The space group of crystals of the three complexes is $C2/c$. The structures were solved by the Patterson method. The structures of the Cu(II) and Co(II) complex were refined to a final R_w (on $|F|$) of 0.050 and 0.068 for 1918 and 2455 independent reflections, respectively, as measured with a modified Picker diffractometer. The structure of these complexes consists of coordination polyhedra with formulation $[M(H_2O)_2(\beta\text{-picoline})_4]^{2+}$ and perchlorate counterions. The ions are connected by hydrogen bonds of average length 2.76 Å in the Co(II) complex and 2.82 Å in the Cu(II) complex. The four N atoms of the β-picoline ligands form an equatorial plane with average [M—N] distances of 2.17 Å in the Co(II) complex and 2.03 Å in the Cu(II) complex. The water ligands are in apical positions with [M—O] distances of 2.124(6) Å and 2.493(10) Å in the Co(II) and Cu(II) complexes respectively. This large difference in bond lengths is manifested in marked differences in the appearance of crystals of the two compounds and is consistent with an expected Jahn–Teller effect. The thermal factors suggest that the perchlorate ion undergoes enhanced librational motion.

SHENGZHI HU, RICHARD JAMES BARTON, KEITH JAMES JOHNSON et BEVERLY ELLIS ROBERTSON. Can. J. Chem. **61**, 395 (1983).

Les cristaux des complexes ($[M(H_2O)_2(C_6H_7N)_4](ClO_4)_2$, M = Cu, Co, Ni) ont tous une forme rhomboédrique monoclinique et les méthodes de diffraction révèlent qu'ils sont isomorphes. On a déterminé en détail les structures des complexes du Cu(II) et de Co(II).

Atomie	a	b	c	β (deg)	D_m	D_x	Couleur
Cu(II)	15.292(4)	9.672(2)	20.579(5)	94.73(2)	1.45(1)	1.467	Bleu
Co(II)	15.878(12)	9.374(3)	20.661(7)	96.50(4)	1.45(1)	1.448	Rose
Ni(II)	15.7	9.3	20.4	96.5	1.44(1)		Bleu pale

Les cristaux des trois complexes appartiennent au groupe d'espace $C2/c$. On a résolu les structures par la méthode de Patterson et on a ajusté celles du Cu(II) et du Co(II) jusqu'à des valeurs conventionnelles de R_w (sur F) de 0,050 et 0,068 pour respectivement 1918 et 2455 réflexions indépendantes à l'aide d'un diffractomètre de Picker modifié. La structure de ces complexes consiste en une coordination polyédrique de formule $[M(H_2O)_2(\beta\text{-picoline})_4]^{2+}$ et des ions opposés de perchlorate. Les ions sont reliés par des liaisons hydrogène de longueur moyenne de 2,76 Å dans le complexe de Co(II) et de 2,82 Å dans le complexe de Cu(II). Les quatre atomes d'azote des ligands β-picoline forment un plan équatorial avec des distances moyennes [M—N] de 2,17 Å dans le complexe de Co(II) et de 2,03 Å dans le complexe du Cu(II). Les ligands eau sont disposés au sommet avec des distances [M—O] de 2,124(6) Å et de 2,493(10) Å dans les complexes de Co(II) et de Cu(II) respectivement. Cette grande différence au niveau des longueurs de liaison se manifeste dans les différences profondes d'apparence des cristaux des deux composés et elle est en accord avec l'effet de Jahn–Teller attendu. Les facteurs thermiques suggèrent que l'ion perchlorate subit un mouvement de libration accru.

Introduction

This research is part of a project to form a variety of mixed valence binuclear transition metal compounds by reacting anhydrous complexes with superoxides as has been done with DMSO (1). However, analyses of our products of the synthesis claimed by Brown *et al.* (2) to produce the anhydrous complexes were puzzling. Each of these complexes was found to consist of perchlorate ions and a metal atom coordination polyhedron with four β-picoline and two water ligands by X-ray crystal structure studies. These complexes imply that β-picoline does not substitute readily for all six water molecules in $M(H_2O)_6(ClO_4)_2$ as does DMSO.

Experimental

Preparation of the compounds

$[Cu(H_2O)_2(\beta\text{-pic})_4](ClO_4)_2$ (blue), $[Co(H_2O)_2(\beta\text{-pic})_4](ClO_4)_2$ (pink), and $[Ni(H_2O)_2(\beta\text{-pic})_4](ClO_4)_2$ (pale blue) were prepared by dissolving the appropriate hydrated metal perchlorate in a minimum of 1:1 diethyl ether:95% ethanol, the picoline complexes being formed by dropwise addition of a slight excess of the appropriate picoline, with stirring. All complexes precipitated on refrigeration at 0°C and were recrystallized twice from acetone, dried 14 h at 80°C under high vacuum, and stored in sealed bottles over indicating Drierite, in a desiccator.

Analyses of the β-picoline complexes suggested the general formula $M(\beta\text{-pic})_4(ClO_4)_2 \cdot xH_2O$. In addition, Karl Fisher titrations were carried out to measure the quantities of water present in all samples. Infrared spectra also revealed distinct bands in the region of 3400 cm^{-1} for all complexes, indicating the presence of water. However, it could not be rationalized as strictly complexed water, as in no case did the mole ratio of metal to unknown (assuming the unknown moiety to be water) take integral values.

X-ray crystallographic analysis

Precession photographs provided space groups and approximate unit cell dimensions. Accurate lattice parameters of the Cu(II) and Co(II) complexes wre obtained by a least-squares treatment of the diffractometer setting angles for ca. 20 reflections for which $2\theta_{hkl}$ (MoKα) was between 40 and 45°. Crystal data at 18(2)°C are:

$C_{24}H_{32}Cl_2CuN_4O_{10}$ fw = 670.3

Displacements (Å × 10^3): N(2)−7, C(6)−14, C(7)6, C(8)−25, C(9)−6, C(10)11, C(11)21

Monoclinic, $a = 15.292(4)$, $b = 9.672(2)$, $c = 20.579(5)$ Å, $\beta = 94.73(2)°$, $V = 3033.4$ Å^3, $\rho_o = 1.46(1)$ g cm^{-3}, $Z = 4$, $\rho_c = 1.467$ g cm^{-3}, $F(000) = 1388$, $\mu(MoK\alpha) = 9.85$ cm^{-1}. Absent reflections hkl, $h + k \neq 2n$; $h0l$, $l \neq 2n$, consistent with the space groups C_{2h}^6-$C2/c$ and Cs^4-Cc.

$C_{24}H_{32}Cl_2CoN_4O_{10}$ fw = 665.7

Monoclinic, $a = 15.878(12)$, $b = 9.374(3)$, $c = 20.661(7)$ Å, $\beta = 96.50(4)°$, $V = 3055.4$ Å^3, $\rho_o = 1.45(1)$ g cm^{-3}, $Z = 4$, $\rho_c = 1.448$ g cm^{-3}, $F(000) = 1380$, $\mu(MoK\alpha) = 8.19$ cm^{-1}. The absent reflections are the same as for the Cu(II) complex.

$C_{24}H_{32}Cl_2NiN_4O_{10}$

Monoclinic, $a = 15.7$, $b = 9.3$, $c = 20.4$ Å, $\beta = 96.5°$, $\rho_o = 1.44(1)$ g cm^{-3}. The absent reflections are the same as for the preceding two.

The intensity data of the crystals of the Cu(II) and Co(II) complexes were collected with a modified Picker diffractometer using graphite monochromated MoKα radiation within the limits $3 < 2\theta < 55°$ and $3 < 2\theta < 50°$ respectively for the Cu(II) and Co(II) complexes. The crystal of the Co(II) complex turned opaque gradually during data collection and the intensities of three standard reflections, monitored every 50 reflections, decreased by approximately 12%. The intensities of the standard reflections for the Cu(II) complex revealed no systematic trends during data collection. Data were corrected for the Lorentz and polarizations effects and scaled according to the changes in the standard reflections. Absorption was not considered to be important

because of the relatively small linear absorption coefficient and the small size of the crystals of both samples. The extinction condition (hkl, $h + k = 2n$; $h0l$, $l = n$) indicates the space group Cc or $C2/c$. The distribution of E values supports the latter. The structure of the Cu(II) complex was then solved by Patterson and heavy-atom methods in the space group $C2/c$. The structure of the Co(II) complex was assumed to be similar to that of the Cu(II) complex, as was verified by successful subsequent refinement. Of the 3508 and 2682 measured reflections for the Cu(II) and Co(II) complexes, 1918 and 2455 reflections with $|F_o| > 3\sigma(|F_o|)$ were used in the final refinement of the structure parameters respectively. In the Cu(II) complex the refinement converged to a conventional R factor of 0.099 and $R_w = [\Sigma\omega||F_o| - |F_c||^2/\Sigma\omega F_o^2]^{1/2} = 0.050$ with weighting factor $\sigma^{-2}(F_o)$, where $\sigma(F_o)$ is based on the counting statistics associated with the measurement of $|F_o|$ and an additional factor derived from the excess scatter in the standard reflections over that expected from counting statistics. In the final cycle of refinement the parameter shifts were less than 0.30 of the estimated standard deviations of the parameters for all atoms.

After completion of the initial refinement of the Co(II) structure, it was observed that the structure factors for the reflections 202 and 204 as measured by the diffractometer were in poor agreement with the calculated values of the structure factors. The diffractometer values were also inconsistent with approximate values obtained from film data. Therefore, it was assumed that an error had occurred during data collection, perhaps because of an attenuator malfunction, and the film data with appropriate weights were used to replace the diffractometer data for those reflections. Weighted full-matrix least-squares refinement with anisotropic temperature factors for all atoms except hydrogen yielded an R of 0.076 and $R_w = 0.068$. In the final cycle of refinement the parameter shifts were less than 0.20 of the estimated standard deviations of the parameters for the non-hydrogen atoms.

The data were collected using the National Research Council of Canada diffractometer control package, using the line profiling method. The preliminary solution of the structure was also obtained with this system of programs. Subsequent calculations were carried out using Xray 76 (3).

The atomic coordinates and their standard deviations for the Cu(II) and Co(II) complexes are given in Table 1. Bond distances and angles are reported in Table 2. The atoms are labelled in Fig. 1. A view of the Cu(II) complex is given in Fig. 2. Lists of calculated and observed structure factors and thermal parameters have been placed in the Depository of Unpublished Data.[1]

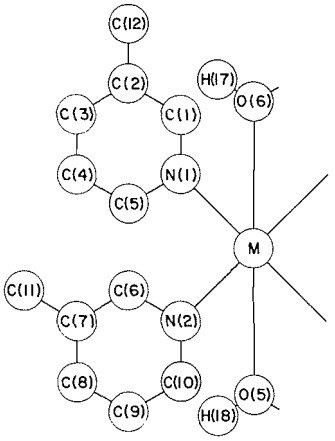

FIG. 1. Atom labelling sequence for the $[M(H_2O)_2(\beta\text{-picoline})_4]^{2+}$ ion.

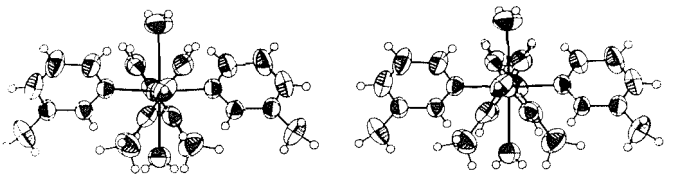

FIG. 2. View of the Cu(II) complex structure; 50% thermal ellipsoids are shown for the non-hydrogen atoms.

Discussion

In attempts to prepare the anhydrous complexes by the reaction of Cu(II), Co(II), and Ni(II) perchlorate with β-picoline, no products with consistent water content analyses were obtained. Consequently, the presently reported study was undertaken to determine the water composition and the coordination about the metal ion.

Both of the structures which we examined in detail show six-coordination about the cation in the form of an approximate octahedron in the case of the Co(II) complex and in the form of an octahedron with a strong tetragonal distortion in the case of the Cu(II) complex. Each coordination site has the symmetry 2. The geometry of the latter is similar to that of the Cu(II) ion in $Cu(NH_3)_4SO_4 \cdot H_2O$ (4), where the water molecule joins adjacent cations to form infinitive chains. In the structure of $[Cu(H_2O)_2(\beta\text{-pic})_4](ClO_4)_2$ the water molecules are hydrogen bonded to the perchlorate counterions.

The average length of the hydrogen bonds is 2.82 Å for the Cu(II) and 2.76 Å for the Co(II) complex. The four N atoms of the β-picoline ligands form an equatorial plane with [M—N] distances of 2.040(5) and 2.015(5) Å for the Cu(II) and 2.173(4) and 2.170(4) Å for the Co(II) complex. The former value is close to the sum of the covalent radii of Cu and N atoms and the latter is slightly longer than the sum of Co and N atoms (5). Conversely the average [Co—O] distance of 2.124(6) Å is close to that of a normal covalent bond whereas the average [Cu—O] distance of 2.493(10) Å is longer than the sum of covalent radii (5). It is of interest to note that the $[CuN_4O_2]$ chromophore provides strong corroboration of the Jahn–Teller predictions of elongation along the axial direction.

The perchlorate counterion undergoes enhanced librational motion in spite of the fact that it is hydrogen bonded to the water molecules. Bond length corrections for thermal motion using the procedure of Shomaker and Trueblood (6) lead to increases in bond length of ca. 0.2 Å. The corrected values are larger than expected for thermally corrected perchlorate bond lengths: 1.47 Å (7). They probably are a result of the inaccuracies in bond length corrections in cases of very large amplitude thermal motion.

The β-picoline ligands tilt from the basal plane of the nitrogen atoms by 40–44°. All the torsion angles as well as the other important parameters of the geometry are summarized in Table 3. The packing diagram of the Cu(II) complex is shown in Fig. 3. The two water molecules coordinated to the metal ions do not account for all of the water indicated to be present by the original quantitative analysis, particularly for the Cu(II) compound. The quantitative analysis of the products of this synthesis have shown variable and usually greater water content than that implied by this structural analysis. More than one product may have been produced in the synthesis. The materials produced showed variable degrees of crystallinity and it has not been possibile to verify this hypothesis by crystallographic examination.

TABLE 3. Some important mean parameters of the geometry of the complexes

Parameter	Value	
	M = Cu	M = Co
[M—N] (Å)	2.027(5)	2.171(4)
[M—O] (Å)	2.493(10)	2.124(6)
|<(L—M—L) − 90°| (L = O, N) (deg)	1.1	1.5
τ(O—M—N—C) (deg)	40	44
[Cl—O] (uncorrected) (Å)	1.31(1)	1.35(1)
[Cl—O] (corrected) (Å)	1.52(3)	1.52(2)
[O—H···O] (Å)	2.82(1)	2.76(1)
|<(O—Cl—O) − 109.47| (deg)	3.4	4.2

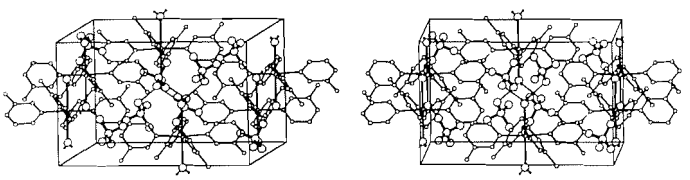

FIG. 3. Packing diagram of the Cu(II) complex. The hydrogen atoms except those associated with water are not shown for clarity.

The final difference map of the Cu(II) compound showed a negative peak corresponding to approximately 1.5 e $Å^{-3}$ at the location of the Cu(II) ion, and four smaller peaks in the vicinity corresponding to approximately 0.3 e $Å^{-3}$. These peaks may arise from the fact that the weights used in the least squares calculation were not constant which would be necessary in order that the difference Fourier map would give the same results as the least squares. The weighting scheme used gave greater significance to the low angle reflections, which reflect the outer electron density better than the higher angle reflections. The presence of a substantial Jahn–Tellar distortion may have perturbed the outer electron density such that the temperature factor of the Cu(II) ion as determined by least squares was lowered from that consistent with the difference Fourier map.

The validity of this hypothesis was investigated by altering the weighting scheme to lessen the significance of the low angle reflections. The changes in the temperature factor of the Cu(II) ion were consistent with the hypothesis but the standard deviations in the atom positions were increased. The difference electron density in the vicinity of the Cu(II) ion did not become completely flat which suggests that it cannot be accurately described by any generalized ellipsoid.

The crystal structure of the Ni(II) complex is isostructural with that of the Cu(II) and Co(II) complexes. The polyhedron around the nickel atom should be much closer to that of the Co(II) complex because of the d^8 configuration of Ni(II) as well as the similarity in lattice parameters between crystals of these two compounds.

o-Nitrophenylethylene glycol as photoremovable protective group for aldehydes and ketones: syntheses, scope, and limitations

D. GRAVEL,[1] J. HEBERT, AND D. THORAVAL

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1

Received July 8, 1982

D. GRAVEL, J. HEBERT, and D. THORAVAL. Can. J. Chem. **61**, 400 (1983).

The preparation of *o*-nitrophenylethylene glycol is described along with its application as a photolabile protective group for aldehydes and ketones. Formation of the acetals and ketals is achieved in good to high yields in the usual manner and deprotection is carried out in fair to high yield, by photolysis at 350 nm in an inert solvent such as benzene. Because of the particular nature of the present protective group, its stability to basic and acidic conditions has been examined and is reported to complete the scope and limitations aspect. From a mechanistic point of view, the isolation and characterization of *o*-nitroso-α-hydroxyacetophenone as the spent reagent demonstrates a mechanistic link with the known *o*-nitrobenzaldehyde to *o*-nitrosobenzoic acid photorearrangement.

D. GRAVEL, J. HEBERT et D. THORAVAL. Can. J. Chem. **61**, 400 (1983).

La préparation de l'*o*-nitrophényléthylène glycol est décrite ainsi que son application comme groupe protecteur photolabile pour les aldéhydes et cétones. La formation des acétals et cétals est effectuée de la manière habituelle avec des rendements qui vont de bon à excellent. La déprotection, d'autre part, est effectuée avec des rendements, de moyen à excellent, par photolyse à 350 nm dans un solvant inerte tel que le benzène. À cause de la nature particulière du présent groupe protecteur, sa stabilité aux conditions basiques et acides a été étudiée et est rapportée afin de compléter l'aspect généralité et limitations de la réaction. Du point de vue mécanisme, l'isolement et la caractérisation de l'*o*-nitroso-α-hydroxyacétophénone comme réactif usé démontre un lien mécanistique entre cette réaction et le réarrangement photochimique connu de l'*o*-nitrobenzaldéhyde en acide *o*-nitrosobenzoïque.

Introduction

Over the years, the use of protective groups in organic synthesis has been refined to a high degree of sophistication and specificity, allowing chemists to synthesize some of the most complex organic structures known. There are at present a great number of protective groups available in the organic arsenal and these have been amply reviewed and organized (1, 2), making them a readily accessible tool even for the non-specialist.

The intrinsic role of a protective group requires that it possess some fundamental qualities such as: efficiency and specificity of introduction, stability under several reaction conditions, and efficiency, ease, and specificity of removal. In recent years, the need for more and more specific protective groups has prompted much research and one area which has been particularly fruitful is that of photochemistry, with the development of photochemically removable protective groups (3, 4) which can be released by irradiation at specific wavelengths.

At the beginning of the century, Ciamician and Silber (5) discovered the photochemical isomerization of *o*-nitrobenzaldehyde (**1**) to *o*-nitrosobenzoic acid (**2**) (eq. [1]) under solar light, a reaction which eventually, through works published in the literature (6), led to the discovery of a series of photoremovable protective groups having the same basic intramolecular rearrangement in common, i.e. the formal transfer of oxygen from the nitro group to the *o*-benzylic position (7).

[1] 
1 **2**

[1]Author to whom correspondence should be addressed.

Amongst the various new protective groups developed, many were designed for peptide (8), carbohydrate (9), and nucleoside synthesis (10). Upon examination of the pertinent literature, it became apparent that no photoremovable protective group had ever been developed for the protection of aldehydes and ketones and that such a tool might render important services in organic synthesis. It further appeared that such a group might easily be developed using the *o*-nitrobenzylic shift as its basis if *o*-nitrophenylethylene glycol (**3**) was available. This reagent should form nitrophenyl acetals and ketals **5** with carbonyl compounds **4** which should be labile under photolysis in aprotic solvents to yield the corresponding nitrosophenyl hemiketal derivative **6** by *o*-nitrobenzylic shift; the latter should then decompose in a ground state reaction to the starting aldehyde or ketone **4** and the spent reagent: *o*-nitroso-α-hydroxyacetophenone **7** (see Scheme 1) (a preliminary account of this work has been published, see ref. 11).

Synthesis of o-*nitrophenylethylene glycol (**3**)*

Although *o*-nitrophenylethylene glycol (**3**) was an unknown compound, its *meta* and *para* isomers were known and had been prepared by two different methods in 1960 (12). In the present case, the desired *ortho* isomer **3** was prepared by simple hydrolysis of *o*-nitrostyrene oxide (**8**) which is available by two known procedures namely: (*i*) from *o*-nitroacetophenone (**9**) via a bromination, reduction, epoxidation sequence reported by Guss (13), or (*ii*) simply by treating *o*-nitrobenzaldehyde (**1**) with diazomethane according to the method of Arndt *et al.* (14) (see Scheme 2).

In the first sequence, the α-bromination of *o*-nitroacetophenone (**9**) in acetic acid according to Guss (13) is reported without any mention of a yield and for that reason we preferred to adapt the method of Shevchuk and Dombrovskii (15) who report 98% yields for the *meta* and *para* isomers. In the present case, bromination is carried out using a bromine–dioxane

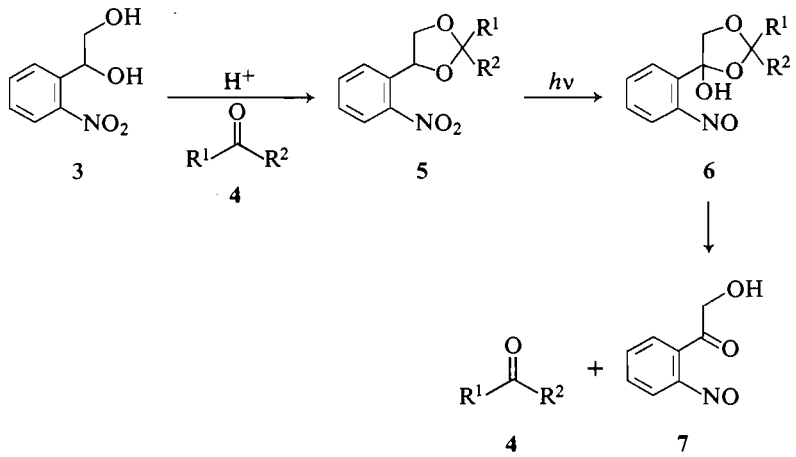
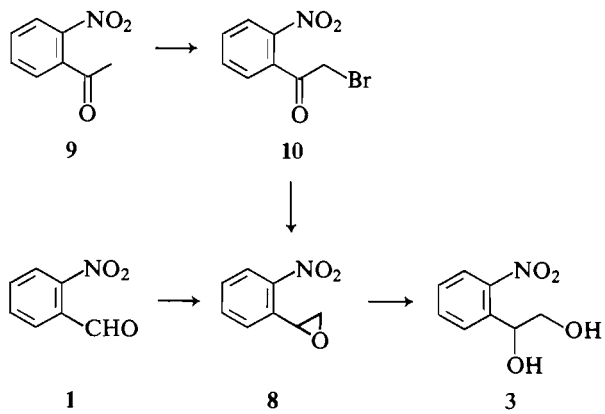


SCHEME 1

complex (16) which reacts almost instantaneously under cooling and in the somewhat more modest yield of 75% to give the desired α-bromo derivative **10**. It may be of interest to point out that, by fractional recrystallization, a small yield (6%) of the corresponding *gem*-dibromo derivative was isolated.

The next step in the sequence, which had also been reported by Guss (13), consisted in reducing the *o*-nitrophenacyl bromide with aluminum triisopropoxide to the corresponding bromohydrin which is isolated and then transformed into the desired epoxide by treatment with aqueous sodium hydroxide. In our particular case, for reasons of simplicity, we adapted the method of Fuchs (17) which uses sodium borohydride as the



SCHEME 2

reducing agent followed by *in situ* generation of the epoxide by the addition of aqueous sodium hydroxide. The desired epoxide **8** is thus obtained in 89% yield and corresponds in all respects to that reported by Guss (13); the overall yield for the sequence starting from *o*-nitroacetophenone (**9**) is 67%.

The second method of preparing *o*-nitroepoxystyrene (**8**) is that first reported by Arndt and Partale in 1927 (14*a*) which describes the reaction of diazomethane on *o*-nitrobenzaldehyde (**1**). In a subsequent article (14*b*), the same group reports that epoxide **8** is the major product (67%) of the reaction, whereas *o*-nitroacetophenone (**9**) is obtained in a 16% yield. Because of its economical advantage and relative simplicity for small scale preparations, the reaction was repeated and found to yield a mixture of at least five products (tlc); however, a crystallization combined with a chromatography of the mother liquors yielded the desired *o*-nitroepoxystyrene (**8**) in a total yield of 61%. There was also obtained an 8% yield of unreacted *o*-nitrobenzaldehyde (**1**) along with 14% of *o*-nitroacetophenone (**9**).

The two methods of obtaining the epoxide **8** are therefore approximately equivalent in yield and whereas that starting from *o*-nitroacetophenone (**9**) is more costly in terms of time and materials it is on the other hand safer to carry out especially on relatively large scales. It is also important to note here that the *o*-nitroepoxystyrene (**8**) cannot be stored for long periods of time, even in the absence of light. Indeed, the epoxide **8**, after an induction period of a few months, decomposes rather rapidly to give a solid black mass.

The last step in the synthesis of the desired glycol **3** was attempted following the procedures used by Yagupolskii *et al.* (12) for the preparation of the *meta* and *para* isomers, namely, sulfuric acid catalyzed hydrolysis of the epoxide to the diol or preparation of the corresponding epichlorohydrin followed by treatment of the latter with an aqueous solution of potassium carbonate. In the event, it turned out that opening of the epoxide ring of **8** under various acidic conditions (sulfuric or hydrochloric) proved unsuccessful, giving rise to complex mixtures of products; on the other hand, since treatment by Yagupolskii *et al.* (12) of their epichlorohydrin with aqueous potassium carbonate yielded the desired diol, it was anticipated that the reaction proceeded via the epoxide which subsequently was hydrolyzed by base catalysis. This assumption proved correct or at least rewarding since, when *o*-nitroepoxystyrene (**8**) was treated with a 10% solution of aqueous potassium carbonate, *o*-nitrophenylethylene glycol (**3**) was obtained with a minimum[2] yield of 78%. The product crystallizes in the form of slightly yellow and hard needles with a melting point of 95–96°C.

It is important to note, although perhaps redundant here, that *o*-nitrophenylethylene glycol (**3**) is light sensitive and therefore must be protected accordingly. For instance, crystals exposed to daylight turned greenish after one week; however, when kept in a brown jar and in a drawer, the reagent can be preserved intact for years without any sign of alteration.

Protection–deprotection of carbonyl compounds

General method of ketalization

The general method chosen to introduce this new protective

[2]The mother-liquors of crystallization retained some of the glycol **3** and were not chromatographed in order to maximize the yield.

group on various substrates is the following: the carbonyl compound **4** is treated with three equivalents of *o*-nitrophenylethylene glycol (**3**) in presence of a catalytic amount of *p*-toluenesulfonic acid in benzene under reflux and water separation conditions (see Experimental and footnote 5). After isolation and purification, the acetals and ketals **5** are protected from light until liberation by photolysis.

The results for a representative set of carbonyl compounds **4** are reported in Table 1.

General method of deprotection

In order to effect deprotection under the best possible conditions, i.e. liberating the carbonyl group under conditions such that the liberated carbonyl and other functional groups of the molecule are not affected, some preliminary irradiations were carried out using different set-ups and different solvents. The results show that a Rayonet apparatus equipped with a Pyrex vessel and 16 monochromatic lamps emitting at 350 nm is a very efficient set-up to effect deprotection since the photochemical reaction is generally "quantitative" after a reasonable time and since most functional groups are either stable or relatively stable at that wavelength. Concerning the choice of solvents for the deprotection reaction, various types were examined, such as carbon tetrachloride, chloroform, benzene, diethylether, dioxane, 1,2-dimethoxyethane, and methanol. Of these, a certain number were rejected for various reasons: methanol is not a good solvent for the ketals examined, carbon tetrachloride leaves a brown precipitate on the walls of the Pyrex vessel, thereby considerably reducing the amount of light transmitted to the solution, and finally, diethyl ether was rejected because of its too great volatility. Although all of the other solvents appeared equally efficient, we chose benzene for the preparative scale irradiations because it seems to have all of the necessary characteristics for this kind of photolysis: it is a good solvent for the ketals, its boiling point is in the right range, minimizing losses by evaporation during photolysis and being easy to evaporate after reaction, it is easy to purify and render anhydrous, it does not absorb light at 350 nm, and most importantly, it is aprotic and chemically inert.

The concentration of ketals in benzene was set at 10^{-3} − 10^{-4} *M* and the irradiations limited to 6 hours on the basis of preliminary trials which revealed only small amounts of unreacted material. Before presenting the various results of deprotection, it may be of importance to give a general description of the reaction as it proceeds: in every case studied, the solution under irradiation very early takes on a greenish color which then rapidly turns to yellow, then to red-brown, as the reaction progresses. Thin-layer chromatographic monitoring of the reaction reveals the appearance of many unstable intermediates, of which many are colored on the plate. Towards the end of the reaction, the photo by-products are all more polar than the starting acetals or ketals **5** and the liberated carbonyl compounds, which facilitates their recovery after reaction. Quite unfortunately, although many of these unstable intermediates were identical in all photolyses, every attempt to isolate any one of them by column chromatography failed (see, however, below under mechanistic aspects).

The results obtained in the photolyses of the six acetals and ketals **5** are reported in Table 2 which shows that after 6 hours of irradiation about 90% of the starting material has been deprotected, giving the liberated carbonyl compound in 80−90% isolated yield except in two cases where yields are fair to low.

As pointed out in Table 2, the case of the deprotection of the ketal of Δ^5-androsten-3β-ol-17-one acetate (**5**) under the standard conditions gave 65% of the liberated ketone but accompanied by a small percentage of its 13α epimer. Since the epimerization of this steroidal ketone is known in the literature (18), it was presumed that some light emitted at 313 nm by the lamps used was responsible for the epimerization of the liberated ketone (**4**). In an effort to control this side reaction, a filter solution composed of aqueous copper sulfate (19) was used in order to eliminate radiation under 320 nm, since the ketone carbonyl n-π^* absorption extends to 310 nm whereas that of the nitro group extends to 360 nm. Unfortunately, however, the results observed were much less impressive than hoped; the yield of the liberated ketone was raised to 71% but there was still a 7% yield of the 13α epimer which most probably came from sensitization by the spent reagent, i.e. *o*-nitroso-α-hydroxyacetophenone (**7**) (*vide infra*) or its reaction products, since a control experiment showed that the starting ketone irradiated for 9 hours through the filter solution remained intact.

In the case of testosterone, the ketal prepared and irradiated is the deconjugated ($\Delta^{5,6}$) isomer and the poor yields of recovered testosterone are again most probably attributable to the photoreactivity of the liberated $\Delta^{5,6}$ isomer of testosterone.[3] In fact, the photochemistry of β,γ-unsaturated ketones is well known (20) and could very well be one of the important limiting factors in this reaction, the other being possibly the instability of $\Delta^{5,6}$-testosterone, under chromatography condi-

[3]All our attempts to prepare the $\Delta^{4,5}$-3-ketal with *o*-nitrophenylethylene glycol **3** were unsuccessful.

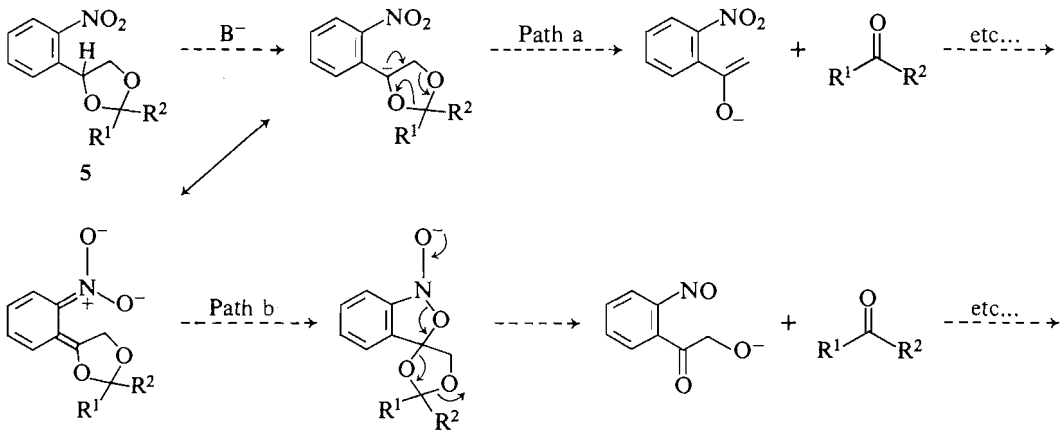
Δ^5-Pregnen-3β-ol-20-one acetate	6	83	13
Testosterone	6	31[d] (37)[d,e]	14 —

[a]Identified as its 2,4-dinitrophenylhydrazone.
[b]Beside the expected 13β isomer there is also observed a small amount of epimer, the 13α isomer, arising most probably by photoisomerization of the liberated ketone.
[c]Same compound using Hanovia reactor and filter solution, does not prevent the formation of 7% 13α epimer.
[d]Isolated as the conjugated form.
[e]Same compound using Hanovia reactor and filter solution.



SCHEME 3

tions, which partly reconjugates but also decomposes. In order to attempt to rectify this situation we, also in this case, carried out the photolysis using the aforementioned filter solution and then treated the crude photolysis product with sodium methoxide in methanol in order to reconjugate the double bond before chromatography. After column chromatography on silica gel there was obtained a 37% yield of testosterone compared to 31% under the other conditions; it therefore appears that here again the limiting factor is the photochemical instability of the liberated ketone under the reaction conditions, possibly again due to sensitization, but this particular aspect was not verified with a pure sample of deconjugated testosterone.

Stability of the o*-nitrophenylethylenedioxy protective group in basic and reducing media*

As is most often the case in organic synthesis, acetals and ketals are used as protective groups for aldehydes and ketones when the substrate bearing such functional groups must be manipulated in basic or reducing media. However, the present group bearing the *o*-nitrobenzyl functionality should be quite susceptible to certain strongly basic conditions and certain specific reducing conditions. In fact, it could even be anticipated that a strong base might liberate the ketone from its protective group as depicted in Scheme 3.[4]

In order to evaluate the stability of the present group under these conditions we chose as representative substrate the *o*-nitrophenylethylenedioxyketal of benzophenone (**5**, $R^1 = R^2$ = Ph) because it is isomerically homogeneous and because it should be free of undesirable side reactions which would complicate analysis of the results. Table 3 shows the stability (or instability, as the case may be) of the title protective group under a series of typical basic conditions and typical reducing conditions. It is readily apparent from these results that the group shows good stability in the presence of sodium hydride in nonpolar solvents, sodium alkoxides in alcohol–dioxane mixtures at room temperature, and aqueous bases such as 10% sodium hydroxide or 10% sodium bicarbonate in dioxane or ethanol. It is also apparent that, under certain conditions, some strong bases (NaH, DME, reflux 20 h, gives 73% of the liberated ketone) can effect deprotection quite cleanly and lead to the liberated ketone, possibly by one of the paths represented in Scheme 3;[4] since no trace of *o*-nitroacetophenone could be found in this type of liberation, path a is eliminated and path b remains as most likely, which is interesting because of its analogy with the photochemical reaction and other *o*-sub-

[4]The *a priori* possible α-elimination path to yield a carbene is considered as unlikely and is not represented.

3% aq. *p*-TsOH − THF	Room temp	Almost completely stable for 5 h

stituted nitrobenzene cyclization reactions (for a review of the generalized *o*-nitrobenzylic shift, see ref. 7*g*). This rather unusual method of liberating a protected ketone could perhaps even be useful in some particular situation! Concerning the stability under various typical reducing media, it turns out, as anticipated, that it is about comparable to that of aromatic nitro compounds (21).

Finally, although stability to acid hydrolysis is not a property usually sought in acetals and ketals, we had observed qualitatively that the *o*-nitrophenylethylenedioxy group is relatively more difficult to introduce than the simple ethylenedioxy group;[5] this then suggested that it could also be possibly, although not necessarily, more difficult to remove under acidic conditions, which would constitute a potentially useful bonus in the present context.

We therefore qualitatively determined the stability to acid hydrolysis of the same model ketal (benzophenone) using tlc monitoring to evaluate the approximate onset or completion of hydrolysis, in order to make the prospective user aware of another facet of the reactivity of this new protective group (see Table 4).

Considering the results of Table 4 and the fact that the ethylenedioxy ketal of benzophenone is completely hydrolyzed at room temperature after 30 min in 5% aqueous HCl−THF (1:1), it may be safely concluded that the *o*-nitrophenylethylenedioxy group shows relatively good resistance to acid hydrolysis.

Concerning the stability to various other reaction conditions, it may be of interest to the prospective user that, since the *o*-nitrophenylethylenedioxy group is made up of a 1,3-dioxolane moiety and an *o*-nitrobenzyl ether moiety, both of which are well known in protective group chemistry, one can glean useful information by consulting the reactivity charts at the end of ref. 1*b*.

Mechanistic aspects

As mentioned in the beginning (see Scheme 1), it was presumed that the ketals or acetals **5** would, upon photolysis, regenerate the carbonyl compound **4** and the spent reagent in the form of *o*-nitroso-α-hydroxyacetophenone (**7**); this prediction was based on the rather well accepted mechanistic scheme proposed (6*g*, 7*a*, 7*b*) for such *o*-nitrobenzylic shifts (Scheme 4). Although the various carbonyl compounds **4** were regenerated upon photolysis of the ketals and acetals **5** in accordance with the scheme, the structure of the spent reagent remained to be proven. As stated above, however, every attempt made to isolate the elusive nitroso compound **7** during the various deprotection photolyses proved unfruitful.

However, since Arndt and Partale (14*a*) had already reported the preparation of the nitroso compound **7** in question, by treatment of *o*-nitrostyrene oxide (**8**) with formic acid at 0°C,

[5]It has been found, however, by R. C. Kelly and his group at Upjohn (22) that for some labile aldehydes the introduction of the *o*-nitrophenylethylenedioxy group is facilitated by exchange with the more easily introduced dimethyl acetal. These authors have provided what is probably, to date, the best illustration of the usefulness of this reagent, in their work related to thromboxane A_2.

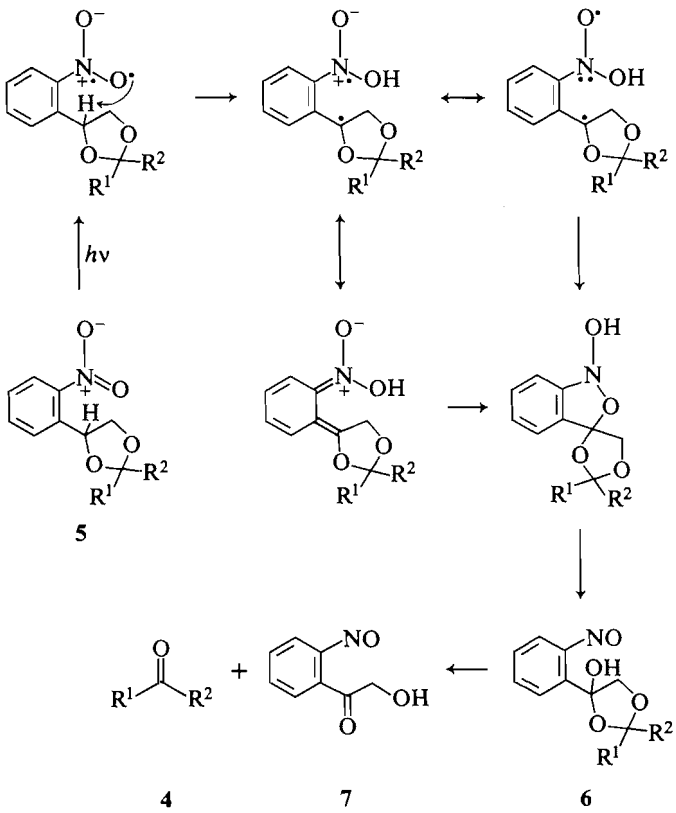
For personal use only.



SCHEME 4

we repeated the procedure and obtained an authentic sample of **7** (mp 102–103°C, lit. (14*a*) mp 104°C), as also shown by nmr, ir, uv, and mass spectrometry (see Experimental). As mentioned by Arndt and Partale (14*a*), the nitroso compound **7** is very unstable and decomposes rapidly under the influence of heat or light.

Having then in hand an authentic sample of **7**, we could show by tlc analysis that, aside from the liberated ketone, the first product formed in the photolysis of every ketal or acetal **5** studied is *o*-nitroso-α-hydroxyacetophenone (**7**) and that the other products formed later result from its decomposition. This result, although rather convincing, did not bring absolute proof of the presence of **7** and therefore one last attempt was made at isolating **7** from a photolysis mixture, taking advantage of the experience acquired in manipulating authentic samples of the compound.

In order to carry out this delicate experiment we chose firstly to prepare and irradiate the *o*-nitrophenylethylenedioxy ketal of acetone because it shows good solubility and therefore hopefully would not interfere with the crystallization of *o*-nitroso-α-hydroxyacetophenone (**7**) and also because the liberated ketone is a solvent for the crystallization of **7**. Secondly, we chose ether as the solvent for photolysis since it does not dissolve the nitroso compound well and, finally, the photolysis was carried out at 0°C in order to minimize the thermal decomposition of **7**.

It was therefore under these conditions that the photolysis was undertaken and monitored by tlc; the reaction was stopped when the concentration of the presumed nitroso compound **7** appeared about at its maximum and the solution was still green. Evaporation of part of the ether allowed the crystallization of a small amount of the suspected *o*-nitroso-α-hydroxyacetophenone (**7**) as shown by comparison with an authentic sample (mp, mixture mp, ir, nmr). This result therefore demonstrates unambiguously the nature of the spent reagent as compound **7**.

Experimental

Melting points were taken on a Büchi apparatus and are uncorrected. The nmr spectra were recorded in $CDCl_3$ (unless otherwise specified) on a Varian model A-60 apparatus or a JEOL model C60-H apparatus using TMS as internal reference; the letters s, d, t, q, and m, meaning respectively singlet, doublet, triplet, quadruplet, and multiplet, are used in the description of the spectra. The ir spectra were recorded in $CHCl_3$ (unless otherwise specified) on a Beckman model IR-8 apparatus. The uv spectra were recorded in ethanol 95% on a Bausch and Lomb Spectronic 505 spectrophotometer. The mass spectra were obtained from AEI MS 902 and Hitachi–Perkin–Elmer RMU 6D mass spectrometers. Photolyses were carried out in a Rayonet photochemical reactor equipped with 350 nm lamps or in a homemade photochemical reactor, equipped with a single Hanovia lamp (450 watts) when the use of a filter solution was necessary. The latter, placed between the lamp and the irradiated solution, was 5 cm thick and prepared by dissolving 38 g of $CuSO_4 \cdot 5H_2O$ in 100 mL of water. Thin-layer chromatography was carried out using Eastman–Kodak 13181 Silica Gel plates. Column chromatography was carried out using 100 to 150 grams of J. T. Baker Silica Gel 60–80 mesh per gram of mixture. Finally, microanalyses were performed by Midwest Microlab Inc., Indianapolis, USA and by Dr. C. Daesslé, Organic Microanalyses, Montreal.

o-*Nitrophenacyl bromide* (***10***) (13, 15, 16)

A solution of bromine (134 g, 0.837 mol) in dioxane (1250 mL) is added dropwise over a 2 h period to a solution of *o*-nitroacetophenone (**9**) (Aldrich) (137.8 g, 0.835 mol) in dioxane (250 mL). The reaction may be monitored by tlc (hexane–ether 1:1) by following the appearance of a major compound, slightly less polar than the starting material. After the addition is completed, the solvent and hydrobromic acid formed are evacuated by evaporation. The oily residue thus obtained is dissolved in ether (1000 mL) and the solution washed successively with a 10% solution of sodium bicarbonate and brine until neutrality. The organic layer is dried over magnesium sulfate and evaporated.

Crystallization of the crude mixture in 95% ethanol affords pure *o*-nitrophenacyl bromide (**10**) (139 g, 0.572 mol) in 68% yield. Distillation under reduced pressure of the mother liquor furnishes 14% (18 g) of the unreacted material (**9**). Purification of the distillation residue by filtration through a silica gel column (eluent: CCl_4) gives a colorless oil which, upon treatment with 95% ethanol, yields pure crystalline dibromo derivative (3.2 g, 9.9 mmol), 6%. The nmr analysis of the noncrystalline residue shows equal proportions of mono and dibromo derivatives by the relative intensities of the signals at δ 4.37 and 6.31.

The pure *o*-nitrophenacyl bromide (**10**) has: mp 54–55°C (95% ethanol) (lit. (13) mp 55–56°C); ir: 1350, 1530, and 1715 cm^{-1}; uv, λ_{max}: 213.0 nm (ε = 10 000), 261.5 nm (ε = 6,000); nmr, δ: 4.37 (s, 2H), 7.40–8.15 (m, 4H). The dibromo derivative has: mp 85–86°C (95% ethanol); ir: 1350, 1530, and 1725 cm^{-1}; uv, λ_{max} 211.0 nm (ε = 11 800), 262.0 nm (ε = 5,900); nmr, δ: 6.31 (s, 1H) and 7.50–8.30 (m, 4H); ms, *m/e*: 242 and 244 (rel. int. 1:1) $M^+ - Br$, *m/e*: 171, 173 and 175 (rel. int. 1:2:1) $CHBr_2^+$.

o-*Nitroepoxystyrene* (***8***) (13, 14)

(a) *From* o-*nitrophenacyl bromide* (***10***) (13, 17)

A suspension composed of sodium borohydride (98%) (22.1 g, 0.580 mol) and water (200 mL) is added dropwise and under stirring to a cooled (ice bath) solution of *o*-nitrophenacyl bromide (**10**) (138.5 g, 0.567 mol) in dioxane (200 mL). The rate of addition (approx. 2 h) is adjusted so as to prevent the temperature from exceeding 5°C. The mixture is then stirred at room temperature for 30 min after which an aqueous solution of sodium hydroxide (30 g/200 mL) is added. After a stirring period of 15 min, a tlc (hexane–ether 6:4) of the crude mixture shows complete disappearance of the starting material and the presence of a less polar compound. After several

extractions with ether, the combined organic layers are washed with brine, dried over magnesium sulfate, and evaporated. Several crystallizations (95% ethanol) of the oily residue afford 83% (78 g, 0.473 mol) of the desired epoxide (**8**), while filtration through a silica gel column (eluent: CCl_4) of the mother liquors furnishes another 5% (5 g, 0.030 mol) of the same epoxide (**8**) for a total yield of 88%. The compound has: mp 63–64°C (95% ethanol) (lit. (13) mp 64–65°C); ir: 1345, 1525, 1580, and 1615 cm^{-1}; uv, λ_{max}: 206.5 nm (ϵ = 13 800), 261.5 nm (ϵ = 6,520); nmr, δ: 2.62 (q, 1H, portion A of AMX, J_{AM} = 6 Hz, J_{AX} = 2.5 Hz), 3.27 (q, 1H, portion M of AMX, J_{MX} = 4.5 Hz), 4.45 (q, 1H, portion X of AMX), and 7.26–8.17 (m, 4H).

(b) *From o-nitrobenzaldehyde (1)* (14)

To an ice-cold ethereal (50 mL) solution of *o*-nitrobenzaldehyde (**1**) (10.0 g, 0.066 mol) is added, over a 15 min period, an ice-cold ethereal solution of diazomethane (0.071 mol). The mixture is stirred at 0°C for 1 h, then at room temperature for 3 additional hours. The ether is partly distilled to eliminate the excess diazomethane and the remainder evaporated under vacuum. Thin-layer chromatography (hexane–ether 1:1) of the crude mixture shows 5 compounds in unequal proportions.

Several crystallizations (methanol) of the crude mixture afford 39% (4.3 g) of the epoxide (**8**), which is the less polar compound on tlc. Column chromatography (eluent: hexane–ether 8:2) of the concentrated mother liquors furnishes an additional 22% (2.4 g) of epoxide (**8**) (for a total yield of 61%), 8% (0.8 g) of the title compound (**1**), and 14% (1.5 g) of *o*-nitroacetophenone (**9**). Spectral data for epoxide (**8**) are identical to those presented in section (a).

o-*Nitrophenylethylene glycol (3)*

Mixed solutions of *o*-nitroepoxystyrene (**8**) (82.5 g, 0.5 mol) in dioxane (100 mL) and 10% aqueous potassium carbonate (800 mL) are heated under reflux and protected from daylight, for a 17 h period. Thin-layer chromatography of the mixture (hexane–ether 1:1) shows complete disappearance of the starting material and the presence of a new, much more polar substance. The cooled mixture is saturated with sodium chloride and extracted several times with chloroform. The combined organic layers are dried over magnesium sulfate and evaporated under vacuum. Several crystallizations in chloroform of the solid yellow residue yield 78% (71.3 g) of the desired diol (**3**). The latter can be stored "indefinitely" providing it is protected from daylight. It has: mp 95–96°C ($CHCl_3$); ir: 1350, 1525, 3615, and 3430 cm^{-1}; uv, λ_{max}: 206.0 nm (ϵ = 2,750), 259.0 nm (ϵ = 5,300); nmr (DMSO-d_6), δ: 3.43–3.63 (m, 2H), 4.93–5.33 (m, 2H), 5.78 (d, J = 4.5 Hz, 1H) and 7.50–8.20 (m, 4H); nmr (DMSO-d_6 + D_2O), δ: 3.60 (d, J = 6 Hz, 2H) and 5.25 (t, J = 6 Hz, 1H) *etc.*; nmr (CD_3COCD_3), δ: 3.42–3.95 (m, 2H), 4.15 (t, J = 5.5 Hz, 1H), 4.83 (d, J = 4.5 Hz, 1H), 5.15–5.50 (m, 1H), and 7.35–8.10 (m, 4H); nmr (CD_3COCD_3 + D_2O), δ: 3.50–4.02 (8 lines, AB portion of ABX, 2H) and 5.30–5.48 (q, X portion of ABX, 1H) *etc.*; ms, *m/e*: 152 (M^+ – CH_2OH). *Anal.* calcd. for $C_8H_9NO_4$: C 52.46, H 4.95, N 7.65; found: C 52.30, H 5.11, N 7.57.

Protection of carbonyl groups

General method of ketalization (see footnote 5)

A solution composed of the carbonyl compound (0.01 mol), *o*-nitrophenylethylene glycol (**3**) (5.49 g, 0.03 mol), *p*-toluenesulfonic acid (100 mg), and anhydrous benzene (125 mL) is heated under reflux in an apparatus protected from daylight and equipped with a Dean–Stark water separator or a Soxhlet extractor with the thimble filled with anhydrous magnesium sulfate. The reaction is monitored by tlc using an appropriate eluent. The reaction is stopped after all the starting material is consumed or when no noticeable change can be observed in the progress of the reaction. The mixture is then allowed to cool to room temperature and filtered to recover the excess diol **3**. The filtered solution is washed with a 10% solution of sodium bicarbonate and then with brine until neutrality. The organic layer is dried over magnesium sulfate and evaporated. The crude acetals or ketals are then purified by column chromatography or in certain cases by crystallization (*vide infra*).

Cyclohexanone ketal

The reaction can be monitored by tlc (hexane–ether 6:4) and is complete in one hour. The oily residue obtained after work-up is purified by column chromatography (eluent: benzene) to afford 96% (2.53 g) of pure ketal as a colourless oil, bp 142°C/0.25 Torr; ir: 1345, 1525, 1580, and 1610 cm^{-1}; uv, λ_{max}: 206.5 nm (ϵ = 12 500), 262.0 nm (ϵ = 5,500); nmr, δ: 1.2–2.0 (m, 10H), 3.74 (q, 1H, portion A of AMX, J_{AM} = 6.0 Hz, J_{AX} = 6.8 Hz), 4.66 (q, 1H, portion M of AMX, J_{MX} = 6.8 Hz), 5.62 (t, 1H, portion X of AMX) and 7.25–8.20 (m, 4H); ms, *m/e*: 263 (M^+).

p-*Nitrobenzaldehyde acetal*

The reaction is monitored by tlc (hexane–ether 1:1) and is complete in 2 h. The oily residue obtained after work-up is crystallized in hexane–dichloromethane to afford 72% (2.28 g) of a pure acetal, mp 118–119°C, shown below to be the *cis* isomer. Concentration of the mother liquors and column chromatography of the residue (eluent: benzene) yields a mixture of the *cis* and *trans* acetals which is recrystallized to afford 25% (0.78 g) of acetal. The nmr analysis shows, by comparing relative intensities of peaks at δ 6.10 and 6.42, that the mixture contains 60% of the *cis* isomer (less polar compound on tlc) and 40% of the *trans* isomer (more polar compound on tlc). Analytical samples of the two isomers are obtained either by fractional crystallization or column chromatography (eluent: benzene–ether 9:1).

cis Isomer, mp 118–119°C; yield, 58%; ir: 1345, 1520, and 1610 cm^{-1}; uv, λ_{max}: 203.0 nm (ϵ = 21 200), 261.0 nm (ϵ = 15 800); nmr, δ: 4.04 (q, 1H, portion A of AMX, J_{AM} = 8.2 Hz, J_{AX} = 5.3 Hz), 4.73 (t, 1H, portion M of AMX, J_{MX} = 8.2 Hz), 6.10 (s, 1H), and 7.4–8.6 (m, 8H); ms, *m/e*: 316 (M^+).

trans Isomer, mp 111–112°C; yield, 39%; ir: 1350, 1525, and 1610 cm^{-1}; uv, λ_{max}: 205.0 nm (ϵ = 20 000), 261.5 nm (ϵ = 16 600); nmr, δ: 3.92 (q, 1H, portion A of AMX, J_{AM} = 8.2 Hz, J_{AX} = 6.3 Hz), 4.82 (q, 1H, portion M of AMX, J_{MX} = 6.3 Hz), 5.84 (t, 1H, portion X of AMX), 6.42 (s, 1H), and 7.4–8.5 (m, 8H); ms, *m/e*: 316 (M^+).

Benzophenone ketal

The reaction is monitored by tlc (benzene) and is complete in 12 h. The oily residue obtained after work-up is crystallized from ether–methanol to afford 64% (2.21 g) of pure ketal. Concentration of the mother liquors and column chromatography (eluent: benzene) furnishes 30% (1.06 g) more of the same ketal, mp 115–116°C; yield, 94%; ir: 1350, 1525, 1575, and 1610 cm^{-1}; uv, λ_{max}: 202.5 nm (ϵ = 24 400), 261.0 nm (ϵ = 33 500); nmr, δ: 4.01 (q, 1H, portion A of AMX, J_{AM} = 7.5 Hz, J_{AX} = 5.3 Hz), 4.58 (t, 1H, portion M of AMX, J_{MX} = 7.5 Hz), 5.68 (q, 1H, portion X of AMX), and 7.2–8.2 (m, 14H); ms, *m/e*: 347 (M^+).

Δ^5-Androsten-3β-ol-17-one acetate ketals

The reaction is monitored by tlc (hexane–ether 1:1) and is complete in 3 h. The oily residue obtained after work-up is crystallized in methanol to afford 76% (3.75 g) of pure diastereoisomeric ketals. Concentration of the mother liquors and column chromatography (eluent: benzene–ether 9:1) furnishes 16% (0.81 g) more of ketals as a mixture of diastereoisomers. Yield, 92%; ir: 1725, 1350, 1525, 1580, and 1615 cm^{-1}; uv, λ_{max}: 202.5 nm (ϵ = 16 000), 260.0 nm (ϵ = 5,450); nmr, δ: 0.92 (s, 3H), 1.06 (s, 3H), 2.04 (s, 3H), 3.60–3.84 (m, 1H, portion A of AMX), 4.40–4.75 (m, 2H, H_3 and portion M of AMX), 5.30–5.65 (m, 2H, H_6 and portion X of AMX), and 7.30–8.20 (m, 4H); ms, *m/e*: 435 (M^+ – AcOH).

Δ^5-Pregnen-3β-ol-20-one acetate ketals

The reaction is monitored by tlc (hexane–ether 6:4) and is complete in 10 h. The oily residue obtained after work-up is crystallized in methanol to afford 51% (2.67 g) of pure diastereoisomeric ketals. Concentration of the mother liquors and column chromatography (eluent: benzene) furnishes 29% (1.53 g) more of ketals as a mixture of diastereoisomers. Yield, 80%; ir: 1725, 1350, 1525, 1580, and 1615 cm^{-1}; uv, λ_{max}: 205.5 nm (ϵ = 13 600), 260.5 nm (ϵ = 5,000); nmr, δ: 0.84 (s, 3H), 1.05 (s, 3H), 1.48 and 1.53 (2s, 3H), 2.05 (s, 3H), 3.52–3.88 (m, 1H, portion A of AMX), 4.40–5.00 (m, 2H, H_3 and portion M of AMX), 5.30–5.75 (m, 2H, H_6 and portion X of AMX),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

and 7.30–8.20 (m, 4H); ms, *m/e*: 463 (M^+ – AcOH).

Testosterone ketals

The reaction is monitored by tlc (dichloromethane–ether 8:2) and is complete in 24 h. The oily residue obtained after work-up is crystallized from methanol to afford 1.75 g of diastereoisomeric ketals. Concentration of the mother liquors and column chromatography (eluent: dichloromethane–ether 19:1) furnishes an additional 1.45 g of ketals and 26% (0.75 g) of unreacted testosterone. Total yield of ketals: 70%; ir: 3630, 1350, 1525, 1580, and 1610 cm^{-1}; uv, λ_{max}: 203.5 nm (ϵ = 16 300), 262.0 nm (ϵ = 5,400); nmr, δ: 0.80 (s, 3H), 1.12 (s, 3H), 3.52–3.95 (m, 2H, H_1 and portion A of AMX), 4.50–4.90 (m, 1H, portion M of AMX), 5.30–5.80 (m, 2H, H_6 and portion X of AMX), and 7.30–8.25 (m, 4H); ms, *m/e*: 453 (M^+). The ketals obtained are therefore the $\Delta^{5,6}$ isomers because the ethylenic proton at C-6 appears as a multiplet centered at δ 5.44.

Removal of the protective group by irradiation

General method

The protective group is removed by irradiation at room temperature for 6 h of a 10^{-3} – 10^{-4} *M* solution of the ketal in benzene (200 mL). A Pyrex vessel and uv light of wavelength longer than 320 nm are used. The red-brown residue is chromatographed on silica gel. Yields of regenerated carbonyl compounds are generally good to excellent except in the case of androstenolone acetate and testosterone.

Irradiation of cyclohexanone ketal

A solution of cyclohexanone ketal (1.315 g, 5×10^{-3} mol) in anhydrous benzene (200 mL) is irradiated for 6 h at 350 nm. Thin-layer chromatography (hexane–ether 7:3) of the brownish solution shows complete disappearance of the starting material. The benzene is then slowly removed by distillation and 250 mL of water is added to the residue. Distillation is then pursued and the distillate collected into a freshly prepared solution of 2,4-dinitrophenylhydrazine. The precipitate is filtered; recrystallization in 95% ethanol affords pure cyclohexanone 2,4-dinitrophenylhydrazone (mp 159–162°C) in 85% (1.18 g) yield. This compound is identical (mixture mp, ir, nmr) with an authentic sample prepared from commercially available cyclohexanone.

Irradiation of p-*nitrobenzaldehyde acetals*

A solution of *p*-nitrobenzaldehyde acetals (1.58 g, 5 x 10^{-4} mol) (mixture of *cis* and *trans* isomers in a 60:40 ratio) in anhydrous benzene (200 mL) is irradiated for 6 h at 350 nm. Thin-layer chromatography (hexane–ether 1:1) shows almost complete disappearance of the starting material. The solvent is evaporated under vacuum and the residual mixture purified by column chromatography (hexane–ether 1:1) to yield 11% (0.18 g) of unreacted acetals (mixture of *cis* and *trans* isomers) and 86% (0.65 g) of *p*-nitrobenzaldehyde. Comparison of physical (mp) and spectral (ir, nmr) data of these two compounds with those of authentic samples proves identical.

Irradiation of benzophenone ketal

A solution of benzophenone ketal (1.735 g, 5×10^{-4} mol) in anhydrous benzene (200 mL) is irradiated for 6 h at 350 nm. Thin-layer chromatography (benzene) shows almost complete disappearance of the starting material. The solvent is evaporated under vacuum and the residual mixture purified by column chromatography (benzene) to yield 7% (0.13 g) of unreacted ketal and 90% (0.82 g) of benzophenone. These compounds prove identical (mp, ir, nmr) with authentic samples.

Irradiation of Δ^5*-androsten-3*β*-ol-17-one acetate*

A solution of androstenolone acetate (1.0 g) in anhydrous benzene (100 mL) is irradiated for 6 h at 350 nm. Thin-layer chromatography (dichloromethane–ether 19:1) shows, apart from the starting material, the presence of a less polar compound. The solvent is evaporated under vacuum and the residual mixture purified by column chromatography (dichloromethane–ether 19:1) to yield 30% (0.30 g) of a photoproduct identified as the 13α epimer of androstenolone acetate. An analytical sample is obtained by recrystallization (ether–hexane), mp 138–140°C (lit. (18) mp 140–141°C); ir: 1725 cm^{-1}; nmr, δ: 0.89 (s, 3H), 1.02 (s, 3H), 2.05 (s, 3H), 4.58 (m, 1H), and 5.44 (m, 1H). The second fraction eluted furnishes 56% (0.56 g) of androstenolone acetate, identified by comparison of its physical (mp) and spectral (ir, nmr) properties to authentic material.

Irradiation of Δ^5*-androsten-3*β*-ol-17-one acetate with a filter solution*

A solution of the title compound (0.30 g) in anhydrous benzene (500 mL) is irradiated with a Hanovia medium pressure lamp through 5 cm of a filter solution composed of 760 g of $CuSO_4 \cdot 5H_2O$ in 2 litres of water. Thin-layer chromatography (dichloromethane–ether 19:1) shows, after 9 h of irradiation, the sole presence of the starting material. The solvent is evaporated under vacuum to afford the unchanged 13 β epimer, mp 168–170°C (lit. (18) mp 168–170°C); nmr, δ: 0.89 (s, 3H), 1.08 (s, 3H), 2.05 (s, 3H), 4.58 (m, 1H) and 5.44 (m, 1H).

Irradiation of the ketal of Δ^5*-androsten-3*β*-ol-17-one acetate with the filter solution*

A solution of the title ketal (0.30 g, 6.2×10^{-4} mol) in anhydrous benzene (500 mL) is irradiated according to the conditions described above. After 5 h, tlc (dichloromethane–ether 19:1) shows almost complete consumption of the starting material. The solvent is evaporated under vacuum and the residue purified by column chromatography (dichloromethane–ether 19:1) to yield 12% (0.035 g) of unreacted ketal, 0.7% (0.012 g) of 13α epimer of androstenolone acetate and 71% (0.125 g) of the desired 13β epimer. The physical and spectral data of these compounds are identical to those described above.

Irradiation of the ketal of Δ^5*-pregnen-3*β*-ol-20-one acetate*

A solution of pregnenolone ketal acetate (2.615 g, 5×10^{-4} mol, mixture of diastereoisomers) in anhydrous benzene (200 mL) is irradiated for 6 h at 350 nm. Thin-layer chromatography (hexane–ether 6:4) shows almost complete consumption of the starting material. The solvent is evaporated under vacuum and the residue purified by column chromatography (dichloromethane) to afford 13% (0.33 g) of unreacted ketal and 83% (1.49 g) of pregnenolone acetate, crystallized from hexane–ether. The latter compounds are identical (mp, ir, and nmr) with authentic samples.

Irradiation of testosterone ketal

(a) *Under the standard conditions*

A solution of testosterone ketal (2.265 g, 0.5×10^{-3} mol, mixture of diastereoisomers) in anhydrous benzene (200 mL) is irradiated for 6 h at 350 nm. Thin-layer chromatography (dichloromethane–ether 9:1) shows, in order of increasing polarity: unreacted ketal, $\Delta^{5,6}$ testosterone as the major compound, and its $\Delta^{4,5}$ isomer. The solvent is evaporated under vacuum and the residue purified by column chromatography (dichloromethane) to afford 14% (0.33 g) of unreacted ketal, traces of $\Delta^{5,6}$ testosterone, and 31% (0.455 g) of $\Delta^{4,5}$ testosterone. The latter are identical (mp, ir, and nmr) with authentic samples, except $\Delta^{5,6}$ testosterone which was identified by tlc only.

Using a filter solution

A solution of testosterone ketal (0.50 g, 1.1×10^{-3} mol) in anhydrous benzene (800 mL) is irradiated using the filter solution and the conditions described above. After 4 h, tlc (dichloromethane–ether 9:1) shows almost complete consumption of the starting material. The solvent is evaporated under vacuum and the oily residue submitted to reconjugation conditions, i.e. dissolved in 200 mL of anhydrous methanol to which is added 3 mL (3×10^{-5} mol) of a 0.01 *M* sodium methoxide solution. The solution is stirred at room temperature for 4 h, then treated with a 20% HCl solution until neutrality. After the solvent has been evaporated, the residue is dissolved in dichloromethane (50 mL), washed with brine, dried over magnesium sulfate, and the solvent evaporated. The residue is then purified by column chromatography (dichloromethane) to afford 37% (0.117 g) of $\Delta^{4,5}$ testosterone, identical (mp, ir, and nmr) with an authentic sample.

Synthesis of α*-hydroxy* o-*nitrosoacetophenone (7)* (14*a*)

To 6 mL of ice-cold formic acid is added 1 g (6 mmol) of *o*-nitroepoxystyrene (**8**). The stirred suspension immediately turns to green,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

then to yellow after 5 min. When all of the epoxide **7** has dissolved (20 min), ether (40 mL) is quickly added. The brownish solution becomes yellow again with a beginning of crystallization. After a 10 min stirring period, tlc (hexane–ether 6:4) shows complete disappearance of epoxide **8** and appearance of a much more polar compound. The solution is maintained at 0°C under stirring for 1 h and then filtered. The crystals are washed with ether and dried. The average yield of the reaction is 50%, depending at which time ether is added. The solid can be recrystallized by quickly dissolving it in hot acetone and then rapidly cooling down the solution in a Dry Ice-acetone bath. The compound has: mp 102–103°C (dec.) (lit. (14a) mp 104°C); ir (Nujol): 3430, 1705, and 1600 cm^{-1}; uv, λ_{max}: 286 nm (ϵ = 4,800), 310 nm (ϵ = 4,700); nmr (CD_3COCD_3), δ: 3.07 (m, 1H), 4.65 (s, 2H), and 7.2–8.0 (m, 4H); ms, *m/e*: 165 (M^+).

Detection of the nitroso derivative 7 during the photolysis of acetals, ketals, and diol 3

Detection of the nitroso derivative **7** is accomplished by simultaneously irradiating solutions of the acetals, the ketals, diol **3**, and nitroso derivative **7** (50 mg) in DME (10 mL) at 350 nm. The photolyses are monitored by tlc (ether) at 5 min intervals. The nitroso derivative **7** is readily detected (R_f = 0.6) in the acetals, the ketals, and the diol **3** photolysis solutions. Prolonged irradiation results in further decomposition of the nitroso derivative **7**, giving rise to polar and coloured compounds on tlc.

Synthesis of acetone ketal

A solution of acetone (20 mL), diol **3** (1.83 g, 10^{-2} mol), and *p*-toluenesulfonic acid (100 mg) in anhydrous benzene (125 mL) is heated under reflux in an apparatus protected from daylight and equipped with a Dean–Stark separator. After 30 min, another 20 mL of acetone is added to the reaction mixture. Thin-layer chromatography (hexane–ether 7:3) shows, after a 1 h period, complete disappearance of diol **3**. The mixture is allowed to cool, is then washed with a 10% solution of sodium carbonate and then with brine until neutrality. The organic layer is dried over magnesium sulfate and evaporated. The crude product is purified by distillation under reduced pressure to afford 95% (2.12 g) of ketal, bp 105°C/0.3 Torr; ir: 1345, 1525, and 1610 cm^{-1}; nmr, δ: 1.50 and 1.62 (2s, 6H), 3.76 (q, 1H, portion A of AMX, J_{AM} = 9 Hz, J_{AX} = 6 Hz), 4.69 (q, 1H, portion M of AMX, J_{MX} = 7 Hz), 5.63 (q, 1H, portion X of AMX) and 7.4–8.2 (m, 4H); ms, *m/e*: 223 (M^+).

Isolation of the nitroso derivative 7 during the acetone ketal irradiation

An ice-cold solution of acetone ketal (0.1 g) in ether (50 mL) is irradiated at 350 nm in a Pyrex tube at 0°C. After 1 h, tlc (ether) of the greenish solution shows a considerable amount of the nitroso derivative **7** with some traces of decomposition of the latter. The ethereal solution is concentrated (15 mL) at room temperature under vacuum and placed in the freezer (1 h) to allow crystallization. The precipitate is filtered, washed with ether, and dried. The collected solid (0.075 g) is identical (mixture mp, ir, nmr) with the nitroso derivative **7** prepared from *o*-nitroepoxystyrene (**8**).

Stability of ketals in basic and reductive media

1. *Treatment of benzophenone ketal with sodium hydride; general procedure*

A suspension composed of benzophenone ketal (347 mg, 1 mmol), sodium hydride (240 mg, 5 mmol), and anhydrous solvent (25 mL) is stirred (under reflux or at room temperature) for a certain period of time. Water (1 mL) is then added to quench the excess hydride. The solution is washed twice with water or extracted, then the organic layer dried over magnesium sulfate and evaporated. The reaction can be monitored by tlc (hexane–benzene 3:7) and the mixture separated by column chromatography (benzene).

(a) *In refluxing benzene* After a 22 h refluxing period, tlc shows mostly unreacted starting material and traces of benzophenone. Column chromatography affords 91% (315 mg) of unreacted benzophenone ketal (crystallization in methanol), identified by comparison with authentic material.

(b) *In refluxing toluene* After a 16 h refluxing period, tlc shows unreacted starting material and traces of benzophenone. Column chromatography affords 92% (320 mg) of unreacted ketal.

(c) *In refluxing ether* After a 6 h refluxing period and usual treatment, 96% (335 mg) of unreacted ketal is recovered by column chromatography.

(d) *In DME at 20°C* After a 17 h stirring period, ether (100 mL) and water (100 mL) are added to the mixture. The ethereal layer is decanted and treated in the usual manner. Column chromatography affords 88% (305 mg) of unreacted ketal and 8% (14 mg) of benzophenone.

(e) *In DMF at 20°C* After a 10 h stirring period, tlc shows consumption of nearly all the ketal, leading to benzophenone as the major product. Water (100 mL) is added to the mixture, followed by 2 extractions with dichloromethane. The organic layer is dried over magnesium sulfate and evaporated. Column chromatography affords 19% (65 mg) of unreacted ketal and 40% (70 mg) of benzophenone.

(f) *In DMSO at 20°C* After a 10 h stirring period, tlc shows consumption of nearly all the ketal, leading to benzophenone as the major product. Water (100 mL) is added to the mixture, followed by extraction with ether (100 mL). The organic layer is dried over magnesium sulfate and evaporated. Column chromatography affords 6% (20 mg) of unreacted ketal and 47% (85 mg) of benzophenone.

2. *Treatment of benzophenone ketal with sodium hydroxide*

A solution composed of ketal (347 mg, 1 mmol), dioxane (20 mL), and sodium hydroxide (20 mL of a 10% solution) is heated under reflux for a 12 h period. The solution is extracted with ether and the organic layer dried over magnesium sulfate and evaporated. Column chromatography affords 85% (295 mg) of unreacted ketal and traces of benzophenone (identified by tlc).

3. *Treatment of benzophenone ketal with sodium carbonate*

A solution composed of ketal (347 mg, 1 mmol), ethanol (20 mL), and sodium carbonate (20 mL of a 10% solution) is heated under reflux for a 9 h period. After evaporation of the ethanol, the mixture is extracted with dichloromethane. The organic layer is dried and evaporated. Column chromatography affords 95% (300 mg) of unreacted ketal.

4. *Treatment of benzophenone ketal with sodium ethoxide*

(a) *At 20°C* A solution of absolute ethanol (25 mL) and sodium (230 mg, 10 mmol) is added to a solution of ketal (347 mg, 1 mmol) in dioxane (5 mL). The mixture is stirred for a 24 h period, afterwards water (50 mL) is added, ethanol is evaporated, and the aqueous solution extracted with ether. The organic layer is dried over magnesium sulfate and evaporated. Column chromatography affords 94% (325 mg) of unreacted ketal.

(b) *Under reflux* After a 4 h refluxing period, the solution is treated as described above. Column chromatography affords 23% (80 mg) of ketal and 44% (80 mg) of benzophenone.

5. *Treatment of benzophenone ketal with potassium* tert-*butoxide*

(a) *At 20°C* A solution of anhydrous *tert*-butanol (25 mL) and potassium (195 mg, 5 mmol) is added to a solution of ketal (347 mg, 1 mmol) in dioxane (5 mL). The mixture is stirred for a 9 h period, afterwards water (50 mL) is added, *tert*-butanol evaporated, and the aqueous solution extracted with ether. The organic layer is dried over magnesium sulfate and evaporated. Column chromatography affords 85% (295 mg) of ketal and 10% (20 mg) of benzophenone.

(b) *Under reflux* After a 2 h refluxing period, the solution is treated as described above. Column chromatography affords 58% (106 mg) of benzophenone, the ketal being absent.

6. *Treatment of benzophenone ketal with sodium borohydride*

A solution of sodium borohydride (114 mg, 3 mmol) in ice-cold water (20 mL) is added, dropwise over a 15 min period, to a solution of ketal (347 mg, 1 mmol) in dioxane (10 mL). The mixture is stirred at room temperature for 1 h and extracted with ether (3 × 25 mL). The organic layer is dried over magnesium sulfate and evaporated. Thin-layer chromatography (benzene) shows that no reaction occurred and 95% (330 mg) of the ketal is recovered by crystallization in ether–methanol.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

7. *Treatment of benzophenone ketal with lithium aluminium hydride*

A solution of ketal (347 mg, 1 mmol) in anhydrous ether (20 mL) is added, dropwise over a 15 min period, to an ice-cold suspension of lithium aluminium hydride (114 mg, 3 mmol) in anhydrous ether (10 mL). The mixture is stirred at 0°C for 15 min, afterwards ice-cold water (10 mL) is added cautiously to destroy the excess hydride. The filtered orange suspension is then extracted several times with ether. The organic layer is dried over magnesium sulfate and evaporated to afford 295 mg of a reddish oil. Thin-layer chromatography (benzene) shows complete disappearance of the ketal and two unidentified products contaminated with colored impurities.

8. *Treatment of benzophenone ketal with sodium in ethanol*

To a stirred solution of ketal (347 mg, 1 mmol) in anhydrous DME (5 mL) and absolute ethanol (20 mL) is added small pieces of sodium (460 mg, 20 mmol). The suspension is periodically cooled in an ice bath to maintain a temperature of 20°C. After all the sodium has reacted, stirring is maintained for 30 min at room temperature, afterwards water (100 mL) is cautiously added. The solvents are evaporated and the aqueous layer extracted with dichloromethane. The organic layer is dried over magnesium sulfate and evaporated. Column chromatography affords 56% (194 mg) of unreacted ketal. Other compounds were not investigated.

9. *Treatment of benzophenone ketal with lithium diisopropylamide*

To a solution of ketal (250 mg, 0.729 mmol) in THF (10 mL), cooled to −78°C, is added 2.5 mL (0.9 mmol) of a solution of lithium diisopropylamide (prepared from 0.138 mL diisopropylamine and 0.625 mL of butyllithium (1.6 *M*) in 2 mL of THF). The colour of the solution changes rapidly from orange to black at the beginning of the addition. The mixture is stirred at −78°C for one hour without any evidence of reaction as shown by tlc (benzene). The temperature is then raised gradually to 0°C for one hour and the formation of a new product (benzophenone) is observed by tlc. After 6 h at 25°C, the reaction is quenched with 10% HCl, diluted with 10 mL water, and extracted with 2 × 20 mL CH_2Cl_2. The organic phase is dried on anhydrous magnesium sulfate and evaporated to dryness to yield a brown oil which is chromatographed on silica gel (50 g, 200:1) (benzene−hexane 1:1) to yield 61% (153 mg, 0.446 mmol) of recuperated ketal and 32% (43 mg, 0.236 mmol) of liberated benzophenone.

Stability of ketals in acidic medium

General procedure

Samples of the benzophenone ketal (10 mg, 0.029 mmol) in 0.5 mL THF are treated with 0.5 mL of the appropriate acid in water at 25°C. The acids chosen are: HCl 5%, AcOH 10%, oxalic acid (10 mg/0.5 mL water), H_2SO_4 10%, and *p*-TsOH (15 mg/0.5 mL water). Progress of the reaction is monitored by tlc (benzene) and the results are reported in Table 4. These results are to be compared with that of the ethylenedioxy ketal of benzophenone which is *completely hydrolyzed after 30 min* in HCl 5% in THF (1:1) at room temperature.

1-(Dialkylaminomethyl)-azetidin-2-ones. Intermediates in a highly stereoselective preparation of *trans*-3,4-disubstituted azetidin-2-ones

A. BEVIN HAMLET AND TONY DURST
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received June 4, 1982

A. BEVIN HAMLET and TONY DURST. Can. J. Chem. **61**, 411 (1983).

The use of dialkylaminomethyl derivatives as a new β-lactam N—H protecting group is described. The group is stable to basic reagents but is readily removed with dilute aqueous acids. 1-Dialkylaminomethyl derivatives bearing a 4-substituent are converted in good yield and with high stereoselectivity into *trans*-3,4-disubstituted derivatives via reaction with LDA and subsequent addition of electrophiles. The products of several of these sequences are of interest as intermediates to thienamycin related substances.

A. BEVIN HAMLET et TONY DURST. Can. J. Chem. **61**, 411 (1983).

On décrit l'utilisation des dérivés dialkylaminométhyles comme un nouveau groupe protecteur du N—H des β-lactames. Le groupe est stable en présence de réactifs basiques mais s'élimine facilement en solutions diluées d'acides. On transforme les dérivés dialkylaminométhyles-1 portant un substituant en position 4 avec un bon rendement et avec une grande stéréosélectivité en dérivés disubstitués *trans* en positions 3,4 par l'intermédiaire d'une réaction avec la LDA et l'addition subséquente d'électrophiles. Les produits de plusieurs de ces séries de réaction sont intéressants comme intermédiaire de substances apparentées à la thiénamycine.

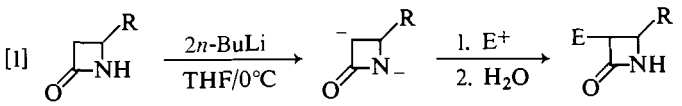
For personal use only.

In 1974 we showed that *N*-unsubstituted azetidin-2-ones (β-lactams) such as **1** reacted with two equivalents of *n*-BuLi at 0°C in THF to yield the dianion **2** (1). Subsequent trapping of **2** with a series of electrophiles furnished 3,4-disubstituted β-lactams in fair to good yield. The products were generally obtained as a mixture of *trans/cis* isomers in ratios varying between 3:1 and about 10:1 (eq. [1]).



1 *R* = Ph

2

3 *cis*
4 *trans*

The discovery of the potent antibiotic thienamycin, **5** (2), has placed importance on highly stereoselective routes to *trans*-3,4-disubstituted azetidin-2-ones bearing a free N—H group. Of particular interest as potential starting points to thienamycin or derivatives thereof are *trans*-3(1′-hydroxyethyl)-4-vinyl-azetidin-2-one **6** and *trans*-3(1′-hydroxyethyl)-4-(3′-butenyl)-azetidin-2-one, **7**, since the corresponding 3-unsubstituted derivatives **6***a* and **7***a*, respectively, have been used to prepare thienamycin itself, from **6***a* (3) the Δ-1 carbapenem (4) and carbapenam ring systems (5), and carbacephems[1] from **7***a*.

We would like to report a facile synthesis of **6** and **7**, both as a 1:1 mixture of stereoisomers in the 3-hydroxyethyl side chain and as samples considerably enriched in the desirable *trans-R*-isomer (thienamycin stereochemistry), starting with the readily available 4-vinyl- and 4(3′-butenyl)azetidin-2-ones, **6***a* and **7***a*, respectively, and utilizing dialkylaminomethyl groups as new, base-stable N—H protecting groups.

Discussion and results

The *tert*-butyldimethylsilyl group has previously been used as an N—H protecting group in β-lactams (6, 7). This group is stable to alkyllithiums and allows the generation of the mono-anion **8** through which a variety of substituents can be introduced at position 3 of the β-lactam ring. Most recently, Bouffard and Christensen (7) have completed a careful study of introduction of the thienamycin side chain into the 1-*tert*-butyldimethylsilyl-4-vinylazetidin-2-one, **8**. These authors reported that, under a variety of conditions, the lithium enolate of **8** reacted with acetaldehyde to give an 85:15 mixture of *trans/cis* isomers. The *trans*-isomer was obtained as an approximately 1:1 mixture of *R* and *S* side chain isomers. Considerably higher ratios of the desirable *trans-R* isomer (thienamycin isomer) could be obtained by first acylating and then reducing the 3-acyl derivative **10** with K-selectride.

Testa and co-workers (8) have reported that β-lactams react readily with secondary amines such as pyrrolidine and morpholine in the presence of 37% formaldehyde solution to afford 1-dialkylaminomethyl β-lactams. We felt that the dialkylaminomethyl group might serve as a useful and inexpensive base-stable protecting group, thereby enabling us to introduce substituents into the 3-position with the desirable *trans*-stereochemistry. The protecting group should be removable under mildly acidic conditions.

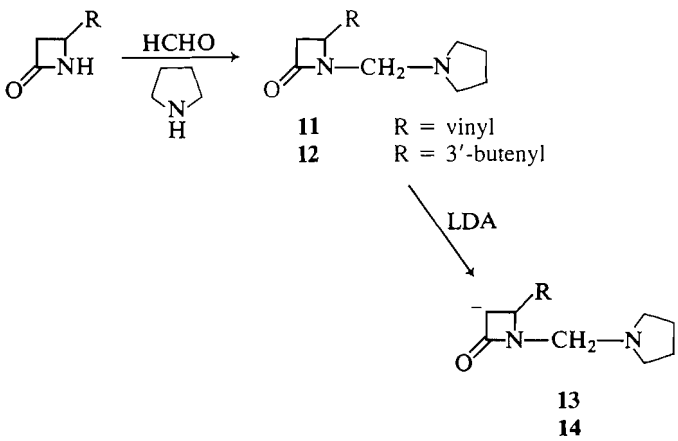
TABLE 1. Reaction of **13** and **14** with electrophiles

Reactant	Electrophile	Product (%)		Deprotection (5)	
13	CH_3CHO	[a]		**17**	(58)[b]
13	$(CH_3)_2CO$	[a]			(52)[b]
13	CH_3COEt	**19**	(63)	**21**	(72)[c]
13	PhCHO		(84)		(85)
13	Ph_2CO		(83)		(91)
13	I_2		(63)		
14	CH_3CHO	[a]			(74)
14	$(CH_3)_2CO$	[a]		**15**	(79)
14	CH_3CO_2Et	**20**	(68)	**22**	(71)[c]

[a]Not isolated.
[b]Overall yield.
[c]K-Selectride reduction and deprotection.

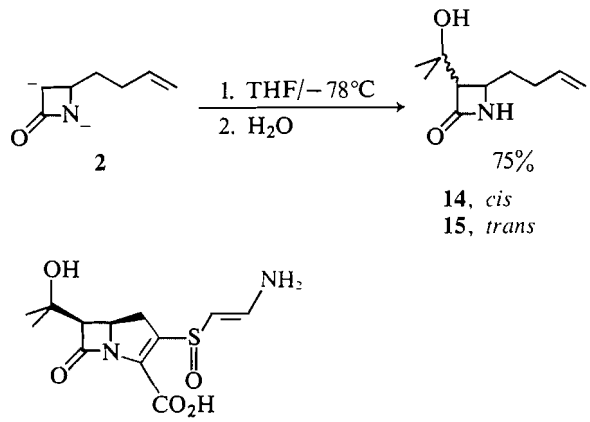


Reaction of **11** and **12**, prepared in 93 and 92% yield from 4-vinyl-, (**6***a*), and 4-(3′-butenyl)azetidin-2-one, (**7***a*), respectively, with LDA in THF at −78°C furnished, essentially instantaneously, the monanions **13** and **14**. These anions were combined with a number of electrophiles, among them acetaldehyde, acetone, ethyl acetate, benzaldehyde, benzophenone, and iodine. In each case the *trans*-3,4-disubstituted isomer was isolated as the sole product in yields varying from 63% for ethyl acetate to over 85% for benzophenone (Table 1).

In the case of the acetone adducts, we had available samples of the pure *cis*-isomers prepared by reaction of the dianion **2** (R = $CH{=}CH_2$ and R = $CH_2CH_2CH{=}CH_2$) with acetone. Thus, using nmr spectroscopy, we were able to place the upper limit of the *cis*-isomer in the reaction of **11** and **12** with acetone at less than 3%. Interestingly, the reaction of **1** (R = $CH_2CH_2CH{=}CH_2$) with acetone gave a 1:1 mixture of the *cis*- and *trans*-disubstituted isomers **15***a* and **15***b*, respectively.

The dialkylamino group, as expected, was readily removed under mildly acidic conditions such as refluxing in methanolic HCl (methanol − 1% aqueous HCl, 1:9) or 1:9 THF − 1% HCl for 4−6 h. The yields for this individual step were generally very good. In most cases, see Table 1, the initial adducts were not isolated but directly deprotected to yield the *N*-unsubstituted lactams.

The 1,3-dianion route appears to give greater amounts of the *cis*-3,4-disubstituted products than any of the monanion reactions (7, 9) and may therefore be of value in the preparation of carpetimycins, **16** (10), and derivatives. Generally the reactions of **2** show less selectivity than those of **13** and **14**, presumably due to the much higher reactivity of the dianions compared to the monanions.



16, carpetimycin A

For the other adducts the *trans* structures were assigned on the basis of the 1.8−2.0 Hz coupling constant between the remaining H(3) and H(4) (7). In the particular case of the reaction of **11** with acetaldehyde, the absence of significant amounts of the *cis* product accompanying the desired *trans*-isomer **17** was ascertained by nmr using the reported chemical shift value of H(3) in *cis*-**18** as model. The overall yield of **17**, obtained as a 1:1 diastereomer mixture from **11**, was 58%.

Highly stereoselective reductions of the 3-acyl derivatives **19** and **20** were obtained using the K-Selectride reduction procedures of Bouffard and Christensen (7). Thus **19** and **20** gave reduction products in 72 and 71% yield, respectively, in which the isomers **21** and **22**, having the desired relative stereo-

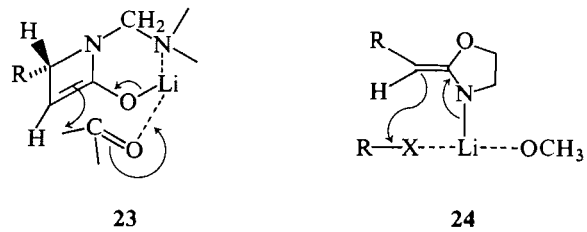

FIG. 1

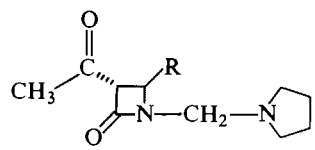
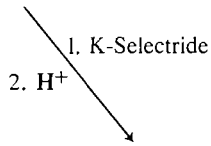
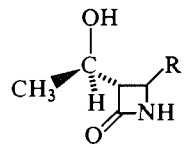
chemistry of thienamycin, predominated in ratios of 4:1 and 9:1. Reduction of **19** with $NaBH_4$ in ethanol gave an isomeric mixture in which **21** represented the minor isomer (1:2 ratio).



19 R = vinyl
20 R = 3′-butenyl





21 (4:1 diastereomer ratio)
22 (9:1 diastereomer ratio)

The higher *trans* selectivity shown in the reactions of the carbanions derived from **6** and **7** as compared with **8** is possibly related to an internal chelation invloving the pyrrolidine nitrogen (Fig. 1, **23**). Such a chelation, which should help deliver the electrophile from the same side as the chelating group, is similar to that proposed by Meyers *et al.* (11) as an explanation of the asymmetric induction observed in the alkylation of the carbanions obtained from optically active 2-alkyl-4-methoxyl-1,3-oxazolines (Fig. 1, **24**).

Experimental

Infrared spectra were recorded as films for liquids and in $CHCl_3$ solution for solids on a Unicam CP-1100 spectrophotometer. The nmr spectra were obtained using Varian HA-100 and T-60 spectrometers; peak positions are given in δ units. Melting points were taken on a Gallenkamp apparatus and are uncorrected. All reactions involving alkyl lithiums were carried out in freshly distilled anhydrous tetrahydrofuan (THF) and under N_2. Usual work-up refers to quenching the reaction with H_2O or aqueous NH_4Cl, extraction with CH_2Cl_2, drying the organic extracts over $MgSO_4$, and evaporation of the solvents under reduced pressure. For the sake of clarity the azetidin-2-one nomenclature is used through this section.

*1-Pyrrolidinomethyl-4(3′-butenyl)-azetidin-2-one, **12** (8)*

A solution of 4-(3′-butenyl)azetidin-2-one (3.0 g, 24 mmol), 2.01 mL of pyrrolidine, and 2.4 mL of 37% formaldehyde in 20 mL of ethanol was refluxed for 2 h. The solvent was evaporated and the crude yellowish oil was purified by distillation. The yield of colorless oil, bp 140–143°C/0.7 Torr, was 4.58 g (92%); ir: 1765 cm^{-1}; nmr: 1.5–2.2 (m, 8H), 2.4–2.7 (m, 5H), 3.05 (dd, J = 16, 5 Hz, 1H), 3.86 (d, J = 13.5 Hz, 1H), 4.12 (d, J = 13, 5 Hz, 1H), 4.9–6.2 (m, 3H): *Anal.* calcd. for $C_{12}H_{20}N_2O$: C 69.19, H 9.68; found: C 69.59, H 9.42.

*1-Pyrrolidinomethyl-4-vinylazetidin-2-one, **11** (8)*

Using the above procedure, 4.0 g (41 mmol) of 4-vinylazetidin-2-one, 4.1 mL of formaldehyde solution, and 3.44 g of pyrrolidine in 45 mL of ethanol afforded 6.87 g (93%) of **11** as a clear oil, bp 109–112°C/0.3 Torr; ir: 1760 cm^{-1}; nmr: 1.7–1.9 (m, 4H), 2.5–2.7 (m, 4H), 2.68 (dd, J = 16, 2 Hz, 1H), 3.23 (dd, J = 16, 5 Hz, 1H), 3.76 (d, J = 13.5 Hz, 1H), 4.14 (d, J = 13.5 Hz, 1H), 4.1 (m, 1H), 5.2–5.6 (m, 3H); *Anal.* calcd. for $C_{10}H_{16}N_2O$: C 66.23, H 8.95; found: C 66.68, H 9.25.

*Formation of lithio derivatives **13** and **14** and their reaction with electrophiles*

General procedure

Lithium diisopropylamide (LDA) was formed by addition of *n*-BuLi (2.4 *M* in hexane) to an equivalent amount of diisopropylamine in THF at −78°C. To the cold, well-stirred LDA solution (1.1 equiv.) was added 1.0 equiv. of the appropriate electrophile and the solution was kept at −78°C for an additional 10–20 min. Usual work-up gave the crude products which were purified by recrystallization on silica gel chromatography or hydrolyzed to the N–H lactams.

The hydrolysis of the 1-pyrroldinomethyl group was achieved by refluxing the protected lactams either with aqueous methanolic HCl or THF–aqueous HCl for 3 h. The hydrolyzed product was isolated by dilution with H_2O and extraction into CH_2Cl_2, drying the organic phase with $MgSO_4$, and evaporation of the solvent. Purification of the products was accomplished by recrystallization or column chromatography. Yields refer to purified materials (See also Table 1).

*Reactions of **13***

(a) *With benzophene*

To a solution containing 2.78 mmol of **13**, prepared from 500 mg of **11** in 10 mL of dry THF, was added 607 mg (3.3 mmol) of benzophenone. Work-up afforded 1.05 g of crude product which was recrystallized from ether–hexane to yield 830 mg (83%) of a white powder, mp 121–125°C.

The pyrrolidinomethyl group was removed by heating 400 mg (1.10 mmol) of the above product with 3 mL methanol and 18 mL of 1% HCl for 3 h. The crude product (280 mg) was recrystallized from ether–hexane to afford 200 mg (65%) of the *trans*-3,4-disubstituted products as fine white needles, mp 118–120°C; ir: 3450, 1760 cm^{-1}; nmr: 2.96 (O*H*), 3.98 (m, 2H), 4.8–5.8 (m, 3H), 6.1 (N*H*), 7.1–7.6 (m, 10H). *Anal.* calcd. for $C_{18}H_{17}NO_2$: C 77.40, H 6.13; found: C 77.37, H 6.12.

(b) *Benzaldehyde*

A solution of 2.8 mmol of **13** in 8 mL of dry THF was reacted with 3.3 mmol of freshly distilled benzaldehyde. Column chromatography (ethyl acetate – hexane 2:1) furnished 667 mg (85%) of a viscous oil which was hydrolyzed as above to yield 85% of a 2:1 isomeric mixture of *trans*-3,4-disubstituted product as pale yellow crystals, mp 93–98°C (CH_2Cl_2–hexane); nmr: 3.2 and 3.3 (2 dd, J = 6.0 and 2.0 Hz for each, ratio 2:1, 1H), 3.85–4.0 and 4.25–4.35 (m, 1H).

(c) *Acetone*

An excess of acetone (1.0 mL) was added to a solution of the monoanion **13** prepared from 400 mg of **11** at −78°C. Work-up gave

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

a crude product which was hydrolyzed by refluxing in a mixture of 5 mL THF and 25 mL of 1% HCl for 3 h. The deprotected 3,4-*trans* adduct (1) was obtained in 52% overall yield as an oil; ir: 3480, 1760 cm^{-1}; nmr: 1.23 and 1.40 (2s, 6H), 2.90 (d, J = 2 Hz, 1H), 3.4 (OH, exchangeable), 4.4–4.5 (m, 1H), 5.0–6.2 (m, 3H), 6.7 (N–H, exchangeable).

(d) *Acetaldehyde*

An excess of freshly distilled acetaldehyde (2.5 mL) was added to a stirred solution of **13** obtained from 2 g of **11** in 51 mL of THF at −78°C. This reaction sequence was continued as in the case of acetone. The crude deprotected product was purified on silica gel using 1:2 ethyl acetate – hexane. The yield of **17** was 58%; ir 3450, 1750 cm^{-1}; nmr: 1.26 and 1.32 (2d, J = 6 Hz, 3H), 2.91 (dd, J = 6, 2 Hz, 1H), 3.6 (OH, exchangeable), 4.0–4.3 (m, 2H), 2.1–6.1 (m, 3H), 6.9 (N—H, exchangeable); ms: $M^{+\cdot}$ 123 (M − H_2O). *Anal.* calcd. for $C_7H_{11}NO_2$: C 59.56, H 7.86, N 9.22; found: C 59.54, H 8.24, N 10.18.

(e) *Iodine*

trans-3-Iodo-4-vinylazetidin-2-one (1) was obtained in 63% overall yield from **11** using 500 mg **11** and 846 mg I_2. The crude initial adduct was immediately hydrolyzed in a 5 mL methanol – 25 mL 1% HCl mixture and the final product purified on column chromatography using 4:1 hexane – ethyl acetate as eluant; nmr: 4.33 (dd, J = 7, 2 Hz, 1H), 4.6 (m, H), 5.3–6.1 (m, 3H), 6.8 (NH, exchangeable).

(f) *Ethyl acetate*

Ethyl acetate (2.6 mL) was reacted with **13** prepared from 4.0 g of **11**. The crude product was purified on hplc (4:1 ethyl acetate – hexane). The 3-acetyl derivative **19** (3.10 g, 63%) thus obtained was quite labile and generally reduced immediately to the 3-hydroxyethyl derivative (see below); ir: 1760, 1712 cm^{-1}; nmr: 1.7–2.1 (m, 4H), 2.32 (s, 3H), 2.5–2.7 (m, 4H), 3.84 (d, J = 14 Hz, 1H), 4.22 (d, J = 14 Hz, 1H), 3.97 (d, J = 2 Hz, 1H), 4.54 (dd, J = 7, 2 Hz, 1H), 5.2–5.9 (m, 3H).

(*i*) *Reduction with sodium borohydride*

The 3-acetyl adduct (800 mg, 3.60 mmol) obtained above was dissolved in 25 mL of ethanol, cooled to −30°C, and reacted with 680 mg (5.2 equiv.) of sodium borohydride for 2 h. The reaction was quenched with saturated NH_4Cl solution, extracted once with 25 mL of ether and 4 times with 25 mL of CH_2Cl_2. The crude product was purified on silica gel using 2:1 ethyl acetate – hexane as eluent. Yield: 577 mg (72%); nmr: 1.26 and 1.35 (2d, J = 6 Hz, 3H), 1.7–1.9 (m, 4H), 2.5–2.8 (m, 4H), 2.93 (dd, J = 7, 2 Hz, 1H), 3.84 (d, J = 13 Hz, 1H), 4.2 (d, J = 13 Hz, 1H), 4.1–4.3 (m, 1H), 5.1–6.1 (m, 3H).

The pyrrolidino group was removed in the usual way using aqueous methanolic HCl. The yield of **17** was 60%; nmr spectroscopy indicated a 2:1 diastereomeric mixture in which the "thienamycin isomer" is disfavoured.

(*ii*) *K-Selectride reduction* (8)

To a solution of 450 mg (2.1 mmol) of 3-acyl derivative and 344 mg of KI in ether at 25°C was added 12.4 mL of K-Selectride (0.5 *M* in ether, 3 equiv.) The reaction mixture was worked up as usual to give 276 mg (60%) of reduced product. The relative intensities of the two methyl doublets indicated an approximately 4:1 diastereomer mixture favouring the "thienamycin isomer."

*Reaction of **14** with electrophiles*

(a) *Acetone*

To a solution of **14** prepared from 1.0 g of **12** in 10 mL of THF at −78°C was added 2.5 mL of reagent grade acetone. The crude adduct obtained after usual work-up was hydrolyzed in a 1:6 mixture of THF – 1% HCl to give, after purification, 694 mg (79%) of **15**. ir: 3450, 1755 cm^{-1}; nmr: 1.24 and 1.40 (2s, 6H), 1.6–2.2 (m, 4H), 2.76 (d, J = 2 Hz, 1H), 3.6 (m, 1H), 5.6–6.3 (m, 3H).

(b) *Acetaldehyde*

Compound **12** 1.86 g, 8.9 mmol) was converted in the usual way to its lithio derivative and reacted with acetaldehyde. The crude product thus obtained was immediately hydrolyzed in THF – aqueous HCl to yield, after chromatography (1:2 ethyl acetate – hexane), 1.12 g (74%) of *trans*-3(1′-hydroxyethyl)-4(3′-butenyl)azetidin-2-one as a 1:1 diastereomer mixture. Infrared: 3450, 1755 cm^{-1}; nmr: 1.27 and 1.32 (2d, J = 7 Hz, 3H), 1.64–1.85 (m, 2H), 2.0–2.4 (m, 2H), 2.81 (dd, J = 6.5, 2 Hz, 1H), 3.2 (OH, exchangeable), 3.4–4.8 (m, 1H), 3.9–4.3 (m, 1H), 5–6.1 (m, 3H), 6.7 (NH, exchangeable); ms: $M^{+\cdot}$ 151 (m − H_2O). *Anal.* calcd. for $C_9H_{15}NO_2$: C 63.88, H 8.93, N 8.28; found: C 63.63, H 9.34, N 7.92.

(c) *Ethyl acetate*

The protected lactam (5.0 g) was lithiated and acylated in the usual manner. The intermediate 3-acyl derivative **20** was purified by hplc using 4:1 ethyl acetate – hexane as eluant. Yield 4.37 g (73%); ir: 1744, 1715 cm^{-1}; nmr: 1.7–2.2 (m, 8H), 2.33 (s, 3H), 2.5–2.7 (m, 4H), 3.93 (d, J = 2Hz, 1H), 3.77 (d, J = 13.5 Hz, 1H), 4.27 (d, J = 13.5 Hz, 1H), 4.1 (m, 1H), 4.9–6.2 (m, 3H):

(*i*) *Reduction of **20** with sodium borohydride*

Acyl derivative **20** (750 mg, 3 mmol), was reduced with $NaBH_4$ (57 mg) in ethanol at −30°C for 2 hours. Work-up as in the case of **19** afforded 530 mg (71%) of the 3-hydroxyethyl derivative as a 1:2 diastereomer mixture (see also below). Hydrolysis in aqueous methanolic HCl gave **22** in 68% yield.

(*ii*) *K-Selectride reduction*

The 3-acyl lactam (4.6 g, 18.4 mmol) was reduced with 3 equivalents of K-Selectride as described for compound **19**. Purification of the crude product by chromatography on silica gel afforded 3.0 g (65%) of protected **22**; nmr: 1.26 (d, J = 6 Hz, only a single doublet could be seen), 1.6–2.13 (m, 8H), 2.76 (dd, J = 7, 2 Hz, 1H), 3.0 (OH, exchangeable), 3.76 (d, J = 13 Hz, 1H), 4.10 (J = 13 Hz, 1H), 3.6–4.2 (m, 2H), 4.8–6.1 (m, 3H).

Hydrolysis in refluxing aqueous HCl–methanol (6:1) afforded **22** essentially as a single diastereomer since only the δ 1.27 methyl doublet remained. The major isomer in the K-Selectride reaction has the same relative stereochemistry as thienamycin and is opposite to that obtained upon $NaBH_4$ reduction.

Reaction of 1,3-dilithio-4(3′-butenyl)azetidin-2-one with acetone

n-BuLi (8.0 mL, 2.0 *M* in hexane) was slowly added to a solution of 1.0 g of 4-vinylazetidin-2-one dissolved in THF at 0°C. After 30 min, the dark solution was quenched with excess acetone (2.5 mL). Usual work-up, followed by filtration through a short silica gel column, afforded 1.09 g (75%) of a 1:1 *cis*/*trans* diastereomer mixture. More careful chromatography gave a separation of the isomers. The *cis*-isomer was obtained as colorless crystals, mp 118–120°C. For the *cis*-isomer, ir: 1755, 3450 cm^{-1}; nmr: 1.35 and 1.46 (2s, 6H), 1.8–2.3 (m, 4H), 3.25 (d, J = 6 Hz, 1H), 3.6–3.9 (m, 1H), 4.9–6.0 (m, 3H). For the *trans*-isomer, ir: 3450, 1755 cm^{-1}; nmr: 1.24 and 1.40 (2s, 6H), 1.6–2.2 (m, 4H), 2.76 (d, J = 2 Hz, 1H), 3.6 (m, 1H), 5.0–6.3 (m, 3H). *Anal.* (for *cis*.) calcd. for $C_{10}H_{17}NO_2$: C 65.65, H 9.35, N 7.64; found: C 65.43, H 9.40, N 7.59.

Fractionation of lignosulphonates released during the early stages of delignification

NORMAN G. LEWIS, DAVID A. I. GORING, AND ALFRED WONG
Pulp and Paper Research Institute of Canada, 570 St. John's Boulevard, Pointe Claire, P.Q., Canada H9R 5J9

Received August 3, 1982

NORMAN G. LEWIS, DAVID A. I. GORING, and ALFRED WONG. Can. J. Chem. **61**, 416 (1983).

High-yield spent bisulphite liquor (HY-SBL) from sulphonated black spruce wood (*Picea mariana*) was fractionated by gel permeation chromatography (GPC) and by high-performance liquid chromatography (HPLC). The GPC fractionation gave a wide bimodal distribution, whereas with HPLC, a more detailed resolution was seen with the bulk of the fraction giving several clearly defined peaks. The paucidisperse material was further concentrated by a bulk fractionation of the crude SBL which included complexing the lignosulphonates with dicyclohexylamine. The isolated paucidisperse material was found to be dialyzable and to constitute 90% of the lignosulphonate in the sample of SBL. If the bisulphite pulp obtained was recooked in fresh acid sulphite liquor to a lower yield, most of the lignosulphonate dissolved was widely polydisperse with no indication of the discrete components resolvable by HPLC. However, 25% of the lignin made soluble was in the form of the paucidisperse fractions. In all, we were able to obtain about 50% of the lignin in spruce wood as a relatively low molecular weight lignosulphonate resolvable into discrete fractions by HPLC.

NORMAN G. LEWIS, DAVID A. I. GORING et ALFRED WONG. Can. J. Chem. **61**, 416 (1983).

De la lessive résiduaire au bisulfite à haut rendement (LRB–HR) de bois d'épinette noire sulfoné (*Picea mariana*) a été fractionée par chromatographie de perméation en gel (CPG) et par chromatographie liquide à haute résolution (CLHR). Le fractionnement CPG a donné une large distribution bimodale, tandis que la CLHR a permis une résolution plus détaillée du matériel dont la principale fraction a été scindée en plusieurs pics bien distincts. Le matériel paucidispersé a été concentré ultérieurement au moyen d'un fractionnement grossier de la LRB d'origine comprenant la formation d'un complexe entre les lignosulfonates dans l'échantillon de LRB. Si la pâte au bisulfite obtenue subissait une nouvelle cuisson dans une lessive fraiche de bisulfite acide jusqu'à un rendement plus faible, la majeure partie des lignosulfonates dissous étaient polydispersés et la plupart des constituants ne semblaient pas séparés par CLHR. Cependant, 25% de la lignine rendue soluble l'était sous la forme de fractions polydispersées. Nous avons pu obtenir environ 50% de la lignine du bois d'epinette sous la forme de lignosulfonates de poids moléculaire relativement bas et pouvant être fractionnés par CLHP.

Introduction

Lignin removal by sulphonation under acidic conditions has been studied for many wood species. Unfortunately, despite numerous investigations, detailed chemical characterisation of these soluble, sulphonated lignin (or lignin-derived) materials have achieved only limited success. For example, an in-depth study of the lignosulphonates obtained from an acid sulphite treatment of the angiosperm, wattle wood (*Acacia mearnsii*) resulted in the isolation and identification of only six sulphonated compounds which were structurally related to sinapyl alcohol (1). Similar studies with the gymnosperms, western hemlock (*Tsuga heterophylla*), and white fir (*Abies lasiocarpa*) afforded materials presumably derived from coniferyl alcohol (2). However, in both studies, these identified components only constituted 1–2% of the original lignin content of the wood.

Previous attempts to fractionate the bulk of the lignosulphonic acids have been based largely upon separations according to molecular size differences by gel permeation chromatography (GPC). For these applications, however, poor resolution constitutes a severe disadvantage, as evidenced, for example, by the incomplete separation of a mixture reported to contain an homologous series of lignosulphonic acids (3). In a similar study, it was estimated that as much as 17% of the lignosulphonate obtained from mixed softwood species, existed as either discrete substances or groups of substances (4, 5). However, in more recent studies, lignosulphonates obtained by the partial delignification of western hemlock were compared with corresponding material derived from milled wood lignin (MWL) (6–8). GPC fractionation, as before, suffered from poor resolution of the lignin-derived components. Indeed, further fractionation and refractionation of such lignosulphonates, as their acetylated lignosulphonic methyl esters, led these authors to conclude that these materials were either in equilibrium with one another (7) or were unstable to further manipulations (8). It is apparent, therefore, that since limited chromatographic resolution has been achieved in previous work, there is a necessity for a rapid and reliable fractionating technique with enhanced resolution.

Experimental

GPC conditions are described in Fig. 1. Sephadex G-50F was obtained from Pharmacia Fine Chemicals. A peristaltic pump (Pharmacia P-1) was used to ensure flow stability.

HPLC analyses were carried out using a Hewlett-Packard liquid chromatograph, model HP 1084B, equipped with a variable wavelength detector set at 280 nm. Columns used were protein I-250, I-125, and I-60 purchased from Waters Associates. All analyses were carried out at pH = 3.0. Samples were adjusted to this pH by addition of 1.0 *M* citric acid or 1.0 *M* disodium hydrogen phosphate, as required.

All solvents (and dicyclohexylamine) were redistilled prior to use. The silica gel used was obtained from Merck, graded Keiselgel 60, 70–230 mesh ASTM.

All uv analyses were carried out using a Pye Unicam SP 8000 instrument. Samples were dissolved in buffer solution (pH = 7.8, 0.1 *M* KH_2PO_4/Na_2HPO_4).

Experiment 1. Preparation of pulp and HY-SBL

Spruce wood chips (2 kg, dry weight, Klason lignin content: 26.8 g/100 g) were steam pretreated (pressure = 138 kPa, 3 min, 3 cycles) in a 20 L batch digester. The wood was then exposed to a sodium-based bisulphite solution (10 L; total SO_2: 2.7%; free SO_2: 1.38%; pH = 3.0). Pulping conditions were as follows: (*i*) temperature raised

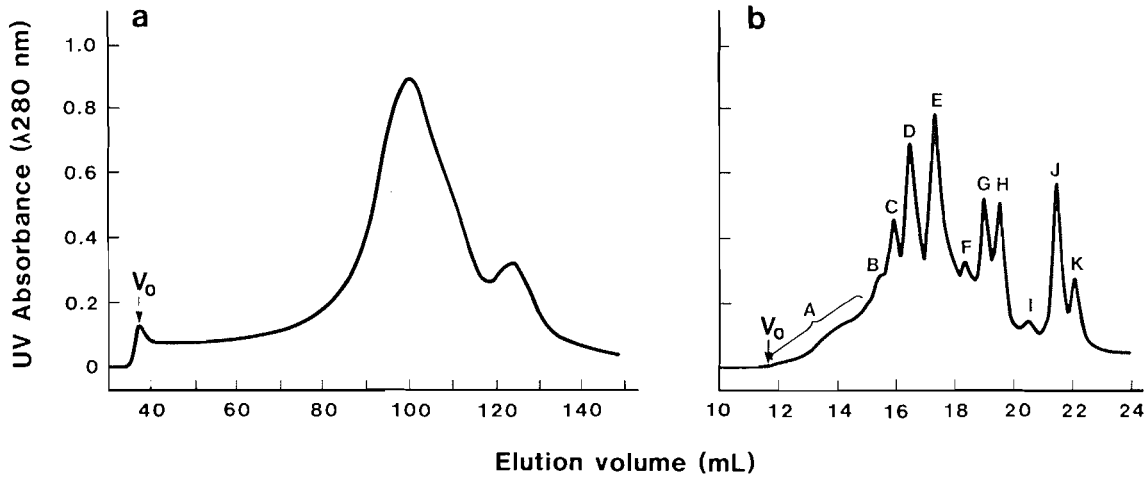

FIG. 1. Chromatograms of dissolved uv-absorbing materials present in an HY-SBL from spruce wood by (*a*) GPC and (*b*) HPLC. (*a*) Sephadex G-50F (10 g) in a glass column (dimensions 65 × 1.5 cm i.d.) and eluted with 0.2 mol/L Li_2SO_4. Flow 1 mL/min. (*b*) Waters I-125 and I-60 protein columns in series and eluted with 50 m*M* citric acid/Na_2HPO_4 buffer, pH 3.0. Flow = 1 mL/min. V_0 = void volume.

from 20°C to 85°C in 10 min, then held for 30 min at 85°C, with maximum pressure = 41.4 kPa and (*ii*) temperature raised from 85°C to 155°C in 120 min and held for 160 min at 155°C with maximum pressure = 483 kPa.

The resulting pulp (1.52 kg dry weight; 76.3% yield, with a Klason lignin content = 22.8 g/100 g pulp) was then removed by filtration to recover the SBL (12 L, solids content = 5.68 g/100 g).

Experiment 2. Fractionation of uv-absorbing materials from SBL

Spent bisulphite liquor (450 mL, pH = 3.0) isolated from Experiment 1 was concentrated down to 116 mL at 35°C under reduced pressure. The concentrate was adjusted to pH = 2.0 with 3.48 *M* sulphuric acid (5.4 mL) and then extracted with *n*-BuOH (2 × 100 mL). The *n*-BuOH solubles were backwashed with water (2 × 50 mL) which was then added to the aqueous solubles. The *n*-BuOH solubles were then evaporated down to dryness to yield extract I (0.766 g, ϵ_{280} = 9.4 L cm^{-1} g^{-1}) in Table 1.

The aqueous phase was further treated as follows. (*i*) 3.48 *M* sulphuric acid (5.4 mL) added and the system then extracted with *n*-BuOH (200 mL) containing dicyclohexylamine (10 mL). (*ii*) The resulting aqueous phase was reacidified and extracted as described in (*i*) and then further extracted with *n*-BuOH (1 × 100 mL). Steps (*i*) and (*ii*) were then repeated with the aqueous phase (3×).

The *n*-BuOH solubles from the dicyclohexylamine extractions were combined and reduced in volume by azeotroping with water to about 50 mL (35°C, reduced pressure), and then dissolved in chloroform–methanol (50 mL, 1:1 v/v). These solubles were rapidly chromatographed on silica gel (200 g, 70–230 mesh) by eluting the column with chloroform–methanol (800 mL, 1:1 v/v). Removal of the solvents afforded the yellowish-white foam, Extract II (29.9 g).

The aqueous solubles remaining, following the *n*-BuOH/dicyclohexylamine extractions, were adjusted to pH = 7.0 (with 1.0 *M* sodium hydroxide), then extracted with diethyl ether, concentrated under reduced pressure, and freeze-dried to give the white solid, Extract IV (18.8 g) in Table 1.

TABLE 1. Relative distribution of uv-absorbing materials following extraction as shown in Fig. 3

Sample	% uv absorbance*
Crude HY-SBL	100
Extract I	8.10
Extract III	73.00
Extract IV	15.00
%Recovery	96.10

*λ = 280 nm.

Experiment 3. Release of uv-absorbing material complexed with dicyclohexylamine

Extract II (100 mg) from Experiment 2 was dissolved in chloroform–methanol (30 mL, 2:1 v/v) and then extracted with 0.1 *M* sodium hydroxide (3 × 10 mL). The sodium hydroxide solubles were combined and backwashed with diethyl ether (2 × 25 mL) and then neutralized with 1.0 *M* sulphuric acid to give Extract III in Table 1. (N.B. for GPC studies, extract II was extracted with 0.1 *M* lithium hydroxide.)

Experiment 4. Dialysis of aqueous solubles (Extract IV)

The freeze-dried material (18.6 g) from Experiment 2 (Extract IV) was dissolved in water (180 mL), placed in an Amicon ultrafiltration unit (Model TCF 10) containing a membrane (De Danske Sukkerfabrikker FS60PP, nominal molecular weight cut-off of 30 000) and dialysed as follows: (*i*) water, 200 mL; (*ii*) 50 m*M* citric acid/disodium hydrogen phosphate buffer, pH = 3.0, 250 mL; and (*iii*) water, 500 mL.

The solution was then reduced in volume (to ca. 50 mL), removed from the apparatus, adjusted to pH = 7.0 with 0.1 *M* sodium hydrox-

iii	2.22	70.6	13.8

*Corrected for excess SO_2 in liquor.

ide (4.08 mL), and freeze-dried to give a white solid (1.55 g, ϵ_{280} = 4.6 L cm^{-1} g^{-1}) which contained 74.3% of the original uv absorbance in Extract IV.

Experiment 5. Resulphonation of HYB pulp

(*i*) Moist bisulphite pulp (30 g, moisture content 61.1%) from Experiment 1 was taken and placed in pH = 2.0 acid sulphite solution (200 mL, 1% Na^+, 6% SO_2) in a stainless steel bomb (250 mL). The temperature was then raised to 130°C in 45 min, held at this temperature for 3 h, and then cooled rapidly. The pulp was then filtered and washed copiously with distilled H_2O to remove any solubles.

This experiment was repeated as described above except for the time of reaction. The results are given in Table 2.

Experiment 6. Dialysis of SSL from resulphonation of a bisulphite pulp

The SSL sample from Experiment 5 (*i*) was dialysed (see Experiment 4 for apparatus used) as follows: (*a*) 385 mL were concentrated to 100 mL at pH = 2.0 and then (*b*) dialysed with water (1000 mL). The concentrate was removed and adjusted to pH = 7.0 with 0.1 *M* sodium hydroxide (10.5 mL) and freeze-dried. This procedure was also adopted for the SSL samples from Experiments 5 (*ii*) and (*iii*). The results are given in Table 3.

Results and discussion

As can be seen from Fig. 1, an HPLC technique, which is designed primarily for protein separations, provided a considerable improvement in the resolution of the components present in a sample of crude, high yield spent bisulphite liquor (HY-SBL) obtained from the pulping of black spruce (*Picea mariana*) when compared to standard gel permeation chromatography.

During the HPLC separation, specific fractions were collected every 15 s and then re-analysed under the same operating conditions. Selected ones are shown in Fig. 2. Fractions obtained during the elution of A (Fig. 1*b*) showed narrow single peaks as evidenced by the representative fraction A_2 (Fig. 2*a*). However, these fractions displayed only polydisperse behaviour since no discernible resolution into individual components occurred. All subsequent fractions collected, however, showed single peaks (for example, E, shown in Fig. 2*b*). In cases where an overlap of components occurred at the point of collection, multiple peaks indicative of mixtures were clearly evident. This is shown in Fig. 2*c* by a fraction that contained both C and D components. Note also that if the 50 individual chromatograms obtained for the re-analysis were combined, an exact facsimile to the chromatogram in Fig. 1*b* would be realised.

We also found that the paucidisperse material (i.e., components B to J in Fig. 1*b*) could be removed from the crude SBL by dialysis using an ultrafiltration membrane with a nominal molecular weight cut-off of 30 000. This suggests that the components of interest have a lower molecular weight than this cut-off value.

It is important to note that the HPLC separation described above may not be due simply to size separation since the columns used possess some ionic and reverse phase characteristics.[1] Thus, if the buffer solution was replaced by water, ionic repulsion would occur resulting in material being eluted at the void (i.e., exclusion) volume, V_0. Buffer concentrations and pH affect the separation and elution volume. For the present work, we chose the conditions given in the Experimental section which are judged to be optimum.

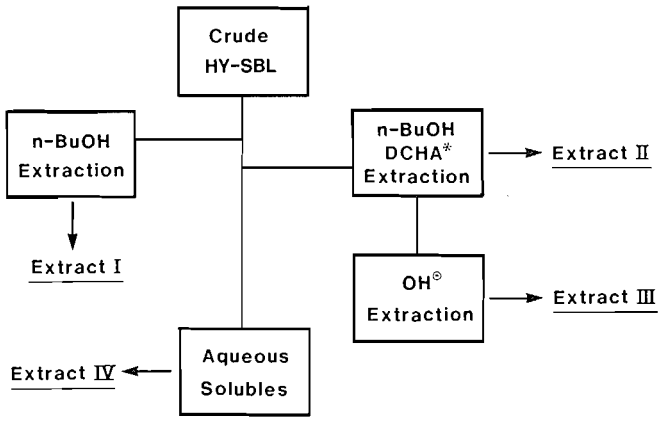

FIG. 3. Extractive fractionation of HY-SBL.
*DCHA = dicyclohexylamine.

Separations of the type shown in Fig. 1 were amenable only to sub-milligram quantities. We undertook, therefore, a bulk fractionation in order to remove both the high and the very low molecular weight material and, thus, to enrich the preparation with the discrete components shown in Fig. 1*b*. The procedure used is shown in Fig. 3 and the proportion of uv-absorbing substances in the various fractions is given in Table 1. About 8% of the uv-absorbing substances were removed (Extract I, Fig. 3) by the initial extraction with *n*-butanol (*n*-BuOH) and they probably consisted mostly of monomeric lignosulphonates (9). The lignosulphonic acids in the aqueous fraction were then complexed with dicyclohexylamine and the complex extracted with *n*-BuOH (10). As can be seen from Table 1, this fraction (Extract III) contained most of the uv-absorbing materials (ca. 75%). Treatment of this complex with sodium hydroxide (see Experimental section) released the lignosulphonates into the aqueous phase and the amine was subsequently removed by extraction with diethyl ether. After pH adjustment, Extract III was analysed by HPLC and GPC (see Fig. 4). It is immediately obvious that on comparison with the original crude SBL (see Fig. 1), considerable simplification of the chromatogram has occurred. Fractions A and K were no longer present.

Following the extraction procedure as described, the residual aqueous solution (Extract IV, Fig. 3) was found to contain mainly higher molecular weight material as evidenced by GPC and HPLC (see Fig. 5). Note that more suitable HPLC columns were used for this molecular size range. If the paucidisperse fractions were removed by dialysis (see Experimental section), the non-dialysable moiety was found to consist almost entirely of polydisperse material solubilised during delignification (Fig. 5*c*). This material has a low extinction coefficient (ϵ_{280} = 4.6 L cm^{-1} g^{-1}); this difference is probably due to the presence of non-dialysable polysaccharides (11).

It was also of interest to establish whether any additional paucidisperse material could be released by recooking the previously cooked fibres in acid sulphite liquor over different time periods (see Experiments 5, 6). About 75% of the material isolated from the low-yield spent sulphite liquor (LY-SSL) after recooking was polydisperse (see Table 3). However, the paucidisperse components removed by dialysis again showed some resolution by HPLC of the type shown in Figs. 1*b* and 4*b*.

It is quite evident that the HPLC method has given a greatly improved fractionation when compared to conventional Sephadex GPC. We believe this fractionation to be genuine since (*i*) the pattern persists before and after complexing with dicyclohexylamine and (*ii*) the components responsible for the peaks are isolable and reproducible upon further fractionation. It is our opinion that if the chromatograms of all the lignosulphonate extracts obtained by the bisulphite and sulphite treatment as described are taken into account, then approximately 50% of the lignin in spruce wood after sulphonation is isolable in paucidisperse form. It is interesting to note that this finding was anticipated by work published in 1964 (11). Lignosulphonates formed at various stages of delignification (0–95% removal) were isolated, almost immediately upon dissolution from spruce wood, by means of a continuous flow acid sulphite process. About 35% of the lignin sulphonates made soluble were removable by dialysis through a cellophane membrane. Resulphonation of high molecular weight non-dialysable lignosulphonates, whilst causing a net decrease in molecular weight, did not provide any appreciable quantities of dialysable material. This behaviour is in accord with our present recooking experiments.

The results of our present work support the view (11) that there are at least two broad classes of lignosulphonic acids produced on sulphite pulping of spruce wood, as depicted in Table 4. Type I lignosulphonates consist of dialysable material

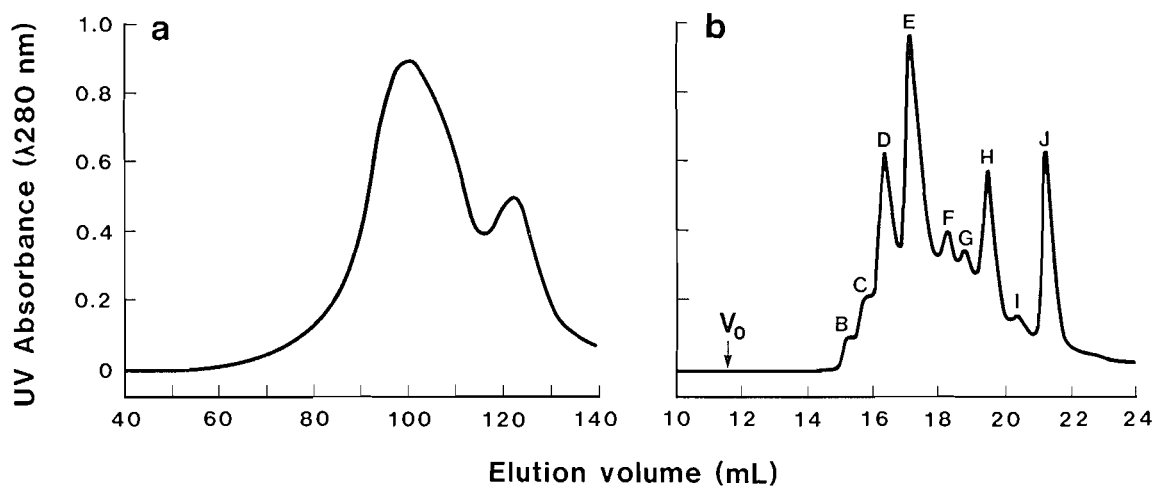

FIG. 4. Chromatograms of uv-absorbing material obtained by hydroxide treatment of lignosulphonate–DCHA complex. (*a*) GPC and (*b*) HPLC (see Fig. 1 for chromatographic conditions).

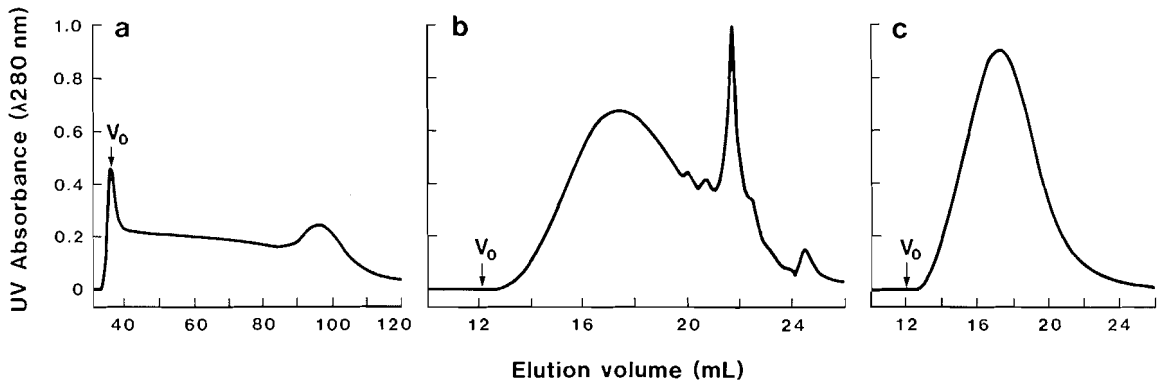

FIG. 5. Chromatograms of uv-absorbing residuals in aqueous solution following extraction with *n*-BuOH/DCHA. (*a*) GPC, (*b*) HPLC, and (*c*) non-dialysable components from (*b*). Chromatographic conditions are as for Fig. 1 except that for (*b*) and (*c*) columns used were Waters I-250 and I-125 in series.

TABLE 4. Polydispersity of lignosulphonates present in spent sulphite liquors from spruce wood

Lignosulphonic acid	Molecular size differences	Polydispersity	Percentage in HY-SBL*	Percentage in LY-SSL†
Type I	Dialysable	Paucidisperse	90	25
Type II	Non-dialysable	Widely polydisperse	10	75

*% Lignin removed = 36%.
†Remaining lignin removed on recooking = 64%.

whose average molecular weight is presumably higher than that of a simple sulphonated coniferyl alcohol derivative. Type II lignosulphonate is widely polydisperse, non-dialysable, and has a high average molecular weight, as would be expected from earlier studies (11).

The parallel between our Type I lignosulphonates and the hemilignin of Forss and Fremer (3) is apparent.

Many questions remain and are currently being addressed. For example: (*1*) Are the Type I lignosulphonates composed of isolable, individual molecular entities? If so, what are the detailed chemical structures of these components? (*2*) Is the random three-dimensional infinite polymeric network model for lignin (12–18) compatible with the observable paucidispersity of the Type I lignosulphonates? (*3*) Are Type I or Type II lignosulphonates associated with any particular morphological region in the wood? (*4*) Are Type II lignosulphonates produced by polymerisation of the protolignin during the sulphonation? This possibility cannot be entirely eliminated since it has been shown that SBL from spruce wood can be induced, by further thermal treatment, to undergo polymerisation to yield higher molecular weight material (19). (*5*) Can we produce a higher proportion of Type I material by altering the conditions of delignification?

More efficient use of the soluble lignins from high yield pulping processes may be facilitated by finding the answers to such questions.

The iodo-Tamoxifens: molecular structures and syntheses of estrogens for external imaging of carcinoma

DUNCAN H. HUNTER,[1] NICHOLAS C. PAYNE,[1] ASADUR RAHMAN, JOHN F. RICHARDSON, and YOLANDA ZEA PONCE
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 26, 1982

DUNCAN H. HUNTER, NICHOLAS C. PAYNE, ASADUR RAHMAN, JOHN F. RICHARDSON, and YOLANDA ZEA PONCE. Can. J. Chem. **61**, 421 (1983).

The *E*- and *Z*-isomers of an iodo-Tamoxifen **1** (1-(*p*-(β-dimethylaminoethoxy)phenyl)-2-(*p*-iodophenyl)-1-phenyl-1-butenes) have been prepared from the corresponding *E*- and *Z*-amino-Tamoxifens **2** (2-(*p*-aminophenyl)-1-(*p*-(β-dimethylaminoethoxy)phenyl)-1-phenyl-1-butenes) and the molecular structures have been determined from three dimensional X-ray data. Crystals of *E*-**1** are triclinic, space group $P\bar{1}$, with $Z = 2$ in a cell of dimensions $a = 10.714(2)$, $b = 14.125(3)$, $c = 8.240(2)$ Å, $\alpha = 95.78(1)$, $\beta = 92.91(1)$, and $\gamma = 71.41(1)°$; those of *Z*-**1** are monoclinic, space group $P2_1/n$, with $Z = 4$ and cell dimensions $a = 12.675(2)$, $b = 19.553(3)$, $c = 9.483(1)$ Å, and $\beta = 92.22(1)°$. Intensity data collected on an automated four circle diffractometer were used for full-matrix least-squares refinement on *F*, which converged for *E*-**1** at $R = 0.054$, 2736 observations, and for *Z*-**1** at $R = 0.042$, 3644 observations. The solution of these structures determines the configuration of these isomers as well as the respective amino precursors and allows an unambiguous assignment of the proton nmr spectra of **1**, **2** and the Tamoxifens.

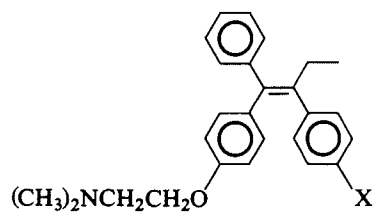
DUNCAN H. HUNTER, NICHOLAS C. PAYNE, ASADUR RAHMAN, JOHN F. RICHARDSON et YOLANDA ZEA PONCE. Can. J. Chem. **61**, 421 (1983).

On a préparé les isomères *E* et *Z* des iodo-Tamoxifènes (**1**), (*p*-(β-diméthylaminoéthoxy)phényl)-1 (*p*-iodophényl)-2 phényl-1 butènes-1, à partir des amino-Tamoxifènes *E* et *Z* correspondants (**2**), (*p*-aminophényl)-2 (*p*-(β-diméthylaminoéthoxy)phényl)-1 phényl-1 butènes-1 et on a déterminé les structures moléculaires à partir des données tridimensionnelles fournies par les rayons-X. Les cristaux du composé **1**-(*E*) sont tricliniques et appartiennent au groupe d'espace $P\bar{1}$ avec $Z = 2$ et des dimensions de maille de $a = 10{,}714(2)$, $b = 14{,}125(3)$, $c = 8{,}249(2)$ Å, $\alpha = 95{,}78(1)$, $\beta = 92{,}91(1)$ et $\gamma = 71{,}41(1)°$. Les cristaux du composé **1**(*Z*) sont monocliniques et appartiennent au groupe d'espace $P2_1/n$ avec $a = 12{,}675(2)$, $b = 19{,}553(3)$, $c = 9{,}483(1)$ Å, $\beta = 92{,}22(1)°$, $Z = 4$. On a recueilli les données d'intensité à l'aide d'un diffractomètre automatique à quatre cycles et on les a affinées par la méthode des moindres carrés (matrice entière) sur *F* jusqu'à des valeurs conventionnelles de $R = 0{,}054$ pour 2736 observations dans le cas du composé **1**-(*E*) et de $R = 0{,}042$ pour 3644 observations dans le cas du composé **1**-(*Z*). La solution de ces structures détermine la configuration de ces isomères aussi bien que celle de leurs précurseurs respectifs permet d'interpréter sans ambiguité les spectres de rmn du ^1H des composés **1** et **2** et des Tamoxifènes.

[Traduit par le journal]

A forthcoming article (1) describes the preparation of the *E* and *Z* isomers of the amino-Tamoxifens **2** which are intended primarily as precursors for radiolabelled estrogens or anti-estrogens for external imaging of receptor positive carcinoma by radiology techniques. The iodo-derivatives (*E*- and *Z*-**1**) were chosen for our initial study since it was felt that the iodine atom, although large, would not seriously alter the affinity of the molecule for estrogen receptors. There are also several isotopes of iodine available which can serve a variety of purposes: iodine-127 for characterization, iodine-131 and 123 for external imaging, and iodine-125 for tissue counting and, in the extreme, for site-selective radiotherapy. We were encouraged in the use of iodine isotopes by the report (2) of the preparation of aromatic iodo compounds from aromatic diazonium salts and Na 131-I at carrier-free concentrations, albeit in modest yields (6–10%).

The iodo-Tamoxifens also provided good quality crystalline samples for structure determination by the X-ray diffraction technique. The reported (3) differences in endocrine activity of the *cis* and *trans* isomers of Tamoxifen itself made the assignment of geometry to the isomers of iodo-Tamoxifen of greater importance. Because the molecular structure of *cis*-Tamoxifen has been determined (4), it would be possible to compare its geometry with the iodo-Tamoxifens. Since the conversions of the amino-Tamoxifens to the iodo-Tamoxifens were expected to be stereospecific, the geometries of the amino-Tamoxifens could also be assigned. Finally, a study of this series of geometric isomers would allow an extension of earlier proton nuclear magnetic resonance assignments (5, 6).



X = I, *Z*-**1**
X = NH_2, *Z*-**2**
X = H, *Z*-Tamoxifen

Results and discussion

As described in the Experimental section, under the usual diazonium ion reaction conditions either *E*-**2** or *Z*-**2** could be converted to the corresponding iodo compounds *E*-**1** or *Z*-**1**, respectively, in about 40% yields. Although these two latter compounds had fortuitously identical melting points and chromatographic behaviour, their nmr spectra were sufficiently dif-

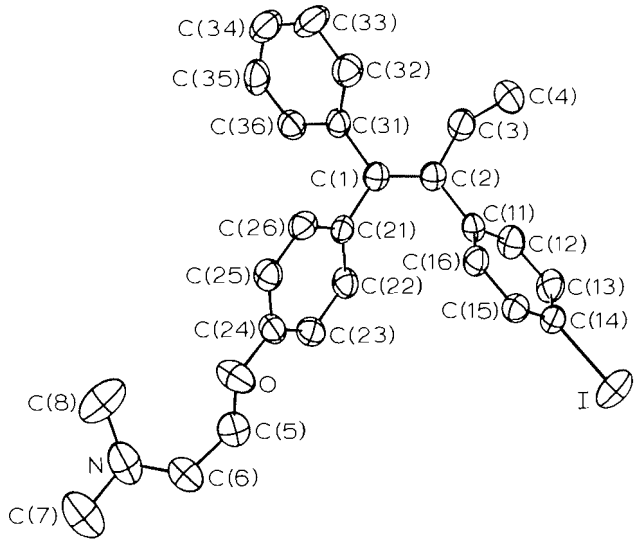

FIG. 1. A perspective view of *Z*-**1** showing the atom numbering scheme used for both isomers. Thermal ellipsoids are drawn at the 50% probability level.

ferent to indicate that one of the isomers of **2** gave one geometrical isomer of **1** and the other isomer of **2** gave the other isomer of **1**. It is assumed in these stereospecific conversions that *E*-**2** yields *E*-**1** and *Z*-**2** yields *Z*-**1**. Thus if the configuration of *E*-**1** and *Z*-**1** can be assigned to the appropriate compounds by X-ray crystallography, then the configurations for the isomers of **2** can be deduced.

It proved possible to obtain satisfactory crystals of each isomer of **1** and, as described in the Experimental section, molecular structures were determined for each, as shown in Fig. 1. It is on this basis that the isomers have been numbered in this and the forthcoming article.

Two single crystal X-ray structure analyses have shown that both structures consist of discrete molecular units; there are no unusual van der Waal's short contacts, with the shortest I—I distances being 4.411(1) Å in *E*-**1** and 4.87(2) Å in *Z*-**1**. The closest intermolecular distance of approach is 2.17 Å between H2C(7) and H2C(23) (equivalent position $1 - x, -y, -1 - z$) for *E*-**1** and 2.45 Å between atoms HlC(3) and HlC(15) at $1/2 + x, 1/2 - y, 1/2 + z$) for *Z*-**1**. Selected intramolecular dimensions for the compounds are presented in Table 1.[2] A perspective view of *Z*-**1**, showing the atom labeling scheme used for both structures, is presented in Fig. 1. Stereoviews of the molecules are given in Fig. 2.

The conformations of the molecules are indicative of major intramolecular interactions between non-bonded atoms. In the absence of such interactions the molecule would be expected to be planar as a result of π-electron delocalization. However, in each structure the phenyl rings are inclined with respect to the plane of the olefinic C atoms. The dihedral angles for the *p*-iodophenyl, *p*-(β-dimethylaminoethoxy)phenyl, and unsubstituted phenyl rings are 57, 59, and 49°, respectively for *E*-**1** and 45, 51, and 63° for *Z*-**1**. These angles compare favourably with angles of 46, 50, and 60°, and 51, 51, and 54° reported for

C(7)—N—C(8)	110.9(6)	110.4(3)

the two conformers of *cis*-Tamoxifen (4). In each Tamoxifen structure the phenyl rings are tilted in the same direction with respect to the plane of the double bond. Other structural features also provide evidence of the strains imposed upon the molecule. For example, dihedral angles of 11.1 and 5.4° between the planes defined by C(1), C(21) and C(31), and C(2), C(3) and C(11) are observed for *E*-**1** and *Z*-**1**, respectively. These angles are comparable to the values of 3.4 and 6.9° reported for the two forms of *trans*-stilbene (7), and that of 8.4° in tetraphenylethylene (8). Furthermore, an inspection of the bond angles about C(1) and C(2) indicates a significant divergence from the expected angles of 120°. Similar variations in such bond angles have been observed for other substituted ethylenes (4, 7, 8).

There is good agreement between chemically related bond distances and bond angles in the two geometrical isomers. Thus the C—I bond distances of 2.104(5) and 2.097(3) Å for the two isomers are equal within experimental error, and comparable to the range of values (2.06–2.10 Å) reported for hexaiodobenzene (9) and *p*-iodotoluene (10). The C(1)—C(2) bond lengths of 1.342(5) and 1.340(3) Å are also equivalent, and are comparable to those reported for other compounds (4, 7, 8).

The conformational similarity observed in the solid state between Tamoxifen and the iodo-Tamoxifens suggests that

[2]Other bond distances and angles, calculated hydrogen atom parameters, anisotropic thermal parameters, and observed and calculated structure amplitudes for *E*-**1** and *Z*-**1** are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

even in solution the molecules should be able to adopt similar shapes. To the extent that steric demands are important in the estrogen receptors, the iodo-Tamoxifens would seem to be able to mimic the Tamoxifens.

With the molecular structures of three pairs of triarylbutenes (Tamoxifen, amino-Tamoxifen, and iodo-Tamoxifen) firmly established, it was possible to extend and support proton nmr assignments made earlier for Tamoxifen (5, 6). A comparison of the proton nmr spectra of the amino and iodo-Tamoxifens shows only slight differences in the methyl or methylene hydrogens between compounds or isomers. However, there seem to be systematic chemical shift differences in the multiplet (analyzed as an AB) due to the hydrogens on the aromatic ring bearing the β-dimethylaminoethoxy group (ring 1 of Table 2). In the *E*-isomers these signals appear about 0.3–0.4 ppm higher than in the *Z*-isomers. Conversely, the multiplet due to the aromatic hydrogens of the monosubstituted ring (ring 2 of Table 2) appears centered near 7.3 ppm for the *Z*-isomers and near 7.0 ppm for *E*-isomers of **1** and **2**. On this basis the two phenyl signals of Tamoxifen can be assigned as in Table 2 with more confidence. As suggested earlier this shift difference is presumably due to a shielding effect of the aromatic ring on C-2

of the butene chain and is a consequence of its non-coplanarity with the double bond as seen in the X-ray crystal structures.

Carbon-13 nmr spectra for *E*- and *Z*-**2** showed only slight differences (±1 ppm) and the uv spectra for both isomers were very similar.

Experimental section

Synthesis

Preparation of E-*1 and* Z-*1*

To a solution of 1.15 g (3 mmol) of the previously prepared (1) isomer of **2** of mp 123−124°C in 20 mL of 5 *M* hydrochloric acid at 5°C was added slowly 0.3 g (4.3 mmol) of sodium nitrite in 10 mL of H_2O. After stirring for 10 min, 0.3 g of urea was added to destroy excess sodium nitrite. After stirring an additional 15 min or until bubbling had ceased, a solution of 5 g (30 mmol) of potassium iodide was added. The temperature was then allowed to rise to ambient and the reaction was stirred for 3 h and then heated on the steam bath for a short time.

After cooling, sodium bisulfite was added to destroy any iodine present. The solution was made basic and extracted with methylene chloride. The organic layer was washed with water, dried, and evaporated to yield 0.95 g of crude material which nmr and tlc showed to be primarily *E*-**1**.

The crude reaction product was purified by column chromatography (alumina − 1% methanol in ether) and yielded 0.52 g (35%) of *E*-**1** of mp 109−110°C (from hexanes).

Its nmr spectrum ($CDCl_3$) showed a triplet (3H, 0.93 ppm), a singlet (6H, 2.25 ppm), a quartet (2H, 2.47 ppm), a triplet (2H, 2.73 ppm), a triplet (2H, 4.07 ppm), aromatic multiplets (11H, 6.8−7.3 ppm), and a doublet (2H, 7.47 ppm). *Anal.* calcd. for $C_{26}H_{28}INO$: C 62.79, H 5.67, I 25.51, N 2.82; found: C 62.83, H 5.77, I 25.28, N 2.91. Exact mass determination: calcd. for $C_{26}H_{28}INO$: *m/e* 497.122; found *m/e* 497.121.

Similarly the isomer of **2** of mp 119−120°C gave a 38% yield of *Z*-**1** of mp 109−110°C (from hexanes). Nmr($CDCl_3$) showed a triplet (3H, 0.90 ppm), a singlet (6H, 2.30 ppm), a quartet (2H, 2.42 ppm), a triplet (2H, 2.64 ppm), a triplet (2H, 3.97 ppm), and aromatic multiplets (6H, 6.5−6.9 ppm; 5H broad singlet, 7.3 ppm; 2H doublet, 7.50 ppm). *Anal.* calcd. for $C_{26}H_{28}INO$: C 62.79, H 5.67, I 25.51, N 2.82; found: C 62.89, H 5.93, I 25.15, N 3.03. Exact mass determination: calcd. for $C_{26}H_{28}INO$: *m/e* 497.122; found *m/e* 497.122.

Structure determination

Clear, colourless, prismatic crystals of *E*-**1** were obtained by recrystallization from a hexane solution. A preliminary photographic examination, employing Weissenberg and precession techniques,

[a]Estimated standard deviations in this and other tables are given in parentheses, and correspond to the least significant digit.
[b]$U(\text{eq}) = (1/3)\ \sum_i \sum_j a_i^* a_j^* \mathbf{a}_i \mathbf{a}_j$.

showed the crystals possess triclinic symmetry. The space group $P\bar{1}$ (C_i^1, No. 2) (11) was chosen, and this choice was later confirmed by the successful refinement of the structure. The crystal data are summarized in Table 3.

The crystal chosen for data collection was mounted on a Picker FACS-1 computer-controlled (12) diffractometer with [100] offset approximately 17° from coincidence with the diffractometer ϕ axis. Five standard reflections were regularly monitored during data collection. These, together with an examination of crystal mosaicity at the beginning and the end of data collection, showed no significant decomposition had occurred. Coincidence losses in counting were minimized for strong reflections by using Cu foil attenuators. Details of the parameters associated with data collection are given in Table 4.

After data collection was complete the crystal was measured for an absorption correction. Seven faces were identified as $(\bar{1}00)$, $(21\bar{1})$, (321), and the forms {010} and {012}. The recorded intensities were corrected for monochromator polarization, background, Lorentz and polarization effects, and a standard deviation $\sigma(I)$ was assigned to each intensity (I), such that $\sigma(I) = [C + \frac{1}{4}(t_c/t_b)^2(b_l + b_h) + (pI)^2]^{1/2}$, where C = total counts measured in time t_c, b_l and b_h are background counts each measured in time t_b,[3] p was chosen as 0.04. A total of 3309 reflections was measured; 2387 unique data with $I > 3\sigma(I)$ were used in the solution and preliminary refinement of the structure. The data were corrected for absorption effects using the analytical method (13). Transmission coefficients varied from 0.782 to 0.900.

Clear, pale yellow, prismatic crystals of *Z*-**1** were obtained by recrystallization from petroleum ether (bp 60−80°C) solutions. Preliminary photography showed the crystals belong to the monoclinic system. The systematic absences identified, $h + l$ odd for $h0l$ and k odd for $0k0$, uniquely define the space group as $P2_1/n$ (alternate setting of $P2_1/c$, $C_{2_h}^5$, No. 14 (11)); equivalent positions $\pm(x,y,z$ and $1/2 + x, 1/2 - y, 1/2 + z)$. Crystal data are given in Table 3.

The crystal selected for data collection was mounted with [100] offset approximately 35° from coincidence with the spindle axis. The monitoring of six standard reflections revealed a steady decrease in intensity, the total decrease being about 10% over the period of data collection. A correction for this decay was applied. The intensity of the nth reflection, observed with a value I, was adjusted to I_n, where $I_n = I/(1.0 - n(2.034 \times 10^{-5}))$. The experimental conditions associated with data collection are given in Table 4.

The crystal was measured following data collection, and ten faces were identified as (110), $(1\bar{1}0)$, $(1\bar{1}1)$, (212), and the forms $\{010\}$ and $\{11\bar{1}\}$. Two fractured faces were assigned the indices $(20\bar{1})$ and $(\bar{1}2\bar{1})$. The recorded intensities were processed as before and p was chosen as 0.03. The data were corrected for absorption effects using the Gaussian method with a 8 × 14 × 6 grid (14). Transmission coefficients varied from 0.561 to 0.666. Of the 4538 reflections collected, 3184 unique observations with $I > 3\sigma(I)$ were used in the solution and preliminary refinement of the structure.

Solution and refinement of the structures

E-**1**: The I atom was located from a three-dimensional Patterson synthesis. Structure factor and difference Fourier synthesis calcu-

[3]Computing was performed on the DEC PDP-10 and the CDC Cyber 73/14 at the University of Western Ontario. Among the programs used were: cell refinement and orientation matrix, PICKTT, based on Hamilton's MODE 1; Fourier syntheses, Zalkin's FORDAP; least-squares refinement, WOCLS, a version of Ibers' NUCLS; absorption correction, AGNOST, by Cahen and Ibers; Johnson's ORTEP for illustrations; and ORFFE, Busing, Martin, and Levy's function and error program.

For personal use only.

lations revealed the positions of the remaining 28 nonhydrogen atoms. Refinement of atomic parameters was carried out by full-matrix least-squares techniques on F, minimizing the function $\sum w(|F_o| - |F_c|)^2$ where the weight w is given by $4F_o^2/\sigma^2(F_o^2)$. Scattering factors for neutral nonhydrogen atoms were taken from Volume IV of ref. 11, while those for H were from Stewart *et al.* (15). The anomalous dispersion contribution to the scattering factor was included for the I atom and was taken from Cromer and Liberman (16).

The 28 hydrogen atoms were readily located from difference Fourier maps with electron density ranging from 0.3(1) to 0.5(1) e $Å^{-3}$. These were included in idealized positions (sp^2 or sp^3 hybridization at C, C—H 0.95 and 1.00 Å, respectively) but not refined. For the final cycles positional and anisotropic thermal parameters were refined for all nonhydrogen atoms, and the idealized H atom positions were recalculated after each cycle. The model converged (2736 unique data for which $I > \sigma(I)$, 262 variables) with agreement factors $R_1 = \sum||F_o| - |F_c||/\sum|F_o| = 0.054$ and $R_2 = (\sum w(|F_o| - |F_c|)^2/\sum wF_o^2)^{1/2} = 0.028$.

In the final cycle no parameter shift exceeded 0.06 of its estimated standard deviation. A statistical analysis of R_2 in terms of $|F_o|$, indices, $\lambda^{-1}\sin\theta$, and the diffractometer setting angles χ and ϕ showed no unusual trends. The standard deviation on an observation of unit weight is 2.33 electrons. The highest peak in a difference Fourier synthesis is of electron density 0.58(4) e $Å^{-3}$ at fractional coordinates (0.122, 0.011, 0.358) and is of no chemical significance. No evidence was found for secondary extinction. Final atomic positional parameters for nonhydrogen atoms are presented in Table 5. H atom parameters and structure amplitudes listed as $10F_o$ and $10F_c$ in electrons have been deposited.[2]

Z-**1**: The structure was solved by the heavy atom method, and all 29 nonhydrogen atoms located from a series of difference Fourier syntheses and least-squares refinements. The 28 H atoms were located with electron density varying from 0.3(1) to 0.7(1) e $Å^{-3}$, and their idealized contributions included in the calculations of F_c. The refinement of 262 variables with 3644 unique observations ($I > \sigma(I)$) converged at $R_1 = 0.042$ and $R_2 = 0.026$.

The largest shift in the final cycle was 0.02 esd. A statistical analysis of the structure factors showed no abnormal trends. Secondary extinction effects could be ignored. The error in an observation of unit weight is 3.62 electrons. The highest peak in a difference Fourier synthesis is of electron density 0.13(3) e $Å^{-3}$ at fractional coordinates (−0.196, 0.029, 0.012), and is of no chemical significance. Final positional parameters for the nonhydrogen atoms are given in Table 5. H atom parameters and a list of observed and calculated structure amplitudes (× 10 in electrons) have been deposited.[2]

Received June 2, 1982

MIROSLAW CYGLER and JANUSZ SKOLIMOWSKI. Can. J. Chem. **61**, 427 (1983).

Crystal structures of 2,2,6,6-tetramethyl-4,4-diphenyl-1,4-azaphosphorinanium perchlorate (**I**) and 2,2,6,6-tetramethyl-4-oxo-4-phenyl-1,4-azaphosphorinan-1-oxyl (**II**) were determined. Compound **I** crystallizes in the monoclinic space group $C2/c$ with unit cell dimensions a = 18.2967(7), b = 10.9413(6), c = 20.8714(13) Å, β = 90.79(1)° (at 115 K), and **II** crystallizes in the orthorhombic space group $Pn2_1a$ with a = 8.076(1), b = 10.139(1), c = 17.894(1) Å. Intensity data were measured on a diffractometer at 115 K for **I** and at the room temperature for **II**. The structures were solved by a combination of heavy-atom and direct methods and refined to R = 0.036 (3968 reflections) for **I** and 0.039 (1451 reflections) for **II**.

The azaphosphorinane ring adopts a chair conformation in both molecules, being flattened in the P part in **I** and in the N part in **II**. In molecule **I** the equatorial phenyl group is nearly parallel to the approximate plane of symmetry of the molecule, and the axial phenyl group is perpendicular to that plane. In molecule **II** the P=O bond is axial and the phenyl group is equatorial. The CN(O)C group is not planar. The N—O bond makes an angle of 18.0(3)° with the CNC plane. The CNC angle of 129.3(3)° is larger than that found in nitroxypiperidine analogues.

MIROSLAW CYGLER et JANUSZ SKOLIMOWSKI. Can. J. Chem. **61**, 427 (1983).

On a déterminé les structures cristallines du perchlorate de tétraméthyl-2,2,6,6 diphényl-4,4 azaphosphorinanium-1,4 (**I**) et du tétraméthyl-2,2,6,6 oxo-4 phényl-4 azaphosphorinane-1,4 oxyl-1 (**II**). Le composé **I** cristallise dans le groupe d'espace monoclinique $C2/c$ avec des dimensions de maille de: a = 18,2967(7), b = 10,9413(6), c = 20,8714(13) Å, β = 90,79(1)° (à 115 K) et le composé **II** cristallise dans le groupe d'espace orthorhombique $Pn2_1a$ avec a = 8,076(1), b = 10,139(1), c = 17,894(1) Å. On a relevé les données d'intensité à l'aide d'un diffractomètre à 115 K pour le composé **I** et à la température ambiante pour le composé **II**. On a résolu les structures par une combinaison d'atomes lourds et de méthodes directes et on les a affinées jusqu'à des valeurs de R = 0,036 (pour 3968 réflexions) dans le cas du composé **I** et de R = 0,039 (1451 réflexions) dans le cas du composé **II**.

Le cycle azaphosphorinane adopte une conformation chaise dans les deux molécules et il est applati dans la région de l'atome de phosphore dans le cas du composé **I** et dans la région de l'atome d'azote dans le cas du composé **II**. Dans la molecule **I**, le groupe phényle équatorial est quasi parallèle au plan approximatif de symétrie de la molécule et le groupe phényle axial est perpendiculaire à ce plan. Dans la molécule **II**, le lien P=O est axial et le groupe phényle est équatorial. Le groupe CN(O)C n'est pas plan. La liaison N—O fait un angle de 18,0(3)° avec le plan CNC. L'angle CNC de 129,3(3)° est plus grand que celui trouvé dans les analogues de la nitroxypipéridine.

Introduction

Compounds containing heterocyclic rings with phosphorus have been widely studied recently. Much interest has been focused on 1,3,2-dioxaphosphorinanes and 1,3,2-azaoxaphosphorinanes as well as other 6-membered ring systems containing, in addition to P, other heteroatoms such as sulfur or nitrogen (1). X-ray diffraction studies of these compounds have shown that in the solid state the heterocyclic ring adopts, in most cases, a chair conformation, usually flattened at the P end. Non-chair conformations are rarely observed in the solid state. It has been suggested that the twist conformation observed in some 1,3,2-dithiaphosphorinanes (e.g. *cis* and *trans* isomers of 2-phenyl-2-oxo-5-*tert*-butyl-1,3,2-dithiaphosphorinane (2) and 2-*tert*-butyl-2-oxo-5,5-dimethyl-1,3,2-dithiaphosphorinane (3)) is due to the lowering of the chair-twist energy difference by the introduction of sulfur atoms to the ring. Incorporation of bulky substituents may also lead to non-chair conformations as is the case in *cis*-2-*tert*-butylamino-2-seleno-4,4,6-trimethyl-1,3,2-dioxaphosphorinane where the twist conformation is adopted in the solid state to avoid pronounced 1,3 *syn*–axial interactions existing in both chair forms (4).

We have pursued the synthesis of 1,4-azaphosphorinane derivatives with bulky substituents and have also succeeded in the preparation of stable nitroxy radicals incorporated in such systems (5). To the best of our knowledge, there is only one example of the crystal structure of a 1,4-azaphosphorinane derivative reported in the literature (1-methyl-4-phenyl-1,4-azaphosphorinan-4-sulfide (6)). There is no steric strain in that molecule, and the ring adopts the usual chair form. Nitroxy radicals incorporated in six-membered rings (piperidine analogues) cause a distortion of the ring, but the chair conformation is still the most stable, even if severe 2,4,6 axial interactions are present (7).

The X-ray analysis of 2,2,6,6-tetramethyl-4,4-diphenyl-1,4-azaphosphorinanium perchlorate (**I**) and 2,2,6,6-tetramethyl-

I II

4-oxo-4-phenyl-1,4-azaphosphorinan-1-oxyl (**II**) was undertaken to establish the conformation of the azaphosphorinane ring in the presence of 2,4,6 axial interactions, and to determine the influence of the nitroxy group on the ring shape.

Experimental

X-ray analysis of ***I***

Suitable crystals were obtained from a mixture of methanol and water by slow evaporation. Systematic absences on Weissenberg photographs indicated Cc or $C2/c$ as possible space groups. The presence of a perchlorate anion in the structure, often reported as being disordered, prompted us to collect X-ray data at a temperature of 115 K. Cell constants were calculated from the setting angles of 26 reflections (room temperature) and 48 reflections (low temperature), centered automatically on a Picker diffractometer. Crystal data and pertinent details of data collection are shown in Table 1. No absorption correction was applied.

E-statistics pointed toward the centrosymmetric space group $C2/c$. Direct methods (MULTAN (8)) applied in that space group gave a reasonable model. Successful refinement confirmed the space group choice. All H atoms were located on a difference map and were included in the refinement with isotropic temperature factors. The extinction parameter (9)[2] was also refined; it converged to $g = 0.457$. The NRCC PDP8-E system of programs (10) was used for data collection and structure determination. Final atomic parameters are given in Table 2.[3]

X-ray analysis of ***II***

Suitable crystals were obtained from a mixture of *n*-hexane and chloroform. Systematic absences on Weissenberg and precession photographs indicated that the possible space groups were $Pnma$ and $Pn2_1a$. Data were collected on a Picker diffractometer at room temperature. Table 1 presents the crystal data and the procedure of data collection. No absorption correction was applied.

E-statistics strongly favoured the non-centrosymmetric space group $Pn2_1a$. Attempts to solve the structure with direct methods (MULTAN) in that space group and later in $Pnma$ were unsuccessful. The position of the P atom was then determined from the Patterson map. The appearane of peaks on the Harker section $u1/2w$ but neither on $1/2vw$ nor $uv1/2$ was yet another indication in favour of space group $Pn2_1a$. Further attempts to solve the structure were performed in that space group. The position of the P atom (y coordinate set arbitrarily to 0.5) was used to calculate phases for reflections with $E > 1.7$ and $|F_c| > 0.4\,|F_o|$. These phases were input to FASTAN and were kept constant during phase refinement. The resulting E-map was centrosymmetric (as one should expect); a seven atom fragment from one enantiomorph was recognizable. The next cycle of tangent refinement, based on phases calculated from that fragment, led to the recognition of an additional five atoms. The Fourier map calculated at this point revealed all non-hydrogen atoms ($R = 0.19$). The model had not $^y m$ symmetry as would be necessary for $Pnma$ space group with $Z = 4$. Successful refinement confirmed the choice of the space group. A difference map allowed us to locate the positions of all H atoms. Their positional parameters were included in the refinement.

Scattering amplitudes for neutral atoms were taken from International tables for X-ray crystallography (11). All calculations, except direct methods, were performed with NRC crystallographic programs (12). Final atomic parameters are given in Table 3.[3]

Results and discussion

Crystal structure of ***I***

A view of the molecule with the numbering scheme is shown in Fig. 1, and bond lengths, valence and torsion angles in Table 4. The azaphosphorinane ring adopts a chair conformation in the solid state. The axial phenyl group is nearly perpendicular

[2] Expression for extinction correction used was $F_c^{corr} = |F_c|\,(1 + g|F_c|^2 Lp_2/p_1)^{-1/2}$ where L = Lorentz factor, $p_n = (1 + \cos^{2n} 2\theta)$.

[3] Tables of observed and calculated structure factors and of temperature factors are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

* B_{eq} is the arithmetic mean of the principal axes of the thermal ellipsoid.

to the pseudo-mirror plane of the ring, being rotated 85.8° around the C(21)—P bond, while the equatorial phenyl group is nearly parallel to that plane (rotated by 4.9° around C(11)—P). It has been found from X-ray studies that the phenyl group attached axially to a trivalent phosphorus in the phosphorinane ring displays similar orientation (13, 14). Molecular mechanics calculations performed for 1-phenyl-4-phosphorinanone (15) indicated that another orientation of an axial phenyl group is energetically unlikely because of the interactions with axial ring hydrogens. The calculated energy

TABLE 3. Final atomic parameters and B_{eq} for 2,2,6,6-tetramethyl-4-oxo-4-phenyl-1,4-azaphosphorinan-1-oxyl. E.s.d's refer to the last digit printed

*B_{eq} is the arithmetic mean of the principal axes of the thermal ellipsoid. Isotropic temperature factors for H atoms were made equal to B_{eq} of the atoms to which they are attached, and were not refined.

of a conformation with an equatorial phenyl group parallel to the pseudo-mirror plane of the phosphorinane ring was the same as that with a phenyl group perpendicular to that plane. Both these conformations were indeed found in the solid state in 1-phenyl-4-phosphorinanon-1-oxide, where two crystallographically independent molecules exhibited equatorial phenyl groups rotated 17.8 and 77.1° from the pseudo-mirror plane of the phosphorinane ring (16). These calculations predicted, however, the equatorial position as being slightly more favorable (0.4 kcal/mol) than the axial one, contrary to X-ray and nmr findings (1*b*, 13). Arrangements of phenyl substituents similar to that in **I** have also been found in **III***a* (17).

Comparison to other similar structures shows that the steric interactions of axial substituents on the ring are relaxed to some extent by ring flattening. The mean ring torsion angle of 48.0° is very close to the value of 47.2° found in **IV** (18) where similar steric interactions exist, but is 9.7° smaller than in **III***a* and 7.8° smaller than in **III***b* (17). The ring is more flattened in the P end, a rather typical effect for a phosphorinane moiety (Table II in ref. 19). All P—C bond lengths are equal within the experimental error, with the mean value 1.793(2) Å. The CNC angle of 122.4(1)° is 11° larger than the corresponding angle in **V** (6) and 3.1° larger than in **IV** (18). A very similar value (123.1(3)°) was found, however, in a seven-membered analogue **VI***a* (20). The wide range of observed CNC angles may indicate a relatively low bending potential around the N atom as compared to C.

Comparison of the geometry of molecule **I** with that of **III***a* shows changes which may be attributed to more severe steric interactions in the former. While the endocyclic CPC angle is equal in both molecules within experimental error, the exocyclic CPC angles indicate that the axial phenyl group in **I** has moved more toward the outside of the ring, slightly pushing the equatorial phenyl group toward the center of the ring (C_{ph}^{ax}—P—C_{ring} is 4.2° larger, C_{ph}^{ax}—P—C_{ph}^{eq} is 1.3° smaller, and C_{ph}^{eq}—P—C_{ring} is 3.5° smaller than in **III***a*). This is accompanied by an increase in endocyclic PCC angles in **I** by 4.9° on average.

The C_{meth}^{ax} . . . C_{meth}^{ax} distance of 3.243(3) Å is very similar to that found in 2,2,6,6-tetramethylpiperidines (3.214–3.383 Å,

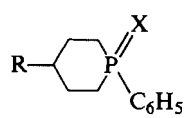
Table 2 in ref. 21) or in **VI***a* (3.270 Å (20)).

The H atom attached to N(1) is in close contact with O(4) of the perchlorate anion. The corresponding geometry is N . . . O = 3.208(4), H . . . O = 2.42(3) Å, and the angle N—H . . . O = 146(1)°. This weak hydrogen bond may be responsible for stabilizing the H atom in an axial position.

The perchlorate anion is tetrahedral, with bond distances and valence angles in the range 1.426(2)–1.435(2) Å and 108.9(1)–110.1(1)° respectively. The anion, although not disordered, exhibits a large amplitude of thermal motion having temperature factors with twice the magnitude of those of the azaphosphorinane moiety.

Crystal structure of ***II***

A view of the molecule with the numbering scheme is shown in Fig. 2, and bond lengths, valence and torsion angles are given in Table 4. Like **I**, this molecule also exists in a chair conformation in the solid state. The phenyl group at the P assumes an equatorial position, being nearly parallel to the pseudo-mirror plane of the ring (rotated 6.1°), while the P=O bond is axial. The same axial/equatorial preferences have also been found in **VII***a* and **VII***b* (16) and in *trans*-**VII***c* (22). In



VII *a*, X = O; R = O

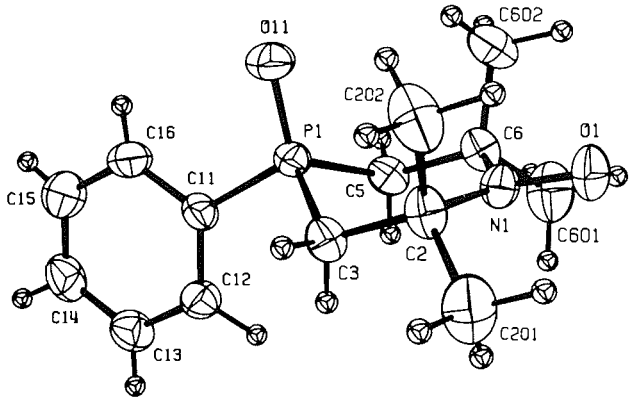

FIG. 2. View of the 2,2,6,6-tetramethyl-4-oxo-4-phenyl-1,4-phosphorinan-1-oxyl molecule, **II**. 50% thermal ellipsoids are shown for non-hydrogen atoms.

the latter case, however, the conformational preference was biased by the presence of the *tert*-butyl group, and in its *cis* isomer the phenyl group was assigned to an axial position on the basis of the nmr spectra.

Interestingly, in **V** the P=S bond assumes an equatorial position, and the phenyl group is axial (6). From the structural information available for 2-*R*-2-oxo-1,3,2-dioxaphosphorinanes, it was concluded that the P=O bond prefers an equatorial position rather than an axial one (23) and an explanation based on the interactions of lone pairs on the 1,3 oxygen atoms with an adjacent group on the P was proposed (24). An equatorial arrangement of P=O and P=S bond has also been found in the crystal structures of 1-phenyl-4,4-dimethyl-1,3,2-dithiaphosphorinan-1-oxide and -1-sulfide (3).

The conformation of the azaphosphorinane ring in **II** is influenced by the presence of the nitroxy group and differs significantly from **I** and **V**. The N part of the ring is flattened, having mean torsion angles about N—C bonds of only 26.7(6)°. The corresponding angles in **I** and **V** are 52.0 and 68.9°, respectively. The carbon analogue of **II** with the N—O group replaced by C=O, **VII***a*, does not show flattening around the carbonyl group (τ = 55.3°). Such a flattening, although to a smaller extent, was observed in piperidine nitroxides. Torsion angles around N—C bonds in these molecules vary between 30.1° (2,2,6,6-tetramethylpiperidin-4-ol-1-oxyl (25)), and 38.3° (4,7-oxido-7-methyl-7-hydroxymethyl-2,2,6,6-tetramethylpiperidin-1-oxyl (26)), with an average of ≃ 35°. In the only example of a nitroxy radical incorporated in the seven-membered ring, **VII***b* (20), the flattening is similar to that in **II** (τ_{CNCC} = 29.6°).

The flattening of the N part of the azaphosphorinane ring in **II** is correlated with puckering of the P part. The torsion angles about P—C bonds are 16° larger than in **I**.

The P—C bond lengths of 1.797(4) Å in the heterocyclic ring are in good agreement with those found in **I** and with values reported for other phosphorinane rings, while P—C_{phenyl} = 1.819(3) Å is slightly longer than the average value (≃1.800 Å) found in similar compounds. It may be noted that a similar bond length was reported for **V** (1.818(2) Å).

The nitroxy group geometry does not differ significantly (except for the CNC angle) from that found in other cyclic nitroxy derivatives. The N—O distance of 1.289(4) Å falls well within the range of observed values (see, for example, ref. 26). The CN(O)C group is not planar. The NO bond forms an angle of 18.0° with the CNC plane. The CNC angle (129.5°) is significantly (≃4°) larger than in piperidine analogues (26). A similar value was observed in the seven-membered analogue **VI***b* (20).

The comparison of the P part of the ring in **II** with analogous moieties in **VII***a* and **VII***c* shows a decrease of the endocyclic CPC angle by ≃3.3°, accompanied by a movement of the P=O bond toward the equatorial phenyl group. The latter effect is evident from the increase of the O=P—C_{ring} angle (116.5° in **II** vs. 113.2° in **VII***a* and 114.9° in **VII***c*) and the decrease of the O=P—C_{ph} angle (111.3° in **II** vs. 112.2° in the two others).

We have pointed out above that the CNC angles in **I** and **II** have values close to those found in the seven-membered ring analogues containing the same N parts, **VI***a* and **VI***b*, respectively. There are also similarities in the geometries of other corresponding fragments in these molecules, such as C(2) . . . C(6), C(3) . . . C(5), and C^{ax} . . . C^{ax} distances. One could conclude that the N part of the rings in **I** and **II** differs from that of their piperidine analogues because of the replacement of a C atom by an atom having a larger covalent radius, rather than by any particular properties of phosphorus.

Acknowledgments

The authors are grateful to Dr. E. Gabe and Dr. Y. Le Page for their aid in the data collection and for helpful discussions.

Synthèses et epimérisation de déoxy-spiro C-1 sucres

GEORGES REMY, LOUIS COTTIER ET GÉRARD DESCOTES
Laboratoire de Chimie Organique II, Université Lyon I, ERA 689 du C.N.R.S., 69622 Villeurbanne, France

Reçu le 12 juillet 1982

GEORGES REMY, LOUIS COTTIER et GÉRARD DESCOTES. Can. J. Chem. **61**, 434 (1983).

Les (oxo-3)-butyl-β-D-glucopyranosides de type déoxy-2, didéoxy-2,3 synthétisés à partir du tri-*O*-acétyl-D-glucal sont photolysés en hydroxyspirocétals selon un processus de type Norrish II non stéréosélectif. Leur réactivité est comparée à celle des dérivés α correspondants. L'épimérisation acidc des produits de cyclisation conduit préférentiellement aux spiro C-1 sucres de configuration α en accord avec les effets stéréoélectroniques des spirocétals.

GEORGES REMY, LOUIS COTTIER, and GÉRARD DESCOTES. Can. J. Chem. **61**, 434 (1983).

2-Deoxy and 2,3-dideoxy-3-oxo-butyl-β-D-glycopyranosides were synthesized starting from tri-*O*-acetyl-D-glucal. These β compounds undergo Norrish II type photocyclization giving the corresponding hydroxyspiroketals without stereoselectivity but with greater reactivity than the α derivatives. Acidic epimerization of these spiro C-1 sugars leads to the α anomers in accord with known stereoelectronic effects.

L'étude de la photocarbocyclisation des (oxo-3)-butylglycopyranosides a précédemment montré que la formation de spiro C-1 sucres était stéréospécifique (β-*gluco*) ou stéréosélective (α et β-*manno*) avec une réaction facilitée si l'hydrogène anomérique se situe initialement en position axiale (1−3). De même, les α-didéoxy-2,3-(oxo-3)butylglycosides subissant des photocyclisations difficiles (2), nous avons entrepris la synthèse des anomères β correspondants et étudié leur comportement photochimique pour le comparer à celui des anomères α.

Résultats

*Synthèse des déoxy-2 et didéoxy-2,3-β-D-glucopyranosides **4** et **5***

L'addition d'acétate mercurique sur le tri-*O*-acétyl-D-glucal **1** en présence d'hydroxy-1 butanone-3 permet d'obtenir selon le procédé décrit par Inglis *et al.* (4) et amélioré par Baer et Hanna (5) le composé **2** brut qui peut être soit traité par l'iodure de sodium pour donner **3**, soit photolysé en déoxy-2 glycoside **4**. Les rendements en **3** et **4** à partir de **1** sont respectivement de 25% et 16%. L'hydrogénation catalytique de **3** permet enfin de préparer **5** avec un rendement de 80% (Schéma 1).

Les structures des composés **3**, **4** et **5** sont déduites des spectres de rmn ^{1}H (tableau 1) par analogie des déplacements chimiques et constantes de couplages des protons du cycle et des protons anomériques H-1 avec les données de la littérature (5). Ainsi pour **3**, les déplacements chimiques de H-1, H-2 et H-3, (5,10 et 5,85 ppm) sont en accord avec ceux de l'éthylglycoside correspondant (5). De plus, la position de l'insaturation en 2−3 est justifiée par le processus rétro Diels−Alder de fragmentation en spectrométrie de masse (m/e = 198) caractéristique de cette structure (5). La configuration initiale β de **5** (δH-1, dd, 4, 60, $J_{1,2a}$ = 10 Hz, $J_{1,2e}$ = 4,5 Hz) permet de justifier la configuration β de **3** et la *trans*-addition de la réaction de synthèse à partir de **1**. De même, le composé **4** présente des déplacements et constantes de couplage analogues à ceux de **5** correspondant à une conformation chaise régulière pour le cycle.

*Photolyse de **3**, **4** et **5** et épimérisation des produits de photocyclisation **6**, **7** et **8***

L'irradiation en solution benzénique des composés **3**, **4** et **5** permet d'obtenir les mélanges de diastéréoisomères de spiro C-1 sucres correspondants (Schéma 1).

Comparativement aux anomères α précédemment étudiés (2) la photolyse de **3** et **5** est plus rapide et donne de meilleurs rendements en produits de photocyclisation. La séparation des quatre mélanges a été partiellement menée à bien pour **7** et **8** et non effectuée pour **6**. En effet, par chromatographie sur colonne de silice, on peut isoler les couples de diastéréoisomères se différenciant au niveau du carbone carbinolique (*cis*: A + B et *trans*: C + D) dont les structures sont établies par rmn. L'action des acides sur les mélanges permet d'aboutir aux spiro C-1 sucres thermodynamiquement les plus stables. Ainsi **7** (A + B) ou **7** (C + D) conduisent par traitement à l'acide paratoluène sulfonique avec des rendements voisins (70%) aux seuls composés **7**A et **7**C. Ces derniers composés stables en milieu acide sont de configuration α. De même, les spiro C-1 sucres insaturés **8** obtenus par photolyse de **3** donnent après traitement acide, les dérivés **8**A et **8**C avec un plus faible rendement du fait de leur fragilité (Rdt = 40%).

Ces épimérisations résultent de l'ouverture de l'un des cycles du système spirocétalique (6, 7). Pour confirmer ce processus sur un composé isolé pur précédemment (2, 8), un essai de traitement acide a été effectué sur le spiro [méthyl-3′-tétrahydrofurannol-3′]-1-2′ tétra-*O*-acétyl-2,3,4,6-β-D-glucopyranoside *trans* **9** qui a été transformé en un seul dérivé α *cis* **10** (Rdt = 70%) (Schéma 2).

Structures des spiro C-1 sucres

L'identification des spiro C-1 sucres résulte d'analyses rmn ^{1}H et ^{13}C sur les isomères **7**A,B,D isolés qui ont été appliquées aux dérivés **6** et **8**.

L'isomérie *cis-trans* localisée sur le cycle tétrahydrofuranique permet de préciser la configuration du carbone carbinolique qui est déduite des différences de déplacements chimiques Δδ en rmn ^{1}H et ^{13}C des carbones 3′ et 3″ (tableaux 1, 2, 3) précédemment établies dans d'autres séries (3, 9). Ainsi, les différences Δδ(**7**A − **7**D et **7**A − **7**C) exprimées en ppm (Δδ H-3″ = 0,20 et 0,13; Δδ C-1 = −3,0 et −3,2; Δδ C-3″ = +1,92 et 2,58) sont en accord avec une isomérie *cis* pour **7**A et *trans* pour **7**C et **7**D.

Les configurations α ou β au niveau du carbone anomère sont confirmées en rmn ^{1}H par les déplacements chimiques des protons H-3a et H-3e. Si la différence Δδ H-3a − H-3e est

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

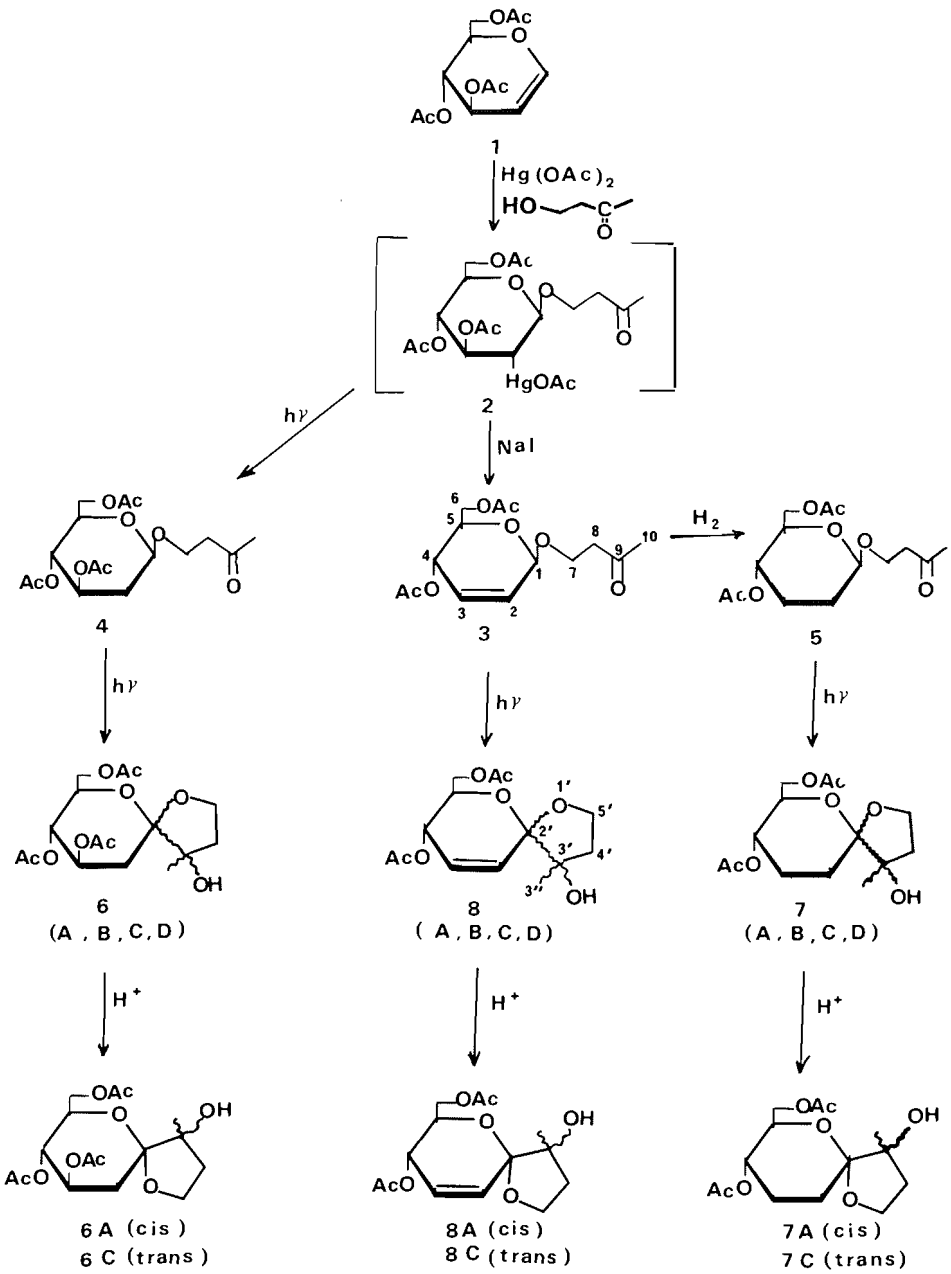

SCHÉMA 1. Synthèse et épimérisation des déoxy spiro C-1 sucres.

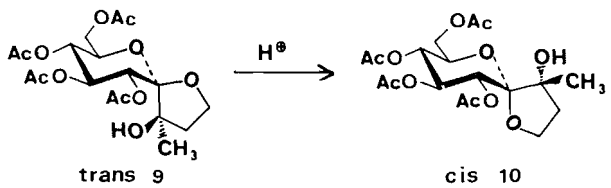

SCHÉMA 2

positive, la liaison furannique C—O est axiale (α) et provoque le déblindage de H-3a. Si cette même différence est négative, la liaison furannique C—O est équatoriale (β). Ainsi, les différences Δδ de 0,22, 0,11 et −0,22 observées respectivement pour **7**A, **7**B et **7**D confirment les configurations α de **7**A et **7**C et β de **7**D. Cette attribution est confirmée par rmn ^{13}C en comparant les déplacements chimiques des carbones C-5 des spiro C-1 sucres et du produit de départ **5**. En effet, les anomères α (**7**A et **7**C) ont un déplacement chimique pour C-5 (69,2 et 69,8 ppm) voisin de l'anomère α de **5** précédemment préparé (2) (68,6 ppm), alors que l'anomère β **7**D subit un effet γ d'environ 4 ppm (73,2 ppm).

Enfin, la conformation du cycle pyranosique correspond à une chaise qui confère aux protons du cycle des constantes de

TABLEAU 1. Déplacements chimiques (δ ppm, $CDCl_3$) des composés **8** (60 MHz), **3** (80 MHz), **5**, **10** (100 MHz) et **4**, **6**, **7** (250 MHz)

couplage $J_{2,3}$, $J_{3,4}$ et $J_{4,5}$ voisines de 10 Hz pour **7**A et **7**C et de 7 Hz pour **7**D qui doit présenter une certaine déformation moléculaire.

Si ces méthodes de détermination structurales utilisées pour **7** ont pu être appliquées aux dérivés **6**, les configurations des spiro C-1 sucres insaturés **8** ne peuvent être établies directement par rmn ^1H. Par contre, en rmn ^{13}C, on utilise également les différences de déplacement chimique des C-1 et C-5 pour **8**A et **8**C comparées à ceux des produits de départ **3** (5) pour lever le doute (tableau 3).

Discussion des résultats

Les données du tableau 4 montrent que les anomères β en série déoxyglucosidique sont plus réactifs que les anomères α précédemment étudiés (2). Cependant, les différences de réactivité sont plus faibles qu'en série *gluco* (2) ou *manno*. De telles différences de réactivité ont été récemment observées dans la réduction radicalaire de dérivés *O*-thiocarbonylés par les hydrures d'étain: en effet, la présence d'atome d'oxygène en β du carbone radicalaire semble favorable à sa stabilité (10). De la même façon, la présence d'un groupe acétate en 2 en position axiale ou équatoriale favorise le processus de type Norrish d'arrachement d'hydrogène anomérique.

La stéréosélectivité de la réaction de photocarbocyclisation, comme dans le cas des anomères α (2) est faible ou nulle. Cependant, un défaut de stéréosélectivité peut être compensé par une épimérisation acide qui facilite la formation de spiro C-1 sucres de configuration α. La stabilisation particulière de ces anomères résulte des effets anomères et exoanomères favorables à de telles structures, en accord avec les précédentes observations de Deslongchamps *et al.* (7) sur l'équilibre des spiroacétals.

L'influence de la conformation moléculaire devrait pouvoir être mieux cernée par l'étude en cours de la photocyclisation de systèmes présentant un équilibre conformationnel C1 ⇄ 1C comme pour les arabinosides.

Partie expérimentale

Synthèse des (oxo-3)-butyl glycosides

Les points de fusion non corrigés ont été déterminés sur un appareil Buchi. Les spectres rmn ^1H ont été tracés à température ambiante avec un spectromètre Varian A. 60 ou XL. 100, un Bruker WP 80 CW ou Cameca 250 et les spectres de rmn ^{13}C avec un Bruker WP 60 fonctionnant à 15,08 MHz par transformée de Fourrier. Les séparations chromatographiques ont été réalisées en faisant passer 0,3 à 3 g de produit brut sur 50 g à 150 g de silice (Merck 0,040−0,060 mm) contenue dans une colonne de 50 cm (ϕ 3,5 cm).

*Synthèse de l'(oxo-3)-butyl-di-*O*-acétyl-4,6-didéoxy-2,3-β-D-*érythro *hexéno-2 pyranoside* ***3***

Dix grammes (0,037 mol) du composé **1** ont été dissous dans 32,56 g (0,37 mol) d'hydroxy-1-butanone-3. Le mélange est agité sous 5 mm de mercure avec 12,3 g (0,037 mol) d'acétate mercurique. Après 2 h d'agitation, le mélange est filtré puis lavé 3 fois à l'eau, séché sur sulfate de sodium. Le mélange brut ainsi obtenu est mis en réaction avec de l'iodure de sodium (6 g) dans 200 mL d'éthanol 75%. Après 30 min d'agitation le tiers du solvant est évaporé sous vide et le résidu est extrait 7 fois à l'éther. Ces extraits sont réunis puis lavés à l'eau contenant du thiosulfate de sodium et enfin une fois à l'eau. On sèche sur sulfate de sodium. Après filtration et évaporation du solvant, le résidu est chromatographié sur colonne de silice (éther/hexane 70:30) donnant 2,8 g (0,92 mol) du composé **3** (rendement: 25%); liquide incolore; $[\alpha]_D^{23}$ +128° (*c* 1,0, $CHCl_3$). *Anal.* calc. pour $C_{14}H_{20}O_7$: C 55,89, H 6,71; trouvé: C 55,70, H 6,80.

*Synthèse de l'(oxo-3)-butyl-di-*O*-acétyl-4,6-didéoxy-2,3-β-D-*erythro *hexopyranoside* ***5***

On a hydrogéné 568 mg ($1,9 \times 10^{-3}$ mol) du composé **3** en présence de palladium sur charbon dans 20 mL d'éthanol absolu. Après filtration et chromatographie sur colonne du produit brut (éther/hexane 70:30) 487 mg ($1,61 \times 10^{-3}$ mol) du composé **5** ont été obtenus (rendement 80%); liquide incolore; $[\alpha]_D^{20}$ +144° (*c* 0,25, $CHCl_3$). *Anal.* calc. pour $C_{14}H_{22}O_7$: C 55,62, H 7,34; trouvé: C 55,80, H 7,28.

*Synthèse de l'(oxo-3)-butyl-tri-*O*-acétyl-3,4,6-déoxy-2-β-D-*gluco *hexopyranoside* ***4***

Un gramme du composé **1** (3,7 mmol) a été condensé avec l'hydroxy-1 butanone-3. Le produit brut qui en résulte a été dissous dans 40 mL de benzène (les conditions opératoires restent identiques à celles des (oxo-3)-butyl glycosides lors de la carbocyclisation) et irradié dans un tube de quartz. La réaction s'accompagne d'un dépôt de mercure; une filtration de la solution benzénique s'avère nécessaire par période de 4 h pour laisser passer la lumière. Après 20 h d'irradiation, la solution est filtrée puis le solvant est évaporé. Le résidu, chromatographié sur colonne de silice (acétate d'éthyle/hexane 7:3) donne 213 mg (0,06 mol) du composé **4** (rendement 16%); composé amorphe; $[\alpha]_D^{20}$ +57° (*c* 1,0, $CHCl_3$). *Anal.* calc. pour $C_{16}H_{24}O_9$: C 53,33, H 6,71; trouvé: C 53,60, H 6,90.

Photolyse et épimérisation des (oxo-3)-butyl glycosides

La photolyse a été réalisée dans les conditions opératoires déjà décrites (2). La lampe est munie d'un filtre Vycor. Après photolyse le solvant est évaporé puis le résidu est chromatographié sur colonne de silice.

TABLEAU 4. Caractéristiques de la photolyse des oxo-3-butyl glycosides

Composés	Temps d'irradiation (h)	Taux de conversion (%)	Rendement global (%)
3β	6	100	43
3α	10	80	29
5β	30	80	40
5α	48	90	33

Glycoside ***4***: 916 mg du composé **4** dissous dans 50 mL de benzène ont été irradiés pendant 60 h. Le produit brut obtenu après évaporation est traité à température ambiante avec 380 mg d'acide paratoluène sulfonique. Après 4 h d'agitation, le milieu réactionnel est neutralisé avec $NaHCO_3$ dissous dans l'eau. Après séchage, filtration et évaporation du solvant, le résidu est chromatographié sur colonne de silice (dichloro-1,2 éthane/acétone 85:15) pour conduire aux spiro [méthyl-3′-tétrahydrofuranol-3′] 1-2′tri-*O*-acétyl-3,4,6-α-D-*arabino* hexopyranoside **6A** *cis* (34 mg, 10^{-4} mol) et **6C** *trans* (46 mg, $0,13 \times 10^{-3}$ mol) et 182 mg ($0,55 \times 10^{-3}$ mol) de composé **4** qui n'ont pas été photolysés (rendement 10%).

Composé ***6A***: liquide jaune; $[\alpha]_D^{23}$ +84° (*c* 1,0, $CHCl_3$). *Anal.* calc. pour $C_{16}H_{24}O_9$: C 53,33, H 6,71; trouvé: C 53,60, H 6,80.

Composé ***6C***: liquide jaune; $[\alpha]_D^{23}$ +125° (*c* 1,0 $CHCL_3$). *Anal.* calc. pour $C_{16}H_{24}O_9$: C 53,33, H 6,71; trouvé: C 52,90, H 6,50.

Glycoside ***5***: 388 mg ($1,3 \times 10^{-3}$ mol) du composé **5** dissous dans 25 mL de benzène ont été irradiés pendant 60 h. Après évaporation du solvant et chromatographie sur colonne de silice (dichlorométhane/acétone 85:15) pour conduire à 63 mg (0,16 mmol) de composé **7** A + B *cis* et 92 mg (0,23 mmol) de composé **7** C + D (poids total 155 mg; rendement 40%). Epimérisation: 300 mg (10^{-3} mol) du mélange **7** A + B ont été traités par 184 mg (10^{-3} mol) d'acide paratoluènesulfonique, comme le composé **4**. Après séparation sur colonne de silice (dichloro-1,2 éthane/acétone 85:15), 211 mg ($0,7 \times 10^{-3}$ mol) du spiro [méthyl-3′ tétrahydrofuranol-3′]1-2′-di-*O*-acétyl-4,6-didéoxy-2,3-α-D-*erythro* hexopyranoside *trans* **7C** ont été isolés (rendement 70%). Solide blanc, *F* 74−76°C; $[\alpha]_D^{23}$ +105° (*c* 1,0, $CHCl_3$). *Anal.* calc. pour $C_{14}H_{22}O_7$: C 55,62, H 7,34; trouvé C 55,61, H 7,41.

Trois cent milligrammes du mélange **7** C + D ont été traités avec l'acide paratoluène sulfonique dans les mêmes conditions que le composé **4** et donnent 215 mg ($0,7 \times 10^{-3}$ mol) de spiro [méthyl-3′-tétrahydrofuranol-3′] 1-2′-di-*O*-acétyl-4,6-didéoxy-2,3-α-D-*erythro* hexopyranoside *cis* **7A** (rendement 70%); solide blanc; *F* 68°C; $[\alpha]_D^{24}$ +67,2° (*c* 1,0, $CHCl_3$). *Anal.* calc. pour $C_{14}H_{22}O_7$: C 55,62, H 7,34; trouvé: C 55,79, H 7,37.

Glycoside ***3***: 366 mg ($1,22 \times 10^{-3}$ mol) du composé **8** ont été dissous dans 26 mL de benzène et irradiés pendant 25 h. Après évaporation du solvant et chromatographie sur colonne de silice

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

(dichlorométhane/acétone 85:15), 90 mg du mélange **8** A + B *cis* et 93 mg de **8** C + D *trans* ont été isolés. Poids total 183 mg (0,61 mmol, rendement 43%). Epimérisation: 300 mg (10^{-3} mol) de chaque série *cis* et *trans* ont été traités en présence d'acide paratoluène sulfonique dans du dichlorométhane pour donner respectivement 123 mg de spiro [méthyl-3′-tétrahydrofuranol-3′] 1-2′-di-*O*-acétyl-4,6-didéoxy-2,3-α-D-*erythro* hexeno-2-pyranoside *trans* **8**C et 120 mg de *cis* **8**A. *Anal.* calc. pour $C_{14}H_{20}O_7$: C 55,99, H 6,71; trouvé: C 55,74, H 6,95.

Epimérisation du composé ***9*** *(2, 8)*: 150 mg (0,36 mmol) du composé **9** ont été traités avec 66 mg (0,36 mmol) d'acide paratoluène sulfonique. Après neutralisation et chromatographie sur colonne de silice (acétate d'éthyle/hexane 70:30), 105 mg (0,25 mmol) du composé **10** ont été isolés (rendement 70%); solide blanc (éther); *F* 112°C; $[\alpha]_D^{23}$ +55° (*c* 1,0, $CHCl_3$). *Anal.* calc. pour $C_{18}H_{26}O_{11}$: C 51,67, H 6,26; trouvé: C 51,90, H 6,30.

Remerciement

Changing regioselectivity patterns in metal hydride reductions of unsymmetrically substituted cyclic anhydrides

MARGARET M. KAYSER[1]

Received September 9, 1982

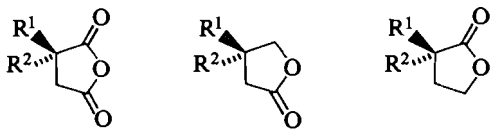
MARGARET M. KAYSER, JUDITH SALVADOR, and PETER MORAND. Can. J. Chem. **61**, 439 (1983).

A study of L- and K-selectride reductions of unsymmetrical cyclic anhydrides attached to six-membered rings and to bridged six-membered systems sheds a new light on the effect of the conformation of the substrate molecule on the regioselectivity of metal hydride reductions. Thus, in addition to intrinsic reactivity of the carbonyl group, the antiperiplanar effect, and steric congestion, the conformation of the parent molecule should be considered in predicting regioselectivity of nucleophilic additions to cyclic anhydrides.

MARGARET M. KAYSER, JUDITH SALVADOR et PETER MORAND. Can. J. Chem. **61**, 439 (1983).

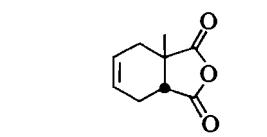
Une étude des réductions, par les sélectrides de type L et K, des anhydrides cycliques non symétriques attachés à des cycles à 6 chaînons et à des systèmes cycliques pontés à six chaînons fournit des précisions nouvelles sur l'effet de la conformation de la molécule de substrat sur la régiosélectivité des réductions par les hydrures métalliques. Ainsi, en plus de la réactivité intrinsèque du groupe carbonyle, de l'effet anti-périplanaire et de l'encombrement stérique, on doit considérer la conformation de la molécule de départ lorsqu'on prévoit la régiosélectivité des additions nucléophiles sur les anhydrides cycliques.
[Traduit par le journal]

The *gem*-disubstituted succinic anhydrides **1**, **2**, and **3** react with simple metal hydrides ($NaBH_4$ and $LiAlH_4$) to give the corresponding lactones **1***a*, **2***a*, and **3***a*, reduced selectively at the more highly substituted carbonyl group (1, 2). Similar patterns of regioselectivity are observed for $NaBH_4$ and $LiAlH_4$ reductions of anhydrides **4** and **5**, which yield respectively the lactones **4***a* (3) and **5***a* (1) as products.



1	$R^1 = R^2 =$ Me	**1***a*	**1***b*
2	$R^1 = R^2 =$ Ph	**2***a*	**2***b*
3	$R^1 =$ Me $R^2 =$ Et	**3***a*	**3***b*

Recently (4) we have reported that reversal of selectivity (i.e. formation of lactones reduced at the less substituted carbonyl function) can be achieved when compounds **1**, **2**, and **3**, are reduced with K- or L-selectrides. We expected a similar reversal of regioselectivity in selectride reductions of anhydrides **4** and **5**, but to our dismay the only products observed were the lactones **4***a* and **5***a*. On the other hand, the bridged anhydride **6** was reduced with selectrides similarly as with $NaBH_4$ or $LiAlH_4$ exclusively at the less substituted carbonyl group, to the lactone **6***b* (Table 1).



4

TABLE 1. Reductions of unsymmetrically substituted cyclic anhydrides

Anhydride	Method	Ratio of lactone *a*	Ratio of lactone *b*	% Yield of *isolated* lactonic product
4	$NaBH_4/LiAlH_4$	100	—	80
	selectride	100	—	50
5	$NaBH_4/LiAlH_4$	100	—	80–90
	selectride	100	—	62
6	$NaBH_4/LiAlH_4$	—	100	84–86
	selectride	—	100	50–60

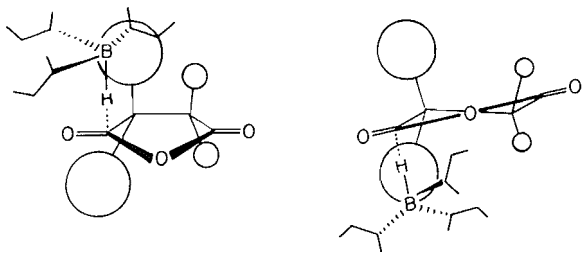

FIG. 1. Due to the size and the shape of the reagent molecule the approach to the more hindered carbonyl function is particularly unfavourable regardless of the conformation of the anhydride ring.

the more substituted carbonyl group, even with highly hindered selectrides, while compound **6** is reduced at the less hindered carbonyl group under comparable conditions?

We have suggested previously (5) that the following three factors control the regioselectivity of metal hydride reductions: (a) the intrinsic reactivity of the carbonyl group; (b) the antiperiplanar effect; (c) steric hindrance. The regioselectivity of selectride reductions of compounds **1**, **2**, and **3** may be rationalized in terms of these effects in the following manner. Due to the high steric demand of the reagent,[2] steric congestion (c) becomes the dominant factor overriding the influences of the effects (a) and (b). The reagent's approach to the more hindered carbonyl function is difficult regardless of the conformation, plannar or twisted, of the anhydride ring (Fig. 1). Thus the reaction occurs selectively at the less substituted carbonyl group.

At first glance one might expect the same type of interaction in the selectride reduction of the anhydrides **4** and **5**. However, it appears that the approach of the reagent is restricted in a different fashion. The six-membered carbocyclic ring assumes preferentially a chair-like configuration, and in the process the attached anhydride ring is distorted from a planar to a twisted configuration suitable for the antiperiplanar attack at the C—CH_3 bond (Fig. 2). In effect, while the attack on the "top" face of the anhydride ring is hindered by the methyl substituent, the "bottom" face is slightly more open. As a result, the nucleophilic attack should occur preferentially on the "bottom" face of the molecule. Moreover, as the two electronic effects promote reduction of the carbonyl group adjacent to the methyl substituent, since (a) the more highly substituted carbonyl function should be intrinsically more reactive toward nucleophilic attack (6), and (b) the conformation of the molecule permits attack antiperiplanar to the C—CH_3 bond (7), we

[2]The selectride reagent resembles in shape a large and rigid umbrella of which H is a handle.

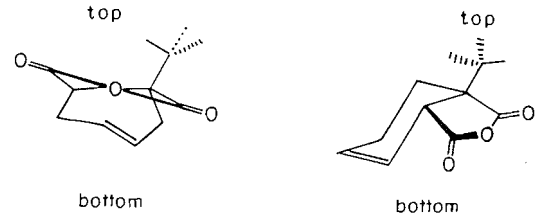

FIG. 2. The anhydride ring attached to the six membered cyclic system is distorted from planarity. Attack by the nucleophile from the "top" side is disfavoured by the presence of methyl substituent. The preferred attack: antiperiplanar to the C—CH_3 bond from the "bottom" side explains the regioselectivity observed in these reductions.

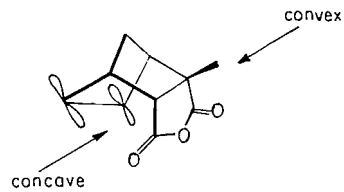

FIG. 3. Nucleophilic addition to the carbonyl group takes place from the more open convex side. The approach to the concave face is prevented by the π electrons of the double bond.

might expect hydride transfer occurring at this site (i.e. from the "bottom" side of the molecule at the carbonyl group adjacent to the methyl group).

The above considerations explain the regioselectivity observed in the reduction of anhydrides **4** and **5** by selectride reagents as well as by simple metal hydrides. The situation is different in the case of the bridged anhydride **6**. Here, the geometry of the six-carbon ring is fixed in the boat conformation by the methylene bridge. The anhydride attached to such a system is rigidly planar. It has been shown that in analogous bridged systems the nucleophile adds only from the "convex" side of the molecule (8). Thus as the attack from the "concave" side is prevented by the π electrons of the double bond, hydride must be transferred to the "convex" face of the molecule (Fig. 3).

In this case the simple metal hydrides, as well as the selectrides, can add more easily to the carbonyl function adjacent to the hydrogen atom than to the carbonyl group neighbouring the methyl substituent. Thus the reaction occurs regioselectively at the less hindered carbonyl function.

In conclusion, these examples confirm the previously proposed hypothesis stating that at least three different factors are implicated in the control of regioselectivity of metal hydride addition to the carbonyl group. The conformation of the molecule and the steric constraints associated with it, the intrinsic reactivities of two carbonyl functions, and the possibility of the antiperiplanar attack are all intimately involved. The observed selectivity is the net result of the interplay between these effects.

Experimental

The preparation of the anhydrides (**1** to **6**) has been described previously (1, 3).

Analyses of the reduction products were carried out on the crude reaction mixtures by gas–liquid chromatography and/or ^1H nmr. The lactonic product yields reported in Table 1 are the isolated yields. The modest quantities of lactones obtained reflect the difficulties encoun-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

tered in isolation and purification procedures, chiefly due to the high solubility of lactones in the aqueous phase.

Melting points were determined on a Thomas Hoover capillary melting point apparatus and are uncorrected. Infrared spectra were obtained on a Beckman IR-20 spectrophotometer and ^{1}H nmr spectra in $CDCl_3$ or DMSO with TMS as internal standard on a Varian AA-100 or EM 360 A instrument. Tetrahydrofuran was refluxed under nitrogen with potassium and benzophenone until the solution became purple, then was distilled into an oven-dried flask containing the anhydride to be reduced.

General reduction procedure

The anhydride (0.005 mol) was placed in a three-neck oven-dried flask into which 50 mL of THF was subsequently distilled. The flask was fitted with an inlet post for syringes, gas inlet and outlet tubes, and a magnetic stirrer. The solution swept with a slow stream of nitrogen was cooled to −70°C in a Dry Ice − acetone bath. K- or L-selectride (1.0 *M* solution in THF, 11 mL) was injected slowly into the reaction flask. The temperature of the reaction mixture was allowed to rise to 0°C over a period of 30 to 90 min, NaOH (4 *N* solution, 2 mL) and 30% H_2O (3 mL) were added cautiously. After stirring for 15 to 20 min sodium bisulfite was added to destroy the excess peroxide. The reaction mixture was acidified to pH 2 with 6 *N* HCl and was stirred overnight. The layers were separated and the acidic aqueous layer saturated with NaCl and extracted with ether and with methylene chloride. The extraction was a crucial step due to the lactones' solubility in water. In some cases a liquid−liquid extraction of the aqueous layer with ether was carried out for 24 h. The combined organic layers were dried, the solvent reduced in volume, and the product analyzed using a Varian Vista 6000 gas chromatograph with an ionization detector using a 6 ft 3% PC 3210 column.

Lactone identification

Individual lactones were separated by chromatography on silica gel:

β,β-Dimethyl-γ-butyrolactone (1) **1***a*, ν_{max}: 1775 cm^{-1} (lactone C=O); δ: 1.20 (s, 6H, $2CH_3$), 2.34 (s, 2H, CH_2—C=O), 3.98 (s, 2H, CH_2—O).

α,α-Dimethyl-γ-butyrolactone (1) **1***b*, ν_{max}: 1770 cm^{-1} (lactone C=O); δ: 1.28 (s, 6H, $2CH_3$), 2.12 (t, 2H, CH_2—C=O), 4.26 (t, 2H, CH_2—O).

β,β-Diphenyl-γ-butyrolactone (1) **2***a*, mp 108−109°C (lit (9) mp 109−110°C); ν_{max}: 1780 cm^{-1} (lactone C=O); δ: 3.28 (s, 2H), 4.90 (s, 2H), 7.36 (m, 10H).

α,α-Diphenyl-γ-butyrolactone (1) **2***b*, mp 77−79°C; ν_{max}: 1780 cm^{-1} (lactone C=O); δ: 2.9 (t, 2H), 4.2 (t, 2H), 7.3 (s, 10H).

β-Ethyl, β-methyl-γ-butyrolactone **3***a*, ν_{max}: 1780 cm^{-1} (lactone CO); δ: 1.1 (m, 6H), 1.5 (q, 2H), 2.3 (s, 2H), 3.95 (s, 2H).

α-Ethyl, α-methyl-γ-butyrolactone **3***b*, ν_{max}: 1780 cm^{-1} (lactone CO); δ: 1.1 (m, 6H), 1.5 (q, 2H), 2.1 (m, 2H), 4.2 (t, 2H).

cis-1-Methylcyclohex-4-ene-1,2-discarboxylic acid anhydride **4***a* (3), ν_{max}: 1770 cm^{-1} (lactone CO): δ: 1.3 (s, 3H, CH_3), 2.3 (m, 6H), 3.95 (q, 2H, CH_2—O). 5.65 (m, 2H).

Steroidal lactone **5***a* (1), mp 174−176°C; ν_{max}: 1765 cm^{-1} (lactone CO); δ: 1.18 (s, 3H, CH_3), 3.80 (s, 3H, OCH_3), 4.00 (q, 2H, CH_2—O).

exo-2-Methylnorborn-5-ene-*endo*-(3-methyl-2-carbo-3a) lactone **6***b* (1), mp 137−139°C; ν_{max}: 1765 cm^{-1} (lactone CO); δ: 1.52 (s, 3H, CH_3), 4.02 (m, 2H, CH_2—O), 6.33 (m, 2H).

Methylenecyclohexenes: inversion barriers from the far-infrared spectra

TRACY L. SMITHSON, NAN IBRAHIM, AND HAL WIESER[1]
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received August 2, 1982

TRACY L. SMITHSON, NAN IBRAHIM, and HAL WIESER. Can. J. Chem. **61**, 442 (1983).

The far-infrared spectra of 3-methylenecyclohexene, 4-methylenecyclohexene, and 1-methyl-3-methylenecyclohexene in the region of 80–400 cm^{-1} are reported and interpreted mainly with a view to the two lowest out-of-plane deformations of the cyclohexene ring. Typical C-type band sequences are observed and interpreted in terms of ring inversion modes. Barriers to inversion are determined by means of a one-dimensional Hamiltonian with a quadratic-quartic potential function. Possible ground state geometries and forms of the inversion coordinates are discussed and compared to those thought to occur in the analogous cyclohexenones.

TRACY L. SMITHSON, NAN IBRAHIM et HAL WIESER. Can. J. Chem. **61**, 442 (1983).

On rapporte les spectres infrarouges du méthylène-3 cyclohexène, du méthylène-4 cyclohexène et du méthyl-1 méthylène-3 cyclohexène dans la région allant de 80 à 400 cm^{-1} et on les interprète principalement en fonction des deux déformations hors plan les plus faibles du cycle du cyclohexène. On a observé des suites de bandes de type-C typiques et on les a interprétées en fonction des modes d'inversion du cycle. On a déterminé les barrières à la rotation au moyen d'un Hamiltonien unidimensionnel avec une fonction de potentiel quadratique-quartique. On discute des géométries de l'état fondamental possible et des formes des coordonnées d'inversion et on les compare avec celles qu'on croit trouver dans les cyclohexanones analogues.

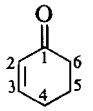
Introduction

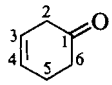
Recent far-infrared studies of cyclohexenones (1) showed that the position of the carbonyl group in relation to the double bond significantly affects the geometry of the cyclohexene ring, the barrier to planarity for the planar configuration, and the dynamic path followed by the ring inversion. It was of interest to us to pursue the underlying thought also for methylenecyclohexenes, molecules that, while similar, differ in important respects.

3-Methylenecyclohexene (3MCH)

4-Methylenecyclohexene (4MCH)



2-Cyclohexene-1-one (2CHO)



3-Cyclohexene-1-one (3CHO)

In the following we report the far-infrared spectra of 3-methylenecyclohexene and 4-methylenecyclohexene. In addition we investigated the same region of the infrared spectrum for 1-methyl-3-methylenecyclohexene (1M3MCH) with the hope of probing the effect of methyl substitution on the inversion barrier. No far-infrared or microwave spectra or electron diffraction studies have been reported previously for these compounds.

Experimental

Synthesis of the compounds

Although all three compounds have been made previously (2), our synthetic routes differed substantially from the earlier reported methods and are therefore described briefly below.

(i) 3-Methylenecyclohexene

3-Bromocyclohexene (3) was first reacted with triphenylposphine in acetonitrile to give cyclohex-3-en-1-yltriphenylphosphonium bromide (4) (96% yield, mp 220.2°C, lit. (4) mp 222–224°C). 3MCH was then prepared via the Wittig reaction (5) by adding excess paraformaldehyde to a solution of cyclohex-3-en-1-triphenylphosphine ylid, made from the bromide (43 g) and n-butyllithium (7 g) in ether (100 mL) (38% yield, bp 100–105°C, lit. (2*a*) bp 100–110°C). Final purification was achieved by preparative gc; nmr (60 MHz, $CDCl_3$): 6.30–5.55 (multiplet, 2H, vinyl), 4.70 (broad singlet, 2H, *exo*-CH_2), 2.50–1.40 (multiplet, 6H, C4 to C6 protons).

(ii) 1-Methyl-3-methylenecyclohexene

1M3MCH was made via the Wittig reaction (5) from 3-methylcyclohex-2-en-1-one (purchased from Aldrich) and methylenetriphenylphosphine ylid. The latter was prepared from triphenylmethylphosphonium bromide (29 g) (5) and n-butyllithium (55 mL of 1.6 *M* solution in hexane) in ether (200 mL). The overall yield after distillation was 42%, bp 25–28°C/12 Torr (lit. (2*b*) bp 135–136°C); nmr (60 MHz, $CDCl_3$): 5.94 (broad singlet, 1H, vinyl), 4.63 (broad singlet, 2H, *exo*-CH_2), 2.43–1.75 (multiplet, 6H, C4 to C6 protons), 1.80 (singlet, 3H, methyl).

(iii) 4-Methylenecyclohexene

The precursor 1-bromomethyl-3-cyclohexene was first synthesized by reaction of the alcohol and PBr_3 (6) in low yield (28%) and containing several other addition products. With the preferred procedure 3-cyclohexen-1-methyltosylate was refluxed with LiBr in acetone (7) giving the desired bromide in 74% yield (bp 72°C/12 Torr, lit. (6) bp 100–120°C/35 Torr). Dehydrobromination of 1-bromomethyl-3-cyclohexene was affected by reaction with DBU. The crude liquid product (30% yield) was purified by redistillation (bp 100–104°C, lit. (2*c*) bp 104–106°C); nmr (60 MHz, $CDCl_3$): 5.65 (broad singlet, 2H, vinyl), 4.72 (broad singlet, 2H, *exo*-CH_2), 2.75 (broad singlet, 2H, allylic), 2.25 (muliplet, 4H, allylic) (2*c*).

The spectra

All spectra were obtained with a Nicolet Series 8000 Interferometer, equipped with a 60 m matched variable path gas cell manu-

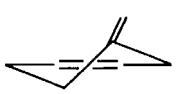
factured by the same company. A liquid helium cooled bolometer operating at 4.2 K with the appropriate cut-on filter was used as detector. The beamsplitter was a 6 μm Mylar and the resolution was set at 0.12 cm^{-1} with boxcar apodization. The spectra were run with saturated or reduced vapour pressures and 45 m path. On the average, 200–500 scans were accumulated to achieve optimum signal-to-noise ratios. The reported positions of the sharp absorptions are believed to be accurate to at least 0.02 cm^{-1}.

Molecular geometries and the inversion mode

In this work we are concerned primarily with the out-of-plane deformations of the cyclohexene ring. In the absence of any structure determination by microwave or electron diffraction we need to make some reasonable guesses about the ground state geometries and the probable forms of the three vibrational modes.

In all likelihood the structure of 3MCH will resemble that of 2CHO, namely, all atoms except C5 should lie in one plane (8). If a double minimum vibration is observed, therefore, we can logically assign it to an inversion of the C5 atom through that plane (ν_i), as was done for 2CHO. One reasonable choice for the second mode is a torsion about the C2—C3 (in 3MCH) bond, ν_τ. It would be restricted by the double bond character resulting from the conjugation of the two C=C groups. Indeed, there is some indirect evidence in 2CHO suggesting that the inversion of C5 is accompanied by a torsion about that bond (C1—C2 in that case) (1). We note that this same torsion is the double minimum vibration in 1,3-cyclohexadiene (9). Its barrier to planarity of 1099 cm^{-1} compares to that in 2CHO of 3640 cm^{-1} and is lower at least partially as a result of the fewer methylene hydrogen interactions. The torsion in 2CHO can be assigned to the broad Raman feature reported near 250 cm^{-1} (10) corresponding to a weak sequence of A-type Q branches spreading from 244 to 248 cm^{-1}.[2] The third out-of-plane deformation undoubtedly resembles a torsion about the endocyclic double bond. Invariably that mode is observed at higher wavenumbers (about 300–400 cm^{-1}) in other cyclohexene-type molecules and does not appear to couple significantly with the lower modes (11). It is therefore not of direct interest in our deliberations and we shall not discuss it any further.

For 4MCH (and 3CHO) we can visualize at lease two possible ground state conformations. One of these, the twisted (half-chair) form, obviously resembles that of cyclohexene in its lowest state. The second is a "bent" (boat) form which, we note, can be reached from the planar conformation by either folding the ring about the C3—C6 axis, or by rotating the two



Twisted

Bent

planes containing the two double bonds against one another with C3 serving as the fulcrum. The two routes differ in the extent by which the exocyclic double bond is displaced out of the plane containing the endocyclic double bond. The true pathway likely is some combination attempting to minimize all interactions and is not easily determined from the infrared spectra, certainly not of only one isotopic species. We expect the energies of the two vibrations, namely the twist, ν_t, and the bend, ν_b, to be similar to those observed for other cyclohexene-type molecules where the latter always occurs at lower wavenumbers (11). For 3CHO we have therefore ascribed the "bend" to a sequence of Q branches starting at 77.23 cm^{-1} (1). It is this mode which is subject to a double minimum potential function, suggesting that the ground state of 3CHO is the "bent" conformation. The twist in 3CHO appears to give rise to a broad, nearly featureless absorption around 155 cm^{-1}.[2] Initially we might expect 4MCH to behave similarly to the ketone. The CCC angle of the carbonyl group is nearly the same as the corresponding angle in the vinyl group (12), and both groups apparently prefer a conformation where the C—H bonds on the adjacent C atoms are eclipsed with the π bond. We might look for a difference between the two compounds as a result of the different torsional barriers (cf. barrier to methyl torsion of 272 cm^{-1} (0.777 kcal mol^{-1}) in acetone (13) vs. 773 cm^{-1} (2.21 kcal mol^{-1}) in 2-methylpropene (14)).

Results

3-Methylenecyclohexene

The survey spectrum of 3MCH in the region of 80–440 cm^{-1} is displayed in the top field of Fig. 1. The two out-of-plane deformations, ν_i and ν_τ, are clearly seen as weak Q branch sequences. They are replotted on an expanded scale in Fig. 2. The inversion mode ν_i forms a descending series, starting at 111.13 cm^{-1}, characteristic of a double minimum vibration subject to a relatively high barrier. We fitted the transitions with a one-dimensional Hamiltonian containing a quadratic-quartic potential function, using a computer program described elsewhere (15). The transitions and the fitting parameters are listed in Table 1.

The torsion mode ν_τ also exhibits several Q branches which evidently must arise from some kind of combination transitions. Such combinations, however, do not appear to take place with ν_i in the first instance. Rather, they can be correlated with the fundamental at 373 cm^{-1} and its sequence of combination bands displayed to lower wavenumbers (Fig. 3), as shown in the energy level diagram drawn in Fig. 4a. The fundamental of ν_τ is thereby placed at 259.39 cm^{-1} (see right field of Fig. 2). We believe that the 373 cm^{-1} fundamental can be assigned to the in-plane deformation of the exocyclic vinyl group, labelled ν_{ip} in the figures. The additional fine structure on that absorption and on its hot bands with ν_i probably is due to other combinations, but explicit assignments are very difficult. For example, one such difference band sequence based on ν_i may be observed near 265 cm^{-1} (see right field of Fig. 2 and energy level diagram in Fig. 4b), but a lack of corroborative transitions precludes a more definitive assignment. A combination sequence with ν_i is seen also on the 303 cm^{-1} fundamental which we believe is due to the out-of-plane deformation of the ex-

ocyclic vinyl group, ν_{op}, with its corresponding sum band series near 415 cm^{-1} (see Figs. 4c and 5).

1-Methyl-3-methylenecyclohexene

The survey spectrum of 1M3MCH is pictured in the center field of Fig. 1. The clearly separated ν_i sequence of 3MCH at 111 cm^{-1} is replaced by a complex C-type band near 152 cm^{-1}. Some of the structure of that band can be related unambiguously with the methyl torsion absorption ($\nu_{m\tau}$) near 190 cm^{-1} (see Figs. 6 and 7), placing the ν_i and $\nu_{m\tau}$ fundamentals at 152.74 and 192.85 cm^{-1} and revealing the ground state sequence of ν_i. This sequence is again fitted with the quadratic-quartic potential function; the results are listed in Table 1. The barrier to methyl torsion is estimated to be 900 cm^{-1} using the first two transitions (see Fig. 7) with a V_3 potential energy term in a conventional program (16) for that purpose and an optimized F number of 5.4576 cm^{-1} (standard deviation of observation of 6.0 cm^{-1}). The fundamental ν_τ has shifted to slightly lower wavenumbers upon methyl substitution, namely 248.42 cm^{-1} (see Fig. 1). Although this absorption shows a distinct Q branch sequence, its members cannot be correlated with any other vibrations in this region. Possibilities of such an interaction include the inversion mode, or the in-plane deformation of the exocyclic vinyl group as in 3MCH. There are lines among the ν_i and $\nu_{m\tau}$ bands that were left unassigned which may be inversion and/or methyl torsion transitions in the excited states of ν_τ.

