A solution of Cu(acac)$_2$ (ca. 2 mmol), benzophenone (5 mmol), and a terminal acetylene (5 mmol) in methanol (200 mL) was irradiated under nitrogen for 2–4 h to form a yellow-colored precipitate. The precipitate was filtered and washed with methanol to afford amorphous solid of the copper(I) acetylide. The pale blue filtrate was diluted with water (200 mL) and extracted with ether (3 × 50 mL). The ether solution was washed with water, dried, and evaporated. The residue was analysed by gc (10% SE-30, 100–240°C at 10°/min) to give peaks corresponding to acetylacetone (rt 1.2 min), the acetylene, and benzophenone (rt 7.3 min, nearly quantitative recovery by internal standards).

When *t*-butylacetylene was used in the photolysis a yellow solution was obtained. The photolysate was diluted with water and extracted with ether to afford a crude product. The crude product was chromatographed on silica gel; ether elution gave copper(I) *t*-butylacetylide **3** (102 mg, 37%); mp 82°C decomp. (lit. mp 80–140°C) (6); ir (CCl_4) 2000(w) cm^{-1}; nmr (CCl_4) δ 1.83(s) ppm.

The biscuprous acetylide **4** was obtained as a dark brown solid (70% yield) and exploded when dried in desiccator; mp 140–155°C decomp.; ir (Nujol) 2120(w), 1280(s), 1020(w) cm^{-1}; nmr (pyridine) 4.07 ppm(s).

Copper(I) *n*-butylacetylide **2** was obtained as a yellow–green solid in 90% yield; mp 145–185°C decomp. (lit. mp 182°C decomp.) (7); ir (Nujol) 1927 cm^{-1}. The *n*-butylacetylide **2** (50 mg) and triphenylphosphine (92 mg) in acetonitrile (30 mL) were stirred at room temperature for 48 h. The precipitate was recrystallized from acetonitrile to afford hexynyl(triphenylphosphine)copper(I) (29 mg); mp 157°C decomp.; ir 3050, 1585, 1480, 1432, 1090, 740, and 695 cm^{-1}. *Anal.* calcd. for $C_{24}H_{24}PCu$: C 70.85, H 5.90; found: C 71.33, H 5.95.

Copper(I) phenylacetylide **1** was obtained as a yellow solid (72%); mp 230°C decomp. (lit. 230–235°C) (7); ir (Nujol) 1930(w), 1485(m), 750(s), 690(s) cm^{-1}. The acetylide **1** (50 mg) and triphenylphosphine (80 mg) were stirred in acetonitrile (10 mL) under nitrogen for 12 h. The residue was recrystallized from toluene – petroleum ether to give yellow needles of phenylethynyl(triphenylphos-

phine)copper(I) (71 mg, 55%); mp 201–203°C decomp. (lit. mp 202–204°C decomp.) (8); ir (Nujol) 2030(m), 1435(s), 750(s), and 700 cm^{-1}. *Anal.* calcd. for $C_{26}H_{20}CuP$: C 73.17, H 4.69; found: C 72.92, H 4.76.

The reaction of copper(I) acetylide with iodobenzene

A mixture of an acetylide (1–0.5 mmol) and an equivalent amount of iodobenzene (1–0.5 mmol) in dry pyridine was heated at 120°C for 8 h. The solution was diluted with water and extracted with ether. The residue was analysed by gc peak-matching method or gc–ms to show the percentage yield of phenylacetylenes. 1,6-Diphenyl-1,5-hexadiyne was recrystallized from ethanol as light yellow crystals (44%); mp 45–48°C (lit. mp 48°C) (9); nmr ($CDCl_3$) 2.70(s,4H), 7.27(m,10H); ms *m/e* 230 (m^+,15), 115(100).

Photolysis of $Cu(acac)_2$ in the presence of internal acetylenes

A solution of $Cu(acac)_2$ (500 mg), benzophenone (2.5 g), and diphenylacetylene (700 mg) in methanol (200 mL) was irradiated under nitrogen to give a white crystalline precipitate after 20 min. Filtration under nitrogen atmosphere afforded Cu(acac)(PhC≡CPh) **12** (194 mg, 29%); mp (sealed under N_2) 225°C decomp.; ir (Nujol) 1970(m), 1593(s), 1540(s), 1280(m), 1035(m), 793(m), 767(s), and 705(s) cm^{-1}; ms *m/e* 340(M^+,1.0), 179(20), 178(100), 152(16); ms by chemical ionization *m/e* 356(1.0), 180(14), 179(100), 101(70). Prolonged photolysis caused the darkening of the solution and eventual copper metal deposition. The white crystals on exposure to air turned greenish and to a dark black solid. Even working in a nitrogen glove box, **12** did not give good elemental analysis. The white crystals **12** were placed in an nmr tube and $CDCl_3$ was condensed in the tube in a vacuum line. On warming to room temperature, it turned to a brownish solution which showed signals at 2.02 and 2.30 ppm (s for CH_3) and 7.43(m) in a ratio of 6:10.

The complex **12** (50 mg) and triphenylphosphine (100 mg) in ether (10 mL) was stirred under nitrogen for 48 h. The solution was filtered to give $Cu(acac)(PPh_3)_2$ (26 mg); mp 171–176°C (1).

A similar photolysis in the presence of 3-hexyne turned the photolysate to pale blue in 20 min and then to dark brown in 35 min. At this point, copper metal started to appear. On exposure of the photolysate to air, it turned to blue solution. To the photolysate triphenylphosphine was added. After stirring for 2 h, the solution was worked up to give $Cu(acac)(PPh_3)_2$ (124 mg) (1).

Photolysis of $Cu(acac)_2$ in the presence of alkynol ***9***

A solution of $Cu(acac)_2$ (500 mg), benzophenone (1 g), and 3,5-dimethyl-1-hexyn-3-ol, **9** (500 mg), in methanol (200 mL) was irradiated under nitrogen for 4 h to give a dark yellow solution. The solution was diluted with water and was extracted with ether to give dark brown ether layer and pale blue aqueous layer. The ether solution was worked up under nitrogen purging to give a brown solid which showed ir pattern superimposable with $Cu(acac)_2$. The filtrate was analysed by gc peak matching to give benzophenone and alkynol **9** but no other peaks. In a separate photolysis, the dark yellow photolysate was stirred with triphenylphosphine under nitrogen for 5 h to give $Cu(acac)(PPh_3)_2$ (190 mg, 30%); mp 175–178°C (1).

Copper(I) acetylide of alkynol ***9***

A solution containing $CuSO_4 \cdot 5H_2O$ (5 g), concentrated ammonium hydroxide (20 mL), and water (80 mL) was treated with hydroxylamine hydrochloride (2.84 g) under nitrogen for 10 min. To this pale blue solution, alkynol **9** (2.52 g) was added to give an orange precipitate. The precipitate was dissolved in ether and was dried. The residue from the ether extracts was dried in a desiccator to give amorphous orange semi-solid (550 mg); ir (KBr) 3500–3400, 2950(s), 1470(m), 1370(s), 1260(m), 1160(s), 1080(w), 975(w), 935(m), 920(m), and 860(w) cm^{-1}. The compound **11** dissolved in methanol was warmed up to 50°C. On cooling, copper metal deposited on the bottom. The filtrate was worked up to give alkynol **9**. Compound **11** and triphenylphosphine in ether deposited a red amorphous solid; no melting below 300°C; ir (KBr) 3400, 3040, 2940, 1560, 1475, 1430, 1150, 1090, 740, and 690 cm^{-1}.

Results and discussion

Irradiation of a solution of benzophenone and $Cu(acac)_2$ in ethanol or 2-propanol rapidly deposited black precipitates which were quantitatively changed to metallic copper under prolonged irradiation. The black precipitates were formed much faster in these solvents than in methanol (1). The heterogeneous photolysate was rapidly oxidized by air to give a quantitative yield of $Cu(acac)_2$, and the air oxidation was even faster when more acetylacetone was added to the photolysate. Under nitrogen, the black precipitate in the suspension was slowly disproportionated to copper metal and $Cu(acac)_2$; the concentration of the latter was exactly one-half of the original as shown by the absorption at 620 nm (Fig. 1). The black precipitates were sparingly soluble in most solvents and in the solid state slowly changed to $Cu(acac)_2$ and an unkown solid under air in several days. Fortunately, the precipitates in the photolysate reacted readily with triphenylphosphine to afford stable $Cu(acac)(PPh_3)_2$ which was obtained previously by photolysis in methanol in the presence of triphenylphosphine. The black precipitates were also obtained in the direct photolysis of $Cu(acac)_2$ in alcohols by irradiation of the charge-transfer ligand to metal (CTTM) band at 240 nm (Corex filter), and have been assumed to be $Cu(acac)(ROH)_x$, where ROH was an alcohol (10). This formulation was obviously incorrect since all black precipitates obtained in various alcohols or tetrahydrofuran exhibited the same ir spectrum which contained neither typical ir absorption bands of alcohol ligands nor the OH absorption. Since the ir spectrum was very similar to that of $Cu(acac)_2$ except for some details, the black precipitates are more likely polymers of Cu(acac). Polymeric complexes of copper(I) derivatives are well known; some of them have been shown to have short Cu—Cu distances(2.71 Å) implying facile interactions (11).

However, the benzophenone-sensitized photolysis of $Cu(acac)_2$ in the presence of various ligands, such as 1,2-diamino derivatives, 2,5-dithiahexane (DTH), bis(2-methoxyethyl)ether (diglyme), carbon monoxide, acetylenes, and olefins (except cyclohexene), did not form the black precipitates but, instead, gave colored solutions. These solutions exhibited varied stability toward air oxidation with visual lifetimes ranging from several minutes to several seconds on exposure to air. For example, while colored solutions derived from 1,10-phenanthroline (phen), 2,2′-dipyridine (bpy), and DTH are relatively stable, those derived from ethylenediamine (en) and carbon monoxide were oxidized instantly on exposure to air. Most of these solutions react with triphenylphosphine to give $Cu(acac)(Ph_3P)_2$ indicting the presence of the copper(I) complexes. The solutions of copper(I) complexes derived from bpy, phen, and DTH were stable under nitrogen and, also toward the photolysis conditions for more than 16 h. The absorption maxima of these copper(I) complexes were determined to give the following data: for bpy λ_{max} 427 nm (ϵ, 2500) and 520 nm (shoulder), for phen λ_{max} 430 nm (ϵ, 7600) and 570 nm (ϵ, 2600), and for DTH λ_{max} 575 nm (ϵ, 1400). The absorption maxima in the former two are in close agreement with those of $Cu(bpy)_2^+$ and $Cu(phen)_2^+$ at λ_{max} 435 nm, which has been assigned to a charge transfer to ligand (CTTL) band (12, 13) according to the assumption that phen and bpy are relatively good π-acceptors and weak α-donors. The copper(I) complex of carbon monoxide was stable under continuous carbon monoxide purging but rapidly disproportionated to give copper metal and a blue solution of $Cu(acac)_2$ when carbon monoxide was displaced by nitrogen from the solution. It showed a weak

absorption at 2100 cm^{-1}. This low frequency, in comparison to 2143 cm^{-1} for CO, suggests a weak back donation of copper $3d$ electron to a CO π-antibonding orbital. Carbonyl complexes of copper(I) are rare (14, 15) due to their lability. Though these informations do not reveal the structure, these complexes probably have molecular formulae of $Cu(acac)L_x$, where $x = 1$ or 2 for the bidentate or monodentate ligands L, respectively. The reaction pattern is summarized in Scheme 1.

$$Cu(acac)_2 + R_2CHOH \xrightarrow[Ph_2CO]{} Cu(acac) + acacH + R_2CO$$

$$\text{Cu(acac)} \longrightarrow \text{Polymeric solid} \xrightarrow[acacH]{O_2} Cu(acac)_2 + H_2O$$

$$\text{Cu(acac)} \xrightarrow{L} Cu(acac)L_x \xrightarrow{L} Cu(acac)(PPh_3)_2 \quad (PPh_3)$$

$$Cu(acac)L_x + acacH \xrightarrow{O_2} Cu(acac)_2 + H_2O + xL$$

$$2Cu(acac)L_x \xrightarrow{N_2} Cu^0 + Cu(acac)_2 + xL$$

SCHEME 1

Owing to their instability toward oxygen, these copper(I) complexes could not be isolated for further investigation. However, the solutions of these copper(I) complexes exhibited a wide range of stability toward disproportionation in the dark under nitrogen and prolonged irradiation under the same photolysis conditions. While the following observations were qualitative, they provided some indication of their reactivity and stability. The solutions of copper(I) complex from phen, bpy, and DTH were stable under nitrogen and also were hardly photolabile. The phosphine complexes, Cu(acac) $(PPh_3)_2$, and probably other analogues (16–19), were most stable presumably due to extensive back bonding and could be handled under ambient conditions indefinitely. At the other extreme were the cases of the sensitized photoreduction in the presence of diglyme and norbornene in which copper metal was almost immediately formed as the blue solution started to bleach. This indicates that olefins and polyethers coordinate with Cu(acac) so weakly that their complexes are readily decomposed by disproportionation or photolysis, or by both pathways. Indeed, it is well known that olefins form labile copper(I) complexes (20–30). Similar photolysis in the presence of styrene was very slow, owing to the quenching of triplet state benzophenone by styrene. The solutions of copper(I) complexes containing carbon monoxide and en were generated rapidly by photolysis as colorless solutions. Under an inert atmosphere in the dark, these solutions started to deposit copper metal within a few hours. On continuing irradiation these solutions were photolysed to deposit copper metal in about the same time required for disproportionation. These complications prevented us from drawing a clear conclusion as to whether the copper formations were due to disproportionation or photolysis; the former cause was more probable. In all these photolyses, the black precipitates were not formed and the photolysates readily reacted with PPh_3 to give Cu(acac) $(PPh_3)_2$; these observations confirm the formation of Cu(acac) complexes.

Because of competitive quenching of triplet state benzophenone, it was not feasible to prepare copper(I) complex of a conjugated olefin by this photoreduction. However, a photolysate of the Cu(acac) complex of carbon monoxide reacted with styrene or 1,3-pentadiene to give solutions containing the corresponding Cu(acac) complexes under carbon monoxide. As the resulted solutions did not disproportionate for a long time under argon, it was concluded that the Cu(acac) complexes of these olefins had been formed.

Similar photolysis of $Cu(acac)_2$ and benzophenone in the presence of terminal acetylenes in methanol proceeded rapdily to give the corresponding acetylides **1**–**4** (Table 1) as colored solids or solutions. Bisacetylide **4** derived from 1,5-hexadiyne is *explosive when dry*. From the photolysates, benzophenone was recovered quantitatively and acetylacetone and unreacted acetylenes were detected by gc. Though it is known that a $Cu^{2+}-Cu^{+}$ salt mixture is a good catalytic system for the coupling of terminal acetylenes (24), such products were not detected by gc analysis. These acetylides were identified by reacting with iodobenzene in pyridine (6, 7) to give the corresponding phenylacetylenes **5**–**8** (see Table 1). In addition, acetylides **1** and **2** reacted with triphenylphosphine to give crystalline complexes $[(PhC{\equiv}C)Cu(PPh_3)]$ and $[C_4H_9C{\equiv}CCu(PPh_3)]$ (8). The latter was formed only in the presence of a large excess of triphenylphosphine and was not prepared previously.

$$Cu(acac)_2 + RC{\equiv}CH \xrightarrow[Ph_2CO]{h\nu} CuC{\equiv}CR + 2acacH$$

$$CuC{\equiv}CR + C_6H_5I \xrightarrow[Pyridine]{} PhC{\equiv}CR + (CuI)$$

Similar photolysis of $Cu(acac)_2$ and benzophenone in the presence of 3,5-dimethyl-1-hexyn-3-ol (**9**) gave a dark yellow solution which was quantitatively oxidized in air to a blue solution of $Cu(acac)_2$. The same dark yellow solution was also obtained when photolytically generated black precipitate was reacted with alkynol **9**. This complex reacted with triphenylphosphine to give Cu(acac)$(PPh_3)_2$, indicating that the Cu(acac) complex of the alkynol **10** was formed. The copper(I) acetylide derived from alkynol **9**, $[(CH_3)_2CHCH_2C(CH_3)(OH)C{\equiv}CCu]$ **11**, was stable to air oxidation and exhibited an ir absorption at 2000 cm^{-1}. The photolysate was worked up by ether extraction to give alkynol **9**, benzophenone, and $Cu(acac)_2$. The unstable complex **10** must contain acetylacetonate and alkynol **9** as ligands. The latter, conceivably, contributes both α-hydroxy and acetylenic groups as two coordination sites as shown in the proposed structure. Analogy to such a complex can be found in platinum–alkynol complexes (25). The sensitized photolysis of $Cu(acac)_2$ in the presence of 2-butyn-1,4-diol gave similar results; as the complex decomposed much faster under various conditions, it was not investigated further.

A similar photolysis in the presence of diphenylacetylene gave Cu(acac)$(C_6H_5CCC_6H_5)$ **12**, as colorless needles showing an ir absorption at 1975 cm^{-1}. Dissolution of the complex **12** in methanol, chloroform, or other organic solvents quickly decomposed it to give a brown solution; the solution in $CDCl_3$, however, displayed the signal for the methyl protons of acetylacetone at 2.02 and 2.30 ppm and that for phenyl protons at 7.43 ppm in a 6:10 ratio. The complex **12** also readily reacted with triphenylphosphine to give Cu(acac)$(PPh_3)_2$ and slowly decomposed on storage either under nitrogen or oxygen. In the presence of 3-hexyne, similar photolysis apparently gave $[Cu(acac)(EtC{\equiv}CEt)]$ **13** which showed a similar pattern of behavior as above. Further studies of this complex were not carried out owing to its instability.

The limited data on structure shown indicate that **12** has the

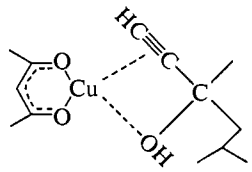
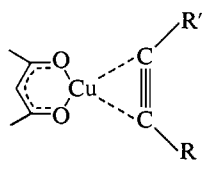
*The product obtained from the acetylides reaction with iodobenzene.
†This acetylide was obtained as a soluble compound; others precipitated directly from photolysates.
‡The carbon–carbon stretching bond for acetylides in which 2120 cm^{-1} for **4** is weak.

molecular formula Cu(acac)(PhCCPh) and that the carbon–carbon triple bond is probably coordinated in the side-on mode (26–28) in view of the ir absorption at 1975 cm^{-1} and ease of



10



12

the displacement of the diphenylacetylenic moiety by triphenylphosphine. Assuming that complex **12** has a monomeric constitution, the acetylene should act as a bidentate ligand by donating four electrons (26) to the copper(I) center. The number of known mononuclear metal complexes which contain coordinated acetylene remains few in spite of extensive studies on acetylene coordination complexes with various transition metals (29–34). Such mononuclear complexes are generally regarded as intermediates in the catalytic process of acetylene oligomerization on account of the activated triple bond (31–34). Although the isolation of acetylene complexes of copper(I) tetrachloroaluminate have been reported (35, 36), the details are not available. In view of well established X-ray structures of nickel (37), palladium (32, 38), platinum (33, 39), and tungsten (26) complexes of acetylenes, the structure as shown is suggested as the copper(I) complex of diphenylacetylene. Such a structure is explained by an in-plane σ-bond and perpendicular π-orbital overlap between the metal and acetylenic linkage (26–28).

Purely from the consideration of pK_a values of acetylene (pK_a 25) and acetylacetone (pK_a 9), a bimolecular displacement on Cu(acac) does not seem to be a reasonable mechanism for the formation of copper(I) acetylides from terminal acetylenes. It is simplest to assume that all acetylenes reacted with Cu(acac) to form coordinate complexes similar to that shown in structure **12**. For terminal acetylenes, the $C_{(sp)}H$ bond becomes polarized because of electron donation to the metal center. A similar proposal has been made to account for carbonium ion-like reactivity of acetylene carbons in platinum complexes (33). The acetylides are most likely formed from intramolecular displacement, and precipitated as polymers.

$$\text{Cu(acac)(RC}{\equiv}\text{CH)} \rightarrow \text{Cu(acac)(RC}{\equiv}\text{C}^-) + \text{H}^+$$
$$\rightarrow \text{CuC}{\equiv}\text{CR} + \text{acacH}$$

While adequate information could not be obtained to assign structures to each copper(I) complex owing to failure in isolation, the lack of the formation of polymeric Cu(acac) as well as the formation of Cu(acac)$(PPh_3)_2$ on reacting with triphenylphosphine indicates that the benzophenone-sensitized photoreduction of Cu(acac)$_2$ generates Cu(acac) which can coordinate with various types of ligands to form a variety of copper(I) complexes. By analogy with copper(I) acetylides (8) and halides (40), the insolubility, non-crystallinity, and ready disproportionation in solid states of the black precipitates may suggest that they are polymers of Cu(acac) with indeterminate compositions and structures. Polymeric copper(I) complexes are not uncommon (40) and generally utilize heteroatoms for bridging of copper(I) centers as shown by X-ray analysis. While the reactivities of these copper(I) complexes show a wide range of variations, their reactions toward oxidation, substitution, photolysis, and/or disproportionation vary considerably with changes in ligands. Presumably, these reactivities are related to the strength of the copper–ligand bonds and depend on the extent of the back donation of electrons through π-overlap of the bonds. It is noteworthy that under the photolysis conditions, the oxetenes, or their derivatives, corresponding to the addition of triplet state benzophenone to these acetylenes (41) are not detected. This is not surprising since we have demonstrated that Cu(acac)$_2$ quenches triplet-state benzophenone efficiently with $k_q = (3.6–6.8) \times 10^9\ M^{-1}\ s^{-1}$ (42): the reaction of the latter with acetylenes is obviously unimportant at the concentration ratio of Cu(acac)$_2$ to acetylenes used in the photolysis.

It is well known that certain copper(II) complexes are readily reduced by phosphines (16–19) and electrolysis (43). In spite of the difficulty encountered in the isolation of the copper(I) complexes, the present sensitized photoreduction demonstrates an advantageous route to prepare certain copper(I) complexes that are difficult to prepare by conventional reduction methods. First, since the reducing species is generated by photoexcitation and at any given time its concentration is low, the rate and extent of the reduction can be regulated easily to avoid over-reduction. Secondly, the reducing power is related to *excited state reduction potential*, e.g., the sum of the reduction potential and the triplet state energy of a ketone (42). It is, in theory, possible to choose a matching sensitizer to effect the reduction of a specific step without affecting others. Thirdly, the system offers certain manoeuverability in ligand interchange reactions, in particular, if ligands, such as styrene and 1,3-pentadienes, react with triplet-state sensitizers and cannot be added in the photolysis. For example, the Cu(acac) complex of carbon monoxide can be made easily by the sensitized photoreduction and a desired ligand then added to give the corresponding Cu(acac) complexes.

Bis(acetylacetonato)copper(II), $Cu(acac)_2$, quenches triplet excited states of ketones and polynuclear aromatic hydrocarbons efficiently, but only aromatic ketones with high triplet energy successfully sensitize photoreduction of $Cu(acac)_2$ in alcohols under nitrogen to give derivatives of acetylacetonatocopper(I), Cu(acac). For the triplet state benzophenone-sensitized photoreduction of $Cu(acac)_2$, the quantum yields of photoreduction (Φ_C) and those of benzophenone disappearance (Φ_B) were determined in methanol with various concentrations of $Cu(acac)_2$. The values of the quenching rate constant, k_q, determined from these two types of monitors on the basis of the proposed mechanism were in good agreement ($6.89 \sim 7.35 \times 10^9\ M^{-1}\ s^{-1}$). This value was higher, by a factor of about two, than that obtained from the monitor of the benzophenone triplet decay rates generated by flash photolysis in the presence of $Cu(acac)_2$. The quenching rate constants of various aromatic ketone and hydrocarbon triplet states by $Cu(acac)_2$ were determined by flash photolysis to be in the order of the diffusion rate constant and the quantum yields of these photoreductions were found to be far from unity. Paramagnetic quenching, with contributions of electron exchange and charge transfer, was proposed as a possible quenching mechanism. For a series of aromatic ketone sensitizers with higher triplet energy, this mechanism was used to rationalize the observed high quenching rate constants in contrast to the low quantum yields of photoreduction.

YUAN L. CHOW, GONZALO E. BUONO-CORE, BRONISLAW MARCINIAK et CAROL BEDDARD. Can. J. Chem. **61**, 801 (1983).

Le bis(acétylacétonato)cuivre(II) $Cu(acac)_2$ inhibe efficacement les états excités triplets des cétones et des hydrocarbures aromatiques polynucléaires mais seules les cétones aromatiques avec un triplet à haute énergie sensibilisent avec succès la photoréduction du $Cu(acac)_2$ dans les alcools sous atmosphère d'azote en donnant des dérivés d'acétylacétonato-cuivre(I), Cu(acac). On a déterminé, dans le méthanol et pour diverses concentrations en $Cu(acac)_2$, les rendements quantiques de photoréduction (Φ_C) et ceux de la disparition de la benzophénone (Φ_B) lors de la réduction du $Cu(acac)_2$ photosensibilisée par la benzophénone à l'état triplet. Les valeurs de la constante d'inhibition, k_q, déterminées à partir de ces deux types de contrôle sur la base du mécanisme proposé s'accordent bien ($6{,}89 \sim 7{,}35 \times 10^9\ M^{-1}\ s^{-1}$). Cette valeur est plus élevée d'un facteur d'environ de deux que celle obtenue à partir du contrôle de vitesse de désintégration du triplet de la benzophénone produite par la photolyse flash en présence du $Cu(acac)_2$. On a déterminé les constantes de vitesse d'inhibition de plusieurs cétones aromatiques et des états triplets des hydrocarbures par le $Cu(acac)_2$; elles sont de l'ordre de la constante de vitesse de diffusion et on a trouvé que les rendements quantiques de ces photoréductions sont loin d'être unitaires. On propose comme mécanisme possible d'inhibition, une inhibition paramagnétique avec des contributions d'échange d'électron et de transfert de charge. Dans le cas d'une série de sensibilisateurs de cétone aromatique avec un triplet à grande énergie, on a utilisé ce mécanisme pour rationaliser les fortes constantes d'inhibition observées par contraste avec les faibles rendements quantiques de la photoréduction.

