercaptoalkanols

As the final point of discussion we turn to the possible mechanisms of conversion of **4** into **1** and **5** by the action of chlorine and water. In the top line of Scheme 4 we show a simple pathway from **4** to **5**. We have not specified the route from **4** to **25**, but of the numerous possible (and perhaps parallel) paths the sequence **4** → $HO(CH_2)_nSCl$ → $HO(CH_2)_nSCl_3$ → **25** has the advantage that there is precedent for each step, though under somewhat different conditions, in reactions reported by Douglass *et al.* (50). Two other valuable observations reported by Douglass in his pioneering studies (51) are also relevant to the proposed scheme. The first, that alcohols react very quickly with a sulfinyl chloride, fits with the proposed conversion of **25** to **26**; this cyclization must be quick to compete with the hydrolysis of the sulfinyl chloride (**25** → **28**) which is known in the general case also to be rapid. The second point from Douglass' work (51) is his observation that chlorination of methyl methanesulfinate gives methanesulfonyl chloride and methyl chloride; this is the simplest possible

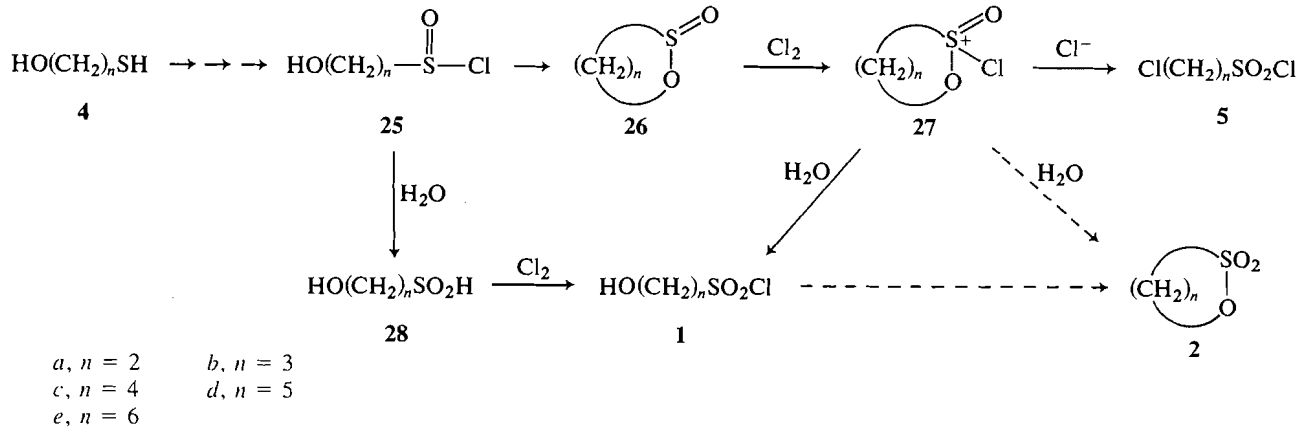
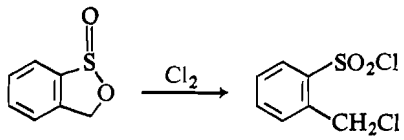


SCHEME 4

precedent for the proposed reaction **26** → **5**. We have noted (52) a closely related process,



and it seemed likely at the time that a chlorooxasulfoxonium ion (like **27**) was an intermediate in this conversion (53). This view has since been strengthened by reports of (a) the isolation of stable aryloxysulfoxonium salts (54), and (b) the observation of products readily derivable from other closely related sulfoxonium intermediates (55–58). A further point in support of the mechanism in Scheme 4 is the comment by Goethals and Verzele (20) that their sample of **5***c* "contains 5% butane sultone" (**2***c*), a by-product nicely consistent with the intermediacy of **27***c*.

For the formation of the hydroxysulfonyl chloride (**1**) Scheme 4 shows two possible paths, one by way of the open-chain sulfinic acid (**28**), the other via the sulfoxonium ion (**27**); a third possibility in which **26** is hydrolyzed to **28**, which then gives **1**, is probably not significant owing to the comparative slowness of the acid-catalyzed hydrolysis of sulfinic esters (59). The sequence **25** → **28** → **1** is well-precedented but, lest it be too quickly favoured over the other route, we should point out that if **5** is indeed formed from **27** then it is highly likely that at least some **1** is, too. As has already been mentioned above in our discussion of the role of β-sultone in the hydrolysis of **1***a*, a 0.5 *M* aqueous solution of chloride ion in reaction with an electrophile with a Swain–Scott *s*-value of 0.65 should give about equal amounts of the products of reaction with chloride ion and water, respectively. If, as seems reasonable to us, the selectivity of **27** is no higher than that of **2**, then in the early stages of the reaction at least, in which $[Cl^-] < 1$ or 2 *M*, a significant fraction of **27** must give **1**. It should be noted, however, that reaction of one equivalent of **4** with excess chlorine generates four to six equivalents of chloride ion, and, as a result, the chloride ion concentration jumps abruptly during the reaction, and less **1***a* would be formed from **27***a* as the final concentration of chloride ion is reached.

In the course of this study we have also had a brief look at chlorination of 3-mercapto-1-propanol (**4***b*) under our conditions. We found no sign of the hydroxysulfonyl chloride (**1***b*), the organic-soluble product being a mixture of 3-chloropropane-1-sulfonyl chloride (**5***b*) and the propane sultone (**2***b*), each in about 25% yield. To check to see if the γ-sultine (**26***b*) could be an intermediate in the reaction of **4***b*, we chlorinated a sample of **26***b* and indeed obtained both the sultone (**2***b*) and the sulfonyl chloride (**5***b*); the yields (77% and 13%, respectively) were different from those obtained from **4***b*, though this is probably due to the much lower concentration of chloride ion present in the reaction of the sultine (**26***b*). It is possible that no **1***b* was formed at all in this reaction, but it seems to us more likely that it was, in fact, formed and was all rapidly converted to **2***b*. The correct explanation of this and a number of other points of mechanism raised in this paper, however, must await futher experiments, which we hope to be able to describe in due course.