4-Methylenecyclohexene

Changing the relative position of the two double bonds evidently affects the appearance of the spectrum dramatically (see lower field of Fig. 1). The distinct Q branch sequences near 111 and 174 cm^{-1} are assigned to the bend (ν_b) and the twist (ν_t) modes of the cyclohexene ring. Both exhibit pronounced substructure (see Figs. 8 and 9) which can be identified unambiguously with the help of the first overtone transitions starting at 222 and 345 cm^{-1} (shown in Fig. 10). The assignment is summarized in the energy level diagram depicted in Fig. 11 and the peak positions are listed in Table 2. Both modes in their ground and several excited states are amenable to solution with the one-dimensional Hamiltonian with a quadratic-quartic potential function, as shown in Tables 3 and 4.

Discussion and conclusions

We have analyzed the inversion absorptions for all three compounds with a one-dimensional Hamiltonian that includes a quadratic-quartic potential function and a constant reduced mass in the kinetic energy. Although the out-of-plane defor-

[a]The apparent most prominent member of a series of Q branches.

stants, given in the tables in terms of the dimensionless coordinates, are to be viewed as effective constants, particularly for the inversions in the excited states of another mode. Although the method used here is not able to provide any explicit information about the dynamic form of the vibrations, other than comfirming double minimum situations, we believe it does yield reasonable estimates of barriers to inversion for the ground state conformations. Considering that we are dealing with high barriers that are determined from a relatively small number of the lowest transitions, a certain error due to extrapolation to the top of the well is also unavoidable. The uncertainties on these barriers quoted in the tables reflect the estimated standard deviations of the potential constants. A more realistic estimate of these uncertainties may be about ±10%.

In Table 5 the positions of the two lowest out-of-plane ring deformations of the methylenecyclohexenes are compared to those of the corresponding ketones. We find that the spectrum of 3MCH is similar to that of 2CHO, the fundamental of ν_i being shifted slightly to higher wavenumber and the separation between successive inversion transitions being somewhat greater (e.g., difference of 1.27 cm^{-1} between the first two transitions in 3MCH vs. 0.57 cm^{-1} in 2CHO). The intensity of ν_i is much reduced, while that of ν_τ is comparable. The latter mode again does not appear to couple with ν_i to any great extent. These observations confirm the presumption that the structure, and the form of the inversion mode, of 3MCH are quite similar to those of the ketone. The barrier to inversion, however, is considerably lower in 3MCH. This drop in barrier height is consistent with the reduced degree of conjugation of the endocyclic double bond with the vinyl group as compared to the more polar carbonyl group. The intervening single bond is thereby again implicated in the inversion mode, supporting the earlier suggestion that the inversion of C5 through the plane is facilitated to some extent by a torsion about that bond.

Methyl substitution in 3MCH appears to affect the position of the ν_i fundamental significantly as compared to the parent compound and to the corresponding ketones, whereas ν_τ remains virtually unchanged. There is clear evidence of ν_i interacting with the methyl torsion. There also are indications of ν_τ coupling with one other or possibly more vibrations, but no definitive assignments of sum or difference bands are possible. While we can pick out one sequence of ν_i, seemingly the ground state sequence, and fit it with a quadratic-quartic potential function, we cannot be assured that this is the only way of describing the vibration. This interpretation, however, which suggests a ground state conformation and a form of the inversion mode resembling that of the parent compound, is at least consistent with the notion that methyl substitution on C1

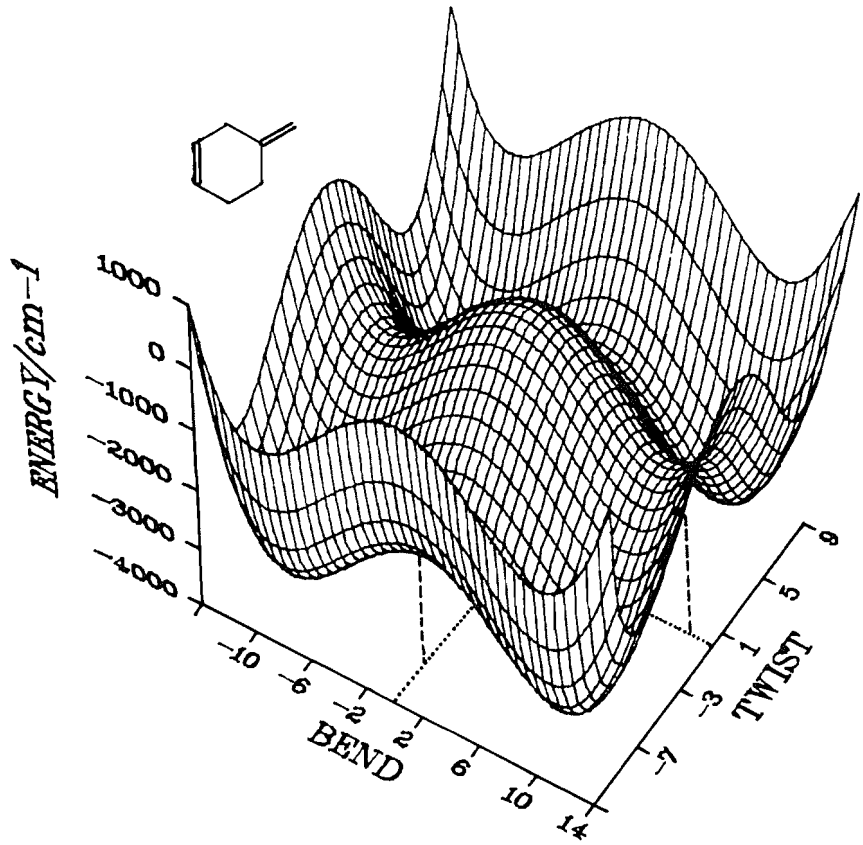

FIG. 12. Bend–twist potential energy surface in the ground state of all other modes for 4-methylenecyclohexene, using the potential function constants quoted in Tables 3 and 4.

in 3MCH diminishes the degree of conjugation. If a torsion about the C2—C3 bond accompanies the inversion of C5, the decreased conjugation indeed would lead to a lowering of the barrier to inversion. In the ketone, on the other hand, the methyl group stabilizes the conjugation thereby increasing the double bond character of the single bond (C1—C2 in that case) and hence raising the inversion barrier.

The picture emerging for 4MCH is substantially different from either the conjugated methylenecyclohexene or, surprisingly, also from the corresponding ketone, 3CHO. The fit of the one-dimensional double minimum potential for both ν_b and ν_t suggests two independent vibrations. If this interpretation is correct, 4MCH to our knowledge would constitute the first example of the type of a molecule referred to as Case 5 for five-membered rings described by Harris *et al.* (17), where the interaction term in the potential function between two out-of-plane deformation modes approaches zero and the two double minimum vibrations are completely independent. To test this hypothesis further we attempted to determine the best fitting two-dimensional potential surface described by a function of the form

$$V(x_1,x_2) = V_{21}x_1^2 + V_{22}x_2^2 + V_{41}x_1^4 + V_{42}x_2^4 + V_{mix} \times x_1^2x_2^2$$

in the appropriate Hamiltonian, using a computer program outlined elsewhere (18). When the potential constants for the two modes in their ground state are entered and constrained, V_{mix} is allowed to vary, and all excited state information is used, a very small mixing term of 0.00222(69) cm^{-1} is calculated with the effect that the fit of all transitions is being averaged. When average quadratic and quartic constants for both modes are first adjusted to produce an average fit, constraining V_{mix} to zero at the same time and using all transitions, and then these average constants are held fixed while floating V_{mix}, the calculations always attempt to drive the mixing term to zero. The fit to all observed transitions produced in this way is the same as with the first procedure. Finally, if all constants are allowed to vary simultaneously, convergence cannot be achieved and the calculation is ill-determined. These results support the interpretation of the spectrum in terms of two independent double minimum modes.

Additional evidence, in our view, is provided by the appearance of the spectrum itself. The sequence of ν_b and ν_t as well as that of their first overtones are quite regular. Members of a series in a sequence of excited states of the second mode differ very little. These observations contrast the experience made with other cyclohexene-type molecules where the sequences frequently reverse their direction and the bend and twist modes are known to interact extensively (see for example ref. 11).

The resulting potential surface is pictured in Fig. 12. The lowest energy state is 3691 cm^{-1} below the central barrier (also the barrier to planarity) and corresponds to a conformation that is somewhere between the two forms designated above as bent and twisted. The molecule may interconvert from one of the four equivalent "bent–twist" minima to another via the twisted conformation 1476 cm^{-1} above the minimum, or via the bent conformer 2215 cm^{-1} above the minimum. It must be remembered that the designation of the conformations as "bent" or "twisted" may not describe the actual situations properly since neither the infrared spectra nor the calculations referred to

above are capable of yielding any explicit information about the molecular geometry.

In summary, we note that the methylenecyclohexenes and their related ketones have provided interesting new insights into the dynamics of the out-of-plane deformations of cyclohexene-type molecules. When the double bonds are conjugated, the form of the inversion vibration appears to differ considerably from those observed previously for other related compounds. The trends in the inversion barriers follow accepted chemical concepts. When the double bonds are isolated, new and different situations arise and one can observe a trend of behaviour. Cyclohexene itself (19, 20) and oxygen substituted analogues (11, 21), being in a twisted ground state conformation, exhibit the characteristic sequences of transitions for the bend and twist vibrations. The latter is a true double minimum mode, while the former, at least in the ground state of the twist, is an anharmonic vibration constrained in the relatively deep well of the twist. The bend transitions, although they form a descending sequence, do not represent a double minimum situation; rather, the lowering in wavenumbers of consecutive members reflects the anharmonicity in the twist minimum. The molecule can interconvert between the equivalent twisted forms via a bent conformation without going through the much higher energy planar geometry, though there still seems to be some question whether the bent form constitutes a saddle point or a local minimum (21, 22). In 4MCH we find a molecule which has four equivalent conformations that are neither "twisted" nor "bent", but some intermediate. The two vibrations are independent of one another, each subject to its own double minimum potential function and displaying the characteristic descending series of transitions. Interconversion between the equivalent forms of the ground state geometry can take place via either the twisted or bent conformations which form saddle points on the potential surface. The barrier to planarity, we note, is of similar magnitude as in other cyclohexene-type molecules (e.g., 3,6-dihydropyran and 1,3-dioxene (11)). Finally, 3CHO appears to adopt a "bent" ground state geometry with a low barrier to inversion through the planar conformation. The bend vibration shows the series of absorptions typical for such a double minimum potential. The twist vibration may or may not be anharmonic, but in any event does not appear to dominate the other out-of-plane deformation.

Acknowledgements

On this occasion we would like to express our sincere gratitude to the Natural Sciences and Engineering Research Council of Canada (NSERCC) for the award in 1980 of a Major Equipment Grant which allowed us to purchase our interferometer and without which none of the work currently in progress would be possible. T.L.S. also acknowledges with thanks the award of an NSERCC Postgraduate Scholarship. This research was supported partly through a normal Operating grant from NSERCC and recently also through a generous Special Project grant from the Alberta Environment Research Trust (both to H.W.). We wish to thank A. Dunham and R. A. Kydd of this Department for permission to use their internal rotor/pseudorotation program.

The copper catalysed reaction of α-diazo esters with pyrroles has been known for five decades (1) and continues to be the subject of mechanistic and synthetic studies (2). It is, in fact, still one of the most reliable methods for the synthesis of pyrrole-2-acetic acid esters (3). The intramolecular version of this reaction has, to our knowledge, never been reported in the chemical literature. This paper describes the utilization of such a process for the synthesis of ethyl 1,2-dihydro-3*H*-pyrrolo-[1,2-*a*]pyrrole-1-carboxylate **7**.

The α-daizo ester **6**, required for this study, was synthesized by means of a four-step sequence from 1-(2-hydroxyethyl)-pyrrole **1**.[3] Thus, the methanesulfonate **2**, derived from **1**, was converted into the iodide **3**, and this compound, upon reaction with the sodium salt of diethyl formamidomalonate, gave the expected alkylation product **4**. Selective hydrolysis of the formamido moiety in **4** was effected with hot, dilute, aqueous hydrobromic acid, and the α-amino malonate **5**, thus obtained, was converted directly into the α-diazo ester **6** with isopentyl nitrite (29% yield from **3**).

The accessibility of the α-diazo ester permitted an investigation of the potential utility of this compound as a source of 1,2-dihydro-3*H*-pyrrolo[1,2-*a*]pyrrole-1-carboxylic acid derivatives. Thus, curpic tetrafluoroborate catalysed decomposition of the diazo compound, in boiling hexane, gave a 70:17:13 mixture (see Table 1) of the desired bicyclic ester **7** and the *cis* and *trans* olefinic esters **9** and **10** in about 14% yield. The bicyclic ester was positively identified by saponification and conversion into the dicyclohexylammonium salt (4) of the carboxylic acid **8**, while the identity of the olefinic esters was established by means of their ir (strong CH out of plane bending band at 980 cm^{-1} for **10**) and nmr (J_{cis} = 12.0 Hz for **9** and J_{trans} = 15.7 Hz for **10**) spectroscopic properties (also see experimental section). The ratio of the bicyclic ester to the olefinic ester depended both on the amount and the nature of the promoter. In general, the combined product yields were the highest when equimolar amounts of the diazo compound and the copper reagent were used, but in no case did this yield exceed 35%. Hydrated copper(II) acetylacetonate was unique in that it gave the greatest proportion of the cyclized product and that no *cis* olefinic ester was formed.

The results described above demonstrate that intramolecular

[a]Average of two determinations.
[b]Commercial solid (Alfa) was pulverized and then dried under high vaccum, first over potassium hydroxide pellets (24 h), then over phosphorous pentoxide (24 h).

carbenoid reactions with pyrroles are indeed possible, but that, at least in the present case, preparatively useful yields of the bicyclic product are not obtained. Presumably the entropy factor, which is expected to make attack of the putative carbenoid on the pyrrole α-carbon atom more favourable, is more than offset by other effects, such as strain, and the propensity to undergo a hydrogen shift to produce olefinic products (6)[4] analogous to that observed for the carbenoids derived from α-alkyl-α-diazoketones (7).

p-Toluenesulfonic acid catalysed decomposition of **6** produced only the olefins **9** and **10**. In contrast, some cyclization did take place when the diazo ester was decomposed, at low temperature, with boron trifluoride etherate in dichloromethane solution. This reaction, which presumably is similar to the intramolecular alkylation of aromatic systems by α-diazoketones (8), deserves to be investigated further.

Experimental

The melting points were determined in a Mel-Temp melting point apparatus and are not corrected. The infrared spectra were measured with a Perkin–Elmer Model 237 grating infrared spectrophotometer. The ultraviolet spectra were recorded on a Perkin–Elmer Model 402 ultraviolet visible spectrometer. The nmr spectra were obtained with a Varian T-60 spectrometer. The chemical shifts are expressed in ppm (δ) from internal tetramethylsilane. The low and high resolution mass spectra were measured with Varian MAT CH-7 and 311A spectrometers, respectively. The gas–liquid chromatographic analyses were made with a Hewlett–Packard Model 5750 Research chromatograph (6 ft, 10% Sil. rubber S.E.30, 120°C, N_2 flame ionization).

1-(2-Methanesulfonyloxyethyl)pyrrole **2**

Triethylamine (27.9 g, 276 mmol) was added to a stirred solution of 1-(2-hydroxyethyl)pyrrole[3] (25.0 g, 225 mmol) in anhydrous dichloromethane (100 mL) cooled to −8°C. A solution of methanesulfonyl chloride (20.9 g, 270 mmol) in dichloromethane (50 mL) was added dropwise at the above temperature over a 0.75 hour period. The mixture was then mixed with 10% sodium bicarbonate solution, the organic phase was separated, washed with water and with saturated sodium chloride solution. The dichloromethane solution was dried over sodium sulfate and evaporated *in vacuo*. The residual oil (42.2 g) was sufficiently pure for use in the next step. It crystallized on standing and on recrystallization from methanol it had mp 42–42.5°C, uv (MeOH): 220 (4370) nm; ir ($CHCl_3$): 1356, 1167 cm^{-1}; nmr ($CDCl_3$) δ: 2.70 (s, 3H), 4.00–4.56 (m, 4H), 6.13 (m, 2H), 6.55 (m, 2H). *Anal.* calcd. for $C_7H_{11}NO_3S$: C 44.42, H 5.86, N 7.40; found C 44.65, H 5.91, N 7.38.

1-(2-Iodoethyl)pyrrole **3**

A solution of the methanesulfonate (25.0 g, 132 mmol) in anhydrous acetonitrile (400 mL) containing dry sodium iodide (98.4 g, 655 mmol) was heated at reflux temperature for 1.5 hours. The solution was cooled, the solvent was removed *in vacuo*, and water was added to the residue. The product was extracted into dichloromethane, the extract was dried over sodium sulfate and evaporated *in vacuo*. The residual oil (27.4 g, 94%) was sufficiently pure to be used in the next step. For analysis, a small portion of the crude iodide was subjected to column chromatography on silica gel using hexane–dichloromethane (1 : 1) as the eluting solvent; uv (MeOH): 225 (5890), 260 sh (794) nm; nmr ($CDCl_3$) δ: 3.16–3.53 (m, 2H), 4.03–4.40 (m, 2H), 6.13 (m, 2H), 6.61 (m, 2H). *Anal.* calcd. for C_6H_8IN: C 32.60, H 3.64, N 6.33; found: C 32.79, H 3.59, N 6.16.

Ethyl 2-formamido-2-ethoxycarbonyl-4-(pyrrol-1-yl)butanoate **4**

Sodium hydride in mineral oil (50%, 5.25 g, 109 mmol) was washed with hexane and then suspended in dry dimethylformamide (100 mL). Diethyl formamidomalonate (22.0 g, 109 mmol) was added to the magnetically stirred suspension and after 0.67 hours 1-(2-iodoethyl)pyrrole (20.0 g, 90 mmol) dissolved in dimethylformamide (20 mL) was added and the solution was then heated at reflux temperature for 5 hours. The cooled solution was poured into 10% hydrochloric acid solution and the product was extracted into toluene. The extract was dried over sodium sulfate and evaporated *in vacuo*. The residue was subjected to column chromatography on silica gel (50 g/g of crude product) and the desired material was eluted with hexane – ethyl acetate (89:11). The solid thus obtained (17.0 g, 64%) on crystallization from acetone–hexane had mp 88–89°C; uv (MeOH): 222 (5500) nm; ir ($CHCl_3$): 3415, 1745, 1697 cm^{-1}; nmr ($CDCl_3$) δ: 1.29 (t, 6H, J = 7.0 Hz), 2.93 (t, 2H, J = 6.7 Hz), 3.97 (t, 2H, J = 6.7 Hz), 4.30 (q, 4H, J = 7.0 Hz), 6.17 (m, 2H), 6.56 (m, 2H), 7.08 (m, 1H, exchanged with D_2O), 8.22 (s, 1H). *Anal.* calcd. for $C_{14}H_{20}N_2O_5$: C 56.74, H 6.80, N 9.45; found: C 56.78, H 6.78, N 9.49.

Ethyl 2-amino-2-ethoxycarbonyl-4-(pyrrol-1-yl)butanoate **5**

A mixture of the above formamide (5.00 g, 16.9 mmol) and 47% hydrobromic acid (14.9 g, 86.5 mmol) in water (150 mL) was stirred at reflux temperature for 0.75 hours. The solution was cooled to 5°C and made alkaline by the cautious addition of concentrated ammonium hydroxide solution. The product was extracted into ethyl acetate, the extract was washed with water, dried over sodium sulfate, and evap-

[4]We thank Dr. B. E. Maryanoff, McNeil Laboratories, for pointing this out and for providing us with relevant references.

For personal use only.

orated *in vacuo* to give an oil (2.94 g, 65%); uv (MeOH): 222 (4170), 303 (2460) nm; ir ($CHCl_3$): 3405, 3340, 1739 cm^{-1}; nmr ($CDCl_3$) δ: 1.29 (t, 6H, J = 6.5 Hz), 2.02 (m, 2H, W_H = 6 Hz, exchanged with D_2O), 2.39 (t, 2H, J = 7.2 Hz), 4.05 (t, 2H, J = 7.2 Hz), 4.23 (q, 4H, J = 6.5 Hz), 6.15 (m, 2H), 6.58, (m, 2H). This compound was converted into the neutral oxalate salt in ethanol for analysis. After crystallization from acetone it had mp 76–78°C. *Anal.* calcd. for $C_{28}H_{40}N_4O_8$:$C_2H_2O_4$: C 53.66, H 6.76, N 8.95; found: C 53.60, H 6.59, H 8.59.

Ethyl 2-diazo-4-(pyrrol-1-yl)butanoate ***6***

A solution of the above amine (5.60 g, 20.9 mmol) in chloroform (50 mL) containing isopentyl nitrite (15.3 g, 130 mmol) was stirred at room temperature for 1 hour and then poured into dilute sodium bicarbonate solution. The organic phase was separated, combined with a chloroform extract of the aqueous phase, and then it was dried over sodium sulfate. The solvent was removed *in vacuo* and the residue was subjected to column chromatography on silica gel (50 g/g crude mixture). The pure diazo compound was eluted with hexane–dichloromethane (95:5) to give an oil (2.95 g, 69%) which was distilled *in vacuo* for analysis, bp 89–92°C/0.15 Torr; uv (MeOH): 218 (8320), 262 (10 000) nm; ir ($CHCl_3$): 2065, 1685 cm^{-1}; nmr ($CDCl_3$) δ: 1.28 (t, 3H, J = 7.3 Hz), 2.69 (t, 2H, J = 6.4 Hz), 4.06 (t, 2H, J = 6.4 Hz), 4.25 (q, 2H, J = 7.3 Hz), 6.19 (m, 2H), 6.66 (m, 2H); mass spectrum m/e (relative intensity): 179(30), 150(32), 134(20), 106(100), 80(45), 53(25). *Anal.* calcd. for $C_{10}H_{13}N_3O_2$: C 57.95, H 6.32; found: C 58.03, H 6.11.

Decomposition of the diazo compound ***6****. Formation of ethyl 1,2-dihydro-3*H*-pyrrolo[1,2-*a*]pyrrole-1-carboxylate* ***7****, and* cis *and* trans *ethyl 4-(pyrrol-1-yl)buten-2-oates* ***9*** *and* ***10***

The promoter was added to a solution of the diazo compound in the desired solvent (200 mL/g diazo compound; see Table 1) and the reaction was carried out at the temperature specified. When the diazo compound was no longer present the mixture was filtered through Celite and the filtrate was evaporated *in vacuo*. The residue could be subjected to quantitative analysis by gas–liquid partition chromatography, or separation by preparative tlc (even for gram quantities) using dichloromethane–hexane (3:2). The least and most polar compounds by tlc were **9** and **10**, respectively. A large amount of very polar material remained at the origin.

The bicyclic ester **7** was an oil; uv (MeOH): 222 (5250) nm; ir ($CHCl_3$): 1725 cm^{-1}; nmr ($CDCl_3$) δ: 1.27 (t, J = 7.2 Hz, CH_3), 2.53–2.97 (m, 2-CH_2), 3.80–4.17 (m, 1-CH and 3-CH_2), 4.25 (q, J = 7.2 Hz, OCH_2), 5.97 (m, H-6), 6.38 (m, H-7), 6.60 (m, H-5); ms (*Exact Mass*, high resolution mass spectrum) calcd. for $C_{10}H_{13}NO_2$: 179.0946; found: 179.0942.

The *cis* ester **9** also was an oil; ir ($CHCl_3$): 1717, 1645 cm^{-1}; nmr ($CDCl_3$) δ: 1.30 (t, J = 7.1 Hz, CH_3), 4.17 (q, J = 7.1 Hz, OCH_2), 5.07 (dd, J = 2.0, 6.2 Hz, NCH_2), 5.82 (dt, J = 2.0, 12.0 Hz, α-CH(olefinic)), 6.14 (m, H-3,4(pyrrole)), 6.28 (dt, J = 6.2, 12.0 Hz, β-CH(olefinic)), 6.65 (m, H-2,5(pyrrole)); ms (*Exact Mass*, high resolution mass spectrum) calcd. for $C_{10}H_{13}NO_2$: 179.0946; found: 179.0944.

The *trans* ester **10** was also an oil; ir ($CHCl_3$): 1723, 1670, 980 cm^{-1}; nmr ($CDCl_3$) δ: 1.26 (t, J = 6.9 Hz, CH_3), 4.21 (q, J = 6.9 Hz, OCH_2), 4.62 (dd, J = 1.7, 5.0 Hz, NCH_2), 5.67 (dt, J = 1.7, 15.7 Hz, α-CH(olefinic)), 6.18 (m, H-3,4(pyrrole)), 6.63 (m, H-2,5(pyrrole)), 7.02 (dt, J = 5.0, 15.7 Hz, β-CH(olefinic)); ms (*Exact mass*, high resolution mass spectrum) calcd. for $C_{10}H_{13}NO_2$: 179.0946; found: 179.0942.

*1,2-Dihydro-3*H*-pyrrolo[1,2-*a*]pyrrole-1-carboxylic acid* ***8***

A solution of the ester **7** (1.00 g, 5.59 mmol) in methanol (15 mL) and water (15 mL) containing sodium hydroxide (0.44 g, 11 mmol) was stirred at room temperature for 18 h. The methanol was removed *in vacuo*, water was added to the residue, and the solution was extracted with dichloromethane. The aqueous phase was cooled to 0°C and made acidic with concentrated hydrochloric acid. The product was extracted with ethyl acetate, the extract was washed with water and dried over sodium sulfate. The solvent was removed *in vacuo* and the residual oil was taken up in dichloromethane (20 mL). Dicyclohexylamine (1.3 mL) was added and after 0.5 hour the solvent was removed *in vacuo*. The residual solid was crystallized from dichloromethane–hexane giving material (1.52 g, 82%) with mp 152–153°C, identical in all respects to an authentic speciment of this salt (4).

Effect of the partial pressures of oxygen and water vapour on the dispersity of α-Cr_2O_3 obtained by thermal decomposition of hydrated chromium(III) oxide

DIMITAR G. KLISSURSKI AND VLADIMIR N. BLUSKOV

Institute of General and Inorganic Chemistry, Bulgarian Academy of Sciences, 1040 Sofia, Bulgaria

Received August 24, 1981[1]

DIMITAR G. KLISSURSKI and VLADIMIR N. BLUSKOV. Can. J. Chem. **61**, 457 (1983).

The effect of water vapour and oxygen partial pressure on the thermal decomposition of hydrated chromium(III) oxide has been studied. A decrease in the water vapour partial pressure from 20 to 1×10^{-3} mm Hg has been found to produce a sharp increase in the specific surface area of the decomposition product (α-Cr_2O_3). Decomposition in an argon atmosphere leads to highly dispersed α-Cr_2O_3 even at relatively high temperatures (400–500°C).

DIMITAR G. KLISSURSKI et VLADIMIR N. BLUSKOV. Can. J. Chem. **61**, 457 (1983).

On a étudié l'influence de la vapeur d'eau et de la pression partielle d'oxygène sur la décomposition thermique de l'oxyde de chrome(III) hydraté. On a trouvé qu'une diminution de la pression partielle de la vapeur d'eau de 20 à 1×10^{-3} mm de Hg produit une augmentation nette de la surface spécifique du produit de décomposition (α-Cr_2O_3). La décomposition sous atmosphère d'argon conduit à du α-Cr_2O_3 hautement dispersé même à des températures relativement élevées (400–500°C).

Introduction

The preparation of highly dispersed α-Cr_2O_3 is of considerable interest since this compound is a component of many oxide-type catalysts. Hydrated chromium oxides are mostly used as initial compounds.

The thermal decomposition of hydrated chromium oxides has been the subject of many investigations (1–12). Some of them have established a measurable effect of the partial pressure of oxygen on the mechanism of decomposition.

The present paper contains results of a study dedicated to the effect of the partial pressure of oxygen and water vapour on the thermal decomposition of α-$Cr_2O_3 \cdot nH_2O$ and on the dispersity and specific surface area of the α-Cr_2O_3 obtained.

Experimental

The initial xerogel of the highly dispersed α-$Cr_2O_3 \cdot nH_2O$ was obtained by a method described by Brauer (13) using precipitation from solutions of $Cr(NO_3)_3 \cdot 9H_2O$ and NH_4OH (25%) at a final pH = 7–8. The thermal decomposition was carried out in a flow of pure argon, oxygen, or air at different partial pressures of the water vapour ranging from 1×10^{-3} to 17.5 mm Hg. The samples were preliminarily dried for 15 h at 50°C.

The sintering of the initial α-$Cr_2O_3 \cdot nH_2O$ and of the obtained α-Cr_2O_3 was investigated in an argon flow at a water vapour partial pressure of 17.5 mm Hg.

The solid products of thermal decomposition were subject to thermal analysis, ir spectroscopy, and X-ray phase analysis. The specific surface areas of the samples were determined by the BET method using low-temperature nitrogen adsorption.

Results and discussion

The water content in the initial samples dried at 50°C as established by thermal analysis was 32.3%.

Figure 1 shows the effect of the water vapour partial pressure on the specific surface area of α-Cr_2O_3. The changes of this parameter for samples obtained by thermal treatment (3 h) in air at different water vapour partial pressures, in argon and oxygen flows, are shown.

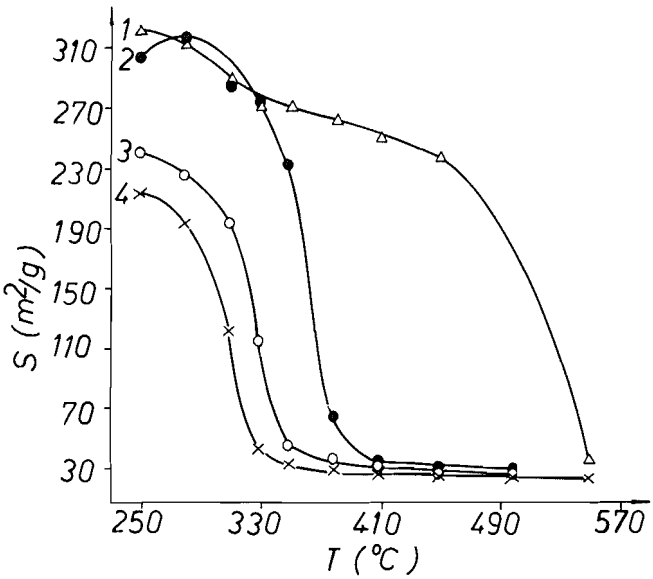

FIG. 1. Change of the specific surface areas of chromium oxides obtained: in an argon flow (curve *1*); in a "dry" air flow (curve *2*); in a "humid" air flow (curve *3*); in an oxygen flow (curve *4*).

Two temperature ranges are characteristic of the decomposition in both "humid" air (P_{H_2O} = 17.5 mm Hg) and "dry" air ($P_{H_2O} = 1 \times 10^{-3}$ mm Hg). The first interval comprises temperatures up to 330°C for "humid" air and 350°C for dry air, and is characterized by a relatively smooth decrease of the specific surface area with increasing temperature of thermal decomposition. A pronounced tendency to decrease in the specific surface areas of the α-Cr_2O_3 samples obtained in "humid" air compared to the specific surface area of samples obtained in "dry" air is observed mainly in this temperature range.

The second temperature range of decomposition is characterized by two main features: a sharp decrease in the specific surface areas and the absence of a noticeable effect of the water vapour partial pressure on the dispersity of the α-Cr_2O_3 obtained.

[1]Revision received October 5, 1982.

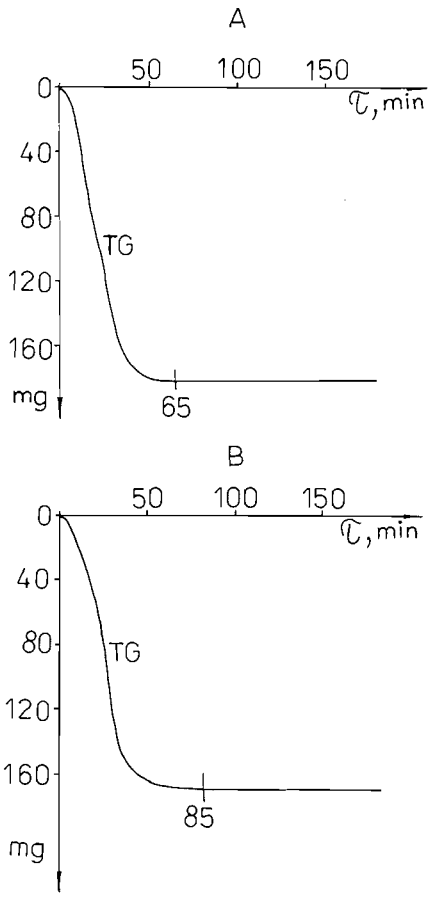

FIG. 2. TG curves obtained: *A*, in a "dry" air flow; *B*, in a "humid" air flow.

The more pronounced decrease of the specific surface areas of the samples obtained in "humid" air, which is observed mainly during the first stage of thermal decomposition, can be considered as a result of three parallel processes: (*a*) The increase of the water vapour partial pressure in the reaction space can lead to a certain decrease in the rate of thermal decomposition of the initial xerogel. (*b*) The highly dispersed α-Cr_2O_3 can be sintered according to an adsorption–desorption mechanism with the participation of water vapour (15). (*c*) The water vapour can accelerate the processes of initial crystallization and recrystallization of the α-Cr_2O_3 obtained. They proceed spontaneously with a very high rate at the second stage.

The increase in the partial pressure of the reaction product obtained during thermal decomposition may inhibit the decomposition of the initial compound. In "humid" air the initial α-$Cr_2O_3 \cdot nH_2O$ should decompose more slowly due to inhibited diffusion of the water vapour. The intensity of the diffusion flow, I, which affects the decomposition rate is defined (14) by the expression:

$$I = K(P_{Bm} - P_{H_2O})/P_{Bm}$$

where K is the rate constant, P_{H_2O}, the water vapour partial pressure, and P_{Bm}, the equilibrium dissociation pressure of the water vapour for the dehydration process

$$Cr_2O_3 \cdot 4H_2O \rightleftharpoons \alpha\text{-}Cr_2O_3 + 4H_2O_{(vapour)}$$

If the highly dispersed α-$Cr_2O_3 \cdot nH_2O$ decomposes for a longer

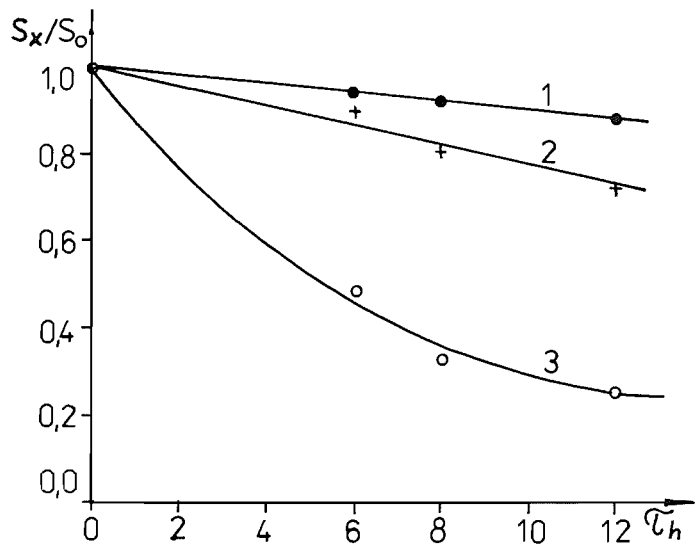

FIG. 3. Effect of sintering on the relative change in the specific surface area S_x/S_0, where S_x denotes the specific surface areas of samples sintered for different times, and S_0 is the specific surface area of the initial sample. Curve *1* presents the sintering of α-Cr_2O_3 in "dry" argon at 450°C; curve *2* corresponds to the sintering of α-Cr_2O_3 in "humid" argon at 450°C; and curve *3* shows the sintering of α-$Cr_2O_3 \cdot nH_2O$ in "humid" argon at 200°C.

time due to the increase of the water vapour partial pressure, this may accelerate the sintering.

Figure 2 shows the TG curve of the thermal decomposition of α-$Cr_2O_3 \cdot nH_2O$ in the presence of water vapour (curve *B*) and in dry air (curve *A*). Evidently, the retardation of decomposition under our conditions is insignificant. However, even when the water vapour partial pressure has no effect on the xerogel decomposition kinetics, it can measurably affect the kinetics of sintering.

Separate studies on the sintering of the initial xerogel and that of the high-dispersity α-Cr_2O_3 showed the effect of the water vapour on the sintering of xerogel to be more pronounced (Fig. 3). Because of the relatively large free surface of α-Cr_2O_3 its sintering proceeds most probably by the adsorption–desorption cycle mechanism (anion-exchange mechanism) proposed by Anderson *et al.* (15). This mechanism gives a mode of transport for a surface O^{2-} ion, which favours the sintering. It is accepted that during the desorption of a H_2O molecule it can remove an oxygen ion from the oxide surface. At the same time, O^{2-} from the initially chemisorbed water molecule remains in an adjacent position on the surface. After repeated adsorption and desorption, the surface mobility of the oxygen anions increases and the larger crystallites begin to grow at the expense of the smaller ones. The small change in the S_x/S_0 ratio is in agreement with the sintering mechanism assumed (16).

A study by thermal analysis, ir spectroscopy, and X-ray phase analysis showed that the α-Cr_2O_3 obtained crystallized only to a negligible extent within the first temperature range of decomposition. A surface structure of $HCrO_2$ was revealed by ir spectroscopy. The ir spectra showed bands at 955 and 1625 cm^{-1} which are characteristic of $HCrO_2$ (Fig. 4) (see ref. 6). The disappearance of this structure along with intensive crystallization and recrystallization were observed within the second temperature range of decomposition. The exothermal peak on the DTA curves which corresponds to the recrystallization

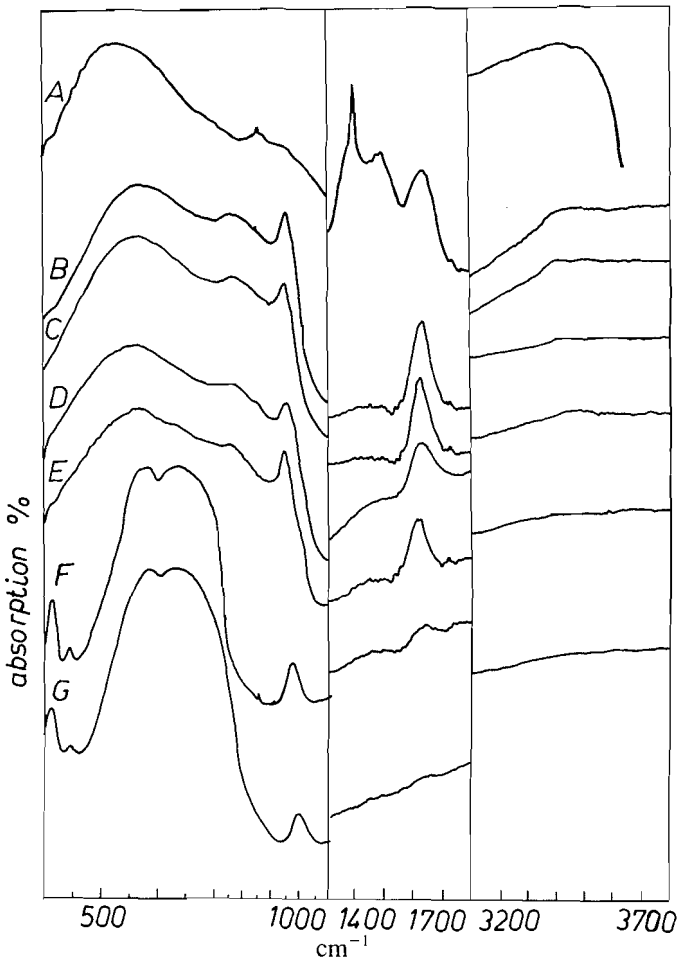

FIG. 4. Infrared spectra of: *A*, the initial xerogel; *B*, *D*, and *F*: the gel heated at 250, 330, and 350°C, respectively, in "humid" air; and *C*, *E*, and *G*: the gel heated at 250, 350, and 380°C, respectively, in dry air.

of α-Cr_2O_3 was observed at 380°C during decomposition in "humid" air and at 400°C when decomposition proceeded in "dry" air.

In addition to the water vapour, the oxygen partial pressure also substantially influenced the dispersity of the α-Cr_2O_3 obtained. Figure 1 (curves *1* and *4*) shows the results of a comparative investigation on the thermal decomposition of α-$Cr_2O_3 \cdot nH_2O$ in an oxygen flow and in a flow of pure argon. Obviously, the α-Cr_2O_3 samples obtained under argon have large specific surface areas. In this case the maximum of the exothermal peak which corresponds to the recrystallization processes is observed only at 550°C. This temperature is considerably higher than the temperature of intensive recrystallization in "dry" and "humid" air (Fig. 5). On the contrary, with increasing oxygen partial pressure (Fig. 1, curve *4*), the specific surface area of α-Cr_2O_3 decreases. The acceleration of recrystallization is in agreement with the results and interpretation of Fenerthy and Sing (1). These authors showed that CrO_3 appears during recrystallization in an oxygen atmosphere, and subsequently decomposes, forming α-Cr_2O_3. Thus centers of intensive recrystallization are created. The results of the present study unambiguously show that the dispersity of α-Cr_2O_3 obtained by thermal decomposition of $Cr_2O_3 \cdot nH_2O$ can be controlled over a large range by changing the gas phase

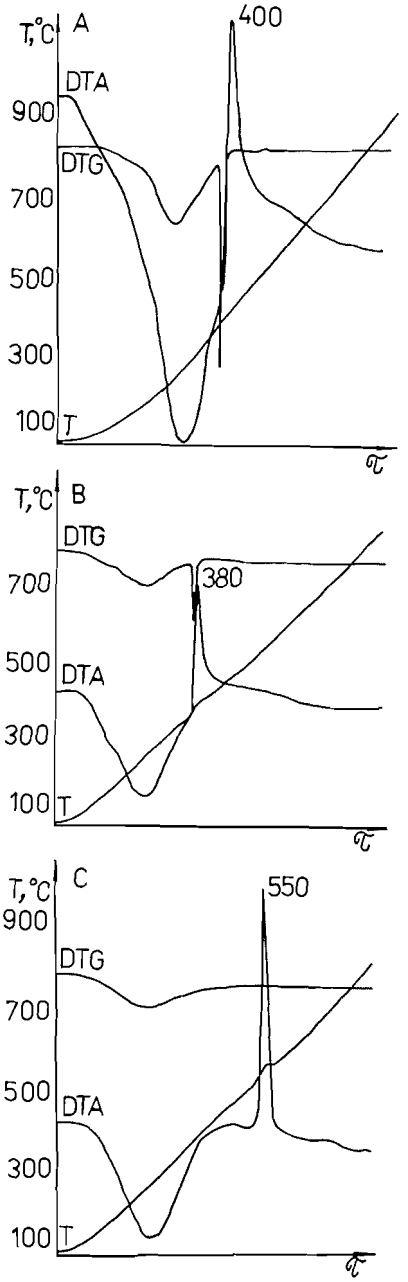

FIG. 5. DTA curves of α-$Cr_2O_3 \cdot nH_2O$, heated: *A*, in "dry" air; *B*, in "humid" air; *C*, under argon.

composition in the reaction space. This possibility is of considerable practical importance.

D,L-Hamamelose (2-*C*-hydroxymethyl-D,L-ribose) has been synthesized from 2,2′-*O*-methylene-bis-D-glycerose by application of the sequential reactions aldol condensation, mercaptolysis, and demercaptalation. The structures of the intermediate thioglycosides of D,L-hamamelose have been established by use of ^{1}Hmr and ^{13}Cmr spectroscopy. The exact composition of the equilibrium mixture of D,L-hamamelose in aqueous solution has also been established by the concomitant use of ^{1}Hmr and ^{13}Cmr spectroscopy. D-Hamamelose has been obtained from the D,L-mixture by preferential crystallization.

WALTER A. SZAREK, B. MARIO PINTO et T. BRUCE GRINDLEY. Can. J. Chem. **61**, 461 (1983).

On a synthétisé le D,L-hamamélose (*C*-hydroxyméthyl-2 D,L-ribose) à partir du *O*-méthylène-2,2′ bis-D-glycérose en faisant appel à une condensation aldolique, suivie d'une mercaptolyse et d'une élimination du mercaptan. On a établi les structures des thioglycosides intermédiaires du D,L-hamamélose en utilisant la spectroscopie de la rmn du ^{1}H et du ^{13}C. On a également établi la composition exacte du mélange à l'équilibre de D,L-hamamélose en solution aqueuse en utilisant en même temps la spectroscopie de la rmn du ^{1}H et du ^{13}C. On a obtenu le D-hamamélose par cristallisation préférentielle d'un mélange D,L.

[Traduit par le journal]

Introduction

The major product derived from the intramolecular aldol condensation of 2,2′-*O*-methylene-bis-D-glycerose (**1**), namely 2-*C*-hydroxymethyl-2,4-*O*-methylene-D,L-ribose (**2**) (1), is of interest since it represents a simple derivative of the naturally occurring branched chain sugar, hamamelose (2-*C*-hydroxymethyl-D-ribose) (**3**). Several syntheses of D-hamamelose or its derivatives have appeared in the literature (2–5). However, only two of these approaches (4, 5) gave stereospecific syntheses of the desired compounds; the other two approaches afforded mixtures of D-hamamelose and its C-2 epimer, D-epihamamelose. Accordingly, the conversion of 2,2′-*O*-methylene-bis-D-glycerose (**1**) into D,L-hamamelose was undertaken. This transformation would also constitute a chemical structure proof of the stereochemistry of the products derived from the intramolecular aldol condensation of **1**. It was anticipated that treatment of the products of the aldol condensation (1) with ethanethiol would result in the formation of the diethyl dithioacetals, as illustrated in Scheme 1. Prolonged reaction times would then be expected to give rise to the thioglycosides resulting from cleavage of the methylene acetal and subsequent displacement of an ethylthio group by one of the hydroxyl groups, as shown in Scheme 2. Since the thioglycosides can be readily converted into the free sugar, the mercaptolysis of the products of the aldol condensation was investigated as a means of converting 2,2′-*O*-methylene-bis-D-glycerose (**1**) into D,L-hamamelose.

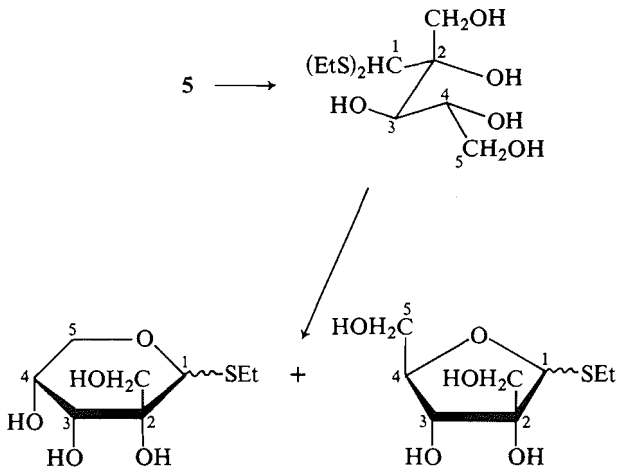
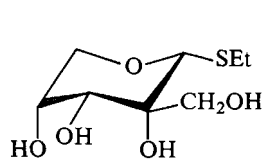


SCHEME 2

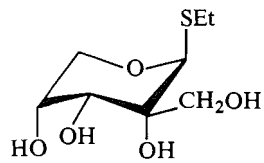
Results and discussion

Treatment of the aldol-condensation product mixture (1) with ethanethiol and hydrochloric acid for 2 h, followed by acetylation of the resulting mixture, afforded, after recrystallization, white needles which were identified as being 2-*C*-acetoxymethyl-3,5-di-*O*-acetyl-2,4-*O*-methylene-D,L-ribose diethyl dithioacetal (**7**). In contrast, treatment of the aldol-condensation product mixture with ethanethiol and hydrochloric acid for 63 h, followed by acetylation, afforded a multicomponent mixture. Fractionation of the mixture by means of high performance liquid chromatography yielded six different components. In order to facilitate further discussion, these compounds are numbered as **8**–**13**, in order of increasing polarity. Examination of the ^{1}Hmr spectra of these derivatives indicated that they were indeed thioglycosides. However, **8**, **9**, and **10** each contained four acetate groups whereas **11**, **12**, and **13** each contained only three acetate groups. It is likely that the tertiary hydroxyl group in the latter set of compounds remains unacetylated under the conditions employed (6). Deacetylation of either **8** or **11** afforded the same compound, labelled as **14**. Similarly, deacetylation of either **9** or **13** afforded **15**. Deacetylation of **10** and **12** gave separate compounds which are labelled as **16** and **17**, respectively. The structures of the four thioglycosides **14**–**17** were deduced by examination of their mass spectra, ^{1}Hmr spectra, and ^{13}Cmr spectra, as described in the following section.

Examination of the ^{13}Cmr spectral data for **14**–**17** (see Table 1) indicates that the C-4 signals in the spectra of **14** and **15** appear at δ 83.5 and δ 85.8, respectively, whereas the corresponding signals in the spectra of **16** and **17** appear at δ 69.9 and δ 70.3, respectively. It is well established (cf. refs. 7 and 8*d*) that the C-4 signals in the spectra of methyl glycopentofuranosides appear in the range δ 79 – δ 85 whereas the corresponding signals in the spectra of methyl glycopentopyranosides appear at δ 66 – δ 70. On this basis, compounds **14** and **15** can be assigned pentofuranoside structures and **16** and **17** can be assigned pentopyranoside structures. This assignment is further corroborated by the chemical-shift data for C-1 in the various compounds; the C-1 signals in the furanosides resonate at lower field than those in the pyranosides. Closer examination of the data indicates that the chemical shift of C-1 in both the furanosides has virtually the same value. This result suggests that both **14** and **15** have the same configuration at the anomeric centre since anomers of pentofuranosides generally display significant chemical-shift differences in C-1 signals. Moreover, the shielding effect of a 1,2-*cis* interaction between ethylthio and hydroxyl groups is expected to be different from that resulting from a 1,2-*cis* interaction between ethylthio and hydroxymethyl groups; if **14** and **15** were indeed anomers, then this situation would prevail and would be manifested in a chemical-shift difference between C-1 signals in the spectra of the two compounds. For example, a chemical-shift difference of 3.2 ppm for the C-1 signals in the spectra of ethyl 2-*C*-hydroxymethyl-α- and β-D-xylofuranoside, and a chemical-shift difference of 4.8 ppm for the C-1 signals in the spectra of ethyl 2-*C*-hydroxymethyl-α- and β-D-arabinofuranoside have been reported (3). Compounds **14** and **15** must, therefore, be epimeric at C-3. Since **15** was only present in low quantity, it must have resulted from the diethyl dithioacetal **6** that was, in turn, derived from the minor component of the aldol-condensation reaction (1). Hence, compound **14** is assigned the *ribo* configuration and compound **15** is assigned the *xylo* configuration. On the basis of the available data, it is not possible to assign the configuration at the anomeric centre in these two compounds. However, on the basis of an additional experiment (see later), both compounds have been assigned the stereochemistry in which the ethylthio group at C-1 and the hydroxyl group at C-2 bear a *syn* relationship to one another.



16



17

The assignment of stereochemistry in the pentopyranosides **16** and **17** was also performed on the basis of the ^{13}Cmr spectral data. The only major difference observed in the chemical-shift data for the two compounds is that for the C-5 carbons. Thus, C-5 in **17** is shielded by 4.7 ppm relative to C-5 in **16**; the result strongly suggests the operation of γ-*gauche* effect in the case of **17**. In this case, it is likely that **16** and **17** differ in configuration only at the anomeric centre since epimers at C-3 would also have resulted in a substantial chemical-shift difference between the C-3 signals for the two compounds; the presence of an axial hydroxyl group at C-3 would be predicted to shield both C-5 and C-1 by virtue of the γ-*gauche* effect. Compound **16** is, therefore, assigned a structure in which the ethylthio group adopts an equatorial orientation and compound **17** is assigned a structure in which the ethylthio group adopts an axial orientation. The assignment may be further substantiated by examination of the relative magnitudes of the one-bond coupling constants between C-1 and H-1 in the gated-decoupled spectra of **16** and **17**. In the case of pyranoid sugars it has been well established (8) that $^1J_{^{13}C_1-H_1}$ for the anomer in which H-1 is equatorial is greater (~10 Hz) than that for the anomer in which H-1 is axial. The difference may be a consequence of $n_O \rightarrow \sigma^*_{C-H}$ hyperconjugation in the latter case (9). The values of $^1J_{^{13}C_1-H_1}$ in **16** and **17** (153 Hz and 161 Hz, respectively) are consistent with expectations based on the above criterion. Therefore, compound **16** is identified as being ethyl 2-*C*-hydroxymethyl-1-thio-α-D- and α-L-ribopyranoside and compound **17** is identified as being ethyl 2-*C*-hydroxymethyl-1-thio-β-D- and α-L-ribopyranoside.

TABLE 1 *(Concluded)*

Compound[b]	Carbon 1	2	2′	3	4	5	SCH_2CH_3	SCH_2CH_3	$COCH_3$
 **18** R = CH_2OH	99.7	80.3	[c]	[c]	83.2	[c]	—	—	—
 **19** R = CH_2OH	103.3	83.7	[c]	[c]	84.5	[c]	—	—	—

[a] The spectra of compounds **8–13** were measured in chloroform-*d*; chemical shifts are given in ppm downfield from internal TMS. The spectra of compounds **14–21** and **26** were measured in deuterium oxide with internal acetone as reference; chemical shifts are given with respect to the chemical shift of acetone which was taken as being 32.8 ppm.

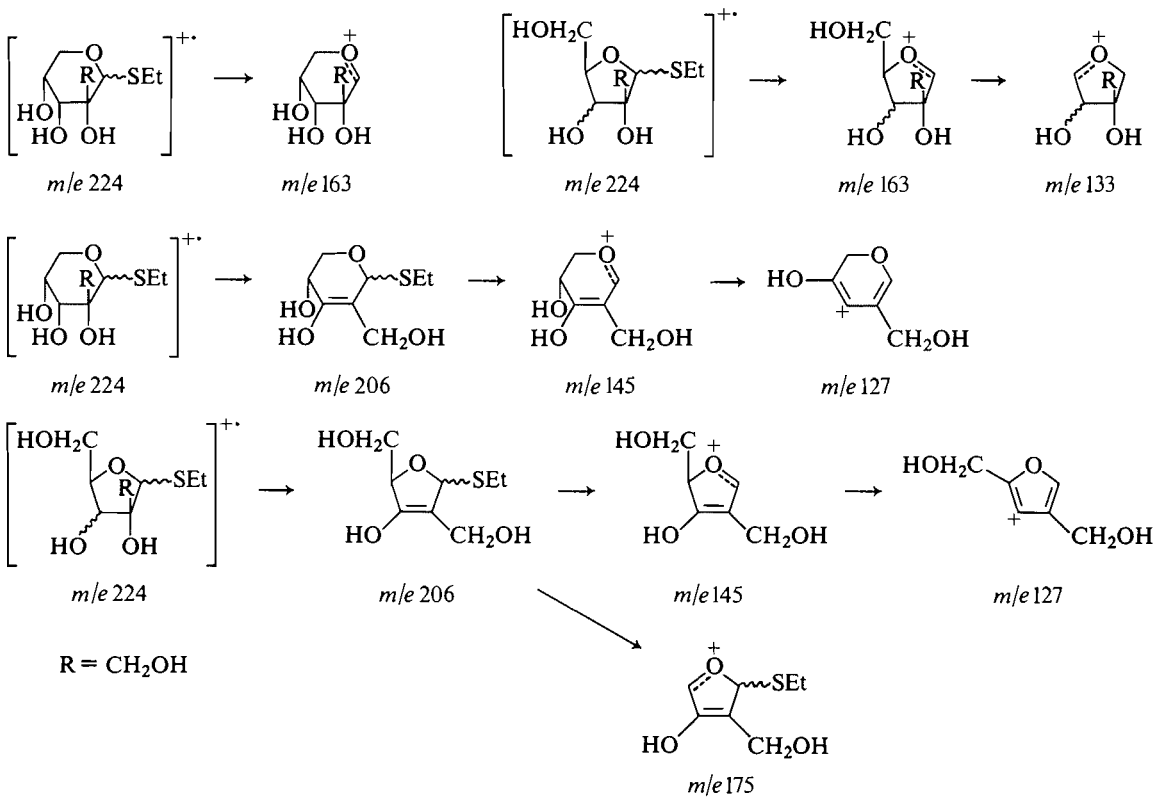
[b] Owing to overlap of signals, only the signals for C-1 were assigned in the spectra of compounds **20**, **21**, and **26**. C-1 in **20** resonated at 97.2 ppm; C-1 in **21** resonated at 96.7 ppm; C-1 in **26** resonated at 94.7 ppm.

[c] Assignment is tentative owing to the presence of an impurity.

[d] In the gated-decoupled spectrum, these peaks appeared as triplets which showed further long-range coupling.

[e] Extensive overlap of signals did not permit unambiguous assignment of these resonances.

*Assignments may be interchanged.



SCHEME 3

The mass-spectral data for compounds **14–17** are also consistent with the assignment of furanoid structures to **14** and **15** and of pyranoid structures to **16** and **17**. Two fragmentation modes are observed for all four compounds; the first involves loss of the ethylthio group to give an oxonium ion (*m/e* 163) and the second involves the loss of water as the initial fragmentation step to give an ion transition at *m/e* 206. The characteristic feature of the spectra of the furanosides **14** and **15** is the presence of ion transitions at *m/e* 175 and *m/e* 133; these peaks are attributed to the loss of the hydroxymethyl group at C-4 from ions having *m/e* values of 206 and 163, respectively. The peaks at *m/e* 175 and *m/e* 133 are absent in the spectra of the pyranosides **16** and **17**. The proposed fragmentation modes to account for the main ion transitions are summarized in Scheme 3.

The structures of compounds **11–17**, deduced on the basis

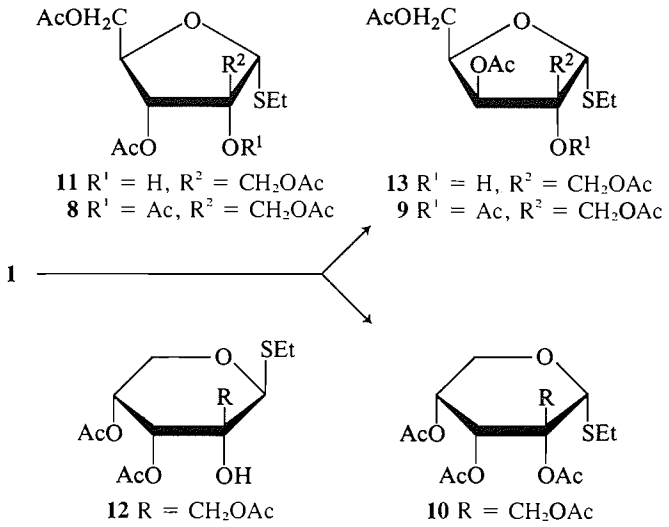


SCHEME 4

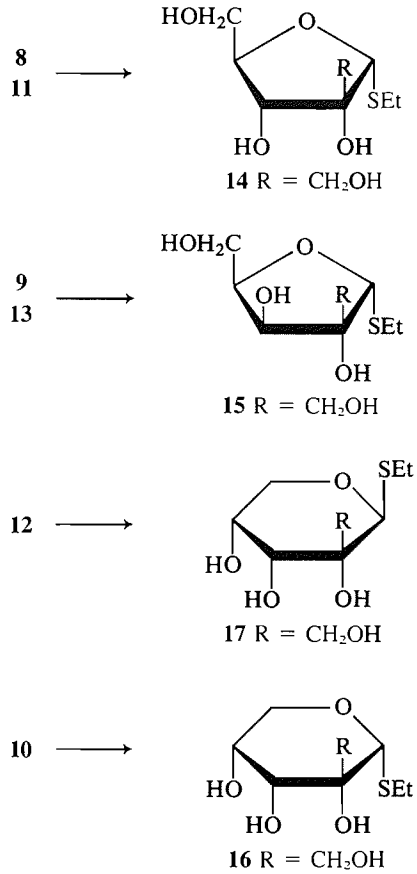
of the evidence presented in the preceding sections, are shown in Schemes 4 and 5. The ^{13}Cmr data for these compounds are presented in Table 1.

Treatment of a mixture of the thioglycosides **14** and **16** with mercuric chloride and cadmium carbonate in water (see Scheme 5) afforded, after ion-exchange chromatography, a syrup whose ^{1}Hmr spectrum in deuterium oxide was identical to that of an authentic sample[2] of D-hamamelose. The syrup had an optical rotation of $-1.4°$ in water at equilibrium. Since the reported values for the rotations of D- and L-hamamelose are $-7.0°$ (2) and $+7.3°$ (6), respectively, the syrup obtained in the above experiment must consist of a mixture of D- and L-isomers. This result is not surprising in view of the expected formation of D,L-pairs of isomers in the aldol-condensation reaction which preceded the mercaptolysis reaction (1). The sugar was further characterized by formation of the crystalline *p*-tolylsulfonylhydrazone (2, 6). Interestingly, upon seeding of the syrupy product with an authentic sample of D-hamamelose, preferential crystallization of only the D-isomer ensued, as evidenced by the optical rotation of the crystals ($[\alpha]_D^{33}$ (after 0.5 h) $-7.2°$ (*c* 0.56, H_2O)). The sample was identical in all respects with the authentic sample of D-hamamelose.

Several reports (2–6) have appeared in the literature on the synthesis of D- or L-hamamelose. However, the exact composition of the equilibrium mixture in aqueous solution has not yet been determined. Accordingly, the ^{1}Hmr and ^{13}Cmr spectroscopic investigation of the equilibrium proportions of the α- and β-furanoses and pyranoses in aqueous solution was undertaken.

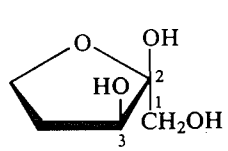
The ^{1}Hmr spectrum (at 220 MHz and at 301 K) of hamamelose in deuterium oxide indicated the presence of four singlets at δ 4.79, 5.13, 5.21, and 5.28 which were attributed to the anomeric hydrogens in the two pyranoses and the two furanoses. Measurement of the spectrum under conditions of partial relaxation resulted in suppression of the residual water peak and permitted the integration of these signals; the relative intensities of the four signals at δ 4.79, 5.13, 5.21, and 5.28 were found to be 1.7:1:2.4:3, respectively. The ^{13}Cmr spectrum of hamamelose also indicated the presence of four signals attributable to the anomeric carbons in the two pyranoses and

[2]The authors are grateful to Dr. Pak-Tsun Ho for a gift of synthetic D-hamamelose.

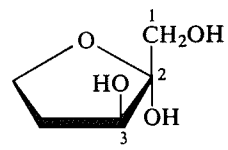


SCHEME 5

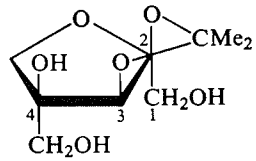
the two furanoses (see Table 1). The signals at δ 103.3 and δ 99.7 were assigned to the C-1 signals in the furanoses and those at δ 97.2 and δ 96.7 were attributed to the pyranoses. The differentiation of the signals for the two furanose anomers can also be made on the basis of the ^{13}Cmr chemical-shift data. Several ^{13}Cmr studies of ketohexofuranoses have appeared in the literature which suggest that a 1,2-*cis* interaction between two hydroxyl substituents in a furanoid ring results in greater shielding of the carbon atoms to which they are attached than a 1,2-*cis* interaction between a hydroxyl substituent and a hydroxymethyl substituent in the corresponding anomer (10), that



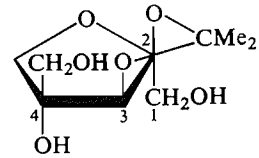
22



23



24



25

is, C-2 and C-3 in **22** are shielded relative to C-2 and C-3 in **23**. This "*cis* effect" has also been noted in certain derivatives of L-dendroketose (11). Thus, C-3 and C-4 in **24** were shielded by 5.2 ppm and 3.0 ppm, respectively, relative to the correspond-

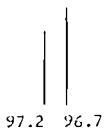
18 R¹ = H, R² = OH **20** R¹ = H, R² = OH
19 R¹ = OH, R² = H **21** R¹ = OH, R² = H

SCHEME 6

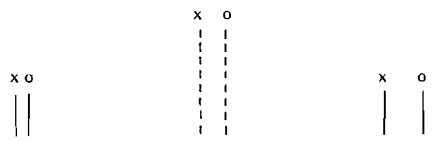
ing carbons in **25**. On the basis of these results, the signal at δ 103.3 in the ^{13}Cmr spectrum of hamamelose is assigned to C-1 in **19** and that at δ 99.7 is assigned to C-1 in **18** (see Scheme 6). In agreement with expectations, the C-2 signal in the spectrum of **18** is also shifted upfield relative to the C-2 signal in the spectrum of **19** (see Table 1).

The assignment of the signals at δ 97.2 and δ 96.7 in the spectrum of hamamelose to C-1 in **20** and **21** (see Scheme 6) should, in theory, be possible by examination of the differences in the magnitudes of the $^{1}J_{^{13}C_1-H_1}$ coupling constants, as described previously. However, the small chemical-shift difference between signals and the presence of two-bond and three-bond couplings complicated the situation since distinct doublets were not observed for the C-1 signals in the gated-decoupled spectrum. Nonetheless, the assignment can be made by careful examination of the spectra. Two situations can arise.

^{1}H-Decoupled spectrum

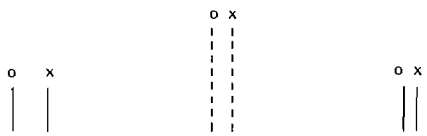


Gated-decoupled spectrum; situation A



o peaks owing to **21**
× peaks owing to **20**

Gated-decoupled spectrum; situation B



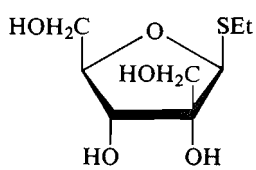
o peaks owing to **21**
× peaks owing to **20**

SCHEME 7

If the peak at δ 96.7 ppm is attributed to C-1 in **21**, then situation A in Scheme 7 will prevail since $^{1}J_{^{13}C_1-H_1}$ in **21** is expected to be larger than that in **20** (8). If, however, the peak at δ 96.7 ppm is attributed to C-1 in **20**, then situation B will prevail. Close examination of the gated-decoupled spectrum of hamamelose shows the presence of multiplets for each of the halves of the doublets for the C-1 signals of **20** and **21**. The low-field multiplet has a width at half-height of about 18 Hz whereas the high-field multiplet has a width at half-height of about 9 Hz. Since the spectrum resembles that expected for situation B in Scheme 7, the signal at δ 96.7 ppm is attributed to C-1 in **20** and that at δ 97.2 ppm is attributed to C-1 in **21**. In summary, the signals at δ 103.3, 99.7, 97.2, and 96.7 ppm in the spectrum of D-hamamelose are assigned to the anomeric carbons in the β-furanose, α-furanose, β-pyranose, and α-pyranose species, respectively.

In order to estimate the proportion of each species present at equilibrium in deuterium oxide, the ^{13}Cmr spectrum of a D-hamamelose solution (0.6 *M*) was recorded in deuterium oxide at 302 K under conditions[3] such that integrated intensities are a reliable measure of the concentration of the individual isomers present in solution. The relative intensities of the relevant ^{13}Cmr peaks were measured by means of a planimeter. The relative intensities of the peaks at δ 103.3, 99.7, 97.2, and 96.7 were 2.1:3.0:1.6:1, respectively. Therefore, D-hamamelose exists in deuterium oxide at 302 K as an equilibrium mixture of the α-furanose, β-furanose, β-pyranose, and α-pyranose isomers which are present in the ratio of 39:28:20:13 (see Table 2). The calculated ratios compare favorably with those (38:29:21:12) obtained by integration of the H-1 signals in the ^{1}Hmr spectrum of D-hamamelose in deuterium oxide at 296 K. This coincidence of values can thus be employed to assign the H-1 signals to the particular isomers of hamamelose. On this basis the singlets at δ 5.28, 5.21, 5.13, and 4.79 in the ^{1}Hmr spectrum of D-hamamelose are assigned to H-1 of the α-furanose, β-furanose, α-pyranose, and β-pyranose isomers, respectively (see Table 2).

One last point remains to be clarified, namely the question of the stereochemistry at the anomeric centre of the furanose thioglycoside **14**. Since this question is difficult to answer when only one anomer is available for investigation, an attempt was made to generate the alternate anomer of **14**. Treatment of a mixture of D,L-hamamelose with ethanethiol and hydrochloric acid for 80 h afforded a mixture of the four isomers of hamamelose as well as three thioglycosides (see Scheme 8), as judged by examination of the ^{13}Cmr spectrum of the mixture. The peaks attributable to C-1 of the thioglycosides appeared at δ 89.8, 92.0, and 94.7. The peak at δ 89.8 was assigned to C-1 of **16**, and that at δ 92.0 was assigned to C-1 of **14**. The peak at δ 94.7 did not correspond to C-1 of any of the three thioglycosides previously synthesized. This signal was, thus, assigned to C-1 of the alternate anomer of **14**, namely ethyl 2-*C*-hydroxymethyl-1-thio-β-D- and α-L-ribofuranoside (**26**). The shielding of C-1 in **14** relative to that in **26** is expected on



26

the basis of the "*cis* effect", as discussed previously. Compound **14**, one of the products of the original mercaptolysis

[3]The ^{13}Cmr spectra were measured on a Varian CFT-20 spectrometer using 66° pulses and 2.6 s pulse intervals. For a discussion of intensity measurements on sugars by ^{13}Cmr spectroscopy, see ref. 12.

SCHEME 8

reaction, is, therefore, identified as being ethyl 2-*C*-hydroxymethyl-1-thio-α-D- and β-L-ribofuranoside. On the basis of arguments presented previously, compound **15**, the minor product of the original mercaptolysis reaction is also assigned the α-D- or β-L-configuration. Interestingly, when the nmr sample was let stand at ambient temperature for 30 h and the ^{13}Cmr spectrum was recorded again, the spectrum indicated the presence of three signals attributable to C-1 of thioglycosides at δ 92.0, 89.8, and 88.1. The absence of the peak owing to C-1 of **26** (δ 94.7) and the appearance of the peak attributable to C-1 of **17** (δ 88.1) suggest that the sample had equilibrated since the recording of the first ^{13}Cmr spectrum. The deuterium oxide solution was found to have a pD value of 4. Apparently, the ratio of thioglycosides obtained in the thioglycosidation reaction differs from that obtained in the mercaptolysis reaction. Preparative thin-layer chromatography of the mixture obtained from the thioglycosidation reaction afforded a mixture of the thioglycosides **14**, **16**, **17**, as indicated by ^{1}Hmr and ^{13}Cmr spectroscopy; in the case of the ^{13}Cmr spectrum, all of the signals for each of these compounds could be assigned.

Experimental

Melting points were determined with a Fisher–Johns apparatus and are uncorrected. Mass spectra were recorded on a CEC21-104 mass spectrometer under electron-impact conditions at 70 eV ionizing voltage. Proton magnetic resonance (^{1}Hmr) spectra were recorded on Bruker HX-60 or Varian HR-220 spectrometers; spectra were recorded at 60 MHz, unless otherwise stated. Carbon-13 magnetic resonance (^{13}Cmr) spectra were recorded on a Bruker HX-60 spectrometer equipped with a FT60M Fourier transform accessory at 15.09 MHz or a Varian CFT-20 spectrometer at 20.0 MHz. Spectra were measured in chloroform-*d* with tetramethylsilane (TMS) as internal standard, unless otherwise stated. Chemical shifts are given in ppm downfield from TMS. Spectra recorded in deuterium oxide solution were measured with respect to internal acetone whose chemical shift was taken as being 2.225 ppm relative to TMS for the ^{1}Hmr spectra and 32.78 ppm relative to TMS for the ^{13}Cmr spectra. Optical rotations were determined on a Perkin–Elmer 141 polarimeter.

Analytical thin-layer chromatography (tlc) was performed on precoated glass plates with Merck silica gel 60F-254 as the adsorbent (layer thickness 0.25 mm). The developed plates were air-dried and exposed to uv light and/or sprayed with a solution of cerium sulfate (1%) and molybdic acid (1.5%) in 10% aqueous sulfuric acid, and heated at 150°C. Preparative thin-layer chromatography was performed on precoated glass plates with Merck silica gel 60F-254 as the adsorbent (layer thickness 2 mm). Column chromatography was performed on Brinkman silica gel (70–235 mesh, E. Merck). High performance liquid chromatography was performed on a Waters Associates Prep LC/ System 500. The chromatographic solvents (v/v) employed in this work are as follows: (*A*) benzene – ethyl acetate, 1:1; (*B*) ethyl acetate – ethanol, 20:1; (*C*) 10:1; (*D*) *n*-propanol – ethyl acetate – water, 3:1:1; (*E*) toluene – ethyl acetate, 6:1.

Solvents were evaporated under reduced pressure and below 40°C.

2-C-Acetoxymethyl-3,5-di-O-acetyl-2,4-O-methylene-D,L-ribose diethyl dithioacetal (7)

The aldol-condensation product mixture (16 g), obtained from 2,2′-*O*-methylene-bis-D-glycerose (**1**) by treatment with 0.1 *N* sodium hydroxide for 7 h (1), was treated with concentrated hydrochloric acid (24 mL) and ethanethiol (24 mL) at 0°C for 1 h and then at room temperature for 1 h. The solution was poured with stirring into dry lead carbonate. Water was added and the solids were removed by filtration. The solids were thoroughly washed with water, and the combined filtrate and washings were concentrated to afford a syrup. The syrupy residue was acetylated with acetic anhydride (30 mL) and pyridine (50 mL) in the usual manner. The mixture was poured into ice-water, upon which a solid deposited. The solid was collected by filtration (15.4 g). Recrystallization from ethanol afforded a small amount of white crystals which were identified as being one of the products derived from the Cannizzaro reaction of **4** (1), namely 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-2,4-*O*-methylene-D,L-*threo*-pentitol (**27**) (0.64 g), mp 144–146°C (lit. (13) mp 147–148°C for the L-isomer). The mother liquor afforded white needles which were identified as being the title compound **7**, mp 112–113°C, $[\alpha]_D^{24}$ −25.7° (*c* 1.2, chloroform); ^{1}Hmr data ($CDCl_3/C_6D_6$ (7:5)) δ: 1.11 (3H, t, SCH_2CH_3), 1.75, 1.78, 1.80 (three 3H s's, 3 OAc's), 2.66

(2H, q, SCH_2CH_3), 3.67 (1H, m, H-4), 3.98 (1H, s, H-1), 4.12 (2H, m, H-5, H-5′), 4.55 (1H, d, J = 12.8 Hz, H-2′), 4.75 (2H, AB, J = 7 Hz, O—CH_2—O), 4.96 (1H, d, J = 12.8 Hz, H-2″), 5.97 (1H, d, J = 10.2 Hz, H-3). *Anal.* calcd. for $C_{17}H_{28}O_8S_2$: C 48.2, H 6.6, S 15.1; found: C 48.0, H 6.5, S 15.0.

Mercaptolysis of 2-C-hydroxymethyl-2,4-O-methylene-D,L-ribose (2) and 2-C-hydroxymethyl-2,4-O-methylene-D,L-xylose (4)

The aldol-condensation product mixture (4.32 g), obtained by treatment of 2,2′-*O*-methylene-bis-D-glycerose (**1**) with 0.05 *N* sodium hydroxide for 3.5 h, was dissolved in concentrated hydrochloric acid (9.4 mL), and ethanethiol (9.4 mL) was added with stirring. The mixture was stirred at room temperature for 63 h and was then poured into solid lead carbonate (60 g). Water (50 mL) was added and the slurry was filtered. The solids were washed with an additional amount of water (200 mL). The filtrate and washings were concentrated to afford a syrupy solid, which was treated with pyridine (30 mL) and acetic anhydride (20 mL) at room temperature for 12 h. Sodium hydrogen carbonate solution (250 mL) was added and the mixture was stirred for several hours. The mixture was extraced with methylene chloride (4 × 75 mL). The extracts were dried over anhydrous magnesium sulfate, and concentrated to give a syrup. Thin-layer chromatography (solvent *A*) indicated the presence of a multicomponent mixture. The mixture was chromatographed using high performance liquid chromatography using solvent E as eluant to yield six different components as syrups. The component having an R_f value of 0.69 was identified as being ethyl 2-*C*-acetoxymethyl-1,3,5-tri-*O*-acetyl-1-thio-α-D- and β-L-ribofuranoside (**8**) (0.3 g); ^{1}Hmr data ($CDCl_3$) δ: 1.29 (3H, t, SCH_2CH_3),2.05, 2.10 (two 6H s's, 4 OAc's), 2.65 (2H, q, SCH_2CH_3), 4.15–4.35 (2H, m's), 4.60, 4.84 (2H, AB q, J = 12 Hz), 5.20 (2H, m), 5.62 (1H, s, H-1). The component having an R_f value of 0.64 was not obtained pure but was contaminated with compound **8** (combined yield 0.21 g). It was identified as being ethyl 2-*C*-acetoxymethyl-2,3,5-tri-*O*-acetyl-1-thio-α-D- and β-L-xylofuranoside (**9**); ^{1}Hmr data ($CDCl_3$) δ: 1.26 (3H, t, SCH_2CH_3), 2.07, 2.10, 2.12 (s's, 4 OAc's), 2.60 (2H, q, SCH_2CH_3), 4.0–4.4 (2H, m's), 4.50, 4.75 (2H, AB q, J = 12 Hz), 5.40 (2H, m), 5.51 (1H, s, H-1). The component having an R_f value of 0.59 was identified as being ethyl 2-*C*-acetoxymethyl-2,3,4-tri-*O*-acetyl-1-thio-α-D- and β-L-ribopyranoside (**10**) (0.231 g); ^{1}Hmr data ($CDCl_3$) δ: 1.31 (3H, t, SCH_2CH_3), 2.09, 2.10 (s's, 4 OAc's), 2.72 (2H, q, SCH_2CH_3), 3.9–4.5 (4H, m's), 4.78 (1H, s, H-1), 5.19 (2H, m). The component having an R_f value of 0.55 was identified as being ethyl 2-*C*-acetoxymethyl-3,5-di-*O*-acetyl-1-thio-α-D- and β-L-ribofuranoside (**11**) (0.45 g); ^{1}Hmr data ($CDCl_3$) δ: 1.31 (3H, t, SCH_2CH_3), 2.09, 2.12, 2.15 (s's, 4 OAc's), 2.69 (2H, q, SCH_2CH_3), 4.0–4.4 (5H, m's), 4.63–5.0 (2H, m), 5.34 (1H, s, H-1). A mixture of compounds **11** and **10** was also obtained (1.09 g). The component having an R_f value of 0.49 was identified as being ethyl 2-*C*-acetoxymethyl-3,4-di-*O*-acetyl-1-thio-β-D- and α-L-ribopyranoside (**12**) (0.355 g); ^{1}Hmr data ($CDCl_3$) δ: 1.30 (3H, t, SCH_2CH_3), 2.08, 2.10, 2.14 (s's, 3 OAc's), 2.64 (2H, q, SCH_2CH_3), 3.4–4.55 (5H, m's), 5.03–5.3 (3H, m's, includes H-1). A mixture of compounds **11** and **12** was also obtained (0.14 g). The component having an R_f value of 0.42 was identified as being a mixture of ethyl 2-*C*-acetoxymethyl-3,5-di-*O*-acetyl-1-thio-α-D- and β-L-xylofuranoside (**13**) and an unidentified compound that was present in low quantity (0.37 g); ^{1}Hmr data ($CDCl_3$) δ: 1.30 (3H, t, SCH_2CH_3), 2.04, 2.10, 2.14 (s's, 3 OAc's), 2.60 (2H, q, SCH_2CH_3), 4.0–4.5 (m's), 5.07 (1H, s, H-1), 5.1–5.35 (m).

Base-catalyzed solvolysis of compound 11

The triacetate **11** (0.45 g) was dissolved in chloroform (2 mL) and methanol (5 mL) and the solution was cooled to 0°C. Sodium methoxide (0.4 mL, 1.1 *N* in methanol) was added and the mixture was stored at 0°C for 12 h. Thin-layer chromatography (solvent *A*) indicated the disappearance of starting material and the appearance of a component at the baseline. The mixture was neutralized with moist Amberlite IR-120 (H^+). The resin was removed by filtration and washed with ethanol. The filtrate and washings were concentrated to yield a syrup (0.28 g) which solidified on standing. Recrystallization from chloroform afforded an amorphous solid which was identified as being ethyl 2-*C*-hydroxymethyl-1-thio-α-D- and β-L-ribofuransoside (**14**), mp 65–67°C; ^{1}Hmr data (D_2O with $(CH_3)_2CO$) δ: 1.28 (3H, t, SCH_2CH_3), 2.71 (2H, q, SCH_2CH_3), 3.59–4.04 (6H, m's), 5.36 (1H, s, H-1); M calcd. for $C_8H_{16}O_5S$: 224; found: m/e 224 (M^+). Ethyl 2-*C*-benzoyloxymethyl-3,5-di-*O*-benzoyl-1-thio-α-D- and β-L-ribofuranoside were prepared by treatment of compound **14** with benzoyl chloride and pyridine, in the usual manner. The sample was recrystallized from chloroform – petroleum ether (bp 60–80°C), mp 136–137°C. *Anal.* calcd. for $C_{29}H_{28}O_8S$: C 64.9, H 5.3, S 6.0; found: C 65.2, H 5.4, S 5.9.

Base-catalyzed solvolysis of compounds 8, 9, 10, 12, and 13

Each of the fractions obtained from the liquid chromatographic separation was subjected to the solvolysis conditions, as described for the solvolysis of compound **11**.

Base-catalyzed solvolysis of the tetraacetate **8** afforded compound **14** (0.19 g). The fraction containing **8** and **9** afforded a mixture of **14** and ethyl 2-*C*-hydroxymethyl-1-thio-α-D- and β-L-xylofuranoside (**15**) (0.13 g). Solvolysis of the fraction containing **13** afforded a syrup which was shown by tlc (solvent *B*) to consist of a component having an R_f value of 0.24 and a component at the origin. The component having an R_f value of 0.24 was obtained as a syrup by preparative thin-layer chromatography using solvent *B* as eluant, and was identified as being compound **15** (0.07 g); ^{1}Hmr data (D_2O with $(CH_3)_2CO$) δ: 1.25 (3H, t, SCH_2CH_3), 2.74 (2H, q, SCH_2CH_3), 3.64–4.24 (6H, m), 5.18 (1H, s, H-1). M calcd. for $C_8H_{16}O_5S$: 224; found: m/e 224 (M^+). Treatment of compound **10** under the solvolysis conditions afforded a syrup which was identified as being ethyl 2-*C*-hydroxymethyl-1-thio-α-D- and β-L-ribopyranoside (**16**) (0.16 g); ^{1}Hmr data (D_2O with $(CH_3)_2CO$, 340 K) δ: 1.28 (3H, t, SCH_2CH_3), 2.74 (2H, q, SCH_2CH_3), 3.44–4.14 (6H, m's), 4.79 (1H, s, H-1). M calcd. for $C_8H_{16}O_5S$: 224; found: m/e 224 (M^+). Solvolysis of the fraction containing **10** and **11** afforded a mixture of **14** and **16** (0.53 g). Base-catalyzed solvolysis of compound **12** afforded a solid (0.22 g) which was recrystallized from chloroform, and was identified as being ethyl 2-*C*-hydroxymethyl-1-thio-β-D- and α-L-ribopyranoside (**17**), mp 84–85°C; ^{1}Hmr data (D_2O with $(CH_3)_2CO$) δ: 1.27 (3H, t, SCH_2CH_3), 2.66 (2H, q, SCH_2CH_3), 3.44–4.24 (6H, m's), 5.11 (1H, s, H-1). M calcd. for $C_8H_{16}O_5S$: 224; found: m/e 224 (M^+). *Anal.* calcd. for $C_8H_{16}O_5S$: C 42.8, H 7.2, S 14.3; found: C 42.9, H 7.2, S 14.2.

2-C-Hydroxymethyl-D,L-ribose (D,L-hamamelose) (18), (19), (20), and (21)

To a solution of the thioglycosides **14** and **16** (0.532 g) in water (30 mL) was added mercuric chloride (0.90 g) and cadmium carbonate (0.50 g) and the suspension was stirred for 60 h at room temperature. The mixture was filtered through Celite and the filter cake was washed with water. The filtrate and washings were concentrated, and the syrupy residue was triturated with a small volume of ethanol. The remaining solid was filtered, and the filtrate was concentrated to a syrup which was deionized by passing it through a column of Amberlite IR-120 (H^+) and then through a column of Amberlite IR-45 (OH^-). Concentration of the resulting aqueous solution afforded a syrup (0.42 g). Thin-layer chromatography (solvent *D*) indicated the presence of a homogeneous spot having an R_f value of 0.55. The sample was identified as being 2-*C*-hydroxymethyl-D,L-ribose (**18**–**21**), $[\alpha]_D^{33}$ (after 0.5 h) −1.4° (*c* 4.18, H_2O) (lit. (2, 6) $[\alpha]_D$ +7.3° (equil. *c* 2.2, H_2O) for the L-isomer and −7.0° for the D-isomer); ^{1}Hmr data (220 MHz, D_2O with $(CH_3)_2CO$, 301 K) δ: 3.52–4.4 (m's), 4.79, 5.13, 5.21, 5.28 (four s's, H-1's). The ^{1}Hmr spectrum was identical to that of an authentic sample of D-hamamelose. The sugar (0.05 g) in methanol was heated at reflux temperature with *p*-tolylsulfonylhydrazine (0.05 g) for 1 h. Upon cooling of the reaction mixture, white crystals separated which, when recrystallized from ethanol, had mp 155–157°C (lit. (2, 6) mp 155–156°C). The syrupy sugar was seeded with a crystal of D-hamamelose. After two weeks at 0°C, a portion of the sample crystallized. The syrupy residue was

triturated with cold methanol and the crystals were collected. The crystals were identified as being 2-*C*-hydroxymethyl-D-ribose, mp 110–111°C (lit. (2) mp 110–111°C); $[\alpha]_D^{33}$ (after 0.5 h) −7.2° (*c* 0.56, H_2O) (lit. (2) $[\alpha]_D$ −7.0°).

Reaction of D,L-hamamelose with ethanethiol

D,L-Hamamelose (0.092 g) was treated with concentrated hydrochloric acid (1 mL) and ethanethiol (1 mL) at room temperature for 80 h. The mixture was poured onto solid lead carbonate. The slurry was filtered through Celite and the residue was washed with water and 95% ethanol. The filtrate and washings were concentrated to afford a syrup which was taken up in ethanol. The remaining solid was removed by filtration, and the filtrate was concentrated to afford a syrup (0.095 g). The ^{13}Cmr spectrum of the syrup in D_2O solution indicated the presence of all four isomers of hamamelose (**18**–**21**), as indicated by the four C-1 signals, as well as three C-1 signals attributable to thioglycosides. The latter peaks appeared at δ 89.8, 92.0 (major), and 94.7. The peak at δ 89.8 was assigned to C-1 of compound **17** and that at δ 92.0 was assigned to C-1 of **14**. The peak at δ 94.7 did not correspond to the C-1 signal of any of the three thioglycosides previously synthesized. This peak was, therefore, assigned to C-1 of ethyl 2-*C*-hydroxymethyl-1-thio-β-D- and α-L-ribofuranoside (**26**). The original D_2O solution of the syrup was let stand at ambient temperature for 30 h, and the ^{13}Cmr spectrum was recorded again. The spectrum now indicated the presence of three C-1 signals attributable to thioglycosides at δ 92.0, 89.8, and 88.1. The absence of the peak owing to C-1 of **26** (δ 94.7) and the appearance of the peak attributable to C-1 of **17** (δ 88.1) suggested that the sample had equilibrated since the recording of the first ^{13}Cmr spectrum. The D_2O solution was found to have a pD value of 4. Preparative thin-layer chromatography of the sample using solvent *C* as eluant gave the mixture of thioglycosides **14**, **16**, and **17**, as indicated by ^{1}Hmr and ^{13}Cmr spectroscopy.

Sedum alkaloids. V. Sedacrine, the major alkaloid of *Sedum acre*, and related bases

BRIGITTE COLAU AND CLAUDE HOOTELÉ[1]

Service de Chimie Organique, Faculté des Sciences, Université Libre de Bruxelles, B-1050 Bruxelles, Belgium

Received May 18, 1982[2]

BRIGITTE COLAU and CLAUDE HOOTELÉ. Can. J. Chem. **61**, 470 (1983).

Sedacrine, the major alkaloid of *Sedum acre*, is assigned structure **5** on the basis of spectroscopic and chemical evidence. Two minor bases, sedinone **6** and dihydrosedinine **7**, are described. Sedacrine **5**, sedinone **6**, dihydrosedinine **7**, and sedinine **3** are correlated. The absolute configurations of these alkaloids and that of sedacryptine **2** are established.

BRIGITTE COLAU et CLAUDE HOOTELÉ. Can. J. Chem. **61**, 470 (1983).

La sédacrine **5** est l'alcaloïde majeur de *Sedum acre*; sa structure est établie sur la base de ses propriétés spectrales et chimiques. Deux bases mineures, la sédinone **6** et la dihydrosédinine **7** sont décrites. La sédacrine **5**, la sédinone **6**, la dihydrosédinine **7** et la sédinine **3** de configuration absolue connue, ont été corrélées. La configuration absolue de la sédacryptine **2** est également établie.

A variety of 2- and 2,6-disubstituted piperidine alkaloids were isolated some years ago from *Sedum acre* (1–3). Some additional bases, whose structures were tentatively inferred from their fragmentation patterns, were also detected in the same species (4, 5). Recently, we described two new Sedum alkaloids, sederine **1** (6, 14) and sedacryptine **2** (7), and we assigned sedinine the modified structure **3** (8). In this communication we report the isolation and structure determination of three alkaloids: sedacrine **5**, sedinone **6**, and dihydrosedinine **7**.

10

The crude alkaloids (0.05%) were obtained by treatment of fresh plants of *Sedum acre* with 2% aqueous hydrochloric acid and were separated mostly by countercurrent distribution and by fractional crystallization. In addition to known compounds, **5**, **6**, and **7** were isolated in the pure state.

Sedacrine 5

Sedacrine[3] (oil; $[\alpha]_D^{20}$ −130° (*c* 1.1, EtOH), $C_{17}H_{23}NO_2$ by high resolution mass spectrometry) was characterized as its perchlorate (mp 168–169°C). The free base is thermolabile and does not survive a prolonged heating in solution: although sedacrine is the major alkaloid of *Sedum acre* (0.01% from the fresh plant), it was absent in the extracts obtained by treatment of the plant material with refluxing methanol. Structure **5** is assigned to sedacrine on the base of chemical and spectroscopic evidence. The ir spectrum of **5** (CCl_4) showed the presence of a ketone carbonyl group (1720 cm^{-1}) and an intramolecularly bonded OH (broad band at 3200 cm^{-1} unaffected by dilution). The ^{1}Hmr spectrum of sedacrine established the presence of a N—CH_3 group (3H, s, 2.3 ppm), a —CH_2COCH_3 chain (3H, s, 2.1 ppm; 2H, m, 2.7 ppm; these signals disappeared after deuterium exchange in alkaline D_2O), a —CH_2-CHOH-C_6H_5 chain (1H, dd, J = 10 and 3 Hz, 4.9 ppm; 1H, broad signal, 6 ppm; 5H, m, 7.3 ppm), two protons on carbon atoms adjacent to the nitrogen (2H, 2m, 3.3 and 3.6 ppm), and two vinylic protons (2H, m, 5.3 to 5.9 ppm). The position of the double bond in **5** was established by double irradiation experiments: irradiation of the proton appearing at 3.6 ppm showed that it was coupled with the methylenic protons adjacent to the carbonyl group and with the vinylic protons. The double bond is therefore between C-3 and C-4 and not between C-4 and C-5.

The fragmentation pattern of **5** is characteristic of a 2,6-disubstituted *N*-methylpiperidine derivative (10); the major fragment ions were observed at m/z 216, 152, and 94; their compositions were ascertained by high resolution measurements.

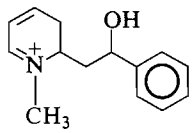
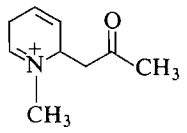
[2]Revision received August 12, 1982.

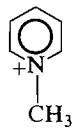
[3]The name sedacrine was coined by A. Nordal (11) for a Sedum base (oil, $C_{17}H_{23}NO_2$?, $[\alpha]_D^{15}$ −51.77° (*c* 2.4, EtOH 96%), insufficiently characterized and of questionable homogeneity. We propose therefore to retain the name sedacrine for compound **5** of the present communication.



m/z 216



m/z 152



m/z 94

Reduction of the carbonyl group of **5** by lithium tri-*tert*-butoxyaluminum hydride yielded a 4:1 mixture (by ^{1}Hmr) of two epimeric alcohols. The major compound appeared identical (mp, mixture mp, [α], ^{1}Hmr) with sedinine **3** (8), implying that sedacrine and sedinine have the same relative and absolute configuration. The minor compound is therefore 8-episedinine **4**. When sedacrine was treated with α-phenylbutyric anhydride in pyridine (9), laevorotatory α-phenylbutyric acid was formed. This result establishes the absolute configuration of sedacrine as depicted in **5** (2*R*, 6*S*, 10*S*) and provides a confirmation of the absolute configuration deduced previously for sedinine **3** by application of Horeau's method to 10-deoxydihydrosedinine **11** (8).

Being a β-aminoketone, sedacrine **5** epimerizes at C-2 (retro-Michael reaction followed by recyclisation) in a variety of conditions. In methanol, at room temperature, sedacrine **5** equilibrated with 2-episedacrine **9** to give a 4:1 mixture (by ^{1}Hmr) in favor of the 2,6-*trans* compound **5**. Pure 2-episedacrine **9** could be isolated from the equilibrium mixture. The same 4:1 mixture of sedacrine **5** and 2-episedacrine **9** was obtained from **5** or from **9** in chloroform; in this case the reaction is slower than in methanol. On the other hand, sedacrine hydrochloride does not epimerize in water or in methanol at room temperature.

Sedinone 6

Sedinone was first isolated and characterized by B. Franck (1) who tentatively suggested (2) that this base had structure **6** (without stereochemical implications). Our results confirm this hypothesis and establish the relative and absolute configuration of sedinone as depicted in **6**.

The empirical formula $C_{17}H_{25}NO_2$ proposed (2) for sedinone was confirmed by high resolution mass spectrometry. The fragmentation pattern is similar to that of sedacrine **5**, the fragment ions appearing 2 units higher on the spectrum of **6** (*m/z* 218, 154, and 96). The presence of a N—CH_3 group and of the side chains —CH_2COCH_3 and —CH_2-CHOH-C_6H_5 was evident from the examination of the ^{1}Hmr spectrum. Sedinone must therefore be either identical or diastereoisomeric with dihydrosedacrine **8**.

Catalytic hydrogenation of sedacrine hydrochloride yielded dihydrosedacrine hydrochloride **8**·HCl whose ^{1}Hmr properties are different from those of sedinone hydrochloride. However, the free base **8** epimerized in methanol at room temperature to give a 1:1 mixture (by ^{1}Hmr) of **8** and **6**. Fractional crystallization of the mixture of the corresponding hydrochlorides led to the isolation of pure 2-epidihydrosedacrine hydrochloride, identical with sedinone hydrochloride (mp, mixture mp, [α]). Sedinone is therefore correctly represented by **6** (2*R*,6*S*,10*S*).

Dihydrosedinine 7

Dihydrosedinine $C_{17}H_{27}NO_2$ (by high resolution mass spectrometry) is a new minor base from *Sedum acre*. The structural attribution rests on the interpretation of the spectral properties of the base and was confirmed by direct comparison of the hydrochloride (mp, mixture mp, ir, [α]) with a sample prepared from sedinine **3** (2). The absolute configuration of dihydrosedinine is therefore as depicted in **7** (2*S*,6*S*,8*R*,10*S*). Dihydrosedinine **7** is diastereoisomeric with a base isolated from *Lobelia inflata* (12).

Absolute configuration of sedacryptine 2

The structure and relative configuration of sedacryptine **2** have previously been determined by X-ray analysis (7).

Treatment of **2** with α-phenylbutyric anhydride in pyridine led to the esterification of the hydroxyl group at C-10 (^{1}Hmr) and to the formation of laevorotatory α-phenylbutyric acid. The absolute configuration of sedacryptine is therefore (2*S*,6*S*,8*S*,10*S*) as depicted in **2**.

It is worthy of note that all the 2,6-disubstituted piperidine alkaloids isolated so far from *Sedum acre* (i.e. sederine **1**, sedacryptine **2**, sedinine **3**, sedacrine **5**, sedinone **6**, and dihydrosedinine **7**) have a common stereochemical feature: the absolute configuration at C-6 and C-10 is the same through all this series and is identical with that of the corresponding carbon atoms (C-2 and C-8) of (−)-sedamine **10** (13).

Isolation and structure determination of other Sedum alkaloids are under progress in our laboratory.

Experimental

Melting points were determined on a Kofler microscope and are uncorrected. The infrared spectra were determined on a Perkin–Elmer 237 spectrometer. Nuclear magnetic resonance spectra were recorded in $CDCl_3$ (unless otherwise stated) with TMS as internal standard on a JEOL JNM-MH-100 apparatus. Mass spectral data were obtained on a Micromass 7070F spectrometer. Optical rotations were measured on a Perkin–Elmer 141 polarimeter. The countercurrent distribution were analyzed by measuring the optical density (420 nm) of the $CHCl_3$ phase of each tube after basification (NH_4OH), drying, and addition of a $CHCl_3$ solution of picric acid.

Isolation of the alkaloids of Sedum acre

Fresh whole plants (40 kg) of *Sedum acre* (collected in October near Brussels) were treated at room temperature with 2% aqueous HCl (80 L). After three days, the solution was filtered, basified with NH_4OH, and extracted with $CHCl_3$. Evaporation of the solvent at room temperature under reduced pressure yielded a brown residue (20 g) containing the crude alkaloids. This fraction was distributed between $CHCl_3$ (250 mL) and McIlvaine buffer (pH 6.4; 250 mL). Evaporation of the organic phase yielded fraction A (18 g). The aqueous phase was basified and extracted with $CHCl_3$; removal of the solvent yielded fraction B (2 g).

Sedacrine 5

Fraction A (18 g) was dissolved in 2-butanone (50 mL) and a solution of perchloric acid in acetone was added dropwise until neutralization. Upon standing, a crystalline precipitate separated. Two successive crystallizations from 2-butanone yielded sedacrine perchlorate (5 g), mp 169°C, $[\alpha]_D^{20}$ −115° (*c* 2, methanol): ir (KBr): 3420, 3080, 2900, 1710, 1490, 1360, 1300, 1100, 765, 730, and 705 cm^{-1}. The usual work-up yielded sedacrine (oil), $[\alpha]_D^{22}$ −156° (*c* 1.7, $CHCl_3$); ms: 273 ($M^{+\cdot}$, 3%; $C_{17}H_{23}NO_2$, found: 273.1723, calcd.: 273.1730), 258 (3; $C_{16}H_{20}NO_2$, found: 258.1484, calcd.: 258.1495), 230 (6; $C_{15}H_{20}NO$, found: 230.1545, calcd.: 230.1546), 216 (25; $C_{14}H_{18}NO$, found: 216.1391, calcd: 216.1389), 152 (24; $C_9H_{14}NO$, found: 152.1071, calcd.: 152.1076), 110 (19), 108 (20), 96 (36), 94 (100; C_6H_8N, found: 94.0648, calcd.: 94.0657), 79 (16), 77 (18); the ^{1}Hmr spectrum was described above.

Sedacryptine 2

Fraction B (2 g) was subjected to a countercurrent distribution ($CHCl_3$/McIlvaine buffer pH 6; 23 transfers). Tubes 15–23 (fraction

C, 1.2 g) contained sedamine, allosedamine, and dihydrosedinine (*vide infra*). Tubes 5–14 were fractionated again by countercurrent distribution in the same conditions. Tubes 7–14 gave a colourless residue (0.7 g) which was dissolved in dry ether and treated with HCl. Crystallization of the precipitate from 2-butanone afforded 137 mg of sedacryptine hydrochloride, mp 142–143°C, $[\alpha]_D^{22}$ −49° (*c* 1.6, MeOH); ir (KBr): 3500, 3220, 3170, 2930, 2880, 2620, 2560, 1450, 1430, 1240, 1130, 1090, 1060, 1010, 960, 910, 770, and 700 cm^{-1}. The usual work-up yielded sedacryptine, mp 130–131°C (from cyclohexane), $[\alpha]_D^{22}$ −14° (*c* 1.5, $CHCl_3$); ^{1}Hmr; δ: 7.5–7.2 (5H, phenyl), 4.85 (dd, *J* = 10.5 and 2.5 Hz, 1H, C10-H), 4.05 (m, 1H, C3-H), 2.65 (m, 1H, C2-H?), 2.2 (s, N—CH_3), 1.4 (s, C8-CH_3); ms: 291 ($M^{+\cdot}$, 3%), 273 (2), 234 (3), 230 (6), 170 (100), 152 (29), 128 (3), 126 (5), 112 (46), 110 (9), 105 (5), 100 (9), 95 (26), 94 (19), 84 (11), 82 (6).

Sedinone **6**

After concentration, the mother-liquors from the sedacryptine hydrochloride crystallization afforded another crystalline residue. Three successive crystallizations from 2-butanone yielded colorless needles (95 mg) of sedinone hydrochloride, mp 176–178°C (dec.), $[\alpha]_D^{22}$ −77° (*c* 1.1, MeOH) (lit. (1) mp 175°C, $[\alpha]_D^{20}$ −79.4° (*c* 1, MeOH); ^{1}Hmr (D_2O); δ: 2.87 (s, N^+CH_3), 2.4 (s, CO—CH_3); ^{1}Hmr of the free base, δ: 7.4–7.2 (5H, phenyl), 4.9 (dd, *J*= 10 and 3 Hz, 1H, C10-H), 3.5–3.1 (2H, C2-H and C6-H), 2.5 (m, 2H, C7-2H), 2.25 (s, 3H, N—CH_3), 2.1 (s, 3H, CO—CH_3); ms: 275 ($M^{+\cdot}$, 8%, $C_{17}H_{25}NO_2$, found: 275.1891, calcd.: 275.1887), 218 (27; $C_{14}H_{20}NO$, found: 218.1545, calcd: 218.1546), 154 (100, $C_9H_{16}NO$, found: 154.1233, calcd.: 154.1233), 96 (83).

Dihydrosedinine **7**

Fraction C (1.2 g) was subjected to two successive countercurrent distributions ($CHCl_3$/McIlvaine buffer pH 7.1; 23 transfers). HCl was added to the residue (51 mg) from tubes 7–14, dissolved in ether. Crystallization from 2-butanone of the precipitate afforded dihydrosedinine hydrochloride, mp 165°C, $[\alpha]_D^{22}$ −64° (*c* 0.4, MeOH) (lit. (2) mp 168°C, $[\alpha]_D^{20}$ −67.1° (*c* 1.4, MeOH)); ^{1}Hmr of the free base, δ: 7.4–7.1 (5H, phenyl), 4.7 (dd, *J* = 9.5 and 4 Hz, 1H, C10-H), 3.85 m, 1H, C8-H), 3.1 (m, 2H, C2-H and C6-H), 2.3 (s, 3H, N—CH_3), 1.15 (d, *J* = 6 Hz, C8-CH_3); ms: 277 ($M^{+\cdot}$, 9%; $C_{17}H_{27}NO_2$, found: 277.2047, calcd.: 277.2043), 262 (2), 218 (41; $C_{14}H_{20}NO$, found: 218.1545, calcd.: 218.1546), 156 (100; $C_9H_{18}NO$, found: 156.1390, calcd.: 156.1389), 98 (42), 96 (24).

Epimerization of sedacrine

Sedacrine **5** (190 mg) was dissolved in MeOH (4 mL) and the solution was left at room temperature for one day. After evaporation of the solvent, the mixture (**5**/**9** ratio of 4:1 by ^{1}Hmr) was dissolved in 2-butanone and a solution of perchloric acid in acetone was added until neutralization. Sedacrine perchlorate (220 mg) was eliminated by repeated fractional crystallizations. The mother-liquors were evaporated to dryness and the free bases were liberated. Crystallization from cyclohexane afforded 2-episedacrine **9** (6 mg), mp 91–93°C, $[\alpha]_D^{22}$ −71° (*c* 3.3, $CHCl_3$); ir (KBr): 3100, 3020, 1715, 1450, 1435, 1355, 1325, 1140, 1050, 750, 695, and 680 cm^{-1}; ^{1}Hmr, δ: 7.4–7.2 (5H, phenyl), 5.75 (m, 1H, C4-H), 5.4 (m, 1H, C3-H), 4.9 (dd, *J* = 10 and 3 Hz, 1H, C10-H), 4.1 (m, 1H, C2-H), 3.4 (m, C6-H), 2.6 (m, 2H, C7-2H), 2.25 and 2.2 (2s, 6H, N—CH_3 and CO—CH_3); ms: 273 ($M^{+\cdot}$, 5%), 258 (3), 230 (7), 216 (48), 152 (41), 110 (39), 108 (39), 96 (72), 94 (100), 79 (48), 77 (40).

*Reduction of sedacrine with lithium tri-*tert*-butoxyaluminum hydride*

Sedacrine perchlorate (1.2 g) in THF (10 mL) was allowed to react at room temperature with lithium tri-*tert*-butoxyaluminum hydride (2 g). After 15 min, ethyl acetate was added and the mixture was evaporated to dryness. The residue was dissolved in water, basified with NH_4OH, and extracted with $CHCl_3$ to give a 4:1 mixture (by ^{1}Hmr) of sedinine **3** and 8-episedinine **4**. Fractional crystallization from 2-butanone of the mixture of the hydrochlorides (prepared by the usual work-up) yielded sedinine hydrochloride (694 mg), mp 170–172°C, $[\alpha]_D^{22}$ −145° (*c* 0.4, MeOH); the free base (mp 119–120.5°C without depression with an authentic sample, $[\alpha]_D^{22}$ −98° (*c* 0.44, MeOH) is identical with sedinine. The mother-liquors were evaporated to dryness and the residue dissolved in water, basified with NH_4OH, and extracted with $CHCl_3$. Two crystallizations from petroleum ether yielded 8-episedinine **4**, mp 120–121.5°C, $[\alpha]_D^{22}$ −102° (*c* 0.45, MeOH) (the epimeric alcohols **3** and **4** have very similar properties but the mixture melting point was strongly depressed (106–120°C); ir (KBr): 3340, 3020, 2920, 2790, 1450, 1130, 1080, 1070, 1060, 880, 760, 740, and 700 cm^{-1}; ^{1}Hmr, δ: 7.4–7.2 (5H, phenyl), 5.6 (2m, 2H, C3-H and C4-H), 4.9 (dd, *J* = 10.5 and 2.6 Hz, 1H, C10-H), 4.05 (m, 1H, C8-H), 3.3 (m, 2H, C2-H and C6-H), 2.35 (s, 3H, N—CH_3), 1.2 (d, *J* = 6 Hz, 3H, C8-CH_3); ms: 275 ($M^{+\cdot}$, 7%), 260 (5), 216 (100), 154 (77), 96 (54), 94 (65). Reduction of sedacrine perchlorate by $LiAlH_4$ afforded a 3:7 mixture of **3** and **4** in THF at room temperature and a 1:1 mixture of **3** and **4** in refluxing THF.

Catalytic hydrogenation of sedacrine

Sedacrine hydrochloride (55 mg) was dissolved in MeOH (2 mL) and hydrogenated over Pt at room temperature under 4 atmospheres for 10 min. Filtration and evaporation of the solvent yielded dihydrosedacrine hydrochloride, ^{1}Hmr (D_2O), δ: 2.8 (s, N^+CH_3), 2.2 (s, $COCH_3$).

Epimerization of dihydrosedacrine

Dihydrosedacrine was liberated from its hydrochloride and dissolved in methanol. After 5 hours at room temperature a 1:1 mixture of dihydrosedacrine **8** and sedinone **6** was obtained. Fractional crystallization from 2-butanone of the mixture of the corresponding hydrochlorides yielded sedinone hydrochloride, mp 175–179°C (dec.; mixture mp without depression), $[\alpha]_D^{22}$ −80° (*c* 0.5, MeOH).

Absolute configuration of sedacryptine and sedacrine by Horeau's method

A solution of α-phenylbutyric anhydride (0.04 mmol) in pyridine (0.5 mL) was added to the alkaloid (0.02 mmol); the mixture was allowed to stand for 15 h at room temperature. A little water was added and after 30 min the mixture was basified with NH_4OH and extracted twice with $CHCl_3$. The aqueous phase was acidified and extracted three times with $CHCl_3$. After evaporation of the solvent, the rotation of α-phenylbutyric acid was measured at the D line in benzene.

Alkaloid	Sign of the acid	Optical yield
Sedacryptine **2**	(−)	29%
Sedacrine **5**	(−)	26%

The partial molar volumes of aqueous metal cations: their prediction and relation to volumes of activation for water exchange

THOMAS W. SWADDLE AND MARK K. S. MAK
Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received August 19, 1982

THOMAS W. SWADDLE and MARK K. S. MAK. Can. J. Chem. **61**, 473 (1983).

Partial molar volumes $\bar{V}^0$ of the Fe^{2+}, Ni^{2+}, Fe^{3+}, Cr^{3+}, Rh^{3+}, and $M(NH_3)_5OH_2^{3+}$ (M = Cr, Co, Rh, Ir) aqueous ions have been obtained by extrapolation from density measurements at 298.15 K on the perchlorate salt solutions containing added $HClO_4$ where necessary to suppress hydrolysis or oxidation. The values for these high-spin aqua-ions and others in the literature can be represented satisfactorily for ionic charges z = 1 through 4 by

$$\bar{V}^0_{abs} = 2.523 \times 10^{-6}(r + 238.7)^3 - 18.07n_c - 417.5z^2/(r + 238.7)$$

where $\bar{V}^0_{abs}$ is the absolute partial molar volume in $cm^3\ mol^{-1}$ of $M^{z+}(aq)$ relative to $\bar{V}^0_{abs} = -5.4\ cm^3\ mol^{-1}$ for $H^+(aq)$, and r is the Shannon radius in pm of M^{z+} with coordination number n_c. Volumes of activation ΔV_{ex}* for water exchange correlate inversely with $\bar{V}^0$ within the series $M^{2+}(aq)$ and $M(NH_3)_5OH_2^{3+}(aq)$ at least, allowing predictions of ΔV_{ex}* to be made from $\bar{V}^0$ or the above equation. The physical origin of these correlations is considered.

THOMAS W. SWADDLE et MARK K. S. MAK. Can. J. Chem. **61**, 473 (1983).

On a obtenu les volumes molaires partiels $\bar{V}^0$ des ions aqueux de Fe^{2+}, Ni^{2+}, Fe^{3+}, Cr^{3+}, Rh^{3+} et $M(NH_3)_5OH_2^{3+}$ (M = Cr, Co, Rh, Ir) par extrapolation à partir des mesures de densité à 298,15 K des solutions de perchlorate contenant du $HClO_4$ ajouté là où c'est nécessaire pour supprimer l'hydrolyse ou l'oxydation. On peut représenter les valeurs de ces ions aqueux à haut spin et les autres valeurs répertoriées dans la littérature pour des charges ioniques de z = 1 jusqu'à 4 par l'équation:

$$\bar{V}^0_{abs} = 2{,}523 \times 10^{-6}(r + 238{,}7)^3 - 18{,}07n_c - 417{,}5z^2/(r + 238{,}7)$$

où $\bar{V}^0_{abs}$ est le volume molaire partiel absolu en $cm^3\ mol^{-1}$ de $M^{z+}(aq)$ par rapport à $\bar{V}^0_{abs} = -5{,}4\ cm^3\ mol^{-1}$ pour $H^+(aq)$ et r est le rayon de Shannon en pm de M^{2+} avec un nombre de coordination de n_c. Il existe une relation inverse entre les volumes d'activation, ΔV_{ex}*, pour l'échange d'eau et $\bar{V}^0$ au moins dans les séries $M^{2+}(aq)$ et $M(NH_3)_5OH_2^{3+}(aq)$; on peut donc ainsi prédire ΔV_{ex}* à partir de $\bar{V}^0$, ou à partir de l'équation ci-dessus. On considère l'origine physique de ces corrélations.

[Traduit par le journal]

Our interest in the precision measurement of volume properties of aqueous metal ions stems from the observation (1, 2) that volumes of activation ΔV_{ex}* for the exchange of coordinated water on $M^{2+}(aq)$, $M(NH_3)_5OH_2^{3+}(aq)$, and possibly $M^{3+}(aq)$ seem to correlate inversely with the apparent molar volumes ϕ_v or partial molal volumes at infinite dilution $\bar{V}^0$ of the respective aqueous ions within each of these series. If this observation has any general validity, the transition states volumes must be much less sensitive to the nature of M than are either ΔV_{ex}* or $\bar{V}^0$, i.e., the transition states must resemble each other relatively closely within a series despite some differences in reaction mechanism which ΔV_{ex}* is thought to reveal (1). Furthermore, the correlations themselves would permit prediction of unknown ΔV_{ex}* values from known $\bar{V}^0$ data (or vice-versa). Finally, if a physically meaningful model is available for the prediction of $\bar{V}^0$, we have the prospect of predicting ΔV_{ex}*, and so arguably the mechanistic predisposition of a metal aqua-ion, from basic principles and quantities.

The establishment and subsequent application of such correlation and models, however, require values of $\bar{V}^0$ that are accurate to within 2 $cm^3\ mol^{-1}$ or better. Good modern data are available for aqueous Mn^{2+}, Co^{2+}, and Ni^{2+} (3–7), but for $Fe^{2+}(aq)$ there exist only older $\bar{V}^0$ values which range from −17.7 to −26.4 $cm^3\ mol^{-1}$ (8–10) (relative to $\bar{V}^0 = 0$ for $H^+(aq)$), possibly because of the rapidity of aerial oxidation of $Fe^{2+}(aq)$ in the absence of added acid (11). For $Fe^{3+}(aq)$, the $\bar{V}^0$ value cited in Millero's comprehensive review (10) can be traced back to density data of precision no better than 1 part in 10^4, which implies uncertainties in the derived molar volume of at least ±2 $cm^3\ mol^{-1}$ at 0.05 mol L^{-1}; solution densities reproducible to about 2 parts in 10^6 are now routinely measurable. In any case, addition of substantial amounts of acid is necessary to suppress hydrolysis and polymerization of iron(III) ($pK_a \sim 2$).

[1] $Fe^{3+}(aq) + H_2O \rightleftharpoons H^+ + FeOH^{2+}(aq) \rightleftharpoons$ polymers

Suppression of hydrolysis is also important for $Rh^{3+}(aq)$, ($pK_a \sim 3$), for which no $\bar{V}^0$ data have been reported, but less so for $Cr^{3+}(aq)$ ($pK_a \sim 4.5$), although a high-acidity redetermination of the $\bar{V}^0$ value of Hepler *et al.* (12) for $Cr^{3+}(aq)$ is desirable as a reference point for the other $\bar{V}^0$ data obtained from density measurements on mixed electrolyte solutions. Apparent molar volumes ϕ_v of aqueous $[M(NH_3)_5OH_2](ClO_4)_3$ at concentrations of ~0.01 mol kg^{-1} have been reported for M = Cr, Co, Rh, and Ir (13, 14), but extrapolation to infinite dilution should be attempted. We have therefore determined the ϕ_v values as a function of concentration for aqueous iron(II), iron(III), chromium(III), and rhodium(III) perchlorates in the presence of controlled amounts of perchloric acid, using nickel(II) perchlorate (3, 4) as a check on our procedures. Values of ϕ_v have also been obtained for various concentrations of $[M(NH_3)_5OH_2](ClO_4)_3$, but without added acid, since hydrolysis is unimportant for these complexes ($pK_a \sim 6$) and, in any event, the volume change accompanying simple hydrolysis is very small (15–17).

Experimental

Preparation of materials

Distilled water was passed through Barnstead deionizer and organic removal cartridges before use.

Nickel(II) and iron(II) perchlorates were made by dissolving the metals (>99.9% pure) in a slight excess of 70% $MClO_4$, warming as necessary, and evaporating to produce the solid hydrates, which were then recrystallized from dilute (<0.1 mol L^{-1}) $HClO_4$. Oxygen was excluded in all operations involving iron(II). The products contained no detectable chloride, but comparison of their H^+-ion-exchange equivalents (14) with direct metal-ion analyses (by EDTA/Zn^{2+} back-titration for Ni^{2+}, and dichromate titration for Fe^{2+}) showed that some 0.7% $HClO_4$ was typically present.

Chromium(III) perchlorate was made by reducing CrO_3 with H_2O_2 in aqueous $HClO_4$, and the recovered solid hydrate was recrystallized from 0.1 mol L^{-1} $HClO_4$. The ultraviolet spectrum of this product showed the chromium to be present exclusively as $Cr(H_2O)_6^{3+}$, free of hydrolytic polymers (18), but comparison of the chromium content (19) with the H^+-ion-exchange equivalent again showed that some 0.7% $HClO_4$ was present in the hydrate. Similarly, an iron(III) perchlorate hydrate sample from Fluka AG, of otherwise acceptable purity (17), was shown by two independent methods (reduction to Fe^{2+} followed by dichromate titration, and direct EDTA titration, versus H^+-ion-exchange) to contain 1.640% $HClO_4$ (cf. Hunt and Taube (20)).

Hexaaquarhodium(III) perchlorate was prepared by the method of Ayres and Forrester (21) and was free of $HClO_4$, according to elemental analysis and its H^+-ion-exchange equivalent.

Aquapentaammineiridium(III) perchlorate was made by base hydrolysis of $[Ir(NH_3)_5Cl]Cl_2$ (Spex HiPure) followed by precipitation with 70% $HClO_4$ and two recrystallizations from hot water. Its visible–uv spectrum was in excellent agreement with that previously reported (22). Aquapentaamminechromium(III), -cobalt(III), and -rhodium(III) perchlorates were made as described elsewhere (14, 23). In all cases, the purity of these anhydrous aquapentaammines was confirmed by H^+-ion-exchange titrations (14).

Density measurements

Solution samples of $[M(NH_3)_5OH_2](ClO_4)_3$ were prepared individually by weight. The available concentration range was limited by problems of solubility and density measurement precision. The other perchlorate salts were freely soluble but somewhat hygroscopic; their solutions were also made up by weight, individually for the higher concentrations or by dilution of stock solutions below 0.04 mol kg^{-1}, but were analyzed definitively for metal salt and (by H^+-ion-exchange) $HClO_4$ content in every case. Iron(II) perchlorate solutions were kept oxygen-free; oxidation was undetectable below 0.04 mol kg^{-1} iron(II) and negligible at the higher concentrations, after completion of the density measurements.

The density measurements were made on degassed solutions with a Sodev 02-D vibrating tube flow densimeter thermostated at 298.16 K with a constancy of ±0.001 K. The reference fluids were pure water (density d^0 = 0.997048 g cm^{-3} (24)) and dry nitrogen gas at atmospheric pressure (87 kPa).

Results

For solutions of a metal perchlorate (component 2) alone in water (component 1), the usual expression

$$[2]\quad \phi_v = [\{(1 + m_2M_2)/d\} - 1/d^0]/m_2$$

may be used to calculate the apparent molar volume ϕ_v of component 2 (formula mass M_2) at molal concentration m_2 mol kg^{-1} from the densities d and d^0 g cm^{-3} of the solution and pure water respectively (10). Equation [2] sufficed for the studies of $[M(NH_3)_5OH_2](ClO_4)_3$, but for all the other salts examined in this work a third component, perchloric acid, was also present and had to be allowed for in deriving $\phi_{v(2)}$ for component 2. The total volume V of a solution can be expressed in terms of the partial molal volumes $\bar{V}_j$ of the jth components as

$$[3]\quad V = n_1\bar{V}_1 + n_2\bar{V}_2 + n_3\bar{V}_3$$

when n_j moles of the jth component are present. For component 2, we have

$$[4]\quad \begin{aligned}\phi_{v(2)} &= (V - n_1V_1^0 - n_3\bar{V}_3)/n_2 \\ &= \{[(n_1M_1 + n_2M_2 + n_3M_3)/d] - n_1V_1^0 - n_3\bar{V}_3\}/n_2 \\ &= \{[(1 + m_2M_2 + m_3M_3)/d] - (1/d^0) - m_3\bar{V}_3\}/m_2\end{aligned}$$

The concentration dependence of $\phi_{v(3)}$ for $HClO_4$(aq) happens to be negligible over the range of ionic strengths I used here (25), so we have

$$[5]\quad \bar{V}_3 = \phi_{v(3)} + I(\partial\phi_{v(3)}/\partial I) \approx \phi_{v(3)}$$

Our measured value of $\phi_{v(3)}$ = 43.9 ± 0.2 cm^3 mol^{-1} at ~0.1 mol kg^{-1} was used for $\bar{V}_3$ in eq. [4] rather than the slightly larger literature value (25), so as to cancel possible calibration errors. Values of $\phi_{v(2)}$, hereinafter called simply ϕ_v, are listed in Table 1, together with the corresponding uncertainties $\delta\phi_v$ which were calculated by summing pessimistic estimates of possible errors in m_2, m_3, and d. These uncertainties are greater for $M(ClO_4)_2$ and $M(ClO_4)_3$ than for the ammines because the concentrations of the former solutes and of the $HClO_4$ present had to be determined titrimetrically using standardized reagents, whereas the ammine solutions were made up directly without perchloric acid from dry solid salts of established composition. The titrimetric concentrations did, however, agree with m_2 estimates based on the weights of solid hydrated salt taken, to well within the calculated error limits. The density measurements (±2 to 3 parts per million) were minor sources of error.

The question of the most appropriate way of representing the concentration dependence of ϕ_v so as to derive realistic values of the infinite-dilution value ϕ_v^0, which equals the sum of the (*additive*) infinite-dilution partial molar volumes of the aqueous ions of component 2, has been widely discussed (3, 10, 26–28). The simple Masson equation

$$[6]\quad \phi_v = \phi_v^0 + S_vc^{1/2}$$

where S_v is an empirical constant and c is the concentration of component 2 in mol L^{-1}, is now recognized to be inadequate for purposes of extrapolation to infinite dilution (10, 28).[1] Millero (10, 28) suggests the use of the Redlich–Meyer (29) equation

$$[7]\quad \phi_v = \phi_v^0 + kw^{3/2}c^{1/2} + b_vc$$

for extrapolation to infinite dilution; here, k is the Debye–Hückel slope (= 1.868 at 25°C), w is the "valence factor" (= $0.5\Sigma\nu_iz_i^2$, where z_i and ν_i are the charge and molar number of ions of the ith kind formed by component 2), and b_v is an empirical parameter which may, however, exhibit some dependence on c or I. For the system considered here, a means of handling ϕ_v data for mixed electrolyte solutions was needed. We have therefore fitted our data to the equation

$$[8]\quad \phi_v = \phi_v^0 + kwI^{1/2}/(1 + I^{1/2}) + B_vc$$

in which B_v, the only adjustable parameter, turned out to be

[1]We have chosen to convert concentrations to the molar (mol L^{-1}) scale for use with eqs. [6]–[9], in accordance with the Debye–Hückel theory.

much less important than the b_v of eq. [7], i.e., any dependence of B_v on I can be neglected for our purposes. Equation [8] is an adaptation of that proposed by Millero (27) on the basis of the specific interaction model for mixed electrolyte solutions, and incorporates Güntelberg's assumption (30) that $\mathring{a}$ is about 310 pm. Equations [7] and [8] both reduce to the Debye–Hückel limiting law at low concentrations, as they should, whereas eq. [6] does not and is therefore invalid.

Values of ϕ_v^0 and B_v, computed using kw = 5.604 and 11.208 for 2:1 and 3:1 electrolytes respectively, are given in Table 2. By way of comparison, the Redlich–Meyer treatment (eq. [7]) of the data for $[M(NH_3)_5OH_2](ClO_4)_3$ gave ϕ_v^0 = 203.3, 209.6, 209.7, and 213.7 cm^3 mol^{-1} with b_v = −59, −58, −102, and −85 L mol^{-1} for M = Co, Rh, Ir, and Cr respectively. Conversely, reduction of the data of Hepler *et al.* (4–6) for aqueous M^{2+} and M^{3+} salts by eq. [8] gave ϕ_v^0 values which were slightly but not significantly larger than the results obtained by these authors by use of eq. [7] (e.g., for $Cr(NO_3)_3$(aq), ϕ_v^0 = 45.9 cm^3 mol^{-1} with B_v = −9.7 cm^3 L mol^{-2} according to eq. [8], cf. ϕ_v^0 = 45.4 cm^3 mol^{-1} and b_v = −41.1 cm^3 kg mol^{-2} with eq. [7] on the molal scale (12)). Finally, for $Ni(ClO_4)_2$ (aq), values of $[\phi_v - kwI^{1/2}(1 + I)^{1/2}]$ agreed satisfactorily at a given c for $[HClO_4]$ = 0.002 and 0.10 mol kg^{-1}.

Table 3 shows that our conventional partial molar volume $\bar{V}^0_{conv}$ for Ni^{2+}(aq) falls within the range of modern values, confirming that our measurements and use of eq. [8] are compatible with the best recent work. We therefore consider our data on Fe^{2+}(aq) to supersede the widely-ranging $\bar{V}^0$ values implied by earlier measurements on $FeCl_2$, $FeBr_2$, and $FeSO_4$ (8–10).

The ϕ_v value for $Fe(ClO_4)_3$ seems to be the first reported for this salt, and the extrapolated $\bar{V}^0_{conv}$ for Fe^{3+}(aq) is in only fair agreement with that obtained from imprecise data on $Fe(NO_3)_3$ (−43.7 cm^3 mol^{-1}) (9, 10). Since we have taken pains to suppress hydrolysis and have allowed for residual acid present in the solid salt, we feel our value of −36.5 ± 1.2 cm^3 mol^{-1} is the more reliable. With $Cr(ClO_4)_3$, we calculate $\bar{V}^0_{conv}$ = −36.7 ± 1.5 cm^3 mol^{-1}, which is in better agreement with the old estimate derived from $CrCl_3$ (−39.5 cm^3 mol^{-1}) (9, 10) than with the more precisely-measured value of Hepler *et al.* (12) (−41.1 ± 1.2 cm^3 mol^{-1}, recalculated via eq. [8] for consistency). The $Cr(NO_3)_3$ solutions used by Hepler *et al.* (12) contained significant quantities of nitric acid (up to about 0.03 mol L^{-1}), however, and it is not clear how the contributions of HNO_3 to the densities were taken into account. We believe our $\bar{V}^0_{conv}$ for Cr^{3+}(aq) to be realistic, but the contrast with the value of −47 cm^3 mol^{-1}, derived by Hepler *et al.* from

data by Lumme (12) for $Cr(ClO_4)_3$, is disquieting. No data on Rh^{3+}(aq) salts could be found in the literature; the present value is somewhat less precise than those for Cr^{3+}(aq) and Fe^{3+}(aq) because of the limited amount of $[Rh(H_2O)_6](ClO_4)_3$ available, but it is clear that $\bar{V}^0_{conv}$ for Rh^{3+}(aq) is some 7 cm^3 mol^{-1} more negative than $\bar{V}^0_{conv}$ for Cr^{3+}(aq) and Fe^{3+}(aq).

Apparent molar volumes for $[M(NH_3)_5OH_2](ClO_4)_3$ could not be measured over a wide concentration range because of solubility limitations, and consequently the ϕ_v values in Table 1 appear to be almost independent of concentration within the experimental uncertainty, much as do the ϕ_v data for $M(ClO_4)_2$ and $M(ClO_4)_3$ over the range 0.01–0.04 mol kg^{-1}. This is evidently due to the fortuitous near-cancellation of the second and third terms in eqs. [7] and [8] over this concentration range. That ϕ_v should indeed decrease markedly below this range as infinite dilution is approached is illustrated by recent densimetric studies of salts of large cations (including some N-base complexes) in aqueous solution at high dilution (32, 33). Interpolated values of ϕ_v for the midrange (and typical experimental) concentration of $[M(NH_3)_5OH_2](ClO_4)_3$ of 0.02 mol L^{-1}, listed in Table 2, are perhaps more closely representative of the actual experimental data than are ϕ_v^0, and agree well with the published ϕ_v values (13, 14) in this concentration regime.

Discussion

Theoretical interpretation of absolute molar volumes of M^{2+}(aq)

The data of Table 3 make it clear, for the first time, that $\bar{V}^0$ for M^{2+}(aq) varies monotonically from M = Mn through Fe and Co to Ni, and that some correlation with the crystallographic radii r of M^{2+} exists (except for M = Ca). Numerous theories have been proposed (see, e.g., refs. 3, 9, 10, 28, 34–39) to rationalize $\bar{V}^0$ for M^{z+}(aq) in terms of r, variously defined, but we propose a further one in which the existence of a first coordination sphere of n_c water ligands is explicitly acknowledged, and solvent from the second coordination sphere outwards (i.e., from the distance of closest approach of the solvent to the $M(H_2O)_{n_c}^{z+}$ unit) is treated as a continuous dielectric under electrostriction according to the Drude–Nernst equation. The effective volume V_c of the $M(H_2O)_{n_c}^{z+}$ unit must be estimated; crystallographic experience (31) indicates that this is best expressed in terms of an effective radius $(r + \Delta r)$ which allows arbitrarily for the contribution of packing voids to V_c and for the general lack of direct knowledge of the distance of closest approach of electrostricted solvent.

$$[9] \quad V_c = 4\pi N(r + \Delta r)^3/3$$

The assignment of n_c waters to the unit of volume V_c reduces the volume of the solution system by n_c times the molar volume of liquid water (18.068 cm^3 mol^{-1} at 298.15 K and 0.1 MPa). This turns out to be a major factor in $\bar{V}^0$, leading to strongly negative values at high n_c. Finally, the Drude–Nernst electrostrictive term (10) may be taken to operate at effective radius of $(r + \Delta r)$, and for r in pm we have

$$[10] \quad \bar{V}^0_{abs} = 2.523 \times 10^{-6}(r + \Delta r)^3 - 18.07n_c - 417.5z^2/(r + \Delta r)$$

where $\bar{V}^0_{abs}$ is the partial molar volume of M^{z+}(aq) on the absolute scale, with $\bar{V}^0_{abs} = -5.4$ cm^3 mol^{-1} for H^+(aq) (10). The data of Table 3 (less Cd^{2+} and Ca^{2+}), together with our $\bar{V}^0_{abs}$ values of −52.9 and −52.7 cm^3 mol^{-1} for Cr^{3+}(aq) and Fe^{3+}(aq), fit eq. [10] well with $\Delta r = 239.0 \pm 0.5$ pm when n_c is set to 6.0; there is ample evidence from nmr, EXAFS, X-ray diffraction, visible spectroscopy, and isotopic dilution that this assignment of n_c is justified, at least for the transition metal ions listed. If all the $\bar{V}^0$ data presented in Fig. 1 are fitted, with the adoption of the coordination numbers indicated, $\Delta r = 238.4 \pm 0.7$ pm. Since we consider the first data set to be more reliable on average than the second (which consists of the first set plus further values from Millero's 1972 compilation (10)), a value of $\Delta r = 238.7$ pm has been adopted in calculating the $\bar{V}^0_{abs}$ values presented in Fig. 1, in which the straight line represents perfect agreement between calculated and experimental $\bar{V}^0_{abs}$.

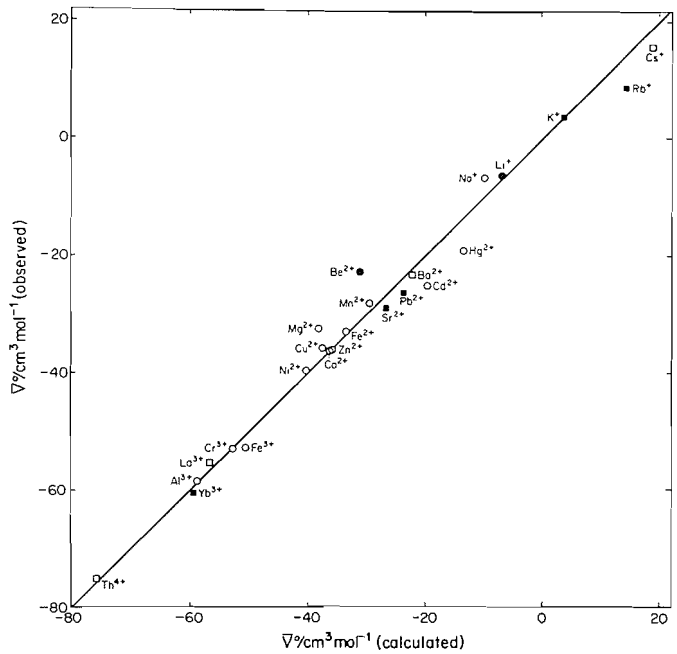

FIG. 1. Calculated and observed absolute partial molar volumes of aqueous metal ions at 298.15 K and infinite dilution, relative to $\bar{V}^0_{abs}(H^+) = -5.4$ cm^3 mol^{-1}, according to eq. [10]. Primary coordination numbers n_c are taken to be 4 (filled circles), 6 (open circles), 8 (filled squares), or 9 (open squares). Experimental $\bar{V}^0_{abs}$ values are taken from Tables 2 and 3 or from Millero's compilation (10).

This approach has an antecedent in Akitt's model of 1971 (36), but there are important differences. Akitt set Δr equal to the diameter of a water molecule, or 276 pm, whereas much closer approach of electrostricted water is possible in interligand space (e.g., along a threefold axis of octahedral $M(H_2O)_6^{z+}$), and allowance for void-space contributions needs to be made in estimating V_c. The difference between his and our Δr values is important, as a 1 pm change in $(r + \Delta r)$ results typically in about 1 cm^3 mol^{-1} change in $\bar{V}^0_{abs}$. For the same reasons, it is important to use r values appropriate to the coordination number n_c; we used Shannon's critical compilation (31) in which n_c is specified for each ionic radius given. The Shannon radii are often given only to the nearest pm, and are subject to the usual uncertainties that beset division of internuclear distances into ionic contributions, so that eq. [10] cannot be expected to predict $\bar{V}^0_{abs}$ values to better than ±1 cm^3 mol^{-1}. As noted above, however, experimental $\bar{V}^0$ data for M^{z+}(aq) are themselves often subject to uncertainties of ±2 cm^3 mol^{-1}, while the assumption of an absolute partial molar volume of −5.4 cm^3 mol^{-1} for H^+(aq) (10) is open to

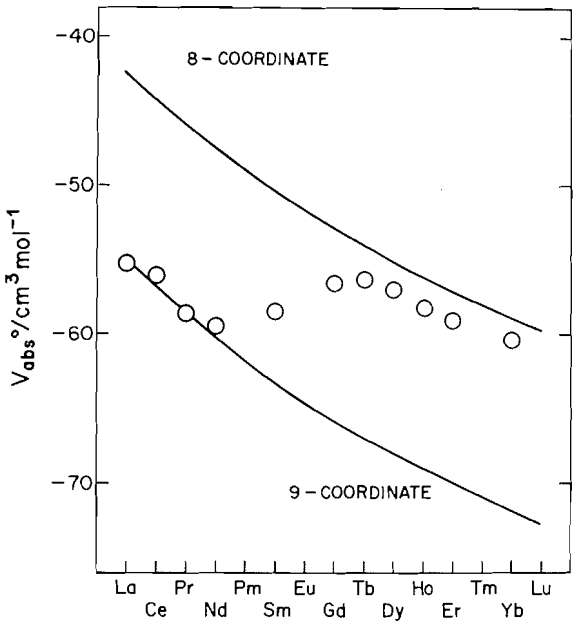

FIG. 2. Comparison of the experimental absolute partial molar volumes of Spedding *et al.* (42) for aqueous lanthanoids(III) with the predictions of eq. [10], assuming (upper curve) $n_c = 8$ and (lower curve) $n_c = 9$.

question. All in all, eq. [10] accounts for the widely-ranging experimental $\bar{V}^0$ data as well as can be expected, and we are therefore confident that the model on which it is based is a realistic representation of all simple $M^{z+}(aq)$ ions for $z = 1$ through 4.

Primary coordination numbers

The single adjustable parameter Δr in eq. [10] can be determined as accurately as necessary with measured $\bar{V}^0$ values for ions of well-established primary coordination number n_c in solution. Then, because the term 18.07 n_c (as well as the dependence of r upon n_c) makes the calculation of $\bar{V}^0_{abs}$ very sensitive to n_c, known $\bar{V}^0$ data can provide realistic n_c values so long as the appropriate crystallographic radii are available (31). In almost every case tested, we found that the $\bar{V}^0$ values corresponded to $n_c = 4$, 6, 8, or 9, as would be anticipated on geometrical grounds. For example, for $Na^+(aq)$, we calculate $\bar{V}^0_{abs} = 23.7$, 6.5, −9.9, −17.9, and −31.2 $cm^3\ mol^{-1}$ for coordination numbers 4, 5, 6, 7, and 8 respectively; the observed value of −6.6 $cm^3\ mol^{-1}$ is consistent with $n_c = 6$, in agreement with a recent X-ray diffraction study (40). Similarly, for $Sr^{2+}(aq)$, $\bar{V}^0_{abs}$ is predicted to be 1.4, −13.7, −26.7, −39.6, and −52.4 $cm^3\ mol^{-1}$ for 6-, 7-, 8-, 9-, and 10-coordination respectively; the observed value of −29.0 supports the X-ray result of $n_c = 8$ (41). Only for $Ca^{2+}(aq)$ did n_c appear to be 7, for which $\bar{V}^0_{abs}$ (calculated) is −28.0 $cm^3\ mol^{-1}$; significantly, two X-ray research groups (41, 42) have independently concluded that n_c is between 6 and 8 for $Ca^{2+}(aq)$, and probably both $Ca(H_2O)_6^{2+}$ and $Ca(H_2O)_8^{2+}$ are present simultaneously, giving a time-average n_c near 7. If water is taken to be a hard sphere of radius 138 pm, the transition from 6- to 8-coordination (octahedral to simple cubic) becomes possible when the radius of M in $M(H_2O)_6^{z+}$ is 101 pm or more; for Ca^{2+} in octahedral environments, $r = 100$ pm, and higher for higher n_c (31).

For the aqueous lanthanoid(III) ions, Spedding, Pikal, and Ayres (43) suggested that the partial molar volumes reflected a progressive changeover from predominant 9-coordination for $La^{3+}(aq)$ to 8-coordination for $Tb^{3+}(aq)$ and the higher lanthanoids(III). In Fig. 2, we display the $\bar{V}^0_{abs}$ values of Spedding *et al.* together with curves representing the smoothed theoretical $\bar{V}^0_{abs}$ data calculated with eq. [10] using Shannon's radii (31) for the appropriate coordination numbers. The separation of the two curves is about 13 $cm^3\ mol^{-1}$, so that the coincidences of $\bar{V}^0_{abs}$ of $La^{3+}(aq)-Nd^{3+}(aq)$ with the lower curve and of $Tb^{3+}(aq)-Yb^{3+}(aq)$ with the upper, within the accuracy of $\bar{V}^0$ measurements and of eq. [10], combine with recent X-ray diffraction results (44) to provide strong support for the theory of Spedding *et al.* (43).

Interestingly, $H^+(aq)$ ($r \sim 0$) fits eq. [10] reasonably well with $n_c = 2$ (giving $\bar{V}^0_{abs} = -3.6$ $cm^3\ mol^{-1}$, cf. −5.4 assumed), suggesting that its central unit consists of two water molecules joined by a short linear H-bond, much as in the structure reported (45) for the discrete ion $H_{13}O_6^+$.

Contribution of electrostriction

The average value of r for the ions covered by Fig. 1 is ~80 pm, so $(r + \Delta r)$ is typically ~320 pm and the classical electrostriction (Drude–Nernst) component of $\bar{V}^0_{abs}$ is $-1.30z^2$ $cm^3\ mol^{-1}$, which amounts to only −1.3, −5.2, −11.7, and −20.8 cm^3 mol for $Z = 1$, 2, 3, and 4 respectively. Departures of r from this average value contribute only minor discrepancies to the calculated $\bar{V}^0_{abs}$ in terms of $cm^3\ mol^{-1}$, and so eq. [10] may be approximated as follows with only minor loss of accuracy (Δr having been slightly adjusted).

$$[11]\quad \bar{V}^0_{abs} = 2.523 \times 10^{-6}(238.5 + r)^3 - 18.07n_c - 1.305z^2$$

The second term generally far outweighs the third, that is, actual complexation by solvent, rather than coulombic electrostriction, is the primary factor that leads to negative $\bar{V}^0_{abs}$ values for many metal ions in solution.

The Güntelberg approximation (30), in which the effective radii of aqueous cations is set to about 310 pm in the extended Debye–Hückel equation, may be seen to succeed for the same reason as eq. [11], viz., that water may be treated as a continuous dielectric beyond the distance of closest-approach to the complex $M(H_2O)_{n_c}^{z+}$ which has an effective radius within a few percent of 310–320 pm, electrostatic interactions being rather insensitive to the exact value of this large radius.

Hydrolysis of metal ions

The volumes V_c of the unit $M(H_2O)_{n_c}^{z+}$ and its conjugate base $M(H_2O)_{(n_c-1)}OH^{(z-1)+}$ should be virtually identical. According to eq. [11], then, the volume change ΔV_a for the reaction

$$[12]\quad M(H_2O)_{n_c}^{z+} \rightleftharpoons M(H_2O)_{(n_c-1)}OH^{(z-1)+} + H^+$$

should be

$$[13]\quad \Delta V_a = -5.4 + 1.305[z^2 - (z-1)^2] = 2.6z - 6.7$$

For $z = 3$, ΔV_a is therefore expected to be close to +1 $cm^3\ mol^{-1}$, which is precisely what is observed for $Fe^{3+}(aq)$ (17). Similar near-zero ΔV_a values have been found for the hydrolyses of other $M(H_2O)_{n_c}^{3+}$ and $M(NH_3)_5OH_2^{3+}$ ions (15–17), and the conflict with our original naive expectations of $\Delta V_a \sim +25$ $cm^3\ mol^{-1}$ (15) is now resolved.

Failures of eq. [10]

Poor predictions of $\bar{V}^0_{abs}$ can be anticipated where r is deviant or subject to substantial uncertainty, e.g., for Be^{2+}, for which n_c is almost certainly 4 but the Shannon radius (27 pm) is

For personal use only.

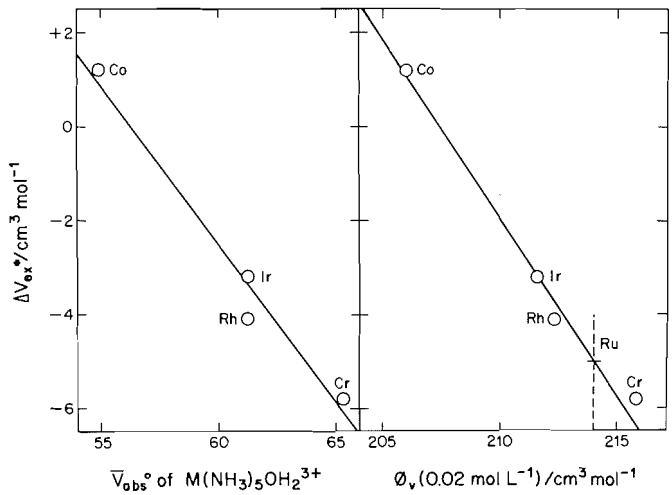

FIG. 3. Correlations of the volumes of activation ΔV_{ex}^* for water exchange on aqueous $[M(NH_3)_5OH_2](ClO_4)_3$ with (left) the absolute partial molar volumes of $M(NH_3)_5OH_2^{3+}(aq)$ and (right) the apparent molar volumes ϕ_v for the perchlorate salts (M = Co, Rh, Ir, Cr) (2).

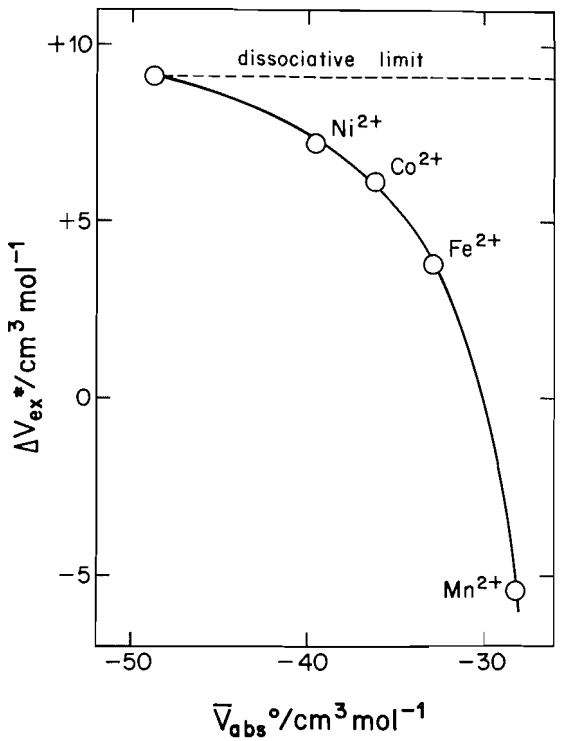

FIG. 4. Correlation of the volumes of activation ΔV_{ex}^* for water exchange on aqueous M^{2+} (M = Mn, Fe, Co, and Ni (47), and the hypothetical M^{2+} of radius 57.2 pm representing closest-packing of six water ligands) with the absolute partial molar volumes of $M^{2+}(aq)$. $\bar{V}^0_{abs}$ values from Table 3, except for the hypothetical $M^{2+}(aq)$ (from eq. [10]).

smaller than the cavity in a closest-packed tetrahedron of waters of 138 pm radius (31 pm). It would appear, however, that eqs. [10] and [11], as they stand, are simply inapplicable to *low-spin* transition metal ions. This can be anticipated from our data on $M(NH_3)_5OH_2^{3+}(aq)$; $\bar{V}^0_{abs}$ = 54.6, 60.9, 60.9, and 65.0 cm^3 mol^{-1} for M = Co, Rh, Ir, and Cr, but the corresponding ionic radii are 54.5, 66.5, 68, and 61.5 pm (31), the first three referring to spin-paired (t_{2g}^6) ions. Not surprisingly, $\bar{V}^0_{abs}$ for $Rh^{3+}(aq)$ is calculated to be −49.0 cm^3 mol^{-1} from eq. [10], whereas the measured value is −59.7 cm^3 mol^{-1}. Thus, solvated spin-paired ions are even more compact than their measured crystallographic ionic radii would suggest. More $\bar{V}^0$ data are required here.

Correlations of $\bar{V}^0$ *with* ΔV_{ex}^*

Our early observations (1) suggested that ΔV_{ex}^* correlated roughly linearly with $\bar{V}^0$ (or ϕ_v at a suitable reference concentration) with slope near −1. Figure 3 shows that this is a fair statement for the $M(NH_3)_5OH_2^{3+}$ water exchanges, although the slope is more accurately −0.71 or −0.74, depending on whether one correlates ΔV_{ex}^* with $\bar{V}^0$ or, perhaps more realistically, with ϕ_v for $c \sim 0.02$ mol L^{-1}, the mid-range of concentration in most experiments. The latter correlation permits prediction of ΔV_{ex}^* for $Ru(NH_3)_5OH_2^{3+}$ of −5 cm^3 mol^{-1}, on the basis of ϕ_v(0.02 mol L^{-1}) = 214.0 cm^3 mol^{-1}, calculated for the perchlorate salt from the data of Fairhurst and Swaddle (46). Direct measurement of this ΔV_{ex}^* is difficult (46), but will be attempted again.

For aqua exchange on $M^{2+}(aq)$, ΔV_{ex}^* is indeed inversely correlated with $\bar{V}^0$, but the correlation now seems not to be linear (Fig. 4). Nevertheless, we can use the correlation to predict ΔV_{ex}^* = +6 and −8 cm^3 mol^{-1} for M = Zn^{2+} and Cd^{2+}, from the data of Table 3. For $Cu^{2+}(aq)$, the Jahn–Teller distortion of the hexacoordinate ion makes the interpretation of kinetic parameters ambiguous (48), but in any case the correlation predicts ΔV_{ex}^* just less than +6 cm^3 mol^{-1}. The calcium ion probably does not belong in this correlation because of the possibility noted above that the coordination number may be more than six.

Included in Fig. 4 is a theoretical upper limit to ΔV_{ex}^*, estimated by assuming the water molecule to be a sphere of radius 138 pm. Since, in the limit of steric stability, the waters in $M(H_2O)_6^{z+}$ are closest-packed around a cavity of radius 57 pm (= r of M^{z+}) and therefore have an effective molar volume of 8.95 cm^3 mol^{-1} each (calculated for a cubic closest-packed array of spheres of radius 138 pm), the volume change for a limiting S_N1 or D-type process will be 18.07 − 8.95 = +9.1 cm^3 mol^{-1} (1, 49). This applies to an ideal, limiting-octahedral $M(H_2O)_6^{2+}$ ion which will have $\bar{V}^0_{abs}$ = −48.7 cm^3 mol^{-1} (eq. [10]) and has been entered as the top left limit to the correlation curve of Fig. 4. Real $M(H_2O)_6^{2+}(aq)$ should have ΔV_{ex}^* less than +9.1 cm^3 because (*a*) the ligands are not usually closest-packed, (*b*) the mode of activation may have a degree of associative character, and (*c*) the reduction of coordination number in the residual complex may lead to reduced M—OH_2 bond lengths (49, 50). All three factors will tend to increase in importance with increasing r; hence, ΔV_{ex}^* becomes less positive as r and therefore also $\bar{V}^0_{abs}$ (from eq. [11]) increase, for a given z and reaction type. The result is that the volumes of the transition states for solvent exchange, which we represent for convenience by ($\Delta V_{ex}^* + \bar{V}^0$), do not vary strongly as M is changed within a series; in each case, the reacting system seeks to make the best of the steric limitations primarily by adjusting factor (*b*).

Published ΔV_{ex}^* data on $M^{3+}(aq)$ are limited to the values −5.4 and −9.3 cm^3 mol^{-1} for $Fe^{3+}(aq)$ and $Cr^{3+}(aq)$, which refer to vastly different ionic strengths and temperatures (17, 51). Nevertheless, if correlations similar to those for $M^{2+}(aq)$ and $M(NH_3)_5OH_2^{3+}(aq)$ apply, we can anticipate that ΔV_{ex}^* for $Rh^{3+}(aq)$ will be 0 ± 2 cm^3 mol^{-1}, on the basis of Table 2.

The crystal structure of free base cocaine, $C_{17}H_{21}NO_4$

RONALD J. HRYNCHUK,[1] RICHARD J. BARTON, AND BEVERLEY E. ROBERTSON[2]
Faculty of Science, University of Regina, Regina, Sask., Canada S4S 0A2

Received June 9, 1982[3]

RONALD J. HRYNCHUK, RICHARD J. BARTON, and BEVERLEY E. ROBERTSON. Can. J. Chem. **61**, 481 (1983).

The crystal structure of free base cocaine has been determined in order to compare the conformation with that observed in its salts, and to clarify the powder pattern of the pure compound. Crystals of (−)-cocaine are monoclinic, space group $P2_1$, a = 10.130(1), b = 9.866(2), c = 8.445(1) Å, β = 106.92(1)°, Z = 2, D_x = 1.25 g cm^{-3}. Data were collected with MoK$_\alpha$ radiation on a modified Picker diffractometer using the NRCC diffractometer control system. The structure was solved by direct methods and refined by least squares to final R and R_w of 0.065 and 0.062 ($w = 1/\sigma^2(F)$) using the 1818 independent reflections with $\sin\theta/\lambda < 0.7048$ and $|F|/\sigma(|F|) \leq 3.0$.

The free base exists in a piperidine chair conformation similar to the methiodide salt and the hydrochloride salt. However, the piperidine ring carbon−nitrogen bonds in the free base are shorter than those in the salts; 1.460(7) and 1.467(6) Å in the free base compared to 1.55(2) and 1.51(2) Å in the methiodide salt and 1.50(1) and 1.49(1) Å in the hydrochloride salt. Further, the orientations of the benzoxy group and the methoxycarbonyl group, with respect to the piperidine rings, are significantly different from that common to both salts. The calculated powder diffraction pattern of (−)-cocaine showed that several previously reported weak lines in powder diffraction data for this alkaloid should not be present.

RONALD J. HRYNCHUK, RICHARD J. BARTON et BEVERLEY E. ROBERTSON. Can. J. Chem. **61**, 481 (1983).

On a déterminé la structure du cristal de la base libre cocaine dans le but de comparer sa conformation avec celle de ses sels et dans le but de clarifier le diagramme de poudre du composé pur. Les cristaux de la (−)-cocaine sont monocliniques et appartiennent au groupe d'espace $P2_1$ avec a = 10,130(1), b = 9,866(2), c = 8,445(1) Å, β = 106,92(1)°, Z = 2, D_x = 1,25 g cm^{-3}. Faisant appel à un système de contrôle de diffractomètre de type NRCC, on a recueilli les données à l'aide d'une radiation MoK$_\alpha$ d'un diffractomètre de Picker modifié. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs conventionnelles de R et de R_w de 0,065 et de 0,062 ($w = 1/\sigma^2(F)$) pour 1818 réflexions indépendantes avec $\sin\theta/\lambda < 0{,}7048$ et $|F|/\sigma(F) \leq 3{,}0$.

La base libre existe sous une conformation chaise de la pipéridine semblable au méthiodure et au chlorhydrate. Cependant les liaisons C—N du cycle pipéridine de la base libre sont plus courtes que celle des sels; 1,460(7) et 1,467(6) Å dans la base libre comparées à 1,55(2) et 1,51(2) Å pour le méthiodure et 1,49(1) Å pour le chlorhydrate. De plus, les orientations du groupe benzoxy et du groupe méthoxycarbonyle par rapport au cycle de la pipéridine sont significativement différentes de celles communes au deux sels. Le diagramme de diffraction de la poudre calculé pour la (−)-cocaine montre que plusieurs des lignes faibles rapportées antérieurement dans les données de diffraction de poudre pour cet alcaloide ne devraient pas être présentes.
[Traduit par le journal]

Introduction

The purpose of this work is to examine the structure of (−)-cocaine as its free base. The present stereochemical configuration of the natural product is derived from the crystal structure of its salts. Gabe and Barnes (1) have determined the crystal structure of (−)-cocaine hydrochloride. They showed that it had a bridged 1,5 piperidine chair conformation. Shen *et al.* (2) showed that cocaine methiodide also has a chair conformation, but there were differences in the orientations of the benzoxy and methoxycarbonyl substituents. These differences affected intramolecular contact distances and their electrostatic interactions. We determined the crystal structure of (−)-cocaine as its free base in order to compare it to that of these salts. The absolute configuration of (−)-cocaine is known to be (−)-2*R*-methoxycarbonyl-3*S*-benzoxytropane (3).

The identification of (−)-cocaine is important in forensic science because it is a drug of abuse. Pharmacologically, it acts as an anaesthetic or as a central nervous system stimulant (4). X-ray powder diffraction methods can be used for identifying cocaine and its salts. Powder diffraction methods cannot differentiate between the (−) and (+) enantiomers of cocaine, but it can distinguish these from (±)-cocaine as a racemic mixture (5). Powder data for (−)-cocaine (6−8), (−)-cocaine hydrochloride (6, 7, 9), and (−)-cocaine sulfate (6) have been published in various works. Some discrepancies exist in the powder data for (−)-cocaine since some lines were not consistently reported and, further, some lines were not observed in powder patterns of (−)-cocaine as measured by us. Therefore, in addition to comparing the structure of the free base to that of its salts, we determined the crystal structure of (−)-cocaine in order to clarify the powder pattern data. The calculated powder pattern of (−)-cocaine hydrochloride (9), from the crystal structure determination of this salt by Gabe and Barnes (1), shows that two lines in the powder pattern reported previously by Barnes and Sheppard (6) in 1954 and Owen *et al.* (7) in 1972, could not be assigned reflections. Canfield *et al.* (10, 11) solved the crystal structure of diacetylmorphine (heroin) in order to explain differences in the observed powder pattern of this drug with previously published data (6).

All of the above noted discrepancies are relatively weak lines and are probably due to sample impurities. Folen (12) lists powder diffraction data for many of the excipients and impurities commonly encountered in drug samples. Barnes and Sheppard (6), in their extensive compilation of powder data on eighty-three narcotics, emphasized the need for single crystal data.

[a]Thermal parameters are of the form:

$$\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* + 2U_{13}hla^*c^* + 2U_{23}klb^*c^*)]$$

where

$$U(\text{equiv.}) = \frac{1}{3}\sum_{\substack{i=1\\j=1}}^{3}[U_{ij}a_i^*a_j^*(\mathbf{a}_i\cdot\mathbf{a}_j)]$$

Experimental

(−)-Cocaine was recrystallized by slow evaporation from absolute ethanol as clusters of large, transparent, colorless, birefringent plates, from which a crystal of dimensions 0.7 mm × 1.0 mm × 0.2 mm was used for crystal structure determination. Symmetry and systematic absences were determined from precession and Weisenberg photographs. Lattice parameters were refined by least-squares methods and intensities were measured on a modified Picker diffractometer using the NRCC diffractometer control system (13). Crystal data are:

(−)-Cocaine, $C_{17}H_{21}NO_4$ Mol. wt. 303.35

Monoclinic, space group $P2_1$, a = 10.120(1), b = 9.866(2), c = 8.445(1) Å, β = 106.92(1)°, T = 25°C, V = 807.48 Å^3, Z = 2, D_x = 1.25 g cm^{-3}, D_m = 1.25(1) cm^{-3}, $\mu(\text{MoK}_\alpha)$ = 0.0958 cm^{-1}.

A total of 2489 reflections with $\sin\theta/\lambda < 0.7048$ were measured using graphite monochromatized MoK_α radiation (λ = 0.71069 Å). Of these reflections, 1818 were considered as observed with $|F|/\sigma(|F|) > 3.0$.[4] Corrections for absorption were not made.

[4]The standard deviation of an individual reflection is calculated from the counting statistics associated with its measurement with an additional factor derived from the extent by which the scatter of the standard reflections exceeds that predicted from their own counting statistics.

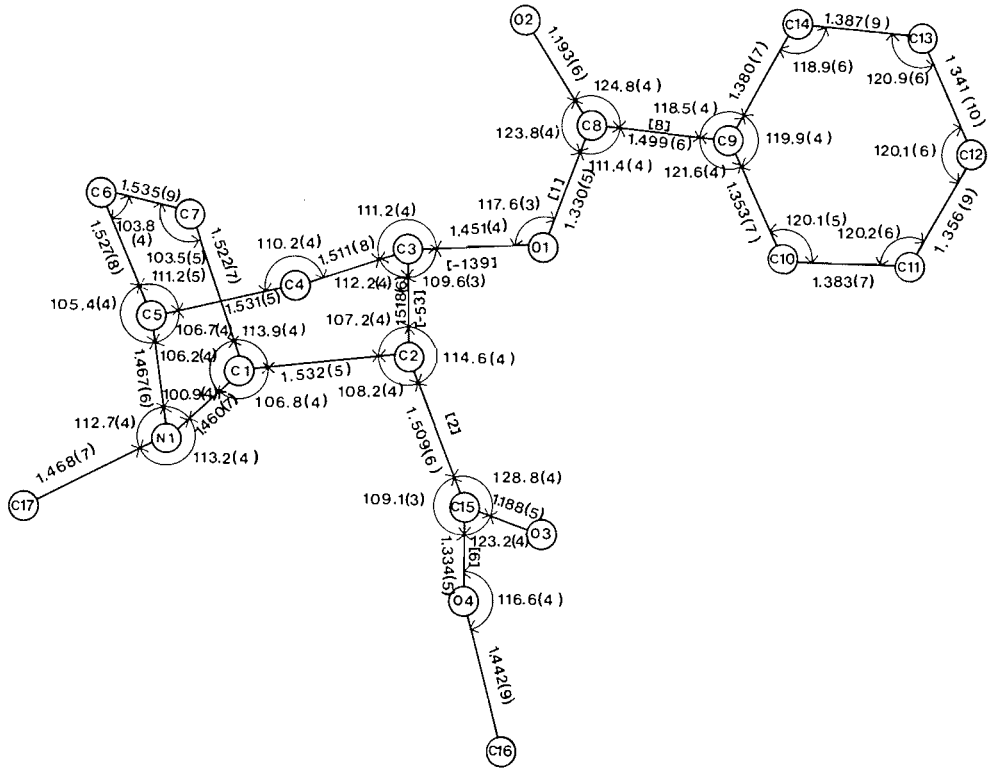

FIG. 1. Atom labelling, bond lengths, bond angles, and torsional angles for (−)-cocaine with estimated standard deviations. Numbers in square brackets are torsional angles.

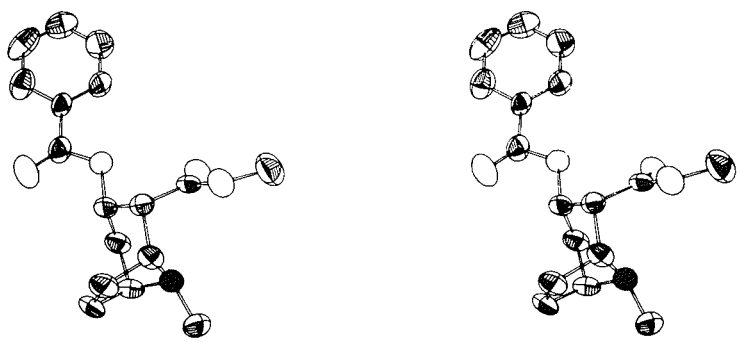

FIG. 2. Stereoscopic view of the molecule of (−)-cocaine. The nitrogen atom is black and the oxygen atoms are blank.

The crystal structure was solved by direct methods. The assignment of phases to normalized structure factors by MULTAN produced an *E*-map from which 12 of 22 nonhydrogen atoms were found. The remaining nonhydrogen atoms and some of the hydrogen atoms were located after the calculation of an electron density map. The atom positions and anisotropic temperature factors for all nonhydrogen atoms were refined by least squares. A difference map revealed all remaining hydrogen atoms. The parameters for the nonhydrogen atoms and atom positions with isotropic temperature factors for the hydrogen atoms were further refined by several cycles of least squares. It was necessary to divide these parameters into three blocks in order to accommodate the available core memory. The *x* coordinate of the nitrogen atom was held constant to fix the origin of the polar space group. This refinement converged to final agreement factors of:

$$R = \Sigma(|F_o| - |F_c|) / \Sigma|F_o| = 0.065$$

$$R_w = [\Sigma w(|F_o| - |F_c|)^2 / \Sigma w|F_o|^2]^{1/2} = 0.062 \qquad (w = 1/\sigma^2)$$

with a maximum shift/error of 0.260, and an average shift/error of 0.025 for all atoms.

All data treatment steps including structure factor calculations and preliminary least-squares refinement were carried out using the NRCC system (13). Final least-squares refinement of atom positions and temperature factors was carried out using the XRAY76 (14) system of crystallographic programs. Molecular projections were drawn using ORTEP (15).

Table 1 lists the atom positions and temperature factors for all atoms. Figure 1 shows the configuration of (−)-cocaine with atoms labelled. Bond distances and bond angles with standard deviations are indicated for nonhydrogen atoms.[5] A stereogram of the molecules is shown in Fig. 2.

Table 2 lists the calculated powder diffraction pattern, using XRAY76 (14), including the relative observed line intensities for each

[5]The structure factor table, a table of the complete atomic parameters with anisotropic thermal parameters, and a table of hydrogen atom structural parameters are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

reflection. A total of 107 reflections with I(cal) ≥ 1 are listed to a maximum 2θ of 30° (MoK$_\alpha$).

A single crystal of (−)-cocaine from the same sample as that used for structure determination was carefully ground to a powder. Its diffraction pattern was measured using a 114.6 mm Debye–Scherrer camera with CuK$_\alpha$ (λ = 1.5418 Å) radiation. This measured powder pattern is listed in Table 3. Line intensities from the film were visually estimated. Exposure times of up to two hours were used.

Discussion

Molecular structure

The configuration of (−)-cocaine as a free base is shown in Fig. 1 with atoms labelled and bond lengths, bond angles, and torsional angles indicated.

Like its salts, (−)-cocaine exists in a piperidine chair conformation. The angles between the planes of the ring are given in Table 4. The C(1)—N(1) and C(5)—N(1) bond lengths are 1.460(7) and 1.467(6) Å, respectively, and are shorter than those reported in the salts: 1.55(2) and 1.51(2) Å in the MeI salt, and 1.50(1) and 1.49(1) Å in the HCl salt. In the free base the C(17)—N(1) bond length is 1.468(7) Å. These shorter equivalent C—N bond lengths in the free base are comparable to the average C—N bond length of 1.475 Å expected for an unprotonated amino group (16).

The methoxycarbonyl substituent at C(2) is axial, the benzoxy substituent at C(3) is equatorial, and the methyl substituent at N(1) is also equatorial, in accordance with the known absolute configuration of (−)-cocaine (3). The orientations of these substituents relative to the bridged piperidine ring vary in the structures of the free base and its salts.

The major change in the position of the methoxycarbonyl group is shown by the C(1)—C(2)—C(15)—O(4) torsion angle. Shen *et al.* (2) observed an increase of 29° in the magnitude of this angle for the MeI salt (−46°) compared to the HCl salt (−17°) as reported by Gabe and Barnes (1). They attributed this increase to the presence of the C(18) methyl group on N(1), and its effect on the O(4)—C(1) intramolecular interaction. In the HCl salt, this O(4)—C(1) distance is only 2.63 Å compared to 2.84 Å in the MeI salt, due to the influence of the larger methyl substituent in the MeI salt. An increase in the C(1)—C(2)—C(15) bond angle was also observed: 115° in the MeI salt versus 109° in the HCl salt. In the free base, one might expect the C(1)—C(2)—C(15)—O(4) torsion angle to be less than that of the salts in order to decrease the O(4)—C(1) distance. However, this torsion angle is in fact increased in magnitude by 15° from the MeI salt to −61°. This is due to a reduction in the C(1)—C(2)—C(15) bond angle to 108.2(4)° (compared to 115(1)° and 109(1)° in the MeI and HCl salts, respectively), and a reduction in the N(1)—C(1)—C(2) bond angle to 106.8(4)° (compared to 112(1)° and 113(1)° in the MeI

Plane 1 and 3	68°
Plane 1 and 4	69°
Plane 1 and 5	75°

and HCl salts, respectively). This orientation of the methoxycarbonyl group in the free base produces an O(4)—C(1) contact distance of 2.79(1) Å. Thus, even though the torsion angle in the free base is larger than in the MeI salt, the O(4)—C(1) contact distance is slightly shorter.

The major change in the position of the benzoxy group is shown by the C(2)—C(3)—O(1)—C(8) torsion angle. In the MeI and HCl salts this angle is approximately equivalent, with values of −77° and −73°, respectively. In the free base, this angle is increased to −139° through rotation about the C(3)—O(1) bond, to a position that approximately bisects the ethylene bridge on the piperidine ring (the angle between the plane of the benzene ring and the plane defined by C(1), C(2), C(4), and C(5) is 75°). This increase in torsion angle is probably due to the relative position of the methoxycarbonyl substituent at C(2), and interaction between O(1) and O(3) in these two groups, respectively. The O(3)—O(1) contact distance in the HCl salt is reported as 2.79 Å. In the free base, this is increased to 2.86 Å. Thus, in the free base, O(3) and O(1) are farther away from each other, reducing their interactions and allowing the benzoxy group to rotate to a more stable conformation. This is reflected by the bond angles about C(3) which are more equivalent in the free base than in either of the salts. The benzoxy group itself is not quite planar. The O(2)—C(8)—C(9)—C(14) torsion angle is the same in the free base and the MeI salt; i.e. +8°. This torsion angle is larger than the reported value for the HCl salt (+2°). No apparent reason for this difference is evident.

In the piperidine ring of (−)-cocaine, the ethylene bridge decreases the distance between C(2) and C(4), and C(1) and C(5) to 2.15 Å and 2.26 Å, respectively. These distances are less than those reported by Gabe and Barnes (1) (2.75 Å and 2.35 Å) because the C(1)—N(1) and C(5)—N(1) bond lengths in the free base are shorter. The piperidine ring atoms (C(1), C(2), C(4), and C(5)) are planar within 0.02°. In the free base, the C(7)—C(1)—N(1) and C(6)—C(5)—N(1) angles are larger, 106.2(4)° and 105.4(4)°, respectively, compared to 101(1)° and 102(1)° in the HCl salt and 102(1)° and 102 (1)° in the MeI salt. There is a concomitant reduction of the C(2)—C(1)—N(1) and C(4)—C(5)—N(1) bond angles in the free base.

Powder pattern

The calculated powder pattern for (−)-cocaine is listed in Table 2. A total of 107 lines with a relative $I(\text{cal}) \geq 1$ are included to a maximum 2θ of 30°. Powder patterns of (−)-cocaine, measured on the same sample used for the structure determination, and the powder patterns of (−)-cocaine, as reported in the literature, are listed in Table 3.

The calculated and measured powder patterns agree well with each other. All of the observed lines in the measured powder pattern are accounted for. The bulk of data from Barnes and Sheppard (6), and Owen *et al.* (7) also agree with the calculated powder pattern. However, each report several lines that cannot be accounted for. These lines are noted with a "+" in Table 3. Other lines reported by these authors and not observed by us, as shown in Table 3, could be accounted for from the calculated powder pattern in Table 2. These lines, however, were very weak and were not observed in the exposure times used by us. Barnes and Sheppard (6) report lines at *d* values of 7.71, 5.69, and 2.30 Å for which no reflections could be assigned. Owen *et al.* (7) report lines at *d* values of 12.8, 7.64, 6.44, 6.06, 5.60, 4.61, 3.98, and 2.30 Å for which no reflections could be assigned. No lines with these *d* values were observed in powder patterns obtained in this work, even when exposure times were lengthened. These additional lines must therefore be due to sample impurities and should not be attributed to (−)-cocaine. The data reported by Sullivan and O'Brien (8) do not agree with the other measured powder patterns, nor with the calculated patterns.

These unassigned *d* values reported above were compared to standard powder pattern data. Apart from the excipients and impurities often encountered in drugs as described by Folen (12), (−)-cocaine as a natural product occurs with other minor alkaloids of similar structure (17), such as *cis*- and *trans*-cinnamoylcocaine, methylecgonine, and benzoylecgonine. Other impurities, such as pseudococaine, can be introduced in the cocaine isolation process. However, no likely materials could be identified as the cause of these unassigned lines.

Carbon-13 chemical shifts as a probe for conformational and electronic effects in alkyl vinyl ethers

JOHN G. K. WEBB[1] AND DAVID K. YUNG
College of Pharmacy, Dalhousie University, Halifax, N.S., Canada B3H 3J5

Received August 11, 1982

JOHN G. K. WEBB and DAVID K. YUNG. Can. J. Chem. **61**, 488 (1983).

The principle of additivity of substituent chemical shifts (SCS) is applied to the carbon-13 chemical shifts of β carbons (δ_β) in a number of 1,1-disubstituted ethylenes and propenes, which includes some α-substituted alkyl vinyl ethers. An additivity relationship is observed for 34 compounds that indicates an independent polarization mechanism across the double bond for each geminal substituent. Positive deviations from additivity are observed for compounds bearing bulky substituents. The magnitude of deviations is taken as an indication of the severity of steric interactions among substituents.

Reductions in efficiency of transmission of substituent effects in ring substituted α-phenyl alkyl vinyl ethers, relative to *para*-substituted styrenes, are interpreted as the result of a variable dihedral angle between the ring and vinyl group. An explanation of the relationship between conformation and transmission of substituent effects is presented as an alternative to existing views. An angular dependence of π-polarization and resonance effects is consistent with the chemical shift data.

JOHN G. K. WEBB et DAVID K. YUNG. Can. J. Chem. **61**, 488 (1983).

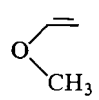
On applique le principe d'additivité des déplacements chimiques du substituant (DCS) aux déplacements chimiques du carbone-13 des carbones en β (δ_β) d'une série d'éthylènes et de propènes disubstitués en position 1,1, incluant quelques éthers alkyl-vinyles substitués en position α. On a observé une relation d'additivité pour 34 composés; ceci suggère l'existence d'un mécanisme indépendant de polarisation à travers la double liaison pour chaque substituant géminé. On a observé des déviations positives par rapport à l'additivité pour des composés ayant des substituants encombrants. On considère l'ordre de grandeur des déviations comme un indice de la sévérité des interactions stériques parmi les substituants.

On interprète les diminutions de l'efficacité de la transmission des effets de substituant, dans les cycles substitués d'α-phényl alkyl vinyl éthers par rapport aux styrènes substitués en position *para*, comme étant le résultat d'un angle dièdre variable entre le cycle et le groupe vinylique. On présente une explication de la relation entre la conformation et la transmission des effets de substituant, comme une alternative aux données existantes. Une dépendance angulaire de la polarisation π et des effets de résonance est en accord avec les données de déplacements chimiques.

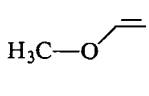
[Traduit par le journal]

Introduction

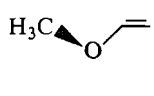
It has been established that the stable rotational isomer of methyl vinyl ether has a planar *s-cis* conformation (1–3). A minor component, originally thought to be the nonplanar *gauche* isomer, has been identified as having an *s-trans* conformation by infrared (4) and photoelectron spectroscopy (5). Molecular orbital studies at the *ab initio* level have confirmed these experimental findings (6–8).



s-cis



s-trans



gauche

For other alkyl vinyl ethers, the nature of the alkyl group and the degree of substitution around the olefinic bond will influence conformational preferences. Accordingly, transmission of electronic effects between substituents and double bond will be affected. In our opinion these factors have not received full consideration in discussions of carbon-13 chemical shift data, particularly for α-substituted alkyl vinyl ethers (9, 10).

There has been some controversy in the literature on the mechanism of transmission of electronic effects in α-phenyl alkyl vinyl ethers. Taskinen has offered the view that the smaller ρ values observed in correlations of β-carbon chemical shifts (δ_β) versus Hammett σ constants, compared to ρ values for styrenes, are due to methoxyl induced polarization of the double bond (10). He argues that the $p-\pi$ conjugation between oxygen and the double bond results in more single bond character for the olefinic bond and a diminished response for δ_β to substituents in the phenyl ring.

Huet *et al.* have developed a different interpretation (9). These authors state that the effect of a phenyl ring on δ_β can be divided into $\beta-\pi$ and $\beta-\sigma$ effects. The first effect is considered to be diamagnetic and the second paramagnetic. They suggest that when there is a deviation of the ring from coplanarity with the double bond there is a reduction in $\beta-\pi$, whereas $\beta-\sigma$ remains unchanged. Deviations from the principle of additivity of substituent chemical shifts (SCS) are used as a foundation for this interpretation.

Our own analysis has led to a conclusion that differs essentially from Taskinen's and suggests that Huet and co-workers have inappropriately used the principle of additivity to reach a conclusion that is similar in some respects to ours. We attempt to show by means of additivity of SCS and transmission of substituent effects that nonplanarity of ring and vinyl group does account for existing carbon-13 chemical shift results in α-phenyl vinyl and propenyl ethers.

Results and discussion

Application of the principle of additivity

In applying the principle of additivity in this work, vinyl and propenyl ethers have been considered as a subgroup within a broader series of geminally substituted ethylenes, $R^1R^2C{=}CH_2$, and propenes, $R^1R^2C{=}CH(Me)$. Additivity of SCS for β-carbons in these compounds can be detected using

[a] Chemical shifts are in ppm relative to TMS.
[b] Individual SCS values were obtained from chemical shifts for monosubstituted ethylenes as found in the literature; see refs. 27, 29, 33, 22, and 21. For a discussion of values used for alkoxyl groups, see text.
[c] Deviations from the least-squares line for compounds not included in the correlation.

the following equation:

$$[1]\quad \delta_\beta = b(\Sigma\,\mathrm{SCS}) + \delta_0$$

The ΣSCS for disubstituted ethylenes is $(\beta(R^1) + \beta(R^2))$ and equals $(\beta(R^1) + \beta(R^2) + \alpha(\mathrm{Me}))$ for the trisubstituted compounds. The individual SCS values are derived from chemical shifts in monosubstituted ethylenes. For a perfect additivity relationship, application of eq. [1] will give a straight line of slope 1.0 and intercept equal to the chemical shift of ethylene (122.8 ppm). Chemical shifts and values for ΣSCS obtained from the literature are given in Table 1.

Some comment is required on the SCS for alkoxyl groups because of the sensitivity of these values to conformation. SCS for alkoxyl groups in vinyl ethers have negative values, which decrease in the order *s-cis* > *s-trans* ≫ *gauche*. A value of −38.0 ppm is obtained for the SCS of a methoxyl group in an *s-cis* conformation from the observed δ_β for methyl vinyl ether (85.15 ppm, this work; 85.13 (11)), and an estimated isomer

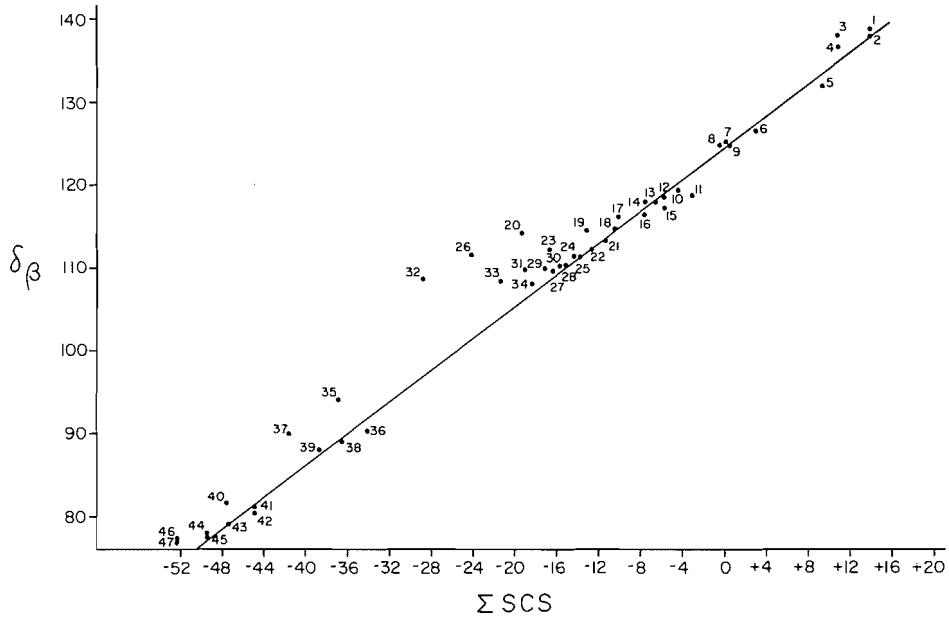

FIG. 1. Plot of δ_β vs. ΣSCS for compounds listed in Table 1.

composition of ~90% *s-cis*, with the remainder as *s-trans* (12). Estimates for the SCS of a methoxyl in an *s-trans* conformation come from two sources, δ_β in *tert*-butyl vinyl ether (SCS = −32.3 ppm) (11), and δ_β values in (*Z*)-alkyl propenyl ethers (SCS = −32.6, −32.6, and −32.4 ppm for OMe, OEt, and OiPr)[2] (13). The alkoxyl groups in these compounds are accepted as having predominantly an *s-trans* conformation (13, 14), and it has been shown by ir spectroscopy that the resonance interaction between alkoxyl and vinyl groups is independent of the size of the alkyl group (4). Both occurrences are reflected in nearly constant SCS values for these alkoxyl groups. The absence of a shielding γ-effect on δ_β for a methoxyl in an *s-trans* conformation accounts for the lower SCS value relative to a methoxyl group in an *s-cis* conformation (13–15). The chemical shift of the terminal olefinic carbon in 2-methylene-tetrahydropyran (16) provides an approximation for the SCS of a *gauche* methoxyl of −15.8 ppm. Although perhaps a rough estimate for a *gauche* methoxyl in an acyclic vinyl ether, this value does show the weak $p-\pi$ conjugation for a methoxyl group in a *gauche* conformation (16, 17).

In the α-substituted vinyl and propenyl ethers in Table 1, the α-substituent should ensure an almost complete preference for the *s-cis* conformation. Accordingly, the value of −38.0 ppm is used for β(OMe) for the methyl ethers. This same value is taken as an estimate for an *s-cis* ethoxyl, since the small difference in δ_β between methyl and ethyl vinyl ether (δ_β = 85.70 ppm (11)) likely arises from a slight increase in the *s-trans*/*s-cis* ratio for the ethyl compound, rather than from a significant difference in γ-effect between the two substituents; however, a δ-effect in ethyl vinyl ether might also contribute to the chemical shift difference.

A plot of δ_β versus ΣSCS is shown in Fig. 1. The overall trend is linear with some obvious exceptions, especially when one or both geminal substituents are large. Nonadditivity can be expressed in several ways in this type of plot. For example, a linear relationship with slope other than 1.0 but with intercept of 122.8 would suggest a constant relative enhancement or attenuation of the sensitivity of δ_β to the combined effect of the geminal substituents, depending on whether $b > 1$ or < 1. A linear relationship with slope equal to 1.0 but with intercept other than 122.8 would indicate additivity of SCS, but with each compound in the series experiencing the same constant deviation in δ_β. A combination of these two effects, as well as the observation of nonlinearity are also possible.

Our interpretation of Fig. 1 is that large positive deviations from linearity arise from steric interactions between substituents; therefore, compounds that show this effect are excluded from the calculation of regression coefficients for the least-squares line. The compounds are **2**, **19**, **20**, **23**, **26**, **31**, **32**, **33**, **35**, **37**, **40**, **46**, and **47**, and they have in common at least one bulky substituent and a deviation from the line in excess of 2 ppm. The parameters for the remaining 34 points are $b = 0.95 \pm 0.02$, $\delta_0 = 124.1$ ppm, $\bar{r} = 0.9982$. The uncertainty in the slope is expressed at the 95% confidence level (18). These values of slope and intercept indicate that additivity is nearly quantitative for this series of compounds.

The observation of additivity as shown in Fig. 1 has an important structural implication. If each substituent in the geminally disubstituted compounds exerts essentially the same effect on δ_β as in a monosubstituted ethylene, then the transmission of the effect of each substituent is independent of the presence of the other. This conclusion appears to be generally valid for combinations of geminal substituents which have different electronic properties, provided that certain steric requirements are met. For example, compounds **3**, **4**, **6–8** have a combination of electron-accepting substituents and a methyl group; compounds **10–16**, **25**, **27–30** have two alkyl groups; compounds **22**, **36–39**, **41–45** electron-donating and alkyl groups; **9** and **21** have two donors; and compound **5**, a donor and acceptor.

The effect of a substituent on δ_β in a monosubstituted ethylene is thought to arise from polarization of the double bond (19). This view is not surprising for substituents that are traditionally accepted as being π-electron donating or accepting,

[2] The chemical shift, δ_β, of *tert*-butyl propenyl ether reflects the presence of a small amount of *gauche* isomer (13).

TABLE 2. Correlations of δ_β's in α-substituted styrenes

Compound	No. of substituents, n	Slope, b	Uncertainty of slope,[a] $s_b(t)$	Correlation coefficient, $\bar{r}$	Ref.
23	10[b]	0.77	0.025	0.9992	24
26	9[b]	0.21	0.09	0.9070	24
40	6[c]	0.72	0.07	0.9973	10
35	5[d]	0.43	0.14	0.9790	10
48	5[d]	0.87	0.05	0.9993	10

[a] Product of the standard deviation of the slope, s_b, and the t distribution at the 95% confidence level for the n data points, see ref. 18.

[b] Substituents in the *para* position for **23** were: H, Me, *t*-Bu, F, Cl, OMe, NMe_2, NO_2, $SiMe_3$, and $SnMe_3$; for **26**, H, Me, *t*-Bu, F, Cl, Br, OMe, NMe_2, and NO_2.

[c] Substituents in the *para* position for **40** are: H, Me, OMe, F, Cl, and NO_2. A value of 82.06 ppm for δ_β was used for the *para* NO_2 derivative. An adjustment for solvent effect was added to the value given in ref. 9 for this compound.

[d] Substituents in the *para* position for **35** and **48** are: H, Me, OMe, F, and Cl.

TABLE 3. Comparison of deviations from additivity with twist angles of phenyl ring

Compound	Deviation from additivity[a] Δ	Twist angle, nmr method[b] θ	Twist angle, uv methods θ	Ref.

31	3.5	—	38	25
20	4.1[c]	—	43.5	25

[a] In ppm, as derived from Fig. 1.

[b] In degrees, as derived from slopes in Table 2; $\theta = \cos^{-1}(b^{1/2})$.

[c] One-half of the observed deviation, as each phenyl ring is considered to be twisted to the same extent; see ref. 25.

but is also confirmed for alkyl groups in a theoretical study by Libit and Hoffmann (20). It was shown that the methyl group in propene causes a net polarization of the vinyl group with the terminal carbon being more negative. Whereas there is no net transfer of electrons to the double bond, the polarization in this direction occurs through a redistribution of π-electrons. For substituents which are either donors or acceptors both charge transfer and polarization of π-electrons occur in the same direction to give more negative or positive terminal carbons, respectively. SCS values are consistent with this view, e.g., β(OMe) = −38.0 ppm, β(Ph) = −9.6 ppm, and β(Me) = −6.85 ppm. Further support is gained by linear correlations between δ_β's and π-electron densities in monosubstituted ethylenes (21) and substituted styrenes (22).

The significance of the theoretical studies, in relation to the observation of additivity for the compounds in this work, is that the π-electron redistribution brought about by charge transfer and (or) polarization mechanisms by each geminal substituent is additive as well. Thus, the presence of a strong donor like methoxyl should not so alter the character of the double bond as to inhibit an α-substituent from exercising its full polarization effect across the double bond. This is confirmed for compounds **36**, **38**, **39**, **41**–**45** where additivity is observed for δ_β. However, this conclusion does contradict Taskinen's explanation for diminished ρ values in correlations of δ_β versus σ for substituted **35** and **40** (10). He has assigned this reduction to less double bond character in the vinyl group because of $p-\pi$ conjugation between the methoxyl group and the double bond. In our opinion, the diminished ρ values and the deviation from additivity observed for **35** and **40** arise from a common source, i.e., a steric interaction wherein the phenyl ring is twisted out of the plane of the double bond.

Conformational dependence of the transmission of substituent effects

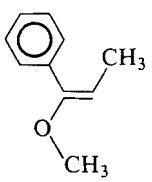
The magnitude of the deviations given for those compounds in Table 1 appears to be related to the size of the substituents, and reflects the severity of structural distortion caused by overcrowding around the double bond. Strain due to overcrowding can be released by three types of conformational change. Any or all three of the following could conceivably occur: widening of bond angles, rotation of bulky groups around single bonds adjacent to the double bond, and out-of-plane twisting deformation of the double bond. Ermer and Lifson (23) have shown that the first two mechanisms are more important except for very highly crowded olefins. Torsion around the double bond is not likely to be a factor for any of the compounds in Table 1.

Although no attempt has been made to assess the relative importance of either remaining strain-releasing mechanism, torsion around the phenyl ring – C_α bond likely provides a significant contribution to the deviations from additivity in **20**, **23**, **26**, **31**, **35**, and **40**. Additional insight into this con-

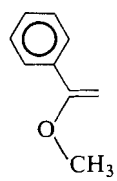
formational effect can be obtained by considering transmission of the effect of substituents in the phenyl ring on δ_β's. This can be accomplished with a linear free energy correlation and comparison of ρ-values with that of a suitable reference. Alternatively, an equivalent but more direct method is to plot δ_β values for a series of compounds versus corresponding values in the reference system, here, a series of *para*-substituted styrenes. The slope of this line is a measure of the efficiency of transmission of substituent effects and is equivalent to the ratio of ρ values obtained from δ_β vs. σ plots.

Regression coefficients are given in Table 2 for correlations of δ_β's for 1,1-disubstituted ethylenes and propenes, where one of the substituents is a substituted phenyl ring, with δ_β values of series of *para*-substituted styrenes. The slopes in Table 2 can be used to estimate the interplanar angle between phenyl and vinyl groups, if this rotation is an important factor in determining the efficiency of transmission of substituent effects. Hamer *et al.* have shown that in *para*-substituted styrenes both field (π-polarization) and resonance contributions to δ_β are primarily through-bond effects when the dihedral angle θ is $<90°$ and do vary as $\cos^2\theta$ (22, 24). Accordingly, the slopes listed in Table 2 can be taken as a measure of $\cos^2\theta$ since styrene and its *para* derivatives are considered to be planar (22, 25). Values of θ determined in this way are listed in Table 3, along with literature data for related systems and deviations from additivity, where appropriate. The values of θ for **23** and **26** are in excellent agreement with values obtained by Reynolds and co-workers (24) using uv spectroscopic methods, and provide support for the reliability of the method. It is also apparent from Table 3 that twist angles roughly parallel deviations from additivity.

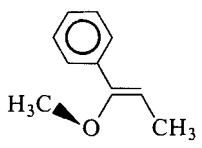
Consideration of twist angles for **35**, **40**, and **48** reveals some interesting conformational features for these molecules. That



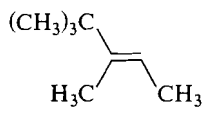
35



40



48



18

35 should undergo more geometrical distortion than **40** is not surprising since the *cis* methyl group in (*Z*)-1-phenylpropene causes a twist angle of ~35° for the phenyl ring (25). The extra strain introduced by an α-methoxyl group is presumably relieved by a further rotation of the phenyl ring to an angle of ~49°. It is perhaps surprising that there is apparently less strain in **48** than in **40** as indicated by a twist angle of ~21°. However, there is support for less strain with groups in this configuration from the observation of no deviation from additivity in Fig. 1 for **18**. We offer these torsional angles as an alternative explanation for the ρ values observed by Taskinen (10) for **35**, **40**, and **48**.

Unfortunately, the additivity principle cannot be applied to (*Z*)-α-substituted methyl propenyl ethers. Because the methoxyl group in these compounds is prevented from assuming an *s-cis* conformation, a mixture of molecules in *s-trans* and *gauche* conformation exists, with the proportion of *gauche* isomer increasing as the size of the α-substituent increases (17). Although it is likely that the methoxyl group in (*Z*)-α-*tert*-butyl methyl propenyl ether and in **48** adopts a predominantly *gauche* conformation (9, 10, 17), there is, to our knowledge, no reliable value available for the SCS of a *gauche* methoxyl in an uncrowded environment.

Our approach to additivity relationships differs from that of Huet *et al.* (9), who present an argument for a dihedral angular dependence of β−π, defined as a diamagnetic contribution to the observed β-effect of a phenyl group across a double bond, that is based on deviations from additivity for δ_β in **35**, **40**, **48**, and **49** (1-methoxy-1-phenyl-2-methylpropene). The main difficulty with their approach is that both **48** and **49** have a methoxyl group that is predominantly *gauche*, whereas the reference compounds from which the deviations were calculated ((*Z*)-1-methoxypropene and 1-methoxy-2-methylpropene) have methoxyl groups predominantly in the *s-trans* conformation (13, 14). The reported deviations of 17.0 and 14.8 ppm for **48** and **49** are therefore unrealistically large, because the effect of a *gauche* methoxyl on δ_β is considerably less than that of a methoxyl group in the *s-trans* conformation (16, 17). The conclusion, based on these values, that the conformation of the methoxyl group essentially determines the twist angle of the phenyl ring, and that a *gauche* methoxyl is more effective in this regard, is erroneous in our opinion.

There is also doubt concerning the interpretation of transmission of substituent effects in **40** and **49** given by Huet and coauthors. Although a reliable estimate of twist angle for **49** was not forthcoming from their data (9) because of uncertainty in the slope ($b = 0.89 \pm 0.30$, $n = 4$), we disagree with their conclusion that there is no resonance interaction between the ring and double bond, and that the large observed ρ values are due to a $\pi + \sigma$ inductive effect. We suggest that the response of δ_β in these compounds to substituents in the ring is similar to the response in α-alkyl-substituted styrenes (24). Verification of this, at least for *para*-substituted **40**, comes from a dual substituent parameter (DSP) correlation. The field (F) and resonance (R) parameters of Swain and Lupton (26) for the substituents given in Table 2 were used to find the following relationship.

$$[2]\quad \delta_\beta = 2.24\,F + 5.14\,R + 81.6,\ n = 6,\ \bar{r} = 0.9955$$

The correlation does show a sizeable resonance contribution, but with a coefficient less than the value of 7.14, which has been observed for the planar *para*-substituted styrenes (22). This observation leads to the conclusion that δ_β in substituted α-phenyl alkyl vinyl ethers reflects both π-polarization and resonance effects, and to a large extent, these effects vary as a function of dihedral angle.

Experimental

The carbon-13 nmr spectrum of methyl vinyl ether was obtained for a 20% solution in $CDCl_3$ on a Varian CFT-20 spectrometer with tetramethylsilane as internal reference.[3]

MURRAY H. BROOKER, S. SUNDER, PETER TAYLOR, and VINCENT J. LOPATA. Can. J. Chem. **61**, 494 (1983).

Four basic lead carbonates were prepared and identified by X-ray powder diffractometry. These were hydrocerussite ($Pb_3(OH)_2(CO_3)_2$), plumbonacrite ($Pb_{10}O(OH)_6(CO_3)_6$), and the two adducts $MOH \cdot 2PbCO_3$ (M = Na, K). New diffraction data are presented for the latter two compounds; they both have primitive hexagonal lattices with two formula units per unit cell. The unit cell dimensions of the sodium and potassium compounds are $a = 5.273 \pm 0.002$ Å, $c = 13.448 \pm 0.005$ Å and $a = 5.348 \pm 0.002$ Å, $c = 13.990 \pm 0.005$ Å, respectively. Six possible space groups are discussed.

Raman and infrared spectra are reported for all four compounds, and compared with those of cerussite ($PbCO_3$); assignment of the spectral features is discussed. Vibrational spectra of the two MOH adducts indicate that they are isostructural, and that the structure contains a well-defined lead sub-lattice, consistent with the X-ray data. The spectra of hydrocerussite and plumbonacrite indicate that lead is present as oxygen-bridged polymeric moieties in these solids. The carbonate ions occupy two and three independent sites in hydrocerussite and plumbonacrite, respectively.

MURRAY H. BROOKER, S. SUNDER, PETER TAYLOR et VINCENT J. LOPATA. Can. J. Chem. **61**, 494 (1983).

On a préparé quatre carbonates alcalins de plomb et on les a identifiés par la diffraction des rayons-X. Ce sont: l'hydrocérussite ($Pb_3(OH)_2(CO_3)_2$), le plumbonacrite ($Pb_{10}O(OH)_6(CO_3)_6$) et les deux adduits $MOH \cdot 2PbCO_3$ (M = Na, K). On présente des nouvelles données de diffraction pour les deux derniers composés; les deux ont des réseaux hexagonaux primitifs avec deux molécules par maille élémentaire. Les dimensions respectives de la maille pour les composés de sodium et de potassium sont: $a = 5{,}273 \pm 0{,}002$ Å, $c = 13{,}448 \pm 0{,}005$ Å et $a = 5{,}348 \pm 0{,}002$ Å, $c = 13{,}990 \pm 0{,}005$ Å. On discute des six groupes spaciaux possibles.

On rapporte les spectres infrarouges et Raman des quatre composés et on les compare avec ceux de la cérussite ($PbCO_3$); on discute de l'attribution des caractéristiques spectrales. Les spectres de vibration des deux adduits MOH indiquent qu'ils sont isostructuraux et que la structure contient un sous-réseau de plomb bien défini qui est en accord avec les données de rayons-X. Les spectres de l'hydrocérussite et du plumbonacrite indiquent que le plomb est présent dans ces solides sous la forme d'unités polymérisées ayant l'oxygène en position de pont. Les ions carbonates occupent respectivement deux et trois sites indépendants dans l'hydrocérussite et dans le plumbonacrite.

I. Introduction

We are investigating the efficacy of heavy-metal oxides for removing low concentrations of $^{14}CO_2$ formed in the heavy-water of CANDU[2] nuclear reactors (1). A review of the chemistry of different lead carbonates indicated that, while the structure and spectra of cerussite ($PbCO_3$) have been studied in detail, the information available about the other carbonates of lead is incomplete, or contradictory (2–18). Apparently, there have been no reports on the Raman spectra of any lead carbonate except cerussite (2, 11, 15). We report here the infrared and Raman spectra of hydrocerussite ($Pb_3(OH)_2(CO_3)_2$), plumbonacrite ($Pb_{10}O(OH)_6(CO_3)_6$), and two complex compounds of lead carbonate, probably $NaOH \cdot 2PbCO_3$ and $KOH \cdot 2PbCO_3$, here called Na – Phase I and K – Phase I, respectively. In addition, we report powder X-ray diffraction data for the latter two phases. Spectra of cerussite ($PbCO_3$) were also recorded for comparison.

II. Experimental

(a) Preparation of lead carbonates

Cerussite was prepared by passing CO_2 through a stirred suspension of PbO in 10^{-2} mol dm^{-3} acetic acid. Hydrocerussite was prepared by the reaction of cerussite with a KOH solution in which the pH was maintained at 11 with an automatic titrator. Plumbonacrite was made by refluxing hydrocerussite in a 0.1 mol dm^{-3} solution of K_2CO_3, with the pH adjusted to 13. These preparations are described in more detail elsewhere.[3]

(b) Preparation and chemical characterization of "Na-Phase I" and "K-Phase I"

We first observed Na-Phase I as a product of reactions between cerussite or hydrocerussite with 0.1 mol dm^{-3} Na_2CO_3 solutions, around pH = 11. It was conveniently prepared as a pure phase in gram quantities by shaking a suspension of cerussite or hydrocerussite (~1 g) in Na_2CO_3 solution (0.1 mol dm^{-3}, 50–100 cm^3) in a screw-topped plastic bottle for 1–2 days at room temperature. The purity of the solid product, isolated by filtration, was readily established by X-ray diffractometry (see Table 1). The potassium analogue, K-Phase I, was not formed in analogous reactions with K_2CO_3 replacing Na_2CO_3. However, we did observe it in reactions between the various lead carbonates and more concentrated solutions of K_2CO_3, indicating that K-Phase I is somewhat more soluble than Na-Phase I. It was conveniently prepared by refluxing cerussite or hydrocerussite at ≃100°C in K_2CO_3 solution (5 mol dm^{-3}, 100 cm^3) for 1–2 days, then isolating the solid product by filtration. Care is needed in washing, to remove excess K_2CO_3 without inducing partial decomposition of the product.

[a]Hexagonal, a = 5.2727 Å, c = 13.447 Å.
[b]Hexagonal, a = 5.3473 Å, c = 13.990 Å.
[c]Relative diffractometer peak heights; estimated error ±2 for $I/I_0 \leq 20$; ±5 for $I/I_0 > 20$, except for basal planes, 00*l*(†), which showed slight preferred orientation.
[d]The list for M = K does not strictly follow descending order of d, to facilitate comparison between the phases.

These two solids were analyzed for K, Na, and Pb by atomic absorption spectrophotometry (AAS) of material dissolved in dilute nitric acid, and for volatile components by thermogravimetry. The alkali data are in good agreement with the formulation $MOH \cdot 2PbCO_3$ (calcd. Na 4.0, K 6.6; obsd. Na 4.7, K 6.5). The lead analyses were relatively imprecise, due to the limitations of AAS, but the estimate of ≃70 wt.% is consistent with calculations (Na phase 72.1, K phase 70.2). Thermogravimetric measurements at a heating rate of 10°C min^{-1} showed a weight loss, after initial moisture loss, in good agreement with the calculated ($H_2O + CO_2$) contents (Na phase calcd. 13.1, obsd. 13.0, 13.0; K phase calcd. 12.7, obsd. 11.9, 12.2). In a nitrogen atmosphere the weight loss occurred in a single step at 260–370°C for each salt. In a carbon dioxide atmosphere the weight loss occurred in at least two stages, over the temperature ranges 330–510°C (Na salt) and 330–570°C (K salt). No further weight losses were observed to 600°C, the maximum temperatures of the runs. On the basis of these analytical measurements, and the similarity between our infrared spectrum for Na-Phase I and that previously reported (12) for "$3PbCO_3 \cdot Pb(OH)_2 \cdot Na_2CO_3$" ($NaOH \cdot 2PbCO_3$), we tentatively assign the formulation $MOH \cdot 2PbCO_3$ to these phases.

(c) X-ray powder diffraction (XRD) data

X-ray diffractograms were obtained from lightly packed powder samples, using a Philips PW-1150 powder diffractometer, CuK_α radiation and a diffracted-beam monochromator. Diffractograms were recorded on a strip-chart recorder for $10° \leq 2\theta \leq 140°$. Peak positions in the range $10° \leq 2\theta \leq 70°$ were determined by recording half-second integrated counts at a 2θ scan rate of 1 deg min^{-1}.

(d) Vibrational spectra

Infrared spectra were recorded on two different spectrophotometers, Perkin-Elmer models PE457 and PE225. Agreement between the two sets of spectra was excellent. Polycrystalline samples were dispersed in KBr pellets and no evidence of ion exchange was apparent. Spectra were recorded as percentage transmission between 200 and 4000 cm^{-1}.

Raman spectra were recorded using a Coderg PHO Raman spectrometer, as previously described (19). Spectra were excited using the 488.0 or 568.2 nm lines of a Control 52b Ar/Kr laser. Plasma lines from the laser were removed by narrow band-pass interference filters. Radiation power at the sample was about 200 mW at 488.0 nm, and

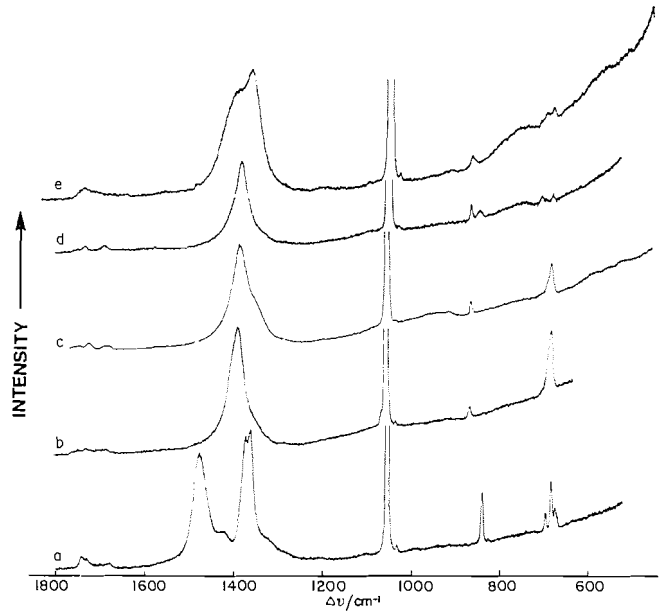

FIG. 2. Raman spectra of (*a*) cerussite, (*b*) Na-Phase I, (*c*) K-Phase I, (*d*) plumbonacrite, and (*e*) hydrocerussite as polycrystalline solids for the regions 600–1800 cm^{-1}. Spectral band pass ~2 cm^{-1}, excitation = 488.0 nm.

100 mW at 568.2 nm. Excess laser power from the blue line caused the sample to take on a yellow colouration with a concomitant loss of signal. The frequency scale was calibrated using plasma lines emitted by the laser. A 90° scattering geometry was used for recording the Raman spectra. Spectra were recorded between 20 and 4000 cm^{-1}. At a later stage of this work, a SPEX 1403 Raman spectrometer became available and all the Raman spectra were recorded again, using the new spectrometer. Agreement between the spectra obtained from the two spectrometers was excellent. Samples were polycrystalline powders, contained in Pyrex capillary tubes.

III. Results and discussion

(a) X-ray diffraction

Diffraction data for cerussite, and peak positions for hydrocerussite and plumbonacrite, were in good agreement with literature reports (9, 14, 20). As previously noted by Olby (9), preferred orientation caused some variation in the relative intensities observed for the latter two phases, especially plumbonacrite. As stated earlier, a full structure determination has only been reported for cerussite (14). Information about hydrocerussite and plumbonacrite is limited to two partial structure analyses based on electron diffraction data (21, 22). These reports predated Olby's resolution of the distinction between hydrocerussite and plumbonacrite (9). Phases described in these papers as hydrocerussite and "$PbCO_3 \cdot PbO \cdot 2H_2O$" appear now to be plumbonacrite and hydrocerussite, respectively (9).

The diffraction pattern for Na-Phase I bears little resemblance to that tabulated for "$3PbCO_3 \cdot Pb(OH)_2 \cdot Na_2CO_3$" ($NaOH \cdot 2PbCO_3$) by Bulakhova *et al.* (12), but the infrared spectrum that we obtained (Fig. 1) is very similar to that which they presented. We note that their XRD data for cerussite and hydrocerussite are also at variance with other reported data (9, 20), and with our work. Their XRD tabulation thus appears to be in error.

The diffraction patterns for Na-Phase I and K-Phase I were both indexed on the basis of primitive hexagonal unit cells, with $a = 5.273 \pm 0.002$ Å, $c = 13.448 \pm 0.005$ Å and $a = 5.348 \pm 0.002$ Å, $c = 13.990 \pm 0.005$ Å, respectively. Observed and calculated *d*-spacings of all features with $2\theta < 70°$ (CuK_α radiation) are listed in Table 1. Discrepancies between observed and calculated 2θ values were all less than 0.03°. Inspection of diffraction patterns up to $2\theta = 140°$ did not reveal any features that could not be indexed. Assuming the formula $MOH \cdot 2PbCO_3$ and $Z = 2$, calculated specific grav-

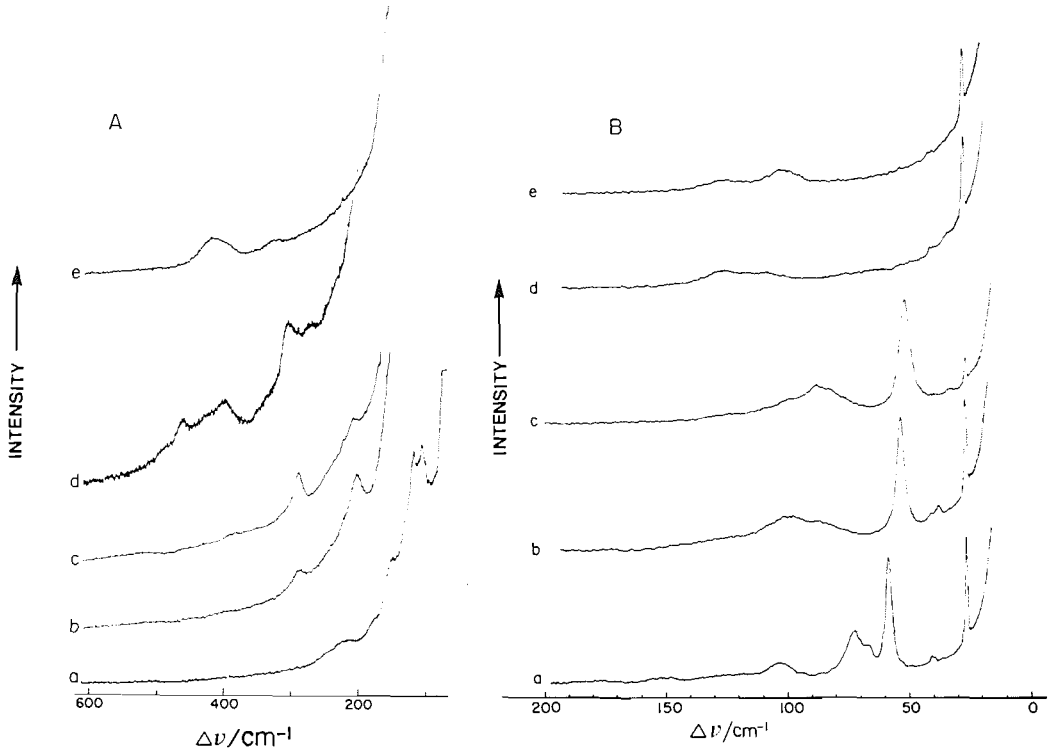

FIG. 3. Raman spectra of (*a*) cerussite, (*b*) Na-Phase I, (*c*) K-Phase I, (*d*) plumbonacrite, and (*e*) hydrocerussite as polycrystalline solids. Spectral band pass ~2 cm^{-1}. Figure 3A is for the 600−200 cm^{-1} region using 488.0 nm excitation and Fig. 3B is for the 200−20 cm^{-1} region using 568.2 nm excitation. Peaks at ~26, 38, and 41 cm^{-1} are due to plasma lines.

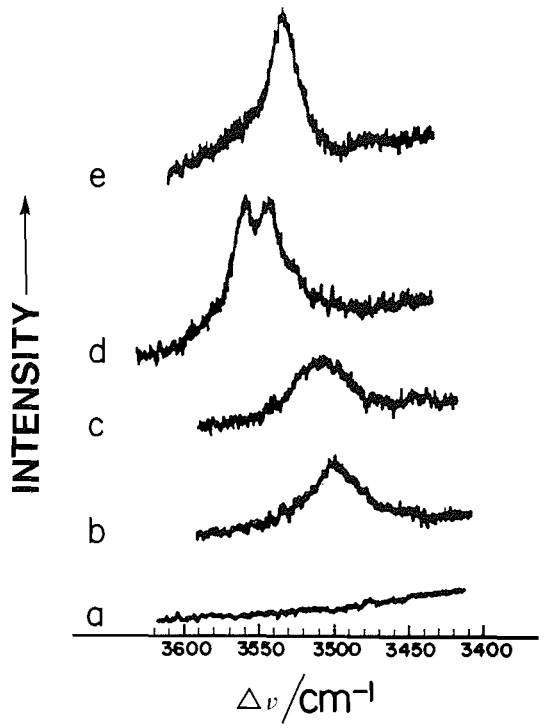

FIG. 4. Raman spectra of (*a*) cerussite, (*b*) Na-Phase I, (*c*) K-Phase I, (*d*) plumbonacrite, and (*e*) hydrocerussite as polycrystalline solids for the OH stretching region, using 568.2 nm excitation and spectral band pass ~2 cm^{-1}.

ities of the sodium and potassium salts are 5.89 and 5.66. The somewhat lower density of the potassium salt is consistent with reported density measurements for most pairs of salts NaX/KX (23). The former number is somewhat higher than the experimental value of 5.50 reported by Bulakhova *et al.* (12). Comparison of crystallographic volumes with the sum of known crystallographic volumes of $2PbCO_3$ + MOH (Table 2) shows a volume reduction of about 3% associated with reaction [1] below.

[1] $2PbCO_3(s) + MOH(s) \rightarrow MOH \cdot 2PbCO_3(s)$

A similar observation was previously reported for the adduct $Na_3PO_4 \cdot NaOH$ (24).

The similar relative intensities of features in the two diffraction patterns confirm that these phases are isostructural. Inspection of the observed reflections listed in Table 1 shows that the unit cells are primitive hexagonal. The only apparent systematic absences involve reflections with $h - k = 3n$ and $l = 2n + 1$. Since the diffraction intensities are dominated by the contribution from lead atoms, possible lead atom positions can be deduced. The observed systematic absences are consistent with the lead atoms occupying special positions *c* and *d*, or *f*, in one of the space groups $P6_3/m(C_{6h}^2)$, $P6_322(D_6^6)$, $P\bar{6}2c(D_{3h}^4)$, or $P6_3/mmc(D_{6h}^6)$, or possibly two pairs of special positions of type "*b*" in space group $P6_3(C_6^6)$ or $P6_3mc(C_{6v}^4)$ (the notation follows ref. 25). The first of these three possible allocations of special positions would result in a hexagonal lead sub-lattice with a lead atom spacing of $a/\sqrt{3}$ within the hexagonal layers, and an inter-layer spacing of $c/2$. Spectroscopic evidence for such a sub-lattice is discussed below. More detailed discussion of structure is not possible without single-crystal diffraction data.

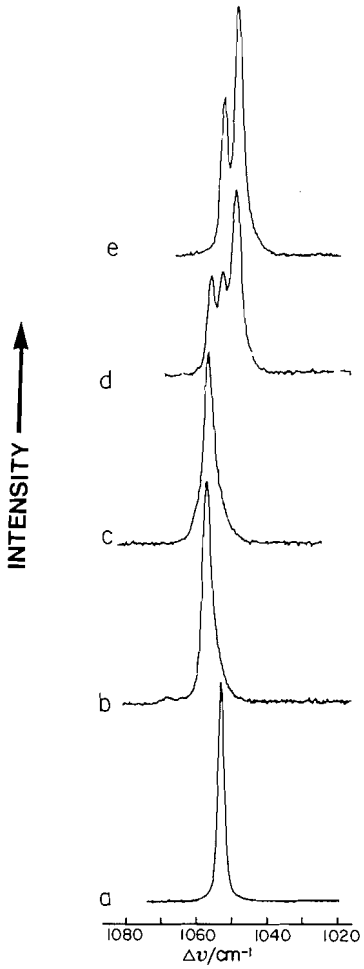

FIG. 5. High-resolution Raman spectra for (*a*) cerussite, (*b*) Na-Phase I, (*c*) K-Phase I, (*d*) plumbonacrite, and (*e*) hydrocerussite as polycrystalline solids for the ν_1 region, using 488.0 nm excitation and spectral band pass ~1 cm^{-1}.

(b) Vibrational spectra

Infrared spectra of cerussite, Na-Phase I, K-Phase I, plumbonacrite, and hydrocerussite are shown in Fig. 1. The Raman spectra are shown in Figs. 2 to 5. Figure 2 shows the Raman spectra for the region between 1800 and 600 cm^{-1} and encompasses all the fundamental internal vibrations of the carbonate ion (26, 27). Figure 3 shows the spectra below 600 cm^{-1}, down to 20 cm^{-1}, while Fig. 4 displays the spectra for the hydroxyl stretching region. Figure 5 shows the ν_1 mode band on an expanded frequency scale, recorded at higher resolution. As expected, this is by far the strongest band in the Raman spectra of the carbonates (2, 13, 15, 26–29). Frequency values for the spectral features shown in Figs. 1 to 5 are listed in Tables 3 to 5: Table 3 for cerussite, Table 4 for Na-Phase I and K-Phase I, and Table 5 for hydrocerussite and plumbonacrite. The frequency accuracy is estimated to be ±1 cm^{-1} for sharp features and ±0.2 cm^{-1} for peaks in the ν_1 region. These tables also contain qualitative relative intensities of the observed spectral features (the intensities are relative within the same compound). The Raman spectra shown in Figs. 2 to 5 were recorded under different vertical expansions for a clearer presentation and are uncorrected for the spectral response of the spectrometer.

The assignment of the bands arising from the fundamental internal vibrations of the carbonate ion is well established (2, 13, 15, 26–29) and does not require any further detailed discussion. Here we have followed Herzberg's nomenclature and numbering system (26) for the different carbonate vibrations. Although the assignment of the bands due to fundamental vibrations is straightforward, the same cannot be said for the other weaker features seen in the spectra of the carbonate minerals. White (15) has reviewed the six different assignments given in the literature for the weak feature seen about 15–20 cm^{-1} below the band assigned to the ν_2 fundamental in the infrared spectra of the carbonates. We agree with the suggestion of Sterzel *et al.* (30, 31) and Brooker and Bates (28) that this feature is due to the presence of the $^{13}CO_3^{2-}$ species in about 1% abundance in the carbonate minerals. Sterzel *et al.* have studied ^{13}C-enriched aragonite and their data support the assignment suggested in Tables 3 to 5 for this weak feature. We have collected the data for this feature in the five lead carbonates studied here in Table 6, and an average difference of about 18 cm^{-1} between the bands assigned to the ν_2 mode of $^{12}CO_3^{2-}$ and $^{13}CO_3^{2-}$ is consistent with the work of Sterzel *et al.* Similarly, there is a weak feature about 22 cm^{-1} below the strongest

[b]Pb–Pb sub-lattice vibrations.

band (ν_1) in the Raman spectra of the carbonates (see Table 6). We believe that this weak feature is due to the presence of $C^{18}O^{16}O_2^{2-}$ moieties in the carbonates. Support for this suggestion comes from ^{18}O isotopic substitution studies on nitrates (32–34). Nitrate and carbonate ions have similar planar structures with symmetry D_{3h}. The ν_1 mode in $N^{16}O_3^-$ occurs at 1049 cm^{-1} while the same mode in $N^{18}O^{16}O_2^-$ occurs at 1028 cm^{-1}. This difference of 21 cm^{-1} compares favourably with the data for the ν_1 mode of carbonates collected in Table 6 and is consistent with the relative intensity measurements.