Introduction

We have shown (1) that bis(acetylacetonato)copper(II), $Cu(acac)_2$, can undergo ketone-sensitized photoreduction to form copper(I) complexes in hydrogen-donating solvents such as alcohols and tetrahydrofuran. Transition metal ions and complexes of β-diketonates are known to be efficient quenchers of the triplet state of a number of organic sensitizers (2–6). Porter and Wright (4) have defined this process as paramagnetic quenching. This explanation has been widely adapted to describe the interaction of excited states with radicals, such as nitric oxide (7), nitroxides (7–15), oxygen (16, 17), and paramagnetic metal ions and complexes (2–6). Investigations aiming to clarify the mechanism of the quenching process generally utilize simpler stable radicals as quenchers (7–13) which enhance deactivation of electronically excited molecules. The paramagnetic quenching of triplet state sensitizers by metal ions and complexes is generally investigated by flash excitation (2–5); however, the fate of the quenchers has not attracted any serious studies. Spin-allowed catalyzed intersystem crossing (4, 7, 9, 10, 18, 19) has been proposed to account for such quenching without physical changes in quenchers. While energy transfer has been ruled out for this quenching process (2, 4), at least one group favors this mechanism (3, 8). We are intrigued by the fact that, in spite of efficient quenching, certain ketones (e.g., benzophenone, anthrone, xanthone, etc.) sensitize the $Cu(acac)_2$ reduction efficiently, while fluorenone and *p*-methoxyacetophenone are totally inefficient as sensitizers (1).

On the basis of qualitative observations (1), we have described the general reaction pattern and have suggested that the sensitized photoreduction occurs by electron transfer from $Cu(acac)_2$ to the triplet excited states of ketones but probably not by energy transfer. The main reasons for this conclusion are the failure to correlate the triplet energy levels of these ketones with the occurrence of the sensitized photoreduction. We have since recognized that a monolithic mechanism cannot explain the whole range of quenching reactions and the overall mechanism may involve a complex sequence of charge transfer, electron exchange, and hydrogen abstraction. We have concentrated our efforts on unravelling the kinetics and mechanism of triplet state benzophenone-sensitized $Cu(acac)_2$ photoreductions. The results are described in this report.

2.0	—	0.40[c]
2.0	—	0.52[d]

[a]The solutions (5 mL) were irradiated for 5–20 min to cause percentage decomposition of $Cu(acac)_2$ as indicated. For each reaction about three readings were taken to give the average quantum yields.

[b]Except for the last two sets of data, the concentrations of benzophenone and triphenylphosphine were 0.4 *M* and 0.01 *M*. For the last two sets the corresponding concentrations were 0.1 *M* and 4×10^{-3} *M* respectively.

[c]The quantum yield was measured in ethanol.

[d]The quantum yield was measured in isopropanol.

Results

Quantum yield determinations

We have found that, among the Cu(acac) complexes obtained in benzophenone-sensitized photoreduction, only $Cu(acac)(Ph_3P)_2$ was not oxidized by air and was thermally and photolytically stable under the photolysis conditions. Taking advantage of the stability, as well as the low reactivity of triphenylphosphine relative to $Cu(acac)_2$ with the triplet state benzophenone (20) (*vide infra*), the reaction was run in the presence of triphenylphosphine so that the photolysate could be analyzed spectroscopically at 620 nm for $Cu(acac)_2$ and/or by gas and liquid chromatography. The analytical data provided the quantum yield of benzophenone disappearance (Φ_B) and that of $Cu(acac)_2$ disappearance (Φ_C).

[a]The solutions (5 mL) were irradiated for 15 min to cause <12% of the benzophenone decomposition.

[b]Averaged values from two sets of experiments.

[c]The quantum yield, in the absence of $Cu(acac)_2$ but in the presence of triphenylphosphine (10^{-2} *M*), was taken as Φ_B^0.

Quantum yields were measured in methanol solutions containing proper concentrations of materials (Fig. 1) on the merry-go-round apparatus, using a benzophenone–benzhydrol actinometer (21). The quantum yield of disappearance of $Cu(acac)_2$, Φ_C, in methanol in the presence of triphenylphosphine and benzophenone was determined at various concentrations of $Cu(acac)_2$ by following the decrease in the 620 nm absorption (Fig. 1). The quantum yield, Φ_C, increased steadily in the $Cu(acac)_2$ concentration range of 10^{-3}–10^{-2} *M* and reached nearly the limiting value of 0.25 at 10^{-2} *M* (Table 1). At this concentration, the photoreduction of benzophenone was drastically reduced, as could be seen later in the quantum yields of benzophenone disappearance, Φ_B (Table 2). In preparative scale experiments, where concentrations of $Cu(acac)_2$ were higher than 10^{-2} *M*, the formation of the benzopinacol and the loss of benzophenone were not observed. The quantum yields of $Cu(acac)_2$ disappearance, Φ_C, under comparable conditions in methanol, ethanol, and 2-propanol were found to increase in the same order (Table 1), indicating higher quantum yields in better hydrogen-donating solvents.

In order to evaluate the nature of quenching processes, the quantum yields of the $Cu(acac)_2$ disappearance by various sensitizers were determined under comparable conditions and the reduction half-wave potential (E_{A/A^-}) of sensitizers was measured by cyclic voltammetry. These data are summarized in Table 3. In these experiments, the sensitizer concentrations were adjusted so that >98% of the incident light was absorbed by the sensitizers in every case except biacetyl. In the last case, only 68% of the light was absorbed by biacetyl and its quantum yields were normalized to the 100% absorption. For the purpose of maintaining the same conditions to compare the efficiency of quenchings, the concentration of $Cu(acac)_2$ was set at 2×10^{-3} *M*. While this did not give the limiting quantum yields for each sensitizer, it did provide the comparison of the overall reduction efficiency of sensitizers.

Unfortunately, the quantum yields Φ_C in the absence of

[e]The reduction potential values are quoted from ref. 23.

[f]The two reduction potentials are quoted from Wagner (24). We are grateful to Professor Wagner for the data and other suggestions.

[g]The correlation of k_{obs} with the concentrations of $Cu(acac)_2$ was poor.

[h]The transient signal was weak, and only an approximate value was obtained.

triphenylphosphine could not be accurately determined because of the formation of black precipitates and their easy air oxidation to regenerate $Cu(acac)_2$. As it was desirable to know Φ_C unencumbered by the presence of triphenylphosphine, the quenching experiments were run without triphenylphosphine, and the photolysates were quickly filtered from the black precipitate for uv determinations. This method did not afford reproducible Φ_C values and provided only approximate data. However, it was noted that, for anthrone, benzophenone, xanthone, acetophenone, and biacetyl sensitizations, the Φ_C values obtained by this method were in the same decreasing order and the same order of magnitude shown in Table 3.

Studies by flash photolysis

In view of the drastic quenching of the photoreaction of triplet state benzophenone, as shown by the lack of the formation of benzopinacol in the preparative studies, as opposed to the low quantum yields of the photoreduction of $Cu(acac)_2$ (see Table 1), it was necessary to measure the quenching rate constants of sensitizer triplet states by $Cu(acac)_2$ under comparable conditions. Taking advantage of the fact that most triplet state absorption spectra are well known by the flash excitation technique, the rate constants of these reactions could be determined directly without being encumbered by the follow-up reactions. Thanks to Scaiano, who made his nitrogen laser-pulsed flash photolysis apparatus (337.1 nm, 8 ns, 3 mJ) (25) available to us, we measured the lifetimes of the triplet state decay of these sensitizers in the absence ($\tau_0 = 1/k_0$) and in the presence ($\tau_{expt} = 1/k_{expt}$) of the various concentrations of $Cu(acac)_2$ ranging from 10^{-3} to $10^{-5}\ M$. The concentrations of sensitizers were about $10^{-4}\ M$ and the kinetics of the triplet state decays were monitored at the wavelength indicated (Table 3). In each case, the decay of the triplet signals was analyzed by fitting of the corresponding time profiles from which the pseudo-first-order decay patterns were ascertained and their rate constants, k_{expt}, determined. The quenching rate constants, k_q, were determined from the Stern−Volmer plots according to eq. [1] where [A] is the concentration of $Cu(acac)_2$.

$$[1] \quad k_{expt} = k_0 + k_q[A]$$

In Fig. 2, log k_q was plotted against the lowest triplet state energies (E_T) and also against $-(E_T + E_{A/A^-})$, the free energy available in the electron transfer process for sensitizers, according to Weller's empirical relation (26−28).

Analysis of Fig. 2*a* and 2*b* by a non-linear least-square data analysis (a program written by K. E. Newman of this Department) showed the correlations were poor in both but slightly better in the latter case. The correlation coefficients were improved if the point due to benzil was omitted. Unusually low quenching rate constants of the benzil triplet have been noted previously (2), and the transient spectra in the presence of $Cu(acac)_2$ showed signals other than the triplet signal. The poor correlation of the plots failed to support either an energy transfer or a simple electron transfer mechanism. However, the general trends hinted that subtle relations might exist between k_q and E_T, as well as E_{A/A^-}. It was visually noted that moderately good correlation could be made with those points arising from aromatic ketones, i.e., excluding the points due to aromatic hydrocarbons and benzil. Characteristically, the variation of k_q was only within an order of magnitude in spite of large variations in E_T or $-E_T - E_{A/A^-}$; that is, the imaginary slopes were about 0.2 per eV. The resistance of diamagnetic Cu(I) complexes of triphenylphosphine, 2,2′-dipyridine, and 1,10-phenanthroline toward the photoreduction was confirmed (1). The diamagnetic acetylacetonates of magnesium(II) could not be photoreduced under similar benzophenone sensitization conditions, nor was the rate of benzophenone photoreduction affected. It was reported that diamagnetic $Cu(CN)_2^-$, Zn^{2+}, and Ga^{3+} ions failed to quench triplet state naphthalene. As the

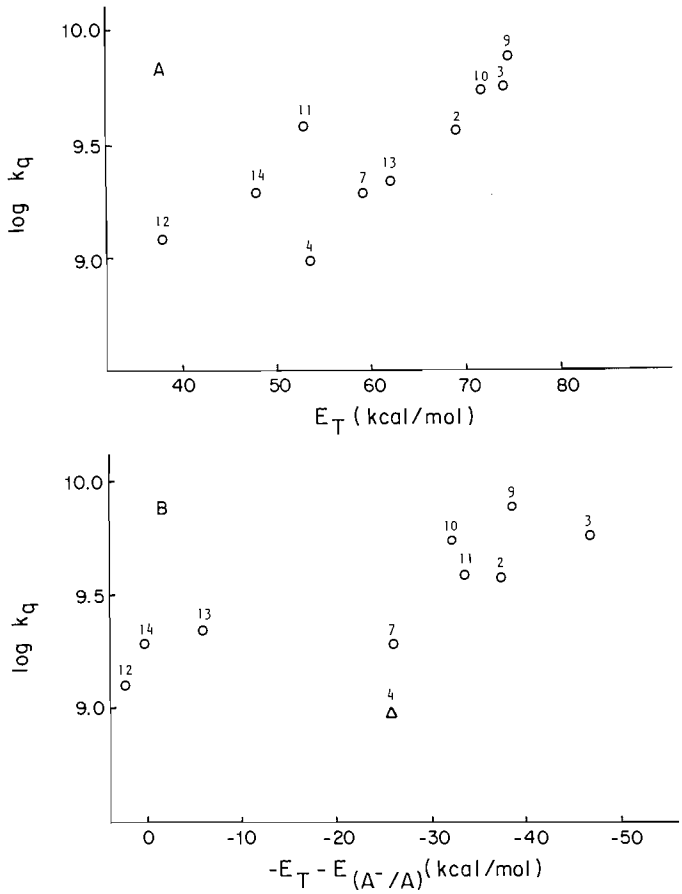

FIG. 2. The correlation of log k_q with (*a*) the lowest triplet state energy E_T and (*b*) $-E_T - E_{A/A^-}$.

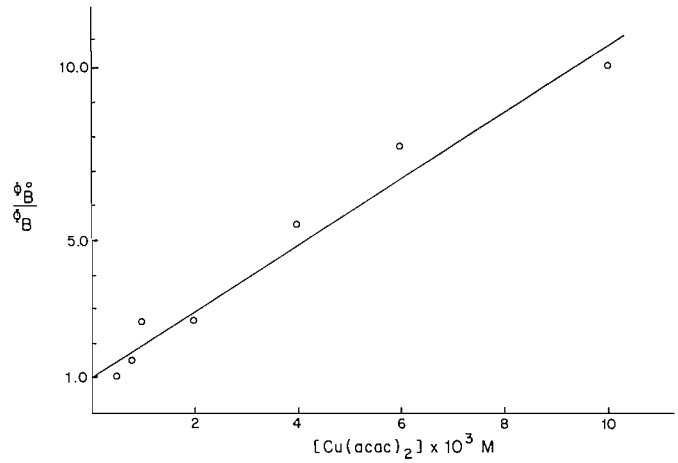

FIG. 3. The Stern–Volmer plot of benzophenone disappearance against the concentrations of $Cu(acac)_2$.

copper(II) state is paramagnetic and $Cu(acac)_2$ in methanol shows distinct esr signals, $Cu(acac)_2$ must quench triplet state sensitizers by paramagnetic interaction as proposed previously (4, 7, 18, 19).

Kinetic analysis

The results presented so far have led us to assume that the interaction of the sensitizer triplet state with $Cu(acac)_2$, which is referred to as a complex for the moment, must be partitioned into a successful reduction yielding Cu(acac), benzophenone, acetylacetone, and the $\cdot CH_2OH$ radical on one hand, and an unsuccessful reduction on the other. On the basis of this assumption, a mechanism as represented by reactions [2]–[7] was proposed for the kinetic analysis of the sensitized reduction of $Cu(acac)_2$. The unsuccessful reaction is shown in reaction [7] in which the complex reverts to benzophenone and $Cu(acac)_2$. The successful reaction as in reaction [6] involves an irreversible hydrogen abstraction from methanol, the rate constant k_p of which contains the term of fixed concentration of methanol and [C] is the concentration of the complex.

$$[2] \quad Ph_2CO \xrightarrow[I]{h\nu} Ph_2CO(\text{singlet})$$

$$Ph_2CO(\text{singlet}) \xrightarrow{\alpha} Ph_2CO(\text{triplet}) \qquad \alpha I$$

$$[3a] \quad {}^*Ph_2CO + CH_3OH \rightarrow Ph_2\dot{C}OH + \dot{C}H_2OH \qquad k_m[B^*][MeOH]$$

$$[3b] \quad {}^*Ph_2CO + Ph_3P \rightarrow \text{Products} \qquad k_n[B^*][PPh_3]$$

$$[4] \quad {}^*Ph_2CO \rightarrow Ph_2CO + \Delta + h\nu \qquad k_d[B^*]$$

$$[5] \quad {}^*Ph_2CO + Cu(acac)_2 \rightarrow [\text{Complex}] \qquad k_q[B^*][A]$$

$$[6] \quad [\text{Complex}] + CH_3OH \rightarrow acacH + \dot{C}H_2OH + Ph_2CO + Cu(acac) \qquad k_p[C]$$

$$[7] \quad [\text{Complex}] \rightarrow Cu(acac)_2 + Ph_2CO \qquad k_b[C]$$

On the basis of this mechanistic assumption, the following equations are derived where α is the fraction of the intersystem crossing ($\alpha = 1$ for benzophenone) (29) and [A] is the concentration of $Cu(acac)_2$.

$$[8] \quad \frac{\Phi_B^0}{\Phi_B} = 1 + k_q\tau[A]$$

where $\tau = 1/(k_d + k_m[MeOH] + k_n[Ph_3P])$

$$[9] \quad \frac{1}{\Phi_C} = \frac{1}{\alpha\beta} + \frac{1}{\alpha\beta k_q\tau[A]}$$

where $\beta = k_p/(k_p + k_b)$.

The efficiency of quenching of triplet state benzophenone by $Cu(acac)_2$ was elaborated by measuring the quantum yields of benzophenone disappearance, Φ_B, in the presence of varying concentrations of $Cu(acac)_2$ as shown in Table 2. A Stern–Volmer plot of Φ_B^0/Φ_B against $Cu(acac)_2$ concentration according to eq. [8] gave a straight line (correlation coefficient = 0.9854, see Fig. 3) with a slope of $k_q\tau = 9.65 \times 10^2\ M^{-1}$.

The quantum yields of $Cu(acac)_2$ disappearance, Φ_C, obtained in methanol (Table 1), were used to plot $1/\Phi_C$ vs. $1/[A]$, according to eq. [9] as shown in Fig. 4. This correlation gave a straight line with a correlation coefficient 0.9793 from which the slope ($= 1/\beta\tau k_q$) 3.91×10^{-3} and intercept ($= 1/\beta$) 3.86 were obtained. The term $k_q\tau$ was calculated to be $9.87 \times 10^2\ M^{-1}$ in excellent agreement with that obtained from the Stern–Volmer plot, i.e., the monitoring of benzophenone disappearance. The intercept of 3.86 also shows that the limiting Φ_C in the benzophenone-sensitized $Cu(acac)_2$ decomposition is ca. 0.25 and k_b/k_p is calculated to be ca. 2.9.

The lifetime τ in eqs. [8] and [9] contained a component due to the quenching of triplet state benzophenone by triphenylphosphine. As the presence of triphenylphosphine is an experimental imperative, it was necessary to evaluate the contribution of this quenching process to the lifetime τ. Although the bimolecular rate constant of the quenching of triplet state benzophenone by triphenylphosphine was determined to be $4 \times 10^8\ M^{-1}\ s^{-1}$ in benzene (20), it is desirable to determine the

For personal use only.

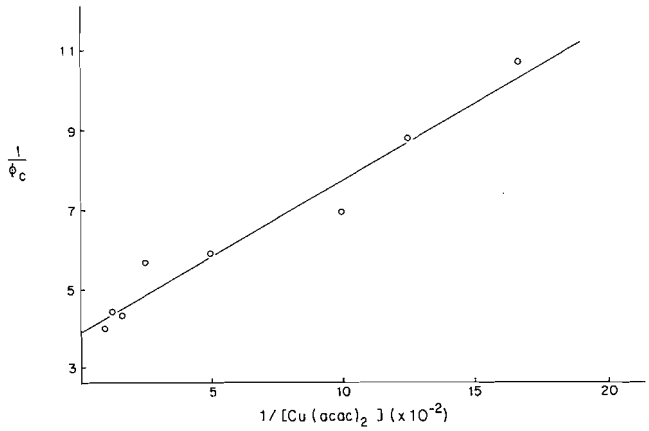

FIG. 4. The plots of reciprocals of the quantum yield of $Cu(acac)_2$ disappearance against reciprocals of $Cu(acac)_2$ concentrations in methanol.

quenching rate constant in methanol since, in a separate study, we found that this quenching induced some reactions involving methanol. For this purpose, the benzophenone photoreduction in methanol was run in various concentrations of triphenylphosphine and the quantum yields of benzophenone disappearance, Φ_n, were determined. The Stern–Volmer plot gave a slope of 92.93 M^{-1} (correlation coefficient 0.9917), according to eq. [10], where τ^0 is the decay lifetime of triplet state benzophenone in methanol.

$$[10] \quad \Phi^0/\Phi_n = 1 + k_n\tau^0[PPh_3]$$

It is obvious in these static quenching experiments that the absolute values of k_n and k_q can be calculated if the accurate value of τ^0, or $1/(k_d + k_m[CH_3OH])$, is known. If we adapt the decay rate constant of triplet state benzophenone in methanol, as measured by flash photolysis (30), as the starting point, $k_d + k_m[CH_3OH]$ is 3.8×10^6 s^{-1} and, therefore, τ^0 is 2.6×10^{-7} s, from which the following quenching rate constants are obtained.

$$k_n = (3.5 \pm 0.4) \times 10^8\ M^{-1}\ s^{-1}$$
$$k_q = (6.89 \pm 1.0) \times 10^9\ M^{-1}\ s^{-1}$$
(from Φ_B monitor, Fig. 3)

or

$$k_q = (7.35 \pm 1.4) \times 10^9\ M^{-1}\ s^{-1}$$
(from Φ_C monitor, Fig. 4)

Discussion

For a photochemical reaction as complex as the present one, the proposed mechanism as shown in reactions [2]–[7] is probably just the essential steps to visualize the sensitization and redox processes. Since the kinetic analysis based on the monitor of benzophenone disappearance Φ_B (Fig. 3) and of $Cu(acac)_2$ disappearance Φ_C (Fig. 4) gives reasonably good straight lines and their $k_q\tau$ values are in excellent accord, this mechanistic scheme provides a basis for the discussion. An immediate question is the higher values of k_q determined by the static quenching experiments by a factor of about 2 than that determined by flash photolysis (Table 3). Remembering that computation of the former static quenching rate constants k_q (and also k_n) depends on the size of the lifetime of triplet state benzophenone τ^0 in methanol, the discrepancy may not be real and may even be acceptable in view of the diversity of techniques. In addition, the higher k_q values may be attributed to the presence of triphenylphosphine in the static experiments. Since the absorption spectrum >400 nm of $Cu(acac)_2$ in the presence of up to 0.05 M triphenylphosphine is not changed at all, there is no new complex species present in the solution. As this solution is photostable, there is no direct interaction between excited state $Cu(acac)_2$ and triphenylphosphine. However, it is not inconceivable that triphenylphosphine participates during the course of the interaction of triplet state benzophenone with $Cu(acac)_2$ in some way facilitating the quenching processes; e.g., a participation in substitution reactions with the proposed complex (*vide infra*) is quite conceivable.

The proposed mechanism contains two contentious steps that require discussion, namely, the nature of the quenching process and the decay pattern of the complex. We shall discuss the latter first. The kinetic analysis leads us to conclude that the limiting quantum yield Φ_C, obtained in the benzophenone-sensitized photoreduction of $Cu(acac)_2$, arises from the partition of the complex between successful photoreduction (reaction [6]) and unsuccessful one (reaction [7]); i.e., k_b/k_p is determined to be 2.9 from Fig. 4. This conclusion is supported, firstly, by the observation that the quantum yields Φ_C at the same concentration of $Cu(acac)_2$ increase in better hydrogen-donating solvents as shown in Table 1; e.g., increasingly higher Φ_C in MeOH < EtOH < 2-PrOH. Secondly, as shown in Table 3, the relatively invariable k_q values of quenching as opposed to the wide variation of Φ_C requires that the efficient quenching process must be modified by a partition scheme to account for product patterns.

For the nature of the quenching process, while the data of Table 3 and the plots of Fig. 2 do not support a single mechanism either by energy transfer or electron transfer for the whole range of quenching studied, at least they indicate that log k_q of aromatic ketone triplets (except benzil) is related to $-E_T - E_{A/A^-}$. The invariance of k_q of duroquinone and benzophenone with respect to the E_T difference may be cited as an example, among others, which is contrary to an energy transfer. This is not a viable mechanism since the majority of these sensitizers (Table 3) have insufficient triplet energy levels to cause electronic transition of the $Cu(acac)_2$ CTTM band at 240 nm, the electronic transition which results in photodecomposition by direct photolysis (1). The advocate of energy transfer also suggested that only when the metal complex ligand field state can accept electronic energy with appreciable rates, such energy transfer may occur (3).

A pathway based on the reduction of $Cu(acac)_2$ by the ketyl radical $Ph_2\dot{C}OH$ formed in reaction [3*a*] merits consideration since it is known that xanthone, benzophenone, and acetophenone can be photoreduced while fluorenone and *p*-methoxyacetophenone do not undergo photoreduction in alcohols (31–33).[1] Indeed, this mechanism has been invoked to explain the photolytic dehydrogenation of cyclohexane in the presence of benzophenone and copper(II) pivalate (33). On the following grounds, we believe this mechanism cannot be operating. First of all, since triplet state benzophenone is almost totally quenched at $Cu(acac)_2$ concentrations above 10^{-2} M and the limiting quantum yield of copper(I) complexes at these concentrations is far below unity ($\Phi_C = 0.25$), one would still obtain photoreduction products of benzophenone, e.g., benzopinacol, if reaction [3*a*] is the sole quenching pathway. As the benzophenone photoreduction is virtually reduced to insignificant amounts above 10^{-2} M $Cu(acac)_2$, it contradicts the hy-

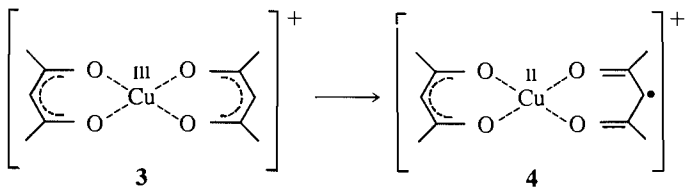
drogen abstraction mechanism. Secondly, the quenching rate constant (k_m) for reaction [3*a*], that is, the bimolecular rate constant for the hydrogen abstraction by triplet state benzophenone, cannot be higher than $1.5 \times 10^5\ M^{-1}\ s^{-1}$ as judged from the lifetime in methanol (30). Considering $k_q = 3.6 \times 10^9\ M^{-1}\ s^{-1}$ for reaction [5], as determined by monitoring the triplet state decay in flash photolysis, hydrogen abstraction of triplet state benzophenone from methanol will not be competitive unless the $Cu(acac)_2$ concentration is 10^{-2} or lower. It will be most unlikely that two mechanisms are operating in the sensitized photoreduction of $Cu(acac)_2$ depending on the concentrations of quenchers.