Experimental

Melting points were obtained with a Gallenkamp melting point apparatus and are uncorrected. Refractive indices were determined on a thermostatically controlled Bausch and Lomb Abbé refractometer. Infrared (ir) spectra were recorded on Perkin–Elmer 621 or Beckman 4250 spectrometers; spectra were calibrated using a polystryrene film. The ^{1}Hmr spectra were obtained with Varian T-60 or XL-100 instruments, with all reported δ values from spectra run on the latter instrument; peak positions are in ppm downfield from tetramethylsilane (TMS) except for D_2O solutions for which either sodium 3-(trimethylsilyl)propionate (TSP) or sodium 3-(trimethylsilyl)propanesulfonate (DSS) was the reference compound. The pH-stat apparatus consisted of a Radiometer Model 25 pH meter equipped with a Radiometer Titrator 11 automatic titrator, a Radiometer GK2401B electrode, and an Aminco automatic burette with a 3 mL syringe reservoir. The reaction vessel was a Radiometer V520 vessel equipped with a V525 thermostatting jacket. The temperature was maintained constant by a Haake FJ constant temperature circulating apparatus.

Unless otherwise indicated, solvents and regular reagents were reagent grade and used as supplied. 2-Mercaptoethanol, 1,3-propanedithiol, 1,3-propane sultone, 3-mercapto-1-propanol, neopentyl alcohol, sodium 2-chloroethanesulfonate, and quinuclidine were supplied by Aldrich Chemical Col. and sodium 2-hydroxyethanesulfonate (as "isethionic acid, sodium salt") by Eastman Kodak. Authentic samples for spectroscopic identification of reaction products were obtained and (or) purified as follows: (*i*) sodium 2-chloroethanesulfonate (**12**) by recrystallization of the commercial material from absolute ethanol; (*ii*) 2-chloroethanesulfonyl chloride (**5***a*) by the method of Le Berre *et al.* (18); (*iii*) sodium ethenesulfonate (**13**) by hydrolysis of **5***a* at pH 11.0 followed by recrystallization from absolute ethanol (mp >385°C); (*iv*) butyl and neopentyl ethenesulfonates (**22***a* and **22***b*) (**22***a* by Dr. M. Aslam) from reaction of the alcohol with **5***a* and trimethylamine (43); (*v*) pyridine betaine (**16** and **19***a*) as described by Le Berre *et al.* (60); (*vi*) the trimethyl betaine (**19***b*) by the method of Blumbergs *et al.* (61); (*vii*) 3-chloro-1-propanesulfonyl chloride (**5***b*) from J. D. Lock (43); (*viii*) 2-chlorethanesulfonic and

2-hydroxyethanesulfonic acids by passing an aqueous solution of the sodium salt down a column of Rexyn 101 (H^+) resin (Fisher), eluting with water until the eluant was not acidic, and evaporation of the water under reduced pressure.

In the normal work-up of a reaction mixture all organic-layer extracts were dried over magnesium sulfate, filtered, and the solvent evaporated under reduced pressure with a rotary evaporator.

*2-Hydroxyethanesulfonyl chloride (**1**a)*[7]

Chlorine was bubbled very rapidly into a solution of 2-mercaptoethanol (**4***a*) (30 mL, 0.43 mol) in water (100 mL) cooled in an ice bath; the temperature of the solution changed rapidly from ~4°C to ~40°C. The reaction mixture was then extracted with (a) benzene (4 × 50 mL), (b) methylene chloride (5 × 50 mL), and then, after saturation with NaCl, the mixture was finally extracted with (c) methylene chloride, first with four 50-mL portions and then in a continuous extractor for 3 h. The ^{1}Hmr spectra of the three sets of extracts (after work-up) showed: (a) benzene extract (oil, 11.3 g), a singlet at 4.0 ppm appropriate to 2-chloroethanesulfonyl chloride (**5***a*) surrounded by a characteristic symmetrical multiplet in the range 3.5–4.5 ppm, judged by integration to correspond to a 57:43 mixture of **5***a* and **1***a* (or respective yields of 10% and 7%); (b) the first CH_2Cl_2 extract (yellowish slightly viscous liquid, 8.8 g); and (c) second CH_2Cl_2 extract (colorless liquid, 8.4 g); both showed only the multiplet pattern with no sign of the singlet due to **5***a* (28% combined yield of **1***a* from extracts (b) and (c)). The purest specimens of **1***a* obtained in this way (extract (c)) were colorless, slightly viscous liquids with the following properties: n_D^{25} 1.4902; ir (CH_2Cl_2) ν_{max}: 3590 (s), 3460 (br,w), 3060 (w), 2925 (w), 2890 (w), 1375 (vs), 1168 (vs), 1058 (vs), 1015 (m), 840 (w), 592 (s), 550 (br s) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.82 (s, 1H, disappeared on addition of D_2O), and a characteristic pattern of two "triplets" (at 100 MHz) (each 2H) centred at 3.98 and 4.28 ppm; ^{13}Cmr ($CDCl_3$) δ: 56.9, 67.6. *Anal.* calcd. for $C_2H_5ClO_3S$: C 16.61, H, 3.49, S 22.18, Cl 24.52; found: C 16.88, H 3.63, S 22.23, Cl 24.30. A reasonably pure specimen of **1***a* could also be obtained by extraction of the aqueous solution with methylene chloride, and then triturating the mixture of sulfonyl chlorides isolated in this manner repeatedly with cyclohexane to remove **5***a*, leaving **1***a* behind as a colorless liquid.

If the rate of addition of chlorine was not fast or if the period of chlorination was less than 10 min, then the isolated material stank of reduced sulfur compounds and the ^{1}Hmr spectrum showed extra peaks around 2.6–3.0 and 3.5–3.9 ppm. The addition of ice during the chlorination period (final temperature ~30°C) or the use of methylene chloride instead of benzene for the initial extractions had little effect on the overall yield of **1***a* obtained.