The assignments of the PbOH deformation vibrations given in Tables 4 and 5 follow the suggestion of Bulakhova *et al.* (12) and Nakamoto (27), but are only tentative without data for isotopically substituted material. The assignment of PbO stretching vibration to bands seen between 300–500 cm^{-1} in Tables 4 and 5 is in general agreement with the literature (35–37). Obviously, this region of the spectra may also contain contributions from the "combination modes" and "overtones" involving lattice vibrations. The present data are insufficient to identify in detail the origin of the different bands seen in this spectral region. The possible presence of polynuclear hydroxolead(II) cations in the basic lead carbonate structures is discussed briefly below.

The only previous report on the lattice mode of any carbonate of lead is the classic study of Couture (2), who reported single-crystal Raman spectra for cerussite. Her data are included in Table 3 for comparison purposes. Our spectra indicate a few minor additional weaker features (see Table 3) observable with the laser excitation and better instrumentation now available. The detailed symmetry assignment of the lattice modes will be discussed elsewhere in a new single-crystal study of cerussite.[4] The assignment of the OH-stretching region requires no comments.

Assignments in the 1600–1800 cm^{-1} region do require a comment. Normally, for nitrates and carbonates one observes that $2\nu_2$ is strongly Raman active only, while $\nu_1 + \nu_4$ is observed only in the infrared region (19, 28). Our assignments reflect this generality even though the regions overlap for some compounds. The multiplet structure observed in ν_2 and $2\nu_2$ of cerussite has been shown to be due to correlation field effects similar to those reported for KNO_3 (19, 34). Oriented single-crystal studies of cerussite have shown that there are two infrared peaks at 838 and 871 cm^{-1}, due to the B_{1u} and B_{2u}

factor-group components,[4] respectively. The overtone region is complicated because the $k = 0$ selection rules are modified for overtones.

(c) Spectra-structure correlations

Cerussite has a structure analogous to aragonite and a factor-group analysis of the systems with aragonite structure (space group Pmcn, D_{2h}^{16} with four MCO_3 formula units per unit cell) has been discussed by many workers (2, 13, 15, 29). As the spectra of cerussite have been discussed earlier, we concern ourselves here mainly with the other four carbonates. The ν_1 mode is relatively weaker in the infrared spectra of the other four carbonates, particularly in Na-Phase I, K-Phase I, and plumbonacrite, compared with the spectra of cerussite (see Fig. 1). This suggests that the reduction in site symmetry of the carbonate ion is less in these compounds than in cerussite, as the ν_1 mode is infrared inactive for species with D_{3h} symmetry (27, 38). This conclusion is also supported by the Raman spectra of these compounds, the ν_2 mode being more intense in cerussite than in the other carbonates of lead (see Fig. 2). The spectra of Na-Phase I and K-Phase I are very similar, supporting the conclusion drawn from X-ray diffraction data that these salts are isostructural.

The ν_1 band in the Raman spectra showed no splitting for cerussite, although factor-group analysis predicts two bands (15). Similar behaviour is shown by aragonite (29). The ν_1 mode in Na-Phase I and K-Phase I shows only one apparent band in each Raman spectrum (see Fig. 5), but the bands are clearly asymmetric and broader than that of cerussite. This indicates the presence of at least two unresolved features, which suggests that in these compounds the carbonate ions are either on two nonequivalent sites, or the factor-group splitting is slightly greater than in cerussite. The ν_1 mode in the Raman spectra of hydrocerussite and plumbonacrite shows well-resolved bands (see Fig. 5). The results for cerussite, Na-Phase I, and K-Phase I, as well as aragonite (2, 15, 29), indicate that the factor-group splitting of the ν_1 mode in the carbonates is very small. The splitting seen in the ν_1 band of hydrocerussite and plumbonacrite must therefore be due to the presence of carbonate moieties on nonequivalent sites, or different "orbits" (39) in the unit cell. With the above assumption, one has to conclude that carbonate ions are present on at least three different sites in plumbonacrite and on at least two different sites in hydrocerussite. Furthermore, in hydrocerussite one type of carbonate site has twice the occupancy of the second type, as the two peaks in the ν_1 band of hydrocerussite have relative intensities in the raio of ~2:1. Because a unit cell of hydrocerussite contains six carbonate ions (9), there must be four of one type and two of the other. The presence of carbonates on more than one nonequivalent site in hydrocerussite and plumbonacrite is also suggested by the splittings seen for their ν_2 mode, both in their infrared and Raman spectra (see Figs. 1 and 2).

The very strong peak at 57.4 cm^{-1} in the Raman spectrum of cerussite can be assigned to a motion of the lead sub-lattice that forms a pseudohexagonal planar array. The high intensity of this band compared to that of the CO_3^{2-} rotatory band at about 100 cm^{-1} would be due to the high polarizability of Pb^{2+}. The presence of strong bands at 51.7 cm^{-1} and 50.0 cm^{-1} for Na-Phase I and K-Phase I, respectively, suggests that they also have a structure with a well-defined lead sub-lattice, similar to that of cerussite. This is consistent with the tentative conclusions drawn from the diffraction data, as discussed above.

The Raman spectrum of plumbonacrite shows two well-resolved peaks for the OH stretching band (see Fig. 4), which suggests that the OH species occupy two kinds of sites in this compound, if one assumes that the splitting is not due to factor-group splitting. Support for this assumption is provided by the absence of any splitting in the corresponding band of the other lead carbonates.

It is possible that hydrocerussite and plumbonacrite contain polymeric hydroxolead(II) cations. For example, $Pb_6O(OH)_6^{4+}$ is known to occur in the solid state as a perchlorate salt (40, 41), and probably also in aqueous solution (42). Features in the Pb—O stretching region of the Raman and infrared spectra of plumbonacrite resemble those reported for a solid later shown to contain the $Pb_6O(OH)_6^{4+}$ cation (35, 40, 43). It is possible, therefore, that plumbonacrite has the structural formula $[Pb_6O(OH)_6^{4+}][Pb^{2+}]_4[CO_3^{2-}]_6$.

Heats of vaporization of some monosubstituted cyclopropane, cyclobutane, and cyclopentane derivatives. Some observations on the enthalpies of isodesmic ring opening reactions of cyclobutane derivatives

RICHARD FUCHS and JOHN H. HALLMAN

Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.

Received June 11, 1982

RICHARD FUCHS and JOHN H. HALLMAN. Can. J. Chem. **61**, 503 (1983).

The following heats of vaporization at 25°C (ΔH_v^0) have been measured by vaporization calorimetry: cyclopropyl methyl ketone (39.41 ± 0.09 kJ mol^{-1}), methyl cyclopropanecarboxylate (41.27 ± 0.06 kJ mol^{-1}), cyclobutyl cyanide (44.34 ± 0.20 kJ mol^{-1}), methyl cyclobutanecarboxylate (44.72 ± 0.09 kJ mol^{-1}), ethylcyclobutane (31.24 ± 0.03 kJ mol^{-1}), and cyclopentyl cyanide (48.12 ± 0.09 kJ mol^{-1}). Values of ΔH_v^0 of the last four compounds have been combined with liquid state heats of formation to give new values of the gaseous state heats of formation (ΔH_f(g)).

When cyclobutyl cyanide, ethylcyclobutane, and cyclobutylamine are involved in hypothetical isodesmic reactions with ethane to give propane and isopropyl derivatives, the enthalpies of reaction are −102.1 ± 1.7 kJ mol^{-1} (−24.4 ± 0.4 kcal/mol), 8.3 kJ mol^{-1} (2.0 kcal/mol) less exothermic than the value for cyclobutane. Possible origins of this difference are discussed.

RICHARD FUCHS et JOHN H. HALLMAN. Can. J. Chem. **61**, 503 (1983).

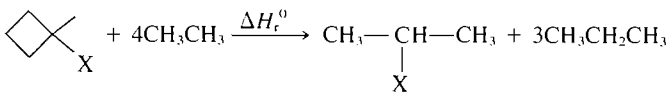
Faisant appel à la calorimétrie de vaporisation, on a mesuré les chaleurs de vaporisation des composés suivants à 25°C (ΔH_v^0); la méthylcyclopropylcétone (39,41 ± 0,09 kJ mol^{-1}), le cyclopropanecarboxylate de méthyle (41,27 ± 0,06 kJ mol^{-1}), le cyanure de cyclobutyle (44,34 ± 0,20 kJ mol^{-1}), le cyclobutanecarboxylate de méthyle (44,72 ± 0,09 kJ mol^{-1}), l'éthylcyclobutane (31,24 ± 0,03 kJ mol^{-1}) et le cyanure de cyclopentyle (48,12 ± 0,09 kJ mol^{-1}). On a combiné les valeurs de ΔH_v^0) des quatre derniers composés avec les chaleurs de formation de l'état liquide pour obtenir les nouvelles valeurs des chaleurs de formation de l'état gazeux (ΔH_f(g)).

Quand le cyanure de cyclobutyle, l'éthylcyclobutane et la cyclobutylamine sont impliqués dans des réactions isodesmiques hypothétiques avec l'éthane pour donner des dérivés du propane et de l'isopropyle, les enthalpies de réactions sont −102,1 ± 1,7 kJ mol^{-1} (−24,4 ± 0,4 kcal/mol), moins exothermiques que les valeurs pour le cyclobutane par 8,3 kJ mol^{-1} (2,0 kcal/mol). On discute des origines possibles de cette différence.

[Traduit par le journal]

The cyclopropane ring has long been described as having "double bond character". Various types of addition reactions, and evidence of conjugation with adjacent unsaturated groups have been observed or calculated (1−5). The cyclobutane ring is somewhat less distorted and strained, and undergoes relatively few ring-opening reactions, with considerable difficulty. Nevertheless, the four-membered ring does have properties characteristic of strained rings (6), and calculations at the STO-3G level (5) suggest that appreciable stabilization should result from the introduction of substituents such as cyano (19 kJ mol^{-1}) and methyl (6 kJ mol^{-1}). The calculations indicate somewhat smaller stabilization of cyclobutanes than the similarly substituted cyclopropanes.

Experimentally, stabilization can be assessed from enthalpies of isodesmic reactions of substituted vs. unsubstituted cyclobutanes, which are calculated from the gaseous state heats of formation (ΔH_f^0(g)) of the reactants and products (4, 5):



where X = H, CN, Et, and NH_2, and $\Delta H_r^0 = \sum \Delta H_f^0$(g) (products) − $\sum \Delta H_f^0$(g) (reactants). In this "group separation method" (5) each —CH_2— and —CHX— of the cyclobutane derivative is transferred to the simplest open-chain (and unstrained) compound having the same group. The reaction is exothermic due to relief of ring strain, and $-\Delta H_r^0$ is the strain energy. ΔH_r^0 should be the same where X = H and all other nonconjugating substituents, but ΔH_r should be less exothermic when a stabilizing interaction of X and the ring occurs. Stabilization or destabilization may be influenced not only by the ring-substituent bond character, but also by variation in antibonding character (strain) within the ring (5).

A few experimental thermochemical data on cyclobutane derivatives have been available (7−9) (Table 1). Based on these, the calculated values of ΔH_r^0 are: cyclobutane, −110.4 ± 1.5 kJ mol^{-1}; cyclobutyl cyanide, −96.1 ± 1.8 kJ mol^{-1}; ethylcyclobutane, −105.0 ± 1.7 kJ mol^{-1}; and cyclobutylamine, −102.5 ± 1.5 kJ mol^{-1}. ΔH_f^0(g) for methyl cyclobutanecarboxylate has been reported, but not for the isodesmic reaction product, methyl isobutyrate. Relative to cyclobutane, cyclobutyl cyanide appears to be stabilized by 14.3 kJ mol^{-1}, ethylcyclobutane, by 5.4 kJ mol^{-1}, and cyclobutylamine, by 7.9 kJ mol^{-1}, in acceptable agreement with calculated values (5).

We have reservations concerning these conclusions for two reasons. First, it has recently been demonstrated (4) that no appreciable thermochemical stabilization results from the introduction of cyano, methyl, and amino substituents onto the cyclopropyl ring, which is a more favorable system for ring-substituent interactions. We are also concerned with the sizable uncertainties in the heat of vaporization measurements on which ΔH_f^0(g) values depend (ΔH_f^0(g) = ΔH_f^0(l) + ΔH_v^0), particularly data from a source (8) containing several ΔH_v values in substantial disagreement with other measurements (4, 7).

It is the objective of the present study to provide ΔH_f^0(g)

data of improved accuracy, so that a critical assessment of cyclobutane-substituent thermochemical stabilization can be made.

Experimental

Ethylcyclobutane (99.92%) was an API Standard Reference Material, and was used as received. Methyl cyclobutanecarboxylate was synthesized by refluxing cyclobutanecarboxylic acid with an excess of methanol in the presence of sulfuric acid as catalyst. The ester was isolated, dried, and fractionally distilled. A purity of 99.9% was established by gas chromatography, using a Shimadzu Mini 2 gc with a glass-lined system, a 30 m × 0.25 mm id SE-30 silica capillary column, and a Hewlett-Packard 3390A integrator. Cyclobutyl cyanide was obtained from Columbia Organic Chemicals Co., and the other compounds were Fluka products. Each was fractionally distilled and examined by gc. The purities were: cyclopropyl methyl ketone, 99.96%; methyl cyclopropanecarboxylate, 99.87%; cyclobutyl cyanide, 99.95%; and cyclopentyl cyanide, 99.96%.

Heats of vaporization were determined at 25.0°C by evaporating 3−11 100 μL samples of each substance in a vaporization calorimeter (4) under reduced pressure (2−200 mm Hg (0.27−27 kPa) depending on the sample volatility), and with a nitrogen flow of 0.4−2.0 mL/min. The evaporations were complete in 13−23 min. Samples over 4A molecular sieve in Mininert bottles were transferred by syringe and introduced directly into the calorimeter. Details of the calorimeter design and operation, and comparison of the results with literature values have been reported previously (4). ΔH_v^0 of *n*-hexane was measured as a model for ethylcylobutane. The new value is 31.54 ± 0.18 kJ mol^{-1}; the previously reported value (7) is 31.55 ± 0.04 kJ mol^{-1}.

Results and discussion

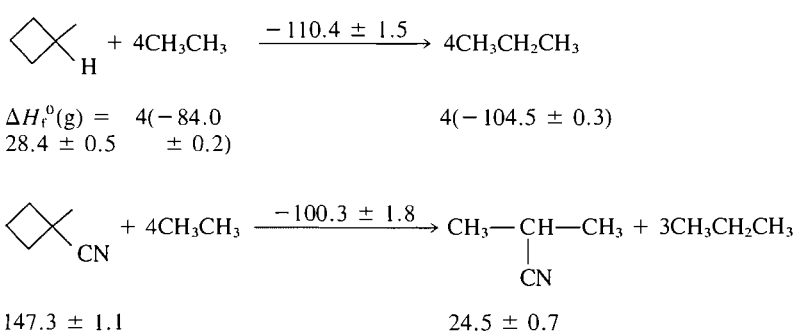
Heats of vaporization and gaseous state heats of formation

The standard heats of vaporization and gaseous state heats of formation at 25.0°C of cyclopropyl methyl ketone, methyl cyclopropanecarboxylate, cyclobutyl cyanide, methyl cyclobutanecarboxylate, ethylcyclobutane, and cyclopentyl cyanide are listed in Table 1. The indicated uncertainties are twice the standard deviations.

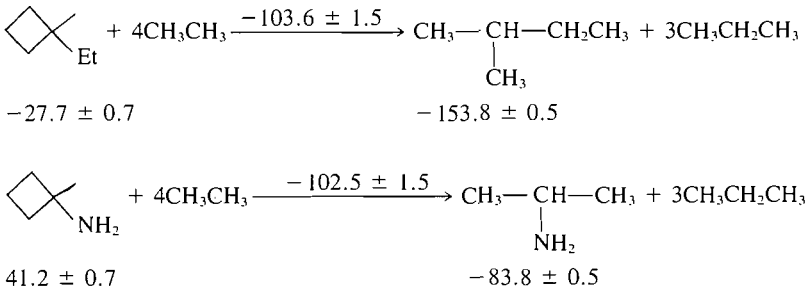
The first published values of ΔH_v^0 of cyclopropyl cyanide, cyclobutyl cyanide, cyclopentyl cyanide, and cyclohexyl cyanide (8) were 39.8 ± 0.4, 40.0 ± 0.4, 41.1 ± 0.4, and 43.6 ± 0.4 kJ mol^{-1}, respectively. The methylene increments in ΔH_v^0 are far smaller than are normally observed. The last two compounds were reexamined by Konicek (10), and higher values of 43.4 ± 0.2 kJ mol^{-1} and 51.9 ± 0.3 kJ mol^{-1} were obtained. This represents an extraordinarily large increment. Methylene increments in typical homologous series are usually 2.5−4 kJ mol^{-1} for the few lowest members of the series, increasing to ~5 kJ mol^{-1} in the higher members. We believe that the best values of ΔH_v^0 for the cyclic cyanides are 41.94 ± 0.11 (4), 44.34 ± 0.20, 48.12 ± 0.09, and 51.9 ± 0.3 kJ mol^{-1} (10).

Isodesmic reactions of cyclobutane derivatives

The following are isodesmic reactions of cyclobutane, cyclobutyl cyanide, ethylcyclobutane, and cyclobutylamine:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.



The mean value of ΔH_r^0 for the three substituted derivatives is -102.1 kJ mol^{-1}, and no individual value differs from the mean by more than the experimental uncertainty. There is, therefore, no basis for stating that these three substituents are exerting appreciably different effects. This is not to say that the —CN group, for example, has the same interactions with the cyclobutane ring as does the ethyl group, but rather that the overall thermochemical effect of various stabilizing and destabilizing interactions by the two substituents are the same. On the other hand, the substituted cyclobutanes appear to be rather uniformly stabilized by about 8.3 kJ mol^{-1} (2.0 kcal/mol) relative to cyclobutane. This is surprising, since recent data indicate no thermochemical stabilization of substituted cyclopropanes (4).

It is difficult to accept the idea that substituents stabilize cyclobutane, but not cyclopropane, particularly because the effects of three quite different substituents on cyclobutane are so uniform. One can imagine several possible explanations: (*A*) cyclobutane interacts with substituents more favorably (energetically) than does cyclopropane, for quite unrecognized reasons. (*B*) values of ΔH_f^0(g) for the substituted cyclopropanes are substantially incorrect, and are really less exothermic. These compounds would then be stabilized relative to cyclopropane. (*C*) ΔH_f^0(g) of cyclopropane is incorrect, and should be >10 kJ mol^{-1} more endothermic. The substituted cyclopropanes would be uniformly stabilized. (*D*) ΔH_f^0(g) of the substituted cyclobutanes are really all ~8 kJ mol^{-1} more endothermic than the values reported above, and none is stabilized. (*E*) the published value of ΔH_f^0(g) for cyclobutane is incorrect and should be 8.3 kJ mol^{-1} less endothermic. The substituted cyclobutanes (and cyclopropanes) would all be nonstabilized. Of these possibilities (*C*) and (*E*) seem most likely, each depending on only one incorrect value of ΔH_f^0(g). (*C*) requires that three diverse substituents have the same thermochemical effect on cyclopropane, and a uniform effect on cyclobutane. We feel that (*E*) is the most likely explanation, but it should be emphasized that we have no independent reasons to doubt the published value of ΔH_f^0(g) for cyclobutane (11–14).

The composition of the carbohydrates in the middle lamella and secondary wall of tracheids from black spruce wood

P. WHITING AND D. A. I. GORING

Pulp and Paper Research Institute of Canada and Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2A7

Received July 22, 1982

P. WHITING and D. A. I. GORING. Can. J. Chem. **61**, 506 (1983).

Carbohydrate analyses were performed on fractions of tissue from the middle lamella and secondary wall of black spruce tracheids. The concentrations of glucose and mannose were found to be smaller in the middle lamella than in the secondary wall while the concentrations of galactose, arabinose, and xylose were slightly larger in the middle lamella than in the secondary wall. The results obtained are compared with data available in the literature for other softwood species.

P. WHITING et D. A. I. GORING. Can. J. Chem. **61**, 506 (1983).

Nous avons effectué des analyses d'hydrates de carbone sur des fractions de tissu de la lamelle médiane et la paroi secondaire de trachéides d'épinette noire. On a trouvé que les concentrations de glucose et de mannose étaient plus faibles dans la lamelle médiane que dans la paroi secondaire tandis que les concentrations de galactose, d'arabinose et de xylose étaient légèrement plus fortes dans la lamelle médiane que dans la paroi secondaire. Les résultats obtenus sont comparés aux données trouvées dans la littérature pour d'autres espèces de résineux.

Introduction

Little research has been published on the composition of the carbohydrates in the various morphological regions of the tracheids in coniferous woods. Most of the recent work in this area has dealt with the primary walls (1) and cambial tissue (2, 3) of hardwoods.

In 1961, Meier (4) measured the carbohydrate composition in the cell wall of conifer tracheids by analysis of fractions obtained through microdissection. Fibres of different degrees of maturation were microscopically distinguished and isolated. Meier found that the relative amounts of glucose and mannose were lower in the hydrolysates from the compound middle lamella than in those from the secondary wall. Galactose and arabinose showed the reverse trend. Burke *et al.* (5) measured the sugar content of the polysaccharides in the primary walls of suspension-cultured Douglas fir cells and found very little mannose and relatively high concentrations of galactose and arabinose. More recently, Hardell and Westermark (6) have developed a method for peeling layers of the cell wall from single fibres. Samples as small as 20 ng were analyzed for their carbohydrate contents. Only small differences in the relative amounts of monosaccharides were found in the various cell layers of spruce tracheids. Most notably, the authors did not find a large reduction in the relative amounts of glucose and mannose in the compound middle lamella, as was noted by Meier (4).

Recent work in our laboratory has made possible the separation of centigram quantities of tissue from the middle lamella and secondary wall of black spruce tracheids (7). In the present paper, the analyses of the carbohydrate portions of these tissue fractions are described. Results are compared with those of previous workers.

Experimental

Five samples of black spruce (*Picea mariana* (Mill.) B.S.P.) tissue of varying lignin contents were isolated according to the method of Whiting *et al.* (7). The lignin contents were measured using the acetyl bromide method described previously (7). The secondary wall tissue sample contained 22% lignin and the whole wood sample contained 27% lignin. Three samples of middle lamella tissue were prepared, ML-1, ML-2, and ML-3, with lignin contents of 39%, 50%, and 60%, respectively.

TABLE 1. Lignin and monosaccharide contents of tissue fractions expressed as grams component per gram of tissue

Component	SW*	WW†	ML-1‡	ML-2‡	ML-3‡
Lignin	0.22	0.27	0.39	0.50	0.60
Glucose	0.55	0.47	0.36	0.23	0.14
Mannose	0.15	0.16	0.10	0.09	0.05
Xylose	0.07	0.07	0.07	0.08	0.07
Galactose	0.03	0.04	0.04	0.06	0.07
Arabinose	0.02	0.02	0.04	0.05	0.05

*SW: secondary wall tissue.
†WW: whole wood flour.
‡ML: middle lamella tissue.

The polysaccharides in the tissue samples were hydrolyzed by means of a modified version of the method of Fengel and Wegener (8). Five milligrams of dry tissue were weighed accurately into a 12 × 100 mm test tube and 1.6 mL of trifluoroacetic acid was added to each sample. The tube was covered with Parafilm and allowed to stand for 48 h at room temperature. The Parafilm was removed and 0.4 mL of H_2O was added. The contents were then frozen using dry ice and acetone, and the tube was sealed under vacuum. The sealed tubes were brought to room temperature and then heated in a 100°C oven for 2 h. After cooling, the tubes were opened and dried over NaOH in a vacuum desiccator at room temperature. After drying, 1 mL of water was added and the evaporation and drying were repeated. A final cycle of water addition, evaporation, and drying was then performed on the sample. A known amount of myo-inositol was added as an internal standard.

The dried samples were dissolved in 0.8 mL of silylation-grade dimethylsulfoxide and derivatized to trimethylsilyl esters with 0.8 mL "Tri-Sil Concentrate" (Pierce Chemical Co.). The derivatized monosaccharides were separated by gas chromatography using a J & W 30 m fused silica capillary column (0.253 mm i.d.) coated with SE-30. The gas chromatograph was temperature-programmed as follows: 160°C to 220°C at 1.5°C per min; 220°C for 2 min.

The quantity of a particular monosaccharide in each tissue fraction was obtained by comparing the total area of the appropriate peaks in the chromatogram with the peak area of the internal standard.

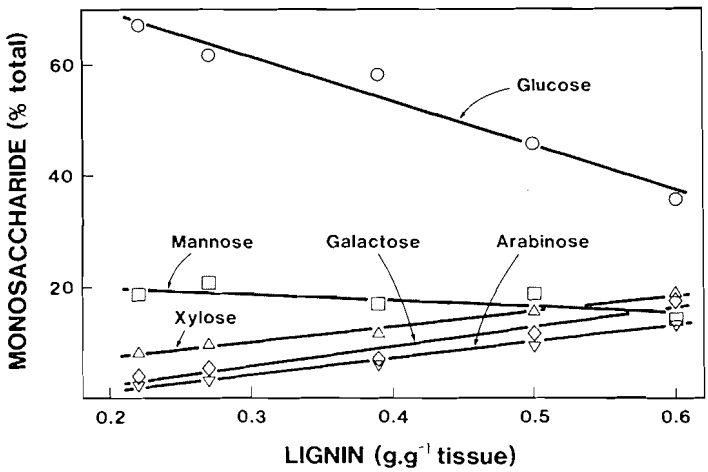

FIG. 1. Monosaccharide expressed as percent total monosaccharide vs. the lignin content for the various tissue fractions studied. The straight lines are least squares with an average correlation coefficient of 0.94.

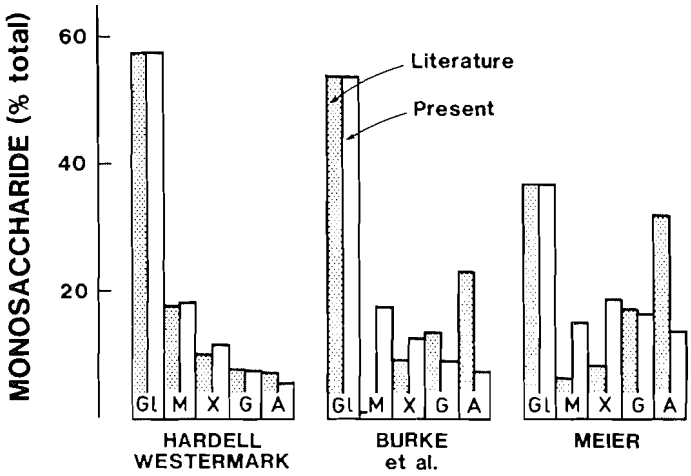

FIG. 2. Comparison of literature with present data for the distribution of monosaccharides. The present distributions were obtained from Fig. 1 by normalizing to a glucose content equal to that given in the literature. Gl, M, X, G, and A mean glucose, mannose, xylose, galactose, and arabinose respectively.

Each tissue fraction was analyzed at least three times, and the results expressed as grams of monosaccharide per gram of tissue. The reproducibility in measurement was about ±4%.

Results and discussion

The monosaccharide content of each of the tissue fractions is shown in Table 1. The monosaccharide contents, converted to percentage of the total monosaccharides, are plotted against lignin contents in Fig. 1. Note that the linear trends obtained do not represent the distribution of components across the cell wall. They arise because each tissue fraction is a mixture of secondary wall, primary wall, and middle lamella in varying proportions.

Figure 1 indicates that the contents of glucose and mannose are lower in the middle lamella than in the secondary wall, while the contents of xylose, galactose, and arabinose increase in the fractions rich in middle lamella tissue. These results are qualitatively in agreement with the trends reported by Meier (4) and Burke *et al.* (5).

We may now attempt a more quantitative comparison of the results of the present work with the data in the literature. Fractions as nearly representative of the compound middle lamella as possible were chosen. The literature data used are those of Hardell and Westermark for the M+P layer in white spruce (6), Burke *et al.* for suspension-cultured Douglas fir (5), and Meier for the M+P layer in white spruce (4). The percentage of total sugar in the hydrolysate as glucose was used to locate the tissue fraction on the line for glucose in Fig. 1. The percentage of the four other sugars corresponding to the glucose percentage was then read off. Thus we obtained the monosaccharide distribution as given by the present data corresponding to the glucose content of the plant tissues analyzed by the other workers. A comparison of these distributions with the distributions given by the other workers is shown in Fig. 2. Note that Burke *et al.*'s data for Douglas fir were recalculated on basis that the content of the five monosaccharides added together equals 100% (5).

The comparisons shown in Fig. 2 are revealing. The agreement with the data of Hardell and Westermark (6) is excellent. This is not the case with the data of Burke *et al.* (5) and Meier (4). Not only is the agreement bad but the errors are in the same directions for the two sets of comparisons, i.e., our results are high for mannose and xylose and low for galactose and arabinose in both cases. Similar trends were found when we compared our data with the results by Côté *et al.* (9) for the M+P layer in the normal wood of balsam fir.

In speculating on the origins of these discrepancies, perhaps we should note the physiological similarity of the preparations of Burke *et al.* (5), Meier (4), and Côté *et al.* (9). Meier obtained his M+P fraction by separation of the layers of cells nearest to the cambial layer (4, 10). So did Côté *et al.* (9). Burke *et al.* studied tissue-cultured primary walls (5). In all these cases a "nascent" primary wall material was used. In contrast, Hardell and Westermark fractionated single tracheids teased from lignified wood (6). In the present work, the fractions obtained were also from lignified wood (7).

Does the carbohydrate composition of the compound middle lamella change as the secondary wall grows and the cell lignifies and dies? Hardell and Westermark have posed a similar question (6). The comparisons shown in Fig. 2 suggest that it does. However, this suggestion is made with caution because of the different origins of the tissue fractions used and also because of possible differences in the species compared.

Synthetic approaches to haplophytine. 1. Synthesis of 1-methoxy- and 1-hydroxy-6-phenyl-6-(2-pivaloylamidophenyl)non-8-ene-4,5-dione and 1-methyl-3-phenyl-3-(2-pivaloylamidophenyl)-2-pyrrolidinone

PETER YATES AND DAVID AARON SCHWARTZ

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received August 24, 1982

PETER YATES and DAVID AARON SCHWARTZ. Can. J. Chem. **61**, 509 (1983).

An analysis of the structures of the alkaloid haplophytine and its dihydrobromide which is formed with rearrangement, shows that they are both derived from a 7-(2-amino-3-hydroxyphenyl)-7-aryl-9-(methylamino)-5,6-dioxononanoic acid moiety (**3**). Approaches to the synthesis of compounds related to **3** are described. The dianion **13** of phenyl(2-pivaloylamidophenyl)methane, that of methyl 2-phenyl-2-(2-pivaloylamidophenyl)acetate, and the trianion **37** of 2-phenyl-2-(2-pivaloylamidophenyl)acetic acid undergo C-alkylation and C-acylation with nucleophiles. Acylation of **13** with methyl 2,2,5-trimethoxypentanoate followed by hydrolysis gives 6-methoxy-1-phenyl-1-(2-pivaloylamidophenyl)-2,3-hexanedione. This with allyl bromide and sodium carbonate gives the O-allyl derivative, which on thermolysis is converted to its C-allyl isomer, 1-methoxy-6-phenyl-6-(2-pivaloylamidophenyl)non-8-ene-4,5-dione. The corresponding 1-hydroxy compound was prepared analogously via acylation of **13** with methyl tetrahydro-2-methoxyfuran-2-carboxylate. C-allylation of the trianion **37** gives 2-phenyl-2-(2-pivaloylamidophenyl)pent-4-enoic acid, whose methyl ester on ozonolysis followed by treatment with methylamine hydrochloride and sodium cyanoborohydride gives 1-methyl-3-phenyl-3-(2-pivaloylamidophenyl)-2-pyrrolidinone, a potential advanced intermediate for the synthesis of compounds related to **3**.

PETER YATES et DAVID AARON SCHWARTZ. Can. J. Chem. **61**, 509 (1983).

Une analyse des structures de l'alcaloide haplophytine et de son dérivé provenant d'une addition de deux moles d'acide bromhydrique qui se fait avec une transposition révèle que les deux composés proviennent de la même unité, soit l'acide (amino-2 hydroxy-3 phényl)-7 aryl-7 (méthylamino)-9 dioxo-5,6 nonanoique (**3**). On décrit des voies d'accès à des composés reliés à l'acide **3**. Le dianion **13** du phényl(pivaloylamido-2 phényl)méthane, celui du phényl-2 (pivaloylamido-2 phényl)-2 acétate de méthyle et le trianion **37** de l'acide phényl-2 (pivaloylamido-2 phényl)-2 acétique subissent une C-alkylation et une C-acylation avec les nucléophiles. L'acylation du composé **13** avec le triméthoxy-2,2,5 pentanoate de méthyle, suivie d'une hydrolyse, donne la méthoxy-6 phényl-1 (pivaloylamido-2 phényl)-1 hexanedione-2,3. Cette dernière, en présence du bromure d'allyle et du carbonate de sodium, donne le dérivé O-allyle qui, par thermolyse, se transforme en son isomère C-allyle, la méthoxy-1 phényl-6 (pivaloylamido-2 phényl)-6 nonène-8 dione-4,5. D'une façon analogue, on a préparé le composé hydroxy-1 correspondant via l'acylation du composé **13** avec le méthoxy-2 tétrahydrofuranne carboxylate de méthyle. Une C-allylation du trianion **37** conduit à l'acide phényl-2 (pivaloylamido-2 phényl)-2 penthène-2 oique dont l'ester méthylique, par ozonolyse suivie de la réaction avec le chlorhydrate de la méthylamine et le cyanoborohydrure de sodium, donne la méthyl-1 phényl-3 (pivaloylamido-2 phényl)-3 pyrrolidinone-2, un intermédiaire potentiel avancé en vue de la synthèse des composés apparentés au composé **3**.

[Traduit par le journal]

The structure of the alkaloid haplophytine incorporates the moiety **1**, where Ar is the aromatic ring of a lactonic aspidosperma alkaloid residue (1). On formation of the dihydrobromide of haplophytine the moiety **1** is converted to the moiety **2**. On treatment of the salt under mildly basic conditions, haplophytine is regenerated, i.e., the rearrangement of **1** to **2** is reversed. This reversible rearrangement reflects the fact that **1** and **2** are both condensed versions of system **3**. In order to examine transformations of type **1** ⇌ **3** ⇌ **2** further and to lay the groundwork for the synthesis of haplophytine, we have undertaken synthetic studies directed towards **4** (or an equivalent), a closely related model of **3**.

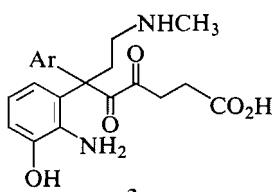
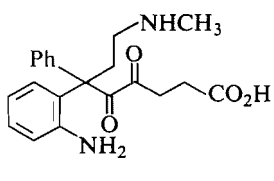
2

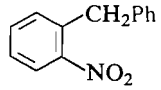


3

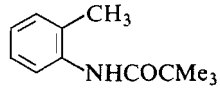


4

Our synthetic strategy (Scheme 1) entailed the use of an *o*-aminodiphenylmethane equivalent (**5**), which on substitution at the benzylic carbon with an α-oxoglutaryl equivalent would give an intermediate **6**, which on allylation at the benzylic carbon would give **7**. Oxidative cleavage of the double bond to the aldehyde followed by reductive methylamination or reductive amination and N-methylation would give **4**. Preliminary studies were conducted with *o*-nitrodiphenylmethane (**8**) as an equivalent of *o*-aminodiphenylmethane (**5**),[1] but substitution reactions at the benzylic carbon were found to occur only in low yield or not at all. We then turned our attention to the use



8



9

[1]Cf. the use of the anion of *o*-nitrotoluene as a nucleophile (2).

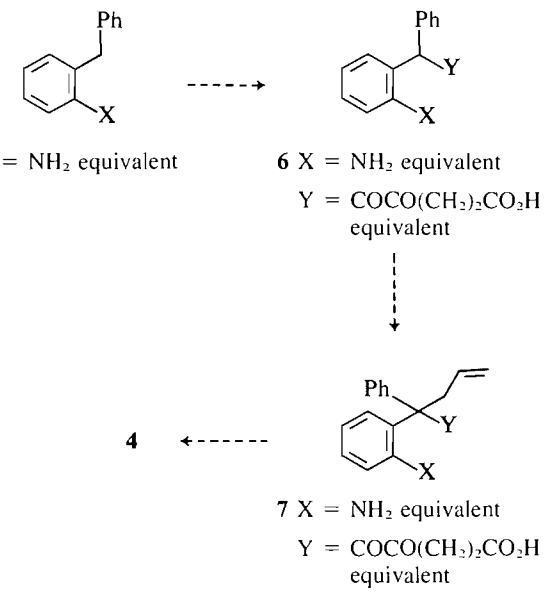

SCHEME 1

of a pivaloylamido group ($NHCOCMe_3$) as an NH_2 equivalent, based on the report of Fuhrer and Gschwend (3) that *N*-pivaloyl-*o*-toluidine (**9**) can be converted to a dianion that reacts with various electrophiles exclusively at the benzylic carbon; subsequent to this report, others have utilized pivalamides as protected amines (4). We report now on the synthesis of two compounds of type **7** by the route shown in Scheme 1 with the use of the pivalamido group as the NH_2 equivalent. It was not found possible to convert these to compounds of type **4**; attempts to surmount this hurdle are also described.

Reduction of *o*-aminobenzophenone (**10**) with sodium and ethanol (5) gave *o*-aminodiphenylmethane (**11**), which was converted to its pivaloylamide (**12**)[2] with pivaloyl chloride. Compound **12** was converted to its yellow-orange dianion **13** by treatment with two equivalents of *n*-butyllithium/TMEDA or of lithium diisopropylamide in tetrahydrofuran at −20°C. The formation of this dianion was verified by reaction with benzaldehyde to give in 98% yield a 1:1 mixture of the diastereomeric products **14** arising by exclusive attack at carbon (Scheme 2). These isomers had similar spectra, but the formation of a 1:1 mixture was apparent from the presence in the ^1H nmr spectrum of the product of two singlets of equal intensity at δ 1.05 and 1.10 ppm, assigned to the *tert*-butyl protons; they were separated and individually characterized, but individual structural assignments were not made.

We next sought to utilize the dianion **13** to introduce a latent α-oxoglutaryl residue at the benzylic carbon of **12**. The dithiane **15** was prepared from ethyl 1,3-dithiane-2-carboxylate and 3-bromo-1-methoxypropane by the general procedure of Eliel and Hartmann (6) and treated with the dianion **13**. However,

[2]The ^{13}C nmr chemical shifts for **12** and related *o*-pivaloylamidodiphenylmethyl derivatives are compared in Table 1.

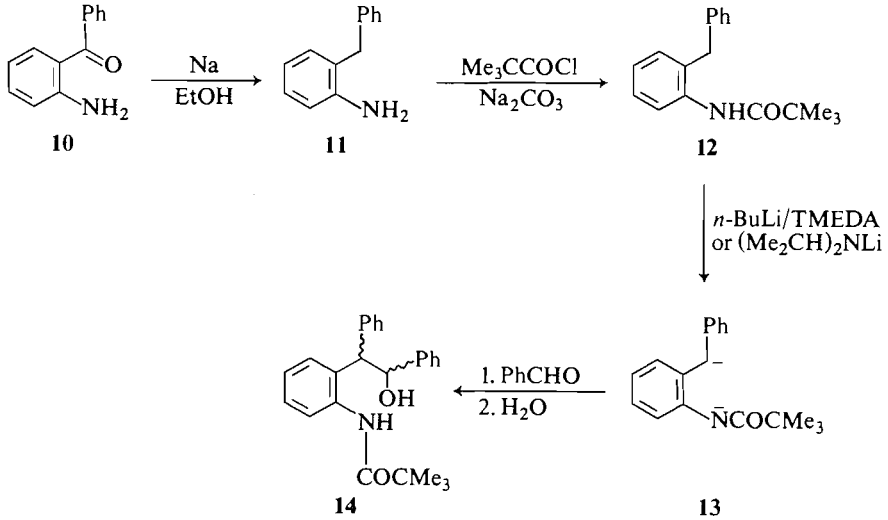
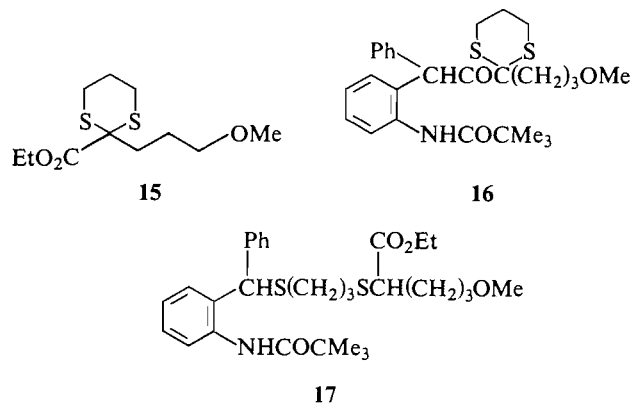
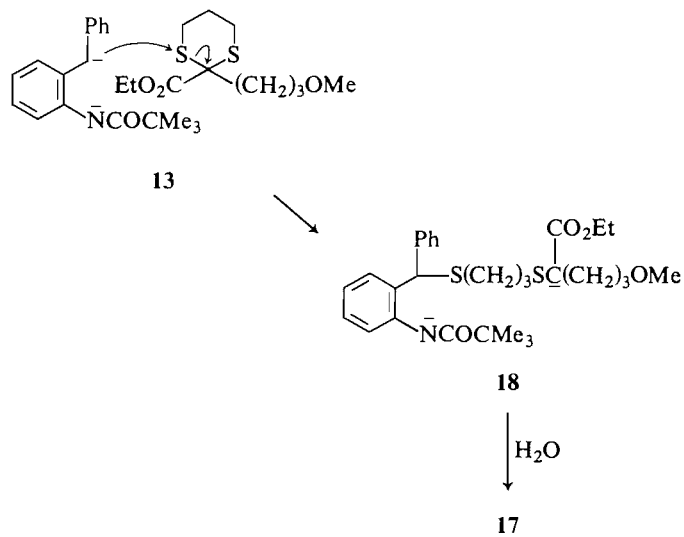


SCHEME 2

the desired acylation product **16** was not formed; instead a product was formed whose ^1H and ^{13}C nmr spectra showed it retained a carboethoxy group. This product is assigned structure **17** on the basis of the spectroscopic data (see Experimental) and is considered to arise by the route shown in Scheme 3. The unusual course of the reaction can be attributed to steric inhibition of attack by **13** on the carboethoxy group of **15** and facilitation of displacement at sulfur because of stabilization of the resulting anionic centre in **18** by that group.



In order to circumvent this problem we turned to the use of a different latent α-oxoglutaryl residue and prepared the ketal **19** by the route shown in Scheme 4, which is analogous in part to the route used by Öhler and Schmidt (7) for the preparation of the triethoxy analogue of **20**. It was considered that use of the ketal **19** rather than the thioketal **15** would be advantageous in that there would be less steric hindrance to attack at the ester group and less propensity for anionic displacement on oxygen than on sulfur. In fact, treatment of the dianion **13** with the ketal **19** gave a product in good yield that is considered to be the desired ketone **21**, based on its elemental composition and spectra. Two features of these spectra merit comment. First, in the ir spectrum the carbonyl-stretching band occurs at 5.78 μm, which is at shorter wavelength than normal for simple acylic ketones (5.84 μm); this shift is attributed to dipole–dipole interaction of the carbonyl and C—OMe bonds (cf. the carbonyl-stretching band of 3,3-dimethoxy-2-butanone: 5.78 μm (8)). Second, in both the ^1H and ^{13}C nmr spectra



SCHEME 3

of **21** the signals of the ketal methoxy groups are distinct, due to chemical nonequivalence engendered by the benzylic chiral centre.

It was next desired to introduce an allyl group at the benzylic carbon of **21**. However, attempts to do this via dianion formation followed by treatment with allyl bromide or chloride were fruitless. One contributing factor to this failure may be that severe steric interaction in the dianion inhibits its formation. We therefore hydrolyzed the ketal **21** to the yellow α-diketone **22** with 90% formic acid (9). It was anticipated that alkylation of **22** would be more readily achieved than that of **21** because of the greater acidity of the benzylic hydrogen atom, and indeed this proved to be the case. Treatment of **22** with allyl bromide and sodium carbonate in aqueous acetone gave a product whose ^1H and ^{13}C nmr spectra showed that the allyl group had been incorporated. However, these spectra and the ir spectrum of the product showed that O-allylation rather than C-allylation had occurred and that it was a 3:1 mixture of the geometrical isomers **23** rather than the desired product **24**. It was nevertheless possible to obtain the latter by heating the O-allyl isomer mixture **23** at 90°C in toluene when Claisen

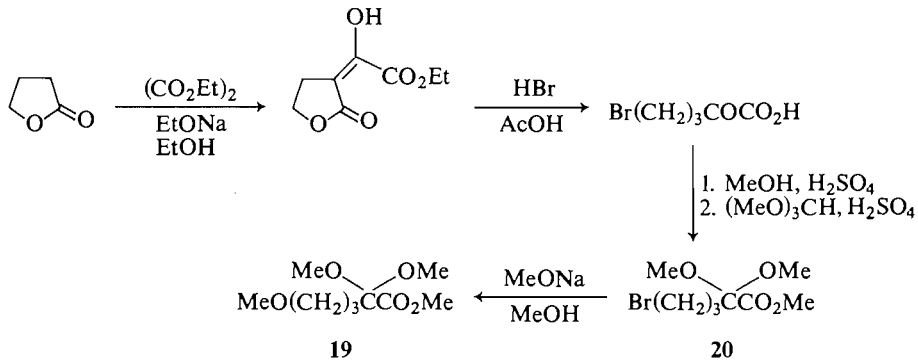
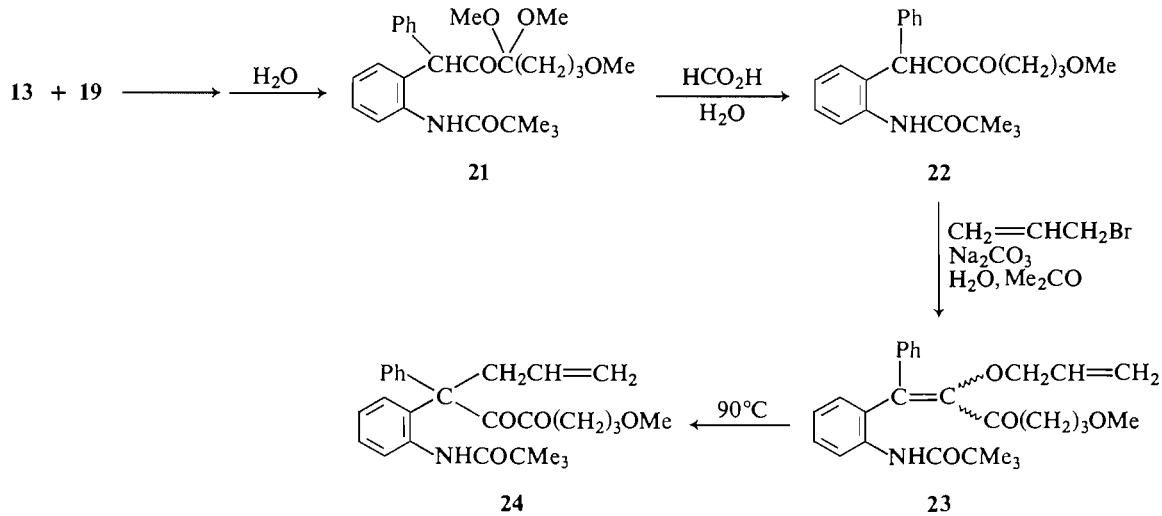


SCHEME 4

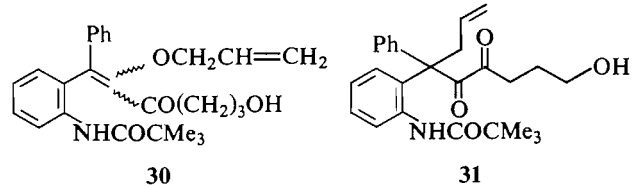


SCHEME 5

rearrangement occurred to give the α-diketone **24** (Scheme 5).[3]

Our synthetic strategy called for the eventual conversion of the methoxymethyl group of **24** to a carboxylic acid function (*vide supra*). Because we anticipated that this might call for reaction conditions that would be inimical to the other functional groups present in the molecule, we undertook the synthesis of the hydroxymethyl analogue of **24**, by a route similar to that of Scheme 5. The dianion **13** was acylated with the ester **25** (11) to give the desired ketone **26** as a 1:1 mixture of diastereomers. Hydrolysis of **26** was not straightforward: treatment with 90% formic acid gave three products **27**–**29** in turn (Scheme 6). The structural assignments are based largely on their ^{1}H nmr spectra. The hemiacetal **27** was isolated as a mixture of diastereomers and its spectrum showed two *tert*-butyl proton singlets at δ 1.10 and 1.20 ppm and two benzylic proton signals at δ 5.84 and 5.88 ppm. In the spectrum of the α-diketone **28** there is a single *tert*-butyl signal at δ 1.20 ppm and a single benzylic proton signal at δ 6.14 ppm; the downfield shift of the latter relative to the benzylic proton signals of **27** parallels the relationship of these signals in the spectra of the keto ketal **21** and the α-diketone **22**. The hemiketal **29** was also isolated as a mixture of diastereomers and its spectrum showed two *tert*-butyl proton singlets at δ 1.36 and 1.40 ppm and two benzylic proton singlets at δ 5.00 and 5.05 ppm; the upfield shift of the latter relative to the benzylic proton signals of **27** reflects the circumstance that these protons no longer have an α relationship to a ketonic group.

Although products **27**–**29** were not obtained entirely free of one another, this was not a handicap since it was found that both **27** and **28** could be converted to the allyl enol ether **30** under similar conditions to those used for the O-allylation of **22** (Scheme 5). Thus the hydrolysis of **26** was allowed to proceed for 10 minutes only, when **27** was formed as the major product accompanied by **28**, but not **29**, as a minor product, and the resulting mixture of **27** and **28** was subjected to O-allylation to give **30** in good yield. Heating of **30** in toluene at 90°C as before brought about rearrangement to the C-allyl product **31**, the desired hydroxymethyl analogue of **24**.



The next stage in our projected synthetic sequence was the oxidative cleavage of the ethylenic double bond in **24** or **31** followed by reductive amination. Unfortunately it was not found possible to effect this oxidation without concomitant oxidation of the α-diketone function and attempts to protect the

[3]Dauben *et al.* have recently utilized a similar reaction sequence for the C-allylation of diosphenols (10).

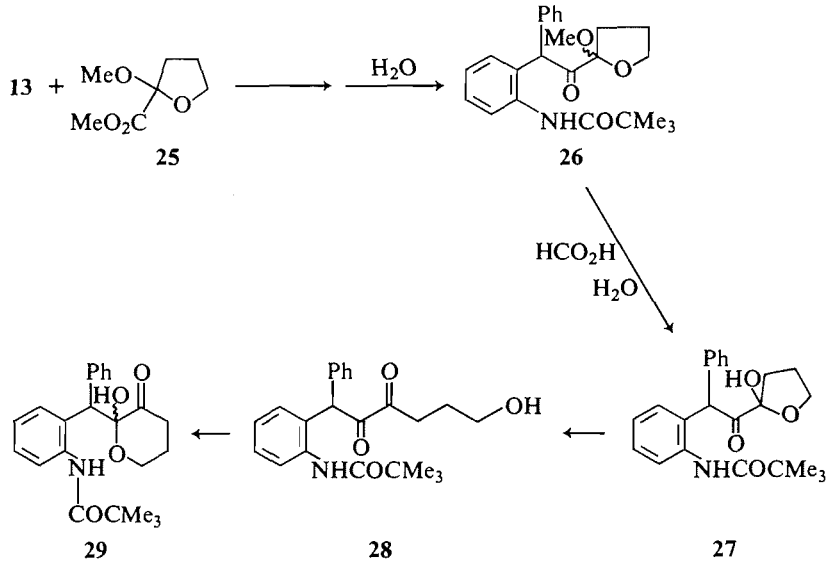
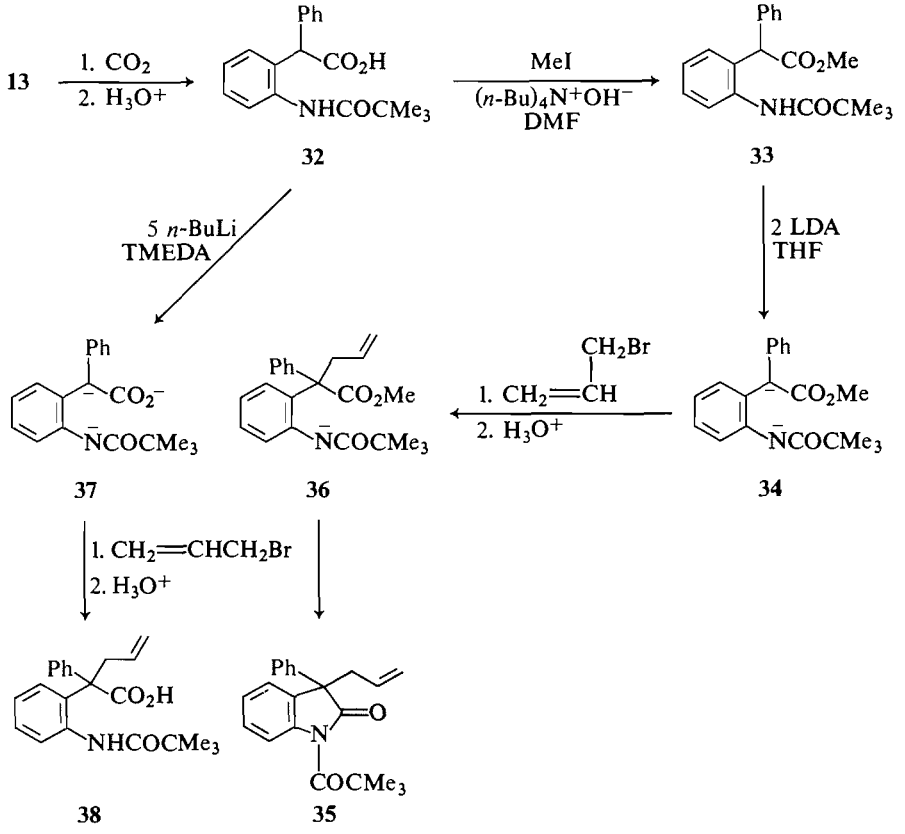


SCHEME 6



SCHEME 7

latter as a mono- or diketal failed because of the instability of **24** and **31** under acidic conditions.

We attempted to circumvent this problem by introducing the allyl substituent before elaboration of the α-diketonic residue so that its oxidative cleavage might be effected without complication. The acid **32** was prepared by carboxylation of the dianion **13** and was converted to its methyl ester **33**. An attempt to C-allylate this by treatment of its dianion **34** with allyl bromide gave the oxindole **35**. This was readily identified by comparison of its spectra with those of 3-allyl-3-phenyloxindole, which we had prepared in the course of other work. It was clear that the desired C-allylation of **33** was occurring but was accompanied by elimination of methoxide ion from the intermediate monoanion **36**. The recourse was clear, viz., reduction of the propensity of the carbonyl residue in **36** to undergo nucleophilic attack. This was achieved by the use of trianion **37** of the acid **32**, formed by treatment with five equivalents of *n*-butyllithium/TMEDA, which on reaction with allyl bromide followed by aqueous work-up gave **38** (Scheme 7).

The acid **38** was subjected to ozonolysis in aqueous meth-

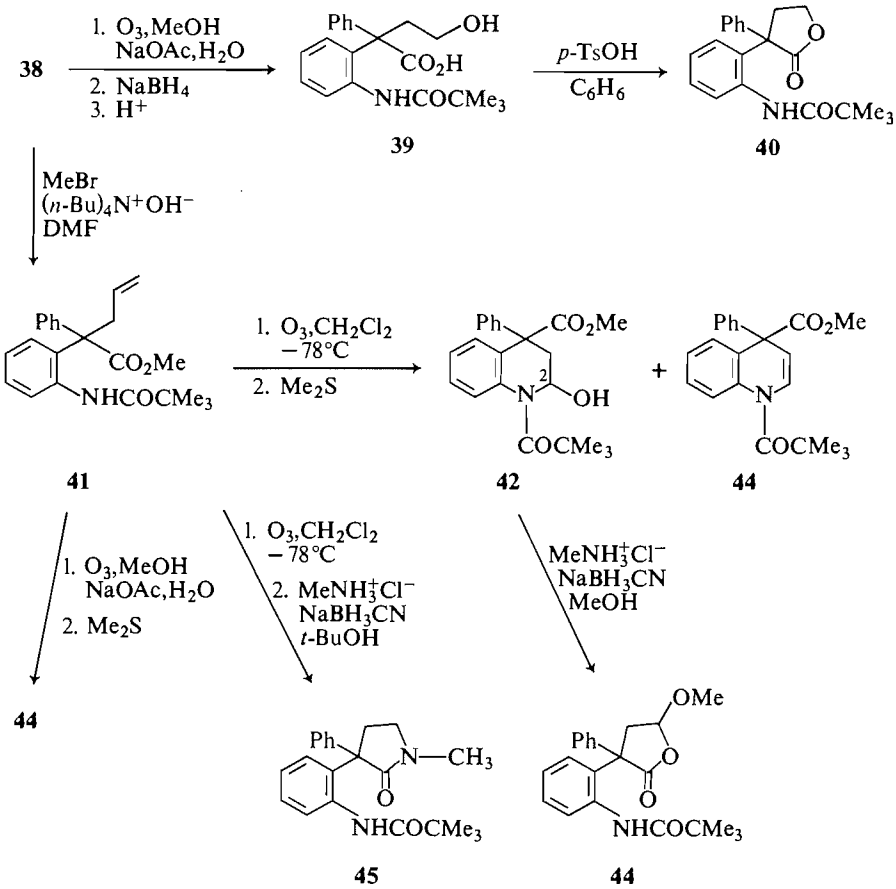
For personal use only.



SCHEME 8

anolic solution containing sodium acetate (12) followed by reductive cleavage of the resulting ozonide with sodium borohydride to give the hydroxy acid **39**, which was lactonized with *p*-toluenesulfonic acid in benzene to **40** (Scheme 8). Attempts to reduce this with diisobutylaluminum hydride to the corresponding lactol were unsuccessful. We therefore undertook to introduce the N-methylamino function by ozonolysis of **41**, the methyl ester of **38**, to the corresponding aldehyde followed by reductive amination with methylamine. Reductive work-up of the ozonide from **41** with dimethyl sulfide gave a mixture of the hemiaminal **42**,[4] derived by attack of the amide nitrogen on the aldehyde, and a small amount of its dehydration product **43**. Treatment of **42** with methylamine hydrochloride and sodium cyanoborohydride by the method of Borch *et al.* (13) gave a mixture of diastereomeric methoxy lactones **44**, rather than the desired lactam **45**; substantiation of this structural assignment was gained from the fact that ozonolysis of **41** in aqueous methanol containing sodium acetate followed by treatment with dimethyl sulfide gave an identical product. The lactam **45** was obtained from **41** by the procedure of Martin *et al.* (14), in which the ozonide is subjected directly to reductive amination conditions with an amine and sodium cyanoborohydride in *tert*-butyl alcohol (Scheme 8). Compound **45** contains latently the 2-(methylamino)ethyl grouping of **4** and has the potential for elaboration to **4** or an equivalent, based on the methodology developed in the present work. However, the yield of its formation from **41** is low, and it will be necessary to improve this yield for it to serve as a viable intermediate.

[4]The ^{1}H nmr spectrum of **42** shows that it is a single diastereomer and that the C-2 proton is pseudoequatorial. Its ir spectrum shows that the hydroxyl proton is strongly hydrogen-bonded to the amide carbonyl group. It is tentatively assigned the configuration with the phenyl group *trans* to the hydroxyl group and pseudoequatorial.

Experimental

Melting points are uncorrected. Unless otherwise specified, the ir spectra were recorded for $CHCl_3$ solutions and the ^{1}H and ^{13}C nmr spectra for $CDCl_3$ solutions. Mass spectra were recorded at 70 eV and peak positions (*m/e*) are followed by relative abundances in parentheses. Preparative thin layer chromatography was carried out on 20 × 20 × 1-mm or 20 × 20 × 2-mm Merck silica gel "60 PF_{254}" plates with uv visualization; the bands were extracted with MeOH, the residues obtained after filtration and evaporation were slurried with $CHCl_3$, and the solutions were filtered and evaporated to give the products. Solutions in organic solvents were dried over anhydrous $MgSO_4$ and evaporated by means of a rotary evaporator at water aspirator pressure.

2-Aminodiphenylmethane (11)

This compound was prepared from *o*-aminobenzophenone (**10**) by reduction with sodium in ethanol in 90% yield according to the method of Hewett *et al.* (5); bp 110–120°C/0.05 Torr (lit. (15) bp 171–172°C/12 Torr); ir λ_{max}: 2.98 (m), 6.30 μm; ^{1}H nmr δ: 3.3 (br s, 2H; D_2O exchangeable), 3.80 (s, 2H), 6.4–7.4 (m, 9H).

Phenyl(2-pivaloylamidophenyl)methane (12)

A solution of amine **11** (20.0 g, 0.11 mol) in dichloromethane (70 mL) was added to a solution of sodium carbonate (10 g) in water (100 mL). To the stirred heterogeneous mixture, cooled in an ice water bath, was added dropwise a solution of pivaloyl chloride (14.5 g, 0.12 mol) in dichloromethane (30 mL). After the addition the ice bath was removed and the reaction mixture was stirred at room

temperature for 3 h. The phases were separated and the aqueous phase was extracted with dichloromethane (30 mL). The combined organic solutions were dried and concentrated to yield an oil which crystallized on standing. Recrystallization from hexanes yielded **12** (23.3 g, 80%) as white needles, mp 78–80.5°C; ir λ_{max}: 2.94 (w), 5.95 μm; ^{1}H nmr δ: 1.10 (s, 9H), 4.00 (s, 2H), 7.0–7.5 (m, 9H), 8.0 (m, 1H); ^{13}C nmr δ: 27.3 (q), 38.5 (t), 39.4 (s), 123.6, 124.8, 126.8, 127.6, 127.6, 128.2, 128.9, 130.6, 131.0, 136.3, 138.8, 176.4 (s); *m/e*: 267 (51), 210 (100). *Anal.* calcd. for $C_{18}H_{21}NO$: C 80.86, H 7.92, N 5.24; found: C 80.85, H 7.85, N 5.29.

*Formation of the dianion **13** of **12***[5]

Method A (n-BuLi)

A solution of amide **12** (1.00 g, 3.75 mmol), THF (5 mL), and tetramethylethylenediamine (TMEDA; 1.12 mL, 7.49 mmol) was cooled to -20°C (Dry Ice/CCl_4) and 1.95 *M* *n*-BuLi in *n*-hexane (3.84 mL, 7.49 mmol) was added dropwise with stirring. Formation of the dianion **13** was indicated by the immediate appearance of a yellow-orange color on addition of the second equivalent of base. Stirring at −20°C was continued for 10 min.

Method B (LDA)

A 2.05 *M* solution of *n*-BuLi in *n*-hexane (0.402 mL; 0.824 mmol) was added dropwise to a solution of diisopropylamine (0.124 mL, 0.824 mmol) in THF (5 mL) at −20°C. After 15 min a solution of amide **12** (0.100 g, 0.374 mmol) in THF (1.5 mL) was added dropwise with stirring at −20°C. The solution immediately became yellow-orange in color.

*Standard work-up procedure of reaction mixtures from **13***[6]

Saturated aqueous ammonium chloride was added to the reaction mixture and the heterogeneous solution was extracted twice with ether. The combined ethereal extracts were washed with saturated aqueous ammonium chloride. The combined aqueous solutions were back-extracted with ether. The combined ethereal extracts were dried and concentrated to yield the reaction product.

*1,2-Diphenyl-2-(pivaloylamidophenyl)ethanol (**14**)*[5]

To a stirred solution of dianion **13**, formed by Method A from amide **12** (1.00 g, 3.75 mmol), TMEDA (1.13 mL, 7.50 mmol), and 2.20 *M* *n*-BuLi in *n*-hexane (3.40 mL, 7.50 mmol), in THF (10 mL) at −30°C was added benzaldehyde (0.400 mL, 3.77 mmol). The reaction mixture was stirred at −30°C for 30 min and at room temperature for 1 h. The standard work-up procedure yielded 1.38 g (98%) of crude **14** as a mixture of diastereomers, mp 155–160°C.

The mixture was chromatographed on silica gel with $CHCl_3$ – ethyl acetate (1:1) as eluant to give the individual diastereomers. Diastereomer 1 (R_f 0.51), mp 170–171°C; ir λ_{max}: 2.80 (w), 2.95 (m), 5.99 μm; ^{1}H nmr δ: 1.05 (s, 9H), 3.0 (br s, 1H; D_2O exchangeable), 4.30 (d, *J* = 8 Hz, 1H), 5.40 (d, *J* = 8 Hz, 1H), 7.0–8.0 (m, 15H); *m/e*: 373 (<1), 210 (100). *Anal.* calcd. for $C_{25}H_{27}NO_2$: C 80.39, H 7.29, N 3.75; found: C 80.69, H 7.28, N 3.74. Diastereomer 2 (R_f 0.35), mp 189.5–190°C; ir λ_{max}: 2.80 (w), 2.95 (m), 5.99 μm; ^{1}H nmr δ: 1.10 (s, 9H), 3.0 (br s, 1H; D_2O exchangeable), 4.40 (d, *J* = 8 Hz, 1H), 5.40 (d, *J* = 9 Hz, 1H), 6.9–7.2 (m, 13H), 7.50 (m, 1H), 7.95 (br s, 1H); *m/e*: 373 (1), 210 (100). *Anal.* calcd. for $C_{25}H_{27}NO_2$: C 80.39, H 7.29, N 3.75; found: C 80.52, H 7.31, N 3.69.

Ethyl 1,3-dithiane-2-carboxylate

This compound was synthesized from ethyl diethoxyacetate (16), 1,3-propanedithiol, and boron trifluoride etherate in chloroform according to the procedure of Eliel and Hartmann (6); bp 90–94°C/0.25 Torr (lit. (6) bp 75–77°C/0.2 Torr).

*Ethyl 2-(3-methoxypropyl)-1,3-dithiane-2-carboxylate (**15**)*[5]

The general procedure of Eliel and Hartmann (6) was followed. Sodium hydride (50% dispersion in oil; 1.12 g, 24.3 mmol), washed with benzene (2 × 20 mL), was covered with benzene (30 mL). A solution of 3-bromo-1-methoxypropane (3.30 g, 21.2 mmol) and ethyl 1,3-dithiane-2-carboxylate (4.10 g, 21.2 mmol) in dimethylformamide (10 mL) was added dropwise to the stirred suspension of sodium hydride in benzene at 0°C over 1 h. The reaction mixture was allowed to warm to room temperature and stirred overnight. The deep red mixture was poured into water (50 mL). The phases were separated and the aqueous phase was extracted with benzene (30 mL). The combined organic solutions were dried and evaporated to yield **15** (4.69 g, 85%) as a colorless oil; ir λ_{max}: 5.80 μm; ^{1}H nmr δ: 1.35 (t, *J* = 7 Hz, 3H), 1.5–3.2 (m, 10H), 3.35 (s, 3H), 3.50 (t, *J* = 6 Hz, 2H), 4.25 (q, *J* = 7 Hz, 2H); ^{13}C nmr δ: 14.2 (q), 24.6 (t), 24.8 (t), 27.8 (t), 35.5 (t), 52.1 (s), 58.3 (q), 61.6 (t), 72.3 (t), 170.7 (s); *m/e*: 264 (15), 191 (100). *Accurate Mass* calcd. for $C_{11}H_{20}O_3S_2$: 264.0853; found: 264.0843.

*Addition of ester **15** to dianion **13**. Formation of **17***

To a stirred solution of dianion **13**, formed by Method A from amide **12** (0.150 g, 0.56 mmol), TMEDA (0.17 mL, 1.12 mmol), and 2.30 *M* *n*-BuLi in *n*-hexane (0.50, 1.15 mmol), in THF (5 mL) at −20°C was added dropwise a solution of ester **15** (0.140 g, 0.56 mL) in THF (1 mL). The reaction mixture was stirred at −20°C for 1 h and at room temperature for 15 min. The standard work-up procedure yielded an oil. The oil was placed in a molecular still and heated at 120°C (oil bath)/0.025 Torr to remove starting material. The pot residue consisted of crude **17** as an oil; ir λ_{max}: 3.00 (w), 5.74, 5.90 μm; ^{1}H nmr δ: 1.70 (s, 9H), 1.25 (t, *J* = 7 Hz, 3H), 1.5–2.0 (m, 6H), 2.5–2.9 (m, 5H), 3.20–3.50 (m, 2H), 3.25 (s, 3H), 4.20 (q, *J* = 7 Hz, 2H), 5.33 (s, 1H), 7.0–8.0 (m, 8H), 7.95 (br d, *J* = 7 Hz, 1H), 8.20 (br s, 1H); ^{13}C nmr δ: 14.2 (q), 27.4 (q), 39.5 (s), 46.6 (d), 51.9 (d), 58.5 (q), 61.4 (t), 72.0 (t), 136.5 (s), 138.3 (s), 172.5 (s), 176.5 (s); *m/e*: 531 (<1), 265 (100), 266 (80).

α-Ethoxalyl-γ-butyrolactone

This compound was prepared in 78% yield by the method of Plieninger (17) from γ-butyrolactone, diethyl oxalate, and sodium ethoxide in ethanol under nitrogen.

5-Bromo-2-oxopentanoic acid

This compound was prepared in 86% yield from α-ethoxalyl-γ-butyrolactone and hydrobromic acid in acetic acid by the method of Öhler and Schmidt (7); bp 100°C/0.05 Torr (lit. (7) bp 115°C/0.01 Torr).

Methyl 5-bromo-2-oxopentanoate

A solution of 5-bromo-2-oxopentanoic acid (28.13 g, 0.144 mol), methanol (160 mL), and concentrated sulfuric acid (2 mL) was stirred overnight at room temperature. The solvent methanol was removed, the residue was dissolved in ether (200 mL), and the solution was washed with saturated aqueous sodium bicarbonate (50 mL). The ethereal solution was dried and concentrated to yield methyl 5-bromo-2-oxopentanoate (26.17 g, 87%) as a colorless oil. The product was used without further purification; ir λ_{max}: 5.77 μm; ^{1}H nmr δ: 2.20 (m, 2H), 3.05 (t, *J* = 6.5 Hz, 2H), 3.50 (t, *J* = 6.5 Hz, 2H), 3.82 (s, 3H).

*Methyl 5-bromo-2,2-dimethoxypentanoate (**20**)*

Methyl 5-bromo-2-oxopentanoate (10.0 g, 47.8 mmol), trimethyl orthoformate (10.20 g, 96.2 mmol), methanol (15 mL), and concentrated sulfuric acid (2 drops) were stirred under nitrogen for 48 h at room temperature. Sodium bicarbonate (2 g) was added and the mixture was stirred for 0.5 h, filtered, and concentrated. The colorless liquid residue was distilled to yield ketal ester **20** (9.95 g, 75%), bp 78–83°C/0.025 Torr; ir λ_{max}: 5.72 μm; ^{1}H nmr δ: 1.5–2.2 (m, 4H), 3.20 (s, 6H), 3.37 (t, *J* = 6 Hz, 2H), 3.80 (s, 3H).

*Methyl 2,2,5-trimethoxypentanoate (**19**)*

Sodium (1.07 g, 0.046 g-atom) was added to methanol (50 mL). Following reaction of the sodium and cooling of the solution to room temperature, ester **20** (8.75 g, 34.3 mmol) was added. The solution was stirred at room temperature for 72 h. The methanol was removed,

[5]These experiments were conducted under rigorously anhydrous conditions under a positive pressure of nitrogen.

[6]This procedure is referred to in later experiments as the standard work-up procedure.

For personal use only.

the residue was dissolved in dichloromethane (30 mL), and the solution was washed with water (15 mL). The organic solution was dried and concentrated to yield **19** (6.15 g, 87%), bp 68–70°C/0.01 Torr; ir λ_{max}: 5.74 μm; ^{1}H nmr δ: 1.2–2.2 (m, 4H), 3.22 (s, 6H), 3.24 (s, 3H), 3.35 (t, J = 6.5 Hz, 2H), 3.60 (s, 3H); ^{13}C nmr δ: 23.2 (t), 30.0 (t), 49.1 (q), 51.6 (q), 57.8 (q), 71.4 (t), 102.1 (s), 168.9 (s); *m/e*: 175 (M−OCH_3; 9), 148 (100). *Anal.* calcd. for $C_9H_{18}O_5$: C 52.41, H 8.80; found: C 52.26, H 8.77.

3,3,6-Trimethoxy-1-phenyl-1-(2-pivaloylamidophenyl)-2-hexanone (21)[5]

A slution of ketal ester **19** (4.20 g, 20.6 mmol) was added dropwise over 5 min to a stirred solution of dianion **13**, formed by method A from amide **12** (5.00 g, 18.0 mmol), TMEDA (5.64 mL, 36 mmol), and 1.90 *M* *n*-BuLi in *n*-hexane (19.7 mL, 36 mmol) at −30°C. The reaction mixture was stirred at −30°C for 30 min and at room temperature for 16 h during which time a precipitate formed. The standard work-up procedure yielded 8.5 g of an oil, which was shown by ^{1}H nmr spectroscopic analysis to be a mixture of starting amide and ketone **21**. Preparative scale medium-pressure liquid chromatography with hexane − ethyl acetate (4:1) as eluant yielded starting amide **12** (1.20 g) and ketone **21** (5.95 g, 73%; 93% based on recovered starting material) as a pale yellow oil; ir λ_{max}: 3.05 (w), 5.78, 5.94 μm; ^{1}H nmr δ: 1.10 (s, 9H), 1.2–2.2 (m, 4H), 3.14 (s, 3H), 3.25 (s, 3H), 3.35 (s, 3H), 3.20 (m, 2H), 6.00 (s, 1H), 7.0–8.5 (m, 8H), 7.95 (m, 1H), 8.35 (br s, 1H); ^{13}C nmr δ: 23.1 (d), 27.2 (q), 29.6 (d), 39.4 (s), 49.7 (q), 49.8 (q), 54.7 (d), 58.3 (q), 105.0 (s), 124.7, 125.3, 126.9, 127.0, 128.0, 128.5, 132.4, 137.2, 137.5, 176.7 (s), 208.3 (s); *m/e*: 410 (M − OCH_3; <1), 147 (100). *Accurate Mass* calcd. for $C_{25}H_{32}NO_4$ (M − OCH_3): 410.2331; found: 410.2329.

6-Methoxy-1-phenyl-1-(2-pivaloylamidophenyl)-2,3-hexanedione (22)

Ketal ketone **21** (1.00 g, 2.26 mmol) and 90% formic acid (10 mL) were stirred under nitrogen for 1 h at room temperature during which time the solution became bright yellow. Water (25 mL) was added and the solution was extracted with dichloromethane (2 × 30 mL). The combined organic extracts were dried and concentrated to an oil. The product was crystallized from hexane–benzene as long yellow needles. The yield of **22** in two crops was 600 mg (67%), mp 68–70°C; ir λ_{max}: 2.94 (w), 5.83, 5.96 μm; ^{1}H nmr δ: 1.20 (s, 9H), 1.90 (m, 2H), 2.80 (m, 2H), 3.20 (s, 3H), 3.35 (t, J = 6Hz, 2H), 6.20 (s, 1H), 7.0–8.0 (m, 10H); ^{13}C nmr δ: 24.0 (t), 27.3 (q), 33.5 (t), 39.5 (s), 51.3 (t), 58.3 (q), 71.4 (t), 125.5, 127.5, 128.1, 128.7, 128.8, 129.9, 131.6, 136.2, 136.6, 177.2 (s), 196.5 (s), 199.2 (s); *m/e*: 396 (M + 1; 6), 210 (100). *Accurate Mass* calcd. for $C_{24}H_{29}NO_4$: 395.2096; found: 395.2098.

2-Allyloxy-6-methoxy-1-phenyl-1-(2-pivaloylamidophenyl)hex-1-en-3-one (23)

A mixture of diketone **22** (1.15 g, 2.91 mmol), sodium carbonate (0.295 g, 2.89 mmol), acetone (28 mL), water (12 mL), and allyl bromide (0.50 mL, 5.78 mmol) was stirred under nitrogen at room temperature for 4 h. The acetone was removed under reduced pressure and the residue was extracted with dichloromethane (2 × 20 mL). The combined organic extracts were dried and concentrated to yield **23** (1.10 g; purity >90% by ^{1}H nmr analysis) as a 3:1 mixture of *cis*/*trans* isomers; ^{1}H nmr δ: 1.17, 1.25 (2 s, 9H), 1.80 (m, 2H), 2.40 (m, 2H), 3.1-3.4 (m, 5H), 4.20 (d, J = 5 Hz, 2H), 5.0–6.0 (m, 3H), 7.0–7.6 (m, 8H), 7.9–8.3 (m, 2H); ^{13}C nmr δ: 71.4 (t), 176.9 (s), 201.7 (s).

1-Methoxy-6-phenyl-6-(2-pivaloylamidophenyl)non-8-ene-4,5-dione (24)

A. Preliminary investigation

A ^{1}H nmr tube was charged with a solution of the enol ethers **23** (60 mg) in toluene-d_8 (1 mL). The tube was immersed in an oil bath at 90°C. At various intervals (~2 h) ^{1}H nmr spectra were taken and the progress of the reaction was followed by the diminution of the intensity of the *tert*-butyl peaks at δ 1.0 and 1.2 and the concomitant growth of the butyl peak at δ 0.95. The reaction was complete in ~24 h.

B. Preparative method

A solution of the enol ethers **23** (3.00 g) and toluene (30 mL) under nitrogen was immersed in a 90°C oil bath and heated for 24 h. The solvent was removed yielding 3.00 g of an oil. Purification by medium-pressure liquid chromatography with hexanes − ethyl acetate (4:1) as eluant yielded **24** (1.50 g, 45% from diketone **22**) as a yellow oil; ir λ_{max}: 2.96, 5.85, 5.96 μm; ^{1}H nmr δ: 0.95 (s, 9H), 1.4–3.2 (m, 8H), 3.22 (s, 3H), 4.7–5.7 (m, 3H), 6.9–8.0 (m, 10H); ^{13}C nmr δ: 22.6 (t), 26.8 (q), 35.5 (t), 39.5 (s), 42.3 (t), 53.8 (q), 60.8 (s), 71.2 (t), 119.3, 125.4, 125.9, 127.5, 127.9, 128.3, 128.6, 129.1, 129.3, 132.6, 136.9, 138.3, 176.6 (s), 200.1 (s), 200.4 (s); *m/e*: 435 (<1), 101 (100). *Accurate Mass* calcd. for $C_{27}H_{33}NO_4$: 435.2409; found: 435.2409.

Methyl tetrahydro-2-methoxyfuran-2-carboxylate (25)

A solution of 5,6-dihydro-2*H*-pyran-2-one (11) (0.750 g, 6.57 mmol), methanol (15 mL), and concentrated sulfuric acid (3 drops) was boiled under reflux for 17 h. The reaction mixture was cooled to room temperature and neutralized with solid sodium bicarbonate. Excess sodium bicarbonate was removed by filtration and the filtrate was concentrated to yield methoxy ester **25** (925 mg, 88%), bp 23–25°C/0.05 Torr; ir λ_{max}: 5.70 μm; ^{1}H nmr δ: 1.9–2.2 (m, 4H), 3.35 (s, 3H), 3.80 (s, 3H), 4.0 (m, 2H); ^{13}C nmr δ: 23.3 (t), 35.8 (t), 50.1 (q), 51.6 (q), 68.4 (t), 105.5 (s), 169.2 (s); *m/e*: 139 (15), 59 (100).

1-(2-(2-Methoxy)tetrahydrofuranyl)-2-phenyl-2-(2-pivaloylamidophenyl)ethanone (26)[5]

A solution of ester **25** in THF (5 mL) was added dropwise to a stirred solution of dianion **13**, formed by method A from amide **12** (4.84 g, 18.1 mol), TMEDA (5.47 mL, 36.2 mmol), and 2.15 *M* *n*-BuLi in *n*-hexane (16.86 mL, 36.2 mmol), in THF (40 mL) at −30°C. The reaction mixture was stirred at −30°C for 1 h and at room temperature for 2.5 h. The standard work-up procedure yielded 8.0 g of an oil. Preparative medium-pressure liquid chromatography with hexane − ethyl acetate (4:1) as eluant yielded amide **12** (1.0 g) and the diastereomeric ketones **26** (4.30 g, 62%; 76% based on recovered starting material), which crystallized on standing. Ketone **26** was recrystallized from hexanes, mp 88–89.5°C; ir λ_{max}: 2.99 (w), 5.80, 5.95; ^{1}H nmr δ: 1.00, 1.05 (2s, 9H), 1.6–2.2 (m, 4H), 3.00, 3.15 (2s, 3H), 3.8–4.2 (m, 2H), 5.82 (s, 1H), 6.8–8.0 (m, 9H), 8.40 (br s, 1H); ^{13}C nmr δ: 24.4 (t), 24.5 (t), 27.2 (q), 33.1 (t), 39.4 (s), 50.5 (q), 55.1 (d), 55.2 (d), 69.4 (t), 69.6 (t), 109.7 (s), 110.0 (s), 124.6, 125.2, 125.4, 126.8, 127.1, 127.9, 128.1, 128.4, 128.6, 131.9, 132.8, 137.3, 137.6, 176.8 (s), 207.4 (s), 207.8 (s); *m/e*: 395 (5), 101 (100). *Anal.* calcd. for $C_{24}H_{29}NO_4$: C 72.84, H 7.39, N 3.54; found: C 72.84, H 7.38, N 3.52.

1-(2-(2-Hydroxy)tetrahydrofuranyl)-2-phenyl-2-(2-pivaloylamidophenyl)ethanone (27)

Aqueous formic acid (90%; 18.5 mL) was added to **26** (2.39 g, 6.04 mmol) and the mixture became homogeneous and was stirred at room temperature for 15 min. The reaction mixture was poured into water (50 mL) and extracted with dichloromethane (2 × 50 mL). The combined organic extracts were washed with saturated aqueous sodium bicarbonate (25 mL), dried, and evaporated to yield crude **27** (2.20 g, 95%); ir_{max}: 2.95 (m), 5.80, 5.96 μm; ^{1}H nmr δ: 1.04 and 1.12 (2 s, 9H), 2.0 (m, 5H), 4.05 (m, 2H), 5.74 and 5.78 (2 s, 1H), 6.9–7.9 (m, 9H), 8.1 (br s, 1H); *m/e*: 363 (M − H_2O; <1), 210 (100). *Accurate Mass* calcd. for $C_{23}H_{25}NO_3$ (M − H_2O): 363.1834; found: 363.1829. This product was used without further purification.

6-Hydroxy-1-phenyl-1-(2-pivaloylamidophenyl)-2,3-hexanedione (28) and tetrahydro-2-hydroxy-2-(phenyl(2-pivaloylamidophenyl)methyl)-3-oxopyran (29)

Aqueous formic acid (90%; 1 mL) was added to **26** (0.075, 0.197 mmol) and the mixture became homogeneous and was stirred at room temperature for 4 h. Water (10 mL) was added and the mixture

For personal use only.

was extracted with dichloromethane (2 × 15 mL). The combined organic extracts were washed with saturated aqueous sodium bicarbonate, dried, and concentrated to yield 180 mg of an oil. Preparative thin-layer chromatography with hexanes – ethyl acetate (7:3) as eluant gave two major bands. Band 1 (R_f 0.24–0.44) gave **28** (36 mg, 50%) as a yellow oil; ir λ_{max}: 2.95 (m), 5.80, 5.95 μm; ^{1}H nmr δ: 1.17 (s, ~9H), 1.7–2.2 (m, 3H), 2.75–3.0 (m, 2H), 4.08 (t, J = 6 Hz, 2H), 6.08 (s, 1H), 7.0–8.0 (m, ~10H); *m/e*: 363 (M – H_2O; <1), 210 (100). *Accurate Mass* calcd. for $C_{23}H_{25}NO_3$ (M – H_2O): 363.1834; found: 363.1850. Band 2 (R_f 0.45–0.64) gave **29** (16 mg, 25%) as a colorless oil; ir λ_{max}: 3.00 (m), 5.74, 5.95 μm; ^{1}H nmr δ: 1.24 and 1.26 (2s, 9H), 2.0 (m, ~5H), 4.15 (m, ~2H), 4.82 and 4.98 (2s, 1H), 7.0–8.0 (m, ~10H); *m/e*: 363 (M – H_2O; 100). *Accurate Mass* calcd. for $C_{23}H_{25}NO_3$ (M – H_2O): 363.1834; found: 363.1831.

2-Allyloxy-6-hydroxy-1-phenyl-1-(2-pivaloylamidophenyl)hex-1-en-3-one (30)

Diketone **28** (1.50 g, 3.94 mmol), acetone (50 mL), water (12.5 mL), allyl bromide (0.700 mL, 8.09 mmol), and sodium carbonate (0.420 g, 3.96 mmol) were combined and the mixture was stirred under nitrogen at room temperature for 18 h. Following removal of acetone the residue was treated with brine (15 mL) and extracted with dichloromethane (2 × 20 mL). The combined organic extracts were dried and concentrated to give **30** (1.50 g, 90%) as a pale yellow oil; ir λ_{max}: 2.95 (w), 5.78, 5.95 μm; ^{1}H nmr δ: 1.05 and 1.12 (2 s, 9H), 1.5–2.5 (m, ~5H), 3.45 (t, J = 7 Hz, 2H), 4.2 (m, 2H), 5.0–6.0 (m, 3H), 6.9–8.2 (m, ~10H).

1-Hydroxy-6-phenyl-6-(2-pivaloylamidophenyl)non-8-ene-4,5-dione (31)

A solution of enol ethers **30** (1.00 g) and toluene (10 mL) under nitrogen was immersed in a 90°C oil bath and heated for 24 h. The solvent was removed yielding 1.00 g of an oil. Purification by medium-pressure liquid chromatography with hexanes – ethyl acetate (4:1) as eluant yielded **31** (0.50 g, 45% from ketone **27**) as a yellow oil; ir λ_{max}: 2.87 (m), 5.80, 5.95 μm; ^{1}H nmr δ: 0.95 (s, 9H), 1.5–3.8 (m, 9H), 4.7–5.7 (m, 3H), 6.8–7.8 (m, ~10H); *m/e*: 403 (M – H_2O; 13), 267 (100). *Acurate Mass* calcd. for $C_{26}H_{29}NO_3$ (M – H_2O): 403.2147; found: 403.2149.

2-Phenyl-2-(2-pivaloylamidophenyl)acetic acid (32)[5]

A solution of dianion **13** was formed by method A from amide **12** (7.00 g, 26.2 mmol), TMEDA (8.50 mL, 56.4 mmol), and 1.97 *M* *n*-BuLi in *n*-hexane (26.6 mL, 52.4 mmol), in THF (60 mL) at −30°C. Carbon dioxide was bubbled through the stirred solution until the color was quenched. Stirring at −30°C was continued for 10 min and at room temperature for 10 min. Ether (50 mL) was added and the solution was extracted with aqueous 5% sodium hydroxide (2 × 50 mL). The combined aqueous extracts were acidified at 0°C with concentrated hydrochloric acid and extracted with dichloromethane (2 × 50 mL). The combined organic extracts were dried and concentrated to yield 8.00 g of a viscous oil. Crystallization from hexane–benzene yielded **32** (6.58 g, 80%) as a white solid, mp 139.5–141.5°C; ir λ_{max}: 3.0–4.0, 5.85, 6.0 μm; ^{1}H nmr δ: 0.98 (s, 9H), 5.15 (s, 1H), 7.0–7.4 (m, 8H), 7.8 (m, 1H), 8.5 (br s, 1H), 10.7 (br s, 1H; D_2O exchangeable); ^{13}C nmr δ: 27.1 (q), 39.3 (s), 55.5 (d), 125.8, 126.5, 127.4, 127.7, 128.7, 129.5, 131.6, 136.3, 176.9 (s), 177.7 (s); *m/e*: 311 (4), 209 (100). *Anal.* calcd. for $C_{19}H_{21}NO_3$: C 73.29, H 6.80, N 4.50; found: C 73.36, H 6.84, N 4.34.

Methyl 2-phenyl-2-(2-pivaloylamidophenyl)acetate (33)

The general procedure of Wegenknecht *et al.* (18) was used. Benzene (25 mL), acid **32** (0.970 g, 3.12 mmol), and 0.4 *M* tetra-*n*-butylammonium hydroxide in water (8.00 mL, 3.20 mmol) were combined and the mixture was boiled under reflux under nitrogen in a flask equipped with a Dean–Stark head and condenser. After complete azeotropic removal of the water the benzene solution was concentrated to yield a colorless oil. The oil was dissolved in dimethylformamide (15 mL) and excess methyl iodide (2 mL) was added to the stirred solution. The reaction mixture was stirred overnight at room temperature. Ether (20 mL) was added and the solution was washed with water (2 × 20 mL), saturated aqueous ammonium chloride (20 mL), water (20 mL), saturated aqueous sodium bicarbonate (15 mL), and brine (20 mL). The organic solution was dried and concentrated to yield an oil, which was passed through a plug of Florisil (15 g) with hexane – ethyl acetate (7:3) as eluant. Concentration of the eluate gave ester **33** (0.900 g, 88%) as a colorless oil. Crystallization from hexane–benzene provided an analytical sample, mp 71–73°C; ir λ_{max}: 2.89 (w), 5.78, 5.97 μm; ^{1}H nmr δ: 1.00 (s, 9H), 3.80 (s, 3H), 5.15 (s, 1H), 7.0–7.5 (m, 8H), 7.97 (br d, J = 7 Hz, 1H), 8.4 (br s, 1H); ^{13}C nmr δ: 27.2 (q), 39.4 (s), 52.8 (q), 55.8 (d), 125.0, 127.5, 128.2, 128.8, 131.6, 136.4, 137.1, 174.6 (s), 176.6 (s); *m/e*: 325 (15), 209 (100). *Anal.* calcd. for $C_{20}H_{23}NO_3$: C 73.82, H 7.12, N 4.30; found: C 73.66, H 7.03, N 4.07.

2-Phenyl-2-(2-pivaloylamidophenyl)pent-4-enoic acid (38)[5]

To a stirred solution of acid **32** (4.49 g, 14.4 mmol) and TMEDA (10.80 mL, 71.7 mmol) in THF (70 mL) cooled to −30°C was added dropwise 2.15 *M* *n*-BuLi in *n*-hexane (34.00 mL, 73.1 mmol). The solution became dark brown in color and stirring was continued at −30°C for 45 min. Allyl bromide (4 mL, 22.5 mmol) was added dropwise at −30°C, when the solution became light yellow in color. Stirring was continued at −30°C for 1 h and at 0°C for 4 h during which time a copious white precipitate was produced. Water (100 mL) was added and the solution was washed with ether (2 × 35 mL). The aqueous solution was acidified at 0°C with concentrated hydrochloric acid and extracted with dichloromethane (2 × 50 mL). The combined organic extracts were dried and concentrated to yield crude **38** (4.80 g, 95%) as a colorless oil. The product was crystallized from hexane–benzene, mp 139–140°C; ir$_{max}$: 3.0–4.0, 5.90, 6.00 μm; ^{1}H nmr δ: 0.92 (s, 9H), 3.10 (br t, J = 6 Hz, 2H), 4.6–5.4 (m, 3H), 7.0–8.0 (m, 9H), 8.4 (br s, 1H), 10.35 (br s, 1H; D_2O exchangeable); ^{13}C nmr δ: 26.8 (q), 39.2 (s), 43.7 (t), 58.8 (s), 118.8, 125.2, 126.9, 127.2, 127.9, 128.2, 128.6, 131.8, 133.3, 136.8, 140.5, 177.3 (s), 177.6 (s); *m/e*: 351 (50), 208 (100). *Anal.* calcd. for $C_{22}H_{25}NO_3$: C 75.19, H 7.17, N 3.99; found: C 75.15, H 7.44, N 4.03.

α-Phenyl-α-(2-pivaloylamidophenyl)-γ-butyrolactone (40)

Ozonized oxygen was bubbled through a solution of **38** (3.40 g, 10.0 mmol) and sodium acetate (1.55 g, 11.4 mmol), methanol (50 mL), and water (2.5 mL) cooled to −78°C. After the appearance of a persistent blue color the excess ozone was displaced with oxygen followed by nitrogen. Sodium borohydride (1.54 g, 4.05 mmol) was added at −70°C and the solution was stirred and allowed to warm to room temperature. On warming, the evolution of a gas was apparent. The solvent was removed and water (25 mL) was added to the residue. The aqueous solution was acidified with concentrated hydrochloric acid and extracted with ether (3 × 20 mL). The combined ethereal extracts were dried and concentrated to yield **39** (3.00 g) as a fluffy white solid. The solid was dissolved in benzene, a few crystals of *p*-toluenesulfonic acid were added, and the mixture was stirred at room temperature for 6 h. The benzene solution was washed with water (15 mL), dried, and concentrated to yield crude **40** (2.80 g, 83%) as a white solid. Recrystallization from hexane–benzene provided an analytical sample, mp 145–145.5°C; ir λ_{max}: 3.00 (w), 5.70, 5.96 μm; ^{1}H nmr δ: 0.95 (s, 9H), 2.2–3.4 (m, 2H), 4.40 (dd, J = 8, 6 Hz, 2H), 6.8–8.0 (m, 10H); ^{13}C nmr δ: 27.1 (q), 38.9 (s), 39.2 (t), 56.5 (s), 66.2 (t), 124.8, 126.6, 126.9, 127.7, 127.9, 128.8, 129.0, 137.5, 140.5, 176.6 (s), 179.2 (s); *m/e*: 337 (100). *Anal.* calcd. for $C_{21}H_{23}NO_2$: C 74.75, H 6.87, N 4.15; found: C 74.52, H 6.80, N 4.05.

Methyl 2-phenyl-2-(2-pivaloylamidophenyl)pent-4-enoate (41)

The esterification of acid **38** was accomplished in a manner similar to that used for methyl ester **33**. Compound **41** was obtained in 86% yield as a viscous, colorless oil; ir λ_{max}: 2.96 (w), 5.80, 5.95 μm; ^{1}H nmr δ: 0.93 (s, 9H), 3.15 (m, 2H), 3.65 (s, 3H), 4.7–5.6 (m, 3H), 7.0–7.7 (m, 8H), 7.9–8.1 (m, 2H); *m/e*: 365 (41), 208 (100). *Accurate Mass* calcd. for $C_{23}H_{27}NO_3$: 365.1990; found: 365.2001.

*Methyl 1,2,3,4-tetrahydro-2-hydroxy-4-phenyl-1-pivaloyl-4-quinolinecarboxylate (**42**) and methyl 1,4-dihydro-4-phenyl-1-pivaloyl-4-quinolinecarboxylate (**43**)*

Ozonized oxygen was bubbled through a solution of **41** (450 mg, 1.23 mmol) in dichloromethane (25 mL) cooled to −78°C. After the appearance of a persistent blue color the excess ozone was displaced by oxygen followed by nitrogen. Dimethyl sulfide (1.5 mL) was added and the solution was allowed to warm to room temperature and to stand for 24 h. It was washed with water (3 × 10 mL), dried, and concentrated to yield 450 mg of a colorless oil. Dissolution of the oil in hexane − ethyl acetate (4:1) led to precipitation of **42** as a white solid (130 mg), mp 120−122°C; ir λ_{max}: 2.80 (w), 5.76, 6.12 μm; ^{1}H nmr δ: 1.20 (s, 9H), 2.02 (dd, J = 13, 7 Hz, 1H), 3.28 (dd, J = 13, 7 Hz, 1H), 3.72 (s, 3H), 4.20 (d, J = 3 Hz, 1H; D_2O exchangeable), 5.83 (td, J = 7, 3 Hz, 1H), 6.6−7.5 (m, 9H); *m/e*: 367 (3), 206 (100). *Accurate Mass* calcd. for $C_{22}H_{25}NO_4$: 367.1784; found: 367.1792.

The residue (270 mg) from the mother liquor was separated by preparative thin-layer chromatography (silica gel) with hexane − ethyl acetate (4:1) as eluant into two major bands. Band 1 (R_f 0.3−0.53) yielded a colorless oil (100 mg), whose ^{1}H nmr spectrum indicated the presence of at least three components. On standing for a week this oil crystallized and was shown by ^{1}H nmr analysis to be mainly **42**. Band 2 (R_f 0.54−0.68) yielded **43** (43 mg) as a colorless oil; ir λ_{max}: 5.74, 5.93 (m), 6.01 (m) μm; ^{1}H nmr δ: 1.30 (s, 9H), 3.78 (s, 3H), 5.78 (d, J = 7 Hz, 1H), 6.9−7.5 (m, 9H), 7.84 (m, 1H); *m/e*: 349 (2), 206 (100). *Accurate Mass* calcd. for $C_{22}H_{23}NO_3$: 349.1678; found: 349.1688.

*γ-Methoxy-α-phenyl-α-(2-pivaloylamidophenyl)-γ-butyrolactone (**44**)*

*A. From **42***

Methylamine hydrochloride (12 mg) was added to a solution of hemiaminal **42** (35 mg, 0.095 mmol) and sodium cyanoborohydride (7 mg, 11.1 mmol) in dry methanol (2 mL) over 3 Å molecular sieves. The reaction mixture was allowed to stand overnight at room temperature. The methanolic solution was decanted and the molecular sieves were treated with methanol (2 × 5 mL). The combined methanolic solutions were concentrated and the residue was treated with 0.5 *N* hydrochloric acid (5 mL) and extracted with dichloromethane (2 × 5 mL). The combined organic extracts were dried and concentrated to yield a crude mixture of diastereomeric lactones **44** (30 mg, 85%) as a colorless oil; ir λ_{max}: 2.96 (w), 5.68, 5.95 μm; ^{1}H nmr δ: 0.88 and 0.94 (2 s, 9H), 2.4−3.4 (m, 2H), 3.54 and 3.60 (2 s, 3H), 5.5 (m, 1H), 7.0−8.0 (m, 9H), 8.3 (br s, 1H); *m/e*: 367 (39), 306 (100). *Accurate Mass* calcd. for $C_{22}H_{25}NO_4$: 367.1783; found: 367.1771.

*B. From **41***

The general procedure of Wender and Lechleiter (12) was followed. Ozonized oxygen was bubbled through a solution of **41** (95 mg, 0.26 mmol) and sodium acetate (0.04 mg) in water (0.25 mL) and methanol (5 mL) at −78°C. After the appearance of a persistent blue color the excess ozone was displaced by oxygen followed by nitrogen. Dimethyl sulfide (1 mL) was added and the solution was allowed to warm to room temperature and stand for 5 h. The solvent was removed *in vacuo*. Ether (20 mL) was added and the solution was washed with brine (2 × 10 mL). The ethereal solution was dried and concentrated to yield **44** (80 mg, 83%) as a colorless oil; its ^{1}H nmr spectrum was identical to that of the product from **42**.

*1-Methyl-3-phenyl-3-(2-pivaloylamidophenyl)-2-pyrrolidinone (**45**)*

The general procedure of Martin *et al.* (14) was followed. Ozonized oxygen was passed through a solution of olefin **41** (0.153 g, 0.42 mmol) in dichloromethane (5 mL) at −78°C. After the appearance of a persistent blue color the excess ozone was displaced by oxygen followed by nitrogen.The reaction mixture was allowed to warm to room temperature and the solvent was removed. The residue was dissolved in dry *tert*-butyl alcohol and the solution was treated with sodium cyanoborohydride (0.42 mmol) and stirred for 20 min. Methylamine hydrochloride (0.106 g, 0.84 mmol) was added and the reaction mixture was stirred for 35 h at room temperature. Hydrochloric acid (1 *N*; 10 mL) was added and *tert*-butyl alcohol was removed. Water (10 mL) was added to the residue and the aqueous solution was extracted with dichloromethane (2 × 15 mL). The aqueous solution was basified with powdered KOH and extracted with dichloromethane (2 × 10 mL). The combined organic extracts were dried and concentrated to give **45** (40 mg, 20%) as an oil; ir λ_{max}: 3.00, 5.97 μm; ^{1}H nmr δ: 0.87 (s, 9H), 2.05−2.60 (m, 2H), 2.95 (s, 3H), 3.4−3.7 (m, 2H), 6.9−7.6 (m, 8H), 7.85 (m, 1H), 9.8 (br s, 1H); ^{13}C nmr δ: 27.3, 30.8, 37.4, 39.3, 47.2, 57.9, 124.2, 126.1, 126.6, 126.7, 127.4, 128.3, 128.6, 129.8, 138.2, 146.8, 176.1, 176.5; *m/e*: 350 (35), 293 (100). *Accurate Mass* calcd. for $C_{22}H_{26}N_2O_2$: 350.1994; found: 350.2003.

Synthesis of piperazine-2,5-diones related to bicyclomycin: 3-acetoxy-1,4-dibenzyl-3-[1-(2-methoxyethyl)- and 1-(2-hydroxyethyl)ethenyl]piperazine-2,5-dione. 1. Route via acyclic intermediates[1]

PETER YATES AND JOHN HAROLD HOARE
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received September 10, 1982

PETER YATES and JOHN HAROLD HOARE. Can. J. Chem. **61**, 519 (1983).

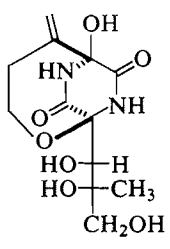
3-Acetoxy-1,4-dibenzyl-3-[1-(2-methoxyethyl)ethenyl]piperazine-2,5-dione (**32**) and its 2-hydroxyethyl analogue (**46**), which possess several of the structural features of the antibiotic bicyclomycin, have been synthesized by a route involving construction of the piperazine-2,5-dione ring at a late stage in the reaction sequence. Treatment of ethyl 3-(2-methoxyethyl)-3-methylglycidate with acetic anhydride and sulfuric acid gives ethyl 2-acetoxy-3-(2-methoxyethyl)-3-butenoate (**10**), which is converted to the corresponding carboxylic acid by ethanolysis, hydrolysis, and reacetylation. This, on conversion to its acid chloride and reaction with *N,N'*-dibenzylglycinamide, gives 2-acetoxy-*N*-benzyl-*N*-(2-benzylamino-2-oxoethyl)-3-(2methoxyethyl)-3-butenamide (**21**). Compound **21**, on hydrolysis and oxidation, gives the corresponding 2-oxo compound, which on treatment with magnesium isopropylcyclohexylamide followed by acetylation yields **32**. Demethylation of **21** with alkylthiotrimethylsilanes gives the corresponding 2-hydroxyethyl compound, whose tetrahydropyranyl ether on subjection to the above reaction sequence gives the 2-(tetrahydropyran-2-yloxy)ethyl analogue of **32**. This, on hydrolysis, gives a 3:1 mixture of compound **46** and a spiro compound formed by displacement of the acetoxyl group by the hydroxyl oxygen atom of **46**.

PETER YATES et JOHN HAROLD HOARE. Can. J. Chem. **61**, 519 (1983).

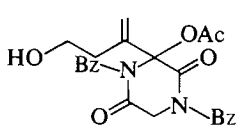
On a synthétisé l'acétoxy-3 dibenzyl-1,4 [(méthoxy-2 éthyl)-1 éthenyl]-3 pipérazinedione-2,5 (**32**) et son analogue hydroxy-2 éthyle (**46**) qui possède plusieurs caractéristiques structurales de l'antibiotique bicyclomycine. On a réalisé cette synthèse selon une méthode qui fait intervenir l'élaboration du cycle pipérazinedione-2,5 lors de la dernière étape d'une série de réactions. Le (méthoxy-2 éthyl)-3 méthyl-3 glycidate d'éthyle réagit avec l'anhydride acétique et l'acide sulfurique en donnant l'acétoxy-2 (méthoxy-2 éthyl)-3 butène-3 oate d'éthyle (**10**) que l'on transforme en acide carboxylique par une éthanolyse, suivie d'une hydrolyse et d'une réacétylation. L'acide transformé en son chlorure, réagit avec la *N,N'*-dibenzylglycinamide en donnant l'acétoxy-2 *N*-benzyl *N*-(benzylamino-2 oxo-2 éthyl)(méthoxy-2 éthyl)-3 butène-3 amide (**21**). Le composé **21**, par hydrolyse suivie d'une oxydation, donne le composé oxo correspondant qui, par une réaction avec l'isopropylcyclohexylamide de magnésium suivie d'une acétylation, conduit au dérivé **32**. La déméthylation du composé **21**, par les alkylthiotriméthylsilanes, donne le composé hydroxy-2 éthyle correspondant dont l'éther tétrahydropyrannyle, soumis à la même série de réactions décrite plus haut, conduit à l'analogue (tétrahydropyrannyl)-2 oxy)-2 éthyle du composé **32**. Ce dernier soumis à une hydrolyse donne un mélange 3:1 du composé **46** et d'un composé spiro formé par déplacement du groupe acétoxyle par l'atome d'oxygène du groupe hydroxyle du composé **46**.

[Traduit par le journal]

Bicyclomycin, an antibiotic produced by *Streptomyces sapporoensis* and *S. aizuensis* (2), is a member of the large class of naturally occurring piperazine-2,5-diones with the unusual structure **1** (3, 4). It has been found to be active against Gram-negative bacteria and does not cause cross resistance to the usual antibiotics; it has also been found to stimulate the growth of chickens and swine (5). There have been several recent synthetic approaches to bicyclomycin of considerable interest (4, 6–10). We have undertaken the synthesis of the 3-acetoxypiperazine-2,5-dione derivative **2** (Bz = benzyl), which we anticipated might serve as a structural prototype for closure to the bicyclic ring system of bicyclomycin. Although



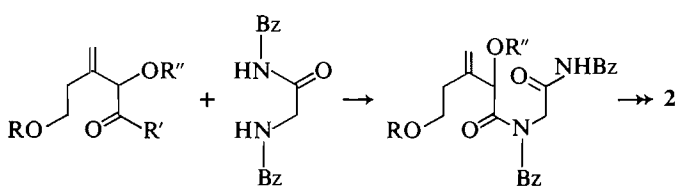
1



2

2 lacks the trihydroxyisobutyl side chain of **1**, the work of Nakatsuka *et al.* (7) gives promise that this can be introduced at a later stage.

Two general types of synthetic strategy were envisioned for the construction of **2**: (*i*) *route via acyclic intermediates*: construction of an intermediate of type **3**, reaction of this with *N,N'*-dibenzylglycinamide (**4**) to form a diamide **5**, and closure



3 **4** **5**

SCHEME 1

to the piperazine-2,5-dione ring at a late stage in the synthetic sequence (Scheme 1), and (*ii*) *route via cyclic intermediates*: construction of the piperazine-2,5-dione ring at an early stage of the synthesis in the form of a 3-alkylidene derivative of type **6**, conversion to an epoxide of type **7**, and manipulation of this to introduce the desired functionality (Scheme 2). We report here on the successful application of the first approach.

[1]For a preliminary account of part of this work, see ref. 1.

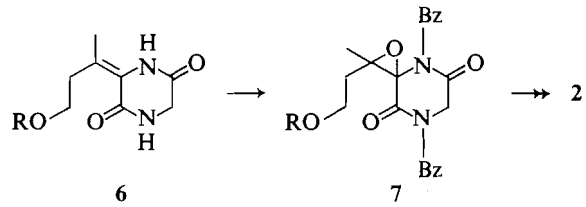
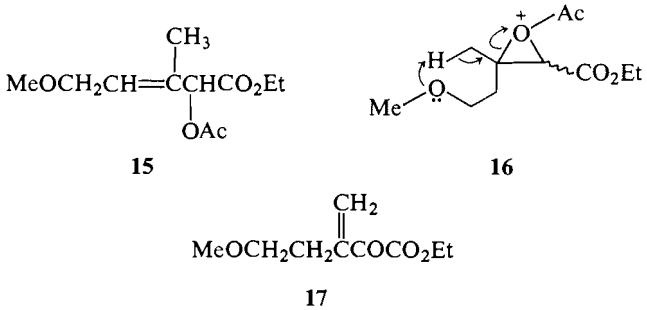
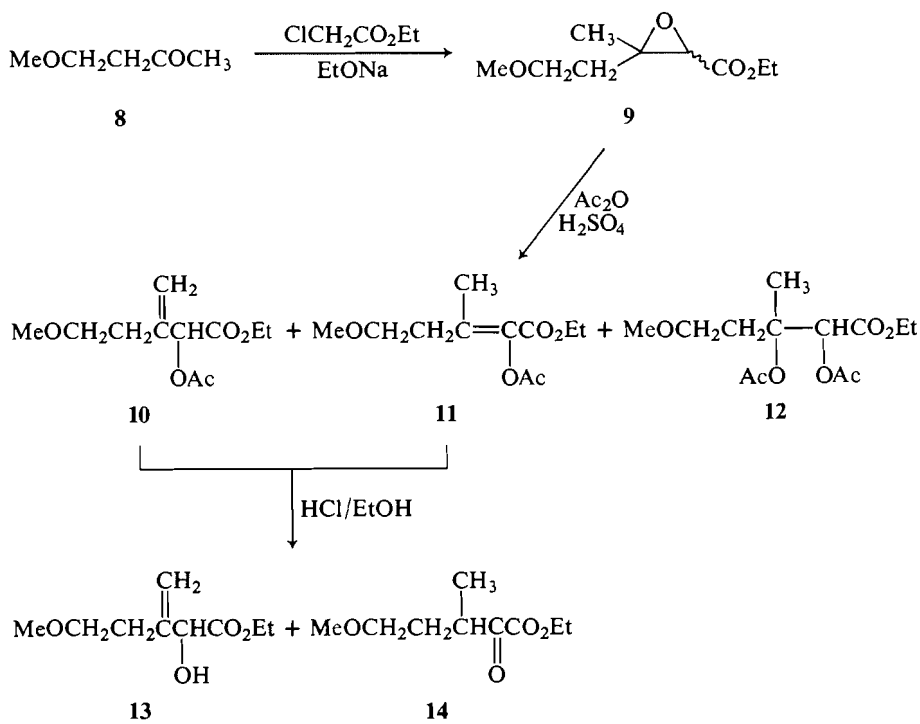


SCHEME 2

We commenced our preparation of compounds of type **3** with the synthesis of ethyl 2-hydroxy-3-(2-methoxyethyl)-3-butanoate (**13**) by the route shown in Scheme 3, based on an earlier synthesis of 2-hydroxy-3-methyl-3-butenoate by Vogel and Schinz (11). 4-Methoxy-2-butanone (**8**), prepared by addition of methanol to methyl vinyl ketone (12), was subjected to a Darzens reaction with ethyl chloroacetate and sodium ethoxide by the general procedure of Burness (13) to give the glycidic ester **9** as a mixture of *E* and *Z* isomers.[2] Treatment of **9** with acetic anhydride and sulfuric acid gave a mixture of the acetates **10**, **11**, and **12** from which the monoacetates **10** and **11** could readily be separated by distillation. The ^{1}H nmr spectrum of the mixture of monoacetates showed that very little of the acetate **15** was formed in the epoxide ring opening reaction; we attribute the regioselectivity of this reaction to the participation of the methoxyl group in the removal of a proton from the *C*-methyl group via a six-membered transition state (cf. **16**). Although it was possible in the ethyl 3,3-dimethylglycidate series (11) to convert the diacetate corresponding to **12** to the monoacetate corresponding to **10** by pyrolysis, this was not found to be possible in the case of the diacetate **12**. The mixture of monoacetates **10** and **11** was ethanolized with ethanolic hydrogen chloride giving a mixture of the unsaturated hydroxy ester **13** and the keto ester **14**, from which the latter could be removed by Girard's reagent T to give the desired compound **13**.



Although the secondary alcohol group of **13** would have at some stage to be oxidized to a ketonic group for the formation of **2**, we decided to convert **13** first to an amide, as indicated in Scheme 1. This was because we anticipated that oxidation of **13** to **17** might lead to complications in forming the amide bond both because of Michael-type addition to the α,β-unsaturated ketone system and the previously observed formation of pyrrolidones in reactions of pyruvic esters with amines (15). The hydroxy ester **13** was hydrolyzed with aqueous sodium hydroxide at room temperature to the hydroxy acid **18**, which was acetylated to give the acetoxy acid **19**, which was in turn converted to its acid chloride **20**. This was added to two equivalents of *N*,*N*′-dibenzylglycinamide (**4**), prepared by treatment



SCHEME 3

[2]In preliminary work we carried out model studies with ethyl 3,3-dimethylglycidate. This was initially prepared by the Darzens reaction of acetone with ethyl chloroacetate and potassium *tert*-butoxide (14); however, we found that under these conditions a mixture of the ethyl and *tert*-butyl esters of the glycidic acid was formed. This problem was avoided by the use of sodium ethoxide.

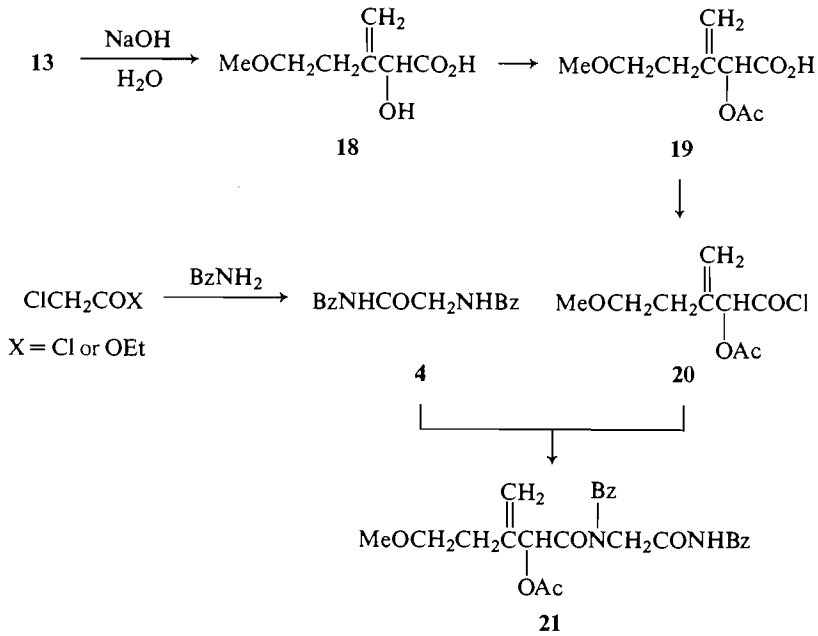
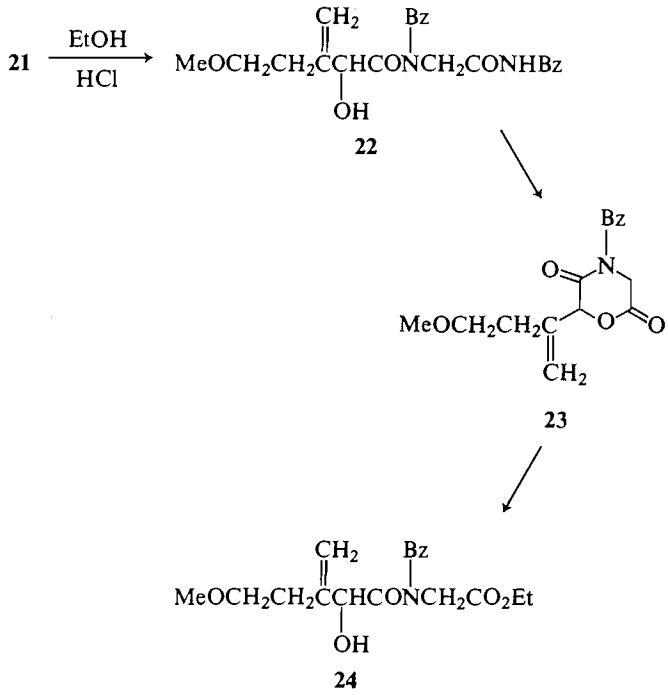


SCHEME 4

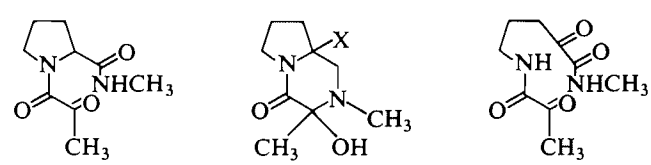


SCHEME 5

of benzylamine with chloroacetyl chloride or ethyl chloroacetate (16), giving the desired diamide **21** and the hydrochloride salt of **4** (Scheme 4). Rotational isomerism about one of the amide carbon–nitrogen bonds in **21** led to doubling of some of the signals in its ^{1}H nmr spectrum: the acetyl protons gave rise to two singlets at δ 2.17 and 2.23 ppm and the acetoxy methine proton to two singlets at δ 5.53 and 5.82 ppm.[3] Such effects of rotational isomerism together with effects due to the diastereotopic nature of the benzylic proton served to complicate the ^{1}H nmr spectra of many of the compounds related to **21** prepared in the present work.

It was now necessary to remove the acetyl group so that oxidation of the secondary alcohol to a ketonic group could be effected. An initial attempt to remove the acetyl group by treatment of **21** with ethanolic hydrogen chloride gave the ester **24**. This unusually facile amide cleavage is considered to involve the initial formation of the desired alcohol **22**, which by intramolecular displacement of benzylamine is converted to the lactone **23**, which in turn is ethanolyzed to **24** (Scheme 5). This complication was avoided by hydrolysis of **21** under basic conditions; reaction with sodium hydroxide in ethanol gave the alcohol **22** (Scheme 6). This was then oxidized with activated manganese dioxide to the ketone **25** whose formation was readily detected by ^{1}H nmr spectroscopy, in that its vinylic proton signals (δ 6.12 and 6.30 ppm) were shifted appreciably downfield relative to those of **21** (δ 5.17 ppm) and its precursors as a result of conjugation of the ethylenic double bond and the ketonic group.

The stage was now set for the closure of **25** to the corresponding piperazine-2,5-dione. It has previously been observed that oxo diamides such as **26** close spontaneously to piperazine-2,5-dione of type **27** and that the more entropically disfavored closure of the dioxo diamide **28** to the piperazinedione **29** could be effected by acid catalysis (17). However, attempts to bring about the closure of **25** at room or elevated



temperatures or under a variety of acidic conditions were unsuccessful. Treatment of **25** in benzene with lithium, sodium, or potassium hydride gave homogeneous reaction mixtures which gave only polymeric material on work-up. Success was

[3]Although each amide group may give rise to rotational isomers, it seems probable that the effects on the signals referred to originate from isomerism at the internal amide group.

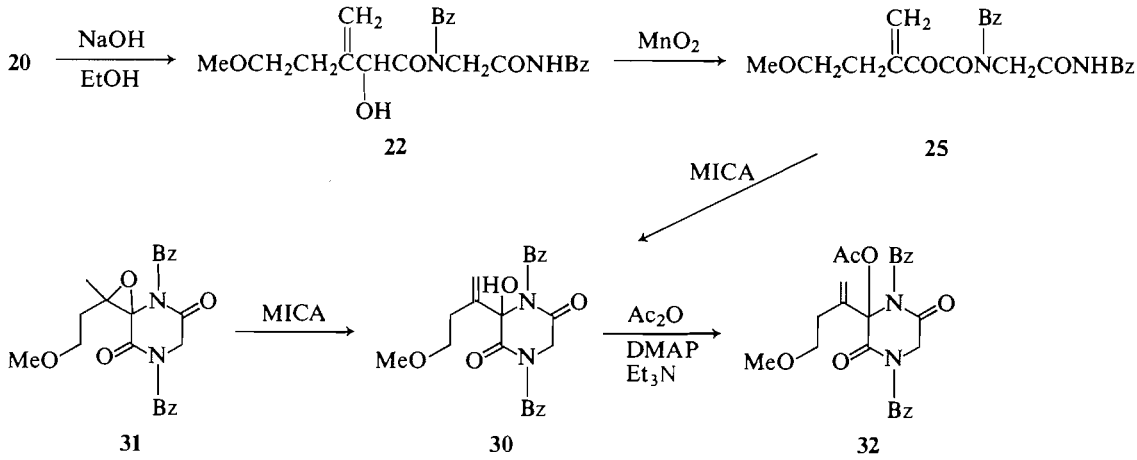
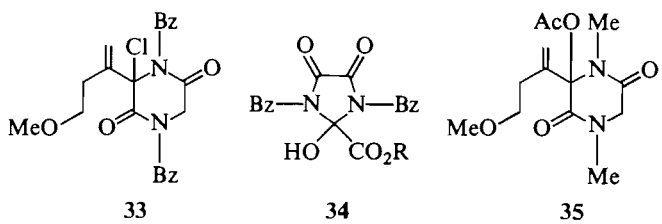


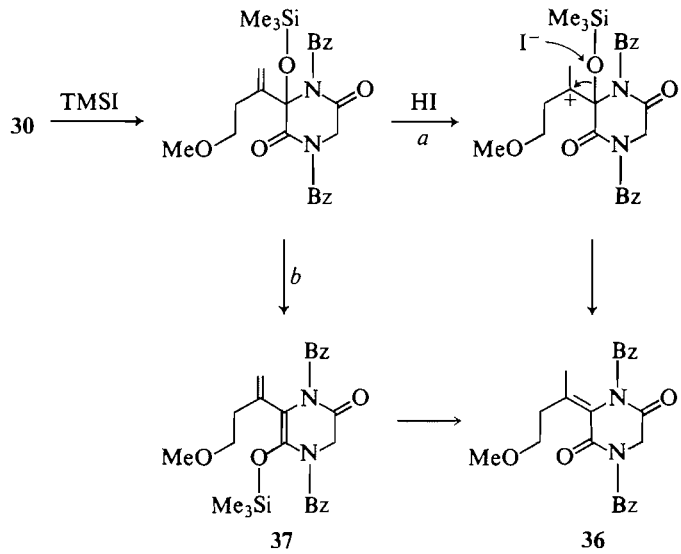
SCHEME 6

finally achieved by the use of magnesium isopropylcyclohexylamide (MICA), a reagent introduced by Corey *et al.* (18) for the conversion of epoxides to allylic alcohols, whose use for the present purpose was suggested to us by its successful application in the conversion of the epoxide **31** to **30** in our work on the synthesis of the latter via cyclic intermediates (19).

Since we had observed that the piperazine-2,5-dione **30** reverted in part to the acyclic precursor **25** on chromatography on silica (19), we decided to acetylate the hydroxyl group in order to prevent ring opening. Treatment with acetyl chloride gave a product that is considered to be the chloride **33** since it showed neither hydroxyl nor acetoxyl bands in its ir spectrum; attempted crystallization of **33** from aqueous acetone gave a mixture of **25** and **30**. Successful acetylation of **30** was accomplished with acetic anhydride and pyridine, or better with acetic anhydride, 4-(dimethylamino)pyridine (DMAP) and triethylamine (20), to give **32** (Scheme 6). Although the ir spectrum of **32** shows a normal acetoxyl band at 5.76 μm, the acetoxyl protons give rise to an abnormally high field signal in the ^{1}H nmr spectrum of **32** at δ 1.30 ppm. This is considered



to be due to shielding resulting from "folding over" of a benzyl group; such an effect has been observed before in the spectra of some 3-benzylpiperazine-2,5-diones (21) and we have observed an analogous effect in the case of the alkoxyl protons of a series of *N,N'*-dibenzyl-4,5-dioxoimidazoline-2-carboxylic acid esters (**34**) (22). In order to confirm that the very unusual position of the acetoxyl signal of **32** was due to shielding by a benzyl group (and not to a structural misassignment!), we synthesized **35**, the *N,N*-dimethyl analogue of **32**, by a route entirely analogous to that used for the synthesis of **32**. The ^{1}H nmr spectrum of **35** showed a normal acetoxyl proton signal at δ 2.15 ppm, confirming that the abnormal position of this signal in the spectrum of **32** is due to the presence of the benzyl groups. The ^{1}H nmr spectra of **35** and its precursors were simpler than those of **32** and its precursors because of the



SCHEME 7

absence of diastereotopic benzylic methylene proton signals, and served further to corroborate the structural assignments.

The eventual synthesis of the bicyclic system of bicyclomycin (**1**) will require bond formation between the oxygen atom of the methoxyl group in **32** and C-6 of the piperazinedione ring. Such bond formation would be expected to occur more readily if the oxygen atom were part of a hydroxyl rather than a methoxyl group. We therefore undertook the synthesis of the hydroxy analogue of **32**.

We initially attempted to prepare this from **32** by treatment with trimethylsilyl iodide (TMSI) (23). This gave none of the desired product. Since we suspected that the lability of the acetoxyl group of **32** was responsible (cf. the formation of **33** from **30** and acetyl chloride), we investigated the reaction of **30** with two equivalents of TMSI in an attempt both to silylate the hydroxyl group and cleave the methyl ether. Surprisingly, the product obtained was the (*E*)-alkylidenepiperazinedione **36** (19). One possible mechanism for this reaction is depicted by path *a* in Scheme 7. A related reaction has been reported in which TMSI reduces α-hydroxy ketones to the corresponding ketones (24); a mechanism analogous to one proposed for this reaction (path *b* in Scheme 7) would lead to **37**, which could be converted to **36** upon acidic work-up.

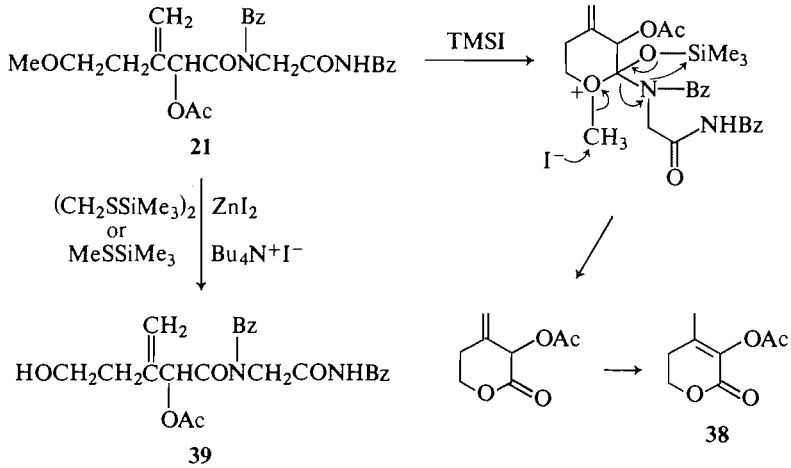
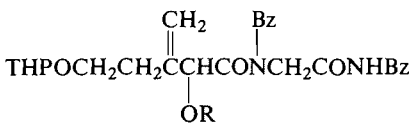
For personal use only.



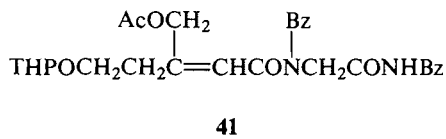
SCHEME 8

In view of these difficulties we decided to remove the *O*-methyl group at an earlier stage in the synthetic sequence. Treatment of **21** with TMSI or with TMSI generated *in situ* from trimethylsilyl chloride and sodium iodide (25) gave the *O*-acetyl derivative of 5,6-dihydro-3-hydroxy-4-methyl-2*H*-pyran-2-one (26), which could arise by the route shown in Scheme 8. Hydriodic acid generated *in situ* from *p*-toluenesulfonic acid and sodium iodide (27) failed to react with **21**. Treatment of **21** with aluminum trichloride and ethanethiol (28) gave sulfur-containing products in which the acetoxyl group had been lost. We finally investigated the use of the procedures recently introduced by Hanessian and Guindon for the cleavage of methyl ethers with thiotrimethylsilanes, zinc iodide, and tetrabutylammonium iodide (29). Compound **21** was resistant to phenylthiotrimethylsilane but was demethylated, albeit in low yield, by the use of the more reactive 1,2-ethanedithiobis(trimethylsilane) or methylthiotrimethylsilane to give the desired alcohol **39** (Scheme 8). Its formation was indicated by the appearance of a band at 2.95 μm in the ir spectrum of **39** and the absence of a methoxyl proton signal in its ^{1}H nmr spectrum.

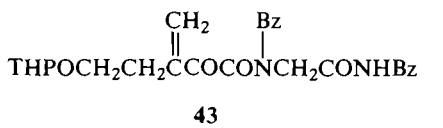
The alcohol **39** was converted to its tetrahydropyranyl derivative **40** by reaction with 2-(*tert*-butoxy)tetrahydropyran and hydrochloric acid in methylene chloride (30),[4] which was converted to the piperazine-2,5-dione **44** via the intermediates **42** and **43** by the same sequence of reactions that had been used in the conversion of the methyl ether **20** to the piperazine-2,5-dione **30**. Attempted acetylation of **44** suffered from extensive ring opening. However, it was found that the magnesium alk-



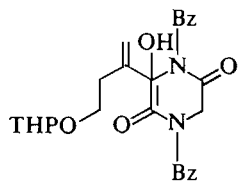
40, R = Ac
42, R = H



41



43



44

oxide formed as an intermediate in the cyclization of **43** to **44** with MICA could be acetylated directly with acetic anhydride to give the acetoxypiperazinedione **45**. The tetrahydropyranyl group of **45** was removed with acetic acid in aqueous tetrahydrofuran by the general procedure of Grieco *et al.* (31) to give a 3:1 mixture of the target compound **46** and the spiro compound **47** (Scheme 9), which were separated by chromatography. The ir spectrum of **46** showed a hydroxyl-stretching band at 2.90 μm and its ^{1}H nmr spectrum showed the absence of the multiplet at δ 1.6 ppm characteristic of the tetrahydropyranyl group. The spiro compound **47** showed only amide bands at 5.97 μm in the carbonyl-stretching region of its ir spectrum; in its ^{1}H nmr spectrum the vicinal methylene protons no longer gave rise to simple triplet signals as they did in the spectrum of **46** but gave rise to complex multiplets as a result of ring formation.

The acid-catalyzed conversion of **46** to **47** finds precedent in the chemistry of bicyclomycin (1) itself, which has been found (4) to undergo acid-catalyzed rearrangement to the diastereomeric spiro compounds **48** and **49** (Scheme 10).

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Unless otherwise specified, the ir spectra were recorded for $CHCl_3$ solutions and the ^{1}H and ^{13}C nmr spectra for $CDCl_3$ solutions. Mass spectra were recorded at 70 eV and peak positions (m/e) are followed by relative abundances in parentheses. Chromatographic separations were carried out by liquid column chromatography except where otherwise indicated. All R_f values were

[4]A minor product formed in this reaction is considered to be **41**, formed by allylic rearrangement.

determined on analytical thin-layer chromatographic silica gel plates. Preparative thin-layer chromatography was carried out on 20 × 20 × 1-mm or 20 × 20 × 2-mm silica gel plates containing a fluorescent indicator. The bands were extracted with methanol and the residue obtained after filtration and evaporation was triturated with chloroform or dichloromethane; filtration and evaporation yielded the product; iodine or uv visualization was employed. Apparatus for the experiments that were carried out under nitrogen was flame dried immediately prior to use under a dry nitrogen flow. All organic extracts were dried over anhydrous $MgSO_4$ and evaporated by means of a rotary evaporator at water aspirator pressure.

Ethyl 3,3-dimethylglycidate

When a Darzens reaction was performed on acetone and ethyl chloroacetate with potassium *tert*-butoxide as base (14) a 1:1 mixture of ethyl and *tert*-butyl glycidates was obtained.

The procedure of Burness (13) was therefore used. Sodium ethoxide was prepared from sodium (3.61 g, 0.157 mol) and ethanol; removal of the ethanol *in vacuo* gave a solid (22.30 g) which was found to contain ~48% by weight sodium ethoxide by titration with potassium hydrogen phthalate. This solid was added portionwise with mechanical stirring to acetone (9.10 g, 0.157 mol), ethyl chloroacetate (28.85 g, 0.235 mol), and ether (125 mL) cooled to −10°C in an ice–salt bath under nitrogen. The temperature was kept below −5°C during addition of base. The mixture was then stirred in the ice–salt bath for 2 h; the ice–salt bath was removed and stirring was continued overnight at room temperature. A solution of acetic acid (2 mL) in water (48 mL) was added and the ether layer was separated. The aqueous layer was washed with ether (3 × 25 mL). The combined ether phases were dried, filtered, concentrated, and distilled at 88°C (20 Torr) to give 14.9 g (66%) of ethyl 3,3-dimethylglycidate; ir λ_{max}: 5.77 μm; ^{1}H nmr δ: 4.17 (q, J = 7 Hz, 2H), 3.25 (s, 1H), 1.38 (s, 3H), 1.35 (s, 3H), 1.27 (t, J = 7 Hz, 3H).

Reaction of ethyl 3,3-dimethylglycidate with acetic acid anhydride. Formation of ethyl 2-acetoxy-3-methyl-3-butenoate, ethyl 2-acetoxy-3-methyl-2-butenoate, and ethyl 2,3-diacetoxy-3-methylbutanoate

The procedure of Vogel and Schinz (11) was followed. Ethyl 3,3-dimethylglycidate (14.32 g, 99.5 mmol) was stirred at room temperature in freshly distilled acetic anhydride (13.4 mL). Concentrated H_2SO_4 (0.5 mL) was added with stirring and the mixture became hot. The solution was cooled on ice and after 10 min another 0.25 mL of concentrated H_2SO_4 was added. The mixture was stirred for 1 h at room temperature and 30 min at 100°C. The cooled mixture was dissolved in ether (50 mL) and the solution was washed with water (10 mL) and aqueous 10% $NaHCO_3$ (10 mL). The ether phase was dried, filtered, and concentrated. The residue was fractionally distilled. Ethyl 2-acetoxy-3-methyl-2-butenoate and ethyl 2-acetoxy-3-methyl-3-butenoate distilled at 90–95°C (10 Torr) and the diacetate, ethyl 2,3-diacetoxy-3-methylbutanoate, distilled at 98–103°C (10 Torr). The diacetate (ir λ_{max}: 5.76 μm; ^{1}H nmr δ: 5.40 (s), 4.33 (q, J = 7 Hz), 1.82 (s), 1.98 (s), 1.58 (s), 1.53 (s), 1.27 (t, J = 7 Hz)) was converted into the monoacetate mixture by pyrolysis with a Bunsen burner flame. The combined monoacetate mixture was redistilled at 95°C (10 Torr) to give ~10 g (59%) of ethyl 2-acetoxy-3-methyl-2-butenoate and ethyl 2-acetoxy-3-methyl-3-butenoate; ir λ_{max}: 5.75 μm; ^{1}H nmr δ: 5.32 (s), 5.0–5.2 (m), 4.17 (q, J = 7 Hz), 2.10 (s), 1.78 (s), 1.25 (t, J = 7 Hz).

Ethyl 2-hydroxy-3-methyl-3-butenoate

A solution of the mixture of ethyl 2-acetoxy-3-methyl-2-butenoate and ethyl 2-acetoxy-3-methyl-3-butenoate (7.11 g) in 4% HCl in ethanol (14 mL) was boiled under reflux for 1.5 h. After cooling, solid $NaHCO_3$ was added to neutralize the solution which was then filtered, concentrated, and distilled at 71–74°C (12 Torr) to give a quantitative yield of the ethanolyzed material. This mixture (4.56 g), methanol (20 mL), acetic acid (2.1 mL), and Girard reagent T (2.0 g) were boiled under reflux for 0.5 h. The cooled solution was dissolved in methylene chloride (50 mL) and the solution was washed with water (10 mL). The aqueous phase was washed several times with methylene chloride. The combined methylene chloride phases were dried, filtered, and concentrated. The residue was distilled at 68–69°C (10 Torr) to give ethyl 2-hydroxy-3-methyl-3-butenoate (3.53 g, 70%); ir λ_{max}: 2.98, 5.78 μm; ^{1}H nmr δ: 4.8–5.1 (m, 2H), 4.48 (s, 1H), 4.18 (q, J = 7 Hz, 2H), 3.28 (s, 1H), 1.73 (m, 3H)0, 1.27 (t, J = 7 Hz, 3H).

Ethyl 3-(2-methoxyethyl)-3-methylglycidate (9)

4-Methoxy-2-butanone (**8**) was prepared in 60% yield by addition of methanol to methyl vinyl ketone (12).

Ketone **8** (50.7 g, 0.497 mol) was subjected to a Darzens reaction with ethyl chloroacetate (97.3 g, 0.794 mol) and sodium ethoxide (48% by weight NaOEt; 70.7 g, 0.499 mol) in ether (425 mL) in analogous fashion to the preparation of ethyl 3,3-dimethylglycidate. Ethyl 3-(2-methoxyethyl)-3-methylglycidate (**9**) was obtained as a mixture of *cis* and *trans* isomers, bp 93–98°C (0.35 Torr), in 78% yield; ir λ_{max}: 5.62, 8.95 μm; ^{1}H nmr δ: 4.20 (q, J = 7 Hz, 2H), 3.72 and 3.33 (2 s, 1H), 3.45 (t, J = 6 Hz, 2H), 3.28 and 3.25 (2 s, 3H), 1.90 and 1.87 (2 t, J = 6 Hz, 2H), 1.42 and 1.37 (2 s, 3H), 1.28 (t, J = 7 Hz, 3H); m/e: 188 (0.2), 173 (2), 157 (5), 115 (45), 45 (100). *Anal.* calcd. for $C_9H_{16}O_4$: C 57.43, H 8.57; found: C 57.01, H 8.47.

Ethyl 2-hydroxy-3-(2-methoxyethyl)-3-butenoate (13)

Ethyl 3-(2-methoxyethyl)-3-methylglycidate (**9**) (43.54 g, 0.231 mol) was treated with acetic anhydride (34 mL) by an analogous procedure to that used for the opening of the epoxide ring of ethyl 3,3-dimethylglycidate except that only 15 drops of concentrated H_2SO_4 were used and the mixture was heated on a steam bath for ~8 h. The work-up was the same as before.

Ethyl *cis*- and *trans*-2-acetoxy-5-methoxy-3-methyl-2-pentenoate (**11**) and ethyl 2-acetoxy-3-(2-methoxyethyl)-3-butenoate (**10**) were fractionally distilled at 66–68°C (0.01 Torr) in 45% yield from ethyl 2,3-diacetoxy-5-methoxy-3-methylpentanoate (**12**), which could not be distilled without decomposition. Pyrolysis of the diacetate **12** resulted in decomposition with loss of methanol.

A solution of monoacetate mixture **10** and **11** (32.60 g, 0.142 mol) in 4% HCl in ethanol was boiled under reflux for 1.5 h and worked up in analogous fashion to the work-up of ethyl 2-hydroxy-3-methyl-3-butenoate. A quantitative yield of crude ethanolyzed mixture was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

obtained. A solution of this mixture (30.75 g, 0.163 mol) and Girard's reagent T (20.0 g, 0.119 mol) in methanol (115 mL) and acetic acid (13 mL) was boiled under reflux for 0.5 h and worked up as before. The residue was distilled at 55–65°C (0.005 Torr) to give **13** in 65% yield; ir λ_{max}: 2.90, 5.76 μm; ^{1}H nmr δ: 5.13 (s, 1H), 4.98 (m, 1H), 4.62 (br s, 1H), 4.25 (q, J = 7 Hz, 2H), 3.82 (br s, 1H), 3.46 (t, J = 6 Hz, 2H), 3.37 (s, 3H), 2.33 (t, J = 6 Hz, 2H), 1.28 (t, J = 7 Hz, 3H); *m/e*: 189 (2), 188 (0.3), 171 (3), 156 (11), 115 (27), 83 (100). *Accurate Mass* calcd. for $C_9H_{16}O_4$: 188.1049; found: 188.1057.

*2-Acetoxy-3-(2-methoxyethyl)-3-butenoyl chloride (**20**)*

Ethyl 2-hydroxy-3-(2-methoxyethyl)-3-butenoate (**13**) (35.45 g, 0.188 mol) in aqueous 25% NaOH (125 mL) was stirred for 4 days at room temperature. The basic solution assumed a dark red-brown color during this time. It was then cooled in an ice bath and acidified with concentrated hydrochloric acid. The light yellow aqueous solution was saturated with sodium chloride and the resulting solution was extracted several times with methylene chloride. The combined methylene chloride phases were dried, filtered, and concentrated giving a quantitative yield of crude 2-hydroxy-3-(2-methoxyethyl)-3-butenoic acid (**18**) as a viscous yellow syrup; ir λ_{max}: 3–4, 5.64, 5.81 μm; ^{1}H nmr δ: 7.67 (bs, 2H), 5.23 (s, 1H), 5.07 (br s, 1H), 4.60 (s, 1H), 3.52 (t, J = 7 Hz, 2H), 3.32 (s, 3H), 2.35 (t, J = 6 Hz, 2H).

Compound **18** (10.0 g, 62 mmol) was dissolved in methylene chloride (50 mL) and acetyl chloride (7.35 mL, 104 mmol) was added. The mixture was stirred at room temperature for 12 h and concentrated. The residue was dissolved in saturated aqueous $NaHCO_3$ with stirring. This solution was acidified with 3 *N* hydrochloric acid and extracted several times with methylene chloride. The combined methylene chloride phases were dried, filtered, and concentrated giving 10.1 g (80%) of 2-acetoxy-3-(2-methoxyethyl)-3-butenoic acid (**19**) as a viscous syrup; ir λ_{max}: 5.79 μm; ^{1}H nmr δ: 10.32 (s, 1H), 5.40 (s, 1H), 5.31 (s, 1H), 5.15 (br s, 1H), 3.57 (t, J = 6 Hz, 2H), 3.32 (s, 3H), 2.43 (t, J = 6 Hz, 2H), 2.13 (s, 3H).

A solution of **19** (456 mg, 2.40 mmol) and oxalyl chloride (1.42 mL, 16.5 mmol) in methylene chloride (5 mL) was stirred at room temperature for 12 h. The reaction mixture was concentrated under high vacuum and the residue was distilled at 54°C (0.015 Torr) giving 2-acetoxy-3-(2-methoxyethyl)-3-butenoyl chloride (**20**) (318 mg, 60%) as a clear, colorless liquid; ir λ_{max}: 5.60, 5.74 μm; ^{1}H nmr δ: 5.55 (s, 1H), 5.38 (s, 1H), 5.30 (m, 1H), 3.57 (t, J = 6 Hz, 2H), 3.35 (s, 3H), 2.45 (t, J = 6 Hz, 2H), 2.20 (s, 3H).

*2-Acetoxy-N-benzyl-N-(2-benzylamino-2-oxoethyl)-3-(2-methoxyethyl)-3-butenamide (**21**)*

Acid chloride **20** (2.38 g, 10.8 mmol) in methylene chloride (50 mL) was stirred at room temperature while *N*,*N*′-dibenzylglycinamide (**4**) (16) (5.47 g, 21.5 mmol) in methylene chloride (10 mL) was added dropwise. After addition was complete, the mixture was stirred for 20 min. The *N*,*N*′-dibenzylglycinamide hydrochloride that had formed was filtered. The filtrate was washed with aqueous 10% $NaHCO_3$ (10 mL), aqueous 6 *N* hydrochloric acid (10 mL), and water (20 mL). The methylene chloride solution was dried, filtered, and concentrated to give a quantitative yield of 2-acetoxy-*N*-benzyl-*N*-(2-benzylamino-2-oxoethyl)-3-(2-methoxyethyl)-3-butenamide (**21**) as a pale yellow gum which resisted crystallization; ir λ_{max}: 2.99, 5.69, 5.95 μm; ^{1}H nmr δ: 7.17 (m, 11H), 5.82 (s, 0.5H), 5.53 (s, 0.5H), 5.0–5.3 (m, 2H), 3.7–4.8 (m, 6H), 3.42 (t, J = 6 Hz, 2H), 3.15 (s, 3H), 2.37 (t, J = 6 Hz, 2H), 2.33 (s, 1.5H), 2.17 (s, 1.5H); ^{13}C nmr δ: 171.4 (s), 171.0 (s), 168.9 (s), 168.0 (s), 167.4 (s), 139.6 (s), 139.5 (s), 138.2 (s), 136.0 (s), 135.3 (s), 127.2–128.9 (d), 119.2 (t), 119.1 (s), 74.6 (d), 71.3 (t), 71.2 (t), 58.5 (q), 52.1 (t), 50.3 (t), 49.4 (t), 43.4 (t), 43.3 (t), 32.9 (t), 20.6 (q); *m/e*: 438 (2), 379 (12), 91 (100). *Accurate Mass* calcd. for $C_{25}H_{30}N_2O_5$: 438.2155; found: 438.2215.

*N-Benzyl-N-(2-benzylamino-2-oxoethyl)-2-hydroxy-3-(2-methoxyethyl)-3-butenamide (**22**)*

A solution of compound **21** (1.796 g, 4.10 mmol) and NaOH (170 mg, 4.25 mmol) in ethanol (20 mL) was stirred for 8 h at room temperature. The ethanol solution was concentrated and the residue was dissolved in methylene chloride (20 mL). The solution was washed with water (5 mL), dried, filtered, and concentrated, giving a quantitative yield of **22** as a clear yellow gum; ir λ_{max}: 3, 5.95, 6.04 μm; ^{1}H nmr δ: 7.13 (m, 11H), 4.8–5.2 (m, 2H), 3.6–4.8 (m, 8H), 3.40 (t, J = 6 Hz, 2H), 3.17 (s, 3H), 2.30 (t, J = 6 Hz, 2H); *m/e*: 396 (1), 379 (2), 288 (4), 257 (6), 106 (31), 91 (100). *Accurate Mass* calcd. for $C_{23}H_{27}N_2O_3$ (M − OH): 379.2022; found: 379.2048.

*N-Benzyl-N-(2-benzylamino-2-oxoethyl)-3-(2-methoxyethyl)-2-oxo-3-butenamide (**25**)*

Compound **22** (4.37 g, 11.0 mmol) and activated manganese dioxide (32) (25 g) in methylene chloride or chloroform (170 mL) was stirred at room temperature for 14 h. The mixture was filtered through Celite and the solid was washed with hot chloroform (3 × 50 mL). The combined filtrates were concentrated leaving a quantitative yield of **25** as a pale yellow gum; ir λ_{max}: 2.98, 5.96, 6.09 μm; ^{1}H nmr δ: 7.17 (m, 11H), 6.30 (s, 1H), 6.12 (s, 1H), 3.6–4.7 (m, 6H), 3.42 (t, J = 6 Hz, 2H), 3.17 (s, 3H), 2.53 (t, J = 6 Hz, 2H); ^{13}C nmr δ: 193.6 (s), 193.4 (s), 168.2 (s), 167.4 (s), 167.1 (s), 142.6 (s), 142.2 (s), 138.0 (t), 137.8 (t), 135.4 (s), 134.6 (s), 134.2 (s), 128.9–126.7 (d), 70.7 (t), 58.4 (q), 52.5 (t), 46.5 (t), 43.4 (t), 29.5 (t); *m/e*: 394 (6), 349 (1), 303 (3), 281 (8), 253 (21), 246 (6), 91 (100). *Accurate Mass* calcd. for $C_{23}H_{26}N_2O_4$: 394.1893; found: 394.1909.

*Cyclization of **25**. Formation of 1,4-dibenzyl-3-hydroxy-3-[1-(2-methoxyethyl)ethenyl]piperazine-2,5-dione (**30**)*

A solution of magnesium isopropylcyclohexylamide (MICA) (18) in dry tetrahydrofuran (15 mL) was prepared from magnesium turnings (35 mg, 1.4 mmol), methyl bromide, and isopropylcyclohexylamine (0.5 mL, 3 mmol). Compound **25** (353 mg, 0.894 mmol) in dry tetrahydrofuran (4 mL) was syringed slowly dropwise into the stirred MICA solution at room temperature over a period of 2.5–3 h. The mixture was stirred for 18 h at room temperature and then cooled in an ice bath. Aqueous 2 *M* KH_2PO_4 (5 mL) was added to the cooled mixture. The acidified mixture was washed with methylene chloride (3 × 15 mL). The combined methylene chloride extracts were washed with water (10 mL), dried, filtered, and concentrated giving crude piperazine-2,5-dione **30** as a pale yellow gum (350 mg); ir λ_{max}: 2.98, 6.02 μm; ^{1}H nmr δ: 7.23 (m, 10H), 5.07 (m, 3H), 4.0–5.0 (m, 6H), 3.43 (t, J = 6 Hz, 2H), 3.30 (s, 3H), 2.33 (m, 2H).

Attempted crystallization of this product from combinations of chloroform, ether, ethyl acetate, and hexanes or cyclohexane was unsuccessful. Attempted crystallization from acetone–water resulted in its reversion to **25**.[5]

*3-Acetoxy-1,4-dibenzyl-3-[1-(2-methoxyethyl)ethenyl]piperazine-2,5-dione (**32**)*

Compound **30** (678 mg, 1.72 mmol) was treated with 4-dimethylaminopyridine (9 mg), acetic anhydride (2 mL), and triethylamine (2 mL) for 4 h at room temperature. The mixture was concentrated *in vacuo* and the residue was dissolved in methylene chloride (15 mL). The solution was washed with 3 *M* hydrochloric acid (5 mL) and water (5 mL), dried, filtered, and concentrated. The residue was chomatographed on silica with 20% ethyl acetate – chloroform as eluent. The product (R_f = 0.6) was eluted and the fraction concentrated to give the acetylated product **32** (359 mg, 48%) as a pale yellow gum which resisted crystallization; ir λ_{max}: 5.76, 5.98 μm; ^{1}H nmr δ: 7.20 (s, 5H), 7.15 (s, 5H), 5.60 (s, 1H), 5.40 (s, 1H), 3.7–5.3 (m, 6H), 3.50 (t, J = 6 Hz, 2H), 3.30 (s, 3H), 2.28 (t, J = 6 Hz, 2H), 1.30 (s, 3H); *m/e*: 436 (6), 393 (3), 378 (30), 113 (29), 91 (100). *Accurate Mass* calcd. for $C_{25}H_{28}N_2O_5$: 436.1998; found: 436.1995.

*3-Acetoxy-3-[1-(2-methoxyethyl)ethenyl]-1,4-dimethylpiperazine-2,5-dione (**35**)*

The following reaction sequence was carried out in analogous fash-

[5]Although neither **30** nor its precursors could be obtained in crystalline form, its spectra corresponded with those of **30** obtained by treatment of **31** with MICA; **31** and several of its precursors have been obtained in crystalline form and characterized by combustion elemental analysis (19).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

ion to the preparation of compound **32** and its precursors.

Acid chloride **19** (1.14 g, 5.17 mmol) in methylene chloride (50 mL) was treated with *N*,*N'*-dimethylglycinamide (33) (1.08 g, 10.6 mmol) in methylene chloride (5 mL) to give 2-acetoxy-3-(2-methoxyethyl)-*N*-methyl-*N*-(2-methylamino-2-oxoethyl)-3-butenamide as a yellow gum (1.32 g, 89%); ir λ_{max}: 2.95, 5.71, 5.93 μm; ^{1}H nmr δ: 7.03 (br s, 0.3H), 6.57 (br s, 0.7H), 5.63 (s, 0.7H), 5.47 (s, 0.3H), 5.27 (m, 2H), 4.12 (s, 1H), 3.92 (s, 1H), 3.53 (t, J = 6 Hz, 2H), 3.33 (s, 3H), 3.11 (s, 2H), 2.98 (s, 1H), 2.80 (s, 2H), 2.73 (s, 1H), 2.43 (t, J = 6 Hz, 2H), 2.17 (s, 3H).

A solution of this product (1.03 g, 3.60 mmol) and sodium hydroxide (174 mg, 4.35 mmol) in ethanol (20 mL) was stirred for 10 h at room temperature to give 2-hydroxy-3-(2-methoxyethyl)-*N*-methyl-*N*-(2-methylamino-2-oxoethyl)-3-butenamide as a water-soluble yellow gum; ir λ_{max}: 3.02, 6.05 μm; ^{1}H nmr δ: 6.28 (br s, 1H), 5.12 (m, 2H), 4.73 (bs, 1H), 3.8–4.5 (m, 3H), 3.48 (t, J = 6 Hz, 2H), 3.28 (s, 3H), 3.00 (s, 3H), 2.74 (d, J = 4 Hz, 3H), 2.30 (t, J = 6 Hz, 2H).

This alcohol (571 mg, 2.34 mmol) and activated manganese dioxide (4.5 g) in methylene chloride (30 mL) were stirred at room temperature for 11 h to give 3-(2-methoxyethyl)-*N*-methyl-*N*-(2-methylamino-2-oxoethyl)-2-oxo-3-butenamide as a pale yellow gum (435 mg, 77%); ir λ_{max}: 3.01, 5.98, 6.02 μm; ^{1}H nmr δ: 6.90 (br s, 1H), 6.30 (m, 2H), 4.05 (m, 2H), 3.50 (t, J = 6 Hz, 2H), 3.30 (s, 3H), 3.00 and 2.93 (2 s, 3H), 2.77 (d, J = 4 Hz, 3H), 2.62 (t, J = Hz, 2H).

A solution of this product (435 mg, 1.80 mmol) in tetrahydrofuran (2 mL) was syringed into a solution of MICA prepared from magnesium turnings (63 mg, 2.6 mmol), methyl bromide, and isopropylcyclohexylamine (0.5 mL), in dry tetrahydrofuran (12 mL). The mixture was stirred overnight at room temperature and treated with 3 *M* hydrochloric acid (5 mL) to give 3-hydroxy-3-[1-(2-methoxyethyl)ethenyl]-1,4-dimethylpiperazine-2,5-dione as a pale yellow gum (403 mg, 93%), which was ether insoluble and resisted crystallization; ir λ_{max}: 6.04 μm; ^{1}H nmr δ: 5.23 (br s, 1H), 5.17 (m, 2H), 3.97 (m, 2H), 3.47 (t, J = 6 Hz, 2H), 3.30 (s, 3H), 2.98 (s, 3H), 2.90 (s, 3H), 2.27 (t, J = 6 Hz, 2H).

The hydroxy piperazinedione (40.3 mg, 1.66 mmol) was acetylated in a solution of acetic anhydride (2 mL), triethylamine (2 mL), and a few crystals of 4-dimethylaminopyridine. The mixture was stirred for 18 h at room temperature to give a gummy residue which was chromatographed on silica with 10% methanol – ethyl acetate as eluent. The product (R_f = 0.5), 3-acetoxy-3-[1-(2-methoxyethyl)ethenyl]-1,4-dimethylpiperazine-2,5-dione (**35**), was a pale yellow gum (311 mg, 66%), which resisted crystallization in a variety of solvents; ir λ_{max}: 5.79, 6.01 μm; ^{1}H nmr δ: 5.57 (s, 1H), 5.27 (m, 1H), 4.03 (s, 2H), 3.48 (t, J = 6 Hz, 2H), 3.32 (s, 3H), 2.92 (s, 3H), 2.75 (s, 3H), 2.27 (t, J = 6 Hz, 2H), 2.15 (s, 3H); *m/e*: 284 (12), 225 (100), 192 (19), 180 (14). *Accurate Mass* calcd. for $C_{13}H_{20}N_2O_5$: 284.1372; found: 284.1346.

*Reaction of **30** with trimethylsilyl iodide. Formation of (E)-1,4-dibenzyl-3-(4-methoxy-2-butylidene)piperazine-2,5-dione (**36**)*

Piperazine-2,5-dione **30** (91 mg, 0.21 mmol) was dissolved in $CHCl_3$ in an nmr tube and trimethylsilyl iodide (TMSI) (66 μL, 0.46 mmol) was added. The solution turned dark red-brown on addition of the TMSI. The reaction was followed by ^{1}H nmr spectroscopy for 19 h at room temperature. The contents of the nmr tube were dissolved in methylene chloride (15 mL) and the solution was washed with saturated aqueous Na_2SO_3 (5 mL), 3 *N* hydrochloric acid (5 mL), aqueous 10% $NaHCO_3$, and water (5 mL). The methylene chloride solution was dried, filtered, and concentrated. The residue was chromatographed on a 1-mm preparative silica gel plate with 20% ethyl acetate – chloroform as eluent. The band (R_f = 0.3) was eluted with methanol–chloroform, and the fraction concentrated, giving a gum (64 mg) whose ^{1}H nmr spectrum was identical with that of (*E*)-1,4-dibenzyl-3-(4-methoxybut-2-ylidene)piperazine-2,5-dione (**36**) (19).

*Reaction of **20** with trimethylsilyl iodide. Formation of 3-acetoxy-5,6-dihydro-4-methyl-2H-pyran-2-one (**38**)*

(*i*) Compound **20** (100 mg, 0.229 mol), TMSI (65 μL, 0.48 mmol), and $NaHCO_3$ (100 mg, 1.19 mmol) in methylene chloride (2 mL) were stirred for 18 h at room temperature. The mixture was washed with saturated aqueous Na_2SO_3 (1 mL), 3 *N* hydrochloric acid (1 mL), aqueous 10% $NaHCO_3$ (1 mL), and water (1 mL), dried, filtered, and concentrated. The residue was chromatographed on a 1-mm preparative silica gel plate with 20% ethyl acetate – chloroform as eluent. The strongly fluorescent band (R_f = 0.46) was eluted with methanol–chloroform giving **38** (26) (30 mg, 77%) as a yellow oil; ir λ_{max}: 5.65, 7.78 μm; ^{1}H nmr δ: 5.20 (t, J = 6 Hz, 2H), 2.53 (t, J = 6 Hz, 2H), 2.25 (s, 3H), 1.88 (s, 3H).

Compound **20** gave the same product on treatment with one equivalent of TMSI.

(*ii*) Reaction of **20** (114 mg, 0.260 mmol) with sodium iodide (83 mg, 0.55 mmol) and trimethylsilyl chloride (66 μL, 0.52 mmol) in acetonitrile (2 mL) for 10 h at room temperature gave a mixture of **38** and unconsumed **20** after work-up as in (*i*).

(*iii*) Reaction of **20** (152 mg, 0.347 mmol) with zinc iodide (761 mg, 2.39 mmol) and TMSI (0.35 mL, 2.46 mmol) in methylene chloride (2 mL) for 5 min at room temperature gave a mixture of **38** and unconsumed **20** after work-up as in (*i*).

*2-Acetoxy-*N*-benzyl-3-(2-hydroxyethyl)-*N*-(2-benzylamino-2-oxoethyl)-3-butenamide (**39**)*

The general procedure of Hanessian and Guindon (29) for the cleavage of methyl ethers with thiotrimethylsilanes in the presence of tetrabutylammonium iodide and zinc iodide was employed.

(*i*) A solution of **21** (185 mg, 0.422 mmol), zinc iodide (purified by washing with carbon tetrachloride; 0.65 g, 2.0 mmol), tetra-*n*-butylammonium iodide (0.47 g, 1.3 mmol), and phenylthiotrimethylsilane (34) (0.72 g, 4.0 mmol) in 1,2-dichloroethane (8 mL) was heated with stirring at 73–75°C for 20 h. Work-up with aqueous 10% $NaHCO_3$ returned only **21**.

(*ii*) A solution of **21** (125 mg, 0.285 mmol), zinc iodide (273 mg, 0.855 mmol), tetra-*n*-butylammonium iodide (167 mg, 0.428 mmol), and 1,2-ethanedithiobis(trimethylsilane) (34) (407 mg, 1.71 mmol) in 1,2-dichloroethane (5 mL) was heated with stirring at 80°C for 13 h. The mixture was cooled, washed with aqueous 10% $NaHCO_3$, dried, filtered, and concentrated. The residue was loaded on a silica gel plug with chloroform. After removal of sulfur-containing compounds by elution with chloroform, the product was eluted with ethyl acetate. Concentration of the ethyl acetate solution gave a 35% yield of **39**.

(*iii*) A similar reaction of **21** with a 2:5:1.5:1 molar ratio of 1,2-ethanedithiobis(trimethylsilane), zinc iodide, tetrabutylammonium iodide, and **21** for 3 h at 75°C gave dihydropyrone **38** and unconsumed **21** after work-up with aqueous 10% $NaHCO_3$.

(*iv*) A solution of **21** (8.27 g, 18.9 mmol), zinc iodide (15.84 g, 49.65 mmol), methylthiotrimethylsilane (12.44 g, 103 mmol), and tetra-*n*-butylammonium iodide (1.22 g, 3.30 mmol) in 1,2-dichloroethane (155 mL) was heated at 80°C for 1.5 h. During this time the solution became yellow. The solution was cooled, washed with 3 *N* hydrochloric acid (50 mL), dried, filtered, and concentrated. The residue was dissolved in chloroform and ether was added slowly to precipitate tetra-*n*-butylammonium iodide as white crystals. The solution was filtered and concentrated and the residue was chromatographed on silica with ethyl acetate as eluent. The first materials eluted were sulfur-containing compounds; **39** was then eluted (R_f = 0.4) and obtained as a viscous yellow gum which assumed a dark green color after being pumped on under high vacuum overnight (3.02 g, 38%); ir λ_{max}: 2.93, 5.74, 5.96 μm; ^{1}H nmr δ: 7.22 (m, 11H), 5.72 and 5.48 (2 s, 1H), 2.8–4.8 (m, 11H), 2.83 (t, J = 6 Hz, 2H), 2.07, 1.95 (s, 3H). Its spectra indicated that this was a cleaner product than that obtained by procedure (*ii*).

*2-Acetoxy-*N*-benzyl-*N*-(2-benzylamino-2-oxoethyl)-3-[2-(tetrahydropyran-2-yloxy)ethyl]-3-butenamide (**40**) and 3-acetoxymethyl-*N*-benzyl-*N*-(2-benzylamino-2-oxoethyl)-5-(tetrahydropyran-2-yloxy)-2-pentenamide (**41**)*

A mixture of crude **39** (3.02 g, 7.11 mmol) and tetrahydropyran-2-yl *tert*-butyl ether (15 mL) in methylene chloride (5 mL) and three drops of concentrated hydrochloric acid was stirred for 18 h at room temperature. Solid $NaHCO_3$ and $MgSO_4$ were added and the mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

was filtered after stirring for a few min. The filtrate was concentrated under high vacuum and the residue was chromatographed on silica with 1 : 1 ethyl acetate – cyclohexane as eluent. A fraction (R_f = 0.4) was eluted after elution of residual tetrahydropyran-2-yl *tert*-butyl ether which was found to contain two components whose R_f values were very similar in a variety of solvent systems. It was re-chromatographed twice on silica with an increasing proportion of ethyl acetate (20%, 40%, 60%) in the ethyl acetate – cyclohexane eluent. The minor component (211 mg, 6%) with a slightly higher R_f was obtained as an orange gum and is considered to be **41**; ir λ_{max}: 5.75, 6.03 μm; ^{1}H nmr δ: 7.30 (m, 11H), 6.15, 5.38 (m, 1H), 3.2–5.4 (m, 13H), 2.50 (t, J = 6 Hz, 2H), 2.03, 1.95 (s, 3H), 1.13–1.80 (m, 6H); *m/e*: 449, 423, 394, 364, 255 (29), 253 (19), 91 (100).

Compound **40** was eluted last as a yellow gum (2.80 g, 77%), ir λ_{max}: 2.98, 5.71, 5.92 μm; ^{1}H nmr δ: 7.28 (m, 11H), 5.80 (s, 0.7H), 5.18 (s, 0.3H), 5.0–5.4 (m, 2H), 3.1–4.8 (m, 11H), 2.42 (t, J = 6 Hz, 2H), 2.10 (s, 1H), 2.03 (s, 2H), 1.0–1.8 (m, 6H); *m/e*: 423 (6), 364 (10), 120 (20), 106 (31), 91 (100). *Accurate Mass* calcd. for $C_{24}H_{27}N_2O_5$ (M − C_5H_9O): 423.1920; found: 423.1927.

N-*Benzyl*-N-*(2-benzylamino-2-oxoethyl)-2-hydroxy-3-[2-(tetrahydropyran-2-yloxy)ethyl]-3-butenamide (42)*

Compound **40** (2.53 g, 4.99 mmol) and sodium hydroxide (203 mg, 5.10 mmol) in absolute ethanol (50 mL) were stirred for 8 h at room temperature. An analogous work-up to that used in the preparation of **24** gave a quantitative yield of **42** as a viscous yellow gum; ir λ_{max}: 2.91, 5.98, 6.05 μm; ^{1}H nmr δ: 7.17 (m, 11H), 3.1–5.2 (m, 15H), 2.37 (m, 2H), 1.13–1.80 (m, 6H).

N-*Benzyl*-N-*(2-benzylamino-2-oxoethyl)-2-oxo-3-[2-(tetrahydropyran-2-yloxy)ethyl]-3-butenamide (43)*

Compound **42** (2.33 g, 4.99 mmol) was oxidized with activated manganese dioxide (15 g) in chloroform (150 mL) for 18 h at room temperature and worked up as in the case of **25** to give a quantitative yield of **43** as a pale yellow gum; ir λ_{max}: 2.97, 5.96, 6.08 μm; ^{1}H nmr δ: 7.27 (m, 10H), 6.73 (br s, 1H), 6.42 (m, 2H), 3.1–4.8 (m, 11H), 2.60 (t, J = 6 Hz, 2H), 1.1–1.8 (m, 6H); *m/e*: 380 (2), 363 (18), 272 (13), 181 (23), 91 (100). *Accurate Mass* calcd. for $C_{22}H_{24}N_2O_4$ (M − C_5H_8O): 380.1736; found: 380.1714.

3-Acetoxy-1,4-dibenzyl-3-[1-(2-(tetrahydropyran-2-yloxy)ethyl)-ethenyl]piperazine-2,5-dione (45)

A solution of MICA was prepared from magnesium (86 mg, 3.6 mmol), methyl bromide, and isopropylcyclohexylamine (0.6 mL) in dry tetrahydrofuran (60 mL) as in the previous cases. Compound **43** (1.274 g, 2.741 mmol) in dry tetrahydrofuran (10 mL) was syringed dropwise into the MICA solution at room temperature under nitrogen over a period of 3 h. The mixture was stirred for 15 h at room temperature during which time it turned cloudy. Acetic anhydride (0.80 mL, 8.5 mmol) was syringed into the reaction flask and the mixture was stirred for an additional 5 h at room temperature. The solution was poured into water (20 mL) and the aqueous solution was extracted with chloroform (4 × 25 mL). The combined chloroform extracts were dried, filtered, concentrated, and pumped on for 1 h under high vacuum. The residue was chromatographed on silica with 60% ethyl acetate – cyclohexane as eluent. Compound **45** was eluted first (R_f = 0.57), the next fraction (R_f = 0.43) was acetylated isopropylcyclohexylamine, and the final fraction (R_f = 0.36) contained uncharacterized polymeric products. Compound **45** was obtained as a pale yellow gum (878 mg, 63%); ir λ_{max}: 5.76, 5.99 μm; ^{1}H nmr δ: 7.27 (s, 5H), 7.23 (s, 5H), 5.70 (s, 1H), 5.47 (s, 1H), 3.3–5.4 (m, 11H), 2.33 (t, J = 6 Hz, 2H), 1.4–1.8 (m, 6H), 1.33 (s, 3H); *m/e*: 506 (1), 422 (7), 363 (11), 271 (8), 106 (24), 91 (93), 84 (100). *Accurate Mass* calcd. for $C_{29}H_{34}N_2O_6$: 506.2417; found: 506.2411.

3-Acetoxy-1,4-dibenzyl-3-(3-hydroxy-1-methylenepropyl)piperazine-2,5-dione (46) and 6,9-dibenzyl-4-methyleneoxa-6,9-diazaspiro-[4.5]decane-7,10-dione (47)

A solution of **45** (878 mg, 1.73 mmol) in acetic acid (15 mL), water (6 mL), and tetrahydrofuran (3 mL) was stirred for ~15 h at room temperature. The solvent was removed *in vacuo* and the residue was chromatographed on silica with 60% ethyl acetate – cyclohexane as eluent. The initial fraction (R_f = 0.57) returned unconsumed **45** (25 mg). The second fraction (R_f = 0.45) gave **47** (153 mg, 21%), which was crystallized from ethanol–water, mp 93–95°C; ir λ_{max}: 5.97 μm; ^{1}H nmr δ: 7.25 (m, 10H), 5.25 (m, 1H), 4.95 (m, 1H), 3.9–4.8 (m, 8H), 2.87 (m, 2H); *m/e*: 362 (15), 271 (12), 229 (9), 124 (11), 91 (100). *Accurate Mass* calcd. for $C_{22}H_{22}N_2O_3$: 362.1630; found: 362.1643.

The final fraction (R_f = 0.27) gave **46** as a colorless gum (425 mg, 58%); ir λ_{max}: 2.90, 5.70, 5.95 μm; ^{1}H nmr δ: 7.28 (s, 5H), 7.23 (s, 5H), 5.67 (s, 1H), 5.47 (s, 1H), 3.6–5.4 (m, 8H), 2.93 (br s, 1H), 2.33 (t, J = 6 Hz, 2H), 1.30 (s, 3H); *m/e*: 363 (3), 272 (3), 230 (2), 91 (22), 83 (100). *Accurate Mass* calcd. for $C_{22}H_{23}N_2O_3$ (M − $C_2H_3O_2$): 363.1709; found: 363.1704.

Structure–activity studies of β-carbolines. 1. Molecular structure and conformation of *cis*-3-carboxylic acid-1,2,3,4-tetrahydroharmane dihydrate

PENELOPE W. CODDING
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received August 16, 1982

PENELOPE W. CODDING. Can. J. Chem. **61**, 529 (1983).

The crystal structure of *cis*-3-carboxylic acid-1,2,3,4-tetrahydroharmane dihydrate, $C_{13}H_{13}N_2O_2 \cdot 2H_2O$, a putative ligand of the benzodiazepine receptor is reported. The space group is $P2_1/c$ with a = 14.850(4), b = 6.560(3), c = 14.746(4) Å and β = 117.411(8)°, Z = 4. The molecule crystallizes as a zwitterion with the unsaturated ring in a half-chair conformation. Hydrogen bonding to the water molecules included in the lattice determines the molecular packing arrangement.

PENELOPE W. CODDING. Can. J. Chem. **61**, 529 (1983).

On rapporte la structure du cristal de l'acide tétrahydro-1,2,3,4 harmane carboxylique-3 dihydrate *cis*, $C_{13}H_{13}N_2O_2 \cdot 2H_2O$, un ligand putatif du récepteur benzodiazépine. Le groupe d'espace est du type $P2_1/c$ avec a = 14,850(4), b = 6,560(3), c = 14,746(4) Å et β = 117,411(8)°, Z = 4. La molécule cristallise sous forme de zwiterrions avec une conformation demi-chaise du cycle insaturé. Les liaisons hydrogènes des molécules d'eau incluses dans le réseau déterminent l'arrangement de l'aggrégat moléculaire.

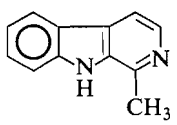
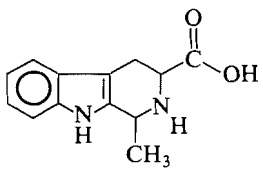
Introduction

Historically, harmala alkaloids have been used therapeutically for their hypotensive activity; however, recent interest has focussed on other neurological effects. Within the last 5 years workers have found harmane (1-methyl-β-carboline, **1**), tetrahydro-β-carboline, and β-carboline-3-carboxylate derivatives in brain tissue and in urine (1, 2). The physiological function of the β-carboline compounds has been intensively studied. One proposal is that a β-carboline compound is the endogenous ligand of the benzodiazepine receptor in parallel with the endorphins and the opiate receptor (3). Harmane and other β-carbolines exhibit high-affinity competitive inhibition of a class of benzodiazepine receptors; but the specific endogenous β-carboline has not, as yet, been identified (2).

Further, Müller *et al.* (4) have demonstrated with in vitro testing that harmane and similar drugs interact with a number of neurotransmitter systems in addition to the benzodiazepine



1



2

receptor; these include opiate, cholinergic, muscarinic, serotonin, and dopamine receptors. Minor changes in the β-carboline structure lead to substantially different affinities for these receptors. Such data, coupled with the in vivo presence of these drugs, suggest that β-carbolines may act as neurotransmitters or neuromodulators themselves.

As part of a study of the neurobiology of β-carbolines, determination of the crystal structure of 3-carboxylic acid-1,2,3,4-tetrahydroharmane (hereafter THHCA, **2**) was undertaken to obtain topochemical information on the precursor of the ester derivatives found in vivo. Conformational analysis via ^{13}C nmr of other 1,3-disubstituted unsaturated β-carbolines (5) predicted that for this compound the *cis* diastereomer with the 1,3 hydrogen atoms in axial positions would predominate.

Experimental

A racemic, commerical sample (Sigma Chemical Co., St. Louis, Missouri, U.S.A.) of the title compound was recrystallized from a water/methanol/ethanol mixture by slow evaporation. A colorless needle-shaped crystal was used for data collection on an Enraf Nonius CAD4F diffractometer. The crystal data are in Table 1. After alignment of the crystal, 25 reflections were found and indexed using the automatic searching, centering, and indexing routines of the instrument. The cell was identified as monoclinic; this lattice assignment was confirmed and the space group was determined by the examination of the intensities from a data collection ($2° < \theta \leq 10°$) over the entire sphere of reflection. Systematic absences of (0k0), $k = 2n + 1$ and ($h0l$), $l = 2n + 1$ and the symmetry of the intensities identified the space group as $P2_1/c$. Data were collected at room temperature using an $\omega/2\theta$ scan of a speed varied (for ω) between 0.8° and 6.7°/min to obtain $I > 2.5\sigma(I)$ within a measurement time of 120 s. The scan width was calculated as given in Table 1 and 2/3 of the scan time, at the center of the scan, was taken as peak (P) and 1/6 of the time at each side was taken as background (B_1 and B_2). Then $I = [P - 2(B_1 + B_2)]Q$, where Q is the scan rate and the standard deviation of the intensity is $\sigma(I) = [P + 4(B_1 + B_2)]^{1/2}Q$. Lorentz and polarization corrections were applied and E values were calculated by applying a K curve.

The structure was solved using the direct methods program PHASE from the XRAY76 system (6). All nonhydrogen atoms of THHCA were identified in the E-map which was calculated from the predicted phases. Least-squares refinement using isotropic temperature factors produced an R value of 0.30 and a difference Fourier synthesis revealed the positions of the oxygen atoms of two water molecules. After inclusion of the oxygen atoms and further isotropic refinement to R = 0.10, a difference Fourier synthesis indicated the positions of all hydrogen atoms. The zwitterionic nature of the molecule was evident at this point. Hydrogen atoms were assigned isotropic thermal parameters that were 20% larger than the atom to which they were bonded and were included in the model; however, only their positional

parameters were refined. Refinement was blocked so that anisotropic least-squares refinement of the atomic parameters of all the nonhydrogen atoms was alternated with refinement of the atomic coordinates of the hydrogen atoms. The least-squares analysis converged with a maximum shift/error of 0.017 and an R value of 0.055 using unit weights. Atomic coordinates[1] are given in Table 2 with the atoms labeled as shown in Fig. 1. Bond distances are shown in Fig. 1 and bond angles are given in Table 3.

All computations were done using the XRAY76 system programs (6) on a Honeywell computer using the Multics operating system. Scattering factors are those of Cromer and Mann (7).

[1]The anisotropic thermal parameters, hydrogen atom parameters, and the observed and final calculated structure amplitudes are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

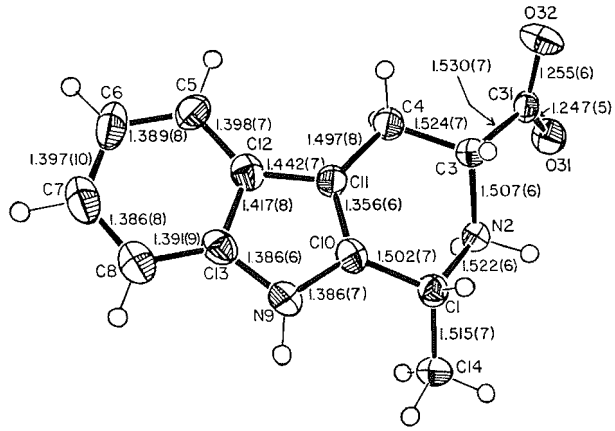

FIG. 1. Molecular structure, atomic labeling, and interatomic distances for *cis*-3-carboxylic acid-1,2,3,4-tetrahydroharmane as drawn with the computer program ORTEP(6). Probability ellipsoids were drawn at the 50% level and hydrogen atoms were assigned a spheroid of radius 0.1 Å.

Results and discussion

Figure 1 shows the structure and the interatomic distances for the zwitterion of THHCA. The two water molecules which are hydrogen-bonded to the carboxylate group are shown in Fig. 2 which shows the conformation of the molecule. The 6-membered heterocyclic ring is in a half-chair conformation with C3 0.317 Å above and N2 0.461 Å below the least-squares plane of the other four atoms (σ (plane) = 0.006 Å). Both the 1-methyl and the 3-carboxylic acid substituents are equatorial, thereby minimizing steric repulsion. This conformation can be expected to predominate in the active molecules since similar substitution patterns are observed in those β-carbolines.

In this determination THHCA is found as a zwitterion with a positive charge on N2 and the negative charge distributed over the two oxygen atoms of the carboxylate group. Although those β-carbolines with 3-substituents thus far isolated have been esters rather than acids, the evidence from ^{13}C nmr is that the half-chair conformation as observed here is determined by

the bulk of the substituents rather than by the charge. It remains important that the molecule assumes an ionic form in hydrophilic solvents as this may be a key to the transport and activity of the drug. Indeed, a recent report (8) ascribes the inactivity of THHCA at BZD receptors to a negatively charged carboxylate group; however, the zwitterionic form may be what was present in these tests. Zwitterionic THHCA was obtained from the free base simply by recrystallization at a nominal pH of 7. The zwitterion is confirmed by the equal C31-to-oxygen atom distances (C31—O31 1.247(5) Å and C31—O32 1.235(6) Å) and the identification of two hydrogen atoms within bonding distance of N2 (N2—H2A 0.92(5) Å and N2—H2B 1.00(5) Å).

Since the zwitterion is formed at physiological pH and appears to be the stable form of THHCA it is useful to study the hydrogen bonds formed by this moiety as they may well reflect potential THHCA–receptor interactions. The pattern of hydrogen bond formation is shown in Fig. 2 and the dimensions of these bonds are given in Table 4. Each potential donor or acceptor of the THHCA moiety is utilized; thus THHCA could bind quite strongly to a receptor site.

The carboxyl oxygen atoms each form two hydrogen bonds, O32 bonds to each of the two water molecules of the asymmetric unit as shown in Fig. 2 and O32 bonds to the protonated nitrogen atom N2 at $(1 - x, y - \frac{1}{2}, \frac{1}{2} - z)$ and to the other

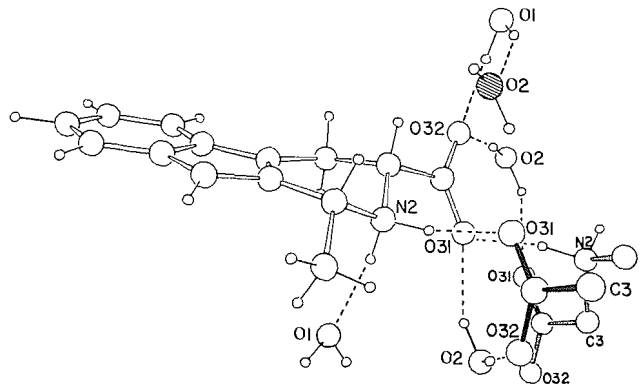

FIG. 2. Hydrogen bonding scheme for THHCA; the hydrogen bonds are dashed lines. The molecular fragment with black bonds is at $(1 - x, \frac{1}{2} + y, \frac{1}{2} - z)$; the fragment with striped bonds is at $(1 - x, y - \frac{1}{2}, \frac{1}{2} - z)$. The shaded water molecule 1 is at $(x, \frac{1}{2} - y, \frac{1}{2} + z)$, the hatched water molecule 2 is at $(x, y + 1, z)$, the water molecule 2 with dark bonds is at $(1 - x, \frac{1}{2} + y, \frac{1}{2} - z)$. Plotting done by ORTEP(6) with arbitrary spheres of radius 0.3 Å for all but H atoms (0.1 Å).

TABLE 4. Hydrogen bond dimensions for THHCA

Atoms X···H—Y	X···H (in Å)	H—Y (in Å)	X···H—Y (in °)
O32···H1(O1)—O1	1.88(6)	0.96(6)	171(5)
O32···H1(O2)—O2	1.85(6)	0.98(6)	172(6)
O31···H2B—N2	1.83(5)	0.99(5)	164(4)
O31···H2(O2)—O2	1.96(5)	0.89(4)	156(6)
O1···H2A—N2	1.91(5)	0.91(5)	169(5)
O2···H2(O1)—O1	2.11(6)	0.84(5)	148(7)

hydrogen atom of water molecule 2 at $(1 - x, \frac{1}{2} + y, \frac{1}{2} - z)$. Due to the equatorial position of the carboxylic acid moiety, an intramolecular hydrogen bond between that group and the protonated nitrogen atom is not possible. Thus N2 donates a hydrogen atom to water molecule 1 at $(x, \frac{1}{2} - y, \frac{1}{2} + z)$ and to O31 of the molecule at $(1 - x, \frac{1}{2} + y, z - \frac{1}{2})$. Facile hydrogen bond formation appears to determine the packing in these crystals; there are no other significant intermolecular contacts.

THHCA appears to be composed of a hydrophobic moiety, the indole group, and a hydrophilic moiety which participates in the hydrogen bonding. The indole group is planar (σ = 0.010 Å) and forms an angle of 58.9° to the plane of the carboxylate group. The torsion angle positioning the carboxylate group appears to be dependent on hydrogen bond formation rather than any steric effects. All the bond distances and angles found in THHCA are typical for structures of this type and confirm the ionic nature of the molecule.

It appears that maximal utilization of hydrogen bond donors and acceptors is a strong stabilizing effect in these molecules and is probably important in receptor binding. Work is in progress on several esters of the β-carbolines to further our understanding of the topochemistry of these drugs.

Arylation de glycals catalysée par les sels de palladium: nouvelle synthèse de *C*-glycosides

STANISLAS CZERNECKI ET VERONIQUE DECHAVANNE

Laboratoire de Cinétique et Mécanismes de Réactions Organiques, CNRS ER 84, Université Pierre et Marie Curie, 4, Place Jussieu, Paris, France

Reçu le 29 juillet 1982

STANISLAS CZERNECKI et VERONIQUE DECHAVANNE. Can. J. Chem. **61**, 533 (1983).

L'arylation des glycals peracétylés catalysée par les sels de palladium constitue une nouvelle synthèse de *C*-glycosides. Cette réaction est appliquée à plusieurs aromatiques, incluant des dérivés fluorés et nitrés. La régiosélectivité de la réaction au niveau de l'aromatique est expliquée par la formation d'un arylpalladium directement à partir de l'aromatique et du sel. Un mécanisme en deux étapes, impliquant une *syn*-addition de l'arylpalladium sur la double liaison du glycal, suivie d'une *syn*-élimination est proposé et discuté.

STANISLAS CZERNECKI and VERONIQUE DECHAVANNE. Can. J. Chem. **61**, 533 (1983).

The arylation of peracetylated glycals catalyzed by palladium salts provides a new synthesis of *C*-glycosides. The title reaction is applied to several aromatic compounds, including fluoro and nitro derivatives. The regioselectivity of the reaction with respect to the aromatic nucleus is explained by the formation of an arylpalladium directly from the aromatic compound and the salt. A two-step mechanism, involving *syn*-addition of the arylpalladium to the glycal double bond, followed by a *syn*-elimination is proposed and discussed.

Introduction

Notre intérêt pour l'activation sélective des glucides éthyléniques (1) nous a amené à considérer que l'arylation des oléfines catalysée par des sels de palladium pouvait présenter des potentialités intéressantes dans le domaine des glucides. Cette réaction, qui représente un exemple des nombreuses applications du palladium en chimie organique (2), est globalement la substitution d'un hydrogène de l'oléfine par un groupement aromatique. Nous avons montré récemment (3) que son application à des glycals peracétylés pouvait constituer une nouvelle synthèse de *C*-glycosides car l'arylation se fait sur le carbone C1 du dérivé glucidique. Nous reportons dans cet article l'ensemble de nos résultats concernant cette réaction aussi bien du point de vue synthétique que mécanistique.

L'arylation des oléfines simples catalysée par le palladium peut être réalisée en faisant réagir un excès de celle-ci sur un iodure d'aryle (4*a*), un organomercurique aromatique (4*b*) ou l'aromatique lui-même (4*c*). Cette réaction a été l'objet de nombreuses études, aussi bien dans le but d'en améliorer les possibilités synthétiques (2) que d'en définir le mécanisme (5). Bien que celui-ci ne soit pas complètement élucidé, un processus en deux étapes est généralement admis (2*a*, *b*) pour les deux premières méthodes; d'abord une *syn*-addition, sur la double liaison, d'un arylpalladium (ArPdX) formé *in situ* à partir des réactifs, ensuite une *syn*-élimination de HPdX qui se décompose en HX et palladium métallique. Dans le cas de l'arylation avec l'aromatique, un mécanisme différent faisant intervenir des intermédiaires à liaisons π a été également envisagé (4*c*). En fait, l'existence d'un arylpalladium n'a pas été clairement établie dans ce cas, car cette réaction a été surtout appliquée à des oléfines simples qui ne permettent pas d'étudier les implications stéréochimiques de l'intervention d'un arylpalladium.

En revanche, les exemples d'arylation d'éther d'énols catalysée par les sels de palladium sont rares; à notre connaissance, il n'y a eu que quatre tentatives de phénylation de tels composés de cette manière (6), en dehors de la notre. Les plus anciennes (6*a*, *b*), réalisées sur des éthers d'énols simples, ont conduit à des mélanges complexes avec des rendements faibles. Plus récemment, il a été montré que la phénylation du 3,4-dihydro-4*H*-pyranne à l'aide de l'iodobenzène (6*c*) conduisait au 2-phényl-3,4-dihydro-2*H*-pyranne avec un rendement acceptable. Des expériences réalisées sur des éthers de vinyle et d'alkyle (6*c*, *d*) ont révélé que la réaction était sensible à l'encombrement de la double liaison. Enfin, un travail récent (7*a*) a montré que l'alkylation et la phénylation de dérivés du dihydrofuranne et du dihydropyranne étaient également réalisables par action de carbanions sur les complexes π-allyliques du palladium de ces dérivés.

L'utilisation du palladium dans le domaine des glucides est très récente. Arai et Daves, Jr. (8) ont étudié la possibilité d'obtenir des *C*-nucléosides par action du 1,3-diméthyl-2,4-pyrimidinedione-5-yl-palladium, préparé par échange à partir de l'organomercurique correspondant, sur des glycals peracétylés. Ils ont montré que la réaction était régiospécifique, mais qu'elle conduisait essentiellement au produit résultant de l'ouverture du cycle pyrannique. D'autre part, Baer et Hanna (9) ont étudié de façon détaillée l'alkylation et l'amination de complexes π-allyliques du palladium dérivés d'alkyl hex-2-énopyranosides. Enfin, la méthoxypalladation de glycals peracétylés a été réalisée avec de bons rendements (7*b*).

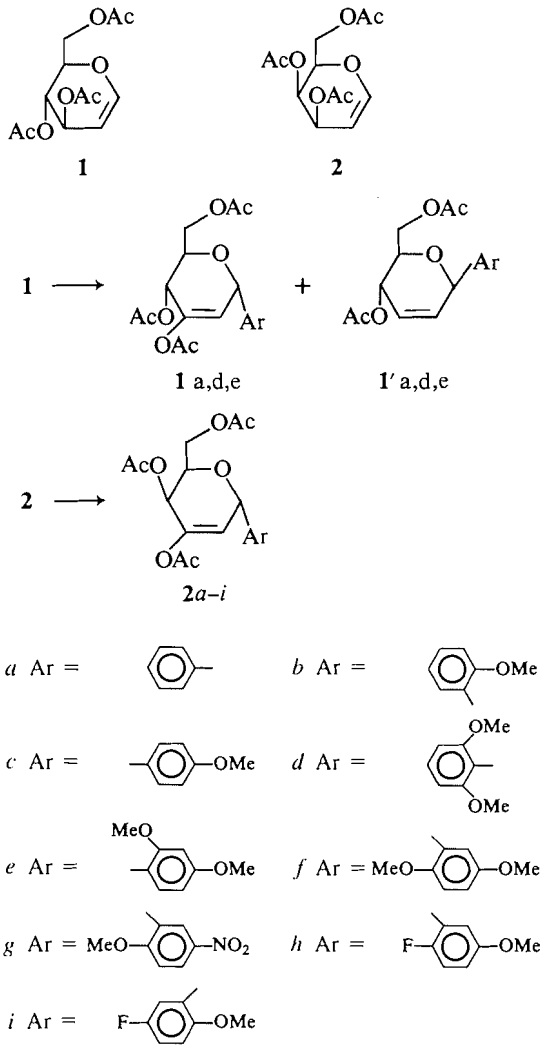
Les principaux substrats que nous avons utilisés pour évaluer l'utilité de l'arylation des oléfines dans le domaine des glucides sont les 3,4,6-tri-*O*-acétyl-1,5-anhydro-2-désoxy-D-*arabino*-hex-1-énitol (tri-*O*-acétyl-D-glucal) **1** et son isomère de configuration D-*lyxo* (tri-*O*-acétyl-D-galactal) **2** qui sont faciles d'accès.[1] En ce qui concerne les aromatiques, outre le benzène, nous avons utilisé l'anisole, le *m*-méthoxyanisole, le *p*-méthoxyanisole, le *p*-nitroanisole et le *p*-fluoroanisole.

Résultats et discussion

Aspect synthétique

En faisant réagir le glycal **2** avec un excès de composé

[1]Le 3,4,6-tri-*O*-acétyl-D-glucal est commercial (Aldrich) et le 3,4,6-tri-*O*-acétyl-D-galactal a été préparé selon la référence 10.



aromatique en présence d'une quantité stoechiométrique d'acétate de palladium, en solution dans l'acide acétique, on observe rapidement la formation d'un précipité noir de palladium métallique et la chromatographie sur couche mince indique la disparition du produit de départ. Après traitement (voir partie expérimentale), les composés de couplage **2***n*[2] sont isolés par recristallisation ou chromatographie sur colonne avec des rendements de 41 à 67% selon l'aromatique utilisé (Tableau 1). Le *C*-glycoside formé est accompagné de sous-produits car, dans le système étudié, plusieurs réactions parasites sont possibles. En particulier, l'isomérisation d'acétate allylique par les sels de palladium a déjà été décrite (11), et, avec les glycals peracétylés, elle conduit à des mélanges complexes, comme l'isomérisation par l'étherate de trifluorure de bore étudiée par Ferrier et Prasad (12). Nous avons vérifié qu'elle était relativement lente dans les conditions utilisées et, de plus, dans quelques cas où la transformation du glycal **1** était incomplète, nous avons pu récupérer du sucre éthylénique de départ inchangé.

Du milieu réactionnel, nous avons pu également isoler des composés plus polaires de masse molaire élevée correspondant à la dimérisation du produit de départ, réaction qui est également catalysée par les sels de palladium (13). Ces composés ont été caractérisés par spectroscopie de masse et rmn. L'importance de ces deux réactions concurrentes a été diminuée en utilisant un grand excès d'aromatique et des temps de réaction aussi courts que possible (1,5 ou 2 h à 120°C).

La troisième réaction parasite possible, la dimérisation de l'aromatique, n'est pas un inconvénient majeur, car les dimères obtenus sont aisément séparés des produits de couplage, mais elle consomme inutilement du sel de palladium. En fait, le meilleur catalyseur pour cette réaction est le chlorure de palladium (14) et avec l'acétate que nous avons utilisé, les composés biphénylés sont peu importants.

Des essais comparatifs avec d'autres sels ou en présence de triphénylphosphine (essais n° 9, 10 et 11) ont donné des rendements plus faibles ou nécessité des temps de chauffage prolongés.

Dans un premier temps, nous avons utilisé une quantité stoechiométrique de sel de palladium, car le palladium métallique qui précipite est récupéré de façon presque quantitative dans la plupart des cas (voir partie expérimentale) et peut être réoxydé en acétate avec de bons rendements (15). Nous avons montré qu'il était possible d'utiliser une quantité catalytique de sel et de réoxyder *in situ* le palladium avec de l'acétate de cuivre (essais n° 5 et 8). Toutefois, dans ces conditions, la réaction est plus lente et le rendement en *C*-glycoside diminue légèrement au profit de l'isomérisation et de la dimérisation.

Enfin, lorsque les positions de substitution sur le noyau aromatique n'étaient pas équivalentes, nous avons isolé et caractérisé les isomères correspondants (essais n° 9 et 14), sauf dans le cas de l'anisole pour lequel les produits substitués en *ortho* ou en *para* du groupe méthoxyle n'ont pas été séparés (essai n° 6) et le *p*-nitroanisole où un seul composé est formé en *ortho* du méthoxy (essai n° 13).

La réaction entre le tri-*O*-acétyl-D-glucal **1** et divers aromatiques (essais n° 1, 2, 7 et 8) conduit également à des triacétates de *C*-2-désoxyglyc-2-énosides **1***n* avec des rendements comparables. Mais dans ce cas, nous avons pu également isoler et caractériser des diacétates **1′***n*[3] qui ne possèdent pas de groupement ester d'énol sur le carbone C3.

Aspect structural

La formule des composés résultant de l'arylation a été confirmée par analyse élémentaire et leur structure déterminée par des méthodes spectroscopiques.

Les spectres d'absorption infra-rouge et ultraviolette confirment l'existence des différentes fonctions. En particulier, dans le spectre ir, on observe la bande caractéristique de la fonction ester d'énol à 1775 cm^{-1}. Les spectres uv montrent que la glycosylation de l'aromatique ne modifie pas sensiblement son absorption, ce qui confirme que la double liaison n'est pas conjuguée avec le noyau.

La spectroscopie de masse confirme la formule brute, mais surtout, nous a permis d'établir la régiosélectivité de la réaction. En effet, l'existence d'un pic intense (20−30%) correspondant à l'ion $(Ar—C{\equiv}O)^+$ dans le spectre de masse de tous les composés de couplage confirme que l'aromatique s'est bien fixé sur le carbone C1 du dérivé glucidique. Un tel type de fragmentation a été également observé pour des dérivés du dihydropyranne possédant une ramification en position 2 (6*c*). Il est à noter que la fragmentation rétrodiénique, caractéristique (9, 16, 17) des hexopyranosides correspondants a été observée, mais les pics résultants sont peu intenses.

[2]Le chiffre rappelle le glycal de départ et la lettre désigne l'aromatique.

[3]Le chiffre rappelle le glycal de départ, la lettre désigne l'aromatique et le prime signifie que le composé est 2,3-didésoxy.

[a]$Pd(OAc)_2$ en quantité stoechiométrique sauf indication contraire.
[b]Position du reste glucidique sur l'aromatique.
[c]0,2 Équivalent de $Pd(OAc)_2$ et 1,6 équivalent de $Cu(OAc)_2 \cdot H_2O$.
[d]Proportions déterminées par rmn ^1H.
[e]Pourcentages déterminés par clhp analytique.

Les données de rmn ^1H concernant les composés résultant de l'arylation de ces glycals sont réunies dans le tableau 2. Les signaux correspondants aux protons aromatiques permettent de fixer sans ambiguité la position de la partie glycosidique sur l'aromatique sauf dans le cas du *p*-fluoroanisole pour lequel nous avons eu recours à la rmn ^{13}C. C'est la valeur de la constante de couplage entre le carbone aromatique lié à la partie glucidique et le fluor qui permet de trancher. Pour **2***g*, on observe un couplage J = 16,5 Hz pour ce signal (δ = 124,8) qui correspond à la position *ortho* par rapport au fluor. Pour **2***i*, le couplage plus faible (J = 6,1 Hz, δ = 126,9) montre que le glucide est en *méta* du fluor. Ces valeurs, quoique légèrement plus faibles, sont en accord avec celles observées par Weigert et Roberts dans le fluorobenzène (18).

Dans la série de composés **2***n* dérivés du tri-*O*-acétyl-D-galactal **2**, la faible valeur de la constante de couplage $J_{4,5}$ = 1,5 Hz est compatible avec les données de la littérature concernant des 2,3-didésoxy-*C*-glyc-2-énosides (19, 20) et correspond à une configuration *thréo* pour les carbones C4 et C5 à condition que le *C*-glycoside insaturé adopte la conformation demi-chaise $^0H_5$. Le couplage $^3J_{1,2}$ se faisant à travers, un carbone hybridé sp^2, il nous a paru hasardeux de déduire de cette seule donnée la configuration du carbone anomère. En effet, comme le soulignent Baer et Hanna (9), la relation proposée par Garbisch (20) n'est pas d'un grand secours dans le domaine des énopyranosides. Finalement, la structure du 3,4,6-tri-*O*-acétyl-2-désoxy-α-D-*thréo*-hex-2-énopyrasosylbenzène **2***a* a été déterminée par diffraction des rayons X;[4] elle montre que le glycoside possède bien la conformation demi-chaise $^0H_5$ et que le noyau phényle est en position quasi-axiale, c'est-à-dire que le carbone anomère possède la configuration α. Tous les membres de cette série étant fortement lévogyres, nous en concluons qu'ils possèdent tous la même configuration et que la nature de l'aglycone affecte peu la valeur du pouvoir rotatoire.

Dans la série de composés **1***n* dérivés du tri-*O*-acétyl-D-glucal **1** la valeur de la constante de couplage $J_{4,5}$ = 4 Hz montre que l'équilibre conformationnel de ces composés est, cette fois, en faveur de la conformation demi-chaise $^5H_0$. Dans cette conformation, le groupement acétoxy porté sur le C4 se trouve en position quasi axiale, ce qui est un facteur de stabilisation, comme l'ont montré Ferrier et Sankey (21), car les répulsions stériques et électriques avec le groupement acétoxy

[4]Cette structure, déterminée au Laboratoire de Chimie Structurale Biomoléculaire (Université Paris-Nord) dirigé par le Prof. H. Gillier-Pandraud fera l'objet d'une publication ultérieure.

[b]$J_{5,6}$ = 3; $J_{6,6}$ = 12.

du C3 sont alors minimisées.[5] Dans cette conformation, le groupement volumineux CH_2OAc se trouve en position axiale, mais, du fait de la présence d'une double liaison entre C2 et C3, ceci n'entraîne pas de fortes interactions 1−3 déstabilisantes (21). Enfin, le carbone C1 n'étant pas lié à un hétéroatome, il n'y a pas d'effet anomère pouvant influencer profondément l'équilibre conformationnel. Les *C*-glycosides suivant généralement la règle de Hudson (22), nous avons attribué la configuration α à la liaison anomérique des composés **1***n*, car ils sont davantage dextrogyres que leurs homologues **1′***n*, dont le carbone anomère possède la configuration β (*vide infra*). Mais des déviations à cette règle ayant été observées par plusieurs auteurs aussi bien pour des alkyl 2,3-didesoxy-hex-2-énopyranosides (9, 23) que pour un couple de *C*-glycosides (24), cette configuration α des composés **1***n* a été vérifiée par rmn ^{1}H après transformation de la fonction ester d'énol en oxime (3).

En ce qui concerne les composés **1′***n*, nous avons analysé en détail le spectre rmn ^{1}H (250 MHz) du 4,6-di-*O*-acétyl-2,3-didésoxy-β-D-*érythro*-hex-2-énopyranosyl benzène **1′***a*. Une telle analyse n'a pas été possible pour les composés similaires **1′***e* et **1′***d* obtenus lors de l'arylation du tri-*O*-acétyl-D-glucal **1** avec le *m*-méthoxyanisole car ceux-ci, isolés sous forme d'huile, étaient souillés de trace de produit résultant de l'isomérisation du glycal de départ. Les protons oléfiniques résonnent vers 6 ppm sous forme d'un quartet AB ($J_{2,3}$ = 9 Hz) dont chaque signal est dédoublé par de faibles couplages vicinaux ou allyliques. Il est à noter que, comme dans les glycosides correspondants (9, 25), c'est H2 qui résonne au champ le plus fort. La constante de couplage $J_{4,5}$ = 7,5 Hz est en accord avec la valeur donnée par Ferrier pour des acétates analogues (21) et montre clairement que la configuration des C4 et C5 est *érythro* et que la conformation favorisée est demi-chaise $^0H_5$. Comme dans le cas des composés **1***n* et **2***n*, la configuration de la liaison anomérique de **1′***a* n'a pu être déterminée à l'aide de la constante de couplage $^3J_{1,2}$ qui est d'ailleurs très faible. C'est en nous fondant sur la valeur du pouvoir rotatoire que nous attribuons la configuration β au composé **1′***a*. En effet, celui-ci est faiblement dextrogyre (+3°) alors qu'un *C*-glycoside analogue, le 4′-(4,6-di-*O*-acétyl-2,3-didésoxy-α-D-*érythro*-hex-2-énopyranosyl) anisole préparé

[5]A titre de comparaison, on remarquera que la conformation $^0H_5$, adoptée pour les composés **2***n* correspond bien à une position quasi axiale de l'acétate allylique du C4.

d'une autre manière par Grinkiewicz et Zamojski (26) est fortement dextrogyre (+250°). En toute rigueur, l'aromatique n'est pas le même dans ces deux composés, mais nous avons montré dans la série dérivée du tri-*O*-acétyl-D-galactal **2** que la nature de l'aromatique influençait peu le pouvoir rotatoire.

Aspect mécanistique

En ce qui concerne le mécanisme de cette réaction, la principale question posée était de savoir si, comme pour les autres méthodes d'arylation, un arylpalladium à liaison σ était impliqué dans la réaction étudiée avec les conséquences stéréochimiques habituelles de l'intervention d'un composé de ce type (voir introduction).

Considérons d'abord la régiosélectivité de la réaction au niveau de l'aromatique. Nos résultats sont conformes à ceux obtenus par Fujiwara *et al.* (27) lors de l'arylation du styrène avec divers aromatiques et montrent que la réaction suit l'effet *ortho–para* directeur du méthoxy et *méta* orienteur du groupe nitro. Dans le cas de l'halogène (fluoro), on observe un fort pourcentage de réaction en *ortho* de celui-ci comme dans la mercuration d'aromatiques (28). Toutefois, nous ne pensons pas que la réaction soit une substitution électrophile où le rôle du palladium serait de polariser la double liaison du glycal sous forme d'un complexe π allylique cationique qui se substituerait ensuite à un hydrogène de l'aromatique. En effet, dans ce cas, le composé de couplage ne devrait pas posséder d'acétate en C3. De plus, nous n'avons pas observé de différences dramatiques de vitesse pour les aromatiques diversement substitués comme on pourrait s'y attendre dans le cas d'une substitution électrophile. Enfin, nous avons obtenu un fort pourcentage de réaction en position 2 du noyau avec l'anisole (47%) et le *m*-méthoxyanisole (40%) (tableau 1). Or, la glycosylation par substitution électrophile de l'anisole par le tri-*O*-acétyl-D-glucal **1** et le tri-*O*-acétyl-D-galactal **2** ne se fait pas en *ortho* du méthoxy (26) et celle du *m*-méthoxyanisole par des trichloroacétimidates de glycosyle en présence d'acide de Lewis ne se fait pas entre les deux groupes méthoxy (29).

L'ensemble de ces observations nous incite fortement à penser que la première étape de cette réaction est la formation d'un arylpalladium, directement à partir de l'aromatique et du sel de palladium (30). Dans le cas du *m*-méthoxyanisole, nous pensons qu'une coordination intramoléculaire de l'atome métallique favorise la palladation sur ce site. En effet, ce fort pourcentage se retrouve pour les deux glycals étudiés et reflète donc bien le site de palladation de l'aromatique. De plus, ce pourcentage décroît lorsque le palladium est fortement coordiné par d'autres ligands (acétyl-acétonate et triphényl phosphine), la coordination intramoléculaire devenant moins efficace (essais n° 10 et 11). Enfin, un tel type de coordination a été envisagée pour des organométalliques aromatiques (31) et pour des arylpalladium contenant des fonctions azotées (2*a*). Inversement, il a été montré que l'arylation catalysée par le palladium ne se fait pas entre les deux méthyles du *m*-xylène (32) pour lequel une telle coordination intramoléculaire n'est pas possible.

En ce qui concerne la régiosélectivité de l'addition de l'arylpalladium sur la double liaison du glycal, le produit principal que nous avons isolé résulte de la fixation de l'aromatique sur le carbone C1 ce qui est en accord avec les résultats de l'arylation d'éther cyclique avec un arylpalladium (6*c*, *d*) et ceux que Arai et Daves, Jr. ont obtenus lors de la préparation de *C*-nucléosides par réaction d'organopalladium sur des glycals (8).

En définitive, il nous semble raisonnable de penser que l'arylpalladium formé rapidement dans une première étape,

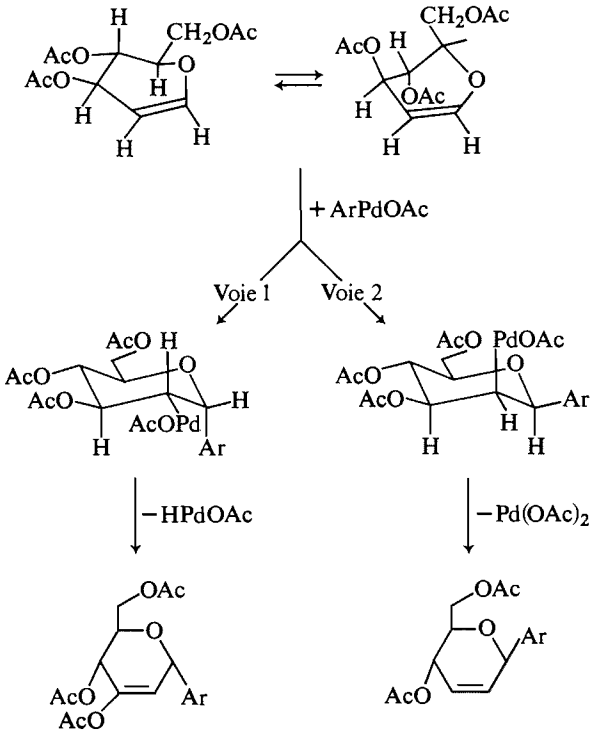

SCHÉMA 1

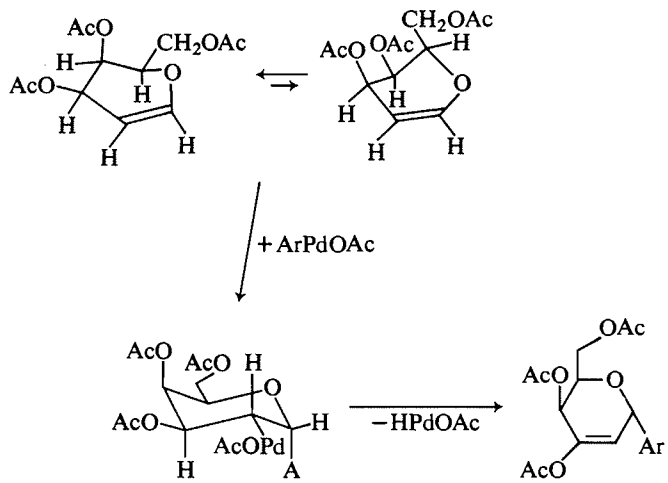

SCHÉMA 2

réagit ensuite comme à l'accoutumée sur la double liaison; *syn*-addition avec formation d'un alkylpalladium puis, dans une seconde étape, perte de XPdOAc dirigée par des facteurs stériques, le groupe X issu du glucide devant être dans une position qui permette une *syn*-élimination. Avec cela en tête, nous proposons d'expliquer les différences observées avec le tri-*O*-acétyl-D-glucal **1** et le tri-*O*-acétyl-D-galactal **2** de la façon suivante (Schémas 1 et 2).

Les conformations de ces glycals en solution ont été déterminées par rmn ^{1}H (33, 34). L'examen des modèles correspondants montre que pour le tri-*O*-acétyl-D-glucal **1** l'encombrement stérique des diastéréofaces de la double liaison est très similaire et la *syn*-addition de ArPdOAc est possible des deux côtés conduisant à deux alkylpalladium. L'un, par *syn*-élimination de HPdOAc conduit au produit principal (voie 1), tandis que le second, par *syn*-élimination de $Pd(OAc)_2$ (voie 2),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

conduit à l'autre produit d'arylation. La réaction se faisant d'ailleurs vraisemblablement sur le conformère où la double liaison est la plus accessible (conformation $^4H_5$) (schéma 1).

Dans le cas du tri-*O*-acétyl-D-galactal **2**, la situation est toute autre, car l'encombrement stérique de chaque diastéréoface de la double liaison est cette fois très différent et même dans la conformation $^4H_5$ où la double liaison est la plus accessible, la présence du groupe acétate en position axiale sur C4 favorise la fixation de ArPdOAc conduisant à l'anomère α dans lequel la *syn*-élimination de HPdOAc est possible et conduit à un seul composé possédant la fonction ester d'énol (schéma 2).

Cette différence de comportement des glycals **1** et **2** n'est pas particulière à la réaction étudiée ici, mais apparaît dans d'autres réactions d'addition sur la double liaison; par exemple dans la méthoxy-mercuration (35) où le tri-*O*-acétyl-D-glucal **1** conduit à un mélange de deux organomercuriques, tandis qu'à partir du tri-*O*-acétyl-D-galactal **2**, il ne s'en forme qu'un seul. Quant à la perte de $Pd(OAc)_2$, elle a été observée par Heck (6*a*) lors de l'arylation d'acétate ou d'éther vinyliques par un mercurique aromatique en présence d'un sel de palladium. Cependant, il faut signaler qu'à partir du tri-*O*-acétyl-D-glucal, Arai et Daves, Jr. (8) ont reporté un comportement différent d'un alkylpalladium analogue de celui formé par la voie 1 (schéma 1). Ces auteurs évoquent une *anti*-élimination d'un alkoxyde pour expliquer l'ouverture du cycle pyrannique de l'unité glucidique conduisant au produit majoritaire qu'ils ont isolé et caractérisé.

Conclusion

L'arylation des glycals peracétylés par un aromatique en présence d'acétate de palladium constitue une nouvelle synthèse de *C*-glycosides. Elle présente l'avantage de transformer, en une seule étape, des dérivés faciles d'accès en composés hautement fonctionnalisés qui possèdent une fonction ester d'énol en C3, ce qui en fait des précurseurs de 2-désoxy-*C*-glycosides. La régiosélectivité de la réaction au niveau de l'aromatique peut s'expliquer par la formation d'un arylpalladium directement à partir de l'aromatique et du sel. Un mécanisme en deux étapes, impliquant la *syn*-addition de l'arylpalladium sur la double liaison du glycal suivie d'une *syn*-élimination rend bien compte de la stéréochimie des composés obtenus.

Partie expérimentale

Les points de fusion ont été déterminés en tube capillaire sur un appareil de Hoover et ne sont pas corrigés. Les pouvoirs rotatoires ont été mesurés en solution chloroformique dans une cuve de 1 dm de longueur sur un appareil Perkin–Elmer 141. Les spectres d'absorption infra-rouge (ir) ont été enregistrés sur un appareil Unicam SP3-300. Les spectres d'absorption ultraviolette (uv) de solutions dans l'éthanol 95% ont été enregistrés sur un spectromètre Beckman DK 2A. Les spectres de rmn ont été enregistrés sur des appareils Varian ou Brucker pour le proton et sur un appareil JEOL PS 100 pour le carbone. Les solvants utilisés ont été CCl_4, $CDCl_3$ et C_6D_6. Les déplacements chimiques (δ) sont exprimés en ppm en prenant le tétraméthylsilane comme référence interne. Les constantes de couplage sont exprimées en Hz. Les microanalyses ont été effectuées par le service de Microanalyse de l'Université P. et Marie Curie.

Les chromatographies sur couche mince (ccm) ont été réalisées sur des plaques prêtes à l'emploi (Alufolien, gel de silice 60 F-254 Merck de 0,2 mm d'épaisseur). La révélation des plaques était assurée, soit par observation à l'aide d'une lampe uv, soit par vaporisation d'une solution 6 *N* d'acide sulfurique suivie de chauffage à 100°C, soit en combinant les deux techniques. Les éluants utilisés étaients des mélanges d'éther éthylique distillé sur anhydride phosphorique et d'éther de pétrole (Eb: 45–55°C); éluant A: éther éthylique – éther de pétrole, 2:1, v/v; éluant B: éther éthylique – éther de pétrole, 80:20, v/v; éluant C: éther éthylique – éther de pétrole, 20:80, v/v.

Les chromatographies sur colonne ont été réalisées sur gel de silice 40 (70–230 mesh ASTM, Merck) avec l'éluant A. Les fractions étaient recueillies à l'aide d'un collecteur ISCO modèle 348 équipé d'un détecteur uv ISCO UA-5. Les chromatographies sur colonne sous pression (15 bars) ont été réalisées avec l'éluant B sur gel de silice H 60 (5–40 μm) à l'aide d'un appareil Chromatospac 100 (Jobin–Yvon) muni d'un détecteur réfractométrique. Les chromatographies liquides haute performance (clhp) ont été réalisées sur une colonne de silice (μ Porasil, l = 30 cm, Waters) à l'aide d'un appareil Constametric II équipé d'un détecteur uv à longueur d'onde variable. Pour chaque famille de composés, celle-ci correspondait au maximum d'absorption uv préalablement déterminé pour chaque chromophore, ce qui permettait le calcul des proportions des différents composés directement à partir des surfaces des pics enregistrés. L'élution était faite avec un mélange THF–heptane, 20:80, v/v (Gold Label, Aldrich) (débit 0,8 mL/min).

L'acide acétique (Rectapur, Prolabo), les composés aromatiques (Aldrich) et l'acétate de palladium (Ventron) ont été utilisés sans purification préalable.

Procédé général d'arylation

Dans un ballon muni d'un réfrigérant ascendant et protégé de l'humidité extérieure, 3 mmol de glycal sont dissoutes dans 24 mL d'acide acétique et 500 mmol de composé aromatique (ArH). On ajoute ensuite 3 mmol d'acétate de palladium. Le ballon est plongé dans un bain d'huile de silicone maintenu à température constante. On observe l'apparition rapide d'un miroir de palladium métallique sur les parois du ballon. L'avancement de la réaction est suivi par ccm (éluant A). Lorsque la réaction est terminée, on filtre le mélange réactionnel sur papier afin de récupérer le palladium métallique qui peut être ultérieurement réoxydé en acétate (15). L'acide acétique et l'aromatique sont successivement éliminés à l'aide d'un évaporateur rotatif équipé d'une trompe à eau, puis d'une pompe à palette (0,1 Torr). Le mélange brut est redissout dans 50 mL de THF et 10 mL d'eau. Après refroidissement à 0°C, on ajoute, en agitant, 100 mg de KBH_4 afin de réduire les traces de sels de palladium qui colorent la solution. Après 30 min, un nouveau précipité de palladium est obtenu et la solution est complètement décolorée. Après filtration et évaporation du THF, on extrait avec 100 mL de chloroforme. La solution chloroformique est lavée à l'eau jusqu'à pH neutre. Après séchage sur $MgSO_4$, filtration et évaporation du solvant sous pression réduite, on obtient le mélange brut. La composition de celui-ci est déterminée par clhp analytique. Dans certains cas, le produit principal cristallise directement et peut être isolé par recristallisation dans l'éthanol 95%. Les eaux-mères de recristallisation sont ensuite analysées par chromatographie sur colonne de silice. Dans les autres cas, c'est le mélange brut qui est chromatographié.

Lorsque l'arylation a été réalisée avec des quantités catalytiques de sel de palladium, le palladium métallique a été réoxydé à l'aide du monohydrate de l'acétate cuivrique. Par exemple, pour la réaction utilisant 20% d'acétate de palladium (0.6 mmol), on ajoute 4,8 mmol (959 mg) de $Cu(OAc)_2 \cdot H_2O$, au mélange réactionnel. Le traitement est également légèrement modifié. Après filtration et évaporation de l'acide acétique, le brut est dissout dans 100 mL d'éther éthylique, lavé à l'eau (3 × 20 mL), décoloré par agitation à 0°C avec 10 mL d'eau contenant 100 mg de KBH_4. La phase organique est à nouveau lavée à l'eau jusqu'à pH neutre. Après séchage sur $MgSO_4$ et filtration, le solvant et l'aromatique sont évaporés sous pression réduite à une température inférieure à 60°C. Le mélange brut obtenu est analysé comme ci-dessus.

Arylation du tri-O-acétyl-D-glucal ***1*** *avec le benzène*

L'arylation de 3 mmol de glycal **1** en présence de 3 mmol d'acétate de palladium est terminée en 8 h à 80°C comme le montre la ccm réalisée avec l'éluant C (3 élutions). La filtration permet de récupérer 240 mg de Pd (75%). La chromatographie sous pression a permis d'isoler successivement les composés suivants.

3,4,6-Tri-O-*acétyl-2-désoxy*-α-D-érythro-*hex-2-énopyranosylbenzène* ***1a***: 565 mg (54%); huile; R_f 0,50 (éluant A); $[\alpha]_D^{20}$ +69° (*c* 1,7, $CHCl_3$); ir (film): 1755 (ester d'énol), 1740 (ester), 1690 (C=C); uv ϵ_{257} = 291; spectre de masse: 348 (ϵ) 105 (68%) (Ar—C≡O)$^+$; *Anal.* calc. pour $C_{18}H_{20}O_7$ (348,4): C 62,06, H 5,79; trouvée: C 61,82, H 5,62.