The mechanistic interpretation of the quenching of triplet sensitizers by paramagnetic metal ions and complexes is complicated by solvent effects and electrostatic effects of the partners. The theory of paramagnetic quenching has evolved along the idea of "catalyzed intersystem crossing", developed by Porter and co-workers (7, 10, 18, 19). On the basis of nitric oxide quenching of aromatic hydrocarbon triplet states (7), Porter's group has proposed that paramagnetic quenching involves contributions from electron exchange (9, 10) mixed with charge transfer (7, 18) within a collision complex. While the extent of the contributions of charge transfer depends on solvent polarity, redox potentials and triplet state energy levels, this contribution tends to be more important in the higher triplet energy region of sensitizers. The quenching rate constants are also higher in this region (7).

As a group, aromatic ketones (except benzil) show similar photochemical and sensitization behavior. The moderately good correlations of log k_q vs. $-E_T - E_{A/A^-}$ as well as log k_q vs. E_T for the aromatic ketones with higher triplet energy shown in Fig. 2 suggest that the dual quenching mechanism discussed above can be operating for these sensitizers. In analogy to the proposal made by Porter's group (34), a complex from excited state ketones and $Cu(acac)_2$ in polar solvent, such as methanol, should have a high dipole moment which would lower the energy level of the charge transfer state. Thus, reasonably stabilized ketyl radical anions might be formed under the conditions unless a methoxyl group at the *para* position destabilizes the formation (see Table 3, No. 10). $Cu(acac)_2$ exhibits two irreversible oxidation waves by cyclic voltametry in acetonitrile at +1.47 and 1.72 eV. Certainly, at the first oxidation potential, most triplet excited ketones have enough reduction energy to complete the charge transfer interaction. Therefore, the complex proposed in reaction [5] may be elaborated as **1** or **2**. Direct electron transfer from triplet state benzophenone to $Cu(acac)_2$ is deemed unlikely for energetic reasons (35), and supported by the failure of triplet state *p*-methoxyacetophenone to sensitize the photoreduction. The transient $Cu(acac)_2^{\ddagger}$ species should have the copper(III) state as in **3** but may rapidly transfer to Cu(II)–ligand radical species as in **4** by analogy with general intramolecular redox behavior of copper(III) complexes (36, 37). We assume a loose association of $Cu(acac)^+$ with the acetylacetonyl radical as in **2** as the intermediate from which the latter reacts irreversibly by hydrogen abstraction from methanol (or solvents) as in reaction [6]. The back transfer of an electron from the benzophenone ketyl radical anion to $Cu(acac)^+$ completes the successful reduction process. At this stage, all the reactants become neutral species and no significant electrostatic attraction can be encountered. The overall reaction consists of an indirect electron migration from the ligand to the copper center using triplet state benzophenone as an energy pump.

$$*Ph_2CO + Cu(acac)_2 \rightarrow \underset{\mathbf{1}}{[Ph_2CO^{\cdot-} \ldots Cu(acac)_2^{+\cdot}]} \rightarrow$$

$$\underset{\mathbf{2}}{[Ph_2CO^{\cdot-} \ldots Cu(acac)^+ \ldots acac^{\cdot}]} \rightarrow Ph_2CO + Cu(acac) + acac^{\cdot}$$



3 **4**

From the quantum yield dependence of the photoreduction on alcohols, it is most appropriate to view reactions [6] and [7] as competing processes in which a higher degree of the charge transfer contribution and a better hydrogen-donating alcohol leads to higher quantum yields in the sensitized photoreduction. In this context, the failure of triplet state aromatic hydrocarbons to sensitize the photoreduction may be interpreted as a rapid reverse charge transfer (reaction [7]), which may be regarded as the spin-allowed intersystem crossing (7, 10).

While the proposed mechanistic model is in reasonable agreement with the observations and kinetic analysis, it needs more refinements and supporting evidence. The presence of the acetylacetonyl radical during the photoreduction has been gained by trapping of the radical by simple olefins as the addition products and by 2-nitroso-2-methylpropane as the stable nitroxide radical (38). In the presence of 5 mol% of *p*-dinitrobenzene, a good electron scavenger (39, 40), the benzophenone-sensitized photoreduction of $Cu(acac)_2$ is inhibited for 5–6 h while the uninhibited photoreduction completed the reaction in only 3 h: both *p*-nitrobenzene and benzophenone are recovered (41). Control experiments show that *p*-dinitrobenzene is completely decomposed by a benzophenone-sensitized photoreaction, probably by the energy transfer process, and that *p*-dinitrobenzene is extremely inefficient to sensitize $Cu(acac)_2$ photodecompositions. While the quenching mechanism by *p*-dinitrobenzene has not been determined, the quenching certainly indicates that some kind of electron transfer is involved in the sensitized photoreduction.

In conclusion, this report demonstrates that the triplet state of various sensitizers are quenched by $Cu(acac)_2$, and also by other paramagnetic transition metal β-diketonate complexes as well (2), very efficiently by paramagnetic quenching but only aromatic ketone sensitizers with relatively high triplet energy successfully sensitize the $Cu(acac)_2$ photoreduction via a charge transfer intermediate in the presence of hydrogen-donating solvents. The efficiency of the sensitized photoreduction depends on the degree of charge transfer contribution of the collision complexes and the hydrogen abstraction of the acetylacetonyl radical. Energy transfer from triplet state aromatic ketones to $Cu(acac)_2$ is probably slow, at least by an order of magnitude, in spite of the fact that the latter has a low energy level.

Experimental

General conditions and materials

Ultraviolet and visible spectra were obtained with a Cary 17 spectrophotometer. A Hewlett-Packard Model 5985 spectrometer was used to perform gc coupled with mass spectrometry. The hplc machine was constructed with a LDC Model 711 solvent delivery system, a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Rheodyne Model 7120 syringe loading sample injector, a Partisil PXS 10/25 Whatman analytical column, and LDC Model 1203 UV monitor (254 nm). Commercially available sensitizers were purified by distillation or recrystallization–sublimation. Other conditions are the same as those described in the previous papers (1).

Apparatus

For large scale preparations, an immersion type photocell or an overhead irradiation set-up, as described previously (1), were used. Quantum yield determinations were carried out in small phototubes in a "merry-go-round". The Pyrex phototubes of ca. 5 mL capacity (1.2 cm diameter × 10 cm length) were equipped with a gas inlet and outlet which had a mercury seal. The light source was a Hanovia 450-W (679A36) or 200-W (654A36) medium pressure lamp, placed in a Pyrex water cooling jacket.

Cyclic voltammetry

The half-wave reduction potentials ($E_{1/2}$) were determined in acetonitrile by cyclic voltammetry using a three-electrode cell with a P.A.R. Electrochemistry System Model 170 (Princeton Applied Research Corp., Princeton, NJ). The working electrode was a platinum microdisc and the counter electrode was a platinum wire. A silver wire electrode was used as a reference electrode which was shown to be 100 mV more positive to a sce in water and 0.1 *M* tetraethylammonium chloride (TEAC) as supporting electrolyte. The half-wave potential of $Cu(acac)_2$ was determined in acetonitrile in the presence of tetraethylammonium perchlorate with reference to sce. The measured data were subtracted by 0.1 eV to afford E_{A/A^-} given in Table 3.

Quantum yield determination

Generally, stock solutions of $Cu(acac)_2$, triphenylphosphine, and sensitizers were prepared. Aliquots of each solution were pipetted into a volumetric flask (10 mL) to prepare solutions for irradiation with the required concentrations. For actinometry, benzene solutions 0.05 *M* in benzophenone and 0.1 *M* in benzhydrol were used. The remaining benzophenone was determined by following the changes in the optical density at 333 nm and/or by hplc analysis. A quantum yield of 0.74 was assumed for the secondary actinometry (21). The solutions (4 or 5 mL) in phototubes were deaerated with purified nitrogen and irradiated for a prescribed length of time (generally 5–20 min) to cause <20% conversion. The photolysates were analyzed immediately for decreases of $Cu(acac)_2$ by determining the absorbance at 620 nm. After that, hplc analyses of photolysates were carried out using 2% isopropanol in hexane solvent to afford the quantum yields of benzophenone disappearance. For each series of measurements, two to four tubes of solutions were irradiated for 5, 10, 15, or 20 min, and the solutions were analyzed. The quantum yields were calculated and the average values were obtained.

For sensitized photoreduction, the concentrations of various sensitizers were adjusted to absorb more than 98% of incident light, except biacetyl. In this case, biacetyl absorbs only 68% of the incident light, calculated at 330 nm. The quantum yields were corrected to compensate for the partial absorption of light. For the benzophenone-sensitized photoreduction, the proportion of the incident light absorbed by benzophenone was calculated using the absorbance at 330 nm. The decrease of benzophenone and $Cu(acac)_2$ was corrected to represent the total incident light. From these data, the quantum yields of benzophenone and $Cu(acac)_2$ disappearance were calculated and tabulated in Tables 1 and 2.

For determinations of the quantum yields of $Cu(acac)_2$ without added triphenylphosphine, phototubes containing the solutions (5 mL) of $Cu(acac)_2$ and benzophenone were irradiated in the usual manner. The solutions were filtered through a sintered glass filter quickly. The uv spectra of the solution were taken immediately. The quantum yields of a single series varied as much as ±10%. The order of the Φ values was the same as shown in Table 3.

For the determination of the quenching rate constant of the triplet state benzophenone by triphenylphosphine, solutions of benzophenone (0.05 *M*) in methanol containing triphenylphosphine (0.0025–0.035 *M*) were irradiated for 55 min to cause 8 ~ 35% conversion. For each concentration, the average of two readings was taken. Two series of experiments were run to give the averaged $k_q\tau$.

Flash photolysis

For flash photolysis, methanol (Aldrich, Gold Label) was used as received. The solutions of sensitizers (ca. 10^{-2}–10^{-3} *M*) and $Cu(acac)_2$ (10^{-3}–10^{-4} *M*) were placed in Suprasil quartz cells of 3 mm optical path and deaerated with oxygen-free argon. The samples were excited with the pulses from a Molectron UV-400 nitrogen laser. The flash apparatus, interfaced to a PDP 11/55 computer, as described previously (25), was used. The Stern–Volmer plots and quenching rate constants for each series were carried out by the same computer.

Infrared absorption and resonance Raman scattering of photochromic triphenylformazans

J. W. LEWIS and C. SANDORFY

Département de chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3V1

Received June 7, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

J. W. LEWIS and C. SANDORFY. Can. J. Chem. **61**, 809 (1983).

The infrared and resonance Raman spectra of the two long-lived forms of triphenylformazan and several of its derivatives have been examined. The spectra of unsymmetrically ^{15}N-labelled derivatives suggest that two tautomers exist for each of the two forms. This observation is confirmed by the spectra of 1-(*p*-halophenyl)-3,5-diphenylformazans. The spectra of the non-chelate forms of these latter compounds demonstrate that the position of the tautomeric equilibrium is influenced by the electron-attracting ability of the *para*-halo-substituent. A comparison of the resonance Raman spectra of the two forms leads to the conclusion that excited state proton transfer is the initial photoevent in the photochromism of the triphenylformazans.

J. W. LEWIS et C. SANDORFY. Can. J. Chem. **61**, 809 (1983).

Les spectres infrarouges et Raman de résonance des deux formes de longue durée de vie du triphénylformazane et quelques uns de ses dérivés ont été examinés. Les spectres des dérivés asymétriquement marqués par ^{15}N montrent qu'il existe deux tautomères pour chacune des deux formes. Cette observation est confirmée par les spectres du 1-(*p*-halophényl)-3,5-diphénylformazane. Les spectres des formes non-chélatées de ces derniers composés montrent que la position de l'équilibre tautomérique est influencée par le pouvoir attracteur d'électron de l'halogène substitué en position *para*. La comparaison des spectres Raman de résonance des deux formes nous amène à conclure que le transfert d'un proton à l'état électroniquement excité est l'étape photochimique initiale de la transformation photochromique des triphénylformazanes.

Introduction

1,3,5-Triphenylformazan and some of its derivatives are characterized by rather unusual ground state as well as excited state properties. The unusual ground state properties afford comparative studies of tautomeric pair structures. The excited state properties of these compounds offer excellent opportunities for investigations of proton transfer, photochromism, and photo-induced isomerization. The electronic absorption spectrum of the triphenylformazan species that is eventually generated by means of a photo-initiated first event is characterized by an absorption band at higher energy than that of the initial molecular species. Most photochromic compounds, on the other hand, exhibit new absorption bands at lower energy upon irradiation.

The photochromic properties of triphenylformazan have been studied on four occasions. Kuhn and co-workers (1, 2), on the basis of ultraviolet–visible absorption measurements, proposed a cyclic scheme involving three photochemical and three thermochemical reactions to account for their results (Scheme 1, left). More recently Langbein (3) and Grummt and Langbein (4), on the basis of flash photolytic investigations, proposed the modified scheme (Scheme 1, right). Despite the obvious differences between the two schemes, both clearly suggest that under continuous irradiation a photostationary state involving **D** and **C** should be achieved.

The work of Otting and Neugebauer (5) appears to be the

only infrared spectroscopic investigation of both the chelate and non-chelate forms of triphenylformazan. These authors, by means of partial ^{15}N-labelling, assigned several infrared absorption bands of isomers **A** and **D** and retained for them the structures proposed by Kuhn and co-workers. Other authors (6–10) also studied the infrared absorptions of isomer **A** of triphenylformazan, several derivatives of triphenylformazan, and several metal complexes of these derivatives. In spite of these several studies, there still appear to exist ambiguities in the infrared band assignments.

Fischer and co-workers (11), in a nuclear magnetic resonance study of ^{15}N-proton coupling in unsymmetrically substituted triphenylformazan derivatives, demonstrated that the two structures which might be drawn for isomer **A** are not resonance hybrids but tautomeric pairs. It was further shown that the position of the tautomeric equilibrium is a function of the substituents present on the phenyl groups at N_1 and N_5.

The present investigation, involving infrared absorption (IR) and resonance Raman (RR) scattering, is designed to probe the photochromic transformation, to provide a more complete assignment of the vibrational bands of the chelate and non-chelate forms of triphenylformazans, to further explore the tautomeric-pair structures of these forms, to investigate the possibility of excited state proton transfer, and to furnish a more intimate description of the vibrational bands associated with the chromophores. In this latter aspect, RR spectroscopy is a most powerful tool since only a few of the many possible vibrations are selectively enhanced.

The photochromic triphenylformazans are well suited to RR investigation since broad band or relaxed fluorescence is not a problem for either the chelate or non-chelate forms of the compounds, resonance with the lowest energy electronic transition of both forms is easily attained with an argon-ion laser, and the long lifetime of the non-chelate forms permits the independent study of both forms. In addition, both species are not subject to photochemical degradation so long as the exciting wavelengths are limited to the visible region of the spectrum. In order that the above goals might be achieved, IR absorption and RR scattering data for the chelate and non-chelate forms of several triphenylformazans are presented and discussed in some detail. The triphenylformazans investigated in this study include 1,3,5-triphenylformazan (TPF), (1-^{15}N)TPF, (1,2-^{15}N)TPF, (2,4-^{15}N)TPF, and (1,2,4,5-^{15}N)TPF, as well as the 1-(*p*-chlorophenyl)-, 1-(*p*-bromophenyl)-, and 1-(*p*-iodophenyl)-3,5-diphenylformazans (1-(*p*-XP)-3,5-DPF) and 1-(*p*-bromophenyl)-2-^{15}N-3,5-diphenylformazan.

Experimental

The TPF used in this study was prepared by reducing triphenyltetrazolium chloride with dextrose in basic solution and by means of the procedure of Neugebauer and Küchler (12). (2,4-^{15}N)TPF was prepared by means of the literature method (5). The remaining ^{15}N-labelled derivatives were prepared by means of suitable modifications of these procedures. Aniline-^{15}N and sodium nitrite-^{15}N, both of 95% isotopic purity, were products of Merck, Sharp and Dohme, Ltd., Montreal. The remaining derivatives were also prepared by means of suitable modifications of the above procedures.

The ultraviolet–visible and IR absorption spectra were recorded by means of a Cary 17 spectrometer and a Perkin-Elmer 621 spectrometer, respectively. The RR spectra were recorded by means of a Spex Ramalog-6 spectrometer which was equipped with a Coherent Radiation Innova 90-5 argon-ion laser.

The presented RR spectrum of the chelate form of each of the derivatives was recorded from a 25 mL solution of the derivative in carbon tetrachloride. This solution was circulated through a 0.8 mm glass capillary by means of a peristaltic pump. The short lifetime of the non-chelate form in carbon tetrachloride solution insures that a substantial buildup of this form will not occur; however, each of the spectra contains contributions from a few percent of the non-chelate form.

The RR spectra of the non-chelate forms of these compounds were recorded by means of the rotating cell technique (13, 14). In the laser beam the small quantity of the chelate form in the rotating cell is rapidly converted to the non-chelate form; hence, an essentially pure spectrum of this form was obtained without resorting to computer subtraction techniques.

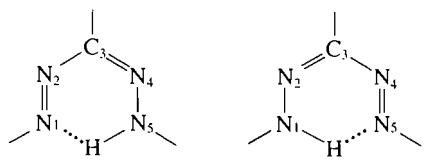
In pure, dry benzene and dichloromethane the lifetimes of the non-chelate forms of these compounds are sufficient for the recording of the IR spectra by means of standard techniques. Thus, the spectrum of the chelate form was recorded, the solution within the IR cell was irradiated for approximately 15 min, and then the spectrum of the corresponding non-chelate form was recorded.

The irradiation source was an Oriel Model 7340 equipped with a 200 W medium pressure mercury arc. The source output was filtered by 12 cm of water to remove the IR portion of the spectrum and by a cut-off filter, Corning 3387, to remove the ultraviolet–visible portion of the spectrum below about 475 nm.

Results and discussion

The solution spectra of TPF and the ^{15}N-labelled derivatives, recorded before and after irradiation, are reproduced in Figs. 1 and 2. A comparison of the spectra of the chelate and non-chelate forms would seem to imply that the C=N stretching bands occur at higher frequencies in the spectra of the non-chelate forms. The shifts of these bands to higher frequencies, upon irradiation, were explained (5) in terms of the rupture of the hydrogen bond and the loss of the resonance stabilization of the six-membered chelate ring.

The C=N stretching bands located near 1510 cm^{-1} in the unirradiated solution spectra are complicated by the fact that they are overlapping with phenyl group bands. It is thus difficult to precisely locate these bands in terms of wavenumbers. Upon irradiation and the resultant opening of the chelate ring, the C=N stretching bands shift to higher energy as expected and appear as well-defined bands. The 1500 cm^{-1} phenyl group bands are now also easily distinguished. Note that (see Scheme 2) two discernable C=N stretching bands are expected only in the case of (1,2-^{15}N)TPF. While it is not possible to fully characterize these two bands in the unirradiated solution spectrum, the irradiated solution spectrum exhibits two bands, at 1565 and 1551 cm^{-1}, which are attributable to the C=^{14}N and C=^{15}N stretching modes, respectively. These data are not consistent with a possible assignment of these bands as ^{14}N—H and ^{15}N—H deformation modes, since, if this were true, two bands would also be expected in the spectrum of (1-^{15}N)TPF.



SCHEME 2

The RR spectra of the chelate forms and the corresponding spectra of the non-chelate forms of the triphenylformazans are given in Figs. 3 and 4, respectively. In order to facilitate the direct comparison of the two forms, the spectra of the chelate

and non-chelate forms of TPF are reproduced in Fig. 5. For reference purposes the ultraviolet–visible absorption spectra of the two forms of TPF are also shown in Fig. 6.

The RR spectral results for TPF should be compared with those of *trans*-azobenzene (15–27). Raman bands of *trans*-azobenzene have been observed (15) at 1589 (phenyl), 1489 (phenyl), 1472 (phenyl), 1442 (νN=N), 1313 (phenyl), 1183 ("Azo-Schlange" (Snake vibration)?), and 1146 cm^{-1} (νC—N). In general it can be seen that the RR spectra of TPF and its derivatives are very similar to that of *trans*-azobenzene. This is especially true for the non-chelate forms of TPF derivatives since these are, in reality, *trans*-azoaromatics. Except for the absence or weakness of TPF bands corresponding to the 1489 and 1472 cm^{-1} phenyl bands of *trans*-azobenzene, there is a one-to-one correspondence for the other bands. In addition, the spectra of the TPF derivatives contain a few bands not reported in the RR spectra of *trans*-azobenzene. (Bands equivalent to the 1277 and 1212 cm^{-1} Raman bands of TPF may also exist for *trans*-azobenzene. See, for example, the IR spectroscopic study of Kübler and co-workers (26) and the Raman study of Brandmüller and co-workers (16).) It is then of interest to analyze a few of the more important bands in the spectra of the chelate forms of the TPF derivatives and to compare these results with those of the non-chelate forms and with those of *trans*-azobenzene.

A medium intensity band appears in the 1600 cm^{-1} region of

all the spectra shown in Fig. 4. This 1604 cm^{-1} band exhibits no sensitivity to ^{15}N-labelling but does show sensitivity to substitution on the phenyl groups (see below). For these reasons the 1604 cm^{-1} band is most probably attributable to a vibration of the phenyl groups and is not, therefore, attributable to the stretching vibration of the C=N group as previously postulated (9).

The relative intensity of the 1604 cm^{-1} band decreases in the spectra of the non-chelate forms. The chelate form of TPF is probably approximately planar; hence, the 1604 cm^{-1} RR band contains contributions from all three phenyl groups. On the other hand, it is doubtful that the non-chelate form of TPF could be planar and a decrease in the intensity of the 1604 cm^{-1} RR band is therefore expected. A similar decrease in intensity was not observed in the IR spectra shown in Figs. 1 and 2. The origin of this band is undoubtedly similar to that of the 1589 cm^{-1} band of *trans*-azobenzene reported by Hacker (15).

The bands that occur in the 1360−1335 cm^{-1} region of the spectra of the chelate forms exhibit the largest (up to 20 cm^{-1}) isotope shifts of all the spectral bands and are attributed to the N=N stretching vibration. Brandmüller and co-workers (16) observed a 10 cm^{-1} decrease in the N=N stretching frequency of *trans*-azobenzene upon replacing one nitrogen atom with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

nitrogen-15 and the present spectra of (1-^{15}N)TPF indicate an 11 cm^{-1} and a 14 cm^{-1} shift for the chelate and non-chelate forms, respectively. The larger isotope shifts observed in the spectra of TPF derivatives indicate that these N=N motions are purer than is that of *trans*-azobenzene.

The low value, 1357 cm^{-1}, of the N=N stretching energy of TPF is probably due to the intramolecular hydrogen bond and to some chelate ring resonance, although it is believed that the former has the largest effect. The N=N stretching band of the non-chelate form of TPF is located at 1418 cm^{-1} or 61 cm^{-1} to higher energy than that of the chelate form. This stretching energy may be slightly perturbed since, as indicated above, the N=N stretching motion of the non-chelate forms may couple with a higher energy phenyl group vibration. The intensity of the phenyl group band is largest for the unlabelled TPF and it decreases with increasing ^{15}N-substitution. The 1418 cm^{-1} N=N stretching band of the non-chelate form of TPF should therefore be compared with the 1442 cm^{-1} N=N stretching band of *trans*-azobenzene (15, 16).

It was previously implied that two distinguishable N=N stretching bands were possible for (1-^{15}N)TPF and (1,2-^{15}N)TPF. These bands are weak in the IR spectra and most of the corresponding bands of the non-chelate forms are obscured by solvent absorption. These bands are, however, among the strongest bands in the RR spectra. There can thus be no question concerning the origins of these pairs of bands in the spectra of both the chelate and non-chelate forms. The pairs of bands in the spectra of (1-^{15}N)TPF must arise from the ^{14}N=^{14}N and ^{14}N=^{15}N stretching motions and those in the spectra of (1,2-^{15}N)TPF must arise from the ^{14}N=^{14}N and ^{15}N=^{15}N stretching motions. Thus, two tautomers or labelled isomers (5, 11) must exist for these compounds in both forms.

It should also be noted that the N=N stretching motions of the chelate forms may couple with a lower energy motion. The intensities and isotope shifts of these particular N=N stretching bands therefore may not reflect their true values.

The weak bands in the 1360−1335 cm^{-1} region of the spectra of the non-chelate forms represent the N=N stretching bands of a small fraction of the unconverted chelate forms. Compare, for example, the spectra reproduced in Fig. 5.

One or two very weak bands are also observed in the 1420−1380 cm^{-1} region of the spectra of the chelate forms. These bands are due to small quantities of the non-chelate forms that are produced at the laser focal point in the solutions. The origins of these bands were established by varying the peristaltic pump speed. A decrease in pump speed results in an increase in the intensity of this band. (Also, see Fig. 5 for a direct comparison of the spectra of the two forms.)

The second most intense RR band in the spectrum of the chelate form of TPF is located at 984 cm^{-1}. The equivalent bands in the spectra of the ^{15}N-labelled analogues shift to lower energy as the number of ^{15}N-atoms increases. It will also be noticed that the position of this band is also sensitive to the location of the ^{15}N-atoms in the formazan ring. For example, (2,4-^{15}N)TPF exhibits a band at 975 cm^{-1} while the corresponding band of (1,2-^{15}N)TPF is found at 979 cm^{-1}.

Otting and Neugebauer (5) attributed a weak band near 980 cm^{-1} in the IR spectrum of TPF to the breathing mode of a six-membered unsaturated ring. The present RR data confirm this assignment since the band position is a function of both the number and location of ^{15}N-atoms in the formazan ring, the band disappears upon the irradiation of the solution (i.e., the formation of the non-chelate form) and shifts to 960 cm^{-1} in the spectrum which is recorded from a TPF solution in methanol-d_1 where the ring hydrogen is replaced by deuterium.