A series of ^{1}Hmr spectra of a sample of neat **1***a* kept at −20°C, and of a $CDCl_3$ solution (6 mg in 0.5 mL) kept at room temperature, showed no change over a 3 month interval, but that of a neat sample kept at room temperature over the same period showed a gradual decrease in intensity and loss of detail in the 3.5 to 4.5 ppm region, with an estimated half-life of roughly 3 weeks. The products of the decomposition were not apparent from the spectra; there was no sign of either ethenesulfonyl chloride or 2-chlorethanesulfonyl chloride (**5***a*). In an experiment to determine how efficiently it may be recovered from aqueous solution, 1.50 g of the sulfonyl chloride (**1***a*) was dissolved in a saturated solution of sodium chloride in water (50 mL) at room temperature. After standing for 2–3 min the solution was extracted with methylene chloride (3 × 50 mL). The organic extracts were combined, dried, filtered, and evaporated to yield 1.32 g (88%) of **1***a*.

*Reaction of 2-hydroxyethanesulfonyl chloride (**1**a) with acetyl chloride*

2-Hydroxyethanesulfonyl chloride (**1***a*) (1.5 g, 10 mmol) was combined with acetyl chloride (5.0 mL, 70 mmol). After 72 h at room temperature the excess acetyl chloride was evaporated and the oily residue distilled under reduced pressure (bath temperature 110°C, 2.5 Torr) in a cold finger apparatus to yield a clear colorless oil (1.6 g, 83%). The refractive index, ir, and ^{1}Hmr spectra of this material were identical to those of an authentic specimen of 2-acetoxyethanesulfonyl chloride (**6**), prepared from sodium 2-acetoxyethanesulfonate and phosphorus pentachloride as described by Anschütz (7). The pure compound was obtained by distillation of the crude product under reduced pressure (bp 72–73°C, 0.1 Torr); n_D^{25} 1.4639 (lit. (7) n_D^{25} 1.4633); ir (neat) ν_{max}: 2995 (w), 2935 (w), 1745 (vs), 1370 (vs), 1230 (vs), 1160 (vs), 1070 (s), 1035 (s), 705 (s), 535 (s) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.13 (s, 3H), 4.07 (t, 2H), 4.65 (t, 2H).

*Chlorination of 2-mercaptoethanol (**4**a) in aqueous acetic acid*

2-Mercaptoethanol (**4***a*) (20 mL, 0.29 mol) was dissolved in a 1:1 mixture (100 mL) of water and acetic acid, and the solution cooled in an ice bath. Chlorine was bubbled into this solution with vigorous magnetic stirring for 30 min. The yellow solution was extracted with methylene chloride (4 × 30 mL), the extracts on work-up followed by azeotroping with toluene gave a crude product (37 g) which was then distilled under reduced pressure (bp 70–72°C, 0.1 Torr) to yield a colorless oil (15 g, 30%); the ^{1}Hmr and ir spectra were identical to those of an authentic specimen of 2-acetoxyethanesulfonyl chloride (**6**).

*2-Hydroxyethanesulfinic acid (**8**)*

A solution of sodium sulfite (3 g, 24 mmol) in water (15 mL) was added to 2-hydroxyethanesulfonyl chloride (**1***a*) (1.0 g, 6.9 mmol). The resulting solution was allowed to stand at room temperature for 2 h, then extracted twice with methylene chloride. The aqueous layer was acidified to pH 1.0 with 2 *M* sulfuric acid, and continuously extracted with ether for 72 h. The organic extract yielded a pale yellow oil (0.55 g, 75%), n_D^{25} 1.4235; ir (neat) ν_{max}: 3360 (b), 1058 (s), 813 (m) cm^{-1}; ^{1}Hmr (D_2O) δ: 3.04 (t, 2H), 4.01 (t, 2H).

A mixture of barium hydroxide octahydrate (387 mg, 1.23 mmol) in water (20 mL) was combined with 2-hydroxyethanesulfinic acid (**8**) (270 mg, 2.45 mmol) at room temperature. After stirring for 75 min, the solvent was evaporated under reduced pressure (water bath temperature 35°C) to yield **10** as an off-white solid (0.430 g, 50%) which decomposed above 350°C; ir (Nujol) ν_{max}: 1060 (m), 1010 (sh), 985 (s), 950 (m) cm^{-1}; ^{1}Hmr (D_2O) δ: 2.60 (t, 2H), 3.92 (t, 2H); *Anal.* calcd. for $BaC_4H_{10}O_6S_2$: C 13.51, H 2.83; found: C 13.22, H 3.09. 2-Hydroxyethanesulfinic acid (**8**) (750 mg, 6.8 mmol) was dissolved in water (10 mL) and the pH adjusted to 6.0 with 1.0 *M* sodium hydroxide solution. After standing for 10 min at room temperature the solvent was evaporated to yield **7** as a gummy residue which crystallized upon standing (0.83 g, 92%), mp 81–83°C; ^{1}Hmr (D_2O) δ: 2.58 (t, 2H), 3.91 (t, 2H). The salt (**7**) was used without further purification in the following reaction.

*Reaction of sodium 2-hydroxyethanesulfinate (**7**) with ethyl iodide*

The sodium sulfinate (**7**) (0.75 g, 5.7 mmol) was dissolved in absolute alcohol (25 mL) containing ethyl iodide (9.75 g, 62.5 mmol), and the solution refluxed for 22 h and then evaporated under reduced pressure to yield a red solid. This residue was triturated with chloroform (3 × 25 mL), the extracts were combined and dried, and the solvent was removed to yield a red oil (0.45 g). The oil was dissolved in water (10 mL) and the solution maintained at pH 10–11 with 1.0 *M* NaOH solution for 2 h. Extraction with chloroform gave a light yellow oil (100 mg, 15%). Recrystallization of this material from benzene gave colorless needles (17 mg) whose mp and ^{1}Hmr and ir spectra were identical to those of an authentic sample of ethyl 2-hydroxyethylsulfone (**9**) prepared as described below.