Arylation du tri-O-*acétyl*-D-*glucal* ***1*** *avec le* m-*méthoxyanisole*

Réalisée sur 3 mmol de glycal **1** en présence de 3 mmol d'acétate de palladium, la réaction est terminée en 1 h 30 à 120°C. Par filtration, on récupère 214 mg (67%) de palladium. Par chromatographie sous pression, on isole les produits suivants.

3'-Methoxy-2'-(4,6-di-O-*acétyl-2,3-didésoxy*-β-D-érythro-*hex-2-énopyranosyl) anisole* ***1'd***: 84 mg (8%); huile; R_f 0,6 (éluant A); $[\alpha]_D^{20}$ +57° (*c* 0,76, $CHCl_3$); spectre de masse: 350 (ϵ) (pic moléculaire) 165 (Ar—C≡O)$^+$.

5'-Méthoxy-2'-(4,6-di-O-*acétyl-2,3-didésoxy*-β-D-érythro-*hex-2-énopyranosyl) anisole* ***1'e***: 40 mg (4%); huile; R_f 0,5 (éluant A). Ce produit a été décelé par ccm et clhp analytique. On lui attribue cette structure d'après son temps de rétention par comparaison avec ceux des produits de couplage **1***d* et **1***e*.

3'-Méthoxy-2'-(3,4,6-tri-O-*acétyl-2-désoxy*-α-D-érythro-*hex-2-énopyranosyl) anisole* ***1d***: 245 mg (20%); huile; R_f 0,42 (éluant A); $[\alpha]_D^{20}$ +75° (*c* 1,03, $CHCl_3$); ir: 1775 (ester d'énol), 1740 (ester), 1690 (C=C); spectre de masse: 408 (ϵ), 165 (50%) (ArC≡O)$^+$.

5'-Méthoxy-2'-(3,4,6-tri-O-*acétyl-2-désoxy*-α-D-érythro-*hex-2-énopyranosyl) anisole* ***1e***: 305 mg (25%); *F* = 88 − 89°C; R_f 0,38 (éluant A); $[\alpha]_D^{20}$ +58° (*c* 1,8, $CHCl_3$); ir: 1775 (ester d'énol), 1740 (ester), 1690 (C=C); uv ϵ_{277} = 2727, ϵ_{282} = 2475; spectre de masse: 408 (12%), 165 (45%) (Ar—C≡O)$^+$; *Anal.* calc. pour $C_{20}H_{24}O_9$ (408,4): C 58,87, H 5,93; trouvée: C 58,68, H 6,15.

Nous avons également isolé un composé plus polaire (R_f 0,25, éluant A) dont le spectre de masse présente, entre autres, un pic moléculaire de *m/e* = 542. Ce composé résulte de la réaction du tri-*O*-acétyl-D-glucal **1** sur lui-même, qui conduit à un diène selon la réaction décrite par Volger (13).

La réaction a été aussi effectuée de façon catalytique, elle donne un rendement total de 36% correspondant aux produits **1***d* et **1***e*.

Arylation du tri-O-*acétyl*-D-*galactal* ***2*** *avec le benzène*

Réalisé sur 3 mmol de glycal **2** en présence de 3 mmol de $Pd(OAc)_2$, elles est terminée en 2 h à 120°C. Par filtration, on récupère 288 mg (90%) de palladium. Par cristallisation et chromatographie, on isole le 3,4,6-tri-*O*-acétyl-2-désoxy-α-D-*thréo*-hex-2-énopyranosylbenzène ***2a***: 532 mg (51%); *F* = 126−126,5°C (éthanol 95%); R_f 0,56 (éluant A); $[\alpha]_D^{20}$ −195° (*c* 1,63, $CHCl_3$); ir (KBr): 1775 (ester d'énol), 1750 (ester); uv ϵ_{257} = 291; spectre de masse: 348 (ϵ), 105 (60%) (Ar—C≡O)$^+$; *Anal.* calc. pour $C_{18}H_{20}O_7$ (348,34): C 62,06, H 5,79; trouvée: C 62,08, H 5,74.

La réaction a été également réalisée sur 3 mmol de glycal **2** en présence d'une quantité catalytique (0,6 mmol, 135 mg) d'acétate de palladium et d'acétate de cuivre monohydrate (4,8 mmol, 958 mg) dans les mêmes conditions de concentrations à 120°C. La réaction est terminée en 13 h. Par cristallisation du brut dans le méthanol et chromatographie sous pression des eaux-mères, on isole le produit de couplage **2***a* (310 mg) avec un rendement de 30%. Lors de cette manipulation, on a pu isoler aussi un produit isomère du produit de départ, l'acétate de 4,6-di-*O*-acétyl-2,3-didésoxy-D-hex-2-énopyranosyle: 103 mg (12,6%); spectre de masse: 272 (ϵ) (pic moléculaire). Son R_f dans l'éluant A est de 0,36 alors que pour le tri-*O*-acétyl-D-galactal **2** il est de 0,51.

Arylation du tri-O-*acétyl*-D-*galactal* ***2*** *avec l'anisole*

La réaction a été réalisée sur 3 mmol de glycal **2** en présence de 3 mmol d'acétate de palladium, la réaction est terminée en 2 h à 120°C. La filtration permet de récupérer 221 mg (70%) de palladium.

Le 2'-(3,4,6-tri-*O*-acétyl-2-désoxy-α-D-*thréo*-hex-2-énopyranosyl) anisole ***2b*** et le 4'-(3,4,6-tri-*O*-acétyl-2-désoxy-α-D-*thréo*-hex-2-énopyranosyl) anisole ***2c*** formés respectivement par fixation du glucide en *ortho* ou en *para* du groupe méthoxy de l'aromatique n'ont pas pu être séparés par chromatographie préparative sous pression. Le mélange recueilli (465 mg) correspond à un rendement d'arylation de 41%; *Anal.* calc. pour $C_{19}H_{22}O_8$ (378,38): C 60,37, H 5,87; trouvée: C 60,51, H 6,03. Les proportions des deux composés ont été estimées à partir des signaux des hydrogènes des groupes méthoxy qui possèdent des δ différents en rmn ^{1}H (3,98 ppm pour **2***b* et 3,87 ppm pour **2***c*). Elles correspondent à 47% de composé *ortho* **2***b* et 53% de composé *para* **2***c*.

Arylation du tri-O-*acétyl*-D-*galactal* ***2*** *avec le* m-*méthoxyanisole*

Réalisée sur 3 mmol de glycal **2** en présence de 3 mmol d'acétate de palladium, la réaction est terminée en 1 h 30 à 120°C. On récupère 211 mg (66%) de palladium. Par chromatographie, on isole les deux composés suivants.

3'-Méthoxy-2'-(3,4,6-tri-O-*acétyl-2-désoxy*-α-D-thréo-*hex-2-énopyranosyl) anisole* ***2d***: 281 mg (23%); *F* = 90−91°C (éther−pentane); R_f 0,47 (éluant A); $[\alpha]_D^{20}$ −179° (*c* 0,8, $CHCl_3$); ir (KBr): 1740 (ester), 1690 (C=C); uv ϵ_{278} = 2156; spectre de masse: 408 (14%), 165 (24%) (Ar—C≡O)$^+$; *Anal.* calc. pour $C_{20}H_{24}O_9$ (408,4): C 58,87, H 5,93; trouvée: C 58,56, H 6,13.

5'-Méthoxy-2'-(3,4,6-tri-O-*acétyl-2-désoxy*-α-D-thréo-*hex-2-énopyranosyl) anisole* ***2e***: 355 mg (29%); *F* = 103−104°C (éther−pentane); R_f 0,40 (éluant A); $[\alpha]_D^{20}$ −159° (*c* 0,88, $CHCl_3$); ir (KBr): 1740 (ester), 1690 (C=C); uv ϵ_{282} = 2475, ϵ_{278} = 2727; spectre de masse: 408 (11%), 165 (26%) (Ar—C≡O)$^+$; *Anal.* calc. pour $C_{20}H_{24}O_9$ (408,4): C 58,87, H 5,93; trouvée: C 57,87, H 7,23.

Arylation du tri-O-*acétyl*-D-*galactal* ***2*** *avec le* p-*méthoxyanisole*

L'arylation de 3 mmol de **2** en présence de 3 mmol d'acétate de palladium est terminée en 1 h 30 à 120°C. La filtration permet de récupérer 224 mg (70%) de palladium. Par cristallisation et chromatographie, on isole le 4'-méthoxy-2'-(3,4,6-tri-*O*-acétyl-2-désoxy-α-D-*thréo*-hex-2-énopyranosyl) anisole ***2f***: 516 mg (43%); *F* = 113−114°C (éthanol 95%); R_f 0,34 (éluant A); $[\alpha]_D^{20}$ −213° (*c* 1,06, $CHCl_3$); ir (KBr): 1775 (ester d'énol), 1755 (ester); uv ϵ_{293} = 5028; spectre de masse: 408 (ϵ), 165 (47%) (Ar—C≡O)$^+$; *Anal.* calc. pour $C_{20}H_{24}O_9$ (408,4): C 58,87, H 5,93; trouvée: C 58,89, H 5,85.

Arylation du tri-O-*acétyl*-D-*galactal* ***2*** *avec le* p-*nitroanisole*

Réalisée sur 3 mmol de **2** en présence de 3 mmol de $Pd(OAc)_2$, elle est terminée en 2 h à 120°C. On récupère 300 mg (94%) de palladium par filtration. Par chromatographie sous pression, on isole le 4'-nitro-2'-(3,4,6-tri-*O*-acétyl-2-désoxy-α-D-*thréo*-hex-2-énopyranosyl) anisole ***2g***: 320 mg (25%); *F* = 144−145°C (éthanol absolu); R_f 0,22 (éluant A); $[\alpha]_D^{20}$ −162° (*c* 0,5, $CHCl_3$); ir (KBr): 1775 (ester d'énol), 1755 (ester), 1510, 1335 et 1370 (C—NO_2 aromatique), uv ϵ_{305} = 11 203; spectre de masse: 423 (ϵ), 180 (30%) (Ar—C≡O)$^+$; *Anal.* calc. pour $C_{19}H_{21}O_{10}N$ (423,4): C 53,95, H 5,00, N 3,31; trouvée: C 54,07, H 5,02, N 3,38.

Arylation du tri-O-*acétyl*-D-*galactal* ***2*** *avec le* p-*fluoroanisole*

Réalisée sur 3 mmol de **2** en présence de 3 mmol de $Pd(OAc)_2$, elle est terminée en 4 h à 120°C. Par filtration, on récupère 310 mg (98%) de palladium. La chromatographie sous pression permet d'isoler les deux composés suivants.

4'-Fluoro-3'-(3,4,6-tri-O-*acétyl-2-désoxy*-α-D-thréo-*hex-2-énopyranosyl) anisole* ***2h***: 392 mg (31%); *F* = 95−96°C (éther−pentane); R_f 0,51 (éluant A); $[\alpha]_D^{20}$ −204° (*c* 1,09, $CHCl_3$); ir (KBr): 1775 (ester d'énol), 1750 (ester); uv $\epsilon_{282.5}$ = 3736; rmn ^{13}C ($CDCl_3$): 124,8 d (J_{C-C-F} = 16,5 Hz) C'3, 155,4 d (J_{C-F} = 242,6 Hz) C'4; spectre de masse: 396 (ϵ), 153 (18%) (Ar—C≡O)$^+$; *Anal.* calc. pour $C_{19}H_{21}O_8F$ (396,4): C 57,62, H 5,35; trouvée: C 57,48, H 5,45.

4'-Fluoro-2'-(3,4,6-tri-O-*acétyl-2-désoxy*-α-D-thréo-*hex-2-énopyranosyl) anisole* ***2i***: 324 mg (28%); *F* = 102−103°C (éthanol

95%); R_f 0,43 (éluant A); $[\alpha]_D^{20}$ −182° (*c* 1,03, $CHCl_3$); ir (KBr): 1775 (ester d'énol), 1750 (ester); uv ϵ_{282} = 4180; rmn ^{13}C ($CDCl_3$): 126,9 d ($J_{C-C-C-F}$ = 6,1 Hz) C′2, 156,6 d (J_{C-F} = 241,5 Hz) C′4; *Anal.* calc. pour $C_{19}H_{21}O_8F$ (396,4): C 57,62, H 5,35; trouvée: C 57,44, H 5,24.

Remerciements

Nous remercions J. Mercier et O. Convert qui ont réalisé, respectivement, les spectres de masse et de rmn au Centre de Spectrochimie de l'Université P. et M. Curie. Nous remercions également la Direction Générale à la Recherche Scientifique pour son support financier.

Crystal and molecular structure of hexadecamethylcyclooctasiloxane, $[(CH_3)_2SiO]_8$

NORMAN L. PADDOCK, STEVEN J. RETTIG, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received September 21, 1982

NORMAN L. PADDOCK, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **61**, 541 (1983).

Crystals of hexadecamethylcyclooctasiloxane are tetragonal, a = 13.9442(5), c = 8.5573(4) Å, Z = 2, space group $P4/nnc$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to a final R of 0.034 and R_w = 0.042 for 730 reflections with $I \geq 3\sigma(I)$. The molecular structure closely resembles that of $[(CH_3)_2PN]_8$. Its comparatively rigid conformation, in which the silicon atoms form a crown, is dependent on the efficient use of van der Waals interactions between two sets of four methyl groups. Important molecular dimensions (bond lengths corrected for libration) are: Si—O = 1.629(1) and 1.635(1), Si—C = 1.862(2) and 1.848(3) Å, O—Si—O = 108.99(6), Si—O—Si = 157.8(1) and 148.8(2)°.

NORMAN L. PADDOCK, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **61**, 541 (1983).

Les cristaux de l'hexadécaméthylcyclooctasiloxane sont tétragonaux, a = 13.9442(5), c = 8.5573(4) Å, Z = 2, groupe d'espace $P4/nnc$. On a résolu la structure par les méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.034 et R_w de 0.042 pour 730 réflexions avec $I \geq 3\sigma(I)$. La structure moléculaire se ressemble presquement à cela de $[(CH_3)_2PN]_8$, sa conformation comparativement rigide, dans laquelle les atomes de silicium forment une couronne, étant dépendante de l'usage efficient des interactions van der Waals entre les deux ensembles de quatre groupes méthyles. Les dimensions moléculaires importantes (longeurs de liaisons corrigées pour les librations) sont: Si—O = 1.629(1) et 1.635(1), Si—C = 1.862(2) et 1.848(3) Å, O—Si—O = 108.99(6) et Si—O—Si = 157.8(1) et 148.8(2)°.

Introduction

The cyclic dimethylsiloxanes $[(CH_3)_2SiO]_n$ are isoelectronic with the cyclic dimethylphosphazenes $[(CH_3)_2PN]_n$, and there is at least a limited structural correspondence between the two series. The trimeric molecules could indeed hardly be different; the early determination of the structure of $[(CH_3)_2SiO]_3$ (1) has been repeated at −165°C (2), and the Si_3O_3 ring, like the P_3N_3 ring in $[(CH_3)_2PN]_3$ (3), found to deviate from planarity. Eight-membered rings are more conformationally versatile, but the same structures occur in both series. In the solid at low temperatures, $[(CH_3)_2SiO]_4$ has the chair conformation, with symmetry C_i (4), which changes to S_4 above −16.3°C (5, 6). The symmetry is not lowered in the liquid phase (7), the crown conformation (C_{4v}) (5, 6, 8) being specifically excluded by the Raman depolarization values (9). The corresponding phosphazene has S_4 symmetry in the crystal (10), and a metastable crystalline polymorph has been found,[1] in which the molecule has crystallographically imposed C_i symmetry and is presumably chair-shaped. No detail is known of the structures of the cyclic siloxanes $[(CH_3)_2SiO]_{5-7}$, though the central 12-membered ring in 2,2,4,4,14,14,16,16-octaphenyl-8,8,10,10,19,19,21,21-octamethyldispiro[5,5,5,5]decasiloxane is chair-shaped (11), like the P_6N_6 ring in $[(CH_3)_2PN]_6$ (12).

A comparison of the crystal structures of the dimethylphosphazenes up to $[(CH_3)_2PN]_8$ (12–14) shows the increasingly frequent occurrence of the sterically favorable GG and GT local conformations at P, and suggests that stable structures are determined by steric interactions. The comparability of the two series is apparently lost at $[(CH_3)_2SiO]_8$, because, if the molecular symmetry were S_4, as deduced from a partial structure determination (15), the molecule would contain GG′ fragments of high energy. We have therefore redetermined the crystal structure of $[(CH_3)_2SiO]_8$, both to check this point, and to allow a detailed comparison with the structure of $[(CH_3)_2PN]_8$.

[1]Tetragonal, a = 15.953, c = 7.645 Å (H. P. Calhoun, personal communication). Cf. a = 15.705, c = 6.425 Å for the stable form (10).

Experimental

Crystals of hexadecamethylcyclooctasiloxane were provided by Professor J. Dale. The crystal was mounted in a general orientation and had dimensions of ca. 0.17 × 0.34 × 0.50 mm. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 30–50°) measured on a diffractometer with Mo-Kα_1 radiation (λ = 0.70930 Å). Crystal data (at 22°C) are:

$C_{16}H_{48}O_8Si_8$ fw = 593.25

Tetragonal, a = 13.9442(5), c = 8.5573(4) Å, V = 1663.9(1) Å^3, Z = 2, ρ_c = 1.184 g cm^{-3}, $F(000)$ = 640, μ(Mo-Kα) = 3.08 cm^{-1}. Absent reflections: $hk0$, $h + k$ odd, $0kl$, $k + l$ odd and hhl, l odd, space group $P4/nnc$ (D_{4h}^4, No. 126). Lattice constants agree with those reported earlier (15) but the space group reported previously ($P\bar{4}2_1c$) is not consistent with the observed systematic absences.

Intensities were measured with graphite-monochromated Mo-Kα

*Here and elsewhere in this report primed and double-primed atoms are related to those in Table 1 by the symmetry operations $x, 1/2 - y, 1/2 - z$ and $1/2 - y, 1/2 - x, 1/2 - z$ respectively.

radiation ($\lambda = 0.71073$ Å) on an Enraf-Nonius CAD4-F diffractometer. An $\omega-2\theta$ scan at 1.44–10.06° min^{-1} over a range of (0.65 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to $2\theta = 60°$. The intensities of three check reflections, measured every 3600 s throughout the data collection, decreased uniformly by 15%, the data being corrected for isotropic decay. After data reduction, an absorption correction was applied using the Gaussian integration method (16, 17). Transmission factors ranged from 0.880 to 0.924 for 80 integration points. Of the 1211 independent reflections measured, 730 (60.3%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods, the coordinates of the ring atoms being determined from an E-map and those of the carbon atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.062$, all six hydrogen atoms were positioned from a difference map and were refined with isotropic thermal parameters in subsequent least-squares cycles. The scattering factors of ref. 18 were used for non-hydrogen atoms and those of ref. 19 for hydrogen atoms. Anomalous scattering factors from ref. 20 were used for the Si atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of refinement. Convergence was reached at $R = 0.034$ and $R_w = 0.042$ for 730 reflections with $I \geq 3\sigma(I)$. For all 1211 reflections $R = 0.069$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.002 and 0.03σ respectively. The mean error in an observation of unit weight was 1.757. A final difference map showed no unusual features. The final positional and thermal parameters appear in Tables 1 and 2 respectively.[2] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

The ellipsoids of thermal motion for the non-hydrogen atoms are

[2]The structure factor table and Table 2 (anisotropic thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (21). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0011 Å^2. Analysis of the SiO_2C_2 unit gave rms ΔU_{ij} = 0.0009 Å^2 and physically reasonable rigid-body parameters. The appropriate bond distances have been corrected for libration (21, 22), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 4. Torsion angles are listed in Table 5.

Results and discussion

The cell dimensions obtained here are identical within experimental error to those obtained by Frevel and Hunter (15), but the space group is different. It is indeed not impossible that there should be two closely related polymorphic forms, but, in any case, the diffraction symmetry of the crystals we have examined is unambiguous, with the required molecular symmetry D_4 (Fig. 1). O(1) is in position 8(i), O(2) in 8(h), and other atoms in 16(k) (origin is taken at the centre, $\bar{1}$). The oxygen atoms thus lie on twofold axes and are all coplanar, with the Si atoms displaced alternately above and below the plane by 0.8099(4) Å. The lengths of the Si—O bonds to O(1) are slightly less (1.629(1) Å) than to O(2) (1.635(1) Å), the greater length being associated with the smaller angle, as expected if the inequality is a result of differences in σ-hybridization. The ring angle at silicon (109.0(1)°) and the C—Si—C angle (110.7(2)°) are unremarkable, and though the lengths of the Si—C bonds are significantly different (Si—C(1)(eq) = 1.862(2) Å, Si—C(2)(ax) = 1.843(3) Å), their mean value, 1.855(2) Å, is typical. The ring angles at O(1) and O(2) are 157.8(1) and 148.8(2)°, respectively.

The molecular conformation of $[(CH_3)_2SiO]_8$ is strikingly similar to that of $[(CH_3)_2PN]_8$ (14). Their molecular dimensions are similar, and both have a direct fourfold axis. Comparison

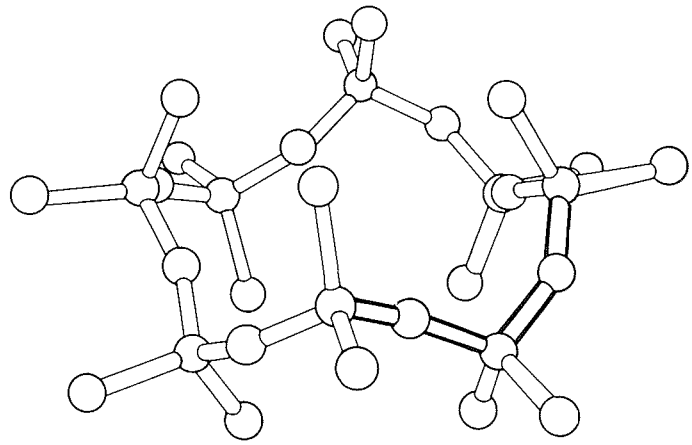

FIG. 2. General view of hexadecamethylcyclooctasiloxane showing the local conformations at silicon (heavy lines).

of the ring torsion angles shows that the local conformations are nevertheless different in the two molecules. In $[(CH_3)_2PN]_8$, GG and GT conformations alternate.[3] In $[(CH_3)_2SiO]_8$, the local conformation at silicon (shown more clearly in Fig. 2) is close to CT, the angle between the Si′—Si—Si″ and O(1)—Si—O(2) planes being 13.1° (ideally 0°). The conformational difference from $[(CH_3)_2PN]_8$ is less than might appear, because the distinctions between GG, GT, and CT disappear as the angle at O (or N) approaches 180°, and the siloxane angles are especially large (mean 153.3°). Model calculations nevertheless show that the highly polar bonds likely in the siloxanes would favor the CT conformation. The general shape of the molecules seems to be governed by the intramolecular contacts between the axial methyl groups; 3.96 Å in $[(CH_3)_2SiO]_8$, 3.82, 4.01 (mean 3.92 Å) in $[(CH_3)_2PN]_8$. These distances are attained by the slight twisting of the CT local conformation noted above, in turn made possible by a low barrier to rotation about the Si—O bond, at most a few hundred cal mol^{-1} (23). The small temperature factors (Table 2) show that the molecule is much more rigid than, for instance, $[(CH_3)_2SiO]_3$ (2), but less so than the sterically hindered $[(t\text{-}C_4H_9)_2SiO]_3$ (24). The particular conformation found (Fig. 2) clearly allows efficient use of the Van der Waals interactions at the top and the bottom of the molecule, and the consequent comparative rigidity, unusual for dimethylsiloxanes, is in agreement with the high entropy of fusion of $[(CH_3)_2SiO]_8$ (25), and with the comparatively sharp and simple spectrum of the solid (7). The methyl groups do not rotate freely about the Si—C axes.

More generally, the flexibility of the dimethylsiloxanes in the liquid and vapor phases (5, 7, 9, 25, 26), and (apart from $[(CH_3)_2SiO]_8$) their likely conformational inhomogeneity in the solid (25) results primarily from the high polarity of the Si—O bond (27), which increases the angle at oxygen, thereby increasing its deformability and decreasing the rotational barrier. This can happen in two ways. The lone pairs on oxygen may be partially delocalized into the *d*-orbitals of silicon, so becoming stereochemically ineffective. Alternatively, *d*-orbitals may not be used. If the Si—O—Si angle then approaches 180°, the unshared electrons eventually occupy orthogonal *p*-orbitals at oxygen, their density distribution being cylindrically symmetrical about the Si—O bond, and the torsional barrier

[3]Terminology of Mizushima (34).

then vanishes.

The O—Si—O angle is close to the regular tetrahedral angle, suggesting, by comparison with the phosphazene series, and in agreement with *ab initio* calculations (27), that the *d*-orbital interaction is small and the polar effect dominant. A similar conclusion was reached earlier for Si—N interactions, $X\alpha$ calculations (28) showing that polar interactions were more important than π-bonding in ensuring the skeletal planarity of $N(SiH_3)_3$.

If the torsional barrier about the Si—O bond is small, the molecular conformation of individual dimethylsiloxanes will be controlled principally by the interaction of the exocyclic groups. In making comparisons with organic structures (25, 29), it is then perhaps more appropriate to compare siloxanes $[(CH_3)_2SiO]_n$ with the cycloalkanes $(CH_2)_n$ rather than $(CH_2)_{2n}$. The conformations of cyclooctane and its derivatives have been frequently investigated by spectroscopic and X-ray methods; the boat–chair conformation is usually found. In the vapor, a large number of conformations occur (30); the crown form, specifically, being only slightly less stable, both by experiment (31) and calculation (32), than the boat–chair. In the absence of torsional barriers, the crown conformation would be expected (33), and this is indeed the arrangement found for the Si atoms in $[(CH_3)_2SiO]_8$.[4] It is not yet known whether the neglect of the torsional barrier about the Si—O bond can be helpful in the qualitative interpretation of related structures.

A. BRUCE MCKAGUE, STEVEN J. RETTIG, JAMES TROTTER, GEORGE R. DOUGLAS, and EARLE R. NESTMANN. Can. J. Chem. **61**, 545 (1983).

Aqueous chlorination of dihydroconiferyl alcohol, a phenol present in pulping liquors, gave a mixture of three products. The two major products, which formed an inseparable mixture, yielded the crystalline epoxides **1** and **8** when reacted with diazomethane. The epoxide **1** had previously been obtained by reacting one of the components isolated from mutagenic fractions of chlorination-stage effluent from a bleached kraft pulp mill with diazomethane. The results indicate dihydroconiferyl alcohol retained with pulp is chlorinated in the bleach plant to give a mixture of the spirocyclohexenediones **5** and **6**. Crystals of **8** are orthorhombic, a = 24.3048(15), b = 12.5403(9), c = 7.8653(6) Å, Z = 8, space group *Pbca*. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.029 and R_w = 0.035 for 1308 reflections with $I \geq 3\sigma(I)$. The structure analysis shows that **8** has the same relative stereochemistry as that reported earlier for **1**, but exists as a different conformer in the solid state.

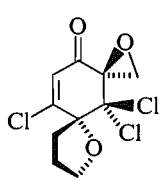
A. BRUCE MCKAGUE, STEVEN J. RETTIG, JAMES TROTTER, GEORGE R. DOUGLAS et EARLE R. NESTMANN. Can. J. Chem. **61**, 545 (1983).

La chloration aqueuse de l'alcool dihydroconiféryle, un phénol que l'on trouve dans les liquides provenant de la fabrication de la pâte à papier, conduit à un mélange de trois produits. On ne peut par séparer les deux produits principaux mais ils réagissent avec le diazométhane pour donner deux époxydes cristallins (**1** et **8**). On a préparé antérieurement l'époxyde **1** en faisant réagir du diazométhane avec un des composés isolés des fractions mutagéniques rejeté à l'étape de la chloration dans une usine de pâte Kraft blanchie. Les résultats indiquent que l'alcool dihydroconiféryle retenu avec la pâte est chloré dans l'usine de blanchissage et donne un mélange des spirocyclohexènediones (**5** et **6**). Les cristaux du composé **8** sont orthorhombiques et appartiennent au groupe d'espace *Pbca* avec a = 24,3048(15), b = 12,5403(9), c = 7,8653(6) Å, Z = 8. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,029 et de R_w = 0,035 pour 1308 réflexions avec $I \geq 3\sigma(I)$. L'analyse de la structure révèle que le composé **8** a la même stéréochimie relative que celle rapportée antérieurement pour le composé **1**; toutefois sa conformation a l'état solide est différent.

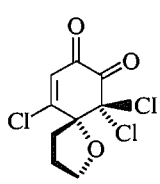
[Traduit par le journal]

Introduction

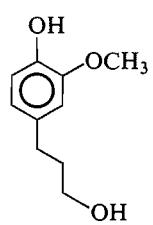
Recently we reported the structure determination of the trichlorocyclohexenone **1** (1). Since the compound was obtained by reacting one of the constituents of bleached kraft chlorination-stage effluent with diazomethane, the corresponding cyclohexenedione **2** was suggested as the parent compound present in the effluent.



1



2



3

Analysis of the basic structural features of **2** revealed that dihydroconiferyl alcohol, **3**, a phenol present in black liquor (2, 3) and unbleached whitewater (4), contained the necessary carbon skeleton and functionality to serve as a precursor of **2**. The guaiacyl nucleus is a known source of *o*-quinones which are produced during bleaching of pulp (5, 6). Cyclization of hydroxypropyl side chains on *para*-substituted cyclohexenones to form spirotetrahydrofuranylcyclohexenones has been achieved by displacement of a leaving group at the cyclization point (7). This paper describes the remarkable transformation of dihydroconiferyl alcohol upon chlorination.

Experimental

Melting points were taken on a Kofler Micro Hot Stage and are uncorrected. Infrared (ir) spectra were recorded on a Perkin Elmer Model 727 Spectrophotometer; ultraviolet (uv) spectra on a Beckman DB-GT Spectrophotometer. Proton magnetic resonance (^{1}H nmr) spectra were recorded in deuteriochloroform using a Varian XL-100 spectrometer. Chemical shifts are given in δ units with tetramethylsilane as the internal standard. A Varian MAT CH 4B mass spectrometer was used to obtain low resolution mass spectra; an AEI MS 12 for high resolution spectra. Microanalytical services were provided by Canadian Microanalytical Service Ltd., 5704 University Blvd., Vancouver, B. C.

Liquid chromatography (lc) was performed on a Hewlett Packard Model 1084B High Performance Liquid Chromatograph equipped

with a 20 μL valve injector and variable wavelength ultraviolet detector set at 254 nm. Reverse phase partition chromatography was done on a 4.6 × 20 cm RP-8 column, 5 μm particle size, using isocratic elution with acetonitrile:water, 70:30 and a flow of 0.75 mL/min. Precoated aluminum silica gel plates containing fluorescent indicator (254 nm) were used for thin-layer chromatography (tlc).

Chlorination of dihydroconiferyl alcohol

Chlorine was gently bubbled through a stirred solution of dihydroconiferyl alcohol (500 mg, 2.75 mmol) in water (250 mL) at 50°C for 20 min. After cooling to room temperature, the yellow solution was extracted with ether. The combined extracts were washed with water, dried over anhydrous magnesium sulfate, and evaporated to give a yellow oil (700 mg). The product was purified by preparative tlc using hexane:ethyl acetate 2:1 as the developing solvent. Isolation of the major less polar band gave a mixture of 1-oxa-6,10,10-trichlorospiro[4.5]dec-6-en-8,9-dione, **5**, and 1-oxa-6,7,10,10-tetrachlorospiro[4.5]dec-6-en-8,9-dione, **6** (Scheme 1) as a clear colorless oil (295 mg); ir (film): 1710 cm^{-1}; uv (ethanol) λ_{max}: 247 nm; ^1H nmr δ: 2.2 and 4.3 (complex multiplets), 6.3 (s). A more polar, minor product was also isolated but has not been investigated.

1,6-Dioxa-4,4,10-trichlorodispiro[2.1.4.3]dodec-10-en-12-one, 7, and 1,6-dioxa-4,4,10,11-tetrachlorodispiro[2.1.4.3]dodec-10-en-12-one, 8

Diazomethane, generated from *N*-nitrosomethylurea, was bubbled through a solution of a mixture of the two diones obtained above (200 mg) in ether:methanol 9:1 (10 mL) for 1.5 h. After evaporation of the solvent the product was fractionated by preparative tlc on silica gel (benzene:ethyl acetate 95:5). Isolation of the two major uv-absorbing bands gave products which were obtained crystalline by titration with cold hexane. Recrystallization of the more polar product from ether–hexane gave colorless prisms of the trichlorodispirocyclohexenone **7**; mp 88–89°C; ir (Nujol): 1695, 1605 cm^{-1}; uv (ethanol) λ_{max}: 244 nm (ε 11 400); ^1H nmr δ: 2.3 (m, 2H), 2.8 (m, 2H), 3.15 (diffuse m, 1H), 3.45 (doublet, 1H, J = 6 Hz), 4.25 (m, 2H), 6.5 (s, 1H); ms *m/e* (% relative intensity): 284 (1.6), 282 (1.7) M^+, 136 (100). *Anal.* calcd. for $C_{10}H_9Cl_3O_3$: C 42.56, H 3.22, Cl 37.21; found: C 42.82, H 2.98, Cl 37.43. This epoxide was identical to the epoxide **1** whose structure was previously determined by X-ray crystallography (1).

Recrystallization of the less polar diazomethane product from ether–hexane gave colorless prisms of the tetrachlorodispirocyclohexenone **8**; mp 109–110°C; ir (Nujol): 1705, 1570 cm^{-1}; uv (ethanol) λ_{max}: 262 nm (ε 9,900); ^1H nmr δ: 2.3 (m, 2H), 2.8 (m, 2H), 3.15 (diffuse m, 1H), 3.5 (doublet, 1H, J = 6 Hz), 4.25 (m, 2H); ms *m/e* (% relative intensity): 320 (0.7), 318 (1.2), 316 (1.1) M^+, 281 (100), 145 (100). Exact mass calculated for $C_{10}H_8Cl_4O_3$: 315.9228; found: 315.9214.

X-ray crystallographic analysis of the tetrachlorodispirocyclohexenone 8

A crystal bounded by the five faces (followed by their distances in mm from a common origin): ±(−2 1 1), 0.069, (−2 1 −2), 0.088, (3 1 1), 0.113, and (−1 −2 0), 0.131 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Mo-Kα$_1$ radiation (λ = 0.70930 Å). Crystal data at 22°C are:

$C_{10}H_8Cl_4O_3$ fw = 317.98

Orthorhombic, a = 24.3048(15), b = 12.5403(9), c = 7.8653(6) Å, V = 2397.2(3) Å^3, Z = 8, ρ_c = 1.762 g cm^{-3}, $F(000)$ = 1280, μ(Mo-Kα) = 9.83 cm^{-1}. Absent reflections: 0kl, k odd; $h0l$, l odd; and $hk0$, h odd; uniquely indicate the space group $Pbca$ (D_{2h}^{15}, No. 61).

Intensities were measured with graphite-monochromatized Mo-Kα radiation (λ = 0.71073 Å) on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 0.96–10.06° min^{-1} over a range of (0.65 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 3%. After data reduction,[1] an absorption correction was applied using the analytical method (8, 9). Transmission factors ranged from 0.795 to 0.895. Of the 2732 independent reflections measured, 1308 (47.9%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from an E-map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to R = 0.045, all eight hydrogen atoms were located on a difference map and were refined with isotropic thermal parameters in subsequent cycles of refinement. The scattering factors of ref. 10 were used for non-hydrogen atoms and those of ref. 11 for hydrogen atoms. Anomalous scattering factors from ref. 12 were used for the Cl atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of refinement. Convergence was reached at R = 0.029 and R_w = 0.035 for 1308 reflections with $I \geq 3\sigma(I)$. For all 2732 reflections R = 0.112. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.06 and 0.70σ respectively. The mean error in an observation of unit weight was 1.508. A final difference map showed maximum fluctuations of −0.42 to +0.35 e Å^{-3} in the vicinity of the chlorine atoms. The final positional and thermal parameters

appear in Tables 1 and 2[2] respectively. The largest parameter shift was associated with the x coordinate of H(2a). Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (13). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0017 Å^2. Analysis of all non-hydrogen atoms except the carbonyl oxygen atom gave rms ΔU_{ij} = 0.0044 Å^2 and physically reasonable results. The appropriate bond distances have been corrected for libration (13, 14), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in

[2]The structure factor table, Table 2 (anisotropic thermal parameters) and other material mentioned in the text are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

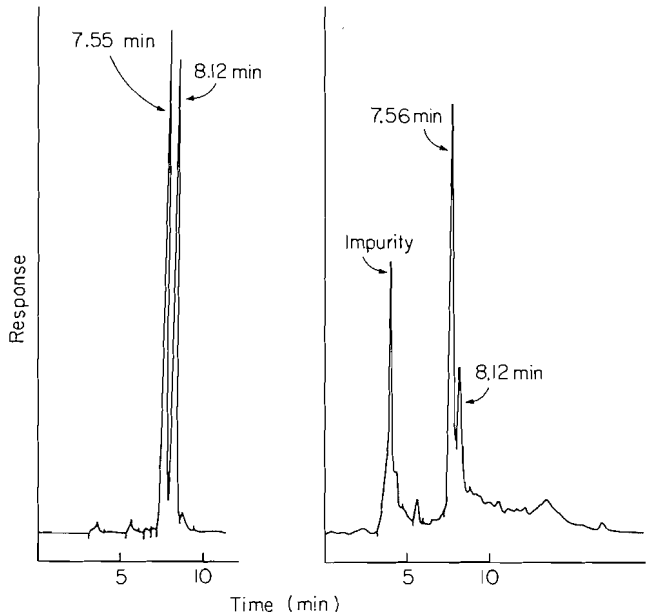

FIG. 2. Liquid chromatograms of the major product from the chlorination of dihydroconiferyl alcohol (left) and material isolated from chlorination-stage effluent (right).

Table 3 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of five- and six-membered rings are listed in Table 5. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 6–8) are included as supplementary material.

Results and discussion

Three products were obtained from the aqueous chlorination of dihydroconiferyl alcohol **3**. The two major products, obtained in a yield of 59% (by weight) after preparative thin-layer chromatography (tlc), could not be separated and remained non-crystalline. Liquid chromatography (lc, Fig. 2) indicated nearly equal amounts of the two components were present. The third product, obtained in 18% yield (by weight) was more polar and has not been investigated at this stage.

The mixture of the two major products contained carbonyl absorption at 1710 cm^{-1} in the ir spectrum. Complex multiplets were present at δ 2.2 and 4.3 in the ^1H nmr spectrum and an olefinic hydrogen appeared as a singlet at δ 6.3. Ultraviolet absorption was present at 247 nm. Spectral features of the mixture were very similar to the material isolated from chlorination-stage effluent during the previous study (1). In addition, the mixture had the same Rf and color reaction with 2,4-dinitrophenylhydrazine on tlc as the isolated material and the retention times were identical by lc (Fig. 2). The only difference between the product from the chlorination of dihydroconiferyl alcohol and the material isolated from chlorination-stage effluent, apart from the presence of an impurity in the isolated material (Fig. 2), was the ratio of the two components. Whereas nearly equal amounts of each component were present in the chlorination product, the isolated material contained approximately a 4:1 ratio of the same components. Since separation and complete characterization of the two major products from the chlorination of dihydroconiferyl alcohol was not possible, further characterization was done on the diazomethane reaction products as was done with the material isolated from chlorination-stage effluent (1).

Nearly equal amounts of two compounds were obtained by reaction of the two major dihydroconiferyl alcohol chlorination products with diazomethane. The two compounds were readily separable by the tlc and the more polar of these was identical to the previously described epoxide **1**. The less polar diazomethane product had carbonyl absorption at 1705 cm^{-1} and olefinic absorption at 1570 cm^{-1} in the ir spectrum. The absorption frequencies of the carbonyl and olefinic groups were shifted 10 cm^{-1} higher and 35 cm^{-1} lower, respectively, relative to the corresponding frequencies in **1**. No olefinic hydrogens were present in the ^1H nmr spectrum and the absorption maximum in the uv spectrum appeared at 262 nm, 18 nm higher than the absorption maximum of **1**. These spectral features, coupled with a molecular formula of $C_{10}H_8Cl_4O_3$ from mass spectrometry, suggested the second diazomethane reaction product was a tetrachlorocyclohexenone epoxide derived from **6**. A complete structure determination by X-ray crystallography, described in the following section of this paper, showed that the compound was **8**. By analogy with the work described previously (1), the two major products from the chlorination of dihydroconiferyl alcohol are the cyclohexenediones **5** and **6**.

A mechanism to account for formation of the cyclohexenediones is shown in Scheme 1. Demethylation of guaiacols is known to occur rapidly with aqueous chlorine (5, 15) to give the chlorinated catechols found in chlorination-stage effluent. Formation of the spirotetrahydrofuran ring could occur by displacement of chloride from a dienone-type intermediate such as **4**. A similar cyclization has recently been reported in the synthesis of theaspirone (7). Conversion of ketones to epoxides is known to be efficient when chlorine substituents are present in the α-position (16).

Crystals of **8** consist of discrete molecules (Fig. 1). The relative stereochemistry at the chiral centres (C(4) and C(6)) is the same in **1** (1) and **8**, i.e. *RR* (or *SS*, the materials being racemic), with the furan and epoxy oxygens *trans*. However, the two molecules exist in different conformational forms in the solid state, **1** having O(furan) pseudo-axial and O(epoxy) pseudo-equatorial, with these orientations reversed in **8** (Fig. 1); conformational inversion of Fig. 1[3] produces a geometry (which is not found in the solid state) which is identical with that of **1** (mirror image of Fig. 1 in ref. 1), apart from the

[3]The enantiomer of **8** in Fig. 1 has intentionally been shown with opposite chiralities at C(4) and C(6) relative to those of **1** (1) in order to compare conformations of the cyclohexenone rings.

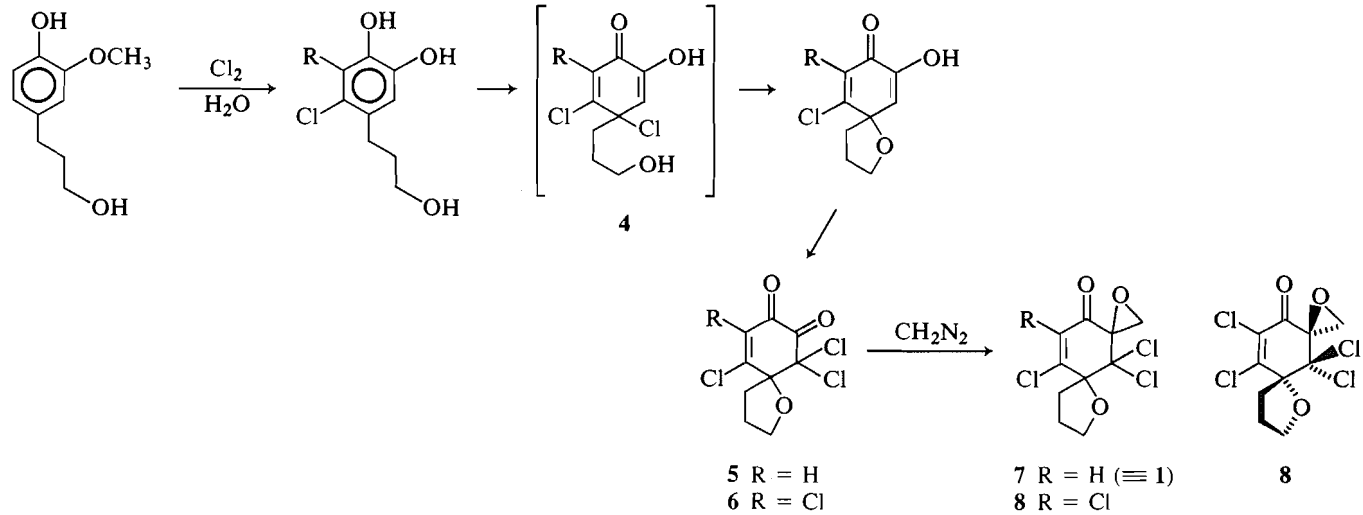

SCHEME 1

additional Cl substituent in **8**.

The geometry of the oxirane ring (area 0.909 Å^2) is normal (17, 18), although the O(2)—C(6) bond in **8** (1.435(4) Å) is 0.015(4) Å longer than that in **1** (1.420(2) Å). This difference, as well as a 0.015(4) Å shortening of the C(4)—C(5) bond (1.549(4) versus 1.564(2) Å in **1**), is believed to result from the conformational inversion of the central ring. The additional chlorine substituent at C(9) induces a significant lengthening of the C(9)=C(10) double bond (from 1.334(3) in **1** to 1.350(4) Å), consistent with the ir results discussed above. The C(1)—C(2) and C(2)—C(3) bond distances in the oxolane ring are anomalously short, probably a result of minor disordering of atoms C(1) and C(2). Other bond lengths in **8** are equal within experimental error to those in **1**. The sp^2 hybridized carbon atoms (C(8), C(9), and C(10)) are all slightly but significantly displaced from the planes of their substituents (by 0.018(4), 0.015(3), and 0.025(3) Å respectively).

Calculation of vertical ionization potentials of hydrogen peroxide by perturbation corrections to Koopmans' theorem

TSUTOMU MINATO[1] AND DELANO P. CHONG

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received September 10, 1982

TSUTOMU MINATO and DELANO P. CHONG. Can. J. Chem. **61**, 550 (1983).

Vertical ionization potentials (VIP's) of hydrogen peroxide are calculated by perturbation corrections to Koopmans' theorem and its conformation is investigated on the basis of the calculated VIP's. The calculated VIP's compare well with the observed values. The analysis based on the VIP's gives a reasonable conformation, although the energy-optimizing procedure cannot reproduce the skew conformation. The lone pair − lone pair interactions are also discussed.

TSUTOMU MINATO et DELANO P. CHONG. Can. J. Chem. **61**, 550 (1983).

On a calculé les potentiels d'ionisation verticale (PIV) du peroxyde d'hydrogène par des corrections de perturbation du théorême de Koopman et on a étudié sa conformation à partir des PIV calculés. Les PIV calculés se comparent bien aux valeurs observées. L'analyse, fondée sur les PIV, donne une conformation raisonnable bien que le procédé d'optimisation d'énergie ne peut reproduire la conformation du squelette. On discute également des interactions doublet libre − doublet libre.

I. Introduction

Recently, the conformation of organic molecules has been discussed by means of photoelectron (PE) spectroscopy if there are orbital interactions which depend on a dihedral angle (1). For example, the study on hydrazines has given a clear understanding for the lone pair − lone pair interaction as a function of a dihedral angle (2) and this understanding is used to determine the conformation of hydrazines. The lone pair − lone pair interaction in hydrogen peroxide has been studied (3). Unlike hydrazines, the situation of hydrogen peroxide is complicated by two lone pairs of each oxygen atom.

In the last few years, corrections to Koopmans' theorem (KT) have been computed with ordinary third-order Rayleigh−Schrödinger perturbation theory (RSPT) and it is shown that RSPT is capable of giving vertical ionization potentials (VIP's) corresponding to valence MO's with an average error of 0.5 eV for a double-ζ basis set (4). This accuracy is sufficient to investigate the relationship between the VIP's and the dihedral angle of hydrogen peroxide. While hydrogen peroxide is the simplest member in the family of peroxides which represents an important class of compounds, most calculations on its VIP's have been carried out within KT. The present calculations are, therefore, carried out by RSPT in order to have a basis for understanding of the experimental PE spectrum of hydrogen peroxide. Furthermore, the relationship between the VIP's and the dihedral angle is discussed and the lone pair − lone pair interactions are investigated.

II. Calculations and results

The SCF calculations are carried out with the GAUSS 76 program and the basis set is the standard 4-31G valence-double-ζ set internal to the program (5). The estimation of VIP's by RSPT has been given elsewhere (4). The truncation criterion $T = 2.6$ is used in the present calculation. Figure 1 shows the experimental geometry of hydrogen peroxide (6).

The numerical results for the VIP's at $\theta = 111.5°$, the observed value, are summarized in Table 1 together with other calculations (3, 7). In Table 1, $\Delta E(3)$ represents the difference in perturbation energies truncated after the third order. $\Delta(E^{GA})$

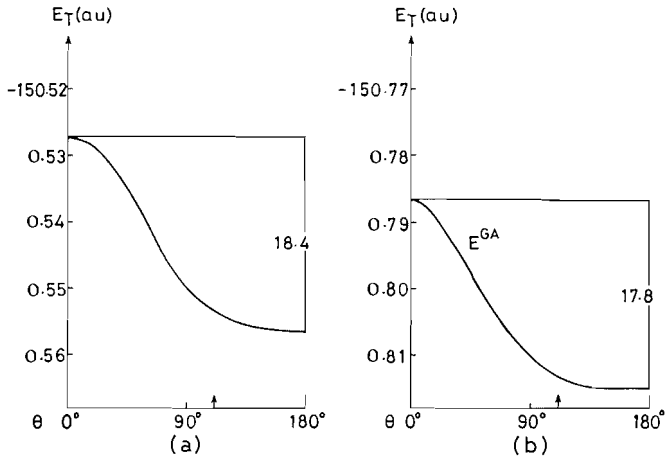

FIG. 2. The potential energy profile along the dihedral angle (θ). The arrows in this figure denote the observed dihedral angle. The energy change is in kcal/mol. (*a*) E_T calculated by the SCF method. (*b*) E_T calculated by E^{GA}.

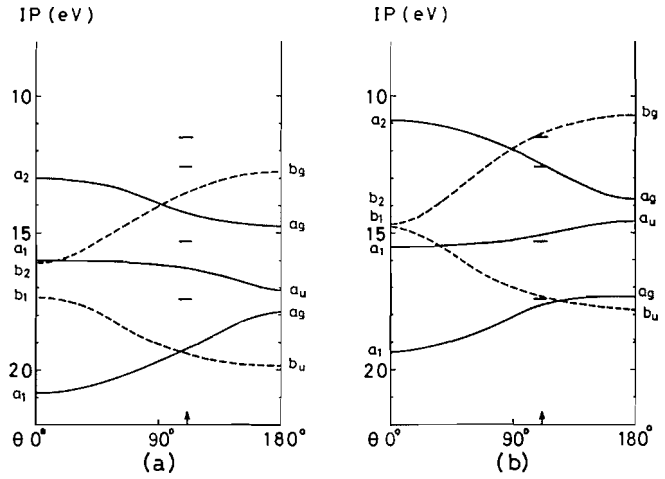

FIG. 3. The relationship between the VIP's and the dihedral angle. The arrows in this figure denote the observed dihedral angle. The bold lines stand for the PE bands. (*a*) The VIP's estimated by KT. (*b*) The VIP's estimated by $\Delta E(3)$.

is the difference between E^{GA}'s of the parent molecule and its cationic state, and E^{GA} is calculated by a geometrical approximation. The difference in scaled energy-expectation values ($\Delta\mathscr{E}$) is meaningful only for the lowest cationic state of each symmetry. Unlike other molecules, the VIP's for H_2O_2 estimated by $\Delta E(3)$ are closer to the observed values than those estimated by $\Delta(E^{GA})$. The $\Delta\mathscr{E}$ approximation also gives good values for the lowest cationic state in each symmetry. It should be noted that the assignment of the bands in the observed PE spectrum is based on the present calculation. However, the overlapping bands at ~17.4 eV cannot be unambiguously assigned on the basis of the present calculation because of the small basis set. There is a likely breakdown of Koopmans' ordering of $(3a)^{-1}$ and $(3b)^{-1}$ states.

It is interesting to check whether the energy-optimizing procedure reproduces the skew conformation of H_2O_2 or not, because calculations with a small basis set sometimes fail to reproduce the conformation of H_2O_2 (7). Therefore, the total energy of H_2O_2 (E_T) is calculated at a given θ at fixed bond lengths. Figure 2 shows E_T's by the SCF calculation and the geometrical approximation. Both calculations show that the dihedral-angle optimized geometry is a *trans*-form, although H_2O_2 is nonplanar in the ground state. In other words, such a simple procedure with a 4-31G basis set cannot reproduce the conformation of H_2O_2 .

The VIP's are calculated at a given θ by KT and $\Delta E(3)$. The results are depicted in Fig. 3. The VIP's estimated by KT are too high to be compared with the observed values as Fig. 3(*a*) shows. When the observed values are moved down in the figure by ~2 eV, the good correspondence is obtained at θ = ~110°. This θ value is in line with the observed dihedral angle, θ = 111.5° (6). On the other hand, the VIP's estimated by $\Delta E(3)$ show the good correspondence to the observed values at θ = ~110° without any movement of the observed values. Thus, the analysis based on the VIP's is more useful for investigating the conformation of H_2O_2 than the energy-optimizing procedure when the calculation is carried out with a small basis set.

III. Discussion

The lone pair − lone pair interactions are investigated in terms of localized MO's (LMO's) (8) in order to obtain the correspondence of the interactions to the PE bands. Since canonical MO's spread over a molecule, it is difficult to understand a chemical bond and a lone pair by them. On the other hand, the LMO's represent a chemical bond and a lone pair well. Therefore, the LMO's of H_2O_2 are determined and the canonical MO's are represented as linear combinations of the LMO's.

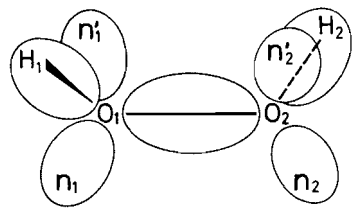

FIG. 4. Schematic presentation of the valence LMO's.

Figure 4 gives a schematic presentation of the valence LMO's. Two O—H bond orbitals and four lone pair orbitals are obtained together with the O—O bond. It is found that H_2O_2 has the eclipsed conformation for the O—H bonds and the lone pairs.

Table 2 summarizes the coefficients of the LMO's when the canonical MO's are represented as linear combinations of the LMO's. The first band ($(4b)^{-1}$) is assigned to the out-of-phase interactions between the lone pairs, and the main component is the interaction between the eclipsed lone pairs. The second band ($(5a)^{-1}$) corresponds to the in-phase interaction between the staggered lone pairs. The third band ($(4a)^{-1}$) is the ionization of an electron from the O—O bond with the in-phase interaction between the eclipsed lone pairs. The overlapping bands at 17.4 eV correspond to the interaction between the O—H bonds and that between the lone pairs.

The orbital interactions ascertain the assignment of the PE bands. Since the binding energy of an electron in the lone pairs is lower than that in the chemical bonds (the O—O and O—H bonds), the first two bands are assigned to the ionization from the lone pairs. Furthermore, the out-of-phase interaction between the eclipsed lone pairs destabilizes the orbital energy, whereas the in-phase interaction between the staggered lone pairs makes the energy level slightly low. Thus, the ionizations

TABLE 2. The coefficients of the LMO's in the canonical MO's[a]

MO	n_1	n_1'	O_1H_1	O_1O_2	n_2	n_2'	O_2H_2	Orbital character
$4b$	0.60	−0.34	−0.18	0.0	−0.60	0.34	0.18	n^e_-, n^s_-
$5a$	−0.04	0.62	−0.22	−0.36	−0.04	0.62	−0.22	n^s_+, O_1—O_2
$4a$	−0.51	0.11	−0.13	0.65	−0.51	0.11	−0.13	O_1—O_2, n^e_+
$3b$	0.17	0.53	−0.44	0.0	−0.17	−0.53	0.44	n^s_-, O—H$_-$
$3a$	0.39	−0.03	−0.51	0.42	0.39	−0.03	−0.51	O—H$_+$, O_1—O_2, n^e_+

[a]n^e_- and n^e_+ denote the out-of-phase interaction and the in-phase interaction between the eclipsed lone pairs, respectively. n^s_+ and n^s_- mean the interactions between the staggered lone pairs. O—H$_+$ and O—H$_-$ stand for the interactions between the O—H bonds.

from the lone pairs are ordered as mentioned in the previous section. The third band corresponds to the ionization from the O—O bond, because the O—O bond is more unstable (lower binding energy) than the O—H bonds. As for the overlapping bands, the ordering by KT is different from that by RSPT. The orbital interaction supports the latter ordering, because the $(3b)^{-1}$ band corresponds to the out-of-phase interactions between the O—H bonds and between the lone pairs. Furthermore, the $(3a)^{-1}$ band corresponds to the in-phase interaction between the O—H bonds and that between the eclipsed lone pairs, and the latter interaction stabilizes the $3a$ orbital well.

IV. Concluding remarks

In this study, the calculation of the VIP's of H_2O_2 based on the RSPT corrections to KT is presented, and the relationship between the VIP's and the dihedral angle of H_2O_2 is discussed. Since the present calculation is carried out with a limited basis set (4-31G), the overlapping bands at 17.4 eV cannot be unambiguously assigned. In spite of this limitation, some important results emerge. The energy-optimizing procedure with this basis set cannot reproduce the observed conformation of H_2O_2. However, a reasonable conformation is obtained by the investigation of the relationship between the VIP's and the dihedral angle. Furthermore, the orbital interactions are shown to support the assignment of the PE bands by RSPT.

Received September 17, 1982

TOYOAKI KIMURA, KAZUHIRO YASUDA, SHIGEKI FUKUDA, and KENJI FUEKI. Can. J. Chem. **61**, 553 (1983).

An optical absorption study has been made on electrons (e^-_{alc}) trapped in alcohol clusters in γ-irradiated 1-propanol (PrOH) − 2,2,4-trimethylpentane (TMP) − 2,2-dimethylbutane (DMB), 1-butanol (BuOH) − TMP − DMB, and 1-pentanol (PnOH) − TMP − DMB mixture glasses at 77 K. Hitherto electron transfer from the hydrocarbon region into alcohol clusters has been known to be a major process for e^-_{alc} formation in γ-irradiated alcohol−hydrocarbon glasses. However, in the present systems of PrOH−TMP−DMB, BuOH−TMP−DMB, and PnOH−TMP−DMB, this type of electron transfer was not observed and the e^-_{alc} formation was found to result only from the direct radiolysis of alcohols. In the alcohol concentration range lower than 0.2 electron fraction the yields of e^-_{alc} are less than those expected from the direct radiolysis of alcohols. The average number of alcohol molecules in a cluster in these systems is estimated to be four in the lower alcohol concentration range studied. The position of the absorption maxima for e^-_{alc} in these systems is constant within experimental uncertainties independent of alchohol concentration, which is consistent with the results of a semicontinuum model calculation.

TOYOAKI KIMURA, KAZUHIRO YASUDA, SHIGEKI FUKUDA et KENJI FUEKI. Can. J. Chem. **61**, 553 (1983).

Opérant à 77 K, on a fait une étude d'absorption optique des électrons (e^-_{alc}) piégés dans des agrégats d'alcools dans des verres irradiés aux rayons γ et formés soit de propanol-1 (PrOH)-triméthyl-2,2,4 pentane (TMP) − diméthyl-2,2 butane (DMB), soit de butanol-1 (BuOH) − TMP − DMB ou de pentanol-1 (PnOH) − TMP − DMB. On croyait savoir jusqu'à maintenant que le transfert d'électrons de la section hydrocarbonée des agrégats d'alcool était un processus important dans la formation de e^-_{alc} dans des verres d'alcool−hydrocarbure irradiés aux rayons γ. Toutefois dans les systèmes de PrOH−TMP−DMB, BuOH−TMP−DMB et PnOH−TMP−DMB étudiés ici, on n'a pas observé ce type de transfert d'électrons et on a trouvé que la formation de e^-_{alc} provient uniquement de la radiolyse directe des alcools. Pour une concentration en alcool inférieure à 0,2 fraction d'électron, les rendements en e^-_{alc} sont inférieures à ceux attendus pour une radiolyse directe des alcools. Dans ces systèmes, on évalue que pour la limite inférieure des concentrations étudiées le nombre myen de molécules d'alcool dans un agrégat est égal à quatre. Dans le domaine des incertitudes expérimentales indépendantes de la concentration d'alcool la position du maximum d'adsorption de e^-_{alc} dans ces systèmes est constante. Ceci est en accord avec les résultats obtenus en faisant un calcul en utilisant un modèle semi-continu.

[Traduit par le journal]

Introduction

Solvated or trapped electrons in alcohol−hydrocarbon mixtures have been widely investigated (1−15) and it is well known that two optical absorption bands are observed in the visible and ir regions, which are ascribed to electrons trapped in alcohol aggregates (16−21) and those trapped in a hydrocarbon matrix, respectively. In a previous study we have investigated the mechanism of electron trapping by alcohol clusters and explained this in terms of quasifree electron scavenging by alcohol clusters or electron transfer from unrelaxed hydrocarbon traps into alcohol clusters (22). In this work we have investigated trapped electrons in γ-irradiated alcohol−TMP−DMB mixture glasses at 77 K in order to obtain further information on this problem.

Neat TMP or DMB freezes at 77 K into the crystalline state. However, we have found that a mixture of TMP and DMB makes a clear glass at 77 K and that trapped electrons are not observed at all in this mixture glass when γ-irradiated at 77 K (23). The absence of trapped electrons in a γ-irradiated TMP−DMB mixed glass seems to indicate that electrons are not stably localized in this glass. In view of this it is interesting to examine how electrons can be localized in alcohol clusters in this mixed glass. There is an advantage to using the TMP−DMB mixture as a hydrocarbon component in alcohol−hydrocarbon glasses. In this glass the optical absorption spectrum of e^-_{alc} in the visible region does not overlap the high energy tail of the spectrum of trapped electrons in hydrocarbons. This makes it possible to determine directly the yield of e^-_{alc} in alcohol−TMP−DMB mixture systems.

We have used PrOH, BuOH, and PnOH as alcohols and added these alcohols to a mixture of TMP and DMB. The ratio of TMP to DMB was 1:1 in volume at room temperature.

Experimental

Hayashi Pure Chemical PrOH and BuOH (guaranteed reagent) and Nakarai Chemicals PnOH were purified by refluxing over sodium borohydride. Nakarai Chemicals DMB (guaranteed reagent) and Kishida Chemical TMP (spectro-grade) were purified using molecular sieves 13 X. Samples were degassed on a vacuum line and sealed into optical cells made of Supracil quartz. γ-Irradiation was made with ^{60}Co γ-rays. Optical absorption spectra were measured on a Hitachi Model 323 spectrophotometer. When the alcohol concentration was low, an optical cell of 10 mm optical path length was used and the dose was 2.5×10^5 rad, whereas for samples of high alcohol concentrations the optical path length was 1 or 2 mm and the dose was 0.8×10^5 rad. With these variations in the dose and the optical path length, the normalized values of observed optical densities for trapped electrons cover four orders of magnitude. The γ-irradiation and optical absorption measurement were made at 77 K.

Results and discussion

The mixture of TMP and DMB gives a clear and crackfree glass at 77 K. Since trapped electrons are not formed in this TMP−DMB glass (23), only the low energy tail of e^-_{alc} spectrum is observed in the ir region in alcohol−TMP−DMB sys-

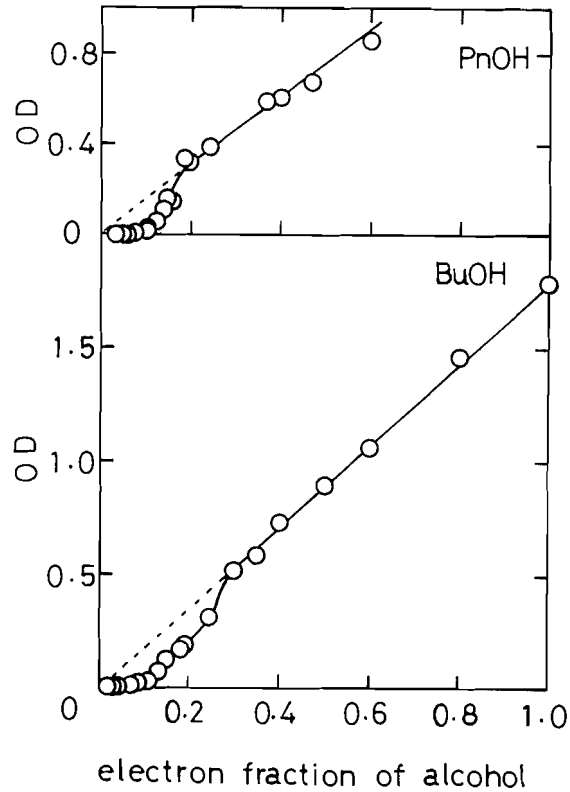

FIG. 2. Optical densities of e^-_{alc} at λ_{max} in PnOH–TMP–DMB (top) and BuOH–TMP–DMB (bottom) systems at 77 K vs. electron fraction of alcohol.

tems at 77 K. The position, λ_{max}, of the absorption maximum of e^-_{alc} is unchanged within the experimental uncertainty independent of the alcohol concentration for the PrOH–TMP–DMP, BuOH–TMP–DMB, and PnOH–TMP–DMB systems (540, 580, and 600 nm, respectively). Therefore, assuming that the molar extinction coefficient is constant, independent of the alcohol concentration (6), the relative yields of e^-_{alc} in alcohol–TMP–DMB systems can be represented by the optical densities of e^-_{alc} at λ_{max} normalized to the optical path length of 10 mm and the dose of 0.8×10^5 rad.

1. Yields of trapped electrons in alcohol clusters

Optical densities of e^-_{alc} in PrOH–TMP–DMB systems are shown as a function of electron fraction (e.f.) of PrOH in Fig. 1. It can be seen in Fig. 1 that the experimental data fit the straight line, which is drawn between the origin and the point for neat PrOH (e.f. = 1), over the PrOH concentration range from 0.2 to 1.0 e.f. and that the data points deviate downwards considerably from the straight line at PrOH concentrations less than 0.2 e.f. This contrasts remarkably with the previous results (22) for PrOH – methylcyclohexane (MCH) and PrOH – 2-methylpentane (2MP) systems, which are shown in the inset of Fig. 1 together with the present results for PrOH–TMP–DMB systems. Optical densities in the inset of Fig. 1 are normalized to the dose of 1.1×10^5 rad and the optical path length of 3 mm. The dashed line in the inset of Fig. 1 is drawn so that it extrapolates to the observed optical density of e^-_t in neat PrOH glass. All other experimental data on the yields of e^-_{alc} in alcohol–hydrocarbon glasses so far reported are similar to those in PrOH–MCH and PrOH–2MP glasses shown in the inset of Fig. 1; yields of e^-_{alc} are higher than those expected from the linear dependence on the e.f. of alcohol, implying electron transfer from the hydrocarbon region into alcohol clusters.

Optical densities of e^-_{alc} in BuOH–TMP–DMB and PnOH–TMP–DMB systems are shown as a function of e.f. of alcohol added in Fig. 2. In higher alcohol concentration range of PrOH–TMP–DMB, BuOH–TMP–DMB, and PnOH–TMP–DMB systems, the yield of e^-_{alc} is linearly dependent on the e.f. of each alcohol in the concentration range from 0.2 ~ 0.3 to 1.0 e.f. This fact indicates that the overall electron transfer from the hydrocarbon region into alcohol clusters does not seem to occur in these systems. The reason for the absence of electron transfer from the hydrocarbon region into alcohol clusters in PrOH–TMP–DMB, BuOH–TMP–DMB, and PnOH–TMP–DMB systems may be accounted for by the difference of the properties of a TMP–DMB matrix from other hydrocarbon matrices such as MCH or 2MP. Hitherto, trapped electrons have been studied in hydrocarbon glasses such as 3MP, 2MP, and MCH, in which electron mobilities are low and V_0 values are high; electrons are localized (we denote these as type I hydrocarbons). On the other hand, it is well known that electron mobilities are high and V_0 values are low in liquid methane and neopentane, in which electrons are not localized (we denote these as type II hydrocarbons). However, the type II hydrocarbons themselves do not make glasses at 77 K. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

electron mobilities and V_0 values in TMP and DMB lie between those in the type I hydrocarbons and those in the type II hydrocarbons (24–33). Therefore, we are tempted to say that the absence of electron transfer from the TMP–DMB region into alcohol clusters implies that electrons are not localized in TMP–DMB glasses. If we accept that electron transfer from unrelaxed hydrocarbon traps into alcohol clusters is the most plausible mechanism for e^-_{alc} formation in alcohol–hydrocarbon glasses at 77 K, the absence of electron transfer from the TMP–DMB region into alcohol clusters appears to indicate the absence of unrelaxed trapped electrons in the TMP–DMB region. A pulse radiolysis study is necessary to determine whether unrelaxed trapped electrons exist in TMP–DMB glasses at 77 K.

Free ion yields in TMP and DMB are higher than those in 2MP and MCH (27, 34, 35). Thus it appears that quasifree electron scavenging by alcohol clusters (4) is not the mechanism of e^-_{alc} formation in alcohol–hydrocarbon systems. The fact that the yield of e^-_{alc} is only that from direct γ-radiolysis of the added alcohols indicates that quasifree electrons generated in the TMP–DMB region are not scavenged in alcohol clusters. However, a quasifree electron scavenging mechanism cannot necessarily be excluded for e^-_{alc} formation in alcohol – type I hydrocarbon systems, because there is the possibility that the efficiency of electron scavenging by alcohol clusters is significantly lower in TMP–DMB glasses at 77 K. We have found that electron scavenging efficiencies are lower for some scavengers in TMP–DMB glasses than in type I hydrocarbon glasses at 77 K.[1]

It is interesting to compare the present results with those of Brandon and Firestone (6). According to their results by pulse radiolysis at room temperature, yields of e^-_{alc} in ethanol–neopentane and ethanol–DMB solutions are similar to those in ethanol–3MP solutions at ethanol concentrations greater than 20 mol%. This implies that the mechanism of e^-_{alc} formation in ethanol–neopentane and ethanol–DMB solutions at room temperature is different from that in alcohol–TMP–DMB glasses at 77 K. Previously we have shown that irphotobleaching of electrons trapped in the hydrocarbon matrix in PrOH – type I hydrocarbon glasses causes e^-_{alc} to be formed when the viscosity of the matrix is low (such as 3MP), but not when it is high (such as MCH) (22). Therefore, it appears that the viscosity of the matrix plays an important role for e^-_{alc} formation in alcohol–hydrocarbon systems. It has been shown that matrix viscosity affects electron scavenging in hydrocarbon glasses at 77 K (36).

2. *Number of alcohol molecules in an alcohol cluster in the lower alcohol concentration range*

In PrOH–TMP–DMB, BuOH–TMP–DMB, and PnOH–TMP–DMB systems, the yield of e^-_{alc} is considerably lower than those expected from the contribution of direct radiolysis of added alcohols when alcohol concentrations are lower than 0.2 e.f. as shown in Figs. 1 and 2. For the systems containing <0.2 e.f. alcohols, the concentration of alcohol clusters and the cluster size (the number of alcohol molecules in a cluster) would decrease with decreasing alcohol concentration. When alcohol concentrations are higher than 0.1 *M*, it has been reported that alcohol tetramers are predominant at room temperature (16–19). Thus, in our present case, it can be expected that average cluster size is four. This can be supported by the following treatment. When alcohol monomers exist together with alcohol clusters which are predominantly *n*-mers, we have the equilibrium

$$[1]\quad nA \overset{K_n}{\rightleftarrows} A_n$$

where A and A_n are alcohol monomer and *n*-mer, respectively and K_n is the equilibrium constant. Then the concentration of alcohol *n*-mers can be written as

$$[2]\quad [A_n] = K_n[A]^n$$

Equations [1] and [2] do not necessarily mean that the production of A_4 is by four A molecules coming together simultaneously but they simply provide the relation between the concentration of A_4 and A. Even if there exist a series of equilibria between A_n and A_{n-1} (n = 2, 3, and 4), it can be shown that eq. [2] holds for the overall equilibrium between A_4 and A. Assuming that the yield of e^-_{alc} is proportional to the concentration of alcohol clusters at low alcohol concentrations, the yield of e^-_{alc} is proportional to the *n*th power of the concentration of alcohol monomers which is approximated by the concentration of alcohol added. In Fig. 3, optical densities of e^-_{alc} over the lower alcohol concentration range are plotted against the fourth power of alcohol concentration. In each case of Fig. 3, the yield of e^-_{alc} is linearly dependent on the fourth power of alcohol concentration, implying the average cluster size is four in PrOH–TMP–DMB, BuOH–TMP–DMB, and PnOH–TMP–DMB glasses at 77 K.

Studies on alcohol–hydrocarbon solutions at room temperature have revealed that primary alcohols exist as monomers when the mole fraction of the alcohol is less than 0.001 for

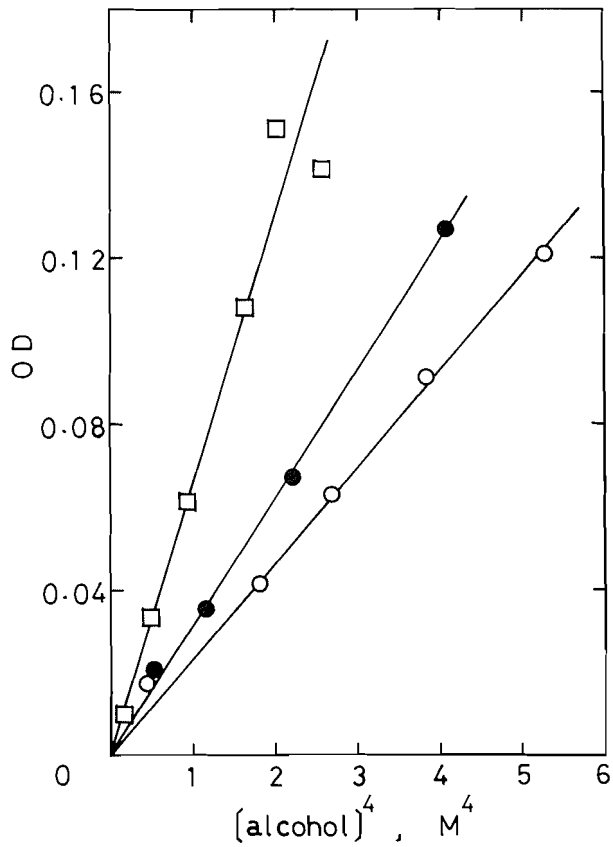

FIG. 3. Optical densities of e^-_{alc} at λ_{max} in PrOH–TMP–DMB (○), BuOH–TMP–DMB (●), and PnOH–TMP–DMB (□) systems at 77 K vs. [alcohol]⁴.

[1] T. Kimura, T. Yoshida, and K. Fueki, unpublished results.

primary alcohol − *n*-hexane (or cyclohexane) solutions (10). The value of mole fraction = 0.001 in this case corresponds to $8 \sim 9 \times 10^{-3}$ *M*. Brown *et al.* (20) and Baxendale and Sharpe (8) have shown that e^-_{alc} exist in dimer clusters over the alcohol concentration range <0.1 *M*. As has been described above, tetramers are predominant at alcohol concentration range >0.1 *M*. In our present case, the lowest alcohol concentrations studied are 0.1, 0.1, and 0.2 *M* for PrOH, BuOH, PnOH, respectively. Therefore our result that the average cluster is formed by four alcohol molecules in the present systems is consistent with those reported above (16−19). In the particular case of methanol−hydrocarbon solutions, the average alcohol cluster has been reported to be pentamer (11) and hexamer (8) even though the methanol concentration is lower than 0.1 *M*. We have also tried to investigate methanol−TMP−DMB and ethanol−TMP−DMB systems but unfortunately neither methanol nor ethanol is soluble in TMP−DMB at 77 K.

It is interesting to note that the slope of the straight line in Fig. 3 increases with increasing number of carbon atoms in an alcohol molecule. The ratio of the magnitude of the slope for PrOH−TMP−DMB, BuOH−TMP−DMB, and PnOH−TMP−DMB is 1:1.3:2.8. Taking the molar extinction coefficients of e^-_t in PrOH, BuOH, and PnOH into consideration (1.3, 0.71, and 1.25×10^4 M^{-1} cm^{-1}, respectively (37)), the ratio of electron scavenging efficiencies by PrOH, BuOH, and PnOH clusters turns out to be 1:2.5:2.9. This ratio is related to the equilibrium constant, K_n, in eq. [2], and the cross section of reaction between an electron and an alcohol cluster.

3. *Optical absorption spectrum of* e^-_{alc}

It is known that the extent of aggregation of alcohol molecules in a cluster increases with increasing alcohol concentration in a hydrocarbon matrix. Thus, it is expected that the number of alcohol layers which surround e^-_{alc} would increase with increasing alcohol concentration. In view of this, it is significant to examine how the optical absorption spectrum of e^-_{alc} is related to the number of alcohol layers. We have calculated energy levels of e^-_{alc} in a PrOH cluster with *l* PrOH layers ($l = 1 \sim 10$) in PrOH−TMP−DMB systems. The calculation was carried out within the framework of a semicontinuum model (38). The details of the present calculational procedure should be referred to ref. 38. Only the outline of calculation is given here. We have assumed that an excess electron is surrounded by the first solvation layer which consists of *N* PrOH molecules ($N = 4$ or 6). Alcohol molecules orient their dipoles symmetrically toward the electron located at the center of the cavity. Ths first solvation layer is surrounded by the second, third, ····, and *l*th layer of PrOH. We have assumed also that the excess electron interacts with the first solvation layer by a short-range interaction and beyond the first solvation layer by a long-range interaction. The total energy of the excess electron in the *i*th state is given by eq. [3],

$$[3] \quad E_t(i) = E_k(i) + E^s_e(i) + E^s_m(i) + E^l_e(i) + E^l_m(i) + E_q(i) + E_v$$

where E_k is the kinetic energy of the excess electron; E^s_e and E^s_m are the short-range electronic and medium rearrangement energies, respectively; E^l_e and E^l_m are the long-range electronic and medium rearrangement energies, respectively; E_q is the short-range repulsive interaction energy between the excess electron and the medium electrons; E_v is the energy required to form a cavity in the medium. Hydrogenic wavefunctions are used in this calculation.

TABLE 1. The calculated wavelengths, $\lambda_{1s\rightarrow 2p}$, corresponding to the $1s\rightarrow 2p$ transition energies of e^-_{alc} in PrOH−TMP−DMB systems at 77 K

Number of solvation layers (*l*)	Number of molecules in the first solvation layer (*N*)	$\lambda_{1s\rightarrow 2p}$, nm
1	4	428
	6	592
2	4	429
	6	606
3	4	435
	6	609
4	4	437
	6	609
5∼10	4	437
	6	609

The $1s\rightarrow 2p$ transition energies are calculated by eq. [4] for e^-_{alc} in a PrOH cluster.

$$[4] \quad h\nu_{1s\rightarrow 2p} = E_t(2p) - E_t(1s)$$

The corresponding wavelengths are given by $\lambda_{1s\rightarrow 2p} = c/\nu_{1s\rightarrow 2p}$. The results of calculation are shown in Table 1. It should be noted that $\lambda_{1s\rightarrow 2p}$ is nearly constant for $l = 1 \sim 10$. The observed position of absorption maxima, λ_{max}, of e^-_{alc} spectra in PrOH−TMP−DMB systems is constant within experimental uncertainties (520−540 nm). Thus, the calculated results agree, at least semiquantitatively, with the experimental results. Values of λ_{max} are also constant for BuOH−TMP−DMB and PnOH−TMP−DMB systems. The constancy of $\lambda_{1s\rightarrow 2p}$ can be accounted for by the strong short-range interaction due to the permanent dipoles of alcohol molecules in the first solvation layer. It is interesting to compare the present results with that for e^-_t in 3MHx−TMP−DMB glasses at 77 K (23), where the calculated and experimental results show that λ_{max} increases with decreasing 3MHx concentration. In this case the short-range interaction is not so strong as those in alcohol−TMP−DMB systems because the 3MHx molecule has no permanent dipole.

The linewidth of the ^{23}Na resonance in sodium tetraethylaluminate in benzene has been measured as a function of the ratio of [donor]:[Na^+] using the strong complexing agent hexamethylphosphoramide. In this system changes in the sodium linewidth arise primarily from changes in the nuclear quadrupole relaxation at the sodium nucleus which in turn arise from changes in the electric field gradient. As the ratio of hexamethylphosphoramide to sodium ion is increased up to 3:1 the ^{23}Na linewidth progressively decreases due to an increase in cation–anion distance in the ion pair. After a ratio of 4:1 is reached, essentially no linewidth change is noted, indicating a stable solvation number of 4 for hexamethylphosphoramide. The results of this study indicate that this is a new and promising approach to the determination of solvation numbers of the sodium ion.

JAMES HAROLD MEDLEY, EDDIE STEVEN MOOBERRY et MARION CLYDE DAY. Can. J. Chem. **61**, 558 (1983).

On a mesuré la largeur des raies de la résonance du ^{23}Na du tétraéthylaluminate de sodium dans le benzène en fonction du rapport [donneur]:[Na^+] en utilisant un puissant agent complexant: l'hexaméthylphosphoramide. Dans ce système, les variations de la largeur des raies du sodium proviennent principalement des variations de la relaxation quadrupolaire nucléaire au niveau du noyau du sodium qui a leur tour proviennent des variations du gradient de champ électrique. Quand le rapport de l'hexaméthylphosphoramide sur l'ion sodium augmente jusqu'à 3:1, la largeur des raies du ^{23}Na diminue progressivement à cause d'une augmentation de la distance cation–anion de la paire d'ions. Lorsqu'on atteint un rapport de 4:1, on n'observe plus de variation de la largeur des raies ce qui indique un nombre de solvatation stable de 4 pour l'hexaméthylphosphoramide. Les résultats de cette étude indiquent que c'est une approche nouvelle et prometteuse pour la détermination des nombres de solvatation de l'ion sodium.

Introduction

With the commercial availability of high resolution multinuclear nmr spectrometers, there has been a corresponding upsurge in the interest in nmr spectroscopy of the less commonly observed nucleii (1–4). Of particular interest here is the study of the solvation of the sodium ion by means of ^{23}Na nmr (5–10), a system that is of considerable interest biologically as well as in terms of fundamental solvation theory.

Because of its spin of 3/2, the relaxation time of the ^{23}Na nucleus is dominated by the coupling of the nuclear quadrupole moment with the time-dependent electric field gradient. Presently there is no single unambiguous theory for the origin of the fluctuating electric field gradient at the nucleus that covers the full range of ion–ion and ion–solvent interactions encountered by the sodium ion in solution (11–14). Rather there are two fundamentally different theoretical models. The electrostatic approaches formulated by Valiev (11) and by Hertz (12) describe a static electric field gradient in terms of the action of point charges and electric dipoles on the central nucleus with a time dependence arising from either the lifetime of a vacancy in the first solvation sphere of the central ion (11) or the over all lifetime of the solvated state (12). The electrostatic model has met with some success in predicting the relaxation times of alkali metal and halide ions in dilute aqueous solutions (15, 16). The other model, formulated by Deverell (13), takes into account the shielding effect of the outer shell electrons on the central nucleus and is based on distortions of the inner shell *s* and *p* orbitals resulting from short range repulsive forces. The repulsive forces are postulated to arise from the interaction of another ion or solvent molecule at a distance less than the minimum of attractive potential during random collisions. These distortions can induce a fluctuating electric field gradient at the nucleus. An important result of the Deverell model arises from the contribution of the overlap integral to both the electric field gradient and the paramagnetic shielding constant which are reflected in the quadrupole relaxation time and the chemical shift respectively. Such a correlation between the ^{23}Na relaxation time and the chemical shift has been observed for a number of systems. For example, one may compare the results of a study on the solvent dependence of relaxation time of the sodium ion (17, 18) with the paper by Ehrlich, Roach, and Popov (19) on the solvent dependence of the ^{23}Na chemical shift in the limit of infinite dilution.

Recently, Delville *et al.* (14) have introduced a significant modification of the Deverell approach involving the interpretation of the correlation time, τ_c. They have made a simplifying assumption of long-lived solvation complexes, thereby identifying τ_c with the overall reorientational correlation time of the solvated complex. This approach was based on an earlier study by Kintzinger and Lehn (20). For many mixed solvent systems where there is a significant degree of preferential solvation, this approach can be very useful in the analysis of the relaxation times.

Both the Hertz–Valiev model and the Deverell model have been used with some success in describing the relaxation rates of alkali metal ions in solution. However, the selection of the solvent system seems to determine the choice of the appropriate model. The Hertz–Valiev model has been proven to be reasonably successful for dilute aqueous solutions whereas the Deverell model seems to be more appropriate in solutions of lower dielectric constant. In such solvents the extent of ion pairing may become more significant in determining the relaxation rate. Detellier *et al.* have used the Deverell approach in interpreting the ^{23}Na nmr data obtained in a study of solutions of

sodium perchlorate in mixed solvents consisting of THF and various unidentate and bidentate amines (6, 9, 10, 14). However, in mixed solvent systems where the two components have similar solvating abilities, a major complication in the interpretation of spectroscopic data can arise from competition for coordination sites by the two solvents. Additionally, in a chemically exchanging system the correlation time may be strongly dependent on the exchange rate (8).

A more desirable system is one in which the competition between the bulk solvent and the second solvent for coordination sites on the cation is minimal. Essentially the only known sodium salts which permit this type of system are the sodium tetraalkylaluminate salts. The solubility of these salts in hydrocarbon solvents such as cyclohexane or benzene, permits a system of the type:

$$NaAl(alkyl)_4 - \text{inert solvent} - \text{donor}$$

We have specifically selected the system:

$$NaAlEt_4 - \text{benzene} - \text{HMPA}^2$$

The usefulness of the sodium tetraalkylaluminate salts in other studies of ion–ion and ion–solvent interactions has been well documented (21).

In this study we have measured changes in the ^{23}Na nmr linewidth at one-half height as a function of the mole ratio HMPA:Na^+ in benzene solutions. The effect of the bulk solution viscosity on the linewidth is examined in light of the Debye–Stokes–Einstein expression for the rotational correlation time of a particle in solution. The results of this study (*a*) support the identification of the nmr correlation time with the rotational correlation time of a solvated species; (*b*) support the hypothesis that the solvation of the sodium ion by HMPA in benzene solution occurs via the formation of a series of stable solvated complexes of successive stoichiometries; and (*c*) indicate that this method offers a new and promising approach to the determination of solvation numbers of the sodium ion.

Experimental procedures

Sodium tetraethylaluminate was prepared by a previously reported synthesis (22). Benzene was allowed to reflux for 24 h over calcium hydride prior to distillation under a nitrogen atmosphere onto sodium wire. HMPA was refluxed for 48 h over calcium hydride at approximately 0.5 Torr prior to distillation. Deuterated benzene obtained as 99+ atom% from Aldrich Chemical Company was checked for water content by observing the reactivity with sodium tetraethylaluminate and subsequently used without further purification.

The solutions were prepared in an argon atmosphere dry box by the appropriate addition by weight of HMPA to the salt followed by dilution with benzene. Approximately 10% deuterated benzene was added for the purpose of locking on the deuterium resonance in the spectrometer. The nmr samples were prepared in 10 mm tubes in the dry box. Because of the reactivity of the salt, all spectra were recorded within one day of preparation.

Sodium-23 nmr spectra were recorded on a Bruker WP 200 FT nmr spectrometer operated at 52.94 MHz and 4.7 Tesla. The spectrometer is equipped with a broad-band tunable probehead and a PTS variable frequency source. Because of the large linewidth of the ^{23}Na resonance of some of the solutions, the spectra were acquired with a spectral window of 50 kHz with 2K memory for a digital resolution of 50 Hz/pt. Elimination of the broad sodium signal from the glass nmr tubes was accomplished by using a delay of 100 μs before the acquisition. This was determined to have no appreciable effect on the observed linewidths. Approximately 10 000 scans were required for an adequate signal-to-noise ratio. The accurately determined 90 degree pulse width was used for each acquisition. Linewidth determinations had estimated errors of ±10%.

Viscosity measurements were made using specially modified Canon-Fenske viscometers. Both arms of the viscometer were open to a nitrogen line with an oil bubbler at the nitrogen exit. The temperature was maintained to within ±0.05° with a Sargent-Welch Thermonitor constant temperature bath filled with dry mineral oil. The viscometer constants were determined with Dow-Corning Viscosity Standard silicone oil. The densities of the solutions were measured with calibrated pycnometers.

It should be noted that an unusual property of this system is the separation into two liquid phases. Since the upper phase has been observed to contain only excess benzene, spectra were recorded for the lower phase only. An unfortunate consequence of this two phase behavior is the inability to maintain a constant salt concentration over the entire range of solutions. In this particular study, the concentration ranges from 2.3 *M* for the 1:1 HMPA:$NaAlEt_4$ solution to 0.2 *M* for the 6:1 solution.

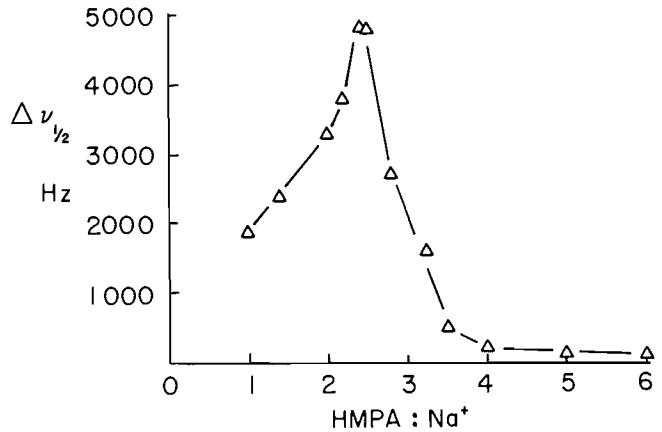

FIG. 1. Linewidth of the ^{23}Na resonance as a function of the HMPA:Na^+ ratio. Temperature 303 K.

Discussion

In Fig. 1, the dependence of the ^{23}Na nmr linewidths at one-half height is shown as a function of the HMPA:$NaAl(C_2H_5)_4$ mole ratio. Here it is noted that the linewidths show a rapid increase up to an HMPA:salt ratio of 2.5 followed by a rapid decrease. Further, it can be seen from Fig. 2 that the ^{23}Na linewidth is related closely to the solution viscosity with a maximum in the linewidth occurring where a corresponding maximum in viscosity is observed. The viscosity maximum occurring at a ratio of 2.5 implies a viscosity dependence of the linewidth. It is an accepted practice (5, 6, 14) to express the ^{23}Na linewidth as the linewidth reduced to unit viscosity. This is based on a prior assumption of a theoretical dependence of the linewidth on the viscosity. One such approach was developed by Kintzinger and Lehn (20) in a study of sodium cryptands. They used Abragam's equation for the relaxation time of a quadrupolar nucleus (23) (eq. [1]) and determined the correlation time by means of the Debye–Stokes–Einstein equation for the rotational correlation time of a particle in solution (eq. [2]).

$$[1]\quad \frac{1}{T_1} = \frac{1}{T_2} = \frac{3}{40}\frac{2I+3}{I^2(2I-1)}\left(1+\frac{\sigma^2}{3}\right)\left(\frac{e^2Qq_{zz}}{\hbar}\right)^2\tau_c$$

[2] HMPA ≡ hexamethylphosphoramide.

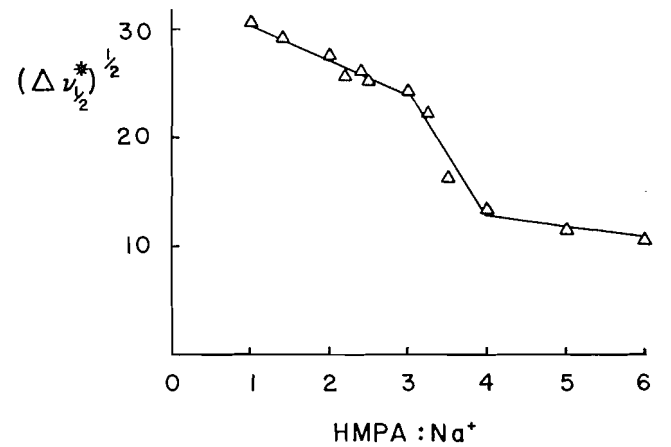

FIG. 4. Square root of the reduced linewidth ($\Delta\nu_{1/2}/\eta$) vs. the HMPA:Na^+ ratio. Temperature 303 K.

where σ = asymmetry parameter and $(e^2Qq_{zz}/\hbar) = \chi$, the quadrupole coupling constant.

$$[2] \quad \tau_c = \frac{4\pi\eta a^3}{3kT}$$

where η = viscosity and a = Stokes radius.

By a separate determination of the correlation time using the ^{13}C spin label method, they were able to show that τ_c for the complex may be described by eq. [2] provided that a correction is made for the relationship between the bulk viscosity and the microscopic viscosity. Delville *et al.* (14) have expanded this approach to include all cases where the sodium ion may be thought to exist in a stable solvation complex.

In the $NaAlEt_4$–benzene–HMPA system the correlation time for the quadrupole relaxation rate may be related to either the reorientational correlation time of a long-lived solvation complex or to a chemical exchange equilibrium such as:

$$[3] \quad [Na^+ \cdot n\text{HMPA} \cdot AlEt_4^-] + \text{HMPA} \rightleftharpoons [Na^+ \cdot (n+1)\text{HMPA} \cdot AlEt_4^-]$$

(n = 1, 2, 3). Such an equilibrium has been observed with $NaAlBu_4$ in THF (24). However, THF (Gutmann donor number = 20.0) is a much poorer donor than HMPA (donor number = 38.8). It has been shown by ^1H nmr, that in this system the equilibrium lies sufficiently far to the complexed side that a 4:1 ratio of HMPA:Na^+ consists of only solvent separated ion pairs (25). Thus it would seem probable that up to a ratio of HMPA:Na^+ of 4, there is effectively no uncomplexed HMPA in solution.

The substitution of eq. [2] into eq. [1] would imply a linear dependence of the linewidth on the η/T quotient in a nonexchanging system. Such a family of curves is shown in Fig. 3 for several different HMPA:Na^+ ratios. Here we see the expected linear behavior thereby supporting the Kintzinger–Lehn approach (20). The validity of this approach derives from the existence of stable solvated complexes.

Identification of τ_c with the rotational correlation time via eq. [2] implies that the quadrupole coupling constant, χ, should be proportional to the square root of the linewidth reduced to unit viscosity at constant temperature. A plot of the square root of the reduced linewidth versus the mole ratio HMPA:Na^+ is shown in Fig. 4. The linear decrease in the curve up to a value of 3:1 HMPA:Na^+ may be related to a linear decrease in the electric field gradient. Such a decrease can be rationalized by an increase in the cation–anion distance in the ion pair species caused by the steric influence of the bulky HMPA molecules. This decrease may be compared with the reported decrease in χ with increased complexation in the systems investigated by Delville *et al.* (14). If the linear decrease in χ is due entirely to a decrease in the electric field gradient at the nucleus by successive displacement of the anion, such linearity is expected. An additivity in the chemical shift of the ^{23}Na for successive complexes was reported by Delville *et al.* (14). Covington and Newman (26) have also predicted that additive chemical shifts should be expected for successive complexation. Under the Deverell model an additivity in the chemical shifts implies directly a linearity in χ.

The rapid decrease in the curve between 3:1 and 4:1 HMPA:Na^+ must be related to the change from contact ion pairs to solvent separated ion pairs. Above the 4:1 ratio there is very little change in the curve indicating that the solvation sphere of the sodium ion is complete at 4:1. Based on this evidence and the linear dependence of the linewidth on the viscosity temperature quotient we have therefore concluded that the solvation of the sodium ion in this system occurs via a stepwise association forming a series of solvated contact ion pairs of stoichiometries:

$(Na^+ \cdot 1HMPA|AlEt_4^-)$, $(Na^+ \cdot 2HMPA|AlEt_4^-)$, and $(Na^+ \cdot 3HMPA|AlEt_4^-)$

The previously reported (25) formation of solvent separated ion pairs at a ratio of HMPA:Na^+ of 4:1 combined with the results of this study indicate very strongly that the solvation number of the sodium ion in HMPA is four. This value does not agree with the value of three obtained by Martir *et al.* (27) and by Darensbourg *et al.* (28). However, the value of four based on our earlier study is now becoming accepted (29).

It must be noted that we have depended entirely on the measured ^{23}Na linewidth for data and not on the chemical shifts. The extremely broad resonances obtained for certain ratios (up to 5000 Hz) precludes any accurate determination of changes in the ^{23}Na chemical shift since the normal range of ^{23}Na chemical shifts is only 30 ppm (less than 2000 Hz at 52.9 MHz) (3). Covington and Newman (26) have reported the absence of any observable signal in the similar system $NaB(C_6H_5)_4$–nitromethane–HMPA in solutions where the concentration of HMPA is relatively low. This is undoubtedly caused by the extremely broad resonances such as what we observe here.

CHIU-MING WONG, HING-YAT LAM, WASIMUL HAQUE, AI-QIAO MI, and GUI-SHU YANG. Can. J. Chem. **61**, 562 (1983).

The important intermediate 2-acetyl-5,8-dimethoxytetralin (**8**) in the syntheses of anthracycline antitumor drugs is easily prepared in high yield on a large scale. Conversion of 2,4-pentanedione to 3-(2,5-dimethoxybenzyl)-hex-5-en-2-one (**9**) was carried out in a three-step, one-pot process by C-alkylating it with 2,5-dimethoxybenzyl bromide, then allyl bromide followed by a retro-Claisen condensation. Conversion of **9** to the tetralin (**8**) was done first by ozonolysis to the aldehyde (**10**) followed by cyclization and reduction of the latter by trimethylsilane in trifluoracetic acid – acetone.

CHIU-MING WONG, HING-YAT LAM, WASIMUL HAQUE, AI-QIAO MI et GUI-SHU YANG. Can. J. Chem. **61**, 562 (1983).

On a préparé, avec de bons rendements et sur une grande échelle, l'acétyl-2 diméthoxy-5,8 tétraline (**8**), un intermédiaire important lors de la synthèse des médicaments antituméraux du type anthracycline. On réalise la tranformation de la pentanedione-2,4 en (diméthoxy-2,5 benzyl)-3 hexène-5 one-2 (**9**) en trois étapes effectuées dans un même récipient en faisant une C-alkylation avec le bromure de diméthoxy-2,5 benzyle, puis une autre avec le bromure d'allyle, le tout suivi d'une condensation du type rétro-Claisen. On a réalisé la transformation du composé **9** en la tétraline (**8**) d'abord à l'aide d'une ozonolyse qui conduit à l'aldéhyde (**10**) puis par une cyclization et une réduction de cette dernière à l'aide du triméthylsilane dans un mélange d'acide trifluoroacétique et d'acétone.

[Traduit par le journal]

Introduction

The anthracycline antibiotics are a group of molecules, members of which, such as adriamycin (**1**), daunomycin (**2**) and carminomycin-1 (**3**) are recognized as some of the most potent and clinically useful antitumor drugs (1). Despite the wide clinical application of these three compounds and their simple derivatives, commonly regarded as the first-generation anthracycline antitumor drugs, their cumulative dose-related cardiotoxicity (2) severely restricts their usefulness, especially as maintenance therapeutic agents. During the past decade this has triggered a surge of intensive research activity for better analogues. Derivatives both of synthetic and natural origin, such as 4-demethoxydaunomycin (**4**) (3), 11-deoxydaunomycin (**5**) (4), 4-demethoxy-11-deoxydaunomycin (**6**) (5), and 4-demethoxy-4′-deoxyadriamycin (**7**) (6) show great potential as substitutes for the first-generation anthracycline drugs. The preferred synthetic process for these anthracycline molecules is the classical approach developed earlier in our laboratory and slightly modified by the Farmitalia group using 2-acetyl-5,8-dimethoxytetralin (**8**)[2] or its simple derivatives as intermediates. A number of such processes were reported (5–7). However, our early synthesis of the tetralin (**8**) is difficult to handle on a large scale and other processes reported later were also found to be unsatisfactory for large-scale production. We would like to report a process which greatly simplifies the preparation of this tetralin on a large scale.

Results and discussion

The intermediate 3-(2,5-dimethoxybenzyl)-hex-5-en-2-one (**9**) was prepared via a three-step process without isolation by alkylating 2,4-pentanedione with 2,5-dimethoxybenzyl bromide and then with allyl bromide in acetone solution in the

[1]American Leukemia Society Fellow, School of Medicine, University of Manitoba.

[2]More appropriate according to the "Definitive Rules for the Nomenclature of Organic Chemistry" than 1,4-dimethoxy-6-acetyltetralin used in our early publications.

presence of excess potassium carbonate, followed by evaporating the acetone and a retro-Claisen condensation in basic methanolic solution. The crude product so obtained was purified by distillation under reduced pressure. The olefinic bond of (**9**) was then cleaved by ozonolysis giving the aldehyde (**10**) in excellent yield. Large scale preparation of 2,5-dimethoxybenzyl bromide was carried out by irradiating, with a Hanovia medium pressure mercury lamp, an anhydrous carbon tetrachloride solution of 2,5-dimethoxytoluene and *N*-bromosuccinimide under a stream of dry nitrogen. Ring bromination becomes the major reaction if moisture or high concentration of bromine is present. Two lamps were required for larger scale preparation.

The tetralin (**8**) was formed in over 85% yield by dissolving the aldehyde (**10**) in trifluoroacetic acid followed by reduction with trimethylsilane in the presence of excess acetone.

Conversion of the tetralin (**8**) or its simple derivative to daunomycin (2), 4-demethoxydaunomycin (3), 11-deoxydaunomycin (4), 4-demethoxy-11-deoxydaunomycin (5), and other anthracyclines have been reported. This facile and economical process greatly simplified the large-scale preparation of many important anthracyclinones.

Experimental

Infrared spectra were recorded on a Perkin–Elmer 710 infrared spectrometer. Nuclear magnetic resonance spectra were recorded on a Varian A-56/60A or a Bruker WH-90 spectrometer, using $CDCl_3$ as solvent and tetramethylsilane as internal standard unless otherwise specified. Mass spectra were recorded on a Finnigan 1015 and high resolution mass spectra were recorded on a A.E.I. MS-50 mass spectrometer. Melting points were measured on a Fisher–Johns apparatus and were not corrected.

*Preparation of 3-(2,5-dimethoxybenzyl)-hex-5-en-2-one (**9**)*

To a five-liter three-necked flask equipped with a mechanical stirrer, mercury seal, dropping funnel, and condenser was added finely ground anhydrous potassium carbonate (420 g), acetone (3 L), 2,4-pentanedione (100 g), and 2,5-dimethoxybenzyl bromide (260 g). This was heated under reflux for a period of 30 h with vigorous stirring. Allyl bromide (150 mL) was then added through the dropping funnel and reflux was continued for an additional 24 h. The acetone solution was cooled in an ice bath, filtered, and the filtrate was evaporated under reduced pressure to give a syrupy residue. To the residue was added an aqueous methanolic sodium hydroxide solution (2.5 L) (water 1 L, methanol 1.5 L, sodium hydroxide 150 g) and the solution was heated for 10 h in an oil bath kept at 70°C, concentrated by distilling off part of the methanol under reduced pressure, diluted with water (1 L), and extracted with chloroform (3 × 800 mL). The combined chloroform extracts, after washing with water and drying over anhydrous magnesium sulfate, were evaporated to give the crude product (**9**) (187 g) which was purified by distillation, (152 g) (130–140°C/3 Torr). The distilled product shows ir (cm^{-1}): 1700 (CO), 1640 (C=C), 1595 (aromatic); nmr (δ): 6.67 (broad s, 5H, aromatic), 5.75 (m, 1H, —C*H*=CH_2), 4.95 (m, 2H, —CH=C*H*$_2$), 3.70 (s, 3H, —OCH_3), 3.64 (s, 3H, —OCH_3), 1.95 (2, 3H, —$COCH_3$); mass spectrum *m/z:* 248, 207, 149, 121; *Exact Mass* (high resolution mass spectrum, 100%) calcd. for $C_{15}H_{20}O_3$: 248.1407; found: 248.1404.

*Preparation of 3-(2,5-dimethoxybenzyl)-1,4-dioxopentane (**10**)*

Ozone from two ozone generators (12 000 V, 60 mA transformers) was introduced through two gas dispersion tubes into a two-liter flask containing methylene chloride (1 L) and the hexenone (**9**) (90 g), while keeping the solution at −20°C until thin-layer chromatography showed the complete disappearance of the starting material (~4 h). Nitrogen was passed through the solution instead of ozone during the development of the thin-layer plate. Trimethyl phosphite (60 mL) was added to the solution which was then heated under reflux for a period of 16 h. The solution was then cooled, washed with water, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure to give a colorless oily residue (90 g) which crystallized from ether after cooling in a Dry-Ice bath; mp 44–45°C; ir (cm^{-1}): 2750 (aldehyde C—H), 1730 (aldehyde C=O), 1710 (ketone); nmr (δ): 9.38 (s, 1H, —C*H*O), 6.60–6.82 (m, 3H, aromatic), 3.80 (s, 3H, —OCH_3), 3.75 (s, 3H, s, —OCH_3), 2.19 (s, 3H, s, —$COCH_3$); mass spectrum, *m/z*: 250, 175, 150; *Exact Mass* (100%), calcd. for $C_{14}H_{18}O_4$: 250.1200; found: 250.1204.

*Preparation of 2-acetyl-5,8-dimethoxytetralin (**8**)*

Trifluoroacetic acid (500 mL) was cooled in an ice–salt bath to −7°C. To the acid was added the aldehyde (**10**) (50 g) in portions within one minute with vigorous stirring which was continued for a period of 15 min, while maintaining the same temperature (−5 to −7°C). Acetone (150 mL) was added followed by trimethylsilane (21 g) and stirring was continued for an additional 10 min. Most of the excess acetone and trifluoracetic acid were then removed under reduced pressure and the residue was dissolved in chloroform (700 mL) and the solution washed with water, 5% sodium bicarbonate solution, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure to give an oily residue (46 g) which was crystallized from methanol; mp 101–102°C. The total crystalline product (38 g) is identical in every respect and showed no melting point depression with the sample previously reported from our laboratory.

Stereospecific vicinal oxyamination of *N*-substituted 1,2,3,6-tetrahydropyridines and 1,2-dihydropyridines by *N*-chloro-*N*-metallocarbamates

SUSHIL K. DUBEY AND EDWARD E. KNAUS[1]

Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alta., Canada T6G 2N8

Received July 14, 1982

SUSHIL K. DUBEY and EDWARD E. KNAUS. Can. J. Chem. **61**, 565 (1983).

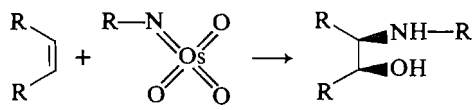
The vicinal oxyamination of 1-substituted 1,2,3,6-tetrahydropyridines (**2**) affords a mixture of the regioisomeric *cis*-hydroxycarbamates **3** and **4**. The *tert*-butoxycarbonylamino and hydroxyl substituents for **3** and **4** assume the equatorial and axial orientations respectively, irrespective of the substituent position. Acid hydrolysis of **3***a* and **4***a* affords the *cis*-aminoalcohols **5** and **6**. The regiospecific oxyamination of 1-methyoxycarbonyl-1,2-dihydropyridine occurs at the 5,6-olefenic bond to yield the hydroxycarbamates **15** and **16**. Reduction of **15** or **16** with palladium on charcoal affords the same vicinal hydroxy and methoxycarbamates **17** to **20** which may arise via the aziridine intermediate **21**.

SUSHIL K. DUBEY et EDWARD E. KNAUS. Can. J. Chem. **61**, 565 (1983).

L'oxyamination vicinale des tétrahydro-1,2,3,6 pyridines (**2**) substituées en position 1 donne un mélange d'hydroxycarbamates *cis* régioisomères **3** et **4**. Les substituants *tert*-butoxycarbonylamino et hydroxyle des composés **3** et **4** sont respectivement en positions équatorial et axiale indépendamment de la position du substituant. L'hydrolyse acide des composés **3***a* et **4***a* conduit aux aminoalcools *cis* **5** et **6**. L'oxyamination régiospécifique de la méthoxycarbonyl-1 dihydro-1,2 pyridine a lieu au niveau de la liaison oléfinique en positions 5,6 en donnant les hydroxycarbamates **15** et **16**. La réduction des composés **15** et **16** par le palladium sur du charbon fournit les mêmes hydroxy et méthoxycarbamates vicinaux **17** à **20** qui peuvent être obtenus via un intermédiaire aziridine **21**.

[Traduit par le journal]

The stereospecific vicinal oxyamination reaction of olefins developed by Sharpless and co-workers is a useful procedure for the synthesis of *cis*-β-aminoalcohol derivatives. One of these procedures employs a stoichiometric quantity of a (*tert*-alkylimido)-osmium reagent (**1***a*) (1). The other procedures, which require a catalytic quantity of osmium tetroxide, use Chloramine-T for the *in situ* generation of **1***b* (2) and *N*-chloro-*N*-metallocarbamates for the *in situ* generation of **1***c* (3).



1*a* R = *tert*-Alkyl
b R = Ts
c R = Alkyl(arylalkyl)OCO

In earlier studies, we reported that reduced pyridyl nitrogen heterocycles offer potential for the development of new agents (4) with significant analgesic, hyperglycemic, antiinflammatory, and antimicrobial activities (5). It was therefore of interest to investigate the reaction of reduced pyridines with **1***c* as a method to effect the *cis* addition of hydroxyl (OH) and carbamate (*t*-BuOCONH) moieties across an olefenic bond. Heterocyclic *cis*-β-aminoalcohols are attractive medicinal intermediates for use (6) in the design of pharmacologically active nitrogen heterocycles. We now describe the vicinal oxyamination of *N*-substituted 1,2,3,6-tetrahydropyridines (**2**) and 1,2-dihydropyridines (**14**) using the powerful *N*-chloro-*N*-argento(mercury)carbamate-based oxyamination reagent **1***c*.

The oxyamination of 1-benzoyl-1,2,3,6-tetrahydropyridine (**2***a*) afforded a 1:1 mixture of the regioisomers *cis*-1-benzoyl-3-hydroxy-4-*tert*-butoxycarbonylaminopiperidine (**3***a*) and *cis*-1-benzoyl-3-*tert*-butoxycarbonylamino-4-hydroxypiperidine (**4***a*) in 18 and 63% yield, using Procedures A and B respectively (Scheme 1). Similar reactions employing 1-benzenesulfonyl- (**2***b*), 1-*tert*-butoxycarbonyl- (**2***c*), 1-methoxycarbonyl- (**2***d*), and 1-acetyl- (**2***e*) 1,2,3,6-tetrahydropyridines also yielded a mixture of regioisomers **3** and **4** (Table 1). We found that the *t*-BuOCONClNa + $AgNO_3$ (1:2) carbamate-based oxyamination system (Procedure B) was superior to the *t*-BuOCONClNa + $Hg(NO_3)_2$ + Et_4NOAc (1.5:0.75:1) system (Procedure A) since it provided higher yields of **3** and **4**, required shorter reaction times, and gave rise to a cleaner reaction mixture from which the products could be isolated more easily. The lower yield of **3** and **4** and the failure of **2***b* to react, using Procedure A, may be due to the competitive formation of an organomercury complex (**3***b*). *N*-Benzyl-1,2,3,6-tetrahydropyridine (**2***f*) did not react using either procedure. This is most likely due to some type of complexation with the free electron pair on nitrogen at the 1-position of **2***f*. On the other hand, oxyamination of 1-cyano-1,2,3,6-tetrahydropyridine (**11**) gave 1-aminocarbonyl-1,2,3,6-tetrahydropyridine (**13**) in 16.2 and 20% yield, using Procedures A and B respectively. The most likely intermediate in the oxidation of **11** to **13** is **12** since **11** does not react with osmium tetroxide. Furthermore, **11** did not react with *t*-BuOCOClNa and $AgNO_3$ (Procedure B) when OsO_4 was not present in the reaction mixture. The lone electron pair on the tetrahydropyridine nitrogen of **11** appears to play a significant role in the oxidation of **11** to **13** since the cyano group of acetonitrile[2] and 3-cyanopyridine (Procedure B) does not react under similar conditions.

The *tert*-butoxycarbonyl moiety of **3** and **4** was easily removed, affording the desired *cis*-β-aminoalcohols **5** and **6**. Treatment of **3***a* and **4***a* with 30% hydrogen bromide in acetic acid yielded **5** (76%) and **6** (81%) respectively. Reaction of **5** with thiophosgene and phosgene gave the respective bicyclic

products 3-benzoyl-9-oxa-3,7-diazabicyclo[4.3.0]nonan-8-thione (**7**, 12.7%) and the 8-one analogue **8** (34.7%). A similar thiophosgene cyclization of **6** gave rise to **9** (13.3%). The *tert*-butoxycarbonylamino group was readily converted to a methylamino group since reduction of **3***a* using lithium aluminum hydride afforded the *cis*-β-methylaminoalcohol (**10**) in quantitative yield.

The assignment of the regiochemistry and stereochemistry for the two regioisomers **3** and **4** formed in the vicinal oxyamination of **2** was based largely on ^{1}H nmr and mass spectral studies. Proton resonance assignments rest largely on decoupling experiments. The question whether the vicinal oxyamination reaction affords products **3** and **4** in which the hydroxyl and carbamate substituents are *cis* to each other was solved by measurement of the coupling constants or width at half-height (W_H) of the protons at C-3 and C-4 in their ^{1}H nmr spectra. The ^{1}H nmr spectra of **3** and **4***a*,*c*–*e* were poorly resolved at room temperature. The poor resolution observed, even at 200 MHz, may be due to strong hydrogen-bonding (4*i*) and/or to the presence of rotational conformers which differ in configuration at the carbonyl-to-nitrogen (amide) bond of the piperidine ring nitrogen (4*g*, 7). The spectra of **3***a* and **4***a* are well resolved at 120°C which should be sufficient to disrupt hydrogen bonding and/or induce coalescence of the rotamers. In contrast, the spectra of **3***b* and **4***b*, in which hindered internal rotation abut NSO_2Ph is not possible, exhibited well-resolved spectra at room temperature.

Extensive decoupling experiments were performed for **3***a*, **4***a*, **3***b*, and **4***b* to establish the stereochemistry of the substituents at C-3 and C-4, whereas selected double resonance studies were carried out for the remaining products **3** and **4**, as required, to assign the position of the hydroxyl and *tert*-butoxycarbonylamino substituents. The N*H*CO_2-*t*-Bu and OH groups exhibit absorptions in the 4.5 to 6.5 δ range. The hydroxyl group appears at higher field and displays a coupling constant of 4 to 5 Hz while the carbamoyl proton absorbs at lower field and generally appears as a broad multiplet or doublet (J = 7 to 8 Hz) (Table 1).

Irradiation at the resonance frequency for the NH proton at C-4 of **3***a* led to the identification of the signal due to the C-4H appearing at 3.6 δ. Specifically, irradiation at the frequency of the C-4H identified the signals due to the protons at C-3 and C-5. Irradiation of the signal at 3.72 δ due to the C-3 proton identified the methylene protons at C-2 which were assigned the axial and equatorial positions based on the magnitude of their coupling to the H-3 proton. The axial proton at C-2 appears as a doublet (J = 13 Hz) of doublets (J = 2 Hz) with the large coupling due to geminal coupling of the C-2 protons.

[a]All compounds gave analyses for C, H, and N within ± 0.4% of theoretical values.
[b]The nmr spectrum was determined at 120°C.
[c]Products **3** and **4** were separated by silica gel column chromatography.
[d]Exchange with deuterium oxide.
[e]The nmr spectrum was determined at 25°C.
[f]The nmr spectrum was determined at 60°C.
[g]On standing **3***d* cyrstallizes from the reaction mixture. Washing with hexane–ether removes the soluble **4***d*.
[h]The nmr spectrum was determined at 110°C.
[i]Separated by fractional recrystallization from benzene–hexane.

Irradiation at the resonance frequency of the C-3 proton resulted in the collapse of the small coupling (J = 2 Hz) for the C-2_{ax} proton. This small coupling constant of 2 Hz for J_{2ax-3} can only be explained if the proton at C-3 is equatorial and the C-3 hydroxyl substituent is axial. The width at half-height (W_H) for the resonance of the C-4H is large compared to that for the C-3H indicating that the C-4H must be axial (8). These assignments are consistent with the observation that irradiation of the frequency due to the C-4NH results in simplification of the C-4H to a multiplet exhibiting coupling constants of 10.5, 4, and 3 Hz. The large coupling constant of 10.5 Hz is possible if the C-4H is axial, which would be consistent with the large $J_{4ax-5ax}$ and smaller $J_{4ax-5eq}$ and $J_{4ax-3eq}$ coupling constants observed. Thus, the C-4 *tert*-butoxycarbonylamino group must be equatorial with the C-3 and C-4 substituents in a *cis*-configuration.

The ^{1}H nmr spectrum of **4***a* exhibited a doublet (J = 12 Hz) of doublets (J = 9 Hz) for the C-2_{ax} proton with the large 12 Hz coupling due to geminal coupling of the C-2 methylene protons. The 9 Hz coupling is characteristic of a $J_{2ax-3ax}$ interaction indicating that the C-3H must be axial and the carbamate substituent is equatorial. The width at half-height (W_H = 10.5

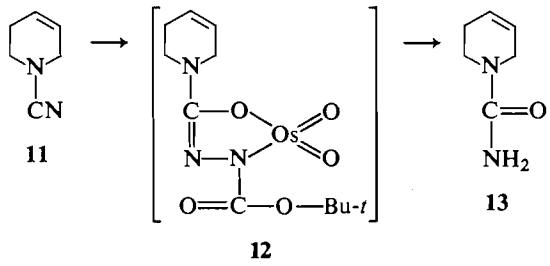


SCHEME 2

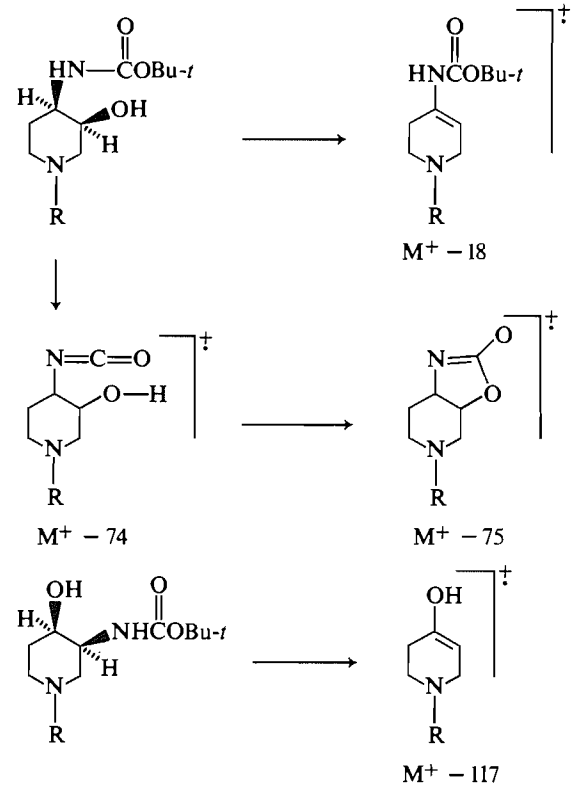
Hz) for the resonance due to the C-4H suggests it is equatorial (8). Irradiation of the resonance due to the C-4 hydroxyl proton resulted in the simplification of the absorption for the C-4H to a multiplet showing three nearly equivalent coupling constants of about 4 Hz at 3.84 to 3.96 δ. These observed couplings also indicate the C-4H is equatorial, in which case one would expect $J_{4eq-5ax}$, $J_{4eq-5eq}$, and $J_{3ax-4eq}$ coupling constants of about 4 Hz, thereby establishing the configuration of the C-4 hydroxyl substituent as axial.

The results of these ^{1}H nmr studies indicate that the vicinal oxyamination reaction of *N*-substituted -1,2,3,6-tetrahydropyridines (**2**) affords *cis*-aminoalcohol derivatives **3** and **4** in which the *tert*-butoxycarbonylamino and hydroxyl substituents assume the equatorial and axial orientations respectively, irrespective of the substituent position.

The regioisomers **3** and **4** are readily distinguished using mass spectrometry. For example, the 3-hydroxy isomers **3** exhibit a low abundance $M^+ - 18$ peak due to the loss of water, a very prominent $M^+ - 75$ ion which corresponds to the bicyclic structure illustrated in Scheme 3, and usually a less abundant $M^+ - 117$ ion due to loss of a *t*-BuOCONH$_2$ fragment. On the other hand, the 4-hydroxy isomers **4** do not exhibit a $M^+ - 18$ ion but they do display a very prominent $M^+ - 117$ ion relative to $M^+ - 74$ and $M^+ - 75$ peaks. The difference in the fragmentation pathways for **3** and **4** suggests 1,3-interactions are important. The regiochemistry of the isomers **3** and **4** can therefore be readily assigned using mass spectrometry (see Table 2).

The oxyamination reaction of 1-substituted 1,2-dihydropyridines was also examined. Thus, reaction of 1-methoxycarbonyl-1,2-dihydropyridine (**14**) with *N*-chloro-*N*-sodio-*tert*-butylcarbamate and silver nitrate afforded a mixture of the two regioisomers **15** and **16** (50%) in a ratio of 1:1. A similar reaction employing mercuric nitrate and tetraethylammonium acetate (Procedure A) in place of silver nitrate (Procedure B) gave a very complex reaction mixture from which **15** and **16** could not be readily isolated. The oxyamination reaction of 1-methyl-1,2-dihydropyridine using Procedures A and B also afforded a complex mixture of products, whereas no reaction occurred with 1-methanesulfonyl-1,2-dihydropyridine and 1-ethoxycarbonyl-1,4-dihydropyridine.

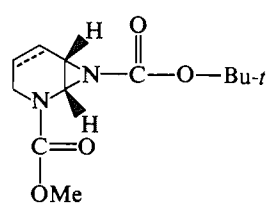
The identification of the two regioisomers **15** and **16** was based primarily on ^{1}H nmr and ir spectral data. The ^{1}H nmr spectra of **15** and **16** clearly indicated that addition occurred at the 5,6- rather than the 3,4-olefenic bond of **14**. The small $J_{2,3}$ coupling constant of 3 Hz suggests the C-2 hydroxyl and C-3 *tert*-butoxycarbonylamino substituents of **15** are in the *cis*-configuration which is consistent with the known mechanism of this reaction (1–3). The dihedral angle between a C-3 pseudoequatorial or pseudoaxial hydrogen and the C-4H is very similar, thereby precluding assignment of the stereochemistry



SCHEME 3

of the C-3H based on the magnitude of the coupling constant for $J_{3,4}$. The ^{1}H nmr spectrum of **16** was very complex, even at 100°C, due to strong hydrogen-bonding effects and/or the presence of two rotational conformers which differ in configuration at the carbonyl-to-nitrogen (carbamate) bond of the tetrahydropyridine ring nitrogen (4*g*, 7).

The 4,5-olefenic bond of the 1,2,3,6-tetrahydropyridines **15** and **16** was hydrogenated using palladium on charcoal and hydrogen gas. It was expected the stereochemistry of the C-3 substituents could then be assigned from the magnitude of the $J_{3,4}$ values. Reduction of **15** in this way afforded **17** (19.5%), **18** (9.7%), **19** (24.5%), and **20** (29.9%). The mechanism for the formation of **17**–**20** is not known. One plausible explanation is attack by methoxyl (**17** and **18**) and hydroxyl (**19** and **20**) species upon an aziridine intermediate such as **21** (6). It is not known why the hydroxy species is incorporated solely into



21

the C-3 position and the methoxyl species only into the C-2 position. The hydroxycarbamates **15** and **16** are stable in the presence of 10% palladium on charcoal in methanol at 25°C. A similar reduction of **16** gave **17** (14.1%), **18** (14.1%), **19** (40.6%), and **20** (4%).

The stereochemistry of the C-2 and C-3 substituents in which the C-3H is axial can be assigned the *cis*-configuration based on the small $J_{2,3}$ values for **17** and **19**, which are 2.8 and 5 Hz

[a]High resolution electron impact (70 ev) spectra unless otherwise indicated.
[b]Chemical ionization (NH_3) mass spectra.

respectively. This indicates that the C-2H of **17** and **19** must be equatorial and the respective methoxy and *tert*-butoxycarbonylamino substituents would therefore be axial. On the other hand, when the C-3H is equatorial, as for **18** and **20**, it is not possible to assign the stereochemistry of the C-2 substituents since $J_{2,3ae}$ is similar to $J_{2,3ee}$. The chemical shift values (δ) observed for the H_2 protons of **17** (5.24), **18** (5.14), **19** (5.7), and **20** (5.61) would suggest that the C-2H of **18** and **20** are also equatorial. This assignment would be consistent with the fact that a 2-methyl or 2-(3-pyridyl) substituent on a 1-benzoylpiperidine ring system exists in the axial orientation (10,11).

Experimental

Melting points were determined with a Büchi capillary apparatus and are uncorrected. Infrared spectra (potassium bromide unless otherwise noted) were taken on a Unicam SP 1000 spectrometer. Nuclear magnetic resonance spectra were determined for solutions in deuterochloroform or deuterodimethylsulfoxide with a Bruker WH-200, WH-400, or Varian EM 360A spectrometer. Double resonance studies were used to confirm assignments. Mass spectra were measured on a AEI MS-50 mass spectrometer. Preparative high pressure liquid chromatography was performed using a Water's Prep LC/System 500A using Prep Pak-500 Silica cartridges. The *N*-substituted -1,2,3,6-tetrahydropyridines **2** were prepared using standard procedures for acylation or alkylation of 1,2,3,6-tetrahydropyridine. 1-Methoxy-

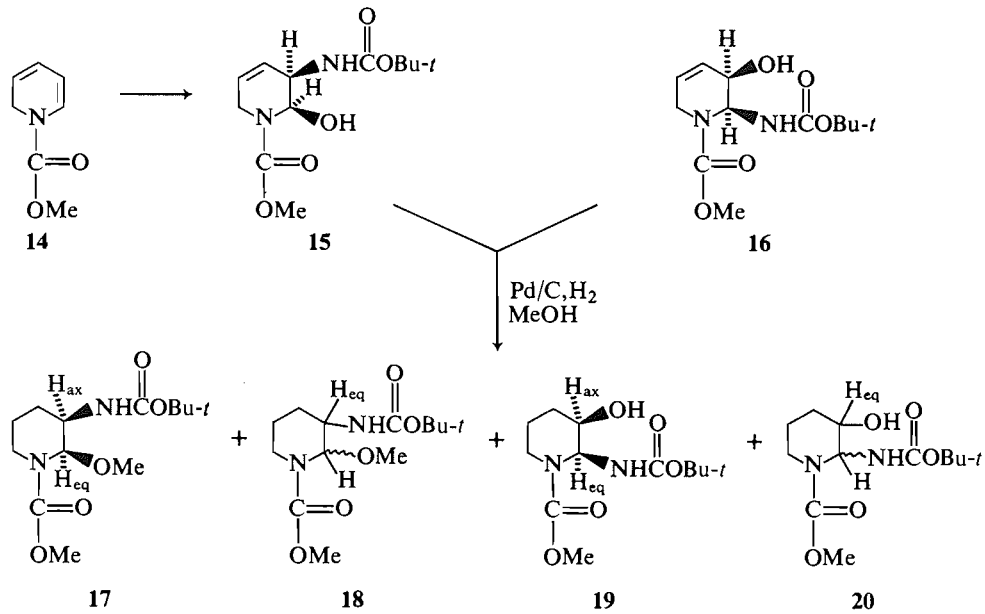

SCHEME 4

carbonyl-1,2-dihydropyridine was prepared according to the procedure of Fowler (9).

cis-*1-Substituted-3-hydroxy-4*-tert-*butoxycarbonylaminopiperidines (3) and* cis-*1-substituted-3*-tert-*butoxycarbonylamino-4-hydroxypiperidines (4)*

Procedure A

In a one-necked flask (250 mL), a mixture of *N*-chloro-*N*-sodio-*tert*-butylcarbamate (3*b*) (7.5 mmol) and mercuric nitrate (3.75 mmol) in acetonitrile (100 mL) was stirred for 15 min. To this suspension water (22 mmol), *N*-substituted-1,2,3,6-tetrahydropyridine (**2**, 5 mmol), and a solution of osmium tetroxide (0.05 mmol) in *tert*-butyl alcohol (2*b*) was added. The mixture was stirred at 25°C for 5–10 min after which tetraethylammonium acetate (5 mmol) was added. The reaction was allowed to proceed until the 1,2,3,6-tetrahydropyridine **2** was consumed (see Table 1 for times). When the reaction was completed, a saturated solution of sodium chloride was added to precipitate the remaining metallic ion.[3] The solution was filtered and extracted with chloroform (3 × 50 mL). The combined organic extracts were washed with a saturated solution of sodium chloride, dried (Na_2SO_4), and the solvent removed *in vacuo* to yield the crude hydroxycarbamates **3** and **4**. Regioisomers **3** and **4** were separated by silica gel column chromatography or fractional crystallization as indicated in Table 1.

Procedure B

A mixture of *N*-chloro-*N*-sodio-*tert*-butylcarbamate (3*b*) (7.5 mmol) and silver nitrate (15 mmol) in acetonitrile (100 mL) was allowed to stir for 15 min at 25°C. Water (22 mmol), *N*-substituted 1,2,3,6-tetrahydropyridine (**2**, 5 mmol), and a solution of osmium tetroxide (0.05 mmol) in *tert*-butyl alcohol (2*b*) were added to this suspension. The reaction was allowed to proceed with stirring at 25°C until all the olefin was consumed as indicated by tlc. The isolation procedure was identical to that of Procedure A.

cis-*1-Benzoyl-3-hydroxy-4-aminopiperidine (5)*

A solution of 30% HBr in acetic acid (5 mL) was added to a solution of **3***a* (1.6 g, 5 mmol) in methanol (10 mL) at 0°C with stirring. The reaction was allowed to proceed at 25°C for an additional 20 min. The solvent was removed *in vacuo* and the residue basified to pH 10, using aqueous sodium hydroxide prior to extraction with ether (20 mL) and then chloroform (3 × 50 mL). The combined organic extracts were dried (Na_2SO_4) and the solvent removed *in vacuo* to yield **5** as an oil which solidified on standing at room temperature after several days, yield 0.84 g (76%); mp 130–131°C; ir: 3380, 3300, 3100–3180 (OH and NH_2), 1620–1635 (CO); nmr ($CDCl_3$) δ: 7.48 (m, 5H, Ph), 2.8–5.0 (m, 6H, H_2, H_6, H_3, H_4), 2.28 (br s, 3H, NH_2, OH, exchange with deuterium oxide), 1.4–2.0 (m, 2H, H_5). *Exact Mass* calcd. for $C_{12}H_{16}N_2O_2$: 220.1212; found (high-resolution ms): 220.1210.

cis-*1-Benzoyl-3-amino-4-hydroxypiperidine (6)*

Hydrolysis of **4***a*, using the procedure outlined for the preparation of **5**, afforded **6**: yield (81%); mp 120–122°C; ir: 3360, 3300, 3140–3220 (OH, NH_2), 1635 (CO); nmr ($CDCl_3$) δ: 7.42 (m, 5H, Ph), 2.76–4.24 (m, 6H, H_2, H_6, H_3, H_4), 2.15 (br s, 3H, NH_2, OH, exchanges with deuterium oxide), 1.6–2.0 (m, 2H, H_5). *Exact Mass* calcd. for $C_{12}H_{16}N_2O_2$: 220.1212; found (high resolution ms): 220.1210.

3-Benzoyl-9-oxa-3,7-diazabicyclo[4.3.0]nonan-8-thione (7)

A solution of thiophosgene (0.228 mL, 3 mmol) in dry tetrahydrofuran (5 mL) was added dropwise to a solution of **5** (0.66 g, 3 mmol) and triethylamine (0.9 mL, 6 mmol) in dry tetrahydrofuran (30 mL) at −65°C with stirring over a 20 min period. The reaction was allowed to proceed for 30 min prior to warming to 25°C. Triethylamine hydrochloride was removed by filtration, the filtrate was concentrated *in vacuo*, and the residue was washed with water. Chromatography on a 0.5 cm × 9.0 cm silica gel column with chloroform as eluant afforded **7**, yield (0.1 g, 12.7%); mp 203°C; ir: 3360 (NH), 1630 (CO); nmr ($CDCl_3$ + DMSO-d_6) δ: 7.46 (m, 5H, Ph), 4.82–5.38 (m, 1H, H_1), 4.2–4.62 (m, 1H, H_6), 3.32–4.08 (m, 4H, H_2, H_4), 3.1 (br s, 1H, NH, exchanges with deuterium oxide), 1.76–2.32 (m, 2H, H_5). *Exact Mass* calcd. for $C_{13}H_{14}N_2O_2{}^{32}S$: 262.0776; found (high resolution ms): 262.0773.

3-Benzoyl-9-oxa-3,7-diazabicyclo[4.3.0]nonan-8-one (8)

Reaction of **5** with phosgene using the procedure outlined for the preparation of **7**, afforded **8**, yield (34.7%); mp 145–146°C; ir: 3280 (NH), 1750–1760 (OCO), 1625 (COPh); nmr ($CDCl_3$) δ: 7.4 (m, 5H, Ph), 6.85 (s, 1H, NH, exchanges with deuterium oxide), 4.55–5.05 (m, 1H, H_1), 3.24–4.38 (m, 5H, H_6, H_2, H_4), 1.62–2.18 (m, 2H, H_5). *Exact Mass* calcd. for $C_{13}H_{14}N_2O_3$: 246.1005; found (high resolution ms): 246.1004.

3-Benzoyl-7-oxa-3,9-diazabicyclo[4.3.0]nonan-8-thione (9)

Reaction of **6** with thiophosgene, using the procedure outlined for

[3]The sodium bisulfite treatment to reduce and remove the small amount of osmium that may be bound to the organic products was omitted since this resulted in a more complex reaction mixture.

the preparation of **7**, gave **9**, yield (13.3%); mp 210–211°C; ir: 3360 (NH), 1630 (COPh); nmr ($CDCl_3$ + DMSO-d_6) δ: 7.45 (m, 5H, Ph), 4.97–5.38 (m, 1H, H_6), 4.0–4.54 (m, 1H, H_1), 3.2–3.9 (m, 4H, H_2, H_4), 2.84 (br s, 1H, NH, exchanges with deuterium oxide), 1.9–2.4 (m, 2H, H_5). *Exact Mass* calcd. for $C_{13}H_{14}N_2O_2{}^{32}S$: 262.0776; found (high resolution ms): 262.0775.

cis-*1-Benzoyl-3-hydroxy-4-methylaminopiperidine (10)*

Lithium aluminum hydride (0.3 g, 8 mmol) was added slowly to a solution of **3***a* (0.64 g, 2 mmol) in dry tetrahydrofuran (25 mL) with stirring at 0°C. The reaction mixture was allowed to reflux for 24 h. After cooling, a solution of 10% aqueous sodium hydroxide was added to destroy the lithium aluminum hydride, the mixture was filtered, and the solvent was removed *in vacuo* to give a viscous oil. Purification of the reaction mixture by elution from a 1 cm × 20 cm silica gel column using chloroform–methanol (9:1 v/v) as eluant gave **10** as a viscous oil, yield (0.32 g, 72.7%); nmr ($CDCl_3$) δ: 7.37 (m, 5H, Ph), 3.78–4.1 (m, 1H, H_3), 3.56 (s, 2H, CH_2Ph), 2.0–3.24 (m, 7H, H_2, H_4, H_6, OH, NH), 1.52–2.0 (m, 2H, H_5). *Exact Mass* calcd. for $C_{13}H_{20}N_2O$: 220.1576; found (high resolution ms): 220.1574.

1-Aminocarbonyl-1,2,3,6-tetrahydropyridine (13)

The oxyamination of **11** (5 mmol) as outlined in Procedure A afforded a solid which was purified by elution from a silica gel column using a gradient of hexane–chloroform to afford **13**, yield (16.2%); mp 121–122°C; ir: 3400, 3220 (NH_2), 1660 (CO); nmr ($CDCl_3$) δ: 5.83 (m, 2H, H_4, H_5), 4.7 (br s, 2H, NH_2, exchanges with deuterium oxide), 3.95 (m, 2H, H_6), 3.56 (t, $J_{2,3}$ = 6 Hz, 2H, H_2), 2.25 (m, 2H, H_5). *Exact Mass* calcd. for $C_6H_{10}N_2O$: 126.0794; found (high resolution ms): 126.0795. This product was identical (ir, nmr) to an authentic sample prepared from the reaction of 1-chlorocarbonyl-1,2,3,6-tetrahydropyridine with ammonia.

Oxyamination of **11** using Procedure B afforded **13** (20%).

cis-*1-Methoxycarbonyl-2-hydroxy-3*-tert-*butoxycarbonylamino-1,2,3,6-tetrahydropyridine (15) and* cis-*1-methoxycarbonyl-2*-tert-*butoxycarbonylamino-3-hydroxy-1,2,3,6-tetrahydropyridine (16)*

A mixture of *N*-chloro-*N*-sodio-*tert*-butylcarbamate (7.8 g, 45 mmol) and silver nitrate (15 g, 90 mmol) in acetonitrile (200 mL) was allowed to stir for 15 min at 25°C. Water (132 mmol), 1-methoxycarbonyl-1,2-dihydropyridine (9) (4.17 g, 30 mmol), and a solution of osmium tetroxide (0.3 mmol) in *tert*-butylalcohol was added to this suspension. The reaction was allowed to proceed with stirring at 25°C for 24 h. The mixture of **15** and **16** obtained, following the isolation procedure described in Procedure A, was separated by preparative hplc using hexane–ether (1:4 v/v) at a flow rate of 250 mL/min. Removal of the solvent from the 1000–1500 mL fractions gave **15** (1.85 g, 22.7%), mp 119–120°C; ir: 3340–3360 (OH, NH), 1720 (NHCO), 1680 (NCO_2Me); nmr (Me_2SO-d_6, 50°C) δ: 6.26–6.44 (m, 1H, NH), 5.84 (d, J = 5 Hz, 1H, OH), 5.68–5.8 (d, $J_{4,5}$ = 10 Hz of d, $J_{3,4}$ = 3 Hz of d, $J_{4,6ax}$ = 3 Hz of d, $J_{4,6eq}$ = 3 Hz, 1H, H_4), 5.6–5.68 (m, $J_{2,3}$ = 3 Hz, 1H, H_2), 5.36–5.48 (d, $J_{4,5}$ = 10 Hz of d, $J_{5,6ax}$ = 1.5 Hz of d, $J_{5,6eq}$ = 1.5 Hz, 1H, H_5), 4.03–4.16 (m, 1H, H_3), 3.86–4.03 (d, J_{gem} = 18 Hz of d, $J_{4,6eq}$ = 3 Hz of d, $J_{3,6eq}$ = 3 Hz, 1H, H_{6eq}), 3.66 (s, 3H, CO_2Me), 3.44–3.68 (m, 1H, H_{6ax}), 1.4 (s, 9H, *t*-Bu). *Exact Mass* calcd. for $C_8H_{11}N_2O_5$ (M^+ − 57): 215.0668; found (high resolution ms): 215.0655; CI (NH_3) for $C_{12}H_{20}N_2O_5$: M + 1, 273 and 2 M + 1, 545. Collection of the 1500–1750 mL fraction yielded a mixture of **15** and **16** (0.4 g, 4.9%), whereas the 1750–2750 mL eluate afforded **16** (1.82 g, 22.4%) as a viscous oil; ir: 3420–3460 (OH), 3350–3380 (NH); nmr (Me_2SO-d_6, 100°C) δ: 5.4–6.3 (m, 4H, NH, H_2, H_4, H_5), 5.04 (d, J = 6 Hz, 0.5H, H-bonded OH), 4.24 (m, 0.5H, OH), 3.34–4.08 (6H, H_3, H_6, OMe), 1.4 (s, 9H, *t*-Bu). *Exact Mass* calcd. for $C_{12}H_{20}N_2O_5$: 272.1372; found (high resolution ms): 272.1363.

cis-*1-Methoxycarbonyl-2-methoxy-3*-tert-*butoxycarbonylaminopiperidine (17)*, *1-methoxycarbonyl-2-methoxy-3*-tert-*butoxycarbonylaminopiperidine (18)*, cis-*1-methoxycarbonyl-2*-tert-*butoxycarbonylamino-3-hydroxypiperidine (19)*, *and 1-methoxycarbonyl-2*-tert-*butoxycarbonylamino-3-hydroxypiperidine (20)*

Hydrogenation of **15** (0.6 g, 2.2 mmol) in 200 mL methanol using 100 mg 10% palladium on charcoal and hydrogen gas at 25 psi for 7 h at 25°C, followed by filtration and removal of the solvent *in vacuo*, afforded a mixture of **17–20**. Purification on a 1 cm × 30 cm silica gel column using chloroform as eluant gave initially a mixture of **17** and **18** (0.185 g, 29.2%) in a ratio of 2:1, calculated from the integrals for the C-2H of **17** and **18** at 5.24 and 5.14 δ respectively. Fractional crystallization of this mixture from hexane–ether (1:9 v/v) gave pure samples of **17** and **18** which showed the following spectral data.

Compound **17**, ir: 3360 (NH), 1720 (NHCO), 1695–1705 (NCO_2Me); nmr (Me_2SO-d_6, 70°C) δ: 6.18–6.38 (m, 1H, NH), 5.24 (d, $J_{2eq-3ax}$ = 2.8 Hz, 1H, H_{2eq}), 3.66–3.82 (d, $J_{6eq-6ax}$ = 12.5 Hz of d, $J_{2,3}$ = 3 Hz, 1H, H_{6eq}), 3.66 (s, 3H, CO_2Me), 3.26–3.48 (m, 1H, H_{3ax}), 3.2 (s, 3H, OMe), 2.66–2.90 (m, 1H, H_{6ax}), 1.34–1.86 (m, 13H, H_4, H_5, *t*-Bu); *Exact Mass* calcd. for $C_{13}H_{24}N_2O_5$: 288.1685; found (high resolution ms): 288.1679.

Compound **18**, mp 110–111°C; ir: 3340 (NH), 1720 (NHCO), 1680–1690 (NCO_2Me); nmr δ: 6.70–6.96 (br s, 1H, NH), 5.14 (d, $J_{2,3}$ = 1.5 Hz, 1H, H_2), 3.70–3.82 (d, $J_{6eq-6ax}$ = 12.5 Hz of d, $J_{5,6}$ = 3 Hz, 1H, H_{6eq}), 3.50–3.67 (m, 1H, H_{3eq}), 3.63 (s, 3H, CO_2Me), 3.18 (s, 3H, OMe), 2.8 (ddd, 1H, H_{6ax}), 1.64–1.88 (m, 2H, H_4), 1.2–1.5 (m, 11H, H_5, *t*-Bu). *Exact Mass* calcd. for $C_{13}H_{24}N_2O_5$: 288.1685; found (high resolution ms): 288.1685.

Further elution with chloroform gave **20** (0.18 g, 29.9%), mp 160°C; ir: 3360, 3460 (OH, NH), 1715 (NHCO), 1685–1700 (NCO_2Me); nmr (Me_2SO-d_6, 50°C) δ: 7.24 (d, J = 7.5 Hz, 1H, NH), 6.8–6.9 (br s, 1H, OH), 5.52–5.7 (m, 1H, H_2), 3.78 (m, 4H, H_{6eq}, CO_2Me), 3.38–3.48 (m, 1H, H_{3eq}), 2.91 (sextet, 1H, H_{6ax}), 1.16–2.08 (m, 13H, H_4, H_5, *t*-Bu). *Exact Mass* calcd. for $C_{12}H_{20}N_2O_4$ (M^+ − 18): 256.1423; found (high resolution ms): 256.1427; CI (NH_3): M + 1, 275.

Continued elution with chloroform gave **19** (0.148 g, 24.5%), mp 161–163°C; ir: 3460 (OH), 3340 (NH), 1720 (NHCO), 1685–1700 (NCO_2Me); nmr (Me_2SO-d_6, 50°C) δ: 6.74 (d, J = 8 Hz, 1H, NH), 5.7 (d, $J_{2,NH}$ = 8 Hz of d, $J_{2eq,3ax}$ = 5 Hz, 1H, H_{2eq}), 4.86 (d, J = 5 Hz, 1H, OH), 3.64–3.7 (m, 1H, H_{6eq}), 3.6 (s, 3H, CO_2Me), 3.48 (sextet, $J_{3,4ax}$ = 10 Hz, $J_{3,4eq}$ = 5 Hz, $J_{2,3}$ = 5 Hz, $J_{3,OH}$ = 5 Hz, 1H, H_{3ax}), 2.81 (ddd, 1H, H_{6ax}), 1.2–1.8 (m, 13H, H_4, H_5, *t*-Bu). *Exact Mass* calcd. for $C_{12}H_{22}N_2O_5$: 274.1529; found (high resolution ms): 274.1526.

Hydrogenation of **16** (0.5 g, 1.84 mmol), as outlined for **15** above, afforded a mixture of **17** and **18** (0.15 g, 28.3%) in a ratio of 1:1, **20** (0.021 g, 4%), and **19** (0.215 g, 40.6%).

Synthesis of (±)-epiisopodophyllotoxin

MARGARET B. GLINSKI AND TONY DURST

Ottawa–Carleton Institute for Graduate Studies and Research in Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received July 23, 1982

MARGARET B. GLINSKI and TONY DURST. Can. J. Chem. **61**, 573 (1983).

The synthesis of (±)-epiisopodophyllotoxin commencing with 6-bromopiperonal dimethyl acetal is described. The carbon skeleton of isoepipodophyllotoxin was assembled via a Diels–Alder reaction between the hydroxyquinodimethane generated photochemically from 6-(3′,4′,5′-trimethoxybenzyl)-piperonal, obtained from the bromoacetal above, and dimethyl fumarate. This Diels–Alder adduct was converted in five steps into the title compound. The overall yield for the seven steps was 15%.

MARGARET B. GLINSKI et TONY DURST. Can. J. Chem. **61**, 573 (1983).

On décrit une synthèse de la (±) épiisopodophyllotoxine faisant appel à l'acétal diméthylique du bromo-6 pipéronal comme produit de départ. On a édifié le squelette carboné de la isoépipodophyllotoxine en utilisant une réaction de Diels–Alder entre le fumarate de diméthyle et l'hydroxyquinodiméthane produit photochimiquement à partir du (triméthoxy-3′,4′,5′ benzyl)-6 pipéronal provenant du bromoacétal. L'adduit de Diels–Alder permet d'obtenir le composé mentionné dans le titre. Le rendement global des 7 étapes est de 15%.

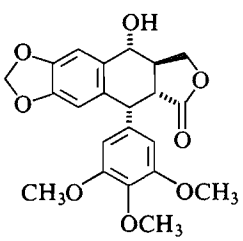
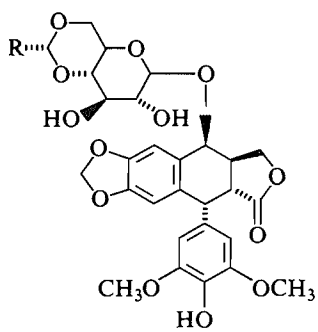
Introduction

Podophyllotoxin **1**, a naturally occurring lignan lactone isolated from *Podophyllum peltatum* is of considerable interest due to its cytotoxic activity (for a recent review, see ref. 1). Indeed, two glycosylated derivatives of **1**, Etoposide, **2** (VP-16), and Teniposide, **3** (VM-26), are in clinical use as agents against small cell lung and bladder cancers (2).

As part of a program concerning the synthesis of podophyllotoxin derivatives, we have completed the synthesis of (±)-epiisopodophyllotoxin **4**.[1] This compound still contains the highly strained *trans*-fused lactone of podophyllotoxin which is considered important for biological activity (3), but has a *trans* relationship between the 1-aryl substituent and the lactone carbonyl group, compared to the *cis* arrangement of these substituents in podophyllotoxin. (±)-Epiisopodophyllotoxin has previously been synthesized by Gensler and Johnson (4) in low overall yield commencing with 3,4,5-trimethoxybenzene and piperonylic acid.



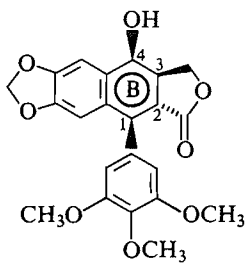
1



2 R = CH_3

3 R =

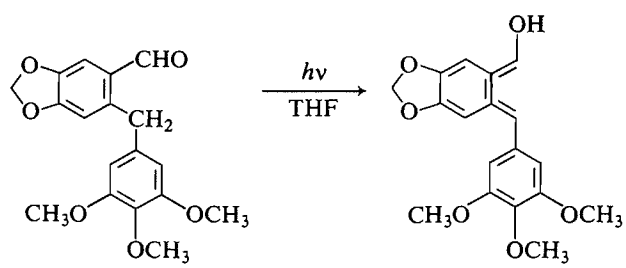
[1]In the nomenclature for these compounds, "iso" and "epi" refer to inversion of configuration at positions 1 and 4, relative to naturally occurring podophyllotoxin.



4

Discussion and results

The carbon skeleton of **4** was generated via a Diels–Alder reaction between the dienol **5** obtained by photoenolization of 6-(3′,4′,5′-trimethoxybenzyl)-piperonal, **6**, and dimethyl fumarate. Sammes and co-workers (5) have shown that in general, *ortho*-substituted benzaldehydes undergo isomerization to *o*-quinodimethanes when irradiated in solvents such as benzene, acetone, or THF with a medium-pressure Hg lamp, and that these intermediates can be trapped with a variety of dienophiles including dimethyl acetylene dicarboxylate and maleic anhydride (6).



6 **5**

A synthesis of **6** had previously been reported by Sammes and co-workers (6) via a six-step sequence with an overall yield of 17%, utilizing 6-bromopiperonal ethylene ketal and 3,4,5-trimethoxybenzaldehyde as starting materials. We have found it possible to prepare **6** in 84% yield from 6-bromopiperonal dimethyl acetal, by treatment with *n*-BuLi, *n*-$Bu_3P \cdot CuI$, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

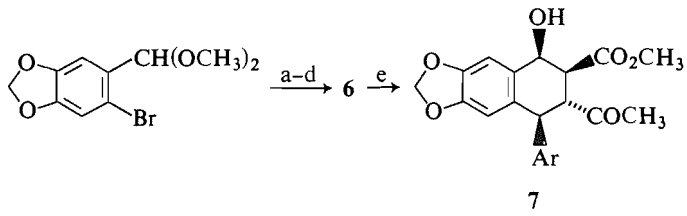
3,4,5-trimethoxybenzyl bromide. The use of n-$Bu_3P \cdot CuI$ was crucial for the coupling reaction; no coupling was observed in the absence of the above reagent or when it was replaced by $MgBr_2$, CuI, or $FeCl_3$.

Irradiation of **6** in THF in the presence of dimethyl fumarate afforded the diester **9**, mp 198°C, as the only isolable adduct in 47% yield. The structure was assigned as **7**, based on analogy with earlier work (5) which had shown that the Diels–Alder reaction of dienols such as **5** with dimethyl fumarate or maleic anhydride gave adducts in which the hydroxyl group and the *"ortho"* carbonyl substituent were *cis* to each other. This was corroborated by the proton nmr spectrum of **7** (see Experimental section) and those of the derivatives **10**, **11**, and **4** (see Scheme 2).

The ester group *ortho* to the hydroxyl function in **7** was selectively reduced upon reaction with 3 equiv. of $LiHBEt_3$ in THF at −78°C, followed by warming to 25°C to furnish the crystalline diol **8**, mp 155°C, in 70% yield.

Direct saponification of **8** to the acid **9** was not possible without considerable decomposition. Consequently the diol was protected as the acetonide **10** (90%), prior to carrying out the basic ester hydrolysis (83%). Subsequent deprotection furnished **9**, mp 230–234°C (dec.) in 65% overall yield from **8**. Lactonization of **9** to (±)-epiisopodophyllotoxin, mp 258–260°C (lit. (4) mp 255°C (dec.)), was accomplished using DCC as the activating agent, Scheme 2. The sequence from **7** to **4** was based on a similar series of reactions developed by Kuhn and co-workers (7) and by Rajapaksa and Rodrigo (8) for the conversion of **11** to podophyllotoxin **1**.

The stereochemical assignments for **4** and the intermediates **7**–**10** were readily confirmed by the observed coupling constants in the B-ring (structure **4**) in these intermediates. In particular, in the acetonide **10**, the 3.0 Hz coupling between H_3 and H_4 is clearly consistent with an axial–equatorial arrangement between H_3 and H_4, while the large 11.6 Hz J for H_1 (δ = 4.06) requires a diaxial relationship between H_1 and H_2.



7

Reagents: (a) n-BuLi/THF, −78°C; (b) n-$Bu_3P \cdot CuI$; (c) 3,4,5-tri-methoxybenzyl bromide; (d) H^+/H_2O; (e) $h\nu$/THF/dimethyl fumarate.

SCHEME 1

H_3 in **11** appears as a triplet, J = 11.6 Hz, thus necessitating two axial–axial relationships. In (±)-epiisopodophyllotoxin, **4**, $J_{H_1H_2}$ and $J_{H_3H_4}$ are 11.0 Hz, and 3.0 Hz, respectively, while the same two coupling constants in podophyllotoxin are 4.4 and 9.1 Hz.

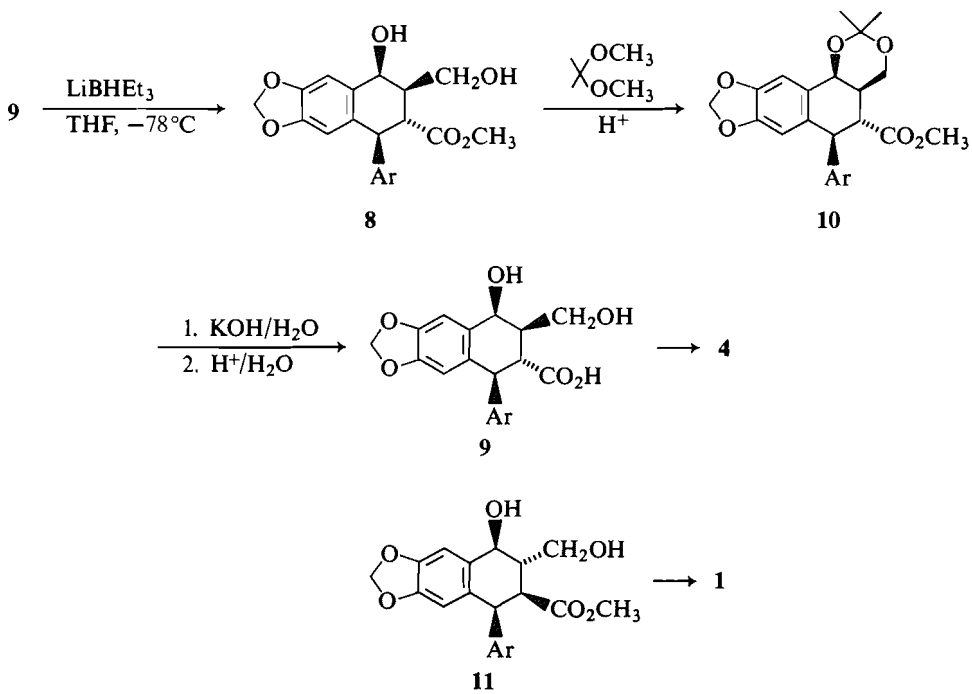
Experimental

General comments

Nuclear magnetic resonance spectra were taken on Varian HA-100, T-60, and FT-80 spectrometers in $CDCl_3$ solution with TMS as internal standard. Infrared spectra were obtained in $CHCl_3$ solution using a Perkin–Elmer 470 spectrophotometer. Melting points, Gallenkamp apparatus, are uncorrected.

6-(3',4',5'-Trimethoxybenzyl)-piperonal (6)

To a solution of 278 mg (1 mmol) of 6-bromopiperonal dimethyl acetal (8) in 1 mL of dry THF at −78°C under N_2 was added 0.42 mL of n-BuLi (2.4 M in hexanes). The solution was stirred for 10 min and then treated with 196 mg (0.5 mmol) of n-$Bu_3P \cdot CuI$ dissolved in 0.5 mL of THF. After a further 10 min at −78°C, 130 mg (0.5 mmol) of 3,4,5-trimethoxybenzaldehyde, dissolved in a small volume of THF, was added. The reaction mixture was kept at −78°C for 1 h and then at room temperature for a further 18 h before quenching with a



SCHEME 2

saturated NH_4Cl solution. A typical work-up followed by column chromatography on silica gel (3:1 hexanes – ethyl acetate) afforded 148 mg of a colorless oil which was identified by nmr as the dimethyl acetal of the desired aldehyde; ^1H nmr: 3.27 (3, 3H), 3.80 (3, 9H), 3.93 (s, 2H), 5.88 (s, 2H), 5.90 (s, 1H), 6.35 (s, 2H), 6.45 (s, 1H), and 7.07 (s, 1H).

The oil was dissolved in 10 mL of methanol and 1 mL of 5% HCl was added. The title aldehyde began to crystallize from the solution within a short time. The product was filtered and recrystallized from ether–hexanes to yield 140 mg (84%, overall) of 6-(3′,4′,5′-trimethoxybenzyl)-piperonal as fine colorless needles, mp 123°C (lit. (6) mp 124–125°C); ir: 1690 cm^{-1}; ^1H nmr: 3.84 (s, 6H), 3.86 (s, 3H), 4.34 (3, 2H), 6.08 (s, 2H), 6.38 (s, 2H), 6.72 (s, 1H), 7.36 (s, 1H), 9.93 (s, 1H); ^{13}C nmr: 189.6, 153.4, 152.6, 147.1, 140.4, 136.7, 135.9, 128.6, 111.0, 109.0, 105.7, 102.1, 60.9, 56.1, 37.7.

Photolysis of ***6*** *in the presence of dimethyl fumarate*

A solution of **6** (660 mg, 2.0 mmol) and 288 mg (2.0 mmol) of dimethylfumarate in 100 mL of dry THF was irradiated for 18 h in a quartz apparatus with a long uv lamp at room temperature under a nitrogen atmosphere. The solvent was evaporated and the crude solid was recrystallized from $CHCl_3$–ether to furnish 450 mg (47%) of **7**, mp 198°C, as colorless plates; ir: 3300–3500 (br), 1720 (s), 1590 (s) cm^{-1}; ^1H nmr: 2.27 (OH), 3.19 (dd, J = 12, 3 Hz, 1H), 3.42 (dd, J = 12, 10.5 Hz, 1H), 3.50 (s, 3H), 3.75 (s, 3H), 3.79 (s, 6H), 3.85 (s, 3H), 4.02 (d, J = 10, 1H), 5.07 (d, J = 3 Hz, 1H), 5.89 (s, 2H), 6.47 (s, 1H), 6.54 (s, 2H), 6.77 (s, 1H); ^{13}C nmr: 174.9, 172.8, 153.3, 153.0, 143.2, 146.6, 138.3, 131.7, 108.9, 108.6, 106.0, 101.22, 68.0, 60.9, 56.2, 52.3, 51.8, 48.7, 45.6. *Anal.* calcd. for $C_{24}H_{26}O_{10}$: C 60.75, H 5.53; found: C 61.13, H 5.71.

Reduction of diester 7

Diester **7** (474 mg, 1 mmol) was dissolved in 10 mL of dry THF and cooled to −78°C under a nitrogen atmosphere. $LiBEt_3H$ (3.0 mmol) was added by syringe and the solution was allowed to warm for an hour to room temperature and then stirred for an additional 18 h. The reaction mixture was quenched with 1% HCl and then worked up in the usual manner to yield a yellowish solid which was recrystallized from ether–hexanes to afford 312 mg (70%) of the diol **8** as colorless needles, mp 155°C; ir: 3300–3500 (br), 1725 (s), 1600 (s) cm^{-1}; ^1H nmr: 2.45 (m, 1H), 3.00 (t, J = 11 Hz, 1H), 3.52 (s, 3H), 3.79 (3, 6H), 3.84 (s, 3H), 3.80 (OH, 2H), 4.0–4.3 (m, 3H), 5.01 (d, J = 3 Hz, 1H), 5.89 (s, 2H), 6.26 (s, 1H), 6.30 (s, 2H), 6.83 (s, 1H). *Anal.* calcd. for $C_{23}H_{26}O_9$: C 61.87, H 5.87; found: C 61.63, H 5.55.

Ketalization of diol 8

The diol **10** (340 mg, 0.76 mmol) and TsOH (10 mg) were dissolved in 2,2-dimethoxypropane (5 mL). The solution was kept at room temperature for 3 h, diluted with 25 mL of CH_2Cl_2, and washed with 25 mL of 10% $NaHCO_3$. The organic extracts were dried and the solvent evaporated. Recrystallization of the crude product from ether–hexanes afforded 330 mg (90%) of the acetonide **9** as colorless needles, mp 181–182°C; ir: 1720 (s), 1590 (m) cm^{-1}; ^1H nmr: 1.47 (s, 3H), 1.63 (s, 3H), 2.03 (m, 1H), 3.40 (t, J = 11.6 Hz, 1H), 3.43 (s, 3H), 3.65 (dd, J = 12.0, 2.0 Hz, 1H), 3.75 (s, 6H), 3.80 (s, 3H), 4.06 (d, J = 11.6 Hz, 1H), 4.18 (dd, J = 12.0, 3.5 Hz, 1H), 4.83 (d, J = 3.0 Hz, 1H), 5.87 (d, J = 1.4 Hz, 1H), 5.91 (d, J = 1.4 Hz, 1H), 6.23 (s, 1H), 6.30 (s, 2H), 6.67 (s, 1H). *Anal.* calcd. for $C_{26}H_{30}O_9$: C 64.18, H 6.22; found: C 64.12, H 5.96.

Diolcarboxylic acid ***9***

The acetonide **10** (50 mg) was saponified by heating for 4 h in a 1:1 mixture of 1% aqueous KOH and dioxane. Ether was added to the cooled mixture and the aqueous phase was separated and acidified. The acid was extracted from the aqueous phase by extracting 3 times with 10 mL of CH_2Cl_2. The extracts were dried and evaporated, yielding 40 mg (83%) of the intermediate ketal acid as a colorless powder, mp 181–183°C; ir: 2500–3500 (br), 1700 (s), 1590 (s) cm^{-1}; ^1H nmr: 1.46 (s, 3H), 1.63 (s, 3H), 2.01 (m, 1H), 3.48 (t, J = 11.6 Hz, 1H), 3.69 (dd, J = 12.0, 2.0 Hz, 1H), 3.80 (s, 6H), 3.85 (s, 3H), 4.01 (d, J = 11.6 Hz, 1H), 4.09 (dd, J = 12.0, 3.5 Hz, 1H), 4.81 (d, J = 3 Hz, 1H), 5.86 (d, J = 1.4 Hz, 1H), 5.88 (d, J = 1.4 Hz, 1H), 6.24 (s, 1H), 6.35 (s, 2H), 6.71 (s, 1H), 11.20 (br, COOH); *Mol. Wt.* calcd.: 472.4; found: 472. *Anal.* calcd. for $C_{25}H_{28}O_9$: C 63.55, H 5.97; found: C 63.20, H 6.17.

The above acetonide (130 mg) was converted to **9** by stirring at room temperature for 24 h with a mixture of 12 mL of 1:1 of 1% HCl and dioxane. Usual work-up afforded, after recrystallization from acetone–ether, 100 mg of **9** as small colorless needles, mp 230–234°C; ir: 2500–3500 (br), 1710 (s), 1590 (s) cm^{-1}; nmr: 2.47 (m, 1H), 3.08 (t, J = 11.0 Hz, 1H), 3.79 (s, 6H), 3.84 (s, 3H), 3.95 (br, 3 × OH), 4.00–4.27 (m, 3H), 5.07 (d, J = 3.0 Hz, 1H), 5.85 (s, 2H), 6.26 (s, 1H), 6.30 (s, 2H), 6.82 (s, 1H). *Anal.* calcd. for $C_{22}H_{24}O_9$: C 61.10, H 5.60; found: C 61.28, H 5.69.

(±)-Epiisopodophyllotoxin, ***4***

Acid **9** (50 mg, 0.12 mmol) and DCC (30 mg, 0.12 mmol) were dissolved in 4 mL of dry THF. The solution was kept at room temperature for 3 h, treated with 0.2 mL of H_2O and 0.1 mL of glacial acetic acid, and left for an additional 30 min. The solvents were then evaporated and the residue triturated with 5 mL of CH_2Cl_2. The CH_2Cl_2 soluble fraction was purified on preparative tlc (ether) and afforded 37 mg (75%) of **4** as a colorless powder, mp 258–260°C ($CHCl_3$/ether) (lit. (4) mp 255°C); ir: 3350–3550 (br), 1775 (s) cm^{-1}; nmr: 2.03 (OH), 2.68 (m, 1H), 3.29 (dd, J = 14.0, 11.2 Hz, 1H), 4.11 (m, 1H), 3.82 (s, 6H), 3.85 (s, 3H), 4.03 (d, J = 10 Hz, 1H), 4.46 (m, 1H), 4.94 (d, J = 3.0 Hz, 1H), 5.93 (s, 2H), 6.39 (s, 1H), 6.44 (s, 2H), 6.78 (s, 1H). *Anal.* calcd. for $C_{22}H_{22}O_8$: C 63.76, H 5.35; found: C 63.89, H 5.41.

The effect of stereochemistry on $^1J_{C-H}$ at the sp^2 carbons of oxime, hydrazone, and imine derivatives of aldehydes

ROBERT R. FRASER AND MONIQUE BRESSE

Ottawa–Carleton Institute for Research and Graduate Studies in Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received September 7, 1982

ROBERT R. FRASER and MONIQUE BRESSE. Can. J. Chem. **61**, 576 (1983).

A comparison of the magnitudes of $^1J_{C-H}$ at the aldehydic carbon of both the *syn* and *anti* isomers of aldehyde derivatives (oximes, hydrazones, and imines) has shown a consistently greater value, by about 20 Hz, for the *syn* isomer. Regardless of its origin, this stereochemical correlation should prove useful in providing configurational assignments.

ROBERT R. FRASER et MONIQUE BRESSE. Can. J. Chem. **61**, 576 (1983).

On a effectué une comparaison des ordres de grandeur des $^1J_{C-H}$ au niveau du carbone aldéhydique des isomères *syn* et *anti* des dérivés d'aldéhyde (oximes, hydrazones et imines); cette valeur est systématiquement plus grande d'environ 20 Hz pour l'isomère *syn*. Sans tenir compte de son origine, cette corrélation stéréochimique devrait s'avérer utile pour faire des attributions de configuration.

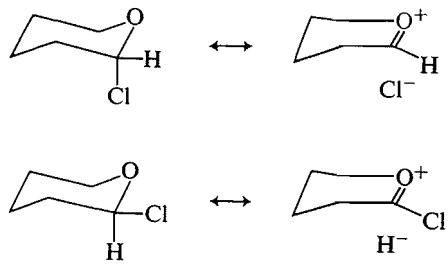
Introduction

One of the most widely studied of all nmr parameters is $^1J_{C-H}$, the coupling constant between a carbon atom and a hydrogen atom directly bonded to it. A recent review (1), which summarizes both the experimental and the theoretical contributions to the field, identifies a number of structural features which affect ^1J, but only one of these, the hybridization of the carbon atom, appears to be the dominant factor.

There have been many studies involving a correlation between the stereochemistry of a pair of diastereomers and the magnitude of $^1J_{C-H}$. An axial H at C-1 of carbohydrates or at C-2 in simple tetrahydropyrans generally exhibits a $^1J_{C-H}$ which is 8 to 10 Hz smaller than that for an equatorial C—H (2, 3). In piperidine derivatives, $^1J_{C-H}$ for a proton α to nitrogen and *trans* to the lone pair on nitrogen (i.e., axial) is 6 to 10 Hz smaller than when *gauche* (equatorial) (4). Similar lone pair effects have been noted in trimethylene sulfites (5) and 1,3-dioxanes (6). The effect can be rationalized on the same basis as the anomeric effect. Thus, as shown in Scheme 1, the axial conformer of 2-chlorotetrahydropyran possesses a resonance structure involving an $n-\sigma^*$ interaction between an unshared pair of electrons at oxygen and the axial C—Cl bond. This should produce an increase in the "*s*-character" of the equatorial C—H bond and hence a larger $^1J_{C-H}$. The analogous $n-\sigma^*$ interaction involving an axial C—H in the equatorial conformer should be much less important. In the absence of a substituent at C-2 this $n-\sigma^*$ interaction with an axial C—H will contribute more *p*-character to the axial C—H bond, thereby accounting for the smaller $^1J_{C-H}$ for axial hydrogens α to a lone pair.

In both aziridines (7) and oxaziridines (8) a C—H bond *trans* to the lone pair shows a 6–10 Hz smaller value for $^1J_{C-H}$ than when *cis* to it for similarly expressed reasons.

The influence of lone-pair orientation on $^1J_{C-H}$ when the carbon involved has sp^2 hybridization has received considerable theoretical attention. For oximes, the *syn* (*Z*) isomer has been calculated to have the larger $^1J_{C-H}$. Three independent theoretical treatments have estimated the difference to be from 10 to 60 Hz (9–11). A few calculations were also reported for



SCHEME 1

acetaldehyde hydrazone and two imines of acetaldehyde. The results of all the theoretical calculations are presented in Table 1. In contrast to the theoretical interest, only two pairs of *syn–anti* isomers, those of acetaldoxime and isobutyraldoxime have been determined and the experimental values for $^1J_{C-H}$ in these compounds are also reported in Table 1. The best agreement with these values, in both absolute magnitude and *syn–anti* differences, is provided by the calculations of Pople's group (9).

In view of the lack of any experimental data on imines and hydrazones, coupled with current developments in the synthesis of *syn* aldimines (13) and hydrazones (14), we have prepared two pairs of *syn* and *anti* hydrazones and four diastereomeric pairs of imines in order to measure $^1J_{C-H}$ in each compound. We have also examined the isomeric propionaldoximes for comparison with earlier results. The results should provide data to indicate possible stereochemical effects on $^1J_{C-H}$ as well as for comparison with the theoretical predictions.

Results

We have synthesized each *syn* aldimine and hydrazone by the reaction sequence presented in Scheme 2. As has been shown for a wide range of carbonyl derivatives, including oximes and their ethers, hydrazones, and imines (14), the products of lithiation (for a recent review, see ref. 15) and of their subsequent alkylation (13–15) both possess the *syn* config-

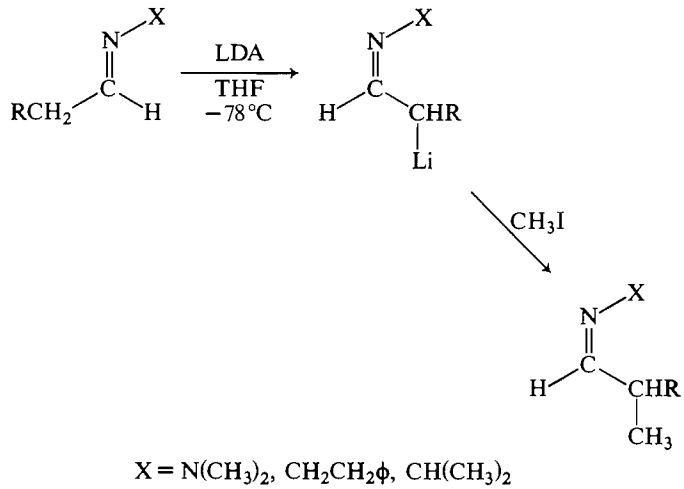
[a] The values appearing in brackets are values measured experimentally.

uration at the central C—N bond.[1] There is, however, a significant difference in oximes and their ethers in that they are configurationally stable at room temperature. Hydrazones and imines, on the other hand, slowly invert at nitrogen, the rate being dependent upon their structure and the medium. Half-lives of a few minutes to a few hours are normal (16). For both aldimines (13, 17) and aldehyde hydrazones (14) the equilibrium, once attained, gives exclusively the *anti* isomer. For our purpose of measuring the ^{13}C spectra of the initial *syn* alkylation product, it was necessary to retard the inversion process by measuring each spectrum below ambient temperature. A sufficiently low temperature was utilized to allow accumulation of ^{13}C transients over a four-hour period without significant inversion taking place. In this way, fully coupled spectra were obtained having signal-to-noise ratios sufficient to allow the measurement of $^1J_{C-H}$ to a precision of ±2 Hz in most cases. In those cases where the precision exceeded ±2 its value is given in Table 2. The fully-coupled spectra of the *anti* isomers were accumulated overnight, thereby yielding values for ^1J of slightly better precision. For two of the *anti* isomers the spectra were also obtained at low temperatures. In each of these instances, ^1J did not change with the change in temperature. The results of all the measurements of ^1J are presented in Table 2.

There is a clear correlation between the magnitude of ^1J and the configuration at the sp^2 nitrogen atom. For all *syn–anti*

[1]The first *ab initio* calculations (18) suggested a repulsive interaction between the lone pair on nitrogen and the electron density at the α carbon to be responsible for destabilization of the *anti* isomer. Recent, more refined calculations suggest a considerably more complex rationale is required (19).



X = $N(CH_3)_2$, $CH_2CH_2\phi$, $CH(CH_3)_2$

TABLE 2. Values for $^1J_{C-H}$ in carbonyl derivatives[a]

Compound	$^1J_{syn}$ (Hz)	$^1J_{anti}$ (Hz)
(a) Oxime		
$CH_3CH_2CH{=}N \sim OH$	173	160
(b) Hydrazones		
$CH_3CH_2CH{=}N{\sim}N(CH_3)_2$	174(−20)[b]	155
$(CH_3)_2CHCH{=}N{\sim}N(CH_3)_2$	170(−20)	154
(c) Imines		
$CH_3CH_2CH{=}N{-}(CH_2)_2\phi$	170(−35)	153
$(CH_3)_2CHCH{=}N{-}(CH_2)_2\phi$	171(−30) [±3][c]	154
$(CH_3)_3CCH{=}N{\sim}(CH_2)_2\phi$		155(−18) 155
$CH_3CH_2CH{=}N{-}CH(CH_3)_2$	170(−20) [±4][c]	151(−25) 152.5
$(CH_3)_2CH{-}CH{=}NCH(CH_3)_2$	170(−50)	152
$(CH_3)_3CCH{=}N{-}CH(CH_3)_2$		150

[a] Unless specified by the figure in brackets, the temperature is 25°C.
[b] Temperature at which spectrum was measured appears in brackets.
[c] Square brackets indicate the precision, if it exceeds ±2 Hz.

pairs $^1J_{syn}$ is greater than $^1J_{anti}$ or, expressed in an alternate way, a C—H bond *trans* to the lone pair on nitrogen exhibits the smaller $^1J_{C-H}$. This of course parallels the correlations between $^1J_{C-H}$ and the lone pair orientation at nitrogen in three-membered rings and in various oxygen and nitrogen heterocycles. Whether it is more appropriate to attribute the smaller ^1J to a greater $n-\sigma^*$ interaction when the lone pair is *trans* to the C—H bond in imines and hydrazones or to differences in the N—C—H bond angle[2] is primarily a question of semantics since the two factors are related.

One clear indication of the results in Table 2 is the constancy of $^1J_{syn}$ (170–174 Hz), $^1J_{anti}$ (150–155 Hz), and Δ^1J (12–13 Hz for oximes, 16–19 Hz for hydrazones, and 17–19 Hz for imines). ^1J also appears to be insensitive to the location of the substituent and to whether the substituent is primary or secondary. These results are in contrast to the predictions of Maciel *et al.* (9) whose calculation suggested a decrease in Δ^1J in the

[2]Bond angle effects on ^1J cycloalkanes have long been recognized and are still a subject of current interest (21).

series oximes > hydrazones > imines. The same prediction of the effects of substituents at nitrogen was also made earlier in a qualitative sense by Gil and Teixeira-Dias (20). Obviously, the coupling constants do not show the anticipated sensitivity to the electronegativity of a β-substituent.

The large and constant difference between $^1J_{syn}$ and $^1J_{anti}$ provides the chemist with a useful complement to the existing methods for the determination of configuration in carbonyl derivatives. For example, the *syn–anti* differential shifts normally seen for protons (12) and ^{13}C nuclei (22, 23) would not be reliably applied to sterically congested systems such as the two imines of pivalaldehyde whose ^1J values are given in Table 2. These two imines were obtained as the sole products from lithiation and methylation of the analogous isobutyraldimines. The values for ^1J of 150 and 155, for the *N*-isopropyl and *N*-(2)-phenethyl derivatives respectively, are a strong indication of the *anti* configuration for both, as is the fact that neither one shows a tendency to isomerize. This proof of configuration is obtained very simply and directly compared to the classical alternative of having to synthesize the same imine from a highly inaccessible class of compounds, the tertiary carboxaldehydes.

Experimental

All ^{13}C nmr spectra were recorded using a Varian FT-80 spectrometer operating at a frequency of 20 MHz. All coupling constants were obtained from fully coupled spectra by measuring the separation of the centers of the two multiplets for the sp^2 carbon atom. The chemical shifts of those carbons which were unobscured by background absorption could be readily assigned by analogy with previous data on aldehyde derivatives (21) and are presented below. For all nmr measurements, 1 *M* solutions in tetrahydrofuran were used and the chemical shifts are reported using the solvent signal at δ 69.00 as reference.

Propionaldoxime was prepared from the reaction of 5 g of hydroxylamine hydrochloride in 40 mL of 4% sodium hydroxide with 2.5 mL of propionaldehyde at 40°C for fifteen minutes. Extraction of the reaction mixture with ether and drying of the extracts gave a mixture of the two propionaldoximes in a *syn/anti* ratio of 40:60; ^{13}C nmr δ_{syn}: 19.6 (Cα), 151.8 (C=N); δ_{anti}: 24.5 (Cα), 153.0 (C=N).

The *anti* hydrazones were prepared by the method described by Corey and Enders (24). The two *syn* hydrazones were prepared by lithiation and alkylation of acetaldehyde and propionaldehyde hydrazones as reported earlier (14) and in each case the crude product in tetrahydrofuran solution was transferred to an nmr tube under an argon atmosphere, then capped and wrapped with Parafilm prior to the accumulation of transients at low temperature. *anti*-Propionaldehyde *N*,*N*-dimethylhydrazone gave ^{13}C signals at δ 27.8 (Cα), 138.7 (C=N); the *syn* isomer gave one visible signal at δ 161.9 (C=N). The *anti* form of isobutyraldehyde *N*,*N*-dimethylhydrazone gave ^{13}C signals at δ 33.2 (Cα), 143.0 (C=N); the *syn* isomer gave a signal at δ 167.9 (C=N).

The *anti* imines have been prepared by the reaction of the requisite aldehyde and amine at 0°C in pentane (except for the isopropyl imine of acetaldehyde whose low boiling point required the use of toluene as solvent). After one hour the pentane solution was decanted from the water which had formed and was dried over potassium carbonate. The filtered solution was then distilled to yield the imine. From the ^{13}C spectra, the chemical shifts for the sp^2 carbon (C=N) and the sp^3 (N—C) carbon of both isomers were obtained and are summarized below. Propionaldehyde *N*-isopropylimine, *anti* isomer, δ: 162.6 (C=N), 62.9 (N—C); *syn* isomer, δ: 163.4 (C=N), 52.1 (N—C). Isobutyraldehyde *N*-isopropylimine, *anti* isomer, δ: 166.0 (C=N), 63.5 (N—C); *syn* isomer, δ: 169.5 (C=N), 51.5 (N—C). Pivalaldehyde *N*-isopropylimine, *anti* isomer, δ: 168.7 (C=N), 61.4 (N—C). Propionaldehyde 2-phenethylimine, *anti* isomer, δ: 165.9 (C=N), 64.5 (N—C); *syn* isomer, δ: 170.8 (C=N), 54.3 (N—C). Isobutyraldehyde 2-phenethylimine, *anti* isomer, δ: 169.9 (C=N), 64.3 (N—C); *syn* isomer, δ: 174.0 (C=N), 53.9 (N—C). Pivalaldehyde 2-phenethylimine, *anti* isomer, δ: 172.4 (C=N), 64.1 (N—C).

Structure and magnetism in a hydroxy bridged binuclear copper(II) system with a "tunable" binuclear centre

LAURENCE K. THOMPSON
Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received September 24, 1982

LAURENCE K. THOMPSON. Can. J. Chem. **61**, 579 (1983).

The molecular structure of $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$ (PAP = 1,4-di(2′-pyridyl)aminophthalazine) has been determined by single crystal X-ray diffraction. $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$ belongs to the space group $P2_1/c$ with a = 7.266(1), b = 15.269(1), c = 25.870(1) Å, β = 96.40(1)°, V = 2852.2 Å^3, Z = 4. The copper coordination geometry lies between a square pyramid and a trigonal bipyramid and the two copper(II) centres are bridged by three groups: N_2 (phthalazine), hydroxide, and bidentate iodate, in a structure which is analogous to that reported for $[Cu_2(PAP)(OH)Cl_3].1.5H_2O$. Replacing the chlorine bridge by iodate has the effect of forcing the two metal centres further apart, thus creating a larger Cu—O—Cu bridge angle. This increase in oxygen bridge angle (101° to 114°) is also reflected in the enhanced antiferromagnetic exchange ($-2J(Cl)$ = 201 cm^{-1}, $-2J(IO_3)$ = 335 cm^{-1}). Other groups of varying size (e.g. Br, NO_3, SO_4) can act as bridges between the two copper centres in systems of this sort with the resultant variation in copper–copper separation and oxygen bridge angle.

LAURENCE K. THOMPSON. Can. J. Chem. **61**, 579 (1983).

On a déterminé la structure moléculaire du $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$ (PAP = di-(pyridil-2′)amino-1,4 phtalazine) par diffraction de rayons-X sur un monocristal. Le composé $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$ appartient au groupe d'espace $P2_1/c$ avec a = 7,266(1), b = 15,269(1), c = 25,870(1) Å, β = 96,40(1)°, V = 2852,2 Å^3, Z = 4. La géométrie de coordination du cuivre se situe entre une pyramide à base carrée et une bipyramide trigonale et les deux centres de Cu(II) sont en position de pont entre trois groupes; le N_2 (phtalazine), l'hydroxyde et l'iodate bidentate dans une structure qui est semblable à celle rapportée par le $[Cu_2(PAP)(OH)Cl_3].1,5H_2O$. Le remplacement du chlore en position de pont par un iodate a pour effet d'obliger les deux centres métalliques à s'éloigner l'un de l'autre créant ainsi un angle de pont Cu—O—Cu plus grand. Cette augmentation de l'angle du pont oxygène (101° à 114°) se réflète également dans l'augmentation de l'échange antiferromagnétique ($-2J(Cl)$ = 201 cm^{-1}, $-2J(IO_3)$ = 335 cm^{-1}). D'autres groupes de dimensions variables (par exemple: Br, NO_3, SO_4) peuvent agir comme pont entre les deux centres cuivre des systèmes de ce type avec comme conséquence une variation de la séparation cuivre–cuivre, et de l'angle du pont oxygène.

[Traduit par le journal]

Introduction

Binuclear copper(II) complexes involving antiferromagnetic exchange between metal centres are potential models for binuclear copper protein centres which take part in biological reactions involving molecular oxygen, such as oxygen transport (1) and oxygen activation (2–4). Magnetic measurements on protein extracts indicate strong antiferromagnetic exchange between the copper(II) centres in Rhus vernicifera laccase (5) ($-2J > 1000$ cm^{-1}) and in oxyhemocyanin (Megathura crenulata; $-2J > 1250$ cm^{-1}) (5, 6). Strong antiferromagnetic exchange is observed in binuclear copper(II) systems involving single hydroxy bridges (7–9) and exchange increases with increasing bridge angle (7). In systems of this sort the copper(II) centres are assumed to be superexchange coupled via the hydroxy bridge. An oxygen bridge, from, e.g., tyrosine or even a hydroxide group itself, has been suggested as the superexchange medium for both oxyhemocyanin (9, 10) and enzymes containing Type III copper centres (8) and other donor groups around the copper centres are thought to include histidine (8, 11–13). Metal–metal separations in oxyhemocyanins are reported to be in excess of 3.50 Å (3.55 Å (12) and 3.67 Å (13)) according to EXAFS studies.

Complexes of the type $[Cu_2(PAP)(OH)X_3]$ (X = Cl, Br, IO_3), $[Cu_2(PAP)(RCOO)_3]$ (Fig. 1, PAP = 1,4-di(2′-pyridyl)-aminophthalazine) have been reported (14) and X-ray structural studies on $[Cu_2(PAP)(OH)Cl_3].1.5H_2O$ indicate a triple bridge between the metal centres, including chloride and hydroxide bridges in addition to the phthalazine N—N bridge (14–16) (Fig. 2). Two independent molecules exist in the structure with Cu–Cu separations of 3.001(2) and 2.972(2) Å and Cu—O—Cu bridge angles of 101.8(2) and 100.1(2)° respectively. Moderate antiferromagnetic exchange is observed for this system $-2J = 201$ cm^{-1}. This complex has been shown to exhibit catecholase activity (17) and also appears to catalyze the oxidation of ascorbic acid (18).

In this report the full structural details of the complex $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$ are presented and the effect of altering the size of the non-hydroxy bridge group (Cl, Br, IO_3) on the dimensions of the binuclear unit, especially the Cu—O(H)—Cu bridge angle, and the magnitude of the magnetic exchange between the metal centres is examined.

Experimental

Deep turquoise-blue crystals of $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$ were obtained according to the procedure previously described (14). Satisfactory elemental analyses were obtained for this compound. Magnetic susceptibility data were collected for $[Cu_2(PAP)(OH)X_3].1.5H_2O$ (X = Cl, Br) as a function of temperature (4.2–109 K) using a PAR 150A, VSM, courtesy of Professor J. Reedijk, State University Leiden, Leiden, Netherlands. The data were corrected for underlying diamagnetism (19) and temperature-independent paramagnetism ($N_\alpha = 60 \times 10^{-6}$ egsu/mol Cu). X-ray structural data have been provided by Dr. A. W. Hanson, National Research Council (Atlantic Research Laboratory).

X-ray crystallographic analysis for $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$

Crystal data (at 22°C) are:

$C_{18}H_{23}N_6O_{14}I_3Cu_2$ fw = 1055.22

Monoclinic, $P2_1/c$, a = 7.266(1), b = 15.269(1), c = 25.870(1) Å,

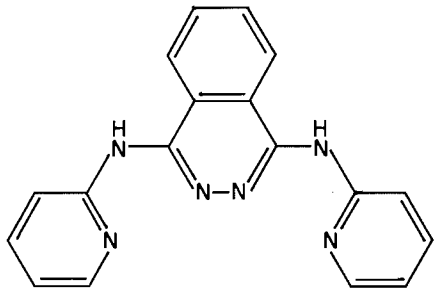

FIG. 1. PAP(1,4-di(2′-pyridyl)aminophthalazine).

$\beta = 96.40(1)°$, $V = 2852.2$ Å^3, $Z = 4$ (MoKα, $\lambda\alpha_1 = 0.7093$ Å); $\mu = 4.9$ mm^{-1}, $D_x = 2.457$ g cm^{-3}.

The crystals were deep blue, and of compact habit. The specimen used for all measurements was a solid bounded by faces {001}, {011}, and {100}, of extreme dimensions 0.13 and 0.24 mm. The relative intensities of the independent reflections with $2\theta < 55°$ were measured with a Picker four-circle diffractometer, using MoKα radiation (graphite monochromator). The $\theta-2\theta$ scan method was used, and individual reflection profiles were analysed as described by Grant and Gabe (20). The standard deviations of the measured intensities were evaluated from counting statistics, and those for which $I_{net} < 2\sigma(I_{net})$ were considered to be unobserved and were omitted from the analysis. The observed reflections numbered 5185, of a possible 6599. Absorption corrections (ranging from 1.67 to 2.48) were applied.

The structure was solved by direct methods (MULTAN) (21). The Cu and I positions were apparent in the first E-map, and a Fourier synthesis, phased on the contributions of these atoms, revealed the positions of the remaining non-H atoms of the PAP and iodate groups. Refinement was by block-diagonal least-squares, minimizing $\Sigma\omega\Delta F^2$, where $\omega^{-1} = \sigma^2(F_o) + 0.001F_o^2$. When the refinement converged a difference Fourier synthesis revealed five residual peaks at about the right distance (2.6 to 3.0 Å) from the iodate O atoms, and from each other, to be attributed to water molecules. Two of these peaks were smaller than the rest, and as only four water molecules were believed to be present, a disordered structure was postulated. The three largest peaks were assumed to be O atoms with full occupancy, and the remaining two to be O atoms with an occupancy ratio of 0.5. The H atoms of the PAP groups were assigned reasonable starting positions, and the hydroxyl H atom located in a ΔF synthesis. The H atoms of the water molecules were not located. Refinement converged at $R = 0.028$ (observed reflections only; including unobserved $R = 0.046$; $R_\omega = 0.044$). Although the refinement is satisfactory, and the disordered water structure is physically reasonable, it must be emphasized that the distribution of occupancy ratios has been assumed quite arbitrarily. However, any attempt to refine the occupancy ratios would require equally arbitrary assumptions concerning the thermal motion. The computer program system is specified in ref. 22. The atomic scattering factors were taken from ref. 23. The final fractional coordinates and thermal parameters appear in Tables 1 and 2[1] respectively. Observed and calculated structure factors (Table 3) have been placed in the Depository of Unpublished Data.[1]

Results and discussion

Infrared data have suggested that a variety of anions, other than hydroxide, can be introduced as bridge groups between the metal centres in binuclear copper complexes of pyridylphthalazine ligands, and preliminary X-ray studies have shown the presence of a nitrate bridge and a sulphate bridge in

[1]Tables 2 and 3 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

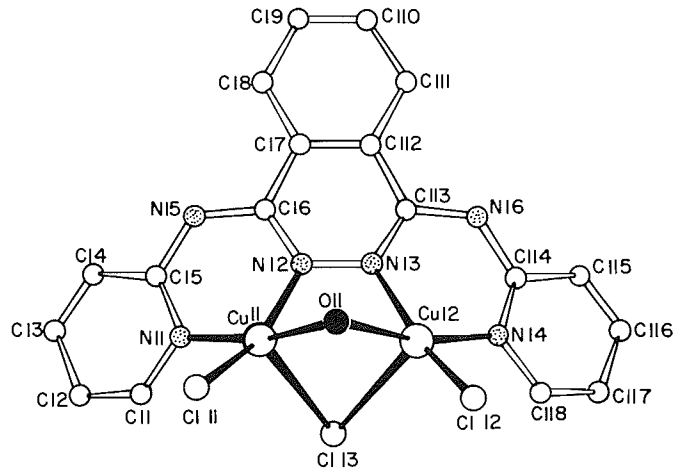

FIG. 2. Molecular structure and labelling scheme for $[Cu_2(PAP)(OH)Cl_3].1.5H_2O$.

the related systems $[Cu_2(PAP4Me)(OH)(H_2O)_2(NO_3)_2]NO_3$ (PAP4Me = 1,4-di(4′-methyl-2′-pyridyl)aminophthalazine) (24, 25) and $[Cu_2(PAP)(OH)Cl(SO_4)].2H_2O$ (25). A bromide bridge is also found in the complex $[Cu_2(PAP)(OH)Br_3].1.5H_2O$ (25). As the size of the anionic bridge group is varied (X = Cl, Br, IO_3, NO_3, SO_4 etc.) the metal–metal separation and hydroxy bridge angle change accordingly (tuning).

Structure description of μ-[1,4-di(2′-pyridyl)aminophthalazine-N^1,N^3,N^4,N^6]-μ-iodato-diiodato-μ-hydroxodicopper(II) tetrahydrate

The molecular structure of $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$ is shown in Fig. 3 and consists of a pair of copper(II) centres bound simultaneously to the tetradentate phthalazine ligand and bridged by three groups: the phthalazine N_2, a hydroxide, and a bidentate iodate. Selected intramolecular bond distances and angles are given in Table 4. The copper coordination sphere, CuN_2O_3, has a five-coordinate structure intermediate between a trigonal bipyramid (hydroxide group axial) and a square pyramid (apical ligand from the bridging iodate) and can be described as a distortion of either. A distorted square pyramidal description is preferred, however, because it better describes the copper coordination geometry in the related compounds $[Cu_2(PAP)(OH)Cl_3].1.5H_2O$ (16), $[Cu_2(PAP)(OH)Cl(SO_4)].2H_2O$ (25), and $[Cu_2(PAP)(OH)Br_3].1.5H_2O$ (25) (Cl, SO_4, Br, respectively, at the apical sites). In one further example, $[Cu_2(PAP4Me)(OH)(H_2O)_2(NO_3)_2]NO_3$ (24, 25), a six-coordinate geometry occurs at each copper centre, which can be seen as the result of a sixth ligand being added to a basic square pyramidal structure. A bidentate chelating nitrate group is bound at one copper centre while two water molecules occur at the other.

Copper–nitrogen bond lengths are close to 2 Å and are similar to those found in the complex $[Cu_2(PAP)(OH)Cl_3].1.5H_2O$ (16), as are bond lengths in the ligand framework itself. The bond lengths of the two copper centres to the oxygen bridge atom are somewhat smaller (2.4% on average) than those in the chloro complex, and since the copper–copper separation is larger (3.165 Å) the Cu—O—Cu bridge angle increases accordingly. The ligand has a non-planar configuration in which the pyridine rings are canted with respect to the phthalazine group. The average dihedral angle between the

average plane of a pyridine ring and the mean plane of the phthalazine moiety is 25° whereas for the complex $[Cu_2(PAP)(OH)Cl_3].1.5H_2O$ it is 29° (15).

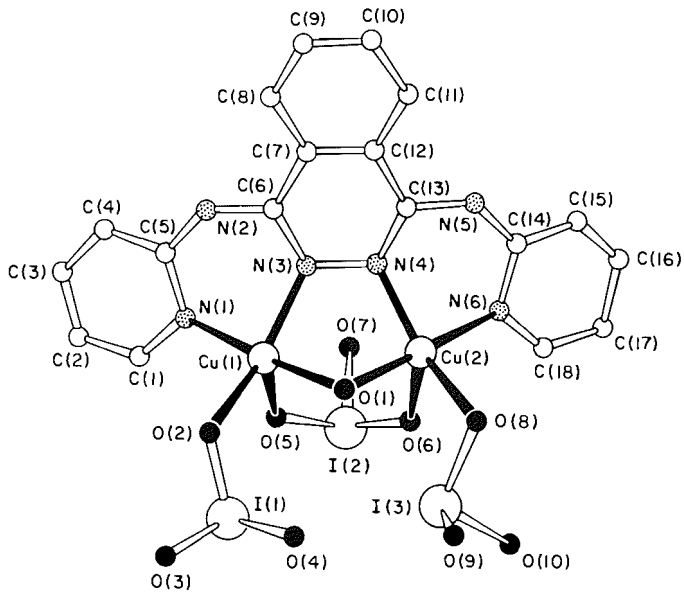

FIG. 3. Molecular structure and labelling scheme for $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$.

The structure of the iodate complex is also of special interest because of the role of the iodate groups. Examples of inorganic compounds involving ionic, monodentate, bidentate, and even tridentate iodate have been reported (26–29) where the polyfunctional nature of the iodate often involves loosely bound layers and chains of metal centres. However, examples of coordination complexes involving nitrogen donor ligands and bound iodate appear to be lacking and the structure of $[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$ may be the first example of such a system involving iodates with mixed functionality. As is typical of iodates three oxygen atoms are bound to the iodine in a trigonal pyramidal arrangement with I—O bond lengths in the range 1.773–1.842 Å while more distant contacts (I—O 2.764–3.464 Å) complete coordination spheres of six or seven oxygen atoms around each iodine.

An X-ray structural study of the complex $[Cu_2(PAP)(OH)Br_3].1.5H_2O$ has shown this system to be isomorphous with $[Cu_2(PAP)(OH)Cl_3].1.5H_2O$ (Fig. 2, Br replaced by Cl). Bond lengths and angles not involving Br are effectively identical to those found for the chloro derivative (25). Some relevant structural data for this system are given in Table 5.

Magnetism and structure

Magnetic susceptibility data for $[Cu_2(PAP)(OH)Br_3].1.5H_2O$ are shown as a function of temperature in Fig. 4 with a best fit line which was calculated using the Van Vleck equation (30) for an exchange coupled pair of copper(II) ions (eq. [1]):

$$[1]\quad \chi_m = \frac{N\beta^2 g^2}{3kT}\left[1 + \frac{1}{3}\exp(-2J/kT)\right]^{-1} + N_\alpha$$

where $2J$ is the singlet–triplet splitting or exchange integral. The parameters giving the best fit for this compound are $\langle g \rangle = 2.10$ and $2J = -186$ cm^{-1}, which were obtained by minimizing the function

$$E = \Sigma\,[(\chi_{obs} - \chi_{calc})T]^2$$

A sharp rise in the susceptibility is observed below 10 K, which can be attributed to the presence of monomer impurity. How-

ever, considering the magnitude of the exchange, the correction due to this paramagnetic species is considered to be small and so has not been included. Magnetic exchange data for the chloro- and iodato-complexes are calculated similarly and listed in Table 5, which includes relevant structural data for the binuclear centres in these systems. Other preliminary structural data for the systems $[Cu_2(PAP)(OH)Cl(SO_4)].2H_2O$ and $[Cu_2(PAP4Me)(OH)(H_2O)_2(NO_3)_2]NO_3$ are also included for comparison (24, 25). These complexes have bidentate sulphate and nitrate bridges, respectively, between the copper centres, in addition to the N_2 (phthalazine) and hydroxy bridges. The oxygen bridge angles in these systems (Table 5) are slightly larger than that observed for the iodate complex and although exchange integrals have not yet been measured the lower room temperature magnetic moments indicate enhanced exchange. It is evident that as the metal–metal separation is increased, together with the Cu—O—Cu angle, the spin exchange between the two copper(II) centres is enhanced. Dimensions at the binuclear centres in the chloro- and bromo-complexes are very similar and the presence of the larger bromine bridge between the two copper(II) centres appears to have had little effect on the metal–metal separation and the oxygen bridge angle. Rather, the bromine bridge has been accommodated with somewhat longer metal–halogen bonds and a smaller bridge angle than in the chloro-complex. The exchange integrals for these two complexes are comparable reflecting the general similarity in the dimensions at the binuclear centres.

Recent reports of binuclear copper complexes involving just single hydroxy bridges have included nitrogen-containing ligands with much more flexibility than the pyridylphthalazines, and which do not have binucleating fragments, like the diazine nitrogen pair, situated together (8, 9). Oxygen bridge angles, metal–metal separations and hence exchange integrals are somewhat larger in these systems. In one case for an oxygen bridge angle of 143.7° and a Cu–Cu separation of 3.642 Å an exchange integral $-2J \simeq 1000\ cm^{-1}$ was observed (9). Exchange integrals of this magnitude approach those observed in real protein systems (5, 6).

The PAP and PAP4Me binuclear copper complexes involving Cl, Br, IO_3, NO_3, and SO_4 bridges have metal–metal separations of <3.25 Å and Cu—O—Cu bridge angles of <116°. Clearly with these ligands, even with large bridge groups inserted between the copper centres, the metal–metal separation and oxygen bridge angle cannot be increased to levels at which protein-like exchange is likely to exist. However, in the case of binuclear copper complexes of the ligands PAP6Me and PAP46DiMe (methyl groups at the 6-position and 4,6-positions of the pyridine rings respectively), for which room temperature magnetic moments of <0.9 BM have been observed (24, 31) it is possible that larger metal–metal separations and oxygen bridge angles exist. No structural or variable temperature susceptibility data are yet available on these systems.

The copper centres in the PAP(R) (R = H, 4Me) complexes are part of six-membered chelate rings and a comparison of the dimensions of the binuclear centres in these systems with those in comparable systems involving five-membered chelate rings reveals that for such systems larger metal–metal separations exist and in one case a larger oxygen bridge angle is found. In

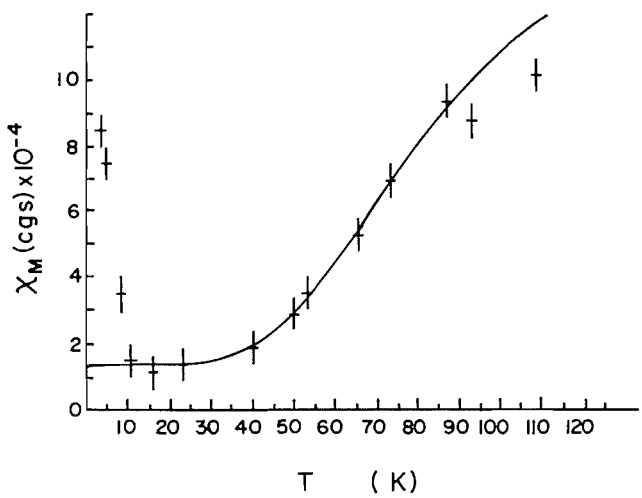

FIG. 4. Magnetic susceptibility data (†) for $[Cu_2(PAP)(OH)Br_3].1.5H_2O$. The solid line was calculated from eq. [1] with $g = 2.10$, $2J = -186\ cm^{-1}$, and $N_\alpha = 120 \times 10^{-6}$ cgsu.

TABLE 5. Magnetic and key structural parameters for $[Cu_2(PAP)(OH)X_3].yH_2O$ (X = Cl, Br, y = 1.5; X = IO_3, y = 4) and related systems

	Cu—O—Cu (deg)	Cu - - -Cu (Å)	$\langle g \rangle$	$-2J$ (cm^{-1})	μ (BM) (RT)
$[Cu_2(PAP)(OH)Cl_3].1.5H_2O$	101.8(2), 100.1(2)	3.001(2), 2.972(2)	2.28	201	1.60
$[Cu_2(PAP)(OH)Br_3].1.5H_2O$	102.9(3), 101.3(3)	3.010(2), 2.986(3)	2.10	186	1.66
$[Cu_2(PAP)(OH)(IO_3)_3].4H_2O$	113.8(2)	3.165(1)	1.95	335	1.34*
$[Cu_2(PAP)(OH)Cl(SO_4)].2H_2O$	115.6(2)	3.211(1)	—	—	1.01
$[Cu_2(PAP4Me)(OH)(H_2O)_2(NO_3)_2]NO_3$	115.3(2)	3.138(1)	—	—	1.12

*Magnetic data from ref. 14.

the complex $[Ni_2(dhph)_2(H_2O)_4]Cl_4.2H_2O$ (dhph = 1,4-dihydrazinophthalazine) a metal–metal separation of 3.791 Å is found (32) while the complex $[Cu_2LCl_3(OH)(H_2O)]$ (L = 3,6-bis-(2′-pyridyl)pyridazine) has a metal–metal separation of 3.376 Å and a Cu—O—Cu bridge angle of 126.5° (no exchange data are quoted for this system) (33).

Diazine systems are, therefore, capable of forming binuclear complexes with metal–metal separations approaching those found in protein systems. It seems likely that tetradentate phthalazine and pyridazine ligands, with biomimetic nitrogen donor substituents, capable of forming five-membered chelate rings could produce binuclear copper complexes with dimensions and exchange characteristics typical of oxyhemocyanin and the Type III copper centres. We are currently involved in a programme of synthesis of copper complexes of such systems involving histidine-like substituents and their structural and magnetic characterization.

JACQUES EINHORN, JEAN-LOUIS SOULIER, CATHY BACQUET et DANIEL LELANDAIS. Can. J. Chem. **61**, 584 (1983).

L'oxydation anodique d'acides carboxyliques porteurs en β de la fonction acide d'un groupement dioxolanne conduit avec de bons rendements aux γ-bisdioxolannes symétriques. L'hydrolyse de ces composés fournit aisément les γ-dicétones correspondantes. La méthode de préparation des acides de départ est décrite.

JACQUES EINHORN, JEAN-LOUIS SOULIER, CATHY BACQUET, and DANIEL LELANDAIS. Can. J. Chem. **61**, 584 (1983).

Anodic oxidation of carboxylic acids with β-dioxolane substituents leads to good yields of symmetrical γ-bisdioxolanes. Hydrolysis of these compounds easily provides the corresponding γ-diketones. The synthesis of the starting acids is described.
[Journal translation]

L'oxydation anodique de carboxylates β-cétonique (type A) en milieu hydroorganique nous avait conduit à des γ-dicétones symétriques (1) par dimérisation du radical intermédiaire selon le schéma 1.

Cependant cette réaction n'est pas univoque, et à côté de la γ-dicétone, une cétone saturée $R^1COR^2R^3H$ se forme, issue de la capture par le radical d'un hydrogène du milieu.

Nous montrons que cette difficulté peut être levée dans certains cas, lorsque les β-cétocarboxylates sont remplacés par leurs dioxolannes. Nous avons alors obtenu, avec des rendements élevés des γ-bisdioxolannes qui conduisent facilement aux γ-dicétones.

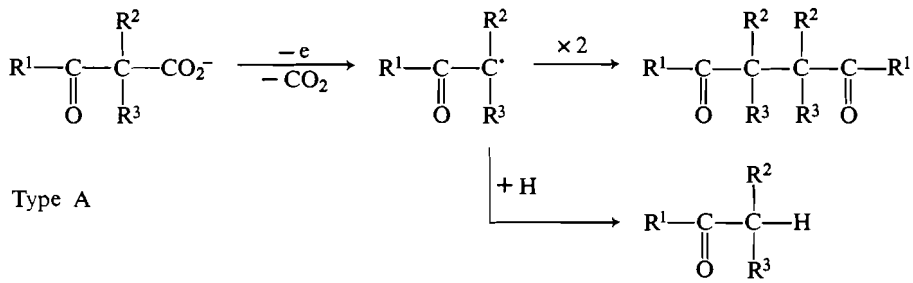

SCHÉMA 1

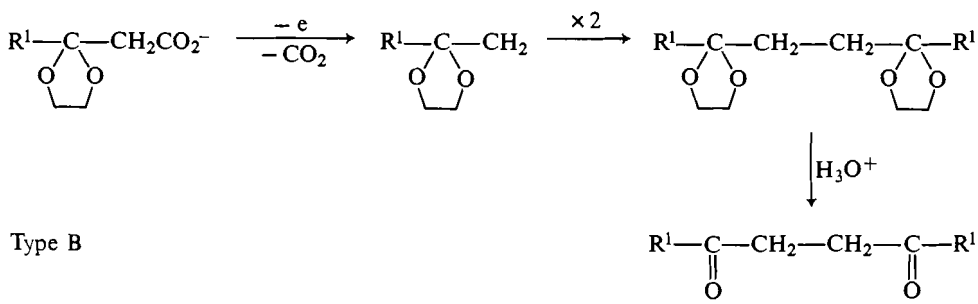

SCHÉMA 2

Comme nous le verrons préalablement, l'obtention de ces composés a nécessité d'une part l'étude générale du comportement électrochimique des carboxylates β-cétaliques, d'autre part la mise au point d'une synthèse des acides correspondants.

[1]Auteur à qui adresser toute correspondance.

I. Comportement électrochimique des carboxylates β-cétaliques. Recherche des conditions conduisant à la dimérisation

L'électrolyse des carboxylates β-cétaliques (type B), dans les conditions qui avaient mené à la dimérisation dans le cas de carboxylates β-cétoniques (type A), s'effectue avec un rendement en courant anormalement faible (inférieur à 5%) et la

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

SCHÉMA 3

plus grande partie du carboxylate de départ est retrouvée en fin de réaction. Il en est de même si l'électrolyse est conduite en milieu acide (90% d'acide β-cétalique et 10% du carboxylate correspondant), pourtant connu pour favoriser la formation du radical (2).

Une explication à ce phénomène peut être proposée: dans les conditions de travail utilisées, le potentiel imposé supérieur à 2,2 V ne suffit pas à bloquer l'oxydation de l'eau, comme c'est généralement le cas dans la réaction de Kolbe classique (3). Au contraire l'oxydation de l'eau se poursuit parallèlement à celle des ions carboxylates (type B) ce qui affaiblit beaucoup le rendement en courant. Il est probable que les ions carboxylates β-cétaliques soient solvatés par l'eau au niveau des atomes d'oxygène du groupement dioxolanne et contribuent eux-mêmes au transport de l'eau au voisinage de l'électrode. L'utilisation du milieu aqueux ou hydroorganique étant donc exclu, notre intérêt s'est porté sur les solvants organiques en particulier le méthanol réputé (2) favorable à la dimérisation.

En fait l'électrolyse du carboxylate B en solution dans le méthanol sur électrode de platine (condition favorisant là aussi le radical) fournit, avec un rendement médiocre, un mélange de deux produits en quantité équivalente: le bisdioxolanne issu de la voie radicalaire et le méthoxy-2 méthyl-2 dioxanne-1,4 issu d'une oxydation ultérieure du radical en carbocation selon le schéma 3. (L'étude de la voie cationique a été décrite par ailleurs (4).)

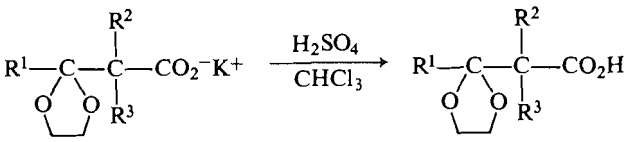
Finalement le dimère ne peut être obtenu qu'en travaillant sur platine, dans le méthanol anhydre et en milieu acide c'est à dire en utilisant au départ un mélange de 90% d'acide β-cétalique et 10% du sel de potassium correspondant. La réalisation de toutes ces conditions imposait une dernière difficulté; en effet l'obtention des acides β-cétaliques n'était pas évidente à priori, vue la sensibilité relative du groupement dioxolanne en milieu acide.

II. Préparation d'acides β-cétaliques

Nous avons dû mettre au point une méthode facile d'accès à ces composés jusqu'alors peu ou mal connus puisque seuls deux d'entre-eux sont cités dans la littérature.

L'un (5) a été obtenu avec un rendement médiocre à partir de l'acide pentyne-3 oïque, l'autre (6) n'a pas été isolé. Afin

TABLEAU 1. Préparation des acides β-cétaliques



No	R^1	R^2	R^3	Rendement
6	CH_3	H	H	95
7	C_2H_5	H	H	97
8	$(CH_3)_2CH$	H	H	99
9	$(CH_3)_3C$	H	H	98
10	$CH_3(CH_2)_4$	H	H	98
11	Cyclohexyle	H	H	99
12	CH_3	CH_3	H	95
13	CH_3	CH_3	CH_3	95

d'éviter au maximum la dégradation ultérieure de l'acide β-cétalique nous l'avons relargué et extrait du milieu réactionnel aqueux au fur et à mesure de sa formation. Ainsi l'hydrolyse par une solution d'acide sulfurique 12 *N*, à froid, des carboxylates β-cétaliques en solution dans un mélange eau–chloroforme (1:1) saturé en chlorure de sodium fournit les acides correspondants avec d'excellents rendements (Tableau 1).

III. Synthèse des γ-bisdioxolannes

L'électrolyse des acides β-cétaliques a pu être effectuée avec le maximum de conditions favorables à l'orientation vers la voie radicalaire: pH acide, méthanol, anode de platine, forte densité de courant (voir partie expérimentale). Les rendements en dimère sont consignés dans le tableau suivant (Tableau 2).

Lorsque les γ-bisdioxolannes cristallisent au fur et à mesure de leur formation (R^1 = tertiobutyl, cyclohexyl), en se déposant sur l'anode ils diminuent considérablement la densité du courant qui doit être de l'ordre de 0,25 A/cm^2 pour favoriser la réaction radicalaire (2). Le rendement en bisdioxolanne est alors médiocre. Pour pallier cet inconvénient nous avons ajouté au milieu réactionnel du benzène anhydre, qui en solubilisant le γ-bisdioxolanne formé permet de mener à bien l'électrolyse.

Par ailleurs, le tableau montre que les dimères symétriques sont obtenus avec d'excellents rendements dans tous les cas où R^2 et R^3 sont des atomes d'hydrogène. Dans le cas où R^2 est un groupement méthyle, la réaction conduit, avec un faible rendement global, à un mélange de produits contenant 4% de bisdioxolanne issu de la voie radicalaire. Les autres produits formés, dont le principal est un méthoxy-2 dioxanne-1,4, sont tous issus de la voie cationique (4), voir schéma 1. Dans le cas où R^2 et R^3 sont des groupements méthyle, aucun produit d'origine radicalaire n'a pu être mis en évidence; seul le produit d'origine cationique est isolé.

Il faut donc noter la différence remarquable de comportement électrochimique entre les carboxylates β-cétoniques et les carboxylates β-cétaliques.

Dans le cas des carboxylates β-cétoniques la voie radicalaire est fortement favorisée; en effet il faut deux substitutions en α de la fonction cétonique par des groupement alkyles (inducteurs donneurs de façon plus générale) pour abaisser suffisamment le potentiel d'ionisation du radical formé intermédiairement et permettre une oxydation ultérieure en carbocation (1, 7). Le cas des carboxylates β-cétaliques est inverse:

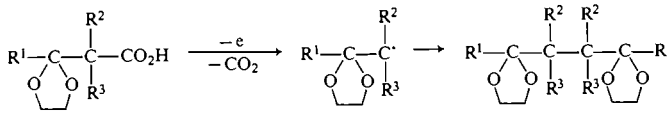
TABLEAU 2. Dimérisation d'acides β-cétaliques



No	R^1	R^2	R^3	Rendements
14	CH_3	H	H	95
15	C_2H_5	H	H	96
16	$(CH_3)_2CH$	H	H	65
17	$(CH_3)_3C$	H	H	74 (26)[a]
18	$CH_3(CH_2)_4$	H	H	85
19	Cyclohexyle	H	H	63 (31)
20	CH_3	CH_3	H	4
	CH_3	CH_3	CH_3	0

[a]Les chiffres entre parenthèses indiquent les rendements obtenus sans addition de benzène.

c'est la voie cationique qui est favorisée (4) et la voie radicalaire ne peut devenir importante que si le carbone en α de la fonction cétalique n'est pas substitué. Enfin, quelque soit la structure du carboxylate (β-cétonique ou β-cétalique), il faut toujours mener la réaction de Kolbe dans les conditions expérimentales les plus favorables à la voie choisie:

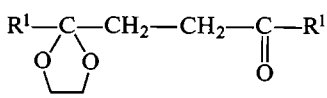
cationique: milieu aqueux basique, anode en graphite
radicalaire: milieu méthanolique acid, anode en platine

IV. Obtention de γ-dicétones symétriques

Par hydrolyse acide des bisdioxolannes obtenus précédemment il est possible de passer aux γ-dicétones avec de bons rendements. Les résultats sont résumés dans le tableau 3.

Dans la plupart des cas, le rendement global en γ-dicétone à partir des esters de départ, est supérieur aux rendements observés au laboratoire pour la dimérisation directe des carboxylates β-cétoniques.

Nous avons constaté par ailleurs qu'un contrôle rigoureux des conditions opératoires lors de l'hydrolyse des γ-bisdioxolannes permet d'isoler le monodioxolanne:



Cette réaction est à l'étude au laboratoire.

Enfin grâce aux bons rendements obtenus dans la dimérisation, il est possible d'effectuer des dimérisations mixtes par couplage entre deux radicaux différents. Les résultats obtenus feront l'objet d'une publication ultérieure.

Partie expérimentale

Les spectres rmn ont été effectués sur un appareil E.M. 360 en solution dans le tétrachlorure de carbone ou le deutérochloroforme (référence interne hexaméthyldisiloxane).

Préparation des esters β-cétoniques et des dioxolannes

1. Mode opératoire, général

Les esters substitués en α de la fonction cétonique ont été préparés par alcoylation de l'acétyl acétate d'éthyle selon Cournot (10). Tous les autres esters ont été préparés selon la méthode de Viscontini (11) suivie d'une méthanolyse (12). Les dioxolannes correspondants sont obtenus selon Salmi (13). Les dioxolannes substitués en α du groupement dioxolanne ont déjà été décrits dans la littérature (14, 15).

TABLEAU 3. Hydrolyse des bisdioxolannes en γ-dicétones

2. Produits isolés

Dioxolanne de l'oxo-3 pentanoate de méthyle, ***1***

Rendement 60%; Eb_2 69°C; rmn ($CDCl_3$): 3,96 (s, 4H), 3,65 (s, 2H), 2,63 (s, 3H), 1,76 (q, 2H), 0,9 (t, 3H) ppm. *Anal.* calc. pour $C_8H_{14}O_4$: C 55,16, H 8,10; trouvée: C 54,93, H 8,17.

Dioxolanne du méthyl-4 oxo-3 pentanoate de méthyle, ***2***

Rendement 42%; Eb_{12} 96°C; rmn ($CDCl_3$): 3,93 (s, 4H), 3,66 (s, 3H), 2,63 (s, 2H), 2 (m, 1H), 0,9 (d, 6H) ppm. *Anal.* calc. pour $C_9H_{16}O_4$: C 57,43, H 8,57; trouvée: C 57,38, H 8,68.

Dioxolanne du diméthyl-4,4 oxo-3 pentanoate de méthyle, ***3***

Rendement 34%; $Eb_{0.5}$ 79°C; rmn ($CDCl_3$): 4 (m, 4H), 3,63 (s, 3H), 2,73 (s, 2H), 0,9 (s, 9H) ppm. *Anal.* calc. pour $C_{10}H_{18}O_4$: C 59,38, H 8,97; trouvée: C 59,47, H 9.