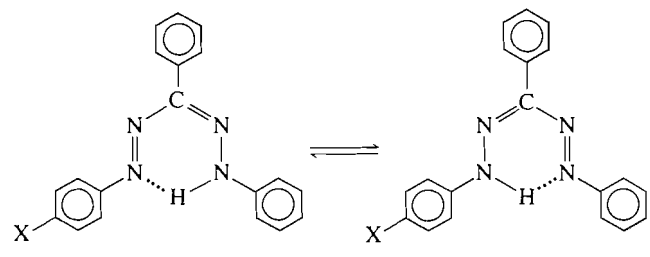
The combination of the IR and RR spectra of TPF and four of the ^{15}N-labelled isomers permits a more complete assignment of the observed bands. Fortunately, some of the most important bands, such as those due to the C=N and N=N stretching modes as well as the chelate ring breathing mode, appear very prominently in one type of spectrum or the other, but not in both types. The combination of IR and RR spectra thus avoids ambiguities in band assignments which might result if only one type of spectrum were examined.

The RR spectra also quite clearly demonstrate that, upon irradiation, the chelate ring opens. These spectra show that conjugation between the N=N group and the C=N group is essentially lost when the chelate ring opens and, thus, that the non-chelate form of TPF must have a considerably distorted geometry. This information concerning a distorted geometry is uniquely contained in the RR spectra.

Finally, the IR and RR spectra demonstrate that two C=N and two N=N stretching bands are observable in the spectra of selectively ^{15}N-labelled derivatives. The isotope shifts observed in these spectra are comparable to those observed in the spectra of model compounds which are not capable of chelate formation. These facts lead to the conclusion that the two forms of unsymmetrically ^{15}N-labelled TPF derivatives exist in solution as an equilibrium mixture of two tautomers.

In the previous paragraphs the major IR absorption and RR scattering bands of TPF were identified and it was shown that two distinguishable tautomers exist for both the chelate and non-chelate forms of suitably ^{15}N-labelled triphenylformazans. In each case where spectroscopically distinguishable tautomers were possible both were confirmed by means of their RR and IR spectra. As intuitively expected, however, the two tautomers were found to be present in nearly equal proportions. We now wish to consider examples for which equal proportions of the tautomers are not expected.

The compounds to be examined here may be represented by Scheme 3 where *p*-X represents a halogen (chlorine, bromine,



a b

SCHEME 3

or iodine). In all these cases the two tautomers are expected in unequal proportions. The proportions of each tautomer in a solution should be a function of the electron-donating ability of the 1-(*p*-X-phenyl) group as pointed out by Fischer and coworkers (11). Despite the fact that the halogens are electron-attracting substituents, it is assumed that the 1-(*p*-X-phenyl) group remains an electron donor, but it is a less effective one.

The RR spectra of the chelate forms of the *p*-halophenyl derivatives shown in Fig. 7 are remarkably similar to that of the parent, TPF. Two regions of these spectra deserve further comment. These are the regions near 1600 cm^{-1} and near 1350 cm^{-1}. The 1600 cm^{-1} region contains the phenyl group

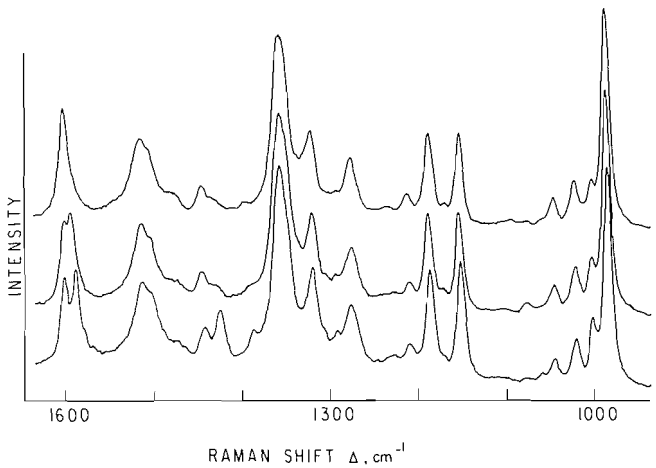


FIG. 7. Resonance Raman spectra of triphenylformazan derivatives in solution. Chelate forms. Top to bottom: 1-(*p*-chlorophenyl)-, 1-(*p*-bromophenyl)-, 1-(*p*-iodophenyl)-3,5-diphenylformazan. The experimental conditions are identical to those listed for Fig. 3.

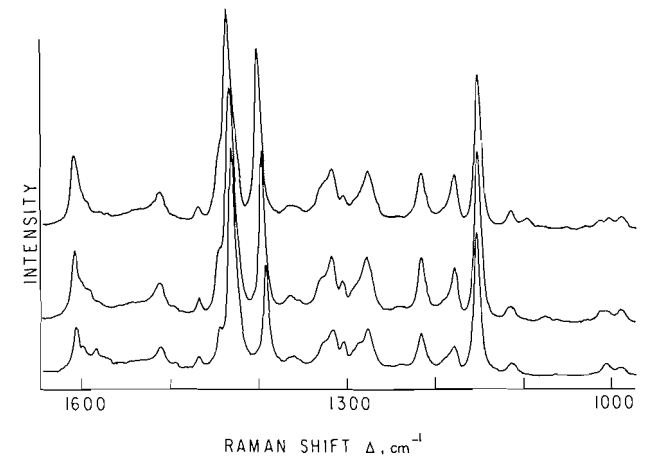

FIG. 8. Resonance Raman spectra of triphenylformazan derivatives in solution. Non-chelate forms. Top to bottom: 1-(*p*-chlorophenyl)-, 1-(*p*-bromophenyl)-, 1-(*p*-iodophenyl)-3,5-diphenylformazan. The experimental conditions are identical to those listed for Fig. 3.

vibrations (28) and it is observed that a distinction may be made between the band of the *p*-halophenyl group and that of the phenyl group. The band of the *p*-halophenyl group occurs at lower energy than that of the phenyl group and decreases in energy as the atomic number of the halogen increases; i.e., the band is found at 1604 cm^{-1} for the chlorophenyl group, 1595 cm^{-1} for the bromophenyl group, and 1589 cm^{-1} for the iodophenyl group. The region near 1350 cm^{-1} contains the N=N double bond stretching band as was previously shown. These particular bands in the spectra of the chelate forms appear to be composed of two overlapping bands and it is probable that these correspond to the N=N double bond stretching of the two tautomers shown in Scheme 3. The differences between the N=N stretching energies of the two tautomers are not sufficient for the resolution of the two bands, but with better electron-withdrawing substituents resolution of the two bands should be possible.

The RR spectra of the non-chelate forms of the *p*-halophenyl derivatives reproduced in Fig. 8 are, however, somewhat different from that of the parent, TPF. First, it will be noticed that the lower energy phenyl group bands, each assigned as a vibration of that phenyl group substituted with a halogen, have essentially disappeared from the spectra. Second, and more importantly, two bands are now observed in the region expected to contain the N=N stretching bands. These pairs of bands occur at 1433 and 1399 cm^{-1}, 1431 and 1395 cm^{-1}, and 1429 and 1390 cm^{-1}, respectively, for the series *p*-chlorophenyl, *p*-bromophenyl, and *p*-iodophenyl. It is observed that the intensities of the lower energy components of these pairs of bands and the energies of both components decrease in the same series order. The interpretation of these pairs of bands in terms of mechanical coupling or Fermi resonance is ruled out since the shift of both bands in the same direction cannot occur in either case. The existence of both *cis*- and *trans*-isomers is also eliminated as a possible explanation since two bands are observed only in cases involving unsymmetrical substitutions.

These results are interpreted to imply that two tautomers exist for both the chelate and non-chelate forms of these molecules and that the relative proportions of a tautomer in solution is a function of the electron-attracting ability of the *para*-substituent on the phenyl group at the 1-position.

In order to assign a particular component of these pairs of N=N stretching bands to a particular tautomer, it is necessary to resort to chemical intuition and to model compound data found in the literature. If, as shown in Scheme 3, the two chelate tautomers are considered as unsymmetrical *trans*-azoaromatics then it should be concluded that "tautomer **a**" with the N=N bond located nearer the *p*-halophenyl group would exhibit the higher energy N=N stretching band. For example, it has been shown (29) that the energies of the N=N stretching bands of a series of *trans*-azoaromatics range from 1463 cm^{-1} for the electron-attracting *p*-nitrophenyl group to 1391 cm^{-1} for the electron-donating *p*-dimethylaminophenyl group. These data are, of course, relevant to non-cyclic azo-derivatives in which the resonance stabilization of a chelate ring cannot tend to equalize the vibrational energies. It is contended, however, that the general trend is applicable to the chelate forms of the triphenylformazans although the differences between the vibrational energies of the tautomers are expected to be smaller and the related two bands of the chelate forms are not resolved. (Compare the asymmetrical shape of the 1357 cm^{-1} bands in Fig. 7 and the symmetrical shape of the corresponding band of TPF in Fig. 3.)

These arguments are particularly applicable to the non-chelate forms of the triphenylformazans illustrated below. These isomers are true unsymmetrical *trans*-azoaromatics; hence, the N=N stretching bands of the two isomers should be well separated and this is certainly observed in the spectra. It is thus concluded that the higher energy, more intense components of the pairs of bands, see Fig. 8, may be attributed to the N=N stretching modes of those tautomers with the N=N bonds nearer the *p*-halophenyl group (isomer **c** shown in Scheme 4).

The question now arises as to which of the chelate tautomers should be the preferred one. Intuitively, one would select tautomer **b** of Scheme 3. It is not possible to determine the identity of the preferred tautomer solely on the basis of the RR spectra of the chelate forms of the *p*-halophenyl derivatives. The relevant N=N stretching bands are broadened when compared to the corresponding band of TPF and are suggestive of two overlapping bands; but, little else can be derived from these observations. Fortunately, the RR spectra of 1-(*p*-bromophenyl)-2-^{15}N-3,5-diphenylformazan shown in Fig. 9 do

c d

SCHEME 4

confirm the proposal made above. The spectrum of the chelate form of this derivative clearly exhibits two bands, at 1359 and 1347 cm^{-1}, which are attributable to the N=N stretching modes of the two tautomers. The lower energy, less intense band is due without question to the $^{14}N=^{15}N$ stretching mode. The corresponding single band of the unlabelled derivative is located at 1357 cm^{-1}. (It should be noted that while the two bands of (1-^{15}N)TPF, Fig. 3, are of equal intensity, the higher energy band of the brominated compound is much more intense.) It should be carefully noted that the $^{14}N=^{15}N$ stretching mode is uniquely possible for that tautomer of 1-(*p*-bromophenyl)-2-^{15}N-3,5-diphenylformazan with the N=N bond adjacent to the *p*-bromophenyl group. *This particular spectrum therefore unequivocally demonstrates that the preferred tautomers of the chelate forms of the* p-*halophenyl derivatives are those with the N=N bond adjacent to the phenyl group; that is to say tautomer* ***b*** *in Scheme 3*. This spectrum, in comparison with other ^{15}N-labelled derivatives, also shows that the energies of the N=N stretching modes of the **a** and **b** tautomers of the *p*-halophenyl derivatives are very nearly equal. For example, energy differences, $(\nu_{(^{15}N=^{15}N)} - \nu_{(^{14}N=^{15}N)})$, of 12 and 11 cm^{-1}, respectively, are observed in the spectra of 1-(*p*-BrP)-2-^{15}N-3,5-DPF and (1-^{15}N)TPF. Thus, for the chelate forms of these molecules the *p*-halo substituent has only a small effect on the N=N stretching mode.

The fact that tautomer **b**, in Scheme 3, of the *p*-halophenyl derivatives is preferentially populated with respect to tautomer **a** is firmly established by these RR experiments. In contrast, the interpretation of the spectra of the non-chelate forms of these compounds leads to the conclusion that tautomer **c**, in Scheme 4, is preferentially populated. *It is therefore necessary to propose that excited state proton transfer must occur. Tautomer* ***c*** *cannot otherwise be formed from tautomer* ***b***.

On the basis of the present experimental data it is postulated that excited state proton transfer occurs as the primary photoevent in the photochromic transformation of triphenylformazans. This proposal also requires that changes be made in the mechanism of the transformation.

As pointed out by Grummt and Langbein (4), if the formation of **C** (Scheme 1) results from two single photon reactions as implicated by the scheme of Kuhn and co-workers (1, 2), then there must exist a range in which the absorbance of **D** that is formed in a single flash exhibits a quadratic dependence on the intensity of the flash (30). Grummt and Langbein found no such dependence and, hence, ruled out the formation of **D** by means of two consecutive single photon reactions. On the other hand, the schemes proposed by both these groups of researchers appear to indicate that **D**⇆**C** photostationary state would be achieved under continuous irradiation.

Under the conditions of the present RR experiments on the non-chelate forms of the triphenylformazans, this photostationary state should certainly be attained. The RR spectra of these non-chelate forms should, therefore, contain contributions from both the *trans-anti* and *cis-anti* isomers. The N=N stretching energies of *trans* and *cis* isomers should be separated by approximately 70 cm^{-1}. For example, the N=N stretching band of *trans*-azobenzene is located at 1442 cm^{-1} (15, 16) in the Raman spectrum and that of *cis*-azobenzene is located at 1511 cm^{-1} (26) in the IR spectrum. All the Raman spectra of the non-chelate form of triphenylformazans exhibit a weak band near 1465 cm^{-1}; but, the band undergoes only a small isotope shift as a result of secondary effects. An assignment of this band as being due to the *cis*-N=N stretching mode is therefore highly questionable. It is concluded that the present Raman data offer no confirmation of the presence of isomer **C** as shown in Scheme 1.

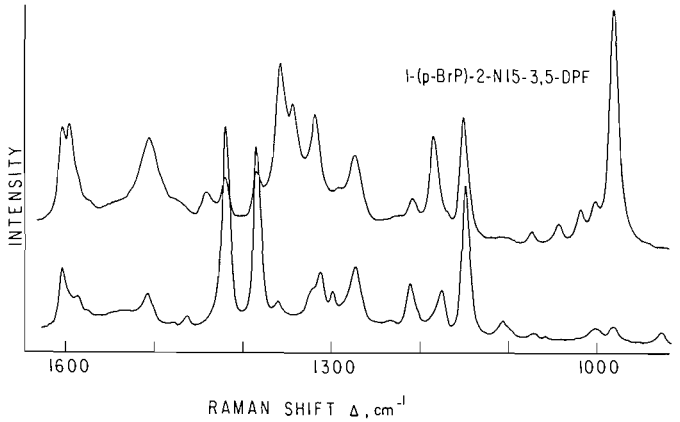

FIG. 9. Resonance Raman spectra of triphenylformazan derivatives in solution. Top: chelate form. Bottom: non-chelate form of 1-(*p*-bromophenyl)-2-^{15}N-3,5-diphenylformazan. The experimental conditions are identical to those listed for Figs. 3 and 4.

Conclusions

The combination of the IR and RR spectra of the two forms of triphenylformazans provides a wealth of information related to the photochromism of these compounds. The IR and RR spectra of unsymmetrically ^{15}N-labelled derivatives clearly demonstrate the presence of two tautomers of the chelate and non-chelate forms. The IR spectrum of the non-chelate form of (1,2-^{15}N)TPF exhibits two C=N stretching bands and the RR spectra of both forms of (1-^{15}N)TPF and (1,2-^{15}N)TPF exhibit two N=N stretching bands. The RR spectra of these derivatives also demonstrate that the N=N stretching mode may couple with either a higher or lower energy mode. The amount of coupling depends on the nearness of the N=N stretching energy to either 1470 or 1325 cm^{-1}. The RR spectra of azoaromatics with N=N stretches in either of these regions should, therefore, be approached with some caution.

The RR spectra of the 1-(*p*-halophenyl)-3,5-diphenylformazans confirm that two tautomers exist for each of the two forms. The spectra of the non-chelate forms of these derivatives show that the position of the tautomeric equilibrium is influenced by the *p*-halo substituent. The combination of ^{15}N-labelling and phenyl substitutions, as evidenced in the RR spectra, lead to the conclusion that excited state proton transfer is the primary photoevent in the photochromism of these compounds.

These RR results cast some doubt on the previously proposed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

mechanisms. Both the previously proposed mechanisms suggest a **D**⇌**C** photostationary state and the present RR investigations give no evidence for isomer **C**, the *cis-anti* isomer. The lifetime of the **C** isomer is given as 90 s (2); hence, under continuous laser irradiation a sufficient amount for detection by RR spectroscopy should be present at a photostationary state.

In view of the facts that excited state proton transfer occurs as a primary photoevent and that the *cis-anti* isomer is not observed in the RR spectra, the present study confirms only the **A** and **D** isomers of triphenylformazan. Further study is needed to establish the presence or absence of the **B** and **C** isomers.

New photoresists for deep ultraviolet (<300 nm) exposure

E. A. CHANDROSS, E. REICHMANIS, C. W. WILKINS, JR., AND R. L. HARTLESS
Bell Laboratories, 600 Mountain Ave., Murray Hill, NJ 07974, U.S.A.

Received June 21, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

E. A. CHANDROSS, E. REICHMANIS, C. W. WILKINS, JR., and R. L. HARTLESS. Can. J. Chem. **61**, 817 (1983).

The increasing density of devices in large scale integrated circuits has created a need for lithographic techniques that have higher resolution (≈1 μm) than can be achieved with conventional (≈400 nm) optical technology. By operating in the deep uv (200−300 nm) region of the spectrum, one can reduce diffraction effects and increase resolution. Because of the high optical density of conventional photoresists in this wavelength range, new materials are needed. This paper presents an overview of new positive resists that we have developed. These include methacrylate polymers that undergo photochemical chain scission and two-component (photosensitive solution inhibitor − alkali soluble matrix resin) systems.

E. A. CHANDROSS, E. REICHMANIS, C. W. WILKINS, JR. et R. L. HARTLESS. Can. J. Chem. **61**, 817 (1983).

L'augmentation de densité des appareils des circuits intégrés à l'échelle industrielle à créé le besoin de recourrir à des techniques lithographiques ayant une résolution supérieure (≈1 μm) à celle que l'on peut atteindre avec la technologie optique conventionnelle (≈400 nm). En opérant dans la région de l'uv lointain (200−300 nm), on peut réduire l'effet de diffraction et augmenter la résolution. À cause de la forte densité optique des photorésistances conventionnelles dans ce domaine de longueur d'onde, on a besoin de nouveaux matériaux. Cette publication présente un survol des nouvelles résistances positives que nous avons mises au point. Elles comprennent les polymères du type méthacrylate qui subissent une scission photochimique de leur chaîne et de systèmes à deux composés (un inhibiteur en solution photosensitive et une résine soluble dans les alcalis). [Traduit par le journal]

Introduction

The manufacture of integrated circuits involves the crucial step of defining mask patterns on a silicon substrate. After intermediate steps, it allows one to add additional elements (dopants) to the silicon which alter its properties, or to fabricate structures such as metal "wires" that are essential for the device. Virtually all circuit production uses a photosensitive thin organic film as the image forming medium. It is exposed by projection or contact printing, processes analogous to the well-known technology of conventional photography. The resist must withstand subsequent chemical processing steps, such as hydrofluoric acid etching of silicon dioxide, and it is also desirable that it be attacked relatively slowly in the fluorocarbon plasma etching processes now coming into use.

Photoresists were originally developed for the manufacture of printing plates and printed wiring boards. This is a well-established technology, going back over a century. A good deal of chemistry and ingenuity has characterized the art of photolithography, and the reader is referred to two books (1, 2) for historical background.

A photoresist film is one whose solubility in an appropriate developer is changed substantially by exposure to actinic radiation. There are two types of resists, positive and negative (Fig. 1). The former become more soluble upon exposure; the latter show opposite behavior. Conventional resists are generally sensitive to light in the 365−436 nm region of the spectrum. These wavelengths imply the use of a mercury arc lamp, the brightest conventional source. As technology has developed, the use of shorter wavelength radiation, such as X-rays and electrons, has been studied. The former is still in development; the latter is used extensively in the manufacture of the masks for optical printing. The reason for going to shorter wavelengths is the search for higher resolution which is needed as device features get ever smaller. At present the state of the art 64 kilobit memory chips require features as small as 2−3 μm.

Optical lithography is a well-established technology, and it is of interest to see how far it can be pushed in the search for higher resolution. There are many aspects to the question of the resolution that can be obtained in a resist film. Much depends

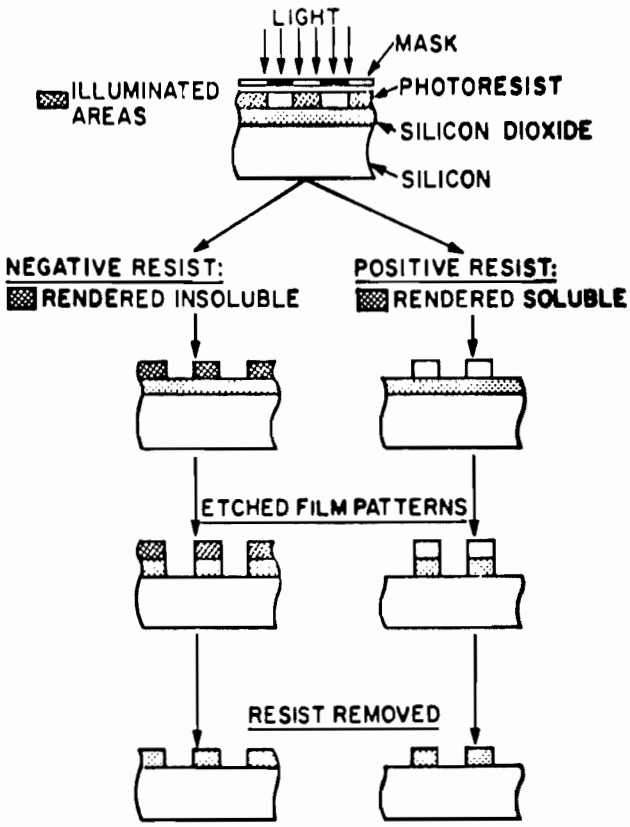

FIG. 1. Pictorial view of the operation of positive and negative resists.

on the properties of the polymer materials and their response to the developers as well as the subsequent processing conditions. Present interest centers about the 1 μm element size. As we approach the wavelength of the light used to form the resist image (≈0.4 μm), it is clear that diffraction effects should increase in importance. This has led to a strong interest in exploring the use of 200−300 nm light to minimize diffraction. Printing equipment for this region of the spectrum is expected to be available in the near future. This paper presents an overview of the routes we have explored for deep uv resist technology.

Resist design

General considerations

The first decision to be made is which wavelength region should be used for resist exposure. We believe that the high pressure mercury arc lamp that is currently used will continue to be the best exposure source for the near future. This implies that resist response should be optimized for the 230−280 nm region. The choice represents a compromise between exposure at the shortest possible wavelength and a reasonable exposure time for a 12.7 cm diameter silicon wafer, allowing for the relatively low Hg lamp output at $\lambda < 300$ nm.

An important consideration is the match between the exposure source output spectrum and the absorption spectrum of the photoresist film which is usually 0.5−1 μm thick. It is important to have relatively uniform exposure throughout the thickness of the film in order to obtain vertical walls in the resist image. This suggests a low optical density, and we prefer to keep the optical density of the film below 0.3 for the range of significant source output. Conventional materials are nearly opaque (OD >1) for $\lambda < 300$ nm, and it is impossible to obtain uniform exposure through the film thickness unless the film is very thin. This is the reason that new photoresists are needed.

Sensitivity is generally defined as the amount of incident exposure light, in J cm^{-2}, that is required to give a satisfactory image after development. This does not take into account the match between the output and absorption spectra mentioned above. We prefer to measure sensitivity at a particular wavelength. The practical measure of sensitivity is simply the time it takes to make a resist image with a given exposure tool.

Resist contrast is defined in a manner similar to that of conventional photography. One plots the amount of resist film thickness remaining after development versus the log of the exposure dose. This usually gives a curve which is fairly linear as the thickness approaches zero. Contrast (γ) is defined as the slope in this region. The higher γ is, the more the resist behaves as if it has a threshold exposure for development. This behavior is desirable because it indicates less sensitivity to stray light and/or diffracted light. High contrast is desirable for high resolution imaging.

Conventional materials require exposures of 50−200 mJ cm^{-2}. For positive resists, it is unlikely that sensitivities significantly better than 50 mJ cm^{-2} can be achieved. It should be noted that sensitivity is fundamentally measured in photons cm^{-2} and one will necessarily have to have more J cm^{-2} to have the same photon flux as the wavelength is decreased. Thus, deep uv lithography will require more light (joules), in a region of decreasing lamp output, to cause the same photochemical effect that would be observed with existing materials at conventional wavelengths.

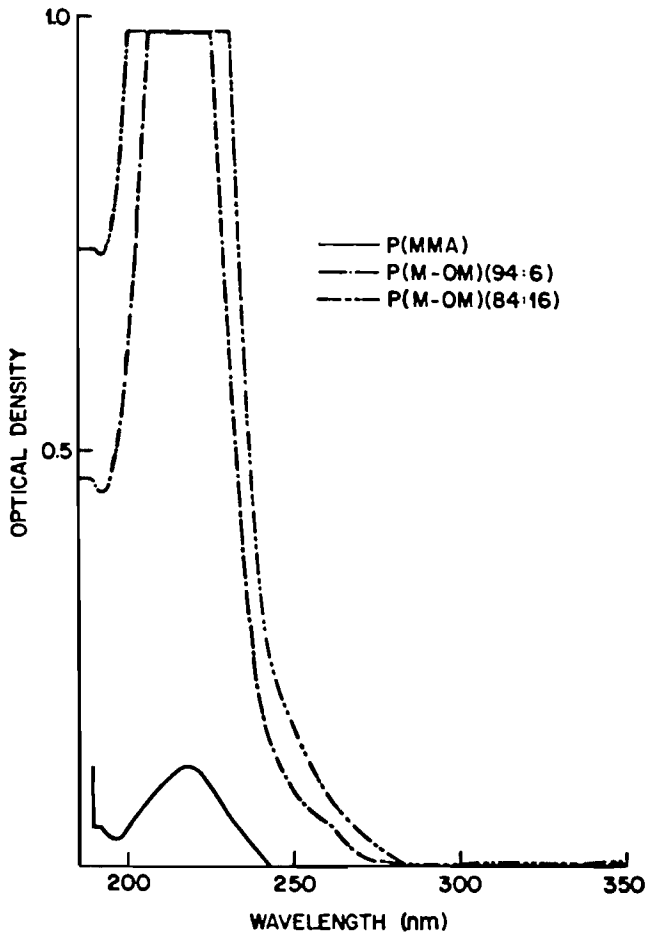

FIG. 2. Absorption spectra of PMMA and P (M−OM) films, nominally 1 μm thick. The mole ratios of the copolymers are given in parentheses.