Utilizing a slight modification of the literature (25) procedure, freshly recrystallized sodium ethanesulfinate (see below) (3.0 g, 25.9 mmol) was dissolved in a mixture of ethanol (30 mL) and water (20 mL) and 2-chloroethanol (2.1 g, 26.2 mmol) added. The solution was heated on a steam bath for 50 h. Evaporation of the solvent under reduced pressure gave a white solid which was dissolved in water and continuously extracted with chloroform for 72 h. Work-up of the organic layer gave a yellow oil (1.0 g) which yielded **9** as colorless needles (0.175 g, 5%) from benzene; mp 40.5–42°C; ir ($CHCl_3$) ν_{max}:

3350 (br w), 3028 (m), 2945 (w), 1460 (w), 1410 (w), 1315 (vs), 1280 (w), 1235 (w), 1128 (vs), 1063 (m) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.42 (t, 3H), 2.36 (s, 1H), 3.00–3.29 (m, 4H), 4.14 (m, 2H). The sodium ethanesulfinate used in this preparation was obtained by reduction of ethanesulfonyl chloride with sodium sulfite using the method described for the preparation of **7**; recrystallization from 95% ethanol gave crystals with a decomposition point >200°C and the following spectra: ir (Nujol) ν_{max}: 1185 (br w), 1040 (s), 1010 (s), 979 (s), 665 (s) cm^{-1}; ^{1}Hmr (D_2O) δ: 1.09 (t, 3H), 2.35 (q, 2H).

*Chlorination of 2-hydroxyethanesulfinic acid (**8**) in deuterium oxide*

2-Hydroxyethanesulfinic acid (**8**) (0.050 g, 0.45 mmol) was dissolved in D_2O (0.5 mL) and placed in an nmr tube. Chlorine was bubbled into this solution for 10 min at room temperature. After this time the ^{1}Hmr spectrum indicated the presence of 2-hydroxyethanesulfonyl chloride (**1***a*), with a trace (~5%) of 2-hydroxyethanesulfonic acid.

*Hydrolysis of 2-hydroxyethanesulfonyl chloride (**1**a)*

The general procedure is illustrated by the reaction at pH 4.0. The sulfonyl chloride (**1***a*) (147 mg, 1.02 mmol) was dissolved in dry 1,2-dimethoxyethane (DME) (1.0 mL). This solution was injected with stirring into water (50 mL) maintained at 25.0°C and pH 4.0 using the pH-stat apparatus with 0.1 *M* sodium hydroxide titrant. After 90 min the pH was adjusted to 7.0 and the solvent evaporated to yield a colorless solid. The ^{1}Hmr spectrum (D_2O) of this material showed absorptions only in the 2.9–4.0 ppm region, corresponding to sodium 2-hydroxyethanesulfonate (**11**), sodium 2-chloroethanesulfonate (**12**), and an unidentified material; the identity of **11** and **12** was shown by comparison with ^{1}Hmr spectra of authentic specimens. Integration of these peaks in the ^{1}Hmr spectrum gave the relative proportions of **11**, **12**, and the unidentified material as 90, 3, and 6%, respectively. These results and those from related reactions are listed in Table 1.

As a control experiment, a solution of sodium 2-hydroxyethanesulfonate (**11**) (100 mg, 0.68 mmol) and sodium 2-chloroethanesulfonate (**12**) (90 mg, 0.54 mmol) (molar percentages: 56% **11** and 44% **12**) in water (100 mL) containing KCl (800 mg, 13 mmol) was divided into equal parts. With the first the pH was adjusted to 4.0 with 1.0 *M* HCl and held at 25.0°C for 2 h; on evaporation of the water and dissolution in D_2O the ^{1}Hmr spectrum showed peaks due to **11** and **12** (only) in the ratio 56 to 44. The second part was treated with 0.1 NaOH to give pH 10.5 and the solution maintained at 20°C for 35 min; the pH was lowered to 7.0 with 1.0 *M* HCl and the water evaporated. Integration of the ^{1}Hmr spectrum showed the presence of only **11** (61%) and **12** (39%).

*Reaction of 2-hydroxyethanesulfonyl chloride (**1**a) with pyridine in deuterium oxide*

The sulfonyl chloride (**1***a*) (0.330 g, 7.27 mmol) was added to a stirred solution of pyridine (2.0 mL, 24.9 mmol) in D_2O (50 mL) maintained at 25°C and apparent pH 6.0 with 2.2 *M* sodium deuteroxide titrant (prepared from sodium and D_2O). After 30 min the pH was adjusted to 7.5 and the solution extracted with ether (4 × 30 mL). The aqueous layer was evaporated under reduced pressure to yield a colorless solid, the ^{1}Hmr spectrum (D_2O) of which showed peaks at 3.0–4.0, 5.0, 5.8–7.0, and 8.0–9.0 ppm, indicating the presence of pyridine betaine (**17**), sodium 2-chloroethanesulfonate (**12**), sodium 2-hydroxyethanesulfonate, and sodium ethenesulfonate (**13**) in the relative proportions (as estimated by integration) of 57%, 7%, 33%, and 3% respectively. No deuterium was evident in any of the products except sodium 2-hydroxyethanesulfonate, which was estimated (by integration of the absorptions at 3.12 and 3.90 ppm) to be half monodeuterated at the α carbon, i.e. 50% **15** and 50% **11**.

In a control experiment a mixture of **11** (110 mg, 0.74 mmol), **12** (38 mg, 0.23 mmol), and **17** (75 mg, 0.4 mmol) was dissolved in D_2O (30 mL); the relative amounts were confirmed by the ^{1}Hmr spectrum and then adjusted to pH 6.0 with DCl in D_2O. After 30 min at room temperature the pH was raised to 7.0 with 0.1 *M* NaOD, the solution extracted with ether, and the residual aqueous layer evaporated; the ^{1}Hmr spectrum showed the presence of **11**, **12**, and **13** in the original proportions, with no deuterium incorporation or other materials in evidence.