Dioxolanne de l'oxo-3 octanoate de méthyle, ***4***

Rendement 70%; $Eb_{0.1}$ 82°C; rmn (CCl_4): 3,9 (s, 4H), 3,6 (s, 3H), 2,46 (s, 2H), 1,96 à 0,56 (m, 11H) ppm. *Anal.* calc. pour $C_{11}H_{20}O_4$: C 61,09, H 9,32; trouvée: C 60,89, H 9,40.

Dioxolanne du β-oxo cyclohexane propionate de méthyle, ***5***

Rendement 48%; $Eb_{0.5}$ 112°C; rmn ($CDCl_3$): 3,96 (s, 4H), 3,7 (s, 3H), 2,66 (s, 2H), 2 à 0,83 (m, 11H) ppm. *Anal.* calc. pour $C_{12}H_{20}O_4$: C 63,13, H 8,83; trouvée: C 63,05, H 9,05.

Saponification des esters β-cétaliques (mode opératoire général)

Une solution de 0,11 mol de potasse dans 40 mL d'eau est ajoutée à température ambiante à 0,1 mol de dioxolanne. Une agitation magnétique est maintenue jusqu'à ce que le milieu soit homogène. Deux extractions à l'éther sont effectuées pour éliminer toute trace d'ester n'ayant pas réagi. Dans le cas des esters substitués en α du groupement dioxolanne il est nécessaire de porter à reflux le mélange réactionnel pour que la saponification soit complète. La solution aqueuse est évaporée à sec.

Synthèse des acides β-cétaliques

1. Mode opératoire général

Un mélange contenant une mol de carboxylate β-cétalique séché, 100 mL d'eau distillée, 200 mL de chloroforme est saturé en chlorure de sodium puis refroidi à 0°C. L'acidification est réalisée à cette température par de l'acide sulfurique 12 *N* jusqu'à pH = 1. Le sulfate de potassium formé et le chlorure de sodium sont filtrés, le filtrat extrait par 2 L de chloroforme. Après séchage sur sulfate de magnésium et évaporation du chloroforme à 25°C, l'acide cristallise, le plus souvent spontanément. Le produit peut être conservé plusieurs mois à 0°C.

2. Produits isolés

Acide (méthyl-2 dioxolanne-1,3 yl-2)-2 acétique, ***6***

Rendement 95%; F 27°C; rmn (CCl_4): 11,6 (s, 1H), 3,9 (s, 4H), 2,6 (s, 2H), 1,45 (s, 3H) ppm. *Anal.* calc. pour $C_6H_{10}O_4$: C 49,31, H 6,90; trouvée: C 49,25, H 6,87.

Acide diméthyl-2,2 (méthyl-2 dioxolanne-1,3 yl-2)-2 acétique, ***13***

Rendement 95%; F 36°C; rmn (CCl_4): 9,7 (s, 1H), 3,9 (s, 4H), 1,35 (s, 3H), 1,20 (s, 6H) ppm. *Anal.* calc. pour $C_8H_{14}O_4$: C 55,16, H 8,10; trouvée: C 55,09, H 8,14.

Obtention des bisdioxolannes

1. Condition d'électrolyse: mode opératoire général

L'appareil utilisé est un potentiostat Tacussel modèle PRT 40-5X permettant d'imposer un potentiel fixe à l'anode. Les mesures coulométriques ont été faites à l'aide d'un intégrateur Tacussel type IG5-LN monté un série sur le circuit. L'intensité du courant est vérifiée par un ampèremètre monté sur le circuit de la cathode. La cellule d'électrolyse est constituée par une cuve de verre entourée d'une jaquette permettant de maintenir une circulation d'eau de refroidissement. L'anode est une lame de platine de 9 cm^2 et la cathode une lame de platine de 3 cm^2.

Dans la cellule non divisée une solution de 0,1 mol d'acide et de 0,01 mol de potasse dans 100 mL de méthanol sec est introduite. L'électrolyse est effectuée sous agitation magnétique et la tension imposée est toujours supérieure à 2,2 volts par rapport à l'électrode de référence au calomel. L'électrolyse est arrêtée quand le pH de la solution devient neutre à légèrement basique, ce qui correspond à 0,3 faradays environ. Dans le cas où le dimère précipite en cours d'électrolyse, du benzène sec est ajouté pour solubiliser le produit formé. Le mélange réactionnel est évaporé, lavé deux fois par 50 mL d'eau, extrait trois fois par 50 mL de chloroforme puis séché sur sulfate sodium. Le chloroforme est évaporé à 25°C. Les bisdioxolannes sont recristallisés dans l'éther de pétrole ou distillés sous vide.

2. Produits isolés

Bis (méthyl-2 dioxolanne-1,3 yl-2)-1,2 éthane (17), ***14***

Rendement 95%; F 58°C; rmn (CCl_4): 3,8 (s, 4H), 1,5 (s, 2H), 1,2 (s, 3H) ppm.

Bis (éthyl-2 dioxolanne-1,3 yl-2)-1,2 éthane, ***15***

Rendement 96%; $Eb_{0.01}$ 112°C; rmn (CCl_4): 3,8 (s, 4H), 1,5 (q, 2H), 0,8 (t, 3H) ppm. *Anal.* calc. pour $C_{12}H_{22}O_4$: C 62,48, H 9,63; trouvée: C 62,68, H 9,72.

Bis (isopropyl-2 dioxolanne-1,3 yl-2)-1,2 éthane, ***16***

Rendement 65%; F 60°C; rmn (CCl_4): 3,8 (s, 4H), 1,43 (s, 2H), 2,06 à 1,33 (m, 1H), 0,83 (d, 6H) ppm. *Anal.* calc. pour $C_{14}H_{26}O_4$: C 65,08, H 10,14; trouvée: C 65,24, H 10,01.

Bis (tertiobutyl-2 dioxolanne-1,3 yl-2)-1,2 éthane, ***17***

Rendement 74%; F 154°C; rmn (CCl_4): 4,16 à 3,8 (m, 4H), 2,66 (s, 2H), 0,9 (s, 9H) ppm. *Anal.* calc. pour $C_{16}H_{30}O_4$: C 67,09, H 10,56; trouvée: C 67,18, H 10,64.

Rendement 4%; F 31°C; rmn (CCl_4): 3,8 (s, 8H), 2,2 à 1,7 (m, 2H), 1,15 (s, 6H), 0.9 (m, 6H) ppm. *Anal.* calc. pour $C_{12}H_{22}O_4$: C 62,48, H 9,63; trouvée: C 62,46, H 9,70.

Obtention des γ-dicétones

1. Mode opératoire général

A une solution de 0,05 mol de bis dioxolanne dans 40 mL de dioxanne, sont ajoutés 50 mL d'une solution à 10% d'acide sulfurique. Le mélange est agité pendant trois heures à température ambiante, puis 50 mL d'une solution molaire de soude sont additionnés. Après trois extractions au chloroforme, séchage sur sulfate de magnésium et évaporation des solvants, le résidu est distillé (voir Tableau 3).

Comment: The H_3O^+ ion in aqueous sulfuric acid

PAUL A. GIGUÈRE
Département de Chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Received October 20, 1982

(Ref. Can. J. Chem. **59**, 2591 (1981))

In a recent paper Cox *et al.* (1) have reported their principal factor analysis of the Raman spectra of aqueous sulfuric acid solutions. One of their conclusions is that two water molecules, rather than one, are required for the first ionization of H_2SO_4. As a result, the only ionic species apparent in the more concentrated solutions are ion pairs of HSO_4^- and $H_3O^+ \cdot H_2O$ (*or $H_5O_2^+$ if this entity has a real existence*). Now, there are enough data in the literature to rule out off-hand the latter hypothesis. In a paper published twenty-five years ago in this journal (2), but not quoted by Cox *et al.*, we reported the first infrared absorption spectra of two concentrated solutions of sulfuric acid: one of composition near the trihydrate, the other, near the monohydrate. The first one showed very clearly the bending band of H_3O^+, ν_4, at about 1740 cm^{-1}, beside the ν_2 water band at 1645 cm^{-1}. In the second one, the two bands had merged, giving a broad maximum ca. 1710 cm^{-1}. A further, more extensive study of these spectra has confirmed the above interpretation (3), showing, in addition, that the characteristic band of HSO_4^- at 1050 cm^{-1} reaches maximum intensity at the dihydrate composition, when that of H_2SO_4 at 967 cm^{-1} has practically disappeared. If the cation were the improbable $H_5O_2^+$, then that solution would be a pure liquid electrolyte, analogous to a fused salt, a most unlikely situation.

What distinguishes the genuine $H_5O_2^+$ ion from a complex like $H_3O^+ \cdot H_2O$, is the very short O···O distance (<2.45 Å) with the excess proton located halfway; that is, in a single-minimum potential well. It has been identified by diffraction methods only in the crystalline dihydrates (or higher hydrates) of some mineral acids (4). Not all of them, however. A case in point is precisely the dihydrate of sulfuric acid, which has been found by three-dimensional, single-crystal analysis (5) to consist exclusively of SO_4^{2-} and H_3O^+ ions. Since the $H_5O_2^+$ ion does not exist in that solid, where it could be stabilized by the crystal field, then *a fortiori* it does not exist in the liquid acid.

In contrast, the H_3O^+ ion, a much more widespread species, has been ascertained, in particular by neutron diffraction, not only in solid acid hydrates, but also in concentrated solutions of hydrochloric acid (6). There is no reason why the cation in aqueous sulfuric acid should be different. Incidentally, in these solutions where fast proton transfer is so predominant, the very short-lived water molecule cannot be viewed as preferably solvating the cation, as implied by the $H_3O^+ \cdot H_2O$ formula (1), rather than the HSO_4^- anion. Likewise, the latter cannot be qualified as "free", even within quotation marks, in these thoroughly hydrogen-bonded solvent systems. A better description would be solvent-separated vs. contact ion pairs.

R. A. Cox has communicated his full agreement with the above conclusions.

An MNDO study of sulfenium ions

JACK LEON GINSBURG[1]
Department of Chemistry, Saint Mary's University, Halifax, N.S., Canada B3H 3C3

AND

RICHARD FRANCIS LANGLER
Department of Chemistry, Florida Institute of Technology, Melbourne, FL 32901, U.S.A.

Received August 24, 1982

JACK LEON GINSBURG and RICHARD FRANCIS LANGLER. Can. J. Chem. **61**, 589 (1983).

An MNDO study has been carried out on a variety of substituted sulfenium ions and sulfides. Relative stabilities in the gas phase have been calculated for several pairs of regioisomeric sulfenium ions. It is shown that sulfenium ions are stabilized by π-donors and that the substituent electronegativity is not an important factor. The potential implications of this result for the mechanism by which chlorosulfonium cations are converted into sulfenium ions in solution is discussed. Substituent effects on the energetics of sulfenium ion formation from sulfides have been obtained. It is shown that these effects also are related to the substituent's π-donating ability. A frontier-orbital analysis of selected sulfenium ions has been done and is discussed.

JACK LEON GINSBURG et RICHARD FRANCIS LANGLER. Can. J. Chem. **61**, 589 (1983).

On a réalisé une étude de MNDO sur une série d'ions sulfénium substitués et de sulfure. On a calculé les stabilités relatives en phase gazeuse de plusieurs paires d'ions sulfénium régioisomères. On montre que les donneurs π stabilisent ces ions sulfénium et que l'électronégativité du substituant n'est pas un facteur important. On discute des implications potentielles de ce résultat sur le mécanisme par lequel on transforme les cations chlorosulfonium en ions sulfénium en solution. On a évalué l'effet des substituants sur les niveaux d'énergie impliqués lors de la formation d'ions sulfénium à partir de sulfures. On montre que ces effets sont également reliés à la capacité de donneur π du substituant. On a effectué une analyse d'orbitale frontière de certains ions sulfénium choisis et on en discute.

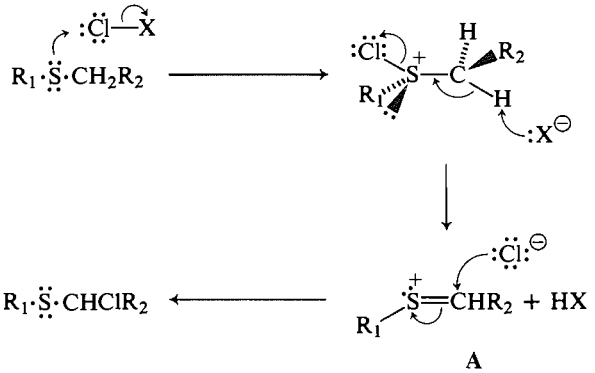
Introduction

As part of our continuing program to study the chlorination reactions of organosulfur compounds, we have reported an examination of sulfide chlorinations conducted in aprotic media (1). The chlorination of asymmetric sulfides may give rise to a pair of regioisomeric α-chlorosulfides as shown in reaction [1].

[1] $R_1CH_2SCH_2R_2 + ClX \rightarrow R_1CH_2SCHClR_2 + R_1CHClSCH_2R_2 + HX$

The presently accepted mechanism for these reactions (*vide* Scheme 1) is due to Wilson and Huang (2) and proceeds through the intermediacy of a sulfenium ion (**A**, Scheme 1).



SCHEME 1

Following Hammond's postulate,[2] we have decided to undertake a theoretical study of sulfenium ions, in the hope that we could shed some light on the nature of substituents which control regiochemistry in the E2 step of the mechanism (shown in Scheme 1) for sulfide chlorinations. Our initial objectives were (*i*) to see if the regioisomeric sulfenium ion with the lower calculated gas phase ΔH_f was the one formed preferentially in solution, (*ii*) to establish whether substituent effects for calculated regioisomeric sulfenium ions would correlate with substituent electronegativity values,[3] and (*iii*) given the absence of solvent effects on regioselectivity in these reactions, to determine whether MO computations would indicate the need for a more complex array of mechanisms to account for the outcome of sulfide chlorinations. We note that the outcome of our study may also have relevance to synthetic reactions involving sulfenium ions. In that area, sulfenium ions are known as thionium ions and are advanced as "supercarbonyl" equivalents (4).

We have chosen to examine the set of sulfenium ions **1***a* → **1***y*, as defined under structure **1**.

Method

All computations were done using the MNDO (Modified Neglect of Differential Overlap) semiempirical method (5–7). Geometries were

[1]To whom all correspondence should be addressed.

[2]"If two states, as for example, a transition state and an unstable intermediate, occur consecutively during a reaction process and have nearly the same energy content, their interconversion will involve only a small reorganization of molecular structure" (3).

[3]Regiochemical outcomes of sulfide chlorinations have been shown to correlate with the substituent electronegativity difference of the groups present in the sulfide substrate (1).

fully optimized[4] using the Davidon–Fletcher–Powell algorithm (8, 9). A program written by Walter Thiel and modified by the National Resource for Computation in Chemistry was used (10). For species for which the occurrence of *cis-trans* isomers is possible, computations were done for both isomers.

The MNDO method has been found to give better results than the MINDO/3 method for, among other properties, heats of formation and molecular geometries (6, 7, 11). It is arguable that, for relative energies, MNDO results are comparable to minimal basis set *ab initio* results (12).

Since its formulation the MNDO method has been used in numerous investigations, including studies involving substituent effects (e.g. refs. 13–16).

Results and discussion

The sulfenium ion geometries will not be discussed in detail but it is important to note that, in all cases studied, the WXC_1SC_2 framework (structure **1**) is planar or nearly so. Hence analysis in terms of a WC_1S or XC_1S π system is valid.

Relative regioisomeric stabilities

Table 1 presents the calculated relative gas phase stabilities, $\Delta\Delta H_f$, of some regioisomeric sulfenium ion pairs. $\Delta\Delta H_f$ is a measure of the stabilizing ability of a substituent relative to that of H (in the case of **1***x* and **1***y*, C_6H_5 relative to Cl). It is noteworthy that $\Delta\Delta H_f$'s do not correlate with substituent electronegativity differences, contrary to the expectation of Ahern *et al.* (1). In fact, the highly electronegative CF_3 group is destabilizing relative to H.

Tables 2 through 4 present results pertinent to the analysis of factors which are important in determining the relative regioisomeric stabilities. Results for the unsubstituted sulfenium

[4]For species containing phenyl substituents, the phenyl rings were constrained to be planar, with equal C—H bond lengths and 120° HCC and CCC bond angles.

ion, **1***s*, are presented to facilitate the analysis. Table 2 shows that, except for the $CO_2C_2H_5$ substituted pair, for which there is virtually no difference in C_1S π bond orders, the more stable regioisomer has the lower C_1S π bond order. The extent of C_1S π bond weakening can be seen by comparing the bond orders to that of the unsubstituted sulfenium ion, **1***s*. Note that the destabilizing CF_3 group causes an increase in the C_1S π bond order when substituted at C_1 with respect to that of the unsubstituted sulfenium ion. These results indicate that substituent participation in the sulfenium ion π system is an important stabilizing factor.

Calculated C_1S π bond length differences, although quite small, reinforce this observation. In each case, the more stable regioisomer has the greater C_1S bond length. Differences range from 0.06 Å for the C_6H_5 or OH substituted pairs to 0.01 Å for the CF_3, Cl, or $CO_2C_2H_5$ substituted pairs. Also, the C_1S bond length of the less stable regioisomer of each pair is within 0.01 Å of that, 1.59 Å, of the unsubstituted sulfenium ion.

Tables 3 and 4 give the results of population analyses of the sulfenium ions studied. Table 3 essentially gives differences between the population analysis of the given sulfenium ion and the population analysis of the isolated components of the sulfenium ion. With the exception of $CO_2C_2H_5$, each stabilizing substituent is a π-donor with respect to the C_1S^+ moiety. The relative degree of stabilization is independent of whether or not the substituent is a good σ-donor or indeed of whether it is a σ-donor or σ-acceptor. There is a rough correlation between $\Delta\Delta H_f$'s and π-donor abilities, but SH would be expected to be a better stabilizer and CH_3 a worse stabilizer based on their π-donor abilities.

Table 4 gives details of the population analyses of the π systems. In the unsubstituted sulfenium ion, **1***s*, C_1 (structure **1**) has a population of 0.5 π electrons and S has a population of 1.5 π electrons. As expected, sulfenium ions having substituents only at C_2 (structure **1**) do not have a π electron distribution significantly different from that of the unsubstituted sulfenium ion. Different π-donor groups substituted at C_1 affect the relative π electron distribution to different extents. The substituent stabilizing abilities correlate with increases in π electron population at S better than with total increases in π electron populations at C_1 and S. For example, OH donates 0.31 π electron to the C_1S^+ moiety, and SH donates 0.29 π electron. OH increases the π electron population at S by 0.21 electron, and SH increases it by 0.13 electron. $\Delta\Delta H_f$ for OH as a substituent is −20 kcal/mol and $\Delta\Delta H_f$ for SH is −13 kcal/mol. The destabilizing CF_3 group, which is neither a π-donor or acceptor, induces a shift in the π electron distribution such that the population at S is 0.08 π electron smaller than it is in the unsubstituted sulfenium ion.

To summarize the preceding results, no correlation between substituent electronegativity values and relative regioisomeric stabilities has been found. Instead it has been found that sulfenium ions are stabilized by substituents which are π-donors with respect to the C_1S^+ moiety. Relative regioisomeric stabilities are roughly correlated with the extent of substituent π electron donation into the C_1S^+ moiety and well correlated with

the amount of π electron population increase at S. Of the substituents studied which do not participate in the π system one, $CO_2C_2H_5$, is weakly stabilizing, and the other, CF_3, is weakly destabilizing.

Mechanistic implications

Table 1 presents a comparison of $\Delta\Delta H_f$ values for pairs of regioisomeric sulfenium ions aong with the sulfenium ion structures implicated by experiment as the actual reaction intermediates.[5] Qualitatively, the theoretical results are in accord with experiment — viz. all experimentally tested substituents are better directing groups than hydrogen. Quantitatively, the trends are somewhat disturbing, i.e. (*i*) the $\Delta\Delta H_f$ (−4 kcal/mol) for the chlorosulfenium ions **1***a*, **1***b* in conjunction with $\Delta\Delta H_f$ (−8 kcal/mol) for the methylsulfenium ions **1***q*, **1***r* suggests that methyl is a better directing group than chlorine, whereas experimentally chlorine is a much better directing group than methyl (1), (*ii*) the direct comparison of chlorine and phenyl in sulfenium ions **1***x*, **1***y* clearly indicates that phenyl is a much better directing group than chlorine, whereas experimentally the opposite is true (1), and (*iii*) the established semiquantitative correlation between ΔX_p and regiochemistry in asymmetric sulfide chlorinations (1, 17) indicates that the regioisomeric sulfenium ion **1***m* should be formed exclusively, whereas the $\Delta\Delta H_f$ value (+4 kcal/mol) indicates that **1***n* should predominate.[6]

In order to integrate the observed directing abilities of the substituents with the calculated parameters, we would like to make the following mechanistic proposals.[7] For sulfides which bear substituents with low electronegativities, such as hydrogen, methyl, and phenyl, the mechanism for the elimination step should be a relatively central E2 elimination as pictured in Scheme 1. Indeed Scheme 1 represents Wilson's conclusion about the chlorination of benzyl methyl sulfide. Substituent directing abilities would then originate with their π electron releasing abilities as indicated by our computations. For sulfides bearing more electronegative substituents such as cyano, chloro, and fluoro, the mechanism would shift towards an $E1_{cb}$-like pathway, with regioselectivity being determined by the substituent's ability to facilitate CH bond breaking. In this transition state, the substituents would be utilizing inductive abilities which are independent of the presence of a carbon *p* orbital with the appropriate orientation for a resonance interaction. This shift in mechanism would tend to make the electronegative substituents better directing groups than methyl or phenyl. In as much as the shift towards as $E1_{cb}$-like mechanism involves an earlier transition state, it makes the transition state-sulfenium ion analogy inapplicable. The possibility that sulfides with strongly electron-withdrawing groups react via the intermediacy of an ylide has been discredited (1).

These mechanistic implications will be investigated using both semiempirical and, where necessary, *ab initio* methods.

Energetics of sulfenium ion formation

Although the $\Delta\Delta H_f$ values (listed in Table 1) for regioisomeric sulfenium ion pairs are most appropriate for a theoretical treatment of chlorination reactions of sulfides, we felt that a more generally useful assessment of substituent effects on the energetics of sulfenium ion formation would be obtained by a comparison of the ΔH_r value for the reaction shown in reaction [2] with the ΔH_r value for the reaction shown in reaction [3].

[2] $XH_2CSCH_3 \longrightarrow XHC{=}\overset{\oplus}{S}CH_3 + \overset{\ominus}{H}$

[3] $CH_3SCH_3 \longrightarrow H_2C{=}\overset{\oplus}{S}CH_3 + \overset{\ominus}{H}$

As expected, the substituents are ordered by the computations in a way which reflects their π-donating abilities. Thus, $\Delta\Delta H_r$, $\Delta H_r[2] - \Delta H_r[3]$, is −28 kcal/mol and −26 kcal/mol for the strong π-donors X = C_6H_5 and X = OH respectively while, for X = CF_3, $\Delta\Delta H_r$ = +15 kcal/mol. Other values of $\Delta\Delta H_r$ range from −15 kcal/mol for X = SH to +4 kcal/mol for X = CN. These results will have obvious relevance for reactions which furnish sulfenium ions reversibly or for irreversible reactions which produce sulfenium ions via a late transition state.

Frontier-orbital analysis

As part of our study of sulfenium ions, we have calculated population numbers for selected sulfenium ion LUMO's,

[5]Experimental results have been presented which indicate that regioiosomeric sulfenium ions are not interconvertible under the usual reaction conditions (1).

[6]We hope to pursue the chlorination of selected 2,2,2-trifluoroethyl sulfides shortly.

[7]It should be noted that (*i*) there are no known cases of sulfide chlorinations for which a change in solvent has induced a significant change in regiochemistry despite the fact that solvents used range in polarity from pentane (1) to aqueous acetic acid (18) and (*ii*) evidence has been presented indicating that sulfenium ion formation is irreversible (1).

‡The results for **1***s* are typical for all sulfenium ions **1** in which X = W = H.

which are presented in Table 5. These population numbers indicate the preferred site for nucleophilic attack in accord with Frontier-Orbital arguments (19). As expected, C_1 (structure **1**), is the preferred electrophilic site in all sulfenium ions studied. The secondary choice for nucleophilic attack in most sulfenium ions is the sulfur atom, which would give rise to an ylide. Sulfur would be expected to become the preferred electrophilic site in systems for which nucleophilic attack at carbon is subject to severe steric hindrance. Interestingly, no sulfenium ion studied develops significant electrophilicity at C_2 (structure **1**), despite the fact that nucleophilic attack there would furnish a ground state thiocarbonyl compound and a disubstituted methane. Finally, we note that sulfenium ions bearing strong π-donors on C_1 tend to develop secondary electrophilic sites in the π-donor rather than on the sulfur atom (i.e. **1***c*, **1***e*, **1***o*, and **1***x*).

Conclusions

1. Sulfenium ions are stabilized by π-donors.
2. There is no correlation between substituent electronegativities and relative regioisomeric sulfenium ion stabilities.
3. The observed directing abilities of the substituents with respect to chlorinations can be reconciled with the calculated relative regioisomeric stabilities if sulfides which have substituents with low electronegativities follow an E2 mechanism and sulfides which have substituents with high electronegativities follow an $E1_{cb}$-like mechanism.
4. C_1 (structure **1**) is the preferred site for nucleophilic attack in the sulfenium ions studied. S is the secondary site in most cases, but sulfenium ions bearing strong π-donors tend to develop secondary sites on the π-donor. No sulfenium ion studied develops significant electrophilicity at C_2 (structure **1**).

I. Order–disorder transitions and solid state reaction kinetics in Na_2SO_4–K_2SO_4 system

FOR ERRATA SEE
V. 62 #6 1984 P. 1227

M. SUNITHA KUMARI AND ETALO A. SECCO[1]

Chemistry Department, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received September 3, 1982

M. SUNITHA KUMARI and ETALO A. SECCO. Can. J. Chem. **61**, 594 (1983).

The physicochemical aspects of the order–disorder phase transitions occurring in the Na_2SO_4–K_2SO_4 system were investigated by thermal analyses, infrared absorption, and X-ray diffraction methods.

Kinetic and structural studies on the compounds $KNaSO_4$ and $K_3Na(SO_4)_2$ are reported in more detail.

M. SUNITHA KUMARI et ETALO A. SECCO. Can. J. Chem. **61**, 594 (1983).

Faisant appel à l'analyse thermique, a l'absorption infrarouge et à la diffraction de rayons-X, on a étudié les aspects physicochimiques des transitions de phase ordre–désordre se produisant dans le système Na_2SO_4–K_2SO_4.

On rapporte d'une façon plus détaillée les études de structure et de cinétique effectuées sur le $KNaSO_4$ et le $K_3Na(SO_4)_2$.

[Traduit par le journal]

Introduction

Our study on phase transitions in Na_2SO_4 (1) has revealed a number of interesting effects such as the dependence of the enthalpy of transition, the dependence of the transition temperature, and the dependence of the transition kinetics on the presence of K_2SO_4. Since Na_2SO_4 and K_2SO_4 are isostructural, orthorhombic at room temperature, our earlier work on phase transitions in K_2SO_4 (2) could be extended to embrace the complete Na_2SO_4–K_2SO_4 composition range.

The early papers of Nacken (3) and Janecke (4) recorded the Na_2SO_4–K_2SO_4 phase diagram showing the existence of solid–solid phase transitions over the whole range of composition. These early phase diagrams, however, leave a number of questions unanswered, e.g. the existence of compounds, the nature of the phase transitions, etc. Although the compounds $KNaSO_4$ and $K_3Na(SO_4)_2$ have been known for some time, it was only recently that Okada *et al.* (5) have determined both structures to be trigonal at room temperature.

This paper reports the results of a study on the condensed phase transitions in the Na_2SO_4–K_2SO_4 system and the kinetics of the solid state reactions between Na_2SO_4 and K_2SO_4 leading to the formation of $KNaSO_4$ and $K_3Na(SO_4)_2$ using thermal analyses, DSC, infrared spectroscopy, and X-ray diffractometry techniques.

Experimental

Anhydrous Na_2SO_4 was from two sources, Fisher Certified Stock and Alfa Products ultrapure grade. Anhydrous K_2SO_4 was Alfa Products ultrapure grade. There was no discernible difference in the measured physicochemical and thermal properties of the Na_2SO_4–K_2SO_4 samples using Na_2SO_4 from both sources.

Fused Na_2SO_4–K_2SO_4 samples were prepared by fusing the requisite composition mixture, previously well ground manually in a mortar and pestle, of the respective sulfates in a Pt crucible.

X-ray diffraction patterns were obtained using a Norelco diffractometer with CuK_α radiation. Diffraction patterns at elevated temperatures were recorded with a Model X-86-N high temperature accessory (Materials Research Corp.) attached to the Norelco unit (6). The infrared spectra were recorded on a Perkin-Elmer Model 180 spectrophotometer equipped with a high temperature cell, maximum 375°C, using the standard KBr disc technique.

DTA traces were obtained on a duPont 990 Thermal Analyzer in a flowing N_2 (ultrapure) atmosphere using ignited Al_2O_3 as reference material. The precision of a melting temperature measurement was ±5°C whereas the transition temperature measurement was better than ±2°C. The enthalpies of transformation were evaluated with the DSC accessory to the 990 DTA module using the heats of fusion or transition for In, Sn, Zn, AgI, CsCl, K_2SO_4 as references; samples were encapsulated in Al containers — identical results, within experimental error were obtained using Au containers.

In the solid state kinetics measurements each sample of Na_2SO_4–K_2SO_4 mixture of constant mass was ground manually to a uniform consistency; the sample was maintained at the set temperature in the DTA cell in the isothermal mode for the required time interval. The fraction of reaction of $KNaSO_4$ or $K_3Na(SO_4)_2$, α, was evaluated by comparing the DSC enthalpic peak areas in the heat mode of the individual transitions in the reacted sample relative to the peak areas of the transitions in the pure state of their respective compounds. A small constant contribution of the second compound was always present; this contribution was subtracted to obtain the net result. Attempts to cross-check the DSC kinetic data with X-ray diffraction data was not possible due to the lack of reproducibility of the characteristic X-ray peak heights originating with a low degree of crystallinity

Results and discussion

Phase diagram

The transition temperatures recorded on DTA traces are plotted versus composition in Fig. 1 (Fig. 1(*a*) represents the solid–liquid phase diagram and Fig. 1(*b*) represents the solid–solid phase diagram along with hysteresis effects) the two plots are in general agreement with Nacken's report (3). Figure 2 gives the enthalpy change, ΔH_t and entropy change, ΔS_t dependence on composition for the solid–solid phase transitions.

The solid–liquid diagram resembles a minimum type solid solution normally expected for isostructural binary systems with the noteworthy absence of the liquidus curve in the 50–100% Na_2SO_4 region. A theoretical analysis of the minimum type solid solution has been done by Reisman (7) using computer-derived models. These models incorporate the ΔH of fusion for both components and involve dimer–monomer transformation or dissociation of one component on melting. The minimum is displaced markedly toward the lower melting component when the higher melting component is assumed to

undergo dissociation and vice versa. The minimum at 75% Na_2SO_4 in Fig. 1(*a*) supports K_2SO_4 dissociation on melting according to the above model.

The solid state phase diagram, Fig. 1(*b*), resembles the solid solution behavior usually encountered in substitutional alloys, e.g. Cu–Au. The substitutional solid solution can incorporate a high degree of order with respect to occupancy of preferred

lattice sites by the ionic species resulting in solid compounds; such structures are also referred to as superlattices or superstructures. Okada *et al.* (5) have identified the specific lattice positions of the Na, K, and SO_4 ions in $KNaSO_4$ and $K_3Na(SO_4)_2$ compound structures. At the transition temperature the ordered arrangement of the ions becomes less ordered and the compound is said to undergo an order–disorder transformation. X-ray diffraction data above the phase transition temperature, Table 1, show the basic structure of $K_3Na(SO_4)_2$ to remain effectively the same whereas the unit cell dimensions in the lattice increase along the *c*-axis. The diffraction pattern for $KNaSO_4$ above the transition temperature, however, shows

only three clearly identifiable peaks indicating that the structure is altered drastically.

From Fig. 1(*b*) the existence of $K_3Na(SO_4)_2$ may be questioned since its composition coincides with the minimum which appears as an eutectoid suggesting a mixture of $KNaSO_4$ and K_2SO_4. However, our X-ray patterns show no evidence of K_2SO_4 lines in 60:40, 67:33, and 75:25 mole ratios for K_2SO_4:Na_2SO_4 at 20°C or 500°C. Furthermore, the trend of ΔH_t and ΔS_t values in Fig. 2 is consistent with the interpretation of mixing for $KNaSO_4$ and $K_3Na(SO_4)_2$.

The infrared spectra at room temperature reveal the absorption frequencies for $KNaSO_4$ and $K_3Na(SO_4)_2$ given in Table 2. The fundamental frequencies for the SO_4 species of T_d symmetry have been reported (8) at 981 cm^{-1} (A_1), 451 cm^{-1} (E), 1104 cm^{-1} (F_2), and 613 cm^{-1} (F_2). Of these four fundamentals only the F_2 modes are ir-active in the free ion state but in the crystal state the selection rules are relaxed (9). The detailed infrared spectra, transmission and reflectance, of $KNaSO_4$ and $K_3Na(SO_4)_2$ single crystals along with their factor group analyses are to be reported elsewhere.

Our infrared data may have a bearing on the recent studies of the high temperature phase transition of Na_2SO_4 reported recently by El-Kabbany *et al.* (10). The samples of Na_2SO_4 were incorporated in a KBr matrix using the disc technique. Their infrared data show a high correlation with our spectral data for prolonged heating of Na_2SO_4 in KBr matrix and also Na_2SO_4–K_2SO_4 fused mixtures. Milne (11) showed that the infrared spectra of M_2SO_4 (M = Li, Na, K, Cs) measured in nine alkali metal halide discs change due to ion exchange and solid solution formation. It is expected that the ion exchange reaction would be accelerated at the high temperature.

The infrared spectra of $KNaSO_4$ and $K_3Na_2(SO_4)_2$ recorded at 375°C, 75–100°C below the transition temperatures, the limit of our high temperature attachment, showed no discernible difference relative to their room temperature spectra. The infrared spectra of 83% Na_2SO_4, showing all the absorption frequencies at room temperature common to $KNaSO_4$ and $K_3Na(SO_4)_2$, displayed no change in its characteristic absorption frequencies, above its transition temperature, 250°C. This latter result suggests that the phase transition involves a relative displacement of Na and K on lattice sites with no change in their interaction with SO_4 species, that is, no alteration of SO_4 symmetry in the solid. Assuming the order–disorder phase transition occurring in 83% Na_2SO_4 to parallel the phase transition in KNa_2SO_4 or $K_3Na(SO_4)_2$, it might be concluded that the order–disorder transition is effected mainly by cation reorientation.

The higher values of ΔH_t and ΔS_t for the $67K_2SO_4$:$33Na_2SO_4$ and $60K_2SO_4$:$40Na_2SO_4$ compositions, Fig. 2, relative to those values for $KNaSO_4$ and $K_3Na(SO_4)_2$ suggest the existence of compounds but X-ray diffraction patterns and infrared spectra do not support this suggestion. The ΔH_t and ΔS_t values for 60:40 and 67:33 are also higher than those values calculated and determined for respective physical mixtures of $KNaSO_4$ and $K_3Na(SO_4)_2$. The 67:33 composition sample, representing 1:1 mole ratio of $KNaSO_4$ and $K_3Na(SO_4)_2$, exhibited only one thermal peak (DTA and DSC) 24 h after fusion, Fig. 3, but resolved itself into the two peaks characteristic of $KNaSO_4$ and $K_3Na(SO_4)_2$ after 15 days storage in a desiccator yielding still higher ΔH_t and ΔS_t values; the two characteristic peaks remained unchanged after 100 days. The additional contribution to ΔH_t and ΔS_t is attributed to mixing or relative increased disorder of the two compounds in the lattice network, i.e. $\Delta S_t = \Delta S_{mix} + \Sigma\Delta S_i$ where ΔS_{mix} is the extra contribution and $\Sigma\Delta S_i$ represents the contribution from the proportionate compounds. Such an interpretation analogous to extra relaxation energy associated with order–disorder model of ion exchange in crystals developed by Barrer and his group (12) leads to ΔS_{mix} = 0.91 J/mol K for the metastable single peak and ΔS_{mix} = 1.54 J/mol K for the stable two peak state in 60:40 sample and ΔS_{mix} = 2.84 J/mol K for the 67:33 composition.

Solid state kinetics

(*i*) Reaction between Na_2SO_4 and K_2SO_4

The best fit between the experimental results and the fifteen known kinetic equations, over the temperature range 529–585°C for reaction fraction α up to 0.80, was obtained for the special case of the treatment given by Avrami (13). The relationship was cast into a second-order rate expression by Honig *et al.* (14) which at sufficiently large t takes the form

$$[1] \quad (1 - \alpha)^{-1} = 1 + \sigma G N_g t$$

where $(1 - \alpha)$ represents the fraction unreacted, σ is the shape factor, G is the lineal growth rate of the new phase, N_g is the initial density of germ nuclei, and t is the time. Equation [1] is also recognized as the integrated form of the second-order rate law, where integration of

$$d\alpha/dt = k(1 - \alpha)^2$$

yields

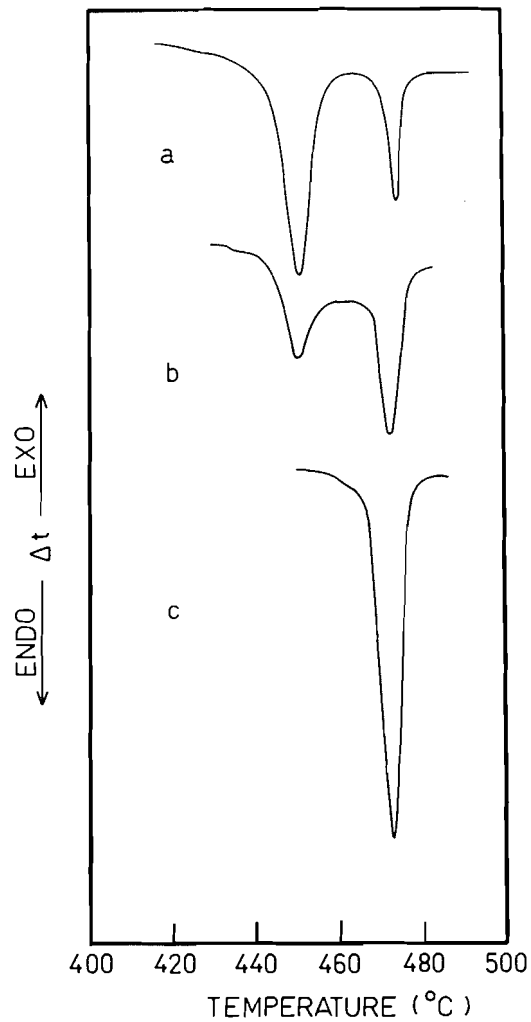

FIG. 3. DSC traces of $67K_2SO_4:33Na_2SO_4$ mole ratio; (*c*) 24 h after fusion, (*b*) after 15 days storage; (*a*) physical mixture.

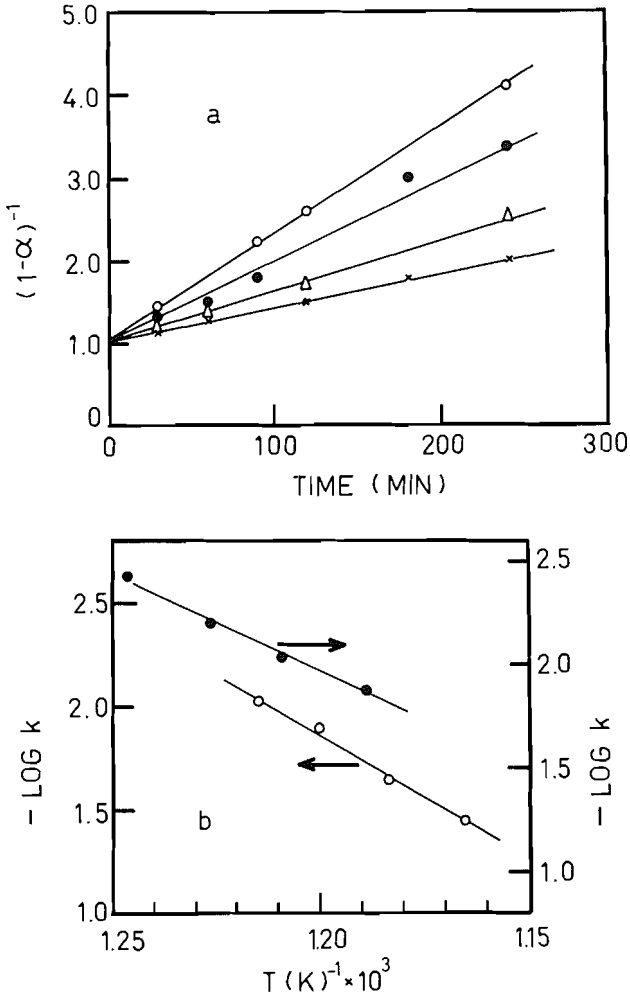

FIG. 4. (*a*) Plot of $(1 - \alpha)^{-1}$ versus time, second order rate law. $KNaSO_4$: ● 550°C, ○ 560°C; $K_3Na(SO_4)_2$: × 529°C, △ 542°C. (*b*) Plot of log k versus T^{-1}. ● $K_3Na(SO_4)_2$; ○ $KNaSO_4$.

$$[2] \quad (1 - \alpha)^{-1} = 1 + kt$$

Plots of $(1 - \alpha)^{-1}$ versus time yield straight lines, typical plots for both compounds are given in Fig 4(*a*), whose slopes equal the composite quantity σGN_g taken to be the formal rate constant k, along with an intercept of unity. The slopes of the standard Arrhenius plots of log k versus $1/T$ K, Fig. 4(*b*), yield activation energy values of 232 ± 20 and 165 ± 15 kJ for $KNaSO_4$ and $K_3Na(SO_4)_2$, respectively.

The Avrami–Honig model was found applicable to the single reactant case (15) where σ and N_g are considered to be effectively constant and the rate constant dependence on temperature was visualized to originate with the term G in the composite rate constant. The second-order rate behavior involving two reactants in solid state reactions is not common and the mechanism for such a reaction rate must incorporate relatively mobile species. The reaction mechanism envisaged for this case is where Na^+ and K^+ are the effective reacting species in a sublattice of SO_4^{2-} units and the fundamental reaction step, to a first approximation, is the ordering of Na^+ and K^+ on crystallographically preferential lattice sites to yield the two compounds. This latter model could be classified as a type of quasi-homogeneous solid state ionic reaction where a simple first-order dependence on the two principal reactants results in the overall second-order rate. The proposed model requires the cations to be highly mobile relative to the reaction rate constants at the temperatures studied. This requirement is satisfied according to the high ionic conductivity data reported in the following article.

(*ii*) Phase transition reaction

The solid–solid phase transition in $KNaSO_4$ and in $K_3Na(SO_4)_2$ exhibit properties characteristic of a first-order transition.

From DSC heating traces for various heating rates, linear plots of log Δt vs. $1/T$ K, where Δt is the peak height at a specific temperature T (16), and log ϕ/T_p^2 vs. $1/T$ K, where T_p is the peak temperature for the specific heating rate ϕ (17) can be used to obtain the activation energy values, E_a, for the phase transition. Highly consistent linear plots of the above relationships gave (*i*) E_a values of 500 ± 80 kJ/mol for recycled stored samples of $K_3Na(SO_4)_2$ and (*ii*) E_a values of 1000 ± 150 kJ/mol for freshly prepared individual samples of $K_3Na(SO_4)_2$ and $KNaSO_4$. These high E_a values are consistent with activation energy values reported for phase transitions in K_2SO_4 (18), ZnS (15), and anthranilic acid (19). The lower E_a value for the recycled samples relative to the freshly prepared individual samples suggest a different activated state.

II. Electrical conductivity and phase transition studies on pure and doped $(Cd^{2+}, Gd^{3+})KNaSO_4$ and $K_3Na(SO_4)_2$

M. SUNITHA KUMARI AND ETALO A. SECCO[1]

Chemistry Department, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received September 3, 1982

M. SUNITHA KUMARI and ETALO A. SECCO. Can. J. Chem. **61**, 599 (1983).

Electrical conductivity measurements on pure and doped $KNaSO_4$ and $K_3Na(SO_4)_2$ reveal high ionic conductivity values in the high temperature phase. High conductivity values ascribed to Na^+ resemble a superionic or fast-ion conductor.

M. SUNITHA KUMARI et ETALO A. SECCO. Can. J. Chem. **61**, 599 (1983).

Les mesures de conductivité électrique du $KNaSO_4$ et du $K_3Na(SO_4)_2$ à l'état pur et à l'état dopé révèlent de fortes valeurs de conductivité ionique dans la phase à haute température. Les fortes valeurs de conductivité attribuées à l'ion Na^+ se rapprochent de celles d'un conducteur superionique ou d'un conducteur de type ion rapide.

[Traduit par le journal]

Introduction

The results of our study on the kinetics of the solid state reaction betwen Na_2SO_4 and K_2SO_4 (1) forming the compounds $KNaSO_4$ and $K_3Na(SO_4)_2$ were interpreted in terms of a model assuming highly mobile Na^+ and K^+ species. The reaction kinetic data suggest diffusion coefficients in the range $10^{-6}-10^{-7}$ cm^2 s^{-1} and ionic conductivity of $\sim 10^{-2}$ (ohm cm)$^{-1}$ for the temperature region studied, that is, ~400°C below the melting temperature. Electrical conductivity measurements on $KNaSO_4$ and $K_3Na(SO_4)_2$ would provide critical data bearing on the proposed model of highly mobile cations.

Solids exhibiting ionic conductivities comparable to those of melts or liquids are referred to as superionic conductors (SIC's) or solid electrolytes. These fast-ion conductors have attracted considerable attention because of (*i*) their promise in applications in high-energy-density-batteries and (*ii*) their unusual transport behavior. Also $(Na,K)_2SO_4$ compositions have been suggested as potential electrolytes in applications for SO_2 detectors (2–4). The prospect that electrical conductivity measurements on pure and doped $KNaSO_4$ and $K_3Na(SO_4)_2$ might be rewarding from the fundamental as well as the practical aspect is the basis for this study.

Experimental

The pure $KNaSO_4$ and $K_3Na(SO_4)_2$ compounds used were from the earlier study (1). The doped compounds (Cd^{2+}, Gd^{3+}) were prepared by fusing the requisite dopant composition previously ground manually in a mortar and pestle, in a covered Pt crucible. The $CdSO_4$ was Fisher Certified grade and $Gd_2(SO_4)_3$ was Alfa Ventron Corp of stated purity 99.9%.

Electrical conductivity measurements were made on compressed specimen in a stainless steel conductivity cell. The experimental procedure for these measurements as described earlier (5), maintained the sample by a spring-loaded support between stainless steel leads using two polished Pt discs as electrodes. The two surfaces of the sample were touched with graphite (Dag # 154 Acheson) to ensure proper contact. The conductivity was measured under reduced pressure ($\sim 10^{-3}$ Torr) at 1 kHz as a function of temperature using a GR 1608-A impedance bridge; the heating rate was 60 deg h^{-1}. Conductivity measurements at 0.1 and 10 kHz revealed indistinguishable σ values up to 600°C for $K_3Na(SO_4)_2$. Temperature was monitored by using standardized chromel–alumel thermocouples with a Keithley digital multimeter.

[1] To whom all correspondence should be addressed.

The compressed polycrystalline sample was 1 mm thick and ~30 mm^2 in surface area approximating a square — it was the crack-free portion recovered from the compressed disc. Our failure to obtain clean compressed discs with $KNaSO_4$ and $K_3Na(SO_4)_2$ is consistent with Garrett's observation (6) that single crystals grown by the Czochralski method shattered on cooling. The pressure- or temperature-promoted order–disorder phase transformation in these compounds is most likely responsible for the disintegrating behavior of the disc or single crystal.

Results and discussion

The temperature dependence of the ionic conductivity is given by the Arrhenius-type expression

$$\sigma = (ne^2\lambda^2\nu/kT) \exp(-\Delta G/kT)$$

which reduces to

$$\sigma = (\sigma_0/T) \exp(-Q_c/kT)$$

where σ_0 represents the composite constant $(ne^2\lambda^2\nu/k)$, n, the number of ions per unit volume, e, the ionic charge, λ, the distance between two jumps positions, ν, the jump frequency, k, the Boltzmann constant, and Q_c is the activation energy for ionic motion, assuming the conductivity to be effectively ionic with negligible electronic or hole contribution.

Plots of log (σT) vs. $1/T$ K for pure and doped $KNaSO_4$ and pure and doped $K_3Na(SO_4)_2$ are presented in Figs. 1 and 2, respectively. Similar plots are given for untreated stock Na_2SO_4, 90:10 mol% Na_2SO_4:K_2SO_4, 33:67 mol% Na_2SO_4:K_2SO_4 along with pure $KNaSO_4$ in Fig. 3 for comparison purposes. $K_3Na(SO_4)_2$ samples doped with 6 mol% $CdSO_4$ and 2 mol% $Gd_2(SO_4)_3$, not shown in Fig. 2, exhibited the same $\sigma-T$ behavior as the 4 mol% $CdSO_4$ doped sample. $KNaSO_4$ doped with 6 mol% $CdSO_4$, not shown in Fig. 1, gave the same $\sigma-T$ behavior as the 4 mol% doped sample. Similar $\sigma-T$ behavior for 6 mol% and 4 mol% $CdSO_4$ in either $K_3Na(SO_4)_2$ or $KNaSO_4$ suggests a saturation point of Cd^{2+} in the lattice. The cooling $\sigma-T$ curve of each Cd^{2+} doped $KNaSO_4$ sample, typified by 2 mol% in Fig. 1, showed an anti-hysteresis in contrast to hysteresis observed for all $K_3Na(SO_4)_2$ samples. The temperature independence and anti-hysteresis of greater than 4 mol% Cd^{2+} concentrations are consistent with vacancy-cation cluster formation as proposed for anion conductors (7). The plots show the expected order–disorder phase transition and hysteresis effects consis-

tent with the DTA traces recorded in part I of this work (1).

The conductivity data presented in Figs. 1, 2, and 3 along with the conductivity data reported for K_2SO_4 (8) lead us to conclude that the major contributing species is the Na^+ ion. Cd^{2+} and Gd^{3+} were chosen as the dopants with the expectation that each would preferentially replace Na^+ in the lattice, $r_{Gd^{3+}} = r_{Cd^{2+}} = r_{Na^+} = 100 \pm 2$ pm, and not K^+ since $r_{K^+} = 133$ pm. The presence of Cd^{2+} or Gd^{3+} on Na^+ sites in the lattice would generate Na^+ vacancies in accordance with the electroneutrality

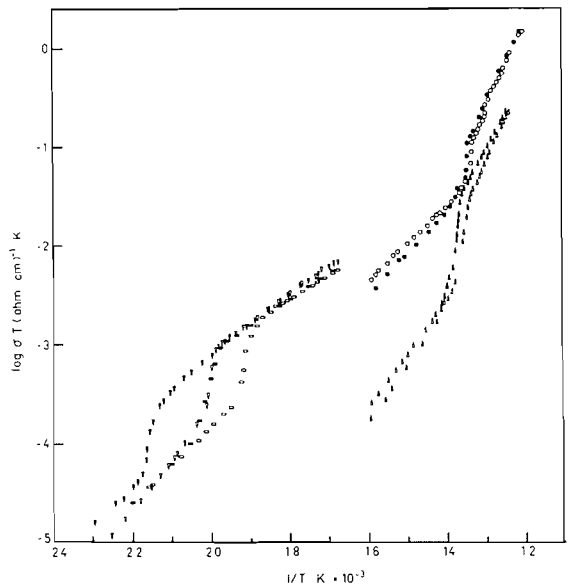

FIG. 3. log σT versus $1/T$ plots for Na_2SO_4 and $(NaK)SO_4$ compositions; ■, □, pure Na_2SO_4, cool and heat modes, respectively; ▼, ▽, 90:10 mol% Na_2SO_4:K_2SO_4, cool and heat modes, respectively; ●, ○, pure $KNaSO_4$, cool and heat modes, respectively; ▲, △, 33:67 mol% Na_2SO_4:K_2SO_4, cool and heat modes, respectively.

requirement — the agreement between 4 mol% Cd^{2+} and 2 mol% Gd^{3+} conductivity suggests equal vacancy concentration. Vacancies would permit greater facility of Na^+-ion mobility and therefore enhance the ionic conductivity consistent with the $\sigma-T$ data shown in Figs. 1 and 2. The activation energy values for ionic conductivity are tabulated in Table 1. The constant Q_c value, 78 ± 3 kJ/mol, for Na_2SO_4 and all $KNaSO_4$ samples in the pre-transition region suggests a common ionic conductivity mechanism; the Q_c values for $K_3Na(SO_4)_2$ compositions show an increasing trend. The constant Q_c value, 71 kJ/mol, for doped $K_3Na(SO_4)_2$ is in contrast with the temperature independence of 4 mol% Cd^{2+} in $KNaSO_4$ in the post-transition region.

The activation energy values for the ionic conductivity Q_c in the temperature region 800–850 K for $KNaSO_4$ and $K_3Na(SO_4)_2$ are 183 ± 18 and 135 ± 15 kJ/mol, respectively. These Q_c values are in acceptable agreement, considering limits of experimental procedures with the activation energy values E_a for the solid state reaction between Na_2SO_4 and K_2SO_4, in the same temperature range, leading to the formation of $KNaSO_4$ and $K_3Na(SO_4)_2$ (1). The agreement between Q_c and E_a values lends strong support for the proposed reaction model of highly mobile cations. Furthermore, the Q_c values for the phase transition reaction were determined to be 610 ± 100 and 700 ± 100 kJ/mol for $KNaSO_4$ and $K_3Na(SO_4)_2$, respectively; these values are within the range of the E_a values determined from DSC heating plots reported earlier (1).

The $\sigma-T$ data reported in this study show that selectively doped simple compounds such as $KNaSO_4$ and $K_3Na(SO_4)_2$ exhibit very high Na^+ ion conductivity in the high temperature phase analogous to the system of compounds $Na_3Zr_2Si_2PO_{12}$ referred to as NASICON (Na superionic conductor) (9). The proposed model of highly mobile Na^+ in a fixed sublattice of SO_4^{2-} in $(K, Na)_2SO_4$ compounds parallels the accepted model of highly mobile Ag^+ in a fixed network of I^- in Ag I compounds (10). This correlation suggests that other mixed alkali

Additivity methods for estimating heats of vaporization of organic compounds

J. PETER GUTHRIE[1] AND KATHLEEN F. TAYLOR

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 27, 1982

J. PETER GUTHRIE and KATHLEEN F. TAYLOR. Can. J. Chem. **61**, 602 (1983).

Additivity methods for heats of vaporization of organic liquids have been developed using both bond and group additivity parameters. For the bond level parameters, 429 compounds could be fitted using 36 parameters, with a weighted standard deviation of 0.32 kcal/mol, and only 23 deviations of more than 1 kcal/mol. For the group level parameters, 388 compounds could be fitted using 57 parameters, with a weighted standard deviation of 0.19 kcal/mol, and only 7 deviations of more than 1 kcal/mol. The problem of correlation among parameters is discussed and the significant terms in the correlation matrix are given. The new parameters are compared to previous parameterization schemes.

J. PETER GUTHRIE et KATHLEEN F. TAYLOR. Can. J. Chem. **61**, 602 (1983).

Faisant appel aux paramètres d'additivité de liaison et de groupe, on a mis au point des méthodes d'additivité pour évaluer les chaleurs de vaporisation des liquides organiques. Dans le cas des paramètres de liaison, on peut adapter 429 composés à 36 paramètres avec une déviation standard pondérée de 0,32 kcal/mol et avec seulement 23 déviations supérieures à 1 kcal/mol. Dans le cas des paramètres de groupe, on peut adapter 388 composés à 57 paramètres avec une déviation standard pondérée de 0,19 kcal/mol et avec seulement 7 déviations supérieures à 1 kcal/mol. On discute du problème de corrélation entre les paramètres. On a comparé les nouveaux paramètres avec les paramètres antérieurs.

Introduction

We have made use of thermochemical determinations of heats of formation of organic compounds in calculating the free energies of formation of these compounds. From free energies of formation of suitable analogs it has been shown to be possible to determine the free energies of formation of unobservable intermediates. As part of this process we have had to obtain heats of vaporization and vapor pressures at 25°C, often from meager experimental data. In order to make it easier to perform these calculations we have looked for ways to make more reliable estimates either from the molecular structure or from such experimental data as may exist.

We wish to report methods based on bond and group additivity for heats of vaporization. Benson (1, 2) has shown the immense utility of additivity methods. In general, in the series of approximations: atom, bond, and group additivity, the higher approximations give better agreement with experiment, but require many more parameters. In a practical sense it is important to determine for each property the lowest level at which useful precision is obtained, so that the maximum number of compounds can be covered by a limited set of parameters, even though one will always use the highest level of approximation for which all of the parameters are available. For entropies and heat capacities atomic additivity leads to useful precision, but for enthalpies at least bond additivity is normally necessary, and group additivity is definitely preferred.

There has been recent interest in additivity relationships for heats of vaporization (3–19). We have endeavored to base the present parameterization exclusively on experimental heats of vaporization, using the more reliable calorimetric values which are now becoming available.

There are, of course, limitations to the use of additivity methods which, if ignored, can lead to misleading estimates. All such methods are only interpolation procedures, and can only be used for compounds which are very similar to those upon which the additivity scheme is based. Since compounds which are chemically interesting often have unusual chemical features, estimation of thermodynamic quantities for such compounds generally involves extrapolation and consequently errors in the thermodynamic quantities, which are larger than for the original parameter fitting. Caution and a due regard for error and propagation of error are in order.

Results

Table S1[2] gives the compounds which we used, the experimental heats of vaporization, and the values calculated at the bond and group additivity levels. Data were gathered from the literature, starting with the compilation of Cox and Pilcher (9), which not only gives heat of vaporization data, but indicates the origin of each value and gives an estimate of the precision of the value. We have tried to gather all available data from the recent literature. The compilation of Pedley and Rylance (20) was very helpful in this regard, although it does not give information about the origin of heat of vaporization values, so that one must check the original papers. Carboxylic acids pose a problem because the acids are partially but not completely dimerized in the gas phase, so that the measured heat of vaporization is a composite quantity (21, 22); we have chosen to use heats of vaporization corresponding to conversion of liquid to monomeric vapor, even though this means that fewer compounds can be included and these values have larger error limits. Our interest is in methods for estimation of thermochemical quantities, which normally means monomeric substances in the gas phase. Compounds which were unique representatives of a parameter were, as far as possible, not included in the final least-squares calculations. This was more of a problem in the group level calculations. For the bond level calculations, the only calorimetric heat of vaporization which

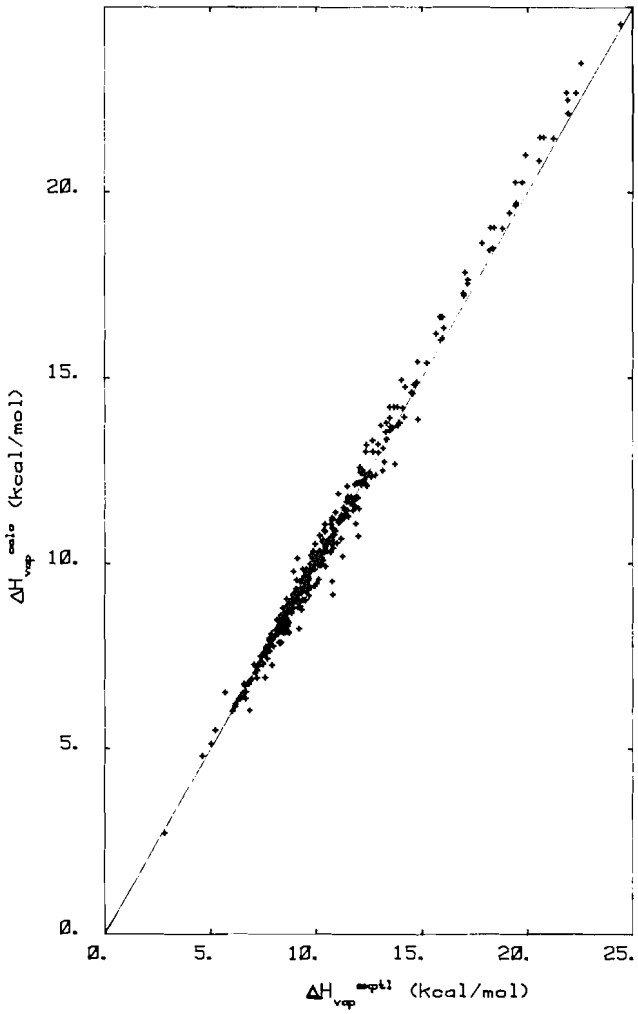

FIG. 2. Calculated vs. experimental values for heats of vaporization using the group level parameters; data from Table S1.

was not included was that for nitrobenzene (9), since this compound has a unique bond. Numerous compounds were left out of the group level calculations, as indicated in Table S1. Figures 1 and 2 show the quality of the agreement which was obtained.

Table 1 gives the bond level parameters which were evaluated by least-squares fitting. Table 2 gives the group level parameters which were evaluated by least squares. For both bond and group parameters we have followed Hine's notation (23) rather than Benson's (2). In both tables we have included the significant (absolute value greater than 0.5) elements of the correlation matrix. This matrix is quite sparse, and is symmetrical, so we have been able to present the relevant parts of it quite consisely; elements appear only once at the lower numbered parameter. A non-zero element in the correlation matrix means that the corresponding parameters are not independent and that there could be major changes in the two parameters with little change in the overall fit, if the changes were properly related. Thus for those parameters for which there is a significant element in the correlation matrix, the present values must be considered provisional, and may change when further data are added to the set. The present set of parameters is self consistent, even if the absolute values of some parameters are not yet well defined. It should be noted that there are sizeable uncertainties in some of the parameters, as reported by the least-squares program. In some cases these reflect the problem of covariance. Clearly any calculations using these ill-defined parameters will be subject to greater uncertainty. It has unfortunately not been common for either the statistical uncertainties in the parameters or the correlation matrix to be reported in similar parameterizations of thermochemical data. We believe that it is important to give this information, in order that anyone planning to use the parameters can assess the probable reliability of calculations based upon them.

It should be noted that the overall fit, as shown in Figs. 1 and 2, and as measured by the weighted standard deviation, is quite good: for the bond level parameters, the weighted standard deviation is 0.32 kcal/mol; for the group level parameters, it is 0.19 kcal/mol. For the bond level parameters, 23 compounds out of 429 showed deviations of calculated from observed of more than 1 kcal/mol; only one showed a deviation of more than 2 kcal/mol. For the group level parameters, 7 compounds out of 388 showed deviations of more than 1 kcal/mol, the largest being 1.6 kcal/mol. We feel that this quality of fit means that for compounds for which the parameters are presently well defined, either of these estimation procedures will give good estimates. It should be stressed that such methods are necessarily interpolation procedures, estimating unknown values on the basis of known values for related compounds; as the estimation becomes more an extrapolation, the accuracy must

be expected to fall.

In these calculations it was necessary to add two points to the set of data in order to force a satisfactory parameterization. At the bond level, the parameters involving aromatic rings are not well defined, because of extensive correlation. To get the program to converge at all it was necessary to include a point for naphthalene, based on the observed heat of sublimation (24) and the heat of fusion (25). With this compound included it was possible to get convergence, but the correlation problem is still severe, and it is obvious that the parameter values will change as more data become available. These problems are a consequence of treating benzene rings as composed of C_B⋯C_B bonds, each being a one-and-a-half bond (23), rather than as hexavalent atoms (1). By so doing, we can easily include nitrogen and sulfur heterocycles at the price of correlation problems, which might have been avoided had we followed Benson and Buss (1). It seemed important to be able to include as many compounds as possible; the problem of correlation should be temporary, since it should disappear with additional data.

At the group level, we observed that there was a strong correlation between $[CH_3(X)]$ and $[CH_2(C)_2]$ which had the effect of generating parameters which did not fit the set of *n*-alkanes very well, although the overall fit was satisfactory. When ΔH_{vap} for the *n*-alkanes is plotted as a function of the number of carbon atoms, a good straight line is obtained. The

[a]Number of correlated parameter, correlation coefficient.

line corresponding to the initial parameters did not fit these points well; the slope was too large, leading to deviations for the longer alkanes. In order to force a good fit to the alkanes we inserted a "value" for ethane which was calculated by extrapolation of the best line through the *n*-alkane data. This value was assigned an error of 0.001 to give it a high statistical

weight. This is really a way of assigning a value to the parameter $[CH_3(X)]$ and led to the results in Tables 2 and S1 and Fig. 2.

Ducros *et al.* (18, 19) have recently reported a group level scheme for heats of vaporization. Their results differ somewhat from ours because they used non-calorimetric as well as calorimetric data and also parameterized rather differently. We have restricted our data base to calorimetric values.[3] Although vapor pressure measurements can lead to accurate heats of vaporization, they have frequently led to values in error by more than the quoted uncertainty. Morawetz has stated (26): "It is quite evident that many vapor pressure measurements, from which most vaporization enthalpies given in the literature are derived, must be rather inaccurate. It is also obvious that uncertainties attached to vaporization enthalpies obtained in this way are often far too optimistic." Furthermore, it seems quite hazardous to base a parameterization, even in part, upon heats of vaporization estimated by empirical rules, even though such rules are often very useful, and seem quite reliable within restricted classes of compound. We have endeavored to delete all non-calorimetric values from our database. In many cases our parameters are very similar to those of Ducros *et al.*, but there are frequent differences. The important lesson is that, because of the problem of parameter correlation, one cannot compare or mix parameters from different fittings without careful consideration of the nature of the data bases used, the parameterization schemes employed, and whether the parameters being compared are relatively independent of other parameters or show tight covariance.

Other, more limited, parameterizations have been reported by Stein (17) and Cramer (16). Stein used only alkanes, and his scheme contains a constant term, RT, included on theoretical grounds. His values are $[CH_3(X)] = 1.14$, and $[CH_2(C)_2] = 1.17$. Since the constant term amounts to 0.593 kcal/mol, these values are in effect very similar in effective fit to the data to our values, at least for the lower alkanes. This can be shown by writing the corresponding equation for heat of vaporization as a function of number of carbons for the *n*-alkanes:

$$[1] \quad \Delta H_{vap} = 2.87 + 1.17\,(n - 2)$$

$$[2] \quad \Delta H_{vap} = 2.72 + 1.21\,(n - 2)$$

Equation [1] represents Stein's parameters, and eq. [2] represents ours. The difference is quite small except for very large n. Cramer has reported a much more ambitious scheme showing that numerous experimental properties of liquids related in some way to intermolecular interactions can be related to a set of two major and three minor intrinsic molecular parameters which are themselves additive constitutive properties depending on structure. ΔH_{vap} was included in the set, although this was by no means a central feature of the paper. From his data we may calculate the corresponding group parameters (his approach can be converted to a group contributions scheme, although this is not the way the correlations are presented): $[CH_3(X)] = 2.206$, and $[CH_2(C)_2] = 0.771$, with a constant term of 0.55 kcal/mol. This appears to be a quite different result from that found in the other treatments, including ours, but in fact the calculated values come out quite similar for hydrocarbons of the size included in Cramer's database, methane to pentane. Furthermore he appears to have used heats of vaporization at the normal boiling point, rather than at 25°C, so that exact comparison is not possible. Where there is intrinsic correlation of the parameters, data spanning a wide range of n are needed to establish both parameters rather than just a correlated pair of values. His values lead to eq. [3].

$$[3] \quad \Delta H_{vap} = 4.46 + 0.77\,(n - 2)$$

There have been reports of group additivity methods for vapor pressures (60, 61) which in principle could lead to heats of vaporization. These methods appear to lead to good estimates of vapor pressures within the, so far, limited range of compounds which have been examined. Jensen *et al.* (60) have not directly considered heats of vaporization. Macknick and Prausnitz (61) showed that heats of vaporization at the normal boiling point, calculated by differentiation of the equation generated by their group equivalents scheme for heavy hydrocarbons, gave an average error of ±5.4%.

There do not appear to have been any previous attempts to determine bond level parameters for H_{vap}. Since the fit is not much worse than with group level parameters, and there is a marked reduction in the number of parameters required to fit a larger number of compounds, we feel that the bond level approach will be useful to chemists carrying out thermochemical calculations. Nevertheless, it remains true that it is preferable to use group level calculations whenever the necessary parameters are known.

[3]Strictly the data of Fuchs and Peacock (27, 30, 33, 46) are not purely calorimetric values since a combined gas chromatographic – calorimetric method was used. Since this semi-calorimetric method has been carefully calibrated by comparison with true calorimetric values (30, 33, 46), we felt it was justifiable to include these data.

Polarized Raman spectra of an oriented single crystal of barium nitrite monohydrate

O. P. LAMBA, H. D. BIST, AND Y. S. JAIN[1]

Department of Physics, Indian Institute of Technology, Kanpur 208016, India

Received August 10, 1982

O. P. LAMBA, H. D. BIST, and Y. S. JAIN. Can. J. Chem. **61**, 608 (1983).

The symmetries of the observed Raman lines in the 4000–30 cm^{-1} region in different orientations of a single crystal of $Ba(NO_2)_2 \cdot H_2O$ have been determined and the spectra have been analysed in terms of the phonons originating from the internal modes of the NO_2^- and H_2O groups and the external lattice modes. The longitudinal-optical and transverse-optical (LO–TO) splittings arising from the Coulomb forces in the crystal are reported for the first time.

O. P. LAMBA, H. D. BIST et Y. S. JAIN. Can. J. Chem. **61**, 608 (1983).

On a déterminé les symétries des raies de Raman observées dans la région de 4000–30 cm^{-1}, pour les différentes orientations d'un cristal unique de $Ba(NO_2)_2 \cdot H_2O$ et on a analysé les spectres en fonction des phonons provenant des modes internes des groupes NO_2^- et H_2O et des modes de réseau externe. On rapporte pour la première fois les déplacements longitudinal-optique et transverse-optique (LO–TO) provenant des forces de Coulomb dans le cristal.

[Traduit par le journal]

1. Introduction

$M(NO_2)_2 \cdot H_2O$ (M = Ba, Sr, Ca, and Mg) form a simple series of hydrated nitrites. Out of these, only $Ba(NO_2)_2 \cdot H_2O$ (BNM) forms stable and well developed crystals, for which recent X-ray reinvestigations (1) have established the correct polar space group C_6^2 (or C_6^3). The solid has been studied extensively by several physical methods (2–8). Special interest has developed in this recently due to its use as pyroelectric infrared radiation detector (9). Infrared and Raman spectra of polycrystalline samples of BNM have recently been published (10–12). The only report on polarized Raman spectra of single crystals (13) utilized a conventional mercury source.

The present Raman investigation was performed using laser excitation in order to obtain unambiguous symmetry assignments of the internal and lattice phonons originating from the optically active motions of the NO_2^-, H_2O, and Ba^{2+} units in the crystal.

2. Experimental

Single crystals were grown by slow evaporation of aqueous solution of BNM prepared by a method reported earlier (12). The axes of the well developed hexagonal prisms elongated along ⟨001⟩ axis (polar Z-axis) were determined from the knowledge of crystal morphology.

The crystals of BNM show maximum transmission and minimum optical rotatory power near 500 nm (5). The 514.5-nm emission line of the Ar^+ ion laser (Spectra-Physics 165-09) was used to excite the Raman scattering from a small crystal (ca. 3 × 2 × 2 mm). The scattered radiation observed at right angles was dispersed in a Spex 1403 double monochromator equipped with a cooled photomultiplier C 31034 tube and a Spex digital photon counting system DPC-2. The spectral slit widths employed were ~1 cm^{-1} – 3 cm^{-1}.

3. Crystal structure and phonon symmetry

The hexamolecular unit cell of BNM crystal belongs to the C_6^2 space group (1). The stoichiometric sheets (consisting of Ba^{2+}, two types of NO_2^- ions, and H_2O molecules, and running normal to the polar axis of the crystal) are interlinked through hydrogen bonds. All these Ba^{2+}, two symmetrically independent NO_2^- ions, and the H_2O molecules occupy the sites of C_1 symmetry in the unit cell. The correlation of the different symmetry species of the free NO_2^- or H_2O groups with the site and the factor groups is shown in Table 1.

TABLE 1. Correlation diagram for the free, site and unit cell symmetry of NO_2^- and H_2O groups in the $Ba(NO_2)_2 \cdot H_2O$ crystal

Free state C_{2v}	Site C_1	Crystal[a] C_6
A_1 (ν_1, ν_2, T_Z)		A (R, ir)
A_2 (R_Z)	A	B (inactive)
B_1 (T_X, R_Y)		E_1 (R, ir)
B_2 (ν_3, T_Y, R_X)		E_2 (R)

[a]In parentheses are shown the activity of the particular symmetry species.

Under the unit cell approximation, the dynamics of BNM crystal can be described in terms of 180 phonon branches including 3 acoustical ones. A factor group analysis of the normal modes at the centre of Brillouin zone ($K = 0$) yields the following symmetry reduction:

$$\Gamma_{180} = 30A(\text{R, ir}) + 30B(\text{inactive}) + 30E_1(\text{R, ir}) + 30E_2(\text{R})$$

The complete optical Raman spectrum is therefore expected to comprise $29A + 29E_1 + 30E_2$ modes. The symmetry species and the number of phonon branches arising from the different modes of H_2O, NO_2^-, and Ba^{2+} groups are presented in Table 2. The vibrational modes are classified approximately into the internal and the external modes.

The Raman tensors for crystals with C_6-hexagonal symmetry are given by Loudon (14). These tensors indicate that the A phonons are polarized parallel to the Z-axis, while the E_1 phonons are polarized in the XY plane. Further, the A and E_1 modes being simultaneously infrared and Raman-active are expected to split into a longitudinal-optical (LO) and a transverse-optical (TO) branch (vide infra, Section 4*F*).

4. Results and discussion

A. Phonon frequencies

Four spectra were recorded for XX, YX, YZ, and ZZ polarizations to define the vibrations of the BNM crystal at room

temperature. Figure 1 depicts mainly the internal mode regions of the H_2O and NO_2^- groups, while Fig. 2 covers the low frequency region. No bands were observed in the multiphonon 1700–3200 cm^{-1} region and the bending mode of H_2O appeared very faintly in the *YX* spectrum only at ~1650 cm^{-1}. Peak frequencies of the Raman active phonons for the observed bands in different spectra are given in Table 3 along with our assignments in column 5. The infrared frequencies measured from the powdered sample (12) are also included in the last column to facilitate comparison. The accuracy for the Raman bands is ±2 cm^{-1} generally, but may be ±5 cm^{-1} in the OH-stretching region.

B. Internal modes of H_2O molecule

The stretching region 3200–3600 cm^{-1} of water molecule in BNM (cf Fig. 1) shows only two modes at 3502 (*YX*, *XX*, and *ZZ* spectra) and around 3360 cm^{-1} (*ZZ* and *YX* spectra), the former being strong in the *YX* spectrum and the latter in the *ZZ* spectrum. This intensity change would go against treating the two bands as ν_3 and ν_1 of water. The large frequency difference 142 cm^{-1} would also suggest that the two bands are due to two independent groups of OH oscillators, with different polarizability derivatives. Wood reports (11) that there is no significant difference in ir absorption for the stretching modes for radiation polarized parallel and normal to *Z*-axis, and he concludes that the two modes have dipole moment changes neither parallel nor perpendicular to the molecular C_2 axis. The polarizability derivatives could still be different for the two OH oscillators.

The six crystallographically equivalent H_2O molecules occupying C_1 sites in BNM lattice are highly distorted. Hence, in group theory, each mode of H_2O is expected to split into three Raman and two ir-active components under the point group C_6 (cf. Table 1). The absence of such splitting in the Raman spectra, as also in the ir spectra (12) even at low temperature, leads us to conclude that the intra- and inter-molecular interactions are extremely weak.

C. Librational modes of H_2O molecules

In our polarized Raman spectra of the single crystal or of the powder, these modes appear as extremely weak and diffuse bands, and therefore no additional information could be drawn regarding their librational dynamics. However, these modes appearing strong in infrared have been characterized on the basis of well known criteria (12).

D. Internal modes of NO_2^- ion

As can be seen from Tables 1 and 2, the internal modes of NO_2^- ion are expected to show multiple structure because there are two non-equivalent NO_2^- ions in the unit cell. The spectra (cf. Fig. 1) show only two bands corresponding to each of the ν_2 and ν_3 modes, which are obviously due to site splitting. The totally symmetric mode ν_1 shows a single band, which has a

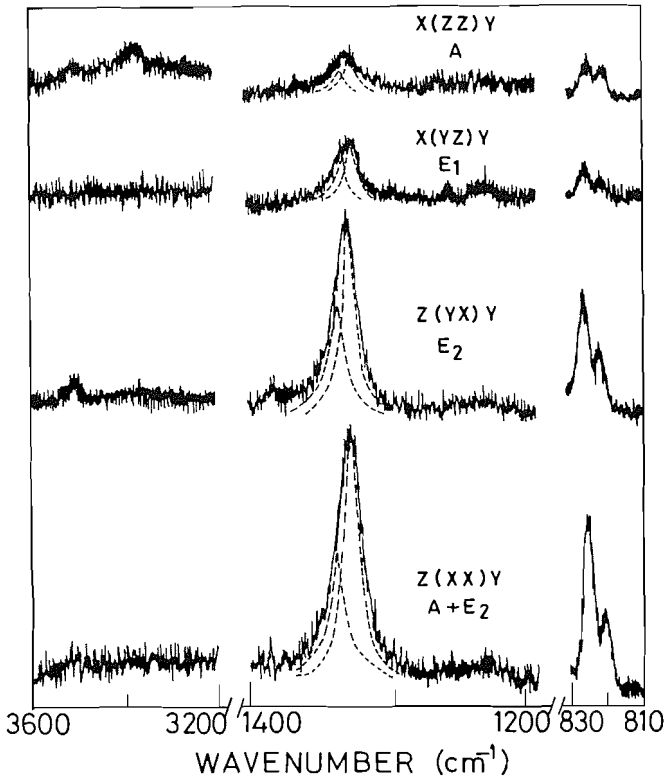

FIG. 1. Polarized Raman spectra of a $Ba(NO_2)_2 \cdot H_2O$ single crystal. For 3200–3600 cm^{-1} region: scan time 1 cm^{-1}/s, slits 300 MIC and laser power at sample ~100 mW. For 810–1400 cm^{-1} region, the respective values are 0.1 cm^{-1}/s, 200 MIC, and ~120 mW. Full scale is 2 K and integrated time 0.5 s for both the regions.

distinct asymmetry, so that a graphical resolution is used to deduce the two components. These modes are assigned and their polarization states are as indicated in columns 1–4 of Table 3. It is noted that the vibrations of NO_2^- ions have their polarizations more or less in both the principal directions of the hexagonal crystal. This is in agreement with Wood's conclusion for ir spectra (11).

The weak modes appearing around 1376 cm^{-1} in this region can be attributed to the multiphonon transition $\nu_2(NO_2^-$ ion) + H_2O libration at 559 cm^{-1} (cf. Table 3, column 6). The possibility that these bands could arise from the possible presence of NO_3^- ion as an impurity was ruled out since the totally symmetric vibration of the NO_3^- ion around 1050 cm^{-1} was non-traceable in the Raman spectra.

E. Low-lying lattice phonons

The $K = 0$ lattice phonons of Ba^{2+}, H_2O, and NO_2^- units in BNM expected below 500 cm^{-1} in the Raman spectrum can be associated with $17A + 17E_1 + 18E_2$ phonons excluding three acoustical $A + E_1$ phonons and $3A + 3E_1 + 3E_2$ modes corresponding to H_2O librations which are not observed in the Raman spectra of the single crystal (cf. Table 2). The observed spectra show that most of the bands occur in all the polarizations (cf. Table 3), which indicates an appreciable mixing of the rotational and translational modes.

In order to assign the modes of NO_2^- we note that: (*i*) the translatory and libratory modes of NO_2^- ion are expected below ~200 cm^{-1} (15) and (*ii*) NO_2^- librations, like those of H_2O, are expected to be weak in the Raman and moderately strong in the infrared spectra. The assignments of the NO_2^- and H_2O groups given in Table 3 are on these criteria. However, further distinction between translations and librations of NO_2^- is not possible due to an appreciable mixing and the reduced site symmetry C_1 (Table 1).

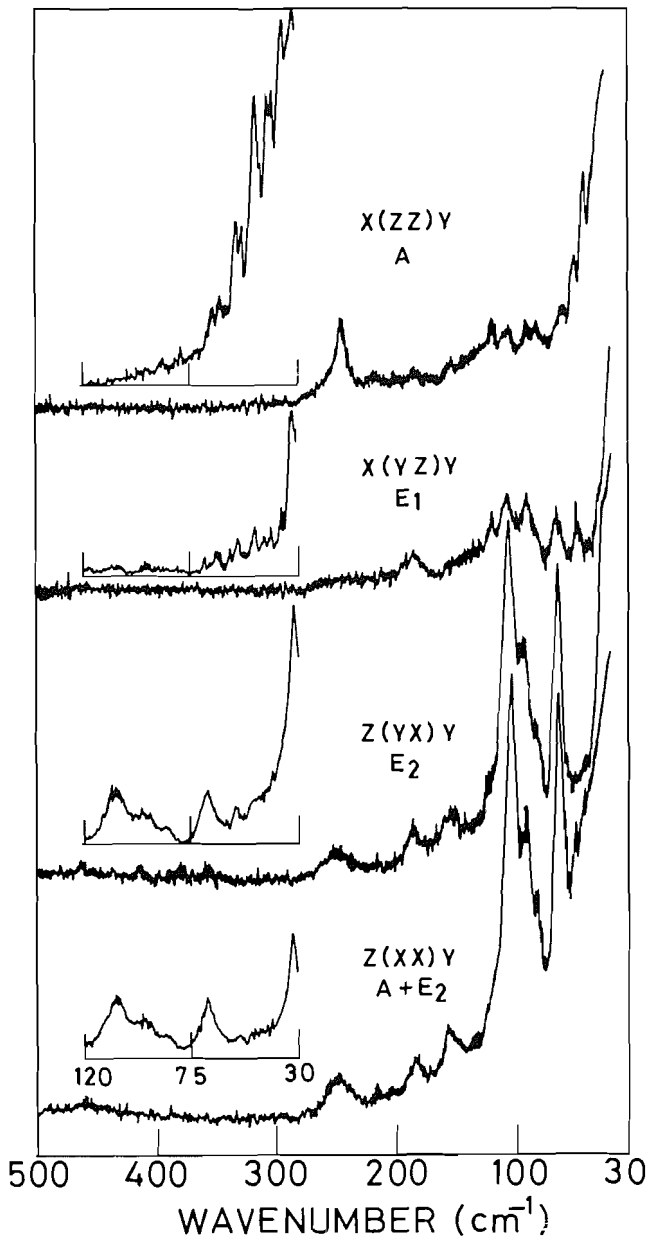

FIG. 2. Polarized Raman spectra of a $Ba(NO_2)_2 \cdot H_2O$ single crystal below 500 cm^{-1}. For 30–500 cm^{-1} region: scan time 0.2 cm^{-1}/s, slits 200 MIC, laser power at sample ~130 mW and full scale 2 K. For inset spectra (30–120 cm^{-1} region), the respective values are 0.2 cm^{-1}/s, 100 MIC, ~150 mW, and 10 K. Integrated time for both the regions are the same as in Fig. 1.

The strong Raman bands near Raleigh wing around 100 cm^{-1} or below this obviously belong to the translations of Ba^{2+} units in view of the large mass of the cation. It is noted that the bands in this region, mainly due to monoatomic units, are observed with almost similar intensities in both the Raman and infrared spectra.

F. LO and TO phonons

As mentioned earlier, the polar phonons comprising A and E_1 representations of point group C_6 are expected to show

[a]Measured from the spectra recorded in the geometries indicated under heads of columns 1–4; uncertain band positions have been question marked (?); bands arising due to spillover of strong bands in other polarizations have been starred (*).

[b]Superscripts W, N, and B refer to the modes of H_2O, NO_2^-, and Ba^{2+} units, respectively, l and t stand for librations and translations of these units.

[c]The bands above 410 cm^{-1} are recorded on P.E.-580 spectrophotometer (ref. 12), and below this are recorded on Polytech-30 instrument at Indian Institute of Technology, Madras, India.

LO–TO splittings. Our spectra of these species do not provide any indication of such splittings on the bands assigned to H_2O or NO_2^-. However, in the low frequency region near the Raleigh wing (cf. insets of *ZZ* and *YZ* spectra in Fig. 2) 8 bands of good intensity are observed, which can be arranged into four pairs, each one arising from LO and TO components of the theoretically allowed phonon branches of A and E_1 species. As expected, the lower frequency component (TO) of each pair has higher intensity than the corresponding LO phonon.

Nuclear analogs of β-lactam antibiotics. XVI. Aldol condensations of N-protected 4-tritylthio-2-azetidinones

ALAIN MARTEL,[1] JEAN COLLERETTE, JACQUES BANVILLE,[2] JEAN-PAUL DARIS, PHILIPPE LAPOINTE, BERNARD BELLEAU,[3] AND MARCEL MÉNARD

Les Laboratoires Bristol du Canada, 100, boul. de l'Industrie, Candiac (Qué.) Canada J5R 1J1

Received September 1, 1982

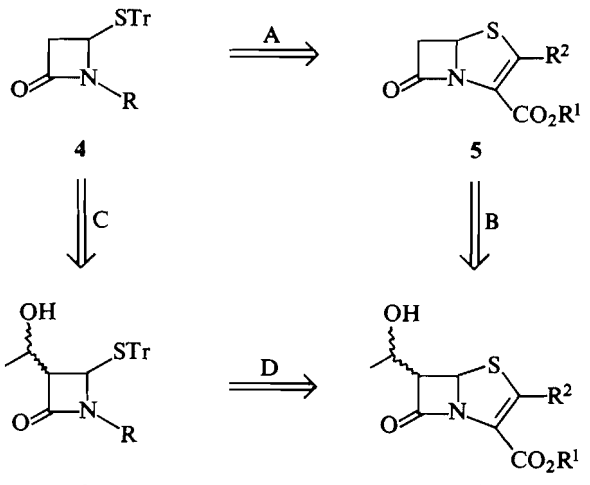
ALAIN MARTEL, JEAN COLLERETTE, JACQUES BANVILLE, JEAN-PAUL DARIS, PHILIPPE LAPOINTE, BERNARD BELLEAU, and MARCEL MÉNARD. Can. J. Chem. **61**, 613 (1983).

The reaction of acetaldehyde with enolates of N-protected 4-tritylthio-2-azetidinones **4***b* and **4***c* was studied. While the lithium enolate of *N*-methoxymethylazetidinone **4***b* gave only *trans S** 3-(1′-hydroxyethyl)azetidinone **8** the corresponding tetrabutylammonium enolate gave a mixture of *trans R** and *trans S** azetidinones **8** and **9**. The metal enolate of *N*-(*tert*-butyldimethylsilyl)-4-tritylthio-2-azetidinone **4***c* gave all four possible isomers.

ALAIN MARTEL, JEAN COLLERETTE, JACQUES BANVILLE, JEAN-PAUL DARIS, PHILIPPE LAPOINTE, BERNARD BELLEAU et MARCEL MÉNARD. Can. J. Chem. **61**, 613 (1983).

On a étudié la réaction de l'acétaldéhyde avec les énolates des tritylthio-4 azétidinones protégées au niveau de l'azote (**4***b* et **4***c*). Alors que l'énolate lithié de la *N*-méthoxyméthylazétidinone (**4***b*) donne uniquement la *S** (hydroxy-1 éthyl)-3 azétidinone *trans* (**8**) l'énolate correspondant du tétrabutylammonium donne un mélange des azétidinones *R** *trans* et *S** *trans* (**8** et **9**). L'énolate métallique de la *N*-(*tert*-butyldiméthylsilyl) tritylthio-4 azétidinone-2 (**4***c*) donne les 4 isomères possibles.
[Traduit par le journal]

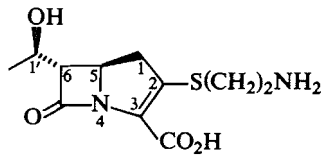
Thienamycin (**1**) (1) and the structurally related olivanic acids (**2**) (2) are characterized, unlike classical β-lactam antibiotics, by a 6-(1′-hydroxyethyl) side chain. Although their configurations at positions 1′ and 6 are inverted, both display remarkable antibacterial properties. Their discovery has generated intensive synthetic work directed towards stereospecific incorporation of such 6-side chains not only to the carbapenem nucleus but also to the related penems (**3**) (3–5). In paper XV (6*a*) of this series we described our own effort at converting preformed 6-unsubstituted penems (**5**) to 6-(1′-hydroxyethyl)



a R = H; *b* R = CH_2OCH_3; *c* R = $Si(CH_3)_2tC_4H_9$

SCHEME 1

and other 6-substituted penems (**7**, **3**): metallation of **5** followed by aldol condensation to acetaldehyde (Scheme 1B) was found to afford a single "unnatural" diastereomeric (1′*R**, 5*R**, 6*R**) 6-hydroxyethylpenem ruling out the use of preformed penems for the preparation of "natural" isomers of **7**.



(1′*R*, 5*R*, 6*S*)

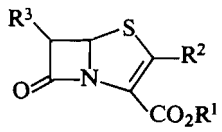
2 *n* = 0,1
R = H, SO_3H



3

To overcome this problem and at the same time retain the versatile methodology developed for the preparation of 6-unsubstituted penems (Scheme 1A) (6*b*) we required an easy conversion of the key intermediate **4** to properly 6-substituted intermediates like **6** which would allow extension of Scheme 1A to Scheme 1D. This paper describes transformation of **4**, via aldol condensation, to all four possible isomers of **6**. Subsequent papers will report stereospecific conversions of **4** to "natural" **6** where the nitrogen protecting group actually consists of the Woodward phosphoranylidene acetic ester residue required to complete the annulation of the thiazole ring.

N—C-3 Dimetallation of azetidinone **4***a* and aldol reaction with acetaldehyde, in a manner similar to that described by Durst *et al.* (7) for 4-alkylazetidinones, would have provided the shortest method for the introduction of the 3-hydroxyethyl substituent. Possibly because of the different nature of the 4-substituent, azetidinone **4***a* proved to be completely unstable, even at −78°C, to dimetallation conditions. On the other hand, properly N-1 protected **4** were found to give stable monometallated enolates that underwent aldol condensation to

SCHEME 2

acetaldehyde in high yields. Two types of protecting group were selected: a sterically small group, with potential metal chelating properties, the methoxymethyl group, and a sterically demanding, chemically inert, N-substituent, the *tert*-butyldimethylsilyl group.

Methoxymethylation of **4***a* was carried out by quenching the nitrogen anion (NaH, THF, MeOH) with bromomethyl methyl ether and afforded crystalline **4***b* in 91% yield. Silylation of **4***a* with *tert*-butyldimethylsilyl chloride in DMF in the presence of triethylamine provided crystalline **4***c* in 89% yield.

The protected azetidinones, **4***b* and **4***c*, were conveniently metallated in an appropriate solvent (Table 1) at −78°C by addition of a slight excess (1.1 equiv.) of preformed LDA (8). Aldol condensation to acetaldehyde was effected under what are assumed to be conditions of kinetic control (−78°C, 10 min) (9*a*). Metal interchange, when required, was achieved by adding an equivalent of anhydrous magnesium bromide (10), zinc chloride (10), or tetrabutylammonium fluoride (11) to the lithium enolate prior to addition of acetaldehyde. Reaction products were separated and purified by hplc. The stereochemical composition of the aldol products under a variety of conditions is summarized in Table 1.

Stereochemical assignments were determined from ^{1}Hmr coupling constants correlation as listed in Table 2.[4] The *cis*−*trans* relationships were readily established on the basis that for 2-azetidinones $J_{3-4}cis > J_{3-4}trans$ (12). It followed that isomers **10***c* and **11***c* with J_{3-4} = 4.5 and 4.6 Hz possessed a *cis* arrangement and **8***b*, **9***b*, **8***c*, and **9***c*, with J_{3-4} = 0.9−2.5 Hz, a *trans* geometry. Configurations at position 1′ were assigned from the observation first made by House *et al.* (10), and corroborated by others in the β-lactam area (4, 5, 13, 14) that, for aldol condensation products, J_{ab} is larger

[4]All compounds described in this paper are racemic mixtures. Structural formulae and stereochemical designations refer to the enantiomer related to natural products, thienamycin and olivanic acid.

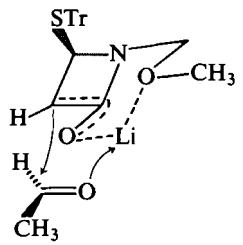
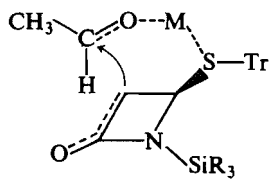
[a]Recorded at 80 MHz in $CDCl_3$ using tetramethylsilane as internal standard. Chemical shifts are in δ (ppm) and coupling constants in Hz.

for the *threo* (*trans R**, *cis S**) than for the *erythro* (*trans S**, *cis R**) isomer. Accordingly the *trans* compounds **9***b*, **9***c*, and **9***d*[5] with $J_{1'-3}$ = 5.5, 3.7, and 6.0 Hz were assigned a *R** configuration and the corresponding **8***b*, **8***c*, and **8***d*, with smaller $H_{1'}-H_3$ coupling constants (4.6, 2.7, and 2.0 Hz), a *S** arrangement. The *cis* isomers **11***c* and **11***d* with $J_{1'-3}$ = 8.2 and 5.6 Hz were given the *S**, and **10***c* and **10***d*, with 0.9 and 0.5 Hz, the *R** configuration.

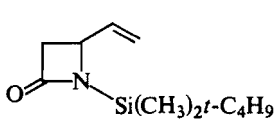
It has been shown by Dubois *et al.* (15), Heathcock and co-workers (9), House *et al.* (10), and Evans *et al.* (16) that aldol stereoselection is governed by a pericyclic process involving the incoming aldehyde, the enolate anion, and the metal countercation. In this hypothesis the stereochemical control of the reaction is effected by the various steric nonbonded interactions in the pseudocyclic transition state. The capacity of the metal cation to accommodate ligands and the polarity of the solvent were also shown to exert an influence on the formation of the cyclic intermediate. Scheme 3 depicts such intermediates for the products of Table 1.



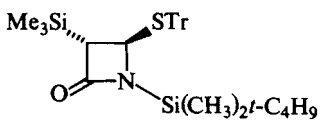
16



18



17



19

[5]Reaction conditions will appear in a future publication.

In the absence of sterically demanding substitution on the nitrogen atom of the azetidinone (Expts. 1 and 2, Table 1) the bulky tritylthio group at 4β directed hydroxylation exclusively to the less hindered α-face of the molecule; no *cis*-aldols were detected in the reaction mixture. The surprisingly high stereochemical control observed with the lithium enolate of **4***b* (Expt. 1), giving exclusively the *S** configuration at position 1′, likely resulted from a combination of two concurrent effects: because of the pseudo 1,3-diaxial interaction with the C-4α-proton in transition state **13**, the methyl group of the incoming aldehyde should end up principally in the equatorial position (**12**) giving the *trans S** **8***b* as the major isomer; internal lithium chelation in the enolate, **16**, prior to addition of acetaldehyde, according to an hypothesis advanced by Meyers and Reider (17) to explain the abnormal behavior of alkoxyalkyl esters in the aldol condensation, should also strongly favor exclusive formation of intermediate **12**. This high stereoselectivity was lost under conditions that do not favor formation of stable metal chelates (Expt. 2): condensation of the ammonium enolate of **4***b* to acetaldehyde was found to be much slower, giving only 33% of a 1:1 mixture of the two *trans* aldols **8***b* and **9***b* after 15 min. This clearly shows that metal chelation provides not only stereochemical control but also reduces the energy barrier to the condensation products.

In the presence of a sterically important substituent on the nitrogen atom (Expt. 3) *trans*/*cis* stereoselectivity was greatly reduced. On the one hand, one could reason that steric interference between the bulky groups at positions 1 and 4 of azetidinone **4***c* would increase the relative population of the α-face N-substituent with the consequence that the C-4α proton is no longer the only important interaction-maker at the α-face. As a result transition states **14** and **15** are not destabilized, relative to **12** and **13**, to the same extent and the proportion of *cis* product is increased accordingly (*trans*/*cis* = 7:3). On the other hand, azetidinone **17** (14), with a smaller size substituent at position 4, was reported to give a *trans*/*cis* ratio of 83:16, which indicates that the presence of a sulfur atom at position 4 of azetidinone **4***c* is partly responsible for the lowered *trans*/*cis*

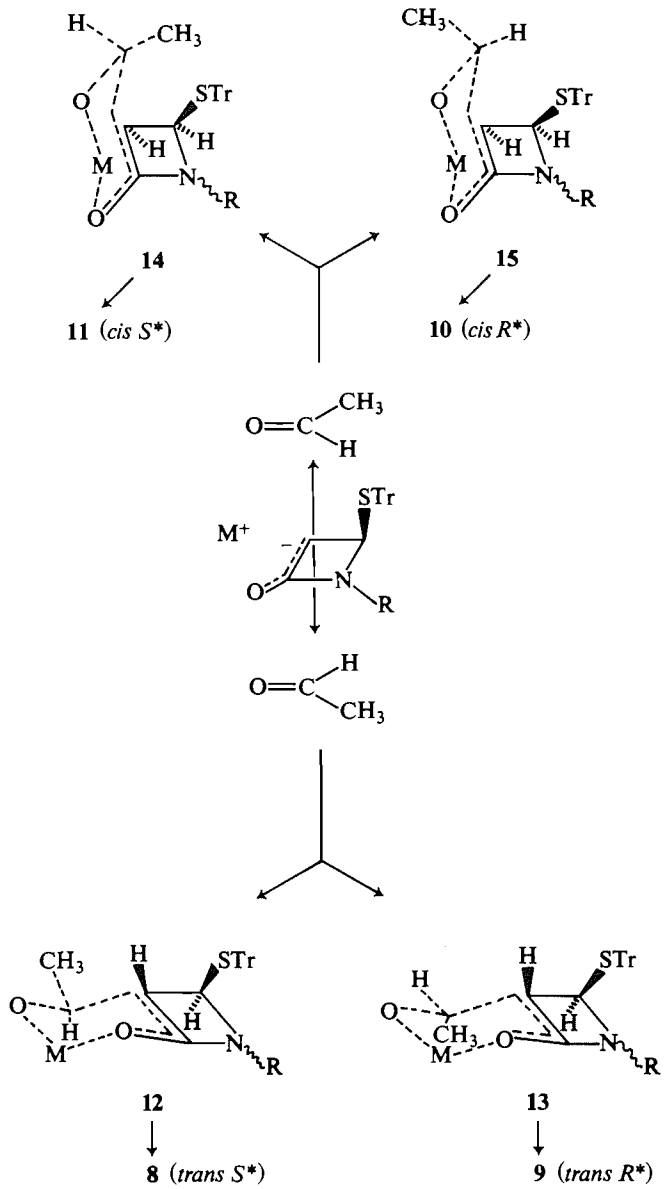

SCHEME 3

ratio observed with **4***c*. Possibly, under conditions of kinetic control, chelation to sulfur (18), as depicted in **18**, would facilitate β-face approach and favor transition to **14** and **15**. This effect was not noted with **4***b* because of the greater propensity of oxygen to chelate with metals. In such a hypothesis enhancement of the chelating properties of the cationic center would strengthen chelation to sulfur and increase the proportion of attack to the more hindered β-face; indeed replacing lithium by the divalent magnesium (19) gave a *trans*/*cis* ratio approaching unity (Expts. 4 and 6).

Little change in the *trans*/*cis* ratio was observed when THF was replaced by a less polar solvent (Expts. 3 and 4) or when the condensation was carried under conditions likely to permit thermodynamic equilibration (Expt. 5). It is interesting to note that the highly abnormal *cis R**/*cis S** < 1 ratio in THF (Expt. 3) changed, in ether (Expt. 4), to a ratio that is more in line with nonbonded interactions in **14** and **15**.

Attempts to disrupt the organized transition state from **4***c* were unsuccessful. Use of the highly dissociating solvent HMPT (9*b*) led to the discovery of a mild deprotection reaction for N-silyl protected azetidinones:[5] solution of **4***c* in HMPT (or DMF), in the presence of a nucleophile (diisopropylamine from LDA, NaN_3,...) at low temperature afforded a quantitative yield of **4***a*. Attempts to generate the ammonium enolate with tetrabutylammonium fluoride also resulted in protecting group removal (the corresponding bromide and iodide were completely insoluble in THF at −78°C and did not bring any change in the *trans*/*cis* ratio). The ammonium enolate could have possibly been obtained by treatment of the O-trimethylsilyl enol ether of **4***c* with an equivalent of tetrabutylammonium fluoride; treatment of the lithium enolate of **4***c* with trimethylsilyl chloride not unexpectedly (20, 21) afforded only the C-silylation product **19**.[6]

In summary, the stereochemistry of aldol condensation products of 4-tritylthioazetidinones with acetaldehyde varied according to the type and size of the nitrogen protecting group, with minimal effect from solvent or reaction conditions. The strength of the chelation of the metal cation, not only with the enolized carbonyl group itself but also with other electronegative groups, on the azetidinone was found to be an important factor in the stereochemical control of the reaction. The four possible isomers of **6** were obtained but neither the methoxymethyl nor the *tert*-butyldimethylsilyl protecting groups provided the "natural" isomers of **6** as major products. Stereoselective conversion of **4** to "natural" **6** will make the object of a forthcoming publication.

Experimental

Melting points were determined on a Gallenkamp melting point apparatus and are not corrected. The infrared spectra were recorded on a Perkin−Elmer 267 grating infrared spectrophotometer.

The ^1H nuclear magnetic resonance data were taken with either a Varian EM-360A (60 MHz) or a Varian CFT-20 (80 MHz) nmr spectrometer using tetramethylsilane as an internal standard. The analyses were performed by Micro-Tech Laboratories, Skokie, Illinois and Daessle Microanalysis, Montréal, Que.

Tetrahydrofuran was freshly distilled from $LiAlH_4$. Anhydrous ether (Mallinckrodt) and *n*-butyllithium in hexane (Aldrich) were used as supplied. Commercial CH_3CHO was distilled prior to use. Diisopropylamine was distilled from CaH_2 and stored over NaOH.

1-Methoxymethyl-4-tritylthio-2-azetidinone (4b)

A solution of 4-tritylthio-2-azetidinone (**4***a*) (1.38 g, 4.0 mmol) in THF (10 mL) was added to a well stirred suspension of sodium hydride (300 mg of commercial 50% oil dispersion, 4.1 mmol, washed with pentane) in THF (10 mL) maintained at −15°C (ice−methanol bath). Methanol (15 drops) was added and the mixture was stirred at −15°C for 0.5 h. Bromomethyl methyl ether (0.58 g, 4.6 mmol) was added, the mixture was stirred for 2 h, diluted with ether, washed with water and brine, dried ($MgSO_4$), and concentrated to leave an oil (1.72 g). Crystallization from pentane gave the title compound **4***b* as a white solid (1.41 g, 3.64 mmol, yield: 91%), mp 72−76°C; ir (CH_2Cl_2) ν_{max}: 1765 (β-lactam C=O) cm^{-1}; ^1Hmr ($CDCl_3$) δ: 7.4−7.2 (15H, m, aromatic H), 4.6−4.37 (H-4), 4.43 (2H, center of ABq, CH_2), 3.25 (3H, s, CH_3), 2.93 (1H, dd, J = 15.4, J = 4.1, H-3), 2.68 (1H, dd, J = 15.4, J = 3.4, H-3). *Anal.* calcd. for $C_{24}H_{23}NO_2S$: C 74.00, H 5.95, N 3.59, S 8.23; found: C 73.97, H 6.02, N 3.74, S 8.20.

*1-(*tert*-Butyldimethylsilyl)-4-tritylthio-2-azetidinone (4c)*

Triethylamine (1.62 mL, 11.6 mmol) was added dropwise in 5 min to a cooled (ice bath) solution of 4-tritylthio-2-azetidinone (**4***a*) (3.50 g, 10.1 mmol) and *tert*-butyldimethylsilyl chloride (1.68 g,

[6]Use of **19** as starting material for new C-3 substituted azetidinones will make the object of a subsequent paper.

12.7 mmol) in DMF (35 mL). The reaction mixture was stirred at room temperature for 18 h, diluted with water (250 mL) and ether (200 mL), the organic phase washed with water (3 × 50 mL), dried, and concentrated to leave an oil (4.33 g). Crystallization from pentane gave the title compound **4***c* as a white solid (4.1 g, 8.9 mmol, yield: 89%), mp 113–114°C; ir (CH_2Cl_2) ν_{max}: 1735 (β-laetam C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 7.8–7.2 (15H, m, aromatic H), 4.2 (1H, dd, J = 4, J = 2, H-4), 2.63 (1H, dd, J = 16, J = 4, H-3), 2.13 (1H, dd, J = 16, J = 2, H-3), 1.0 (9H, s, *t*-Bu), 0.35 (6H, s, CH_3). *Anal.* calcd. for $C_{28}H_{33}NOSSi$: C 73.15, H 7.24, N 3.05, S 6.97; found: C 73.27, H 7.32, N 2.97, S 6.94.

trans S* *3-(1'-hydroxyethyl)-1-methoxymethyl-4-tritylthio-2-azetidinone* (*8*b)

A solution of lithium diisopropylamide was prepared in THF (5 mL) at low temperature (Dry Ice – acetone bath) from *n*-butyllithium (1.0 mL, 1.6 *M* in hexane, 1.6 mmol) and diisopropylamine (0.25 mL, 1.84 mmol). After 30 min a solution of 1-methoxymethyl-4-tritylthio-2-azetidinone (**4***b*) (421 mg, 1.42 mmol) in THF (6 mL) was added dropwise and the solution was stirred for 15 min. Acetaldehyde (3 mL) ws added dropwise followed, after 20 min, by water (30 mL). The mixture was acidified to pH 3 with 2% aqueous HCl and extracted with ethyl acetate (5 × 20 mL). The combined organic phases were washed with brine, dried, and concentrated to leave an oil which crystallized upon trituration with ether (440 mg, 1.01 mmol, yield: 80%) mp 188.5–189°C; ir (CH_2Cl_2) ν_{max}: 3610 (m, OH), 1755 (s, β-lactam C=O) cm^{-1}. *Anal.* calcd. for $C_{26}H_{27}NO_3S$: C 72.02, H 6.28, N 3.23, S 7.39; found: C 71.94, H 6.02, N 3.21, S 7.40.

trans S* *and* R* *3-(1'-hydroxyethyl)-1-methoxymethyl-4-tritylthio-2-azetidinones* (*8*b *and* *9*b)

A solution of lithium diisopropylamide (0.482 mmol) was prepared at −78°C (Dry Ice – acetone bath) in dry ether (3 mL) from *n*-butyllithium (0.101 mL, 2.52 *M* in hexane, 0.482 mmol) and diisopropylamine (0.067 mL, 0.482 mmol). After 20 min, a solution of azetidinone **4***b* (0.171 g, 0.439 mmol) in a mixture of dry ether (1 mL) and THF (1 mL) was added dropwise and the resulting clear solution was stirred at −78°C for 15 min. A solution of tetrabutylammonium fluoride (0.96 mL of a 0.5 *M* solution in THF, 0.48 mmol) was then added. A precipitate was formed with the generation of a slight pink colour. After 5 min at −78°C, the reaction mixture was quenched with acetaldehyde (0.2 mL, excess), and the stirring continued for 15 more min. A saturated solution of NH_4Cl was added and the mixture was extracted with ethyl acetate (2 × 25 mL). The combined organic phases were washed with brine and dried ($MgSO_4$) and concentrated to leave an oil (228 mg). This was chromatographed on silica gel (10 g), using a mixture of benzene and ethyl acetate (6:4) to give back substrate (**4***b*) (106 mg, 62% recovery) and a mixture of two isomeric alcohols which were separated by chromatography on thick layer plates (same solvent system). The alcohol with high R_f (33 mg, 0.076 mmol, yield: 17%) was identical to **8***b*, mp 188.5–189.5°C. The alcohol with low R_f (30 mg, 0.069 mmol, yield: 16%) was obtained as an oil which crystallized with difficulty (hexane), mp 94–95°C; ir (CH_2Cl_2) ν_{max}: 3600 (m, OH), 1760 β-lactam C=O) cm^{-1}. *Anal.* calcd. for $C_{26}H_{27}NO_3S$: C 72.02, H 6.28, N 3.23, S 7.39; found: C 71.77, H 6.36, N 3.15, S 7.43.

trans S* *and* R* *and* cis R* *and* S* *1-(*tert*-*butyldimethylsilyl)-3-(1'-hydroxyethyl)-4-tritylthio-2-azetidinone* (*8*c, *9*c, *10*c, *11*c)

1. *In THF*

To a solution of diisopropylamine (15.0 mL, 10.8 g, 0.107 mmol) in THF (450 mL) maintained at −78°C was added dropwise *n*-butyllithium (42.0 mL, 2.22 *M* in hexane, 0.093 mmol). The mixture was stirred for 30 min and a solution of **4***c* (30.0 g, 65.4 mmol) in THF (250 mL) was added slowly. After 15 min stirring, acetaldehyde (35 mL, excess) was added in one portion. The reaction mixture was allowed to react 15 more min, poured on saturated aqueous NH_4Cl solution (1 L), and acidified to pH 2 with 10% aqueous HCl. The aqueous phase was extracted with ethyl acetate (3 × 500 mL). The organic phases were combined, washed with brine (1 × 500 mL), dried (Na_2SO_4), and concentrated to leave an oil which was found to consist of a mixture of 4 isomers with respective R_f on silica gel MO6F (benzene/ether, 3:1): **8***c*, 0.4; **9***c*, 0.3; **10***c*, 0.5; **11***c*, 0.22. The isomeric ratio was determined on a Waters Associates Prepak-500-Silica column (see Table 1). The same reaction was repeated on **4***c* (294 g, 0.640 mol). Crystallization of the oily residue in petroleum ether 30–60°C after work-up gave a mixture of isomers **8***c* and **9***c* as a white solid. The mother liquor was found to contain mainly isomers **10***c* and **11***c*. All four isomers were then separated by hplc to give title compounds (296.8 g, 0.589 mol) in 92% combined yield.

2. *In ether*

n-Butyllithium (15.6 mL, 1.6 *M* in hexane, 25 mmol) was added dropwise to a solution of diisopropylamine (4.0 mL, 28 mmol) in ether (150 mL) maintained at −78°C (Dry Ice – acetone bath). After 0.5 h a solution of **4***c* (9.2 g, 20 mmol) in ether (100 mL) was added dropwise; after 15 min acetaldehyde (30 mL) was added in one portion. After 1 min an aliquot (10 mL) was quenched with saturated aqueous NH_4Cl and worked up according to the above procedure (see Table 1 for the isomeric ratio). Another aliquot (10 mL) was allowed to warm up to 20°C, stirred for a 2 h period, worked up, and the isomeric ratio determined by hplc (see Table 1).

3. *With the magnesium enolate*

A solution of LDA prepared at −20°C (Dry Ice − CCl_4) from *n*-butyllithium (0.22 mL, 2.52 *M* in hexane, 0.55 mmol) and diisopropylamine (0.077 mL, 0.055 mmol) in THF (3 mL) was stirred for 15 min and cooled at −78°C. It was treated with 1-(*tert*-butyldimethylsilyl)-4-tritylthio-2-azetidinone (230 mg, 0.50 mmol). After 15 min stirring at −78°C the solution was treated dropwise with a solution of $MgBr_2$ in ether (0.224 mL, 2.45 *M*, 0.55 mmol). A precipitate was formed and the mixture was warmed in a CCl_4 − Dry Ice bath for 1 min to solubilize the solid. The clear solution was cooled again (Dry Ice − acetone bath) and acetaldehyde (0.2 mL) was added in one portion. The mixture was stirred for 15 min and worked up as above (see Table 1 for the proportion of isomers).

trans-*1-(*tert-*Butyldimethylsilyl)-3-trimethylsilyl-4-tritylthio-2-azetidinone (**19**)*

A solution of lithium diisopropylamide (25.6 mmol) was prepared at −78°C in THF (120 mL) from diisopropylamine (3.58 mL, 25.6 mmol) and *n*-butyllithium (10.1 mL, 2.52 *M* in hexane, 25.6 mmol). After 30 min at −78°C, a solution of 1-(*tert*-butyldimethylsilyl)-3-tritylthio-2-azetidinone (11.2 g, 24.4 mmol) in THF (25 mL) was added dropwise, followed after 10 min by a solution of trimethylsilyl chloride (2.78 g, 25.6 mmol) in THF (5 mL) containing a few drops (2−3) of triethylamine. After 10 min at −78°C, the clear mixture was poured onto a solution of saturated ammonium chloride (200 mL) and extracted with ethyl acetate (3 × 100 mL). The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated to leave a white solid which was recrystallized from a mixture dichloromethane−hexanes to give white cubes (11.7 g, 22.0 mmol, yield: 90%), mp 157−158°C; ir (KBr disk) ν_{max}: 1742 (s, β-lactam C=O), 840 (C—Si) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 7.9−7.3 (m, 15H, aromatics), 3.84 (d, 1H, *J* = 1.7, H-4), 3.21 (d, 1H, *J* = 1.7, H-3), 0.88 (s, 9H, *t*-Bu), 0.04 and −0.06 (2s, 2 × 3H, $Si(CH_3)_2$), −0.20 (s, 9H, $Si(CH_3)_3$). *Anal.* calcd. for $C_{31}H_{41}NOSSi_2$: C 70.00, H 7.77, N 2.63, S 6.03; found: C 70.25, H 7.91, N 2.65, S 6.10.

Carbonyl ylides and carbenes from thermolysis of oxadiazolines. Substituent effects on intramolecular and intermolecular reactions of carbonyl ylides

MICHEL BÉKHAZI AND JOHN WARKENTIN[1,2]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received June 23, 1982

MICHEL BÉKHAZI and JOHN WARKENTIN. Can. J. Chem. **61**, 619 (1983).

Thermolysis of a 2-methoxy-Δ^3-1,3,4-oxadiazoline involves loss of N_2 with formation of a carbonyl ylide. The fate of the carbonyl ylide depends on its environment and on the other substituents present. Thus, the ylides from 2-methoxy-2,5,5-trimethyl-Δ^3-1,3,4-oxadiazoline (**1**) and from 2-methoxy-2-(4-methoxyphenyl)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**2**) are trapped very efficiently by methanol. However, the ylide from **1** is trapped much less efficiently than that from **2** by dimethylacetylene dicarboxylate, *cis*-1,2-dichloroethylene, or norbornadiene. A major competitive process in the case of **1** is fragmentation of the ylide to carbonyl compounds and carbenes, the latter being trapped by alkenes to form cyclopropanes. An intramolecular 1,4-H transfer is also competitive under some conditions. The ylide from **2** does not appear to fragment, nor does it undergo the 1,4-H transfer, but it cyclizes efficiently to the oxirane in the absence of trapping agents.

Preliminary estimates of rate constants for cyclization of the ylide from **2** to form the oxirane ($k_{cycl}^{31°C} = 1.3 \times 10^6\ s^{-1}$) and for its additions to norbornadiene and to dimethylacetylene dicarboxylate ($1 \times 10^5\ M^{-1}\ s^{-1}$ and $1 \times 10^9\ M^{-1}\ s^{-1}$, respectively) are reported. If it is assumed that the ylide from **1** would add to dimethylacetylene dicarboxylate with a similar rate constant, then the yield for that process can be used to place a lower limit of $10^{10}\ s^{-1}$ on the rate constant for fragmentation of that ylide at 31°C.

MICHEL BÉKHAZI et JOHN WARKENTIN. Can. J. Chem. **61**, 619 (1983).

La thermolyse de la méthoxy-2 Δ^3-oxadiazoline-1,3,4 fait intervenir une perte de N_2 avec formation d'un ylure de carbonyle. Le sort de l'ylure de carbonyle dépend de son environnement et des autres substituants présents. Ainsi, à l'aide du méthanol, on peut piéger très efficacement les ylures provenant de la méthoxy-2 triméthyl-2,5,5 Δ^3-oxadiazoline-1,3,4 (**1**) et de la méthoxy-2 (méthoxy-4 phényl)-2 diméthyl-5,5 Δ^3-oxadiazoline-1,3,4 (**2**). Cependant on piège moins efficacement l'ylure issu du composé **1** que celui provenant du composé **2** lorsqu'on utilise comme piège les composés suivants: l'acétylènedicarboxylate de diméthyle, le dichloro-1,2 éthylène-*cis* ou le norbonène. Un processus compétitif important dans le cas du composé **1** est la fragmentation de l'ylure de carbonyle en composés carbonylés et en carbènes; ces derniers, piégés par les alcènes, conduisent aux cyclopropanes. Dans certaines conditions, un transfert intramoléculaire-1,4 d'hydrogène entre également en compétition. L'ylure provenant du composé **2** ne semble ni se fragmenter ni subir de transfert-1,4 d'hydrogène; toutefois, en l'absence de pièges, il se cyclise d'une manière efficace pour former un oxiranne.

On rapporte les évaluations préliminaires des constantes de vitesse de cyclisation de l'ylure provenant du composé **2** pour donner l'oxiranne ($k_{cycl}^{31°C} = 1,3 \times 10^6\ s^{-1}$ et pour ses additions sur le norbornadiène et sur l'acétylène dicarboxylate de diméthyle ($1 \times 10^5\ M^{-1}\ s^{-1}$ et $1 \times 10^9\ M^{-1}\ s^{-1}$ respectivement). On pense que l'ylure provenant du composé **1** peut s'additionner sur l'acétylènedicarboxylate de diméthyle avec une constante de vitesse identique; le rendement de ce processus peut alors être utilisé pour définir une limite inférieure de $10^{10}\ s^{-1}$ pour la constante de vitesse de fragmentation de cet ylure à 31°C.

[Traduit par le journal]

Introduction

The formation of carbonyl ylides from photochemical or thermal decomposition of Δ^3-1,3,4-oxadiazolines is now well established, eq. [1] (1–5). Although some of the chemistry of

[1] 
carbonyl ylides has been elucidated, including some intermolecular reactions (eqs. [2] and [3]) (1–4) and some intramolecular reactions (eqs. [4]–[6], refs. 2, 3, 6–11), very little is known about the relationships between substituents and the preferred reaction pathway.

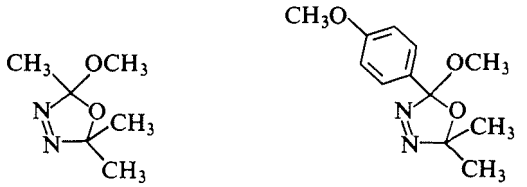
[6] 
We wish to report a comparison of the fates of the alkoxy-substituted carbonyl ylides derived from **1** and **2**. These have the potential to react, not only in accordance with eqs. [2]–[5], which are available to most carbonyl ylides, but also in accordance with eq. [6]. Fragmentation (eq. [6]) appears to require, at one reactive site of the ylide, a substituent, such as amino or alkoxy, capable of conjugative donation of electron density (2, 12).



1 **2**

Results and discussion

Oxadiazolines **1** and **2** were prepared by oxidation of appropriate acylhydrazones of acetone with lead tetraacetate in methanol, eq. [7].

2, R = p-$C_6H_4OCH_3$

*Thermolysis of **1** in methanol-d_4 and in methanol*

Decomposition of **1** in CD_3OD was monitored by ^1H nmr spectroscopy. The reaction was first order with $k^{79.5°C}_{CD_3OD} = 5.3 \times 10^{-6}$ s^{-1} and afforded a mixture of **3** and **4**, eq. [8], in the ratio **3**/**4** ≃ 3:7 (2).

[8] 
3 **4**

Acetone and methylacetate were not obtained and partial fragmentation of the ylide intermediate is therefore ruled out. Thermolysis of **1** in methanol, followed by addition of dilute aqueous HCl, resulted in partial hydrolysis of the products of thermolysis. Acetone, 1,1-dimethoxyethane, methyl acetate, and 2-propanol were found but 2-methoxypropane was not detected. This result is compatible with formation of ^1H analogues of **3** and **4** and it also rules out the intermediacy of 2-propylidene (dimethylcarbene) which would be expected to attack methanol by "insertion" into the OH bond (13–20), eq. [9].

[9] $(CH_3)_2C{:} + CH_3OH \longrightarrow (CH_3)_2CHOCH_3$

Analogous results were obtained when **2** was decomposed in methanol-d_4 at 79.5°C. The absence of acetone, methyl p-methoxybenzoate, and oxirane indicated that trapping of the carbonyl ylide intermediate was complete.

Thermolysis of **1** and **2** was also carried out in neat alkenes and in dimethylacetylene dicarboxylate (**5**) in order to compare the efficiencies of trapping of the corresponding ylides. The ylide from **2** was trapped quantitatively in the neat dipolarophile **5** at 79.5°C (eq. [10]) with formation of the dihydrofuran derivative **6**.

[10] 
5 **6**

When neat norbornadiene was employed as a dipolarophile nearly half of the ylide derived from **2** was intercepted to form **7**, although the major product was the oxirane **8** formed by cyclization of the ylide, eq. [11].

[11]

Estimates of the rate constants for the cycloadditions, and for ring closure to oxirane, were made as follows. The oxadiazoline **2** was subjected to laser flash photolysis[3] in benzene and the decay of the ylide intermediate was followed by monitoring the uv absorption after the flash. Decay followed 1st order kinetics with $k_{benzene}^{31°C} = 1.3 \times 10^6\ s^{-1}$. Since thermolysis of **2** in benzene at 79.5°C leads to oxirane in high yield, the measured rate constant must be that for cyclization. An estimate of the second order rate constant for trapping the ylide by norbornadiene at 31°C could then be made by assuming that the ratio **7**/**8** = 4:5 is independent of temperature in the range from 79.5°C to 31°C and by using 9.4 *M* for the concentration of neat diene.[4] This rough procedure gave $k_{diene}^{31°C} \simeq 1.1 \times 10^5\ M^{-1}\ s^{-1}$. Direct measurement of the rate constant for trapping of the same ylide by **5** in acetonitrile using laser flash spectroscopy[3] gave $k_5^{31°C} = 1.0 \times 10^9\ M^{-1}\ s^{-1}$. It follows that **5** is an excellent trap for ylides; at a concentration as low as $1.2 \times 10^{-3}\ M$ it would capture 50% of that ylide and permit 50% to excape by cyclization to oxirane, provided that the rate constants are not highly solvent dependent. Norbornadiene, which is a very reactive olefin, is about 4 orders of magnitude slower than **5** in this role.

Despite the high reactivity of **5**, complete trapping of the ylide derived from **1** could not be achieved with this dipolarophile. In neat **5**, only about 27% of the ylide generated from **1** was trapped as the cycloadduct **9** at 79.5°C (eq. [12]). The remaining ylide was partitioned among the intramolecular processes described in eqs. [4]–[6]. Those reactions must

[12] 
therefore be extremely fast. If cycloaddition of the ylide (eq. [12]) has a rate constant $\geq 10^9\ M^{-1}\ s^{-1}$ at 79.5°C,[5] then the yield (27%, eq. [12]) implies that the competing unimolecular processes have rate constants of the order of $10^{10}\ s^{-1}$ at 79.5°C.[6] Therefore trapping of an alkoxy trialkyl carbonyl ylide, like that from **1**, is not expected to be efficient unless the trapping agent is a very reactive species, such as **5** or triplet oxygen, present in high concentration.

Neat norbornadiene, for example, did not intercept the ylide derived from **1**, nor did tetramethylethylene or 2-methoxypropene. *cis*-1,2-Dichloroethylene (neat) proved effective in trapping about 20% of the ylide from **1**, indicating that its reactivity rivals that of **5**. These results are in qualitative accord with previously reported effects of dipolarophile substituents on the rates of 1,3-cycloadditions (22, 23). Electron-withdrawing substituents enhance an alkene's reactivity toward a dipole of the HOMO type (22, 23).

The products of ylide trapping by *cis*-1,2-dichloroethylene are shown in eq. [13]. Assignment of gross structure is based on their mass spectra and on their ^{1}H nmr spectra (Experimental section). The isomer with a two-proton singlet at δ4.30 was

[13] 
assigned structure **11**, in which the chemical shifts of the two methine hydrogens are coincidentally identical. The isomer with an AB quartet at δ4.33 and δ4.75 was assigned structure **12** because the different magnetic environments of the methine hydrogens are reasonably attributed to the *cis* methoxy group. A small coupling constant (4.9 Hz) between those hydrogens, together with evidence for the concerted character of 1,3-cycloadditions (24), was used to assign *cis*-dichloro stereochemistry to **12**. The same *cis*-stereochemistry was assigned to **11**, partly on the basis of mechanism (24) and partly on the basis of the magnetic equivalence of the methine hydrogens. If those were in a *trans* relationship, one would have to be *cis* to the methoxy group, making magnetic equivalence less likely.

An interesting conclusion can be drawn from the above estimates of rate constants for the unimolecular reactions of the ylide derived from **1**. Even if that ylide had 100% diradical character it should not be capable of atom abstraction, during its lifetime, from many substrates which are susceptible to attack by radicals. For example, abstraction of Cl from CCl_4, which has a second order rate constant of the order of $10^6\ M^{-1}\ s^{-1}$ at 80°C,[7] is probably too slow by several orders of magnitude in neat CCl_4 (ca. 10 *M*) to compete effectively with fragmentation and 1,4-H transfer.

The products formed on thermolysis of **1** in CCl_4 at 79.5°C are shown in Scheme 1, which also depicts the possible origins. Although some of the routes are speculative at this time, they are based largely on precedents such as radical pair formation

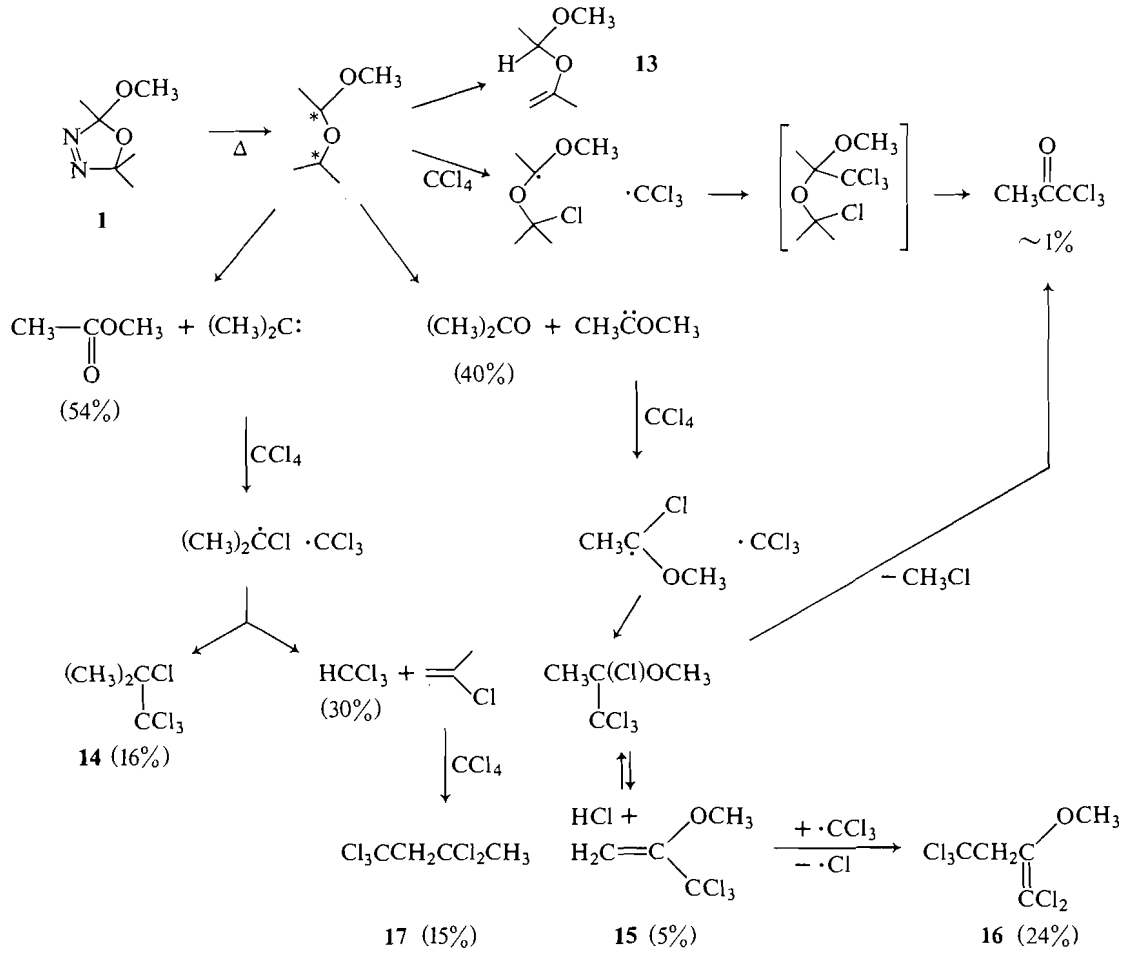
[3] We are grateful to Dr. J. C. Scaiano for running these preliminary experiments for us. A description of the apparatus can be found in ref. 21.

[4] $4(1.3 \times 10^6)[ylide] = 5\ k_{diene}[ylide] \times 9.3$ leads to $k_{diene}^{31°C} = 1.1 \times 10^5\ M^{-1}\ s^{-1}$. The assumption that the first and second order rate constants have the same temperature coefficient should not lead to serious error for a 50° change.

[5] The rate constant for trapping of the ylide from **2** with **5** is $10^9\ M^{-1}\ s^{-1}$ at 31°C (see above). That for trapping of the ylide from **1** with **5** should be at least as large at 79.5°C.

[6] $k_{unimol} \simeq \dfrac{10^9 \times 9.3 \times 73}{27} = 2.5 \times 10^{10}\ s^{-1}$.

[7] The rate constant for abstraction of Cl from CCl_4 by cyclohexyl radical is $5.5 \times 10^5\ M^{-1}\ s^{-1}$ at 80°C (25) and it should represent an upper limit for the rate constant for abstraction by the ylide from **1**, which has "tertiary" radical sites.

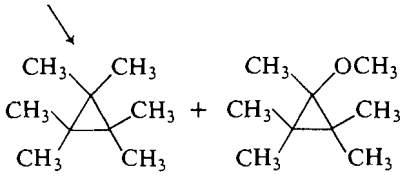


SCHEME 1

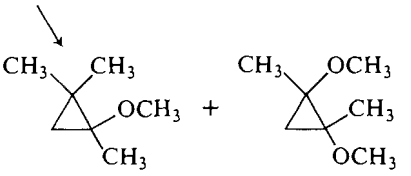
from reaction of singlet carbenes with CCl_4 (26, 27) or with hydrocarbons (28), radical pair disproportionation, ionization of α-halo ethers, and radical chain addition of CCl_4 to olefins. An exception is 1,1,1-trichloroacetone which may have arisen via unprecedented Cl-abstraction by the carbonyl ylide. That process should be slow on the time scale by which the ylide lives, as argued above, and the yield (ca. 1%) is in line with expectation.[8] Products **16** and **17**, which remained to be identified at the time of publication of our preliminary communication (2), look very much like materials derived from radical reactions of CCl_4 with alkene precursors and the route to **17** accounts nicely, in part, for the chloroform that is observed.

Additional evidence (other than that provided in Scheme 1) for the intermediacy of carbenes came from attempts to trap the ylide from **1** with alkenes. Tetramethylethylene and 2-methoxypropene failed to intercept any ylide from **1**, but gave, instead, the cyclopropanes of eq. [14] and [15]. Decomposition

[14] **1** + $(CH_3)_2C{=}C(CH_3)_2$ →



[15] **1** + $CH_2{=}C(OCH_3)CH_3$ →



of **1** in neat **5** gave, in addition to the cycloadduct from ylide trapping, a trace of a compound tentatively identified as 1,2-dicarbomethoxy-3-methoxy-3-methylcyclopropene (**10**), eq. [12]; ^1H nmr δ: 1.30 (s, 3H), 3.71 (s, 3H), 3.86 (s, 6H); ms *m/z* (fragment, %): 185 ($C_8H_9O_5$, 16), 169 ($C_8H_9O_4$, 24), 111 ($C_5H_3O_3$, 100), 83 ($C_4H_3O_2$, 12), 59 ($C_2H_3O_2$, 80). These observations tend to support the postulate of Scheme 1, that free carbenes are involved, although alternative explanations may be possible.

A complete explanation of the substituent effects on intra- and intermolecular reactions of carbonyl ylides is not possible at this time. Electronic effects on thermodynamic stabilities of the different conformations of carbonyl ylides are known (qualitatively) from theory (12) and some thermodynamic barriers to fragmentation have also been estimated (12). Steric effects on the various pathways open to a carbonyl ylide are largely unknown. Further work in this area is in progress.

Experimental

Synthesis of oxadiazoline 1

To an ice-cold solution of lead tetraacetate (44.3 g, 0.10 mol) in dry

[8] An alternative mechanism, in which 1,1,1-trichloroacetone comes from an α-halo ether, is indicated in Scheme 1.

methanol (300 mL) was added acetone-*N*-acetylhydrazone (11.4 g, 0.10 mol), with stirring. When the yellow colour of the solution was discharged, potassium hydroxide (pellets, 10 g) was added and the resulting solution was stirred at ice temperature for 2 hours. After the solution had been concentrated with a rotary evaporator, water was added and the aqueous solution was extracted with CH_2Cl_2. The organic layer was then washed with water and dried over $CaCl_2$ before the solvent was evaporated. The residue was distilled from a bulb at ambient temperature to a receiver in liquid nitrogen, at 10^{-2} Torr, after prior freeze–pump–thaw degassing. Nitrogen was bubbled through the distillate to remove a trace of dichloromethane and the residual liquid was redistilled to afford pure 2-methoxy-2,5,5-trimethyl-Δ^3-1,3,4-oxadiazoline (**1**) 8.5 g, 60%); ^{1}H nmr δ: 1.43 (s, 3H), 1.55 (s, 6H), 3.06 (s, 3H); ^{13}C nmr δ: 23.4, 24.0, 25.1, 50.4 (OCH_3), 119.9 (C-5), 133.7 (C-2); ms (CI/NH_3) *m/z*: 162 (M^+). *Anal.* calcd. for $C_6H_{12}N_2O_2$: C 49.98, H 8.39, N 19.43; found: C 50.28, H 8.39, N 19.32.

Synthesis of oxadiazoline 2

A procedure analogous to the one described above for **1** was used to oxidize acetone-*N*-(4-methoxybenzoyl)hydrazone. The crude product left after the dichloromethane had been removed under reduced pressure was chromatographed on basic alumina in a water-cooled column using 5% ether in hexane. The first fraction to elute from the column was 2-methoxy-2-(4-methoxyphenyl)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline, **2** (59% yield); ^{1}H nmr δ: 1.40 (s, 3H), 1.56 (s, 3H), 3.06 (s, 3H), 3.67 (s, 3H), 6.73 (d, 2H, J = 9.5 Hz), 7.43 (d, 2H, J = 9.5 Hz); ^{13}C nmr (−20°C) δ: 24.06, 24.50, 50.74, 55.28, 113.69, 121.81 (C-5), 127.81, 128.24, 133.22 (C-2), 160.24.

Thermolysis of 1 and 2

In a typical experiment, the oxadiazoline (20 mg) dissolved in about 0.5 mL of freshly distilled solvent, containing CH_2Cl_2 as internal standard, was sealed into an nmr tube after three freeze–pump–thaw cycles at 10^{-2} Torr. The sealed tube was then heated in an oil bath at 79.5°C. For kinetics, the tube was withdrawn from time to time and several integrals of reactant and product signals were recorded along with the integral for internal standard. Such sealed samples were also used to estimate yields of the major products by ^{1}H nmr.

Bulb-to-bulb distillation of the mixture of products was generally employed to separate solvent and volatile products from nonvolatile products. The volatile and nonvolatile fractions were then examined by nmr, gc, and gc/ms to identify the various components. Samples for nmr were collected from a gc column (10 ft × 1/4 in.) packed with OV-17 (10%) unless otherwise indicated.

Thermolysis of 2 in 5

A solution of **2** (23.6 mg, 1.0×10^{-4} mol), in freshly-distilled **5**, was heated for 7 h at 79.5°C. Bulb-to-bulb distillation separated most of the unreacted **5** from the adduct **6**. Column chromatography on basic alumina with 20% ether in CCl_4 for elution was used to purify **6**; ^{1}H nmr ($CDCl_3$) δ: 1.66 (s, 3H), 1.68 (s, 3H), 3.32 (s, 3H), 3.71 (s, 3H), 3.80 (s, 3H), 3.82 (s, 3H), 6.89 (d, 2H, J = 9.0 Hz), 7.41 (d, 2H, J = 9.0 Hz); ^{13}C nmr δ: 26.95, 50.96, 52.16, 55.08, 87.10 (C-5), 111.28 (C-2), 113.40, 128.23, 130.72, 138.62, 142.49, 159.88, 162.73, 163.09; ms *m/z* (fragment, %): 319 ($C_{17}H_{19}O_6$, 100), 260 ($C_{15}H_{16}O_4$, 25), 245 ($C_{14}H_{13}O_4$, 18), 135 ($C_8H_7O_2$, 42), 107 (C_7H_7O, 12), 77 (C_6H_5, 5).

Oxirane 8

A major product from the thermolysis of **2** in norbornadiene, tetramethylethylene, tetrachloroethylene, and ethyl vinyl ether was an oil identified as **8**; ^{1}H nmr δ: 1.02 (s, 3H), 1.54 (s, 3H), 3.21 (s, 3H), 3.84 (s, 3H), 6.93 (d, 2H, J = 9.0 Hz), 7.37 (d, 2H, J = 9.0 Hz); ^{13}C nmr δ: 20.05, 20.30, 52.50, 55.35, 67.33, 100.05, 113.81, 129.52, 131.86, 160.14; ms *m/z* (fragment, %): 208 ($C_{12}H_{16}O_3$, 6), 193 ($C_{11}H_{13}O_3$, 4), 177 ($C_{11}H_{13}O_2$, 2), 151 ($C_9H_{11}O_2$, 100), 135 ($C_8H_7O_2$, 56), 107 (C_7H_7O, 4), 77 (C_6H_5, 9).

Norbornadiene adduct 7

Bulb-to-bulb distillation removed most of the excess norbornadiene from the products, **7** and **8**. Those products were separated by tlc on silica plates (2 mm thick) using 5% ether in CCl_4. The first band contained oxirane **8** and the second consisted of **7**; ^{1}H nmr δ: 0.95–1.02 (m, 1H), 1.38 (s, 3H), 1.51 (s, 3H), 1.80–2.88 (m, 5H), 2.91 (s, 3H), 3.82 (s, 3H), 6.08 (s, broad, 2H), 6.78 (d, 2H, J = 9.0 Hz), 7.36 (d, 2H, J = 9.0 Hz); ^{13}C nmr δ: 23.93, 31.60, 42.63, 43.51, 44.17, 48.70, 55.13, 60.10, 82.02, 109.43, 113.15, 128.57, 131.86, 139.24, 159.05; ms *m/z* (fragment, %): 269 ($C_{18}H_{21}O_2$, 35), 203 ($C_{13}H_{15}O_2$, 100), 135 ($C_8H_7O_2$, 72), 107 ($C_7H_7O_3$, 8), 77 (C_6H_5, 20).

Dihydrofuran derivative 9

Adduct **9** was identified from its ^{1}H and ^{13}C nmr spectra and from its mass spectrum; ^{1}H nmr δ: 1.48 (s, 6H), 1.64 (s, 3H), 3.27 (s, 3H), 3.83 (s, 6H); ^{13}C nmr δ: 26.02, 26.60, 51.24, 53.80, 83.12, 109.39, 133.64, 141.24, 161.06, 162.88; ms *m/z* (fragment, %): 243 ($C_{11}H_{15}O_6$, 18), 227 ($C_{11}H_{15}O_5$, 18), 169 ($C_8H_9O_4$, 100), 157 ($C_7H_9O_4$, 70), 111 ($C_5H_3O_3$, 38), 109 ($C_6H_5O_2$, 7).

Cyclopropene, 10

The adduct **10**, derived from reaction of 1-methoxyethylidene with dimethylacetylene dicarboxylate, was separated from other components of the mixture of products by gc; ^{1}H nmr δ: 1.30 (s, 3H), 3.71 (s, 3H), 3.86 (s, 6H); ms *m/z* (fragment, %): 185 ($C_8H_9O_5$, 16), 169 ($C_8H_9O_4$, 24), 111 ($C_5H_3O_3$, 100), 83 ($C_4H_3O_2$, 12), 59 ($C_2H_3O_2$, 80).

Tetrahydrofuran derivatives, 11 and 12

These products were separated from excess *cis*-1,2-dichloroethylene by bulb-to-bulb distillation at 10^{-2} Torr. They were separated from one another by gc at 120°C with a 10 ft × 0.25 in. column packed with OV-17 (10%); ^{1}H nmr of **12**, δ: 1.39 (s, 3H), 1.42 (s, 3H), 1.54 (s, 3H), 3.30 (s, 3H), 4.33 (d, 1H, J = 4.9 Hz), 4.75 (d, 1H, J = 4.9 Hz); ms *m/z* (fragment, %): 197, 199 ($C_7H_{11}O_2Cl_2$; 10, 6)), 181, 183 ($C_7H_{11}OCl_2$; 40, 28), 161, 163 ($C_7H_{10}O_2Cl$; 36, 13), 145, 147 ($C_7H_{10}ClO$; 32, 10), 119, 121 (C_5H_8ClO; 100, 35), 103, 105 (C_4H_4ClO; 78, 24), 67 (C_4H_3O; 39); ^{1}H nmr of **11**, δ: 1.38 (s, 3H), 1.46 (s, 3H), 1.50 (s, 3H), 3.31 (s, 3H), 4.30 (s, 2H); ms, identical to that of **12**.

1,1,1,2-Tetrachloro-2-methylpropane (14)

The residue left after bulb-to-bulb distillation of the volatiles obtained upon thermolysis of **1** in CCl_4 was chromatographed at 100°C in a column (10 ft × 0.25 in.) packed with DEGS (10%). Product **14** was collected as a white solid which sublimed at 180°C (lit. (29) mp 178.6–179.6°C); ^{1}H nmr δ: 2.0 (s,); ms *m/z* (fragment): 159, 161, 163 ($C_4H_6Cl_3$), 123, 125 ($C_3H_5Cl_2$).

3,3,3-Trichloro-2-methoxypropene (15)

The separation described above afforded **15** as an oil; ^{1}H nmr δ: 4.00 (s, 3H), 4.52 (d, 1H, J = 4.0 Hz), 5.50 (d, 1H, J = 4.0 Hz); ms *m/z* (fragment): 174, 176, 178 ($C_4H_5OCl_3$), 117, 119, 121 (CCl_3), 57 (C_3H_5O).

1-Methoxy-1,2,2-trimethylcyclopropane (18)

This compound was isolated by gc from the products of thermolysis of **1** in 2-methoxypropene; ^{1}H nmr of **18**, δ: 0.13 (d, 1H, J = 4.9 Hz), 0.49 (d, 1H, J = 4.9 Hz), 1.07 (s, 3H), 1.18 (s, 3H), 1.36 (s, 3H), 3.27 (s, 3H); ms *m/z* (fragment, %): 114 ($C_7H_{14}O$, 3), 99 ($C_6H_{11}O$, 100), 83 (C_6H_{11}, 4), 67 (C_5H_7, 24).

trans-*1,2-Dimethyl-1,2-dimethoxycyclopropane (20)*

The products of thermolysis of **1** in 2-methoxypropene included this compound which was isolated by gc; ^{1}H nmr δ: 0.54 (s, 2H), 1.43 (s, 6H), 3.27 (s, 6H); ms *m/z* (fragment, %): 130 ($C_7H_{14}O_2$, 1), 115 ($C_6H_{11}O_2$, 100), 99 ($C_6H_{11}O$, 22), 83 (C_5H_7O, 10), 67 (C_5H_7, 13), 51 (C_4H_3, 4).

Hexamethylcyclopropane and methoxypentamethylcyclopropane

These compounds were isolated by gc from the products of thermolysis of **1** in tetramethylethylene. Hexamethylcyclopropane: ^{1}H nmr δ: 0.96 (s) (lit. (30) 0.94 (s)); ms *m/z* (fragment, %): 126 (C_9H_{18}, 15), 111 (C_8H_{15}, 100), 69 (C_6H_9, 29). 1-Methoxy-1,2,2,3,3-pentamethyl-

cyclopropane: ^{1}H nmr δ: 1.09 (s, 6H), 1.21 (s, 6H), 1.41 (s, 3H), 3.23 (s, 3H); ms *m/z* (fragment, %): 142 ($C_9H_{18}O$, 2), 127 ($C_8H_{15}O$, 100), 111 (C_8H_{15}, 13), 95 (C_7H_{11}, 23), 69 (C_6H_9, 7).

Transfer thermodynamics of *p*-nitroaniline in aqueous solutions of some ionic and non-ionic cosolvents and the structuredness of the solvents

JAYATI DATTA[1] AND KIRON K. KUNDU[2]

Physical Chemistry Laboratories, Jadavpur University, Calcutta - 700 032, India

Received June 30, 1982

JAYATI DATTA and KIRON K. KUNDU. Can. J. Chem. **61**, 625 (1983).

Standard free energies (ΔG_t^0) and entropies (ΔS_t^0) of transfer of *p*-nitroaniline (*p*NA) from water to aqueous mixtures of some ionic and non-ionic cosolvents like KBr, urea (U), propylene glycol (PG), glycerol (GL), dioxane (D), and 1,2-dimethoxyethane (DME) have been determined from solubility measurements at different temperatures. The observed ΔG_t^0–composition profile in KBr solution appears to result from the well known salting-out effect of the salt and those in aqueous poly-ols and ethers are the result of the combined effects of dispersion and "acid–base" type interactions but that in aqueous urea solutions is governed by the "salting-out" type interaction by the predominant zwitterionic form of urea. The observed $T\Delta S_t^0$–composition profiles as well as those obtained after correcting for the "cavity-effect", as estimated tentatively by the scaled particle theory (SPT), were examined in the light of Kundu *et al.*'s semi-quantitative theory proposed earlier. The latter profiles suggest that unlike isopropyl alcohol (IPA), the poly-ols and ethers as well as KBr and urea induce structure breaking of three dimensional (3D) water structure right from the initial compositions. Moreover, the observed "roller-coaster" type behaviour of the profile in aqueous urea is indicative of the effect of urea–water aggregation around 4–10 *m* urea. Also, the observed graded reduction of structure-promoting effect of IPA in PG and GL cosolvent systems confirms that structuring and destructuring ability of a cosolvent depends on the ratio of hydrophobicity to hydrophilicity of the cosolvent.

JAYATI DATTA et KIRON K. KUNDU. Can. J. Chem. **61**, 625 (1983).

A partir des mesures de solubilité à différentes températures, on a déterminé les énergies libres et les entropies de l'état normal (ΔG_t^0) et (ΔS_t^0) de transfert de la *p*-nitroaniline (*p*NA) de l'eau aux mélanges aqueux de quelques cosolvants ioniques et non ioniques tel le HBr, l'urée (U), le propylèneglycol (PG), le glycérol (GL), le dioxanne (D) et le diméthoxy-1,2 éthane (DME). Le profil de composition vs. ΔG_t^0 observé dans une solution de KBr semble provenir de l'effet de relargage bien connu du sel et celui observé dans les polyols et dans les éthers aqueux est le résultat des effets combinés de dispersion et des interactions du type "acide base"; toutefois celui observé pour les solutions aqueuses d'urée est gouverné par une interaction de type relargage provoquée par la forme zwittérionique prédominante de l'urée. On a examiné les profils de composition vs. $T\Delta S_t^0$ observés ainsi que ceux obtenus après corrections pour "l'effet de cavité" tels qu'évalués par la théorie de la particule à l'échelle (TPE) à la lumière de la théorie semiquantitative proposée antérieurement par Kundu *et al.* Les derniers profils suggèrent que contrairement à l'alcool isopropylique (AIP), les polyols et les éthers ainsi que le KBr et l'urée induisent une rupture de la structure tridimensionnelle (3D) de l'eau directement à partir des compositions initiales. De plus, le comportement de type "montagnes russes" du profil dans l'urée en solution aqueuse est une indication de l'effet d'agrégation urée–eau entre 4–10 *m* d'urée. La réduction graduelle observée de l'effet d'activation de la structure de l'AIP dans les systèmes de cosolvant de PG et de GL confirme également que la capacité de structurer et de déstructurer d'un cosolvant dépend du rapport de l'hydrophobicité/hydrophillicité du cosolvant.

[Traduit par le journal]

Introduction

It is now well recognised that transfer enthalpies and entropies of electrolytes and non-electrolytes often provide useful information regarding the relative structuredness of solvents. In fact, transfer enthalpies, ΔH_t^0, and entropies, ΔS_t^0, of various solutes have been found (1–5) to pass through maxima at certain critical compositions of aqueous aliphatic mono-ols, which are believed to stem from enhancement and subsequent breakdown of three dimensional (3D) tetrahedral structure of water (4) in the solvents. In a series of papers (6), we have examined the observed characteristic maxima of ΔS_t^0 of hydrogen halides (HX) in aqueous mono-ols in the light of "four-step transfer process" (7) and demonstrated from a semi-quantitative theory (6) that ΔS_t^0 (HX) might serve as a structural probe. But in view of the fact that electrostatic effect accompanying the transfer of HX is likely to confuse the issue, we have also extended these studies with some suitable non-electrolytes like benzoic acid (HBz) (8) and *p*-nitroaniline (*p*NA) (9) as probes. In fact, by adopting a logical model of these amphiphilic solutes and introducing appropriate modifications of the "four-step transfer process", we have demonstrated (8, 9) that ΔS_t^0 of these non-electrolytes as well might serve as suitable structural probes. Very recently (10), however, when we applied ΔS_t^0 of HBz as a structural probe in various aqueous ionic and non-ionic cosolvents like LiCl, KBr, D, acetonitrile (ACN), PG, and GL, it appeared that the conclusions derived for these non-ionic cosolvents are at variance not only with those obtained from earlier studies but also with that expected from structural and electronic consideration. But when ΔS_t^0's were corrected for the "cavity-effect" ΔS_t^0(cav), as estimated by use of the scaled particle theory (SPT) (11, 12), and the resultant "interaction effect" (12) ΔS_t^0(int) when examined in the light of our theory, impart the expected structural conclusions regarding these cosolvent systems. It has been therefore concluded that "cavity effect" significantly contributes to the observed ΔS_t^0 at least in the case of large-sized non-electrolytes like HBz, and that the rest ΔS_t^0(int) being appertained more to the theory, gives a better reflection of the

[a]The a, b, c values were obtained from the reported values of the coefficients of equation used in ref. 9.

solvent structural features relative to that in water. In view of this, it seems highly imperative to check if this contention is true in the case of pNA as well.

We therefore report here the parallel studies with pNA as a probe in aqueous solutions of various ionic and non-ionic cosolvents like KBr, U, D, DME, PG, and GL. As in the case of HBz, the choice of KBr rests on the fact that being a hydrophilic electrolyte, it is a well known "electrophilic" structure breaker (13) of 3D water structures, the behaviour of $\Delta S_t^0(p\text{NA})$ will be reverse to that in aqueous mono-ols, which are well known 3D water structure makers at initial compositions. And this will then offer an extra confidence to the applicability of $\Delta S_t^0(p\text{NA})$ as a structural probe. Again, it is well known that since structuredness of urea–water solutions is a "hot topic" (refs. 14, 15 and relevant cross references therein and in ref. 16) from the point of biochemical interests. So it has been extensively studied from various angles including $\Delta S_t^0(\text{HX})$ (16a), relative entropies of ionization of water, $\delta(\Delta S_{ion}^0)$ (16b) and $\Delta S_t^0(\text{HBz})$ (8). It should be of particular interest to check if the structural information derived from the present study tallies with those derived from our previous studies in particular. Aqueous solutions of others like D and DME and poly-ols like PG and GL are similar. The latter two cosolvent systems are particularly relevant since the results of these two solvents with graded increase of hydrophilic group from mono-ol IPA to di-ol PG and thence to tri-ol GL are likely to substantiate the earlier (10, 17, 18) contention that an increase in hydrophilicity or H-bonding sites of cosolvents decreases the stabilization of 3D structures of water.

As in our previous papers (8–11), we have evaluated the transfer free energies (ΔG_t^0) and entropies (ΔS_t^0) of pNA from water to the aqueous mixtures of the above-noted ionic and non-ionic cosolvents from the measured solubilities of pNA at seven equidistant temperatures ranging from 5 to 35°C.

Experimental

The quality and methods of purification of the solvents D (18), DME (18), PG (19), and GL (19) have been described. Urea (BDH, AR) was used (16) without further purification, as before. KBr (Merck, GR) was used after drying *in vacuo*. Water used was triply distilled. pNA (Reidel) was used after recrystallizing twice from 75% ethanol and then drying *in vacuo*, as before (9).

The method adopted for the measurement of solubility of pNA in different solutions was essentially similar to that described earlier (9). The saturated solutions were diluted with water as required. Absorbance values of these solutions were determined as 380 nm by use a Perkin Elmer (Model 200) spectrophotometer. As before (9), the molar extinction coefficient of pNA in the diluted solutions was taken to be that in pure water, viz. 1.28×10^4, as the diluted solutions are practically aqueous bereft of the effect of the cosolvents present. Saturation at a given temperature was attained in all the solvents within 7–10 days. The maximum uncertainties in the measured solubilities are about ±1%.

Results

The observed molar solubilities (S) of pNA at different temperatures in different solvents as well as in pure water are given elsewhere.[3] Notably, except in 50 wt.% D and DME mixtures, solubilities of pNA in most other solvents lie below 0.1 m. So, as in previous cases (8–10), assuming the effect of activity coefficient factor to be negligibly small, the free energies of solutions (ΔG_s^0) of pNA at different temperatures were calculated on molar scale using the relation

$$[1] \quad \Delta G_s^0 = -RT \ln S$$

These were then fitted by the method of least squares to an equation of the form

$$[2] \quad \Delta G_s^0 = a + bT + cT \ln T$$

where T is the absolute temperature. The values of the coefficients a, b, and c are presented in Table 1. These reproduce the experimental data to within ±0.02 kJ. The free energies (ΔG_t^0) and entropies (ΔS_t^0) of transfer of pNA from the standard state in water to that in the solvent at 25°C were calculated on mole fraction scale using relations [3] and [4], respectively.

$$[3] \quad \Delta G_t^0 = {}_s\Delta G_s^0(p\text{NA}) - {}_w\Delta G_s^0(p\text{NA}) = -RT \ln S_s/S_w - RT \ln M_s\rho_w/M_w\rho_s = (a_s - a_w) + (b_s - b_w)T + (c_s - c_w)T \ln T - RT \ln M_s\rho_w/M_w\rho_s$$

$$[4] \quad \Delta S_t^0 = (b_w - b_s) + (c_w - c_s) + (c_w - c_s) \ln T + R \ln M_s\rho_w/M_w\rho_s + RT\left[\frac{d \ln \rho_w}{dT} - \frac{d \ln \rho_s}{dT}\right]$$

where T = 298.15 K, M, ρ, and d ln ρ/dT terms are appropriate molar mass, density, and temperature coefficients of $\log_e$ (density) of the solvents, respectively, and the subscript s refers to the solvent mixtures and w to water. The required densities of the solvents were taken from the literature given in Table 2 and those for d ln ρ/dT at 298.15 K were obtained from the slopes of the plots of ln ρ vs. T at that temperature. ΔG_t^0 and ΔS_t^0 values are presented in Table 1. The maximum uncertainties in these quantities as calculated by Please's method (20) are ±0.03 kJ mol^{-1} and ±2 J K^{-1} mol^{-1}, respectively.

Discussion

Transfer free energies

Figure 1 shows the variations of ΔG_t^0 of pNA with mol% of cosolvents including that for IPA + water system taken from our previous paper (9) for the sake of comparison. While the profiles for aqueous solutions of KBr as well as urea become increasingly positive, those for other aquo-organic mixtures become increasingly negative and at any composition the relative order of $|-\Delta G_t^0|$ is D > DME ≫ IPA > PG > GL.

The observed increased destabilization of pNA with increased proportion of ionic cosolvent KBr though conforms with the expected well known salting-out effect (21) that in urea–water mixtures seems to be somewhat intriguing. Now, as indicated in our previous paper (9), the most important contributor of pNA is the zwitterionic form:

And, since the "acid–base" interactions (22) through $=\overset{+}{N}H_2$ and $=NO_2^-$ charge centres of pNA and the "acid–base" centres of cosolvent molecules or their aquo-complexes (22) are likely to be nullified, the overall stabilization of pNA should be guided chiefly by dispersion interactions through the aromatic nucleus. The observed order of $|-\Delta G_t^0|$ of pNA viz. IPA > PG > GL also confirms this, as the hydrophobicity of these cosolvents dictating dispersion interactions also decreases in the same order.

Evidently, the observed order of stabilization of pNA in aqueous aprotic and protic cosolvents, viz. D + water > IPA + water, seemingly suggests that the effect of dispersion interaction of D and DME exceeds that of protic cosolvents like IPA, PG, and GL, as is expected from the larger polarisability and hydrophobicity of the aprotic cosolvents compared to that of the protic cosolvents. Moreover, while the hydrophobicity of DME molecule with $2CH_3$-groups is likely to be more than that of D, the flexibility of CH_3-induced negatively charged ethereal O-centres makes DME molecules more hydrophilic than D (18) and thus compensates the hydrophobic effect to a large extent. It seems that the lesser acidity of DME + water mixtures dictates their relative position.

But, as indicated in our previous papers (8, 16), in urea–water mixtures the predominant zwitterionic form of urea molecule probably makes the solvents increasingly more basic as well as more acidic compared to water. The observed increasingly negative values of $\Delta G_t^0(H^+)$ (16*b*, 23) and $\Delta G_t^0(OH^-)$ (16*b*) based on tetraphenylarsonium tetraphenylboride (Ph_4AsPh_4B) reference electrolyte assumption (24) also confirm the same. Consequently, the acid–base type interactions of pNA through $=\overset{+}{N}_2$ and $=NO_2^-$ charge centres would have caused increased stabilization of pNA. Again, recent studies have shown that although urea is an organic molecule, but possibly because of the effect or predominant zwitterionic form it shows little tendency to undergo such dispersion interaction with aromatic nucleus (8), e.g. its ability to stabilize the large Ph_4As^+ is insignificant compared to dimethyl sulphoxide or alcohols (23), and benzoic acid (8) is only slightly more stabilized in urea + water mixtures than in pure water, despite the fact that stabilization of —COOH group is more in urea + water mixtures than in water. Evidently, increased destabilization of pNA in aqueous urea solutions is an involved problem. Possibly, the predominant zwitterionic form of urea molecules capable of engaging three water molecules through 3 H-bond centres (25, 26) exerts a "salting-out" type effect on pNA molecule as ions do in salt solutions. Apparently, the same is true for HBz (8) in aqueous urea solutions. But the effect of stabilization of —COOH group by more basic aqueous urea possibly overcomes the "salting-out" type effect of zwitterionic form of urea and makes ΔG_t^0(HBz) values slightly negative, as observed (8).

Transfer entropies

Figure 2 shows the observed $T\Delta S_t^0$ composition profiles of pNA for the aqueous mixtures of these ionic and non-ionic cosolvents along with that of IPA (9). Notably, as in the case of HBz (10), the profile of pNA for the salt solutions moves increasingly downward with a hump around 2 to 6 mol% KBr, while that for the urea solutions exhibits a "roller-coaster" type behaviour — with a broad minimum around 3–4 mol% U followed by a maximum around 8 to 10 mol% U. But the

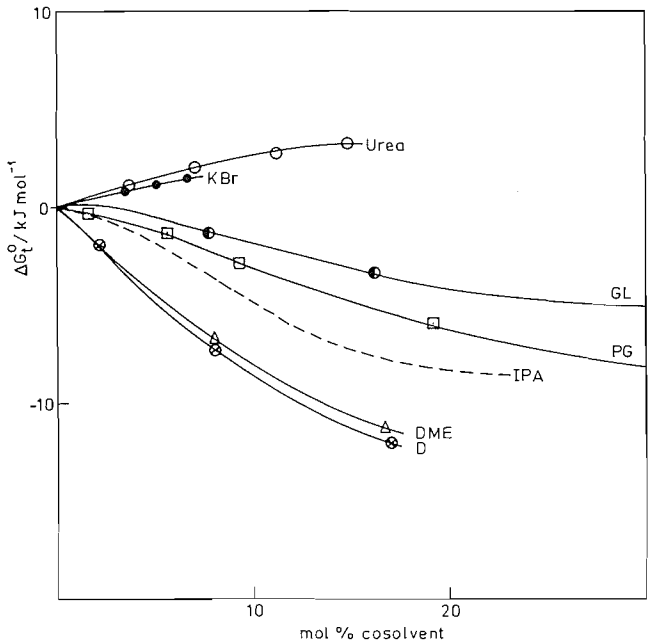

FIG. 1. Variation of ΔG_t^0 of *p*NA with composition in aqueous mixtures of different ionic and non-ionic cosolvents at 25°C.

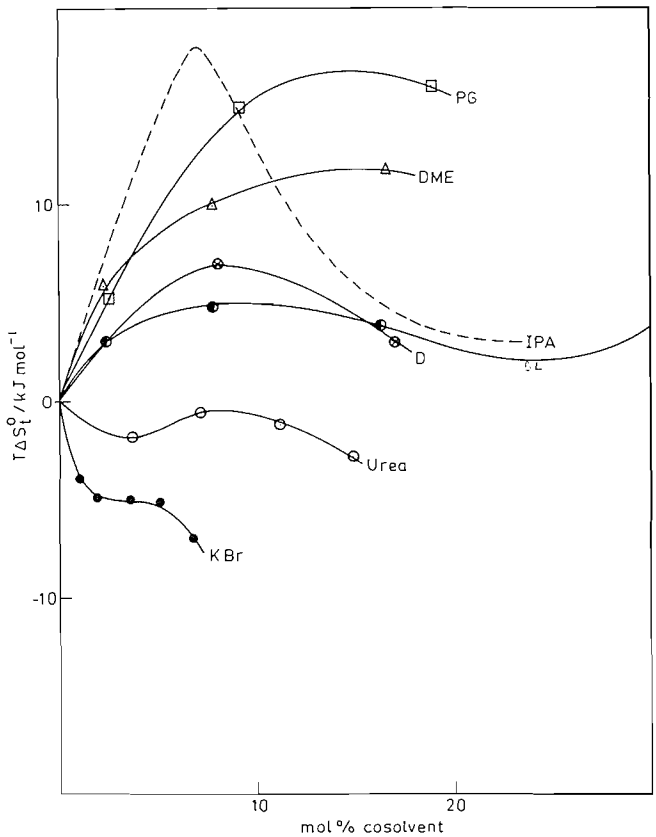

FIG. 2. Variation of $T\Delta S_t^0$ of *p*NA with composition in aqueous mixtures of different ionic and non-ionic cosolvents at 25°C.

profiles for other organic cosolvent systems pass through the characteristic maxima, though fairly broad ones as compared to those for mono-ols, as have been observed in the case of HBz.

If the dictates of the semi-quantitative theory proposed in the previous paper (9) referred to earlier be taken as a guide, then the observed sharply downward trend of $T\Delta S_t^0$–composition profile in KBr solutions is as expected the result of 3D structure-breaking propensity of the salt. Also, the observed hump in the profile is possibly the effect of superimposition of the electrophilic structural order induced by hydration of K^+ and the observed downward trend thereafter is possibly the effect of packing imbalance caused by the shortage of interstitial spaces with the increased proportion of the cosolvent, as is true in other cases. Notably, exactly similar behaviour has also been observed in the case of HBz. Similarly, the initial downward trend of the profile in aqueous urea solutions is indicative of the effect of structure-breaking propensity of urea. This is also in accord with our earlier contention (9, 16*b*) that urea molecules, being sterically debarred from entering the tetrahedral structure of water, occupy interstitial spaces forming a regular solution (27) and thus induce the breakdown of 3D structures of water. The observed broad maximum around 8 to 10 mol% urea is again indicative of the introduction of some structural order in the solvent possibly by the formation of urea–water aggregates (8, 16*b*, 28, 29). The downward trend thereafter is possibly the effect of "packing imbalance", as usual.

On the other hand, according to the tenets of the said theory the observed maxima in $T\Delta S_t^0$–composition profiles for the other aquo-organic cosolvents appear to suggest that, like IPA, all these cosolvents viz. D, DME, PG, and GL promote the 3D structures of water at initial compositions and break down the same at higher compositions due to "packing imbalance". Moreover, the relative behaviour of the profiles in aqueous PG and GL systems compared to that in IPA system is more or less similar to that observed in the case of HBz in these solvent systems and of HX in aqueous ethylene glycol (EG) and GL solvent systems (19). This seemingly confirms our earlier contention that the "structure-promoting" ability of hydrophobic —CH_3 groups in IPA is somewhat reduced due to "specific site hydration effect" (19, 30) when these are successively replaced by partially hydrophilic —CH_2OH groups, as in PG and GL.

However, contrary to the conclusions noted above, various studies (see the appropriate references given in refs. 18, 31) including our recently observed $T\Delta S_t^0$(HX) (18) or transfer entropies of ionization of water $T\delta(\Delta S^0)$ and $T\Delta S_t^0(H_2O)$ derived thereof (31), in D + water and DME + water mixtures have indicated that unlike IPA, D and DME induce 3D structure breaking right from the initial compositions. Moreover, the relative positions of these profiles in D + water and DME + water mixtures are also at variance with those for ΔY_t(HX) $[\equiv \Delta S_t^0(H^+) + \Delta S_{t,ch}^0(X^-)]$ where $\Delta S_{t,ch}^0$ is the non-Born or chemical contribution (18), and also with the expected relative structure-breaking effect of these cosolvents, which is larger in DME than D. These observations substantiate our earlier contention derived from HBz (10) as a probe that there is a missing point in our semi-quantitative treatment for the larger-sized amphiphilic solutes like HBz (8) or *p*NA (9).

In fact, as indicated by various authors (12, 32, 33) including us (10), ΔS_t^0 is effectively composed of two parts: one part ΔS_t^0(cav) is associated with the creation of a cavity of suitable size to accommodate the solute and the other part ΔS_t^0(int) is associated with the interactions of the solvent molecules surrounding the cavity among themselves as well as the solute, both relative to that in water, i.e.

$$[5] \quad \Delta S_t^0 = \Delta S_t^0(\text{cav}) + \Delta S_t^0(\text{int})$$

So, as contended by us earlier (10), the missing point in our

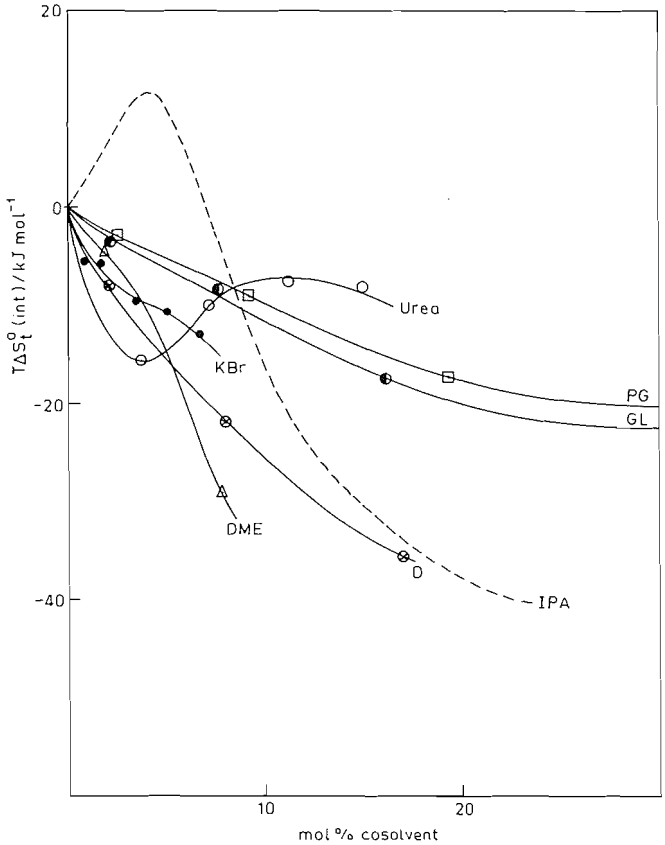

FIG. 3. Variation of $T\Delta S_t^0$(int) of *p*NA with composition in different ionic and non-ionic cosolvents at 25°C.

theory is that these amphiphilic solutes, being somewhat larger in size, at least compared to HX etc., the entropy changes due to cavity formation might significantly contribute to the observed ΔS_t^0 values.

Following a similar procedure as in HBz (10), we have tentatively computed the molar free energy $\bar{G}$(cav), enthalpy $\bar{H}$(cav), and entropy $\bar{S}$(cav) of formation of a cavity of diameter of equivalent hard sphere of *p*NA molecule[4] in water and the aqueous cosolvents including IPA, using Desrosiers' SPT relations (12). The hard sphere diameter of water has been taken as 0.276 nm (32*b*) and those for other cosolvent molecules/ions have been either taken from literature (see Table 2) or computed by Farrell's method (35). The required values of α, the coefficients of thermal expansion of the solvents, were obtained from literature or from the slopes at 25°C of the plots of $-$ log (density) versus temperature in the solvents (see Table 2). The essential parameters so computed: $\bar{G}$(cav), $\bar{H}$(cav), $\bar{S}$(cav), and ΔS_t^0 [$\equiv_s \bar{S}$(cav) $-$ $_w\bar{S}$(cav)] for different solvent systems are presented in Table 2. Significantly enough, ΔS_t^0(int) values as obtained by subtracting the ΔS_t^0(cav) values from the corresponding experimentally observed ΔS_t^0 values, show an exactly similar pattern as has been observed in the case of HBz. Thus, as could be seen from Fig. 3, while $T\Delta S_t^0$(int)–composition profile for IPA–water system still retains the "characteristic maxima", those for all the organic cosolvent systems take downward trends right from the initial composition. The corresponding profile for KBr solution takes more downward trend than that of $T\Delta S_t^0$–composition profile. Thus it confirms that it is the $T\Delta S_t^0$(int)–composition profiles rather than the $T\Delta S_t^0$–composition profiles which are in accord with the dictates of our earlier theory and that it is ΔS_t^0(int) which should really stand for the overall entropy changes involved in the "four-step transfer process" (9, 13) at least for larger sized solutes.

Thus, as contended in the case of HBz, if the characteristic maxima of ΔS_t^0(int)–composition profile of IPA + water mixture be taken to stem from the 3D structure-promoting propensity of IPA, and the downward trend right from the initial composition in salt solution like KBr be taken as the result of 3D structure-breaking effect of the salt, then the observed downward trends of the corresponding profiles in other aquo-organic solvents can be taken as the reflection of the structure-breaking propensities of the organic cosolvents. Strikingly enough, the relative positions of these profiles in D + water and DME + water mixtures get reversed and hence suggest that DME is a more effective structure breaker than D, as is expected from intrinsic and structural features of the cosolvent molecules. The observed initial inverse behaviour of these profiles, however, is possibly the Born-type electrostatic effect on the zwitterionic form of *p*NA, for at this region dielectric constant effects of DME + water mixtures are inverse that of D + water mixtures (18).

Similarly, the pronounced roller-coaster behaviour of ΔS_t^0(int) profiles in urea–water mixtures also substantiates the earlier contention that urea is an effective 3D water structure breaker right from the initial composition but induces some structural order due to the possible formation of urea–water aggregates around 4–10 mol% U, as indicated earlier.

Again, the relative positions of the ΔS_t^0(int) profiles in aqueous mixtures of IPA, PG, and GL systems are also indicative of the fact that the structuring effect of 2 CH_3— groups in IPA is so much reduced by the successive replacement of —CH_3 groups by partially hydrophilic —CH_2OH groups that while PG is a moderate structure breaker, GL is a fairly strong one. This is also expected from the "specific-site" hydration effect of the increasing —OH groups of the latter cosolvents (19).

Thus the results of the present studies fully support the earlier contention that structuring and destructuring ability of a cosolvent depends upon the effective ratio of hydrophobicity to hydrophilicity of the cosolvents. Increase of hydrophobic sites shifts the equilibrium $(H_2O)_{bulky} \leftrightarrow (H_2O)_{dense}$ towards left and increase of hydrophilicity towards right.

[4]The diameter of the equivalent hard sphere of *p*NA molecule was taken to be 0.72 nm as has been tentatively estimated from the structural geometry of the molecule taking the appropriate bond lengths and bond angles etc. from Pauling's monograph (34). Notably, the diameter of the solute is not that sensitive a parameter as the diameters of cosolvent molecules (11, 12, 35) are.

Coupling of allylic pivalates with lithium and magnesium organocopper reagents. Reversal of regiochemistry

HSING-JANG LIU AND LI-KANG HO

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 21, 1982

HSING-JANG LIU and LI-KANG HO. Can. J. Chem. **61**, 632 (1983).

Allylic pivalates undergo efficient coupling with both lithium diorganocuprates and RMgX–CuI (2:1) complexes resulting in the predominant formation of the "S_N2"-type and the "S_N2'"-type products respectively.

HSING-JANG LIU et LI-KANG HO. Can. J. Chem. **61**, 632 (1983).

On décrit des réactions efficaces de couplage de pivalates allyliques à des diorganocuprates de lithium ainsi qu'à des complexes RMgX–CuI (2:1) qui conduisent à la formation prédominante de produits de type "S_N2" et "S_N2'" respectivement.

[Traduit par le journal]

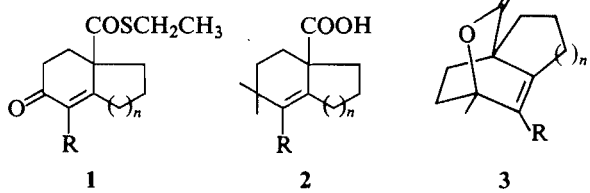
During the course of our recent studies on the synthetic application of thiol esters (1), it was observed that conjugated enones possessing the general structure **1** reacted readily with lithium dimethylcuprate leading directly to compounds of type **2**. Further investigation revealed that the unusual replacement of the ketone carbonyl with a *gem*-dimethyl group occurred via the lactone intermediate **3** which was shown by independent experiments to couple with lithium dimethylcuprate with remarkable efficiency in spite of the steric congestion at the site of reaction. Extrapolation of these results suggested that allylic pivalates might possess interesting properties in coupling with organocuprates.[1] We wish to report here a study of such coupling with organocuprates.



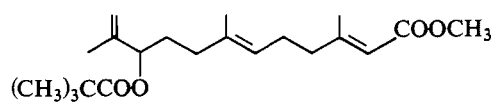
1 **2** **3**

R = H or CH_3; n = 1 or 2

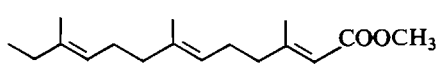
In accordance with our expectations, allylic pivalates were found to react smoothly with lithium diorganocuprates as well as with RMgX–CuI (2:1) complexes under mild conditions, giving rise to coupling products in high yields. In a typical experiment involving lithium diorganocuprate, a solution of alkyllithium (6 mmol) was added with stirring to a suspension of freshly recrystallized (3) cuprous iodide (3.6 mmol) in ether (20 mL) at 0°C under an argon atmosphere. After 10 min, the mixture was chilled to −40°C and a solution of the allylic pivalate (1 mmol) in ether (5 mL) was introduced. The reaction was monitored by tlc. Upon completion (1–4 h), the reaction mixture was acidified with 1 *N* aqueous hydrochloric acid and extracted with ether. Work-up of the extracts in the usual manner gave the crude product which was purified by column chromatography on silica gel and/or by Kugelrohr distillation. With the magnesium cuprates, the reactions were carried out in a similar fashion except that a molar ratio of 6:3:1 was used for alkylmagnesium halide (in place of alkyllithium), cuprous iodide,[2] and the reactant and the reaction temperature was maintained at 0°C throughout. Several reactions attempted at −40°C failed.

Table 1 summarizes the results obtained. The allylic pivalates examined included both the primary and the secondary ones with the double bond substituted in various patterns.[3] In principle, an allylic pivalate could couple with a diorganocuprate in two different ways, involving either the α-carbon bearing the pivaloxy group to give the "S_N2"-type product or the γ-carbon with simultaneous migration of the double bond to give the "S_N2'"-type product. Experimental results showed that the coupling proceeded with a high degree of regioselectivity with both the lithium and the magnesium-containing reagents. More interestingly, a complementary mode of selectivity was displayed by these two types of reagents. With lithium diorganocuprates, the general mode is the displacement at the α-carbon as indicated by the predominant formation of the "S_N2"-type product in all the reactions studied except one (Entry 9) in which the double bond of the allylic pivalate

[1]In an isolated case (cf. ref. 2, Table 1), allyl pivalate **i** was shown to couple with lithium dimethylcuprate giving triene ester **ii** as the major product.



i



ii

[2]The reactions were less effective when smaller amounts of cuprous iodide were used.

[3]These pivalates were readily prepared from the corresponding alcohols by esterification with pivaloyl chloride (1.5 equiv.) and pyridine (1.2 equiv.) in ether at room temperature. We have also attempted to examine the 3° allylic pivalates but have not been able to make these substrates effectively due to their instability; numerous attempts to esterify 3-methyl-4-cholesten-3-ol and *trans*-2-methyl-3-decen-2-ol resulted consistently in the formation of the dehydration products in major quantities.

TABLE 1. Coupling of allylic pivalates with lithium and magnesium organocopper reagents

Entry	Allylic pivalate R = $COC(CH_3)_3$	Reagents	Time[b] (h)	Product(s) (ratio[c])		% Yield
1		*n*-BuLi/CuI	2			100
2		*n*-BuMgBr/CuI	1		(1:3)	95
3		EtLi/CuI	2	 [a]		95
4		EtMgBr/CuI	1.5	[f]	(1:4)	100
5		*n*-BuLi/CuI	2	 [a]		100
6		*n*-BuMgBr/CuI	1	 [f]	(1:6)	99
7		MeLi/CuI	2[e]	 [a]		90
8		MeMgI/CuI	8.5[d]	 [f]	(1:6)	65
9		*n*-BuLi/CuI	1		(6:1)	92
10		*n*-BuMgBr/CuI	1		(2:1)	92
11		MeLi/CuI	4	 [f]	(7:1)	62
12		MeMgI/CuI	3	 [g]	(1:6)	97
13		*n*-BuLi/CuI	2			92
14		*n*-BuMgBr/CuI	1		(1:11)	73
15		*n*-BuLi/CuI	2		(2.2:1)	81
16		*n*-BuMgBr/CuI	1.5		(1.5:1)	86

[a] $E:Z \simeq 2.5:1$.
[b] Unless otherwise stated, reactions were carried out according to the general procedures described in the text.
[c] This reaction was performed at −20°C.
[d] This reaction was performed at room temperature.
[e] The ratios of products were determined by nmr (^1H and ^{13}C) and/or gc analyses.
[f] The ratio of the two geometric isomers could not be determined with reasonable accuracy.
[g] $E:Z \simeq 15:1$.

system is terminal.[4] With the magnesium organocopper reagents, the major product obtained without any exception was found to be that resulting from γ-attack. It is also noteworthy that the double bond geometry remained intact whenever the reaction proceeded via α-substitution (Entries 1, 2, 11, and 12).

The ability of allylic pivalates to undergo efficient coupling with both the lithium and the magnesium organocopper reagents with reversal of regiochemistry promises to have broad synthetic utility. Other allylic esters[5] so far explored often show inconsistent and thus rather unpredictable regioselectivity when subjected to coupling with lithium organocopper reagents and in general do not couple effectively with magnesium organocopper reagents. This is further substantiated by the following experiments. Farnesyl acetate was treated with ethylmagnesium bromide – cuprous iodide (2:1) complex under the same conditions used for the corresponding pivalate (Entry 4). Upon completion of the reaction (1 h), 3-ethyl-3,7,11-trimethyl-1,6,10-dodecatriene and 2,6,10-trimethyl-2,6,10-tetradecatriene were isolated in 4:3 ratio and in 27% total yield. Similarly, treatment of farnesyl acetate with *n*-BuMgBr – CuI (2:1) complex gave a total of 43% yield of two coupling products, 2,6,10-trimethyl-2,6,10-hexadecatriene and 2,6,10-trimethyl-10-vinyl-2,6-tetradecadiene in a ratio of 4:3. These results are considerably inferior to those obtained for farnesyl pivalate (Entries 4 and 6) in terms of yield and regioselectivity.

[4]This finding is in agreement with a previous observation cited in footnote 1.

[5]For a recent review on coupling reactions of allylic esters, see ref. 4.

Total synthesis of the C-3 – C-17 segment of boromycin[1]

Stephen Hanessian, Daniel Delorme,[2] Peter C. Tyler, Gilles Demailly, and Yves Chapleur

Department of Chemistry, University of Montreal, Montreal, P.Q., Canada H3C 3V1

Received November 30, 1982

Stephen Hanessian, Daniel Delorme, Peter C. Tyler, Gilles Demailly, and Yves Chapleur. Can. J. Chem. **61**, 634 (1983).

The C-3 – C-17 segment of boromycin having five asymmetric centers was synthesized from D-arabinose and D-glucose as chiral precursors. Constitutional and stereochemical identity was established by comparison of the synthetic product with a sample obtained from the degradation of the antibiotic.

Stephen Hanessian, Daniel Delorme, Peter C. Tyler, Gilles Demailly et Yves Chapleur. Can. J. Chem. **61**, 634 (1983).

Le segment C-3 – C-17 de la boromycine comprenant cinq centres asymmétriques a été synthétisé à partir du D-arabinose et du D-glucose comme précurseurs chiraux. L'identité constitutionnelle et la stéréochimie du produit synthétique a été vérifiée par comparaison avec un échantillon obtenu à partir de l'antibiotique même.

In a previous publication from this laboratory (1), we described the total synthesis and stereochemical identity of the $C_{18}H_{32}O_5$ lactone degradation product **1** from boromycin (2, 3) (Scheme 1). This entity corresponds to the C-3′ – C-17′ (upper) segment of the antibiotic and constitutes an important advanced intermediate in a program directed at the total synthesis of boromycin (for another approach, see ref. 4). The conceptual basis and overall synthetic strategy of our approach is outlined in Scheme 1 where it is clear that logical bond-breaking sequences lead to the lactones **1** and **2**, which in turn can be related to three chiral precursors. The acyclic fragment can be envisaged to arise from 2-deoxy-D-*erythro*-pentose.

We now wish to report on the total synthesis of the C-3 – C-17 (lower) segment of boromycin, namely, lactone **2** in enantiomerically pure form, based on a strategy that recognizes *carbohydrate-type symmetry* in this challenging target (5).

The starting pentose derivative **3** (oil, $[\alpha]_D$ −7.8°; *m/e* 280, MH^+)[3] (Scheme 2) can be obtained in high yield from the readily available D-arabinose utilizing the useful procedure of Wong and Gray (6). Adjustment of functionality by sequential *O*-protection and desulfonylation gave intermediate **4**, $[\alpha]_D$

[2]NSERCC predoctoral fellow.

[3]New compounds had spectroscopic (^{1}H nmr 400 and 90 MHz) and mass spectral characteristics that were in accord with their structure. Optical rotations were measured in chloroform. The nmr data and other physical characteristics have been submitted as supplementary material and are available on request, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

system is terminal.[4] With the magnesium organocopper reagents, the major product obtained without any exception was found to be that resulting from γ-attack. It is also noteworthy that the double bond geometry remained intact whenever the reaction proceeded via α-substitution (Entries 1, 2, 11, and 12).

The ability of allylic pivalates to undergo efficient coupling with both the lithium and the magnesium organocopper reagents with reversal of regiochemistry promises to have broad synthetic utility. Other allylic esters[5] so far explored often show inconsistent and thus rather unpredictable regioselectivity when subjected to coupling with lithium organocopper reagents and in general do not couple effectively with magnesium organocopper reagents. This is further substantiated by the following experiments. Farnesyl acetate was treated with ethylmagnesium bromide – cuprous iodide (2:1) complex under the same conditions used for the corresponding pivalate (Entry 4). Upon completion of the reaction (1 h), 3-ethyl-3,7,11-trimethyl-1,6,10-dodecatriene and 2,6,10-trimethyl-2,6,10-tetradecatriene were isolated in 4:3 ratio and in 27% total yield. Similarly, treatment of farnesyl acetate with *n*-BuMgBr – CuI (2:1) complex gave a total of 43% yield of two coupling products, 2,6,10-trimethyl-2,6,10-hexadecatriene and 2,6,10-trimethyl-10-vinyl-2,6-tetradecadiene in a ratio of 4:3. These results are considerably inferior to those obtained for farnesyl pivalate (Entries 4 and 6) in terms of yield and regioselectivity.

[4]This finding is in agreement with a previous observation cited in footnote 1.

[5]For a recent review on coupling reactions of allylic esters, see ref. 4.

Total synthesis of the C-3 – C-17 segment of boromycin[1]

Stephen Hanessian, Daniel Delorme,[2] Peter C. Tyler, Gilles Demailly, and Yves Chapleur
Department of Chemistry, University of Montreal, Montreal, P.Q., Canada H3C 3V1

Received November 30, 1982

Stephen Hanessian, Daniel Delorme, Peter C. Tyler, Gilles Demailly, and Yves Chapleur. Can. J. Chem. **61**, 634 (1983).

The C-3 – C-17 segment of boromycin having five asymmetric centers was synthesized from D-arabinose and D-glucose as chiral precursors. Constitutional and stereochemical identity was established by comparison of the synthetic product with a sample obtained from the degradation of the antibiotic.

Stephen Hanessian, Daniel Delorme, Peter C. Tyler, Gilles Demailly et Yves Chapleur. Can. J. Chem. **61**, 634 (1983).

Le segment C-3 – C-17 de la boromycine comprenant cinq centres asymmétriques a été synthétisé à partir du D-arabinose et du D-glucose comme précurseurs chiraux. L'identité constitutionnelle et la stéréochimie du produit synthétique a été vérifiée par comparaison avec un échantillon obtenu à partir de l'antibiotique même.

In a previous publication from this laboratory (1), we described the total synthesis and stereochemical identity of the $C_{18}H_{32}O_5$ lactone degradation product **1** from boromycin (2, 3) (Scheme 1). This entity corresponds to the C-3′ – C-17′ (upper) segment of the antibiotic and constitutes an important advanced intermediate in a program directed at the total synthesis of boromycin (for another approach, see ref. 4). The conceptual basis and overall synthetic strategy of our approach is outlined in Scheme 1 where it is clear that logical bond-breaking sequences lead to the lactones **1** and **2**, which in turn can be related to three chiral precursors. The acyclic fragment can be envisaged to arise from 2-deoxy-D-*erythro*-pentose.

We now wish to report on the total synthesis of the C-3 – C-17 (lower) segment of boromycin, namely, lactone **2** in enantiomerically pure form, based on a strategy that recognizes *carbohydrate-type symmetry* in this challenging target (5).

The starting pentose derivative **3** (oil, $[\alpha]_D$ −7.8°; *m/e* 280, MH^+)[3] (Scheme 2) can be obtained in high yield from the readily available D-arabinose utilizing the useful procedure of Wong and Gray (6). Adjustment of functionality by sequential *O*-protection and desulfonylation gave intermediate **4**, $[\alpha]_D$

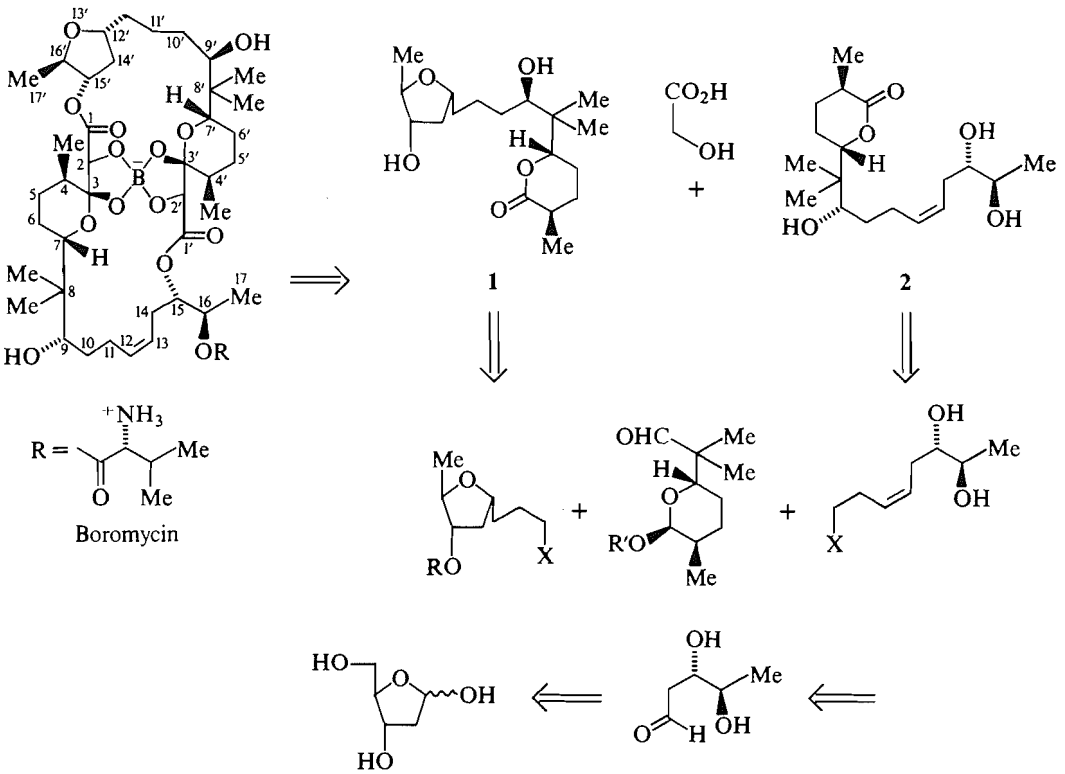

SCHEME 1

$-21.5°$; CI ms, m/e 507, MH^+, in which the hydroxyl groups of the diol are suitably protected. Brominolysis of **4** proved extremely efficient (7) and led to the aldehyde **5**, $[\alpha]_D$ $-32.8°$; CI ms, m/e 401, MH^+, which was subjected to a three-carbon extension reaction using Wittig methodology (8) under conditions that favor the formation of the desired *Z*-olefin (9) to give **6**, $[\alpha]_D$ $-15.6°$; CI ms, m/e 536, MH^+. Indeed, detailed spectroscopic analysis of the product revealed only traces of the isomeric *E*-product. Having access to the aldehyde component, which corresponds to the C-3 – C-9 tetrahydropyran portion of boromycin (1) and is a common intermediate for the elaboration of the lactones **1** and **2**, we were now faced with a choice of C—C bond-forming reaction to secure the C-9 – C-10 junction in the target. Among several options available to us, we chose the sulfone route which proved to be highly efficient. Thus, treatment of **6** with the aldehyde **7** (1) afforded a mixture of diastereoisomeric β-hydroxy sulfones **8** in very high yield. Reductive desulfonylation (10) was easily achieved on the corresponding β-keto sulfone derivative to give **9**, $[\alpha]_D$ $+25.5°$; CI ms, m/e 636, $MH^+ - OMe$; 594, $MH^+ - Me_3CO$, etc., which was reduced with sodium borohydride to a 1:1 mixture of syrupy epimeric alcohols **10**, $[\alpha]_D$ $+11.2°$, and **11**, $[\alpha]_D$ $+26.4°$. These proved to be easily separable by flash column chromatography and the undesired component could be recycled with high overall efficiency by an oxidation (Collins) – reduction sequence.

Having thus completed the total synthesis of an intermediate that corresponds to the C-3 – C-17 segment of boromycin, it was deemed necessary to secure unambiguous evidence for its constitutional and stereochemical identity by correlation with a degradation product of the antibiotic. Thus, in one series of reactions, **10** was converted into the *O*-triacetyl derivative **12**, $[\alpha]_D$ $+17.9°$, by an uneventful sequence of reactions and in good overall yield.[4] In another series of reactions, a sample of desvaline boromycin (1, 3) was subjected to controlled cleavage,[5] and the resulting lactones **1** and **2** were isolated by chromatography. Acetylation (Ac_2O, pyr.) of **2** gave material identical in all respects ($[\alpha]_D$, ms, 400 MHz nmr, and 2-D nmr) with the synthetic sample **12**. High resolution nmr spectroscopy, in particular, proved to be invaluable and led to interesting observations. Thus, it is noteworthy that the chemical shift of the geminal methyl groups in **12** was found at 0.95 ppm as a single peak while in the epimeric **9**(*R*) derivative, prepared independently from **11**, the methyl groups were found to be nonequivalent, with signals at 1.00 and 0.88 ppm. An anticipated difference in the magnitudes of optical rotation (compare, $[\alpha]_D$ $+32.7°$ for the C-9 epimer) also denotes a different orientation about the C-9 – C-10 bond.

We were now ready to transform **10** into the corresponding *O*-protected lactone and the initial judicious choice of protecting groups proved rewarding. Thus, it was possible to selectively hydrolyze the *tert*-butyl glycoside in **10** and to achieve conversion to the syrupy lactone **13**, $[\alpha]_D$ $-10.8°$, in high overall yield. Incorporation of a glycolic acid unit in this lactone, and in its C-3′ – C-17′ counterpart (1), should provide subtargets in forms suitable for esterification and macrolactonization en route to boromycin. These challenging objectives are presently under active study.

[4]The following steps were involved: (a) Bu_4NF, THF; (b) Ac_2O, pyr.; (c) aqueous AcOH; (d) pyridinium chlorochromate, CH_2Cl_2; (e) aqueous HCl, THF; (f) Ac_2O, pyr. Overall yield 50%.

[5]The cleavage was done as follows: (a) Ac_2O, DMAP, CH_2Cl_2; (b) aqueous HCl, THF; (c) H_5IO_6, THF; (d) aqueous LiOH, THF; (e) aqueous HCl, THF; (f) Ac_2O, pyr. DMAP. Overall yield 60% of lactones **1** and **2** (1:1 ratio by weight).

Received November 30, 1982

B. A. KEAY and R. RODRIGO. Can. J. Chem. **61**, 637 (1983).

A convergent AB + CD route to daunomycinone (**1**) is described. The AB segment is synthesized from the Diels–Alder adduct (**3**) of an isobenzofuran and methyl vinyl ketone by means of an unusual 5-*endo*–*trig* cleavage (**3** → **4**). The CD half (**9**) is combined with the AB by the Kraus annelation technique to provide a 9-deoxy daunomycinone derivative (**12***a*) which is subsequently oxygenated.

B. A. KEAY et R. RODRIGO. Can. J. Chem. **61**, 637 (1983).

Voici la description d'un tracé convergent AB + CD vers le daunomycinone (**1**). Le segment AB est synthétisé à partir de l'adduct Diels–Alder d'un isobenzofuranne et méthyl vinyl cétone à l'aide d'un clivage inhabituel 5-*endo*–*trig* (**3** → **4**). La portion CD (**9**) est combinée à AB par la technique d'annellation Kraus afin de fournir un dérivé 9-déoxy daunomycinone (**12***a*) qui est par la suite oxigéné.

[Traduit par le journal]

The glycoside daunomycine, an anthraquinone antibiotic of the anthracycline group, was isolated from *Streptomyces* species in 1963. The deluge of synthetic activity that followed the clinical trial and application of some of these antibiotics in cancer chemotherapy continues unabated and needs no recounting (for a comprehensive review, see ref. 1). Problems in anthracyclinone synthesis have been capably defined (2) and elegantly solved (3), particularly with respect to the aglycone daunomycinone **1**. In this report we offer a synthesis of **1** incorporating regiocontrolled AB + CD convergence and a new, efficient construction of the AB segment.

Our method features the "isobenzofuran – Diels–Alder" techniques developed (4) in this laboratory for a one-step construction of the requisite carbon skeleton. Thus the known lactol **2**, easily prepared from 2,3-dicyanohydroquinone (5) or 2,5-dimethoxybenzyl alcohol,[2] reacts smoothly with methyl vinyl ketone under mild acid catalysis to provide the bridged Diels–Alder adduct **3** in 90% yield. This molecule contains all the desired carbon and oxygen atoms, barring the 9-hydroxyl group, of the AB half of daunomycinone. The 7-hydroxyl group of the molecule, frequently a "difficult" function introduced later in many previous syntheses, develops from the oxygen atom of the isobenzofuran intermediate, the bridging oxygen atom of **3**. It is realized by an unusual 5-*endo*–*trig* reversal, formally a retro-Michael reaction, triggered by treatment of **3** with methanolic methoxide ion. The reaction is a remarkably smooth process (90% of **4**) yielding no other recognizable products, for a supposedly disfavoured pathway (7). We are investigating its mechanism but so far have failed to obtain any firm data to support an alternative rationalization. Sodium amalgam reduction of the enone (95%) and protection of the benzyl alcohol as a *tert*-butyl dimethylsilyl ether (90%) were unexceptional steps which provided **5**, our AB synthon lacking only the C-9 tertiary hydroxyl group of **1**. The addition–cyclization technique developed by Kraus and Sugimoto (8) for anthraquinone synthesis offered the best hope for regiocontrolled production of daunomycinone from **5**, but in subsequent applications of the Kraus method yields were reported (9) to be only moderate when acidic hydrogen atoms or carbonyl functions were present in the enone component. In accordance with these considerations, **5** was reduced with DIBAL-H (90%) and subjected to anodic oxidation (10). The resulting benzoquinone ketal **6** produced in 90% yield was hydrolysed with a pH 5 acetate buffer to provide a 4:1 mixture[3] of monoketals **7***a* and **7***b* (total 86%) which were separated by flash chromatography but are more conveniently carried through as a mixture for separation at a more opportune stage later on. The mixture was silylated (90%) to provide **8***a* and **8***b*, and was now ready for the Kraus annelation.

The cyanophthalide **9**, our CD segment, was easily prepared in three steps from *m*-anisaldehyde. The latter was converted into its dimethyl acetal, regiospecifically deprotonated (11), and quenched with carbon dioxide. Treatment of the resulting

[1]Author to whom correspondence may be addressed.

[2]2,5-Dimethoxybenzyl alcohol was converted to its vinyl ether and lithiated (6). The lithiated species was reacted with dimethyl formamide and hydrolyzed to the lactol **2**.

[3]This was a disappointing result in view of the >95% regioselectivity obtained previously in the hydrolysis of a similar bis-ketal (Swenton and co-workers (9)).

lactol with potassium cyanide and acetic acid provided the cyanohydrin which cyclized to **9** upon crystallization. Deprotonation of **9** with LDA/HMPA, followed by treatment with the monoketal mixture (**8***a* + **8***b*) and work-up with 20% aqueous acetic acid, provided an excellent yield (87%) of anthraquinones **10***a* + **10***b*. Reoxidation of the free alcohol proceeded efficiently (85%, **11**) with PDC in DMF and this was followed by removal (93%) of the silyl protecting group with acid. Therefore the entire AB + CD attachment sequence (**5** → **12***a* + *b*) proceeded in an excellent overall yield of 40% (seven steps). The slight structural differences that exist between regioisomers **12***a* and **12***b* can now be profitably exploited. In particular the *peri*-dihydroxy system at C-6,C-7 in **12***a* was converted to an acetonide (**13**, 80%) by 2-methoxy propene/*p*-toluene sulfonic acid treatment of the mixture in dry methylene chloride; **12***b*, which cannot form such an acetonide, is then easily separated from **12***a* by chromatography.

The ^{1}H nmr spectra of **5** (80 MHz), **11**, and **13** (400 MHz) were examined with and without H-7 decoupling to establish the C-7,C-9 relative configurations shown for these intermediates. All *J* values for protons at C-8, C-9, and C-10 in **11** and **13** were measured and the results in **11** found to be virtually identical with published values[4] for 9-deoxydaunomycinone. Oxygenation of the acetonide **13** was accomplished re-

producibly in 85% yield by a modified Gardner procedure (12) to produce a 2:3 diastereomeric mixture of 9-hydroxy ketones **14**, and followed by brief acid hydrolysis to remove the protecting isopropylidene group. Column chromatography provided the individual diols **15** and **16** in the same ratio. Ring A coupling constants measured from the 400 MHz spectra of **15** and **16** correlate well with those reported (13) for isodaunomycinone and isoepidaunomycinone respectively. Boron trichloride demethylation at −78°C was selective for the C-11 methoxyl group in both cases and subsequent work-up with aqueous bicarbonate provided daunomycinone **1** (from **15**) and epidaunomycinone **17** (from **16**). Again, a 400 MHz spectrum of our synthetic product had all chemical shifts and coupling constants identical with those published (14) for daunomycinone. Since epidaunomycinone **17** has been previously isomerized (15) to daunomycinone, this concludes our synthesis[5] in fourteen steps and ca. 14% yield from **2**.

Page 1143. The ^{1}H nmr spectrum of 3,3-diethoxypropanenitrile was interpreted as resulting from the presence of two different diastereomers in solution. This is unnecessary since the chemical shift nonequivalence of the geminal protons follows from their being diastereotopic. The CH_2 signals should therefore appear as the AB part of the ABX_3 system, which would be compatible with the reported spectrum.

We are grateful to Drs. E. L. Eliel and R. K. Norris for bringing this matter to our attention.

$^{45}Sc(\alpha,\alpha n)^{44}Sc^{m+g}$: a monitor reaction for alpha particle induced reactions[1]

PHILIP A. BEELEY,[2] JUDITH AARONSON, KONSTANTINOS KOKKAS, AND JAMES J. HOGAN

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received August 9, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

PHILIP A. BEELEY, JUDITH AARONSON, KONSTANTINOS KOKKAS, and JAMES J. HOGAN. Can. J. Chem. **61**, 641 (1983).

The excitation function for the $^{45}Sc(\alpha,\alpha n)^{44}Sc^{m+g}$ reactions have been measured at beam energies from 20 to 90 MeV. These provide a beam monitor for alpha particle induced reaction studies. The excitation functions and isomer ratios are discussed with particular reference to an apparent error in the decay scheme of $^{44}Sc^{m}$.

PHILIP A. BEELEY, JUDITH AARONSON, KONSTANTINOS KOKKAS et JAMES J. HOGAN. Can. J. Chem. **61**, 641 (1983).

On a mesuré la fonction d'excitation des réactions $^{45}Sc(\alpha,\alpha n)^{44}Sc^{m+g}$ avec des énergies de faisceau de 20 à 90 MeV. Ces réactions fournissent un contrôle de faisceau pour les études des réactions induites par les particules α. On discute des fonctions d'excitation et des rapports d'isomères en faisant référence particulièrement à une erreur apparente dans le schéma de désintégration du $^{44}Sc^{m}$.

Introduction

In the past several years, there has been considerable interest in the study of alpha particle induced reactions, much of it generated by the wide variety of mechanisms thought to be responsible for the experimental results. These include inelastic scatter of the alpha from the nucleus exciting low lying collective states (1), pickup reactions (2), binary fragmentation of the incident particle (3), dissolution of the alpha particle into four nucleons in the nuclear field (4), and interaction of the alpha with individual nucleons initiating an intranuclear cascade (5). During the latter, the alpha may undergo multiple scatters or break up into four nucleons (6).

Activation experiments to measure excitation functions of alpha particle induced reaction products have been hampered by the lack of a convenient means of monitoring the intensity of the incident alpha beam. This is particularly the case for experiments carried out in the internal beam of a cyclotron, or from stacked foil experiments in which Faraday cup measurements may be impractical.

The commonly used beam monitor at energies above 65–70 MeV is the $^{27}Al(\alpha,4p3n)^{24}Na$ reaction studied by Probst *et al.* (7). The excitation function for this reaction reaches a plateau at 65–70 MeV where the cross section is about 40 mb, then decreases very slowly to about 30 mb at $E_\alpha > 150$ MeV. The reaction is quite clean, producing no other activities with a lifetime between 10 min (^{27}Mg) and 21 h (^{28}Mg).

Unfortunately, this reaction can not be used as a monitor below about 60 MeV, and no other reaction of α on ^{27}Al provides a reasonable alternative, either because of short lifetimes (^{27}Mg, ^{28}Al, ^{29}Al), low cross section (^{28}Mg), low count rate (^{22}Na), or steeply varying excitation function (^{29}Al).

Therefore it was decided to examine the possible alpha induced reactions, "find" a more convenient monitor, and measure its excitation function. The requirements of a good monitor are many; usually one or more must be sacrificed for practical reasons. We sought: (a). a readily available monoisotopic target; (b). a reaction of low threshold energy and moderately large cross section, which is relatively energy insensitive; (c). a product with an easily measureable gamma ray of reasonable half life; (d). minimum production of other activities, and in particular, minimum production of other gamma rays which might interfere with other measurements in activation experiments. This rather stringent set of requirements is met by the reaction $^{45}Sc(\alpha,\alpha n)^{44}Sc^{m,g}$.

Scandium is easily obtainable in high purity as the trioxide powder, Sc_2O_3, or as the pure metallic foil. The excitation function for the metastable and ground states is found to be 100 ± 30 mb and 70 ± 20 mb, respectively, from about 25–30 MeV to 100 MeV and presumably well beyond. The half lives of ≃58 h for the metastable and ≃4 h for the ground state provide a convenient decay period whether for a long irradiation or a short. Moreover each decays through a single intense transition with no other transition occurring with a branch greater than 1%.

The most appealing aspect of this reaction as a monitor, however, is in the dearth of gamma rays produced from other activities at energies up to 1400 keV making it easy to incorporate the Sc_2O_3 powder monitor right into the target mixture of an activation experiment. In Table 1, all nuclides expected to be present ten minutes after irradiation, and all gamma rays more than 10% abundant, are listed. A spectrum measured twelve hours after the end of a one hour irradiation (Fig. 1) is discussed below.

The purpose of this work, then, is to measure the excitation function of the $^{45}Sc(\alpha,\alpha n)^{44}Sc^{m,g}$ reaction for use as an internal beam monitor in alpha particle irradiations. We have used as the primary monitor various reactions measured by Probst *et al.* (7), carrying out two sets of experiments, one at low energies using the 6 min ^{29}Al, the other at high energies using ^{24}Na. The lower portion of Table 1 shows the characteristics of the activities produced in reactions on aluminum.

These experiments, using relatively thick targets and an internal monitor, are also compared with measurements of Chen and Miller (8) of the same reaction at low energies ($E_\alpha < 40$

[1]This work is dedicated to Leo Yaffe. It is particularly appropriate in that he and his colleagues R. B. Moore, D. A. Newton, and S. Sarkar are the authors of the beam monitor study for proton induced reactions used for many years at the McGill University synchrocyclotron.

[2]Present address: Carbohydrate Research Institute, Queen's University, Kingston, Ontario.

TABLE 1. Nuclides with half-life between 1 s and 100 days formed in this work

Nuclide	Half life	Gamma rays, keV	Branch, >10%	Comment

MeV) measured with thin targets in an external beam using a Faraday cup to monitor the beam intensity.

Experimental

Targets

Targets were intimate mixtures of high purity powdered Al and 99.999% Sc_2O_3. Two sets of targets were prepared according to whether the low cross section, short half-life, ^{29}Al was to be used as primary monitor, or the higher cross section, long lived ^{24}Na. It is noteworthy that the measurements of Probst *et al.* (7) on 9.46 min ^{27}Mg were rejected as a monitor in this work out of concern for the (unknown) sensitivity of this reaction cross section to the ^{27}Al(*n*,*p*)^{27}Mg reaction. The analogous ^{27}Al(*n*,α)^{24}Na reaction has been shown to be of minimal concern at energies above 50–60 MeV (9).

The target mixtures, usually about 20 mg, were contained in 1 mm inside diameter, 1-mil (0.025 mm), high purity Al tubing, rolled flat to minimize the target thickness. The specific target arrangements were identical to those used in previous reaction studies undertaken in the McGill Radiochemistry Laboratory (10).

Irradiations

All irradiations were carried out in the internal beam of the McGill University Synchrocyclotron at a radius corresponding to the desired beam energy[3] for periods ranging from 5 s to 5 min. Typically beam currents were about 700 namps.

Counting

After irradiation, the targets were disassembled and the powder was analyzed for gamma ray activity. Samples were counted on a 100 cm^3 activated volume Ge(Li) crystal used in conjunction with 4000 channel pulse height analysis. Typically, the activity was followed for about two weeks or about five half-lives of the longest lived species of interest (58 h ^{44}Sc^{m}).

[3]P. A. Beeley and R. B. Moore, private communication.

Data analysis

The beam energies reported are the nominal beam energies corrected for degradation in passing through the outer aluminum tubing and in the target itself. The stopping power tables and equations of Williamson and Boujot (11) were used to calculate the beam energy entering and leaving the target mixture and an exponential average was determined to be the mean, and therefore reported, beam energy for each experiment. It is estimated that this average energy is known to ±2 MeV while the total variation in energy striking a target may be as great as ±5 MeV. It is for this reason that an excitation function which is relatively insensitive to beam energy is critical for a monitor reaction, and suggests the initial sharp increase from threshold of the excitation functions should not be used in future studies as a monitor.

The gamma ray spectra, about 40 from each of the experiments, were analyzed by hand to evaluate the peak heights of interest. The decay curves generated were followed for a minimum of five half-lives for the longest lived species, and for 8–10 half-lives for short lived ^{29}Al. The decay curves were fit by a weighted least-squares procedure which accounts for both the statistical uncertainty in each data point and the scatter of the data points about the curve.

The efficiency curve for the Ge(Li) detector was taken from analysis of a mixed gamma ray source available from the Atomic Energy Research Establishment, Harwell, England, sold commercially by Amersham Corp., of Oakville, Ont. It consists of nine radionuclides having eleven principal gamma rays evenly spaced between 88 and 1836 keV.

Because some questions will arise in the Discussion, it is worth stating clearly the assumptions made in the decay scheme of ^{44}Sc. The metastable state, ^{44}Sc^{m}, was assumed (12) to undergo isomeric transition to the ground state 98.6% of the time, emitting 866 gamma rays per 1000 decays; the remaining 12.0% goes into conversion electrons. The isomer also decays to excited levels of ^{44}Ti 1.4% of the time, feeding the 1157.0 keV gamma ray transition to the extent of 13.7 gamma rays per 1000 decays. The ground state, ^{44}Sc^{g}, is assumed to populate the same 1157.0 keV level in 99.89% of all decays. With assumed half-lives of 2.44 days and 3.90 hours, respectively, this leaves as the working equation for the decay of the 1157.0 keV line

where the subscripts m and g refer to the metastable and ground states.

The cross sections for the isomers of ^{44}Sc were finally determined by comparison to production of ^{29}Al and ^{24}Na after making corrections for detector efficiency, target composition, and decay characteristics.

Results

As outlined above, two independent means of measuring the cross section for ^{44}Sc^m exist. One is by the 271.2 keV gamma ray emitted in the isomeric transition to the ground state; the other is by analysis of the growth and decay of the 1157.0 keV gamma ray populated following beta decay. When these two analyses were performed on the experimental data, a clearly discernible pattern emerged (see Table 2). Cross sections measured from the isomeric transition were consistently greater than those determined from the growth and decay. The discrepancy is not great. The ratio of the two values is 1.075 ± 0.029 with individual experiments ranging from 1.043 to 1.101. Since the statistical error associated with each analysis is 3–5%, any single experiment has the two values just within the experimental uncertainty. However, that all nine sets of data have a similar discrepancy is felt to be beyond the statistical limits. We return to discuss this point below.

The two sets of results for ^{44}Sc^m are therefore presented in Table 2 along with the cross sections for production of ^{44}Sc^g, the isomer ratios, and the total cross sections for the ^{45}Sc$(\alpha,\alpha n)^{44}$Sc reaction. The latter two columns are calculated using the average of the two sets of ^{44}Sc^m data. In Fig. 2, the

experimental excitation functions are plotted along with data measured earlier at low energies by Chen and Miller (8).

Discussion

The gamma ray spectrum

The gamma ray spectrum recorded in a one-hour count taken twelve hours following the end of a 75 MeV irradiation is shown in Fig. 1. For monitor purposes, the scandium reaction provides an extremely clean spectrum, suitably for use as an internal monitor in activation experiments. Ignoring the ^{24}Na peak, which would not be present if a scandium monitor were being used, there are only two peaks of consequence at energies up to 1400 keV. These are the ^{43}Sc and ^{43}K peaks at 372.9 and 617.2 keV. The peaks of interest, 271.2 and 1157.0 keV, are clearly defined with integrated areas several hundred times greater than background. If analysis of the monitor is deferred for several days or a week, often a convenience in activation experiments, the two remaining interfering peaks are greatly reduced while the peaks of interest remain (due to reduced background) factors of more than one hundred above background.

The cross section of $^{44}Sc^{m}$

As stated above, the two cross sections measured for the production of $^{44}Sc^{m}$ differ by a factor of about 7% depending upon whether they are measured by the 271.2 keV isomeric transition or the 1157.0 keV gamma ray which follows beta decay. In most work, it would suffice to average the two values, either explicitly noting the discrepancy, or including it in the estimate of uncertainty in the data. This was not considered acceptable given the fundamental prupose of this work, to evaluate a monitor excitation function for alpha particle induced reaction studies. Inevitably the usefulness of this work arises from other studies which will be done, and which will evaluate the $^{44}Sc^{m}$ production cross section by one or the other of the two methods. Since it is felt the discrepancy is real, reproducible in nine experiments, both sets of data are reported in Table 2 and shown in Fig. 2.

There are only three likely sources for such a discrepancy: the relative half-lives of the isomer and the ground state, the detector efficiency calibration curve, or the assumed decay schemes.

The half-lives are very well characterized; the "best" values have changed by not more than 1–2% over the quarter century since the isotope was first studied (13). Errors of 10% in the relative half-lives would be needed to produce a 7% error.

The efficiency calibration curve was generated using the mixed gamma ray reference standard produced at the Atomic Energy Research Establishment, Harwell, England. One of the activities, ^{203}Hg, has a line at 279 keV (very near the 271.2 keV isomeric transition); a second, ^{60}Co, has a line at 1173.2 keV, quite close to the transition at 1157.0. These standard sources have an overall uncertainty of ±2.5% and ±1.5%, respectively. Points defining the efficiency curve fit very well along a straight line on a log E – log efficiency plot. A 7% error would be clearly discernible. The efficiency curves are not felt to be the source of the discrepancy.

The decay scheme of ^{44}Sc was taken from the Table of Isotopes (12), wherein the gamma ray intensities have been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

For personal use only.

adopted from the work of Coleman and Meyer (14). The conversion coefficient for the 271.2 keV isomeric transition, measured by Blue and Bleuler (13), is assumed in both the Table of Isotopes and the nuclear data compilation of Endt and Smith (15) to be 0.139, approximately a factor of 2 greater than the value necessary to produce agreement between the measured values. Because that work was performed nearly thirty years ago with NaI detectors and a vintage magnetic spectrograph, it is tempting to suggest this as the source of the discrepancy. However, the remarkable accuracy of gamma ray energies, half-lives, and branching ratios reported in ref. 13 make such an assumption unjustifiable. Blue and Bleuler also suggested the spin of the isomer to be 6+. This was confirmed in the course of atomic hyperfine splitting experiments by Harris and McCullen (16) which were used to determine the nuclear moments of ^{44}Sc.

A theoretical value of the conversion coefficient may be calculated from the formulation of Segrè (17) for an $E4$ transition (6+ $\rightarrow$ 2+) of 271.2 keV. The calculated value of 0.117 is not in unreasonable agreement with experiment (13).

A final possible source of the discrepancy is the branching ratio to the 1157.0 keV level in the daughter ^{44}Ti. However the observed beta transition is normal allowed ($\Delta I = 0, \Delta\pi =$ no) while a transition to the ground state is 2nd forbidden (2, no) and it is very unlikely that any reasonable decay ocurs to the ground state.

Thus, while it is felt that the discrepancy between the two measurements is real, there is no obvious source of the error. As stated above, because of the nature of this work we have reported both values, such that an experimenter may use the one appropriate to his own measurements.

The excitation function for the ^{45}Sc(α,αn)^{44}Sc reaction

The final excitation functions are shown in Fig. 2. The agreement at low incident energies with the earlier work of Chen and Miller (8) is excellent. This is particularly noteworthy because the earlier work was performed with thin targets; the observed agreement serves as a check on the accuracy of the energy determination for the thick targets used in this work (stopping powers calculated from ref. 11). Only in the measurements of the production cross section for the ground state at the highest energies utilized by Chen and Miller is there a discrepancy of about 20%. It should be noted that Chen and Miller evaluated the cross section of ^{44}Sc^{m} using the 271.2 keV isomeric transition; for this reason their data is plotted on the upper graph of Fig. 2. Like ours, they would lie about 7% higher than the middle curve of Fig. 2 for the ^{44}Sc^{m} measured by growth and decay of the 1157.0 keV line.