Resist mechanisms

Negative resists are polymers having reactive groups that undergo photochemical crosslinking reactions either with themselves (e.g., cinnamate dimerization) or with a photosensitive small molecule (e.g., ethylenic polymer groups with bisazido compounds). In general, negative resists exhibit a greater tendency to swell during development than positive resists. The absorption of developer solvent plasticizes the film and limits the resolution that can be obtained to ~2 μm in ~1 μm thick films. For this reason we chose to design new positive resists for use in the deep uv region.

There are two general mechanisms that are used in positive resist chemistry. One involves the degradation of a polymer to material of significantly lower molecular weight. This is essentially opposite to the change induced in a negative resist. If the molecular weight distribution is shifted sufficiently, one can then dissolve the irradiated regions. Poly(methyl methacrylate), PMMA, is the best known example of this group (3). It is capable of extremely high resolution, using deep uv light, e-beam, X-ray, or ion beam exposure, but it is too insensitive to be practical. The low optical sensitivity is not surprising. PMMA has only pivalate ester chromophores, and they absorb weakly at 220 nm (Fig. 2). The combination of weak absorption and poor lamp output does not bode well for a reasonable exposure time. Sensitization is not possible because there is no low-lying excited state of the ester chromophore.

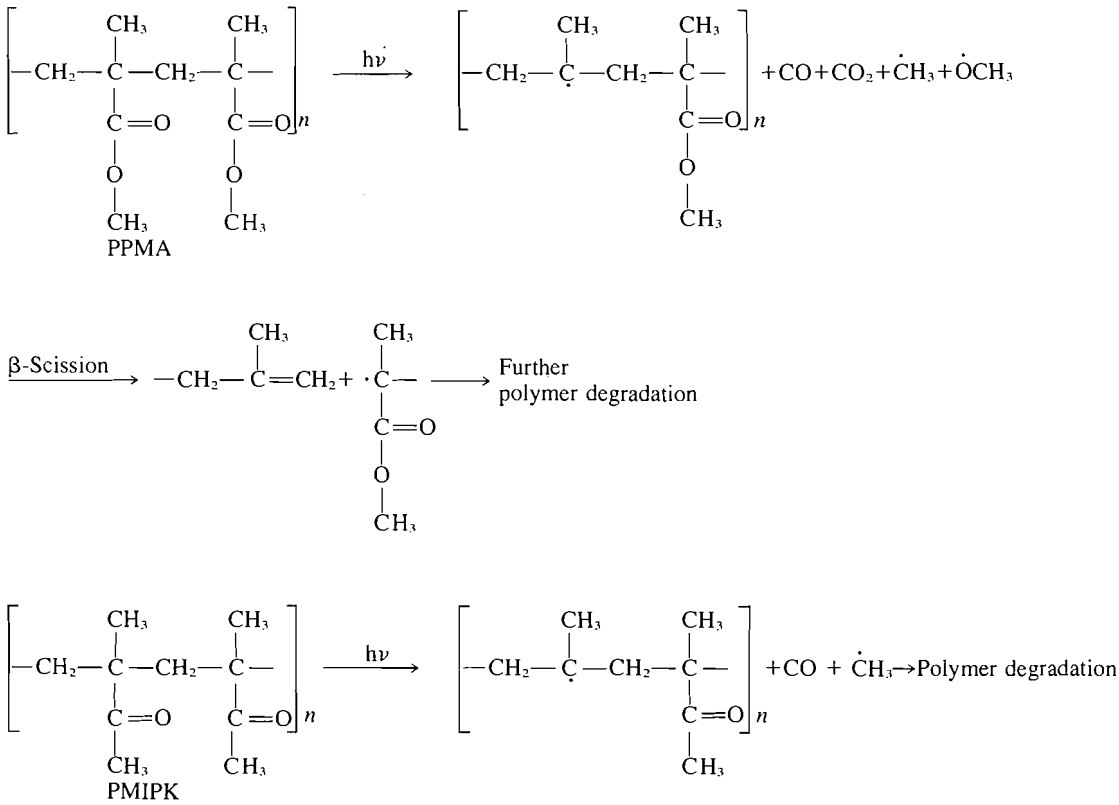

FIG. 3. The mechanism proposed for the photodegradation of PMMA and the poly(vinyl ketone)s.

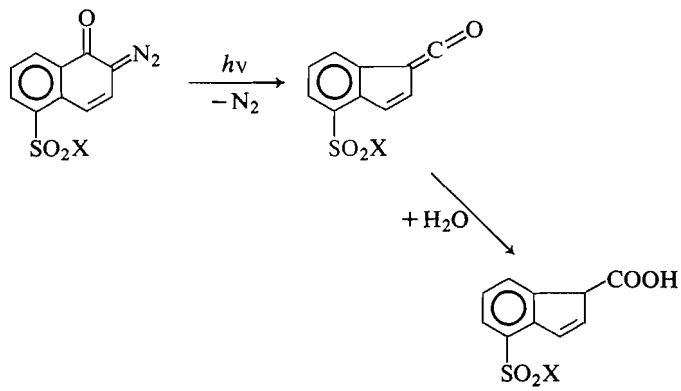

FIG. 4. The photochemical conversion of a naphthoquinone diazide to an alkali-soluble carboxylic acid, as in conventional positive photoresist. X is usually an aryloxy group.

The mechanism of PMMA photodegradation is thought to involve radical formation followed by β-cleavage of the polymer backbone (Fig. 3). The same process can occur in poly(vinyl alkyl ketone)s which have also been used as resists. Because of their weak absorption of light (carbonyl chromophore, $\lambda \approx 280$ nm, $\epsilon \approx 25$), sensitizers are required.

The second type of positive resist has been used extensively for some time. It is a two-component system that operates via an ingenious mechanism.[1] The major component is a Novolak resin (phenol-formaldehyde) that is soluble in aqueous alkali. The minor component is a photosensitive hydrophobic compound, a substituted naphthoquinone diazide, that is photochemically converted to an alkali-soluble indenecarboxylic acid (Fig. 4). The ability of the "solution inhibitor" to prevent developer attack is destroyed by light, and the irradiated portion of the film can be dissolved preferentially by aqueous alkali. These materials are optically dense below 300 nm, even in 0.5 μm films, and thus they cannot be used for deep uv exposure.

New PMMA resists

Our work in this area is based on the hope that it would be possible to add small amounts (>15 mol%) of photosensitive groups that would lead to backbone cleavage while maintaining the excellent filmforming and high resolution properties of PMMA itself.

A known example of this approach is the incorporation of the acyloximino ester chromophore, devised by Delzenne *et al.* (4). They noted that irradiation of solutions of copolymers of MMA and 3-methacryloyloximino-2-butanone, in the 365 nm region (weak absorbance), led to a decrease in molecular weight. This seemed to be a good starting point because the acyloximino group has a strong absorption at 220 nm whose tail extends beyond 240 nm. Photolysis in the solid state is not necessarily the same as that in solution because of the cage effect of the matrix that favors the reformation of broken bonds, but one can expect some similarity.

The absorption spectra of two of these copolymers, as well as that of the parent PMMA, are given in Fig. 2. The photodegradation envisaged for the copolymer is shown in Fig. 5. As expected, the photosensitivity observed increases with the amount of acyloximino monomer incorporated. The results are given in Table 1.

A further increase in sensitivity can be obtained by the incor-

poration of methacrylonitrile (5). It is likely that this is primarily a consequence of polymer properties rather than a direct effect on the photochemical reaction. The most sensitive material was found to be a terpolymer of methyl methacrylate, the oximino methacrylate, and methacrylonitrile, in the ratio of 69:16:15. This polymer is more than 50 times as sensitive as PMMA to 240 nm light. When sensitized with *tert*-butylbenzoic acid, it requires an exposure of less than 30 mJ cm^{-2} and gives high resolution images. The limits of its use for optical printing have not yet been thoroughly explored.

In addition to the use of benzoic acids as short wavelength sensitizers, the polymers can be made sensitive to longer wavelength ($\approx$ 300 nm) light by the addition of photosensitizers such as *N*-acetylcarbazole (Table 2) (6). It appears that singlet energy transfer is involved.

Indenone is another monomer that can be incorporated into PMMA by conventional free radical copolymerization (7). Indenone is prepared by *in situ* hydrolysis of the ethylene ketal just before polymerization because it polymerizes too readily to be stored. The high reactivity of the α,β-disubstituted ethylene is attributed to the presence of the antiaromatic cyclopentadienone moiety. The amount of indenone incorporated into the copolymer is controlled by its concentration in the polymerization solution.

Absorption spectra of typical copolymers are shown in Fig. 6. It is clear that this system can be optimized for exposure in either the 280 or 250 nm region by appropriate choice of the indenone concentration. The amount actually incorporated is readily determined by optical spectroscopy.

We assume that indenone reacts as an α,β-unsaturated ketone, and the mechanism postulated for photodegradation is shown in Fig. 7. It is analogous to that accepted for PMMA and

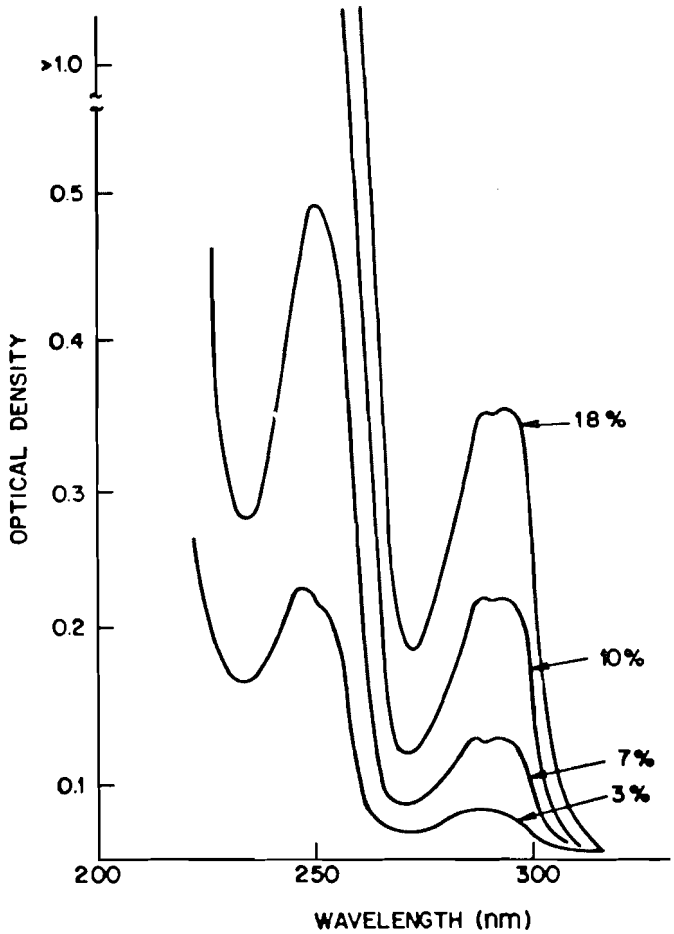

FIG. 6. Absorption spectra of films of poly(methyl methacrylate-co-indenone), ≈1 μm thick. The mol% of indenone is indicated for each curve.

assumes the normal Norrish α-cleavage of a carbonyl group. The copolymer is quite sensitive, requiring an exposure of only 0.06 J cm^{-2} at 248 nm when 3% indenone is present. Sensitivity is proportional to absorption as long as the optical density of the film is low. A complete set of results is given in Table 3. The high sensitivity is explained on the basis of the steric strain present in the cyclopentanone moiety. It is well known that the rate of α-cleavage increases in the order cyclohexanone < cyclopentanone < cyclobutanone. The analogous open chain copolymer incorporating phenyl vinyl ketone is far less sensitive (×80) than the indenone copolymer. A preliminary lithographic evaluation of poly(MMA-co-indenone) indicated that it is capable of high resolution (≈ 1 μm) and that it has a contrast similar to that of PMMA.

Solution inhibitor deep ultraviolet resist (8)

The conventional two-component resist system was described in the introduction. It contains a large fraction of phenol moieties that absorb strongly for λ < 300 nm, a region of high absorption for the quinone diazide additive as well. There is a "minimum" in the resist absorption at ≈260 nm where the optical density is ≈0.5 μm^{-1}. Thus, in order to use a system like this for exposure at λ < 300 nm, both a new matrix resin and a new photosensitive element are necessary.

The choice of a resin seemed straightforward, based on what is known about the performance of the conventional material. We require a film-forming polymer that will dissolve at a reasonable rate in aqueous alkali, serve as a host for the photosensitive solution inhibitor, and not interfere in the photochemistry of the latter. We selected copolymers of methyl methacrylate and methacrylic acid (MAA) because they offer an easy route to adjusting the alkali solubility of the matrix. They are optically transparent in the region of interest to us.

The selection of a photochemical reaction for the solution inhibitor is far less obvious. We were led to the *o*-nitrobenzyl

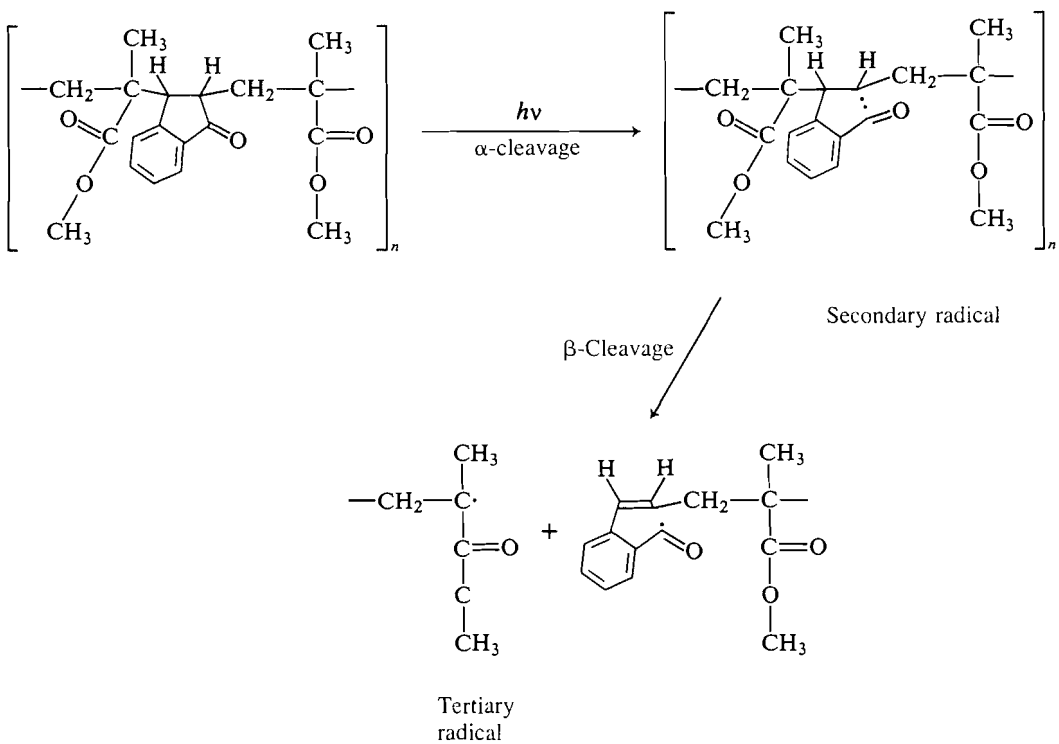

FIG. 7. The mechanism postulated for the photodegradation of poly(methyl methacrylate-co-indenone).

TABLE 3. Photosensitivity of poly(methyl methacrylate-co-indenone)[a]

Indenone content	Film OD		Exposure required (J/cm^2)	
	at 280 nm	at 248 nm	at 280 nm	at 248 nm
3%	0.3	0.22	0.6	0.06
7%	0.7	0.53	0.2	0.02–0.06
18%	0.16	1.1	0.1	0.13

[a]Developed with methyl isobutyl ketone saturated with water.

ester rearrangement for two reasons. This photochemistry is well known for the facile conversion of carboxylic acid esters to the free acids, and the absorption spectrum of the nitrobenzene chromophore seemed well suited to our purpose (Fig. 8).

The *o*-nitrobenzyl ester rearrangement functions as a photochemical switch to liberate the alkali-soluble carboxylic acid (Fig. 9). We thought it would be advantageous to choose the R group to be as large as possible so that it would occupy a substantial volume fraction of the resist film. Such a species would then function as an amplifier for the effect of the change in the small photosensitive moiety. Our first choice was cholic acid. The free acid is very soluble in aqueous alkali

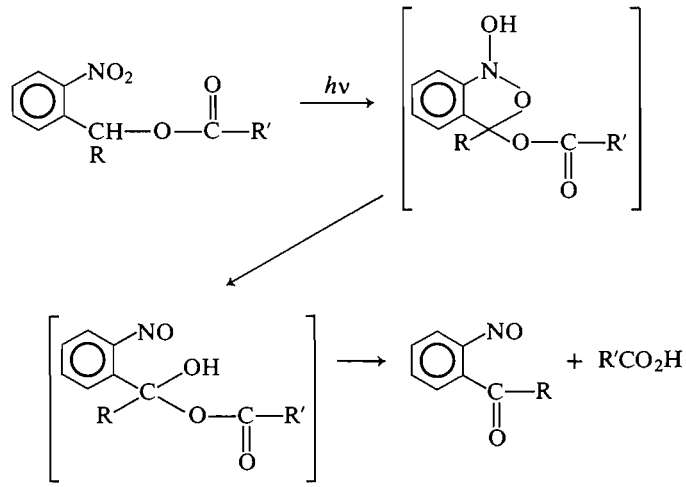

FIG. 9. Photochemical reaction of an *o*-nitrobenzyl ester to liberate the parent acid.

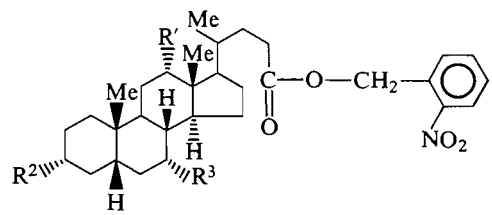

R^1_1, R^2_2, R^3_3 = OH

FIG. 10. Structure of *o*-nitrobenzyl cholate.

(≈500 g L^{-1}), while the aliphatic esters are insoluble. It is far more effective than anything else we have studied such as decanoic acid, fluorenone-3-carboxylic acid (a photosensitizer), and various phthalic acid half-esters.

ortho-Nitrobenzyl cholate (Fig. 10) was synthesized by the reaction of sodium cholate with *o*-nitrobenzyl chloride in aqueous alcohol. The poly(MMA-co-MAA) was prepared by conventional free-radical polymerization. The molecular weight and composition of the resin have an effect on the overall sensitivity; material having a ratio of 75:25 and a molecular weight of ca. 75 000 is quite satisfactory. The solution inhibitor is present at ca. 20% by weight. The developer that works best is an aqueous solution of Na_2CO_3 (10% by weight).

The resist films are spin coated conventionally from cyclopentanone solution. The absorption spectrum of a typical film is shown in Fig. 8. It is clear that this resist is well suited for exposure in the 260 nm region where the sensitivity is ≈0.2 J cm^{-2} for a typical system. Sensitivity depends on a number of factors (inhibitor concentration, baking time and temperature before exposure, developer composition, and procedure) that must be studied further to allow the choice of a practical material. We have made contact prints that demonstrate 1 μm resolution (Fig. 11).

The unexpected result that came out of our initial studies was the unusually high contrast ($\gamma > 5$) of this resist system. The analogous conventional system has a contrast of ≤2.5; the PMMA systems show $\gamma < 2$. There is no way to predict or rationalize contrast, but we can say that this system comes closer to "threshold exposure" behavior than any other organic photoresist. We believe that the clue to understanding the high contrast lies in the unusual development characteristics ob-

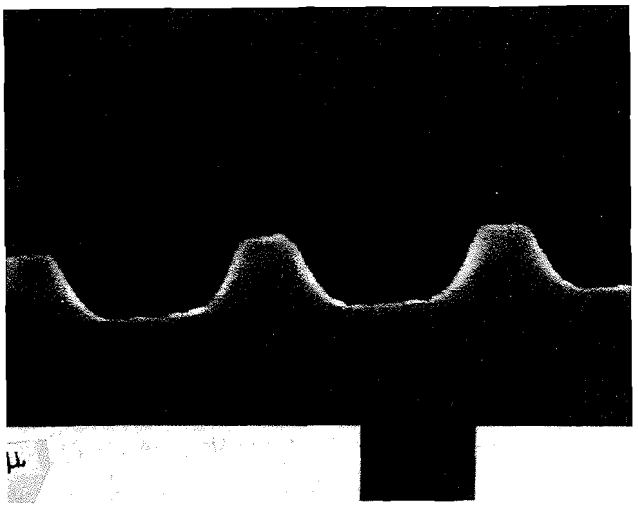

FIG. 11. 1 μm Lines and spaces contact-printed in *o*-nitrobenzyl cholate/P (MMA–MAA) photoresist. The space in the light portion of the figure at the bottom is 1 μm.

served for these films. The exposed regions are swollen but not dissolved directly by the alkaline developer. They dissolve subsequently in the water used to rinse the film. This may be a reflection of "salting out" the ionized resin polymer by the alkaline developer. The swelling does not seem to have a deleterious effect on the resolution that can be obtained. More work has been done on this system, and the reader is referred to recent presentations (9, 10).

Summary

The work described here demonstrates that one can design new resist systems for the deep ultraviolet. There is a lot of work required to optimize any resist system after its basic chemistry is shown to be promising. This investment should become more attractive as imaging equipment for this region of the spectrum becomes available. Optical lithography is a well-known, attractive technology, and we hope that it can be used to make high-density integrated circuit devices having feature sizes less than one micrometer.

Optimization of ion trapping characteristics for studies of ion photodissociation[1]

RICHARD JAMES HUGHES, RAYMOND EVANS MARCH,[2] AND ALEXANDER BALDWIN YOUNG[3]

Department of Chemistry, Trent University, Peterborough, Ont., Canada K9J 7B8

Received June 30, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

RICHARD JAMES HUGHES, RAYMOND EVANS MARCH, and ALEXANDER BALDWIN YOUNG. Can. J. Chem. **61**, 824 (1983).

In order to characterize unambiguously photochemical energy absorption and subsequent intramolecular relaxation dissociation, collision-free conditions are required. Isolated molecule photochemistry may be studied in a quadrupole ion store (QUISTOR) under near collision-free conditions. Photodissociation of primary ions, H_2^+ and CH_4^+, has been described and we have reported on the slow multiphoton induced dissociation of protonated dimers of 2-propanol in the infrared region. Ions may be trapped in a QUISTOR in either a total storage mode wherein ions of different masses are stored simultaneously, or a mass selective mode wherein single ion species are isolated. Utilization of the QUISTOR as an ion/molecule reactor in the total ion storage mode facilitates the formation of secondary ions chosen for study, their isolation, and irradiation. Determination of the ranges of ion masses which may be stored in each mode is described. In the total storage mode, ion mass-to-charge ratios to m/e 455 have been observed. Selective storage to m/e 219 is reported, though with poor resolution. The effects of variation in trapping parameters including drive frequency and physical dimensions of the device are discussed.

RICHARD JAMES HUGHES, RAYMOND EVANS MARCH et ALEXANDER BALDWIN YOUNG. Can. J. Chem. **61**, 824 (1983).

Des conditions de collision libre sont nécessaires pour caractériser sans ambiguité l'absorption d'énergie photochimique et la relaxation et dissociation intramoléculaire subséquentes. On doit étudier la photochimie de la molécule isolée dans une réserve d'ions quadrupolaire (QUISTOR) dans des conditions de quasi collision libre. On a décrit la photodissociation des ions primaires H_2^+ et CH_4^+ et nous avons rapporté la dissociation induite par multiphoton lent des dimères protonés de propanol-2 dans la région infrarouge. Les ions peuvent être piégés dans un QUISTOR soit dans un mode d'emmagasinage total où les ions de masse différente sont emmagasinées silmultanément, soit dans un mode de sélection de masse où les ions simples sont isolés. L'utilisation du QUISTOR comme un réacteur d'ion/molécule dans le mode d'emmagasinage total facilite la formation des ions secondaires choisis pour étude, leur isolation et leur irradiation. On décrit la détermination des intervalles des masses d'ions qui peuvent être emmagasinés dans chacun des modes. On a observé, dans le mode d'emmagasinage total, des rapports masse d'ions/charge de $m/e = 455$. On rapporte un emmagasinage sélectif avec un rapport $m/e = 219$ mais avec une faible résolution. On discute des effets de la variation des paramètres de piégeage incluant la fréquence de conduite et les dimensions physiques de l'appareillage.