*Reaction of 2-hydroxyethanesulfonyl chloride (**1**a) with tertiary amines and primary alcohols in methylene chloride*

In a series of experiments 2-hydroxyethanesulfonyl chloride (**1***a*) (~0.5 g, 3.5 mmol) was dissolved in methylene chloride (~40 mL) containing either 1-butanol or neopentyl alcohol (10 equiv.). The tertiary amine (in excess) was then injected with stirring into the solution at room temperature. With pyridine or trimethylamine a precipitate was observed within the first 5 min of the reaction. Washing with water (1 × 40 mL) and work-up of the methylene chloride layer yielded an oil whose composition was determined by ^{1}Hmr spectroscopy. In all experiments, the oil consisted of the 2-hydroxyethanesulfonate and ethenesulfonate esters (**17** and **22**), as shown by comparison with ^{1}Hmr spectra of authentic specimens. In one reaction a sample of authentic neopentyl ethenesulfonate (**22***b*) was added to a nmr tube containing the crude reaction mixture of esters; the peaks attributed to the **22***b* were increased accordingly.

The aqueous extract was evaporated under reduced pressure, and the residue dissolved in water (1–2 mL). This solution was added to a short column of Rexyn 101 (H^+), and the column eluted with water until the eluant was no longer acidic towards pH paper. The eluant was then evaporated, and the residue triturated repeatedly with anhydrous ether (5 × 30 mL). These ether extracts were combined and evaporated to give an oil. The ^{1}Hmr spectrum (D_2O) showed absorptions in the 3.0–4.0 ppm region indicating the presence of 2-hydroxyethanesulfonic acid and 2-chloroethanesulfonic acid (identified by comparison with ^{1}Hmr spectra of authentic specimens of the acids). The amounts of the two acids (estimated by integration) are reported in Table 2 as overall percentage yields of the salts **20** and **21**. The ether-insoluble residue was weighed and identified as the betaine (**19**) corresponding to the amine employed, by comparison of its ^{1}Hmr spectrum with that of the authentic material.

*Butyl 2-hydroxyethanesulfonate (**17**a)*

The crude reaction mixture containing butyl ethenesulfonate (**22***a*) and butyl 2-hydroxyethanesulfonate (**17***a*) (obtained from reaction of **1***a* with trimethylamine and 1-butanol) was triturated repeatedly with hexanes. The ^{1}Hmr and ir spectra of the residue insoluble in hexanes were identical with those of an authentic specimen of **18***a* prepared by the betylate route (43); ^{1}Hmr ($CDCl_3$) δ: 0.96 (t, 3H), 1.24–1.93 (m, 4H), 2.56 (s, 1H), 3.35 (t, 2H), 4.08 (t, 2H), 4.28 (t, 2H).

*Neopentyl 2-hydroxyethanesulfonate (**17**b)*

The ester (**17***b*) was isolated as a colorless oil by cold finger distillation under reduced pressure (0.002 Torr, oil bath temperature 90°C) of the mixture obtained from a reaction of 2-hydroxyethanesulfonyl chloride (**1***a*) with trimethylamine and neopentyl alcohol; ir (CH_2Cl_2) ν_{max}: 3610 (w), 2970 (m), 1353 (s), 1160 (s), 1058 (m), 900 (vs), 937 (s) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.01 (s, 9H), 2.78 (br s, 1H), 3.37 (t, 2H), 3.93 (s, 2H), 4.09 (t, 2H). *Anal.* calcd. for $C_7H_{16}O_4S$: C 42.68, H 8.24, S 16.30; found: C 42.84, H 8.22, S 16.34.

*Butyl 2-acetoxyethanesulfonate (**24**)*

Butyl 2-hydroxyethanesulfonate (**17***a*) (0.100 g, 0.55 mmol) was dissolved in $CDCl_3$ (0.5 mL). Acetyl chloride (0.5 mL, 7.0 mmol) was added and the solution left overnight. Evaporation of the solvent gave an oil which was distilled in a cold finger apparatus under reduced pressure (0.5 Torr, bath temperature 120°C). The distillate was dissolved in methylene chloride (~1 mL) and run down a short column of silica gel (BDH, 35–70 mesh) using methylene chloride. Evaporation of the solvent gave **24** as a colorless oil (70 mg, 53%); ir (CH_2Cl_2) ν_{max}: 3060 (w), 2965 (m), 2935 (m), 1750 (s), 1360 (s), 1235 (s), 1165 (s), 1050 (m), 1038 (m), 938 (s), 910 (m), 888 (m) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.96 (t, 3H), 1.20–1.90 (m, 4H), 2.10 (s, 3H), 3.44 (t, 2H), 4.27 (t, 2H), 4.49 (t, 2H). *Anal.* calcd. for

$C_8H_{16}O_5S$: C 42.84, H 7.19, S 14.30; found: C 42.78, H 7.02, S 14.38.

*2-(*N-N,N-*Triethylammonio)ethanesulfonate (triethyl betaine,* **19***c)*

Triethylamine (1.4 mL, 0.01 mol) was injected into a solution of sodium 2-bromoethanesulfonate (**61**) (2.0 g, 9.5 mmol) in water (40 mL) and the solution allowed to stand at room temperature for 11 days. Evaporation of the solvent gave a white solid which was dissolved in water (~2 mL), added to a short column of Rexyn 300 (H-OH) resin, and eluted with water. Evaporation of the solvent gave a colorless crystalline solid (0.075 g, 35%), which decomposed above 280°C; ir (Nujol) ν_{max}: 1270 (w), 1238 (m), 1213 (s), 1195 (s), 1155 (w), 1040 (s) cm^{-1}; ^{1}Hmr (D_2O) δ: 1.32 (t, 9H), 3.43 (m, 10H). *Anal.* calcd. for $C_8H_{19}NO_3S$: C 45.91, H 9.15, N 6.69, S 15.32; found: C 46.03, H 9.31, N 6.81, S 15.36.