The last two columns of Table 2 list the isomer ratios and total reaction cross sections for production of ^{44}Sc. In each case, the average of the two ^{44}Sc^{m} measurements has been used in the calculation.

The first peak represents the contribution to the overall reaction of events in which an alpha particle is emitted. The second long plateau arises from reactions in which two protons and three neutrons are emitted as has been previously discussed (6). The isomer ratio shows a dip at energies of 40–50 MeV very similar to that observed and discussed in earlier work performed in this laboratory on similar proton induced reactions (18). The initial small increase reflects the increasing angular momentum deposition in compound nuclear reactions. The dip occurs during a mechanistic change from compound nucleus reactions to those in which pre-equilibrium cascade processes involving emission of an alpha predominate. Finally, when the emission of individual nucleons from a compound nucleus again becomes the primary mechanism, the isomer ratio once more increases. If studies were carried out at still higher energies, it is expected that the isomer ratio would again decrease as pre-equilibrium emission became the dominant mechanism. It is possible that this decrease is just noticeable in this work at the highest energy data point.

Summary

We have presented in this work the excitation function of the ^{45}Sc(α,α*n*)^{44}Sc reaction at incident energies from 20–90 MeV. It is hoped that this work will provide a beam monitor for alpha particle induced reaction studies, analogous to that work performed by Leo Yaffé and colleagues (19) used for many years in proton induced reactions.

In our recent works, a model was developed to calculate many of the features of ^{232}Th(p,X) reactions with incident proton energies to 100 MeV. The model reproduced many properties such as spallation excitation functions, total fission cross sections, the symmetric/asymmetric mass ratio, and fission charge dispersion data. In this work, the model approach is extended to consider the fission probability in ^{232}Th(p,p′$x$nf) fission channels. A comparison of the results calculated from the model to the experimental data shows very good agreement, and again justifies the approach of the model.

CHIEN CHUNG, JAMES J. HOGAN et HANS H. MÜLLER. Can. J. Chem. **61**, 646 (1983).

Dans notre récent travail, nous avons mis au point un modèle pour calculer plusieurs des caractéristiques des réactions du ^{232}Th(p,X) avec des protons incidents d'énergie allant jusqu'à 100 MeV. Le modèle reproduit plusieurs propriétés, telles les fonctions d'excitation de fission, les sections droites de fission totale, le rapport de masse symétrique/asymétrique et les données de dispersion de charge de fission. Dans ce travail, nous avons développé l'approche du modèle dans le but de considérer la probabilité de fission dans les canaux de fission du ^{232}Th(p,p′$x$nf). Une comparaison des résultats calculés à partir du modèle aux données expérimentales montre un très bon accord et justifie encore l'approche du modèle.
[Traduit par le journal]

Introduction

In our recent papers (1–3), a modified version of the Pre-Equilibrium/Exciton Model with fission option, developed by Gadioli and co-workers (4), was applied to the ^{232}Th(p,X) reaction with incident proton energies to 100 MeV. Many features, such as spallation excitation functions, total fission cross sections, the symmetric/asymmetric fission ratio, and fission charge dispersion data were successfully reproduced. More recently (5), the same model calculation was applied to the ^{238}U(p,X) reaction system on which much more experimental data are available. Again, most, if not all, experimental data including the properties mentioned above as well as the post-fission neutron multiplicity were well reproduced. All together, these works comprise a rather comprehensive study of heavy target reaction/fission with excitation energies to 100 MeV.

In this model, the fission probability, P_f, defined as the probability that a nucleus ^{A}Z of given excitation energy fissions, was assumed to be energy dependent. The form of the energy dependence could not be directly tested; however, the excellent agreement between our calculations and 27 excitation functions of spallation products and 133 fission charge dispersion data points suggested our treatment of P_f was valid. This assumption contradicts earlier treatments of P_f as being independent of excitation energy.

In a comprehensive review of 69 fission/spallation reaction cross sections in the 1950's, Vandenbosch and Huizenga (6) concluded that for nuclei with $Z \geq 90$, excited up to 23 MeV, the fission probability which is deduced from such data is independent of excitation energy. With more data available, Hyde (7) later arrived at a similar conclusion for nuclei excited to 40 MeV. It should be pointed out that their conclusions were derived from many simplifying assumptions such as averaging the fissioning mass from different targets and projectiles at different excitation energies, implicitly indicating that the fission probability was independent of, or weakly dependent on, the excitation energy to 40 MeV. Without comparison to a directly measured P_f, the question of the form of the excitation energy dependence or even whether such a dependence exists could not be verified.

A recent experimental contribution of Eder *et al.* (8) measured the P_f of the ^{232}Th(p,p′$x$nf) reaction at E_p = 52.5 MeV, providing for the first time a direct insight into the fission probability of fissioning isotopes with Z of 90 and excited to about 40 MeV. Measurement of the emitted proton energy in coincidence with fission fragments allowed extraction of the excitation energy of the fissioning nucleus. In this work, we have tested our model calculation, using the same energy dependent fissionability and without modification of any parameters, to reproduce the P_f data in this ^{232}Th(p,p′$x$nf) reaction. In the following sections, we provide an interpretation of the experimental data and a brief description of the calculation, followed by discussions of the comparison of the theoretical predictions with the data.

Data and calculation

A. *The fission probability data*

Eder *et al.* (8) irradiated the natural thorium target with

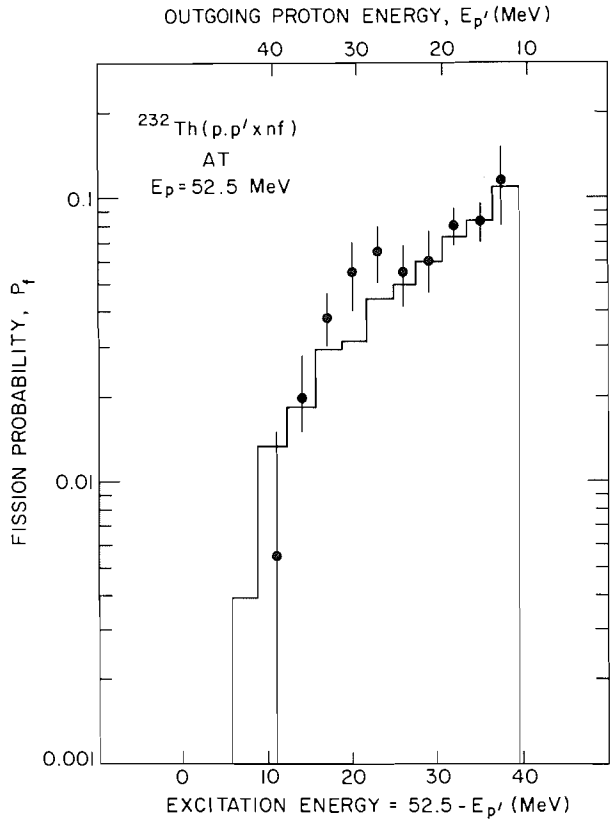

FIG. 1. The fission probability, P_f, of the ^{232}Th(p,p'$x$nf) reaction at 52.5 MeV. The data points and uncertainties are taken from ref. 8; the histogram is the calculated results of the Pre-Equilibrium/Exciton Model performed in this work.

incident protons of 52.5 MeV. With coincidence circuitry, they used an $E - \Delta E$ telescope to measure the outgoing proton kinetic energy, $E_{p'}$, and a Si-surface barrier detector to record the coincident fission fragment. The singles spectrum of proton energies (without coincidence) was also measured to account for all (p,p'X) reactions including the coincident (p,p'$x$nf) fissioning channels. The fission probability, P_f, of the ^{232}Th(p,p'$x$nf) reaction system was then derived from both the singles and coincident spectra. The data for P_f, as a function of proton energy is reproduced in Fig. 1, taken from ref. 8.

With 52.5 MeV incident protons, multi-chance fission, (p,p'$x$nf) with $x = 0-4$, is energetically possible, corresponding to the fissioning isotopes $^{232-228}$Th. Thus each data point represents a mixed P_f from different fissioning nuclides with various excitation energies, weighted according to each fission channel's population. The term *excitation energy* in Fig. 1, taken from the original caption in ref. 8, should be interpreted as the fissioning excitation energy only for the contributions from first chance fission, (p,p'f), and as residual energy for other (p,p'$x$nf) fissioning channels in which some neutrons may have been emitted before fission.

B. The Exciton Model calculation with fission option

The model calculation is essentially identical to that presented and discussed in our recent studies of ^{232}Th(p,X) reactions (1, 3). A modified version of the Pre-Equilibrium/Exciton Model with fission option (1, 4) is used. In the pre-equilibrium stage, α particles as well as nucleons may be emitted and multi-particle emission is allowed. After equilibrium is reached, excited nuclei are allowed to de-excite either by evaporation of neutrons, protons, α particles, or by fissioning. The fission probability, P_f, defined as $\Gamma_f/(\Gamma_f + \Gamma_n + \Gamma_p + \Gamma_\alpha)$ where Γ_f, Γ_n, Γ_p, and Γ_α are the fission, neutron, proton, and α emission widths, respectively, is evaluated at the moment of scission. The energy-dependent widths are calculated exactly as in eqs. [1]–[3] in ref. 1. Fission barriers were evaluated by Gadioli *et al.* (9), while particle binding energies are taken from those compiled by Wapstra and Gove (10), and the pairing energies are those of Nemirovski and Adamchuk (11). The ratio of the level density parameter in the distorted fissioning nucleus to that in the ground state, $a_f/a_{n'} = 1.05$, is the same as that employed in our earlier works (1, 3, 5).

The calculation follows, on an event by event basis, the evolution of the de-excitation of the p + ^{232}Th system. When one and only one proton is emitted and fission follows, i.e., an event of ^{232}Th(p,p'$x$nf) occurs, the following data are stored: the kinetic energy of the outgoing proton, $E_{p'}$, the identity of the fissioning nucleus, ^AZ, as well as its fissioning energy, and the fission probability, P_f. To simulate the experimental conditions, the P_f evaluated from various (p,p'$x$nf) events are further grouped into twelve bins of emitted proton energy. The final fission probability for the system is calculated for each bin weighting by the population in that energy bin.

Discussion

In this work, 40 000 cascades were followed; of these, there were 281 (p,p'$x$nf) events recorded. As a function of the emitted proton energy, the calculated values of the fission probability, P_f, are shown in the histogram of Fig. 1. A good agreement exists between the experimental values and the theory at all energies; the statistical error in the calculation is about 15%.

For residual energies less than 17.5 MeV, the only open fission channel corresponds to (p,p'f) events. Therefore, the data points in this region reflect the probability of fission of ^{232}Th. The experimental data clearly indicate the energy dependence of P_f, and the theory reproduces the variation very well. If the fissionability, P_f, were independent of excitation energy the measured values of P_f would reflect only the spectrum of pre-equilibrium proton energies. This is known (12) to be rather flat at these incident energies.

With increasing residual energy, the Th fission reaction becomes more complex in that more than a single fission channel is open. The experimental value of P_f then reflects not only the energy dependence of the fissionability but also the relative population and energy spectrum of different fissioning nuclei. In the region of "excitation energy" above 27.5 MeV, all fission channels, (p,p'$x$nf), $x = 1-4$, become energetically possible. Again the data are reproduced very well in this region. The good agreement suggests that the Exciton Model is reproducing the energy distributions of each residual nucleus which may undergo fission as well as giving an indication of the energy dependence of the fissionability.

In the intermediate energy region, which the calculation slightly underestimates, the statistical uncertainty in the histogram is approximately 20%. While this does not entirely account for the underestimate, it suggests that a small error in either a neutron binding energy or a fission barrier for a single nucleus could easily compensate for the difference. In either case, the good agreement at both low and high energies underscores the basic validity of the approach taken. In the model calculation, however, no account is taken of angular momentum effects. It is less likely that angular momentum effects seriously alter the results of proton-induced reactions which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

involve only a small angular momentum transfer, although these effects might be expected to play a major role in fission induced by moderate energy α's or heavy ions (13).

In conclusion, an excitation energy dependent P_f calculation coupled with the Pre-Equilibrium/Exciton Model approach has been applied to the ^{232}Th(p,p′$x$nf) reaction. A comparison of the results calculated from the model to the experimental data (8) shows very good agreement. Strong evidence from those data indicates that the fission probability is explicitly energy dependent. The good agreement between the theoretical predictions and the measured P_f, particularly in the low energy region, further justifies the form of the energy dependence used in this, and earlier (1, 3, 5) work.

Yields of products in the spontaneous fission of ^{252}Cf by direct γ-ray spectroscopy

L. TOPPARE, H. N. ERTEN, AND N. K. ARAS
Department of Chemistry, Middle East Technical University, Ankara, Turkey

Received July 15, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

L. TOPPARE, H. N. ERTEN, and N. K. ARAS. Can. J. Chem. **61**, 649 (1983).

Yields of products both in the light and heavy sides in the spontaneous fission of ^{252}Cf were measured by direct γ-ray spectroscopy technique. By suitably choosing collection, cooling, and counting times, it was possible to observe products with half-lives between 1 min and 1 h. A definite fine structure, as observed in the case of thermal neutron fission of ^{235}U and ^{239}Pu, was not observed. A graphical method was utilized to obtain the number of neutrons as a function of fragment mass using cumulative chain yields.

L. TOPPARE, H. N. ERTEN et N. K. ARAS. Can. J. Chem. **61**, 649 (1983).

Faisant appel à la technique de spectroscopie de rayons gamma, on a mesuré les rendements en produits légers et en produits lourds provenant de la fission spontanée du ^{252}Cf. En choisissant convenablement la collection, le refroidissement et les temps de dénombrement, il est possible d'observer des produits dont le temps de demi-vie se situe entre une minute et une heure. On n'a pas observé une structure fine définie, telle qu'observée dans le cas de la fission par neutron thermique de ^{235}U et du ^{239}Pu. On a utilisé une méthode graphique pour obtenir le nombre de neutrons en fonction de la masse du fragment utilisant les rendements de chaîne cumulatifs.

Introduction

In most low energy fission, when the chain yields are plotted as a function of mass number A, a double-humped mass distribution curve is obtained. In the thermal neutron fission of ^{235}U, in the region of the heavy peak, irregularities from smooth behavior were observed (1). These were explained by the influence of shell structure. These shell effects occur also in the spontaneous fission of ^{242}Cm but no such effects are reported for the spontaneous fission of ^{252}Cf (2–4).

With the advent of Ge(Li) detectors, several properties of fission products such as yields, ranges, etc., have been studied by direct γ-ray spectroscopy (5, 6). The high resolving power and the possibility of observing a large number of isotopes in one spectrum are the main advantages of this technique. Another advantage is that this method enables one to study short-lived products without losing time in chemical separations. Measuring fission yields by observing direct γ-ray spectra with semiconductor detectors was utilized by several groups (5, 7, 8). The aim of this work was to study yields of fission products in the spontaneous fission of ^{252}Cf especially those of short half-lives by this technique. By suitably choosing collection times of products, cooling and counting times, it was possible to observe products with half-lives between 1 min and 1 h. Previous yield determinations were restricted to products with half-lives of several hours or longer and were done mainly by radiochemical methods (2–4, 9).

Experimental

A 1 μg ^{252}Cf source electroplated on a nickel backing which was obtained from the Radiochemical Center, Amersham, was used. Fission products were collected using aluminium catcher foils. The thickness of the ^{252}Cf source was much less than the ranges of the fission fragments and the collection efficiencies of the isotopes studied were assumed to be the same. The collection time was systematically varied from a few minutes to several minutes. Three sets of experiments were done. The first set was designed to determine yields of products with half-lives of a few minutes. Five minutes of collection, 30 s of cooling, and 200 s of counting times were found to be suitable in these experiments. In the second set of experiments, collection times of 30 min, cooling time of 5 min, and counting times of 800 s were employed. The last set of experiments was designed to study products with half-lives close to 1 h. Collection times of 1 h and cooling and counting times of 15 min and 67 min, respectively, were used. The γ-ray spectra arising from the products were observed with a 30 cm^3 Ge(Li) detector coupled to a 4096 channel analyzer.

*From refs. 10, 11.

Calculations

The cumulative yields were determined by using a method based on comparison with a reference nuclide. ^{139}Xe, ^{141}Ba, and in some cases, ^{108}Ru and ^{134}Te were used as reference isotopes. Calculations were sometimes done by using more than one γ ray belonging to the decay of a single species as well as using more than one reference species. The γ-ray peak areas were corrected for absolute line intensities, conversion electrons, and efficiency of the detector. Table 1 gives the decay characteristics of the species suitable for the study as well as γ-ray energies and their absolute intensities (10, 11). The decay of γ lines selected for yield determinations was followed for over

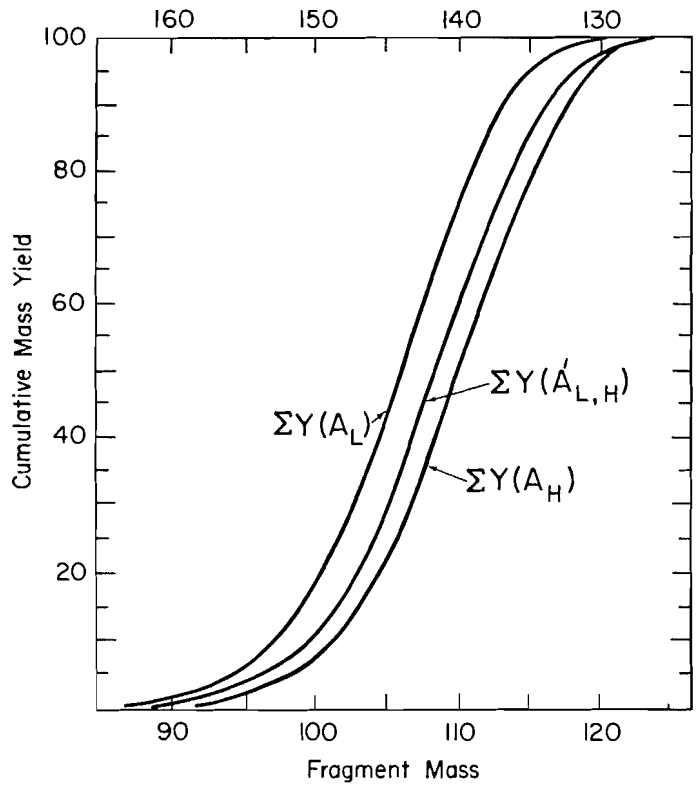

FIG. 2. The cumulative chain yields of light and heavy fission products, ($\Sigma Y(A_L)$, $\Sigma Y(A_H)$), plotted against mass number. Middle curve shows the cumulative chain yields, $\Sigma Y(A'_{L,H})$, before neutron emission from the work of Walsh and Boldeman (17).

four half-lives and only those lines with correct half-lives were used.

If the half-life of a precursor in a chain is very short compared to that of the product of interest and the collection time, the decay chain may be considered to begin at that product. In such cases single growth and decay equations could be used. Those products with appreciable contributions from precursors were dealt with by using Batemann equations.

Results and discussion

Mass chains found to be suitable for study by this technique were 101, 104, 106, 109, 116, 131, 135, 137, 138, 141, 144, 146, 149, and 151. The cumulative fission yield values found in this work are given in Table 2. Chain yields were obtained from these values by estimating fractional cumulative yields (12). In most cases the corrections amounted to less than 10%. A comparison with radiochemical results (4, 13) is also given in Table 2. The errors shown are those arising from counting statistics. As seen in Fig. 1, an asymmetric mass distribution is observed with no convincing evidence of fine structure, in

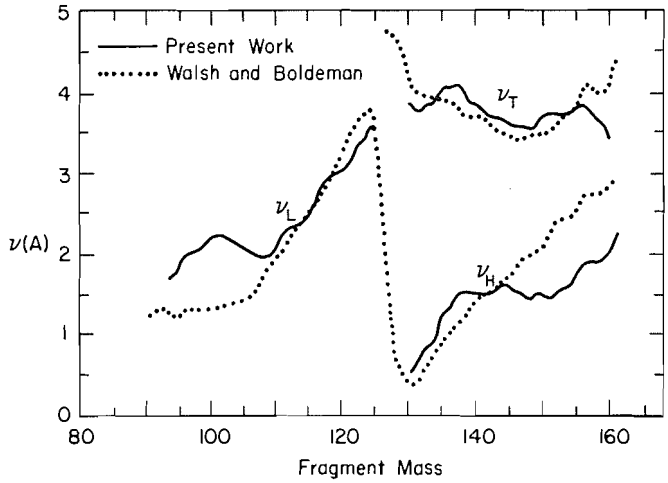

FIG. 3. The variation of number of neutrons as a function of mass number.

agreement with previous literature work (2, 3, 12, 13).

The chain yield values available in the literature and the values obtained in this work enabled us to obtain weighted average chain yields for mass chains 85 through 165. After normalization of the light and heavy peaks to 100% each, average mass values were determined for the two peaks as: $\bar{A}_L = 106.1$ and $\bar{A}_H = 141.8$. The average number of neutrons emitted promptly was obtained from the relation

$$\bar{\nu} = A_f - (\bar{A}_L + \bar{A}_H), \text{ as } \bar{\nu} = 4.1$$

This value is in fair agreement with those reported in the literature (8, 15).

A graphical method first used by Terrell (16) was utilized to obtain the number of neutrons as a function of fragment mass using cumulative chain yields. The cumulative mass yields of light and heavy fission products were plotted versus mass number as shown in Fig. 2. The middle curve shows the pre-neutron emission cumulative chain yields versus fragment mass number taken from the work of Walsh and Boldeman (17). By extrapolating this line horizontally towards the light and heavy sides, neutron number emitted by light and heavy fragment masses were obtained. The results are shown in Fig. 3. The results are in good agreement with those reported in the literature (8, 15, 17, 18) except at very heavy and very light fragments. Also note that the values of ν_A calculated for very light and heavy fragments are known to be unreliable because mass dispersion hinders accurate measurement of fragment yields that are very small.

2-Propanol is shown to be an effective hydrogen donor, in the presence of palladium/carbon, for catalytic transfer hydrogenation reactions of benzylic and styryl compounds, e.g., for the quantitative conversion of cinnamyl alcohol into 3-phenylpropanol. In the reduction of derivatives of cinnamic acid, decarboxylation also occurs. During the latter reaction, the phenyl group appears to function as an anchoring group for the palladium atom, because derivatives of phenylpropanoic acid are decarboxylated more readily than are those of phenylacetic acid. In hydrogenolysis reactions, aryl alcohols undergo disporportionation whereas benzyl ethers, represented by *O*-benzyl and related derivatives of carbohydrates, are smoothly cleaved. Although 2-propanol is less reactive as a hydrogen donor than formic acid, it exhibits greater selectivity, as illustrated by relative rates of hydrogenolysis of *O*-benzyl and *O*-benzylidene substituents. The use of alumina-supported palladium is more effective than palladium/carbon for promoting stepwise removal of *O*-benzyl substituents, as shown by the preparation of methyl 2-*O*-benzyl- and -3-*O*-benzyl-α-D-glucopyranoside from the 2,3-di-*O*-benzyl derivative. A possible relationship between the orientation of *O*-benzyl groups and the chemical shift differences between the diastereotopic benzylic protons is described.

VANGA S. RAO et ARTHUR S. PERLIN. Can. J. Chem. **61**, 652 (1983).

On montre que le propanol-2 est un donneur efficace d'hydrogène en présence de palladium/charbon lors de réactions d'hydrogénation par transfert catalytique, des composés benzyliques et styryles; par exemple, pour la transformation quantitative de l'alcool cinnamique en phényl-3 propanol. Il se produit également une décarboxylation lors de la réduction de l'acide cinnamique. Lors de cette dernière réaction, la fixation de l'atome de palladium semble se faire sur le groupe phényl puisque les dérivés de l'acide phénylpropanoique sont décarboxylés plus facilement que ceux de l'acide phénylacétique. Dans les réactions d'hydrogénolyse, l'alcool arylique subit une dismutation alors que les éthers benzyliques comme les dérivés *O*-benzyle ou apparentés des carbohydrates se clivent de façon douce. En dépit du fait que le propanol-2 est moins actif que l'acide formique en tant que donneur d'hydrogène, il présente une plus grande sélectivité qui est démontrée par les vitesses relatives d'hydrogénolyse des substituants *O*-benzyle et *O*-benzylidène. Le palladium déposé sur de l'aluminium est plus efficace que le palladium/charbon pour promouvoir l'élimination par étapes des substituants *O*-benzyle; cette propriété est illustrée par la préparation des *O*-benzyl-2 et *O*-benzyl-3 α-D-glucopyrannosides de méthyle à partir du dérivé de-*O*-benzyl-2,3. On décrit une relation possible entre l'orientation des groupes *O*-benzyle et les différences de déplacement chimique entre les protons benzyliques diastéréotopiques.

[Traduit par le journal]

Introduction

Transfer hydrogenation reactions catalysed by palladium on carbon (Pd/C) have been reported recently for a number of aryl ethers, aryl alcohols, and styryl derivatives (1). Disproportionation and isomerization reactions were among those observed, and also it was shown (2) that benzyl ethers, notably *O*-benzyl protecting groups of carbohydrate derivatives, were very effectively hydrogenolysed when formic acid was the hydrogen donor. Many other compounds may be utilized as hydrogen donors (3), providing that their oxidation potential is low enough to permit hydrogen transfer under mild conditions. However, as the effectiveness of a donor compound and the characteristics of the reaction it promotes can vary widely, an examination of possible donors is always warranted. 1-Phenylethanol is a recently-found example (1) of a compound that functions well in this capacity. Other secondary alcohols, not necessarily aromatic, also may be suitable. Indeed, 2-propanol has been employed as a hydrogen donor with Raney nickel (4) and $HIrCl_2(Me_2SO)_3$ (5) catalysts. The objective of the present study was to examine the potential of 2-propanol for use with Pd/C catalyst, an additional stimulus being its good solvent properties and its ease of removal from reaction products.

Results and discussion

Reduction of styryl derivatives

Among compounds that have been hydrogenated with 2-propanol and Raney nickel catalyst (4*b*) is *trans*-stilbene (**1**). Bibenzyl (**3**) was obtained as the product in only 40% yield, and a prolonged reaction period led to the formation of 1-cyclohexyl-2-phenylethane. By contrast, bibenzyl (**3**) was isolated in quantitative yield when either *trans*-(**1**) or *cis*-(**2**) stilbene was heated under reflux for 24 h in 2-propanol, in the presence of Pd/C catalyst (Table 1). Similarly, cinnamyl alcohol (**4**) was converted completely into 3-phenylpropanol under the same conditions.

Clearly, then, 2-propanol can serve as an effective hydrogen donor in transfer hydrogenations catalysed by Pd/C. However, other reactions may be promoted as well, depending on the nature of the compounds involved (see Table 1).

An unusual type of example was encountered with *cis*-(**5**) or *trans*-(**6**) 4′-hydroxycinnamic acid and *trans*-3′-methoxy-4′-hydroxycinnamic acid (**7**). That is, when heated under reflux in 2-propanol containing the suspended catalyst, **5**, or **6** and **7** gave 4-ethylphenol (**8**) and 2-methoxy-4-ethylphenol (**9**), respectively, in quantitative yield. It is possible that reduction of the double bond occurred first, by analogy with the reactions of

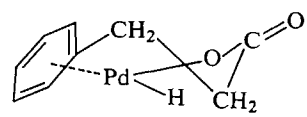
1, **2**, and **4**, and that decarboxylation then followed. Favoring this sequence of events is the fact that the hypothetical reduction product, 3-(4′-hydroxyphenyl)-propanoic acid (**10**), was smoothly decarboxylated in 2-propanol, yielding 4-ethylphenol (**8**). Nevertheless, it was found that Pd/C can promote direct decarboxylation of an α,β-unsaturated acid at an elevated temperature. Hence compound **7**, in refluxing 1,4-dioxane (bp 101°C) for 48 h, was converted into 3-methoxy-4-hydroxystyrene (~65% yield), although at room temperature (in methanol), *trans*-4′-hydroxycinnamic acid (**6**) has been shown (1) to be stable. By comparison, the propanoic acid derivative (**10**) was fully decarboxylated under reflux in 1,4-dioxane in 48 h, and 50% decarboxylated in methanol at reflux temperature. Consequently, as products **8** and **9** were formed quantitatively in 2-propanol (bp 83°C), it is likely that the decarboxylation processes involved mainly the alkanoic acids, rather than **5**, **6**, and **7** directly.

Derivatives of phenylacetic acid, i.e., 3,4-dimethoxy-(**11**) and 4-nitro-(**12**)[1] phenylacetic acid, were decarboxylated only to the extent of ~50% in 48 h over 10% Pd/C in 2-propanol. Nonaromatic acids were even less reactive. Thus, 1,2:3,4-di-*O*-isopropylidene-D-galacturonic acid remained essentially unaffected in the presence of 10% Pd/C or 5% $Pd/CaCO_3$ in either refluxing 2-propanol or 1,4-dioxane, and stearic acid was recovered unchanged after heating under reflux with 10% Pd/C in 1,4-dioxane.

It appears, therefore, that the presence of a phenyl moiety in the substrate is necessary to effect complete, or partial, decarboxylation, possibly because it serves as an anchoring group for the palladium atom in the transition state. The notable difference in reactivity between the phenylpropanoic acid and



13

phenylacetic acid derivatives also suggests that with the former the palladium atom is readily held near the centre of electron density of the phenyl ring in the transition state (e.g., **13**), whereas an equally stable disposition of the atom seems less feasible with the two-carbon chain of the acetic acid derivatives. Similarly, the fact that **7** undergoes only partial decarboxylation suggests a relatively weak interaction due to unfavorable geometry as compared with **13**. Consistent with the latter possibility, it is worth noting that when the hydroxyl groups of 3-(4′-hydroxyphenyl)-propanoic acid (**10**) were deuterated by exchange with deuterium oxide, and decarboxylation with Pd/C in 1,4-dioxane then carried out, the product was the expected 2-deutero-1-(4′-hydroxyphenyl)-ethane.

Hydrogenolysis of aryl alcohols

Previously (1), it was shown that diphenylmethanol (**14**) is hydrogenolysed to diphenylmethane (**15**) by Pd/C in combination with formic acid whereas, when the hydrogen donor was omitted, a mixture of **15** and benzophenone (**16**) was produced. This disproportionation reaction has now been observed as well in attempting to use 2-propanol as the donor, in that **14** yielded a 1:1 mixture of **15** and **16**. Apparently then, diphenyl-

[1]Although the nitro group may be expected to undergo reduction, there was no suggestion from the ^1H nmr spectrum of the material recovered that the aryl moiety had been modified.

[a] Chemical shifts (δ) and spacings (Hz).
[b] Difference in chemical shifts of AB pair.
[c] Assignments may be reversed.
[d] The AB pair was identified by applying a weak rf at the frequency of one of the A or B transitions, and observing the submultiplet pattern of the transitions having an energy level in common with the perturbed transition (see ref. 8).

methanol itself was a more effective hydrogen donor in the formation of **15** than was 2-propanol (although much less effective than formic acid), thereby accounting for a disproportionation (oxidation–reduction) process. The resistance of benzophenone (**16**), accumulated in the reaction mixture, towards reduction by the external hydrogen donor was checked in a separate experiment, in which benzophenone itself was recovered unchanged. This was not unexpected, as carbonyl groups are generally not susceptible to transfer hydrogenation unless a Lewis acid promoter is present (e.g., $FeCl_3$ (3*a*)), or the carbonyl group is part of a potential aromatic system, as in quinones or decalones (3*b*). Also excluded by these experiments was the possibility that disproportionation occurred, rather than complete hydrogenolysis to **15**, because of inactivation of the catalyst or of an inadequate proportion of it.

Selective removal of O-*benzyl substituents of carbohydrate derivatives*

The foregoing results, showing that 2-propanol can serve as an effective hydrogen donor, stimulated a comparison of its use with that of formic acid (2) in the hydrogenolysis of *O*-benzyl and related substituents of carbohydrate derivatives. In general, the reactions promoted by 2-propanol in the presence of Pd/C catalyst proved to be considerably slower than with formic acid, and also showed a remarkably high degree of selectivity.

The use of a 48 h period of reflux in 2-propanol containing a suspension of 10% Pd/C permitted quantitative removal of the two *O*-benzyl groups from methyl 2,3-di-*O*-benzyl-α-D-glucopyranoside (**17**), and of the *O*-trityl group from methyl 6-*O*-trityl-β-D-glucopyranoside (**18**). By contrast, only about 24 h was needed for these hydrogenolysis reactions when formic acid was the hydrogen donor (2). Nevertheless, 2-propanol was found to exhibit much higher selectivity than formic acid in some instances. With methyl 2,3-di-*O*-benzyl-4,6-*O*-benzylidene-α-D-glucopyranoside (**19**), only the *O*-benzyl groups were removed in 48 h, to give methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (**20**) exclusively. This selectivity is analogous to that found (6) in the hydrogenolysis of **19** with palladium hydroxide in the presence of cyclohexene, although the latter reaction was more rapid. In the presence of formic acid (2) only methyl α-D-glucopyranoside was obtained. The latter was formed from **19** in 2-propanol only by extending the reaction period to 144 h. However, the *O*-benzylidene group was far more labile when it was the sole type of hydrogenolyzable function present. Thus, in separate experiments, acetal **20** and its β-anomer (**21**) yielded methyl α- and β-D-glucopyranoside, respectively, in 48 h.

Another instance of the relatively high selectivity of 2-propanol was found in the fact that although the *O*-trityl group of **18** was easily removed, that of the corresponding 2,3,4-tri-*O*-acetyl derivative (**22**) was virtually unaffected, in contrast to its lability in the presence of formic acid (2). Although competitive inhibition (7) by the *O*-acetyl groups was a possible factor, another possibility was steric hindrance of the

trityl C—O bond to adequate exposure on the catalytic surface. Thus, neither the *O*-trityl nor *O*-benzyl substituents of methyl 2,3,4-tri-*O*-benzyl-6-*O*-trityl-β-D-glucopyranoside (**23**) were appreciably susceptible to hydrogenolysis in 48 h under reflux in 2-propanol containing 10% Pd/C. The marked sensitivity to structural variations of 2-propanol, as compared with formic acid, was seen also in its failure to cleanly promote removal of the *O*-benzyl groups of reducing derivatives 2,3,4,6-tetra-*O*-benzyl-D-glucopyranose and 2,3,5-tri-*O*-benzyl-D-arabinofuranose. Although these compounds were converted into D-glucose and D-arabinose, respectively, in the presence of formic acid (2), the products of their reactions with 2-propanol were complex and appeared (nmr evidence) to have incorporated 2-propyl groups.

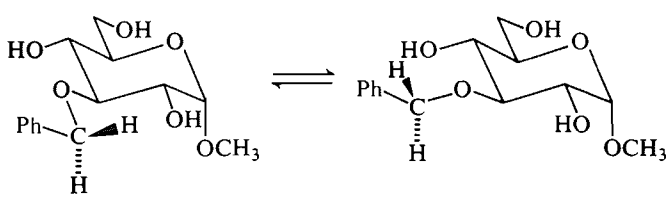
Partial selectivity in the removal of carbohydrate O-benzyl groups

Chemical shifts of benzylic protons

In addition to variations in reaction characteristics offered by a change in the hydrogen donor employed, other differences are also to be expected when the catalyst adsorbant is altered. An example of this is afforded in the *O*-debenzylation of methyl 2,3-di-*O*-benzyl-α-D-glucopyranoside (**17**). The use of palladium (5%) on alumina in 2-propanol led to the formation of substantial quantities of two intermediate products (R_f 0.37 and 0.26, in 1:1 ethyl acetate–acetone) as well as methyl α-D-glucopyranoside, whereas the latter was essentially the sole product of the Pd/C mediated reaction. Isolated chromatographically, the intermediate products were identified as methyl 3-*O*-benzyl-α-D-glucopyranoside (**24**; R_f 0.37) and methyl 2-*O*-benzyl-α-D-glucopyranoside (**25**; R_f 0.26). In an analogous manner, methyl 2,3-di-*O*-benzyl-β-D-glucopyranoside (**26**) afforded the corresponding 3-*O*-benzyl (**27**; R_f 0.40) and 2-*O*-benzyl (**28**; R_f 0.33) glucosides. It is noteworthy that in both series the 2-*O*-benzyl derivative (**25** and **28**) was substantially more polar, perhaps ascribable to more effective cooperative binding to the chromatographic adsorbant by the 3,4,6-trihydroxy sequence in these isomers, as compared with the more dispersed 2,4,6-sequence.

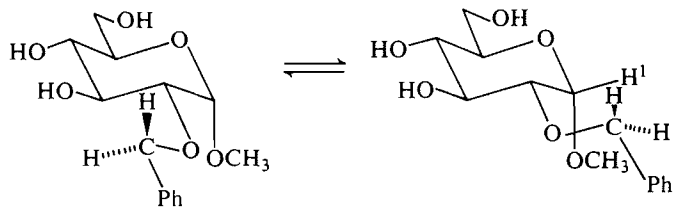
Products **24**, **25**, **27**, and **28** were identified by comparing their ^{1}H nmr spectra with those of the corresponding *O*-acetylated compounds; i.e., the downfield shifts induced on esterification readily gave the positions of the free hydroxyl groups present.

A noteworthy feature of these spectra is the magnitude of chemical shift differences between diastereotopic benzylic protons, because it appears to indicate a specific dependency on the position of a given *O*-benzyl substituent. For example, the two benzylic protons of 3-*O*-benzyl derivative **24** differ in chemical shift by 0.27 ppm (Table 2) whereas those of the 2-*O*-benzyl derivative (**25**) differ by only 0.07 ppm. Models



29 **30**

suggest that the 3-*O*-benzyl group may adopt such energetically favorable orientations as represented by **29** and **30**. In these arrangements, presumably, one of the benzylic protons is exposed to overall stronger deshielding than the other by an adjacent oxygen atom (as illustrated), i.e., by O-2 or O-4, respectively,[2] leading to the substantial differences observed in their chemical shifts. Analogous considerations for the 2-*O*-benzyl group of **25** suggest that a chemical shift difference of a similar order (0.27 ppm) might be expected if the group tends to be oriented as in **31**, although not as in **32**, where neither of the protons would be exposed to the deshielding



31 **32**

influence of a nearby oxygen atom. Possibly, therefore, **32** is the major contributor to the time-averaged orientation of the 2-*O*-benzyl group because of the small difference observed (0.07 ppm, Table 2).

Data for the β-anomers reinforce these proposals. Orientations possible for the 3-*O*-benzyl group of **27** are expected to be closely analogous to those in **24** (i.e., **29** and **30**) and, as can be seen (Table 2), the same difference in chemical shift (0.27 ppm) is found for both anomers. By contrast, the magnetic environment of the 2-*O*-benzyl group of **28** differs from that of its α-anomer (**25**) by being in close proximity to either O-1 (as in **32**, in which H^1 and OCH_3 have been interchanged) or O-3 (as in **31**), thereby allowing for disparate shielding of the two benzylic protons. Indeed, the chemical shift difference (0.27 ppm) is much larger for **28** than for **25**, in accord with expectation.

Additional support for these proposals concerning orientations favored by *O*-benzyl substituents comes from the effects of acetylation on the chemical shifts. That is, the replacement of OH by $OCOCH_3$, which should be associated with a change in magnetic anisotropy, had a marked effect on the chemical shift difference (Table 2) only in those instances when differential shielding by adjacent oxygen atoms has been invoked. Hence, when the 3-*O*-benzyl group is sandwiched between two neighboring *O*-acetyl groups, the difference is reduced from 0.27 ppm for **24** to 0.10 ppm, and for **27** to zero. There was little change, however, upon acetylation of 2-*O*-benzyl derivative **25**, and only a minor decrease (from 0.27 to 0.24 ppm) for its β-anomer (**28**), O-1 of which was unaltered by esterification. It is also worth noting that the chemical shift differences observed (Table 2) for the anomeric 2,3-di-*O*-benzyl glucosides (**17** and **26**) and their 4,6-di-*O*-acetyl derivatives, correspond closely to those found with their mono-*O*-benzyl analogs, and these differences appear to be largely maintained in the presence of a third *O*-benzyl group, at C-4, as in methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranoside (Table 2).

[2]The shielding influence of these oxygen atoms may differ, depending on the rotamer populations of OH-2 and OH-4. Although these populations are not known, the possibility that one rotamer is strongly favored (not necessarily the same one for all secondary OH groups) has been shown (9) for OH-2 of α-D-glucopyranose. Hence, OH groups may help to determine the orientation of an adjacent *O*-benzyl group, and vice versa.

Experimental

Solutions were evaporated below 40°C under diminished pressure. Eastman Chromagram sheets of silica gel with fluorescent indicator were used for thin-layer chromatography. Preparative thin-layer chromatography plates of ~2 mm thickness were made with Merck silica gel GF_{254} (Type 60) containing 13% calcium sulfate as binder. The ^1H nmr spectra of compounds listed in Table 1 were recorded with a Varian T-60 spectrometer. Spectra at 400 MHz (Bruker WH-400) were obtained for compounds **26**–**28**, the diacetates of **17** and **26**, and methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranoside, with the aid of homonuclear decoupling. Spectra of the other carbohydrate derivatives were recorded with a Varian XL-200 spectrometer. Chemical shifts (δ) are reported with reference to tetramethylsilane. Mass spectra were obtained with an LKB 9000 spectrometer at an ion source voltage of 70 eV.

Palladium (5% and 10%) on activated carbon, palladium (5%) on alumina, and compounds **1**, **2**, **4**, **5**, **6**, **7**, **10**, **11**, **12**, **14**, **16**, and stearic acid were obtained from Aldrich Chemical Co. Inc., and 2,3,4,6-tetra-*O*-benzyl-D-glucose and 2,3,5-tri-*O*-benzyl-D-arabinose from Pfanstiehl Laboratories (Waukegan, IL). Compounds **17**–**21**, **22**, **26**, and di-*O*-isopropylidene-D-galacturonic acid were available from earlier work.

Hydrogenolysis of aryl alcohols and reduction of styryl derivatives

A solution of the aryl alcohol or styryl derivative (0.2 g) in 10 mL of 2-propanol (warmed when the compound was not soluble at room temperature) was added to a stirred suspension of 10% palladium on carbon (1 g) in refluxing 2-propanol (10 mL), protected from moisture with Drierite. After 48 h, the catalyst was filtered off and washed with 2-propanol, and the combined filtrate and washings were evaporated. The residue was vacuum dried briefly when the product was not expected to be highly volatile. In all reactions except those of **11** and **12**, tlc indicated that the starting compound was converted quantitatively into a single product (two products from **14**); nmr and mass spectroscopy confirmed that the product was invariably of high purity. Yields of product recovered: from **1** or **2** (0.2 g, 98%, mp 52°C); from **4** (0.2 g, 98%); from **5** or **6** (~0.14 g, 93%, mp 42–45°C); from **7** (0.15 g of **9**, 96%); from **11** (~50% interconversion, estimated by nmr); from **12** (~50% interconversion, estimated by nmr). The product was identified by comparison of its mass spectrum and/or ^1H nmr spectrum with that of an authentic sample.

Removal of O-*benzyl*, O-*benzylidene*, *or* O-*trityl groups of carbohydrate derivatives*

A solution of the carbohydrate derivative (0.2 g) in 2-propanol (10 mL) (warmed when the compound was not soluble at room temperature) was added to a stirred suspension of 10% palladium on carbon (1 g) in refluxing 2-propanol[3] (10 mL), protected from moisture by Drierite. When, as shown by periodic tlc examination, the starting material had disappeared, the catalyst was filtered off, washed successively with 2-propanol and water, and the filtrate and washings were combined and evaporated. The vacuum dried residue, dissolved in a suitable solvent, was characterized by comparing its ^1H nmr spectrum with that of the known compound.

*Selective removal of the 2,3-*O*-benzyl groups of* ***19***

Following the general procedure described above, a solution of methyl 2,3-di-*O*-benzyl-4,6-*O*-benzylidene-α-D-glucopyranoside (**19**) (0.2 g) in 10 mL of warm 2-propanol was added to a slurry of 10% palladium on carbon (1 g) in refluxing 2-propanol (10 mL). After 6 h, tlc (eluant: EtOAC) indicated the presence of 3 components (R_f 0.70 (**19**), 0.65 (trace), and 0.13), whereas at 48 h, **19** had disappeared and only the product of R_f 0.13 remained. The ^1H nmr spectrum of the latter in $CDCl_3$, following exchange with D_2O, was indistinguishable from that of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (**20**).

Removal of individual O-*benzyl groups from* ***17*** *and* ***26***

In a representative experiment, a solution of methyl 2,3-di-*O*-benzyl-α-D-glucopyranoside (**17**) (0.2 g) in 2-propanol (10 mL) was added to a stirred suspension of 5% palladium on alumina (2 g) in refluxing 2-propanol (15 mL), protected from moisture. After 3 h, tlc (1:1 acetone/EtOAC) showed three spots having R_f values of 0.49 (**17**), 0.37, and 0.26, the latter two being relatively faint. At 26 h, at which time all three spots were of about equal intensity, the catalyst was filtered off, washed with 2-propanol, and the combined filtrate and washings were evaporated.[4] The individual components of the residue were separated by preparative thin-layer chromatography on silica plates (~2 mm) using the above solvent mixture as eluant, and were isolated from the silica by washing successively with chloroform, acetone, and methanol, followed by evaporation of the combined washings. The compounds having R_f 0.37 and 0.26 (~0.03 g each) were identified as methyl 3-*O*-benzyl (**24**) and methyl 2-*O*-benzyl-α-D-glucopyranoside (**25**), respectively, by comparing their ^1H nmr spectra with those of the corresponding triacetates (prepared with pyridine and acetic anhydride). The ^1H nmr data for **24**: δ: 3.46 (OCH_3), 3.66 (H-2), 4.78 (H-1, $J_{1,2}$ = 3.6); for its 2,4,6-triacetate: δ: 1.88, 2.01, 2.04 (3 × $COCH_3$), 3.35 (OCH_3), 3.82 (H-5, $J_{5,6}$ = 4.8, $J_{5,6'}$ = 2.4), 3.93 (H-3, $J_{3,4}$ = 9.6), 4.03 (H-6′), 4.16 (H-6, $J_{6,6'}$ = 12.4), 4.84 (H-2, $J_{2,3}$ = 9.6), 4.91 (H-1, $J_{1,2}$ = 3.6), 5.03 (H-4, $J_{4,5}$ = 9.6). The ^1H nmr data for **25**: δ: 3.33 (OCH_3), 3.36 (H-2, $J_{2,3}$ = 9.4), 3.91 (H-3, $J_{3,4}$ = 9.4), 4.60 (H-1, $J_{1,2}$ = 3.6); for its 3,4,6-triacetate: δ: 2.01, 2.03, 2.09 (3 × $COCH_3$), 3.42 (OCH_3), 3.60 (H-2, $J_{2,3}$ = 9.6), 3.98 (H-5, $J_{5,6}$ = 4.4, $J_{5,6'}$ = 2.0), 4.07 (H-6′), 4.30 (H-6, $J_{6,6'}$ = 12.4), 4.70 (H-1, $J_{1,2}$ = 3.6), 5.00 (H-4, $J_{4,5}$ = 9.6), 5.48 (H-3, $J_{3,4}$ = 9.6). The ^1H nmr data for **17**: δ: 3.40 (OCH_3), 3.51 (H-2, $J_{2,3}$ = 9.4), 3.82 (H-3, $J_{3,4}$ = 9.4), 4.63 (H-1, $J_{1,2}$ = 3.6); for its 4,6-diacetate: δ: 1.91, 2.06 (2 × $COCH_3$), 3.39 (OCH_3), 3.59 (H-2, $J_{2,3}$ = 9.5), 3.84 (H-5, $J_{5,6}$ = 5.0, $J_{5,6'}$ = 2.2), 3.92 (H-3, $J_{3,4}$ = 9.5), 4.00 (H-6′), 4.21 (H-6, $J_{6,6'}$ = 12.3), 4.59 (H-1, $J_{1,2}$ = 3.7), 4.99 (H-4, $J_{4,5}$ = 10.2). The data for the benzylic protons of these compounds are given in Table 2.

Following the same procedure with methyl 2,3-di-*O*-benzyl-β-D-glucopyranoside (**26**), three components having R_f 0.53 (**26**), 0.40, and 0.33 were separated by preparative thin-layer chromatography. The latter two were identified as methyl 3-*O*-benzyl- (**27**) (~20% yield) and methyl 2-*O*-benzyl-β-D-glucopyranoside (**28**) (~20% yield), respectively, by comparing their ^1H nmr spectra with those of the derived triacetates. The ^1H nmr data for **27**: δ: 3.37 (H-5, $J_{5,6}$ = 3.6, $J_{5,6'}$ = 4.9), 3.50 (H-2, $J_{2,3}$ = 9.1), 3.56 (OCH_3), 3.79 (H-6′), 3.90 (H-6, $J_{6,6'}$ = 11.8), 4.24 (H-1, $J_{1,2}$ = 7.7); for its 2,4,6-triacetate: δ: 1.96, 2.01, 2.08 (3 × OCH_3), 3.49 (OCH_3), 3.60 (H-5, $J_{5,6}$ = 4.8, $J_{5,6'}$ = 2.4), 3.70 (H-3, $J_{3,4}$ = 9.2), 4.13 (H-6′), 4.24 (H-6, $J_{6,6'}$ = 12.0), 4.35 (H-1, $J_{1,2}$ = 7.6), 5.06 (H-2, $J_{2,3}$ = 9.2), 5.15 (H-4, $J_{4,5}$ = 9.2). The ^1H nmr data for **28**: δ: 3.20 (H-2, $J_{2,3}$ = 9.1), 3.34 (H-5, $J_{5,6}$ = 3.3, $J_{5,6'}$ = 4.7), ~3.5 (H-3, H-4), 3.56 (OCH_3), 3.81 (H-6′), 3.89 (H-6, $J_{6,6'}$ = 11.8), 4.34 (H-1, $J_{1,2}$ = 8.0); for its 3,4,6-triacetate: δ: 1.84, 1.93, 2.01 (3 × $COCH_3$), 3.34 (H-2, $J_{2,3}$ = 9.2), 3.52 (OCH_3), 3.59 (H-5, $J_{5,6}$ = 4.8, $J_{5,6'}$ = 2.4), 4.04 (H-6′), 4.22 (H-6, $J_{6,6'}$ = 12.0), 4.35 (H-1, $J_{1,2}$ = 7.6), 4.91 (H-4, $J_{4,5}$ = 9.2), 5.09 (H-3, $J_{3,4}$ = 9.2). The ^1H nmr data for **26**: δ: 3.34 (H-5, $J_{5,6}$ = 3.6, $J_{5,6'}$ = 5.0), 3.39 (H-2, $J_{2,3}$ = 9.1), 3.46 (H-3, $J_{3,4}$ = 9.1), 3.56 (H-4, $J_{4,5}$ = 9.1), 3.58 (OCH_3), 3.77 (H-6′), 3.88 (H-6 $J_{6,6'}$ = 11.8), 4.37 (H-1, $J_{1,2}$ = 7.7); for its 4,6-diacetate: δ: 1.92, 2.07 (2 × $COCH_3$), 3.49 (H-2, $J_{2,3}$ = 9.1), 3.56 (H-5, $J_{5,6}$ = 4.9, $J_{5,6'}$ = 2.4), 3.58 (OCH_3), 3.60 (H-3, $J_{3,4}$ = 9.1), 4.08 (H-6′), 4.24 (H-6, $J_{6,6'}$ = 12.2), 4.34 (H-1, $J_{1,2}$ = 7.8), 5.04 (H-4, $J_{4,5}$ = 10.0). The

[3]2-Propanol was added when necessary to make up for volume loss due to evaporation, especially when the reaction time was very long.

[4]Methyl α-D-glucopyranoside, the major product (40%), was conveniently separated from the three more mobile products, because it was largely adsorbed on the catalyst (less strongly on Pd/C), from which it was eluted subsequently by washing with water.

data for the benzylic protons of these compounds are given in Table 2.

*Methyl 2,3,4-tri-*O*-benzyl-6-*O*-trityl-β-D-glucopyranoside (**23**) and methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranoside*

Compound **23** was prepared from methyl 6-*O*-trityl-β-D-glucopyranoside (**18**) by benzylation with benzyl bromide and sodium hydride in the presence of tetrabutylammonium iodide in dry tetrahydrofuran according to the procedure described (10) for some related compounds. The ^{1}H nmr data for **23**: δ: 3.27 (H-6′), 3.43 (H-5, $J_{5,6}$ = 2.0, $J_{5,6'}$ = 3.6), 3.57 (H-2), 3.62 (H-6, $J_{6,6'}$ = 10.0), 3.64 (H-3, $J_{3,4}$ = 9.2), 3.69 (OCH_3), 3.87 (H-4, $J_{4,5}$ = 9.2), 4.40 (H-1, $J_{1,2}$ = 7.6), 4.39 and 4.72 (OCH_2, J_{gem} = 10.0), 4.83 and 4.92 (OCH_2, J_{gem} = 11.0), 4.79 and 5.01 (OCH_2, J_{gem} = 11.0), 6.8–7.6 (Ph).

Methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranoside was obtained as a syrup from **23**, by hydrolysis in 70% acetic acid at 100°C for 1 h. The ^{1}H nmr data: δ: 3.39 (H-5, $J_{5,6}$ = 2.7, $J_{5,6'}$ = 4.6), 3.39 (H-2, $J_{2,3}$ = 9.0), 3.56 (OCH_3), 3.57 (H-4, $J_{4,5}$ = 9.5), 3.67 (H-3, $J_{3,4}$ = 9.5), 3.71 (H-6′), 3.87 (H-6, $J_{6,6'}$ = 12.0), 4.35 (H-1, $J_{1,2}$ = 7.8). The data for the benzylic protons, as well as for those of the 6-acetate, are given in Table 2.

The cleavage of aryl-metal bonds by elemental fluorine: synthesis of aryl-fluorides[1]

MICHAEL J. ADAM, JOFFRE M. BERRY,[2] LAURANCE D. HALL,[3] BRIAN D. PATE, AND THOMAS J. RUTH
TRIUMF and Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, B.C., Canada, V6T 2A3

Received August 12, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

MICHAEL J. ADAM, JOFFRE M. BERRY, LAURANCE D. HALL, BRIAN D. PATE, and THOMAS J. RUTH. Can. J. Chem. **61**, 658 (1983).

The reaction of elemental fluorine with phenyl derivatives of tin, lead, germanium, silicon, mercury, and thallium has been studied with the aim of developing a general method for labelling aromatic compounds with radioactive ^{18}F. Rapid synthesis of fluorobenzene was achieved in varying chemical yields up to 70%, depending largely upon the metal substrate used, with aryl–tin compounds giving the highest yields. Radiochemical yields are also given for the synthesis of ^{18}F-fluorobenzene from the cleavage of aryl–tin bonds with ^{18}F-F_2.

MICHAEL J. ADAM, JOFFRE M. BERRY, LAURANCE D. HALL, BRIAN D. PATE et THOMAS J. RUTH. Can. J. Chem. **61**, 658 (1983).

On a étudié la réaction du fluor élémentaire avec les dérivés phénylés de l'étain, du plomb, du germanium, du silicium, du mercure et du thalium, en mettant au point une méthode générale de marquage des composés aromatiques avec le ^{18}F radioactif. On a réalisé une synthèse rapide du fluorobenzène avec des rendements chimiques allant jusqu'à 70% qui varient principalement en fonction du substrat métallique utilisé; on obtient les rendements les plus élevés avec les composés aryle–étain. On donne également les rendements radiochimiques de la synthèse du ^{18}F-fluorobenzène à partir du clivage des liaisons aryl–étain par le ^{18}F-F_2.

Introduction

The group IVB metals (Si, Ge, Sn, Pb) and also mercury and thallium have all been employed successfully in halogenating aromatic compounds (2) with chlorine, bromine, and iodine. There is, however, a paucity of information in the literature on the fluorination of organometallic compounds (3, 4) and also on the use of organometallic compounds, containing the metals listed above, in radiohalogen labelling (5–7). This has prompted us to investigate the utility of these metals in developing a general method for activating aromatic rings toward fluorination for the purpose of labelling with ^{18}F.

The labelling of aromatic compounds with radioactive ^{18}F ($t_{1/2}$ = 110 min), for use in positron emission tomography (PET) (8), places several stringent requirements on the chemistry. The reaction must be rapid, it must use a form of fluorine which can be labelled with ^{18}F, and must be efficient in its use of that active fluorine.

To date, no one satisfactory method exists for synthesizing ^{18}F-labelled aryl fluorides, however, several methods have been used with some success. These include the Balz Schiemann reaction (9), the triazene decomposition method (10), the nucleophilic displacement of fluorine by fluoride (11), and direct fluorination with xenon difluoride (12). Each of these methods has serious limitations and it is generally accepted that there is a need to increase the armamentarium of aromatic fluorination methods available to the radiochemist.

Aryl fluorination is an important area because of the large number of useful and potentially useful pharmaceuticals containing the phenyl moiety. Despite the difficulties of labelling with ^{18}F, a number of ^{18}F-containing aromatic drugs have already been synthesized, such as phenyl amino acids (9) and butyrophenone neuroleptic drugs (9, 13). Other ^{18}F-compounds which may be of interest include phenyl fatty acids, benzodiazepines, and also simple fluorinated aromatics that can be used as precursors of more complex systems. Even fluorobenzene labelled with ^{18}F may be a useful radiopharmaceutical, as it has the potential of being a myelin marker used to study the demyelination process associated with multiple sclerosis; iodobenzene has already been shown to be useful in this regard (14). Clearly these and other areas would be advanced by the development of rapid and efficient methods of aromatic fluorination.

Results and discussion

Simple addition of fluorine to aromatic nuclei is rare (15, 16), because the reaction is usually accompanied by unselective partial or total replacement of hydrogen (15). One method of achieving site selectivity is to metallate one carbon atom in the ring, for which there is ample precedent in the literature (2, 17, 18), forming a carbon–metal bond which is highly reactive toward an electrophilic fluorinating reagent.

For a given organic moiety, attached to the metal centre, the rate ordering for its cleavage by chlorine, bromine, and iodine is similar for all the metals used in this study (2, 19, 20). For example, aryl–metal bonds are cleaved more rapidly than those between metals and alkyl groups. This is particularly important for radiolabelling, since by selecting the other metal substituents to be alkyl groups, the activity can be conserved in the cleaved aromatic ring.

Fortunately, this same rate differential also applies to cleavage by fluorine. As shown in Table 1, only the phenyl group of $PhSn(Bu)_3$ was fluorinated, to produce fluorobenzene; no butyl fluoride could be detected. Since, for the present study,

[a]Not detected.

we were interested in measuring the effect that the various metals have on the metal–phenyl bond cleavage rate, mixed ligands were not necessary for all compounds shown in Table 1.

It was already known that within the group IVB elements the M—C bond becomes progressively more easily broken thermally and chemically (2) as one descends the group. The yields of fluorobenzene obtained from the various group IV metal compounds shown in Table 1 do seem to be in agreement with this predicted pattern with tin and lead substrates giving higher yields of fluorobenzene than the germanium or silicon substrates.

The mercury and thallium salts shown in Table 1 were included in this study because they can be prepared by mild electrophilic addition reactions (17), and it was felt that this might confer a synthetic advantage for some aryl substrates. Of the two classes of mercury compounds studied one would predict, as was observed, that the diphenyl compound would be more reactive than the phenyl mercury salts, since the salts contain highly electronegative anions.

The aryl–mercury salts were, unfortunately, insoluble in $CFCl_3$ and CCl_4, and gave no detectable amount of fluorobenzene upon fluorination. Therefore acetonitrile was used as the reaction solvent; fluorine reacts only slightly with acetonitrile.

The thallium salt failed to yield fluorobenzene in any solvent used, possibly due to the fact that it contains two electron-withdrawing substituents.[4]

The results with mercury and thallium salts are very interesting, since even though fluorine is the most reactive halogen, it fluorinates these compounds very poorly, or not at all, in contrast to the results obtained by treating these same compounds with other halogens (2, 19, 21).

[4]A referee has suggested that the observed lack of reactivity of $ArTl(OCOCF_3)_2$ compounds toward F_2 probably reflects the unusual stability of $ArTlF_2$ intermediates and, hence, their corresponding reluctance to break down to ArF + TlF.

The radiochemical yields were obtained only for the two tin compounds; these were calculated as the percentage of activity associated with the pure ^{18}F-fluorobenzene, after hplc, based on the total ^{18}F-F_2 activity obtained from the target. Radiochemical yields for the other substrates are expected to be approximately half that of the chemical yields when working at the present concentrations of carrier fluorine; 50% radiochemical yield is the maximum obtainable, since one fluorine atom of the F_2 molecule attaches to the tin centre.

The total time required for extraction of the ^{18}F-F_2 gas from the target into the reaction vessel, the reaction itself, and subsequent work-up is on the order of one hour, which is not unduly long compared with the half-life of ^{18}F (110 min.) Another attractive feature of this method is that the precursor organometallic starting materials are stable, and can be stored indefinitely prior to fluorination with ^{18}F-F_2.

Experimental

Tetraphenyltin, diphenylmercury, tetraphenyllead, phenylmercury acetate, and phenylmercury chloride were purchased from Alfa Products, Danvers, MA, and tetraphenylgermanium and tetraphenylsilane were purchased from PCR Research Chemicals Inc., Gainesville, FL. Phenylthallium bis-trifluoroacetate (21), phenylmercury trifluoroacetate (21, 22), and phenyltributyltin (23) were prepared from existing literature methods. Freon-11 ($CFCl_3$) was purchased from Matheson, Edmonton, Alberta, and distilled and stored over 4 Å molecular sieves. Acetonitrile was purchased from BDH Chemicals, Vancouver, British Columbia, and was distilled from calcium hydride and stored over 4 Å molecular sieves. Fluorine (1% in Ne) was purchased from Matheson, Whitby, Ontario, and the amount used assayed by bubbling through potassium iodide and titrating with thiosulfate as described elsewhere (24, 25).

Gas chromatography was performed with a Hewlett–Packard 5840A, equipped with an FID detector using a 6 ft × 1/8 in. stainless steel column packed with 10% SP-1000 on 80–100 mesh Supelcoport (Supelco-Inc., Bellefonte, PA) at 70°C and a nitrogen carrier flow-rate of 12 mL/min. All chemical yields were determined by gc using the internal standard method with toluene as the internal standard. The hplc was performed with a Waters system (Waters Associates, Inc., Milford, MA) using a C-18 Radial-Pak column with an ethanol–water (60:40) eluant and uv detection at 254 mm. The ^1H nmr measurements were performed on a 270 MHz spectrometer and ^{19}F nmr spectra were obtained using a Varian XL-100 spectrometer. Radioactive samples were assayed on a Beckmann 8000 scintillation counter.

Fluorine gas must be handled with great care (26). For this reason we constructed the stainless steel manifold shown in Fig. 1, with stainless steel bellows valves (NUPRO Co., Willoughby, OH). Connections from the manifold to glassware were made with Teflon tubing (1/16 or 1/8 in. od) using Swagelok fittings (Crawford Fitting Co., Salon, OH) and Teflon ferrules. The manifold and fluorine tank are stationed inside a fume hood designed for use with radioisotopes. The gas target system will be described in detail elsewhere, and is essentially a stainless steel, gas-tight cylinder placed in the 500-MeV proton beam line at TRIUMF, and filled with a mixture of 0.1% F_2/Ne via 1/8 in. od stainless steel tubes connected to the gas manifold.

Reaction of elemental fluorine with aryl–metal substrates

The anhydrous organometallic compound (120 μmol) was dissolved or suspended in Freon-11 ($CFCl_3$), CCl_4, or acetonitrile (10 mL) and added to the reaction vessel (1 cm od × 20 cm length with cooling jacket), which had been previously dried and flushed with an inert gas. A stream of inert gas was passed through the mixture which was cooled by solid CO_2 or ice, packed around the outside of the reaction vessel. The gas flow was stopped after the mixture had cooled and then the manifold was flushed several times with dilute fluorine to passivate the system. The 50 mL ballast bulb (see Fig. 1) was then filled to 30 psig with 1% F_2 (60 μmol), sealed off, and the

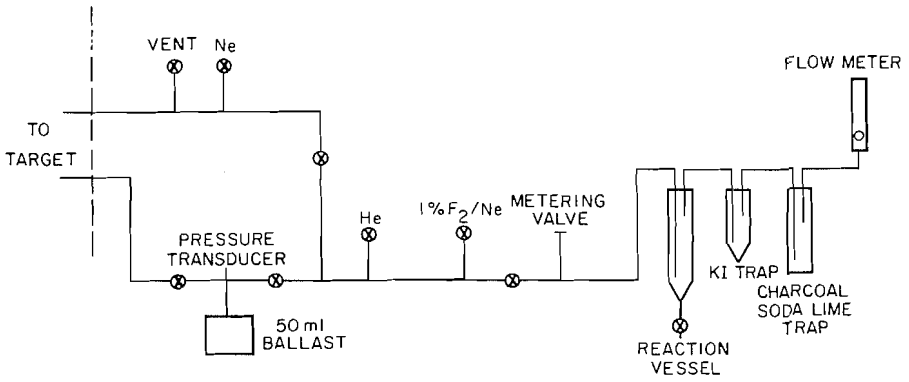

FIG. 1. Schematic of the fluorine gas handling manifold; ^{18}F-F_2 reaction system.

rest of the manifold then flushed with He. The F_2 in the ballast bulk was then allowed to vent into the reaction vessel at <50 mL/min. Any residual F_2 was flushed from the manifold with He gas and added to the reaction. A KI/H_2O trap was placed on the exhaust side of the reaction vessel to detect any F_2 that was not absorbed in the reaction.

After F_2 addition, the mixture was purged with He and then drained from the reaction vessel and distilled. The distillate, now free from starting material and metal fluorides, was analyzed by hplc and gc. In reactions that used CCl_4 as the solvent, ^1H nmr can be used to analyze the products in the distillate directly. The only product detected showed an identical resonance pattern to that of an authentic sample of fluorobenzene.

Synthesis of ^{18}F-fluorobenzene using ^{18}F-F_2

For experiments with radioactive ^{18}F-F_2 the initial non-radioactive F_2 was allowed to bleed from the 50 mL ballast bulk into the target described above, followed by Ne at 150 psig to force the fluorine bolus into the target (18). After irradiation with the proton beam, the radioactive gas was allowed to expand back through the manifold into the reaction vessel under its own pressure. Due to the increased system volume, now including that of the target and transfer lines, the flow rate used was 100 mL/min, and the total time required for extraction of the active gas was 40 min.

Production of ^{18}F-labelled molecular fluorine with a medical mini-cyclotron

MIRKO DIKSIC[1] AND YOJIRO TODA[2]

Medical Cyclotron Unit, Montreal Neurological Institute, McGill University, 3801 University Street, Montreal, P.Q., Canada H3A 2B4

Received August 13, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

MIRKO DIKSIC and YOJIRO TODA. Can. J. Chem. **61**, 661 (1983).

It has been demonstrated that several hundred millicuries of ^{18}F-F_2 can be produced with a small medical cyclotron using deuteron irradiation of a mixture of 0.5% fluorine in neon at an initial pressure of 405 kPa (4 atm). A high-current deuteron beam from a medical mini-cyclotron was used. Extraction efficiency for ^{18}F-molecular fluorine from the target box for the irradiation of one hour or less was 61−68%. Specific activity of extracted anhydrous molecular fluorine is about 133.2 GBq/mmol (3.6 Ci/mmol) and 216.82 GBq/mmol (5.86 Ci/mmol) after one- and two-hour irradiation, respectively. A passivation of the target box by a short irradiation of fluorine−neon mixture was demonstrated.

MIRKO DIKSIC et YOJIRO TODA. Can. J. Chem. **61**, 661 (1983).

On a démontré qu'il est possible de produire plusieurs centaines de millicuries de ^{18}F-F_2 avec un petit cyclotron médical utilisant l'irradiation au deutéron d'un mélange à 0,5% de fluor dans du néon à une pression initiale de 405 kPa (4 atm). On a utilisé un faisceau de deutéron à fort courant provenant d'un mini-cyclotron médical. L'efficacité d'extraction du fluor (^{18}F) moléculaire à partir de la boîte cible pour une irradiation durant une heure ou moins est de 61−68%. L'activité spécifique du fluor moléculaire anhydre extrait est d'environ 133,2 GBq/mmol (3,6 Ci/mmol) et de 216,82 GBq/mmol (5,86 Ci/mmol) respectivement après une et deux heures d'irradiation. On a démontré que la boîte cible est rendue passive par une courte irradiation du mélange de fluor−néon.

Introduction

Several review papers have described radiopharmaceuticals labelled with ^{18}F (1−3). One reagent that has shown great promise in the synthesis of labelled radiopharmaceuticals to be used in conjunction with positron emission tomography for mapping of human organs is ^{18}F-labelled anhydrous molecular fluorine. ^{18}F has a half-life of only 110 min (4), and 1.85−3.7 GBq (50−100 mCi) of ^{18}F-labelled anhydrous fluorine is needed to start the labelling procedure and maintain enough radioactivity at the end for patient use.

The role of ^{18}F-labelled molecular fluorine in the synthesis of ^{18}F-labelled 2-deoxy-2-fluoro-D-glucose (2-FDG) has been well established (5−8).[3] 2-Deoxy-2-fluoro-D-glucose is the tracer most frequently used to measure in vivo regional cerebral glucose utilization with positron emission tomography (PET) in man (8, 9). To date the only available method for synthesis of ^{18}F-2-FDG used in PET studies involves ^{18}F-labelled molecular fluorine. Accordingly heavy demands have been put on medical cyclotrons to produce molecular fluorine.

The production of ^{18}F-labelled molecular fluorine by means of a cyclotron with a deuteron energy of 12 MeV and up has been well documented (5, 6, 10, 11). ^{18}F-fluorine has also been produced with a Tandem Van de Graff with nominal deuteron energy on the target gas of 11 MeV, but because of low beam intensity (7) the amounts produced have not reached levels needed for synthesis of ^{18}F-2-FDG used in clinical studies. Problems with the production of ^{18}F-molecular fluorine and subsequent extraction from the target derive from the chemical characteristics of fluorine, and especially of atomic fluorine. The fluorine produced in a ^{20}Ne(d, α) nuclear reaction is atomic, and very reactive. To overcome these problems the groups involved in the production of ^{18}F-2-FDG use different amounts of molecular fluorine as a carrier.

New syntheses (12−14) for 2-FDG overcome these problems and make mini-cyclotrons even more useful for the preparation of multi-portions of ^{18}F-2-FDG (12, 13) in one-hour irradiation periods. In this paper we report on the targetry used and the yields achieved in routine production of ^{18}F-labelled anhydrous molecular fluorine by means of a high-current medical mini-cyclotron.[4]

Targetry and gas handling system

Target

The target is made from a solid piece of nickel with an oval shaped opening for the gas. The shape of the target resembles the shape of the beam but is larger in size to allow for the spread of the beam which occurs when deuterons are scattered by the target gas (15). The dimensions of our target are shown in Fig. 1 with a cross section in Fig. 2. The beam hits the walls of the target about 10 cm from the entrance foil. The reason for this is a well-known beam spread which has been discussed in more detail in ref. 15. With this scatter the beam apparently becomes wider than 15 mm, which is the height of the target box. From a simple geometrical calculation we have estimated that maximal loss of the beam from this spread is about 5% and the measurements of ^{18}F production described in this paper are not able to detect this loss.

The target's two openings have to be closed with material resistant to the corrosive fluorine atmosphere inside the target box. A 10 mm thick nickel plate is used to close the target on the back (H in Fig. 1). This plate is attached to the target body

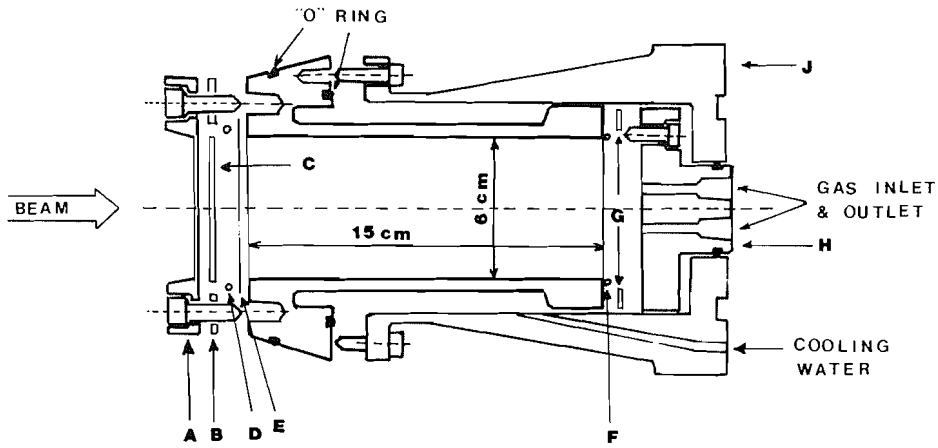

FIG. 1. Cross section of the target assembly for the production of ^{18}F-molecular fluorine (for more details see text).

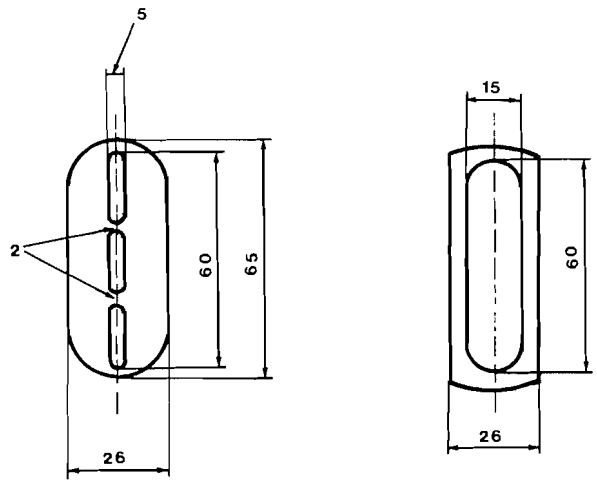

FIG. 2. Entrance foil reinforcement (C) and vertical cross section of the target chamber. All dimensions are in millimeters.

with a few bolts to ensure an even and reliable seal between the plate, metal "O" ring (F in Fig. 1), and the target body. The metal "O" ring is made from stainless steel tubing covered by a thin layer of silver. Spacers (B and G in Fig. 1) are used to prevent overtightening of the plates onto metal "O" rings (D and F in Fig. 1).

Another "O" ring (D in Fig. 1) is used on the front to obtain a seal between the entrance foil (E in Fig. 1), "O" ring, and the cover plate (A in Fig. 1). The entrance foil is sealed with a metal "O" ring attached to the target body and to the entrance plate with twelve bolts. To strengthen the entrance foil an aluminum reinforcement is placed over it (C in Figs. 1 and 2). The entrance foil is made from 20 μm thick aluminum with a 0.3 μm nickel layer on the side exposed to the gases in the target box. This foil is prepared by vacuum evaporation of nickel on aluminum foil. The entire target body is enclosed in an aluminum housing (J in Fig. 1) which is sealed to the body of the target with Buna "O" rings. Appropriate cooling of the target is very important. Deionized water at a temperature of about 20°C circulates between the aluminum housing (J in Fig. 1) and target body at the rate of 3.5 L/min. After the target box is firmly pressed into the target area there is a small space between the cyclotron exit foil and the target entrance foil. Precooled helium gas is pumped into the space to cool both foils.

Passivation

We have experimented to see if there is any need for the passivation described by the Brookhaven group (10, 16). In our first set of experiments the target was passivated by heating it in an oven to 200°C (16) with 1% fluorine in neon at a pressure of 202.7 kPa (2 atm) for two hours. After cooling, the target was evacuated and kept overnight under 202.7 kPa (2 atm) of 0.5% fluorine in neon. After this procedure the target was considered ready for ^{18}F-F_2 production. In the second set, the target was passivated by irradiating 0.5% fluorine in neon at 405 kPa (4 atm) pressure for 15 min with 50 μA. The target was then evacuated and considered ready for production of ^{18}F-labelled molecular fluorine. We observed no difference in production of ^{18}F-fluorine in the target boxes passivated by either procedure. Our observation supports that of the Brookhaven National Laboratory[5] for the target gas irradiated at a pressure of 2533 kPa (25 atm).

Fluorine transport

The fluorine transport system is built from nickel pipe, 3.16 mm (1/8 in.) od and 1.59 mm (1/16 in.) id. Pieces of the pipes are connected with Monel swageloks. The last portion of the fluorine transport pipe is made from small-diameter Teflon tubing, the end of which has been pierced several times with a needle. The holes ensure good contact of ^{18}F-fluorine gas with the reaction solution, e.g. solution of sodium acetate in acetic acid. The valves[6] used are made from Monel with metal gaskets. Whenever the transport system is not being used for production of ^{18}F it is filled with target gas and kept under 152 kPa (1.5 atm) pressure. Before the system is used again, gas is pumped out and a new gas mixture is introduced for irradiation.

Results and discussion

The target used in our work was irradiated with deuterons of a nominal current of about 50 μA and an energy on the target gas of about 6.2 MeV. The energy loss was calculated by using range and stopping power data from ref. 17 and taking the energy of the deflected internal beam as 7.1 MeV. The energy of the deflected beam was determined by measuring spectra of elastically and inelastically scattered particles on ^{12}C and ^{197}Au. These measurements were made by JSW before the cyclotron

was delivered to us. They quote the energy of deuterons as 7.10 ± 0.03 MeV. The target box is electrically isolated and the current integrated during irradiation. The target system has a nominal volume of 135 mL. The beam that actually strikes the target foil reinforcement is about 56 μA. About 6 μA of current is lost on the aluminum reinforcement used to strengthen the entrance foil, as well as in the scatter on the reinforcement. The intensity loss on the reinforcement was also measured by JSW before the cyclotron was shipped to us.

We have used 1% fluorine in research purity neon,[7] diluted in the target box to 0.5% fluorine with research purity neon. Measurement of the actual amount of fluorine contained in our target system before irradiation revealed that it contains 115 ± 5 μmol of molecular fluorine when a pressure of 405 kPa is used. The gases are passed through a HF trap obtained from Matheson. The trap is regenerated every time the fluorine cylinder is changed. The target is irradiated at a pressure of 405 kPa (4 atm) measured with the beam off. The pressure rises to 516.8 kPa (5.1 atm) under irradiating conditions. At the pressure of 405 kPa, the energy loss, as calculated from the range data (17), is more than that needed to degrade the deuteron energy below the threshold for the $^{20}Ne(d,\alpha)$ reaction.

After entering the target, the beam is spread as a result of a scatter. The scattered beam has fewer target atoms between the wall and the place of scatter and accordingly less chance that projectiles will interact with the target nucleus and produce ^{18}F before hitting the wall. Energy loss also resulted from the scatter. Both these factors would reduce the yield of ^{18}F. In our work we made a practical evaluation of these factors on the yield of ^{18}F.

By visual examination we can see that the beam is hitting the walls of the target box about 10 cm from the entrance foil. There is also some indication that the beam is hitting the back plate of the target. In this case, the energy of deuterons hitting the back plate is insufficient to induce $^{20}Ne(d,\alpha)$ reaction and would not contribute to the loss of ^{18}F, at least not to any significant level. We reached that conclusion by irradiating the gas mixture at an initial pressure of 304 (3 atm) and 405 kPa (4 atm) (with beam on, the pressure rises to 4.1 and 5.1 atm, respectively). We have not noticed any significant difference in the yield of ^{18}F-fluorine by irradiating the target gas at an initial pressure of 304 or 405 kPa (3 or 4 atm). If the energy of the beam reaching the back plate were high enough to induce a $^{20}Ne(d,\alpha)$ reaction, then we should notice a decrease in the yield of ^{18}F when the target pressure is reduced. The lower density would increase the energy of deuterons hitting the back plate of the target box and, with that, the yield of fluorine-18 would be reduced.

At the beginning of our work we used a 10 cm long target. The yield of ^{18}F was significantly lower than that obtained with the 15 cm long target presently used (see Table 1). Since the yield of ^{18}F was significantly lower in the shorter target, we have concluded that the energy of deuterons hitting the back plate was high enough to induce a $^{20}Ne(d,\alpha)$ nuclear reaction. The inside surfaces of both targets are well polished to reduce loss of ^{18}F (5, 6, 10, 15, 16) through chemical reaction between atomic fluorine and the surface of the target box. For eight months the target has been in routine use for the production of ^{18}F-labelled molecular fluorine without major problems.

TABLE 1. The yield of molecular fluorine extracted from target box*

Irradiation time	Yield: 10 cm long target (mCi)	Yield: 15 cm long target (mCi)
4 h	300	470 (46)†
2 h	214	330 (49)
1 h	—	250 (61)
30 min	—	150 (67)
20 min	—	105 (68)
15 min	40	80 (68)

*Standard deviation for the yields is 12%.
†Extraction yield in per cent is calculated by taking saturation yield of 1.3 Ci. Before averaging, yields were normalized to 50 μA beam current.

Taking the calculated yield as 100% we are able to extract above 60% of radioactivity from the 15 cm long target box after irradiation times equal to or less than one hour (Table 1). Calculated yields are obtained by integrating the experimental excitation function taken from ref. 18 and the stopping power for deuterons from ref. 17. The thick target calculated saturation activity for 6.2 MeV deuterons is 1.3 Ci. This agrees well with results given in ref. 10. The equation used for the integration has been described elsewhere (19). Since no one else uses the target box at the same pressure we do, it is not possible to compare our extraction yield directly with that of other groups.

Our results for the production of ^{18}F-fluorine are given in Table 1. As expected, a 15 cm long target gives better yields, because in a 10 cm target, the beam does not deposit all effective energy in the target gas. It was observed earlier that the thermal heating reduces the gas density in the beam strike and, along with that, the ^{18}F yield (10, 15). The effective density of the gas is reduced, and as a result the energy of the deuterons in a 10 cm long target box is not deposited into the target gas, as discussed earlier (15). A target 15 cm long maintained at a pressure of 4 atm (beam off), is sufficiently long to reduce the beam energy to a level below that needed to induce a $^{20}Ne(d,\alpha)$ reaction. As observed earlier (15), more fluorine radioactivity is extracted from the target when the irradiation time is shorter.

On average, the target foil is pin-holed after six hours of irradiation and has to be changed. This is certainly not satisfactory and we hope to replace the window with a more durable one. We have experimented with Havar and with nickle-plated Havar foils, as suggested by Dr. Wieland.[8]

Specific activity

Specific activity was determined by first measuring the amount of ^{18}F-fluorine extracted from the target. These measurements were done by reducing ^{18}F-fluorine with potassium iodide and determining the released iodine gravimetrically by precipitating it as AgI (after extracting it with $CHCl_3$) (20), or volumetrically by titrating it with 0.05 *N* sodium thiosulfite. First, the following reaction occurs: $F_2 + 2I^- \rightarrow I_2 + 2F^-$. When iodine is titrated with thiosulfate, the following reaction occurs: $I_2 + 2S_2O_3^{2-} \rightarrow 2I^- + S_4O_6^{2-}$ (21). Radioactivity of ^{18}F-fluoride produced after reduction with I^- was measured in an isotope calibrator. At present we extract from the target after one-hour irradiation about 70 μmol of molecular fluorine (fluorine carrier) as determined by the methods above. After one

[7]Matheson of Canada.

[8]B. W. Wieland, private communication, September, 1982.

hour of irradiation the specific activity of fluorine is 133.2 GBq/mmol (3.6 Ci/mmol) expressed at the EOB. Shorter irradiation times produce lower specific activity fluorine and, with that, lower specific activity final product.

Conclusion

A medical mini-cyclotron with a deflected deuteron energy (before exiting through the exit foil) of 7.10 ± 0.03 MeV and beam intensity on the target gas of about 50 μA can produce, on the average, 12.21 GBq (330 mCi) (EOB) of ^{18}F-labelled molecular fluorine in a two-hour irradiation. This represents the radioactivity extracted from the target box as molecular fluorine available for radiochemical synthesis in our high level radiochemistry laboratory. The activity is sufficient to prepare enough ^{18}F-2-FDG for three PET studies of glucose metabolism in patients when the new high-yield syntheses (12, 13) of ^{18}F-2-FDG is used. After this new high-yield synthesis and a two-hour irradiation, the radioactivity of ^{18}F-2-FDG produced and available for patient use one hour after EOB is about 1.85 GBq (50 mCi). In a more modest operation, a one-hour irradiation should be sufficient to produce enough ^{18}F-F_2 and FDG for two patient studies. We also came to the conclusion that it is sufficient to passivate the target simply by irradiating the target gas in it for 15–20 min.

Our results demonstrate for the first time that good recovery of molecular fluorine can be achieved from a low pressure target irradiated with a high current beam, thereby proving the value of a small medical cyclotron in PET research.

Warning: We would remind our fellow scientists that fluorine is a highly toxic and reactive gas. It should be handled cautiously by trained personnel only.[9]

Acknowledgements

This work was supported in part by the Medical Research Council of Canada, the National Cancer Institute of Canada, the Cone Memorial Research Fund of the Montreal Neurological Institute, and a Killam Fellowship to one of us (M.D.). Our thanks go to Drs. W. Feindel and L. Yamamoto for their continuous encouragement and interest in this work. M.D. expresses special thanks to Professor Leo Yaffe, Department of Chemistry, McGill University, for his interest in this project and permission to use his counting equipment. We also thank the operator of our medical cyclotron, Stephen Irwin, for his dedicated work and Dean Jolly, who helped us in one stage of this project. Our thanks are extended to Dr. V. Lees for editing this manuscript.

Nuclear charge distribution in fission: fractional cumulative yields of isotopes of krypton and xenon in $^{249}Cf(n_{th},f)$ and $^{250}Cf(sp.f)$[1]

H.-H. MEIXLER,[2] K. WOLFSBERG,[3] AND H. O. DENSCHLAG[4]

Institut für Kernchemie, Universität Mainz, D-6500 Mainz, Germany

Received August 23, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

H.-H. MEIXLER, K. WOLFSBERG, AND H. O. DENSCHLAG. Can. J. Chem. **61**, 665 (1983).

The fractional cumulative yields (%) of the following rare gas isotopes were determined radiochemically in the thermal neutron induced fission of ^{249}Cf and in the spontaneous fission of ^{250}Cf and the following results were obtained for the two processes, respectively: ^{89}Kr: 77.6 ± 1.5, —; ^{91}Kr: $31.0^{+3.1}_{-1.7}$, $34.8^{+4.3}_{-3.2}$; ^{92}Kr: 9.5 ± 1.3, $9.9^{+4.2}_{-2.1}$; ^{139}Xe: 32.0 ± 3.5, 23.6 ± 6.0; ^{140}Xe: 12.5 ± 2.0, 14.7 ± 7.0; ^{141}Xe: 4.0 ± 0.3, $9.1^{+10.4}_{-6.7}$; ^{142}Xe: 0.9 ± 0.1, ≤3.61, and ^{143}Xe: 0.22 ± 0.08, —. The results are discussed with respect to the systematics of nuclear charge distribution in fission.

H.-H. MEIXLER, K. WOLFSBERG et H. O. DENSCHLAG. Can. J. Chem. **61**, 665 (1983).

On a déterminé par radiochimie les rendements cumulatifs fractionnaires (%) des gaz rares mentionnés ci-dessous lors de la fission du ^{249}Cf induite par les neutrons thermiques et lors de la fission spontanée du ^{250}Cf. On a obtenu les résultats suivants pour les deux processus: ^{89}Kr: 77,6 ± 1,5, —; ^{91}Kr: $31,0^{+3,1}_{-1,7}$, $34,8^{+4,3}_{-3,2}$; ^{92}Kr: 9,5 ± 1,3, $9,9^{+4,2}_{-2,1}$; ^{139}Xe: 32,0 ± 3,5, 23,6 ± 6,0; ^{140}Xe: 12,5 ± 2,0, 14,7 ± 7,0; ^{141}Xe: 4,0 ± 0,3, $9,1^{+10,4}_{-6,7}$; ^{142}Xe: 0,9 ± 0,1, ≤3,61 et ^{143}Xe: 0,22 ± 0,08, —. On discute les résultats en fonction de la systématique de la distribution de la charge nucléaire lors de la fission.

[Traduit par le journal]

Introduction

The knowledge of independent yields in the fission of ^{250}Cf was very limited at the beginning of the present work, and it was felt that a larger and more representative data basis was important for the purpose of testing and further developing yield systematics. Measurements of both, the thermal neutron induced fission of ^{249}Cf and the spontaneous fission of ^{250}Cf, allow one to consider the effect of excitation energy of the compound nucleus, a parameter that has been studied extensively at higher energies and other fissioning systems by Yaffe and co-workers (1).

We have used the "emanation method" to measure the fractional cumulative yields of various xenon and krypton isotopes in the thermal neutron induced fission of ^{249}Cf and in the spontaneous fission of ^{250}Cf. This method has been developed by Wahl (2) and was applied very successfully to the study of various fission reactions (2–6).

The principle of the emanation technique consists of the stopping of fragments from a thin fission source in a metal stearate layer. Among the fission products only the inert gases (Kr and Xe) are able to diffuse through the stearate into an adjacent volume, where they subsequently decay into longer-lived descendants. Thus during irradiation (or exposure to a spontaneously fissioning source), a continuous (on-line) separation is taking place between descendants produced via inert gas precursors escaping the stearate and those that are formed directly and remain within the stearate. The ratio of the activity of a descendant outside the stearate to the total thus gives directly the fractional cumulative yield of the inert gas precursor.

Experimental

The basic set-up used for the study of the thermal neutron induced fission of ^{249}Cf is shown in Fig. 1. It was made of plexiglass to avoid high (n,γ)-activities for convenient handling of the container after irradiation. The target consisted of 10 μg of ^{249}Cf electrodeposited on a platinum disc. In part of the experiments (^{143}Xe), a target of 10 μg of ^{249}Cf deposited on a steel cylinder was used (Fig. 1, alternative target holder *b*).

Before irradiation the targets were covered with sufficient magnesium stearate to stop all fission fragments. The container was lined with filter paper (Whatman No. 1) and evacuated using a hypodermic needle inserted through a serum bottle stopper. The irradiation was carried out at room temperature in the thermal column of the Mainz TRIGA Reactor for times of 30 min (A = 141, 142), 1 h (A = 91, 92, 139), and 6 h (A = 89, 140, 143) in a neutron flux of 3×10^{10} n/(cm^2 s). After the irradiation and a waiting time sufficient for the rare gas to decay, the container was checked for tightness again, vented, and dismantled.

For the experiments with ^{250}Cf, a set up of nearly identical design made of brass was used. The serum bottle stopper was replaced by a needle valve. The target was 1.2 μg of ^{250}Cf electrodeposited on a platinum disc. The preparation of the container (introduction of magnesium stearate, lining, and evacuation) was as described above for ^{249}Cf. The exposure time to the spontaneously fissioning ^{250}Cf source was 2 h (A = 141, 142), 15 h (A = 139, 140), and 20 h (A = 91, 92). The times were longer than they were for ^{249}Cf in order to improve counting statistics and to minimize errors due to the time required for mounting and dismantling the container. The uncertainty due to the latter problem was included in the errors given.

In both fission reactions the descendants to be counted ($^{89,91,92}Sr$, $^{139-142}Ba$, ^{143}Ce) were isolated chemically from the two fractions (magnesium stearate and paper liner) after complete decay of all precursors. For this purpose, paper and stearate were dissolved separately after the addition of the respective carriers (Sr, Ba, Ce) using mixtures of nitric acid and perchloric acid (2).

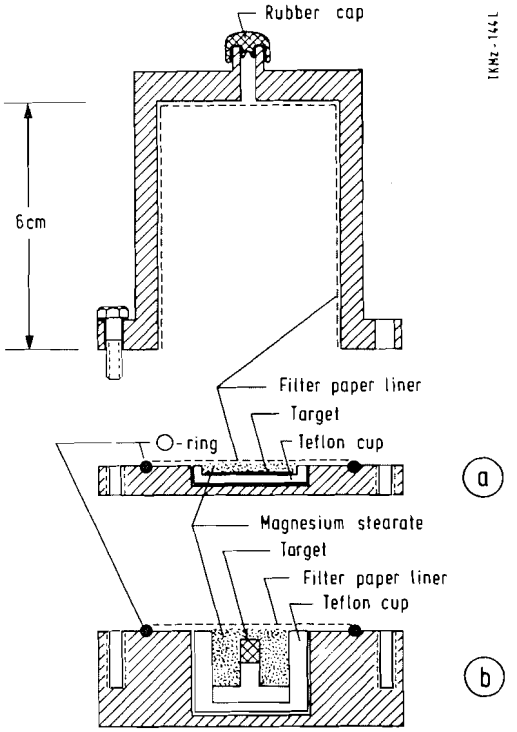

FIG. 1. Cross-sectional view of cylindrical irradiation container with target holders for (*a*) planar targets and (*b*) cylindrical targets.

The separation of barium and strontium (7, 8) was based on the precipitation of the nitrates from cold concentrated nitric acid, a scavenging precipitation of $Fe(OH)_3$ and the precipitation of barium as chromate. Strontium was isolated from the filtrate of the barium chromate precipitate. After a second addition of barium carrier, precipitation of barium chromate and filtration, strontium carbonate was precipitated, centrifuged, and redissolved in HCl. After a scavenging precipitation of $Y(OH)_3$, $SrCO_3$ was reprecipitated.

The chemical separation of cerium (A = 143) was limited to the precipitation of cerium oxalate from the initial fission product solution after a delay time of 1 day because of the selectivity of the γ-ray measurement.

The precipitates of barium chromate, strontium carbonate, and cerium oxalate were filtered on Millipore filters, dried, weighed, and mounted for counting.

For the measurements, the decay of the characteristic γ-rays was followed simultaneously in both fractions using two similar, calibrated Ge(Li) detectors. In the case of mass-89 chain the decay of ^{89}Sr was followed using a low background, anticoincidence β proportional counter.

The fractional cumulative yields (YFC) were calculated according to

$$[1]\quad \mathrm{YFC} = \frac{A_G}{A_G + A_S} \cdot V_k \cdot Y_D$$

where A_G and A_S represent the initial activities, corrected for chemical yield, of the inert gas and stearate fractions, respectively. The correction factor V_k accounts for the small gas volume between the stearate grains; it was 1.012 for the planar target configuration and 1.016 for the cylindrical target. The symbol Y_D represents the fractional cumulative yield of the descendent counted; it amounted to 0.71 ± 0.02 for ^{142}Ba (8) in $^{249}Cf(n_{th},f)$. The value of Y_D, unknown for ^{142}Ba in $^{250}Cf(sp.f)$, was set equal to unity in order to include the full uncertainty into the upper limit obtained for YFC(^{142}Xe). In all other cases it was estimated to be nearly unity on the grounds of the systematics to be discussed later.

The general method outlined above was tested using the neutron induced fission of ^{235}U, and the following results comparable to the corresponding published values (in parentheses) were obtained.

^{139}Xe: YFC = 0.81 ± 0.04 (0.82 ± 0.02 (2))

^{140}Xe: YFC = 0.58 ± 0.01 (0.596 ± 0.01 (2))

TABLE 1. Fractional cumulative yields (%) in the thermal neutron induced fission of ^{249}Cf and in the spontaneous fission of ^{250}Cf

Isotope	$^{249}Cf(n_{th},f)$	$^{250}Cf(sp.f)$
^{89}Kr	77.6±1.5	
^{91}Kr	$32.0^{+3.1}_{-1.7}$	$34.8^{+4.3}_{-3.2}$
^{92}Kr	9.5±1.3	$9.9^{+4.2}_{-2.1}$
^{139}Xe	32.0±3.5	23.6±6.0
^{140}Xe	12.5±2.0	14.7±7.0
^{141}Xe	4.0±0.3	$9.1^{+10.4}_{-6.7}$
^{142}Xe	0.9±0.1	≤3.6
^{143}Xe	0.22±0.08	

Results

The fractional yields obtained in this work are given in Table 1. The errors indicated include systematic errors. In the case of the spontaneous fission of ^{250}Cf they are, however, mainly due to the poor counting statistics obtained because of the rather weak ^{250}Cf source.

Discussion

The fission yields measured in the present work and values found in the literature will be discussed in the framework of the systematics of nuclear charge distribution in the asymmetric region of nuclear fission developed by Wahl and co-workers (3, 9, 10).

The fractional independent yields (YFI) of the isobars with atomic number Z along a β-decay chain are described by the bell-shaped "Gaussian" distributions characterized by their maximum (Z_p) and width (standard deviation, σ) values and modulated by even–odd factors (EOF). Instead of Z_p, ΔZ is frequently given, which is the deviation of Z_p from Z_{UCD}, a value calculated assuming unchanged charge density of compound nucleus and fragments, i.e. fission products prior to prompt neutron emission. The value of ΔZ represents polarization of the nuclear charge in the compound nucleus at scission. The mathematical basis of the systematics model is given in the following equations.

$$[2]\quad \mathrm{YFI}(Z) = F^{-1}\mathrm{EOF}^{a(Z)}\int_{Z-0.5}^{Z+0.5} P(Z)\,\mathrm{d}Z$$

where $a(Z) = +1$ for even Z nuclides and -1 for odd Z nuclides, and

$$[3]\quad P(Z) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left[\frac{-(Z - Z_p)^2}{2\sigma^2}\right]$$

where

$$Z_p = Z_{UCD} + \Delta Z = (A + \nu_A)\cdot\frac{Z_F}{A_F} + \Delta Z$$

A, mass number of fission products; ν_A, average number of prompt neutrons emitted by fragments to form mass A; Z_F and A_F atomic and mass numbers of fissioning nucleus (Z_F = 98 and A_F = 250); and F is a normalization factor assuring that the sum of all fractional independent yields within one chain re-

TABLE 2. Compilation of yields for the thermal neutron induced fission of ^{249}Cf used in the present analysis and number (ν_A) of prompt neutrons emitted (derived from the mass yields in ref. 22 as described in ref. 10); generally, cumulative yields are given; nuclides whose independent yields are stated are marked *; fractional yields derived from absolute yields are in parentheses; calculated fractional yields were obtained from the model using the parameters listed in Table 3 (model F)

[a]Fit model as defined following eq. [6] (F = fragment fit; P = product fit).

least four known yields per mass chain. Because sufficient number of yields are generally not available for individual chains in $^{249}Cf(n_{th},f)$, the global fit method developed by Wahl (10) and verified for the well known fission reactions of $^{235}U(n_{th},f)$, $^{233}U(n_{th},f)$, $^{239}Pu(n_{th},f)$, and $^{252}Cf(sp.f)$ was chosen. In this approach, simple relations are used for the mass dependence of the three parameters (σ, EOF, and ΔZ), thus allowing the increase of the number of input yields in the fit of all mass chains in the asymmetric region.

The relations assumed are: (*1*) The width parameter σ is constant, i.e. independent of A. (*2*) The even–odd factor EOF is composed of an even–odd factor for protons (EOZ) and an even–odd factor for neutrons (EON) that are both independent of A.

$$[6]\quad EOF = EOZ^{a(Z)}EON^{b(N)}$$

$a(Z)$ is set +1 for fission products with even proton numbers (Z) and −1 for those with odd Z. $b(N)$ is defined accordingly for even and odd neutron numbers. However, taking into account the prompt neutron emission, two variants were used. The first one is identical to the one given by Wahl (10) and is based on the neutron number in fission *products* (after neutron emission). The second one is based on the neutron number (N') in fission *fragments*[5] (before neutron emission). The two variants will be differentiated in the following discussion by the terms "product fit" and "fragment fit". (*3*) ΔZ is at most linearly dependent on the mass split (heavy fragment mass $A'_h = A_h + \nu_A$).

$$[7]\quad \Delta Z(A'_h) = \Delta Z^{140} + S(A'_h - 140)$$

where ΔZ^{140} is the charge polarization at fission fragment mass $A' = A + \nu_A = 140$, and S is the slope of the $\Delta Z(A'_h)$ line with respect to A'_h.

The complementarity of heavy and light (primary) fragments entails $\Delta Z(A'_h) = -\Delta Z(A_F - A'_h)$, i.e., ΔZ values of complementary fragments are equal but of opposite sign.

Consequently, the charge distribution in the asymmetric region may be described by the following five parameters: (*i*) ΔZ^{140}, charge polarization at mass $A'_h = 140$; (*ii*) S, variation of charge polarization with mass (slope of ΔZ-line); (*iii*) σ, width of "Gaussian" charge distribution curve; (*iv*) EOZ, even–odd pairing effect for protons; and (*v*) EON, even–odd pairing effect for neutrons.

Table 2 shows the fission yields and ν_A values used in the present analysis of the reaction $^{249}Cf(n_{th},f)$. Absolute fission yields are given when they are sufficiently different from chain yields to allow the calculation of fractional yields.

The yields (absolute or fractional) are given as they were obtained in the respective experiments. For the conversion of absolute yields to fractional yields, the current compilation of chain yields of Meek and Rider (22) was used. The numbers (ν_A) of prompt neutrons emitted were calculated by Wahl using also this compilation of chain yields (22) according to ref. 10 and kindly supplied to us.

In the case of the spontaneous fission of ^{250}Cf no other values of fractional yields are known to us. This reaction will be discussed later.

Equation [3] or [5] above has been fitted to the experimental fractional independent and cumulative yield data, respectively (Table 2), using the computer code LSP (23), a modification of the general least-squares program ORGLS (24).[6] The fit was carried out for the two alternative definitions of EON based on product or fragment neutron numbers as given by eq. [6]. In addition to the experimental error of the yield values, a "model error" $\sigma_{mod} = 0.1(YFI)^{2/3}$, as defined in ref. 10, was included in the analysis, and the larger one of both, σ_{exp} or σ_{mod}, was chosen as error of the input yields.

The resulting two sets of values for the five parameters above are listed in Table 3. A diagnostic number (FIT) that indicates the goodness of fit defined as in ref. 10 is also given in the table.

$$[8]\quad FIT = \left[\frac{1}{n}\sum\frac{(\text{observed} - \text{calculated})^2}{\text{error}}\right]^{1/2} = \left(\frac{\chi^2}{n}\right)^{1/2}$$

n being the number of observations minus the number of parameters varied. For large values of n, FIT = 1 would indicate agreement between data (within their error limits) and model. The values of FIT given in Table 3 indicate that the model is basically applicable to the neutron induced fission of ^{249}Cf. The last column of Table 2 gives values of fractional yields calculated on the basis of the model using the parameters given in Table 3 (fragment fit F). Of the 46 values listed 38 show agreement within the error margins with the corresponding experimental values. This is also considered to indicate reasonable agreement between model and experiment.

In addition to the results concerning the neutron induced fission of ^{249}Cf, Table 3 gives values for the thermal neutron induced fission of ^{235}U and the spontaneous fission of ^{252}Cf that were obtained in an identical calculation by Wahl (10).

The errors of the parameters given in Table 3 are essentially the statistical errors of the fit and do not include systematic errors. Possible systematic errors have been tested for the reaction $^{249}Cf(n_{th},f)$ by carrying out fits with the following vari-

[5]In this second variant, due to correction for prompt neutron emission applied to experimental fission product masses, the fragment neutron numbers are generally non-integer. In the present analysis, N' = even ± 0.5 was considered even and N' = odd ± 0.5 was considered odd.

[6]LSP is a program adapted to the Mainz HB-66/80 from a program kindly supplied to us by A. C. Wahl.

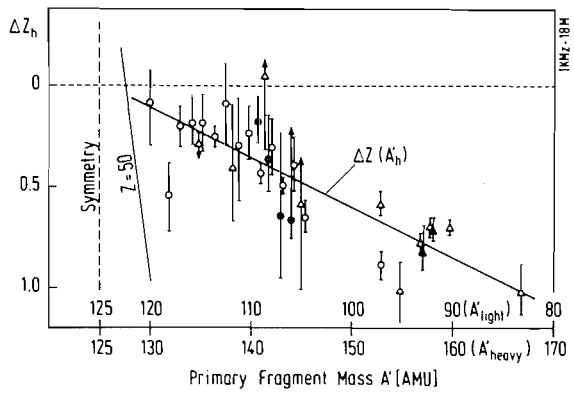

FIG. 2. Plot of ΔZ versus primary fragment mass. The line $\Delta Z(A'_h)$ (eq. [3]) was obtained in the fit. Data points were calculated from the experimental yields using $\sigma = 0.64$, EOZ = 1.07, EON = 1.05 (see Table 3). Triangles: light fragments. Circles: heavy fragments. Open symbols: $^{249}Cf(n_{th},f)$. Full symbols: $^{250}Cf(sp.f)$. Error bars are experimental errors only.

ations of the input values: (*a*) the number of yields included in the fit has been varied; (*b*) the errors associated to the yields have been varied by inclusion or exclusion of the "model errors" discussed above; (*c*) alternative sets of ν_A-values derived from the thermal neutron induced fission of ^{235}U and from the spontaneous fission of ^{252}Cf were used.

The conclusion of these tests was that possible systematic errors are covered when twice the error margins given in Table 3 are assumed.

In the following discussion, the two sets of five parameters of the charge distribution in $^{249}Cf(n_{th},f)$ will be discussed briefly and will be compared to the well known cases of $^{252}Cf(sp.f)$ and $^{235}U(n_{th},f)$ also listed in Table 3.

The first point concerns a comparison of the two fits of $^{249}Cf(n_{th},f)$ based on the even–odd factors of either fragments or products. The reason for these two mathematical approaches is the uncertainty on the origin of a possible even–odd factor for neutrons. In principle, it could be due to two reasons: (*a*) a preferential population of even neutron fission products in prompt neutron emission and (*b*) a survival of paired neutron configurations at scission.

The two cases should be reflected in the model by setting the criterion for even neutron configurations in either fission *products* (model: P in Table 3) or in fission *fragments* (model: F in Table 3).

A comparison of the EON values resulting from the two fits clearly speaks in favor of a survival of paired neutron configurations at scission. The value of EON < 1 in fission *products* that indicates a predominance of *uneven* neutron numbers is due to the emission of predominantly *uneven* neutron numbers ($\nu_A \approx 1$ or 3; Table 2) from predominantly *even* neutron *fragments*. To demonstrate this effect, the fission yield data of ^{249}Cf were divided in two groups: (*1*) with $\nu_A \approx$ even and (*2*) with $\nu_A \approx$ odd, and a product-fit was carried out for each group with the following results:

(1) ν_A even ± 0.5, EON = 1.08 ± 0.11

(2) ν_A odd ± 0.5, EON = 0.87 ± 0.05

Consequently, the fit values based on *fragment* masses are believed to be more reliable and the following discussion will be based on these values. Nevertheless, a certain influence of pairing on the prompt neutron emission cannot be excluded. EON is certainly the parameter with the largest systematical uncertainties. Fortunately, as it turns out from a comparison of the two fit modes for ^{249}Cf (F and P in Table 3), the results on ΔZ, σ, EOZ, and S are almost not affected by the uncertainty of EON.

When comparing the results for $^{249}Cf(n_{th},f)$ with those obtained for $^{235}U(n_{th},f)$ and $^{252}Cf(sp.f)$ (10) some significant differences are found (Table 3). The value of ΔZ^{140} is definitely smaller than the corresponding values for ^{235}U and ^{252}Cf. The value of S, on the other hand, is larger than the corresponding values for ^{235}U and ^{252}Cf and indicates a fairly pronounced slope of the ΔZ line with increasing mass asymmetry of the fission fragments for ^{249}Cf. The ΔZ line resulting from the fit and the ΔZ values derived from the single experimental yield values are shown in Fig. 2.

Our findings are in general agreement with the following two previously made observations: (1) Troutner and co-workers observed that, in the mass range A = 134 to 140, the value of ΔZ_h for $^{249}Cf(n_{th},f)$ is 0.2 (19) or 0.3 to 0.4 (20) charge units smaller than for $^{235}U(n_{th},f)$; (2) Gäggeler and von Gunten (13) found a larger value of ΔZ_h for very asymmetric fission modes in $^{249}Cf(n_{th},f)$. Whereas these earlier statements are based on the assumption of a value of $\sigma = 0.56$ derived from $^{235}U(n_{th},f)$ and no even–odd pairing effect (EOZ = EON = 1) (13) or an even–odd pairing effect identical to the one in $^{235}U(n_{th},f)$ (19, 20), the present analysis is based on experimental values of these constants resulting in the same fit.

The value of σ for $^{249}Cf(n_{th},f)$ is significantly larger than the value found for the fission of ^{235}U (Table 3). This result is in qualitative agreement with other evidence for larger σ-values in $^{249}Cf(n_{th},f)$. Monzyk and Troutner (8) indicate σ-values of 0.68 ± 0.03 and σ = 0.71 ± 0.04 in chains 140 and 142, respectively. Dickens and McConnell (12) observed mean values of σ = 0.67 and σ = 0.58 for heavy and light fragments, respectively. Quantitatively, the values in ref. 8, applying to single chains, are even larger than the average values found in this work. The results of ref. 12 rely on a constant value of $\Delta Z(A'_h)$. This assumption is not in agreement with the results of this work (Fig. 2). The present analysis is based on a more comprehensive experimental information including the results given in refs. 8 and 12 and takes into account the mass dependence of $\Delta Z(A'_h)$ as well as the pairing effects. The values of σ given in Table 3 for $^{249}Cf(n_{th},f)$ are therefore believed to be quantitatively more reliable.

It appears from Table 3 that the σ value of $^{252}Cf(sp.f)$ lies between those of ^{235}U and ^{249}Cf. The situation may be rationalized by the effects of the mass of the fissioning systems and of the excitation energy at scission (spontaneous versus neutron induced fission).

Concerning the rather difficult question of the even–odd factors EOZ and EON, the results obtained in the present work are somewhat preliminary. The evidence is clearly for less pairing than in the fission of ^{235}U, but to our surprise we find indication of survival of some proton pairing which was not found in the fission of ^{252}Cf. The difficulties concerning the evaluation of EON due to prompt neutron emission have been discussed above.

For the spontaneous fission of ^{250}Cf, no fractional yields except those determined in the present work are known to us. Consequently no reliable analysis of the type discussed above for $^{249}Cf(n_{th},f)$ could be made. Since the values of the yields determined in both reactions $^{249}Cf(n_{th},f)$ and $^{250}Cf(sp.f)$ are quite similar (Table 1), the analysis is limited to a simple

comparison of the ΔZ-values calculated from the experimental yields using the parameters $\sigma = 0.64$, EOZ = 1.07, and EON = 1.05 (Table 3) and the ν_A(Cf) values (Table 2) corresponding to the masses of interest, renormalized to a $\nu_{tot} = 3.53$ (13). The resulting values are shown in Fig. 2 (full symbols). No significant difference is found between the two reactions. One may thus conclude that the difference in excitation energy between induced and spontaneous fission of ^{250}Cf seems to be expressed mainly in the number of neutrons emitted.

Acknowledgements

We are grateful to Professor A. C. Wahl for the permission to use his fit program, for his help in adapting it to the HB-66/80 computer at this university, and for providing the prompt neutron data used in this work.

We would like to thank the Transplutonium Production Program of the USDOE for providing the materials used in the experiments. One of us (K.W.) gratefully acknowledges financial support by GSI (Darmstadt) during his stay at this institute.

Muonium atoms in liquid and solid neopentane

B. W. NG, J. M. STADLBAUER, Y. C. JEAN,[1] AND D. C. WALKER

Chemistry Department and TRIUMF,[2] University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received August 23, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

B. W. NG, J. M. STADLBAUER, Y. C. JEAN, and D. C. WALKER. Can. J. Chem. **61**, 671 (1983).

Relatively long-lived muonium atoms have been observed in neopentane (dimethylpropane). The yields of all muon states are found to be essentially the same in liquid and solid neopentane and the same as those in water. These results have bearings on three matters of current interest in muonium chemistry: the origin of the "background" spin relaxation; the formation mechanism; and the change in yields at the liquid–solid phase transition. These data were obtained by the μSR technique (muon spin rotation) at the TRIUMF accelerator.

B. W. NG, J. M. STADLBAUER, Y. C. JEAN et D. C. WALKER. Can. J. Chem. **61**, 671 (1983).

On a observé dans le néopentane (diméthyl propane) des atomes de muonium dont le temps de vie est relativement long. On a trouvé que les rendements de tous les états muon sont essentiellement les mêmes dans le néopentane et également les mêmes que ceux de l'eau. Ces résultats portent sur trois sujets d'intérêt courant dans la chimie du muonium; les fondements de la relaxation de spin, le mécanisme de formation et les variations du rendement à la transition de phase liquide solide. On a obtenu ces données par la technique du RSμ (rotation de spin du muon) dans l'accélérateur TRIUMF.

[Traduit par le journal]

Introduction

Muonium is the short-lived neutral atom (chemical symbol Mu) formed as the bound state of a positive muon with an electron. It has been established as a light isotope of hydrogen, and is particularly useful because it can be observed by nuclear physics counting techniques with great sensitivity and on short reaction timescales (1, 2). Most of the liquid phase studies have involved Mu in water, although it has been detected with reduced lifetime in alcohols (3) and saturated hydrocarbons (4). Its mechanism of formation is not yet settled, nor is it clear why there is always an apparent "background" decay to the Mu signals — though a physical explanation based on the magnetic field has recently been offered (5).

In order to help resolve these problems we have studied purified neopentane in both condensed phases. This compound is of particular interest for three reasons. First, all of its hydrogen atoms are present in methyl groups, so Mu could be long-lived and thus easier to study than in hydrocarbons containing methylene hydrogens. Second, neopentane is known to have an unusually large free ion yield in radiolysis, despite its low dielectric constant. This is attributable to the enormous mobility of quasifree electrons in this medium due to the molecules' being almost spherical (6). Thus, if the spur model of muonium formation (7) is valid, the muonium yield in neopentane should differ markedly from both water and hexane. Third, neopentane has a convenient melting point and a simple solid structure. Therefore it is a suitable medium in which to study the effect of phase transitions on the muon yields.

Experimental

μSR facilities at the TRIUMF accelerator in Vancouver were used in this study. The technique is described in detail elsewhere (1, 2) and the apparatus used is sketched in Fig. 1. A high energy positive muon strikes the sample under study, stops in it, associates chemically with it, then decays to a positron in 2.2 μs on average. The time between the muon's arrival and its decay (when observed by a positron detector) gives one point in a lifetime histogram. The sample is held in a transverse magnetic field, so that the spin of the muon (initially polarized) precesses with a Larmor frequency determined by the chemical state of the muon. As the positron is emitted preferentially along the muon's spin direction, the lifetime histogram has the precession frequency superposed on it. Two types of muon state are readily observable — that of the free muonium atom, and muons in diamagnetic environments (collectively grouped under D). The yields in these two states (A_M and A_D), plus the decay constant of Mu (λ), are obtained by computer-fitting the amplitudes in the time-histogram to eq. [1],

$$[1]\quad N(t) = N_0 \exp(-t/\tau_\mu)\{1 + A_D \cos(\omega_D t + \phi_D) + A_M \exp(-\lambda t) \cos(\omega_M t - \phi_M)\} + B_g$$

where $N(t)$ is the signal amplitude at time t, ω_M and ω_D are the precession frequencies of Mu and diamagnetic muons, with ϕ_M and ϕ_D their initial phase angles, τ_μ is the muon lifetime, N_0 a normalization factor, and B_g the background count rate. The yields are normalized to fractions of the incident muons (P) by use of $P_M = 2A_M/A_0$ and $P_D = A_D/A_0$, where A_0 is the diamagnetic amplitude under identical conditions in a medium, such as CCl_4 or Al, in which all muons are known to form diamagnetic states. The 2 appears in P_M because only that half of the total Mu ensemble with parallel muon and electron spins is observable in μSR. (In the antiparallel atom the muon spin is depolarized by rapid hyperfine oscillations.)

P_M, P_D, and λ are the three parameters of interest obtained from the histograms modulated by the muon spin rotation. In these experiments there is no added solute so λ corresponds to the observed background decay constant in the pure solvent (λ_0). This could correspond to chemical reactions with the solvent, or with residual impurities, or it could be a physical or experimental artifact.

Neopentane was provided for us by Professor Ito, having been carefully purified by shaking with H_2SO_4, washing, drying, and distilling. The sample was deoxygenated by freeze–pump–thaw cycles and vacuum-sealed in a 100 mL round-bottomed glass flask. About 10^7 events were collected on each of three positron counters for the sample held at four temperatures between 209 and 295 K (melting

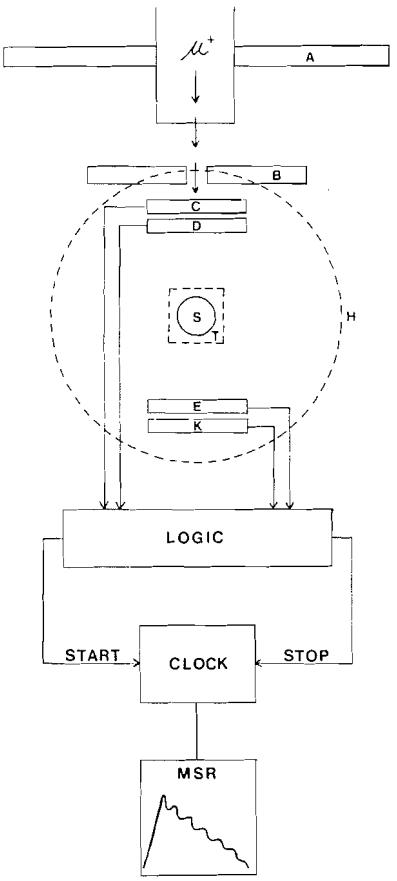

FIG. 1. Sketch of the apparatus used for a typical μSR measurement, showing only one set of positron counters. A is lead shielding; B a lead collimator; C and D are the muon "start" counters; S is the sample sealed in glass bulb after deoxygenation; T is a styrofoam cryostat controlled by flowing cold gas at a controlled rate through it; H are the magnetic field coils giving a field out of the paper so that the longitudinally polarized muon precesses in the plane of the paper; E and K are the positron "stop" counters. The start signal is registered by C, D, $\overline{E}$ and the stop by $\overline{B}$, E, K.

point 253 K). Temperature control was achieved in a closed styrofoam container through which cold helium gas was passed at a variable rate. The temperature was determined by a thermocouple in contact with the cell wall, and was monitored continuously throughout a μSR experiment.

Results and discussion

Figure 2 shows typical μSR histograms for neopentane: in (*a*) only the high frequency Mu precession can be observed, in (*b*) only the low frequency diamagnetic muon signals are discernible. The lines represent the computer fits to eq. [1] by a χ^2-minimization procedure (1, 2). Best values were obtained from the fits for three independent histograms, and the average values of P_M, P_D, and λ_0 are reported in Table 1 for four temperatures. P_L is the "missing fraction" equal to $1 - P_M - P_D$, the fraction of muons which are not observed. In unsaturated compounds some of this fraction appears as muonium radicals, but this is not expected in neopentane.

These results are of interest in three respects. First, they provide a measure of the yields in a hydrocarbon which has some physical properties intermediate between linear hydrocarbons and weakly polar alcohols and ethers — particularly with regard to the radiation chemical free ion yields (9). Neo-

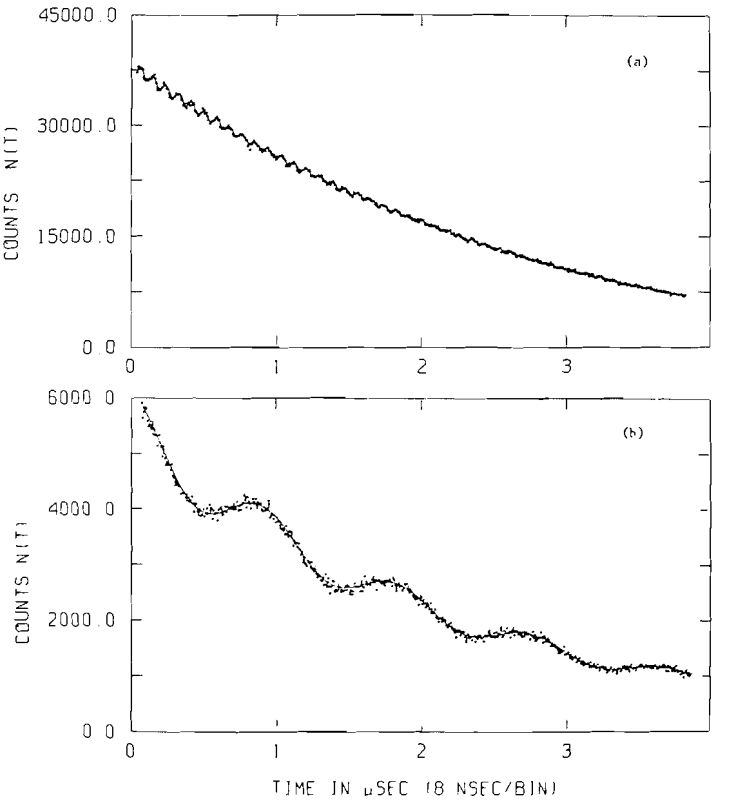

FIG. 2. μSR histograms (dots) and computer fits (lines) for liquid neopentane at 295 K: (*a*) showing the muonium precession with 8 G transverse magnetic field; (*b*) showing the diamagnetic muon precession at 80 G.

pentane provides a medium — attributed to the sphericity and non-polarizability of its molecules (6) — in which quasifree electrons are exceptionally mobile (see Table 2). In finding that the probability of muonium formation is essentially the same as that in water on the one hand, with its large free ion yield, and *n*-hexane on other, with its minute free ion yield, leads us again (4) to the conclusion that the spur model (7) of muonium formation does not account for the yields in different liquids. This is underscored by the comparison provided in Table 2, where the muon yields are seen to be essentially the same for solvents ranging from *c*-hexane to water, despite a complete change in the polarity, solvating power, and spur electron survival probabilities. Instead, one inclines to the view that Mu formation depends on the probability of hot Mu* emerging from the epithermal stages of the track without having undergone a hot atom abstraction or substitution reaction. Perhaps the probability of such hot atom reactions occurring relative to thermalization is very similar for saturated molecules composed of fully hydrogenated C and O atoms.

The second major interest in these results lies in the fact that the yields barely change at the liquid–solid phase transition or with temperature over the range studied. Certainly there is no marked break at the melting point. This is in sharp contrast to water (7) and the condensed noble gases Ar, Kr, and Xe (10), with the Ar result being given in Table 3. Whether this is peculiar to neopentane or common to hydrocarbons remains to be seen. In these other media there was a complete absence of a missing fraction in the solid phase, with P_M increasing markedly as the material was solidified (see Table 3).

Third, the λ_0 value found for neopentane approximately

equals the smallest values found for any system at TRIUMF (4, 11–13) or at Schweizerisches Institut fur Nuclearforschung, Villigen (near Zurich, Switzerland) (3, 14). The implication is, therefore, that this "background" decay rate of Mu is not a genuine chemical process but is an experimental or physical artifact. This has recently been emphasized by the fact that Nagamine *et al.* (5), using a pulsed muon beam with 50 ms between pulses, have obtained much smaller values of λ_0 — down to 0.05×10^6 s^{-1}. Indeed, Miyake *et al.* (15) have just found small λ_0 values in neopentane and tetramethylsilane. The most probable explanation for the difference is suggested (5) to arise from a beating of the two-frequency precession of muonium and field inhomogeneities, even at ~8 G. This seems to be correct because by fitting the relaxation in ultrapure water over long lifetimes (8 μs gate) to a multifrequency equation rather than to [1], there was a significant reduction in the apparent value of λ_0 (16). Our net conclusion is that Mu does not react with neopentane at a measurable rate: therefore, that the abstraction reaction [2]

[2] $\mathrm{Mu} + \mathrm{C(CH_3)_4} \rightarrow \mathrm{MuH} + \mathrm{C(CH_3)_3\dot{C}H_2}$

has a bimolecular rate constant, $k_M < \lambda_0/[\text{neat liquid}]$, i.e. $k_M < 3 \times 10^4\ M^{-1}$ s^{-1}.

Summary

Neopentane (dimethyl propane) has proved to be most interesting in all three aspects of this study. (*i*) On the question of changes at the liquid–solid transition, this is the first compound to show no significant change in muon yields. Previously a marked change was found for both highly-polar, strongly hydrogen-bonded molecules such as water whose structure changes markedly on freezing, and for the avidly non-polar, barely polarizable heavy noble-gas molecules. This absence of a significant change at the melting point of neopentane is found to occur regardless of whether the solid was glassy or polycrystalline. (*ii*) The fact that neopentane has provided the longest-lived muonium hitherto — equal to that of water — tends to corroborate this slowest of rates as a physical artifact rather than a chemical reaction. The result therefore also implies — providing the *n*-hexane and *c*-hexane samples (4) were equally free of reactive impurities — that reaction of Mu with —CH_2— groups is observable whereas that with —CH_3 groups is not. (*iii*) The muon yields are in accord with previous overall conclusions (4): namely, that diamagnetic muon yields are not connected to radiolysis free-ion yields, nor muonium yields with geminate-ion yields of radiolysis. It apparently makes no difference what the electron escape probability is, one gets the same muon yields for all saturated hydrogenated compounds. Such findings seem to be at variance with the expectations of a spur model.

Acknowledgements

We are particularly indebted to Professor Yasuo Ito and Mr. Y. Miyake for kindly providing the purified neopentane,

M. A. WHITEHEAD and G. D. ZEISS. Can. J. Chem. **61**, 675 (1983).

A constrained variational theory is applied to the *ab initio* maximum overlap (MOM) method. The results for N_2, HF, CO, and LiH, in which MOM wavefunctions satisfy constraints based on RHF, experimental or theoretical values, are discussed. The numerical results show that constraining the MOM wavefunctions with one or more constraints corrects the worst deficiencies in accuracy in the wavefunctions.

M. A. WHITEHEAD et G. D. ZEISS. Can. J. Chem. **61**, 675 (1983).

On a appliqué une théorie variationnelle contrainte à la méthode *ab initio* de recouvrement maximum (MOM). On discute des résultats obtenus pour N_2, HF, CO et LiH en utilisant des fonctions d'onde MOM qui satisfont des contraintes basées sur les valeurs RHF expérimentales ou théoriques. Les résultats numériques révèlent que cette contrainte des fonctions d'onde MOM par une plusieurs contraintes corrige, au niveau de l'exactitude, les pires déficiences des fonctions d'onde.

Introduction

The maximum overlap of atomic orbitals on neighboring atoms as a measure of bond strength (1–3), with the concept of hybridization (4, 5) has provided a simple, useful model of the chemical bond (6). Maximum overlap has been used to determine nonequivalent hybrid orbitals in hydrocarbon molecules (7, 8) and to provide qualitative understanding of trends in experimental measurements on these molecules (9, 10).

However, in the face of extended basis set multiconfigurational calculations and the arrival of the multiple-scattering X_α method, the maximum overlap method, MOM, has died out (11–14).

In this paper the authors hope to show how the MOM theory may be resurrected to give good service in the future by ensuring that the MOM wavefunctions can be made as accurate as Hartree Fock wavefunctions, or better, without the need to iterate, thus providing fast accurate results to aid chemical interpretation (14, 16).

Of the procedures for maximum overlap (7, 8, 15–22), that of Lykos and Schmeising (20) was most suitable for the present study, because their MOM wavefunctions can be directly compared with RHF (21, 22) and NDDO[3] wavefunctions. Secondly, the secant-parameterization method used in the constrained RHF calculations (21) is easily adapted to this version of the MOM method. Thirdly, the MOM method of Lykos and Schmeising is similar to other approximate molecular orbital methods, and therefore the results from constrained MOM calculations are relevant to other methods: Lykos and Schmeising (20) and others (23, 24) have shown the close correspondence between the maximum overlap and simple Hückel methods (25, 26). Several semi-empirical approximate RHF methods, among them the CNDO (27–29) and extended Hückel (30) methods, rely on the Wolfsberg–Helmholz (31) approximation, in which interatomic off-diagonal elements of the Fock matrix are assumed to be proportional to the corresponding overlap matrix elements. In the context of the π-electron approximation, Ruedenberg (32) showed that there is a close connection between the validity of the "zero differential overlap" approximation and the extent to which the maximum overlap molecular orbitals approximate the true eigenvectors of the Fock matrix.

The maximum overlap method of Lykos and Schmeising (20) differs from the traditional approach in which the bond overlap between two localized atomic orbitals is maximized (15). The MOM wavefunction determined according to the procedure of Lykos and Schmeising (20) is invariant with respect to unitary transformations of the occupied MO's. Therefore the concept of localized (33) or hybridized atomic orbitals loses some significance; these concepts have their own fundamental problems anyway (33).

This maximum overlap method (20) posseses certain advantages (34) over other approximate molecular orbital methods. Because no parameters are required, the maximum overlap method is an *ab initio* procedure, and a MOM wavefunction is invariant to the same types of transformations as an RHF wavefunction (35), unlike neglect-of-differential-overlap wavefunctions (27).

Free variational MOM wavefunctions are compared with RHF and NDDO wavefunctions elsewhere (21, 22). One-electron property expectation values calculated with MOM wavefunctions are usually poorer than NDDO or RHF expectation values. MOM values of energy-related properties such as T and r_A^{-1} are small because MOM underestimates the charge density in the inner shell region. Both NDDO and MOM wavefunctions suffer from *excessive s–p promotion*. MOM, like the NDDO method, is unreliable in reproducing the quantitative and qualitative characteristics of interatomic charge transfer.

The disadvantages of MOM have been discussed (20, 31): it does not distinguish between basis functions according to energy considerations, which leads to severe distortion in MOM wavefunctions. Thus for CO, free variational MOM wavefunctions give equal $2p\pi_C$ and $2p\pi_O$ populations, and in the absence of constraints, there is no interatomic transfer of π

electron density. For LiH, the wavefunction obtained using MOM is unrealistic; the basis set is not strictly minimal (36) and the lithium 1*s* orbital is considered bonding. A test of the constrained variational method is how effective suitable chosen constraints are in correcting inherent deficiencies in MOM.

The constrained MOM equations

The constrained maximum overlap equations are derived in a manner similar to that used to obtain the constrained RHF equations (27, 37). A single configuration wavefunction is used, and the total molecular overlap Γ, defined (20) by

$$[1] \quad \Gamma = 2 \sum_{\nu}^{n} \sum_{i}^{m} |\langle \chi_i | \phi_\nu \rangle|^2$$

$$[2] \quad = 2 \sum_{\nu}^{n} \sum_{i,j}^{m} c_{i\nu} c_{j\nu} [\mathbf{S}^2]_{ij}$$

where

$$[3] \quad \phi_\nu = \sum_{i}^{m} \chi_i c_{i\nu}$$

where χ_i are known one-electron functions, and $\mathbf{S}^2$ is the square of the overlap matrix, [3] is maximized subject to the usual orthonormality restrictions on the molecular orbitals ϕ_ν, and to the imposed constraint conditions (21) [4],

$$[4] \quad 2 \sum_{\nu}^{n} \sum_{ij}^{m} \langle \chi_i | M_q - \mu_q / 2n | \chi_j \rangle c_{i\nu} c_{j\nu} = 0 \qquad q = 1 \ldots\ldots s$$

where M_q is the property operator of the qth property and μ_q is its known expectation value (37) which constrains the Hamiltonian. By analogy with the constrained RHF equations (21) the constrained maximum overlap equations are written in the form (37)

$$[5] \quad \sum_{j}^{m} G'_{ij} c_{j\nu} = \sum_{j}^{m} S_{ij} c_{j\nu} d'_\nu$$

The "fictitious" total overlap operator matrix G'_{ij} is given by

$$[6] \quad G'_{ij} = [\mathbf{S}^2]_{ij} + \sum_{q}^{s} \lambda_q \langle \chi_i | M_q - \mu_q / 2n | \chi_j \rangle$$

The s Lagrange multipliers λ_q are chosen so that the s constraint equations [4] are satisfied. The d'_ν are the roots of the secular equation

$$[7] \quad |G'_{ij} - d'_\nu S_{ij}| = 0$$

The occupied molecular orbitals are the n eigenvectors of G'_{ij} corresponding to the n largest eigenvalues d'_ν.

If no constraint other than orthonormality is imposed on the wavefunction, then the solutions of [5] are free variational maximum overlap orbitals which are equivalent (20) to the canonically orthogonal orbitals defined by Löwdin (38). Thus, the coefficients determining the free variational maximum overlap molecular orbitals are given by

$$[8] \quad c_{i\nu} = U_{i\nu} d_\nu^{-1/2}$$

where $U_{i\nu}$, $i = 1, m$, is an eigenvector of the overlap matrix S_{ij} and d_ν is the corresponding eigenvalue.

The calculations were performed using the secant-parameterization procedure (21) which was easily adapted to the constrained MOM method; *computation times were very short* because there were *no self-consistency requirements*. As an example, details of a calculation on CO in which the wavefunction is constrained to reproduce the RHF value for the dipole moment are given in Table 1. Although the free variational MOM value of the dipole moment is poor, the constraint procedure converges rapidly to the constrained dipole moment value.

TABLE 1. CO. Determination of a singly constrained MOM wavefunction using the secant-parameterization procedure (21). The wavefunction is constrained to give the RHF expectation value of the dipole moment x_n. The value of the Lagrange multiplier, the remaining error in x_n, and the total overlap are given for each step. Slater exponents were used (37)

Constrained MOM calculations using constraints based on RHF expectation values

Several singly and multiply constrained maximum overlap wavefunctions were determined for four diatomic molecules; N_2, HF, CO, and LiH. Each wavefunction was constrained to reproduce one or more property expectation values calculated with an RHF wavefunction and the same basis set. The resulting constrained maximum overlap wavefunctions are compared with RHF wavefunctions using the same criteria employed previously (19, 39). Constraining a maximum overlap wavefunction may decrease the total molecular energy, and the energy lowering is useful for assessing the effectiveness of constraints.

The maximum overlap calculations used the same STO-4G basis functions with Slater exponents that were employed in the NDDO (23, 40) calculations.

N_2

Most constraints improve property expectation values, Table 2, and lower the Standard Deviation in Reduced Errors, which assesses the overall quality of a wavefunction (39) and energies, Table 3. With the exception of the $[E_N^c]$ constrained wavefunction, constrained wavefunctions improve values of T and r_N^{-1} which indicates improvement in the inner shell regions near the nuclei. Because $-\theta_n^c$, r_n^2, $-q_N^c$, and $T + V_{nc}$ are sensitive to $s-p$ promotion and because constraints decrease $s-p$ promotion they are improved. The $2s$ and $2p\sigma$ gross populations, Table 4, computed with these constrained wavefunctions agree with the RHF values, as do the calculated property expectation values and energies.

The constrained MOM is economical for determining nonvariational wavefunctions: two constraint conditions determine a nonvariational minimum basis set wavefunction for N_2 (to within a unitary transformation). Four complete cycles were required for convergence. The property expectation values and the energy calculated with the $[r_N^{-1}, -\theta_n^c]$ constrained wavefunction reproduce the RHF results.

HF[4]

In most cases single constraints cause lower energies and SDRE (40) values, Table 6, and improve property expectation

values, Table 5. The calculated T, r_F^{-1}, and E_F^e are in better agreement with the RHF values suggesting improved charge density distribution in the fluorine inner shell region.

The gross orbital populations, Table 7, show that most constraints reduce the gross population of the hydrogen $1s$ orbital and increase the fluorine $2s$ population. However, with one exception, constraints significantly lower the $2p\sigma_F$ populations. In MOM, $2p\sigma$ orbitals usually contribute more to the total overlap than $2s$ orbitals, and therefore $2p\sigma$ populations are less altered by perturbations. In the RHF, and to a lesser extent the NDDO method, a $2s$ electron is more tightly bound than a $2p\sigma$ electron, and $2s$ populations are not significantly changed by most single constraints. The $[-q_F^e]$ constraint modifies the $2p\sigma_F$ population and the value is in good agreement with the RHF value. The hydrogen $1s$ population is poor, however.

Double constraints based on one of the properties $-q_F^e$, $T + V_{ne}$, $-\theta_n^e$, or r_n^2, which are sensitive to s–p promotion, and a property such as r_H^{-1}, $-q_H^e$, or x_n, which are sensitive to the apportionment of charge density between the fluorine and hydrogen atoms, lead to wavefunctions close to the RHF wavefunction, even in the fluorine inner shell region.

CO

In almost all cases, constraints lower energies and SDRE (40) values, Table 9, and improve most property expectation values, Table 8, compared to the free variational results. The gross orbital populations, Table 10, indicate that single constraints mainly alter the distribution of π charge density between the carbon and oxygen atoms. The $[r_O^{-1}]$, $[x_n]$, $[r_n^2]$, and $[T + V_{ne}]$ constrained MOM wavefunctions give gross $2p\pi$ populations in good agreement with the RHF values. The only constraints which significantly alter the $2p\sigma$ populations are $[-\theta_n^e]$, $[r_n^2]$, $[T + V_{ne}]$, and $[-q_O^e]$. The $2p\sigma_C$ populations obtained with the $[-\theta_n^e]$ and $[r_n^2]$ constrained wavefunctions agree well with the RHF values. The $[r_n^2]$ constraint is particularly effective, reducing the charge density in the diffuse car-

For personal use only.

bon antibinding region, and improving the π charge distribution. The most effective multiple constraints use x_n or r_O^{-1}, which are sensitive to the distribution of π charge, $-\theta_n^e$ or $T + V_{ne}$, which are sensitive to $s-p$ hybridization in the carbon nonbonding orbital, or $-q_O^e$, which is sensitive to $s-p$ promotion at the oxygen atom. The $[x_n, -\theta_n^e, -q_O^e]$ constrained wavefunctions give $2p\sigma$ and $2p\pi$ populations at both the carbon and oxygen atoms in good agreement with the RHF values.

LiH

The MOM wavefunction for LiH is very poor, because the basis set is not strictly minimal. With the exception of the $[E_{Li}^e]$ and $[F]$ constraints, single constraints dramatically improve property expectation values, Table 11, and lower energies and SDRE values, Table 12. The $[T + V_{ne}]$ constrained wavefunction gives an energy which is only 0.003 hartrees above the RHF value. Most single constraints greatly increase lithium $1s$ populations, Table 13, improve values of T and r_{Li}^{-1}, and reduced $2s$ and $2p\sigma$ populations. The $[T]$, $[r_{Li}^{-1}]$, $[r_n^2]$, $[-q_H^e]$, $[-V_{ne}]$, and $[T + V_{ne}]$ constraints most improve the lithium $1s$ and $2s$ populations. The $[r_H^{-1}]$, $[x_n]$, $[r_n^2]$, $[-V_{ne}]$, and $[T + V_{ne}]$ constraints increase the charge density near the proton and the resulting hydrogen $1s$ populations agree well with the RHF value. The gross populations, property expectation values, and energy calculated with the $[-\theta_n^e, r_n^2]$ constrained wavefunction are in excellent agreement with the RHF values.

Constrained MOM calculations on CO and LiH using constraints based on experimental and theoretical expectation values

Constrained MOM calculations were performed on CO and LiH using constraints based on experimental and theoretical expectation values. CO and LiH were chosen because the MOM wavefunctions for both molecules suffer from severe defects due to inadequacies of MOM. For CO, MOM predicts equal populations for the $2p\pi_C$ and $2p\pi_O$ orbitals. For LiH, MOM gives a completely unreasonable wavefunction mainly because the basis set is not minimal.

CO

With a few exceptions, single constraints improve all property expectation values, Table 14, and lower energies and SDRE values, Table 15. Some of the singly constrained wavefunctions give energies lower than the value calculated with the free variational NDDO wavefunction.[2] As above, $[r_O^{-1}]$, $[x_n]$, $[r_n^2]$, and $[T + V_{ne}]$ give the greatest improvement, mainly due to a more realistic distribution of π charge density in the molecule (37).

Multiple constraints do not significantly improve the energies, or SDRE values, compared to the corresponding singly constrained wavefunctions, because many expectation values calculated with singly constrained wavefunctions are comparable in accuracy with the RHF values, and therefore little further improvement due to additional constraints can be expected.

LiH

For LiH, constraints invariably improve the MOM wavefunction, Table 16 and 17. The most effective constraints, $[T]$, $[r_{Li}^{-1}]$, $[r_n^2]$, $[-V_{ne}]$, and $[T + V_{ne}]$, in the calculations involving RHF constraints, were also found to be the most effective constraints in the present calculations. Note that the energy calculated with the $[T + V_{ne}]$ constrained wavefunction is very close to the RHF value. In several cases multiple constraints result in lower energies, but not lower SDRE values, compared to the corresponding singly constrained wavefunctions.

Conclusion

The constrained MOM calculations based on RHF constraints have been used to compare the effects of different constraints on MOM wavefunctions. Constraints based on r_n^2 and $T + V_{ne}$ were found to be particularly effective in improving MOM wavefunctions. Helmann–Feynman constraints led to poor results. As in the NDDO calculations,[2] single constraints mainly alter the interatomic charge transfer. A significant difference between the NDDO and MOM calculations is that $2p\sigma$ populations are less affected by constraints than $2s$ populations in the MOM calculations. This is because $2p\sigma$ orbitals make a greater contribution to the total overlap than $2s$ orbitals.

MOM suffers from several defects which can cause MOM wavefunctions to be unrealistic, as for CO and LiH. For both molecules single constraints based on *experimental* or *theoretical expectation values* are able to correct the worst deficiencies of the wavefunctions. Calaculated property expectation values and energies are dramatically improved. As in the NDDO calculations, multiple constraints based on experimental or theoretical expectation values were not found to be effective.

Thus by constraining an MOM wavefunction with r_n^2 *or* $T + V_{ne}$, a wavefunction comparable to the RHF wavefunction in SDRE or Energy overall character may perhaps be achieved without iteration, either in the MOM or energy calculation stage. With experimental constraints, the wavefunctions of the MOM method may be made as good overall as the RHF wavefunction, or even "better", if agreement with experiment is the criterion of goodness.

Similar comments may apply to the Hückel (25, 26) and Extended Hückel (30) methods. Consequently, the worst deficiencies of the MOM, Hückel, and Extended Hückel methods, which are so simple in application, can perhaps be removed by constraining. This would ensure that the wavefunctions and thus the atomic, bond, and molecular charges etc. would be chemically significant and theoretically justified.

The present constrained variational maximum overlap method may offer a new future to these well-tried and accepted methods in organic and inorganic chemistry.

Received August 31, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

THEIN KYU, MITSUAKI HASHIYAMA, and ADI EISENBERG. Can. J. Chem. **61**, 680 (1983).

The dynamic mechanical properties of Nafion precursor were determined as a function of the degree of conversion to the sodium ionomer, and those of the acid as a function of the degree of conversion to the cesium salt. A run was also made on the barium neutralized material, as well as on a remolded sample of a partly converted precursor. The precursor shows four dispersions which (in order of decreasing temperature) are identified with the glass transition, motions of the ether side chains, CF_2 groups in the backbone, and pendant SO_2F groups. Four relaxation regions are also seen in the ionomer, which are identified with the glass transition of the ionic regions and of the matrix, as well as with motions of the ether side chains and the backbone CF_2 groups. While the polymers in the acid and the salt forms are compatible, as seen by the gradual movement of the ionic glass transition peak to higher temperatures with increasing degree of neutralization, the salt and the precursor are not compatible. In the barium salt, the ionic glass transition peak occurs at a temperature close to the melting point of the crystalline regions, and most likely contains a contribution from that process also.

THEIN KYU, MITSUAKI HASHIYAMA et ADI EISENBERG. Can. J. Chem. **61**, 680 (1983).

On a déterminé les propriétés mécaniques du précurseur du Nafion en fonction du degré de transformation en l'ionomère du sodium et de celles de l'acide en fonction du degré de sa transformation en sel de césium. On a également fait une détermination sur des composés neutres de baryum aussi bien que sur un échantillon modifié d'un précurseur partiellement transformé. Le précurseur montre quatre dispersions (dans l'ordre d'une diminution de température) que l'on a identifiées avec la transition du verre, et avec les mouvements de la fonction éther des chaînes latérales, des groupes CF_2 du squelette et des groupes SO_2F. On a également vu dans l'ionomère quatre régions de relaxation que l'on a identifiées avec la transition du verre des régions ioniques et de la matrice aussi bien qu'avec les movements de la fonction éther des chaînes latérales et des groupes CF_2 du squelette. Alors que les polymères sous forme d'acide et de sel sont compatibles, comme on l'a vu d'après le mouvement graduel du pic de transition ionique du verre à des températures plus élevées avec une augmentation du degré de neutralisation ionique, le sel et le précurseur ne sont pas compatibles. Dans le cas du sel de baryum le pic de transition ionique du verre apparaît à une température voisine du point de fusion des régions cristallines, et comporte vraisemblablement une contribution de ces régions.

I. Introduction

The dynamic mechanical properties of the Nafion polymers, which are ionic (1), are dramatically different from those of the precursor (2, 3), which is nonionic. As might be expected, the changes depend on the nature and the concentration of the ionic species which is introduced. The precursor is an inert hydrophobic polymer containing the fluorocarbon backbone with perfluorinated ether side chains terminated by an $—SO_2F$ group, which is converted to an $—SO_3H$ group or its salt in Nafion (4, 5).

The structure and properties of the Nafions have been explored extensively by various techniques (5); it has been concluded that the Nafions are phase-separated (1, 6–9) and can be represented by a three phase model with hydrophobic amorphous and crystalline regions and hydrophilic ionic domains (6). Where water is introduced into the Nafions, it is accommodated in the ionic regions (8–15). The unique structure of the Nafions gives them unusual properties such as high water permeability (16), permselectivity with regard to ion transport (17–21), and many other features (5) which are absent in the precursor. It is therefore not surprising that many properties of the Nafions differ profoundly from those of the precursor before ionization.

The results of a previous study (2) of the mechanical and dielectric properties of the precursor are summarized below to demonstrate the dramatic changes which occur on ionization. Four relaxation peaks (labelled α_P, β_P, γ_P, and δ_P in descending order of temperature) were evident over the temperature range from −195°C to ca. 125°C. These peaks were identified with the glass transition of the fluorocarbon matrix, the relaxation of the ether side chains, the local short range motions of the $—CF_2—$ backbone, and the rotation of the $—SO_2F$ groups, respectively. In the original publication (2), the peaks were named α, β', β'', and γ, the β' and β'' peaks coalescing into a broad skewed peak over the frequency range studied. With this revised nomenclature, the γ relaxations in the precursor and in the Nafions now reflect the same mechanism, as will be indicated below.

For Nafion acid, three relaxation peaks termed α, β, and γ in descending order of temperature were observed over the temperature range from −160°C to ca. 150°C (1). Upon neutralization with various alkali salts, the peak temperatures of the α and β regions shifted upward by over 100°C in both cases, while that of the γ peak remained essentially the same. Early evidence revealed that the β peak was strongly affected by the presence of water, but that there was little or no influence of water on the α peak in Nafion acid. The γ peak position was not affected at the low levels of water content investigated

in both the acid and its salts. These α, β, and γ peaks were first assigned to the glass transition of the fluorocarbon matrix, the relaxation of the ionic domains, and the short range molecular motion of the $—CF_2—$ backbone, respectively. The δ peak, which was identified with the rotational motion of the $—SO_2F$ group in the precursor, was not detected in the dielectric and torsional pendulum studies of Nafion acid.

Since the rheological properties of the precursor differ greatly from those of the Nafion salts, there is no doubt that these properties must depend on the extent of ionization. It should therefore be of interest to follow the changes in the mechanical properties of the precursor in the course of conversion to the Nafion salts by preparing samples ionized to varying extents; the results of such a study are presented in the first part of this article. Also, the Nafion acid shows a substantially different relaxation behavior from that of its salts, the properties of which are therefore also expected to depend on the degree of neutralization. The effect of the degree of neutralization of Nafion acid on the mechanical relaxation behavior is explored in the second part of this work. Finally, a comparison is made between the barium and cesium salt of highly neutralized Nafion to confirm the proposed reinterpretation of the α and β peaks in that material.

II. Experimental

A. Materials

1. Preparation of partially ionized Nafion-Na

The precursor material with an equivalent weight of 1200 used in the present study is similar to that employed previously (2). The precursor film proved too thin to be tested directly on the torsional pendulum; accordingly several sheets of the material were melt pressed in a heated laboratory press at 250°C for five minutes and then cooled to ambient temperature. The final sample was 50 mm long, 6 mm wide, and 1 mm thick. Samples were annealed at 130°C for 6 hours in a vacuum oven and then weighed. Partially ionized samples were prepared by immersing the precursor samples in a 10% NaOH solution at ca. 75°C for varying periods of time. The samples thus prepared were dried at 130°C for 6 hours and reweighed. The conversion was calculated from the weight difference of the ionized Nafions and the precursor samples.

As shown in Fig. 1, the conversion of $—SO_2F$ to $—SO_3Na$ is slow initially, reaching ca. 80% after 8 hours and then gradually levelling off at ca. 90% after 24 h. This behavior is in line with the fact that the precursor is a hydrophobic material in which NaOH diffusion must be extremely slow, with the conversion taking place initially at the surface of the sample. Once the outermost layer is converted to the Nafion salt, the rate of water diffusion appears to be greatly enhanced, allowing the conversion of the inner layers into ionic Nafion material. The conversion is therefore expected to occur layer by layer producing a heterogeneous material with a "sandwich" structure, which is a composite of the Nafion salt (outer layers) and the precursor (inner layer). To ascertain whether Nafion is compatible with its precursor, an additional sample with approximately 56% Nafion-Na was prepared by immersing the precursor in a 10% NaOH solution at 75°C for about 6 hours, and remolding at 280°C in a laboratory hot press for about 20 min. If the Nafion salt and the precursor were compatible, this procedure would permit interdiffusion and blending of the two phases. A comparison of the relaxation behaviour of the original and remolded samples would then show whether or not the Nafion-Na and the precursor are compatible (22).

2. Preparation of partially neutralized Nafion-Cs

The starting material used in this study was Nafion acid (Nafion-H) of equivalent weight 1155 in the form of sheets with thickness ca. 1.3 mm, which were cut into strips 6 mm wide and 30 mm long. These samples were dried at 160°C under vacuum for 24 h and weighed. The acid samples were first boiled in distilled water to ensure extensive swelling, and then immersed in 0.1 *N* CsOH solution for differing time periods, which gave varying degrees of neutralization. The samples were again immersed in boiling water for about 24 h in order to achieve a homogeneous distribution of the cations present in the specimens; they were dried again at 160°C and reweighed. The samples prepared in this way were calculated to be ca. 39%, 50%, 76%, and 90% neutralized. In contrast to the partially ionized Nafion-Na samples prepared from the precursor, the diffusion coefficient of the Cs^+H in both Nafion acid and its salts is high (23), resulting in a final sample containing a homogeneous distribution of cations.

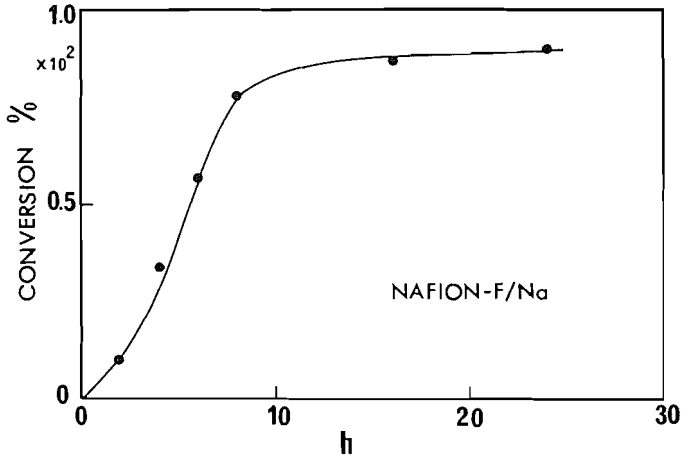

FIG. 1. Conversion of the precursor into partially-ionized Nafion-Na in 10% NaOH solution at ca. 75°C, as a function of time.

3. Preparation of the barium salt of Nafion-H

The divalent Ba salt of Nafion was prepared in a similar manner to the Nafion-Cs samples by immersing Nafion-H in a $BaCl_2$ solution. The degree of neutralization of the Ba salt was determined to be ca. 77%.

B. Experimental procedures

Dynamic mechanical studies were performed on a torsional pendulum which has been described previously (24). The samples were 30–60 mm long, 1.0–1.3 mm thick, and 6 mm wide. The temperature ranges of the experiments were −195°C to 250°C for the partially ionized Nafion-Na samples, −160°C to 250°C for the partially neutralized Nafion-Cs salts, and −160°C to 310°C for the Nafion-Ba sample. The frequencies were ca. 1 Hz at low temperatures, gradually decreasing with increasing temperature to ca. 0.1 Hz.

Since the Nafions are very sensitive to water, all of the samples were dried at 140–160°C under vacuum for 6–24 h to remove absorbed water. The samples were stored under vacuum in a desiccator until the torsional pendulum tests were carried out. Sample clamping in the apparatus was usually accomplished within 5 minutes. All experiments were then conducted in a helium gas environment at low temperatures and under vacuum at high temperatures.

III. Results

1. Partially ionized Nafion-Na

Figure 2 shows the storage and loss shear moduli G' and G'', and the loss tangent tan δ_G of the precursor obtained on the torsional pendulum over the temperature range from −195°C to 130°C at ca. 1 Hz. Although data were acquired at ca. 2.5°C intervals, alternate experimental points only were plotted (at 5°C intervals) for the sake of clarity. Above 130°C, measurements were no longer possible due to experimental limitations resulting from the softness of the sample. The relaxation behavior of the precursor is consistent with previous results from dielectric and vibrating reed studies (2), in which

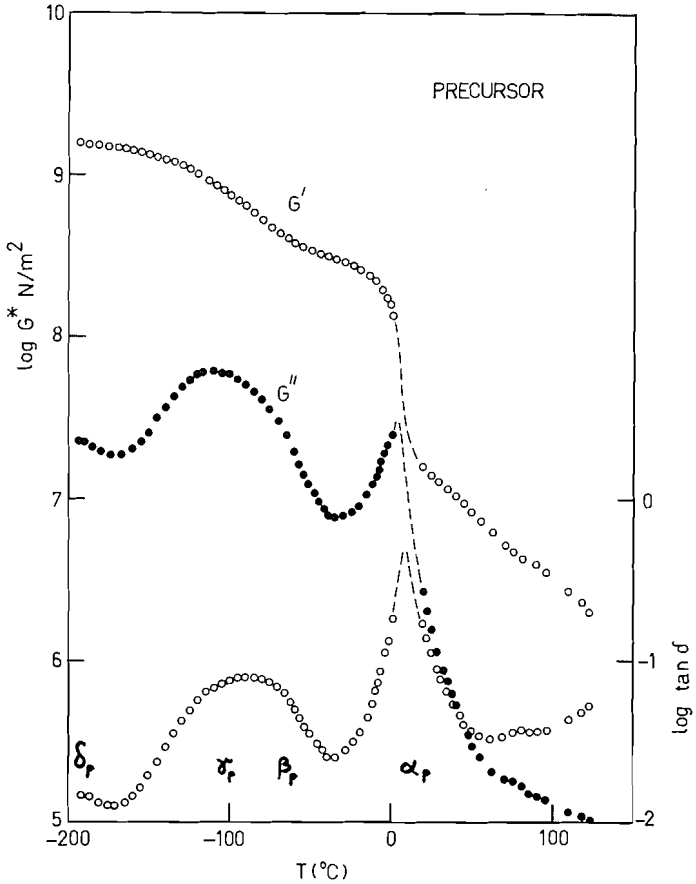

FIG. 2. Variation of G', G'', and tan δ_G with temperature for the precursor from torsional pendulum studies at ca. 1 Hz.

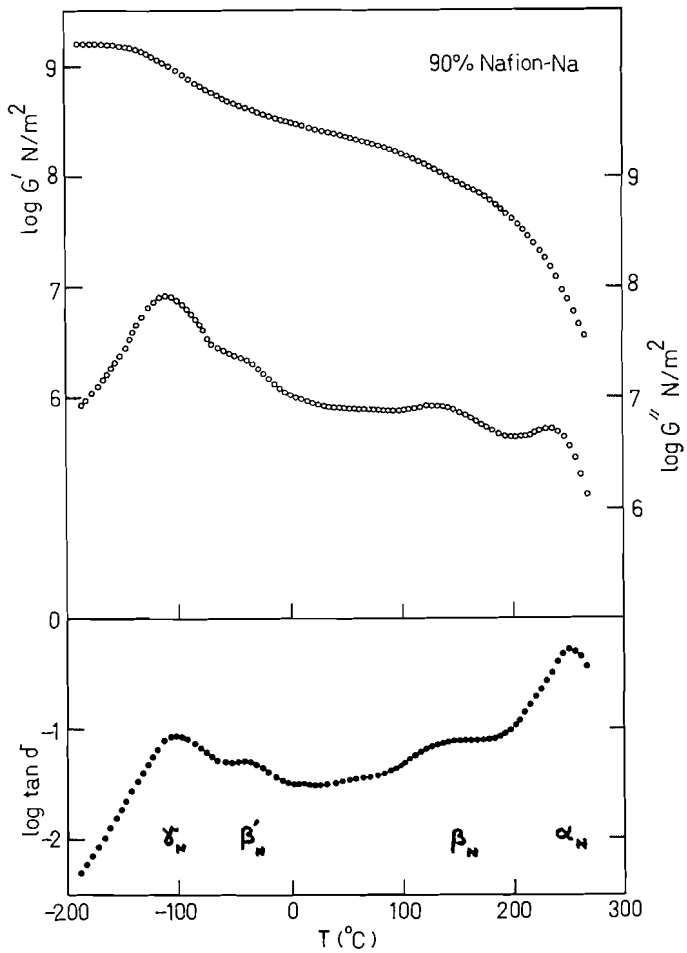

FIG. 3. Variation of G', G'', and tan δ_G with temperature for 90% conversion Nafion-Na from torsional pendulum studies at ca. 1 Hz.

four relaxation regions were seen, one of these manifesting itself as a skewed composite peak (see below). These peaks are labelled, in this paper, α_P, β_P, γ_P, and δ_P, in descending order of temperature. In the previous study (2) they were labelled α, β', β'', and γ; however, the molecular mechanism responsible for the β'' peak in the precursor corresponds to that of the γ peak in the Nafions and in polytetrafluoroethylene (PTFE). Therefore, in order to avoid confusion, the β'' peak has been relabelled as the γ_P peak and the γ peak from the original work was necessarily relabelled as a δ_P peak.

The onset of the δ_P peak is clearly observed in Fig. 2 at ca. -170 to -190°C. Another peak occurs at ca. -100°C in both the G'' and the tan δ_G curves; both of these peaks are broad and skewed, as was previously observed (2). These skewed peaks are considered to be the sum of two overlapping peaks – the β_P and the γ_P relaxations. The highest temperature α_P dispersion is seen at ca. 10°C; the drastic drop in G' and the sharpness of the tan δ_G peak are characteristic of typical glass transition behavior of a neutral amorphous polymer.

Figure 3 shows the relaxation behaviour of the Nafion-Na sample of highest degree of ionization (90%), G', G'', and tan δ_G having been plotted with respect to temperature. Four distinct relaxation regions are evident, the peaks being labelled α_N, β_N, β'_N, and γ_N in order of decreasing temperature. The curves are very similar to those of the previous study (1) with the exception of the β'_N peak which appears at ca. -30°C in the Nafions with the highest degree of ionization; this peak was not as distinct in the mechanical spectrum of the dry samples tested previously as it is in the present study.

The lowest temperature δ_P peak, which was detected as a tail in the spectrum of the precursor, has disappeared both in the G'' and the tan δ_G curves of the highly ionized Nafion-Na samples. Also, this δ peak was not observed in the dielectric studies of the Nafion acid (1), strongly indicating that the peak may be a unique feature of the precursor which is not encountered in the ion-containing Nafion materials. In the previous study, this relaxation was identified with the motion of —SO_2F groups.

In the γ region, G' decreases markedly with temperature, with the corresponding G'' and tan δ_G plots indicating a peak centred around -100°C. The γ peak is more symmetrical and slightly higher in intensity than that of the precursor, supporting the earlier suggestion that the peak which appears at ca. -100°C in the precursor could result from the overlapping of the β_P and γ_P dispersions. In addition, a minor β'_N peak, which is not present as a separate peak in the precursor, is evident at ca. -30°C in the highly ionized Nafion-Na samples.

The highest temperature relaxation (α_N) occurs at ca. 240°C; it is the peak of greatest intensity in tan δ_G curve, with the β_N peak appearing as a shoulder at ca. 140°C. This behavior is identical to that observed previously. The initial assignment of the relaxation mechanisms of these two peaks must be re-evaluated, however; this aspect will be discussed in a later section of this paper.

Figure 4 shows a comparison of the relaxation behaviors of the nonionized precursor and the partially ionized Nafion-Na specimens with varying degrees of conversion (10%, 34%,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

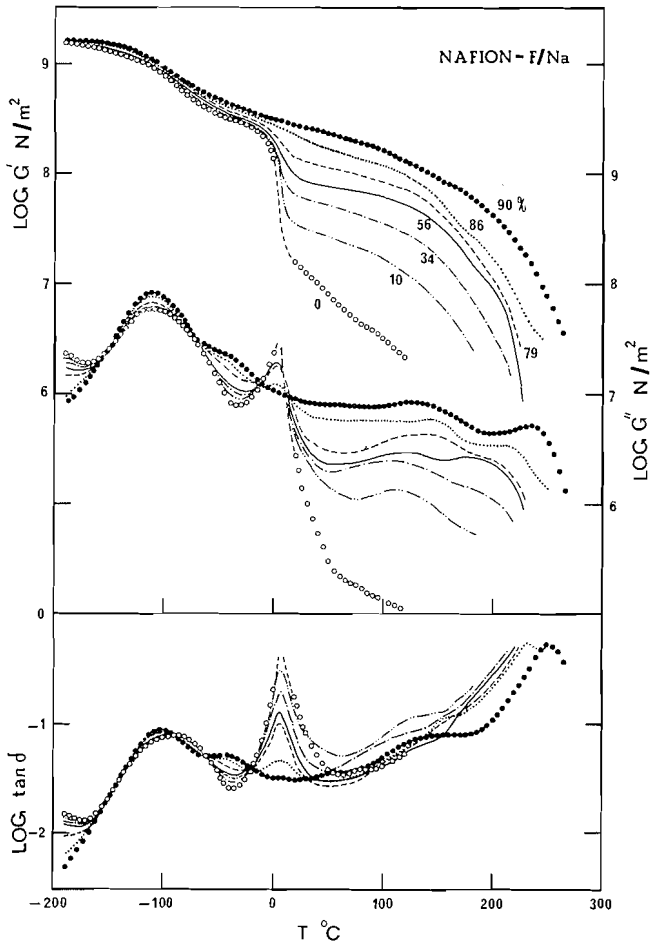

FIG. 4. Variation of G', G'', and tan δ_G with temperature for the percursor and partially ionized Nafion-Na samples at ca. 1 Hz.

56%, 79%, 86%, and 90%). The experimental points for the samples with intermediate extents of conversion have been omitted for the sake of clarity.

At the lowest temperatures achieved, i.e. in the δ region, samples with low degrees of conversion reveal the δ relaxation process as a tail in both the G'' and tan δ_G curves. The intensity of the δ peak decreases with increasing degree of conversion, eventually disappearing in the two highest (86% and 90%) conversion samples. Thus, it is clearly seen that the δ process exists only in the precursor.

At about −100°C, the G'' and tan δ_G curves for the low conversion samples show a skewed peak similar to that observed in the precursor where it was interpreted as being due to overlapping of the β_P and γ_P dispersions. The symmetry and intensity of this peak both increase with increasing conversion, however. Concurrently, a minor β'_N peak gradually appears at ca. −30°C, as a shoulder on the lower temperature γ peak. This would suggest that the overlapping β_P and γ_P relaxation processes in the precursor are split into two separate β'_N and γ_N dispersions, with increasing degree of ionization of the Nafion salt. It should be emphasized that the occurrence of the β'_N peak is prominent only in the Nafion materials of a high level of conversion.

In the glass transition region of the precursor, the α_P relaxation is very clearly defined, with sharp peaks observable in both the G'' and tan δ_G curves along with a dramatic drop-off in the G' plot. The intensity of this α_P peak decreases systematically with increasing degree of conversion, almost disappearing in the highest conversion Nafion-Na sample. The storage modulus G' correspondingly increases with increasing degree of conversion, with values for the highest (90%) conversion sample being over an order of magnitude higher than those of the precursor for temperatures greater than about 0°C.

As the temperature increases further, the G' and G'' curves of the precursor decrease monotonously with no additional peaks seen in the tan δ_G curve. The 10% conversion sample does show a peak (labelled β) in the G'' curve at ca. 130°C; as the degree of conversion increases, another high temperature peak, designated α, is evident in the G'' curves. This α peak is not seen in the tan δ_G curves for the low conversion samples due to an experimental limitation resulting from the softness of the samples. In the G'' plots, both the α and β peak positions shift to higher temperatures with increasing degree of conversion while the magnitudes of G' and G'' increase dramatically. The tendency for the β peak to move to higher temperatures with increasing conversion, accompanied by a slight depression of the G'' peak height, is reflected also in the tan δ_G curves. In the α region, the tan δ_G curves also move to higher temperature with increasing conversion; a clear peak is only evident in the highest conversion samples due to experimental limitations.

The decreasing intensity of the α_P peak (the glass transition of the precursor) accompanied by the increase in that of the α_N and β_N peaks (which will be identified below as the glass transitions of the ionic domains and the polymer matrix, respectively) in Nafion-Na with increasing conversion is reminiscent of typical relaxation phenomena observed in immiscible polymer blends. This behavior is further explored in Fig. 5 in which the torsional pendulum results for the original 56% conversion sample and a remolded specimen are compared. The γ region is almost identical in both cases. In the α_P region, the tan δ_G peaks for both systems are comparable. At elevated temperatures, however, the intensity of the β_N peak in the G'' and tan δ_G curves of the remolded sample is somewhat greater than that of the original Nafion, while the opposite behavior is observed for the α peak. The peak positions of both α and β peaks remain the same, however. This latter observation suggests that the precursor and the Nafion salt are probably incompatible.

2. *Partially neutralized Nafion-H/Cs*

Figure 6 shows torsional pendulum results for Nafion-H and Nafion-Cs samples with various degrees of neutralization (39%, 50%, 79%, and 90%). The Nafion acid (0% neutralization) reveals three distinct peaks in the tan δ_G versus temperature curve, which are termed α, β, and γ in descending order of temperature.

In the γ region, the position of the tan δ_G peak is not affected substantially by changes in the degree of neutralization: its magnitude does increase slightly with increasing degree of neutralization, however. A minor dispersion, analogous to the β'_N peak of the highly ionized Nafion-Na, is seen as a shoulder at ca. −20°C in the case of the 90% neutralized Nafion-Cs.

A broad β peak occurs in the 0−100°C temperature interval for the partially neutralized Nafion-Cs samples. With the exception of the 39% neutralized sample, the position of the tan δ_G peak in the β region shows a tendency to shift to higher temperature with increasing Cs^+ content. The height of the β peak, however, decreases gradually as the degree of neutralization increases. The decrease in G' in this region, while not pronounced, is still discernible.

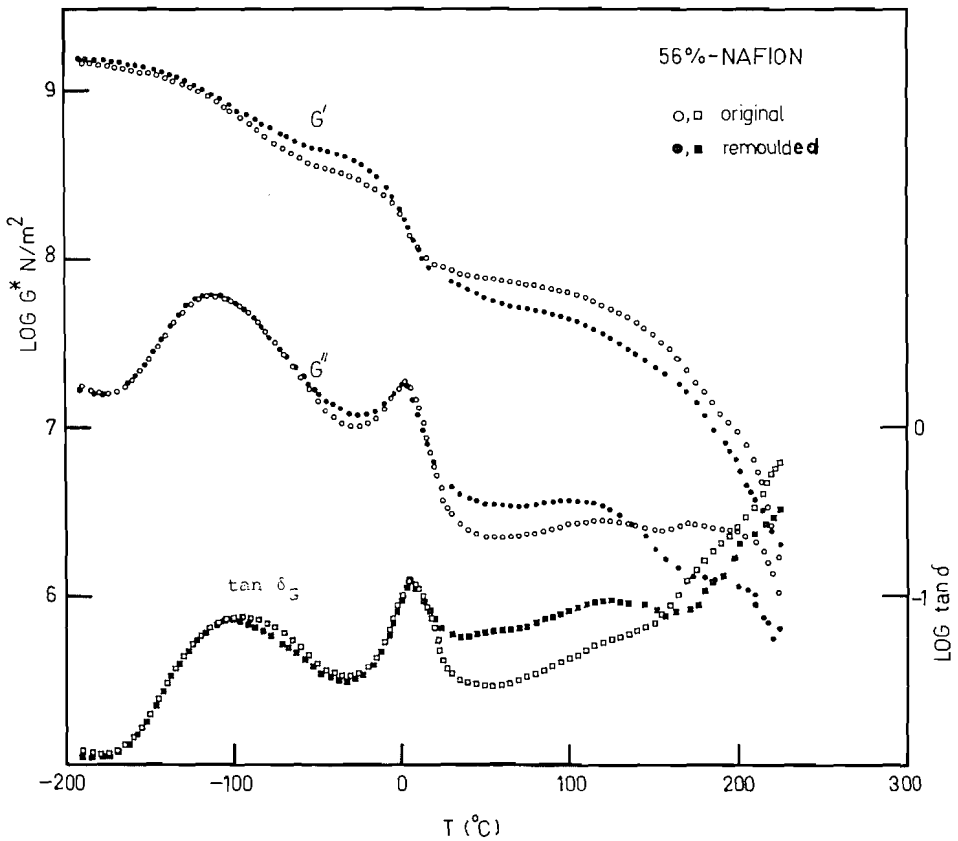

FIG. 5. Comparison of G', G'', and tan δ_G for original and remolded Nafion-Na of 56% conversion.

In the α region, G' drops drastically and a systematic movement of the falling portion of the G' curve to higher temperatures with increasing neutralization is very clear. The corresponding tan δ_G peak (the α peak) migrates to higher temperatures, accompanied by a slight increase in the peak height.

3. The barium salt of Nafion

Figure 7 shows the variation of G', G'', and tan δ_G with temperature for a Nafion-Ba sample. The γ relaxation appears at about the same temperature and has a comparable intensity to that of the monovalent ionic salts of Nafion. The β dispersion, which overlaps with the lower temperature γ peak, appears at ca. -20°C corresponding to the β'_N peak of the highly ionized Nafion-Na (Fig. 3) and the highly neutralized Nafion-Cs (Fig. 6) materials. However, the peak intensity is much greater here than in the monovalent salts.

As the temperature is increased, a very small shoulder is seen at ca. 210 in the G'' and tan δ_G curves. The G' curve, which is very flat up to about 200°C, begins to drop off fairly quickly at higher temperatures, with a peak seen at ca. 270°C in the G'' curve; this peak is not evident in the tan δ_G curve. This dispersion coincides to some extent with the crystal melting temperature of the monovalent salts, as revealed by differential scanning calorimetry (9, 25) and wide-angle X-ray diffraction studies (9, 26). There are probably contributions to this peak from both crystal melting and glass transition processes.

IV. Discussion

1. The precursor and partially ionized Nafion-Na

The low temperature δ_P relaxation of the precursor, previously observed in dielectric and vibrating reed studies, was detected as an increase in the energy dissipation over the temperature range from -170 to -190°C in the present torsional pendulum experiments. It had not been observed in the previous torsional pendulum study, since that work covered a temperature range of only -150 to 25°C. The gradual disappearance of the δ peak with increasing degree of neutralization confirms that the relaxation mechanism involved must be unique to the percursor; it is likely associated with the motion of $-SO_2F$ groups, as has been previously suggested.

The peak present in the spectrum of the precursor at ca. -100°C is broad and skewed, which was considered to be due to the overlapping of the γ_N and β_N peaks. Dielectric and mechanical studies suggest that the relaxation mechanisms responsible for these two peaks involve local $-CF_2-$ backbone motions and ether side chain motions, respectively. For low degrees of conversion from the precursor to the Nafions, the shape and temperature position of this peak are retained. However, materials with higher degrees of conversion yield more symmetrical peaks in the temperature region centred about -100°C, with an additional minor peak (β'_N) appearing at ca. -30°C in the case of the two highest conversion samples. This latter relaxation is not present as a separate dispersion in the precursor. Since the height and symmetry of this minor peak increase with increasing conversion, it is reasonable that the overlapping γ_P and β_P peaks of the precursor are split into two separate peaks with the introduction of a large number of ionic groups into the polymer. Since the β_P peak has been associated with the ether side chain motion, the β'_N process of Nafion may be related to a type of ether side chain motion which is influenced by ionic forces originating with the phase separated ionic domains.

In an earlier study of the Nafions by Yeo and Eisenberg (1) this β' peak was not seen to the extent observed here in the dry

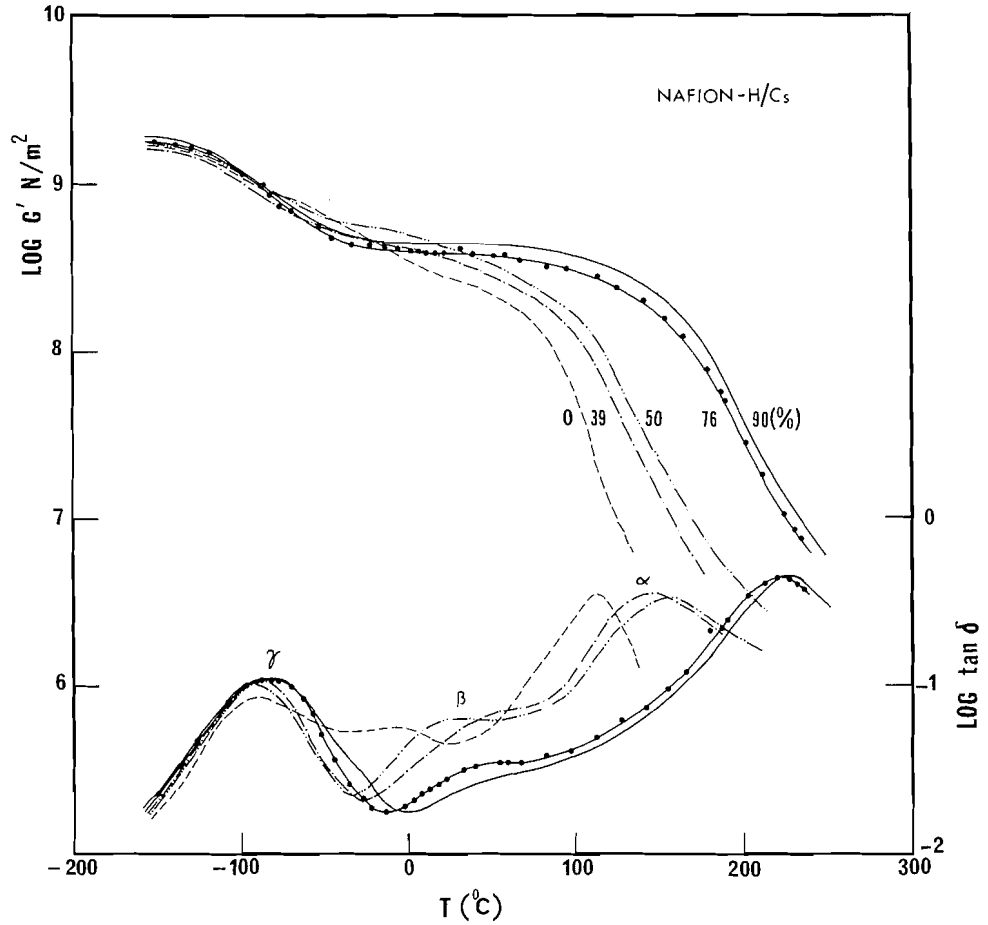

FIG. 6. Variation of G' and tan δ_G with temperature for Nafion-Cs with varying degrees of neutralization at ca. 1 Hz.

monovalent salts. Instead, a similar β peak was found in about the same temperature region in hydrated Nafions, this peak migrating to lower temperatures with increasing water content and eventually merging with the γ peak. It is tempting to suggest that the β′ peak may be related to the water-plasticized β peak observed in the previous Nafion-H samples. If this were the case, however, the position of the β′ peak should depend on the moisture content. Since samples with a low degree of conversion contain fewer ionic sites than those with higher conversions, there should be less residual water in the former materials. Hence the peak would be expected at a higher temperature for a specimen with a lower degree of conversion. Since the β peak appears to move to higher temperatures with increasing conversion, it is probably not related to the previously observed water-plasticized β peak in Nafion-H.

The identification of the γ peak is relatively straightforward; its temperature position in both the precursor and the Nafions is close to that observed for the relaxation in PTFE (27). The activation energy of the process as determined in dielectric studies is also comparable to that observed in PTFE. Thus, the γ relaxation in Nafion may have the same origin as the relaxation in PTFE where it is attributed to local —CF_2— backbone motions.

In the glass transition or α_P region of the precursor, which occurs at ca. 0°C, the intensity of the G'' and tan δ_G peaks decreases with increasing degree of ionization, the peak temperature remaining constant. At higher temperatures still, two peaks (denoted β and α, in ascending order of temperature) appear in the G'' curves of the partially ionized Nafion-Na samples, both peaks shifting to higher temperatures with increasing degree of ionization. These motions reflect the strong ionic interactions within the polymer. Certainly the α_P peak of the precursor is associated with the glass transition of the precursor matrix, while the β_N and α_N peaks of the Nafions could be associated with the glass transitions of the matrix and the ionic domains of the ion-containing phase separated system. This assignment of the α_P peak of the precursor to the T_g of the nonionized matrix is generally accepted, while that of the α_N and β_N relaxations is somewhat speculative, and will be discussed more fully in a subsequent section.

There is considerable similarity between the relaxation behavior of the original and remolded 56% conversion Nafion-Na samples; the temperature positions of the glass transition (or α_P relaxation) of the precursor and those of the glass transitions of the matrix and ionic domains of the Nafion salt (the β_N and α_N dispersions respectively) remain the same. This would suggest that the two systems are independent of each other.

2. *Partially neutralized Nafions*

The γ peak in the partially neutralized Nafion-Cs samples occurs at ca. −90°C, regardless of the degree of neutralization of the specimens, which is consistent with the results of the previous study as well as with those of the partially ionized Nafion-Na materials. The relaxation mechanism is likely the same as that occurring in PTFE or the precursor, where the peak has been assigned to local —CF_2— backbone motions. In contrast to its effect on the α and β peaks, the influence of the degree of neutralization on the temperature position of the γ

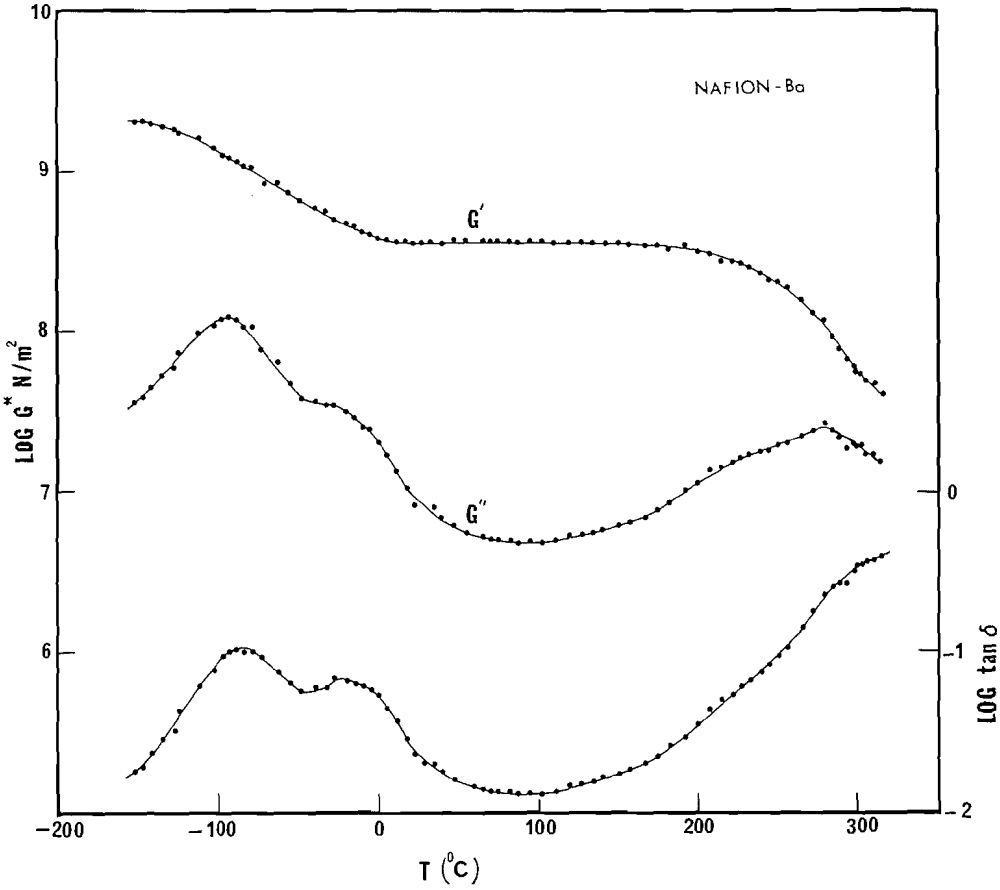

FIG. 7. Variation of G', G'', and tan δ_G with temperature for Nafion-Ba at ca. 1 Hz.

peak appears to be extremely small. A very small dispersion, corresponding to the β'_N minor peak of highly ionized Nafion-Na, occurs at about the same temperature in the case of highly neutalized Nafion-Cs. The relaxation mechanism here is probably the same as that of the β'_N peak.

Except for the 39% neutralization sample, the position of the β peak shifts to higher temperatures with increasing degree of neutralization, while the peak intensity decreases markedly. This behavior is quite common in the hydrocarbon based ionomers which generally show two tan δ peaks in the glass transition region (28, 29), the lower temperature peak showing a gradual movement to higher temperatures with increasing ion content, accompanied by a slight decrease in intensity. This peak is identified with the T_g of the matrix. In the present case, this behavior is explainable on the basis that increased neutralization enhances the strength of the ionic interactions in the material, which in turn reduces the mobility of the fluorocarbon matrix, thereby increasing the peak temperature while depressing the relaxation intensity. If this β relaxation represented the T_g of the ionic region, one would not expect such a decrease in the relaxation strength with increasing degree of neutralization.

The tan δ_G peak position for the α relaxation, which corresponds to a pronounced drop-off in G', moves dramatically to higher temperatures with increasing degree of neutralization, accompanied by a slight increase in the peak height. This feature is common to other ionomer systems in which the higher temperature peak shifts markedly to higher temperatures with increasing ion content. This higher temperature peak may be identified with the T_g of the ionic region.

The qualitative similarity of the tan δ_G behaviour of the Nafions to that of many other ionomers suggests that the initial assignments of the relaxation mechanisms of the α and β peaks to the glass transitions of the non-ionic phase and the highly polar ionic phase respectively should be reevaluated. The original assignments regarding these peaks were based on preliminary results which suggested that the α peak showed little or no sensitivity to moisture content, with the β peak undergoing a dramatic change with water content. This finding does not agree with the results of recent underwater stress relaxation studies (25) in which movement of the primary transition (α relaxation) is clearly observed.

The water sensitivities of both the α and β peaks are not surprising in view of the fact that the sizes of the phase-separated regions are very small. The two phases are expected to be in intimate contact with each other as a result of their small size (5). Therefore, any change in one of the phases would be expected to have a strong effect on the other phase. With the matrix and the ionic regions in such close proximity, water molecules can be accommodated very close to the fluorocarbon backbone, and would thus have the ability to interact with or plasticize the matrix, if only by creating a "soft" surface near the fluorocarbon regions. Since a majority of the ether side chains are expected to be anchored in the ionic regions through their polar end groups, the mobility of the backbone chains may be controlled, to some extent, by these side chains. Plasticization by water of the ionic domains would thus influence not only the molecular motions within the ionic domains, but also motions of the fluorocarbon backbone chains, implying that a water sensitivity for both the α and β peaks is reasonable.

For personal use only.

Thus the α and β peaks may logically be reassigned to the glass transitions of the ionic and nonionic phases respectively.

Further support for this assignment of the α peak may be found in the torsional pendulum results for the divalent Nafion-Ba salt, where the primary relaxation temperature (indicated by a rapid falling-off in G' and a peak in G'') is at a much higher temperature than the corresponding relaxations of the monovalent ionic systems.

The α dispersion possibly contains contributions from the crystal melting process since its temperature position corresponds to the crystal melting temperature found in DSC (9, 25) and WAXD (9, 26) studies of the monovalent salts. It is also likely, however, that the glass transition temperature of the material has been raised to such a high level that the peak would be due to two mechanisms, i.e. crystal melting and the T_g of the ionic region. The assignment of the α region of the Nafions to the matrix T_g is most unlikely; it is difficult to conceive that the matrix T_g would be higher than the crystal melting temperature. Hence it seems reasonable to assign the α peak to the glass transition of the ionic regions while attributing the β peak to the glass transition of the Nafion matrix.

In summary, four relaxation regions are observed in dynamic mechanical studies of the precursors. The highest temperature relaxation, labelled α_P, is due to the glass transition of the material; the β_P relaxation is seen next, and is tentatively assigned to ether side chain motions. Very close to it appears the γ_P relaxation due to CF_2 backbone motions, which is mechanistically identical with the γ peak found in pure PTFE. Finally, the δ_P peak is associated with motions of the SO_2F groups. In the ionomers, the α_N peak is due to glass transition of the dry ionic regions (with possible contributions from crystal melting in the divalent salts), while the β_N peak is associated with the glass transition of the matrix. The β'_N region, in parallel with β_P, is assigned to the ether side chains, while the γ peak, again in parallel with γ_P, is due to backbone CF_2 motions. The assignments of α_N and β_N as due to the glass transitions of the ionic regions and of the matrix, respectively, reverse the previous assignment and are supported by results obtained on a barium neutralized material.

Chemistry of enol silyl ethers. A general synthesis of 3-hydroxyhomophthalates and a biomimetic synthesis of sclerin[1]

P. BROWNBRIDGE, T. H CHAN,[2] M. A. BROOK, AND G. J. KANG
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received August 31, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

P. BROWNBRIDGE, T. H CHAN, M. A. BROOK, and G. J. KANG. Can. J. Chem. **61**, 688 (1983).

A general synthesis of 3-hydroxyhomophthalates is developed and applied to the synthesis of sclerin (**24**), a compound possessing plant-growth activity; the critical step in the synthesis of **24** can be considered as the controlled condensation of a di-β-carbonyl unit with a tri-β-carbonyl unit.

P. BROWNBRIDGE, T. H CHAN, M. A. BROOK et G. J. KANG. Can. J. Chem. **61**, 688 (1983).

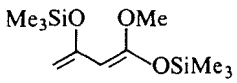
On a développé une synthèse générale des hydroxy-3 homophtalates et on l'a appliquée à la synthèse de la sclérine (**24**), un composé possédant une activité dans la croissance des plantes; on peut considérer que l'étape clé dans la synthèse de **24** est la condensation contrôlée d'une unité β-dicarbonylée sur une unité β-tricarbonylée.

[Traduit par le journal]

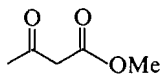
There are no well-established methods for the synthesis of benzenoid compounds from acyclic precursors. The syntheses of polysubstituted aromatic natural products in general rely on the stepwise introduction of substituents on some simpler aromatic precursors based on conventional aromatic chemistry.

It is well recognized though, in nature, that condensation of poly-β-carbonyl compounds is a major pathway for the biogenesis of aromatic natural produts (3, 4). Efforts to mimic this reaction in the laboratory have met, however, with limited success, mainly because of the difficulty of controlling the specificity of the direction of condensation (4). Such control is particularly critical when the poly-β-carbonyl precursor is composed of mixed acetate and propionate units.

Recently, we have introduced (2) the use of 1,3-bis-(trimethylsiloxy)-1-methoxybuta-1,3-diene (**1**) as the dianion equivalent of methyl acetoacetate (**2**) (5). Two factors induced us to examine the reactions of **1** in rather extensive detail



1



2

(1, 2, 6). The first is that enol silyl ethers are known to complement enolate anions in their chemical reactivities. A case in point is that, whereas enolates can be alkylated by primary or secondary halides, enol silyl ethers are alkylated by tertiary halides (7). It is also known that enol silyl ethers can condense with various carbonyl compounds or their functional equivalents under Lewis acid conditions (8) in contrast to the basic conditions inherent in enolate anion chemistry. The second factor is that the acetoacetate unit is one of the fundamental building blocks in the biogenesis of natural products (3, 4). It thus seemed possible that **1** can be quite useful in the synthesis of natural products, especially aromatic compounds derived from the condensation of acetoacetate and other poly-β-carbonyls.

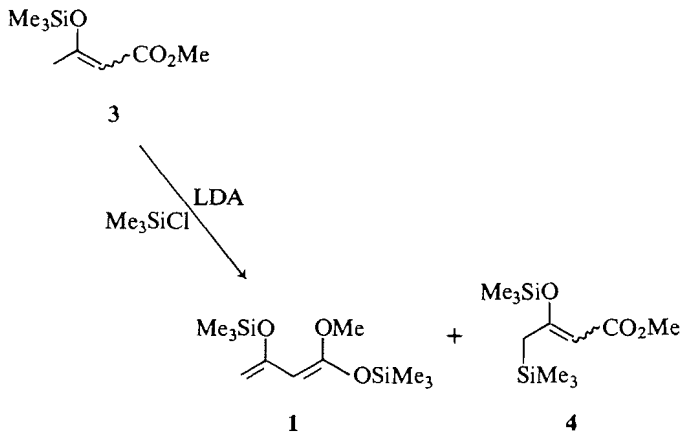
Results and discussion

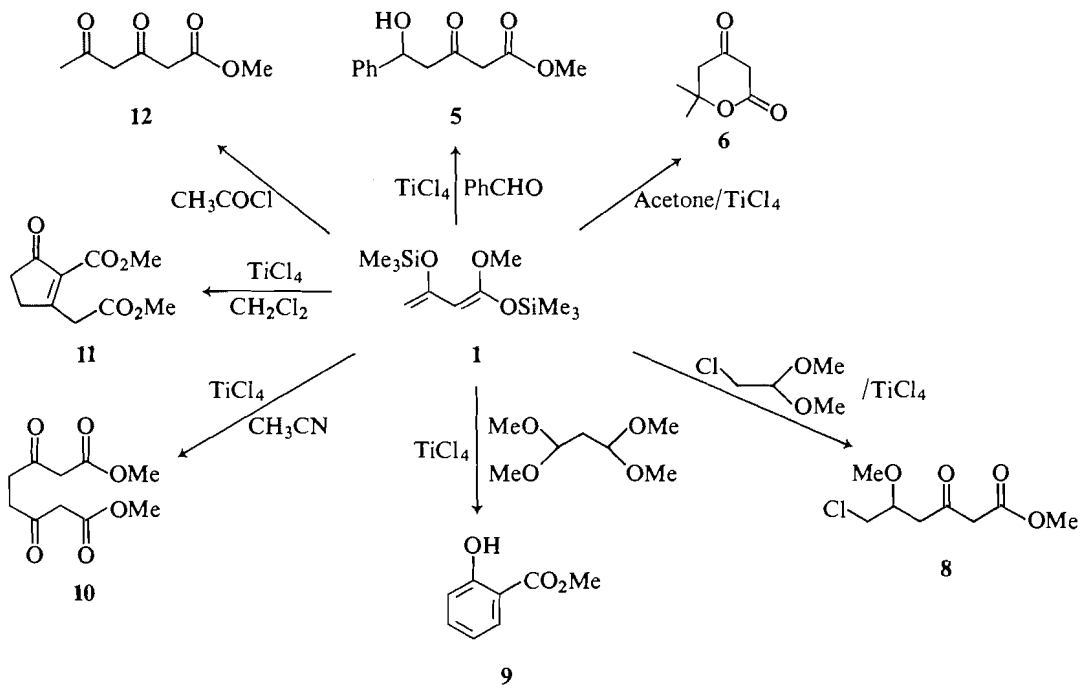
Reaction of electrophiles with 1,3-bis(trimethylsiloxy)-1-methoxybuta-1,3-diene (**1**)

In our original preparation of **1**, methyl 3-trimethylsiloxybut-2-enoate (**3**) was first deprotonated with LDA in THF/TMEDA followed by quenching with trimethylchlorosilane. The removal of TMEDA from the products proves to be tedious since it requires long periods of time under high vacuum and is



1 **4**

accompanied by some decomposition of **1**. We have now modified the procedure and eliminated the use of TMEDA. Furthermore, we have found that the reaction temperature has an effect on the product distribution. In the temperature range of −42° to −78°C, with or without TMEDA, the product is mainly **1** (93−95%), whereas at higher temperatures, the C-silylated isomer **4** is obtained as well. The rearrangement of **1** to **4** is fairly rapid at high temperature (9), for example, during gc conditions, but is sufficiently slow at ambient temperature so that **1** can be kept in the freezer for at least two weeks without obvious isomerization. Judging from its nmr spectrum, **1** exists entirely as one geometrical isomer, tentatively assigned as the *E*-isomer (2). However, in the gc analysis of **1**, two peaks, in addition to the peak for **4**, are invariably observed in a ratio of about 1:3. From gc−ms, the two have the same molecular ion and are believed to be the *E*- and *Z*-isomers of **1**.



SCHEME 1

Reactions of **1** with a number of carbon electrophiles have been examined (Scheme 1). Benzaldehyde reacted with **1** in the presence of titanium tetrachloride to give the adduct **5** in good yield (72%). Similarly, reaction of **1** with acetone and titanium tetrachloride gave the lactone **6** which exists as a mixture of keto–enol tautomers. It is clear that **1**, though having two nucleophilic sites at C-2 and C-4, reacts with electrophiles preferentially at C-4 (γ-attack).[3] While these reactions are not formally different from the reactions of the acetoacetate dianion with the same carbonyl compounds (5), the fact that reactions of **1** are conducted under acid-catalyzed conditions offers new opportunities. Acetals can be used as functional equivalents of carbonyl compounds in the condensation reaction. Thus chloroacetaldehyde dimethyl acetal (**7**) condenses with **1** in the presence of titanium tetrachloride to give the adduct **8**. When malonaldehyde bis(dimethylacetal) is used as the electrophile, methyl salicylate (**9**) is obtained in 48% yield. In the formation of **9**, a second condensation must have occurred at C-2 of **1** and the other acetal function followed by the elimination of the methoxy moiety and aromatization. We have explored this method of cyclo-aromatization and the results have been reported elsewhere (see also below) (11, 12).

Because imines have been reported to condense with enol silyl ethers under $TiCl_4$ conditions (13), we became interested in the possibility of using nitriles as the carbon electrophiles. When **1** was dissolved in acetonitrile in the presence of $TiCl_4$, no condensation product was observed. Instead, the compound dimethyl 3,5-dioxooctanedioate (**10**) was obtained in 77% yield. The compound **10** is clearly derived from the dimerization of **1**. Dimerization of ketene silyl acetal by $TiCl_4$ has previously been observed (14*a*) and has recently been exploited by us as a method of cyclopropane synthesis (14*b*). The formation of **10** can also account for another observation, viz., when **1** was mixed with $TiCl_4$ in methylene chloride as the solvent, the cyclopentenone **11** was obtained as the major product. In the less donating solvent CH_2Cl_2, $TiCl_4$ is sufficiently acidic to effect the cyclization of **10** to **11**. Indeed, this is one of the routes by which methyl *cis*-jasmonate has been synthesized (15).

Reaction of **1** with acetyl chloride occurred readily even in the absence of titanium tetrachloride to give a complicated mixture of compounds. When the reaction was conducted in ether at −78°C, the tri-β-carbonyl compound **12** was isolated in ~30% yield. When **1** was reacted with acetyl chloride *and* titanium tetrachloride, an aromatic compound **13** was isolated in 32% yield (11). It is clear that **13** is derived from two molecules of **1** and one acetyl group. It also seemed to us that this condensation may offer a simple and general synthesis of 3-hydroxyhomophthalate esters. To explore this, we sought to understand the factors which control the reaction, as well as to improve the yield.

A general synthesis of 3-hydroxyhomophthalates

The cycloaromatization reaction proposed by us (11, 12) involves the condensation of two 3-carbon units, one with two nucleophilic sites and the other containing two electrophilic sites, as in eq. (1). Compound **1** and similar bisenol silyl ethers

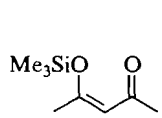
[1] 
constitute the 3-carbon fragments with two nucleophilic sites, with C-4 being more reactive (δ^{--}) than C-2 (δ^{-}). Various equivalents of β-dicarbonyl compounds constitute the 3-carbon electrophilic components. The regiochemistry of the reaction is controlled by the differential reactivities of these sites. In our previous publication, we have established that, within the same component, the order of reactivity of the electrophilic sites is ketone > acetal or monothioacetal. For β-oxy-α,β-unsaturated ketones, the conjugate position is more electrophilic towards **1** than the carbonyl position. We have now established the

[3]Preference for γ-regioselectivity appears to be common for 1-siloxydienes; see ref. 10.

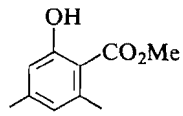
relative reactivities of other carbonyl functional groups or equivalents in their reactions with **1** under $TiCl_4$ conditions.

In a competitive reaction of **1** with an equal mixture of benzaldehyde and 4-trimethylsiloxy-3-penten-2-one (**14**), under $TiCl_4$ activation, a 10:1 mixture of **5** and **15** was obtained. On the other hand, the reaction of **1** with an equal mixture of acetone and **14** under identical conditions gave a ~1:1 mixture of **6** and **15**.

There is, however, no condensation of **1** with ester carbonyls or with the conjugate position β-oxy-α,β-unsaturated esters. For example, **1** did not condense with **3** to give any aromatic compound. These experiments establish therefore qualitatively the following order: aldehyde > conjugated position of β-oxy-α,β-unsaturated ketone ~ isolated ketone > carbonyl position of β-oxy-α,β-unsaturated ketone > acetal or monothioacetal > conjugate position of β-oxy-α,β-unsaturated ester or ester carbonyl.

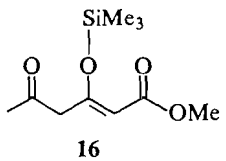


14

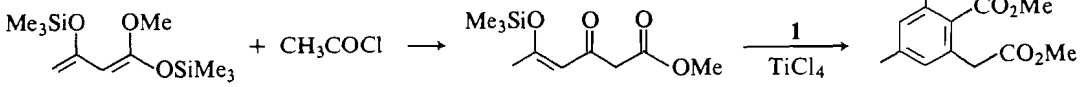


15

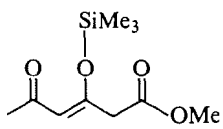
To return to the formation of **12** from the reaction of **1** with $AcCl/TiCl_4$, the first step in the reaction is to form an initial tri-β-carbonyl adduct. While the adduct has most likely the structure **16**, one cannot entirely eliminate from consideration the possibilities **17** or **18**. The tri-β-carbonyl compound reacts then with another molecule of **1** according to eq. [1] to give the aromatic compound **13**. From the order of reactivities discussed above, **17** would have given us the wrong regiochemistry for **13** and is thus excluded. Either **16** or **18** can account for the formation of **13** with the correct regiochemistry.



16

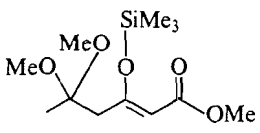


1 **18** **13**

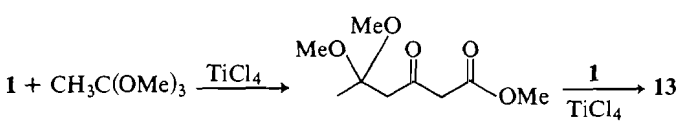


17

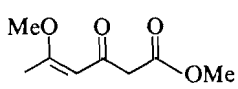
To resolve the two possibilities, we modified the acetylating agent. In place of acetyl chloride, trimethyl orthoacetate was used. The reaction proceeded extremely well and gave a much improved yield of **13** (65% isolated). In this case, the corresponding tri-β-carbonyl adduct would be **19**, **20**, or **21**. Structure **20**, on subsequent cycloaromatization with **1**, would have given the wrong regioisomer. Structure **21**, which has to be derived from **20** by the elimination of MeOH, is considered unlikely under the reaction conditions from our previous experience with β-keto acetals (11, 12). Structure **19**, the equivalent of **16**, can then account for the formation of **13**, provided that the β-oxy-α-β-unsaturated ester group, though unreactive towards **1** in an intermolecular fashion, may well participate in an intramolecular step in the cycloaromatization reaction.



19



20



21

Anhydrides can be used equally as well as the acylation agent in the formation of 3-hydroxyhomophthalate esters. This provides a general synthesis of dimethyl 5-substituted-3-hydroxyhomophthalates (**22**) (Table 1). With isobutyric anhydride, the product contained a substantial amount of methyl 6-methyl-3,5-dioxoheptanoate (**23**, 31%) even though two mole equivalents of **1** were used. We presume that, in this case, the cycloaromatization reaction is slow owing to the steric effect of the isopropyl group. γ-Butyrolactone can, though less effectively, serve as the acylating agent to give compound **22** (R = HO $(CH_2)_3$-).

A biomimetic synthesis of sclerin

Sclerin (**24**), a metabolite isolated from *Sclerotinia* fungi, possesses interesting plant growth activity (16). Its biosynthesis has been investigated extensively by labelling experiments (17–19); essentially, it can be considered as the condensation product of a penta-β-carbonyl precursor. A few chemical syntheses of sclerin have previously been reported (20–22), based on conventional aromatic chemistry, often with the inherent problem of regioselection in electrophilic aromatic substitution and giving low overall yields. We have

TABLE 1. Products of the reaction of **1** with various electrophiles in the presence of $TiCl_4$

Electrophile	Product **22**	% Yield	Melting point (°C)
$HC(OMe)_3$	R = H	68	53–55
$MeC(OMe)_3$	R = Me	65	82–83
$(MeCO)_2O$	R = Me	69	
$(PhCO)_2O$	R = Ph	72	109–110
$(Pr^iCO)_2O$	R = i-Pr[a]	42	165–166.5
	23	31	Oil

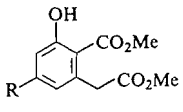
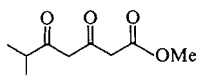
[a]Isolated as the benzylic monoacid.



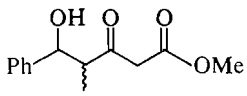
22



23

now applied the cycloaromatization reaction which has the construction of the hexasubstituted benzene ring as the critical step (Scheme 2) to the synthesis of sclerin.

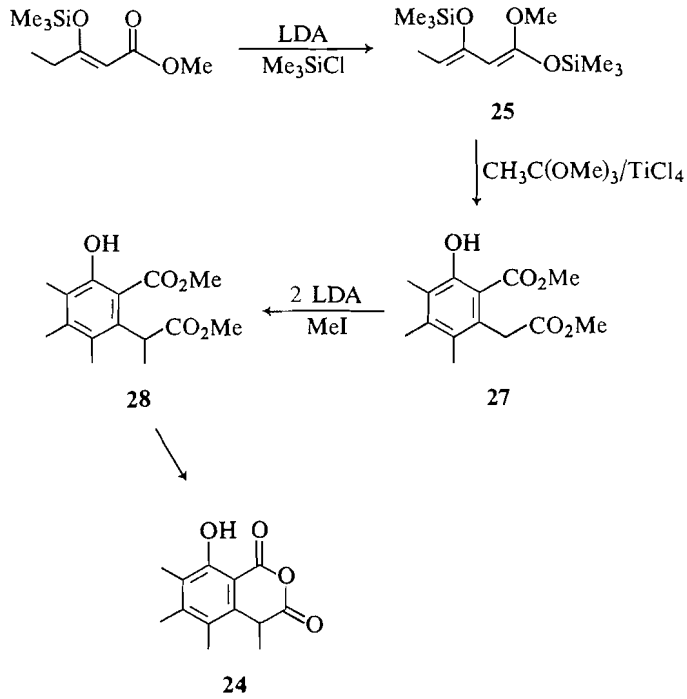
1,3-Bis(trimethylsiloxy)-1-methoxy-penta-1,3-diene (**25**) was prepared from 3-trimethylsiloxy-pent-2-enoate in a manner similar to the preparation of **1**. From its nmr spectrum, **25** appears to exist mainly as one geometric isomer, probably the *E,E* isomer. Compound **25** condenses with benzaldehyde/$TiCl_4$ to give the aldol adduct **26** indicating again that in **25**, C-4 is the more reactive nucleophilic site.



26

Condensation of **25** (2 mole equivalents) with trimethyl orthoacetate in the presence of titanium tetrachloride (2 mole equivalents) gave in 53% yield the aromatic compound **27** as colourless prisms, mp 85–85.5°C. The structure of **27** is evident from its ^1H nmr spectrum ($CDCl_3$) which showed three aromatic methyl peaks (δ 2.17, 2.21, and 2.25), two ester methyl peaks (δ 3.68 and 3.87), methylene hydrogens at δ 3.91, and a phenolic OH at δ 11.04. Its ir (3150 br, 1735, 1663, and 1599 cm^{-1}) in $CHCl_3$ and mass (M^+, *m/e* 266, 83%; *m/e* 234 ($M - MeOH)^+$, 100%) spectra are also consistent with its structure. Methylation of **27** with 2 mole equivalents of LDA and 1 mole equivalent of methyl iodide gave in 80% yield dimethyl sclerinate (**28**), mp 113–114°C (lit. (24) mp 113–116°C). The conversion of **28** into **24** was readily accomplished by using sodium hydroxide followed by acid.

In a recent review article (4), the hope was expressed that the aesthetically pleasing route of biogenetic-type synthesis can, in selected cases, provide commercially attractive routes to natural products of economic importance. In the present synthesis of sclerin, by using enol silyl ethers as the nucleophiles, carbonyl equivalents as the electrophiles, and titanium tetrachloride as the activating agent, a controlled condensation of a dicarbonyl unit with a tri-carbonyl unit in the construction of **27** is demonstrated. It is recognized that the condensation is of the abnormal type, giving a homophthalic acid structure, whereas many phenolic natural products have the resorcinol skeleton derived from a more common type of head-to-tail condensation. Our next task, to show the versatility of the proposed



SCHEME 2

cycloaromatization for the synthesis of phenolic natural products, must therefore aim in that direction (1).

Experimental

General

Melting and boiling points are uncorrected. Infrared spectra were obtained from films on NaCl plates for liquids and from solutions in 0.1 mm NaCl cells for solids, using a Perkin–Elmer 297 spectrophotometer. The ^1H nmr spectra were recorded on Varian T-60 and T-60A instruments, with Me_4Si as internal standard. Mass spectra were obtained on a Hewlett–Packard 5984A or an LKB 9000 machine operating at 70 eV. Column chromatography was performed on silica gel 60 (Merck). Et_3N, $i\text{-}Pr_2NH$, and TMEDA were dried by distillation from CaH_2; hexane, CCl_4, and benzene from P_2O_5; CH_2Cl_2 from P_2O_5 and then from CaH_2. THF was distilled under nitrogen from sodium–benzophenone directly into the reaction vessel. Microanalyses were performed by Guelph Chemical Laboratories Ltd.

1,3-Bis(trimethylsiloxy)-1-methoxybuta-1,3-diene (**1**) was prepared according to reported procedure (11) with slight modification. To a solution of 1.0 mL diisopropylamine (7.1 mmol) in 25 mL of dry THF under argon, 5.0 mL of 1.5 *M* n-butyllithium in hexane was added after cooling to 0°C and the reaction mixture was cooled to −78°C. A quantity of 1.1 g of methyl 3-trimethylsiloxybut-2-enoate (5.9 mmol) was added and the solution stirred for 2 min. Then the reaction was quenched with 1.2 mL trimethylchlorosilane (9.5 mmol). The solvent was removed under reduced pressure after a further 10 min and the residue was washed and filtered with cold dry hexane. The hexane was removed from the filtrate *in vacuo* to yield **1** in 93% yield. When the above preparation was carrried out at room temperature, the product was found to be a mixture of **1** and **4** (~3:1) (9). The ratio of **1** to **4** was changed to about 10:1 when the reaction temperature was lowered to 0°C, and essentially pure **1** was obtained if the reaction temperature was below −23°C. Compound **1** can be kept in a stoppered container for up to 2 weeks in the freezer without obvious decomposition but is slowly hydrolysed to **3** when exposed to air.

1,3-Bis(trimethylsiloxy)-1-methoxypenta-1,3-diene (**25**) was prepared according to literature procedure (12).

Reaction of 1 with benzaldehyde

To a well-stirred mixture of **1** (1.04 g, 4 mmol) and benzaldehyde

(0.43 g, 4 mmol) in 4 mL CH_2Cl_2 under nitrogen at −78°C, titanium tetrachloride (0.45 mL, 4 mmol) was added. After 3 h, the dark red mixture was added to aqueous $NaHCO_3$ and extracted with ether. The extract was dried ($MgSO_4$) and evaporated to give an oil which was column chromatographed (eluant $CHCl_3$) to give *methyl 5-hydroxy-3-oxo-5-phenylpentanoate* (**5**, 0.64 g, 72%) as a colorless oil with spectroscopic data similar to those reported (5).

Reaction of 1 with acetone

The reaction was performed as above except that ethyl acetate was used for extraction. The product, 6,6-dimethyltetrahydropyran-2,4-dione (**6**, 76%), was colorless plates, mp 131−132°C (from CH_2Cl_2); ir ($CHCl_3$): 3350 br, 1727 cm^{-1}; ^1H nmr shows an approximately 2:3 mixture of diketo and enol forms (1:1 $CDCl_3$ − $(CD_3)_2CO$), δ: 1.48 (enol) and 1.52 (keto) (each s, 6H, Me_2C), 2.52 (enol) and 2.73 (keto) (each s, 2H, 5-CH_2), 3.43 (s, $COCH_2CO$), 5.18 (s, $HOC{=}CHCO$), 6.3 (br s, enol OH); ms *m/z*: 142 (M^+, 15%), 127 (41), 85 (90), 84 (100), 56 (72). *Anal.* calcd. for $C_7H_{10}O_3$: C 59.14, H 7.09; found C 59.05, H 7.37.

Reaction of 1 with chloroacetaldehyde dimethyl acetal

The reaction was performed as for above. The crude product was purified by column chromatography (eluant CH_2Cl_2) to give methyl 6-chloro-5-methoxy-3-oxohexanoate (**8**, 35%) as a colorless oil. Infrared (film): 1745, 1719 cm $^{-1}$; ^1H nmr ($CDCl_3$), δ: 2.87 (d, 2H, J = 6 Hz, $CHCH_2Cl$), 3.41 (s, 3H, OMe), 3.51 (s, 2H, CH_2CO_2Me), 3.66 (d, 2H, J = 4 Hz, $CHCH_2CO$), 3.76 (s, 3H, CO_2Me), 3.8−4.2 (m, 1H, $MeOCH$); EI−ms *m/z*: 177 (M − OMe, 1%), 159 (M − CH_2Cl, 22), 101 (53), 93 (72), 85 (64), 69 (100), 59 (68); Cl−ms (isobutane): 211 ($^{37}Cl - MH^+$, 3%), 209 ($^{35}Cl - MH^+$, 12), 177 (100).

Reaction of 1 with malonaldehyde bis(dimethylacetal)

A solution of **1** (1.30 g, 5 mmol) in CH_2Cl_2 (15 mL) was added dropwise to a mixture of 1,1,3,3-tetramethoxypropane (0.82 g, 5 mmol) and $TiCl_4$ (0.55 mL, 5 mmol) in dry CH_2Cl_2 (20 mL) at −78°C under nitrogen. After 3 h, the mixture was allowed to warm to 0°C, added to aqueous $NaHCO_3$, and extracted with ether. The extracts were dried ($MgSO_4$) and evaporated to give an oil (0.73 g). Column chromatography eluted with CH_2Cl_2 gave a colorless oil; which was identified to be methyl salicylate (**9**) from its spectra and characteristic wintergreen odour (0.36 g, 48%).

Dimerization reactions of 1

To a solution of **1** (1.56 g, 6 mmol) in dry CH_2Cl_2 (5 mL) under nitrogen at −78°C was added $TiCl_4$ (0.70 mL, 6.3 mmol). The dark red mixture was allowed to warm to 0°C and stirred overnight. It was added to aqueous $NaHCO_3$ (the aqueous phase was dark blue due to Ti^{3+}; the mixture was stirred vigorously until air oxidation removed the blue colour) and extracted with ether, the aqueous layer being retained. The ether extracts were dried ($MgSO_4$) and evaporated to give only methyl acetoacetate (0.21 g). The aqueous phase was acidified (HCl) and extracted with ethyl acetate. These extracts were dried (Na_2SO_4) and evaporated to give a brownish solid (0.40 g). Recrystallization from cyclohexane gave methyl (2-methoxycarbonyl-3-oxocyclopent-1-enyl)acetate (**11**) (17), colorless plates, mp 75−76°C, 0.33 g (52%); ^1H nmr ($CDCl_3$), δ: 2.4−3.0 (m, 4H, CH_2CH_2), 3.75 and 3.84 (each 3H, s, CO_3Me), 3.89 (s, 2H, CH_2CO_2Me); ms *m/z*: 212 (M^+, 20%), 180 (96), 149 (100), 148 (56). When the reaction was performed as above but with acetonitrile as solvent, the ether extract gave dimethyl 3,5-dioxooctanedioate (17) (**10**, 77% yield after column chromatography eluted with CH_2Cl_2) as a colorless oil. Infrared (film): 1747, 1718 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 2.81 (s, 4H, $COCH_2CH_2CO$), 3.46 (s, 4H, $COCH_2CO_2Me$), 3.68 (s, 6H, CO_2Me); ms *m/z*: 230 (M^+, 13%), 212 (4), 157 (32), 129 (100), 115 (14), 101 (42), 97 (42), 55 (56). No cyclopentenone **11** was formed in this case.

Reaction of 1 with acetyl chloride

A mixture of **1** (1.04 g, 4 mmol) and acetyl chloride (0.23 mL) was stirred in dry Et_2O (3 mL) at −78°C under nitrogen for 4 h. The mixture was poured into dilute HCl and extracted with ether. Drying ($MgSO_4$) and evaporation of the extracts gave a colorless oil (0.48 g) which was an approximately 1:2 mixture of the product and methyl acetoacetate by nmr. This oil was pumped under high vacuum until no more weight loss occurred, to give methyl 3,5-dioxohexanoate (**12**), a colorless oil (0.21 g, 30%) with spectroscopic data similar to those reported (5).

Reaction of 1 with trimethyl orthoformate

A solution of **1** (5.2 g, 20 mmol) in CH_2Cl_2 (10 mL) was added to a mixture of trimethyl orthoformate (1.06 g, 10 mmol) and $TiCl_4$ (2.2 mL, 20 mmol) in CH_2Cl_2 (15 mL) at −78°C under nitrogen. After 3 h, the mixture was allowed to warm to room temperature and stirring continued overnight. It was then added to aqueous $NaHCO_3$ and extracted with CH_2Cl_2. The extracts were dried (Na_2SO_4), evaporated, and the residue purified by column chromatography eluted with CH_2Cl_2 to give methyl (3-hydroxy-2-methoxycarbonylphenyl)acetate (**22***a*, R = H, 1.53 g, 68%) as colorless needles, mp 53−55°C (from pentane) (lit. (23) mp 55−57°C).

Reaction of 1 with trimethyl orthoacetate

When the reaction was performed as above (2:1:2, $TiCl_4$/$MeC(OMe)_3$/**1**), methyl (3-hydroxy-2-methoxycarbonyl-5-methylphenyl)acetate (**13**) (11) was produced in 65% yield as colorless needles, mp 82−83°C.

Reaction of 1 with acetic anhydride

Titanium tetrachloride (1.0 mL) was added to a well-stirred mixture of **1** (2.39 g, 9.2 mmol) and acetic anhydride (0.46 g, 4.6 mmol) in CH_2Cl_2 (10 mL) at −78°C under nitrogen. This dark red solution was stirred for 2 h at −78°C, then overnight at room temperature. It was added to aqueous $NaHCO_3$ and extracted with ether. The extracts were dried, evaporated, and the resulting solid recrystallized from methanol to give methyl (3-hydroxy-2-methoxycarbonyl-5-methylphenyl)-acetate (**13**, 0.75 g, 69%) (11).

Reaction of 1 with benzoic anhydride

Reaction of **1**, benzoic anhydride, and $TiCl_4$ as described above gave methyl 5-hydroxy-4-methoxycarbonyl-(1,1′-biphenyl)-3-acetate (**22**, R = Ph) as colorless prisms, mp 109−110°C (from CCl_4−cyclohexane), in 72% yield: ir ($CHCl_3$): 3400 br, 1739, 1670, 1621 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 3.65 (s, 3H, CH_2CO_2Me), 3.83 (s, 3H, $ArCo_2Me$), 3.89 (s, 2H, CH_2CO_2Me), 6.90 (d, 1H, J = 2 Hz, Ar), 7.14 (d, 1H, J = 2 Hz, Ar), 7.2−7.6 (m, 5H, Ph), 11.3 (br s, 1H, OH); ms *m/z*: 300 (M^+, 88%), 268 (97), 240 (100), 236 (50), 225 (92). *Anal.* calcd. for $C_{17}H_{16}O_5$: C 67.99, H 5.37; found: C 68.08, H 5.46.