Introduction

In a recent review of ion photodissociation by Dunbar (1), three phases of the short history of such studies were recognized. The initial studies in the 1960's were carried out in the laboratories of Dunn (2) and Dehmelt (3); the second stage began in 1970 as photodissociation became a major area of interest to ion cyclotron resonance (ICR) spectroscopy with at least six ICR laboratories active in such studies; and the third stage, beginning in 1973, saw the renewed application of mass-filter type instruments to these problems. To this historical perspective as of 1977, one may add a fourth stage of slow multiphoton induced ion dissociation studies initiated in 1978 with the work of Beauchamp and co-workers (4). Among the early studies originating from Dehmelt's laboratory were a few studies on the photodissociation of H_2^+ and CH_4^+ carried out using RF quadrupole traps (5). Recently, we reported (6) on the slow multiphoton induced dissociation of the protonated dimer of 2-propanol using a quadrupole ion store (QUISTOR). While QUISTOR work may be nearly synonymous with that of ICR (7), in that positive and negative ion storage may be effected under virtually collision-free conditions, resonance ejection may be utilized to identify precursors (8), and ion photodissociation may be induced upon irradiation in the ultraviolet, visible (5), and infrared regions (6), there are essential differences between the two techniques. The QUISTOR may be operated not only as a total ion storage device (cf. ICR), but as a mass spectrometer (9) and as a specific ion reactor (10) in which the device is operated initially in a mass selective mode with relaxation to total ion storage. Furthermore, collisional focusing of the entire ion cloud concentrated at the centre of the quadrupole field, which has been proposed earlier (11) and has been demonstrated by fluorescence observations (12), greatly facilitates ion photodissociation with a single pass of a laser beam through the centre of the device. As it is thus no longer necessary to use mesh electrodes so that the entire storage volume may be illuminated, solid electrodes with concomitant finer control of the quadrupole field may be used to effect mass selectivity of medium resolution, i.e. $M/\Delta M \approx 300$.

The ultimate objective of the present work is to determine the optimum operating conditions for the consecutive creation and storage (in the total ion storage mode) of a primary or secondary ion of choice, isolation of the chosen ion species (in the mass selective mode), followed by simultaneous irradiation of the ion and relaxation of the field (to the total ion storage mode) in order to effect trapping and subsequent mass analysis of the ionic photofragments. In practice, mode switching has been achieved (10) but the mass ranges of ions which can be manipulated thus have not been explored in detail. We report here the present level of optimization of QUISTOR characteristics with respect to the ranges of ion mass-to-charge ratios which

[1]This paper was presented at the 65th Conference of the Chemical Institute of Canada, May 30 – June 2, 1982, in Toronto, under the title Mass storage range of the QUISTOR.

may be stored in the total ion storage mode and in the mass selective mode. In an accompanying publication (28) are reported the results of multiphoton dissociation in the QUISTOR of gas-phase ions derived from 2-propanol and its deuterated analogues using low-intensity infrared CO_2 laser radiation at 944 cm^{-1}.

Theory

The conventional quadruopole mass filter employs four stainless steel rods to which is applied a composite DC and RF potential $\pm\phi_0$. Mass separation is effected according to the criterion of path stability as the ions traverse the length of the rod–electrode assembly from source to detector. With the z-axis as the direction of ion travel, mass separation is achieved by applying $+\phi_0$ to rods in the $x-z$ plane and $-\phi_0$ to rods in the $y-z$ plane. For the QUISTOR, the three electrodes (one ring and two end-caps) are in the form of a hyperboloid of one sheet combined with a hyperboloid of two sheets, respectively. Due to the rotational symmetry of the QUISTOR, any point in the inner volume defined by the electrodes can be expressed in terms of a radial coordinate r and an axial coordinate z. The inner radius of the ring electrode is denoted r_0 and the distance from the centre of the trap to either end-cap electrode is denoted z_0. From the Laplace condition

$$[1] \quad \nabla^2\phi = 0$$

the relative magnitudes of r_0 and z_0 are thence determined to be

$$[2] \quad r_0^2 = 2z_0^2$$

and the entire structure is depicted schematically in Fig. 1.

The form of the potential ϕ_0 is a combination of a DC component U and a sinusoidally varying component V_0 such that

$$[3] \quad \phi_0 = U + V_0 \cos \Omega t$$

where Ω is the angular frequency ($2\pi f$) and V_0 is the amplitude of the alternating potential developed between oppositely charged electrodes. The potential at any point inside the QUISTOR is given by [4].

$$[4] \quad \phi(r, z) = (U + V_0 \cos \Omega t)\,(r^2 - 2z^2)/2r_0^2$$

The force acting upon an ion in the z-direction is given by

$$[5] \quad -eE_z = m\frac{d^2z}{dt^2}$$

which together with [4] gives

$$[6] \quad \frac{d^2z}{dt^2} - \frac{2e}{mr_0^2}(U + V_0 \cos \Omega t)z = 0$$

Expression [6] is in fact an equation of the Mathieu type for which the general form is

$$[7] \quad \frac{d^2z}{d\gamma^2} - (a_z + 2q_z \cos 2\gamma)z = 0$$

with the transformations

$$[8] \quad a_z = \frac{8eU}{mr_0^2\Omega^2}$$

$$[9] \quad q_z = \frac{4eV_0}{mr_0^2\Omega^2}$$

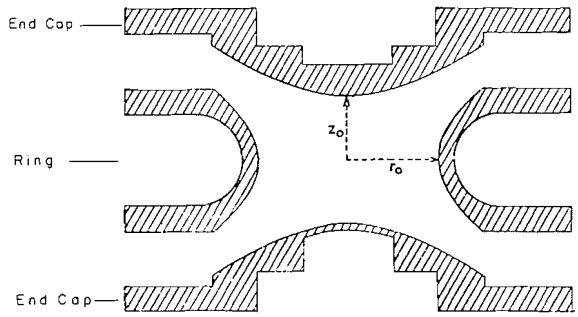

FIG. 1. Section through the hyperbolic structure of the QUISTOR showing the dimensions r_0 and z_0.

$$[10] \quad \gamma = \frac{\Omega t}{2}$$

where U is the DC voltage, V_0 is the 0–p RF voltage, m/e is the mass-to-charge ratio, r_0 is the radius of the ring electrode, and Ω is the radial frequency of the RF voltage.

An analogous treatment of the motion in the r-direction gives

$$[11] \quad \frac{d^2r}{dt^2} + \frac{e}{mr_0^2}(U + V \cos \Omega t)r = 0$$

so that

$$[12] \quad a_z = -2a_r$$

and

$$[13] \quad q_z = -2q_r$$

The detailed solution of the Mathieu equation has been presented elsewhere (13). An essential feature is that the trajectories of the ions within the device are found to be either "stable", i.e. the value of displacement periodically passes through zero, or "unstable" in which case the displacement increases towards infinity. The stability of the trajectory depends upon the numerical values of the parameters a and q and of course, for the practical purpose of trapping ions in a QUISTOR, the trajectories of the ions in the r- and z-directions must both be stable simultaneously. This leads to a "stability envelope" for the QUISTOR in a,q space, which is illustrated in Fig. 2. For any particular ion the values of a and q must be within the enclosed area if it is to have a stable trajectory. The other lines crossing the stability envelope are so-called iso-β lines corresponding to loci of a,q coordinates such that the various wave forms of the trajectories of the ions all possess the same frequencies and general character (14), although the amplitudes of the oscillations may be different. The β values are related to the dominant secular frequencies, ω_r and ω_z:

$$[14] \quad \omega_z = \frac{\beta_z\Omega}{2}$$

As the oscillation frequency is mass dependent, i.e.

$$[15] \quad \omega_z = \beta_z\frac{\Omega}{2} = \left(a_z + \frac{q_z^2}{2}\right)^{1/2}\frac{\Omega}{2}$$

and in the z-direction with $a_z = 0$

$$[16] \quad \omega_z = \left(\frac{q_z^2}{2}\right)^{1/2}\frac{\Omega}{2} = \frac{\sqrt{2}\,eV_0}{mr_0^2\Omega}$$

it is possible to effect resonance ejection of ions of specific mass-to-charge ratio (6).

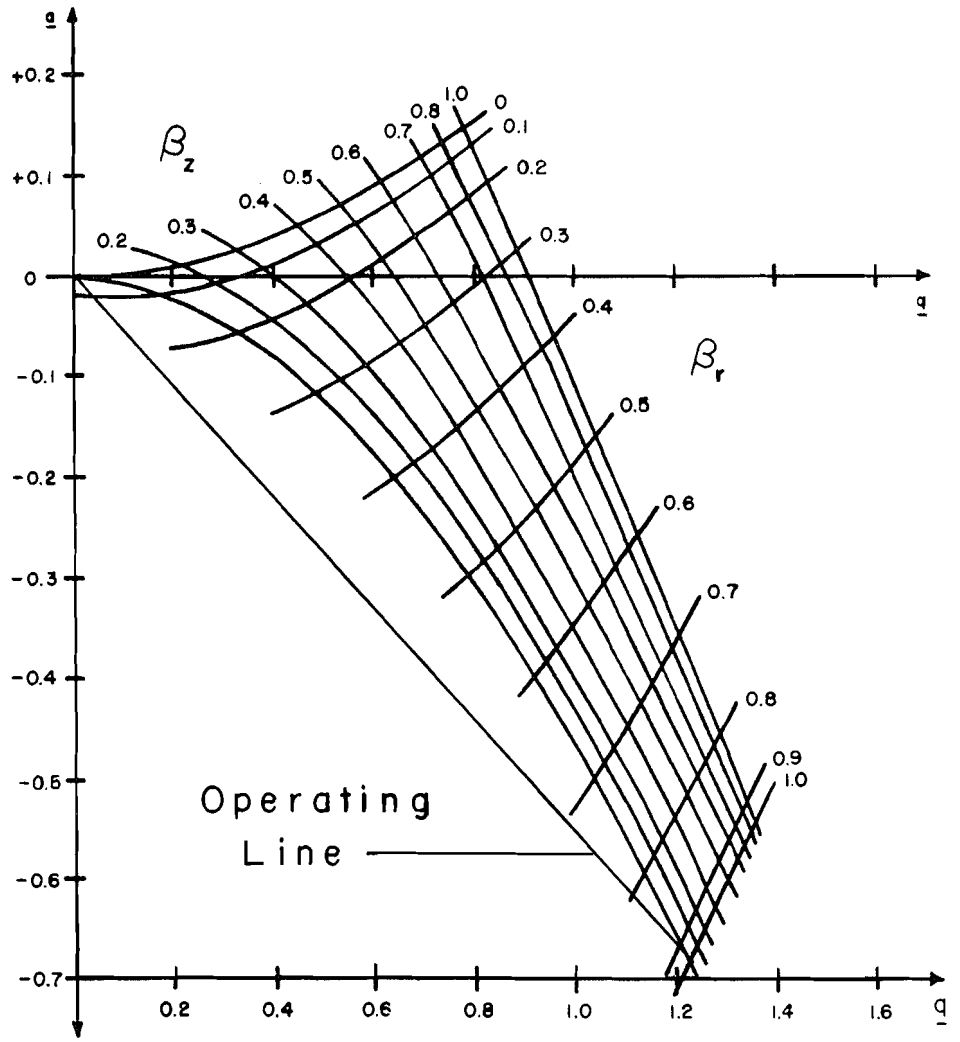

FIG. 2. Stability envelope near the origin for the QUISTOR with the operating line of constant U/V, and showing some iso-β lines.

The trapping potential, ϕ_0, may be applied in various fashions to the QUISTOR electrodes. Bonner (15) has summarized as follows the operating modes according to the application of these potentials. Mode I: Analogous to the operation of the mass filter, the combined RF and DC voltage, ϕ_0, is applied to the ring electrode and $-\phi_0$ to the end-caps. Mode II: ϕ_0 is applied to the ring and the end-caps earthed. Mode III: The DC component of ϕ_0 is applied to the end-caps and the RF component to the ring.

In this laboratory, the QUISTOR is operated exclusively in Mode II. Although Mode I has the advantage of doubling the values of a and q at a given U and V and hence doubling the effective mass range, this mode necessitates interfacing the rectangular extraction pulse, which empties the trap, with the applied RF and DC potential.

Operation of the QUISTOR along the q-axis, i.e. with zero applied DC potential ($a = 0$), corresponds to a total ion storage mode. It is expected from [9] and Fig. 2 that for a fixed value of V_0 a range of values of m/e will be stable, corresponding to q_z ($=-2q_r$) lying within the limits 0 to 0.91. It may be noted that, at a given value of V_0, ions are stored with different efficiencies so a degree of mass selectivity may result (16).

To operate the QUISTOR as a mass spectrometer, mass selective ion storage is used in which applied potentials are chosen so as to yield pairs of a,q values close to either the upper or lower apex of the stability diagram in Fig. 2, so that only ions of one m/e value are stable (and hence stored) at a time. As in the conventional quadrupole mass filter, therefore, a mass spectrum may be generated by varying U and V_0 at a constant ratio of U/V_0 such that for each mass the a,q coordinates move along the operating line shown in Fig. 2. Experimental results for a limited mass range have been reported by Dawson *et al.* (17), Harden and Wagner (18), Mastoris (19), Sheretov *et al.* (20), and more recently by Mather *et al.* (9) operating in Mode I.

The common regions in a,q space for both axial and radial stability give rise to but a single diagram, shown in Fig. 2, which is accessible experimentally. The diagram has two apices of interest, one of which lies above the q-axis and one below. For the mass filter, the stability diagram is symmetric ($a_x = -a_y$) about the q-axis and either apex may be used for mass selectivity. For the QUISTOR, the diagram is asymmetric ($a_z = -2a_r$) and although both apices may be used for mass selectivity the lower apex is preferred as it is more sharp and affords a higher possible resolution. However, when mode switching is required only the upper apex ($q_z < 0.91$) may be used, wherein relaxation of the DC component determines a point on the q-axis lying within the stability diagram. For the

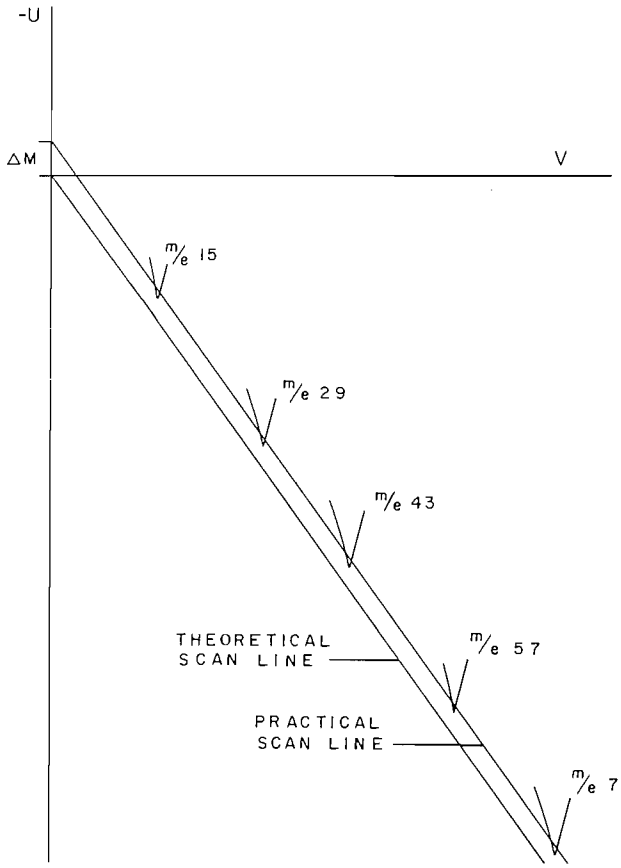

FIG. 3. Lower apices of experimental stability diagrams for five ions in U, V space. The apices are shifted by space-charge within the trap; a DC offset (ΔM) is necessary to intersect the stability diagram apex for each mass.

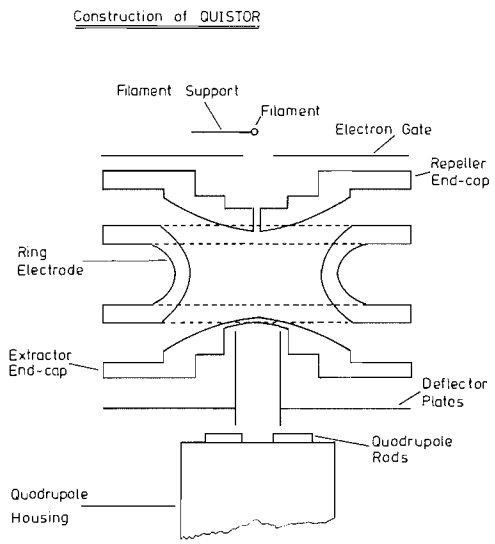

FIG. 4. A section through the QUISTOR showing the orientation with respect to the quadrupole mass filter. The QUISTOR, which is mounted on a separate flange, abuts the ion source of the mass filter. The ion source, which is not shown here, both facilitates ion transmission from QUISTOR to mass filter and provides mass calibration.

lower apex, q_z is always greater than 0.91 and relaxation of the DC component would locate a point on the q-axis lying beyond the stability diagram.

Mass selectivity in the QUISTOR may be visualized more

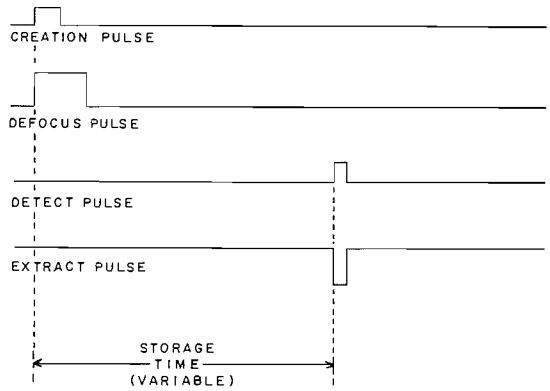

FIG. 5. DC pulse sequence for operation of the QUISTOR in the mass selective mode.

readily when the stability diagrams are plotted in terms of U and V, whereupon a stability diagram is generated for each value of m/e. In order to generate a mass spectrum, the QUISTOR is operated at a constant DC/RF ratio (and multi-pulsed fashion) such that each successive m/e value is stable within the trap as ϕ_0 is ramped, and an apex of each diagram is intersected so as to yield good peak shapes of adequate resolution. The theoretical stability diagrams are derived from consideration of a single ion in the field of the QUISTOR. In practice, may ions are stored simultaneously and the resulting space charge may induce distortion of the stability diagram (14, 21–25). The diagrams are shifted from their predicted locations, as shown in Fig. 3, so that the practical scan line does not go through the origin and does not have the predicted ratio of DC/RF of 0.28. The effect of space charge may be considered in terms of an additional DC voltage to the electrodes leading to a net change in the U coordinate in Fig. 3 and described as ΔM. Experimentally, ΔM is available as a variable parameter as is the ratio of DC/RF. It should be noted that a negative voltage for ΔM must be applied to the ring in order to compensate for the positive space charge. A DC voltage of opposite polarity is required when ΔM is applied to the end-cap electrodes.

From an examination of q_z [9], it is seen that the range of m/e values which can be stored within the useful range of q_z is inversely proportional to the physical dimensions of the QUISTOR (r_0^2) and to the drive frequency (Ω^2). Each of these parameters is examined in turn.

Experimental

The experimental arrangement is depicted in Fig. 4 wherein the QUISTOR is operated in a repetitively pulsed fashion as described elsewhere (6). A typical pulse sequence for mass-selective operation is depicted in Fig. 5. The precise separation of the QUISTOR electrodes was maintained with ruby spheres of diameter 9.5 mm countersunk into the electrodes; the spheres were obtained from the Specialty Ball Company, Rocky Hill, Connecticut, U.S.A. Electrons are produced from the heated tungsten filament which s biased at −70 V. The electron gate is held at −100 V to exclude electrons from the trap and is pulsed periodically to approximately −10 V for 50–200 μs to allow electrons into the trap which then ionize the sample molecules at a pressure of 2–4 mPa. After a predetermined storage time, positive ions are extracted through perforations in the extractor end-cap by a negative rectangular pulse of −60 V amplitude and several RF cycles duration. The ions travel between the deflector plates and then into the mass filter assembly.

In the total storage mode the deflector plates may be held at a low

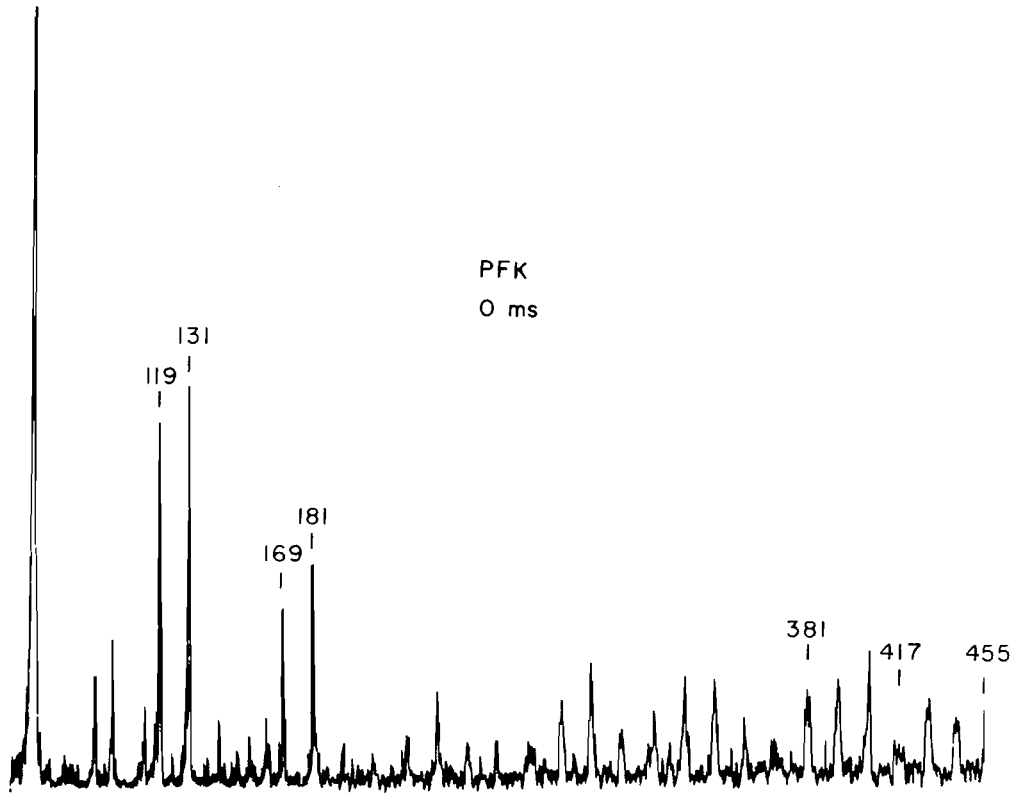

FIG. 6. QUISTOR total storage spectrum of PFK at 3 mPa pressure and 0 ms of storage. RF drive 600 V 0−p at 1.7 MHz. No applied DC (equivalent to e.i. spectrum).

positive potential (2−5 V) to focus the entire ion beam into the mass analyser. In the selective storage mode unstable ions exit the trap spontaneously during the mass sorting process, which takes several hundred microseconds, and a positive pulse (80 V) is applied to one of the deflector plates to defocus these ions and prevent them from reaching the detector. As the mass filter is not actively employed in the selective storage mode, this defocus pulse may be applied to one pair of rods to ensure that unstable ions do not reach the detector (9, 26). The trapping potential ϕ_0 is supplied to the ring electrode by an Extranuclear Laboratories Quadrupole Power Supply, Model 011-15, which was modified as proposed by Todd and co-workers (9) to enable selection of the correct U/V_0 ratios to operate at either the upper or lower apex of the QUISTOR stability envelope.

Results and discussion

Gaseous ions are trapped in the QUISTOR for periods of up to 125 ms which corresponds to the lowest pulse frequency, 8 Hz, at our disposal. Ions may be trapped in the total storage mode ($a = 0$) or mass selectively. Let us examine first the mass range of ions which may be stored simultaneously, i.e. in the total storage mode. In this mode,stored ions are ejected from the QUISTOR and analysed subsequently with a mass filter, thus determination of the range of m/e values stored simultaneously is dependent upon the mass range of the filter tandem to the QUISTOR.

Until recently the trapped ion of greatest m/e value which could be detected from the QUISTOR was $C_4F_9^+$, at m/e 219, which is one of the more abundant ions produced by electron impact of perfluorokerosene (PFK). This mass range determination was restricted by the mass range of the quadrupole mass filter (Vacuum Generator Q7B) which was nominally 200 amu.

A new quadrupole mass filter (Vacuum Generators QXK400) has been used to extend the detectable limit of the total ion storage mass range. In Figs. 6 and 7 are shown the mass spectra of ions derived from perfluorokerosene in the total ion storage mode, at 0 ms (corresponding to a normal electron impact spectrum) and after 30 ms of total ion storage, respectively. The spectrum at zero storage time can be compared with the normal mass spectrum obtained with the quadrupole mass filter as the original filament assembly of the mass filter is intact and in place, and with the calibration mass spectrum of PKF supplied by the manufacturer. Virtually all of the primary ions expected from PFK, up to m/e 455, have been observed with operation of the QUISTOR as an electron impact source. The mass spectrum obtained after 30 ms of ion storage, as shown in Fig. 7, demonstrates the ion storage capability of the QUISTOR up to m/e 455, i.e. $C_{11}F_{17}^+$, at the extreme mass limit of the QXK400. The relatively high intensities of peaks corresponding to $m/e > 380$ is extremely encouraging and indicative that the mass range of the QUISTOR in the total ion storage mode may be considerably in excess of the present observation. In this work, the QUISTOR is driven with a modified Extranuclear Laboratories 011-15 power supply and the mass filter with the QXK400 power supply. The mass range of the mass filter has been extended to approximately 800 amu when driven by the Extranuclear power supply but it is not possible to use the Extranuclear power supply to drive both the QUISTOR and the mass filter simultaneously.