2-(Quinuclidinio)ethanesulfonate (quinuclidine betaine, **19***d)*

The crude betaine (**19***d*) formed in a reaction of the sulfonyl chloride (**1***a*) with quinuclidine and 1-butanol was separated by filtration and recrystallized from absolute alcohol to yield a colorless solid, dec. >390°C; ir (Nujol) ν_{max}: 1277 (m), 1187 (s), 1112 (m), 1040 (s), 792 (m) cm^{-1}; ^{1}Hmr (D_2O) δ: 1.82–2.33 (m, 7H), 3.20–3.68 (m, 10H). *Anal.* calcd. for $C_9H_{17}NO_3S$: C 49.29, H 7.81, N 6.39, S 14.62; found: C 49.29, H 7.89, N 6.44, S 14.71.

*Reaction of 2-hydroxyethanesulfonyl chloride (*1a*) with 1-butanol-*d *and trimethylamine in methylene chloride*

The sulfonyl chloride (**1***a*) (500 mg, 3.45 mmol) was treated with trimethylamine (~0.5 mL, 6 mmol) and 1-butanol-*d* (Merck Sharp and Dohme Canada Ltd., 99 at.% D) (2.65 g, 35 mmol) in dry methylene chloride (40 mL) following the above general procedure. After 1 h at room temperature, the reaction was worked up and the reaction products were observed to be butyl 2-hydroxyethanesulfonate (40%), butyl ethenesulfonate (**22**, R = Bu) (3%), 2-chloroethanesulfonic acid (14%), trimethyl betaine (**19***a*) (40%), and 2-hydroxyethanesulfonic acid (3%). Only the 2-hydroxyethanesulfonate ester was observed to have incorporated deuterium, and was estimated (by integration of the methylene absorptions at 4.27 and 3.34 ppm) to be >80% **18***a*.

Control experiments to determine the effect of reaction conditions and work-up on product ratios

(a) A solution of trimethylammonium 2-chloroethanesulfonate (**20***b*) (130 mg, 0.64 mmol, prepared as described below), the trimethyl betaine (**19***b*) (113 mg, 0.68 mmol), $Me_3NH^+Cl^-$ (210 mg, 0.33 mmol), and 1-butanol (1 mL, 10 mmol) in water (50 mL) was evaporated under reduced pressure. This material was then dissolved in water and run through an ion exchange resin and the products separated by trituration with ether, as described above for the work-up of the aqueous extract from the reaction of **1***a* with a primary alcohol and a tertiary amine. The ether-insoluble residue (90 mg) was shown to be entirely the betaine (**19***b*) (100% recovery) and the ether-soluble material (90 mg) exclusively 2-chloroethanesulfonic acid (98% recovery).

(b) A mixture of the pyridine betaine (**19***a*) (52 mg, 0.28 mmol), neopentyl alcohol (600 mg, 0.68 mmol), pyridinium chloride (140 mg, 1.2 mmol), **12** (180 mg, 1.08 mmol), and **11** (190 mg, 1.28 mmol) was dissolved in water (40 mL), the water evaporated, and the residue treated with Rexyn 101 (H^+) followed by ether trituration as above. The presence of **11**, **12**, and **19***a* was shown by the ^{1}Hmr spectra which, with the weights of the recovered materials, indicated recovery to be 109%, 94%, and 81%, respectively.

(c) Trimethylamine (~0.5 mL, 6 mmol) was added to a solution of butyl 2-hydroxyethanesulfonate (**17***a*) (77 mg, 0.43 mmol) and 1-butanol (320 mg, 4.3 mmol) in methylene chloride (30 mL) and the mixture allowed to stand at room temperature for 1 h. Work-up as before gave **17***a* (61 mg, 79%) and a mixture of 2-hydroxyethanesulfonic acid and the trimethyl betaine (**19***b*) corresponding to 16% and 2% respective yields.

(d) Triethylamine (0.10 mL, 0.72 mmol) was added to a solution of neopentyl 2-hydroxyethanesulfonate (**17***b*) (90 mg, 0.46 mmol) and neopentyl alcohol (350 mg, 4.0 mmol) in methylene chloride (300 mL) and the mixture allowed to stand for 1 h at room temperature. Work-up gave back **17***b* (75 mg) as a pale yellow oil, the ^{1}Hmr spectrum of which showed no sign of neopentyl ethenesulfonate (**22***b*).

(e) Triethylamine (0.20 mL, 1.5 mmol) was added to a solution of neopentyl ethenesulfonate (**22***b*) (88 mg), triethylammonium chloride (60 mg), and neopentyl alcohol (50 mg) in $CDCl_3$ (1.0 mL). The ^{1}Hmr spectrum after 24 h showed no observable reaction.

*Aqueous chlorination of 3-mercapto-1-propanol (*4b*)*

3-Mercapto-1-propanol (**4***b*) (1.3 g, 14 mmol, prepared according to the method of Djerassi and Gorman (62) from 3-mercaptopropionic acid) was dissolved in water (50 mL) and cooled in an ice bath. Chlorine was bubbled into this solution for 10 min with magnetic stirring. The solution was extracted several times with methylene chloride; the extracts on work-up gave a colorless oil (1.0 g) which, by comparison of its ^{1}Hmr spectrum with those of authentic samples, was shown to be an equimolar mixture of 3-chloro-1-propanesulfonyl chloride (**5***b*) and 1,3-propane sultone (**2***b*) (yield of each, 24%). Similar chlorination of 1,3-propane sultine (**26***b*) (0.45 g, 4.2 mmol, prepared from 1,3-propanedithiol by the method of Harpp *et al.* (63)), gave a colorless oil (0.50 mg) shown by ^{1}Hmr to be **2***b* (77%) and **5***b* (13% yield).