Reaction of 1 with isobutyric anhydride

The reaction was carried out under the above conditions to give an approximately 3:2 mixture of methyl [3-hydroxy-2-methoxycarbonyl-5-(1-methylethyl)phenyl]acetate (**22**, R = i-Pr) and methyl 3,5-dioxo-6-methylheptanoate (**23**) which could not be separated by column chromatography. The mixture was dissolved in 5% aqueous NaOH and extracted with ether. The aqueous layer was treated with aqueous NH_4Cl until neutral (pH 8) and extracted again with ether. The ether extract on drying ($MgSO_4$) and evaporation gave a colorless oil (0.29 g, 31%) which was **23**. It had ir (film): 3420 br, 1743 1661, 1618 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 1.14 (d, 6H, J = 7 Hz, Me_2CH), 2.1−2.7 (m, 1H, Me_2CH), 3.21 (S, 2H, CH_2CO_2Me), 3.69 (S, 3H, CO_2Me), 5.51 (S, 1H, HO—C=CH—CO), 13.3 (br s, 1H, enol OH); ms *m/z*: 186 (M^+, 9%), 143 (83), 101 (100). The aqueous layer from the above was acidified (HCl) and further extracted with ether. Drying ($MgSO_4$) and evaporation of these organic extracts gave a colorless solid which was recrystallized from CCl_4. It was [3-hydroxy-2-methoxy-carbonyl-5-(1-methylethyl)phenyl]acetic acid (42% yield), mp 165−166.5°C; ir ($CHCl_3$): 3100 br, 1713, 1669, 1622 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 1.24 (d, 6H, J = 7 Hz. Me_2CH), 2.85 (septet, 1H, J = 7 Hz, Me_2CH), 3.89 (s, 5H, $ArCO_2Me$ and CH_2CO_2H), 6.57 (d, 1H, J = 2 Hz, Ar), 6.82 (d, 1H, J = 2 Hz, Ar), 11.2 (br s, 2H, OH); ms *m/z*: 252 M^+, 56%), 220 (66), 202 (75), 192 (100). *Anal.* calcd. for $C_{13}H_{16}O_5$: C 61.90 H 6.39; for $C_{13}H_{16}O_5 \cdot \frac{1}{2}H_2O$: C 59.79, H 6.51; found: C 60.19, H 6.16.

*Reaction of **1** with γ-butyrolactone*

The reaction was carried out as above and the product on work-up was purified by column chromatography (eluant ether). A considerable quantity of dimethyl 3,5-dioxooctanedioate (**10**) was isolated. In addition, methyl [3-hydroxy-5-(3-hydroxypropyl)-2-methoxy carbonylphenyl]acetate (**22**, R = $HO(CH_2)_2$-) was obtained as a colorless oil (13%). It had ir ($CHCl_3$): 3440 br, 1737, 1669, 1622 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 1.6−2.1 (m, 2H, $CH_2CH_2CH_2$), 2.3 (br s, 1H, CH_2OH), 2.5−2.8 (m, 2H, $ArCH_2CH_2$), 3.63 (t, 2H, J = 6.5 Hz, CH_2CH_2OH), 3.68 (s, 3H, CH_2CO_2Me), 3.27 (s, 5H, $ArCO_2Me$ and $ArCH_2CO_2Me$), 6.55 (d, 1H, J = 2 Hz, Ar), 6.78 (d, 1H, J = 2 Hz, Ar), 11.19 (s, 1H, ArOH); ms m/z: 282 (M^+, 30%), 250 (32), 222 (36), 206 (100), 184 (94).

*Reaction of **25** with benzaldehyde*

To a well-stirred mixture of **25** (1.79 g, 6.5 mmol) and benzaldehyde (0.69 g, 6.5 mmol) in dry CH_2Cl_2 (5 mL) under nitrogen at −78°C, was added $TiCl_4$ (0.72 mL, 6.5 mmol). After 3 h, the mixture was warmed to 0°C, poured into aqueous $NaHCO_3$, and extracted with ether. The extracts were dried ($MgSO_4$) and evaporated to give a yellow oil (1.60 g), which was a 3:1 mixture of diastereoisomers of the aldol condensation product by nmr. Column chromatography eluted with CH_2Cl_2 gave a partial separation of these diastereoisomers, but also caused partial cyclization of the major isomer to the lactone. (4*R*(*S*), 5*S*(*R*))-Methyl 5-hydroxy-4-methyl-3-oxo-5-phenylpentanoate (**26**, the original minor diastereoisomer, 0.35 g, 22%) was a colorless oil, R_f 0.61, ir (film): 3420 br, 1751, 1719 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 1.97 (d, 3H, J = 6.5 Hz, $MeCH$), 3.18 (s, 2H, $COCH_2$), 3.2−3.6 (m, 1H, $MeCHCH$), 3.59 (s, 3H, CO_2Me), 5.07 (d, 1H, J = 8.5 Hz, $PhCHCH$), 7.28 (s, 5H, Ph); ms m/z: 236 (M^+, 23%), 215 (50), 125 (100). (4R(*S*), 5*R*(*S*))-Methyl 5-hydroxy-4-methyl-3-oxo-5-phenylpentanoate (0.37 g, 23%) was a colorless oil, R_f 0.60, ^1H nmr ($CDCl_3$), δ: 0.88 (d, 3H, J = 7 Hz, $MeOH$), 3.2−3.6 (m, 1H, $MeCHCH$), 3.65 (s, 2H, $COCH_2$), 3.73 (s, 3H, CO_2Me), 4.94 (d, 1H, J = 10.5 Hz, $PhCHOH$), 7.30 (s, 5H, Ph); the ir and mass spectra were similar to the above. (5*R*(*S*), 6*R*(*S*))-2,4-Dioxo-5-methyl-6-phenyltetrahydro-(2*H*)pyran (0.37 g, 27%) was colorless needles, mp 161−162°C (from CCl_4), R_f 0.2, ir ($CHCl_3$): 1766, 1731 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 1.00 (d, 3H, J = 7 Hz, $MeOH$), 2.4−3.0 (m, 1H, $MeCHCH$), 3.58 and 3.65 (ABq, 2H, J_{AB} = 19 Hz, $COCH_2$), 5.25 (d, 1H, J = 10 Hz, $PhCHCH$), 7.37 (s, 5H, Ph); ms m/z: 204 (M^+, 14%), 98 (100). *Anal.* calcd. for $C_{12}H_{12}O_3$: C 70.57, H 5.92; for $C_{12}H_{12}O_3 \cdot \frac{1}{4}H_2O$: C 69.08, H 5.99; found: C 69.05, 69.15, H 5.77, 5.95.

*Methyl(3-hydroxy-2-methoxycarbonyl-4,5,6-trimethylphenyl)acetate (**27**)*

A solution of **25** (3.3 g, 12 mmol) in CH_2Cl_2 (6 mL) was added to a mixture of trimethyl orthoacetate (0.72 g, 6 mmol) and $TiCl_4$ (1.3 mL, 12 mmol) in CH_2Cl_2 (6 mL) under nitrogen at −78°C. Stirring was continued for 2 h at −78°C, then overnight at room temperature. The mixture was added to aqueous $NaHCl_3$ and extracted with ether. The extracts were dried ($MgSO_4$) and evaporated, and the remaining oil purified by column chromatography (CH_2Cl_2) to give the *homophthalate derivative* **27** (0.84 g, 53%) as colorless prisms, mp 85−85.5°C (from methanol); ir ($CHCl_3$): 3100 br, 1734, 1663, 1599 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 2.17, 2.21 and 2.25 (each s, 3H, $MeAr$), 3.68 (s, 3H, CH_2CO_2Me), 3.87 (s, 3H, $ArCO_2Me$), 3.91 (s, 2H, CH_2CO_2Me), 11.04 (s, 1H, OH): ms m/z: 266 (M^+, 83%), 234 (100), 206 (86), 202 (77), 191 (87), 174 (85). *Anal.* calcd. for $C_{14}H_{18}O_5$: C 63.14, H 6.81; found: C 63.01, H 6.76.

*Methyl 1-(3-hydroxy-2-methoxycarbonyl-4,5,6-trimethylphenyl)propionate (**28**)*

n-Butyllithium (1.3 mL of a 1.6 *M* solution in hexane) was added to diisopropylamine (0.3 mL, 2.2 mmol) in dry THF (5 mL) under nitrogen at 0°C. The solution was cooled to −78°C and a solution of **27** (0.25 g, 0.94 mmol) in dry THF (10 mL) added dropwise. The yellow anion was stirred for 2 h, then a solution of iodomethane (0.14 g) in dry HMPA (1 mL) was added. The anion was decolorized at once. After 1 h, aqueous NH_4Cl and $Na_2S_2O_3$ were added, the mixture allowed to come to room temperature and extracted with ether. The extracts were dried ($MgSO_4$) and evaporated (finally under high vacuum). The residue was recrystallized from cyclohexane to give dimethyl sclerinate (0.21 g, 80%), colorless prisms, mp 113−114°C (lit. (24) mp 113−116°C), ^1H nmr ($CDCl_3$), δ: 1.50 (d, 3H, J = 7 Hz, $MeCHCO$), 2.17, 2.20 and 2.23 (each s, 3H, $MeAr$), 3.5 g (s, 3H, $CHCO_2Me$), 3.80 (s, 3H, $ArCO_2Me$), 4.20 (q, 1H, J = 7 Hz, $MeCHCO$), 10.70 (s, 1H, OH); ms m/z: 280 (M^+, 54%), 248 (48), 220 (66), 205 (100).

*Sclerin (**24**)*

The above ester **28** (0.20 g) and NaOH (0.10 g) were heated under reflux in aqueous ethanol (5 mL) for 0.5 h. The mixture was cooled, acidified (dilute HCl), and extracted with ethyl acetate. The extracts were dried ($MgSO_4$), evaporated, and the residue recrystallized from CCl_4 to give sclerin, mp 119−121°C, (lit (24) mp 123°C), nmr and ir similar to those reported.

Precise Q_β measurements for $A = 91$ to 93 mass chains

R. IAFIGLIOLA, M. CHATTERJEE,[1] H. DAUTET, AND J. K. P. LEE
Foster Radiation Laboratory, McGill University, Montreal, P.Q., Canada H3A 2B2

Received August 31, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

R. IAFIGLIOLA, M. CHATTERJEE, H. DAUTET, and J. K. P. LEE. Can. J. Chem. **61**, 694 (1983).

The Q_β values of $^{91-93}$Rb, $^{91-93}$Sr, and $^{92-93}$Y were measured using mass-separated Rb sources obtained from an on-line isotope separator. A $\Delta E-E$ detector telescope consisting of a 300 μm × 300 mm^2 Si ΔE- and a 15 mm × 500 mm^2 Ge(HP) E detector was used. Results are in general agreement with recently published values but some discrepancies are indicated.

R. IAFIGLIOLA, M. CHATTERJEE, H. DAUTET et J. K. P. LEE. Can. J. Chem. **61**, 694 (1983).

On a mesuré les valeurs Q_β du $^{91-93}$Rb, du $^{91-93}$Sr et du $^{92-93}$Y, en utilisant des sources de Rb à masse séparée obtenues à l'aide d'un séparateur d'isotope à un canal. On a utilisé un téléscope détecteur de $\Delta E-E$ consistant en un détecteur de ΔE- de 300 μm × 300 mm^2 Si et un détecteur de E de 15 mm × 500 mm^2 Ge(HP). Les résultats s'accordent en général avec les valeurs récemment publiées, mais on indique quelques divergences.

1. Introduction

The measurement of Q_β values for successive β decays along a mass chain is an effective method to deduce atomic masses, and for nuclei far off the β stability valley this is the most versatile and commonly applicable method. In general, two types of detector systems have been used: plastic scintillators and thick Ge(HP) detectors. The plastic scintillation detectors are capable of handling high counting rates, and, therefore, often the data have better statistics. Also, the detector response function for electrons and positrons is simpler, and thereby facilitates the analysis process. On the other hand, the Ge(HP) detector has a built-in energy calibration and is capable of yielding better energy resolution and stability. Under suitable conditions, precise Q_β values can be obtained.

The β spectra of neutron-rich Rb isotopes and their daughters have been studied using both plastic scintillator (1, 2) and Ge(HP) detectors (3, 4) and in some cases, Q_β values with only a few keV uncertainties have been reported (3). However, closer examination of these reported values indicates that there still exist some discrepancies among various groups. We have measured the β-decay energies of $^{91-93}$Rb and their daughter products using a $\Delta E-E$ telescope consisting of solid state detectors. The Q_β values were deduced and the uncertainties due to various contributing factors were examined.

2. Experimental methods

The Rb isotopes were produced by the fission of ^{238}U induced by 100 MeV protons at the McGill synchrocyclotron facility. These fission products were isotopically separated by the McGill on-line mass separator (5, 6) using a Ta foil as ionization surface and then focussed onto a thin aluminium foil located in a low background area, about 8 m away from the target chamber. The detector telescope consisted of a 300 mm^2 × 300 μm thick Si ΔE detector and a 500 mm^2 × 15 mm thick Ge(HP) E detector. A 10 mm thick brass collimator with a 200 mm^2 circular opening was placed in front of the telescope. A fast coincidence between signals from the two detectors opened a linear gate to allow the summed linear pulses from the detectors to be processed by an ADC. The relative energy matching was adjusted using a ^{207}Bi source and the absolute energy calibration was obtained from the E detector response to standard γ-ray sources. Pulser pulses were fed to the preamplifiers to check the electronic stability and to measure the possible pile-up effects.

A typical experimental run proceeded as follows: the Rb source was collected; both the cyclotron and the ion beams were then switched off; and, after an appropriate pause time, the β spectrum was accumulated for a certain time. The cycle was repeated until the desired statistics were reached. For most of the isotopes, different counting rates were used with different source-to-detector distances. In some cases, a Ge(Li) detector was used for β−γ coincidence gating.

The β spectra were analyzed using a multi-branch analysis program. Basically, the analysis consisted of two procedures. First, a search for the β end-point energy was made using the highest energy branch, through a least-square fit method. Then, a multi-branch analysis over a wide energy range was carried out, yielding a distribution of β intensities, feeding various higher excited energy states (or regions). Although, this analysis procedure does not usually allow precise determination of β end-point energies of branches leading to excited states, it does provide a check on the consistency of reported β feeding branches. Under favourable conditions such as a strong isolated feeding branch to one particular level, precise β end-point energy can be deduced. The detector response function used was based on a Monte-Carlo calculation (7), and then adjusted to fit the β spectra of ^{32}P and ^{88}Rb. The resultant fit to the ^{88}Rb spectrum is demonstrated in Figs. 1 and 2. In Fig. 1, a Kurie plot of the highest energy portion of the spectrum is shown. The known shape was incorporated and a Q_β value of 5310 ± 10 keV was obtained. Figure 2 shows a fit down to the 1 MeV region using known branching ratios. The good overall fit indicates the validity of the analysis procedure. For higher electron energies, an extrapolated response function was used and a good fit to the ^{92}Rb data over a wide energy range (6−8 MeV) was obtained.

The uncertainties associated with the measurements are the combined contributions from several sources: energy calibration, β response function, limited energy range where a fit can be made and effects from background pile-up and summing effects. In principle, the energy calibration should contribute little towards the uncertainties. However, there is always a limitation due to the lack of convenient standard high energy γ-rays, the available accumulation time, and the stability of the system. In our case, it is also compounded by the summing of ΔE and E pulses. We estimated this contribution to be 1.5 keV for each MeV of electron energy. To test the dependence of the β end-point energy and the goodness-of-fit on the response function, we have analysed these spectra using slightly different response functions (typically changing the parameters by ~10%). In general, they yield a poorer overall fit (higher χ^2 values) but do not

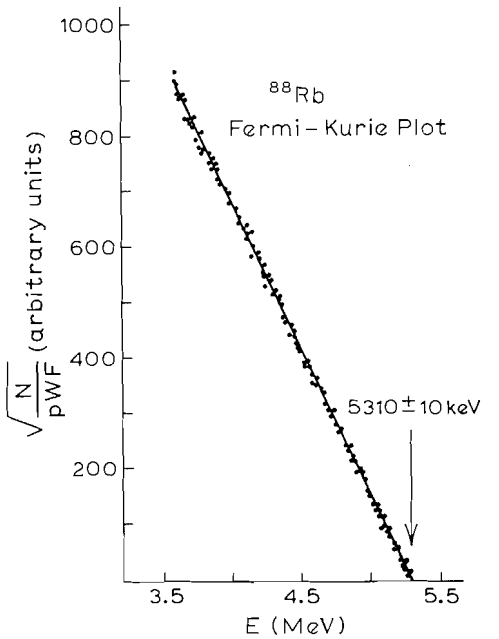

FIG. 1. The Fermi–Kurie plot for the high energy region of the ^{88}Rb β spectrum. The fit extends over an energy range of approximately 1.8 MeV.

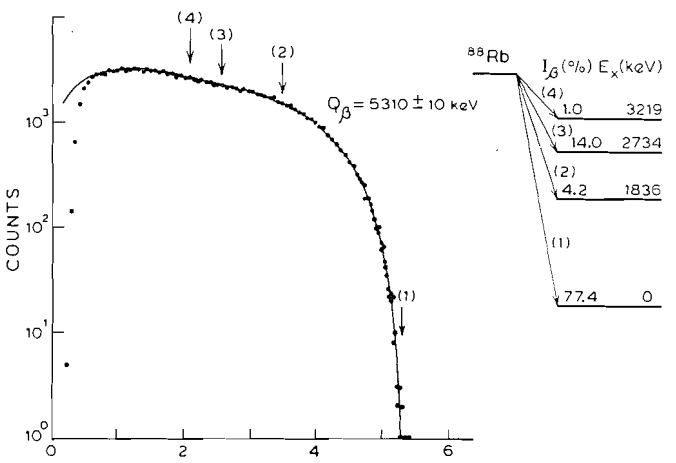

FIG. 2. The ^{88}Rb data and fit obtained by using a multi-branch fitting program. The fit includes the four highest intensity β branches and extends over an energy region of 1.3 to 5.3 MeV.

appreciably alter the β end-point energies. We estimate that this contribution is about 5–10 keV towards the total uncertainty. The effect of the limited energy range for fitting is dependent on the decay characteristics of the isotope being studied. Usually the fitting covers the region from E_{max} until the next important branch occurs, and if this is ~500 keV or more, reliable E_{max} can be extracted. The actual uncertainty, however, is dependent on the relative magnitude of the background to the high energy branch. To achieve high precision it is important that the spectrum be free from background, pile-up and β–γ summing effects. In our actual experimental runs, we have attempted to minimize the interference from these undesirable effects: the ΔE–E coincidence requirement eliminates the γ-ray events; the source-to-detector distance is large (typically ~10 cm) to minimize β–γ summing effect; the counting rate was kept low (≤500 cps) to minimize pile-up; and a low background was achieved by proper ion beam alignment and the switching-off of both cyclotron and ion beams during accumulation. We estimate that these contributed about 5–25 keV towards the quoted uncertainties. Besides these contributions, there are still some other sources of uncertainties such as counting statistics, but they are comparatively small for all the spectra studied here.

It should be noted that in the literature, some β end-point energies were reported with a few keV uncertainties. Since the details of the actual breakdown of the sources of these uncertainties was not presented, it is not possible to make direct comparisons.

3. Experimental results and discussions

The experimental β end-point energies and the deduced Q_β values are tabulated in Table 1, together with some of the recently reported values. The adopted values in the 1977 mass table (8) were also included for comparison. The E_{max} values shown correspond to the end-point energies of the highest energy branches. Among the results from groups using Ge(HP) detectors, generally good agreement in E_{max} is obtained except for ^{93}Rb, where our value is 45 to 50 keV lower, just outside the error bars quoted. Based on these results and using the adopted mass excesses (8) of ^{91}Y, and ^{92,93}Zr, the mass excesses of the isotopes studied were deduced. They are shown in the table together with the results from the direct mass measurements (9).

For ^{91}Rb decay, the E_{max} values obtained from different Ge(HP) measurements are consistent. Rehfield (4) has assigned the high energy branch to feed the 93 keV state in ^{91}Sr while Decker *et al.* (3) have suggested a feeding to the ground state and thus the discrepancy in the Q_β values listed. In the present work, the analysis is not sufficiently sensitive to distinguish this difference and we have accepted the assignment of Decker *et al.* (3).

For ^{92}Sr decay, the coincidence requirement for ΔE and E pulses was bypassed. A ΔE pulse alone opened the linear gate for the summed ΔE and E pulses to be processed by the ADC. The spectrum had a high energy component resulting in a relatively high overall uncertainty for the low energy branch.

In the ^{93}Sr decay β spectrum, the highest energy branch has an E_{max} of 4110 ± 20 keV. The multi-branch analysis yields a β feeding distribution as shown in Fig. 3, consistent with the reported β transition intensities to the excited states of ^{93}Y in the proposed decay schemes (10, 11) of ^{93}Sr. Also, the E_{max} of the β spectrum obtained in coincidence with the 888 keV γ-ray yielded a Q_β value of 4140 ± 50 keV, in agreement with the singles data. The present work therefore yields a β feeding branch of 4.5% from ^{93}Sr to the ground state of ^{93}Y. This conclusion is in contradiction to the proposed ^{93}Sr decay schemes (10, 11), in which the absence of this β branch was used to support a J^π assignment of $7/2^+$ for ^{93}Sr ground state. Therefore, our present conclusion, if adopted, would require the change of the spin-parity assignments for levels in ^{93}Sr and ^{93}Y. This direct ground state feeding was also suggested by Stippler *et al.* (12).

4. Conclusion

We have used a ΔE–E telescope of solid state detectors to study the β spectra from separated $^{91-93}$Rb sources and their daughters. The emphasis was placed on obtaining consistent and clean spectra, with minimal interference from both background and γ-rays, such that β end-point energies could be determined reliably using fits over extended energy regions. Multi-branch analysis was adopted to check consistency with currently existing decay schemes. Results are in general agreement with recently reported values. For the ^{93}Sr decay, our

Momentum transfer in the fragmentation of copper by 400-GeV protons

JAMES B. CUMMING

Chemistry Department, Brookhaven National Laboratory, Upton, NY 11973, U.S.A.

Received August 31, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

JAMES B. CUMMING. Can. J. Chem. **61**, 697 (1983).

Mean momenta transferred to products of the fragmentation of copper by 400-GeV protons have been determined by the thick-target thick-catcher technique. Comparison with data for incident protons and heavy ions indicates that the limiting fragmentation region has been reached and supports a simple relationship between momentum and energy transfers in peripheral reactions which had been proposed previously.

JAMES B. CUMMING. Can. J. Chem. **61**, 697 (1983).

Faisant appel à la technique de la cible épaisse et du récepteur épais, on a déterminé les moments moyens transferrés aux produits résultant de la fragmentation du cuivre par les protons à 400 GeV. La comparaison avec les données relatives aux protons incidents et aux ions lourds indique qu'on atteint la région de fragmentation limite et cette comparaison vient appuyer une relation simple entre le moment et les transferts d'énergie dans les réactions périphériques qui a été proposée antérieurement.

Introduction

Studies of the interactions of high-energy projectiles with complex nuclear targets lead to an overall picture of great complexity (1, 2). Attempts to understand such reactions frequently start with the assumption of a two-step mechanism. For reactions induced by nucleons (3), and more recently, also for heavy-ion-induced reactions (4), this is embodied in cascade plus evaporation (and/or fission) calculations. A two-step mechanism also underlies the various forms of the abrasion–ablation picture of heavy-ion reactions (5). There is considerable evidence that such a model is not appropriate for central collisions with heavy target elements such as gold and uranium. The violent processes that are associated with a high multiplicity of emitted particles and lead to products a hundred or more masses removed from the target are not well understood (6). In particular, unusual fragment angular distributions (7, 8) and evidence (9–11) that the time scale for the production of light- to medium-mass fragments is comparable to the time of the initial interactions appear to pose serious problems for any two-step model.

On the other hand, some simplifications appear if one focuses on the less violent encounters which can be classified under the generic term of target fragmentation. A target fragment is a major remnant of that portion of a target nucleus which appears to have been the spectator to the region of projectile–target interaction or overlap (fireball in one model (12)). Linear momentum transfer between a projectile and a target fragment is expected to be low. For heavy-ion projectiles, an equivalent process in the moving system results in projectile fragments which have nearly the beam velocity. Many observations of target or projectile fragmentation appear consistent with two hypotheses originally associated with peripheral hadron–hadron reactions at high energies (see ref. 13 for a review). The hypothesis of *limiting fragmentation* predicts that both cross sections and energy spectra of fragments should become independent of bombarding energy at sufficiently high energies. The second, *factorization*, asserts that these fragment properties can be written as a product of target and projectile factors. For example, in the case of cross sections, the target fragment mass-yield curve would depend on the type of projectile only via the total cross section as a scaling factor.

The present paper deals with the fragmentation of copper targets where some 70% of the total reaction cross section leads to products consistent with the above hypotheses (14). In previous work (15), a simple model was proposed which related the momentum transferred to a target fragment to the excitation deposited in the initial or abrasion step of these reactions. It was predicted that momentum transfers associated with a given product should approach a limit as bombarding energy increases (consistent with limiting fragmentation) and that this limit was determined by the energetics of the particular reaction selected. In the analysis of the available data (15–17), the validity of the model and the actual positions of the asymptotes depended strongly on data from a single experiment with 28-GeV protons (16). Reported below are new results obtained at 400-GeV which show the existence of asymptotic limits to momentum transfer in a model-independent way and confirm, as well, the predictions of the model based on data for lower energy projectiles.

Experimental

The present experiment was an outgrowth of work at the Fermi National Accelerator Laboratory (FNAL) intended to supply precise absolute cross sections for beam monitoring and diagnostic purposes (18). With recoil catchers in some target stacks, recoil properties could be determined simultaneously with the desired cross sections. The techniques were identical to those reported previously (15, 16). Three thick-target thick-catcher stacks were irradiated in vacuum with 400-GeV protons in the enclosure 99 area of the neutrino hall at FNAL. The first two stacks consisted of a 47 mg/cm^2 Cu foil with 17 mg/cm^2 Mylar catcher foils on the upstream and downstream sides. An additional Mylar on the upstream side served as a blank, and the four foils were vacuum encapsulated between pieces of 11 mg/cm^2 heat sealable Mylar. After irradiations with 10^{15} protons, the stacks were sent to BNL where circular samples, 8.2 cm^2 in area, were punched out. Approximately 99% of the total activity was contained in the punched areas. γ-Ray spectra were recorded for the various samples at a 1-cm distance from a Ge(Li) detector over a period of ~50 days. Full-energy peak intensities were resolved from the spectra

and their decay curves analyzed by various computer programs. In a third irradiation, performed approximately one year after the first two, catcher foils of 7 mg/cm^2 were used to reduce ^{7}Be production which appeared to interfere with the determination of several products. Although the third target was exposed to only 4×10^{14} protons, the simultaneous use of three Ge(Li) detectors and a reduced sample-to-detector distance resulted in some improvement in nominal statistical accuracy of this experiment in comparison with the first two. Also, at the time of the third irradiation, the samples from the first two were combined and assayed to obtain the only results for ^{22}Na and also improved data for the long-lived nuclides, ^{54}Mn and ^{57}Co.

Results

On examination of the extensive data base, 15 nuclides which could be assayed with ≈5% or better precision were selected for further attention. Extending from ^{58}Co to ^{22}Na, these species provide a representative sample of fragments ranging from those having mass numbers near that of the target to species involving the loss of ~40 nucleons. Corrections were applied for the production of ^{22}Na and ^{24}Na from impurities in the catcher foils. In the worst case these amounted to 5% of the activity observed in the back catcher.

Ten of the 15 selected nuclides could be assayed by two or more γ-rays, thus providing checks on the spectral resolution procedures. Also, in the third irradiation, internal consistency between data from three detectors could be examined for all species. Two basic quantities were obtained for each nuclide, γ-ray, detector, and irradiation. These are *FW* and *BW*, where *F* is the fraction of the total activity produced in the target observed in the front catcher, *B* the fraction in the back catcher, and *W* is the target thickness (mg/cm^2). *FW* and *BW* represent the effective mean range of a particular recoil projected in the forward and backward direction, respectively. Where multiple determinations for a species were available in a given run these were averaged initially for the separate runs with statistical weights from the spectral and decay curve resolutions. Data for each nuclide were then averaged for the three runs. In this step, additional 2% errors were folded in to account for possible systematic effects in the individual irradiations. Whenever an average was calculated, checks were made for internal consistency. If these were not satisfactory, errors were increased appropriately.

Mean values of *FW* and *BW* obtained from this analysis are plotted in Fig. 1 as a function of $\Delta A = 63.5 - A_f$, where A_f is the fragment mass number. A typical (average) error on a value of *FW* or *BW* is ±2.5%, comparable to the size of the points. Individual errors range from 1.3% for favorable cases to 5.4% for a few poorly determined species. The straight lines having unit slope in Fig. 1 (a log–log plot) are intended to show the general trends: both *FW* and *BW* are approximately proportional to ΔA and the ratio F/B is not strongly dependent on ΔA.

One of the more striking deviations from smooth trends in Fig. 1 appears for ^{51}Cr at $\Delta A = 12.5$. Values of *FW* and *BW*, particularly the latter, seem low. Chromium-51 was assayed via the 320-keV γ-ray which is present only to the extent of 9.8% of the decays. It was thought that the intense Compton continuum of the 478-keV γ-ray of ^{7}Be interfered with the analysis of the low intensity 320-keV line in the catcher foils, and indeed, values of *FW* and *BW* from the third irradiation, in which the relative amount of ^{7}Be was reduced by a factor of 2.4, were 5 and 8% higher, respectively, than the average results from the first two experiments.

Included in Fig. 1 for comparison with the present results at 400 GeV are data for six nuclides obtained at a bombarding energy of 28 GeV (16). There is a tendency for the lower energy points to fall slightly above those measured at 400 GeV. The mean difference, 3.7%, is not large considering the experimental errors, and it is clear there are no major changes associated with a 14-fold increase in bombarding energy for a wide range of products. The asymptotic region appears to have been nearly reached at the lower energy as we shall see in the more detailed analysis which follows.

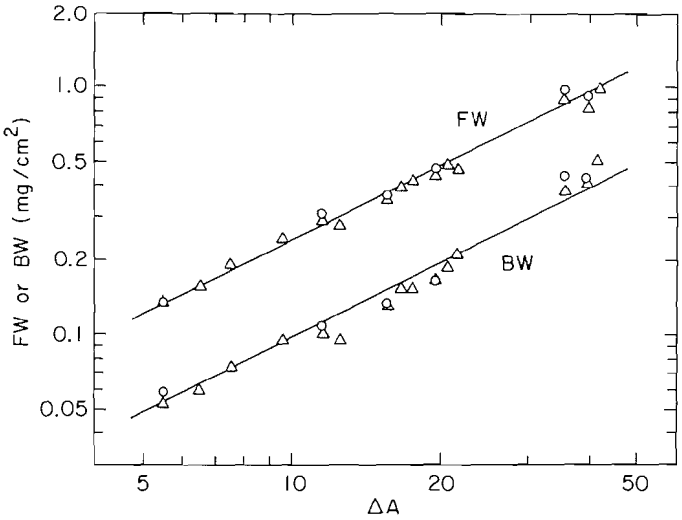

FIG. 1. Dependence of experimentally determined mean ranges projected in the forward and backward directions (*FW* and *BW*) on the mass number difference between the target and fragment ($\Delta A = 63.5 - A_f$). Open triangles show the present results, circles show those obtained at 28 GeV, ref. 16. The straight lines with unit slope indicate general trends.

Analysis and discussion

To examine the results of the present experiment in more detail, it was assumed that the two-step model could be applied to transform the measured values of *FW* and *BW* into mean values for the apparent velocity of the moving source ($\beta_\parallel$ which is $v_\parallel$ in units of *c*) after the initial abrasion interaction and then an additional component of velocity, *V*, due to the second or ablation step of the reaction. The same nonlinear, iterative least-squares procedure incorporating polynominal fits to tabulated range-energy curves (19, 20) was used for this transformation as had been applied in the analysis of the lower-energy results (15). Because we have only two measured quantities, *FW* and *BW*, we can at best derive results for only two parameters $\beta_\parallel$ and *V*.[1]

Focusing first on $\beta_\parallel$, it had been concluded (15) that the measured values at 28 GeV were near their asymptotic limits in the spirit of limiting fragmentation. Analysis in terms of a simple model (to be discussed below) for momentum transfer in peripheral fragmentation reactions predicted that only a 3.3% further decrease should be observed. We compare in Table 1 the values of $\beta_\parallel$ derived from the present experiment with those reported at 28 GeV reduced by this percentage. For the six isotopes in common to the two experiments, agreement between the experimental values at 400 GeV and those pre-

[1]The values derived for $\beta_\parallel$ and *V* are relatively insensitive to additional parameters such as an anisotropic distribution of *V* or a perpendicular component of the first step velocity, see ref. 15.

TABLE 1. Comparison of moving source velocities derived from the present experiment with those predicted from data at 28 GeV

Isotope	Source velocity, $10^3\ \beta_\parallel$	
	Observed	Predicted[a]
^{24}Na	5.45±0.17	5.49±0.38
^{28}Mg	5.41±0.29	5.20±0.35
^{44}Sc	3.38±0.07	3.33±0.07
^{48}V	2.71±0.07	2.70±0.06
^{52}Mn	2.36±0.05	2.34±0.07
^{58}Co	1.25±0.03	1.14±0.07

[a] Values from ref. 15 reduced by 3.3% as suggested by a simple model, see text.

dicted by the model is well within the errors and is strong evidence that the asymptotic limit has now been reached.

A broader picture of the target fragmentation process is given in Fig. 2 where values of V and $\beta_\parallel$ for three representative fragments, ^{24}Na, ^{48}Sc, and ^{58}Co, are plotted as a function of projectile rapidity, Y. Rapidity is a convenient velocity-related variable ($Y = \tanh^{-1}\beta$) which, when small, is nearly equal to β. In this figure the right-most points (at $Y = 6.76$) are from the present work and those at $Y = 4.13$ are the previous results at 28 GeV. At lower rapidities, data for incident ^{4}He and ^{12}C ions are also included. In addition to work from this laboratory, results for ^{24}Na obtained by Crespo *et al.* (17) are also included. A striking feature which has been commented upon previously (15) is the lack of a strong dependence of recoil properties on the projectile type when comparisons are made at the same velocity. Also significant is the fact that the initial abrasion interaction (characterized by $\beta_\parallel$) is much more dependent on projectile rapidity than is the second or ablation step (characterized by V). The arbitrary smooth curves in the upper panel of Fig. 2 suggest the new data on V are a continuation of a slightly decreasing trend. It has been pointed out (15) that the numerical values of V are consistent with those expected from a random-walk addition of small kicks due to the emission of nucleons or small aggregates of nucleons in the ablation step. Some change in the mix of emitted nucleons and α particles as the projectile energy decreases, particularly increased α emission as a more energy-efficient path to fragments, could account for part of the rise in V. However, a more prosaic reason may be problems in the determination of V and $\beta_\parallel$ from the experimental FW and BW values. Assumptions necessary for this transformation become less justified as the F/B ratio becomes large, and this is the case at low rapidity.

We return now to an examination of the dependence of source velocity, $\beta_\parallel$, on Y. The curves in the lower panel of Fig. 2 are least-squares fits to the function,

$$[1]\quad \beta_\parallel = \beta_\parallel^\infty\,(1 + k\sqrt{1-\beta^2})/\beta$$

where $\beta_\parallel^\infty$ is the asymptotic limiting value for a given product and k is a parameter dependent on details assumed for the initial interaction. From the derivation of eq. [1], it follows that $\beta_\parallel^\infty$ can be equated to $\Delta E_T/m_T$, where m_T is the mass of the fragment precursor, i.e., prior to mass loss in the ablation step, and ΔE_T is the prefragment excitation energy. The curves in Fig. 2 are for k held at unity. Although results for only three nuclides are shown in this figure, the fitting procedure simultaneously included data for ^{28}Mg, ^{44}Sc, and ^{52}Mn. In the case of a fit with six independent values of $\beta_\parallel^\infty$, the root-mean-square deviation

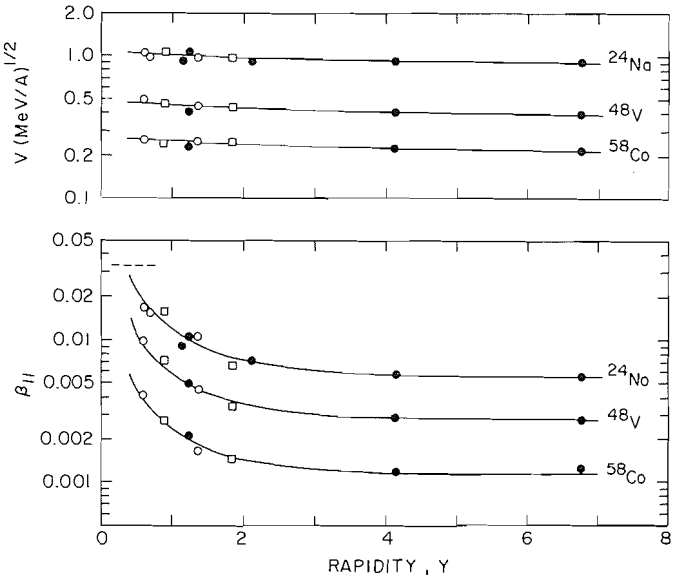

FIG. 2. Dependence of V (upper panel) and $\beta_\parallel$ (lower panel) on projectile rapidity. Filled circles are data for incident protons from the present work (at $Y = 6.76$) and from refs. 15, 16, 17. Open circles are for incident alpha particles from refs. 16, 17. Open squares are results for ^{12}C ions, refs. 15, 16.

of 42 points from the smooth curves was 8.3%. Including k as an additional parameter gave a value of $k = 1.03 \pm 0.10$ with no significant improvement in the quality of the fit. Because the term $\sqrt{1-\beta^2}$ in eq. [1] is only 2×10^{-3} at 400 GeV, the asymptotic limits determined by the new data are nearly independent of k and hence also independent of details of the various possible models.

The $k = 1$ form of eq. [1] may be recognized as being identical to an exact equation derived by Turkevich (quoted by ref. 21), from the assumption that the initial interaction consisted of a single elastic collision between a projectile and a target nucleon in which the latter remained trapped by the nucleus. It was difficult to understand why such a simple model could successfully fit data for reactions which appeared to involve more complex interactions (22). However, recent work (23, 24) has shown that eq. [1] with $k = 1$ can be derived as an approximation from a less restrictive single collision or multiple independent collision model involving small momentum and energy transfers in each step. While such approximations appear to be valid for the fragmentation of light- to medium-mass nuclei such as copper, serious problems appear for more complex (and presumably less peripheral) reactions in heavier targets. For example, for ^{128}Ba production from uranium by high-energy protons, Pandian and Porile (25) have reported a value of $k = 27$ and a $\beta_\parallel^\infty$ value corresponding to an excitation of only 67 MeV, much too low to be reasonable for the loss of 110 nucleons in a deep spallation process. As noted in the Introduction, a breakdown of the underlying two-step assumption occurs for still more complex reactions.

The present experiment has emphasized the high-energy asymptotic region (at energies of many GeV/nucleon) where momentum transfers reach lower limits dictated by the energetic requirements for a particular reaction. Of equal or perhaps greater interest are upper limits to linear momentum transfers which may occur at low energies. Figure 2 indicates a rapid increase of $\beta_\parallel$ for a wide range of products as Y decreases. However, at some point these curves will intersect rising curves

For personal use only.

determined by the projectile's momentum. Maxima in the vicinity of such intersections would signal a transition in reaction mechanism from low- to high-energy processes, i.e., from complete fusion and/or deep inelastic collisions which are efficient in transferring momentum, to the rather inefficient peripheral fragmentation mechanism. Galin *et al.* (26) have recently studied the interaction of 30- to 84-MeV/nucleon ^{12}C ions (Y = 0.24 to 0.42) with Ni, Au, and U targets. They concluded that the maximum momentum transfer associated with the average processes detected with their counter systems was limited to 2 GeV/c. For a copper target, this corresponds to the $\beta_{\parallel} = 0.034$ shown as a dashed line in Fig. 2. Such a limit is not unreasonable given the general trends of Fig. 2, but the radiochemical results do tend to suggest that the limit for a specific product will depend on that product and hence the range of excitation energies which was selected. Extensions of studies of the fragmentation of copper targets into this lower energy region are now in progress to explore this in more detail.

Acknowledgments

On the special occasion of this commemorative issue of the Canadian Journal of Chemistry, I would like to extend warmest personal greetings to Professor Leo Yaffe and acknowledge his significant contributions toward the understanding of high-energy nuclear reactions. The hospitality and cooperation of the FNAL staff during the present work are greatly appreciated. Particular thanks are due Dr. S. I. Baker for arranging the irradiations and air shipments. This work was performed at Brookhaven National Laboratory under contract with the U.S. Department of Energy and supported by its Office of High Energy and Nuclear Physics.

The yields of target fragments from the interaction of 28 GeV protons with ^{238}U have been measured, with special attention being given to those fragments with $160 \leq A \leq 200$. From the measured fragment yields, isobaric production cross sections were calculated. Significant yields ($\sigma(A) \sim 1-10$ mb) of heavy target fragments ($160 \leq A \leq 210$) were found. These fragments are believed to be the non-fissioning survivors from the population of highly excited residual nuclei produced in the initial p-nucleus collision. A pedagogical calculation of the fission − particle emission competition shows how the initial highly excited heavy nuclei could evaporate ~20−50 particles while surviving fission competition.

B. V. JACAK, W. LOVELAND, D. J. MORRISSEY, P. L. MCGAUGHEY et G. T. SEABORG. Can. J. Chem. **61**, 701 (1983).

On a mesuré les rendements en fragments de cibles provenant de l'interaction de protons à 28 GeV avec ^{238}U, en portant une attention spéciale aux fragments avec $160 \leq A \leq 200$. On a calculé les sections droites de production isobare à partir de la mesure de ces rendements de fragment. On a observé des rendements importants ($\sigma(A) \sim 1-10$ mb) en fragments de cibles lourds ($160 \leq A \leq 210$). On croit que ces fragments sont les survivants qui n'ont pas subi de fission et qui faisaient partie de la population de noyaux résiduels fortement excités produits lors de la collision initiale p-noyau. Un calcul pédagogique de la compétition entre l'émission des particules et la fission montre comment le noyau lourd fortement excité initialement peut disperser ~20−50 particules tout en survivant à la compétition de fission.

[Traduit par le journal]

Introduction

Five years ago, Loveland *et al.* (1) reported that in the interaction of 25 GeV ^{12}C with ^{238}U, one observed in addition to the expected fission fragments, large yields of heavy target fragments with $160 \leq A \leq 200$.[3] Subsequently, McGaughey *et al.* (2) reported observing the production of these fragments in the interaction of 8 GeV ^{20}Ne with ^{238}U although the magnitude of their yields was less. These observations were significant for a number of reasons. First, since such products had not been observed in the interaction of relativistic protons with ^{238}U (see ref. 3 for a summary of these data), it appeared that these reaction products were produced by a mechanism unique to nucleus−U collisions as compared to nucleon−U collisions. A study of these products might then offer the possibility of studying unique aspects of nucleus−nucleus collisions. Second, the question arose as to how such products could be formed. If they were spallation products, that meant that ~60 *A* units were removed from the target during the initial reaction and the subsequent deexcitation of the target fragment. Naively one might have expected the heavy nucleus to fission rather than allow such an extended evaporation process to occur.

Because of the importance of the issues raised by the observation of large heavy fragment yields in relativistic nucleus−U collisions, we thought it to be prudent to carefully re-examine the pattern of target fragment yields in relativistic p−U collisions to see if any evidence could be found for heavy target fragment survivors of the primary projectile−target encounter. Accordingly we report in this paper the observation of such fragments, produced in significant quantities, in the interaction of 28 GeV p with ^{238}U. We use a pedagogical model of fission − particle emission competition to show how these heavy target fragments could be formed from the highly excited products of the initial p−U collision.

Experimental

A natural uranium foil of thickness 33.5 mg/cm^2 surrounded by mylar catcher foils of thickness 35.5 mg/cm^2 was irradiated for 63 min in an external beam of 28 GeV protons from the Alternating Gradient Synchrotron at Brookhaven National Laboratory with an average particle intensity of 7.8×10^{13} protons/min. The intensity of the beam striking the target was determined by measuring the yields of ^{22}Na and ^{24}Na in a 12.72 mg/cm^2 Al foil irradiated simultaneously with the U foil. The following monitor production cross sections (4) were used: $\sigma(^{24}Na) = 8.0 \pm 0.3$ mb; $\sigma(^{22}Na) = 9.8 \pm 1.0$ mb.

Following a one day delay for shipment of the irradiated foils to the Lawrence Berkeley Laboratory, analysis of the radioactivities of the target fragments began. The irradiated U foil and the mylar catcher foils were cut approximately in half; the target was counted before and after the cutting process, allowing an exact determination of the relative fractions. One half of the target and its associated mylar catcher foils were subjected to direct γ-ray spectroscopy, while a chemical group separation procedure was applied to the other 33.5 mg/cm^2 U foil half without its catcher foils. In the former case, all of the target fragments should have been stopped in the U foil-catcher assembly (5−15); in the latter case, attention was focused on the yields of the heavy ($160 \leq A \leq 210$) fragments and based upon prior experiments on the ranges of n-deficient heavy rare-earth nuclides (12), only a negligible fraction of the total yield of these products should escape from the U foil. (For the yields of the As and Sb isotopes measured by radiochemical techniques and direct foil counting, no discernible difference between the two measurement techniques was noted.) The chemical procedure used was that developed by Kratz and co-workers (16) with minor modifications. It is based on the volatility and ion exchange behavior of the bromide complexes of the elements. Chem-

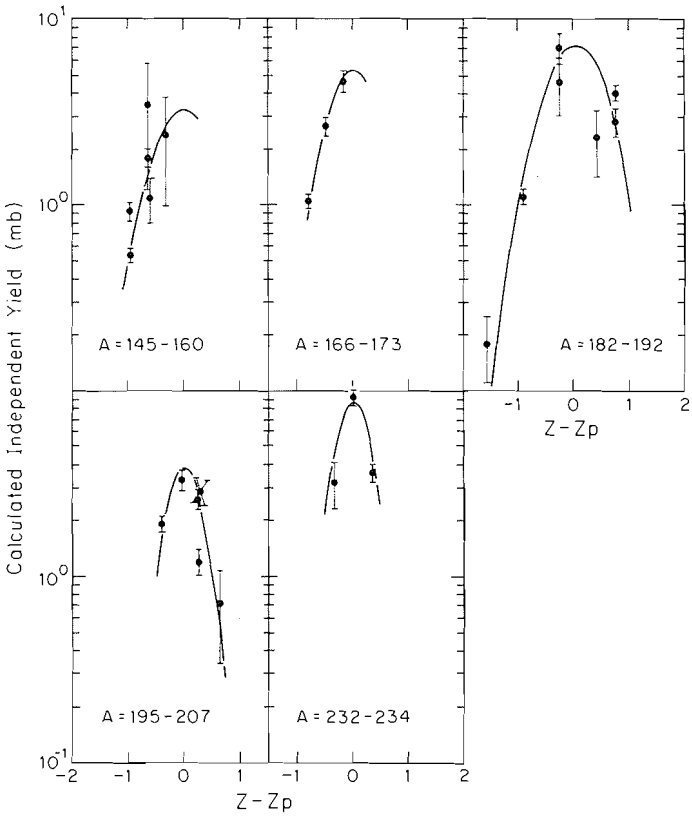

FIG. 1. The charge dispersion curves obtained in this work for the heaviest target fragments are shown as a function of the mass region of the products. The parameters that describe the center and width of the individual curves are given in Table 2.

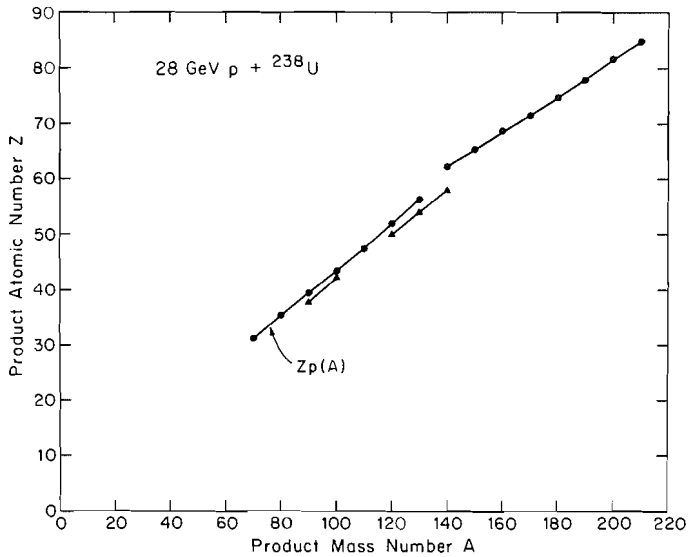

FIG. 2. The values of the most probable primary fragment charge, Z_p, as determined by fitting the data in Figs. 1 and 3 are shown as a function of product mass number. For $84 \leq A \leq 96$ and $118 \leq A \leq 143$, the Z_p corresponding to both the n-rich and n-deficient components of the charge distribution are shown.

ical yields of various elements were calculated by comparison of the separated radioactivities with those in the unseparated foil or where available, by the yield of various tracers employed in the chemistry.

The assay of the target fragment radioactivities and the calculation of measured nuclidic production cross sections from them was done using standard techniques that have been described previously (17).

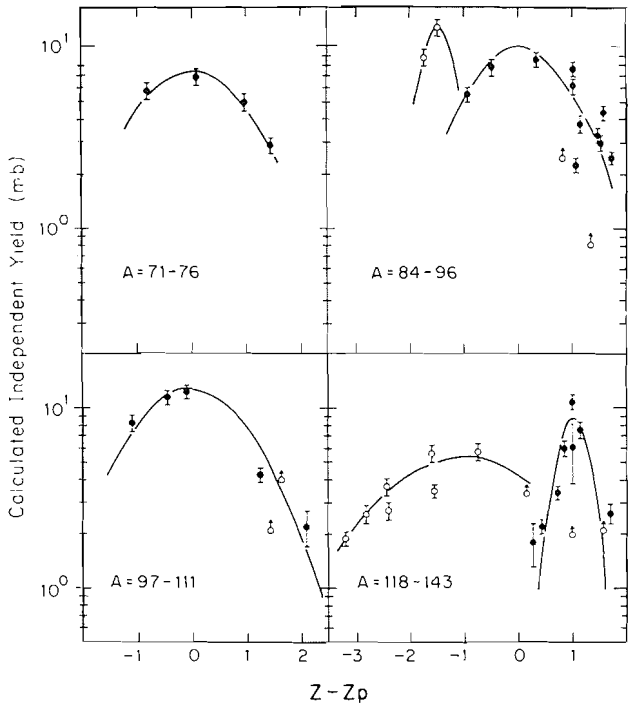

FIG. 3. The charge dispersion curves obtained in this work for the intermediate mass fragments are shown as a function of the mass region of the products.

The results of these measurements for the interaction of 28 GeV protons with ^{238}U are summarized in Table 1. Also tabulated in Table 1 for comparison with the present data are other measurements of the target fragment yields in the interaction of ^{238}U with protons of energy 11.5–29 GeV. (At proton energies above 10 GeV, the target fragment yields are known to be essentially independent of proton energy (8, 18).)

No corrections were made for reactions induced by secondary particles because we have no experimental measurement of the magnitude of the effect for our bombardment. Based upon the known systematics of such corrections (3), we would expect this correction to be very small, given the thickness of our target, for the neutron-deficient nuclides on which this paper focuses and to be 10% for the neutron-rich nuclei.

The measured cumulative-yield production cross sections (which include contributions from nuclei produced by radioactive decay) were corrected for this decay feeding by an iterative fitting of Gaussian distributions to the measured data in a manner described previously (19). These are shown in Table 1 as "calculated independent yield". In making this correction, one assumes Gaussian charge dispersions; i.e., the independent yield cross sections can be represented by a histogram that lies along a Gaussian curve, at constant mass number. This is written as:

$$[1]\quad \sigma(Z,A) = \sigma(A)\left\{[2\pi s_z^2(A)]^{-1/2}\exp\left[\frac{[Z - Z_p(A)]^2}{-2s_z^2(A)}\right]\right\}$$

with the three parameters: $\sigma(A)$ the total isobaric yield, $s_z(A)$ the Gaussian width parameter, and $Z_p(A)$ the most probable Z value for that isobar. By assuming that $\sigma(A)$ varies smoothly and slowly as a function of mass number A and is roughly constant within a small A range, one can iteratively fit the measured data, determining $Z_p(A)$ and $s_z(A)$ for limited mass regions. The results of this procedure are shown in Figs. 1, 2, and 3, with the values of $s_z(A)$ and $Z_p(A)$ being tabulated in Table 2. The values of $s_z(A)$ are believed to be known to 0.1Z units while the values of $Z_p(A)$ are believed to be known to $0.3s_z(A)$. In the mass regions (84–96, 97–111, and 118–143) where fission is an important contributor to the product yields, the charge dispersions are either very broad or double-humped, a fact previously noted (3). The

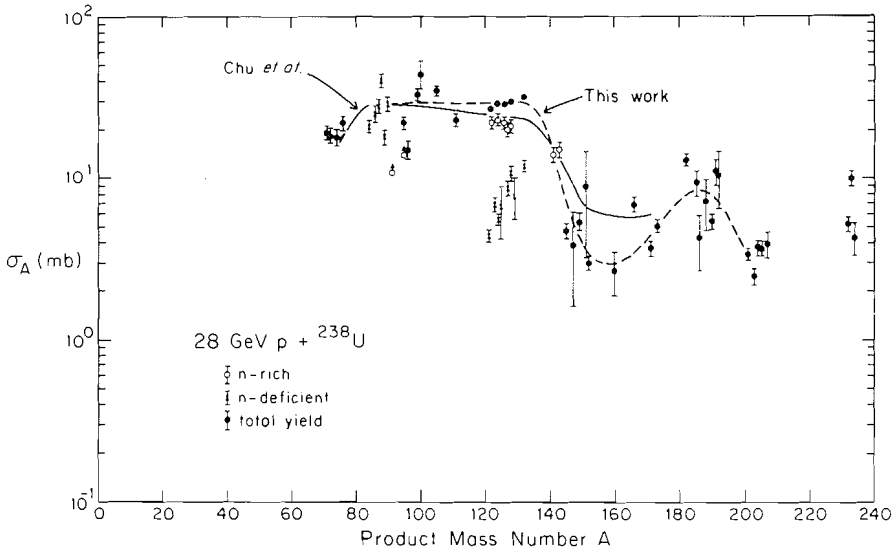

FIG. 4. The target fragment mass distribution, $\sigma(A)$ obtained in this work for the interaction of 28 GeV protons with U is shown along with the previous radiochemical data (3). Closed circles represent the total isobaric yield while the open circles and crosses represent the isobaric yield of the n-rich and n-deficient species at a given A value. The dashed line is to guide the eye through the data of this work.

TABLE 2. Charge dispersion parameters[a]

Mass number range	s_z	$Z_p(A) = a + bA$	
		a	b
71–76	1.00	−0.380	0.450
84–96 neutron-rich	0.300	−1.69	0.439
84–96 neutron-deficient	0.900	−2.600	0.410
97–111	1.00	−1.00	0.439
118–143 neutron-rich	1.50	0.750	0.410
118–143 neutron-deficient	0.300	0.380	0.429

166–173	0.500	15.35	0.330
182–192	0.500	15.2	0.330
195–207	0.300	15.4	0.330
232–234	0.300	7.80	0.368

[a] $s_z(A)$ was taken to be roughly independent of A over a small A range and $Z_p(A)$ was represented by a linear function of A over the same range.

isobaric or mass yield for each data point was calculated (19) and the resulting fragment mass distribution is shown in Fig. 4 and Table 1 along with the previously published work of Chu *et al.* (3).

Results and discussion

Heavy fragment yields

The primary focus of this paper is on the yields of the heavy ($160 \leq A \leq 210$) fragments produced by the interaction of 28 GeV p with ^{238}U. However, since the yields of many of these fragments were measured by off-line γ-ray spectroscopy of chemically separated fractions in which the chemical yields were determined by comparisons with the radionuclide activities in the unseparated foils, the accuracy of the heavy fragment measurements is directly related to the accuracy of all the radionuclide activity measurements. In Fig. 5, we compare the measured cumulative yield radionuclide production cross sections from this work with values determined previously for this or similar reactions (data from Table 1). The average ratio of the cross sections measured in this work to those determined previously is 1.10, indicating overall general agreement between this work and previous work. There is, however, a

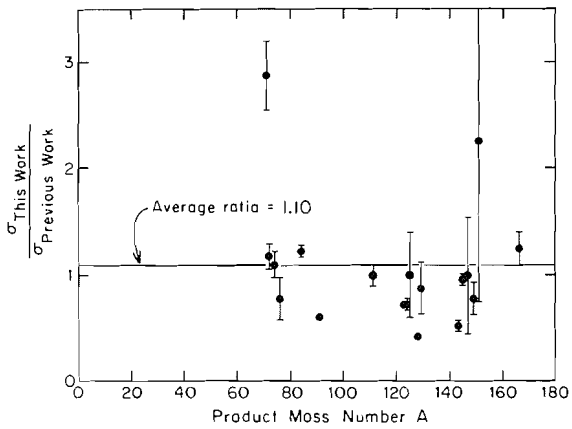

FIG. 5. The ratio of the measured nuclidic production cross sections in this work to those measured previously (see Table 1).

certain scatter to the ratios perhaps due to the fact that the values reported herein were the results of a single measurement rather than the combination of many measurements as frequently reported in the past.

The measured cumulative-yield radionuclide production cross sections for species with $173 \leq A \leq 207$ range, in general, from 1 to 10 mb, indicating without a doubt that these fragments are produced in significant yields in the interaction of 28 GeV p with ^{238}U. The charge dispersions for the species with $182 \leq A \leq 207$ are moderately well-defined (Fig. 1) and thus the isobaric yields derived from them (Fig. 4) of 5–10 mb for these fragments appear to be reasonably well established (they do significantly exceed the measured radionuclide production cross sections because of the correction for unobserved members of the mass chains). The production of these heavy fragments is, therefore, a process with a total cross section of ~250 mb. In any case, the yields of these fragments are significantly higher than would be expected for fission fragments based upon the shapes of the single fragment mass spectra (3, 13, 14), which show a pattern of sharply decreasing yields from $A = 120$ to $A = 170$ (where the isobaric yields are ~5 mb).

Given the existence of significant yields of fragments with

$160 \leq A \leq 210$, the question arises as to the mechanism for their formation. High energy proton induced reactions have generally been described in the framework of a two-step model in which the reaction proceeds via a first step of a fast intranuclear cascade as the incident proton interacts with the target nucleons followed by a slower second step in which the target residue of the first step deexcites by emission of nucleons or light nuclei or fission. Conventional intranuclear cascade calculations (20–22) of the first step of the reaction have been restricted to projectile energies of ~1000 MeV/u where only single isobar or pion production is considered. Other calculational models for the first step of the reaction, such as the abrasion–ablation (23) or firestreak models (24, 25), which do work properly at projectile energies above 1000 MeV/u are not appropriate for proton-induced reactions. (In the firestreak model the incident proton is divided into collinear tubes leading to the stopping of pieces of the proton in the target, an unrealistic situation, while the abrasion–ablation model is generally thought (24) to treat the excitation energy given to the target residue in an overly simplistic and erroneous manner.) Thus we do not have a realistic calculational model for treating the first step of the reaction between a 28 GeV proton and a ^{238}U nucleus.

Nonetheless we have attempted to pursue the question of the origin of the heavy ($160 \leq A \leq 210$) fragments in a didactic manner. We have assumed an initial distribution of target fragment mass, charge, and excitation energy as might be appropriate for the first, fast stage of the p–U collision and then attempted to compute the final product distribution after deexcitation of these primary residues. In doing so, we can show the types of events that could lead to products in the $160 \leq A \leq 210$ region. Figure 6 shows the shape of the assumed fragment distribution from the 28 GeV p + ^{238}U reaction after the first, fast step of the reaction. (This distribution is predicted by the firestreak model (25) for the 28 GeV p + ^{238}U reaction; a very similar distribution is predicted by the VEGAS intranuclear cascade code (20) for the interaction of 1 GeV protons with ^{238}U.) The charge distributions associated with the A and E^* distributions of Fig. 6 are generally centered about the valley of β-stability.

The deexcitation of the members of this initial fragment distribution was calculated using the EVA3 code of McGaughey and Morrissey (26). EVA3 is a modification of the original stepwise Monte Carlo treatment (27–29) of the deexcitation of nuclei by particle emission and fission known as the DFF code. The original DFF code was modified to include a more realistic treatment of fission competition. The excitation energy (E^*) dependence of Γ_f/Γ_n is given by (30)

$$[2]\quad \Gamma_f/\Gamma_n = \frac{4A^{2/3}a_f(E^* - B_n)}{[K_0 a_n 2a_f^{1/2}(E^* - E_f)^{1/2} - 1]} \times \exp\left[2a_n^{1/2}(E^* - B_n) - 2a_f^{1/2}(E^* - E_f)^{1/2}\right]$$

where Γ_f and Γ_n are the fission and neutron emission widths, respectively, A the mass number of the nucleus with excitation energy E^*, neutron binding energy B_n, fission barrier height E_f, and K_0 is the rms value of the projection of the angular momentum on the nuclear axis of symmetry. The values of the level density parameters at the fission saddle point a_f, and the equilibrium deformation a_n, were chosen in a manner discussed later. The fission barrier heights are calculated using the simple approximate formula of Cohen and Swiatecki (31)

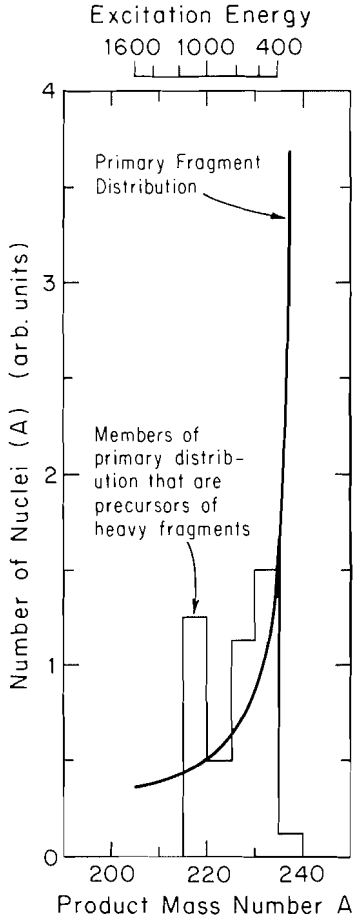

FIG. 6. The shape of the initial primary fragment distribution as a function of product mass number after the fast step of the reaction of 28 GeV p + ^{238}U. Also shown are those members of the initial distribution which deexcited to produce final fragments with $160 \leq A \leq 210$.

$$[3]\quad \begin{aligned} E_f &= 0.38\,(0.75 - x)E_s^0 && \text{for } 1/3 \leq x \leq 2/3 \\ E_f &= 0.83\,(1 - x)^3 E_s^0 && \text{for } 2/3 \leq x \leq 1 \end{aligned}$$

where the fissionability parameter, x, is given by

$$[4]\quad x = \frac{Z^2}{50.88A\left(1 - 1.7826\left(\frac{A - 2Z}{A}\right)^2\right)}$$

and $E_s^0 = 17.80A^{2/3}$. The variations of the widths of the fission mass distributions as a function of the Z, A, and E^* of the fissioning system are calculated using the formalism of Nix (32).

Several thousand deexcitation chains were followed to determine which members of the initial fragment distributions, if any, survive to form fragments with final mass numbers of $160 \leq A \leq 210$. The fraction of the initial population that survives to form heavy fragments is a very sensitive function of the level density parameters a_f and a_n. In Fig. 7 we show the results of two calculations of the final fragment distributions (starting with the initial fragment distribution of Fig. 6) made with two separate assumptions about a_f/a_n, i.e., $a_f/a_n = 1.0$ and $a_f/a_n = 1.1$. (Both of these choices for a_f/a_n are reasonable for the nuclei and excitation energies encountered (30).) The yields of the heavy fragments change dramatically with this small variation in a_f/a_n, as is illustrated in Fig. 7 and was also

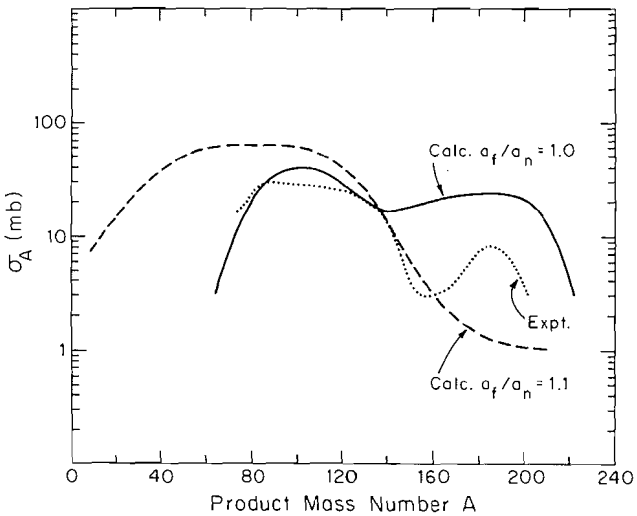

FIG. 7. The effect of two different values of a_f/a_n upon the calculated final fragment distribution is shown.

observed by Wilkins, Steinberg, and Kaufman (33). To study exactly which initial fragments survive fission decay to become heavy fragments, we arbitrarily fixed a_f/a_n using the formula

$$[5] \quad a_f = \left[1 + \frac{0.1}{\log_{10}(E^* - E_f)}\right] a_n$$

Using eq. [5] to fix the a_f/a_n ratio in our model, we then studied the outcome of ~3000 deexcitation chains to see which members of the initial fragment population survived to become heavy fragments and how they "escaped" fission. In Fig. 6 we show those members of the initial fragment population that survived to form fragments with $160 \leq A \leq 210$. As one can see from examining Fig. 6, these survivors are fairly evenly distributed in mass number from 215 to 235. Because the initial distribution falls steeply with decreasing mass number, the lower mass initial fragments from the fast first stage of the reaction must have a greater probability of surviving to become heavy fragments despite their high excitation energy. This is, of course, due to the steeply decreasing fissionability of nuclei within the Ra–Th–U region with decreasing Z and A. Due to this, the yield of heavy fragments should increase in reactions with heavy targets where a larger fraction of the initial fragment distribution has lower Z and A. Thus greater heavy fragment yields are expected in the reaction of high energy protons with ^{232}Th or in the reaction of relativistic heavy ions (which remove more mass from the target than protons) with ^{238}U.

Deexcitation chains that lead to heavy fragments generally start, especially for primary fragments of high Z and A, with copious charged particle emission (to escape the region of high fissionability) followed by long chains of successive neutron emission (as the nuclei are very n-rich due to the charged particle emission). The average deexcitation chain leading from the primary to the final heavy fragment distribution removes 53 nucleons and approximately 770 MeV of excitation energy. The average number of particles emitted is 34, with the relative abundances: n-66%, p-9%, d-9%, t-9%, ^{3}He-1%, and ^{4}He-6%. The relative numbers of particles emitted are approximately what one would expect (27) for any heavy nucleus excited to 700 MeV. One might conclude that events producing fragments with $160 \leq A \leq 210$ contain an unusually large fraction of the "deeper" spallation events from the fast initial stage of the reaction, and of these events the ones leading to heavy fragment survivors consist of those which happen to begin their deexcitation by emitting several charged particles rather than fissioning.

Fission fragment yields

The most important new data reported in this paper are the yields of the heavy fragments from the interaction of 28 GeV protons with ^{238}U. However, as remarked upon earlier, we did measure the yields of the fission fragments simultaneously with the heavy fragments and the two measurements are connected in a variety of ways. Figure 4 shows the isobaric yields of all the fragments (from the 28 GeV p + ^{238}U reaction) measured in this work along with a summary (3) of previous radiochemical measurements for this reaction. For the fragments with $70 \leq A \leq 140$, there is general agreement between the previous work and the isobaric yields from the current work (especially considering that the data reported herein are the result of a single measurement). The fragment yield distribution in this A region appears to have a plateau-like structure unlike the more sharply peaked fragment distribution seen (13, 34) in the reaction of 11.5 GeV protons with ^{238}U. Some fragments with $A < 70$ were observed as well, however the quality of the data was not as high as for the heavier fragments, so these data are not included.

In the fragment mass region $140 \leq A \leq 160$, there is general agreement between the *measured* cumulative yield cross sections of this work and previous work (Table 1, Fig. 5) but disagreement exists as to the isobaric yields that should be deduced from the measured data. The charge dispersions fitted to the data in this work are not well-defined because of the lack of measurements of *very* neutron-deficient and any possible neutron-rich species. In previous work (3), the charge distribution for $A = 147$ was found to be double humped with significant neutron-deficient and neutron-rich components. The neutron-rich nuclides seen by Chu *et al.* (3) were not seen in this work and thus we have no evidence for a broad double-humped charge dispersion in this work. Therefore we conclude that any discrepancies between the isobaric yields measured in this work and previous work are more apparent than real. These discrepancies serve as a warning about the difficulty of deducing fragment isobaric yields in a complex reaction without an extensive set of primary measured radionuclide yields.

Conclusion

The principal things we have learned from this study are:

(1) Heavy fragments ($160 \leq A \leq 210$) are produced with significant yields in the interaction of 28 GeV protons with ^{238}U.

(2) These heavy fragments could result from primary fragments that have emitted large numbers of charged particles early in their deexcitation and could represent the "deeper" spallation portions of the primary fragment distribution.

(3) We would expect larger production cross sections of heavy residues for proton induced reactions with lighter targets such as ^{232}Th or ^{208}Pb, or for heavy-ion induced reactions with ^{238}U.

Some new amide complexes of thorium tetrachloride and *N*-thiocyanate

KENNETH W. BAGNALL, XING-FU LI, PO-JUNG PAO, AND ABDUL-GHANY MOHAMMAD AL-DAHER
Chemistry Department, University of Manchester, Manchester M13 9PL, England

Received August 31, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

KENNETH W. BAGNALL, XING-FU LI, PO-JUNG PAO, and ABDUL-GHANY MOHAMMAD AL-DAHER. Can. J. Chem. **61**, 708 (1983).

The amide complexes $[ThCl_4L_3]$, where L = $CH_3CON(CH_3)_2$ (dma), $C_2H_5CON(CH_3)_2$ (dmpa), $C_2H_5CON(C_2H_5)_2$ (depa), or $(CH_3)_3CCON(CH_3)_2$ (dmpva), $[Th(NCS)_4L_4]$, where L = dmpa, depa, dmiba ($(CH_3)_2CHCON(CH_3)_2$), or dmpva, and $[Th(NCS)_4(dmpva)_3]$ have been prepared and their ir spectra reported. The observations are discussed in terms of the steric crowding about the thorium atom using a cone-packing model.

KENNETH W. BAGNALL, XING-FU LI, PO-JUNG PAO et ABDUL-GHANY MOHAMMAD AL-DAHER. Can. J. Chem. **61**, 708 (1983).

On a préparé des complexes d'amide des types $[ThCl_4L_3]$ où L = $CH_3CON(CH_3)_2$ (dma), $C_2H_5CON(CH_3)_2$ (dmpa), $C_2H_5CON(C_2H_5)_2$ où $(CH_3)CCON(CH_3)_2$ (dmpva), $[Th(NCS)_4L_4]$ où L = dmpa, depa, dmba $(CH_3)_2$), dmpva et $[Th(NCS)_4(dmpva)_3]$ et on rapporte leurs spectres ir. On discute des observations en termes d'encombrement stérique autour de l'atome de thorium en utilisant un modèle d'entassement dans un cone.

[Traduit par le journal]

Introduction

N,*N*-Dialkylamide complexes of thorium tetrachloride, $[ThCl_4L_x]$, where $x = 2$ (L = $(CH_3)_3CCON(CH_3)_2$, dmpva (1)), 3 (L = dmiba (1)), or 4 (L = $HCON(CH_3)_2$, dmf (2) or $CH_3CON(CH_3)_2$, dma (3)) have been recorded, whereas uranium tetrachloride forms bis complexes with the bulkier ligands dmiba, dmpva (1), $C_2H_5CON(CH_3)_2$ (dmpa), and $C_2H_5CON(C_2H_5)_2$ (depa) (4), as well as compounds of composition $UCl_4.2.5L$ (L = dmf (5), dma (6), dmpa, and depa (4)). An x-ray crystal structure determination has shown that $UCl_4.2.5$depa is ionic, $[UCl_3(depa)_4]^+[UCl_5(depa)]^-$, and that the coordination geometry about the 7-coordinate uranium atom in the complex cation is pentagonal bipyramidal (4). In the corresponding complexes of the *N*-thiocyanate, $[U(NCS)_4L_x]$ ($x = 4$, L = dma (7), dmpa or dmiba (8), and $x = 3$, L = dmiba and dmpva (acetone solvate) (8)), the coordination geometry in $[U(NCS)_4(dmiba)_3]$ has also been shown to be pentagonal bipyramidal (8). In contrast to uranium, the only recorded amide complex of thorium thiocyanate appears to be $[Th(NCS)_4(dma)_4]$ (3). It was therefore of interest to attempt the synthesis of complexes formed by thorium tetrachloride and tetrathiocyanate with a series of amides of increasing bulk and to correlate the results in terms of the cone angle approach which we described briefly in a recent paper (9).

Experimental

The handling of air- and moisture-sensitive products and the drying of solvents was carried out as described previously (10). $ThCl_4$ (11), $[ThCl_4(dma)_4]$ (3), and the amides used as ligands (1) were prepared by published methods. Hydrated Cs_2ThCl_6 was prepared from aqueous HCl (17) and dehydrated by heating with thionyl chloride under reflux.

Physical measurements

Infrared spectra were recorded over the range 4000–625 cm^{-1} (NaCl plates) using a Perkin Elmer 257 or Pye Unicam SP3-200 instrument, and for the range 4000–200 cm^{-1} (CsI plates) a Perkin Elmer 225 spectrometer was used. The samples were mounted as Nujol mulls or recorded in dichloromethane solution, using the solvent as the standard. ^{1}H-nmr spectra were recorded for CD_2Cl_2 or d^8-thf solutions using a 60 MHz Perkin Elmer 12B and a 220 MHz PE R34 spectrometer. X-Ray powder photographs of finely divided samples were obtained using a Debye Scherrer 19 cm camera with CuKα radiation (λ = 1.54178 Å).

Analyses

Elemental analyses (C, H, N, Cl, S, Th) were carried out by Mr. M. Hart and staff of the microanalysis laboratory of the Chemistry Department. The chemical analyses are summarized in Table 1.

Preparation of the complexes

(1) $[ThCl_4L_3]$ (L = dmpa, depa, and dmpva)

(*i*) $ThCl_4$ (0.5015 g, 1.345 mmol) was dissolved in thf (30 cm^3); the solution was centrifuged after stirring (10 min) and any insoluble material was discarded. A large excess of dmpa (1 g, 10 mmol) was added and, after stirring for 8 h, the solution was vacuum evaporated to 5 cm^3. A mixture of *n*-pentane and toluene (10 cm^3, 2:1 v/v) was then added to precipitate the white product. The precipitate was washed with the above mixed solvent (2×5 cm^3), then with *n*-pentane (5 cm^3) and vacuum dried. Yield, 40%. $[ThCl_4(depa)_3]$ was prepared in exactly the same way (yield, 40%), whereas for $[ThCl_4(dmpva)_3]$ the thf solution of $ThCl_4$ was vacuum evaporated to dryness before the addition of dmpva (yield, 70%). $[ThCl_4(dmpa)_3]$, $[ThCl_4(dmpva)_3]$, and the known complexes $[ThCl_4(dmiba)_3]$ and $[ThCl_4(dma)_4]$ were also prepared by stirring Cs_2ThCl_6 (1 g, 1.4 mmol) with a large excess of ligand (3 g) overnight. The filtrate was diluted with dichloromethane (~5 cm^3), filtered, and the filtrate was evaporated to small volume (~2 cm^3) and the complexes were then precipitated by the addition of *n*-pentane. Yields, ca. 30%. Alternatively, the reaction of the amide with Cs_2ThCl_6 was carried out using a mixture of acetone and the ligand in the same way; after stirring for 3 days the resulting solution was treated as before. Yields, ca. 30%.

(2) $[ThCl_4(dma)_3]$

$[ThCl_4(dma)_4]$ (1 g, 1.39 mmol) was dissolved in thf (10 cm^3) and stirred (20 min). Addition of a mixture of *n*-pentane and toluene (10 cm^3, 2:1 v/v) precipitated a white solid which was redissolved in thf (10 cm^3) and reprecipitated as above (two cycles). The final product was washed with *n*-pentane (5 cm^3) and vacuum dried. Yield, 40%.

(3) $[Th(NCS)_4L_4$ (L = dmpa, depa, and dmiba)

*Calculated analytical figures in parentheses.

†Well crystalline specimens of these thiocyanate compounds gave low thorium analyses, probably because of free solvent trapped in the crystal lattice.

(*i*) Solid KNCS (0.4883 g, 5.0246 mmol) was added to a suspension of $[ThCl_4(dmpa)_3]$ (0.8505 g, 1.2557 mmol) in thf (30 cm^3). After stirring for 2 h, dmpa (~0.5 g, 5 mmol) was added, and the mixture was stirred for 24 h. The mixture was then centrifuged and the supernatant liquid was vacuum evaporated to dryness. The solid so obtained was washed with a mixture of *n*-pentane and toluene (3 × 5 cm^3, 2:1 v/v), then dissolved in dichloromethane. After centrifugation the supernatant liquid was vacuum evaporated to dryness and finally vacuum dried for 8 h. Yield, 40%.

(*ii*) Solid KNCS (0.3225 g, 3.3185 mmol) was added to a solution of $ThCl_4$ (0.3103 g, 0.830 mmol) in thf (30 cm^3). After stirring for 2 h, dmpa (1 g, 10 mmol) was added, after which the procedure described in (*i*) was followed. Yield, 40%.

$[Th(NCS)_4(depa)_4]$ and $[Th(NCS)_4(dmiba)_4]$ were prepared in the same way as $[Th(NCS)_4(dmpa)_4]$ and were obtained in similar yield. The depa complex was also prepared from Cs_2ThCl_6; KNCS (0.55 g, 5.2 mmol) was added to Cs_2ThCl_6 (1 g, 1.4 mmol) in acetone (20 cm^3). After stirring for 2 h, an excess (2 g, 15.5 mmol) of depa was added and the mixture was stirred for 24 h. The filtrate was evaporated to dryness, the residue was washed with a mixture of *n*-pentane and toluene and dissolved in dichloromethane as in (*i*), and the final solution was evaporated to small volume. Colourless crystals of the complex separated from this solution on addition of the *n*-pentane–toluene mixture (2:1 v/v). These were washed with *n*-pentane and vacuum dried for 5 h. Yield, 25%.

(4) Attempted preparation of $[Th(NCS)_4(dmiba)_3]$

$[U(NCS)_4(dmiba)_3]$ is obtained (8) by adding a mixture of *n*-pentane and toluene (2:1 v/v) to a solution of $[U(NCS)_4(dmiba)_4]$ in dichloromethane until a cloudiness develops, followed by dropwise addition of dichloromethane to clear the solution; on standing the product crystallises out in poor yield. The same procedure left $[Th(NCS)_4(dmiba)_4]$ unaffected.

(5) $[Th(NCS)_4(dmpva)_4]$ and $[Th(NCS)_4(dmpva)_3]$

$[Th(NCS)_4(dmpva)_4]$ was prepared in the same way as the dmpa complex (method (*ii*) above); during the evaporation of the thf solution to 5 cm^3 volume, a yellowish-white solid separated which had the approximate composition $Th(NCS)_4.5dmpva$. However, on completing the dichloromethane/*n*-pentane cycle described for method 3 (*ii*) white $[Th(NCS)_4(dmpva)_4]$ was obtained. Yield, 40%. When this product was dissolved in toluene, in which it is only slightly soluble, and the solution was evaporated to small volume, then treated with *n*-pentane, the white tris complex, $[Th(NCS)_4(dmpva)_3]$, precipitated. Yield, 30%.

Results and discussion

Thorium tetrachloride complexes

As mentioned in the introduction, the stoichiometries of the three known amide complexes of thorium tetrachloride, $[ThCl_4L_x]$, are 1:4 (L = dma (3)), 1:3 (L = dmiba (1)), and 1:2 (L = dmpva (1)) which suggests that the stoichiometry of the complex formed depends on the bulk of the amide ligand. Calculation of the values of the total cone angle factors,[1] Σc.a.f., for these compounds, following the procedure outlined in ref. 9, indicated that the thorium environment in $[ThCl_4(dma)_4]$ was overcrowded (Σc.a.f. ~ 0.92), whereas in $[ThCl_4(dmiba)_3]$ the value of Σc.a.f. was 0.82, in the stable region, and for $[ThCl_4(dmpva)_2]$ Σc.a.f. was calculated to be only 0.72, indicating a marked degree of undercrowding. These calculations suggested that amide complexes of composition $[ThCl_4L_3]$ should be the most stable with respect to the loss or gain of a molecule of ligand in the $ThCl_4$/amide systems.

In considering the equilibria:

$$[ThCl_4L_2] + L \rightleftharpoons [ThCl_4L_3]$$
$$K_3 = [ThCl_4L_3]/[ThCl_4L_2][L]$$

and

$$[ThCl_4L_3] + L \rightleftharpoons [ThCl_4L_4]$$
$$K_4 = [ThCl_4L_4]/[ThCl_4L_3][L]$$

[1]Two terms are used to describe steric effects. Firstly, the cone angle factor (c.a.f.), which is the solid angle of the cone comprising the metal center at the apex and the primary co-ordinating atom or the complete ligand, divided by 4π. Secondly, there is the fan angle which describes the crowding in the plane; this is the angle subtended by the primary co-ordinating atom (f.a.) or the whole ligand (f.a.s.) in the various symmetry planes. For further discussion, see ref. 9.

one can see that the actual number of ligands bonded to the thorium atom will depend on both the ligand concentration in the preparative medium and the complexation constant, K_3 or K_4. Consequently, in order to cover a given system completely, the preparative conditions must be designed to cover not only the normal 2- to 3-fold excess of the stoichiometric requirement of the ligand in the solvent system used, but also the two extreme concentrations, [L] = 0 (solvent only) and the pure ligand. The first condition is simply established by repeatedly washing the complexes which have been isolated by the normal procedure with the solvent, or by repeated recrystallisation if the complexes have a reasonable solubility in the selected solvent, discarding the solution of the ligand released by dissociation, and the second condition is achieved by treating the solid tetrahalide with the pure ligand.

The first procedure, when applied to the known complex $[ThCl_4(dma)_4]$, led to the isolation of $[ThCl_4(dma)_3]$, whereas the second procedure yielded $[ThCl_4(dmpva)_3]$. In the cases of dmpa and depa, the tris complexes yielded products of composition close to $ThCl_4.2.8dmpa$ and $ThCl_4.2.75depa$ when repeatedly washed with thf, and the known (1) $[ThCl_4(dmiba)_3]$ under similar treatment yielded a product of composition close to $ThCl_4.2.5dmiba$, which may be analogous to the known complexes $UCl_4.2.5L$ (L = dmf (5), dma (6), dmpa and depa (4)). However, its X-ray powder photograph is virtually identical to that of $[ThCl_4(dmiba)_3]$. Similar treatment of $[ThCl_4(dmpva)_3]$ yielded the known $[ThCl_4(dmpva)_2]$, although the analysis of the product at an intermediate stage was close to that to be expected for $ThCl_4.2.5dmpva$.

The four new tris amide complexes are white solids, almost insoluble in thf, except for $[ThCl_4(dmpva)_3]$, which has an appreciable solubility, and all are insoluble in acetone and in hydrocarbons, but are soluble in dichloromethane.

In their ir spectra (Table 2), the frequency of ν_{CO} for the amide ligand is decreased by 50 to 80 cm^{-1}, indicating that the amides are bonded to the metal via the carbonyl oxygen atom. In the spectra recorded for dilute solutions of the complexes in thf there is evidently some dissociation, as shown by the weak to very weak free ligand feature at 1650 cm^{-1} in all of them, but this is less marked for the complexes in dichloromethane, in which only the ir spectra of $[ThCl_4(depa)_3]$ and $[ThCl_4(dmpva)_3]$ exhibit additional features for which $\Delta\nu_{CO}$ is only 20 and 10 cm^{-1} respectively, suggesting weakly bonded ligand and, possibly, rapid exchange between bonded and non-bonded ligand.

The ^1H-nmr spectra (Table 3) of the tris complexes, $[ThCl_4L_3]$, were recorded in CD_2Cl_2 (L = dmpa, dmiba) and in d^8-thf (L = dmpva) using TMS as standard. The small induced shifts, $\Delta\delta$, are consistent with slight deshielding of the ligand protons consequent upon electron donation from the carbonyl oxygen atoms of the ligand, and there is no appreciable difference between the spectra recorded at room (27°C) and low (−50°C) temperatures for the dmpa and dmiba complexes. In the case of $[ThCl_4(dmpva)_3]$, the room temperature spectrum shows only two resonances, whereas at −60°C the spectrum indicates that the exchange between bonded and free ligand is slow on the nmr time scale and that the barrier to rotation of the nitrogen methyl groups is increased, leading to the appearance of three main resonances for the (N)—CH_3 groups, which are a combination of the four possible resonances, and two resonances for the (C)—CH_3 groups.

Thorium thiocyanate complexes

The calculated total cone angle factor, Σc.a.f., for the tris amide complexes, $[Th(NCS)_4L_3]$, is only 0.71, indicating that such complexes are unlikely to be isolable unless the groups R

*s = singlet; d = doublet; t = triplet; quart = quartet; quint = quintet.

and/or R′ in the amide $RCON(R')_2$ are bulky, as has been found in the analogous uranium(IV) system, in which tris complexes, $[U(NCS)_4L_3]$ have been isolated only for L = dmiba and dmpva (acetone solvate) (8). The tetrakis amide complexes, $[Th(NCS)_4L_4]$ (L = dmpa, depa, dmiba, and dmpva), were prepared by treating the corresponding chloride complex, Cs_2ThCl_6(depa only), or thorium tetrachloride, with potassium thiocyanate and an excess of the ligand in thf and attempts were made to degrade the dmiba and dmpva compounds to the tris complexes.This was unsuccessful in the case of dmiba complex, but $[Th(NCS)_4(dmpva)_3]$ was obtained by dissolving $[Th(NCS)_4(dmpva)_4]$ in toluene, evaporating to small volume and then precipitating the product by addition of *n*-pentane.

Some features of the ir spectra of these complexes (Nujol mulls and solutions in thf or dichloromethane) are given in Table 2. The shifts in ν_{CO} on complexation are similar in magnitude to those observed for the corresponding chloride complexes and, like the latter, there is evidence for some dissociation of the ligand from the spectra of $[Th(NCS)_4L_4]$ in thf solution for all four ligands, and only for L = dmiba and dmpva in dichloromethane solution. The frequencies of the stretching vibrations ν_{CN} and ν_{CS} of the linear NCS ion are 2040−2045 cm^{-1} and ~740 cm^{-1} respectively for mulls, whereas ν_{CN} for solutions in thf and dichloromethane is 2010 and 2020 cm^{-1} respectively. These values are consistent with N-bonded thiocyanate groups (12−16).

Received August 31, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

GEORGE JUST, CORINNE LUTHE, and MINH TAN PHAN VIET. Can. J. Chem. **61**, 712 (1983).

Methyl 11*R*- and 11*S*-hydroxyeicosa-5*Z*,8*Z*,12*E*,14*Z*-tetraenoate (**17***R*, **17***S*) (11-HETE) and the corresponding 11-hydroperoxide **19** (11-HPETE) have been prepared from readily available starting materials. The yields were approximately 25% for 11*R*,*S*-HETE, and 5% each for 11*R*- and 11*S*-HETE.

Extensive 400 MHz ^{1}H nmr studies of **17** (nOe difference, 2D *J*-resolved) were undertaken to confirm the structure. Some conformational properties are discussed.

GEORGE JUST, CORINNE LUTHE et MIN TAN PHAN VIET. Can. J. Chem. **61**, 712 (1983).

On a préparé les hydroxy-11*R* et 11*S* eicosatétraène-5*Z*,8*Z*,12*E*,14*Z* oate de méthyle (**17***R*,**17***S*) (H-11ETE) ainsi que l'hydroperoxyde-11 (**19**) (HP-11ETE) à partir de produits de départ facilement accessibles. Les rendements sont approximativement de 25% pour les H-11*R*,*S*ETE et de 5% chacun pour les H-11*R* et H-11*S* ETE.

On a fait appel à une étude poussée par rmn du ^{1}H à 400 MHz du composé **17** (différence de eOn, 2D résolu pour *J*) pour confirmer la structure. On discute de quelques propriétés conformationnelles.

[Traduit par le journal]

The total synthesis of enantiomerically pure 11-HETE has only recently been described (1–3). We wish to report full details of an expeditious synthesis of 11*R*- and 11*S*-HETE **17**, and of the corresponding 11-HPETE **19**.

Condensation of the ethoxyethylidene ether of glycidol (**8**) with the lithium anion of the methoxypropylidene ether of propargyl alcohol (**7**) gave adduct **2**, which was acetylated to provide **3**. Mild acid hydrolysis of **3**, followed by mesylation of the resulting alcohol **4**, gave **5** which provided iodide **6** upon treatment with sodium iodide.

Reaction of **6** with an anionic species generated from acetylenic orthoester **1** (2) by addition of one equivalent of butyllithium and one equivalent of cuprous iodide at −78°C gave orthoester **9** in what appeared to be a quantitative yield. This reaction requires some comment since approximately 30% of **9** was formed at −30°C within a few minutes, the balance of the reaction requiring a day at room temperature. The use of less CuI gave variable yields of **9**. Some hydrolysis of the acetate function was noted so that the reaction product was routinely reacetylated. Since tlc of the product showed two spots due to hydrolysis of orthoester **9** to ester **10**, probably in part on the tlc plate but perhaps during work-up, the product was submitted to very mild acid hydrolysis at this stage to give ester **10**.

Catalytic hydrogenation with Brown's nickel boride catalyst (4), followed by acid hydrolysis, gave alcohol **12**. Up to this point, all steps had proceeded seemingly in quantitative yield, as established by tlc and nmr, and no purification beyond extractions was necessary. Nevertheless, since the next few steps all involved sensitive compounds (**13**, **14**, and **15**) which were prone to decomposition upon standing, **12** was submitted to flash chromatography to remove very minor impurities which had accumulated over the 9-step sequence. The fact that the overall yield for the sequence was only ~50% was probably due to the relative volatility of the various intermediates. Certainly, chromatography at intermediate stages did not in any way enhance either yields or purity of alcohol **12**.

Although the simultaneous hydrolysis of the orthoester and ethoxyethylidene functions in **9** could be performed, it was noted that, in contrast to diolefins **11** and **12**, diacetylenes of type **9** or **10** were very fragile molecules which at times decomposed upon mere standing, or on exposure to silica gel.

Oxidation of **12** with dimethyl sulfoxide – oxalyl chloride using the recently described method of Swern and co-workers (5) gave aldehyde *R,S*-**13**. Treatment of *R,S*-**13** with *l*-ephedrine and 10 mol% pyridinium tosylate gave a mixture of diastereomeric ephedrine derivatives **14**, which were separated by flash chromatography.

The major isomers having the highest and second highest R_f-values had the 11*R* and 11*S* configurations, respectively (3). The minor isomers (~10% each) were not isolated, although, on larger runs, this could have easily been done. Hydrolysis of **14***R* and **14***S* gave **13***R* and **13***S*, each in approximately 20% yield, based on alcohol **12**.

Subsequent elaboration of the 12*E*,14*Z* diene systems follows that described for the *tert*-butyldimethylsilyl ether (2) corresponding to acetate **13** (3), and involves reaction of **13** with formylmethylenetriphenylphosphorane (6), followed by transformation of the *E*-α,β-unsaturated aldehyde **15** with triphenylhexylphosphonium bromide to give **16**. Treatment of tetraene acetate **16** thus obtained with methanolic sodium methoxide gave 11-HETE **17**, contaminated with 10–15% of its 14*E*-isomer, which was readily removed by flash chromatography.

When the same sequence was repeated with resolved aldehydes **13***R* and **13***S*, 11*R*-**17**, $[\alpha_D^{21}]$ 11.2° (10.97° (1)) and 11*S*-**17**, $[\alpha_D^{21}]$ −11.3° (CH_2Cl_2) were obtained.

Conversion to 11-HPETE **19** was accomplished in the following manner (7): **17** was transformed to mesylate **18** at −65°C by means of methanesulfonyl chloride/NEt_3. Addition of 90% hydrogen peroxide in ether gave hydroperoxide **19** in approximately 70% yield, contaminated with what appeared to be 30% of various isomers of 15-HPETE. Purification by hplc gave 11-HPETE **19** in 10–30% yield. Its 400 MHz ^{1}H nmr spectrum was virtually indistinguishable from that of **17**, except for the 11-proton, which appeared at 4.5 ppm, 0.3 ppm downfield from that of **17**. Its structure was confirmed by reduction of **19** (70% purity) with methanolic stannous chloride. Flash chromatography gave as major product **17**, identified by gc–ms of its trimethylsilyl ether. Its ^{1}H nmr was virtually identical to that of **17** described by Corey and Kang (1).

An extensive 400 MHz ^{1}H nmr study of **17** was undertaken to establish if the molecule has a conformational preference. This goal could not be achieved. However, a complete assignment was made as described in the following. The proton signals are sufficiently dispersed so that coupling connectivities between protons could be established by use of 1D homodecoupling experiments. Chemical shifts and coupling constants (except for $^3J_{18-19}$) were measured accurately from the 1D spectrum and 2D *J*-resolved spectra and are given in Table 1. The signals of protons H6, H8, H9, and H15 overlap (Fig. 1a); however, the separated signal for each proton could be observed from the nOe difference spectra (8). For example, when H14 was irradiated, the signal of H15 was enhanced while H6, H8, and H9 were not affected; the difference spectra washed out the signals of these latter protons, and only the signal of H15 is observed (Fig. 1b). Due to the spin echo nature of *J*-resolved 2D spectroscopy and the large applied resolution enhancement factor, the small coupling constants and the small differences in coupling constants can be observed and measured. The cross section plots (Fig. 1c) of the *J*-resolved 2D spectrum show well-resolved signals for all but the H8 and H9 olefinic protons. Because of the second order effect, the two latter protons produced the complex pattern depicted in the contour plot (Fig. 1d). The coupling constants $^3J_{5-6}$, $^3J_{8-9}$, $^3J_{12-13}$, and J_{14-15} are fully consistent with the configurations of the double bonds depicted in Fig. 1 (9).

For conformationally labile molecules, nOe data do not present evidence to infer a conformational preference.[1] However, the nOe results when H13 and H14 were irradiated (nOe between H12 and H14, negligible nOe between H13 and H14) indicate that the protons H13 and H14 are *anti*, in perfect agreement with the value $^3J_{13-14}$ (9). The large nOe between H13 and H16 may suggest that the less sterically crowded conformation (C14—C15 bond *anti* to C16—C17 bond) is preferred. Positive and negative nOe were observed when protons H10 were saturated (see Table 2). Where dipole–dipole interaction is the dominant relaxation mechanism, alternating sign nOe is to be expected (10) in a series of neighboring protons. In fact, at least in one conformation, the protons H10b—H10a—H9—H8 are contiguous; for example when H10a was irradiated, the signal of proton H9 increased (positive effect) but the signal of proton H8 decreased (negative effect). The remaining nOe results may be satisfactorily interpreted in terms of the described structure.

Experimental[2]

Methoxyisopropylidene propargyl alcohol (7)

To a solution of propargyl alcohol (8.4 g, 150 mmol) in dry CH_2Cl_2 (400 mL) at 5°C under N_2 were added methoxypropene (11.9 g, 165 mmol) and pyridinium tosylate (3.77 g, 15 mmol). The reaction mixture was stirred at 5°C for 3.5 h; the product was then extracted with CH_2Cl_2 (2 × 500 mL); the CH_2Cl_2 extracts were washed with aqueous $NaHCO_3$ (4 × 50 mL), water (2 × 50 mL), and dried over $MgSO_4$.

[1]The nOe data confirm the assignment and are given in Table 2.

[2]For general procedures, see ref. 11.

TABLE 1. ^{1}H chemical shifts and coupling constants of **17**

Proton	δ(ppm)	J(Hz)
H2	2.197	H2–H3 = 7.3
H3	1.693	H3–H4 = 7.3
H4	2.067	H4–H5 = 7.3; H4–H6 = 1.3
H5	5.383	H5–H6 = 10.7; H5–H7 = 1.5
H6	5.509	H6–H7 = 7.2
H7	2.869	H7–H8 = 7.0; H7–H9≤1.0
H8	5.61	H8–H9 = 10.8; H8–H10a≤1.0; H8–H10b≤1.0
H9	5.58	H9–H10a = 7.1; H9–H10b = 6.5
H10a	2.463	H10a–H11 = 6.9; H10a–H10b = −14.0
H10b	2.377	H10b–H11 = 5.8
H11	4.195	H11–H12 = 6.0; H11–H13 = 1.4; H11–OH = 4.2
H12	5.781	H12–H13 = 15.2; H12–H14≤1.0
H13	6.801	H13–H14 = 11.1; H13–H15 = 1.1
H14	6.202	H14–H15 = 10.3; H14–H16≃1.3
H15	5.536	H15–H16 = 7.6
H16	2.259	H16–H17 = 7.4

H20	0.969	
OCH_3	3.455	
OH	var	

The solvent was removed at atmospheric pressure and the product recovered by vacuum distillation (65°C, 43 Torr) in 70% yield; ^{1}H nmr (CCl_4) δ: 1.26 (s, 6H, $2CH_3$), 2.17 (t, 1H, $J \sim 2$ Hz, H—C≡C), 3.07 (s, 3H, OCH_3), 3.92 (d, 2H, $J \sim 2$ Hz, CH_2).

Ethoxyethylidene glycidol (8)

To a solution of glycidol (8.8 g, 120 mmol) in dry CH_2Cl_2 (400 mL) at 5°C under N_2 were added ethyl vinyl ether (17.3 g, 240 mmol) and pyridinium tosylate (3 g, 12 mmol). After half an hour the reaction mixture was warmed to room temperature and was stirred at 22°C for 3 h. Extraction with CH_2Cl_2 (2 × 500 mL) and washing of the CH_2Cl_2 extracts with aqueous $NaHCO_3$ (4 × 50 mL) and water (2 × 50 mL) gave, after drying over $MgSO_4$ and distillation, **8**, bp 75°C/20 Torr; ^{1}H nmr ($CDCl_3$) δ: 1.25 (t, 3H, $J = 7$ Hz, CH_2CH_3), 1.30 (d, 3H, $J \sim 5$ Hz, $CHCH_3$), 2.47–4.33 (m, 7H), 4.70 (q, 1H, $J \sim 6$ Hz, $CHCH_3$).

Acetylenic alcohol 2

To protected propargyl alcohol **7** (7.7 g, 60 mmol) in dry THF (60 mL) at 5°C under N_2 was added first *n*-butyllithium (55 mmol) and then glycidol derivative **8** (7.3 g, 50 mmol) and dry HMPA (3 mL). The reaction mixture was brought to room temperature and was then stirred at 65°C for ~2.5 h. The solvents were removed at reduced pressure and the residue extracted with ether (2 × 300 mL); the ether extracts were washed with phosphate buffer (pH 4.5, 2 × 50 mL), water (3 × 50 mL), and dried over $MgSO_4$. Evaporation of the solvent yielded fairly pure **2** as an oil which was used as such without further purification; ^{1}H nmr ($CDCl_3$) δ: 1.20 (t, 3H, $J \sim 7$ Hz, CH_2CH_3), 1.32 (d, 3H, $J \sim 5$ Hz, $CHCH_3$), 1.35 (s, 6H, $2CH_3$), ~2.3–4.3 (m, 10H), 3.20 (s, 3H, OCH_3), 4.57–4.90 (m, 1H, OCHOEt); ms (*m/e*, 16 eV): 259 ($M^+ - CH_3$), 201 ($M^+ - CH_3CHOCH_2CH_3$), 171 ($M^+ - CH_2OCHCH_3OCH_2CH_3$), 141 ($Me_2(MeO)COCH_2C{\equiv}CCH_2^+$), 133 ($M^+ - 141$), 103 ($M^+ - 171$), 73 ($CH_3CHOCH_2CH_3^+$).

Acetate 3

To crude alcohol **2** (2.,7 g, 10 mmol) in anhydrous ether (50 mL) were added 4-dimethylaminopyridine (122 mg, 1 mmol) and acetic anhydride (1.9 mL, 20 mmol). The reaction mixture was stirred at room temperature for 1 h and was then extracted with ether (2 × 350 mL); the ether extracts were washed with aqueous $NaHCO_3$ (2 × 50 mL), water (3 × 50 mL), and dried over $MgSO_4$. Evaporation of the solvent, followed by azeotroping the excess acetic acid and acetic anhydride with toluene, yielded acetate **3**, which was used without further purification in the next step; ^{1}H nmr (CCl_4) δ: 1.05 (t, 3H, $J \sim 7$ Hz, CH_2CH_3), 1.18 (d, 3H, $J \sim 5$ Hz, $CHCH_3$), 1.18 (s, 6H, $2CH_3$), 1.90 (s, 3H, $COCH_3$), ~2.3–2.6 (m, 2H), 3.02 (s, 3H, OCH_3), ~3.1–5.0 (m, 8H); ms (*m/e*, 16 eV): 301 ($M^+ - CH_3$), 73 ($CH_3CHOCH_2CH_3^+$).

Propargylic alcohol 4

To acetate **3** (790 mg, 2.5 mmol) in methanol (20 mL) was added PPTS (25 mg); the reaction mixture was stirred at 5°C for ~1 h, and was then extracted with ether (2 × 350 mL); the ether extracts were washed with aqueous $NaHCO_3$. Evaporation of the solvent gave alcohol **4** as an oil, which was used as such for the following reaction; ^{1}H nmr ($CDCl_3$) δ: 1.18 (t, 3H, $J \sim 7$ Hz, CH_2CH_3), 1.28 (d, 3H, $J \sim 5$ Hz, $CHCH_3$), 2.07 (s, 3H, $COCH_3$), ~2.4–2.7 (m, 2H), ~3.1–5.2 (m, 9H); ms (*m/e*, 16 eV): 244 (M^+), 229 ($M^+ - CH_3$), 73 ($CH_3CHOCH_2CH_3^+$).

Mesylate 5

To alcohol **4** (454 mg, 1.86 mmol) in dry CH_2Cl_2 (10 mL) at 5°C, under N_2, were added triethylamine (1.3 mL, 9.3 mmol) and methanesulfonyl chloride (0.58 mL, 7.4 mmol). The reaction was over immediately (tlc); the reaction mixture was extracted with ether (2 × 175 mL); the ether extracts were washed with cold dilute aqueous HCl (2 × 30 mL), $NaHCO_3$ (3 × 30 mL), water (3 × 30 mL), and dried over $MgSO_4$. Mesylate **5**, thus obtained, was used without further purification for conversion into the corresponding iodide; ^{1}H nmr (CCl_4) δ: 1.05 (t, 3H, $J \sim 7$ Hz, CH_2CH_3), 1.08 (d, 3H, $J \sim 5$ Hz, $CHCH_3$), 1.92 (s, 3H, $COCH_3$), ~2.3–2.6 (m, 2H), 2.95 (s, 3H, SO_2CH_3), ~3.0–3.7 (m, 4H), ~4.4–5.0 (m, 4H).

Iodide 6

To mesylate **5** (592 mg, 1.84 mmol) in acetone (10 mL) was added sodium iodide (1.1 g, 7.3 mmol); the reaction mixture was stirred for 1 h at room temperature and was then extracted with ether (2 × 200 mL); the ether extracts were washed with aqueous $NaHCO_3$ (1 × 100 mL, 1 × 50 mL), water (3 × 50 mL), and dried over $MgSO_4$. Iodide **6**, thus obtained, was used without further purification. On several occasions, evaporation of the ether resulted in decomposition of the iodide. This problem was remedied by use of CH_2Cl_2 as extraction solvent; ^{1}H nmr (CCl_4) δ: 1.10 (t, 3H, $J \sim 7$ Hz, CH_2CH_3), 1.18 (d, 3H, $J \sim 5$ Hz, $CHCH_3$), 1.95 (s, 3H, $COCH_3$), ~2.3–2.6 (m, 2H), ~3.2–3.7 (m, 6H), ~4.4–5.0 (m, 2H); ms (*m/e*, 16 eV): 339 ($M^+ - CH_3$), 265 ($M^+ - (OCHCH_3OCH_2CH_3)$).

Ester ***10***

To acetylenic orthoester **1** (146 mg, 0.85 mmol) and CuI (161 mg, 0.85 mmol) in dry THF (1.5 mL) at −78°C under an argon atmosphere, was added dropwise *n*-butyllithium (0.51 mL, 0.81 mmol); after 15 min iodide **6** (250 mg, 0.71 mmol) in THF (1 mL) was added. The reaction mixture was brough to room temperature over a 0.5 h period, stirred at room temperature for 22 h, and added to aqueous pH 4 buffer (~20 mL); the product was extracted with ether (2 × 150 mL), the ether extracts were washed with H_2O (4 × 20 mL) and dried over $MgSO_4$. Evaporation of the solvents at reduced pressure, followed by a standard reacetylation, gave orthoester acetate **9** in about 85% yield.

Orthoester **9** was generally contaminated with some of its hydrolysis product, ester **10**, as could be seen by the ^1H nmr spectrum: 3.12 (s, OCH_3), 3.55 (s, CO_2CH_3).

To crude orthoester **9** (300 mg, 0.75 mmol) in MeOH/H_2O (4:0.1 mL) at 5°C was added PPTS (9 mg, 5%); after 4 h stirring at 5°C the reaction mixture was extracted with ether (2 × 170 mL), the ether extracts were washed with aqueous $NaHCO_3$ (3 × 40 mL), H_2O (3 × 30 mL), dried over $MgSO_4$, and evaporated under reduced pressure to afford ester **10** as an oil in quantitative yield; ^1H nmr (CCl_4) δ: 1.07 (t, 3H, J ~ 7 Hz, CH_2CH_3), 1.15 (d, 3H, J ~ 5 Hz, $CHCH_3$), ~1.5–2.6 (m, 8H), 1.90 (s, 3H, $COCH_3$), ~2.8–3.0 (m, 2H), ~3.0–5.0 (m, 6H), 3.50 (s, 3H, CO_2CH_3); ms (m/e, 70 eV): 263 (M^+ − $OCHCH_3OCH_2CH_3$), 203 (263 − AcOH).

Diolefin ***11***

To nickel acetate (0.5 g, 2 mmol) in a 2-necked flask equipped with a septum, was added 3 mL of 95% ethanol. The flask was connected to the hydrogenation apparatus and was flushed with hydrogen. The catalyst was produced by injecting 4 mL of a 0.5 *M* solution of sodium borohydride in 95% ethanol to the rapidly stirred solution of nickel acetate. The reaction vessel was reflushed with hydrogen and ethylene diamine (0.2 mL) was added. Hydrogenation was then initiated by introducing diacetylenic ester **10** (176 mg, 0.5 mmol) in ~1 mL ethanol via the septum. Hydrogen uptake was quantitative within an hour and then virtually ceased. The reaction mixture was filtered through Celite, the ethanol was removed under reduced pressure, and the residue extracted with ether (2 × 150 mL); the ether extracts were washed with H_2O (4 × 30 mL), dried over $MgSO_4$, and evaporated *in vacuo* to give di-olefinic ester **11** as an oil in 90% yield; ^1H nmr (CCl_4) δ: 1.28 (t, 3H, J ~ 7 Hz, CH_2CH_3), 1.35 (d, 3H, J ~ 5 Hz, $CHCH_3$), ~1.3–4.2 (m, 14H), 2.10 (s, 3H, $COCH_3$), 3.71 (s, 3H, CO_2CH_3), ~4.5–5.2 (m, 2H), ~5.3–5.7 (m, 4H, 2 CH=CH); ms (m/e, 70 eV): 311 (M^+ − OEt), 267 (M^+ − $OCHCH_3OCH_2CH_3$).

*Methyl 11-acetoxy-12-hydroxydodeca-5Z,8Z-dienoate (**12**)*

To acetal **11** (580 mg, 1.63 mmol) in MeOH (7 mL) was added PPTS (20 mg, 0.08 mmol); the reaction mixture was stirred at 35°C for 2 h and was then extracted with ether (2 × 160 mL); the ether extracts were washed with H_2O (1 × 70 mL, 5 × 30 mL) and dried over $MgSO_4$. Evaporation of the solvent, followed by flash chromatography (petroleum ether – ethyl acetate 5:4), gave pure alcohol **12**; ^1H nmr (CCl_4) δ: ~0.9–3.5 (m, 13H), 1.83 (s, 3H, $COCH_3$), 3.42 (s, 3H, CO_2CH_3), ~4.3–4.7 (m, 1H), ~4.9–5.4 (m, 4H, 2 CH=CH); ms (m/e, 70 eV): 224 (M^+ − AcOH), 206 (M^+ − AcOH − H_2O).

Aldehyde ***13***

To a solution of oxalyl chloride (74 mg, 0.58 mmol) in dry methylene chloride (3 mL) at ~55°C, under argon, was added dimethylsulfoxide (91 mg, 1.16 mmol, in 0.75 mL CH_2Cl_2); after 2 min, alcohol **12** (150 mg, 0.53 mmol) in 1 mL CH_2Cl_2 was added. Stirring at −55°C was continued for an additional 15 min and triethylamine (267 mg, 2.64 mmol) added. After 5 min the reaction was warmed to room temperature, water was added, and the mixture was extracted with ether (2 × 150 mL); the ether extracts were washed with water (4 × 25 mL), dried over $MgSO_4$, and evaporated to give aldehyde **13** as an oil. It was used as such in the subsequent resolution with ephedrine or Wittig reaction with formylmethylenetriphenylphosphane; ^1H nmr (CCl_4) δ: ~1.2–3.0 (m, 10H), 2.20 (s, 3H, $COCH_3$), 3.67 (s, 3H, CO_2CH_3), 5.00 (t, J ~ 6 Hz, 1H), ~5.2–5.7 (m, 4H, 2 CH=CH), 9.57 (s, 1H, CHO); ms (m/e, 70 eV): 282 (M^+), 222 (M^+ − AcOH).

l-*Ephedrine derivative* ***14*** *of aldehyde* ***13***

A solution of aldehyde **13** (230 mg, 0.82 mmol), *l*-ephedrine (269 mg, 1.63 mmol), and PPTS (20 mg, 10 mol%) in dry methylene chloride (4 mL) was stirred under N_2 at 40°C for 3 h and at room temperature for 5 h to effect a complete conversion of **13** to **14**. The CH_2Cl_2 was evaporated to yield the two desired ephedrine derivatives **14***R* and **14***S* which were separated by slash chromatography (petroleum ether – ethyl acetate 10:2, 20% yield of each); ^1H nmr ($CDCl_3$) δ of **14***S* (lower R_f): 0.53 (d, 3H, J = 7 Hz, CH_3), ~1.1–3.0 (m, 10H), 1.90 (s, 3H, $COCH_3$), 2.30 (s, 3H, NCH_3), 3.47 (s, 3H, CO_2CH_3), 3.85 (d, 1H, J = 4 Hz), ~4.7–5.4 (m, 7H), 7.13 (s, 5H, C_6H_5); of **14***R* (higher R_f): 0.57 (d, 3H, J = 7 Hz), ~1.1–3.0 (m, 10H), 2.03 (s, 3H $COCH_3$), 2.20 (s, 3H, NCH_3), 3.50 (s, 3H, CO_2CH_3), 3.75 (d, 1H, J = 2 Hz), ~4.7–5.5 (m, 7H), ~7.0–7.4 (m, 5H, C_6H_5); ms (m/e, 70 eV): 429 (M^+), 398 (M^+ − OCH_3), 176 (cyclic—NMeCHMeCHPhOCH—$^+$).

*Aldehydes 14*R *and 14*S

To ephedrine derivative **14***R* (125 mg, 0.29 mmol) in MeOH (5 mL) was added 1 mL aqueous 0.5 *N* HCl. The solution was stirred at 33°C for ~4 h and was then extracted with ether (2 × 150 mL); the ether extracts were washed with dilute aqueous HCl (1 × 50 mL, 1 × 20 mL), water (4 × 20 mL), and dried over $MgSO_4$. Evaporation of the solvent gave crude aldehyde **13***R* in ~90% yield; it was used without further purification in the subsequent Wittig reaction. An identical procedure was used to produce **13***S*.

Methyl 11-acetoxy-14-oxo-tetradeca-5Z,8Z,12E-trienoate (15)

The aldehyde **13** (85 mg, 0.30 mmol) in dry DMF (2 mL) under Ar was added formylmethylenetriphenylphosphorane (100 mg, 0.33 mmol). The reaction mixture was stirred at 42°C for 4 h and was then extracted with ether (2 × 150 mL). The ether extracts were washed with water (4 × 20 mL) and dried over $MgSO_4$; evaporation of the solvent followed by flash chromatography (petroleum ether – ethyl acetate 12:3) gave α,β-unsaturated aldehyde **15** as an oil in ~50% yield; ^{1}H nmr (CCl_4) δ: ~1.4–2.9 (m, 10H), 2.00 (s, 3H, $COCH_3$), 3.53 (s, 3H, CO_2CH_3), ~5.0–5.7 (m, 4H, CH=CH), 6.0 (ABXY octet, 1H, C13, $J_{13,12}$ = 16, $J_{13,14}$ = 7, $J_{13,11}$ = 1 Hz), 6.60 (ABXq, 1H, C12, $J_{12,13}$ = 16, $J_{12,11}$ = 4 Hz), 9.43 (d, 1H J = 7 Hz, CHO); ms (m/e, 70 eV): 248 (M^+ – AcOH).

Methyl 11-acetoxyeicosa-5Z,8Z,12E,14Z(E)-tetraenoate (16)

To *n*-hexyltriphenylphosphonium bromide (107 mg, 0.25 mmol) in dry THF (3 mL) at room temperature under an argon atmosphere and was added *n*-butyllithium (0.18 mmol); after 15 min, the reaction mixture was cooled to −78°C, and aldehyde **15** (46 mg, 0.15 mmol) in THF (1 mL) was added dropwise via syringe. The reaction was over immediately; it was warmed up rapidly by immersion into a 20°C water bath, poured into pH 4 buffer (50 mL), and extracted with ether (2 × 150 mL). The ether extracts were washed with water (4 × 30 mL), dried over $MgSO_4$, and evaporated to give acetate **16** contaminated with some of its 14*E* isomer.

Methyl 11-hydroxyeicosa-5Z,8Z,12E,14Z-tetraenoate (17)

Crude acetate **16** (49 mg, 0.13 mmol) in dry methanol (4 mL) containing a catalytic amount of sodium methoxide was stirred at room temperature for 0.5 h, and was then neutralized with strong acidic resin (AM-120 H^+). Removal of the resin, followed by evaporation of the methanol, gave alcohol **17** contaminated with its 14*E* isomer. The latter was removed by flash chromatography (petroleum ether – ethyl acetate 9:2); me (m/e, 70 eV): trimethylsilylether: 406 (M^+), 283 (M^+ – CH=CHCH=CH$(CH_2)_4CH_3$), 225 ($(Me)_3SiOCHCH$=CHCH=CH$(CH_2)_4CH_3$).

Methyl 11-hydroperoxyeicosa-5Z,8Z,12E,14Z-tetraenoate (19)

To alcohol **17** (10 mg, 0.030 mmol) in dry CH_2Cl_2 (1.6 mL) under an argon atmosphere at −65°C was added triethylamine (0.017 mL, 0.12 mmol), the methanesulfonyl chloride (0.0035 mL, 0.045 mmol). After 0.5 h, 90% hydrogen peroxide (0.04 mL, 1.6 mmol) was added in 0.5 mL ether at −81°C. After 15 min, water was added and the reaction mixture extracted with ether–pentane (2:1) (60 mL); the ether–pentane extracts were washed with cold water (10 × 10 mL), dried over $MgSO_4$, and evaporated to yield hydroperoxide **19** contaminated with ~30% of its 15-hydroperoxy isomers (^{1}H nmr evidence only).

Purification by hplc was carried out using a straight-phase column (Altex Ultra-Sil), and petroleum ether – ethyl acetate as solvent system. The hydroperoxide mixture decomposed on the column, giving first a less polar material, then **19**, followed (shoulder) by other hydroperoxides (15-HPETE's). Only 10–30% of **19** could be isolated.

The crude mixture of HPETE's (1 mg, 70% **19**, 30% others by 400 MHz ^{1}H nmr) was reduced with $SnCl_2$ (12 mg) in 0.5 mL methanol for 2 min at room temperature. Extraction with ether–pentante 1:1, and washing with pH 4 buffer and water gave, after drying, a mixture. Separation by hplc, using the same column and petroleum ether – ethyl acetate (10:1) gave, as the major product, **17**.

Experimental section for ^{1}H nmr of 17

The solution of **17** (~10^{-2} *M*) was made up in C_6D_6, and degassed through 5 cycles of freeze–pump–thaw. The ^{1}H spectra were obtained on the Brüker WH-400 located at the "Laboratoire Régional de RMN" at the Université de Montréal. The 1D FID were accumulated with 16K data points and zero-filled before being Fourier transformed to obtain a digital resolution better than 0.1 Hz. The steady-state nOe difference spectra were obtained by subtraction of FID or transformed spectra; transients were collected after preirradiation (10–12 s) at selective frequencies and recycled to average the drift effect. For the protons H10a and H10b, subsaturation power levels were used to achieve partial selectivity; for other protons, complete saturation power levels were used. The T_1 of the protons obtained by nonselective inversion recovery were in the range of 0.8 to 2 s.

The 2D *J* spectra were obtained with the automated Brüker program. Because of the memory storage limit, the window of f_2 dimension only covers the downfield part of the spectra (1100 Hz), the frequency offset was carefully chosen to avoid the foldover problem. The digital resolution is 0.268 Hz after zero-filling in both f_1 and f_2. A Gaussian resolution enhancement function is applied in both t_1 and t_2 directions before doing the Fourier transform.

The coupling constants are calculated directly by first order analysis for the well-dispersed proton signals and from the simulated spectra using the standard PANIC program from the Brüker software package.

During the heights of ancient Egyptian civilization, statues of deities and pharaohs were often constructed of hard and colourful igneous rocks, such as granite and diorite. Most of these statues remain in an excellent state of preservation. However, others have unexpectedly fragmented, in some cases only a few years after having been excavated in near-perfect condition. In the present work it is shown that two interrelated physicochemical processes contribute to this degradation: (1) the infiltration of saline H_2O and (2) subsequent alteration of the constituent minerals. Conclusions were reached on the basis of neutron activation and atomic absorption analyses of rock samples from two sites in Upper Egypt and leached soluble salts therefrom. These samples were identified as quartz diorites on the basis of petrographic and X-ray spectroscopic examination. The chemical significance of the geological nature of the stone is discussed. Possible precautions to be observed in the field are presented.

JOANNA MCFARLANE, KRISTINE M. WILSON-YANG, SIDNEY JOSEPH, CARLA FREY et GEORGE BURNS. Can. J. Chem. **61**, 718 (1983).

Lors de la grande époque de la civilisation egyptienne, on a souvent construit les statues des déesses et des phaarons avec des roches ignées dures et colorées, tel le granite et la diorite. La plupart de ces statues sont encore en excellent état. Cependant dans quelques cas, d'autres qui étaient dans un état presque parfait lorsqu'elles ont été découvertes se sont fragmentées subitement quelques années après leur excavation. Dans ce travail, on montre que deux processus physicochimiques interreliés contribuent à cette dégradation: (1) l'infiltration d'eau salée et (2) l'altération subséquente des constituants minéraux. Nos conclusions se fondent sur des analyses par activation neutronique et par absorption atomique de deux échantillons de roches provenant de deux endroits de la Haute Egypte; on avait débarassé ces échantillons des sels solubles qu'ils contenaient. Les échantillons sont identifiés comme étant des quartz-diorites en se basant sur l'examen pétrographique et spectroscopique aux rayons-X. On discute de la signification chimique de la nature géologique de la pierre. On suggère quelques précautions à observer dans ce domaine.

[Traduit par le journal]

Introduction

Ancient Egyptians, especially in times of prosperity, honoured their deities and pharaohs with statues and chapels made of strong igneous rock (1). Many beautiful dioritic monuments have been excavated in Giza, near Cairo, as well as in Deir el-Bahri and Karnak, in Upper Egypt. These works of art are representative of the best ancient Egyptian stone craftsmanship and most were discovered in almost perfect condition. A statue of Thutmose[3] III, an 18th dynasty pharaoh (1490–1436 B.C.), unearthed in the Deir el-Bahri complex, dominated by the funerary temple of Queen Hatshepsut, even partly retained its original decorative pigments. Such pigments are rarely retained on dioritic monuments. Unfortunately, a few years after having been exposed to the atmosphere, this statue developed deep cracks. Its condition had so greatly deteriorated in the past fifteen years that it was necessary to encase it in concrete on site to prevent it from completely crumbling under its own weight.

Many other statues of igneous rock have deteriorated in a similar manner, such as a torso of Queen Hatshepsut, now in the Louvre, several dioritic figures, now in the Boston Museum of Fine Art (2), as well as some statues in the National Museum, Cairo. On the other hand, dioritic statues of the goddess Sekhmet, presently in the Louvre, are in nearly perfect condition, as are the statues of Khufu and Menkure which were discovered in Giza.

Little systematic investigation has been done to elucidate the processes which have destroyed statues of diorite. It was suggested (2) that the damage was caused by intense heating and presumably rapid cooling with water. Although the constituent minerals of igneous rocks do have different coefficients of thermal expansion (1, 3),[4] it is unlikely that this phenomenon would have contributed to the sudden degradation of the statues as the rock from which they were sculpted had survived temperature fluctuations over geological time. This theory also fails to explain the pattern of cracking and the apparent lack of carbonaceous material on the surfaces.

A more probable cause of this type of degradation is the infiltration of soluble salts into the rock pores and crystallization of the salts therein. This is a well-known phenomenon and has been seen frequently in modern stone (1). In addition, the geological literature (11–18) provides some insight into the degradative interaction of water and the minerals found in some igneous rocks. The development of possible structural weaknesses would be critical in the extended existence of dioritic monuments.

It was decided therefore to explore these possibilities with

[4]Scientific staff, Deir el-Bahri, private communication.

the aim of providing a reasonable and archaeometrically useful explanation of this deterioration.

Removal of fragments of diorite from ancient Egyptian statues is very ill-advised, since these works of art are clearly irreplaceable. However, we were fortunate to receive permission from the President of the Egyptian Antiquities Organization and its Permanent Committee to collect samples of archaeometric, but not archaeological or Egyptological, value in Karnak and the Deir el-Bahri area. Two specimens were collected, one from the Deir el-Bahri temple complex and one from the Karnak temples. The first was found near the pyramid in the Mentuhotep I Temple. It is most likely that it originated from a wall from the Thutmose III Temple, immediately adjacent, which had collapsed.[5] Upon close inspection, this sample appeared to be identical in composition and condition to the aforementioned statue of this pharaoh, found near the centre of the Thutmose III Temple. The second sample was found near the dioritic doorway of Queen Hathepsut's chapel from which it had fallen. The chapel is adjacent to and immediately north of the Main Sanctuary of the Karnak temples.

It was decided first to classify the rock samples petrographically using multielement X-ray fluorescence and thin-section analyses. The samples were then subjected to a regimen of washing to investigate the presence of soluble salts. The resulting solutions and washed and unwashed samples were then analyzed by atomic absorption and nuclear activation analyses.

Experimental

Samples

The Deir el-Bahri specimen consisted of two subsamples, DG-1 and DG-2, 10 and 57 g in mass respectively. The Karnak sample KG-1 had a mass of 7 g. All samples were stored in sealed polyethylene bags and manipulated with tweezers to avoid salt contamination.

X-ray fluorescence

Sample preparation

Two 400 mg samples of DG-1, chipped from opposite sides of the fragment, were ground with a mortar and pestle to an approximately 200 mesh powder. Two grams of Spectroflux*105 (Johnson Matthey Chemicals) and 10 mg NH_4NO_3 were added to each powdered sample, and intimately mixed. The mixture was fused in a Pt/Au crucible over a Bunsen burner for 15 min and subsequently moulded into a disc 30 mm in diameter and 2 mm thick.

Instrumental procedure

A Philips X-ray spectrograph with a W target and a LiF scintillation detector (Chemistry Department, University of Toronto) operated at a voltage of 28 kV and a current of 24 mA, was used to determine qualitatively the presence of elements heavier than Sc. To extend the quantitative determination to lighter elements a Siemens sequential X-ray spectrometer (Geology Department, University of Toronto), interfaced with a PDP11 microcomputer operated with a Cr target at a voltage of 45 kV and a current of 44 mA, was employed. The following elements were detected: Mg using an ADP[6] crystal; Al, Si, and P using a PET[7] crystal; and Fe, Ca, Ti, K, and Mn using LiF.

Thin section analysis

Sample preparation and instrumental procedure

Fragments, each about 0.7 cm in diameter, of DG-1, DG-2, and KG-1, were placed on a 5 mm thick by 2.5 cm in diameter disk made of 1 drop of hardener/4 mL resin SW (Metaserv Metset). They were then immersed in a 1 drop hardener/5 mL resin mixture, and placed under a light vacuum for 10 min. This allows some impregnation of the samples to avoid losses on cutting. The samples were then sectioned, using anhydrous ethanol as a coolant, and mounted on microscope slides. The minerals in the samples were identified using a Leitz Orthoplan petrographic microscope (Geology Department, University of Toronto).

Atomic absorption and neutron activation analyses

Sample preparation

Three 800-mg subsamples of DG-1 were prepared for analyses of soluble ions present in the rock matrix using the following method. A preliminary wash involved the immersion of each fragment in deionized water for 20 s which was then diluted in a volumetric flask. Each fragment was then stirred in 25 mL of deionized H_2O for 24 h using a magnetic stirrer. The resulting heavy wash solution was filtered, using Whatman #1 filter paper, and diluted in a volumetric flask. Both the preliminary and heavy wash solutions were then analyzed by atomic absorption spectrometry.

Three 1-mL aliquots of one of these pairs of solutions were analyzed by neutron activation analysis, along with a second set of wash solutions. This set was prepared following the method previously described, except the preliminary washes were performed by rinsing the fragments with six small aliquots of deionized H_2O, with a total volume of less than 25 mL.

Six 800-mg fragments were removed from each of the DG-1, DG-2, and KG-1 samples. Half of these fragments underwent preliminary washes. They were immersed and swirled gently three times each in 10 mL of deionized H_2O for 10 s. All the samples were then subjected to heavy washes using the method described earlier. Neutron activation analyses were performed on these solutions, on filter papers used in the preparation of the heavy washed, on one unwashed sample of DG-1, and on blanks of deionized H_2O, deionized H_2O passed through a filter paper, and the filter papers used in the preparation of the blanks. For a subsequent atomic absorption analysis, the wash solutions were further diluted and modified to contain 2% by volume HCl, 214 ppm Sr, and 857 ppm Cs.

Instrumental procedure of atomic absorption analysis

A Techtron Model AA-4 atomic absorption spectrophotometer (Chemistry Department, University of Toronto) was used with Varian Na and Ca, Hanau Original K hollow cathode lamps and an air/acetylene flame. Calibration curves were prepared with standard solutions of 0.5, 1.0, 4.0, and 8.0 ppm Na; 1.0, 4.0, 8.0, 16.0, and 20.0 ppm K; and 1.0, 5.0, 10.0, and 20.0 ppm Ca; and with standard solutions of Na/Ca/K respectively, with concentrations in ppm of 500/4.99/1.67, 1.00/0.998/0.334, 0.500/0.499/0.167, and 0.0500/0.0499/0.0167, prepared to mimic the unknown composition. In addition each standard was 214 ppm in Sr and 857 ppm Cs.

Instrumental procedure of neutron activation analysis

Irradiation of the samples was done in the University of Toronto SLOWPOKE Reactor. Gamma-ray collection and analysis was done using one of the two Ge(Li) detectors coupled with a Canberra 8180 multichannel analyzer.

The wash samples were irradiated in 1-mL vials for 5 min at a neutron flux of 1.0×10^{12} neutrons/cm^2 s. A one minute decay time before gamma counting was necessary for the transfer of the liquid to unirradiated vials for the five minute count. The mass of liquid transferred was determined separately. The concentrations of the elements were calculated with respect to 5.1 ppm Al, 1620 ppm Mg, 960 ppm Ca, 40.8 ppm Na, and 63.2 ppm Cl standard solutions.

The filter paper samples, as well as the unwashed rock sample, were irradiated for one minute at a neutron flux of 1.0×10^{11} neutrons/cm^2 s. After a decay period of 18 min the gamma activity of the samples was counted for 5 min. The concentrations of the elements were determined with respect to standards of 101 ppm Al, 1608 ppm Mg, 19 200 ppm Na, and 25 000 ppm Cl.

K	1.9
P	1.1
Mn	0.2
Total	96.6

[a]DG-1, two subsamples.

qualitatively indicated the presence of La, Fe, and Ti (La is a major constituent of Spectroflux*105). The fairly high abundance of Fe and Ti in the fused sample was verified by the quantitative results from the Siemens spectrometer. These elemental concentrations are listed in Table 1 and were identical for both DG-1 samples studied. The fusion process lowered the sensitivity of the technique because of dilution by Spectroflux*105. The spectra of the lighter elements were especially affected because their fluorescent X-rays were absorbed by the diluent (4). Nonetheless, this effect was counterbalanced by the high concentrations of these elements. The concentrations of the elements sum to 96.6±0.1%. The balance is probably due to the presence of unanalyzed Na and trace elements.

(ii) *Thin section analysis*

The thin sections revealed that the rocks under investigation were quartz diorites, as there was 10 to 15% quartz in the KG-1 sample and 30% quartz present in the Deir el-Bahri rocks. The plagioclase, a sodium–calcium alumino-silicate, of the Deir el-Bahri rocks had been altered to clay minerals to a greater extent than the Karnak plagioclase, which also contained some muscovite. More biotite, but less apatite, was observed in the KG-1 thin section than in those of DG-1 and DG-2. Large crystals of magnetite and 1 grain of calcite were seen in all the samples. The KG-1 rocks also contained hematite, and very small amounts of feldspar and zircon. Approximately 10% hornblende was noticed in the Deir el-Bahri rocks.

(iii) *Atomic absorption analysis*

During the preliminary washes of the sample preparation, many of the fragments broke apart. After overnight stirring, the samples had completely disintegrated. They formed a slurry at the bottom of a suspension of what was suspected to be fine alumino-silicates. The Na, Ca, and K calibration curves were linear well within the range of the diluted wash water samples. The enhancement of the K signal due to the presence of other alkali metals in the rock matrix was simulated in the K standard solutions by the addition of an amount of Na, approximately equivalent to the concentrations found in the sample solutions in the first analysis, and by the preparation of one standard solution to contain both Na and K, in the second. In addition, CsCl was added to the wash solutions to suppress the ionization of K and $SrCl_2$ was added to reduce the formation of Ca oxides in the flame in the second set of analyses[8] (5). Results and calibration curves were statistically analyzed via ref. 19.

The results of the geological samples, of the wash water, and of the filter paper by atomic absorption and neutron activation analyses are listed in Table 2.

(iv) *Neutron activation analysis*

The following elements were observed to be present in the rocks by neutron activation analysis: Mg, Al, Ca, Na, Cl, Mn, V, and Ti, but for only the first five were concentrations determined. I and Br were searched for in the wash waters but no conclusive evidence was obtained for their presence. The standard solutions of Na, Mg, Ca, Cl, and Al were of much greater concentration than the sample wash solutions. They provided good counting statistics with spectral peaks of a few thousand counts above the background. The peak was considered to be statistically significant if the standard deviation, determined as the square root of the gross peak plus background counts, was less than 30% (4). Otherwise, only a detection limit was reported, as indicated by the approximate values of the weight percentages of Mg from the wash water analyses in Table 2.

Al was found in the deionized water blanks. This was probably desorbed from the walls of the polyethylene vials, and was subtracted from the concentration found in the preliminary wash solutions. Measurable concentrations of Na, Al, and Cl were found in the filtered deionized water blanks; these were subtracted from their concentrations in the overnight wash solutions. The filter paper blanks contained significant amount of Na, Al and Ca; the concentrations of these elements were subtracted from the washed rock residue. The Na present in the blanks of the filtered deionized water and the filter papers was most likely from the manual handling of the filter papers. This contamination is suspected to have occurred before the papers were used in these experiments, as special care was taken to avoid direct contact between the paper and the hands of the analyst. Repetitive analyses of the blanks and standard solutions were performed to ensure the reproducibility of these results.

Ratios of the weight percentages of Na/Ca, Na/Cl, Al/Ca, Al/Cl, and Ca/Cl were calculated for the species remaining in the samples after washing, and the elements leached from the rocks during this process, to determine whether the dissolved salts were part of the diorite matrix itself. These ratios are presented in Table 3.

Discussion

The results of the X-ray fluorescence analysis of DG-1 (Table 1) indicate a low silicate and a high ferro-magnetic mineral content characteristic of a diorite[9] (6). The notable Ti concentration characteristic of Egyptian rocks was present in the geological material on the filter papers (7). As the elemental concentrations of the two sampling sites on opposite sides of the fragment were identical, it was felt that the rock was petrographically homogeneous.

The thin sections allowed the samples from both excavation sites to be further classified as quartz diorites. The differences in the mineralogy of these rocks indicated that they may have originated from different quarries, although some of these variations could have been due to the inhomogeneity of the rocks.

It was found that the surface contamination of the rocks, in the form of dust and dirt adsorbed through burial and sub-

[a]From neutron activation analyses.

sequent handling, was not significant. Samples chipped from both the exposed surfaces and the interiors of the rocks showed no notable differences in the concentrations of the elements leached from the different fragments in the preliminary washes. Variations in the masses of dissolved elements indicated the rock had not been homogeneously degraded, not unexpected in a coarse-grained igneous rock.

The Na and Ca concentration, determined by the two different analytical techniques, corroborated each other. The Na results were reproducible between analytical techniques. Those of Ca were less so; however, the observed deviations were found to be statistically insignificant at the 95% confidence level, except for those observed in the results from the Karnak sample. The atomic absorption results have an inherently better precision than those obtained from the neutron activation analysis; the latter technique was employed near its detection limit in many of the samples. However, the precision of both methods was limited primarily by the inhomogeneity of the samples. Inhomogeneity was the probable explanation for the high chloride ion concentration in one of the DG-1 fragments.

The Mg concentrations in the wash waters were only approximated, as the small Mg peak in the gamma-ray spectrum was quite often not statistically significant with respect to the high background count in the same energy region. K was not searched for in the neutron activation analysis, as the 0.017 weight percent observed previously in the atomic absorption study would not have been detectable under the conditions of analysis used.

It was determined that the elemental concentrations of Na, Ca, Cl, Al, and Mg in the washed rocks were very similar among the samples from different sites, as were the rocks' external macroscopic characteristics. In addition, no provenance differences were apparent in the concentrations of the elements leached from the rocks, except in the case of chloride ion. The concentrations of leachable chloride ion in the samples were different, being 0.002 ± 0.001 molal for DG-1, 0.004 ± 0.002 molal for DG-2, and 0.014 ± 0.006 molal for KG-1. The Na/Cl mole ratios were also dissimilar, being respectively 6.5, 5, and 1.6.

In all samples, there were significant differences in concentration ratios as compared to chloride ion, between those calculated from the leachable ions and the nonleachable ones. These are reported in Table 3. The Na/Ca, Na/Al, and Al/Ca ratios did not vary much between those determined from the concentrations of leachable elements and those calculated from the insoluble ones. So, only the chloride ion was proportionately more concentrated in the wash waters than in the geological material left on the filter paper.

This excess of chloride ions washed from the rock samples suggests that chloride salts (8) had been deposited within the

rock matrices. This evidence suggested that degradation of the quartz diorite was due to NaCl and, to a lesser extent, KCl and $CaCl_2$. Sulphates and carbonates, which were not studied in this work, could have participated in this degradation process (9). The Na/Cl mole ratios were greater than unity, indicating an excess of Na which could have been either present in the rock as a salt other than NaCl, or leached from the diorite itself.

The soil of Egypt is known to be saline (8). This suggests that rocks and statues buried for thousands of years will eventually become salinized through salt-transporting ground water or through rare rains percolating through the earth. Since the construction of the first dam on the Nile, and the High Dam near Aswan (1965), irrigation has greatly increased the salt content of soil and monuments at Karnak (10). This increase is not seen at Deir el-Bahri, which is situated in the hills on the West Bank of the Nile. That the Karnak samples were more extensively salinized than the ones from Deir el-Bahri was evident from the greater amount of chloride ion washed from the KG-1 rocks than from the DG-1 and DG-2 rocks. This result is in complete agreement with our recent computational studies of salinization in the Karnak area (10).

Upon excavation of the quartz diorite, the absorbed water gradually evaporated and the salts present crystallized. Pressures on the micropores of the rock, due to the crystallization of the salts, would have likely caused its deterioration. Under natural conditions the NaCl crystal can exert 605 atm on the surrounding minerals, which is enough to crack most rocks (1). The presence of Na, Ca, and K cations in the wash waters provided evidence that the degradation of the quartz diorite samples was at least in part due to the salinization process. Other examples of a similar degradation due to salinization have been observed in granite (11), and in sandy limestone in the Saudi Arabian desert (3).

The existence of salinization does not preclude the presence of other deterioration mechanisms. The rate and extent of degradation of a rock depends also on the weathering of individual minerals within its matrix. Granite has been observed to crumble when water reacts with the biotite in the rock (12). The degradation of plagioclase in diorite may proceed by one or more mechanisms, including the leaching of cations from the silica lattice by hydrogen ion activity on its surface (13, 14), or to depths greater than one or two unit cells (15). The sequence of minerals formed in plagioclase alteration has been studied by transmission electron microscopy (16). The leaching of silica, which in turn renders the rock more porous, is another suspected mechanism of igneous rock weathering (17). Mechanical degradation of rocks was suggested to occur upon their excavation (18). In addition, it is highly probably that microfractures caused by crystallization of soluble salts during burial, i.e. in dry periods between rains, accelerates the destruction of the mineral structure. Fresh surfaces for potential attack by water would be created.

That the quartz diorite in our samples is slightly leached by water, with which it was saturated for thousands of years, was indicated by the similarity between the weight percent ratios of Na/Ca, Na/Al, and Al/Ca in the wash waters and those of the unleached elements in the rock (Table 3). The presence of the fine alumino-siliceous suspension in the wash waters, confirmed in the neutron activation analysis by the high Al concentrations, was an indication of the degree to which the rocks had decomposed. The most conclusive evidence for such a mechanism, however, came from a study of thin sections of the rock, where the alteration products of clay minerals and muscovite were clearly visible in the plagioclase. This weathering process was more extensive in the quartz diorite from Deir el-Bahri than in that from Karnak.

The actual extent to which the quartz diorite was leached was not great, as no significant difference was noted in the elemental concentrations of Na in the washed and unwashed rock samples. But as the concentrations of leached elements were so much lower than those in the rock, their contribution to the elemental concentrations as a whole in the quartz diorite would have been negligible.

In our quartz diorite samples, ground water weathered the plagioclase, and perhaps biotite and other minerals. The clay minerals formed at the site of the weathering and the microcracks in the rock became saturated with water while it was buried, weakening its structure by enlarging these imperfections. Upon excavation and the evaporation of this absorbed water, these plate-like minerals became more compact. This caused strain and distortion of the rock matrix, which eventually contributed to its cracking.

Conclusions

These experimental results strongly suggest that the quartz diorite degradation seen in Egyptian antiquities occurs via two interrelated mechanisms. Cracks in the rock result from the crystallization of salts absorbed into its matrix. Salt-induced dislocations will accelerate weathering during burial and swelling and contraction of subsequent mineral alteration products will contribute to crumbling upon unearthing. The relative importance of these mechanisms has been shown to vary according to the precise mineralogy of the rock and the nature of the soil in which the monument is buried.

Careful observation of burial environments could save many dioritic artifacts from rapid degradation. In the case of obviously damp soils, the objects should be immediately protected from evaporation. Storage, whether in a field warehouse or permanently in a museum, must be in an appropriately humid, isothermal environment. Artifacts which already demonstrate cracking and crumbling require careful encasement in a suitable, safe restraining medium in the field. Consolidation and other conservation treatments must as always only be performed after thoroughly testing all procedures, recalling the often friable nature of these unique treasures.

Acknowledgements

We appreciate greatly the permission granted to us by the Egyptian Antiquities Organization to collect some samples from sites of archaeometric importance. We give special thanks to Drs. Shahata Adam and Ali el Khouli for their efforts on behalf of our endeavours in Egypt. Our field work was greatly facilitated by Mr. Mohammed el Saghir, Chief Inspector of Antiquities at Luxor, Mr. Sayed Abdel Hamid, Chief Inspector at Karnak, Mr. S. G. Bishay of the Research and Conservation Centre, Cairo, and by Mr. Yehia M. Eid, then Inspector of the West Bank, Luxor.

We wish to thank the centre franco-égyptien d'études des temples de Karnak for its interest in our research and especially C. Traunecker for his stimulating discussions. We appreciate the assistance of the American Research Centre in Egypt, Cairo. Our collaboration with the Egypto-Polish Archaeological Expedition, Deir el-Bahri, especially with the Head, Mme. J. Lipinska, is gratefully acknowledged. The initial insight into some of the archaeometric problems in Upper Egypt

was provided to us by Dr. Hismat Messiha and the late Dr. Zaki Iskander.

We wish to thank Mr. T. C. Billard and Mr. K. Nielson of the Chemistry Department at the University of Toronto for their advice on some chemical aspects of our work. We thank Dr. R. Hancock at the SLOWPOKE Reactor, and Drs. M. Gorton, C. Cermignani, and J. M. Allen of the Geology Department for their guidance and enthusiastic advice which they provided in a significant part of our instrumental study.

One of us (J.M.) would like to thank Dr. L. Yaffe for her initiation into the exciting field of Archaeometry.

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

D. L. ANDERSON, G. E. GORDON, and E. A. LEPEL. Can. J. Chem. **61**, 724 (1983).

Neutron-capture prompt γ-ray activation analysis (PGAA) was used to measure concentrations of up to 18 elements in cement, sand, aggregate, and concretes and up to 9 elements in several types of steel. All major elements except oxygen are measurable in both types of samples. The observed elements, especially Ca and B, in concrete and its constituents allow one to determine the amount of cement used in the concrete, but additional elements would be needed to distinguish sand and aggregate.

D. L. ANDERSON, G. E. GORDON et E. A. LEPEL. Can. J. Chem. **61**, 724 (1983).

On a utilisé l'analyse de la capture électronique rapide par activation aux rayons γ (ARAG) pour mesurer les concentrations de 18 éléments du ciment, du sable, du gravier et du béton et de 9 éléments contenus dans différents types d'aciers. On peut mesurer tous les éléments principaux, à l'exception de l'oxygène, dans les deux types d'échantillons. D'après les concentrations d'éléments observés, spécialement le Ca et le B dans le béton et ses constituants, on peut déterminer la quantité de ciment utilisé dans le béton; toutefois il faut des éléments additionnels pour établir une distinction entre le sable et le gravier.

Introduction

Previous studies of neutron-capture prompt γ-ray activation analysis (PGAA) with the use of neutron beams from nuclear reactors have demonstrated the technique's ability to measure concentrations of most major and minor elements and the trace elements B, Cd, Nd, Sm, and Gd in crustal materials such as soil, rocks, coal, and fly ash (1, 2). The uses of PGAA could be greatly expanded if portable systems based on isotope neutron sources (e.g., ^{252}Cf) or 14-MeV generators could be developed. Transportable sources could, for example, be used in geological exploration, for real time analysis of raw material or process streams in industry or to monitor the quality of materials at large construction sites. As both neutrons and high energy prompt γ-rays have long ranges in materials, PGAA has great advantages over essentially all other real time analytical methods, e.g., X-ray fluorescence, for the analysis of bulky, inhomogeneous materials because the other methods use signals of limited range that sample only surface materials, which may not be representative of the bulk material. In one of the first efforts to develop a working system, Reynolds *et al.* (3) developed a prototype ^{252}Cf-based system for analysis of coal for ash and sulfur content, which is now being tested in a coal-fired power plant. Vartsky *et al.* (4) have developed and are using a portable system based on a ^{238}Pu–Be neutron source for *in vivo* determination of Cd concentration in human kidneys and livers. It is being used to screen workers in industrial jobs that subject them to high exposure to Cd.

In general, beams of neutrons from reactors are easier to use than the neutrons from an isotopic source because the latter usually have lower fluxes which vary with distance from the source, as does the thermalization of the energy spectrum. Furthermore, to maximize sensitivity, one generally needs to use a large sample volume, which makes the effective geometry for γ-ray detection a complex function of neutron flux and thermalization. For these reasons, fundamental studies of potential applications of portable systems can be done more easily with neutron beams from reactors. Results of these studies will indicate the maximum number of elements that are likely to be observed with portable systems, and the best accuracy, sensitivity, and limits of detectability achievable. These results would allow a decision to be made as to whether or not it would be worthwhile to attempt development of a portable system for the intended application.

As noted, some potential applications of portable PGAA are in the construction industry, e.g., for quality control in plants that manufacture construction materials such as cement and steel or at construction sites, where contractors or inspectors might wish to monitor the quality of steel beams or concrete prior to or after installation. In order to determine the possible applicability of portable PGAA to these problems, we have used reactor-based PGAA to analyze samples of concrete and its ingredients as well as several types of steel.

Experiment

Cement, sand, aggregate, and concrete were obtained from construction sites of the Washington Public Power Supply System (WPPSS). The sand and aggregates (rock with a size range of 0.6–1.2 cm) used in the WPPSS concrete were obtained from along the Columbia River. The concrete samples were from test borings of shielding concrete intended for use at the WPPS power reactors. Samples for PGAA were prepared by forming ~1-g pellets of concrete, cement, and pulverized aggregate in a high pressure press and sealing them in Mylar bags. Sand would not form pellets and was placed loose in the Mylar bags. The steel samples were also formed into rather loose pellets to yield a geometrical configuration for which

neutron self-shielding corrections could be calculated. The steel pellets had masses of 1.5 to 3 g.

The Mylar bags containing the samples were suspended in the center of Plexiglas sample holders with nylon fishing line to minimize the mass of material in the neutron beam. The sample holders were placed at a 45-degree angle with respect to the beam and to the axis of the Ge(Li) detector collimation system which is perpendicular to the beam. As described elsewhere (1, 5), the PGAA system uses a vertical beam on the top of the National Bureau of Standards (NBS) reactor. The neutron beam has a flux of about 2×10^{8} n/cm^{2}-s over a 3-cm diameter and a Cd (Cu) ratio of about 55. Samples were irradiated for up to 2 h and the spectra were obtained with a Ge(Li) detector of about 24% efficiency (relative to a 7.6- × 7.6-cm NaI crystal) surrounded by a large split-annulus NaI crystal that could be operated as an anti-Compton shield or pair detector. Spectra were stored and interpreted using a Tennecomp TP-5000 multichannel analyzer system based on a Digital Equipment Corp. PDP 11/34 minicomputer.

Typical spectra observed with the PGAA are given elsewhere (1, 5), as well as lists of the γ-rays used for the assay of the various elements. Concentrations of observed elements were determined by relating the areas of up to 5 peaks for each element to those of standards of the pure elements or simple compounds of them, with corrections for any flux changes based on the count rate observed with a Cr standard before or after irradiations of samples and other standards. In order to monitor the performance of the PGAA system, samples of standards for crustal materials were analyzed along with the samples: International Atomic Energy Agency standard soil, IAEA Soil 5, and the U.S. Geological Survey (USGS) standard rock, BHVO-1 (Hawaiian Basalt). In the case of the steels, the NBS Standard Reference Material SRM 1155 Steel was used as the standard for V, Mn, Fe, Co, Ni, and Mo. We used separate standards for Ti and B, whose concentrations are not certified in SRM 1155. To monitor the performance of PGAA for these samples, we also analyzed SRM 123C Steel. Table 1 presents the photopeak energies (and source nuclide) used for analysis in these samples. Note that delayed γ's were used for Al, V, and Mn, and that B is measured via the 477.6 keV γ-ray of ^{7}Li resulting from the ^{10}B(n,α) reaction.

Results

Results of analyses of the soil and rock standards are listed in Table 2. The errors expressed represent the combined procedural and statistical uncertainties in the case where a single photopeak was used. Where more than one photopeak was analyzed, the error represents the standard deviation of the results obtained from these combined with the procedural error. There is agreement within limits of error for all certified values in IAEA Soil 5. This is reasonable agreement with the information values with the major exceptions of B, Gd, and Si. Our value for B is surely the more accurate as our PGAA results for B in many standards have been quite reliable (1). Similarly, PGAA results for Gd are normally very accurate and the information value for Gd is surely much too high, as Sm and Gd concentrations are found to be almost equal in most crustal materials. We suspect that the Si information value is too high. Note that with PGAA, we observe all major and minor elements that are normally measured by geochemists except phosphorus (whose concentration is usually much less than 1%). As the concentration of oxygen is not usually measured, geochemists traditionally account for it by expressing concentrations of the elements in terms of their common oxides (e.g., Al_2O_3, Na_2O, etc.). We use the same method on PGAA data for crustal samples and are usually able to account for 96 to 100% of the sample mass (1). The major ambiguity of this approach for PGAA data is that we cannot distinguish between FeO and Fe_2O_3, which are both determined in wet chemical analyses. In soil, we feel it is safe to assume that the Fe is present as Fe_2O_3. Applying this method to both sets of data, we account for 98% of the soil mass with PGAA, whereas the IAEA data yield 104%, probably because of too high a Si value. Note that in summing the concentrations from PGAA, we are missing small contributions of mainly C and P_2O_5.

Concentrations are not certified in USGS standard rocks. Instead, compilations of data from various laboratories are used to establish accepted values. Except for the B value based on an earlier observation from our laboratory, the agreement of the present results with the data compiled by Gladney and Goode (6) is excellent.

Results of PGAA of the cement, sand, aggregate, and concretes are listed in Table 3. With PGAA we are able to determine concentrations of 20 to 23 elements in these types of samples. Except for the WPPSS sand (for which we suspect a weighting error), the summations of oxides are between 96 and 100%.

A major question in the studies of these materials is that of finding if one can determine the amounts of cement, sand, aggregate, and water present in the concrete on the basis of elements measurable with PGAA. We have made this test by normalizing the sand concentrations to 100% and then attempting to find a linear combination of the constituents that will sum to the average composition of the two WPPS concretes, with the results summarized in Table 4 for elements measured in all but water, which we assume is pure.

As shown in Table 4, we can make quite a reasonable fit to the composition of concrete with a mix of 4% H_2O, 20% cement, 38% sand, and 38% aggregate. There is little uncertainty in the 20% figure for cement, as the concentrations of many elements are quite different in cement from sand and aggregate: B, Na, Al, Si, Ca, Ti, Sm, and Gd. The water content is fixed rather firmly by the residual H after that from the other components is included. However, concentrations of the elements determined by PGAA are so similar in sand and aggregate that we cannot determine their relative contributions to the concrete. This point is emphasized in Table 4, where we show the range of concentrations obtained for sand contributions at the extremes of 0 and 76%. Unfortunately, differences in predicted concentrations in the concrete are so small that we cannot determine the sand/aggregate ratio. The compositions of the sand and aggregate are very similar, probably because the sand formed from the aggregates in the same source region (along the Columbia River) by physical processes (erosion, freezing, and thawing) that caused little chemical modification. In general, one would expect sands to be somewhat different in composition from the aggregates used in concrete. The samples are being subjected to INAA at Pacific Northwest Laboratories in order to determine if there are greater differences for some trace elements that are not observable by PGAA.

In Table 5 are shown the results of the steel analyses. The agreement of our results with the certified values for SRM 123C is extremely good. For the steels we have simply summed the observed concentrations and find that we account for 98 to 100% of the sample masses. We see that PGAA provides very good analyses of steels that pick up nearly all elements whose concentrations determine the physical properties of the steels. The major exception to this is carbon, whose concentration has a strong effect on the properties of steel. We observe carbon with PGAA in materials that contain considerable amounts of it, e.g., coals, biological samples, but the sensitivity for carbon is too low to observe it in these steels.

Discussion

We have shown that, with irradiations less than 2 h, PGAA provides reliable analyses of concrete and its constituents for up to 18 elements and steels for 9 elements, which account for 98

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

to 100% of the masses of the steel samples. The elements observable would allow one to determine the water and cement contents of concrete, but the compositions of the particular sand and aggregate used in this study were so similar that we could determine only the sums of their contributions, but not their relative amounts. In general, there would probably be more difference between their compositions, so one could probably distinguish between them. The PGAA method can be used to observe nearly all elements that determine the properties of steel, the major exception being carbon. In general, the fluxes of neutrons available from portable sources will be lower than those of the neutron beam; however, the effective masses of samples observable could be up to several kg in a field or plant operation, giving the possibility for similar analyses in few-minute periods.

Enhanced production of hydrogen, methane, and ethane from the γ-irradiation of hexamethyldisiloxane (MM) adsorbed onto silica compared to that from liquid MM results from energy transfer from the solid to the adsorbed layer. Chemical reactions with the surface are shown by deuterated products from the irradiation of MM on a deuterated silica and from extensive chemical cross-linking to the surface. These reactions predominate in the first monolayer of coverage.

K-S. MAENG, G. R. BROWN, G. J. TRUDEL et L. E. ST-PIERRE. Can. J. Chem. **61**, 729 (1983).

La production accrue d'hydrogène, de méthane et d'éthane observée lors de l'irradiation aux rayons-γ de l'hexaméthyldisiloxane (MM) adsorbé sur de la silice par comparaison avec les résultats obtenus avec du MM liquide provient d'un transfert d'énergie du solide à la couche adsorbée. On met en évidence des réactions chimiques avec la surface grâce à la formation de produits deutériés lors de l'irradiation du MM adsorbé sur de la silice deutériée et à partir d'une réticulation chimique importante de la surface. Ces réactions prédominent dans la première monocouche de matière.

The use of γ-irradiation to effect chemical cross-linking for the production of rubbers is well-known. Since solid filler materials are used to enhance the properties of the final rubber, the effect of their presence on the irradiation chemistry is of special interest in our preparation of "ideal" elastomers.

Studies of the decomposition by γ-radiation of organic and inorganic materials adsorbed on chemically inert mineral supports have shown that excitation energy delivered to the solid from the radiation can migrate to the surface and become available for decomposition of the adsorbate. This has been evidenced by the enhancement of radiolysis products in the presence of a solid substance. For instance, Rabe *et al.* (1, 2) have reported a twentyfold increase in nitrogen yield for the irradiation of azoethane adsorbed on MgO as compared to the yield from liquid azoethane. Large increases have also been reported in the total gas yields from irradiation of isopropyl benzene at low coverages on silica gel (3) and of N_2O adsorbed onto silica (4).

Chahal and St. Pierre (5) have shown conclusively that chemical reaction occurs between a siloxane and silica when the system is exposed to γ-radiation. Chemical reaction with the surface has also been demonstrated by the fact that 85% of the methane produced by the irradiation of CD_3I in the presence of silica is CD_3H (6).

The present study compares the radiolysis behaviour of pure hexamethyldisiloxane (MM), described previously (7), with that when it is adsorbed onto silica. Through this comparison a number of phenomena, including the energy transfer in the siloxane–silica system, can be defined quantitatively.

Experimental

The materials, irradiation methods, and some of the analytical methods used have been described previously (7, 8). Experimental methods specifically involved with the adsorbed species are described below:

Preparation of the samples

Silica (~2 g, Cabosil M-5, 200 m^2/g) was placed into a 50 mL flask and degassed at room temperature by pumping until the pressure remained unchanged at 10^{-6} Torr for 2–3 h. Previously deaerated MM was transferred into the flask in the amount required for the desired degree of surface coverage, as determined by calculations (9) based on previous studies in this laboratory (10). Hexagonal packing with a cross-sectional area of 78 $Å^2$ was assumed for the adsorbed MM molecules. The flask was sealed, under vacuum, and allowed to equilibrate overnight before irradiation.

Analysis of irradiation products

After irradiation the sample flask was reattached to the vacuum system using a side arm with a "break-seal". The flask was cooled to Dry Ice temperature and the gaseous products were collected and analyzed as described previously (7, 8). The "liquid" products were then distilled from the sample flask, at room temperature, to a trap cooled to liquid nitrogen temperature. These products were analyzed by vpc.

Measurement of chemisorption

After product removal, the samples described above were washed ~30 times with 10 mL aliquots of benzene to remove physisorbed material. After they had been heated at 150° for 24 h in a vacuum oven the samples were pressed into a disc for infrared analysis. From the intensity of the absorption band at 2960 cm^{-1} (due to methyl groups) compared to that prior to irradiation and the data from C—H analysis the nature and amount of material chemically attached to the surface could be obtained.

Deuterated silica

Some deuterated silica was prepared, by exchange with D_2O, to determine whether production of gaseous products involved reactions with the surface. This exchange was accomplished by adding D_2O, under vacuum, to the silica and repeatedly heating to 100°C and cooling to liquid nitrogen temperature. After the water had been removed, this procedure was repeated with another aliquot of D_2O. The extent of deuteration was determined by ir, from the relative intensities of the absorption bands at 3750 and 2760 cm^{-1}, due to OH and OD groups, respectively, on the silica surface.

Results and discussion

Uniform coverage of the surface by the physisorbed MM was

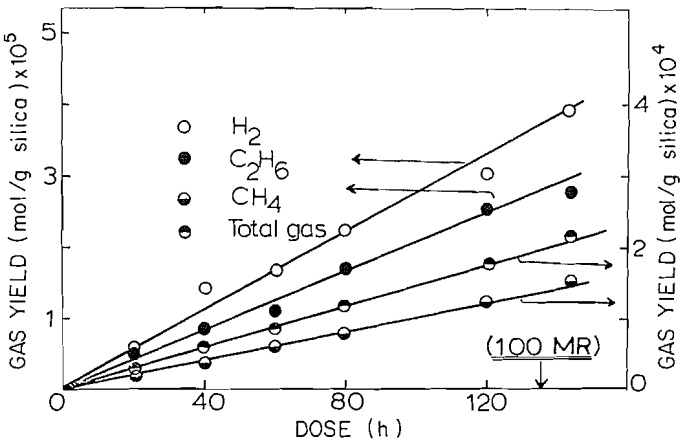

FIG. 1. The effect of radiation dose on gas yields from one monolayer of MM on silica (dose rate = 0.74 Mrad/h).

TABLE 1. *G* values for gas yields from pure MM and from MM on the silica at one monolayer coverage

Gas	Pure MM	Monolayer MM on silica
H_2	0.65	5.34
CH_4	2.22	18.4
C_2H_6	0.35	3.98
Total	3.22	27.7

assumed in the treatment of results. Calculation of the radiation dose received was on the basis of the adsorbed organic layer only. However, when discussing energy transfer, the energy absorbed by the inorganic fraction is considered.

1. *Effect of dose*

A. *Gas products from one monolayer*

The gaseous products of the irradiation of a monolayer of MM adsorbed onto silica are the same three, H_2, CH_4, and C_2H_6, produced by irradiation of pure liquid MM (7). The yields increase linearly with increasing dose up to 106 MR (Fig. 1). The *G* values, calculated from the slopes, along with the *G* values for production from pure MM are in Table 1. The yields of H_2 and of CH_4 are approximately 9 times greater than the yields from pure MM while the C_2H_6 yield is ~11 times greater.

Since MM adsorbed on to silica does not yield gases in the absence of irradiation, even after very long contact times, transfer of considerable radiation energy from the silica to MM is apparent.

B. *Liquid products from one monolayer*

At monolayer coverage of MM on silica the number of liquid products is greatly diminished compared to those from irradiation of pure MM. Only —SiOSiCH$_2$CH$_3$[3] and octamethyltrisiloxane (MDM), are produced. The yields increase nonlinearly with increasing dose (Fig. 2) and the *G* values (Fig. 3) are not much different than those for pure MM (1.1 and 0.5, respectively (11)).

C. *Radiation induced chemisorption*

It is evident from Fig. 2 that the total yield of the two liquid

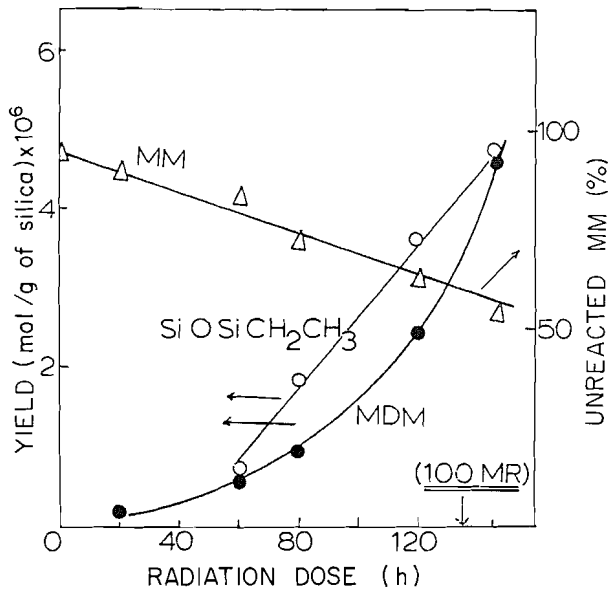

FIG. 2. The variation in the amount of unreacted MM and of the yields of liquid products from the irradiation of one monolayer of MM on silica with dose (dose rate = 0.74 Mrad/h).

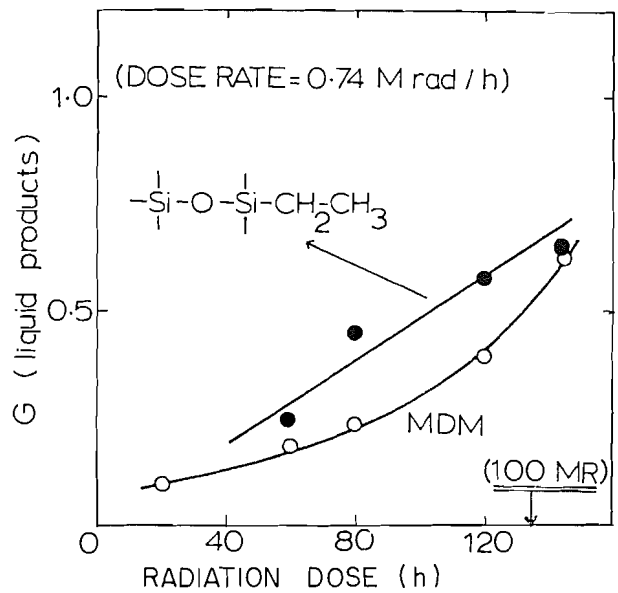

FIG. 3. The dependence on dose of the *G* values for liquid products from the irradiation of one monolayer of MM on silica.

products, at 100 MR, accounts for only 4.5% of the MM reacted (47%). This suggests that much of the MM, or its fragments, reacts in another manner. Accordingly, ir analysis of the washed and devolatilized silica from the irradiation was undertaken, as described in the Experimental section, to determine the degree of chemisorption or "cross-linking to the surface".

The *G* value and yields of MM chemisorbed as function of dose for one monolayer of physisorbed MM are illustrated in Fig. 4. A correction was made for the minute amount of chemisorption (6.5% of total material adsorbed after 10 days) that occurs in the absence of irradiation. Furthermore, in calculating the percentage MM chemisorbed from the amount of carbon present on the silica, the chemisorbed species was assumed to have the same carbon content as MM, specifically 44.4%. This is probably higher than the actual value, since the

[3]This "short" notation is used in this paper. The valence of all Si atoms is satisfied by the required number of methyl groups, thus —Si—O—Si—CH$_2$—CH$_3$ refers to (CH$_3$)$_3$Si—O—Si(CH$_3$)$_2$—CH$_2$CH$_3$.

TABLE 2. Deuterated gas yields from γ-radiolysis of one monolayer of MM on a deuterated silica surface

	Hydrogen			Methane			Ethane			
Product	H_2	HD	D_2	CH_4	CH_3D	CH_2D_2	C_2H_6	C_2H_5D	$C_2H_4D_2$	$C_2H_3D_3$
%	17.1	52.4	30.5	56.1	40.2	3.7	84.6	7.7	5.1	2.6
G (value)	4.55	13.91	8.04	5.94	4.26	0.39	1.35	0.12	0.08	0.04

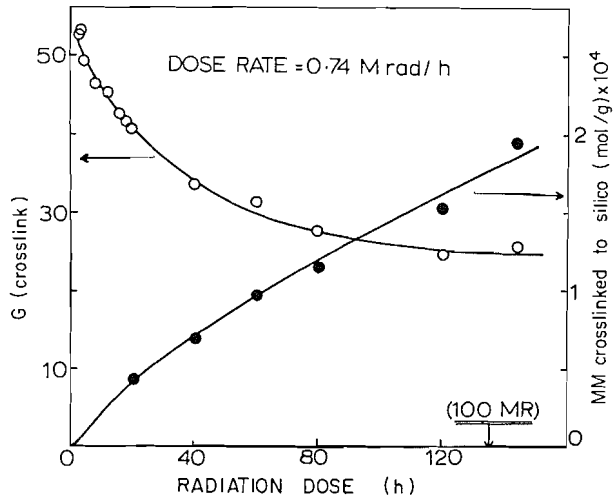

FIG. 4. The effect of radiation dose on the extent of cross-links to the silica surface during irradiation of one monolayer of MM on silica.

fragmentation patterns of pure MM indicate that the irradiation product undergoing chemisorption is probably one lacking a methyl group (40.8% carbon) or lacking a hydrogen atom (44.7% carbon) (12). The amount of MM chemisorbed on the surface increases with increasing dose but the G value for cross-linking to silica decreases with increased dose. This decrease is of course related to the diminishing concentration of unreacted MM with increased time or dose. The maximum coverage shown in Fig. 4 represents a chemical attachment of an MM fragment every ≈200 Å^2 of the silica surface. Based on an area of 78 Å^2 per MM the extent of surface coverage, θ, is ≈0.4.

D. *Chemical reactions at the interface*

That the silica surface is directly involved in the irradiation chemistry is also evident from the mass spectrometric analysis of the gaseous samples obtained from irradiating MM physisorbed on a silica surface which had been treated with deuterium oxide. Approximately 50% of the methane was produced as CH_3D, while 85% of the ethane was C_2H_6 with the remainder being composed of C_2H_5D, $C_2H_4D_2$, $C_2H_3D_3$ (Table 2).

2. *Effect of surface coverage*

For the study of product yields at surface coverages other than a monolayer, samples were prepared by admitting to a known quantity of silica sufficient MM to effect a calculated coverage assuming that all the MM was physisorbed. In the calculations the total MM present was used in calculating the energy absorbed in the organic phase.

A. *Gas products*

The effect of coverage on the yields and on the G values for the gaseous products is presented in Figs. 5 and 6. The G values for H_2 and CH_4 undergo a rapid and continuous decrease with increasing coverage suggesting that they are formed, at least in

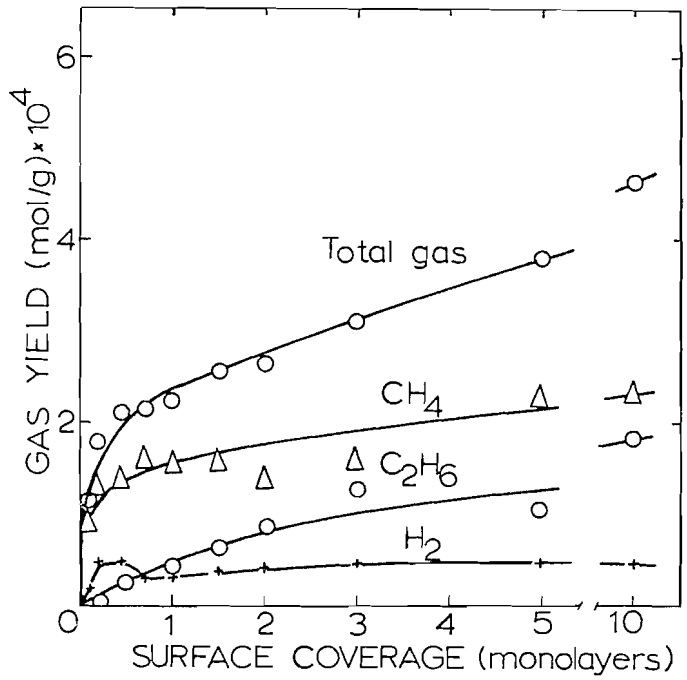

FIG. 5. The dependence on surface coverage of gas yields from the irradiation of MM on silica (dose = 106 Mrad).

part, by a reaction between the silica and the first layer of MM. This is the region where energy transfer to the MM can be expected to take place. The asymptotic approach of the curves to the abscissa shows that the maximum enhancement is realized below one monolayer. At greater coverage the yields approach those for MM in its liquid state.

On the other hand, ethane yields increase up to one monolayer coverage followed by a slight but continuous decrease thereafter. This suggests that although ethane formation is associated with the transferred energy it is not directly dependent on the presence of the silica as appears to be the case for H_2 and CH_4. This suggestion gains credence from the fact that at very low coverage ethane is not formed. This suggests that it is formed by the reaction of CH_3 fragments formed near the silica surface. At very low coverages these fragments react exclusively with the surface to form CH_4 resulting in the very high $G(CH_4)$. As the coverage increases a bimolecular reaction involving a methyl fragment and probably a parent MM molecule becomes more prominent.

From gas yields it is obvious that the highest percentage of energy transfer is realized at coverages well below a monolayer.

B. *Liquid products*

Liquid products were formed in detectable amounts only at one monlayer and above. At one monolayer the liquid products, shown in Fig. 2, were —Si—O—Si—CH_2CH_3 and MDM, with trace amounts of such cyclics as octamethylcyclotetrasiloxane (D_4) and decamethylcyclopentasiloxane (D_5).

At ten monolayer coverage, nine products were found (Table 3). Of the products formed, only the methyl addition product, —Si—O—Si—CH_2CH_3, is present in a yield approximating that from the liquid state. MDM, on the other hand, which is a product from a demethylated fragment, exhibits a tenfold increase over the yield from pure MM. Reference to Fig. 3 shows that the G value for this MDM increases with dose, suggesting that it is formed from reaction products of the initial irradiation event. These products may react either with the surface or with a MM molecule. As the dose increases the surface becomes less available because of the chemisorption and reaction with MM increases.

The fragmentation behaviour of MM (12) suggests the predominant ion fragment is —Si—O—Si^+. This ion can then undertake an electrophilic attack on an unreacted MM molecule yielding MDM.

$$—Si—O—Si^+ + —Si—O—Si— \rightarrow —Si—O—Si—O—Si— + —Si^+$$

Attack by the product ion Me_3Si^+ on MM will, however, result in an exchange with no new product formed. This can be assumed to continue until neutralization or reaction with the surface occurs. The presence of the silica and the energy transfer from that species enhances the yield of the initial ion and thus the yield of MDM. At higher coverages the competition of the MM with the surface for reaction with the initial ion is enhanced, with the resulting increased yields.

The sharply diminished yields in all other liquid products compared to those from pure MM, with the lowest yields being at low coverages, may be explained on the basis of competition at the surface. It seems surprising, however, that even at 10 monolayers the yield of dimer is only ~1/6 that from pure MM.

TABLE 3. Liquid products at ten monolayers of MM on silica[a] (dose = 106 MR)

Products	Moles ($\times 10^6$)	G values ($\times 10^2$) Ten monolayers MM	Pure MM

[a]MM (unreacted): 41.7%.

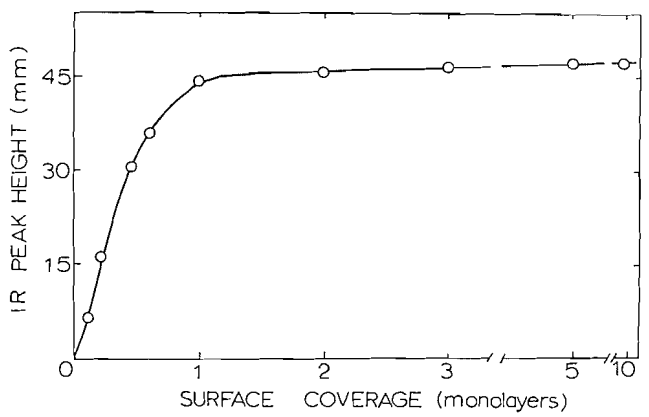

FIG. 7. The effect of MM coverage on the infrared absorption at 2960 cm^{-1} due to material cross-linked to the surface (dose = 106 Mrad).

C. *Chemisorption (fixed dose = 106 MR)*

Figure 7 gives the effect of coverage on the extent of chemisorption that occurs at a dose of 106 MR. These results, obtained by ir analysis of irradiated samples that had been treated as described previously, indicate that the major portion of the silica–MM reaction is between the primary layer of adsorbed MM and the silica.

At a coverage of 0.4 monolayer adsorbed, a maximum is obtained in the fraction of available MM that attaches to the silica (Fig. 8) after irradiation with 106 MR. This suggests that the process of energy transfer occurs only at specific sites on the adsorbent surface and that these are expended at a coverage in excess of 0.4 monolayer. The nature or origin of such centres is a matter of conjecture but will be discussed in a later publication.

It seems reasonable to assume that $G_{(\text{total gas observed})} - G_{(\text{total gas for liquid MM})} = G_{(\text{cross-links to silica})}$. At ten monolayer coverage the G value for total gas is 6.06 (Fig. 6) as compared to 3.22 for pure MM (11). On this basis $G_{(\text{cross-links to silica})}$ is equal to 2.84, which is an excellent agreement with the value of 2.79 obtained directly (Fig. 9). However, the G values for total liquid products at ten-layer coverage and for liquid MM are identical, i.e. 2.8. For pure siloxanes (MM) it is normally found that $G_{(\text{total gas})}$, $= G_{(\text{liquid product})}$ (13). That this is not so for adsorbed MM may be associated with the excess yield of MDM referred to previously. The G value of 2.79 for cross-linking to the surface is in good agreement with the G values found for cross-linking in other siloxane–siloxane systems, e.g.,

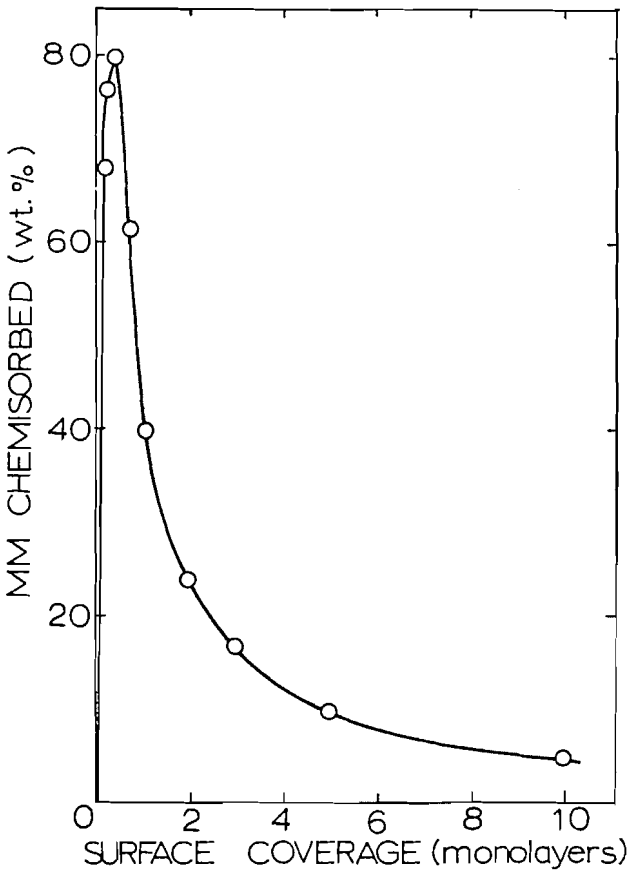

FIG. 8. Percent of initial MM chemically absorbed to silica due to irradiation as a function of surface coverage (dose= 106 Mrad).

2.5 ± 0.3 by Barnes *et al.* (14), 3.0 by Miller (15), and a value of 2.5 ± 0.4 found by St. Pierre *et al.* (13), and would undoubtedly reduce to that value at still higher coverages.

Summary and conclusions

This study of the irradiation chemistry of hexamethyldisiloxane adsorbed onto silica shows some product yields to be markedly enhanced by the presence of the silica while other products have sharply diminished yields. Control of the surface composition has allowed the determination of the interphase reactions occurring, while changes in extent of surface coverage have shown the enhancement to occur predominantly at the surface of the particle. Chemisorption to the surface of the silica is a major result of the irradiation of physisorbed MM. The effects of various parameters on the products and on the interaction between the MM and silica is interpreted on the basis of an energy transfer mechanism. Details of this mechanism will be described in a future publication.

These results will also be used to rationalize the structure and behaviour of elastomeric composites.

Introduction

Reports of the concentration of platinum group elements in the oceans are non-existent. On the basis of recent work it was concluded that the concentration of palladium was less than 4 ng/kg (1). Minute oceanic quantities combined with insufficiently sensitive analytical procedures have undoubtedly contributed to the neglect of this family of elements. The recent development of a kilolitre seawater sampling system (2) has stimulated our interest in oceanic species such as the platinum group that have heretofore eluded detection. Since the crustal abundance of palladium is considerably greater than that of the other platinum group elements, its search was favored as an entree to the subject.

The procedure involved separation of palladium with added bismuth carrier subsequently precipitated as a sulfide from volumes of seawater in the range 660–1680 L. The solids were collected on filter membranes, dissolved therefrom, and then activated with neutrons. After radiochemical purification the radiations from ^{109}Pd were measured by γ-ray spectrometry, a value from which the concentration of palladium in a sample was derived.

This report describes the results of such measurements with Pacific Ocean waters off the coast of California.

Experimental

Chemicals

Palladium carrier solution (9.63 mg/mL) and stock palladium standard solution (122 μg/mL) were prepared by dissolving 99.999% pure palladium in aqua regia and diluting with de-ionized water.

Bismuth carrier solution (4 mg/mL) was prepared by dissolution of 100.0% pure bismuth metal in dilute nitric acid.

Holdback carrier solutions used in radiochemical purification steps were 10 mg/mL of the ion of interest.

Other chemicals used were analytical reagent grade.

Isolation of palladium from seawater

Preliminary experiments with palladium radiotracer in 1 L volumes of seawater indicated that when seawater containing 10 or 20 mL/L of hydrochloric acid and 0.5 mg/L of bismuth is treated with hydrogen sulfide gas, the palladium is quantitatively recovered with the solid phase to the extent of 98.5 ± 4.2% and 94.7 ± 2.8% at the respective hydrochloric acid concentrations.

Separation of particulates from seawater

The separation of solids from seawater was achieved by forcing the fluid through a Hi Vol-60 filtration apparatus (Nuclepore Corporation, Pleasanton, California 94566) at 50 psi with a pump of fiberglass construction powered by a 7 Hp motor. An in-line flow sensor coupled to a batch controller affords measurement of accumulated volume.

The Hi Vol-60 consists of a stainless steel housing which is provided with plastic plates and screens that support up to 60 Nuclepore membrane filters each of which is 293 mm in diameter. With this apparatus certain solids in 3000 L of seawater have been separated in less than 15 min (2).

Samples and sample treatment

Seawater samples were obtained from a Naval Ocean Systems Center facility at the southern end of Pt. Loma, California whose main purpose was to provide large volumes of fresh seawater to tanks that supported marine life. The design was such that water flowed through a 24 in. diameter concrete pipe to a concrete-lined sump whose bottom was 25 ft below sea level. The sea-ward open end of the pipe was situated 760 ft from the shore line, 5 ft above the sediment and at mean-tide, 10 ft from the water surface. From the sump, a pump of stainless-steel construction transports the water to the shore-based tanks through 2 in. diameter polyvinyl chloride (PVC) tubing. Access to this water was available for this study through a shunt controlled with a PVC valve.

From the shunt water was collected in a 40 000 L fiberglass tank on two occasions (27 April and 8 July 1982). Upon accumulation of an appropriate volume, the seawater was immediately filtered through the Hi Vol-60 system fitted with membranes of 0.45 μm porosity. The filtrate was collected in a 3 400 L polyethylene-lined dolphin-holding tank. During this process concentrated hydrochloric acid was siphoned into the sample to give a final concentration of 10 mL/L. Mixing was assisted by the introduction of a stream of compressed air bubbles conducted through a manifold of submerged fritted glass discs. When

mixing was judged to be complete, the requisite quantity of bismuth carrier was introduced into the sample and homogeneity was attained through further mixing. The compressed air stream was then exchanged with a stream of hydrogen sulfide gas to precipitate bismuth sulfide. The precipitate was collected on either 30 or 60 Nuclepore membranes, depending upon the sample volume to be processed. Sample volumes ranged from 660–1680 L. The filtrate from the bismuth sulfide scavenged seawater was collected in another polyethylene dolphin-holding tank, to ultimately provide data on a blank. The volume of water used for the blank was 1400 L.

From 250–500 L fresh water was pumped through the Hi Vol filtration system from another holding tank containing water to remove residual sea salts.

The Hi Vol system was disassembled and the sulfide was dissolved from the surface of the filters by soaking each successively in a basin of freshly prepared aqua regia. The filters were then successively rinsed in another basin of distilled water.

The aqua regia and wash solution were combined and resulted in a volume of 3–3.5 L which was evaporated to a volume of 10 mL. About 25 mL of nitric acid were added and again the volume was reduced. This treatment was twice repeated. The final solution was transferred with concentrated nitric acid washings to two 14-mL polyethylene vials. A known weight of iron wire was affixed to each vial to serve as a flux monitor.

Blanks

The filtrate from bismuth sulfide scavenged seawater, after addition of bismuth carrier and hydrochloric acid equivalent to the quantities added initially, was processed in the manner described for samples.

A reagent blank consisted of 8 L of concentrated hydrochloric acid and 400 mg of bismuth carrier. This mixture, after evaporation to a volume of 10 mL, was prepared for irradiation by repeated nitric acid additions and evaporations, such that essentially all BiOCl was solubilized.

Irradiation and post-irradiation procedure

Samples, blanks, and standards (1.22 μg Pd) were irradiated for 2 h in the lazy susan compartment of the TRIGA nuclear reactor at the University of California, Irvine. The thermal neutron flux was 1.7×10^{12} neutrons cm^{-2} s^{-1}. After irradiation the solutions were transferred from their vials with hot nitric acid. One mL volumes of palladium, sodium, and copper carriers were added to the sample and blank solutions and successive evaporations to near dryness were performed with added nitric and hydrochloric acids.

Following dilution with 50 mL 0.4 *M* nitric acid the solutions were filtered to remove small amounts of BiOCl. A 4 mL volume of 1% dimethylglyoxime was added to each solution and after precipitation of the palladium dimethylglyoximate, the chelate was filtered and washed with 0.4 *M* nitric acid in a sintered glass crucible. The chelate was dissolved in hot concentrated nitric acid and evaporated to dryness.

After dissolution in 0.4 *M* nitric acid and addition of fresh sodium and copper carriers, the precipitation and destruction of the chelate was repeated twice more. The final residue was dissolved in 50 mL 1 *M* hydrochloric acid and hydrogen sulfide gas was bubbled through the solution for about 30 s. The palladium sulfide formed was filtered onto a 1-cm membrane filter, mounted on a 1-cm aluminum planchet, and covered with a thin Mylar film.

The irradiated palladium standards, after addition of palladium carrier, were reduced in volume to remove excess nitric acid and were then precipitated directly as the sulfide and mounted for measurement as described above.

Measurements

The 88 keV photopeak of palladium-109 was counted with a 38-cm^3 Ge (Li) detector linked to a 4096-channel pulse height analyzer. These data were transferred to a computer which provided the net counting rate for this nuclide. The decay of the photopeak was followed through several half-lives.

Flux monitors

The iron wire flux monitors were γ-ray counted with a NaI (Tl) well-type detector coupled to a scaler. ^{109}Pd counting rates were normalized for variations in flux.

TABLE 1. The concentration of palladium in a reagent and seawater blank and in seawater collected on two different dates corrected for the seawater blank

	Volume (L)	Pd concentration ($g/L \times 10^{-10}$)
Blanks		
Reagent	(800)*	0.79
Seawater	1400	0.98
Seawater		
27 April 1982	660	3.47
	990	0.52
	1680	2.37
8 July 1982	890	2.32

*The bismuth carrier and hydrochloric acid which comprised the reagent blank were in amounts equivalent to that added to an 800 L sample.

Palladium carrier recoveries

Sample, blank, and standard palladium sulfide precipitates and 0.5 mL volumes of palladium carrier comparators were transferred to 1.4 mL polyethylene vials after complete ^{109}Pd decay. The vials were irradiated sequentially for 1 min in the pneumatic tube assembly of the TRIGA nuclear reactor at full-power level. The initial ^{109}Pd activity measurements were corrected for chemical yield according to the palladium carrier counting rates.

Results and discussion

The carrier yield for samples and blanks ranged from 40–75% and the yield for the standards was about 97%. Further, with the irradiation schedule used about 700 counts min^{-1} μg^{-1} palladium are acquired in the photopeak area at the end of irradiation. Initial counting period of an irradiated sample was usually 15–30 min in duration and occurred about 6 h after the end of irradiation, a time at which less than 30% of the activity had undergone decay. Thus even for samples of the least activity, the counting error was of the order of 10%.

During the course of radiochemical purification γ-ray spectra were acquired. The major contaminants were ^{24}Na, ^{198}Au, and a 0.51 Mev photopeak which was probably attributable to the copper contaminant in the hydrochloric acid used to acidify the seawater samples. Repeated dimethylglyoxime precipitations were required to eliminate the tentatively identified ^{64}Cu, the other contaminants having been essentially decontaminated with the first purification step.

The decay of samples and blanks was consistent with the half-life of ^{109}Pd (13.5 h).

The concentration of palladium in blanks and seawater samples collected on two different dates appear in Table 1. The quantity of palladium in the reagent blank was 0.79×10^{-10}g/L-equiv. The relative contribution of hydrochloric acid and bismuth salt to this value was not established. The bismuth sulfide scavenged seawater blank (0.98×10^{-10} g/L) was only slightly greater than the reagent blank. This result indicates that manipulations involved in sample treatment from the time of collection up to preparation for irradiation are essentially noncontaminating.

The palladium concentration in four seawater samples, after subtraction of the seawater blank, averaged $2.17 \pm 1.22 \times 10^{-10}$ g/L. The magnitude of the standard deviation is attri-

butable to an inordinately low value of 0.52×10^{-10} g/L for the 990-L sample. The basis for this discrepancy is not understood. During the course of this study adsorption of activated palladium on the surface of the irradiation vials was encountered; however, this source of error was obviated by rinsing the vials with hot nitric acid which effects quantitative desorption. Other explanations such as non-quantitative bismuth sulfide precipitation or collection are considered remote.

The average palladium value is within the range reported for the concentration of a number of the rare earth elements, indium and scandium (3). These appear to be the least concentrated of the non-radioactive elements in seawater. Although factors such as seawater speciation which is principally carbonate for rare earths, hydroxide for indium and scandium (4), and probably chloride for palladium make a comparison uncertain, it appears that only in the case of palladium is a low crustal abundance, 0.01 gt^{-1} (5), accompanied by a low seawater concentration.

Acknowledgement

We thank John Ruffoni, a San Diego State University student, for his assistance in the operation of the large volume sampler to separate bismuth sulfide from seawater.

Received September 17, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

D. F. R. GILSON, G. GOMEZ, I. S. BUTLER, and P. J. FITZPATRICK. Can. J. Chem. **61**, 737 (1983).

The barriers to cyclopentadienyl ring rotation in the solid phase have been measured by spin-lattice relaxation time methods for the organometallic complexes $CpMn(CO)_3$ (7.24 kJ mol^{-1}), $CpRe(CO)_3$ (7.15 kJ mol^{-1}), and $CpV(CO)_4$ (7.07 kJ mol^{-1}), where Cp = η^5-C_5H_5. Nonbonded atom–atom potential calculations of the barriers in these complexes and in $BzCr(CO)_3$ (Bz = η^6-C_6H_6) show that the molecular conformation of the Mn and Re compounds is determined by crystal packing forces and that concerted ring motions are possible for the cyclopentadienyl complexes, but not for the benzene chromium tricarbonyl.

D. F. R. GILSON, G. GOMEZ, I. S. BUTLER et P. J. FITZPATRICK. Can. J. Chem. **61**, 737 (1983).

Faisant appel aux méthodes de temps de relaxation spin-réseau, on a mesuré les barrières à la rotation du cycle du cyclopentadiényle en phase solide des complexes organométalliques $CpMn(CO)_3$ (7,24 kJ mol^{-1}), $CpRe(CO)_3$ (7,15 kJ mol^{-1}) et $CpV(CO)_4$ (7,07 kJ mol^{-1}) où Cp = η^5-C_5H_5. Des calculs de barrières de potentiel entre atome et atome non liés, dans ces complexes et dans le $BzCr(CO)_3$ (Bz = η^6-C_6H_6) montrent que la conformation moléculaire des composés du Mn et du Re est déterminée par les forces d'entassement du cristal et que les mouvements concertés de cycle sont possibles pour les complexes du cyclopentadiényle, mais non pour le benzène chrome tricarbonyle.

[Traduit par le journal]

Introduction

There has been a revival of interest in recent years in the long-standing controversy over the possible bonding modes of the cyclopentadienyl ligand in organometallic π-complexes (1, 2). In most cases the carbon–carbon bond lengths within the cyclopentadienyl ring appear to be equal, but occasionally distortions of the ring geometry are reported and interpreted in terms of contributions from "allyl-ene" or diene structures having C_{2v} symmetry arising from preferential interaction of one of the two degenerate Cp ring π-orbitals with the metal *d* orbitals (3–8). Perhaps the most convincing evidence to date has been presented for complexes containing penta-methyl or penta-chloro substituted cyclopentadienyl ligands where the librational motion of the ring is damped compared with that of the unsubstituted ligands (3, 4, 6). For unsubstituted cyclopentadienyl rings, recent X-ray studies on the rhenium (7) and manganese (8) tricarbonyl complexes, including a low temperature study[2] on the latter, have clearly shown the presence of bond length variations.

Confirmation of such bonding patterns for the cyclopentadienyl ligand via X-ray crystallography requires precise structural studies which include appropriate rigid body librational analyses and corrections to the observed bond distances for thermal effects. Despite the obvious connection between cyclopentadienyl ring motion and these librational effects there has been relatively little attention paid to the dynamics of ring rotation in the solid state. Nuclear magnetic resonance line-width and second moment studies generally do not exhibit line broadening transitions down to 77 K, the lowest temperature easily accessible in such experiments, and thus the barrier to the ring rotation must be less than 12 kJ mol^{-1} (9). Spin-lattice relaxation time measurements have been more profitable and rotational barriers have been reported for Cp_2Fe (10, 11), Cp_2Ru (10, 11), Cp_2TiCl_2, (10), Cp_2MoCl_2 (12), $CpTiCl_3$, $Cp_2Mo_2(CO)_6$, and Cp_2TiS_5 (13). In addition, several less orthodox techniques have been applied. The ^{13}C chemical shift anisotropy in several cyclopentadienyl complexes is averaged by ring rotation at 77 K so that the barriers could not be determined (14), but for the heavily substituted decamethylferrocene, $(\eta^5\text{-}C_5Me_5)_2Fe$, the motion is limited at low temperature permitting the measurement of a barrier of 13.5 kJ mol^{-1} (15). Bennet *et al.* (16) have analysed the X-ray data from several organometallic complexes and derived barrier heights assuming a form for the potential function. Eisenberg *et al.* (17) have employed mechanical spectroscopy to study reorientational behaviour of some cyclopentadienyl platinum complexes dissolved in a polystyrene matrix.

The theoretical studies of molecular conformation and rotational barriers in transition metal complexes have been reviewed by Albright (18). Low barriers are predicted to occur for η^4-cyclobutadienyl – ML_3, η^5-cyclopentadienyl – ML_3, and η^7-cycloheptatrienyl – ML_3 complexes. Such calculations refer, of course, to the electronic contribution to the internal barrier and in the solid phase this will be augmented by intermolecular contributions and the molecular conformation will be affected by crystal packing forces.

Fyfe and co-workers (11) have applied nonbonded, atom–atom potential calculations to ferrocene, ruthenocene, and bis(benzene)chromium(0) complexes and, although their calculations for ferrocene were based upon the wrong crystal structure (19, 20), they demonstrated that this technique can provide useful information on the origin and magnitudes of the various contributions to the rotational barriers. In view of the interest in the structure and conformation of transition metal complexes, we have undertaken spin-lattice relaxation time measurements on cyclopentadienyl complexes of manganese

and rhenium tricarbonyl, for which precise crystal structures are available (7, 8), and the vanadium tetracarbonyl analogue, together with nonbonded atom–atom potential calculations on these compounds and on (η^6-benzene)tricarbonylchromium(0) for which an experimental determination of the barrier to rotation has been reported (21).

Experimental

Tricarbonyl (η^5-2,4-cyclopentadien-1-yl)manganese(I) was a generous gift from Ethyl Corporation. The analogous rhenium complex was prepared by a modification (7) of the procedure reported by Green and Wilkinson (22). Tetracarbonyl(η^5-2,4-cyclopentadien-1-yl)-vanadium(I) was purchased from Strem Chemical Co. and recrystallized from CH_2Cl_2, then sublimed *in vacuo* (10 Torr/40°C). Spin-lattice relaxation times were measured at 33 MHz using a Spin-Lock CPS2 pulsed nmr spectrometer. A 180° – τ – 90° pulse sequence was used and the free induction decays captured on a Biomation 805 transient recorder and then plotted on a strip-chart recorder. The sample temperature was controlled by a flow of cooled nitrogen gas and measured (±1 K) using a copper/constantan thermocouple and digital thermometer.

Atom–atom potential energy calculations were performed using programs written in these laboratories.

Results and discussion

Spin-lattice relaxation time measurements

The experimental T_1 versus reciprocal temperature plots are shown in Fig. 1 for $CpMn(CO)_3$, $CpRe(CO)_3$, and $CpV(CO)_4$. The solid curves were obtained by nonlinear least-squares fits of the data to equation [1]

$$[1]\quad \frac{1}{T_1} = \frac{2}{3}C\left\{\frac{\tau}{1+\omega^2\tau^2} + \frac{4\tau}{1+4\omega^2\tau^2}\right\}$$

where C is a constant related to the change in second moment of the resonance line, ω is the resonance frequency, and $\tau = \tau_0 \exp(E/RT)$ is a correlation time for the motion. This expression exhibits a minimum in T_1 when $\omega\tau = 0.62$. Such minima were observed for $CpMn(CO)_3$, 0.08 s at 105 K, and $CpRe(CO)_3$, 0.10 s at 99 K, but not for the vanadium tetracarbonyl compound at the lowest temperature studied (92 K) and therefore the "high" temperature limit of eq. [1], $\omega\tau \ll 1$, was used;

$$[2]\quad \frac{1}{T_1} = \frac{10}{3}C\tau$$

The T_1 plot for the rhenium complex showed a slight discontinuity in the region 150 to 170 K. This was possibly due to the presence of some diethyl ether which could not be removed during purification.

The results are listed in Table 1 and it can be seen that the barriers to rotation are approximately the same for the three cyclopentadienyl complexes: $CpMn(CO)_3$, 7.24 ± 0.20 kJ mol^{-1}; $CpRe(CO)_3$, 7.15 ± 0.40 kJ mol^{-1}; and $CpV(CO)_4$, 7.07 ± 0.16 kJ mol^{-1}. This result is not too surprising for the manganese and rhenium compounds since these are isostructural (7, 8) with similar packing densities. A comparison with the barrier for $CpV(CO)_4$ cannot be made at this time since the published crystal structure may not be correct (see discussion below).

Also included in the table are values of the barriers to rotation for other cyclopentadienyl complexes that have been measured by spin-lattice relaxation time methods. In the case of Cp_2MoCl_2 and Cp_2TiS_5 there are different barriers for different

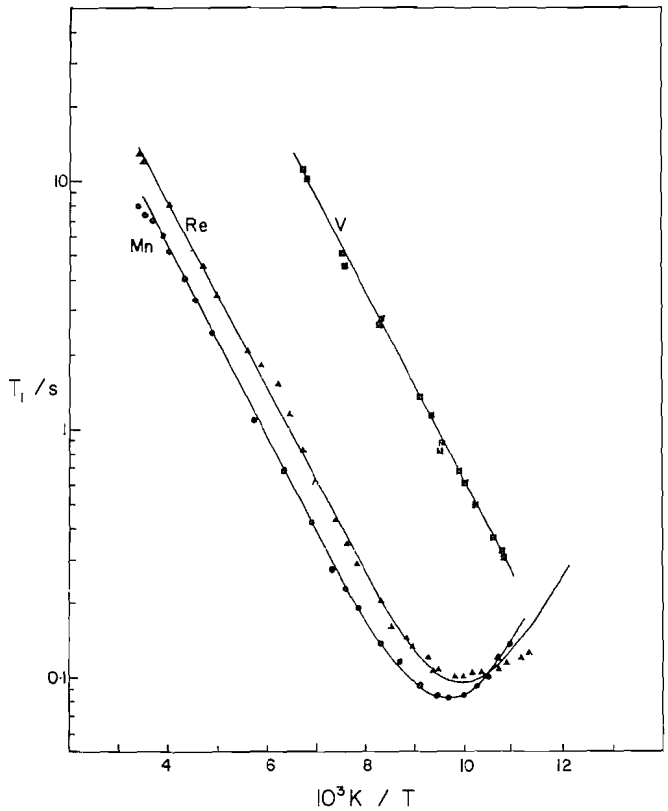

FIG. 1. Spin lattice relaxation time versus reciprocal temperature for $CpMn(CO)_3$, $CpRe(CO)_3$ and $CpV(CO)_4$.

rings which arise from either crystallographic or chemical inequivalence (12, 13). For molecules with "cylindrical" symmetry, i.e, the molecular symmetry axis and the five-fold axis of the ring coincide, the barriers all lie in the range 7–9 kJ mol^{-1}.[3] In X-ray structure determinations such low barriers will result in large anisotropic thermal parameters and thus complicate any attempts to determine small deviations in ring bond lengths. Studies at low temperature are, obviously, advisable for molecules of this type.

Atom–atom potential energy calculations

The energy of interaction between molecules in a solid is assumed to be an additive function of the individual interatomic terms and to depend only on the distance between the atoms. Thus by summing over all interactions within a given cut-off distance the lattice energy can be computed. If this is done as a function of the angle of rotation of a given molecule or group then the dependence of lattice energy on the angle gives the potential barrier for rotation. The "probe" molecule rotates within a rigid lattice, which may overestimate the barrier to rotation (see later discussion).

Various expressions have been used to describe the potential, in particular, the Buckingham (exp-6) and Lennard–Jones (12-6) functions, eqs. [3] and [4] respectively;

$$[3]\quad V(r) = Ar^{-6} + B\exp(-Cr)$$

$$[4]\quad V(r) = 4\epsilon[(\sigma/r)^6 - (\sigma/r)^{12}]$$

where A, B, and C or ϵ and σ are parameters characteristic of a given atom pair and are derived by fitting to experimental

[3]Ruthenocene is a particular exception.

data such as molecular or crystal structures, heats of sublimation, lattice energies, elastic constants, etc. It is assumed that each set of parameters is transferable from one system to another and that appropriate combining rules apply for heteroatomic interactions

$$A_{ij} = (A_{ii} + A_{jj})^{1/2} \; ; \; B_{ij} = (B_{ii} + B_{jj})^{1/2}$$

$$C_{ij} = (C_{ii} + C_{ij})/2$$

and, similarly,

$$\epsilon_{ij} = (\epsilon_{ii}\cdot\epsilon_{jj})^{1/2} \; ; \; \sigma_{ij} = (\sigma_{ii} + \sigma_{jj})/2$$

A large number of different parameter sets have appeared in the literature and Mirsky has reviewed the published data and proposed a set of recommended values (23). Not all the available parameters are suitable since the method of initial parametrization can impose constraints. For instance the choice of C—H distance of ca. 0.95 Å, typically found in an X-ray structure determination, is obviously not appropriate for use in cases where the constants were based on a bond length of 1.08 Å. While the parameters for carbon and hydrogen are fairly well defined, this is not true for oxygen. We have, therefore, arbitrarily chosen empirically derived functions for oxygen together with some of the more commonly used parameter sets since the primary aim of this study was not to determine new parameters but rather to explore the utility of the atom–atom potential method for examining the nature of the barriers.

The potential parameters are given in Table 2. Set I used the general values recommended by Mirsky (23), and sets II and III employed those given by Williams (24, 25) for C···C, H···H, and C···H interactions, based upon his calculations on hydrocarbons, coupled with the oxygen potential constants from Mirsky's review via the combining rules mentioned above. Set II includes the constants suggested by Boyd and Fyfe (26) as the most useful. Lastly, the carbon and hydrogen potentials of sets I–III were combined with parameters for oxygen derived from the empirical equation [5], suggested by Gavezotti and Simonetta (27), to give sets IV–VI.

$$[5] \quad V(r) = 30000 \exp(-13r/d_0) - 0.14\,(d_0/r)^6$$

where d_0 is the sum of the van der Walls radii of the two atoms involved in the potential. A Lennard–Jones potential was used for all interactions involving the metal atoms where the values of ϵ and σ were determined by calculating the lattice energies of several metal carbonyl complexes and comparing these with experimental enthalpies of sublimation. Since the effect upon the calculated barrier height of terms involving metal atom interactions was found to be very small, no further attempt was made to optimize these parameters and the same functions were used for all metals, Table 3.

The manganese and rhenium complexes have the same crystal structure, space group $P2_1/n$, with four molecules per unit cell which are all related by symmetry, and thus the calculations needed to be performed only for one molecule. To

TABLE 4. Calculated barriers[a] to rotation of the Cp ring (kJ mol^{-1})

Parameter set	$CpMn(CO)_3$	$CpRe(CO)_3$
I	11.3	13.0
II	17.6	20.0
III	11.7	13.4
IV	8.8	9.6
V	13.4	14.2
VI	7.9	9.2
Experimental	7.24	7.15

[a]Intramolecular contribution = 0; electronic contribution = 0. The barrier for the $M(CO)_3$ moiety was calculated to be a minimum of 50 kJ mol^{-1} and therefore this group was considered to be rigidly fixed in the lattice.

simplify the computation, idealized symmetric ring coordinates were used rather than the crystallographically determined atomic positions. A cut-off distance of 8 Å was used to save computation time.

The results of the calculations for the manganese and rhenium complexes are given in Table 4. The rather surprising result for the vanadium tetracarbonyl complex was that no significant barrier to rotation occurs. The crystal structure of this compound was reported by Wilford *et al.* (28) to be orthorhombic with four molecules per unit cell, each required to have mirror symmetry. The position of the carbon atoms of the ring was best described by a disorder among two equally preferred orientations rotated by 36° with respect to each other. The existence of the mirror plane would, in fact, lead to a zero barrier height. The electronic barrier in a $CpML_4$ system is expected to be extremely small (29), and therefore it seems likely that the disorder in the crystal has led to an incorrect structure. It is possible that our T_1 measurements were made on a different crystal form or that a phase transition occurs in this compound. In any event a re-examination of the crystal structure of cyclopentadienylvanadium tetracarbonyl appears to be worthwhile.

For the tricarbonyl complexes there is no intramolecular barrier arising from nonbonded interactions and the total potential is entirely intermolecular in origin. From Table 3 it can be seen that parameter sets IV and VI gave barrier heights closest to the experimental values in both cases. The potential functions suggested by Mirsky gave poor agreement, which is somewhat disappointing as these are intended to be the most consistent set and transferable from one system to another.

The major contributions arise from C—H and O—H interactions which together comprise over 80% of the total in all cases. It appears that the parameters used for oxygen and the Williams parameters used in sets II and V are too attractive, although it must be emphasized that it is the rotational barriers that are being compared and not the total lattice energy. The parameters cited by Mirsky for oxygen may not be suitable for carbonyl groups in organometallic complexes of this type. The choice of the Simonetta function has, however, led to quite good agreement. In Fig. 2 the data for $CpMn(CO)_3$, obtained with set IV, are used to illustrate the use of these calculations to derive information on the origin of the barrier. The figure shows the breakdown of the potential into contributions from ring–ring and ring–carbonyl interactions. A significant contribution, about 40–45%, arises from ring–ring terms (the same conclusion can be drawn from all the parameter sets). In calculating the angular dependence of the lattice energy the "probe" molecule or group is rotated in an otherwise rigid

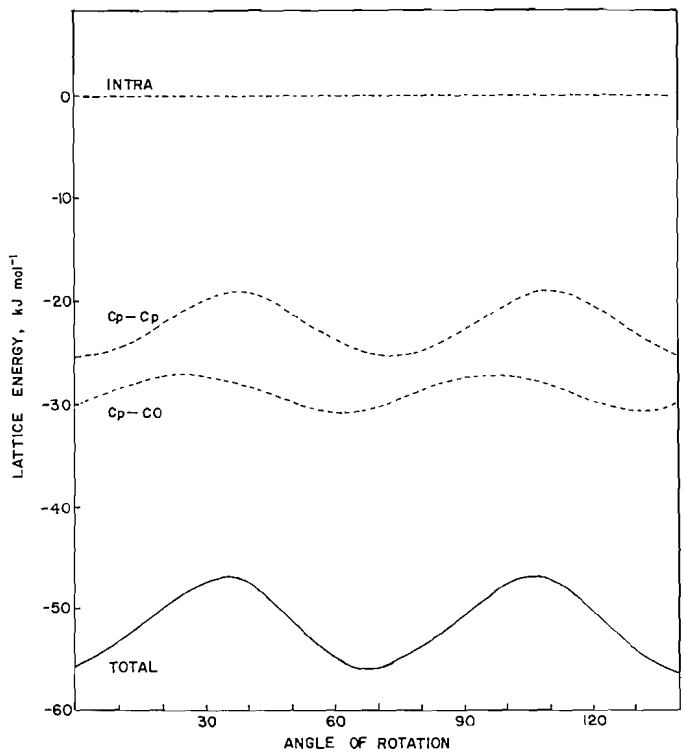

FIG. 2. Angular dependence of the calculated lattice energy for $CpMn(CO)_3$ using parameter set IV.

lattice. This procedure does not take into account the possibility of any cooperative or correlated motion of the reorienting species. An examination of the different contributions shows, however, that ring–ring interactions are very important and therefore close agreement between calculated and experimental barrier heights might not be expected in such cases. In their study of the application of the atom–atom potential method to rotational barriers and lattice energies in planar aromatic hydrocarbons Fyfe and co-workers (30) concluded that the justification for the neglect of concerted motions lies simply in the fact that agreement is obtained between calculation and experiment. This point will be discussed later in more detail.

The actual minimum in the calculated potential for both the manganese and the rhenium complexes does not occur at exactly 0° but is shifted slightly, i.e., the input coordinates are not, apparently, the equilibrium position. Part of the discrepancy may be due to the fact that the input coordinates were modified to an ideal symmetric structure but the separate contributions from ring–ring and ring–carbonyl sources do not themselves have minima at zero angle of rotation. Since there is no internal barrier the molecular conformation depends entirely upon the crystal packing forces and a balance is achieved by rotations of the two halves of the molecule in opposite directions. This is very sensitive to the form of the potential functions and the input coordinates.

The $BzCr(CO)_3$ molecule (Bz = η^6-C_6H_6) seemed to us to be an excellent choice for further testing the atom–atom potential method. The conformation in the crystal is staggered, with the possibility that there is some localization of the bonding in the aromatic ring such that the C—C bonds *trans* to the carbonyl groups are slightly shorter (31). Albright *et al.* (32) have calculated that an electronic barrier to rotation of about 1.3 kJ mol^{-1} exists for the delocalized structure and 81 kJ mol^{-1} if the

TABLE 5. Calculated barriers to rotation of the benzene ring (kJ mol^{-1})

[b]Reference 21.

bonding is completely localized. The activation energy for benzene ring rotation in the solid phase has been measured by Delisle *et al.* (21), using spin lattice relaxation times, to be 17.6 kJ mol^{-1}. Thus this complex provides a system in which the same atom types occur as in the cyclopentadienyl compounds but where the experimental barrier is much larger and includes an internal component with an electronic contribution.

The lattice energies were calculated using the same parameter sets with the crystal structure data of Rees and Coppens (31). The results are given in Table 5. When the total barrier is considered, i.e., the calculated electronic contribution is included, the best agreement with experiment is again found for parameter sets IV and VI. Fig. 3 shows the angular dependence for the total nonbonded atom–atom potential divided into intra- and intermolecular contributions and also into ring–ring and ring–carbonyl dependences. The ring–ring contribution shows almost no angular dependence and thus there is probably no correlated rotation in this complex. The intramolecular barrier is about 1 kJ mol^{-1} which, when added to the calculated electronic value of 1.3 kJ mol^{-1}, is in good agreement with the value of 2.1 kJ mol^{-1} derived from the electron diffraction study (33). The calculated potential shows no shift in the potential from the input coordinates.

The agreement between the experimental and calculated barrier heights for the cyclopentadienyl complexes, where no internal barrier occurs and there is a strong possibility of concerted motion of the rings, and for the benzene ring rotation, where there is a moderate internal barrier and no strong ring–ring interaction, seems to indicate that the neglect of cooperative motions may be justified. However, this conclusion is based only on the agreement for the barrier heights and not for the total lattice energies. The constants in the atom–atom potential functions are derived by fitting to physical properties of materials at or close to equilibrium lattice positions and are more sensitive to the shape of the potential function near its minimum. Rotation of the probe molecule leads to close contact distances with neighbouring molecules and a sensitivity to the repulsive part of the potential. This effect could be overcome if cooperative motions can occur. It is to be expected in such cases that the calculated barrier will be larger than the experimentally determined value. This is what is observed in the present study using parameter sets IV and VI. Alternatively, a potential function with a less steep repulsive term might be more suitable for calculations of barrier heights but would not give acceptable total lattice energies.

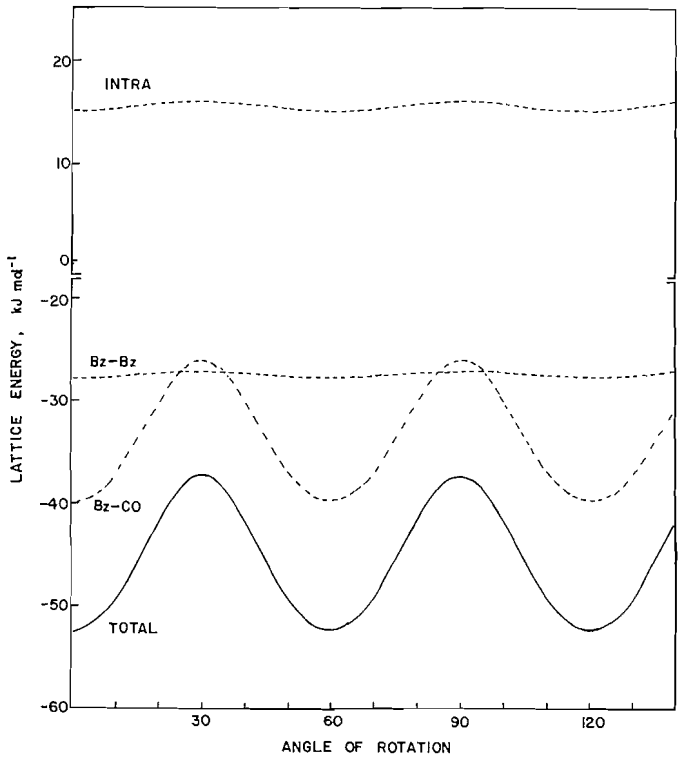

FIG. 3. Angular dependence of the calculated lattice energy for $BzCr(CO)_3$ using parameter set IV.

The preparation and properties of triphenyllead selenocyanate have been reinvestigated. Infrared spectra show that the solid is polymeric with strong Pb—Se and weak Pb—N bonds; in benzene or CH_2Cl_2 solutions ν(CN) values are consistent with the $Ph_3PbSeCN$ bonding mode. The first 1 : 1 adducts of triphenyllead selenocyanate with hexamethylphosphoramide (HMPA), pyridine-*N*-oxide (pyO), 4-picoline-*N*-oxide (4-picO), and triphenylphosphine oxide (TPPO) have been prepared; infrared data show that $Ph_3PbSeCN \cdot L$ (L = pyO, 4-picO, TPPO) are selenocyanates, but the HMPA adduct is an isoselenocyanate. The adducts dissociate in benzene and ν(CN) frequencies show that both N-bonded and Se-bonded adduct isomers are present. In contrast, the adducts $Ph_3PbNCS \cdot L$ (L = HMPA, pyO, 4-picO, TPPO) are N-bonded in the solid state and in benzene solution where they are undissociated. Amine adducts, $Ph_3PbNCS \cdot L$ (L = pyridine, β-picoline, γ-picoline, pyrrolidine (pyrrol), piperidine (pipy), cyclohexylamine ($CyNH_2$)) and $Ph_3PbNCS \cdot 2L$ (L = morpholine (morph)), as well as $Ph_3PbNCSe \cdot$ pipy and 2 $Ph_3PbNCSe \cdot 3L$ (L = pyrrol or morph) have been prepared, but these are less stable than adducts with O-donor ligands. Infrared data suggest that amine adducts of Ph_3PbNCS have N-bonded and/or ionic thiocyanate groups while all $Ph_3PbSeCN$—amine adducts contain the selenocyanate ion.

RYSZARD WOJTOWSKI, IVOR WHARF et MARIO ONYSZCHUK. Can. J. Chem. **61**, 743 (1983).

On a étudié de nouveau la préparation et les propriétés de sélénocyanate triphénylé de plomb. Les spectres infrarouges montrent que le solide est un polymère avec de fortes liaisons Pb—Se et de faibles liaisons Pb—N; dans des solutions de benzène ou de CH_2Cl_2, les valeurs de ν(CN) sont en accord avec le mode de liaison du $Ph_3PbSeCN$. On a préparé les premiers adduits 1 : 1 de sélénocyanate triphénylé de plomb avec l'hexaméthylphosphoramide (HMPA), la *N*-oxyde de pyridine (pyO), la *N*-oxyde de picoline-4 (picO-4) et l'oxyde de triphénylphosphine (TPPO); les données infrarouges révèlent que les $Ph_3PbSeCN \cdot L$ (L = pyO, picO-4, TPPO) sont des sélénocyanates, mais que l'adduit du HMPA est un isosélénocyanate. Les adduits se dissocient dans le benzène et les fréquences ν(CN) montrent que les isomères d'adduits liés par l'azote et liés par le Se sont présents. Par contre, les adduits $Ph_3PbNCS \cdot L$ (L = HMPA, pyO, picO-4, TPPO) sont liés par l'azote à l'état solide et en solution dans le benzène où ils ne sont pas dissociés. On a préparé les adduits d'amine, $Ph_3PbNCS \cdot L$ (L = pyridine, β-picoline, γ-picoline, pyrrollidine (pyrrol), pipéridine (pipy), cyclohexylamine ($CyNH_2$) et le $Ph_3PbNCS \cdot 2L$ (L = morpholine (morph)) ainsi que le $Ph_3PbNCSe \cdot$ pipy et le $2Ph_3PbNCSe \cdot 3L$ (L = pyrrol ou morph) mais ils sont moins stables que les adduits avec les ligands donneurs d'oxygène. Les données infrarouges suggèrent que les adduits d'amine du Ph_3PbNCS ont des groupes thiocyanates liés par l'azote et/ou une façon ionique tandis que tous les adduits du $Ph_3PbSeCN$—amine contiennent l'ion sélénocyanate.

[Traduit par le journal]

Introduction

While several reports of adducts of triphenyltin chalcocyanates with O- and N-donor ligands have appeared (1–4), as well as of diphenyltin isothiocyanate adducts (4–6), much less is known about adducts of phenyllead chalcocyanates. Following the report ten years ago of some anionic complexes, e.g. $Ph_3Pb(NCS)_2^-$ and $Ph_2Pb(NCS)_4^{2-}$ (7, 8), we began a study of adduct formation by phenyllead chalcocyanates, first reporting adducts of diphenyllead isothiocyanate (9) and then adducts of triphenyllead isocyanate (10). This series is now continued with consideration of adduct formation by triphenyllead isothiocyanate and selenocyanate, using NCX group frequencies, particularly ν(CN) and ν(CX), as criteria of bonding mode of the NCX group in both solid state and solution species.

Although triphenyllead isothiocyanate is well known, the selenocyanate analogue has been only partially characterized (11). We now report a more detailed study of this compound together with a convenient synthesis from the readily available starting material, triphenyllead acetate.

[1]Author to whom correspondence should be addressed.