Comparison of the mass spectra in Figs. 6 and 7 yields a great deal of information on the ion-chemistry of the PFK system at 2 mPa. As there is little information in the chemical literature on high molecular weight fluorocarbon ion/molecule chemistry, a brief commentary may be of interest here. $C_2F_5^+$ (m/e 119) and $C_3F_7^+$ (m/e 169) decrease rapidly in intensity

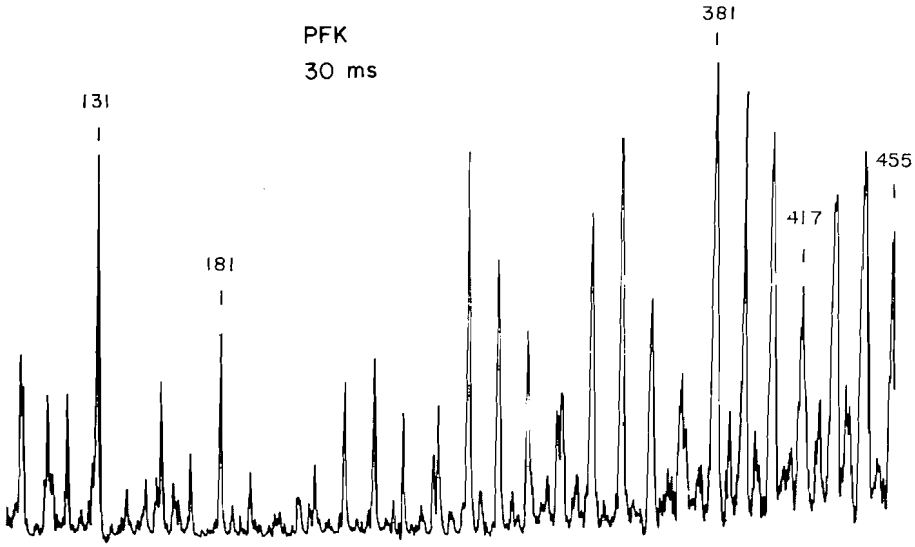

FIG. 7. Total storage spectrum of PFK after 30 ms with operating conditions as in Fig. 6.

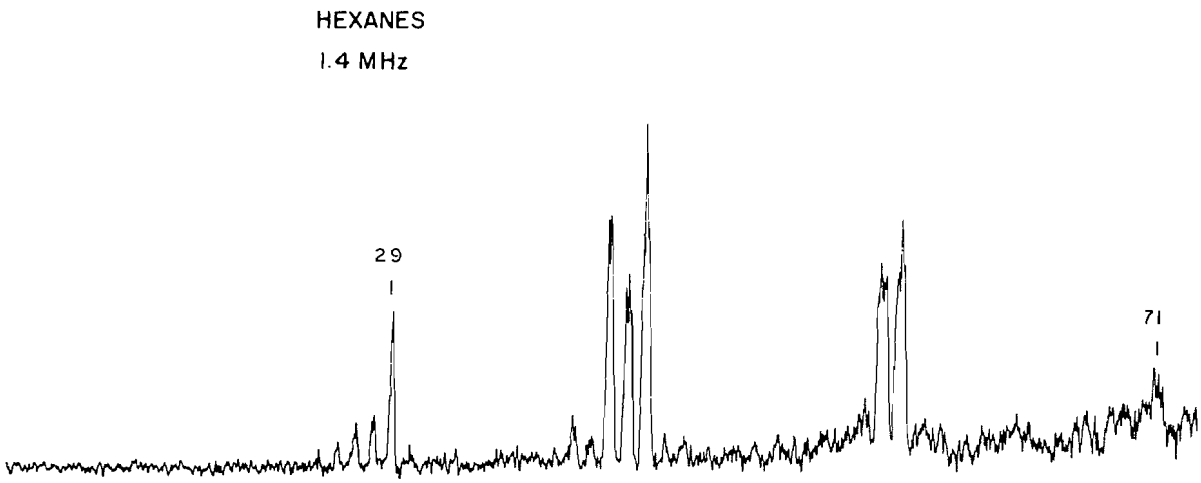

FIG. 8. Illustration of partial mass selectivity in the QUISTOR of ions derived from mixed hexane isomers. Here, the negative DC bias (ΔM) is insufficient to counteract the space-charge and the ramped DC/RF scan line fails to intersect the apices of stability diagrams for ions of low m/e ratio.

with reaction time while $C_3F_5^+$ (m/e 131) and $C_4F_7^+$ (m/e 181) increase in intensity along with $C_6F_{11}^+$ (m/e 281), $C_7F_{13}^+$ (m/e 331), $C_8F_{15}^+$ (m/e 381), and $C_9F_{17}^+$ (m/e 431). Thus there appears to be some degree of enhanced stability (or unreactivity) for ions of the type $C_nF_{2n-1}^+$. Similarly, examination of the peaks for $C_7H_{11}^+$ (m/e 293), $C_8F_{13}^+$ (m/e 343), $C_9F_{15}^+$ (m/e 393), and $C_{10}F_{17}^+$ (m/e 443) indicates a slightly diminished stability for ions of the type $C_nF_{2n-3}^+$; a further diminution in stability is observed for ions of the type $C_nF_{2n-5}^+$. In summary, the ion-chemistry as elucidated from the mass spectra in Figs. 6 and 7 shows that series of ions are formed with increasing stability such that $C_nF_{2n-1}^+ > C_nF_{2n-3}^+ > C_nF_{2n-5}^+$.

Mass selective operation of the QUISTOR has been demonstrated in the range m/e 12 (C^+) to m/e 100 ($C_7H_{16}^+$) with heptane (9), and in cylindrical devices to m/e 86 ($C_6H_{14}^+$) with hexane (26). Both the resolution of the mass spectrum, defined as $M/\Delta M$, and the intensity of each peak are extremely sensitive to the ratio of DC/RF and to the applied DC bias, ΔM. A mixture of hexane isomers was chosen for examination. The gross effects of the magnitude of ΔM and the DC/RF ratio are shown in Fig. 8; a mass spectrum extending from m/e 25–71 was obtained wherein the lower masses have not been selected. In this case the ΔM was insufficiently negative (<-0.8 V) and the DC/RF ratio too low (<0.28). The resolution at m/e 29 is ~100 and diminished to ~70 at m/e 57. In Fig. 9, ΔM is made more negative (−2 V) and the DC/RF ratio in excess of 0.30, only the ions of $m/e < 29$ are observed with good resolution though here the resolution at m/e 29 is ~150 and diminishes with m/e ratio. The diminution of resolution with m/e ratio signifies that the DC/RF is higher than ideal.

For the mass spectrum shown in Fig. 10, where ΔM was set at −0.8 V and the DC/RF ratio at 0.290, a range of masses from m/e 13–71 was selectively stored. Peaks corresponding to C_3 and C_4 ions are seen to be of much higher intensity than the remainder of the spectrum. A change in the DC/RF of 0.67% (0.290 to 0.292) produced the mass spectrum shown in Fig. 11, in which normal relative peak intensities have been restored but m/e 71 was not observed. Thus the question arises as to whether there are unique settings of ΔM and DC/RF ratio at which the potentially high resolution of which the QUISTOR ought to be capable is realizable over a range of masses. Let us examine two factors: (*i*) the magnitude of ΔM which should

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

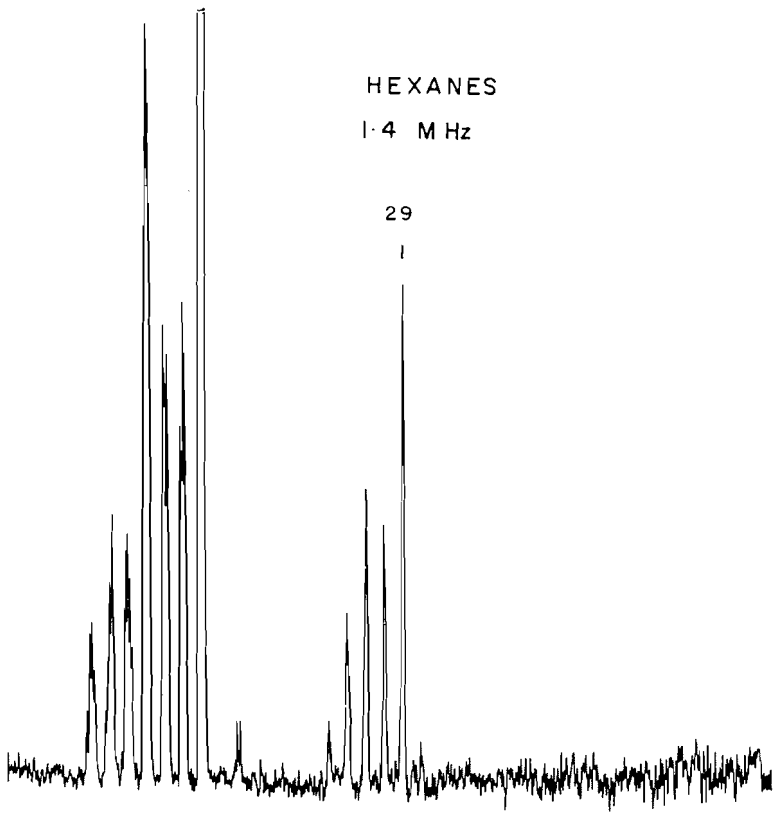

FIG. 9. As for Fig. 8, but here both the ΔM bias and the ramped DC/RF ratio are too high so that only the apices of stability diagrams for $m/e < 30$ are intersected.

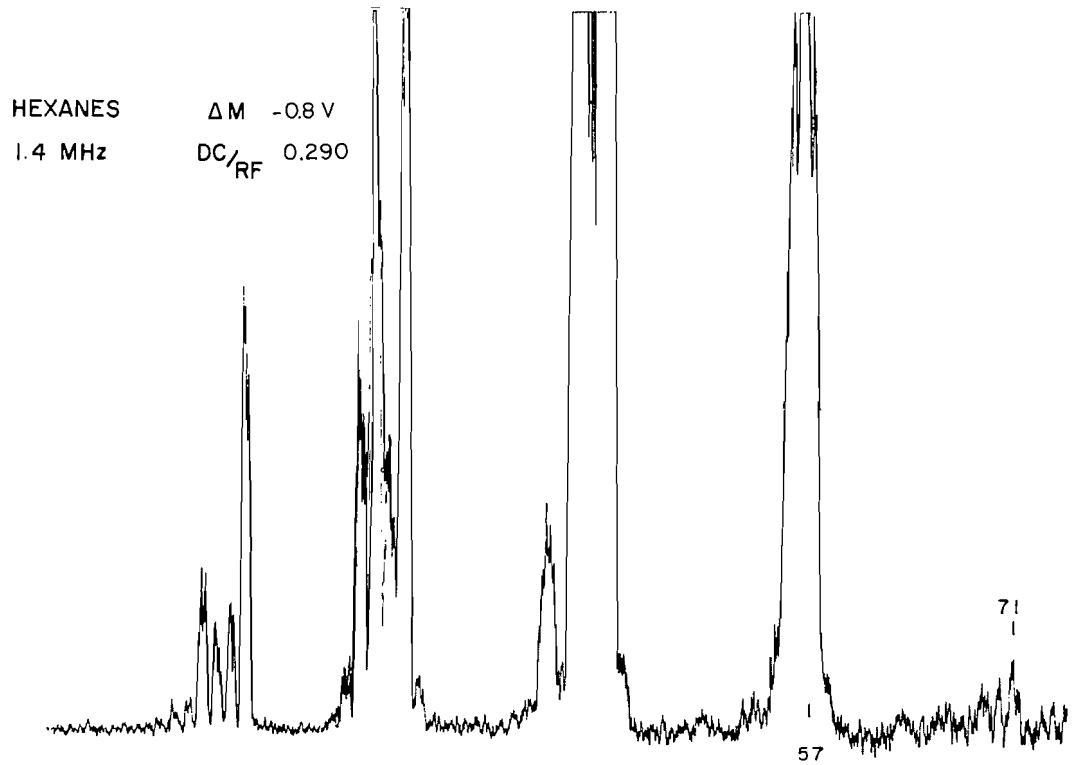

FIG. 10. Illustration of QUISTOR mass selectivity of ions derived from mixed hexane isomers over the range m/e 13−71; 2 mPa, 1.4 Mhz, $\Delta M = -0.8$ V, DC/RF = 0.290.

balance the space charge of the stored ions, and (*ii*) the degree of distortion of stability diagrams for ions of differing m/e values though of equal intensities and stored under similar conditions. Firstly, the variation in relative peak intensities in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

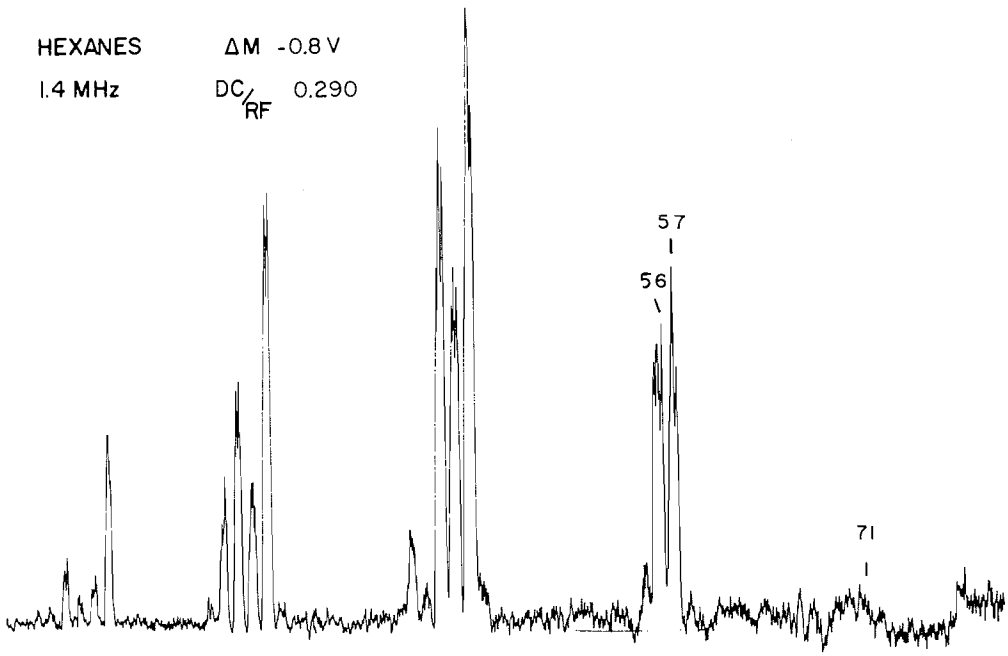

FIG. 11. As for Fig. 10 with the DC/RF ratio increased to 0.292. Resolution of the mass spectrum is considerably enhanced (cf. Fig. 10) with accompanying decrease in signal intensity.

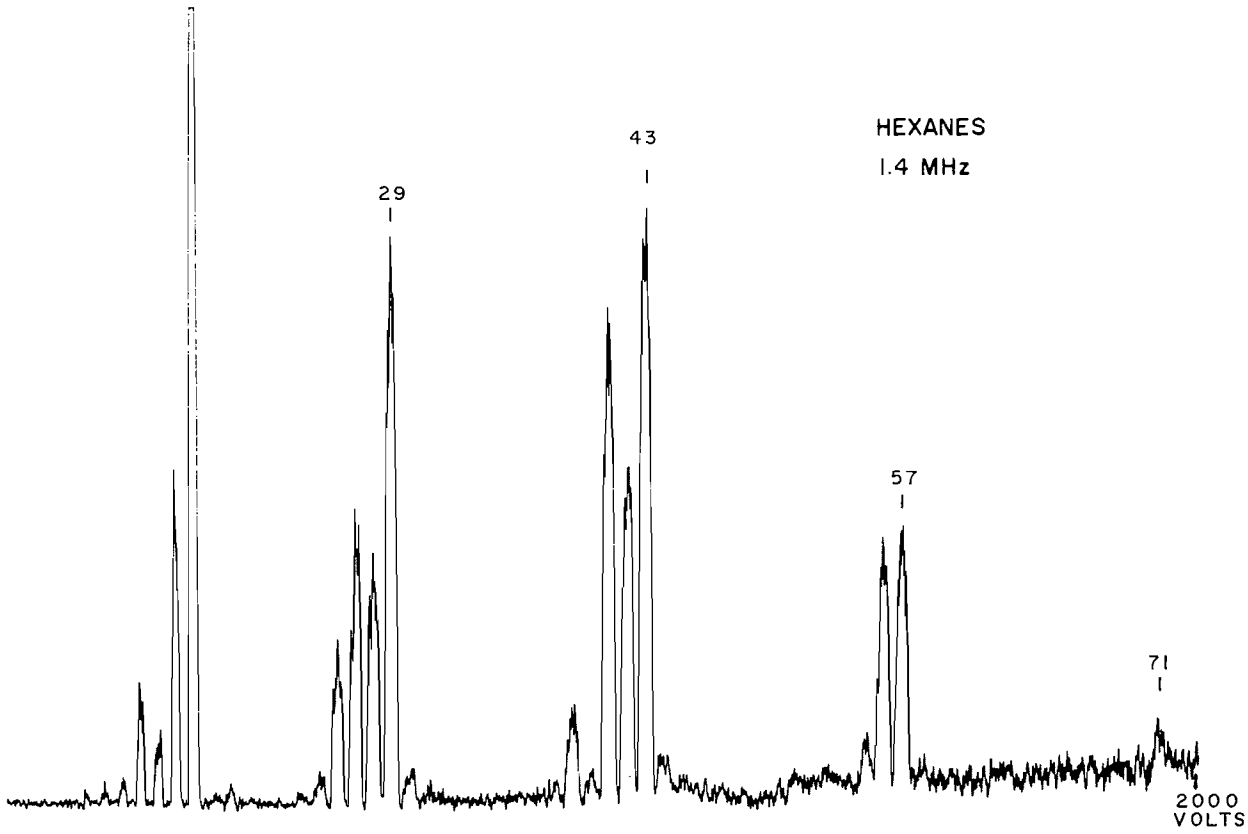

FIG. 12. Optimum mass spectum obtainable with mixed hexane isomers; 2 mPa, 1.4 MHz, $\Delta M = -1.0$ V, DC/RF = 0.293, maximum RF was 2000 V p-p, scan rate = 4 s amu^{-1}.

a normal mass spectrum would indicate that compensation for space charge should vary with m/e value. Secondly, although little experimental work (9, 26) has been carried out in this area, there is some evidence to suggest that stability diagram distortions for Ne^+ and Ar^+ are not identical under similar experimental conditions. Thus it is concluded that ultimate optimization of ΔM and DC/RF ratio would require adjustment of these parameters for each ion species. While such optimization could be achieved possibly with microprocessor control it would yield little of immediate value. Mass selective oper-

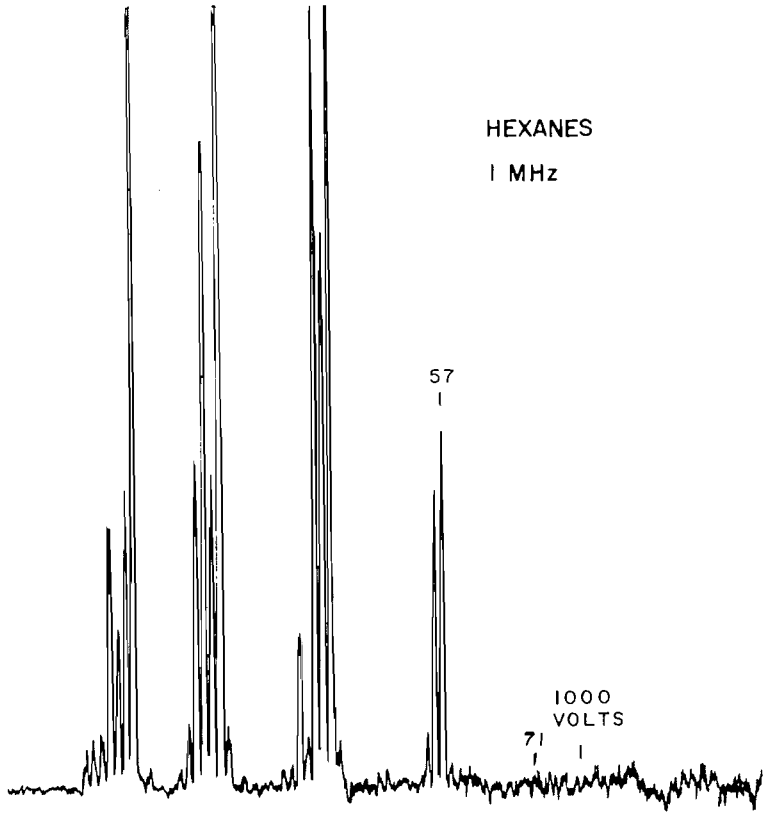

FIG. 13. As for Fig. 12. The drive frequency has been lowered to 1.0 MHz and the maximum RF was 1000 V p-p.

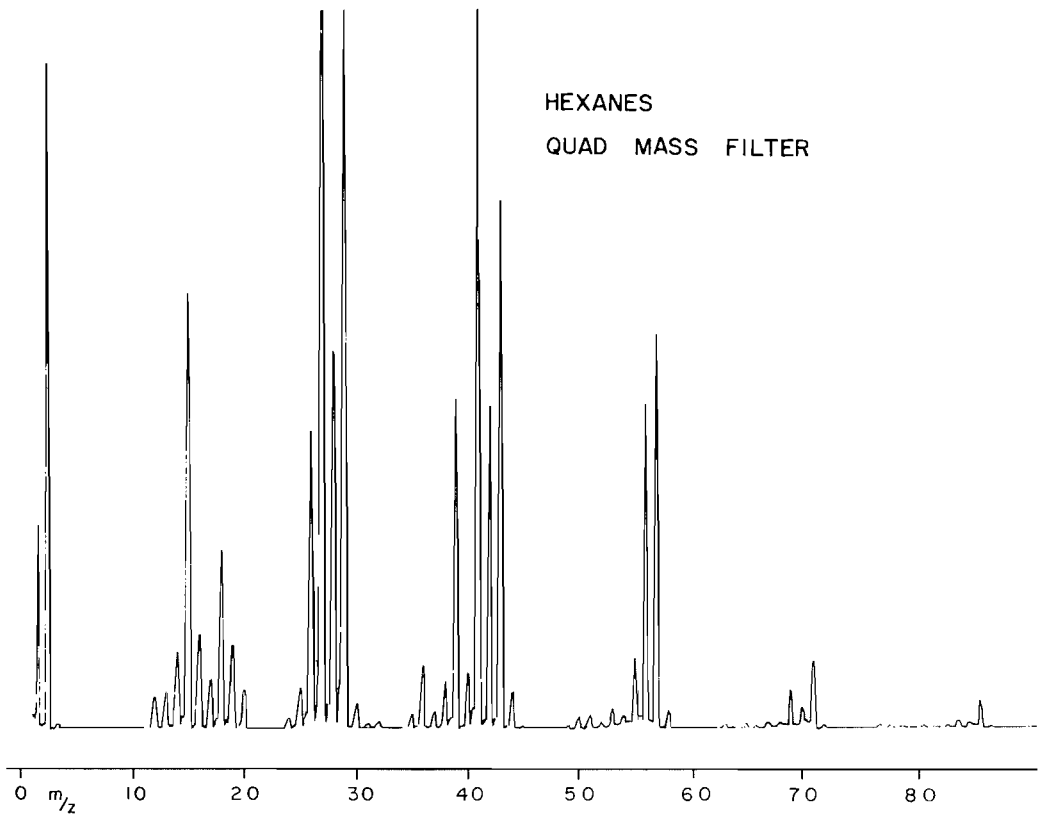

FIG. 14. Electron impact spectrum of mixed hexane isomers obtained from the VG QXK 400 quadrupole mass filter.

ation of the QUISTOR for ion photodissociation studies per se does not necessitate the generation of mass spectra. However, the optimum mass spectrum of mixed hexane isomers at a drive frequency of 1.4 MHz is shown in Fig. 12; it should be noted that m/e 71 was stored selectively with an RF voltage (0−p) of slightly less than 2000 V.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

In accordance with [7] and [8], the a_z and q_z values are inversely proportional to Ω^2, therefore when the drive frequency is reduced to 1.0 MHz the effective mass range should be doubled for a given applied voltage or a given ion should be stored selectively at half the previous voltage. This dependance is shown in Fig. 13 where m/e 71 is observed, albeit faintly at slightly less than 1000 V. The relative peak intensities of the spectrum in Fig. 13 are in good agreement with the electron impact spectrum shown in Fig. 14 which was obtained with the mass filter alone. A prominent peak at m/e 18 in these spectra is due to H_2O^+. The trace of water present served as an indicator of ion/molecule reactions during the mass sorting period which could have produced H_3O^+ at m/e 19; none was observed, hence the selectivity process is rapid.

Values for a_z and q_z are also inversely proportional to r_0^2. All of the above storage spectra were obtained with a QUISTOR for which a value of 1.0×10^{-2} m was chosen for r_0, the internal radius of the ring electrode. While some studies have been carried out with smaller QUISTORS, e.g. $r_0 = 7.0 \times 10^{-3}$ m (27) with an $(m/e)_{max} = 107$ and $r_0 \simeq 3.5 \times 10^{-4}$ m (12) with which Ba^+ ions at m/e 137 were stored, and storage capabilities of quadrupole ion traps of different sizes having cylindrical symmetry have been examined cursorily (26), no systematic examination of the mass storage range dependance on r_0 has been made. A new QUISTOR has been constructed recently in this laboratory with $r_0 = 6.0 \times 10^{-3}$ m. In the total storage mode a mass spectrum of PFK has been obtained for the range m/e 69–381 under the following conditions; 2 ms storage, 2 mPa, 1.8 Mhz, 600 V 0–p. These storage conditions correspond to values for q_z of 0.73 and 0.13 for m/e 69 and m/e 381, respectively. With the small QUISTOR in the mass selective mode, ions derived from m/e 219 are observable though of poor resolution, furthermore the peaks show marked splitting. This work is in progress.

Conclusion

We conclude that the QUISTOR is viable as a photochemical reactor for photodissociation studies of gaseous ions. The ion storage capability in the total storage mode has been shown to extend to m/e 455 and possibly beyond. Though not of direct interest to photodissociation studies, the extended mass storage capability may facilitate low pressure chemical ionization studies, pursued previously for low molecular weight compounds, to molecules of interest with higher molecular weights. The demonstrated ranges for mass selectivity are encouraging for the isolation of single ion species for irradiation.