Rate enhancements for the nickel(II)−PADA complexation in mixed anionic micelles

PAUL D. I. FLETCHER
Chemical Laboratory, University of Kent at Canterbury, Canterbury, Kent, United Kingdom CT2 7NH

AND

JOANNE R. HICKS AND VINCENT C. REINSBOROUGH
Chemistry Department, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received August 3, 1982[1]

PAUL D. I. FLETCHER, JOANNE R. HICKS, and VINCENT C. REINSBOROUGH. Can. J. Chem. **61**, 1594 (1983).

Rate enhancements for the Ni^{2+}_{aq} and pyridine-2-azo-*p*-dimethylaniline (PADA) reaction have been obtained in four simple equimolar binary micellar systems: sodium dodecylsulfate − sodium decylsulfate, sodium dodecylsulfate − sodium octylsulfate, sodium octylsulfate − sodium hexylsulfate, and sodium octylsulfate − sodium octanesulfonate. The rate enhancement curves were similar to those obtained for pure surfactants and were consistent with a 1:1 mixed micelle except for the third system where the micelle was richer in sodium octylsulfate. The kinetic analysis revealed no dramatic changes in hydrophobic or electrostatic forces on forming the mixed micelles

PAUL D. I. FLETCHER, JOANNE R. HICKS et VINCENT C. REINSBOROUGH. Can. J. Chem. **61**, 1594 (1983).

On a obtenu les accroissement de vitesse de la réaction du Ni^{2+}_{aq} et de la pyridine-azo-2 *p*-diméthylaniline (PADA) dans quatre systèmes micellaires binaires simples: dodécylsulfate de sodium − décylsulfate de sodium, dodécylsulfate de sodium − octylsulfate de sodium, octylsulfate de sodium − hexylsulfate de sodium et octylsulfate de sodium − octanesulfonate de sodium. Les courbes d'accroissement de vitesse ressemblent beaucoup à celles obtenues pour les surfactants purs et sont en accord avec une micelle mixte 1:1 à l'exception du troisième système où la micelle est plus riche en octylsulfate de sodium. L'analyse cinétique ne révèle pas de changements importants dans les forces hydrophobes ou électrostatiques lors de la formation des micelles mixtes.

[Traduit par le journal]

Introduction

Surfactants in nature and in industry occur as mixtures of homologs or similar compounds, in which case multicomponent, rather than one-component, micelles are likely responsible for the distinctive properties of the surfactant solutions. Apart from some thermodynamic work relating the critical micelle concentration (cmc) to mole fraction (1,2), little else of a fundamental nature has been done on mixed micellar aqueous systems of this type. Stenius *et al.* recently reported that in the sodium abietate + sodium oleate system, a model system for surfactants in wood, mixed micelles were formed in which larger amounts of additive could be solubilized than in either pure abietate or oleate micelles (3). Such a synergistic effect is of interest because it may explain nature's choice of particular surfactant combinations. Once the principles governing this enhancement in properties are discovered, applications should be possible in medicine and industry.

In this paper, some simple binary anionic surfactant solutions are investigated for variation in micellar form and for any evidence of synergism. The probe that is used is the kinetics of the metal−ligand substitution reaction between Ni^{2+}_{aq} and pyridine-2-azo-*p*-dimethylaniline (PADA). Complexation is strongly accelerated in the presence of anionic micelles since the reagents are preferentially adsorbed into the surface region of the micelles, Ni^{2+}_{aq} by coulombic forces and PADA by hydrophobic attraction. The extent of reaction can be predicted from the distribution coefficients for each reagent partitioning between the bulk water and the micelle surface region and some knowledge of the volume in which the reaction occurs on the micelles (4−7).

Changes in hydrophobicity and electrostatic forces within the micelle are directly reflected in changes in the partitioning constants as shown in our recent study relating the kinetics of this probe reaction to solubilizate sites in pure micelles (8). It should be possible to use this same probe to detect major increases in either of these forces, i.e. to look for evidence of synergism, and to gain insight into the micellar constitution when anionic surfactants are mixed.

Experimental

The experimental procedure and the stopped-flow instrumentation have been described elsewhere (8−10). Essentially, the probe reaction was carried out at 298.2 K with pH fixed at 7.6−7.9 with phosphate buffering. Pseudo-first order conditions prevailed with $[Ni^{2+}] = 1.0 \times 10^{-3}$ or 5.0×10^{-4} mol dm^{-3} and $[PADA] = 1.0 \times 10^{-5}$ mol dm^{-3}. The kinetic rate constants (k_{obs}) were obtained from exponential decay curves in the normal fashion.

A dye-laser photochemical relaxation method was used to measure the faster times (the dead time of the stopped-flow spectrometer was 2−3 milliseconds) and to provide a second measure of the slower times by a different technique for the equimolar SLS−SDS system. A description of the dye-laser photolysis method has been given by Robinson and White (11). The stopped-flow and the photolysis values of k_{obs} were in reasonable agreement in the overlap regions.

The surfactants were obtained from Eastman Kodak, PADA from Sigma, and $Ni(NO_3)_2 \cdot 6H_2O$, the source of Ni^{2+}_{aq}, from Fisher Scientific.

Results and discussion

In this study, four simple, binary, anionic micellar systems were investigated kinetically by means of the probe reaction. The first two were mixes of sodium alkylsulfates where the difference in chain length was two carbon atoms: sodium dodecylsulfate (SLS) − sodium decylsulfate (SDS) and sodium octylsulfate (SOS) − sodium hexylsulfate (SHS). The third system was SLS−SOS with four carbon atoms being the difference in chain length. In the fourth system, the chain lengths of the two surfactants were the same at eight carbons but the head group was modified from sulfate to sulfonate: sodium octyl-

sulfate (SOS) – sodium octanesulfonate (SOSO).