Experimental

All solvents and liquid ligands were stored over molecular sieves, while solid ligands were used as received. Potassium selenocyanate (Aldrich) was used as quickly as possible after being received, while triphenyllead acetate (Alfa) was recrystallized from acetonitrile before use. Triphenyllead isothiocyanate was prepared previously (12). Microanalyses for C, H, and N were done by Guelph Chemical Laboratories Ltd., Guelph, Ontario, while molecular weights were determined by Spang Microanalytical Laboratory, Eagle Harbor, Michigan. Infrared spectra were recorded on a Nicolet-7199 interferometer fitted with a KBr beam splitter. Samples were studied as Nujol mulls or as solutions in 0.1 mm sodium chloride cells. Values of ν(CN) absorbances were obtained by direct integration of the absorbance spectra. The nmr (^{31}P) spectra were obtained as described elsewhere (13).

Preparations

Triphenyllead selenocyanate

Triphenyllead acetate (25.0 g) and potassium selenocyanate (10.0 g) were stirred in refluxing methanol (1.0 L) for 2.5 h. The turbid solution was filtered and left overnight in a refrigerator. The white crystals formed were filtered, washed with water, and air-dried. Further product was obtained by adding water (1 L) to the filtrate and letting the mixture stand for several hours; yield, 90%, mp 192°C

(dec.). *Anal.* calcd. for $(C_6H_5)_3PbSeCN$: C 42.0, H 2.8, N 2.6%; found: C 41.2, H 2.7, N 2.7.

Adducts of triphenyllead selenocyanate

Method A

Triphenyllead selenocyanate (I) was dissolved in a hot toluene solution of the solid ligand. On cooling the clear solution (filtered if necessary) overnight at room temperature (or in the refrigerator) the crystalline *adduct* formed.

Prepared in this manner were *$Ph_3PbSeCN \cdot TPPO$*, from I (1.0 g), TPPO (1.0 g) in toluene (8 mL); yield, 56%, mp 130°C. *Anal.* calcd. for $C_{37}H_{30}NOPPbSe$: C 54.1, H 3.7, N 1.7%; found: C 53.6, H 3.7, N 1.8; *$Ph_3PbSeCN \cdot pyO$*, from I (2.5 g), pyO (2.0 g) in toluene (70 mL); yield, 43%, mp 93°C. *Anal.* calcd. for $C_{24}H_{20}N_2OPbSe$: C 45.1, H 3.2, N 4.4%; found: C 45.3, H 3.1, N 4.5; and *$Ph_3PbSeCN \cdot 4\text{-}picO$*, from I (1.0 g), 4-picO (0.5 g) in toluene (50 mL); yield, 66%, mp 102°C. *Anal.* calcd. for $C_{25}H_{22}N_2OPbSe$: C 46.0, H 3.4, N 4.3%; found: C 46.0, H 3.4, N 4.3.

Method B

Triphenyllead selenocyanate (I) was dissolved in the hot liquid ligand. The crystalline *adduct* formed on allowing the clear mixture to stand overnight at room temperature (or in the refrigerator).

Prepared in this manner were *$Ph_3PbNCSe \cdot pipy$*, from I (1.0 g) in piperidine (6.0 mL); yield, 82%, dec. 100°C. *Anal.* calcd. for $C_{24}H_{26}N_2PbSe$: C 45.9, H 4.2, N 4.5%; found: C 46.1, H 4.3, N 4.7; *$2Ph_3PbNCSe \cdot 3morph$*, from I (1.0 g) in morpholine (6.0 mL); yield, 86%, dec. 105°C. *Anal.* calcd. for $C_{50}H_{57}N_5O_3Pb_2Se_2$: C 44.5, H 4.3, N 5.2%; found: C 44.3, H 4.4, N 5.3; and *$2Ph_3PbNCSe \cdot 3pyrrol$*, from I (2.0 g) in pyrrolidine (2 g); yield, 70%, dec. 77°C. *Anal.* calcd. for $C_{50}H_{57}N_5Pb_2Se_2$: C 46.1, H 4.4, N 5.4%; found: C 46.3, H 4.6, N 5.6.

Triphenyllead isoselenocyanate – hexamethylphosphoramide (1:1)

Adding pentane (10 mL) slowly to a stirred solution of I (2.0 g) in HMPA (8 mL) at room temperatures gave the crystalline adduct; yield, 90%, mp 92°C. *Anal.* calcd. for $C_{25}H_{33}N_4OPPbSe$: C 41.6, H 4.6, N 7.8%; found: C 41.7, H 4.8, N 8.0.

Adducts of triphenyllead isothiocyanate

These were obtained using Method A given above. Reactions of triphenyllead isothiocyanate (II) with amines often gave oils which could only be crystallized with some difficulty.

Prepared in this manner were *$Ph_3PbNCS \cdot TPPO$*, from II (1.65 g), TPPO (2.8 g) in toluene (50 mL); yield, 45%, mp 147–8°C (dec.). *Anal.* calcd. for $C_{37}H_{30}NOPPbS$: C 57.4, H 3.9, N 1.8%; found: C 57.9, H 4.0, N 1.7; *$Ph_3PbNCS \cdot pyO$*, from II (1.65 g), pyO (2.0 g) in toluene (50 mL); yield, 75%, mp 125–126°C. *Anal.* calcd. for $C_{24}H_{20}N_2OPbS$: C 48.7, H 3.4, N 4.7%; found: C 48.7, H 3.4, N 4.8; *$Ph_3PbNCS \cdot 4\text{-}picO$*, from II (1.65 g), 4-picO (2.0 g) in toluene (50 mL); yield, 80%, mp 109°C. *Anal.* calcd. for $C_{25}H_{22}N_2OPbS$: C 49.6, H 3.8, N 4.6%; found: C 49.5, H 3.7, N 4.5; *$Ph_3PbNCS \cdot py$*, from II (1.65 g), py (2.4 g) in toluene (30 mL); yield, 52%, dec. 180°C. *Anal.* calcd. for $C_{24}H_{20}N_2PbS$: C 50.1, H 3.5, N 4.9%; found: C 49.8, H 3.5, N 4.8; *$Ph_3PbNCS \cdot \beta\text{-}pic$*, from II (1.65 g), β-pic (6.4 g) in toluene (100 mL); yield, 70%, dec. 122°C. *Anal.* calcd. for $C_{25}H_{22}N_2PbS$: C 50.9, H 3.8, N 4.8%; found: C 51.0, H 3.7, N 4.7; *$Ph_3PbNCS \cdot \gamma\text{-}pic$*, from II (1.65 g), γ-pic (4.8 g) in toluene (50 mL); yield, 80%, dec. 123°C. *Anal.* calcd. for $C_{25}H_{22}N_2PbS$: C 50.9, H 3.8, N 4.8%; found: C 50.9, H 3.7, N 4.8. *$Ph_3PbNCS \cdot CyNH_2$*, from II (3.3 g), cyclohexylamine ($CyNH_2$) (10.0 g) in toluene (75 mL); yield, 75%, dec. 115°C. *Anal.* calcd. for $C_{25}H_{28}N_2PbS$: C 50.2, H 4.7, N 4.6; *$Ph_3PbNCS \cdot 2morph$*, from II (1.65 g), morpholine (27 g) in toluene (75 mL); yield, 85%, dec. 100°C. *Anal.* calcd. for $C_{27}H_{33}N_3O_2PbS$: C 48.3, H 5.0, N 6.3%; found: C 48.1, H 4.7, N 6.3; and *$Ph_3PbNCS \cdot pyrrol$*, from II (3.3 g), pyrrolidine (1.7 g) in toluene (50 mL); yield, 95%, dec. 133°C. *Anal.* calcd. for $C_{23}H_{24}N_2PbS$: C 48.7, H 4.3, N 4.9%; found: C 48.9, H 4.3, N 4.7.

Triphenyllead isothiocyanate – piperidine (1:1)

Triphenyllead isothiocyanate (1.65 g) was stirred with a refluxing toluene (100 mL) solution of piperidine (4.25 g) for 30 min. The mixture was then stirred at room temperature for 48 h, during which time the oil first formed changed to the crystalline *adduct*; yield, 97%, dec. 140°C. *Anal.* calcd. for $C_{24}H_{26}N_2PbS$: C 49.6, H 4.5, N 4.8%; found: C 49.4, H 4.4, N 4.8.

All adducts were filtered, washed with a little pentane or ether, and dried in vacuum at room temperature.

TABLE 1. Correlation of selenocyanate bonding type with selenocyanate vibrational frequencies (cm^{-1})

Bonding type	ν(CN)	ν(CSe)	δ(NCSe)
$NCSe^-$	2070[a]	558	424, 416
M—NCSe	2090–2050[b] br	650–600	460–410
M—SeCN	2130–2070[c] sp	550–520	410–370
M—NCSe—M	2150–2100	640–550	410–390

NOTE: Integral molar absorptivity ranges (solution spectra) are:
[a] $A_{CN} = (2-3) \times 10^4\ M^{-1}\ cm^{-2}\ (NCSe)^{-1}$
[b] $A_{CN} = (5-12) \times 10^4\ M^{-1}\ cm^{-2}\ (NCSe)^{-1}$
[c] $A_{CN} = (0.5-1.5) \times 10^4\ M^{-1}\ cm^{-2}\ (NCSe)^{-1}$

Results and discussion

The infrared spectra (1700–400 cm^{-1}) of all compounds showed the absorptions expected for the "Ph_3Pb" moiety as well as, for the adducts, ligand peaks including those shifted by ligand coordination to the lead atom. Of particular interest are frequencies for the NCS and NCSe group vibrations as these indicate the mode of coordination. Since the vibrational criteria for NCS bonding types were reproduced earlier (9), the similar criteria (14) for determining NCSe bonding type are now given in Table 1 for use in the discussion below. The ν(CN) ranges overlap considerably implying this criterion should be used with great caution. However, like ν(CS), ν(CSe) appears to provide a better distinction between M—NCSe and M—SeCN bonding modes. In addition, the ν(CSe) absorption is more easily observed since it is of weak to medium intensity and it often occurs in a region relatively free of other absorptions. The deformation modes, δ(NCSe), are less useful since they are weak, overlap with phenyl group bands, and sometimes occur beyond the spectral range (400 cm^{-1}), although the very weak overtones can be observed.

(i) Ph_3PbNCS and $Ph_3PbSeCN$

Infrared data (Table 2) show, using the criteria (14), that triphenyllead isothiocyanate uses bridging thiocyanate groups to form a polymeric structure analogous to those found for crystalline Ph_3SnNCS (15) and Ph_3PbNCO (16), as previously suggested by Bertazzi *et al.* (7) on the basis of ν(CN) alone. All spectra have the expected weak lower frequency $\nu(^{13}CN)$ peak while a $Ph_3Pb^{15}NCS$ sample gave not only the required lower ν(CN) values but also a decrease in ν(CS), indicating the mixing of these two vibrations.

As reported earlier (11), triphenyllead selenocyanate is a white air-stable solid, but it decomposes at a lower temperature than its thiocyanate analogue. The infrared data (Table 3), especially ν(CSe), show the material to have bridging selenocyanate groups giving a polymeric structure, unlike the earlier assumption (11) of lead–selenium bonding only, based on the ν(CN) value alone. Triphenyllead selenocyanate is slightly soluble in benzene and the sharp ν(CN) band (Fig. 1(a)) shifts *upwards* on solution indicating that the lead–selenium bond is retained when the Pb—NCSe—Pb bridge is broken. Tri-

phenyllead selenocyanate is more soluble in dichloromethane and the ir spectrum of this solution (Fig. 2(a)) again has only a single sharp peak whose molar absorptivity indicates a Pb—SeCN structure in solution.

Triphenyllead isothiocyanate with its negligible solubility in noncoordinating solvents and higher decomposition temperature is even more strongly bridging than Ph_3PbNCO (10, 16) with both having Pb—N as the stronger bond. However, $Ph_3PbSeCN$, soluble in noncoordinating solvents, has weaker SeCN bridging with Pb—Se as the stronger bond, in contradiction to Norbury's observation (14) that thiocyanate and selenocyanate groups generally show similar strong bridging properties. This is the case with the analogous tin compounds where $Ph_3SnNCSe$ with ν(CN) at 2110 cm^{-1} (vs br) and ν(CSe) at 594 cm^{-1} (wm) (17) is clearly an isoselenocyanate similar to Ph_3SnNCS (15), with strong NCSe bridges.

(ii) Adducts with O-donor ligands

Triphenyllead isothiocyanate formed adducts with only the stronger O-donor ligands used here (HMPA, 4-picO, pyO, and TPPO). Although toluene solutions of dimethylsulphoxide (DMSO), *N,N*-dimethylformamide (DMF), *N,N*-dimethylacetamide (DMA), or trimethylphosphate (TMP) dissolve the thiocyanate indicating adduct formation, all attempts to isolate a solid adduct always produced unreacted Ph_3PbNCS. This contrasts with the formation of Ph_3PbNCO adducts with these

ligands, and could imply that Ph_3PbNCS is a weaker Lewis acid. Since, however, molecular weight measurements (10) show $Ph_3PbNCS \cdot HMPA$ to be undissociated when compared with its isocyanate analogue, the apparent inability of

Ph_3PbNCS to form adducts must be due to its much lower solubility caused by its more strongly bridged structure as discussed earlier. As expected, no adducts were obtained with weaker ligands like tetrahydrofuran, acetone, urea, etc.

The adducts of Ph_3PbNCS with O-donor ligands reported here are white air-stable solids with sharp melting points, which are soluble in nonpolar solvents like benzene and dichloromethane but are insoluble in pentane. Thiocyanate group vibrational data (Table 2) show all adducts have only N-bonded thiocyanate in the solid state, as is also the case for most of the adducts in benzene solution. However, the TPPO adduct is anomalous by having two ν(CN) absorptions in benzene solution, and further study is required for this more complex system.

Triphenyllead selenocyanate also formed adducts with only the stronger O-donor ligands (HMPA, 4-picO, pyO, and TPPO) used here, and no adduct with DMSO or DMF could be isolated. This is probably a reflection of the weaker acceptor power of $Ph_3PbSeCN$ since this is itself soluble in the preparative solvents used here. Molecular weight data (benzene, 0.01 *M*; 37°C), found (calcd.) for $Ph_3PbSeCN \cdot$4-picO, 471 (653), and $Ph_3PbNCSe \cdot$HMPA, 435 (723), show adducts are dissociated in benzene solution, the value for the HMPA suggesting the acceptor strengths of $Ph_3PbSeCN$ and Ph_3PbCl are similar. A detailed comparison cannot be made since $Ph_3PbNCSe \cdot$HMPA isomerizes in benzene solution (*vide infra*). All adducts are white stable solids with sharp melting points somewhat below those for the thiocyanate adducts.

Adducts of $Ph_3PbSeCN$ with 4-picO, pyO, and TPPO show a sharpening of the ν(CN) band and a decrease in the value of ν(CSe) compared with the Lewis acid (Table 3), consistent with a terminal Se-bonded selenocyanate, showing that the weaker lead–nitrogen bond in $Ph_3PbSeCN$ is broken by these ligands. In contrast, the HMPA adduct has ν(CSe) shifted to higher frequency and the ν(CN) band broadened and shifted to lower frequency, showing this compound to be an *iso*selenocyanate like the O-donor adducts of $Ph_3SnNCSe$ (3, 17). This structural change caused by an apparently minor variation in ligand implies similar bond strengths for the alternate Pb—NCSe and Pb—SeCN bonding modes and raises the possibility of isomers. This was confirmed by the benzene solution spectra of the adducts (Table 3) where ν(CN) absorptions at 2139 (sp), ~2125 (sp), and ~2035 (br) cm^{-1} may be assigned to $Ph_3PbSeCN$, L—(Ph_3)Pb—SeCN, and L—(Ph_3)Pb—NCSe species, respectively. While linkage isomerism for selenocyanate complexes is known in transition metal complexes (18), to our knowledge this is the first example observed involving coordination to a main group (d^{10}) element. That the effect due to change in ligand from HMPA to 4-picO is of molecular rather than crystal lattice origin is evident by comparing the relative intensities of the ν(CN) absorptions for the two isomers in the benzene solution spectra of the two adducts (Fig. 1). Spectra of dichloromethane solutions of the adducts (Table 3, Fig. 2) show two sharp peaks which may be assigned to $Ph_3PbSeCN$ and L(Ph_3)PbSeCN as before. However, the shift to higher frequency (~20 cm^{-1}) of the third band is large when compared with the smaller solvent shifts (<10 cm^{-1}) of the ν(CN) band of $Ph_3PAuNCS$ observed for a wide range of solvents (19), and the 2055 cm^{-1} peak may be due to the selenocyanate ion. The complexity of the system is shown by the ^{31}P nmr spectrum of $Ph_3PbNCSe \cdot$HMPA in $CDCl_3/CH_2Cl_2$ at 190 K, with chemical shifts positive downfield from 85% H_3PO_4 external reference. As well as free HMPA (δ_P = 26.5 ppm), three peaks are observed at: δ_P = 24.64 ppm, $^2J_{Pb-P}$ = 132 Hz; δ_P = 24.3 ppm, $^2J_{Pb-P}$ = 135 Hz; δ_P = 23.4 ppm, $^2J_{Pb-P}$ = 92 Hz; with their intensities decreasing in the same order. These four peaks imply that a process besides dissociation and isomerization, perhaps ionization, occurs in this system.

(iii) Adducts with N-donor ligands

Reactions with amines proved disappointing for Ph_3PbNCS and $Ph_3PbSeCN$ as found earlier for $Ph_2Pb(NCS)_2$ (9) and Ph_3PbNCO (10), and not all adducts obtained had the expected (1:1) stoichiometry. Triphenyllead isothiocyanate formed 1:1 adducts with pyridine and β- and γ-picolines, but not with α-picoline, even when Ph_3PbNCS was mixed with the neat ligand. Similarly, no adducts of Ph_3SnNCS (4) or $Ph_3SnNCSe$ (3) with α-picoline have been reported. While this may be due to steric hindrance by the α-methyl group, calorimetric titration studies (20) of the reactions of pyridine, α-picoline, and γ-picoline with several organotin halides have shown the steric effect is due to an entropy factor rather than a change in the enthalpy of metal–ligand bond formation. Unlike its tin analogue, triphenyllead selenocyanate does not form adducts with pyridine, β-, or γ-picoline, perhaps due to its weaker acceptor power.

Adduct formation with aliphatic amines proved elusive. Only the use of neat morpholine, pyrrolidine, or piperidine gave adducts with triphenyllead selenocyanate, while a cyclohexylamine adduct formed only with Ph_3PbNCS. Other ligands tried were aniline, diethylamine, triethylamine, quinoline, and 2,2′-bipyridine.

The N-donor ligand adducts reported here are white solids except those with pyrrolidine, which are yellow, and $Ph_3PbNCS \cdot CyNH_2$, which is light brown. All lose ligand slowly when heated and the decomposition temperatures were obtained using sealed tubes. All adducts except $Ph_3PbNCS \cdot$pipy dissolved in benzene or toluene containing some excess ligand.

Infrared data for the amine adducts of Ph_3PbNCS (Table 4) and $Ph_3PbSeCN$ (Table 5) show that all except $Ph_3PbNCS \cdot$pyrrol decompose to some extent when mulled, consistent with the general instability of these adducts. Values of ν(CN), ν(CS), and δ(NCS) for the triphenyllead isothiocyanate adducts with pyridines and pyrrolidine are consistent with N-bonded thiocyanate, as in the O-donor ligand adducts. However, for the morpholine adduct, the lower sharp ν(CN) peak together with the ν(CS) and δ(NCS) values indicates the presence of ionic thiocyanate, the compound probably having an ionic structure such as $Ph_3Pb(morph)_2^+(NCS)^-$. For $Ph_3PbNCS \cdot L$ (L = pipy or $CyNH_2$), the two ν(CN) peaks are consistent with the presence of both N-bonded and ionic thiocyanate groups, although the splitting could be a crystal lattice effect. However, the same two ν(CN) absorptions occur in the benzene solution spectrum of $Ph_3PbNCS \cdot$TPPO noted earlier where this cannot be the case. All three $Ph_3PbSeCN$–amine adducts had a lower frequency, sharp ν(CN) absorption, but no increase in ν(CSe) when compared with the parent Lewis acid. This behaviour suggests $(NCSe)^-$ is present, implying an ionic formulation as well for these adducts. Crystal structure determinations are clearly necessary to test the ionic formulae proposed above.

The amine ligands used here have donor strengths, based on their Gutmann donor number (DN) values (21), greater than the O-donor ligands which form stable adducts with Ph_3PbNCS and $Ph_3PbSeCN$. However, the DN value is an enthalpic mea-

sure of donor power and neglects entropy factors which may be more important for amines where the donor atom is embedded in the bulk of the molecule. Thus for attachment of the amine to an aryltin or -lead moiety, while a strong M—N bond might be readily formed, weak steric hindrance could hinder free rotation of the bound amine in solution or constrain the possible arrangements of the bound ligand in the solid state causing an adverse entropy change on adduct formation, and thus accounting for the generally weak nature of the amine adducts formed by Ph_3PbNCO (10), Ph_3PbNCS, and $Ph_2Pb(NCS)_2$ (9). In contrast, the O-donor ligands used here have donor atoms which protrude from the bulk of the molecule causing less steric hindrance for adducts of these ligands. This hypothesis is supported by the results of calorimetric studies by Graddon of the reaction $R_2SnCl_2 + L \rightarrow R_2SnCl_2 \cdot L$ in benzene; e.g. for R = Ph, when L = pyO (22), $\Delta H = -39$ kJ/mol, $K = \infty$ (25°C), and when L = py (20), $\Delta H = -48$ kJ/mol, $K = 80$ (25°C), showing pyridine to be the better donor on an enthalpic basis but entropy effects cause the pyridine adduct to be less stable than that with pyridine-*N*-oxide.

(iv) Factors affecting the mode of chalcocyanate coordination to the triphenyllead moiety

Chalcocyanates (NCX^-; X = O, S, Se, or Te) are all potentially ambidentate ligands and the choice of donor atom (N or X) to complex with a given metal ion has been generally rationalized by Pearson's "hard and soft acid – base principle" as discussed in detail by Norbury (14). A study of the equilibrium, $Ph_3Pb^+(solv) + X^-(solv) \rightleftarrows Ph_3PbX(solv)$ in methanol (23), showed lead in the Ph_3Pb^+ ion to have borderline soft acid character. Thus selenium, being even "softer" than sulphur, will show a greater tendency to bind to lead, in this case sufficient to overcome the intrinsically greater donor ability of the nitrogen atom.

The occurrence of linkage isomers of $Ph_3PbSeCN$ adducts with O-donor ligands may be taken as an example of symbiosis. Coordination of a "hard" O-donor ligand to Ph_3Pb will stabilize the L—Pb—NCSe structure relative to the L—Pb—SeCN isomer, and the possible Pb—N or Pb—Se bonds now become more equivalent in energy which is the condition required for linkage isomerism to occur when, as is the case with main group metal complexes, kinetic control cannot be the cause.

Nuclear mean free paths and transparency at intermediate energies[1]

PAUL J. KAROL

Department of Chemistry, Carnegie–Mellon University, Pittsburgh, PA 15213, U.S.A.

Received September 1, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

PAUL J. KAROL. Can. J. Chem. **61**, 750 (1983).

The soft-spheres model of nuclear reaction cross sections incorporating tapered density distributions is used to evaluate nucleon mean free paths and transparencies at intermediate energies. Comparison with similar calculations employing uniform density distributions shows the latter to give misleading results that nevertheless have been used in recent years as evidence that the physics of the nucleon–nucleon interaction within nuclei is incompletely understood.

PAUL J. KAROL. Can. J. Chem. **61**, 750 (1983).

On a utilisé le modèle de sphères mous des sections droites d'une réaction nucléaire incorporant les distributions de densité non uniforme pour évaluer les trajectoires moyennes libres du nucléon et les transparences à des énergies intermédiaires. La comparaison avec des calculs analogues utilisant les distributions de densité uniforme montrent que ces derniers donnent des résultats erronés que l'on a néanmoins utilisés récemment comme la preuve d'une compréhension incomplète de la physique de l'interaction nucléon–nucléon à l'intérieur du noyau.

[Traduit par le journal]

1. Introduction

Transparency of a nucleus toward an incident projectile has always served as a convenient term for explaining the difference between geometric cross sections and total reaction cross sections. When target nuclei and projectiles have well-defined boundaries, i.e. sharp edges, nuclear transparency can be precisely quantified as has been done by Fernbach *et al.* (1) and Bradt and Peters (2). In a recent report, DeVries and Peng (3) analyzed total reaction cross sections for ^{12}C, ^{16}O, and ^{40}Ca towards medium energy protons, deuterons, and α particles. From a semiclassical formula [2], they derived nuclear transparency values for each experimental case. DeVries and Peng concluded (*i*) that composite-projectile collisions are more transparent than proton collisions with the same nucleus, (*ii*) that such an observation is at variance with conventional experience, and (*iii*) that, therefore, the implications have theoretical significance.

In what will prove to be a related situation, attention has been drawn recently to what has been termed (4) "a serious problem that past theoretical calculations have appeared to yield a mean free path of roughly 3 fermis for nucleons of energy 50–150 MeV whereas the experimental value in this energy range is approximately 5 fermis".

The following report will address both the issue of nuclear transparency and the mean free path of intermediate energy nucleons in complex nuclei.

2. Total reaction cross sections

At and above intermediate energies, where Coulomb effects are negligible, theoretical total reaction cross sections σ_R may be reduced to a calculation of $T(r)$, the probability that at impact parameter r, the projectile will pass through the target without interaction. Then

$$[1] \quad \sigma_R = 2\pi \int [1 - T(r)] r dr$$

$T(r)$ is calculated assuming straight-line trajectory using free two-body nucleon–nucleon collision cross sections σ. At and above intermediate energies, Pauli blocking modifications to σ become relatively minor and will be neglected to keep our discussion simpler. For a single particle point projectile and a uniform density (ρ) target nucleus of radius $R = R_0 A^{1/3}$

$$[2] \quad \sigma_R = \pi R^2 [1 - \{1 - (1 + 2KR)e^{-2KR}\}/2K^2R^2] = \pi R^2 [1 - T]$$

where the attenuation coefficient $K = \sigma\rho$ is the reciprocal of the projectile's mean free path λ. For zero mean free path, the opaque nucleus result $\sigma_R = \pi R^2$ is obtained. The term on the right within the square brackets of [2] is identified with nuclear transparency. Furthermore, for two colliding uniform density composite nuclei, the zero mean free path limit, or *hard-sphere* model gives

$$\sigma_R = \pi R_0^2 (A_P^{1/3} + A_T^{1/3})^2$$

This expression has been phenomenologically modified (2) with limited success to allow for transparency by introducing a corrective overlap parameter b in the form

$$[3] \quad \sigma_R = \pi R_0^2 (A_P^{1/3} + A_T^{1/3} - b)^2$$

implying that

$$T \sim 2b/(A_P^{1/3} + A_T^{1/3})$$

Hudis (5) has pointed out that transparencies calculated according to uniform hard-sphere density distributions are "probably lower limits since the transparency is very dependent on the assumed nuclear density distribution and the use of diffuse nuclear boundary will almost certainly yield higher values". In fact, the assumption or application of a sharp density distribution to either the calculation of nuclear transparency or the estimation of particle mean free paths from experimental total reaction cross sections is misleading as will be shown.

TABLE 1. Comparison of σ_R from the semiclassical soft spheres model with the Glauber Model at 1.05 GeV/A

Projectile + target	σ_R Soft spheres (6)	σ_R Glauber model (9)
p + a	104 mb	108 mb
p + ^{12}C	279	267
p + ^{16}O	338	340
p + ^{40}Ar	647	637
p + ^{208}Pb	1837	1815
a + ^{12}C	550	560
a + ^{16}O	670	680
a + ^{208}Pb	2600	2580
^{40}Ar + ^{208}Pb	4850	4810

Total reaction cross sections for single projectile and composite projectile interactions with target nuclei that incorporate realistically tapered density distributions can be evaluated using the author's *soft-spheres* model (6). In this semiclassical model, which contains no free parameters, $T(r)$ is calculated using Gaussian density distributions for both projectile (P) and target (T). The distributions are normalized to the "true" density profiles at the nuclear surface. One obtains

$$[4] \quad \ln T(r) = \chi \exp\left[-r^2/(a_T^2 + a_P^2)\right]$$

where

$$\chi = \frac{\pi^2 \sigma(E) \rho_T(0) \rho_P(0) a_T^3 a_P^3}{(a_T^2 + a_P^2)}$$

in which

$$a = (2/3)^{1/2} R_{rms} \qquad A \leq 40$$
$$= [(4ct + t^2)/4 \ln 5] \qquad A > 40$$

and

$$\rho(0) = A/(a\pi^{1/2})^3 \qquad A \leq 40$$
$$= \tfrac{1}{2}\rho_0 \exp (c/a)^2 \qquad A > 40$$

where c, t, and ρ_0 are the radial, skin thickness, and central density parameters of the Fermi distribution and R_{rms} is the root mean square radius, all determined from electron scattering data (7). $\sigma(E)$ is the energy-dependent two-body elementary collision cross section (see ref. 6 for complete details). The soft-spheres model using [1] and [4] gives

$$[5] \quad \sigma_R = \pi(a_T^2 + a_P^2)[E_1(\chi) + \ln \chi + \gamma]$$

where E_1 is the exponential integral and γ is Euler's constant (8). At somewhat lower energies, the Coulomb barrier, projectile deBroglie wavelength, and Pauli blocking corrections can be included. That the soft-spheres equation is accurate can be seen by a comparison with recent Glauber model calculations (9) in Table 1 and experiments in Table 2 for a variety of projectile–target systems. In Fig. 1 the soft-spheres calculated results are compared to some experimental σ_R's compiled by DeVries and Peng (10).

3. Transparency

Any attempt to use a diffusely tapered density distribution to calculate nuclear transparency is frustrated by the lack of a defined outer nuclear limit. That is, the transparency approaches 100% because of peripheral contributions where ρ approaches zero asymptotically. One way of illustrating this, which also suggests a scheme for circumventing the problem, is by using a sharp cutoff.

TABLE 2. Comparison of σ_R from the soft spheres model with experiment

*The 530 MeV proton data from ref. 19, the others from unpublished data of J. A. Jaros, LBL-3849 (1975).

Letting σ_R' represent the total reaction cross section of a projectile on a target whose densities have been abruptly truncated at impact distance R, we have

$$[6] \quad \sigma_R' = 2\pi \int_0^R [1 - T(r)] r dr$$
$$= \pi R^2 \left[1 - (2/R^2) \int_0^R T(r) r dr\right]$$

Comparison of [6] with [2] allows us to identify a nuclear transparency, T_R, corresponding to truncation at distance R from the target center:

$$[7] \quad T_R = (2/R^2) \int_0^R T(r) r dr$$

Using $T(r)$ from [4] one may obtain

$$[8] \quad T_R = (a_T^2 + a_P^2)[E_1(\chi_R) - E_1(\chi)]/R^2$$

where χ_R is given by

$$\chi_R = \chi \exp\left[-R^2/(a_T^2 + a_P^2)\right]$$

The sharp cutoff nuclear transparency has been calculated according to [8], as a function of cutoff distance, for the several systems considered by DeVries and Peng. The results of these calculations are plotted in Fig. 2. These demonstrate that, as the sharp cutoff is extended to larger and larger impact parameters, the value assigned to "nuclear transparency" approaches unity.

It is unreasonable, of course, to extend the truncation indefinitely because eventually one reaches impact parameters that contribute negligibly to the total reaction cross section. One can adopt this realization as a means for selecting a reasonable

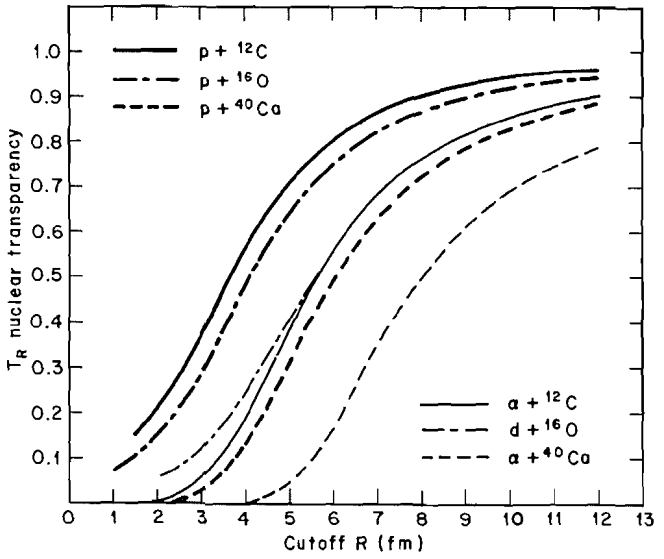

FIG. 2. Nuclear transparencies at E = 300 MeV/A calculated according to [8] for diffuse nuclei as a function of truncation radius R.

cutoff radius. Shown in Fig. 3 is the 300 MeV "fractional" reaction cross section for p + ^{12}C calculated from [8] as a function of the cutoff R. An appropriate *cutoff radius* R_c may be defined by summing the projectile and target radii at which each of the densities falls to 10% of the central values. At $R = R_c$, greater than 90% of the total reaction cross section is accounted for by truncating the overlap between projectile and target density distribution tails. The results of such a procedure are tabulated in Table 3 for the cases examined by DeVries and Peng. Our results demonstrate that the trend in transparency is *not* contrary to conventional expectations.

Chen *et al.* (11), employing step density distributions in

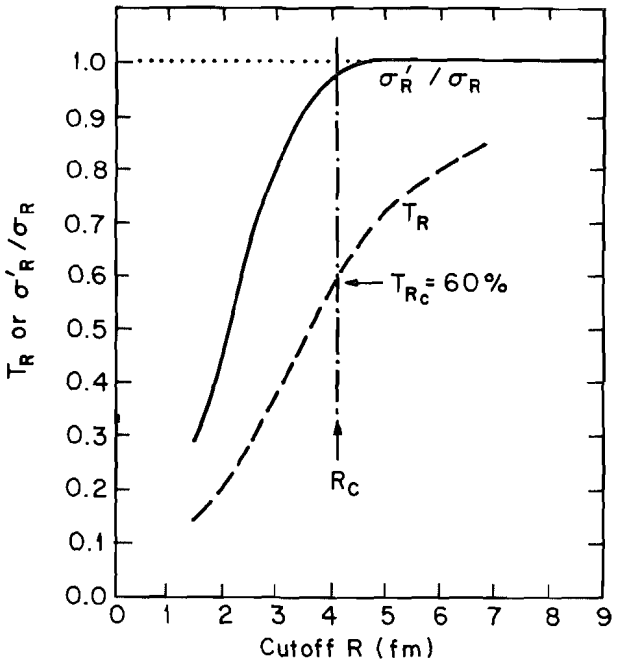

FIG. 3. Determination of sharp cutoff radius and resulting transparency for p + ^{12}C at 300 MeV.

TABLE 3. Extrapolated nuclear transparencies at 300 MeV/A

System	R_c (fm)	T_{R_c} (%) Tapered density (this work)	T (%) Uniform density (ref. 3)
p + ^{12}C	4.05	60	36

p + ^{40}Ca	4.82	29	32
a + ^{12}C	5.08	42	52
d + ^{16}O	6.10	59	59
a + ^{40}Ca	5.84	16	44

intranuclear cascade (INC) calculations for 375 MeV protons on ^{75}As and ^{209}Bi, showed that the "transparency" increased from 13% to 48% and 9% to 37% respectively in going from a square (uniform) distribution to a diffuse-skinned step function that approximated the electron-scattering results. INC calculations are in qualitative agreement with the transparency arguments developed in this work. The truncation method embodied in [8] gives 40% and 29% for the ^{75}As and ^{209}Bi proton transparencies respectively at 375 MeV using R_c as outlined above.

From the above description, it should be clear that use of uniform density distributions can indeed be misleading. Equivalent errors arise when discussions of the mean free path of nucleons in complex nuclei are undertaken. The remainder of the report will address this issue.

4. Nucleon mean free path

In recent years, a number of publications have called attention to the apparent discrepancy between the mean free path of nucleons derived from scattering experiments and that which arises from the impulse approximation. Schiffer (12) and Nadasen *et al.* (13) have considered proton scattering as analyzed through the optical model. Total reaction cross sections derived from the complex optical potential parameters are em-

TABLE 4. Proton total reaction cross sections at 90 MeV

Target	σ_R Using $\lambda = 4.5$ fm	σ_R Using $\lambda = 1/\sigma\rho$	σ_R Experimental
^{12}C	127	288	245
^{27}Al	249	495	430
^{90}Zr	766	1130	1077
^{208}Pb	1384	1845	1831

ployed in [2] to estimate attenuation coefficients K and subsequently λ. As a consequence of using the (inappropriate) uniform density formula, $\lambda = 5.3$ fm is obtained at 150–180 MeV. On the other hand, using $\rho = 0.16$ nucleons/fm^3, $\sigma_{pp} = 2.4$ fm^2, and $\sigma_{pn} = 4.2$ fm^2, one expects $\lambda \sim 2.5$ fm. The discrepancy arises in the misleading application of the sharp density distribution. A tapered density distribution, using the (density-dependent) $1/\lambda = \sigma\rho(r)$ expression, does a reasonable job of reproducing total reaction cross sections derived from optical model analysis of scattering data, being ~15% too large, at the worst, in this energy region as seen in Fig. 1. Moreover, using the soft-spheres model, one may calculate the values for the nucleon–nucleon cross section σ needed to fit the range of σ_R's obtained by Nadasen *et al.* (13) in their optical model analyses and shown as the shaded region in Fig. 1 for ^{208}Pb. Mean free paths are derived from these using $\rho = 0.16$ nucleons/fm^3 and yield $\lambda = 2.9 \pm 0.7$ fm. That value is in distinct contrast to the much larger mean free path obtained using a uniform density nucleus and cited above. Interestingly, Negele and Yazaki (4) use the parameters of ref. 13 to derive a local optical model result $\lambda_L \sim 3$ fm and a non-local result $\lambda_{NL} \sim 4$ fm at 150–200 MeV and conclude that much of the long-mean-free-path discrepancy is resolved in favor of the experimentally determined (sic) $\lambda \sim 5$ fm by proper treatment of non-locality.

Another way of illustrating the discordance associated with long mean free path is to examine the total reaction cross section *predicted* by longer λ. Redish and Schneider (14) claim that with various target nuclei, λ for 90 MeV protons is 4.5 fm. This can be countered in a relatively straightforward manner. With $\lambda = 4.5$ fm, the implication is that the effective nucleon–nucleon collision cross section within the nucleus is 14 mb. Using this value in the soft-spheres model, total reaction cross sections for several nuclei are calculated and listed in Table 4 along with σ_R calculated with "normal" λ and experimental data (15). Long mean free paths are inconsistent with measured σ_R's. At lower energies, Ginocchio and Blann (16) showed that INC calculations for protons on ^{89}Y and ^{54}Fe give poor results when proposed long mean free paths are utilized. However, the validity of semiclassical kinematics is questionable here. Furthermore, Hogan *et al.* (17) pointed out that Ginocchio and Blann, in neglecting refraction and reflection of the intranuclear proton, underestimate σ_R owing to the nonlinear transport through the target. Recalculation by Hogan *et al.* removes much of the discrepancy.

The 5–30% disagreement between σ_R's (and consequently λ's) derived from optical model fits to scattering and those of either attenuation measurements or theoretical calculations involving diffuse nuclear surfaces seems to imply incomplete knowledge about the more complex interactions and pathways in projectile–target interactions, not necessarily reflecting problems with the nucleon–nucleon two-body collisions. Recently, Ray (18) used second order KMT formalism including Pauli, short-range dynamical, and center-of-mass correlation to compute σ_R. Very good agreement was obtained above 400 MeV, but an overestimation by 15–25% at lower energies was regarded as an indication that multiple scattering calculations are inadequate below 400 MeV.

5. Conclusions

The total reaction cross section, perhaps the most basic nuclear reaction observable (4), is calculated semiclassically at intermediate energies by propagation of the projectile through the nuclear environment up to and including the point of first intranuclear particle–particle collision. Whether or not the physics of subsequent propagation, cascading, or other (collective or non-collective) interactions is understood through single or multiple collision pictures is essentially irrelevant following that initial interaction. Consequently, a naive statement about σ_R is that its interpretation entails the fewest theoretical assumptions. An analogous claim can be made for direct experimental measurements of total reaction cross sections, i.e. attenuation measurements. Values for σ_R derived from optical model analysis of elastic scattering are inherently more model dependent. There is no disagreement between experiment and theory concerning the validity of employing mean free paths derived from the impulse approximation nor in the trends of nuclear transparencies that have included proper consideration of the diffuse nuclear surface. Deceptively large λ's and "misbehaving" transparencies are illusions brought about by application of the uniform nuclear density distribution to the interpretation of experimental results.

Identification of 26-minute Zr-84[1]

SEIICHI SHIBATA[2] AND PAUL J. KAROL

Department of Chemistry, Carnegie–Mellon University, Pittsburgh, PA 15213, U.S.A.

Received September 1, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

SEIICHI SHIBATA and PAUL J. KAROL. Can. J. Chem. **61**, 754 (1983).

An unknown γ-ray of energy 112.5 keV was found in zirconium fractions chemically extracted from isotopically enriched molybdenum targets bombarded with 500 and 800 MeV protons. All evidence suggests that the γ-ray is identifiable with the decay of ^{84}Zr to ^{84}Y. A half-life of 25.7 ± 0.5 min was obtained for ^{84}Zr, which is considerably longer than previously reported half-lives. The absolute abundance of the 112.5 keV γ-ray was also determined. Relative production cross sections for ^{84}Zr were calculated using these results and were consistent with the values interpolated from isotopic distribution curves for spallation reactions.

SEIICHI SHIBATA et PAUL J. KAROL. Can. J. Chem. **61**, 754 (1983).

On a trouvé un rayon γ inconnu ayant une énergie de 112,5 keV dans les fractions de zirconium extraites chimiquement des cibles de molybdène enrichies isotopiquement et bombardées avec des protons de 500 et de 800 MeV. Toutes les preuves suggèrent que le rayon γ peut être identifié avec la désintégration du ^{84}Zr en ^{84}Y. On a obtenu une demi-vie de 25,7 ± 0,5 minute pour le ^{84}Zr. Ce temps est de beaucoup supérieur à ceux rapportés antérieurement. On a aussi déterminé l'abondance absolue du rayon γ de 112,5 keV. A partir de ces résultats, on a calculé les sections droites de production relative du ^{84}Zr et les valeurs calculées sont en accord avec celles obtenues par interpolation à partir des courbes de distribution isotopique des réactions où des particules sont éjectées artificiellement du noyau.

In spallation reaction studies by proton activation of enriched isotopic molybdenum targets at intermediate energies, an unassignable gamma-ray of energy 112.5 keV was found. This γ-ray was always observed in zirconium fractions isolated radiochemically from the targets under investigation. Also in the zirconium fractions, γ-rays emitted from neutron-deficient daughter yttrium nuclides were observed. Growth of the 112.5 keV γ-ray activity was not observed in any zirconium fraction.

The half-life of the 112.5 keV γ-ray emission was analyzed by the CLSQ decay curve analysis program (1). The results of these analyses are indicated in Table 1. A half-life of 25.7 min was obtained.

According to the literature (2), there is no appropriate isotope which has a half-life of 26 min. However, in 1971, Doron and Blann (3) had reported the observation of a 112.5 keV γ-ray which decayed with the half-life of 26 min. They used heavy-ion reactions in order to produce nuclides far from the line of β-stability and some γ-rays were unidentifiable, the 112.5 keV among them. Doron and Blann concluded that the 112.5 keV gamma was emitted from either ^{84}Y^{m} or ^{84}Zr based on cross bombardment techniques in combination with compound nucleus evaporation calculations. However, they were unable to obtain further information because growth of the daughter nuclide was not observed in their data analysis.

Following our irradiations of (ammonium molybdate) targets, the chemical separations of yttrium and zirconium from each other and from other elements was performed in every sample. A 6 *M* HNO_3 solution of the target, containing milligram amounts of carriers for niobium, zirconium, and yttrium was extracted with 0.5 *M* TTA in xylene which removed yttrium. Hydrophobic phase separation filter paper was used to speed the separations. The organic phase was diluted with xylene to give 0.05 *M* TTA. Zirconium was extracted using concentrated HCl containing a small amount of hydrogen peroxide to suppress the co-extraction of niobium. Zirconium hydroxide was coprecipitated with base in the aqueous phase following addition of iron(III) carrier. Time from end of bombardment to end of separation was routinely less than ten minutes. In measuring the gamma spectra of the zirconium samples, radiochemical purity was verified by the absence of independent yttrium activities.

TABLE 1. Half-life of ^{84}Zr from measurements of the 112.5 keV γ transition

Target	E_p (MeV)	Half-life (min)
^{92}Mo	800	26.1±1.6
^{92}Mo	800	24.2±0.9
^{96}Mo	800	29.3±2.3
^{92}Mo	800	27.8±1.2
^{100}Mo	800	23.4±2.1
^{92}Mo	800	25.8±1.0
^{92}Mo	500	26.4±2.6
Weighted mean		25.7±0.5

The 112.5 keV γ-ray was never observed in an yttrium fraction. Therefore, it was assumed that ^{84}Zr emitted the 112.5 keV γ-ray despite substantial disparity with the published half-lives of ^{84}Zr; 16 min (4) and 5 min (5). The latter did not report γ-ray emissions from ^{84}Zr. During the course of our determinations, yet another report on ^{84}Zr appeared, this one declaring the half-life to be 3.7 min (6). For analysis via daughter measurement, counting rates of γ-rays emitted from ^{84}Y were assayed. The result for the 1040 keV γ-ray whose abundance is 56.8% (2), is shown in Fig. 1. ^{84}Y also emits 793 keV (98%)

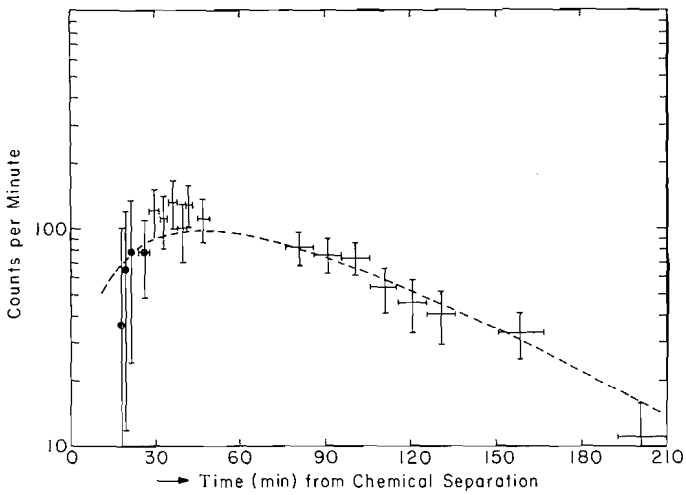

FIG. 1. Counting rate of 1040 keV γ-ray emitted from ^{84}Y in a zirconium fraction plotted as a function of time. Target = ^{92}Mo and E_p = 800 MeV. Dotted curve corresponds to the predicted counting rate of the 1040 keV γ-ray produced from decay of ^{84}Zr.

TABLE 2. Absolute abundance of the 112.5 keV γ-ray

Target	E_p (MeV)	Abundance
^{92}Mo	800	0.978±0.081
^{92}Mo	800	1.060±0.091
^{92}Mo	800	0.966±0.071
^{96}Mo	800	0.917±0.209
^{100}Mo	800	0.828±0.231
Weighted mean		0.984±0.044

and 974 keV (77.5%) γ-rays, but these were interfered with by γ-rays from 1.6-hour ^{84}Zr, also present in the zirconium samples and in greater yield.

The absolute abundance of the 112.5 keV γ-ray was calculated using the standard parent–daughter growth and decay equations (7) and the counting data of 112.5 keV and 1040 keV γ-rays. The results are indicated in Table 2. The calculated growth–decay curve of ^{84}Y produced from the 26-min decay of initially pure ^{84}Zr is compared with the data in Fig. 1 on an absolute basis and is seen to reproduce the data. In the heavy-ion reaction study of Doron and Blann (3), it is likely that the growth of ^{84}Y was not found due to the relatively high yield of ^{84}Y independently produced by the reaction and because chemical separation of yttrium from zirconium was not performed.

The relative production cross sections for ^{84}Zr from intermediate energy proton bombardment of several medium mass targets were calculated using the abundance of 98.4% and the half-life of 25.7 min, each determined in this work. One example is shown in Fig. 2. The production cross section for ^{84}Zr is consistent with the smooth isotopic distribution curve. Similarly good fits were also obtained for samples from other targets not shown, confirming the accuracy of the identification.

If ^{84}Zr were to decay to the reported 4.6-second ^{84}Y^{m} (8), growth of the daughter nuclide's 1040 keV gamma should not be observed and only a 793 keV γ-ray with a half-life of 26 min would have been seen because ^{84}Y^{m} does not decay by isomeric transition to ^{84}Y^{g}. This alternative is inconsistent with the experimental results described above. Therefore, identification of the 112.5 keV γ-ray as being emitted from ^{84}Zr with the half-life of 26 min seems well substantiated. The simple decay scheme proposed for ^{84}Zr → ^{84}Y is shown in Fig. 3.

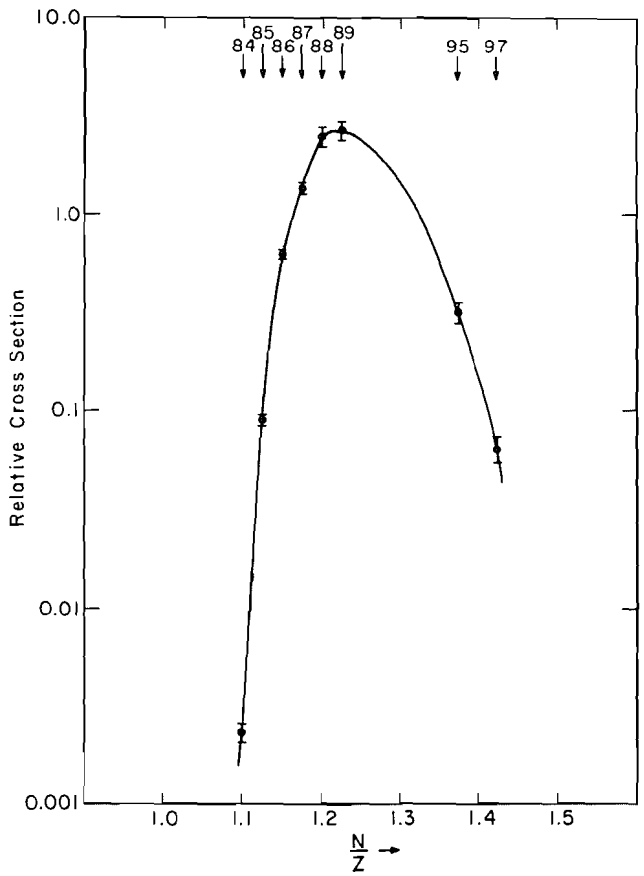

FIG. 2. Isotopic distribution curve for Zr including ^{84}Zr. Target = ^{100}Mo and E_p = 800 MeV.

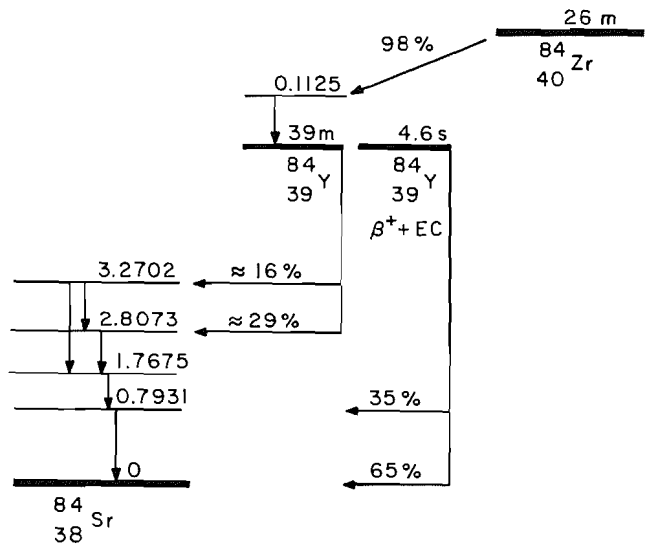

FIG. 3. Proposed decay scheme for ^{84}Zr.

The synthesis of bridged biphenyl and naphthyl compounds by the photolytic and thermal extrusion of SO_2[1]

DAVID N. HARPP[2] AND DENNIS F. MULLINS
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received September 9, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

DAVID N. HARPP and DENNIS F. MULLINS. Can. J. Chem. **61**, 757 (1983).

The photolytic and flash vacuum thermolytic behavior of several SO_2-containing cyclic compounds was studied. The expulsion of SO_2 by flash vacuum thermolysis afforded the corresponding bridged compounds in high yield.

DAVID N. HARPP et DENNIS F. MULLINS. Can. J. Chem. **61**, 757 (1983).

On a étudié le comportement photolytique et le comportement thermolytique sous vide éclair de plusieurs composés cycliques contenant du SO_2. L'expulsion du SO_2 par thermolyse sous vide éclair fournit avec un fort rendement les composés pontés correspondants.

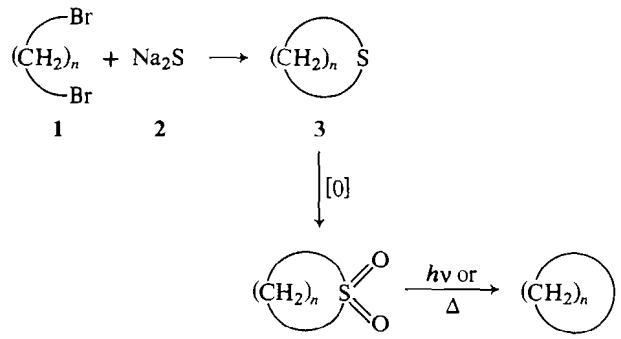
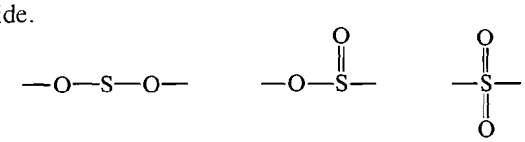
The use of thermolytic (2) and photolytic (3) means to induce expulsion of sulfur dioxide from cyclic molecules as a method for the formation of new carbon–carbon bonds has been employed for many years. Perhaps the area of greatest interest for the past decade has involved sulfone pyrolyses for the preparation of cyclophanes (4).

A standard method for the synthesis of the required sulfone-containing molecule involves the reaction of a dibromide **1** with sodium sulfide **2** to yield a cyclic sulfide **3**. Oxidation of



1 **2** **3** **4** **5**

sulfide **3** provides the cyclic sulfone **4** (5). Thermolytic or photolytic extrusion of SO_2 from **4** and concomitant ring closure results in the formation of **5** with a new carbon–carbon bond. Our interest in such molecules was, in part, stimulated by our development of the chemistry of certain sulfur-transfer reagents (6) which permit easy access to the requisite sulfur-containing precursors (7). These molecules encompass the three types of bonding arrangements for one sulfur and two oxygen atoms, sulfoxylate esters **6**, sulfinate esters **7**, and sulfones **8**. Only the sulfone is obtained by oxidation of a sulfide.



6 **7** **8**

[1]Organosulfur Chemistry, Part 43. For Part 42, see ref. 1.
[2]Author to whom all correspondence should be addressed.

The reaction of bis-benzimidazolyl sulfide **9** with 2,2′-bis-(hydroxymethyl)biphenyl **10** inserts the sulfur between the oxygens to form the cyclic sulfoxylate ester **11** which is sometimes isolable, often depending on the α-substituents (6, 7). This cyclic sulfoxylate thermally rearranges to the thermodynamically more stable cyclic sulfinate ester **12** and eventually to the stable sulfone **13**. Utilizing this approach, a series of cyclic sulfoxylate esters, sulfinate esters, and sulfones were prepared and their thermolytic and photochemical behavior studied.

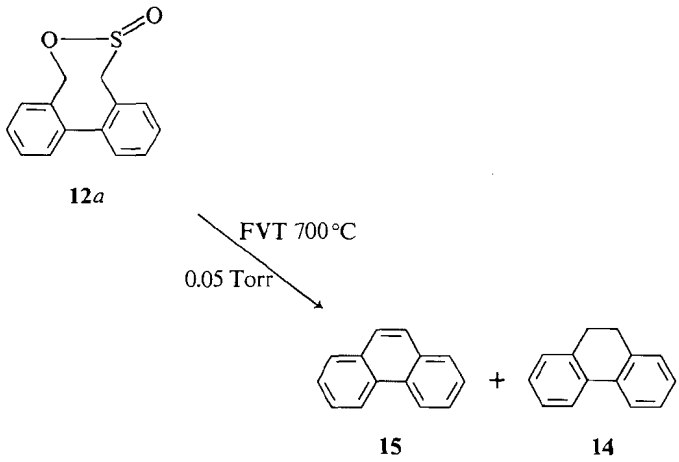
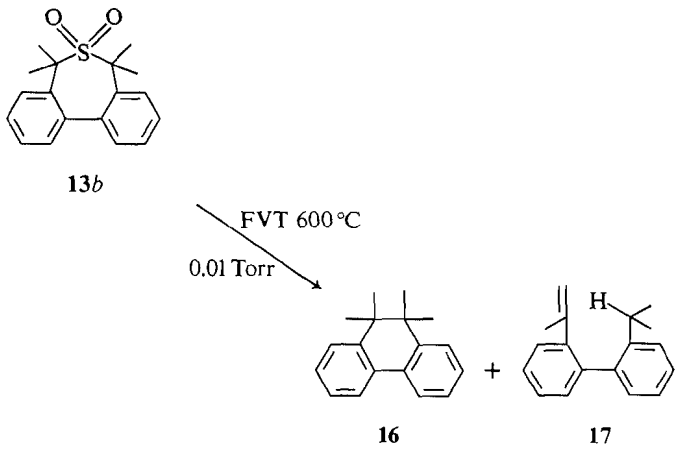
Flash vacuum thermolysis (FVT) of sulfinate ester **12***a* through a quartz tube heated to 700°C at a pressure of 0.05 Torr afforded a 90% isolated yield of 9,10-dihydrophenanthrene **14** containing less than 1% phenanthrene **15**.

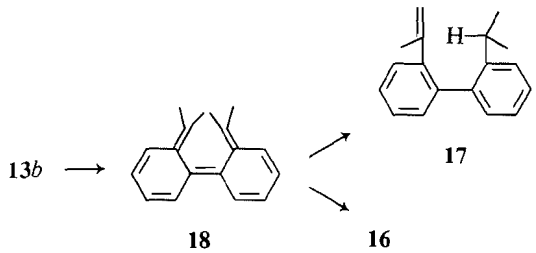
In contrast, Durst *et al.* (3*c*) found that the photolysis of ester **12***a* in degassed methanol at 254 nm gave 9,10-dihydrophenanthrene **14** and phenanthrene **15** in a ratio of 9:1. We performed this photolysis in several other solvents but could not lower the phenanthrene percentage below 10%.



The thermolysis of sulfone **13***b* at 600°C and 0.05 Torr provided a 90% yield of a mixture of 80% 9,9,10,10-tetramethyl-9,10-dihydrophenanthrene **16** and 20% 2-(2-isopropenyl)-2′-(-2-isopropyl)biphenyl **17**; compound **16** is the first example of a 9,9,10,10-tetraalkyl substituted 9,10-dihydrophenanthrene. A possible intermediate formed by the thermal

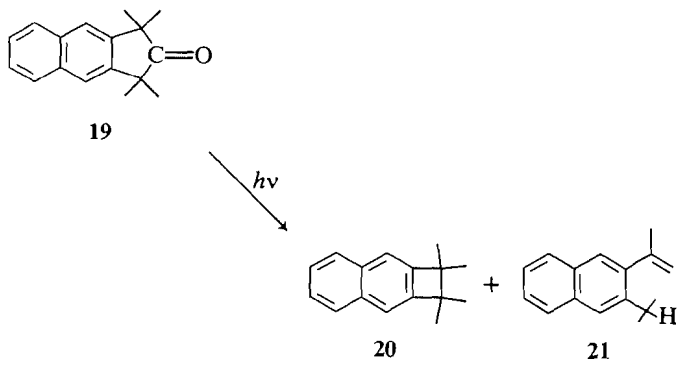


expulsion of SO_2 from **13***b* might be **18**. Electrocyclic ring closure would afford **16**, while a convenient rationalization for the formation of **17** could involve a thermally-allowed antarafacial 1,7-sigmatropic hydrogen shift from **18**.

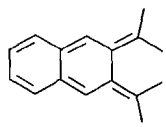


A literature analogy for this pathway is found in the work of McCullough and co-workers (8), in the photolytic conversion of **19** to **20** and **21**. They observed the short-lived transient **22** during the flash photolysis of **19**. They also proposed that the hydrogen transfer from **22** to **21** proceeds by way of a photochemically-allowed antarafacial 1,5-sigmatropic shift.

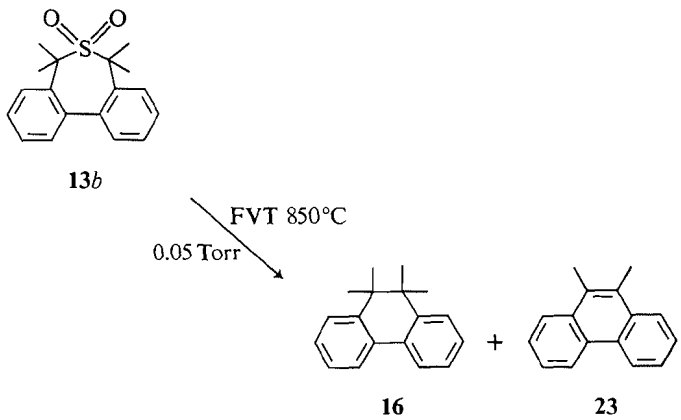
The solution photolysis at 254 nm of sulfone **13***b* yields the



same two products, **16** and **17**. However, in this case the hydrogen transfer product **17** predominates in a ratio of 3:1. Performing this photolysis in different solvents and at different



wavelengths did not significantly change this distribution. Carrying out the thermolysis of sulfone **13***b* at a higher temperature, however, alters the ratio. At 850°C, 9,10-dimethylphenanthrene **23** was formed in 60% yield. This derivative



likely results from the tetramethyl compound **16**. Flash vacuum thermolysis of **16** at 850°C afforded 67% **23** and recovery of starting material **16** (16%) although we have no information as to the disposition of the 2 lost methyl groups.

The cyclic ester **24** produced a quantitative yield of pure acenapthene **25** when subjected to FVT conditions at 500°C and 0.05 Torr. Photolysis in benzene using 360 nm light give the same results.

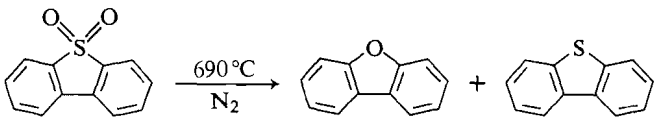
26

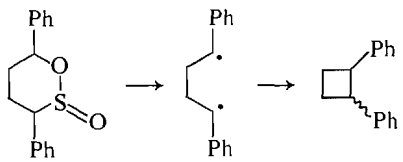
FVT and solution photolysis of the two tetraphenyl sulfoxylates **11***c* and **26** did not yield any identifiable products.

A study of the mass spectra of these SO_2-containing compounds gave some indication as to why the two tetraphenyl sulfoxylates **11***c* and **26** do not lose SO_2 cleanly when subjected to FVT or solution photolysis. The three compounds **12***a*, **13***b*, and **24** which undergo clean SO_2 expulsion and subsequent ring closure show significant peaks corresponding to the loss of SO_2 (see Table 1). The two tetraphenyl sulfoxylates **11***c* and **26** do not show mass spectral fragments corresponding to the loss of SO_2, but rather the loss of SO. The results might suggest that



27 **28** **29**

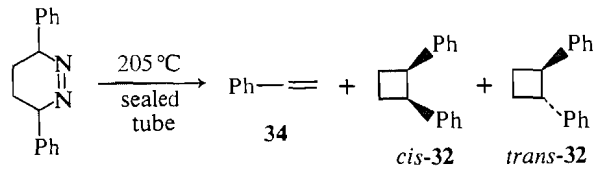
the FVT of these two sulfoxylates would yield cyclic ethers in a manner similar to the thermolysis of dibenzothiophene-5,5-dioxide **27**, which yields dibenzofuran **28** and dibenzothiophene **29** in a ratio of 6:1 (9). However, no such cyclic ethers were observed in the product mixtures.



30 **31** **32**

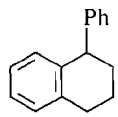
The mass spectrum of the six-membered cyclic sulfinate ester **30** shows a strong molecular ion at *m/e* 272 (70%) and a peak for the loss of SO_2 minus 1H (*m/e* 207, 45%). Based on our previous results, the expected thermolytic pathway would be the loss of SO_2 to form intermediate **31** which could ring close to form the cyclobutane **32**.

Kopecky and Soler (10) have performed FVT studies on a similar system, 3,6-diphenyl-3,4,5,6-tetrahydropyridazine **33**. Thermolysis of *cis*-**33** at 205°C in a sealed tube yielded styrene



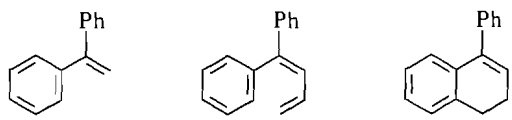
33 **34** *cis*-**32** *trans*-**32**

34 (67%), *cis*-1,2-diphenylcyclobutane *cis*-**32** (21%), *trans*-1,2-diphenylcyclobutane *trans*-**20** (12%), plus a trace of 1-phenyltetralin **35**. The FVT of **30** at 450°C did not yield any diphenylcyclobutane. The crude thermolysate contained three products which were separated by preparative gas chromato-



35

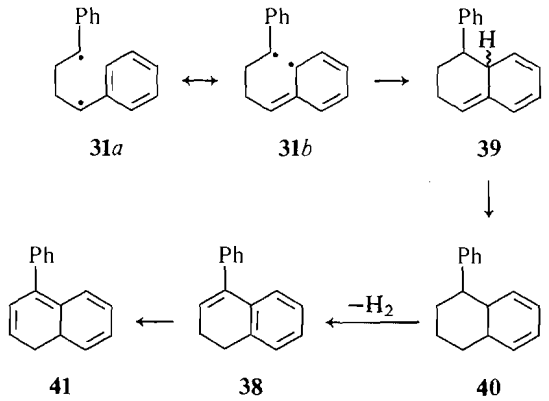
graphy and identified as 1,1-diphenylethylene **36** (19%), 1,1-diphenyl-1,3-butadiene **37** (21%), and 1-phenyl-3,4-dihydronaphthalene **38** (38%).



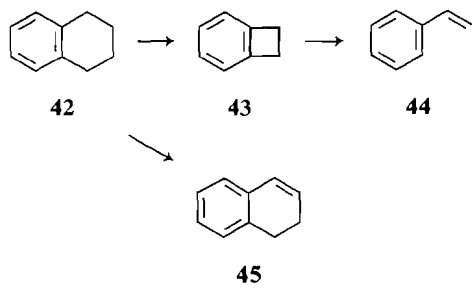
36 **37** **38**

The formation of these products can be rationalized by initial formation of the postulated diradical **31***a* by the loss of SO_2; ring closure of the diradical resonance contributor **31***b* would form the unstable intermediate **39** which upon aromatization

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.



gives 1-phenyl-1,2,3,4-tetrahydronaphthalene **40**. Loss of H_2 from **40** would result in the observed product **38**. A 1,5-sigmatropic shift in **38** would produce 1-phenyl-4,10-dihydronaphthalene **41** which upon electrocyclic ring opening would form the observed 1,1-diphenyl-1,3-butadiene **37**. The reverse reaction, that is the thermal ring closure of **37** to **38**, has been observed by Weber and co-workers, with the 1,5-sigmatropic shift being demonstrated by deuterium labelling (11). The formation of α-phenylstyrene **36** may result from **40** as Trahanovsky and Swenson postulate for the thermolysis of tetralin **42**, that a retro-Diels–Alder produces benzocyclobutene **43** which rearranges to styrene **44**. A small amount of 1,2-dihydronaphthalene **45** is also produced (12).



It must be emphasized that the above reactions are occurring under high vacuum and temperature and "normal" reaction pathways may not be applicable.

Experimental

Chemical reagents were obtained from commercial sources and used without purification, unless otherwise noted. Melting points were obtained in open capillaries on a Gallenkamp block apparatus and, along with boiling points, are uncorrected.

Solvents specified as dry were treated in the following manner: tetrahydrofuran, freshly distilled from the blue sodium ketyl of benzophenone; benzene, distillation of 20% of volume, retaining the residue. Anhydrous diethyl ether was used as obtained from a freshly opened can obtained from Mallinckrodt Canada Ltd. Purified solvents were stored over 4 Å molecular sieves under an atmosphere of dry nitrogen.

Infrared spectra were recorded with a Perkin–Elmer Model 257 or 297 grating spectrophotometer, calibrated with the 1602 cm^{-1} line of polystyrene. The ^1H nmr spectra were recorded on a Varian Associates T-60, T-60A, or XL-200 spectrometer in $CDCl_3$ solution, unless otherwise specified. The ^{13}C nmr spectra were recorded on a Bruker WH90 spectrometer operating at 22.63 MHz. The nmr data are reported in δ units (ppm) relative to internal tetramethylsilane (TMS) using the abbreviations: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; b, broad. The ^1H nmr spectra were recorded at 60 MHz unless otherwise specified and ^{13}C nmr spectra were recorded at 22.63 MHz. Mass spectra were obtained using an LKB 9000 mass spectrometer at 70 eV using a direct insertion probe. Gas-chromatographic mass spectral analyses were obtained using a Hewlett–Packard 5984A system equipped with a 2 m × 3 mm od glass column of 6% OV-101 on Chromosorb W High Performance (100/120 mesh). Mass spectral data are reported as fragment identification *m/e* $M^{+\cdot} - X(\%)$.

Gas-chromatographic analyses were performed on a Hewlett–Packard Model 5751A or 5734A research chromatograph using the following 2 m × 3 mm od stainless steel columns: 10% S.E.-30 Ultraphase on Chromosorb W (A/W-DMCS, 80/100 mesh), 5% OV-101 on Chromosorb W (A/W-DMCS, 80/100 mesh). Preparative gas-chromatographic separations were performed on a Varian Associates Autoprep 700 or Hewlett–Packard 5751A chromatograph equipped with a 2 m × 6 mm od aluminum colum packed with 15% S.E.-30 on Chromosorb W (A/W-DMCS, 60/80 mesh). Thin-layer chromatography (tlc) was performed on E. Merck silica gel 60PF-254 (E. Merck) spread on 20 cm × 20 cm plates to a thickness of 2 mm using the specified solvent systems.

Photolyses were done using a Rayonet Reactor with 254, 300, and 360 nm tubes, using quartz or Pyrex sample tubes. Flash vacuum thermolyses were performed using an all-quartz apparatus with the hot zone heated by an electrical resistance furnace. The cold probe was cooled by Dry Ice – acetone at −78°C.

Ultraviolet absorptions were obtained on a Pye–Unicam spectrophotometer in the designated solvents.

Elemental analyses were carried out by Galbraith Laboratories, Knoxville, Tenn. or by Guelph Microanalytical Services, Guelph, Ont.

*Thermolysis of 5H,8H-dibenzo[d,f][1,2]oxathiocin-1-oxide (**12**a)*

Cyclic sulfinate ester **12***a* (0.1 g, 0.41 mmol) was thermolyzed with a sublimation temperature of 150°C through a hot zone of 700°C at a pressure of 0.05 Torr. The yellow solid which collected on the cold probe (−78°C) was washed off with chloroform and chromatographed by preparative tlc (silica gel, toluene). This afforded 9,10-dihydrophenanthrene **14** (0.065 g, 90%) identified by comparison of the ^1H nmr and gc with an authentic sample.

*Photolysis of 5H,8H-dibenz[d,f][1,2]oxathiocin-1-oxide (**12**a)*

Photolysis of **12***a* (0.1 g, 0.41 mmol) in 15 mL of degassed methanol for 18 h through quartz at 254 nm yielded a mixture of 9,10-dihydrophenanthrene **14** and phenanthrene **15** (9:1) as analyzed by gc (S.E.-30).

*Thermolysis of 2H,7H-2,2,7,7-tetramethyldibenz[a,e]thiepine (**13**b)*

Thermolysis of cyclic sulfone **13***b* (0.1 g, 0.33 mmol) with a sublimation oven temperature of 210°C through a hot zone of 520°C at 0.01 Torr yielded a yellow solid on the cold probe which when chromatographed on preparative tlc (silica gel, hexanes) was separated into two fractions; A: 2-(2-isopropenyl)-2′-(2-isopropyl)biphenyl **17** (0.01 g, 12%); ^1H nmr δ: 7.6–7.2 (m, 8H), 6.1–5.9 (d, 2H), 2.9 (q, 1H, J = 8 Hz), 1.65 (s, 3H), 1.1 (d, 3H, J = 8 Hz), 1.05 (d, 3H, J = 8 Hz); ms $M^{+\cdot}$: 236 (0.1), $M-15$, 221 (2), $M-54$, 182 (63), 105 (100), 77 (60), 50 (30). B: 9,9,10,10-tetramethyl-9,10-dihydrophenanthrene **16** (0.63 g, 80%); ^1H nmr δ: 8.1–7.3 (m, 8H), 1.8–1.0 (bs, 12H); ms $M^{+\cdot}$: 236 (40), $M-15$, 221 (100), $M-30$, 206 (51), $M-58$, 178 (20), 165 (18). *Anal.* calcd.: C 91.30, H 8.71; found: C 91.47, H 8.53.

*Photolysis of **13**b*

Photolysis of cyclic sulfone **13***b* (0.1 g, 0.33 mmol) in 8 mL methanol and 2 mL methylene chloride through quartz at 254 nm for five hours yielded 9,9,10,10-tetramethyl-9,10-dihydrophenanthrene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

16 (25%) and 2-(2-isopropenyl)-2′-(2-isopropyl)biophenyl **17** (74%) by gc. Photolysis in ether at 254 nm and in methylene chloride at 350 nm with benzophenone as sensitizer yielded similar product ratios.

Thermolysis of ***13****b at 850°C*

Thermolysis of **13***b* (0.1 g, 0.33 mmol) 850°C/0.05 Torr yielded three compounds by gc analysis (S.E.-30); 2-(2-isopropenyl)-2′-(2-isopropyl)biphenyl **17** (2%), 9,9,10,10-tetramethyl-9,10-dihydrophenanthrene **16** (24%), and 9,10-dimethylphenanthrene **23** (60%); mp 135–138°C (lit. (13) mp 138–139°C; ^{1}H nmr δ: 8.4–7.0 (m, 8H), 2.5 (s, 6H); ms $M^{+\cdot}$: 206 (89), M − 15, 191 (100).

*Thermolysis of 9,9,10,10-tetramethyl-9,10-dihydrophenanthrene (****16****)*

Thermolysis of **16** (0.1 g, 0.42 mmol) at 850°C/0.05 Torr yielded a mixture of **16** (26%) and **23** (64%) by gc analysis (S.E.-30).

*Thermolysis of 3*H*-naphtho[*d,e*][1,2]oxathiepin-1-oxide (****24****)*

Thermolysis of **24** (0.1 g, 0.46 mmol) 500°C/0.05 Torr with a sublimation oven temperature of 100°C yielded pure acenaphthene **25** (0.06 g, 91%) by gc and nmr comparison with an authentic sample.

Photolysis of ***24***

Photolysis of **24** (0.1 g, 0.46 mmol) in 12 mL degassed benzene at 350 nm through Pyrex for 18 h yielded acenaphthene **25** (80%) pure by gc.

*Thermolysis of 3,6-diphenyl-1,2-oxathiane-1-oxide (****30****)*

Thermolysis of **30** (0.1 g, 0.37 mmol) at 450°C/0.05 Torr with a sublimation oven temperature of 150°C yielded three compounds which were separated by preparative gc (2 m × 6 mm od 15% S.E.-30). They were 1,1-diphenyl ethylene **36** (0.014 g, 20%); ^{1}H nmr δ: 7.35 (s, 10H), 5.45 (s, 2H); ms $M^{+\cdot}$: 180 (100), M − 1, 179 (74), M − 2, 178 (72), M − 15, 165 (70); 1,1-diphenyl-1,3-butadiene **37** (0.016 g, 21%); ^{1}H nmr δ: 7.4–7.2 (m, 10H), 6.8 (d, 1H, J = 11 Hz), 6.5 (m, 1H), 5.3 (d, 1H, J = 17 Hz), 5.1 (d, 1H, J = 11 Hz); ms $M^{+\cdot}$ + 1, 207 (100), M + 2, 208 (59), 102 (61); 1-phenyl-3,4-dihydronaphthalene **38** (0.029 g, 38%); ^{1}H nmr δ: 7.4–7.1 (m, 9H), 5.1 (t, 1H, J = 6 Hz), 2.8 (t, 2H, J = 8 Hz), 2.4 (m, 2H); ms $M^{+\cdot}$: 206 (100), M − 15, 191 (60), 205 (30), 91 (40), identified by comparison of ^{1}H nmr and mass spectral data with published spectra for these compounds.

Mass spectra of some substituted methylcyclosiloxanes

E. PELLETIER AND J. F. HARROD
Chemistry Department, McGill University, 801 Sherbrooke Street West, Montreal, P.Q., Canada H3A 2K6

Received September 15, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

E. PELLETIER and J. F. HARROD. Can. J. Chem. **61**, 762 (1983).

The mass spectra of the substituted methylcyclosiloxanes $+Si(CH_3)(X)O+_n$, where X = H (n = 4, 5 and 6), X = C_6H_5 (n = 3 and 4), X = Br (n = 3 and 4), X = $Co(CO)_4$ (n = 4 and 5) have been measured. The compounds X = H fragment by the same kinds of substituent loss and ring contraction mechanisms as previously reported for the compounds X = CH_3 but also by the loss of methylhydrogensilanone. The compounds X = Ph fragment by loss of benzene from an intramolecularly bridging benzenonium ion, formed from $[M - CH_3]^{+\cdot}$ and by losses of the phenylmethylsilanone fragments. The compounds X = Br only undergo substituent loss without ring fragmentation. The compounds X = $Co(CO)_4$ show stepwise loss of all CO groups from $[M]^{+\cdot}$, $[M - Co(CO)_4]^+$, and $[M]^{++}$.

E. PELLETIER et J. F. HARROD. Can. J. Chem. **61**, 762 (1983).

On a mesuré les spectres de masse des méthylcyclosiloxanes substitués $+Si(CH_3)(X)O+_n$ ou X = H (n = 4, 5 et 6), X = C_6H_5 (n = 3 et 4), X = Br (n = 3 et 4), X = $Co(CO)_4$ (n = 4 et 5). Les composés X = H se fragmentent selon les mêmes mécanismes de perte de substituant et de contraction de cycle rapportés antérieurement pour les composés du type X = CH_3, mais ils se fragmentent également en perdant de la méthylhydrogensilanone. Les composés X = Ph se fragmentent en perdant du benzène à partir de l'ion benzenonium, en position de pont intramoléculaire, formé à partir de $[M - CH_3]^{+\cdot}$ et en perdant des fragments de phénylméthylsilanone. Les composés du type X = Br subissent uniquement une perte de substituant sans fragmentation du cycle. Les composés du type X = $Co(CO)_4$ perdent par étapes tous les groupes CO à partir de $[M]^{+\cdot}$, de $[M - Co(CO)_4]^+$ et de $[M]^{++}$.

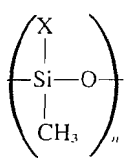
Introduction

In the course of a current project we have used, or newly synthesized, a variety of methylcyclosiloxanes of the general formula **1**. The mass spectra of these compounds have been routinely measured as a part of their structural characterization.



Substituent X	Abbreviation
CH_3	D_n
C_6H_5	D_n^{Ph}
Br	D_n^{Br}
$Co(CO)_4$	D_n^{Co}
H	D_n^H

1

A number of interesting features which have emerged from these studies are presented in the present paper.

The literature on the mass spectrometry of cyclosiloxanes is limited to the detailed study of the fully methylated compounds (1, 2). A useful review of the mass spectrometry of organosilicon compounds has been published by Coutant and Robinson (3).

Results

The methylhydrogencyclosiloxanes

In each spectrum of D_n^H (n = 4, 5, 6) the heaviest ions are $[M - 1]^+$ and $[M - 15]^+$ and the relative intensities of these ions diminish with increasing ring size (Fig. 1). The absence of $[M]^{+\cdot}$ is a common feature of methylsiloxane fragmentation due to the facile loss of $CH_3^{\cdot}$ from the parent ions (1, 2). Another evident feature of the spectrum is the high intensity of the peaks m/e 73, 59, and 45 in D_5^H and D_6^H compared to D_4^H.

The spectra of D_n^H are considerably richer in lines than those of D_n. For example, the spectrum of D_5^H (Fig. 1) shows eleven peaks of relative intensity >10 per cent, whilst D_5 shows only three major peaks at $[M - 15]^+$, $[M - 103]^+$, and m/e 73 (1–3). The two groupings of lines at $[M - 47]^+$, $[M - 61]^+$, and $[M - 75]^+$, and at $[M - 107]^+$, $[M - 121]^+$, and $[M - 135]^+$, consistently present in D_n^H, are separated by a characteristic mass increment of 60 amu. Exact mass measurements on D_5^H show this increment to be in fact due to two processes: loss of SiO_2 and also of $(CH_3)HSiO$ (Table 1). The separation between the lines of these two groups, as well as those between the light ions at m/e 73, 59, and 45, all correspond to a mass increment of 14 amu. Contrary to the case of D_n, no evidence for significant currents of doubly charged ions was observed, except in D_6^H where m/e 179 can be attributed to $[M - 2]^{++}$.

The methylphenyl- and the methylbromocyclosiloxanes

The mass spectra of D_n^{Ph} (n = 3 and 4) are given in Fig. 2. Both compounds show the molecular ion at low intensity on the oscillograms. The major peaks in both spectra occur at $[M - 15]^+$ and $[M - 93]^+$. It is clear that the distribution of peaks in these two compounds is quite different from that in D_n and D_n^H and reflects a very different fragmentation mechanism.

The spectra of D_3^{Br} and D_4^{Br} are notable for their simplicity (Fig. 3). In neither case is $[M]^+$ observed, and the strongest peaks are due to $[M - CH_4]^{+\cdot}$ and $[M - HBr]^{+\cdot}$. Apart from these peaks, the only others with relative abundance >10 per cent are those at m/e 128 and 129 (D_3^{Br}) and at m/e 197, 198, and 199 (D_4^{Br}) attributed to doubly charged $[M - 2Br]^{++}$. As expected, HBr^+ (m/e 80, 82) and Br^+ (m/e 79, 81) are present in both spectra.

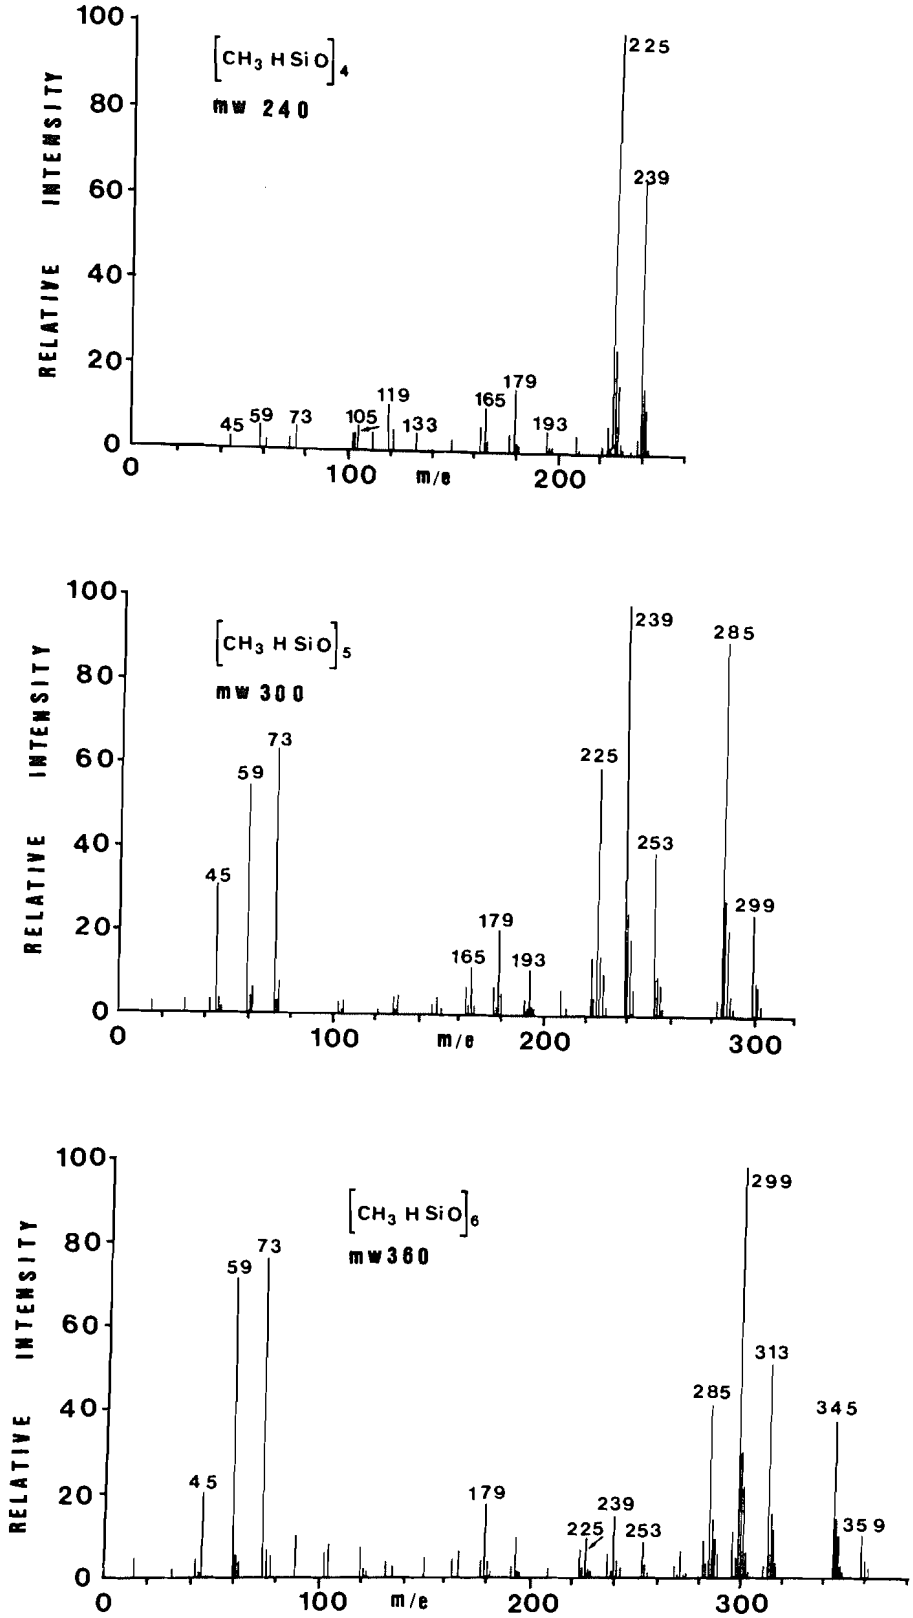

FIG. 1. Mass spectra of methylhydrogencyclosiloxanes, D_n^H (n = 4, 5, 6).

The tetracarbonylcobaltmethylcyclosiloxane

The expanded spectra of D_4^{Co} and D_5^{Co} are shown in Figs. 4 and 5. The presence of geminate series of lines is highlighted. The first series (noted a_1, a_2, a_3...), beginning at the highest mass, corresponds to the stepwise loss of all CO ligands from $[M]^{+\bullet}$. The second series (noted b_1, b_2, b_3...), beginning at $[M - 171]^+$, corresponds to stepwise loss of all CO ligands from $[M - Co(CO)_4]^+$. Also, quite important in terms of total ion current are the series of CO dissociations from doubly charged ions, evidenced by the large number of peaks separated

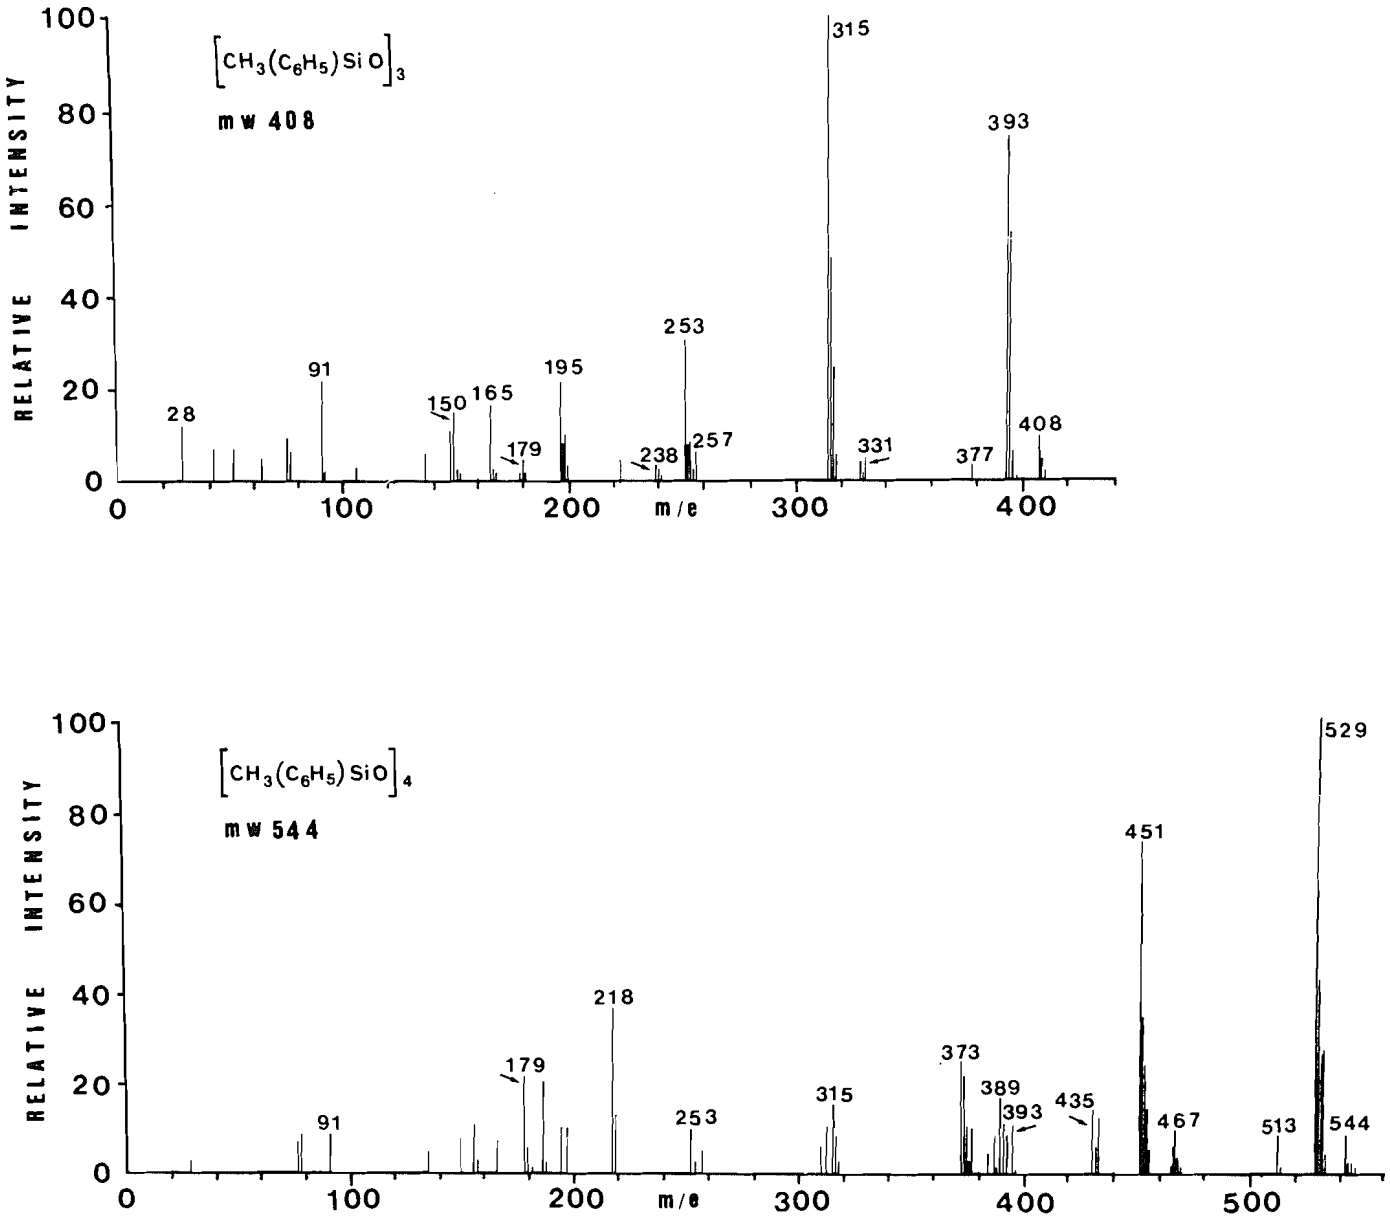

FIG. 2. Mass spectra of methylphenylcyclosiloxanes, D_n^{Ph} (n = 3 and 4).

TABLE 1. (a) Some ions in spectra of D_n^H series

Metastable ions	Observed	Calculated
in D_4^H	142	$(179)^2/225 = 142.4$
D_5^H	201	$(239)^2/285 = 200.4$
D_6^H	259	$(299)^2/345 = 259.1$

(b) High resolution mass measurements on D_5^H:

Ions$^+$	m/e	Observed	Calculated
$[M - 47]^+$	253	252.988	252.984 ($C_4H_{13}Si_4O_5$)
$[M - 61]^+$	239	238.965	238.968 ($C_3H_{11}Si_4O_5$)
$[M - 75]^+$	225	224.951	224.953 ($C_2H_9Si_4O_5$)
$[M - 107]^+$	193	192.958	192.981 ($C_3H_9Si_3O_4$)
$[M - 121]^+$	179	178.999	179.002 ($C_3H_{11}Si_3O_3$)
		178.964	178.965 ($C_2H_7Si_3O_4$)
$[M - 135]^+$	165	164.984	164.986 ($C_2H_9Si_3O_3$)
		164.947	164.949 ($C_1H_5Si_3O_4$)

by 14 amu in the m/e 200 to 500 region of the spectrum of D_5^{Co} (Fig. 5).

Discussion

The methylhydrogencyclosiloxanes

Previous studies of mixed methylhydrogensiloxane systems have shown that fragmentation by either methyl or by hydrogen loss occurs with similar ease. Thus, the cyclopentasiloxane $\text{-(-Si(CH}_3)_2\text{—O-)}_4\text{-(-Si(CH}_3)\text{H—O-)-}$ fragments by loss of both $Si(CH_3)_4$ and $HSi(CH_3)_3$ (2). In the fragmentation of $H(CH_3)_2Si\text{—O-(-Si(CH}_3)_2\text{—O-)-}_2Si(CH_3)_3$ the dominant process, following initial $CH_3^{\cdot}$ loss, is loss of $HSi(CH_3)_3$ to produce $[M - 89]^+$ (3). Either hydrogen or methyl migration could give rise to these products, but the data do not allow a distinction to be made. Thus, it would not be unreasonable to assume that the fragmentation of D_n^H occurs by the same mechanism as previously proposed (1, 2) for D_n ($n \geq 5$), but with both CH_3 and H undergoing dissociation and migration. The key step in this mechanism is a ring contraction in the ion

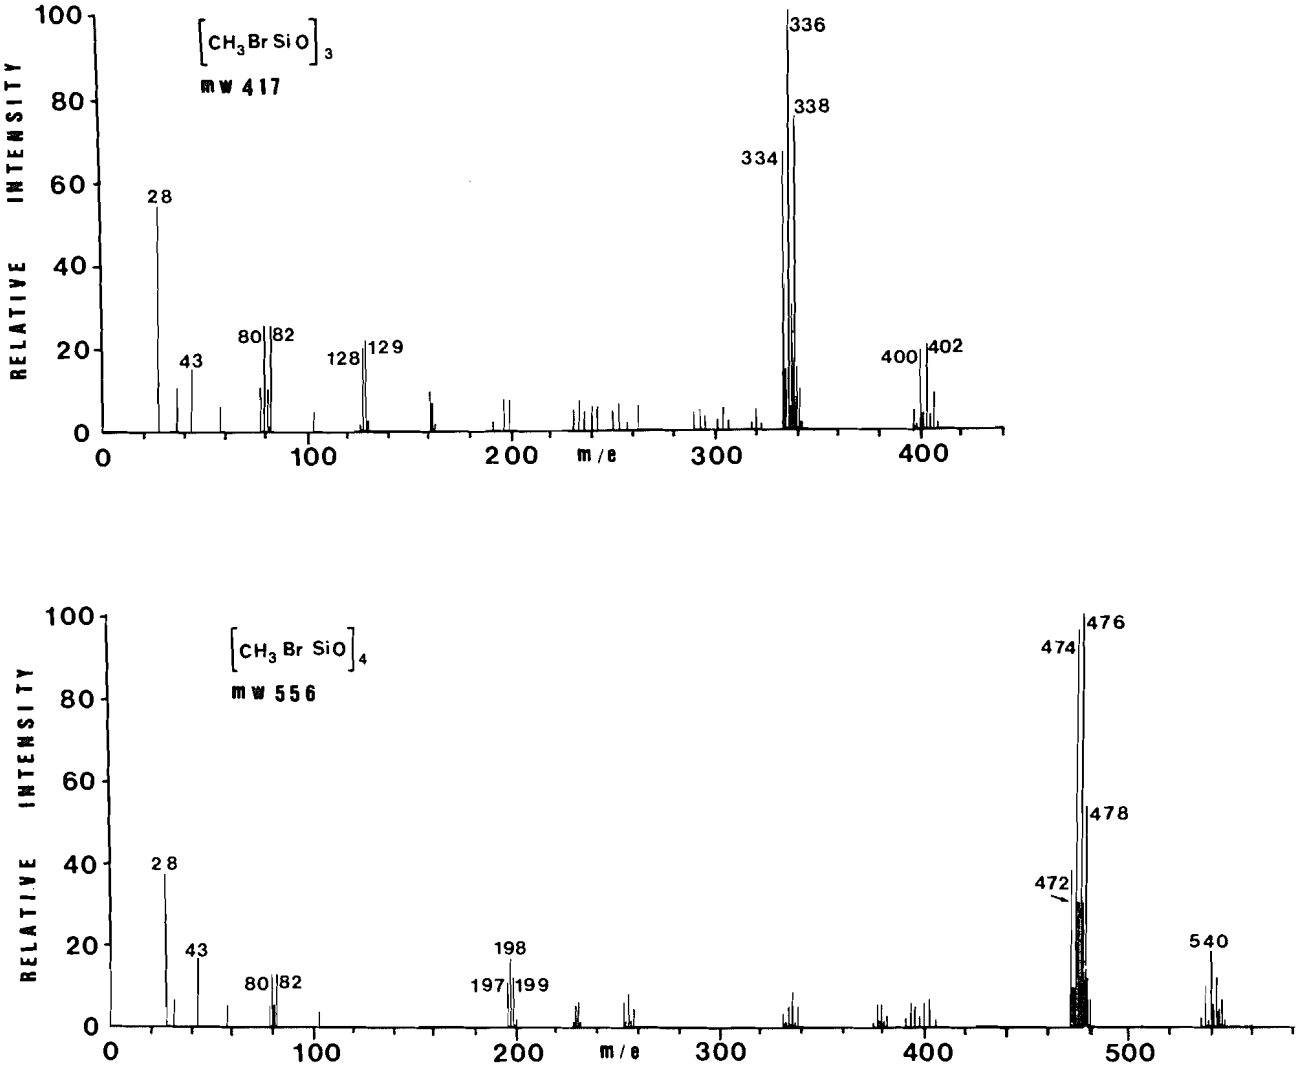

FIG. 3. Mass spectra of methylbromocyclosiloxanes, D_n^{Br} (n = 3 and 4).

following initial loss of $CH_3^{\bullet}$. A similar scheme for D_n^H, where it is assumed that either $CH_3^{\bullet}$ or $H^{\bullet}$ can be lost to form the initial cation fragment, and either CH_3 or H can participate in the subsequent migration accompanying ring contraction, is shown in Scheme 1. The contracted rings $[M - 1]^+$ and $[M - 15]^+$ lead to the formation of the series $[M - 47]^+$, $[M - 61]^+$, and $[M - 75]^+$ by loss of the appropriate neutral silanes, $H_{3-n}Si(CH_3)_n$, as exemplified for $[M - 15]^+$ in Scheme 2. The nature of ions proposed in Scheme 2 is supported by peak matching for D_5^H (Table 1). Metastable ions corresponding to fragmentation $[M - 15]^+ \rightarrow [M - 61]^+ + H_3SiCH_3$ are observed in all spectra of D_n^H. The second grouping of three peaks, $[M - 107]^+$, $[M - 121]^+$, and $[M - 135]^+$, is generated by loss of SiO_2 or $(CH_3)HSiO$ from the first group. Scheme 3 highlights the presence of two ions $[M - 121]^+$ which come from $[M - 61]^+$, both completely resolved in high resolution spectrum of D_5^H (Table 1).

The methylphenylcyclosiloxanes

Since D_5^{Ph} has not been isolated, our measurements were restricted to the n = 3 and 4 compounds. The observed spectra conform quite well to a mechanism recently proposed for the fragmentation of aryl substituted linear siloxanes (4). The most interesting feature of this mechanism, shown in Scheme 4, involves the formation of an intramolecularly bridging benzenonium ion from $[M - 15]^+$, followed by either loss of benzene or, to a much lesser degree, methane (4). A second aspect of the mechanism is the elimination of the elements by phenylmethylsilanone from the $[M - 15]^+$, and for D_4^{Ph} the $[M - 93]^+$ ion. These hypotheses account for most of the important observed heavier ions in D_n^{Ph}.

The rather intense $[M - 155]^+$, m/e 253, and $[M - 213]^+$, m/e 195, for D_3^{Ph} (much weaker in D_4^{Ph}) suggest a relatively important initial fragmentation by loss of $C_6H_5^{\bullet}$, with the resulting ion undergoing losses of either benzene or the elements of phenylmethylsilanone, analogous to the reactions of $[M - CH_3]^+$. The loss of CH_3 from $[M - C_6H_5]^+$ could also make a substantial contribution to $[M - 92]^+$, in addition to that made by loss of $C_6H_5^{\bullet}$ from $[M - CH_3]^+$.

The absence of peaks at $[M - 202]^+$ and $[M - 150]^+$ indicates that ring contractions of the $[M - CH_3]^+$ ion by loss of $[Si(CH_3)_2(C_6H_5)]^+$ and $[Si(CH_3)(C_6H_5)_2]^+$, such as occur with D_n and D_n^H, do not occur with D_n^{Ph}.

No ring contraction, either by transannular migration or by loss of silanone fragments, was observed with D_n^{Br}. The major ions in both spectra, $[M - CH_4]^{+\bullet}$ and $[M - HBr]^{+\bullet}$, are

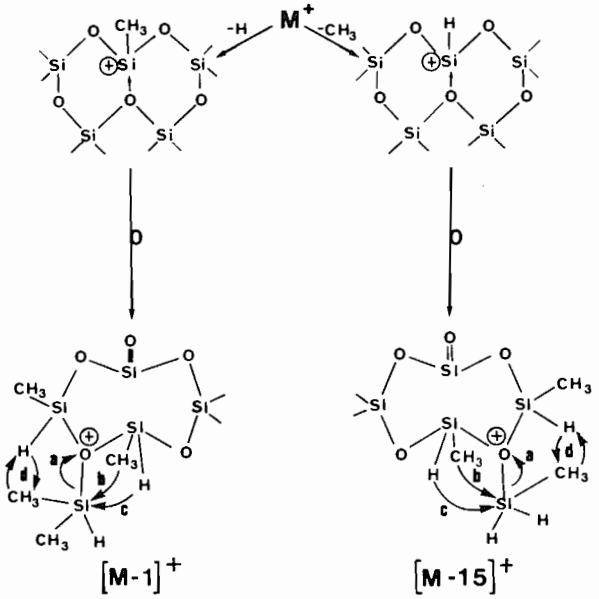
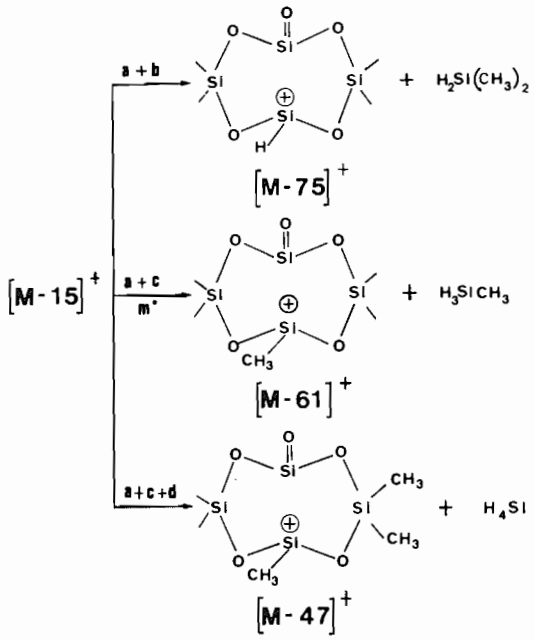


SCHEME 1. Transannular migration and ring contraction of D_n^H.



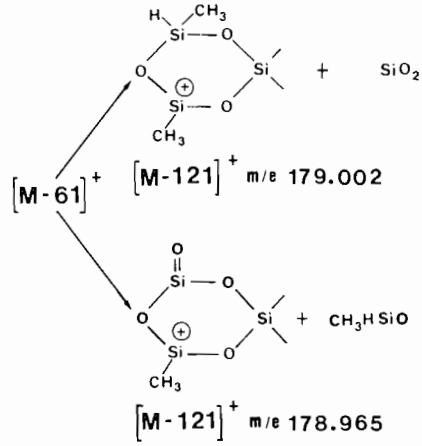
SCHEME 2. Fragmentation of ion $[M - 15]^+$.

formed by the abstraction either by a CH_3 group or a bromine atom of a hydrogen atom from an adjacent or a transannular methyl group. This mechanism is favoured because of the spatial disposition of substituents on the siloxane rings.

The loss of fragments to form doubly charged ions is particularly evident in D_n and D_n^{Br} ($n = 3$ and 4) compared to D_n^{Ph} and D_n^H. Apparently the absence of alternative facile fragmentation pathways is responsible for such behaviour in these cases.

The tetracarbonylcobaltmethylcyclosiloxanes

Metal carbonyls and their derivatives undergo stepwise loss of CO ligands under mass spectrometry conditions (5). It is usual for such compounds to show a stepwise loss of all CO groups to produce the base metal ion, or the metal ion plus



SCHEME 3. Fragmentation of ion $[M - 61]^+$.

original substituents other than CO. The low ionization potentials of transition metal atoms also result in the common appearance of multiply-charged ions in carbonyl mass spectra. To our knowledge, one of the heaviest clusters for which a complete mass spectrometric analysis has been reported is $Ru_6C(CO)_{17}$. This compound shows a stepwise loss of seventeen CO groups from both the singly and doubly charged ions (6).

The mass spectra of several simple silylcobalttetracarbonyls have been reported and they show the typical stepwise loss of CO (7). The spectra of the compounds reported in the present study have a number of novel features. The most striking aspect of the spectra is the fact that one can observe the stepwise loss of such a large number of CO groups. Since D_n^H rings of $n > 5$ are fairly easily obtainable by chromatographic separation of a CH_3SiHCl_2 hydrolysate, and since there is no reason to believe that they cannot be converted to the appropriate D_n^{Co} analogues, one could envisage molecules with many more than the reported twenty CO ligands for D_5^{Co}. The relatively high volatility of these compounds, together with their high molecular weight, suggests that they may have some value as mass markers.

Unlike the fragmentation of carbonyl clusters, where breakup of the metal cluster does not usually occur under mass spectrometer operating conditions, the D_n^{Co} compounds do show loss of metal fragments. Thus, the most obvious feature of the spectra is the presence of the two series corresponding to stepwise loss of $4n$CO molecules from $[M]^{+\cdot}$. A more careful scrutiny of the spectra also shows the presence of a series corresponding to stepwise loss of $4n$CO molecules from $[M]^{++}$ (Fig. 5).

Although $[M - 15]^+$ was detected at low abundance for both $n = 4$ and 5, no CO loss series was detected for this ion.

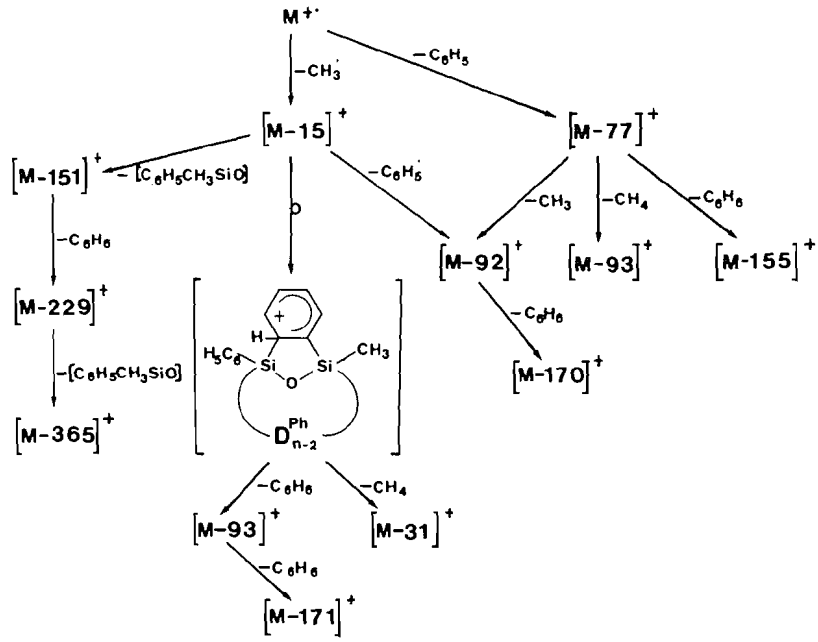
In conclusion, it is evident that the carbonyl fragmentation occurs with such ease that none of the fragmentation processes that occur in other cyclosiloxanes, even the loss of CH_3, are significantly activated in the D_n^{Co} compounds.

Experimental

Synthesis of substituted cyclosiloxanes

The compounds D_n^{Ph} and D_n^H were prepared according to published procedures (8, 9).

The compounds D_n^{Br} were prepared by reaction of D_n^{Ph} with Br_2 at low temperature. The compounds D_n^{Co} were prepared by reactions of D_n^H with $Co_2(CO)_8$, following a modification of published procedures (10). The compound D_3^{Co} could not be prepared due to the great



SCHEME 4. Fragmentation pattern of methylphenylcyclosiloxanes.

instability of D_3^H. An alternative synthesis by reaction of D_3^{Br} with $Co(CO)_4^-$ was unsuccessful.

Measurement of mass spectra

The low resolution spectra of D_n^H and D_n^{Co} were measured on an LKB (model 9000) instrument (electron energy 70 eV, source temperature 270°C). D_4^H was introduced directly as a pure compound at an inlet temperature of 100°C. The spectra of D_5^H and D_6^H were obtained following separation of a CH_3SiCl_2H hydrolysate, stripped of D_4^H, on a two-metre glass column of 6 per cent OV-101 at a temperature of 135°C. Samples of D_4^{Co} and D_5^{Co} were introduced directly at probe temperatures of 46 and 50°C respectively.

The low resolution spectra of D_n^{Ph} and D_n^{Br} were measured on a DuPont 21-492B instrument (electron energy 70 eV, source temperature 250°C). D_3^{Ph} and D_4^{Ph} were introduced directly at probe temperatures of 55 and 80°C respectively. Both D_n^{Br} compounds were sufficiently volatile to be introduced directly at ambient temperature.

The high resolution measurements have been performed on a AEI MP902 spectrometer (at 70 eV ionizing energy and source temperature 250°C) at Laboratoire de spectrometrie de masse, Université de Montréal, Québec.

Received September 21, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

BRYAN E. SNOW, JOHN M. D'AURIA, RICHARD SHUTLER, JR., and JOHN G. PAYNE. Can. J. Chem. **61**, 769 (1983).

Ceramic sherds of "primitive" manufacture from an archaeological site on Fuga Moro Island, Philippines, were analyzed for trace element contents using energy dispersive X-ray fluorescence (EDXRF) to ascertain the probability of obtaining differentiation between stylistic classes (wares) and technological types within the ware. Following analysis and differentiation of these samples, using standard archaeologic and petrographic techniques, the initial focus of the study was to isolate surface factors which could distort or otherwise affect the final elemental characterizations. Once these factors were identified and eliminated, a simple procedure was then developed employing trivariate analysis of specific observed elements that unambiguously segregated the studied sherds, both according to ware and technological type within each ware. The key elements for ware differentiation were Zn, Br, and Sr while type differentiation was achieved using Ca, Ti, Mn, and Rb.

BRYAN E. SNOW, JOHN M. D'AURIA, RICHARD SHUTLER, JR. et JOHN G. PAYNE. Can. J. Chem. **61**, 769 (1983).

On a déterminé la teneur en oligoéléments des fragments de céramique de construction "primitive" provenant d'un site archéologique de l'île de Fuga Moro, Phillipines. On a utilisé la flourescence de rayons-X d'énergie dispersante (FRXED) pour essayer d'établir une distinction entre les classes élégantes (porcelaines) et les types technologiques à l'intérieur de la porcelaine. A la suite de l'analyse et de la différenciation de ces échantillons à partir des techniques archéologiques et pétrographiques normales, le but initial de l'étude est d'isoler les facteurs de surface qui peuvent déformer ou affecter d'une façon ou d'une autre les caractérisations élémentaires finales. Une fois ces facteurs identifiés et éliminés, on a mis au point une méthode simple qui fait appel à l'analyse à "trois variables" des éléments observés spécifiquement que l'on peut isoler sans aucun doute des fragments étudiés selon la porcelaine et le type technologique dans chaque porcelaine. Les éléments principaux qui permettent de différencier les porcelaines sont: le Zn, le Br et le Sr tandis que l'on différencie le type de porcelaine à l'aide du Ca, du Ti, du Mn et du Rb.

[Traduit par le journal]

Introduction

Perhaps the single, most fundamental problem confronting all archaeologists is the classification of observed phenomena. Nowhere is this more demanding than in the study of ancient ceramics. Due to their abundance, ceramics have come to play a major role in archaeological constructs of past peoples and ordinations of cultural developments. They are extensively utilized in both the Old and New World as time markers and cultural diagnostics. By and large, however, archaeologists have responded to the difficulties of ceramic classification in a nonrigorous manner. They have developed a priori, broad generalized classificatory units[3] which rely upon a few selective characteristics or "attributes" to denote membership. In most ceramic classifications, the attributes traditionally employed are stylistic in nature and usually concentrate upon aspects of decoration or surface treatment.

Armed with such classificatory schemes, archaeologists have been invading, in growing numbers and with some success, the realm of the physical sciences. They have been concerned with questions of provenance (i.e., identifying the source(s) of ceramic manufacturing) or characterization (i.e., isolating distinctive chemical patterning). The response of the physical sciences has been laudable. Working independently or jointly with the archaeologists, physical scientists have employed a variety of techniques for multi trace element analysis in an attempt to address these problems (*1–14*). The results have provided some interesting and highly significant information for the study of archaeological ceramics. There is one important fact, however, that characterizes all of this research. The physical scientist is dependent upon the archaeologist for the initial classification of the ceramics and, in all likelihood, the actual selection of the sherd samples to be analyzed. Since all archaeological classifications are essentially interpretations of observed variability, this presents a very basic problem. If the archaeologist has employed a traditional approach, he has formed his classificatory units by visual inspection of a few obvious stylistic attributes. The resultant units are broad and generalized in nature and, if he has merely sorted his ceramics in accordance with pre-existing stylistic typologies, may be completely nonanalytical. Classificatory units obtained in this manner may conceal significant variability in technological or nonstylistic attributes; i.e., variability which may be linked to trace element patterning.

Given the generalizing tendencies of many archaeological classifications, the success enjoyed by the researchers cited above seems nothing short of incredible until one considers the cultural context of the analyzed ceramics. All of these studies deal with ceramics from highly advanced Old World cultures where the production of pottery had reached a high level of standardization, both in clay source utilization and technological process. In such contexts, the most variable attributes at the intra-assemblage level are indeed stylistic and are there-

fore easily and accurately depicted by traditional classifications.

In so-called "primitive" pre-wheel (i.e., potter's wheel) societies, there exists no such sophisticated standardization. Usually, each adult female within a given settlement was responsible for the family's pottery production, so variability becomes markedly intensified. It is within these contexts that stylistic classifications most effectively mask technological variability and may create difficulties for the physical scientist attempting multi trace element analysis.

Perhaps the single, most ambitious multi trace element analysis of "primitive" ceramics was undertaken by Leo Yaffe and his co-workers at McGill University (15). This research examined Ontario Iroquois and St. Lawrence Iroquois pottery. One of its stated objectives was to investigate associations between chemical groups and traditional classificatory units (15). Since Iroquoian ceramic classification is wholly dependent upon stylistic attributes and is extremely generalizing in nature (16), their findings in this regard may have direct relevance to the points just raised. Interestingly, the research could not find any significant correlation between the traditional classificatory units employed by the archaeologists and the analytically determined chemical groups of the physical scientists (15).

Our intent in this report is to examine the relationship of intra-assemblage technological variability to multi trace element patterning in a primitive ceramic context. Specifically, are there chemical patterns present which are dependent upon technological rather than stylistic factors? Further, can such patterns differentiate between different stylistic classes and between different technological groups? We have employed nondestructive, energy dispersive X-ray fluorescence (EDXRF) to address this question. Our study sample is derived from two, distinct, stylistic classes of red slipped[4] earthenware recovered from the 1978 excavation[5] of a small beach ridge site ($78M_1$-Site 2) on Fuga Moro Island, Philippines. We offer the resultant data primarily as an aid to physical scientists who are interested in the chemical analysis of "primitive" ceramics. Furthermore, the results suggest that archaeologists may be oversimplifying the complexity of "primitive" ceramics when they opt for stylistic classifications and, as a result, are overlooking important avenues of research.

Archaeology

Fuga Moro is 1 kilometre east of the mountainous northeastern peninsula of Luzon, along the San Vincente Strait (Fig. 1). It is approximately 1 kilometre in diameter and, during low tide, is connected by a reef along its northernly margin to the larger island of Paluai. As is commonly the case upon many sites in the region, no dateable organic material was recovered during the excavations. The discovery, however, of several Chinese porcelain sherds indicates that the site was being occupied sometime during the 14th to early 16th Centuries A.D. (17).

The two stylistic classes utilized in this study jointly total 679 sherds or approximately 80% of the analyzable ceramics recovered from the site. They are designated herein as Wares A and B, respectively. They exhibit stylistic variability in terms of surface treatment and slip appearance. For the samples studied here the thickness of the slip was less than about 50 microns. Their respective sherd incidences and distinguishing stylistic attributes are briefly summarized in Table 1.

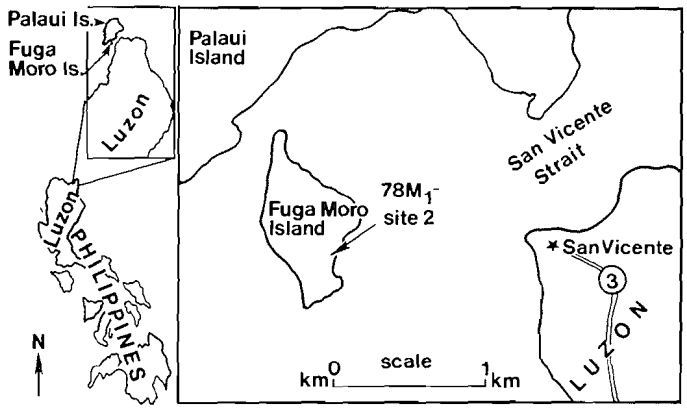

FIG. 1. Geographic position of Fuga Moro Island, Philippines and site location ($78M_1$-Site 2).

The archaeological analysis of these ceramics had been technologically oriented and had provided a detailed understanding of the patterned variability present within each ware. This permitted the segregation of internal "technological types" within each ware which exhibited variability in one or more of the following aspects: (1) apparent paste texture, (2) nonplastic size, (3) plastic state, (4) paste colour, (5) construction, and (6) secondary forming.[6] Wares A and B each had four internal technological types. Each type was numerically labelled according to the ware designation (i.e., Type A1, A2, A3, A4; Type B1, B2, B3, B4). It was noted that the technological types of Ware A were specifically associated with different vessel forms. Type A1 consisted of only jar sherds, Type A2 of only bowl sherds, Type A3 of only lid sherds, and Type A4 of only stove sherds. The technological types of Ware B were composed solely of jar sherds. The respective sherd incidences and technological attributes of each type are summarized in Table 2.

The final step in the archaeological analysis was to mineralogically identify the nonplastics. Sherds were randomly selected from each technological type within the wares, were thin sectioned, and then analyzed petrographically.[7] Two major mineralogical groups were discovered which directly correlated with Wares A and B. In other words, the wares were stylistically *and* petrographically distinct (see Table 3).

All sherds of Ware A, *regardless of technological type*, exhibited unzoned plagioclase, abundant quartz, and dacite. Andesite was extremely rare and volcanic glass absent. Types A1 and A2 comprised a distinct subgroup containing abundant diorite–epidote, clinopyroxene, and lesser green hornblende, while Types A3 and A4 represented a second subgroup characterized by very abundant quartz, higher biotite content, and only red-brown hornblende. (Type A4 also contained large amounts of rice husks and straw.)

All sherds of Ware B, *regardless of technological type*, exhibited abundant porphyritic andesite, often associated with volcanic glass particles. Dacite was of low frequency and

[4]A slip is a fluid suspension of clay applied to a ceramic surface in order to alter surface colour and texture or to render vessels less permeable; typically it is quite thin (~ microns).

[5]Excavation conducted by Dr. Richard Shutler as a joint project with the Philippine National Museum, under the permit granted by the Philippine Center for Advanced Studies.

TABLE 1. Distinguishing stylistic attributes of wares

Ware designation	*n*	Surface finish	Surface texture	Surface lustre	Slip appearance
A	547	Burnished	Smooth	Low	Watery, dark red, uncrazed
B	132	Smoothed	Slightly grainy	Matte	Earthy, weak red, uncrazed

TABLE 2. Technological attributes of types

Type	*n*	Paste texture	Nonplastic size range*	Plastic alteration	Paste colour	Construction	Secondary forming
A1	495	Medium	Fine–medium	Sintered	Uniform, clear, rarely zoned	Modeled	Opposed paddling & scraping (smooth paddle)
A2	30	Medium	Fine–medium	Sintered	Uniform, clear, rarely zoned	Coiled	Scraping (unpaddled)
A3	16	Medium	V. fine – fine	Rarely Sintered	Uniform, clear	Molded	Scraping (unpaddled)
A4	6	Medium	V. fine – v. coarse	Exterior vitrified	Nonuniform exterior highly oxidized	Coiled	Unopposed paddling & scraping (smooth paddle)
B1	54	Dense	Fine–medium	Well sintered	Uniform, clear, rarely zoned	Modeled	Opposed paddling; no scraping (grooved paddle)
B2	35	Medium	Medium–coarse	Sintered	Nonuniform, strongly zoned	Modeled	Opposed paddling; no scraping (smooth paddle)
B3	29	Open–medium	Medium–coarse	Sintered	Nonuniform, strongly zoned	Modeled	Opposed paddling; no scraping (grooved paddle)
B4	14	Medium	V. fine – fine	Sintered	Uniform, brown	Modeled	Opposed paddling; no scraping (smooth paddle)

*Nonplastic size expressed according to the Wentworth scale (20).

quartz, diorite, and epidote were rare or absent. Types B1 and B2 comprised a single subgroup which exhibited lower andesite counts and both red-brown and green hornblende. Type B3 was slightly different and exhibited high andesite counts and only red-brown hornblende. Type B4 was similar to B1 and B2 but displayed high frequencies of clinopyroxene and actinolite.

In summary, therefore, the archaeological analysis had resulted in the separation of two major stylistic groups which were designated Wares A and B. Within each ware, analysis also revealed four technological subdivisions which were termed Types A1–A4 and B1–B4. Subsequent petrographic analysis indicated the nonplastic components of the respective wares were radically distinct. Some evidence of nonplastic variability among the technological types of each ware was also noted. The results of the petrographic study substantially strengthened the archaeological classification and suggested the likelihood that the wares had been manufactured in different locales. The point is stressed that the archaeological classification was completed prior to both the petrographic and subsequent trace element analyses.

Experimental

EDXRF was selected for this study because it is nondestructive and rapid and does not require extensive sample pretreatment. Sherds were analyzed in the intact or pristine state for several reasons. Firstly, a technique could not be devised that achieved complete separation of the plastic (i.e., the clay) from the nonplastic (i.e., mineral and organic inclusions) fraction. The abundance of soft, weathered particles such as plagioclase and andesite within the pastes meant that any attempt to disaggregate the sherds would powder these inclusions and contaminate the plastic anyway. Secondly, if separation of the two fractions could be accomplished, its merits would be questionable. Since primitive potters intentionally modified the characteristics of clay bodies by adding or removing nonplastics, presumably for technological or functional reasons, pertinent behavioural data of archaeological interest could be lost.

It has become common practice to remove by mechanical means the surfaces of ceramic samples prior to trace element analysis in order to analyze the "bulk" composition of the paste. While this may expedite the analytical process and remove the threat of surface contamination, it can also result in the loss of important archaeological data. For instance, all sherds of both Ware A and B are slipped on one or both surfaces. The slips are an integral aspect of the sample; indeed, they are an integral aspect of most Philippine ceramics. They represent a potential source of chemical variability that should be considered in any context in which they occur. Furthermore, when dealing with unslipped pottery, there are numerous techniques and processes which may be employed in contour refinement or surface finish which differentially cause technologically related alterations in the paste structure of the vessel walls and surfaces and could conceivably result in distinctive chemical patterning.

Even if these archaeological concerns are not appreciated, the relative merit of "bulk" over "surface" analysis has been addressed previously and no systematic differences vis-a-vis group segregation were found to exist (8). This suggests that the entire question may be more a debate of technique and preference than a question of scientific

import and that the real concern should be to identify the types of contaminants or alterations which exist within the sample prior to analysis. Because of these considerations, mechanical stripping of the sample surfaces was rejected in this study. Sherds were analyzed instead along their intact surfaces *after* considerable effort was expended to isolate and exclude surface effects which produced distortion in the chemical patterns.

Sample treatment

The only initial treatment given to the sample was a vigorous scrubbing of all sherd surfaces in warm water. When necessary, small portions were broken off the corner of each sherd to permit containment within the sample cup. This produced no loss of sample integrity since the fragments were simply glued back onto the parent sherds after analysis was complete. In all cases, however, the samples could be considered infinitely thick for purposes of X-ray absorption effects. Since absolute concentrations were not determined, interelemental effects were ignored.

Apparatus

Relative determinations of the trace element concentrations in the pottery samples were made by photon-excited, secondary target, energy dispersive X-ray fluorescence analysis. A complete description of this system (Kevex Corp.) is presented elsewhere (21, 22). An Au anode X-ray tube was the primary radiation source while a Mo secondary target/filter system was used in all analyses. The selection of Mo was predicated by the fact that a reasonable number of trace elements in the samples were excited by the Mo (K_α and K_β) radiation. Each sample was analyzed for four minutes with the X-ray tube voltage at 40 keV and current at 20 mA.

The emitted elemental X-rays were detected integrally using a Si(Li) X-ray spectrometer and the spectra accumulated in 512 channel groups with a Nuclear Data, Model 812, data acquisition system. Typical X-ray spectra from the slipped exterior surface of Types A1 and B1 sherds are presented in Fig. 2. In general, X-rays were observed for elements K, Ca, Ti, Mn, Fe, Cu, Zn, As, Br, Rb, Sr, Y, and Pb, in addition to the coherent (Rayleigh) and incoherent (Compton) scattering peaks (see Fig. 2). The intensity of the lines for K and Cu was sufficiently low that they were not useful in further consideration. While the intensity of the lines for As and Pb was sufficiently high to warrant inclusion in this study, they exhibited such wide scale variability that they were not used in any subsequent interpretations.

Spectral analyses and data presentation

Due to the difficulty in obtaining quantitative concentrations for nonhomogeneous, intact sherds and the desire not to disaggregate the archaeological sample, absolute concentrations were not determined. Indeed, recent studies by Saleh *et al.* (14) indicate the importance of interelemental correlations as opposed to individual elemental concentrations in the characterization of ceramic samples. Thus, each photopeak of interest from these infinitely thick samples was simply integrated and normalized to that of the Compton scattering peak. This procedure makes the analysis independent of sample shape and of variations in the incident radiation. The relative errors quoted are due primarily to the statistics accumulated in individual peaks.

Results will be presented graphically on triangular axes plots with these normalized data from groups of three elements expressed as percentages of their combined totals. We opted for this procedure rather than a calculated metric procedure because it provided a quick and visually obvious means for revealing patterns of elemental correlations in large bodies of data, that is understandable to both physical scientists and archaeologists.

Results and discussion

Reproducibility

The reproducibility of the system and the method of data analysis was determined by making ten nonconsecutive analyses of a single arbitrary sherd (Type B2, slipped exterior surface) in different positions. The mean of the observed nor-

malized photopeak areas and the standard deviations are presented in Table 4. While the observed variations were, in general, quite small, a better appreciation of the relative variation in the context of the type of data treatment utilized later can be observed when the normalized peak areas are displayed graphically as percentages on triangular axes. For instance, Fig. 3(a) presents the Ca–Ti–Mn areas, expressed as percentages of their combined totals per location. The *maximum* range along both the Ca and Ti axes is 4.2%, while that along the Mn axis is 3.9%. In other words, such presentations indicate that the observed relative values for these three elements from a single sherd in different positions are, as expected, quite similar.

Surface effects

Of considerable interest was the determination of whether or not *surface state* affected the EDXRF analysis. There were two major factors to consider in this regard. Firstly, some sherds were waterworn. This could conceivably affect surface readings, particularly those of slipped surfaces since the slips were thin and easily eroded. Secondly, many of the sherds exhibited carbon staining or actual carbon encrustations, along one or both surfaces, which had built up during either firing or usage. This too could affect surface readings. To examine first how surface state affected the analysis of slipped exterior surfaces, we randomly selected 37 sherds from Type A1. Twenty-three of these had clean, unworn slipped surfaces free of carbon, 13 had unworn slipped surfaces stained by carbon in degrees varying from slight to intense, and one sherd had a clean slipped surface which was badly waterworn. The normalized data for these samples, labelled I, II, and III, respectively, are summarized in Table 5. Inspection of these data revealed that the mean values were generally similar for each group; however, there were seemingly some small scale variations. Both the carbon stained sherds and the single waterworn specimen ex-

(b) Similar representation as for (a) for Ca, Ti, and Mn along the slipped exterior surfaces of 37 Type A1 sherds comparing carbon stained (●), waterworn (▽), and clean (⊙) specimens. Broken line drawn for convenience only.

hibited slightly higher Ca and slightly lower Ti and Fe relative concentrations. Furthermore, while the Mn levels of the clean group and the carbon stained group were virtually identical, the latter exhibited a higher standard deviation. When these data are presented on a Ca–Ti–Mn triangular plot (Fig. 3(b)) the carbon stained sherds and the single waterworn specimen tended to distort the distribution observed for clean sherds. We decided, therefore, to exclude all carbon stained and/or waterworn sherds from studies of slipped surfaces as these would have interefered with further discrimination of the technological types within each ware.

Along the unslipped interior surfaces, carbon deposition was even more common and more frequently intense. A cursory analysis of interior, carbon stained surfaces of all types indicatd similar broadening in correlations of the elements mentioned above. Accordingly, carbon stained sherds were also excluded from the analysis of unslipped surfaces.

TABLE 6. Water wearing effects: unslipped surfaces

†Type B3/exterior; unworn; 5 samples.
‡Type B3/interior; waterworn; 6 samples.

The effects of water wearing upon unslipped interior surfaces, free of surface carbon, required further specific study. To do this, we selected 11 sherds from Type B3, a type frequently displaying waterworn specimens. Five of the sherds had clean, unslipped surfaces unaltered by water wearing, while 6 had clean, unslipped surfaces altered by water wearing in degrees varying from slight to intense. The normalized data for these two groups (labelled III and IV) are summarized in Table 6. Inspection of these data indicated only slight differences between the two groups. When the peak areas were expressed on a Ca–Ti–Mn triangular plot, both groups formed a single discrete cluster (Fig. 4(a)). Accordingly, the exclusion of waterworn sherds from the analysis of unslipped surfaces could not be justified.

In the above discussion of surface state, it will be noted that a distinction has been drawn between slipped and unslipped surfaces. This distinction is what we termed *surface aspect*. The aspect of a surface is obviously significant and the separation of the two aspects is usually easily maintained; however, care must be taken when dealing with the interior surfaces of jar sherds. Here, the slip is often applied to the interior of the rim and may drip downward depositing slip traces along the body. To examine the variability induced by this phenomenon, 27 Type A1 sherds were analyzed along the interior surface. (These specimens were derived from the same sample of A1 sherds previously employed to study surface effects. Ten of the original 37 were excluded because of interior carbon staining.) Eleven of these lacked slip traces, while 16 exhibited slip traces. The normalized data for the two groups (labelled V and VI) are summarized in Table 7. Upon casual inspection, the mean values did not seem radically different but the standard deviations associated with the slip traces group were considerably higher. When the peak areas were expressed on a Ca–Mn–Y triangular plot, the greater variability of the slip traces group was obvious (Fig. 4(b)). We interpreted these results as indicating that careful segregation of surface aspect was imperative at all times.

In summary, therefore, these initial studies indicated the following.

(1) The range in elemental variability within a single intact sherd was small and well within reproducible limits. The data

Broken line drawn for convenience only.

could be graphically expressed upon triangular axes resulting in discrete clustering.

(2) Surface state affected the EDXRF analysis. Carbon stained or encrusted sherds had to be excluded from the study of both slipped and unslipped surfaces. Waterworn sherds had to be excluded from the study of slipped surfaces but not from the study of unslipped surfaces.

(3) Surface aspect had to be carefully controlled. Slipped surfaces or even those exhibiting slip traces could not be directly compared to unslipped surfaces.

Ware differentiation/slipped surface

Fifty sherds of Ware A and 31 sherds of Ware B were selected for analysis along the slipped surface. Samples were randomly chosen from the remaining sherds of each type after exclusion of all carbon stained and waterworn specimens. In the cases of Type A4 and Types B2–B4, the number of sherds studied represented *all* of the analyzable specimens remaining after exclusion of carbon stained and waterworn sherds. The normalized data for the respective technological types per ware (i.e., A2–A4, B1–B4) are summarized in Table 8 (Col. I of Table 5 presents data for Type A1).

These data indicated significant elemental variability between each ware. Visual inspection revealed that the relative levels of Zn, Br, and Sr exhibited the clearest differences. When these data are expressed as percentages of their combined totals (using a scaling factor of 0.1 for Sr for convenience in the graphical presentation) and displayed graphically on a triangular plot (Fig. 5(a)), two well separated clusters are obtained. Clearly, these two different wares can be differentiated simply using these three elemental levels.

The differences in Br content between the two wares is interesting and merits further comment. The depositional environment is identical for each ware inasmuch as they were found in direct association in the same deposits. As such, the possibility is extremely remote that the differential in Br could have been induced by some post-burial phenomenon. Pearlman and Asaro (6) have suggested that Br is extremely variable, at least, in the context of ceramics from a single Nile Valley site. Perhaps these observations do not apply for other contexts such as Northern Luzon. This requires additional research. The above authors also noted that Br might be sensitive to firing conditions, noting that 90% of the Br disappeared after firing a sample of Nile Valley clay at a temperature of 800°C in an electrical furnace. Since earthenwares may be frequently fired below this temperature and are subject to uneven firing conditions, particularly if open firing is practiced, it is possible that Br could often be retained in such circumstances. It may be, therefore, that the differences in Br between the two wares indicate radically different firing conditions but, although this is a very attractive speculation from the archaeological viewpoint, it, too, requires additional research. The intent in this study is to indicate that the Br content is patterned in direct accordance to the previously defined archaeological wares. In short, there is a significant difference in this element, in addition to Zn and Sr, between the two wares that cannot be discarded a priori simply because previous research in another context has found it extremely variable and less useful in discrimination.

Ware differentiation/unslipped surface

Eleven sherds of Type A1 and 31 sherds of Ware B were selected for analysis along the unslipped surface. Types A2, A3, and A4 were exluded due to surface aspect; i.e., these were slipped on both surfaces. Samples were randomly chosen after exclusion of all carbon stained specimens. In the cases of Types B1, B2, and B4, the number of sherds studies represented *all* of the analyzable specimens remaining after exclusion of carbon stained sherds. The normalized data for Type A1 and Types B1–B4 are summarized in Table 9.

As before, when the peak areas for Zn, Br, and Sr were expressed on a triangular plot, two clusters are obtained (Fig. 5(b)). These clusters were more widely separated than those obtained for the slipped surface although it should be emphasized that the number of sherds representing Ware A was much reduced. Even so, these results indicate that ware differentiation for the unslipped surface was also achieved.

Type differentiation

(a) *Types A1–A4 (slipped surface)*

From the data presented in Table 8, A3 was immediately distinguishable by its relatively low Fe content. A4 was also distinctive due to its high Mn, Rb, and Y levels. Both of these types also exhibited reduced Ti. A1 and A2 seemed the most similar; however, A2 exhibited higher Ca and Mn levels.

When the peak areas for Ca, Ti, and Mn were expressed on triangular axes, A1, A3, and A4 formed discrete, separated clusters. A2 formed a cluster between A1 and A3 and exhibited partial linkage with A1 (Fig. 6). Although there was some overlap between A1 and A2 clusters, the data presented in Fig. 6 clearly indicated that each technological type displayed an individual pattern of interelemental correlations for Ca, Ti, and Mn.

(b) *Types B1–B4 (slipped surface)*

From the data presented in Table 8, significant variation among the four technological types was evident. B1 and B3 seemed most similar, exhibiting low Ti and Fe with very high Sr levels. Alternatively, B2 and B4 displayed much greater Ti and Fe and much lower Sr contents.

There were, however, differences in other elements between each of the above pairs. In the case of B1 and B3, higher Rb was evident in the latter. In the case of B2 and B4, the former was characterized by low Ca and high Y, while the latter was characterized by high Ca and Mn.

When the peak areas for Ca, Ti, and Mn were expressed on a triangular plot, Types B2 and B4 formed separated clusters. A third cluster was formed by the combined B1 and B3 sherds (Fig. 7(a)). Only when Rb was considered, for example, on a

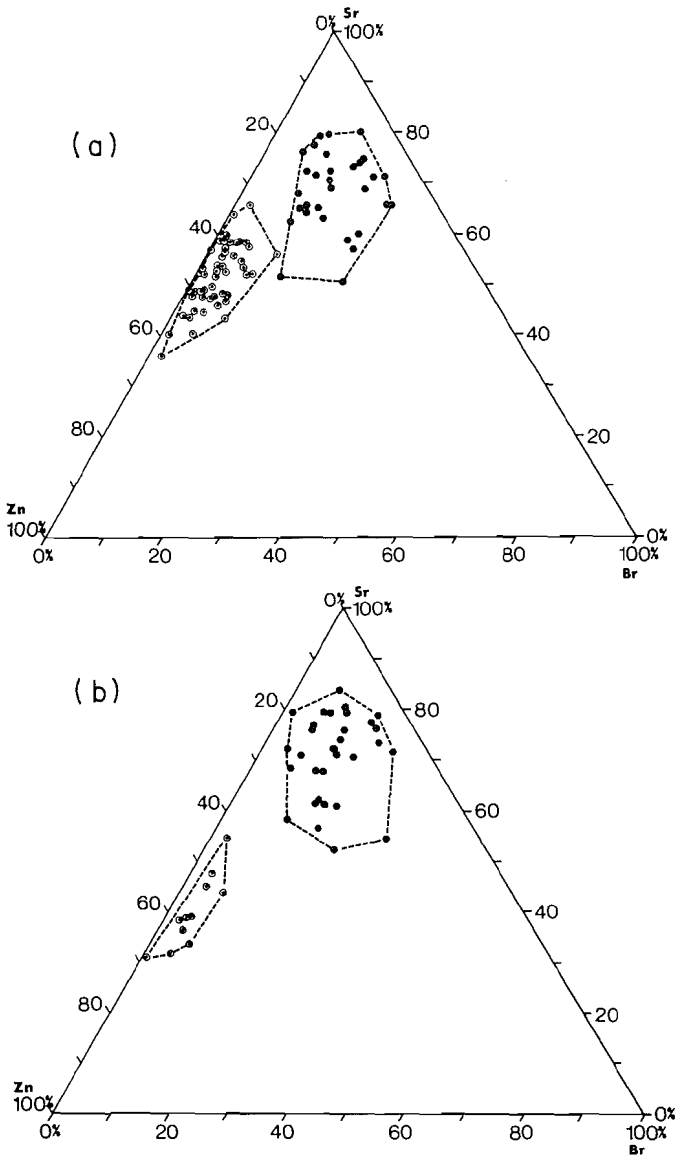

FIG. 5. (a) Similar representation as Fig. 3(a) for Zn, Br, and Sr along the slipped aspect of 60 Ware A (⊙) and 31 Ware B (●) sherds (Sr scaled by a factor of 0.1). Broken lines drawn for convenience only. (b) Similar representation as Fig. 3(a) for Zn, Br, and Sr along the unslipped aspect of 11 Ware A (⊙) and 31 Ware B (●) sherds (Sr scaled by a factor of 0.1). Broken line drawn for convenience only.

Ca–Mn–Rb plot was a distinction visible between B1 and B3 (e.g., Fig. 7(b)). As a result, we were once more left with the conclusion that each technological type displayed an individual pattern of interelemental correlations.

(c) *Types B1–B4 (unslipped surface)*

From the data presented in Table 9, B1 and B3 remained similar in their mutual expression of low Ti and Fe associated with high Sr. B3 still exhibited a slightly higher Rb content but seemingly not to the degree noted along the slipped surface. B2 and B4 continued to exhibit much higher Ti and Fe and much lower Sr, although the amount of Fe in B2 was considerably reduced from that of the slipped surface. B2 remained characterized by low Ca and high Y, while B4 still displayed particularly high Ca and Mn.

When the peak areas for Ca, Ti, and Mn were expressed on triangular axes, B2 and B4 again formed separated clusters.

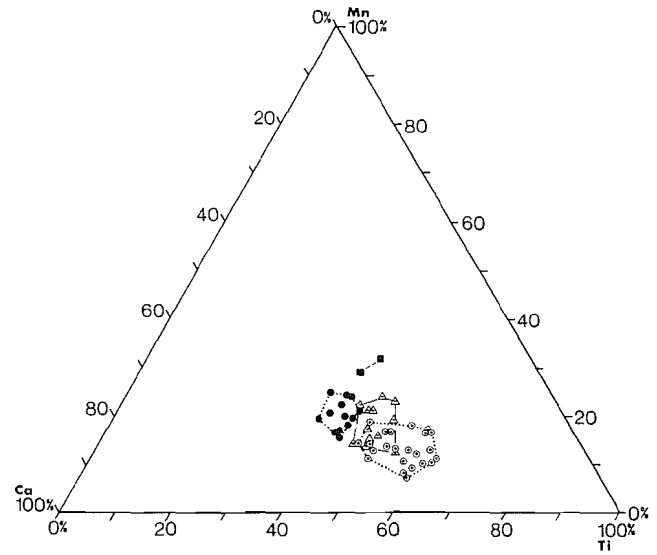

FIG. 6. Similar representation as Fig. 3(a) for Ca, Ti, and Mn for slipped aspect of 23 Type A1 (⊙), 12 Type A2 (△), 13 Type A3 (●), and 2 Type A4 (■) sherds. Broken lines drawn for convenience only.

The cluster for B2 had become much more discrete, even though the number of sherds studied had been increased. B1 and B3 formed a third cluster but the distribution of B3 had also become more discrete (Fig. 8(a)). Differences in Rb were still in evidence for B1 and B3 on a Ca–Mn–Rb plot (Fig. 8(b)). Once again, it was concluded that each technological type exhibited an individual pattern of interelemental correlations.

Conclusion

The primary objective of this report was to examine the relationship of intra-assemblage variability to multi trace element patterning in a primitive ceramic context. The results indicate that it was indeed possible to isolate an interelemental correlation which differentiated the stylistic classes (i.e., Wares A and B). Further, it was also possible to isolate interelemental correlations which reflected chemical differences among each of the four technological types per ware. It should be pointed out that these differentiations were demonstrated using only trivariate correlations, avoiding the need for the use of sophisticated multivariate statistical analyses of the data. The latter approach, however, could lead to a greater, more definitive discrimination, particularly when studying a large, more diverse set of samples.

It is obvious that the ware discrimination would have been evident without any prior archaeological segregation of the samples. In other words, the total sample could have been treated as a single unit, analyzed by EDXRF, and the "archaeologically correct" ware differentiation would have been obvious. It is, however, a debatable point whether or not all of the technological types per ware would have been so readily perceived. Most certainly some, e.g. A3, B2, and B4, would have been easily identified and segregated. Regardless of the latter, however, the importance of understanding and appreciating technological variability within stylistic classes when conducting multi trace element analysis should now be evident.

Another interesting aspect of the results is that surface effects can be recognized and eliminated through careful study, thereby avoiding the necessity of mechanical surface stripping and

the resultant omission of potentially significant clay bodies such as slips from the analysis. In a related point, the whole question of mechanical surface stripping needs critical review in terms of its validity in earthenware contexts. Unlike high temperature ceramics such as porcelains and stonewares, earthenwares are frequently permeable since they are composed of a network of pores and voids which readily permit penetration of "foreign" substances deep within the walls of the vessel. If such substances are not recognized and accounted for at the surface, the "bulk" analysis of earthenware sherds could be seriously questioned. In other words, contaminants on the surface may indicate contaminants within the paste and no amount of surface stripping will avoid the problem.

The use of normalized elemental yields rather than absolute elemental concentrations in this study will undoubtedly draw criticisms. It should be emphasized, however, that the data presentation strongly relies upon interelemental correlations expressed upon triangular plots. These plots have long been recognized as useful tools by geologists and we believe they have a similar usefulness in the presentation of multi trace element data. Both absolute and relative data can be graphically shown on such plots as a series of trivariate correlations. Such correlations may be better able to resolve trace element patterning than treating each element as an independent variable.

From an archaeological perspective, these results open many avenues of research. Firstly, they suggest that ceramic stylistic groups may be directly determined by EDXRF analysis. Secondly, they demonstrate the significance of technological variability. Most importantly, however, they suggest that a study in which archaeological, petrographic, and compositional data are combined can lead to a broader appreciation of the factors governing ceramic variability. If this is the case, there is a very

real possibility that archaeologists may be able to view ceramic variability in terms of human behaviour and manufacturing processes rather than as a series of static, stylistic configurations in space and time.

The decay of ^{148}Ce to levels of ^{148}Pr has been studied using mass-separated sources. A half-life of 56 ± 1 s has been measured for the decay of ^{148}Ce. A level scheme containing 40 γ rays and 15 excited levels is proposed for ^{148}Pr. Strongly β-fed 1^+ levels have been identified at 390 and 520 keV that are similar in position to 1^+ levels observed in isotonic ^{146}La and isotopic ^{146}Pr.

On a étudié la désintégration du ^{148}Ce en divers niveaux de ^{148}Pr en utilisant des sources de masses séparées. On a établi que la demi-vie de la désintégration du ^{148}Ce est de 56 ± 1 s. On propose un diagramme de niveau contenant 40 rayons γ et 15 niveaux excités pour le ^{148}Pr. A 390 et à 520 keV, on a identifié des niveaux 1^+ qui sont fortement favorisés par les particules β; ces niveaux sont semblables du point de vue de la position, au niveau 1^+ observé pour le ^{146}La isotonique et le ^{146}Pr isotopique.

Introduction

In a series of studies of the chemical separation and radioactive decay of neutron-rich Ce fission products (1–3), the half-lives of ^{147}Ce and ^{148}Ce were reported to be 56 and 48 s, respectively. Some difficulty was encountered, however, in assigning the observed γ rays to the correct nuclide and establishing an accurate level scheme for both ^{147}Pr and ^{148}Pr. Subsequent studies (4, 5) of the decay of ^{148}Pr have differed with respect to the ground state spin of ^{148}Pr and on the presence of isomerism in ^{148}Pr. γ-Ray intensity measurements in the $A = 148$ chain on mass separated sources have been reported recently that support the presence of two isomers in ^{148}Pr (6). In this paper, we report a study of the decay of ^{148}Ce isolated from ^{235}U fission products by the on-line mass separator TRISTAN. Forty γ rays are established in a level scheme containing 15 levels, and evidence is presented to support the proposed (5) 1^- ground state for ^{148}Pr.

Experimental procedures

The mass 148 nuclides were produced from fission in an integrated target-ion source assembly of the on-line mass separator TRISTAN located at the High Flux Beam Reactor at Brookhaven National Laboratory. The operation of the TRISTAN facility and the data collection system have been described in several recent publications (7–9) and references therein. For these experiments a high-temperature Re surface-ionization source (9) containing a graphite cloth impregnated by 5 g of 93% enriched ^{235}U was used. The flux of neutrons at the target was 1.5×10^{10} n cm^{-2} s^{-1}. The power input to the ion source ranged up to 2000 W corresponding to a maximum temperature of 2000°C.

The ion beam from the mass separator is deposited on aluminized mylar tape that can be moved from the deposit point (parent port) to secondary positions (daughter ports) at several fixed distances from the parent port. The objectives of these experiments included study of the decay of 0.6-s ^{148}Ba and the 2-min ^{148}Pr isomers, as well as a study of the decay of ^{148}Ce. To accommodate all of these objectives, the activity was accumulated at the parent port for 512 s where the growth of the activities was observed and γ–γ coincidences were measured. The activity was then moved to a daughter port 60 cm away where the decay of the various activities was followed by accumulating sixteen sequential 8192-channel spectra for 32-s time intervals each. During the 2-s transport time most of the 0.6-s ^{148}Ba activity was lost and activity from 1.0-s ^{148}La was observed only in the first of the sixteen spectra.

Three Ge detectors were employed in this study, a 5-cm^3 planar detector with a full-width-at-half-maximum (FWHM) of 480 eV at 121 keV and a low-energy cut-off below 3 keV, a cylindrical 75-cm^3 n-type Ge detector with <1.8 keV FWHM at 1.33 MeV and a low-energy cut-off of 10 keV, and a cylindrical 80-cm^3 p-type Ge detector with <1.8 keV FWHM at 1.33 MeV. The 5-cm^3 planar detector and the p-type cylindrical detectors were used to measure singles and coincidence spectra at the parent port and the n-type detector was used at the daughter port to measure the time-dependent singles spectra.

The energy values for several of the more intense γ rays in the $A = 148$ chain were determined in the high precision measurements of fission product γ-ray energies by Börner *et al.* (10) using a curved crystal spectrometer. We used the intense γ rays at 158.468 ± 0.005 and 301.702 ± 0.016 keV from ^{148}La and ^{148}Pr decay, respectively, for an internal calibration of all three detectors.

In a separate shorter experiment, the 5-cm^3 planar detector was moved to the daughter port to obtain a spectrum free from the γ rays of 0.6-s ^{148}Ba and 1.0-s ^{148}La. For this measurement, activity was collected at the parent port for 72 s and then moved to an intermediate shielded position for 10 s to allow the Ba and La to decay. The activity was then moved to the daughter port where it was counted for 72 s.

The β feeding to the low-spin isomer of ^{148}Pr was studied in a separate experiment in which the $A = 148$ chain was brought to equi-

[2]Present address: 11 Pinsker Street, Rehovot, Israel.

librium at the parent port using a low-temperature Ta surface ionization ion source. A spectrum of the full chain at equilibrium was taken from which the ratio of the intensity 105-keV γ ray in ^{148}Ce decay to the intensity of the 158-keV γ ray in ^{148}La decay could be used to compute the absolute intensity of the 105-keV γ ray from the known (11) decay scheme of ^{148}La to ^{148}Ce. The calculation requires the assumptions that no Ce is independently extracted (9), that there is no significant ground state branching (11) in the decay of ^{148}La to ^{148}Ce, and that there is little E2 mixing in the intense low-energy transitions that feed the ground state (12). The 105-keV γ ray is a clean peak with no known interferences from the decay of ^{148}Ba, ^{148}La, or ^{148}Pr.

Experimental results

In Fig. 1 is shown a portion of the γ-ray spectrum between 90 and 300 keV taken at the parent port during the 512-s collection period with the 5-cm^3 planar detector. In Table 1 are listed the energies, intensities, transition assignments, and major coincidences of the γ rays that are attributed to the decay of ^{148}Ce. These γ rays were identified by their half-lives in the time-dependent spectra, and/or by their presence in coincidence gates set on intense γ rays clearly associated with ^{148}Ce decay.

The energy values that we determine using the internal calibration are in agreement with those found by Börner *et al.* (10). Our best values are for intense γ rays below 200 keV that gave sizeable peaks in the high gain spectrum taken with the 5-cm^3 planar detector. Considerably larger uncertainties are associated with weak γ rays whose energy values were determined in the large detectors because of the high Compton background of the other chain members in the singles spectra or small peak areas in the coincidence spectra.

It is possible that Börner *et al.* (10) may have some assignments of close-lying doublets inverted. They assigned a 120.941 ± 0.003 keV γ ray to ^{148}Ce decay and a 121.169 ± 0.003 keV γ ray to ^{146}Ba decay. Our value of 121.21 ± 0.01 indicates that these assignments should probably be inverted. They also assign γ rays at 117.336, 190.839, 233.844, and 247.086 keV to ^{148}Ce decay that are beyond the uncertainties for their measurements and our measurements for γ rays at 116.92, 191.6, 233.7, and 247.52, respectively. As these are relatively weak γ rays in ^{148}Ce decay, the γ rays observed by Börner *et al.* (10) may be placed in other fission product nuclides or may be part of unresolved doublets or multiplets. In a more complex situation, the 247-keV γ ray that we observe is a part of a doublet with a 246.66 ± 0.06-keV γ ray from ^{148}Ba decay and the γ ray listed by Börner *et al.* (10) is a part of a doublet with a 246.736 ± 0.015-keV that is assigned to ^{132}Sn decay.

A half-life value of 56 ± 1 s was determined from the weighted average for the most intense γ rays whose decay curves are shown in Fig. 2. This value is identical to the half-life attributed to ^{147}Ce decay from the earlier chemical studies (3) and from recent studies of mass separated sources (14). In Fig. 3 is shown a small section of the sum of all 16 singles spectra taken at the daughter port showing the intense 301-keV γ ray from ^{148}Pr decay, the 324-keV γ ray from ^{148}Ce decay and the complete absence of any activity at 314.7 keV which is the most intense γ ray in the decay of 13-min ^{147}Pr (14). Thus we can be certain that the 56 ± 1 s half-life we measure for ^{148}Ce is not influenced by the presence of any mass 147 contamination.

The decay scheme

The proposed decay scheme of ^{148}Ce is shown in Fig. 4. This

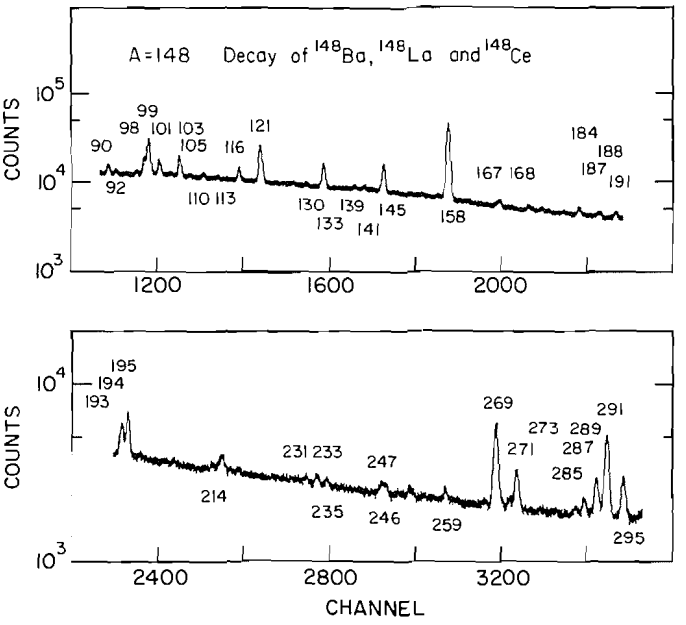

FIG. 1. γ-Ray spectrum taken at the parent port with the 5-cm^3 planar detector showing the region between 90 and 298 keV. The γ-ray energies listed above the spectrum are for ^{148}Ce γ rays and the energies below the spectrum are from ^{148}Ba or ^{148}La decay or background.

decay scheme has been constructed from the coincidence results some of which are tabulated qualitatively in Table 1. The components of the multiplet between 98 and 101 keV and 192 and 196 keV were easily resolved in the coincidence spectra with the exception of the doublet at 98 keV. As the 98 keV peak is observed in its own gate as well as in the 191- and 325-keV gates, a doublet at 98 keV must be postulated. The 101-keV gate was also important as it showed the 191- and 184-keV γ rays and the 98- and 105-keV γ rays as well as the strong 289-keV γ ray.

From the decay scheme we can immediately note that γ rays at 90, 98, 99, 105, and 121 must have conversion coefficients greater than ~0.5 to carry the γ-ray intensity feeding into the 98-, 99-, 105-, 121-, and 196-keV levels to ground. For example, the 121-keV level is fed by γ rays with intensities of at least 1127 (neglecting additional conversion electron feeding). As the intensity of the 121-keV γ ray is only 790, the total conversion coefficient, α_T, must be larger than 0.4. For a 100 keV γ ray, the E1, M1, and E2 α_T values (13) are 0.25, 1.33, and 2.14, respectively. We can thus conclude that the six levels below 200 keV have the same parity and are connected by M1, E2, or M1/E2 mixed transitions.

The strong β feeding of the levels at 390 and 520 keV marks these levels as 0^+ or 1^+ levels. The systematic trends of the odd–odd Pr levels are shown in Fig. 5. These trends and the current (14) spin and parity assignments for ^{147}Ce and ^{147}Pr both indicate negative parity for the low-lying levels of ^{148}Pr. We have thus computed the β-branching and log *ft* values from γ-ray imbalances deduced from the differences between γ-ray and conversion-electron intensities feeding out of and into each level. The conversion-electron intensities have been computed by assuming E1 multipolarity for the transitions out of levels above 380 keV, M1 multipolarity for the γ rays out of the levels below 380 keV, and E2 multipolarity for the 98.0-keV transition to ground that will be described later. The predominance

[a]These data are taken from the curved crystal studies of gross fission product γ-ray decay by Börner *et al.* (10).

[b]The total intensities were computed by assuming pure M1 multipolarity except where noted. Conversion coefficients were interpolated from the data of Rosel *et al.* (13).

[c]As elsewhere in this paper γ rays and level energies in keV are referred to without the decimal and digits beyond the decimal except for the 98.99-keV γ ray which is referred to as 99.

[d]The parentheses contain the uncertainties of the last digits of the numbers to which they are attached.

[e]These γ rays observed by Börner *et al.* (10) may not be the same as we observe in this work.

[f]Qualitative indication of coincidence strength: S = strong, M = medium, W = weak.

[g]Absolute γ-ray intensities per 100 decays may be computed by multiplying the relative intensities by 0.0167.

of M1 transitions in the odd–odd $N = 83$ isotones has been discussed extensively by Macphail and Summers-Gill (12) as a part of their study of ^{144}Pm levels. A Q_β value of 2050 keV has been taken from the studies of Stippler *et al.* (17). A ground state β branch of (4 ± 5)% has been determined from the ratio of γ-ray peaks at 105 and 158 keV in the experiment with the Ta ion source. Because of the uncertainties associated with the possibility of significant E2 mixing in the low-energy γ rays and unobserved weak transitions from higher-lying levels obscured by the other mass 148 activities, β branches with less than 2% intensity have not been shown in Fig. 4 and an upper limit of 9% is shown for the ground state β branch.

Spin and parity assignments

The 390-keV 0^+ or 1^+ level feeds eight of the nine levels below 300 keV that appear to have negative parity. If the 390-keV level were to be a 0^+ level, all eight of these levels would have 1^- spin and parity, as a 0^+ to 0^- γ transition is not possible and a 0^+ to 2^- M2 transition would be highly hindered. As the systematic trends indicate the possibility of both 0^- and 2^- levels near the ground state, the 0^+ assignment for the 390-keV level is quite unlikely. A similar but weaker argument can be made for the level at 520 keV. The 99-, 121-, 196-, 289-, and 352-keV levels show significant γ-ray intensity imbalance that we attribute to β feeding, and are limited to spin

and parity of 0^- or 1^-.

The 98-keV level is the only level below 300 keV that could be a 3^- level as it is the only level below 300 keV that is not fed by the 1^+ level at 390 keV. The gates on the 184- and 191-keV γ rays are shown in Fig. 6. These two γ rays have equal intensities and depopulate the 289-keV level. As the total intensity out of this level is 600 units, gates on these γ rays should each show 99/600 of the 215 intensity units of the 101-keV γ ray that feeds into the 289-keV level. Thus, the 101-keV peak in these spectra should be approximately equal and represent γ rays with 36 units of intensity. The 98- and 105-keV γ rays should reflect the 99 intensity units of the gating γ ray but be reduced by the fraction of the transition that undergoes electron conversion. For the 105-keV transition for which a theoretical M1 or α_T of 1.17 may be calculated, the γ intensity should be 45.6. Thus, the calculated ratio of the peak intensities for the 101- and 105-keV γ rays in the 184-keV gate should be 0.78 ± 0.03 which compares with the observed ratio of those intensities of 0.85 ± 0.07.

It may be seen that the 98-keV peak in the 191-keV gate is smaller than the 101-keV peak. As the detector efficiency varies little from 98 to 105 keV, either the conversion coefficient is higher or another transition depopulates this level. If we use the observed ratio of peak intensities of 0.76 ± 0.06 for the 98- and 101-keV peaks to compute an α_T for the 98-keV transition, a value of 2.6 ± 0.3 is obtained. As the α_T for a 98-keV E2 transition is 2.31, the 98-keV transition to the ground state can be assigned E2 multipolarity.

Discussion

The studies by Ikeda *et al.* (5) that indicated the presence of isomerism in ^{148}Pr suggested $1^{\pm}$ for the spin and parity of the low-spin ^{148}Pr isomer and $4^{\pm}$ for the high spin isomer. Our data could accommodate 0^-, 1^-, or 2^- for the spin and parity of the low-spin isomer. The strong β feeding to the 2^+ level in ^{148}Nd reported by Taylor and Singh (4) and by Ikeda *et al.* (5) rules out the 0^- possibility. As the 98-keV level is fed by the levels at 196 and 289 keV whose spins and parities are limited to 0^- or 1^- by the β feeding from 0^+ ^{148}Ce, an upper limit of 3^- for the spin and parity of the 98-keV level can be established. In view of the E2 character of the 98-keV transition to the ground state, 1^- is the favored choice for the ground state spin and parity of ^{148}Pr, although 2^- cannot be totally excluded. The single-particle half-lives for the 100-keV M2, E3, and M3 transitions are 10 μs, 1 s, and 60 s, respectively. These half-lives indicate that a 4^- 2-min isomer must be below 100 MeV in order to show the sizeable β branching observed by Ikeda *et al.* (5) or that any isomer with a 2-min half-life lying above the (3^-) level at 98 keV would require spin of ≥ 6.

We have searched for evidence of any γ-branching from low-lying levels into any such isomer. In the decay of ^{144}Ba, ~15% of the decay cascades through a single strong E2 transition from a 2^- level into a possible 4^- level at 16 keV (8). We have not observed any low-energy γ rays in the coincidence spectra gated on γ rays that feed the levels at 98, 99, 105, 121, 196, 273, 289, or 332 keV.

The systematic level structure of the low-lying levels of the

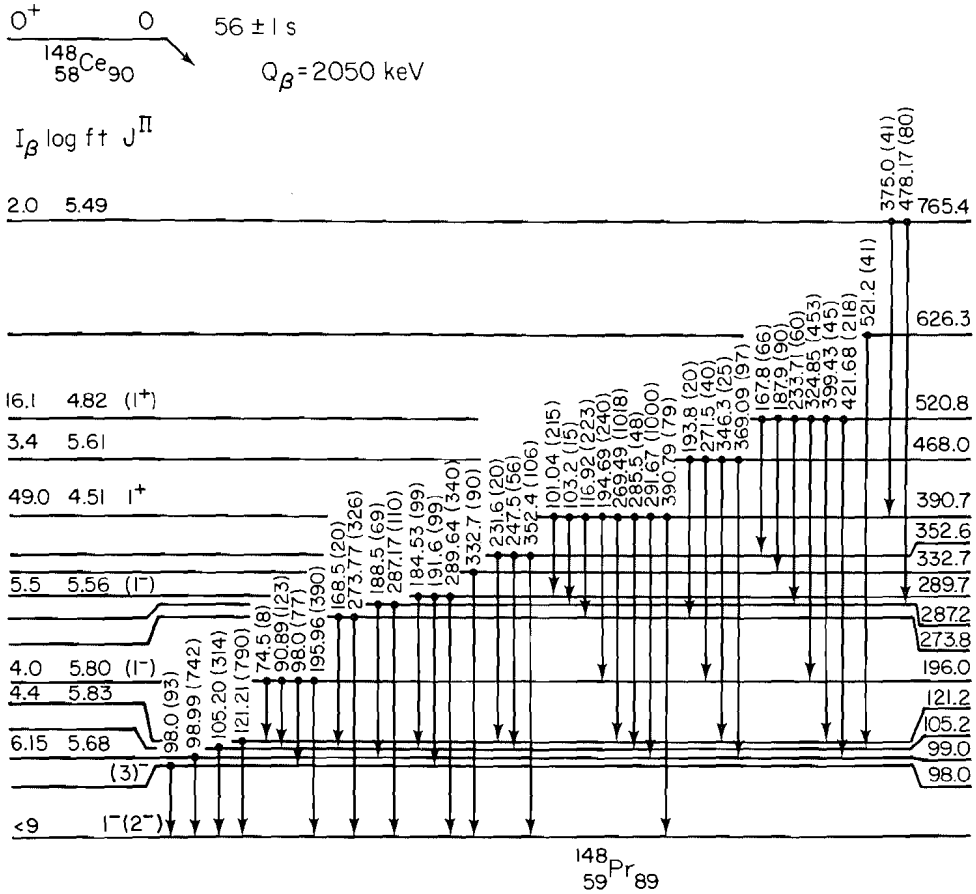

FIG. 4. Decay scheme of ^{148}Ce to levels of ^{148}Pr.

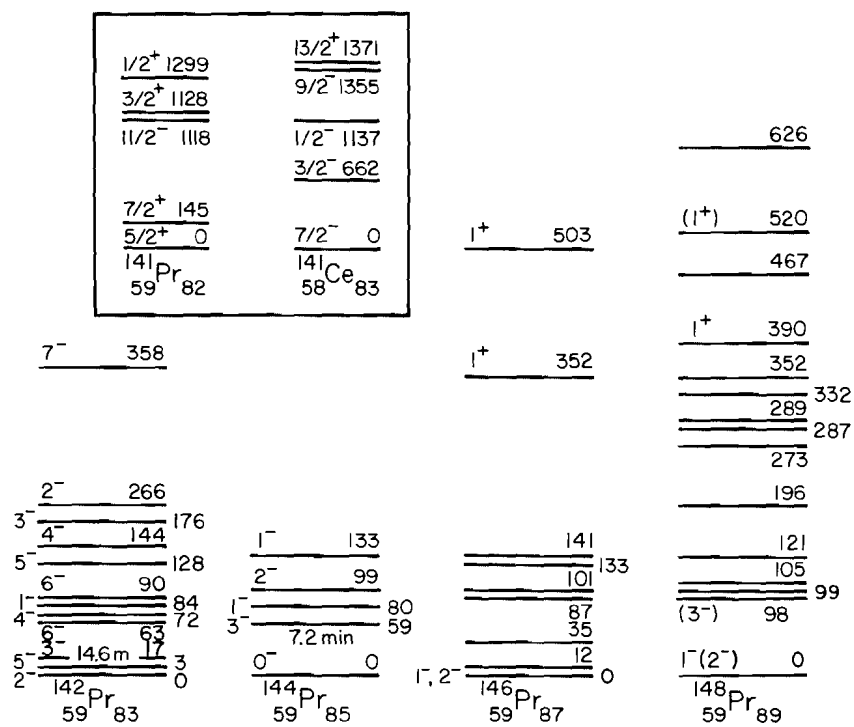

FIG. 5. Low-lying levels of odd–odd ^{142}Pr, ^{144}Pr, ^{146}Pr, and ^{148}Pr along with the single particle levels in ^{141}Pr and ^{141}Ce. The data are taken from refs. 15 and 16.

odd–odd Pr nuclides is consistent with the single particle structures shown in the inset in Fig. 5. The odd proton in $g_{7/2}$ or $d_{5/2}$ positive parity orbitals and the odd neutron in $f_{7/2}$ or $p_{3/2}$ negative parity orbitals combine to give low-lying negative parity

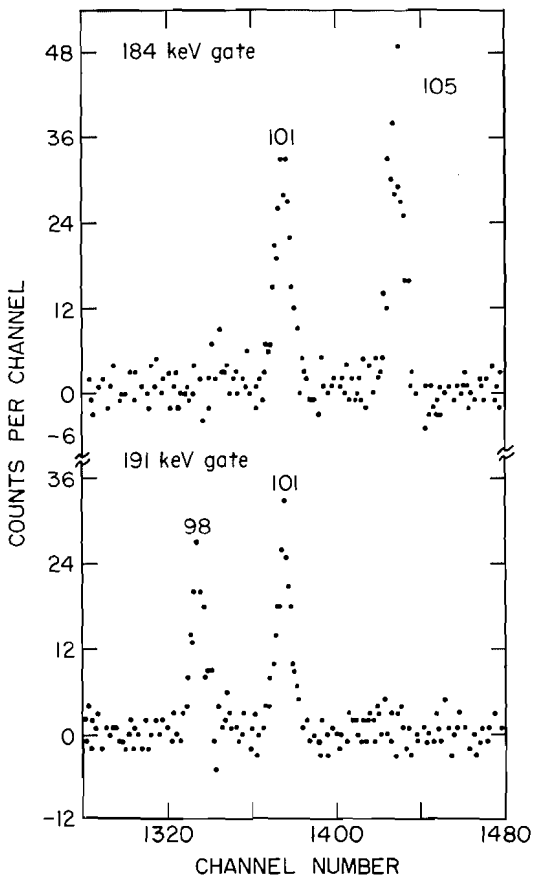

FIG. 6. Portions of the coincidence spectra gated on the 184- and 191-keV γ rays.

multiplets. The presence of low-lying 1^+ states in both ^{146}Pr and ^{148}Pr is not easily attributed to single-particle proton and neutron configurations. Only one such configuration, the $\pi_{h11/2}\nu_{h9/2}$ combination is possible and it should lie at higher energy. More likely is a configuration involving the $f_{7/2}$ or $p_{3/2}$ neutron, the $h_{11/2}$ proton and core excitation. As low-lying negative parity states with spins ranging from 3/2 to 15/2 are known (18) below 600 keV in $^{149}_{61}Pm_{88}$ these states could couple with the odd neutron in a negative parity orbital to give rise to low-lying positive parity states.

In summary, our study of the decay of ^{148}Ce to levels of ^{148}Pr has accounted for the earlier difficulties in assigning γ rays to ^{147}Ce and ^{148}Ce decay. We have shown that ^{148}Ce has a 56 ± 1 s half-life that is undistinguishable from the 55 ± 1 s half-life determined (14) for ^{147}Ce. Moreover, important γ rays near 90, 117, 198, 269, and 284 keV are found in mass-separated sources of both nuclides. The observed low-lying level structure is seen to be analogous to the structure of ^{146}Pr. No direct observation of the high-spin isomer proposed by Ikeda *et al.* (5) has been observed, but its position must lie below 100 keV if it is a 4^- isomer. The 3^- ground state proposed by Taylor and Singh (4) is ruled out by the presence of a 390-keV γ ray from the 1^+ level at 390 keV to the ground state.

Mass spectrometric determination of Rb fission yields from ^{3}He and ^{4}He induced fission of ^{238}U and ^{232}Th[1]

P. L. REEDER

Pacific Northwest Laboratory, Richland, WA 99352, U.S.A.

Received July 15, 1982

This paper is dedicated to Professor Leo Yaffe on the occasion of his 65th birthday

P. L. REEDER. Can. J. Chem. **61**, 786 (1983).

Cumulative and independent fission yields of Rb isotopes have been measured for ^{3}He and ^{4}He induced fission of ^{232}Th and ^{238}U at bombarding energies slightly above the Coulomb barriers. The on-line mass spectrometric technique provided yields for masses 89–97. Mean masses and widths of the Rb independent yield distributions were obtained and were compared to other fissioning systems with excitation energies up to 160 MeV.

P. L. REEDER. Can. J. Chem. **61**, 786 (1983).

On a mesuré les rendements en isotopes de Rb résultant de fissions cumulatives et indépendantes lors de la fission du ^{232}Th et du ^{238}U induite par ^{3}He et ^{4}He à des énergies de bombardement légèrement supérieures aux barrières de Coulomb. La technique de spectrométrie de masse à canal unique fournit des rendements pour des masses de 89 à 97. On a déterminé les masses moyennes et les largeurs des distributions de rendement indépendantes du Rb et on a comparé ces valeurs à celles obtenues avec d'autres systèmes de fission ayant des énergies d'excitation allant jusqu'à 160 MeV.

[Traduit par le journal]

Introduction

The fission of ^{238}U and ^{232}Th by moderate energy helium ions (20–60 MeV) has been studied previously by both radiochemical (1–6) and mass spectrometric techniques (7, 8), to determine cumulative and independent yields of various fission products. Cumulative yields of fission products at or near stability are used to determine the mass–yield curves whereas independent yields are used to determine charge distributions. The particular example of $^4\text{He} + {}^{232}\text{Th} \rightarrow {}^{236}\text{U}$ gives the same compound nucleus as $n_{th} + {}^{235}\text{U} \rightarrow {}^{236}\text{U}$. Hence comparisons of mass and charge distributions can be made as a function of excitation energy for this system. As the excitation energy increases symmetric fission becomes prominent, thus changing the shape of the mass–yield curve. Likewise the most probable charge (Z_p) of a given isobaric mass chain shifts toward stability. This shift is more rapid for isobaric chains in the heavy mass peak than for chains in the light mass peak (8–10). These results along with studies of neutron emission and fission energetics (11) show that the excitation energies of heavy fragments increase more rapidly than the excitation energies of light fragments as the bombarding energy increases. McHugh and Michel (8) have shown that there is no change in the width of the charge distributions up to 39 MeV excitation in ^{236}U whereas other work with proton induced fission from 20–85 MeV does show an increase in the width of the charge distribution (10, 12).

The previous studies of helium ion induced fission have measured yields of relatively long-lived or stable nuclides. In the present work we have measured fission yields for very neutron-rich Rb isotopes with half-lives as short as 0.17 s by use of "on-line" mass spectrometry. "On-line" mass spectrometry was developed for the study of short-lived isotopes of the alkali metals (13–15). Production cross sections for isotopes of Rb and Cs have been measured by this technique for U, Th, and Ta targets bombarded with protons (10, 16–18). Independent fission yields of Rb and Cs isotopes have been measured for thermal neutron fission of ^{235}U (16, 19–21) fast neutron fission of ^{238}U (22), and thermal neutron fission of ^{239}Pu (23).

The work reported here used the "on-line" technique to measure cumulative and independent yields of Rb isotopes from fission of ^{238}U and ^{232}Th by ^{3}He and ^{4}He ions at energies slightly above the Coulomb barrier. The excitation energies are thus intermediate between thermal neutron induced fission and fission with moderate energy protons. The independent yields were analyzed for the mean mass and width of the distributions to determine how these parameters vary with composition of the fissioning system and with excitation energy.

Experimental

The technique of on-line mass spectrometry involves placing a suitable target in the ion source of a mass spectrometer and bombarding the target with projectiles from an accelerator or reactor. Nuclear reaction products diffuse out of a graphite matrix and are ionized by surface ionization on a hot tantalum surface.

At Washington University, St. Louis, a small (15-cm radius, 60 degree magnetic sector) mass spectrometer was installed at the end of an external beam pipe at the 54-in sector-focused cyclotron.[2] The target consisted of ^{238}U or ^{232}Th powder (10 μm size) intimately mixed with graphite powder and pressed into a small block about 100 mg/cm^2 thick. The ratio of metal-to-graphite was 4-to-1 by weight. At 32-MeV, a ^{3}He beam intensity of 1 μA gave a typical ^{91}Rb counting rate of about 15 000 ions/s. The peak-to-valley ratio between equally-abundant adjacent masses was about 4 for Rb fission products. Although Cs fission products were seen with comparable counting rates, the resolution of this small instrument was not sufficient to give reliable yield measurements for Cs.

The maximum energy ^{3}He beam from the cyclotron was 34 MeV. However, the beam had to pass through a 0.010-mm stainless steel foil

[1]Research at Washington University supported by USAEC contract AT(11-1)-1608 and at Pacific Northwest Laboratory by DOE contract DE-AC06-76RLO.

[2]The mass spectrometer was obtained from Dr. R. Bernas, Orsay, and was originally used by Dr. R. Klapisch for on-line studies of Li isotopes (see ref. 24).

separating the cyclotron vacuum from the mass spectrometer vacuum and a 0.013-mm tantalum foil surrounding the target. These foils reduced the beam energy by about 2 MeV. Because of the thick targets, fission could occur at all energies down to the Coulomb barrier. Thus a weighted average energy was calculated based on the known excitation functions for ^{3}He and ^{4}He induced fission of ^{238}U (25–27). The excitation function for ^{3}He + ^{232}Th was not known so the weighted average energy was assumed to be the same as for ^{3}He + ^{238}U at the same bombarding energy.

A critical factor in the measurement of relative yields of different isotopes is the diffusion time of the radioactive isotopes out of the target matrix. Diffusion can be described by the sum of several exponentially decaying components. Up to five components were resolved from the diffusion curves of Chaumont (16).

Diffusion times of three different Rb isotopes were measured for 34 MeV ^{3}He on ^{238}U under the conditions of the experiments here. The accelerating voltage and magnetic field were adjusted to give the desired mass. The cyclotron beam was switched on for a short time interval (0.4 or 1.0 s). A 200 channel multiscaler was switched on simultaneously with the beam-on signal and ion pulses as a function of time were stored for 8 s. Thus the growth and disappearance of ions could be recorded using the same length of beam pulse as in the independent yield measurements described below. Cycles were repeated until sufficient numbers of counts were obtained. The disappearance curves were resolved by a least-squares computer program. Good fits were obtained with just three components. The resulting "half-times" and abundances are shown in Table 1.

The half-times of the two shortest components were corrected for the radioactive decay half-lives and were averaged to obtain the diffusion half-times of 0.12 and 0.61 s. The longest-lived component varies for different isotopes and different bombardment times. It is probably due to a combination of a constant background plus a background which changes due to beam heating. The counting rates of stable Rb and Sr isotopes increased significantly when the beam was switched on. The large abundance and long half-time for the third component at mass 89 may be due to interference from stable ^{88}Sr or decay of ^{89}Kr.

Cumulative yields

The relative cumulative yields of Rb isotopes were measured by scanning the mass spectrum rapidly while the cyclotron beam was on continuously. The mass spectrum was scanned by holding the magnetic field constant and imposing a triangular waveform to the accelerating voltage at a repetition rate of 25 cycles/s. Sweep up and sweep down mass spectra were stored separately in 100 channel segments of a multiscaler. The Rb fission product mass region was covered in two separate runs, one for masses 88–96 and the other for masses 91–99. After each run was a 15 min delay before measuring the background mass spectra. This delay allowed long-lived isotopes to diffuse out of the target. These background spectra had to be normalized to the beam-on spectra since beam heating increased the counting rate of stable isotopes. Normalizations were performed at mass 88 or mass 98 for the two separate runs. The beam-on data were corrected for background, overlap from adjacent peaks (about 5%), saturation factor, loss due to radioactive decay, and loss due to diffusion of Kr precursors.

The saturation factor corrected for those isotopes whose half-lives were an appreciable fraction of the total run time. The maximum corrections were 40% for mass 89 and 2% for mass 90 for a run with 34 MeV ^{3}He on a ^{238}U target.

The correction for radioactive decay requires knowledge of the diffusion components as described above. If there were a single diffusion component, the observed yield would be equal to the true yield times the fraction of Rb ions which diffuse before decaying.

For multiple diffusion components the relationship becomes

$$[1] \quad Y_{obs} = Y_{true} \sum_i A_i \left(\frac{t}{t + t_D^i}\right)$$

where Y_{obs} = observed yield, Y_{true} = true yield, t = radioactive half-life, t_D^i = half-time of i-th diffusion component, A_i = abundance of i-th diffusion component.

Since the longest of the three diffusion components measured here did not correspond to actual diffusion of Rb, only the two shortest diffusion components were used in calculating this correction. This correction amounted to a few percent for masses 92–94 but increased to a factor of 2.15 for mass 97 where the radioactive half-life is only 0.17 s.

In order for the yields measured in these experiments to be truly cumulative, it is necessary that there be no loss of Br and Kr precursors due to diffusion. It is possible to measure the diffusion time of Kr by observing the disappearance curves of Rb isotopes for several minutes after the accelerator beam is shut off. The Rb isotopes with short-lived Kr precursors disappear immediately, indicating that there are no Rb diffusion components with half-times greater than a few seconds. However, ^{89}Rb which has a 3.1 min ^{89}Kr precursor persists in the mass specta for several minutes after the beam is turned off. The observed half-time for ^{89}Rb is about 70 s which is a combination of the 186 s radioactive half-life of ^{89}Kr and a 112 s diffusion half-life of Kr. Similar observations were made on Cs isotopes where ^{135}Cs and ^{137}Cs were seen to persist long after the beam was shut off. (Diffusion times of about an hour were

indicated for Xe.) If there were Kr diffusion components with half-times shorter than the observed 112 s component, the corrections for precursor loss described below would be too small. However, previous studies concerning the diffusion of Kr and Xe under similar target conditions had no evidence for any shorter-lived diffusion components (16, 21). Any longer-lived Kr diffusion component would have little effect since the Kr nuclides of interest would decay before diffusing and thus contribute to the Rb cumulative yield in the normal manner.

Although there is no information on the diffusion times of Br under the conditions used here, the half-lives are considerably shorter — the longest one of interest being 4.5 s for ^{89}Br. Also the contributions of Br isotopes to the cumulative yield of Rb isotopes are no more than 25% for mass 89 and 11% for mass 90. These estimates are based on recommended fission yields for n_{th} + ^{235}U (28). The actual contribution of Br is less for ^{3}He and ^{4}He induced fission because the independent yield distributions for these cases are shifted toward the line of stability as will be discussed below.

With the assumptions that no Br was lost by diffusion and that all the Kr diffuses with a 112 s half-time, the correction for precursor loss by diffusion is given by the expression

$$[2] \quad Y_{obs} = Y_{true}\left(\frac{(CY_{Kr})(F) + (IY_{Rb})}{(CY_{Rb})}\right)$$

where Y_{obs} = observed yield, Y_{true} = true yield, CY_{Kr} = cumulative yield of Kr, CY_{Rb} = cumulative yield of Rb, IY_{Rb} = independent yield of Rb, and F = fraction of Kr which decays before diffusing. The fraction F is estimated from the diffusion time (t_D) and half-life (t) of the Kr isotope according to the expression

$$[3] \quad F = \frac{t_D}{t + t_D}$$

To make this correction, it is necessary to know the isobaric distribution at each mass number. From the work of McHugh and Michel (8), one can estimate independent and cumulative yields for He ion induced fission at these excitation energies using the assumption of a Gaussian charge distribution curve with a constant width parameter. The correction for precursor loss by diffusion raised the mass 89 yield by about 45% and the mass 90 yield by 17% relative to the most neutron-rich isotopes.

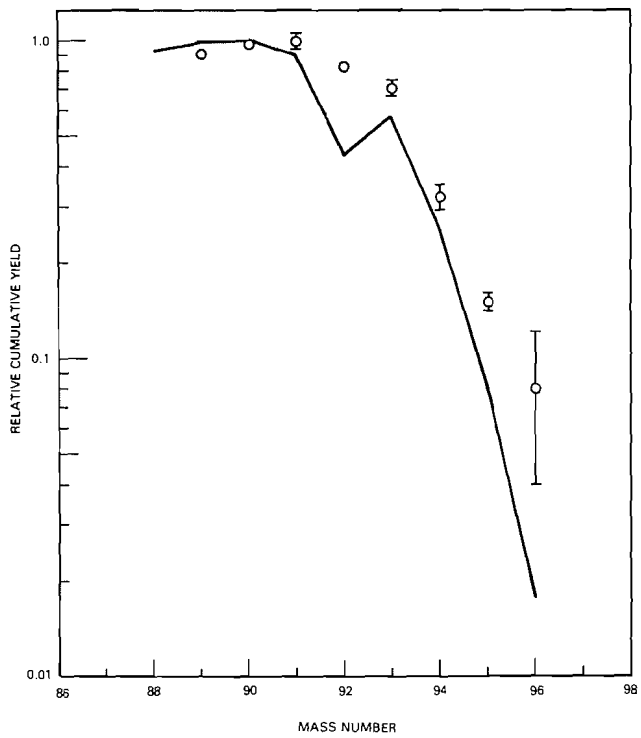

FIG. 1. Relative cumulative yields of Rb isotopes for two fissioning systems with same E^* (20 MeV) and different N/Z. ○, 25.5 MeV ^{4}He + ^{238}U (N/Z = 1.574); —, 14 MeV n + ^{239}Pu (N/Z = 1.553) (recommended yields from ref. 28).

The relative cumulative yields for mass spectra obtained with increasing and decreasing accelerating voltage were calculated separately and were considered as independent determinations. Different runs were normalized to a common isotope. The results were averaged and normalized to 1.00 for the

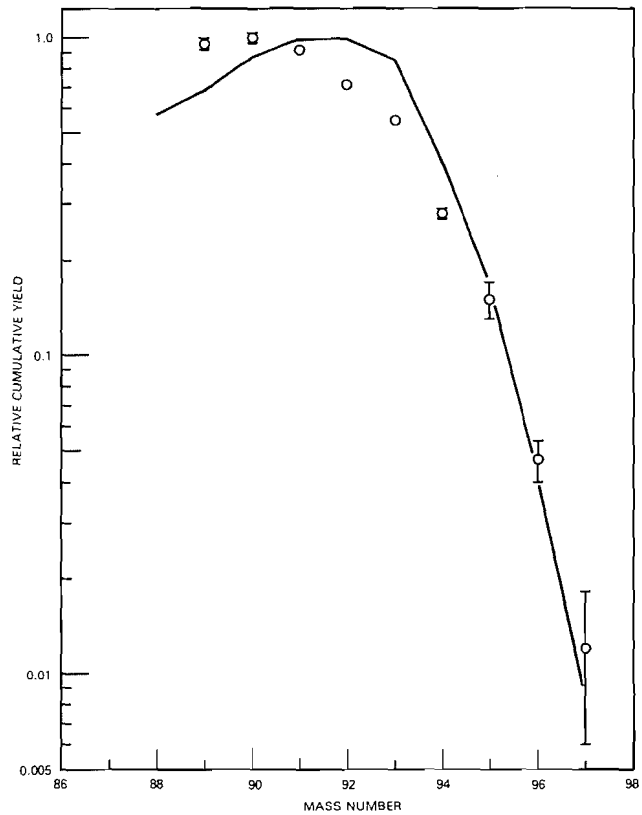

FIG. 2. Relative cumulative yields of Rb isotopes for two fissioning systems with same N/Z (1.564) and different E^*. ○, 28.1 MeV ^{3}He + ^{238}U (E^* = 37 MeV); —, fission spectrum neutrons + ^{240}Pu ($E^* \simeq 7$ MeV) (recommended yields from ref. 28).

most abundant isotope. The final results are presented in Table 2. For comparison, the recommended cumulative yields for thermal neutron fission of ^{235}U are also given (28).

In general, the distributions of relative cumulative yields for fission at moderate excitation energy are similar to those at low excitation energy. Mass 89 appears to be unusually high for 25.3 MeV ^{3}He + ^{238}U and unusually low for 28.1 MeV ^{3}He + ^{232}Th. This may be due to uncertainties in some of the correction factors which were large at this mass number. An additional complication at mass 89 was the possible interference of stable ^{88}Sr due to the relatively poor mass resolution of the mass spectrometer. The present data can be compared with cumulative yields from other fissioning systems to show changes due to composition of the compound nucleus or to excitation energy. For example, the system 25 MeV ^{4}He + ^{238}U has the same excitation energy (20 MeV) as 14 MeV n + ^{239}Pu whereas the compound nuclei are ^{242}Pu and ^{240}Pu, respectively. The Rb cumulative yields for those two systems are plotted in Fig. 1. The 14 MeV n + ^{239}Pu data are the recommended values (28). The distribution of Rb fission products is shifted toward more neutron-rich isotopes for the compound nucleus with more neutrons.

The effect of increasing the excitation energy is illustrated in Fig. 2, which shows the relative Rb cumulative yields for 28 MeV ^{3}He + ^{238}U and for fission spectrum neutron fission of ^{240}Pu (28). Both systems have the compound nucleus ^{241}Pu but the excitation energy is 37 MeV and about 7 MeV, respectively. Higher excitation energy shifts the Rb distribution to more neutron-deficient products.

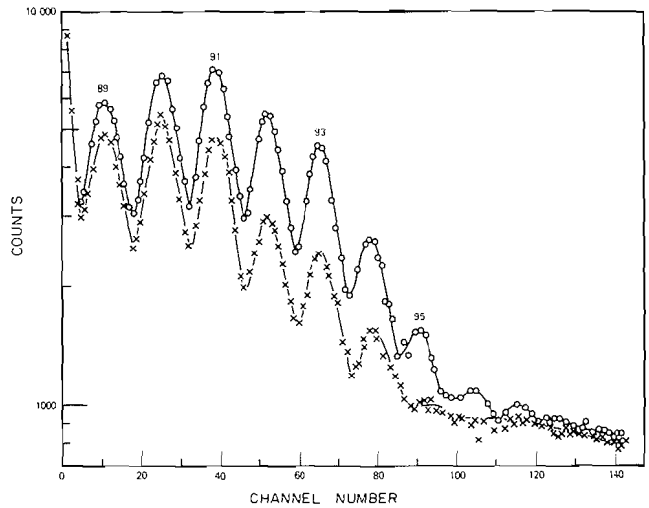

FIG. 3. Mass spectrum from Rb independent yield experiment. Upper curve = beam on. Lower curve = beam off. Beam-off spectrum normalized to beam-on spectrum below mass 89.

Independent yields

The measurement of Rb independent yields must be done in a time interval short compared to the radioactive half-lives of the Kr precursors. Thus a pulsed beam procedure was used in which mass spectra were recorded with "beam-on" for a short time interval and were separately recorded with "beam-off" for the same time interval. The system was automated such that a typical cycle started with 0.4 s of beam during which time 10 scans of the mass spectrum were recorded in the first 200 channels of the multiscaler. The beam was turned off and another 10 scans of the mass spectrum were added to the data in the first 200 channels. These 20 scans were called the "beam-on" spectrum and contained the short diffusion-time components plus background. Then 20 more scans were recorded in the second set of 200 channels and were called the "beam-off" spectrum. This cycle was repeated until sufficient statistics were obtained (up to 80 000 scans). Although equal numbers of scans were recorded in the beam-on and beam-off spectra the two spectra still had to be normalized to each other at a mass region free from fission products to account for the increased background due to beam heating during the beam pulse. The length of the beam pulse and the memory storage locations were controlled by a 4-channel pre-determined timer and mercury relays. The cyclotron beam was shut off by interrupting the Rf power at a low-power stage in the cyclotron Rf amplifier system.

A spectrum composed of two runs covering the Rb fission product region from mass 89–98 is shown in Fig. 3. The beam-off spectrum has been shifted upwards by a factor of 1.16 to account for the beam heating effect.

After normalization of the beam-off spectra to the beam-on spectra, the net counts were obtained for each mass peak. These values were then corrected for the overlap of adjacent mass peaks. As before, sweep-up field and sweep-down field were considered as independent determinations. Counts at each mass peak were calculated relative to a common mass and averaged for the several determinations. The random errors were determined from the standard deviations of the average values. The relative counts obtained in this manner were corrected by a factor which took into account the individual half-

lives of the Rb isotopes and their Kr precursors, the Rb and Kr diffusion times, and the time intervals for beam-on and beam-off. This factor is discussed in the Appendix.

The final results for the relative independent yields of the Rb isotopes are given in Table 3. Included in this table are the recommended values for thermal neutron fission of ^{235}U for comparison (28). The mean value of the isotopic distribution of Rb ($\langle A \rangle$), the N/Z value corresponding to the mean mass, and the standard deviation (width) of this distribution are also given in Table 3 for each of the fissioning systems. The determination of $\langle A \rangle$ and the width using the method of moments adopted in previous works (16, 18) is not adequate here because the mass range covered is not always symmetric about the peak yield. The mean mass and width were therefore determined from a least-squares fit of the data to a Gaussian curve. Previous work has shown that the Rb distributions for both neutron and charged particle induced fission are reasonably well fitted by Gaussian curves although this is not always true for Cs distributions (10, 17).

The shifts in Rb yields as functions of the composition of the compound nucleus and of excitation energy are clearly seen in the independent yield distributions. In Fig. 4 are shown the relative independent yields of Rb isotopes for 25 MeV ^{4}He + ^{238}U and 14 MeV n + ^{239}Pu. The mean mass of the Rb distribution is shifted upwards by 0.86 mass units for the compound nucleus ^{242}Pu relative to the compound nucleus ^{240}Pu when both are at the same excitation energy (20 MeV). The widths of the two distributions are essentially the same. In Fig. 5, the relative independent yields are shown for 28 MeV ^{3}He + ^{238}U and for fission spectrum neutron fission of ^{240}Pu. The ^{241}Pu compound nucleus with 37 MeV excitation energy gives a Rb distribution which is shifted downward by 0.95 mass units relative to ^{241}Pu at 7 MeV excitation energy. The width is broadened for fission at the higher excitation energy.

Discussion

In order to correlate the existing data on Rb independent yield distributions for fission with thermal neutrons, protons, ^{3}He, and ^{4}He, one must consider the differences in excitation energy, E^*, and the differences in the composition of the compound nucleus. A convenient parameter for the composition of the compound nucleus is the neutron-to-proton ratio, $(N/Z)_{CN}$. It would be useful to compare the experimentally measured values of mean mass and width versus one of the parameters E^* or $(N/Z)_{CN}$ independent of the other parameter.

The available data on Rb isotopic distributions are summarized in Table 4. The table includes two sets of yields from thermal neutron fission of ^{235}U which were not measured by the on-line mass spectrometric technique (29, 30). All the other experiments were done with this technique. To make comparisons on a common basis, all the previously published Rb distributions have been fitted to Gaussian curves. The mean mass and width parameters given in Table 4 are the centroid and standard deviation from the least-squares fit. For charged particle fission the parameters given in Table 4 are essentially the same as those given in the original publications even when the original parameters were determined by the method of moments.

Inspection of the widths in Table 4 shows a generally small dependence on $(N/Z)_{CN}$ and a strong dependence on excitation energy, E^*. These trends are illustrated in Fig. 6 where the widths are plotted versus the excitation energy. For thermal neutron fission of ^{235}U, the recommended value (28) is plotted with an error bar corresponding to the range of experimental values. Two of the widths from the present work do not seem to fit the general trend. For the ^{3}He + ^{238}U point at an excitation energy of 27 MeV, the enhanced width can be explained by the Gaussian curve not being a good representation of the experimental data. Omission of the mass 95–97 yields gives a

better fit to the Gaussian curve and results in a smaller width in agreement with the other data. This explanation does not apply to the width of the ^{3}He + ^{232}Th distribution. In this case all the yields are well fit by the Gaussian curve. This distribution is far too wide in comparison with the other data and should be treated with suspicion unless confirmed elsewhere.

The mean masses for the distribution of independent yields of Rb isotopes shown in Table 4 depend on both the excitation energy, E^*, and the $(N/Z)_{CN}$. If one subtracts the N/Z ratio corresponding to the mean mass of the Rb distribution, $\langle N/Z \rangle_{Rb}$, from the $(N/Z)_{CN}$, the dependence on the composition of the compound nucleus is minimized. When $(N/Z)_{CN} - \langle N/Z \rangle_{Rb}$ is plotted versus E^*, the data cluster about a single curve as shown in Fig. 7. All four points from the present work are consistent with the previous work.

The shift of $\langle N/Z \rangle_{Rb}$ away from $(N/Z)_{CN}$ as excitation energy increases is due to increased neutron emission either as pre-fission neutrons, or as post-fission neutrons (10, 17, 18, 31). The relationship between $(N/Z)_{CN} - \langle N/Z \rangle_{Rb}$ and the number of neutrons emitted can be derived from the definition of the most probable charge for a model of charge distribution in fission. The commonly used model of Unchanged Charge Density (UCD) states that the neutron-to-proton ratio of the fragments is equal to that of the fissioning nucleus. The most probable charge (Z_p) for a particular fragment is thus

$$[4] \quad Z_p = A_{frag}\left(\frac{Z_{CN}}{A_{CN} - \nu_{pre}}\right)$$

where A_{frag} is the mass of the fragment, Z_{CN} is the nuclear charge of the compound nucleus, A_{CN} is the mass of the compound nucleus, and ν_{pre} is the number of pre-fission neutrons. With the additional assumptions that the number of neutrons in the fission product (N_{prod}) is equal to the number of neutrons in the fragment (N_{frag}) minus the number of post-fission neutrons (ν_{post}) for that fragment and that the charge of the fission product (Z_{prod}) is equal to the charge of the fission fragment ($Z_{prod} = Z_{frag} = Z_p$) eq. [4] can be rearranged to give

$$[5] \quad [(N/Z)_{CN} - \langle N/Z \rangle_{prod}] = \frac{\nu_{pre}}{Z_{CN}} + \frac{\nu_{post}}{Z_{prod}}$$

For the fissioning systems considered in Fig. 7, Z_{CN} varies by $\leq$3%, so variations in $(N/Z)_{CN} - \langle N/Z \rangle_{Rb}$ are due to the number of neutrons emitted. Previous work (10, 17, 18) has shown that the UCD model is not adequate and that a better model for charge distribution is the Equal Charge Displacement (ECD) model. The ECD model states that the distance of the most probable charge from the most stable charge for that mass is the same as for its complementary fragment. For the particular case of the Rb isotopes, previous work (10) showed that

$$[6] \quad Z_p^{ECD} = Z_p^{UCD} + 0.4$$

Equation [5] is then modified to

$$[7] \quad [(N/Z)_{CN} - \langle N/Z \rangle_{prod}] = \frac{\nu_{pre}}{Z_{CN}} + \frac{\nu_{post}}{Z_{prod}} + \frac{0.4}{Z_{prod}}\left(\frac{A_{CN} - \nu_{pre}}{Z_{CN}}\right)$$

The additional term is rather insensitive to changes in excitation energy, so variations in $(N/Z)_{CN} - \langle N/Z \rangle_{Rb}$ are again dominated by changes in the number of neutrons emitted.

Authors of earlier papers have used a similar analysis with additional information about pre-fission neutron emission to determine the number of post-fission neutrons from the heavy fragment as well as from the light fragment (10, 17, 18). Figure 7 and eq. [7] show that the ^{3}He and ^{4}He induced fission reac-

tions studied here are consistent with the earlier results for proton and neutron induced fission with regard to neutron emission as a function of excitation energy.

Conclusions

The cumulative and independent fission yields of Rb isotopes have been measured here for ^{3}He and ^{4}He induced fission of ^{232}Th and ^{238}U at energies slightly above the Coulomb barrier. The widths of the independent yield distributions for Rb isotopes are dominated by the effect of excitation energy rather than the N/Z of the compound nucleus.

The mean mass of the Rb independent yield distribution is a function of the composition of the fissioning system $(N/Z)_{CN}$ and the excitation energy, E^*. At a constant E^*, the N/Z of the mean mass of the Rb yield distribution is approximately equal to the $(N/Z)_{CN}$ minus a constant which is independent of $(N/Z)_{CN}$. This constant is related to the number of neutrons emitted before fission and to the number of neutrons emitted by the particular fragment after fission.

Acknowledgments

The experimental data for this work was obtained with the assistance of A. Ramamoorthy.

We are indebted to the late Rene H. Bernas who provided us with the mass spectrometer and supported us with valuable advice. We also express our gratitude to Robert Klapisch for many helpful discussions prior to and during this work. The assistance of Lazar Djordjevic with instrumentation for the mass spectrometer is greatly appreciated. Computing facilities at Washington University were supported under National Science Foundation Grant No. G-22296. We are grateful to Ray Warner and Nate Ballou for their comments on this manuscript.

Appendix

The correction factor for growth, decay, and diffusion was derived as follows. For each mass peak the following equations are defined for the observed counts in the "beam-on" spectrum (α) and "beam-off" spectrum (β).

$$\alpha = N_1 + N_1^p + N_2 + N_2^p + B$$

$$\beta = N_3 + N_3^p + B$$

where N_1, N_2, and N_3 refer to the observed counts due to independent formation and diffusion of Rb, N_1^p, N_2^p, and N_3^p refer to the observed counts due to Rb produced by decay of Kr precursors. The subscripts 1, 2, and 3 refer to three time regions: 1. period with beam actually on during "beam-on" spectrum (10 scans); 2. period with beam-off during "beam-on" spectrum (10 scans); 3. period for "beam-off" spectrum (20 scans). B is the counts due to the constant background. The variable background due to beam heating was accounted for by including a third component with the two other diffusion components described in the main text.

For each of the time regions i (i = 1, 2, 3) the number of observed ions is given by

$$N_i = \epsilon n I \sigma F_i$$

$$N_i^p = \epsilon n I \sigma_p F_i^p$$

where ϵ is the overall efficiency of the mass spectrometer for ionizing and detecting a given isotope of Rb (this efficiency was assumed to be constant for all isotopes of Rb), n is the number of target atoms per cm^2, I is the intensity of the incident

beam, σ is the cross section for independent formation of Rb isotopes, σ_p is the cross section for the cumulative formation of Kr isotopes, F_i is the factor which accounts for growth, decay, and diffusion of independently formed Rb during the time interval i, and F_i^p is the factor which accounts for the growth, decay, and diffusion of Rb from decay of Kr precursors during the time interval i.

The F_i and F_i^p factors depend only on the time intervals, the radioactive half-lives of the Rb and Kr isotopes and the Rb and Kr diffusion times. The derivations of the F_i and F_i^p equations are based on standard equations for growth and decay of radioactive species. However, the radioactive decay constants are generally replaced with effective rate constants which include the effect of a particular diffusion component. The factors were calculated separately for each diffusion component, weighted by the relative abundance of each diffusion component, and then combined.

After algebraic manipulation, the expression for the relative cross section of a given Rb isotope becomes

$$\sigma_{Rel} = \frac{\alpha - \beta}{F_1 + F_2 - F_3 + (\sigma_p/\sigma)\,(F_1^p + F_2^p - F_3^p)}$$

Unfortunately σ_p/σ represents the ratio of the cumulative Kr yield to the independent Rb yield both of which are unmeasured quantities for these fissioning systems. In fact, the latter quantity is the number to be determined in this experiment. However, one can adopt the charge distribution parameters of McHugh and Michel (8) and obtain approximate values for the ratio σ_p/σ. The estimated ratios varied from 3.86 at mass 89 to 0.0147 at mass 95. The F_i^p factors were greatest at mass 91 but when combined with the cross section ratios, the greatest correction for Kr precursors occurred at mass 90 with 39% correction. At mass 92 and above, the correction was less than 7%. The correction factors F_i for growth, decay, and diffusion of independently formed Rb were less than 1% for masses up to and including ^{94}Rb for the 0.4 s beam pulse. At mass 95 the correction was 22%. One run with 2 s beam pulses had larger corrections of up to 7% at mass 94 and 42% at mass 95.

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

YUAN L. CHOW and GONZALO E. BUONO-CORE. Can. J. Chem. **61**, 795 (1983).

Triplet-state benzophenone rapidly sensitized the photoreduction of $Cu(acac)_2$ in alcohols to give polymeric Cu(acac) as black precipitates. The binary complexes of Cu(acac) of polypyridines, polysulfide, olefins, acetylenes, and carbon monoxide could be generated in solution under an inert atmosphere when a ligand was present *in situ* during photoreduction or added after an appropriate photoreduction was completed. Except Cu(acac)—$(PPh_3)_2$, the Cu(acac) complexes of various ligands are sensitive to air oxidation, but show a wide range of reactivity towards disproportionation and photolysis. In the presence of terminal acetylenes, amorphous copper(I) acetylides were isolated in good yields.

YUAN L. CHOW et GONZALO E. BUONO-CORE. Can. J. Chem. **61**, 795(1983).

La benzophénone à l'état triplet sensibilise rapidement la réduction photochimique du $Cu(acac)_2$ dans des alcools en donnant le Cu(acac) polymerisé sous la forme d'un précipité noir. Les complexes binaires de Cu(acac), de polypyridines, de polysulfure, d'oléfines, d'acétylènes et de monoxyde de carbone peuvent être produites en solution sous atmosphère inerte lorsqu'un ligand est présent "*in situ*" pendant la photoréduction ou s'il est ajouté après qu'une photoréduction appropriée soit complétée. A l'exception du Cu(acac)—$(PPh_3)_2$, les complexes du Cu(acac) de divers ligands sont sensibles à l'air, mais ils exhibent un large domaine de réactivité vis-à-vis de la dismutation de la photolyse. En présence d'acétylènes terminaux, on isole avec de bons rendements des acétylures de cuivre(I) amorphes.

Introduction

We have shown (1) that bis(acetylacetonato)copper(II), $Cu(acac)_2$, is photoreduced in the presence of certain aromatic ketone sensitizers in hydrogen-donating solvents to give an amorphous black precipitate which reacts with triphenylphosphine to afford crystalline acetylacetonatobis(triphenylphosphine)copper(I), $Cu(acac)(PPh_3)_2$. In this photoreduction, alcohols were concurrently oxidized to the corresponding ketones and acetylacetone was produced in nearly quantitative yields. On prolonged irradiation, the black precipitate was transformed to copper metal. These observations have led us to conclude that in the primary step $Cu(acac)_2$ is photoreduced to a copper(I) complex, the black precipitate, which may react by a combination of disproportionation and/or photoreduction to give copper metal. $Cu(acac)_2$ and several other transition metal acetylacetonates are known to quench triplet transients generated by flash photolysis of aromatic ketones and hydrocarbons (2–5). However, the chemical consequences of the quenching has not been investigated so far, except in our recent report (1).

In order to carry out mechanistic studies of this intriguing sensitization process, it is necessary to clarify the pattern of the photoreduction of $Cu(acac)_2$ to copper(I) complexes. In this report, we describe the benzophenone-sensitized photoreduction in the presence of various ligands aiming to demonstrate the product pattern of the primary photoreduction.

Experimental

General conditions and materials

Melting points were determined on a Fisher-Johns apparatus and were uncorrected. Infrared spectra were obtained with a Perkin-Elmer 457 spectrophotometer, ultraviolet–visible spectra with a Cary 17 spectrophotometer, mass spectra and gc–ms with a Hewlett-Packard Model 5985, and nmr spectra with a Varian A56/60 or XL-100 in $CDCl_3$ solution using TMS as an internal standard. Elemental analyses were carried out by Mr. M. K. Yang on a Perkin-Elmer 240 microanalyser.

Olefins and acetylenes were redistilled and sealed under nitrogen. Other ligands were used as supplied by commercial sources. Unless specified otherwise, an immersion type photocell (Hanovia type) was used. The light source was a Hanovia 450 W or 200 W medium pressure mercury lamp. Nitrogen was scrubbed with a Fieser's solution and dried with H_2SO_4 and NaOH pellets.

Sensitized photoreduction in the absence of ligands

A solution of benzophenone and $Cu(acac)_2$ in methanol, ethanol, 2-propanol, tetrahydrofuran, or a mixture of 2-propanol and *t*-butanol (1:1) was photolyzed in an overhead irradiator (1) under nitrogen to give black precipitates. The precipitates were quickly filtered and washed with the solvent. The ir spectra in Nujol were identical and showed absorptions at 1580(s), 1550(s), 1530(s), 1190(w), 1020(m), 940(m), 785(m). Most of these peaks are shown by $Cu(acac)_2$ with different intensities. The black precipitate gave blue color immediately on exposure to air.

After 24 h, the solid showed the presence of blue particles on the surface. This solid was treated with methanol to give a solution and a solid. The solution was evaporated to give $Cu(acac)_2$. The solid was treated with acetylacetone in ethanol to give $Cu(acac)_2$ under nitrogen and was assumed to be cupric oxide.

A solution of $Cu(acac)_2$ (5.7×10^{-3} *M*) and benzophenone (7.9×10^{-2} *M*) in methanol (100 mL) showed OD of 0.36 at 620 nm (Fig. 1). The solution was irradiated as above for 3 h to give the black precipitate suspended in a clear solution: the residual OD of the clear solution at 620 nm was 0.092. One half of the suspension was left under nitrogen for 12 h to give a blue solution and copper metal; the absorption of the supernatant solution at 620 nm was 0.22. The other half of the suspension was exposed to air for 12 h to give a blue solution with OD 0.36.

Sensitized photoreduction in the presence of various ligands

2,2'-Dipyridine: Irradiation of a solution containing $Cu(acac)_2$ (300 mg, 1.15 mmol), benzophenone (400 mg), and 2,2'-dipyridine (180 mg, 1.15 mmol) in methanol (200 mL) under nitrogen rapidly developed a red color in 1/2 h. This solution was stable for 16 h under nitrogen. On exposure to air, the red color was replaced by a blue color (λ_{max}, 620 nm) with a lifetime of 60 s. To a part of the red solution triphenylphosphine in methanol was added under nitrogen. The solu-

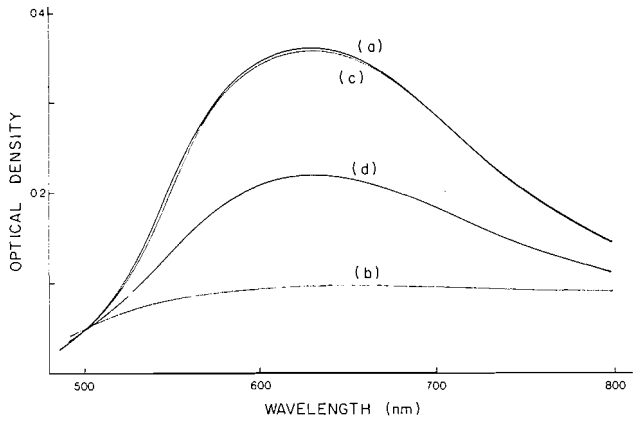

FIG. 1. The spectral changes of triplet-state benzophenone-(7.9×10^{-2} *M*) sensitized photoreduction of Cu(acac)$_2$ (5.7×10^{-3} *M*) in methanol (100 mL): (*a*) before irradiation, (*b*) the photolysate after 3 h irradiation, (*c*) the air-exposed photolysate, (*d*) the photolysate kept under nitrogen in the dark for 12 h.

tion was worked up in a similar way as described previously to afford Cu(acac)(Ph$_3$P)$_2$; mp 175–178°C; the ir spectrum was identical to that of an authentic sample (1). On prolonged photolysis of the red solution for 18 h, a small amount of copper metal was deposited.

Ethylenediamine: A solution of Cu(acac)$_2$ (100 mg, 3.8 mmol), benzophenone (138 mg), and ethylenediamine (46 mg, 7.6 mmol) in methanol (40 mL) exhibited a deep blue color. This solution was irradiated under nitrogen to afford a pale yellow solution in 1.5 h. This solution deposited a trace amount of copper metal and turned to pale blue in 45 min but discharged the color immediately on addition of triphenylphosphine and gave Cu(acac)(Ph$_3$P)$_2$: mp 176–179°C; the ir spectrum was superimposable with the previous one. The pale yellow photolysate immediately became the original deep blue within seconds after exposure to the air. Continued irradiation of the pale blue solution for another 1/2 h caused a deposit of metallic copper on the wall.

2,5-Dithiahexane: A solution of Cu(acac)$_2$ (300 mg, 1.15 mmol), 2,5-dithiahexane (141 mg, 1.15 mmol), and benzophenone (400 mg) in methanol (220 mL) was photolyzed under nitrogen to give a yellow solution in 20 min. This yellow solution remained unchanged for 16 h under nitrogen but became blue (λ_{max} 620 nm) within 30 seconds after exposure to air. A part of this solution (2 mL) and a methanol solution (2 mL, 6×10^{-3} *M*) of 2,2′-dipyridine were mixed under nitrogen to give a red solution showing λ_{max} 427. To the remainder of the photolysate, triphenylphosphine (600 mg) in methanol (30 mL) was added under nitrogen. After 10 h, the solution was worked up in a usual manner to give Cu(acac)(Ph$_3$P)$_2$ (382 mg): mp 165–170°C.

Bis-(2-methoxyethyl)ether: On irradiation of a solution containing Cu(acac)$_2$ (250 mg, 0.95 mmol), benzophenone (500 mg), and bis(2-methoxyethyl)ether (650 mg, 4.75 mmol) in methanol (50 mL) under nitrogen, metallic copper appeared on the wall in 15 min. In 26 min, the solution became colorless and a shiny copper mirror was formed.

Styrene: A solution of Cu(acac)$_2$ (500 mg, 1.92 mmol), benzophenone (1 g), and styrene (9.61 mmol) in methanol (200 mL) was photolysed under nitrogen slowly to give a pale blue solution in 8 h, but no black precipitate was formed. This solution immediately turned to blue color on exposure to air. Part of this solution was taken and reacted with triphenylphosphine in methanol under nitrogen to give Cu(acac)(Ph$_3$P)$_2$: mp 170–175°C. The remaining solution was irradiated further to deposit a trace amount of copper metal in 3 h. The photolysate was diluted with water and extracted with ether in the usual manner to give a crude oil which contained only styrene and benzophenone by gc analysis.

Norbornene: On irradiation of a methanol solution (200 mL) of Cu(acac)$_2$ (500 mg, 1.92 mmol), benzophenone (1.0 g), and norbornene (800 mg, 8.5 mmol), a reddish copper metal suspension developed in 20 min and a copper mirror was formed in 30 min. The red suspension turned to blue solution in 10–15 min on exposure to air. The pale blue solution was worked up as above to give acetylacetone, benzophenone, and norbornene and small amounts of benzhydrol and oxetanes derived from benzophenone.

Carbon monoxide: A methanol solution (5 mL) containing Cu(acac)$_2$ (5.6×10^{-3} *M*) and benzophenone (1.5×10^{-2} *M*) in a Pyrex tube was irradiated under purging of carbon monoxide for 20 min to give a colorless solution. The solution remained clear in the dark under constant carbon monoxide purging for 3 h. The clear solution deposited copper metal and turned to blue rapidly when carbon monoxide was replaced with a stream of argon. To a clear solution obtained from a similar photolysis was added triphenylphosphine (15 mg) in methanol under carbon monoxide. The solution was worked up to give Cu(acac)(Ph$_3$P)$_2$: mp 175–178°C.

To two tubes of the colorless solution obtained in a similar manner, 0.2 mL each of styrene and 1,3-pentadiene was added to each tube, respectively. The solutions remained colorless. When purging of carbon monoxide was replaced by a stream of argon, the two solutions remained clear colorless for 2 and 4 h, respectively; at these times they started to deposit copper metal and showed a pale blueish color.

Spectroscopic determination of Cu(I) complexes: A methanol solution containing known concentration of Cu(acac)$_2$, benzophenone, and a ligand (e.g. byp, phen, and DTH) in a uv cell (10 mm) was irradiated. At each 30 s interval, uv spectra were recorded to show emergence of new maxima. The molar extinction coefficients were calculated from the optical density at the stationary state.

A solution containing Cu(acac)$_2$ (1.2×10^{-2} *M*), benzophenone (6×10^{-2} *M*) in methanol – methylene chloride (1:1, 5 mL) was irradiated under carbon monoxide for 5 h to afford a colorless solution. A sample taken in an ir cell showed weak absorption at 2100 cm^{-1}. Continued irradiation of the colorless solution for 2 h caused the deposition of metallic copper.

Sensitized photoreduction in the presence of terminal acetylenes