The kinetic equation relating the observed rate constants (k_{obs}) to the partitioning constants when the reaction occurs on both the micelle surface and in the bulk aqueous solution is (6, 7)

$$[1] \quad k_{obs} = k_1^{m}[Ni^{2+}]/(CV_s\{1 + (CK_{Ni})^{-1}\}\{1 + (CK_{PADA})^{-1}\}) + k^{m}_{-1}$$

where k_1^{m} and k_{-1}^{m} are the forward and backward kinetic rate constants for the reaction on the micelle surface; C, the concentration in mol dm^{-3} of micellar surfactant, i.e. the total surfactant concentration less the cmc; V_s, the reaction volume per mole of surfactant; K_{Ni} and K_{PADA}, the partitioning constants for each reagent between the bulk water and micellar pseudophase.

The partitioning constants are defined as

$$[2] \quad K_{species} = [Species]_m/C[Species]_{aq}$$

K_{Ni} and K_{PADA} are measured independently through the murexide technique (12, 13) and solubility studies (6, 10) respectively. The value of V_s is found by computer-fitting the k_{obs} data to eq. [1].

In eq. [1], it is reasonable to assume that $k_1^{m} = k_1^{aq}$ and $k_{-1}^{m} = k_{-1}^{aq}$ since the rate-determining step in the complex formation is the ejection of water. The k_{obs} values are more meaningfully plotted as rate enhancement R given by the ratio k_1^{app}/k_1^{aq} where k_1^{app} is the coefficient of $[Ni^{2+}]$ in eq. [1] or the apparent forward rate constant.

First of all, it must be noted that the rate enhancement curves in the four mixed micellar systems resemble in every respect R behaviour in pure surfactant systems (Figs. 1–4). In very dilute solutions no rate enhancement can be detected but, in the region of presumably the cmc of the mixed micelle, there is a sharp increase in R to a maximum over a narrow concentration range and then a more gradual decrease in more concentrated surfactant solution to just a few times the rate in water. No kinks, bumps, or unusual behaviour of any sort can be detected as might be expected if more than one type of micelle can be formed at different concentrations. When cmc values of the pure surfactants are widely separated, there seems to be no "memory" in the R value in the neighbourhood of the larger cmc. All of this argues for a single type of micelle being formed in each mixed surfactant system from the cmc to higher concentrations and implies that in this micelle the two surfactants do not act independently.

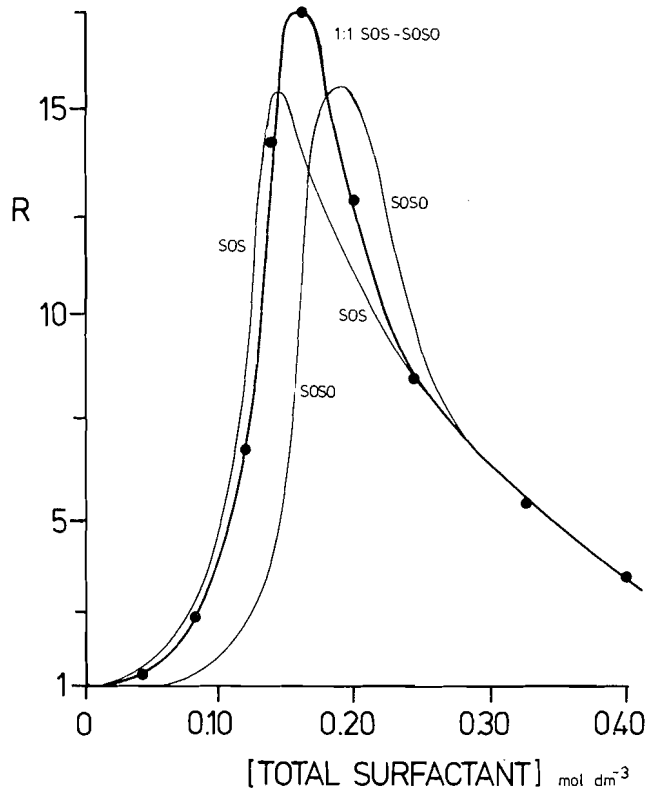

FIG. 4. Rate enhancements for the Ni^{2+}–PADA reaction in the system SOS–SOSO.

Figure 1 compares the R values for the equimolar SLS–SDS system with those of the pure surfactants. The sum of the concentrations of the two surfactants is taken as the surfactant concentration in the mixed system. This manner of plotting the concentration presupposes that the surfactants in the mixed system are both actively involved in micellization and not that one in the presence of the other is merely being solubilized.

The cmc can be estimated from the surfactant concentration at which R is a maximum (C_{max}) from the relationship (10):

$$C_{max} = \text{cmc} + (K_{Ni}\, K_{PADA})^{-1/2}$$

The cmc for the 1:1 mole ratio SLS–SDS system with 10^{-3} mol dm^{-1} Ni^{2+} present is thus 6×10^{-3} mol dm^{-3} in total surfactant. This value is intermediate between the cmc values of the pure surfactant but is closer to the cmc of the longer chained homolog as found by other investigators (14, 15). Table 1 compares the cmc values obtained by this technique for the pure and mixed surfactant systems examined in this study.

R curves were also obtained for the 1:2 and 2:1 mole ratio SLS–SDS systems but are not reproduced here since they were intermediate in predictably proportional fashion between the curves for the pure surfactants. These observations are consistent with a mixed micelle in which the monomers of each surfactant are present roughly in the same ratio in which they are in solution. This is reasonable since the incorporation of either a decylsulfate or dodecylsulfate into the micellar state cannot be much different energetically.

The second system investigated, equimolar SOS–SHS, is again a situation where the surfactant homologs differ by 2 carbon atoms but the chains are shorter and only just sufficiently long to produce micellization.

A complete concentration scan for k_{obs} was possible for this system by the stopped-flow technique since the rate enhancements were not nearly as pronounced (Fig. 2). The R curve resembles that for pure SOS except that, when the sum [SOS] + [SHS] is used to express concentration, the curve was displaced slightly to higher concentration. The cmc for the mixed micelle is slightly greater than for pure SOS.