Multiphoton dissociation of ions derived from isopropanol and deuterated analogues in a QUISTOR with low power CW infrared laser radiation[1]

RICHARD JAMES HUGHES, RAYMOND EVANS MARCH,[2] AND ALEXANDER BALDWIN YOUNG[3]
Department of Chemistry, Trent University, Peterborough, Ont., Canada K9J 7B8

Received June 30, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

RICHARD JAMES HUGHES, RAYMOND EVANS MARCH, and ALEXANDER BALDWIN YOUNG. Can. J. Chem. **61**, 834 (1983).

A versatile technique employing pulsed quadrupole ion storage mass spectrometry and a low power CW CO_2 laser for the study of slow infrared multiphoton dissociation of gaseous ions under near collision-free conditions is described. Multiphoton dissociation of gaseous ions derived from isopropanol, 2-d_1-isopropanol, isopropan-d-ol and perdeuteroisopropanol, with irradiation for up to 110 ms with intensities of ~20 W cm^{-2}, was effected. Irradiation of proton (or D^+) bound alcohol dimers showed that three dissociative reaction channels are utilized in multiphoton dissociation: the photodissociation yield for the dissociative reaction channel of lowest activation energy increases and becomes dominant with collisional and radiative relaxation of the ions. Of the three ionic photoproducts of multiphoton dissociation of proton bound alcohol dimers, only the protonated ether is found to be photodissociative under the prevailing conditions. The photochemical stability of the ion formed by loss of the elements of propene from the proton bound alcohol dimer contrasts sharply with the multiphoton dissociation of the proton bound alcohol–water mixed dimer, and serves to demonstrate the applicability of multiphoton dissociation to distinguish between gaseous ion isomers.

The large extent of dissociation observed with low laser fluence is indicative of both the rapid collisionally-induced migration of ions to the centre of the QUISTOR (and hence the laser beam) and also the predominance of multiphoton absorption over radiative and collisional deactivation processes in the time and pressure domains employed here.

RICHARD JAMES HUGHES, RAYMOND EVANS MARCH et ALEXANDER BALDWIN YOUNG. Can. J. Chem. **61**, 834 (1983).

On décrit une technique versatile qui utilise la spectrométrie de masse à emmaganisage d'ion quadrupolaire pulsé et un laser CW à CO_2 à faible puissance pour étudier la dissociation multiphoton infrarouge d'ions à l'état gazeux dans des conditions pratiquement sans collisions. On effectue la dissociation multiphoton des ions gazeux provenant de l'isopropanol, de l'isopropanol *O*-*d*, de l'isopropanol *d*-2 et du perdeutéroisopropanol avec une irradiation allant jusqu'à 110 ms et des intensités d'environ 20 W cm^{-2}. L'irradiation d'alcools dimères liés par le proton (ou D^+) a montré que trois voies de réaction dissociatives sont utilisées dans la dissociation multiphoton; le rendement de la photodissociation de la voie de réaction dissociative de plus faible énergie d'activation augmente et devient prépondérant avec la relaxation collisionnelle et radiative des ions. Des trois photoproduits ioniques de la dissociation multiphoton des alcools dimères liés par le proton, on a trouvé que seul l'éther protoné peut être photodissocié dans les conditions existantes. La stabilité photochimique de l'ion formé par suite de la perte des éléments du propène à partir de l'alcool dimère lié par le proton contraste nettement avec la dissociation multiphoton du dimère mixte alcool–eau lié par le proton et sert à démontrer la validité de la dissociation multiphoton dans la distinction des isomères d'ions gazeux.

Le fort taux de dissociation observé avec un laser de faible puissance est une indication de la migration rapide induite par collision des ions vers le centre du QUISTOR (et par conséquent la faisceau du laser) et également de la prédominance de l'absorption multiphoton sur les processus de désactivation radiative et collisionnelle dans les domaines de temps et de pression.
[Traduit par le journal]

Introduction

The characterization of intramolecular relaxation subsequent to photochemical excitation requires near collision-free conditions for study; in general, single species chemistry of a molecule or ion cannot be ascertained unambiguously unless the mean time between collisions is greater than that required for excitation and for unimolecular decomposition. Recently, methods have been developed for studying the infrared (ir) multiphoton photochemistry of gas-phase ions under near collision-free conditions, using pulse ion cyclotron resonance (ICR) spectroscopy (1, 2).

Brauman and co-workers (1) have used a pulsed CO_2 laser to study the photophysics of megawatt ir multiphoton dissociation and to probe vibrational relaxation in gas-phase ions. Beauchamp and co-workers (2) have demonstrated that, as dissociation probabilities of *isolated* molecules depend only on energy fluence and not on peak laser power (3), a relatively low power CW CO_2 laser (several watts) can effect dissociation processes in gaseous ions provided that an ion is irradiated for sufficiently long times under nearly collision-free conditions. Among the early studies of ion photodissociation originating from Dehmelt's laboratory in the 1960's (4) were a few studies on the photodissociation of H_2^+ and CH_4^+ carried out using radio-frequency quadrupole traps (5). The application of such a quadrupole ion store (QUISTOR) has been extended now to slow ir multiphoton induced dissociation of gaseous ions. Photodissociation of the protonated dimer of 2-propanol, which was reported earlier (6), was achieved by the absorption of 11 photons in the ir region. A comparison of the characteristics of the QUISTOR with those of ICR is presented in the accompanying paper (12); while the two techniques are similar, ions stored in the QUISTOR are concentrated at the centre of the quadrupole field which has both axial and radial symmetry, and ion photodissociation studies are carried out at 8–10 Hz compared to 1 Hz with ICR.

In view of the extensive work of Bomse and Beauchamp (2*c*) on the multiphoton dissociation of proton bound alcohol dimers, isopropanol was selected for initial study in the QUISTOR and the study was extended to an examination of unimolecular reaction energetics in deuterated analogues of isopropanol. Infrared multiphoton dissociation has been employed (2*f*, *g*) in order to distinguish between structural isomers of gaseous ions, and this technique has been used here to distinguish between a protonated alcohol–water cluster ion and the ion formed by loss of alkene from a proton bound alcohol dimer.

The ion/molecule reactions of protonated aliphatic alcohols have been studied in some detail, with particular emphasis given to isopropanol using ion cyclotron double resonance (7, 8) and by the application of resonance ion ejection to quadrupole ion-storage mass spectrometry (9). Well-characterized bimolecular processes occur in the isopropanol system whereby reaction intermediates are readily prepared as stable species. Primary ions (particularly *m/z* 43) formed by electron impact react with neutral isopropanol molecules to form protonated isopropanol, $(CH_3)_2CHOH_2^+$, *m/z* 61, which reacts further with isopropanol to form the activated protonated dimer, *m/z* 121:

$$[1]\quad \underset{m/z\ 61}{(CH_3)_2CHOH_2^+} + (CH_3)_2CHOH \rightarrow \underset{m/z\ 121}{[(i\text{-}C_3H_7OH)_2H^+]^*}$$

The activated proton bound isopropanol dimer may dissociate back to reactants, or be collisionally or radiatively stabilized

$$[2]\quad [(i\text{-}C_3H_7OH)_2H^+]^* \xrightarrow[-h\nu]{M} \underset{m/z\ 121}{(i\text{-}C_3H_7OH)_2H^+}$$

where M is a neutral isopropanol molecule. Alternatively, H_2O may be eliminated to form a protonated ether

$$[3]\quad \left(\underset{m/z\ 121}{(i\text{-}C_3H_7OH)_2H^+}\right)^* \longrightarrow \underset{m/z\ 103}{(i\text{-}C_3H_7)_2OH^+} + H_2O$$

or propene may be lost

$$[4]\quad \left(\underset{m/z\ 121}{(i\text{-}C_3H_7OH)_2H^+}\right)^* \longrightarrow \underset{m/z\ 79}{(i\text{-}C_3H_7OH)H^+(OH_2)} + C_3H_6$$

In the absence of other specific data, the enthalpy change for [1] is assumed to be comparable to the measured enthalpy changes for the analogous reaction of H_3O^+, $CH_3OH_2^+$, and $(CH_3)_2OH^+$ (10). The activation energies for [3] and [4] are not known, though [3] is reported as the decomposition pathway of minimum activation energy (2*c*). Multiphoton dissociation of the proton bound dimer of isopropanol was induced in order to demonstrate the application of the QUISTOR for single ion photochemistry studies.

Experimental

Although the apparatus has been described in detail previously (6) and in the accompanying paper, some modifications have been made. The laser diffraction grating is replaced by a plane gold surfaced mirror and is thus operating at 944 cm^{-1} for all experiments. The laser power is monitored by a homemade thermocouple device mounted outside the second sodium chloride window. The output of the thermocouple is displayed on a microvoltmeter (Digitec 268) and recorded on a chart recorder (Leeds and Northrup, Speedomax W). The thermocouple output is calibrated to the laser power using a Laser Power Probe (Optical Engineering Inc.). Beam shape is monitored by burning business cards. The QUISTOR/tank/pump assembly is portable and mounted on four adjustable feet. Maximum laser intensity within the QUISTOR is achieved by adjustment of the assembly while the extent of dissociation of the protonated dimer of 2-propanol is monitored.

The time scale of the experiment, typically 100 ms, is provided by a square wave generator (Heathkit model SG18A) also driving a mechanical chopper (PAR 222), which is phase locked to the input signal. The beam is chopped such that a dark period precedes the irradiation period with the duration of each being equal. The square wave generator also triggers the creation pulse (Hewlett Packard Pulse Generator, Model 214A) which in turn triggers the extraction pulse (Hewlett Packard, Model 214B) which is advanced by ~1 ms. The creation pulse (80 V, 90 μs) is applied to an electron gate situated between the filament and the top end cap. The gate is normally held at −90 V to bar electrons from the trap. The extraction pulse (−50 V, 10 μs) triggers a scan delay generator (Ortec Brookdeal Model 9425) which provides a trigger, or detection pulse of 100 μs width, 90 μs after the extraction pulse. The detection pulse drives a Linear Gate (Ortec Brookdeal Model 9415). The QUISTOR is operated in mode II as described in the accompanying paper, the RF potential (typically 500–550 V) being supplied by an Extranuclear Laboratories Quadrupole Power Supply, Model 011-15, modified for QUISTOR storage work. Following irradiation, product ions are mass analyzed by a quadrupole mass filter (Vacuum Generators, QXK 400) either by running a complete mass spectrum or, in this work, by single monitoring. The pulse sequence is shown in Fig. 1.

In those experiments in which Quadrupole Resonance ejection was employed, the output signal of the chopper triggers a toneburst (Wavetek, Model 134) applied to the top end cap concomitant with the laser irradiation period. The toneburst of a chosen frequency resonantly ejects ions of a particular mass-to-charge ratio. The ions ejected in this work are either the protonated (or D^+) parent alcohol or the proton (or D^+) bound dimer of the alcohol.

In studies of dissociation pathways, a third pulse generator (Berkely Nucleonics Corp., Model 8010) is used. In this work, the square wave output is used to trigger the BNC pulse generator which in turn triggers the creation pulse. The extraction pulse is triggered also by the square wave output (negative slope). This mode of triggering allows the creation pulse to be advanced to any position within the 100 ms time frame of the experiment.

The ion structure experiments are performed in two ways, the first being a resonant ejection of *m/z* 121, the protonated dimer of isopropanol, with concurrent laser irradiation while monitoring the behaviour of *m/z* 79, the postulated proton bound dimer of water and isopropanol. In the second set of experiments, *m/z* 83 is synthesized *in situ* by clustering D_2O molecules and deuteronated isopropan-*d*-ol ions. At low pressures (0.7 to 1 mPa) clustering is favoured, whereas at higher pressures (5 mPa) *m/z* 82 is produced via unimolecular dissociation of *m/z* 124, the deuterated analogue of the proton bound dimer of isopropanol.

Some of the isopropanol experiments are performed using pulse sequences previously described (1). All regions labelled Laser On refer to the mechanically chopped laser previously described, whereas Continuous Laser refers to laser irradiation for the total duration of the experiment.

Isopropan-*d*-ol was purchased from Aldrich; perdeuteroisopropanol and 2-d_1-isopropanol were obtained from Merck, Sharp and Dohme. The samples were used without further purification, other than degassing by several freeze/thaw pumping cycles prior to an experiment.

Results and discussion

Bomse and Beauchamp have reported (2*c*) that at pressure $<4 \times 10^{-2}$ mPa ir multiphoton dissociation of the proton bound dimer of isopropanol, $(ROH)_2H^+$ where R is i-C_3H_7, occurs principally by

$$[5]\quad \underset{m/z\ 121}{(ROH)_2H^+} + nh\nu \longrightarrow \underset{m/z\ 103}{R_2OH^+} + H_2O$$

and that the alternate dissociation pathways

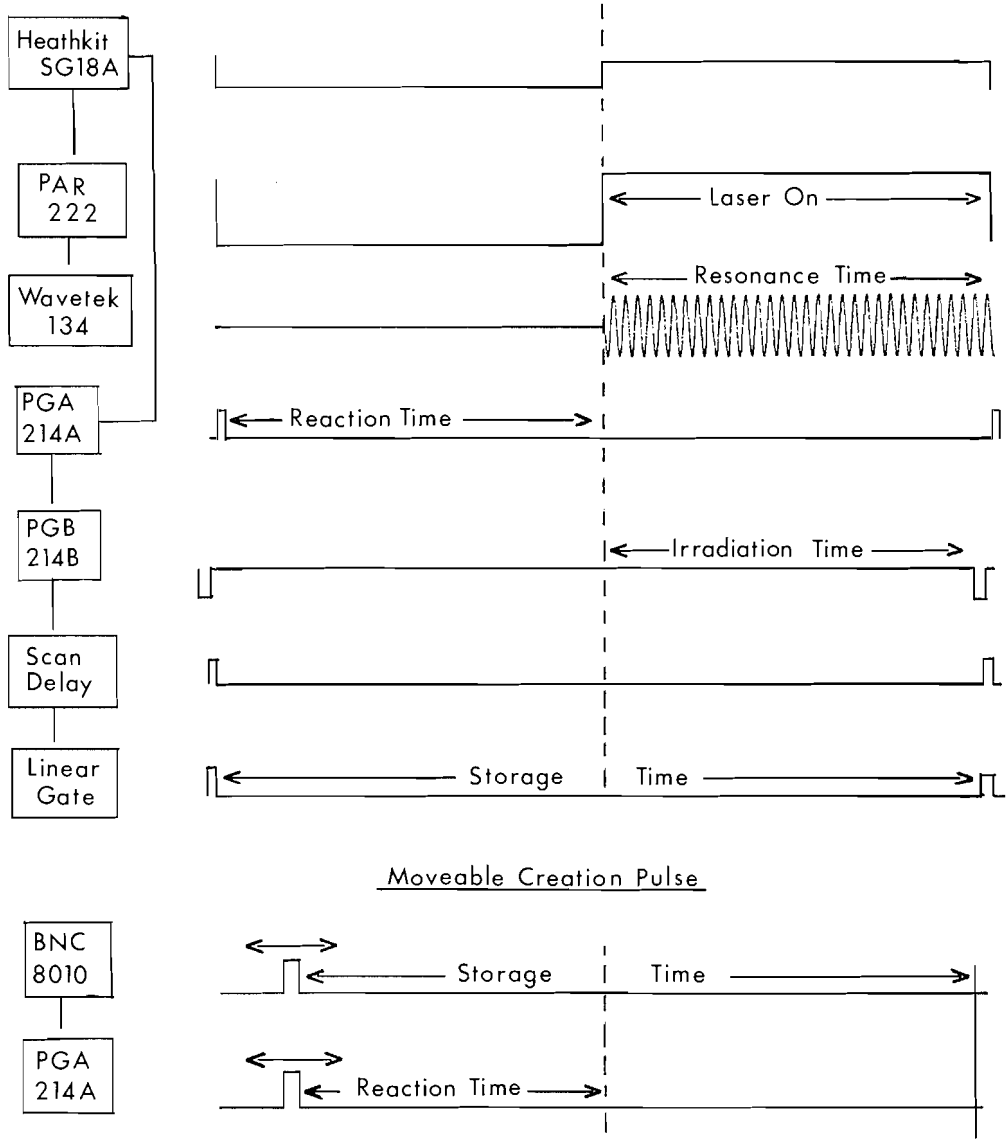

FIG. 1. Pulse sequence used in single ion monitoring with typically 100 ms of ion storage, 50 ms of laser irradiation concurrent with resonance ejection. The appended moveable creation pulse was employed in studies of multiple dissociation pathways induced by multiphoton absorption with respect to variation in internal energy of the irradiated ion.

$$[6]\quad \underset{m/z\ 121}{(ROH)_2H^+} + n'h\nu \longrightarrow \underset{m/z\ 61}{ROH_2^+} + ROH$$

where $n' = 11$, and

$$[7]\quad \underset{m/z\ 121}{(ROH)_2H^+} + n''h\nu \longrightarrow \underset{m/z\ 79}{(ROH)H^+(OH_2)} + C_3H_6$$

together account for not more than 2% of the photodissociated $(ROH)_2H^+$. In apparent contrast with these findings, multiphoton dissociation of $(ROH)_2H^+$ in the QUISTOR at a pressure of 5.3 mPa showed that all three reaction pathways [5], [6], and [7] were open. As the pressure and cycling frequency of the ICR technique are not readily obtained with the QUISTOR, a more circuitous study was carried out in order to verify the observations and to attempt a reconciliation of the conclusions.

In Fig. 2 are shown two single ion monitoring traces of the abundance of proton bound alcohol dimer, m/z 121, throughout the reaction time range 60–100 ms, at a pressure of 5.3 mPa. Resonance ejection of the precursor ion, m/z 61, was initiated at 55 ms reaction time. The upper trace, marked toneburst (m/z 61), shows that the rate of formation of proton bound dimers, m/z 121, is diminishing during the time 60–80 ms due to relatively gentle removal of precursor ion; a maximum abundance is reached at ~80 ms followed by a slow decline in abundance due mainly to ion losses by ion–ion and ion–neutral scattering processes.

The lower trace, marked chopped laser, shows the abundance of m/z 121 under the same conditions of storage but with resonance ejection of precursor after 55 ms of reaction time, concurrent with laser irradiation for up to 55 ms, at the conclusion of which the cycle is recommenced; thus the thermal (or dark) and irradiation periods were of equal duration. Irradiation was carried out with a CW CO_2 laser of 20 Wcm^{-2} at 944 cm^{-1}. The increasing reduction in abundance of m/z 121 throughout the irradiation period shows the degree of photodissociation of the proton bound dimer. The inset in the lower right hand corner of Fig. 2 is illustrative of the technique by which changes in ion abundance (diminution or enhancement) upon laser irradiation of the system is monitored at a specific reaction

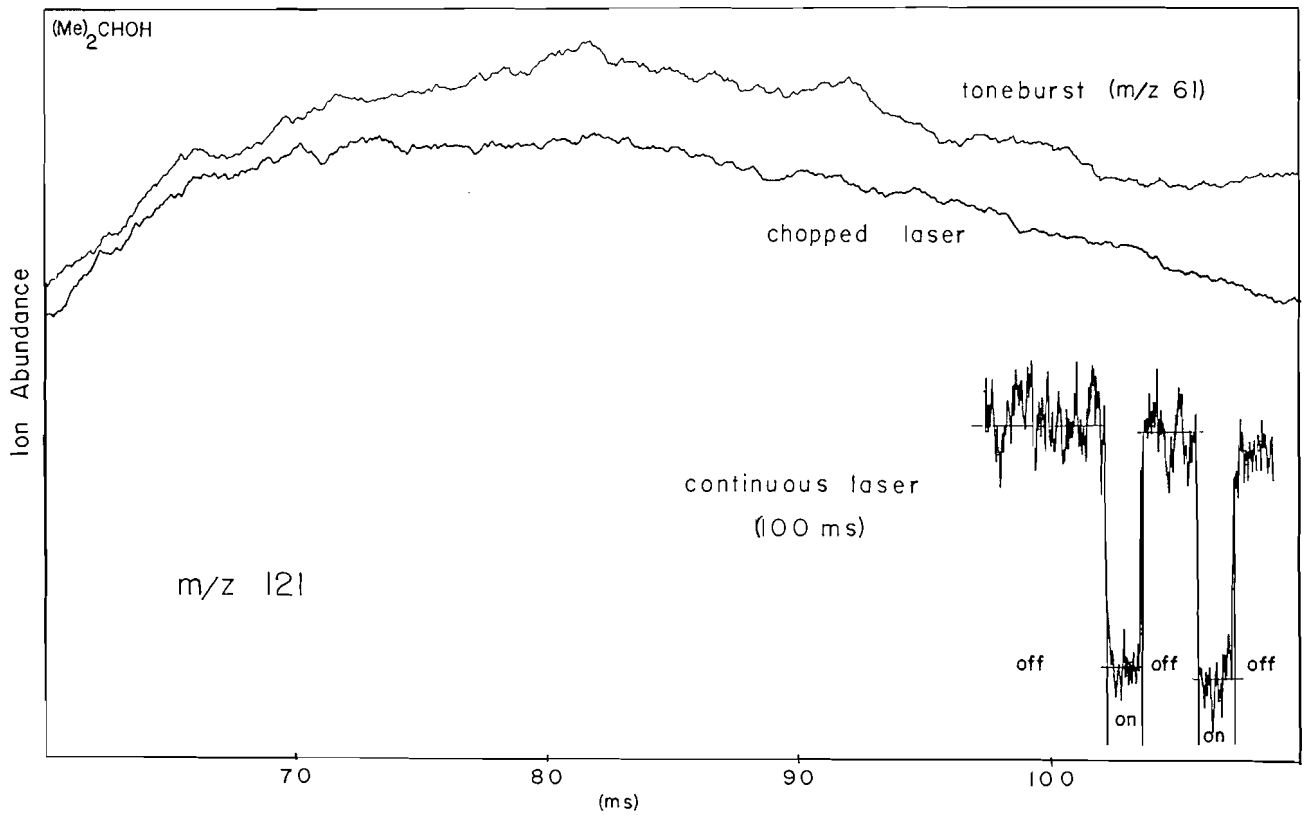

FIG. 2. Ion abundance versus storage time profiles of proton bound alcohol dimer, m/z 121, derived from ion/molecule reactions in isopropanol. Toneburst is QUISTOR resonance ejection (QRE) of m/z 61, the protonated parent alcohol precursor of m/z 121, commencing at 55 ms of storage time. Chopped laser refers to 55 ms of storage followed by 55 ms of laser irradiation with concurrent resonance ejection of m/z 61. Continuous laser refers to irradiation throughout 100 ms of storage time. CW CO_2 laser irradiation of 20 W cm^{-2} at 944 cm^{-1}. All experiments were performed at 5.3 mPa.

time; the baseline which is recorded routinely is not shown here. The observations of m/z 121 abundance shown in the inset were obtained after 100 ms of storage time. The signal intensity due to the steady state attained through the thermal reactions [1]–[4] was monitored initially and designated "off" in that the laser was not employed. During the next several ion creation, storage, reaction, and sampling cycles the laser was "on" continuously during the reaction time of 100 ms, and the ion abundance was reduced due to diminution of the steady state concentration on account of additional photochemical removal processes such as [5]–[7]. Successive thermal steady state abundances shown in the inset show a gradual decline in signal intensity; this effect is due to a diminution in pressure in the QUISTOR caused by heating of the device during continuous irradiation. The effect is more pronounced with a new small QUISTOR, $r_o = 6.0 \times 10^{-3}$ m, as described in the accompanying paper; allowance for the heating of the device was made subsequently.

As photodissociation of the proton bound dimer, m/z 121, was effected with the laser at 944 cm^{-1}, an examination was made of the possible involvement of each of reactions [5]–[7], in turn, and the results are shown in Figs. 3–5, respectively. In Fig. 3, the ion abundance of the protonated ether, m/z 103, over the same reaction time and conditions as for Fig. 2 is shown. The upper and lower traces from the single ion monitoring experiments are similar in profile; the lower trace, marked toneburst m/z 61, is remarkably similar to the corresponding trace for m/z 121 in Fig. 2. The resonance ejection of the precursor ion, m/z 61, initiated at 55 ms of storage causes a falloff in the rate of formation of m/z 103; a maximum abundance at ~90 ms is observed followed by an indication in the next 20 ms of ion loss processes. The time-delayed maximum is as anticipated in that the resonantly ejected m/z 61 ion is a precursor but once removed in that m/z 121 is the immediate precursor of m/z 103. The upper trace was obtained under the same conditions of pressure and resonance ejection of m/z 61 after 55 ms; laser irradiation was initiated after 55 ms (concurrent with resonance ejection). There is a small but significant difference in the upper and lower single ion monitoring traces showing that the abundance of m/z 103 is increased upon laser irradiation, as expected, and that reaction [5] is operative. The inset shown in Fig. 3 is similar to that of Fig. 2; though the signal is noisy the enhancement of the m/z 103 signal intensity upon irradiation is clearly evident.

In Fig. 4 are shown single ion monitoring traces of protonated isopropanol, m/z 61. The trace marked toneburst (m/z 61) illustrates the steady diminution of the m/z 61 ion signal upon gentle resonance ejection; the ions may be ejected more rapidly by increasing the peak-to-peak voltage of the radio-frequency toneburst shown in Fig. 1. The trace marked normal is that of the unperturbed thermal ion abundance showing a steady decline with time as m/z 61 is consumed through, for example, reaction [1]. The top trace shows an enhancement of m/z 61 upon laser irradiation after 60 ms of storage; the increase in m/z 61 was observed also upon continuous irradiation throughout 100 ms of storage as shown in the inset in Fig. 4. Thus reaction [6] is observed to be operative, showing that a minimum of 11 photons (not allowing for collisional deacti-

vation or radiative loss) have been absorbed by the proton bound alcohol dimer.

Reaction [7] was then examined. Chemically activated proton bound alcohol dimer ions formed in [1] may lose an alkene neutral (C_3H_6) as in [4] to produce the m/z 79 ion which may be tentatively identified as a proton bound mixed dimer of isopropanol and water. The lower traces each marked toneburst (m/z 61) in Fig. 5 show that the m/z 79 ion abundance profile

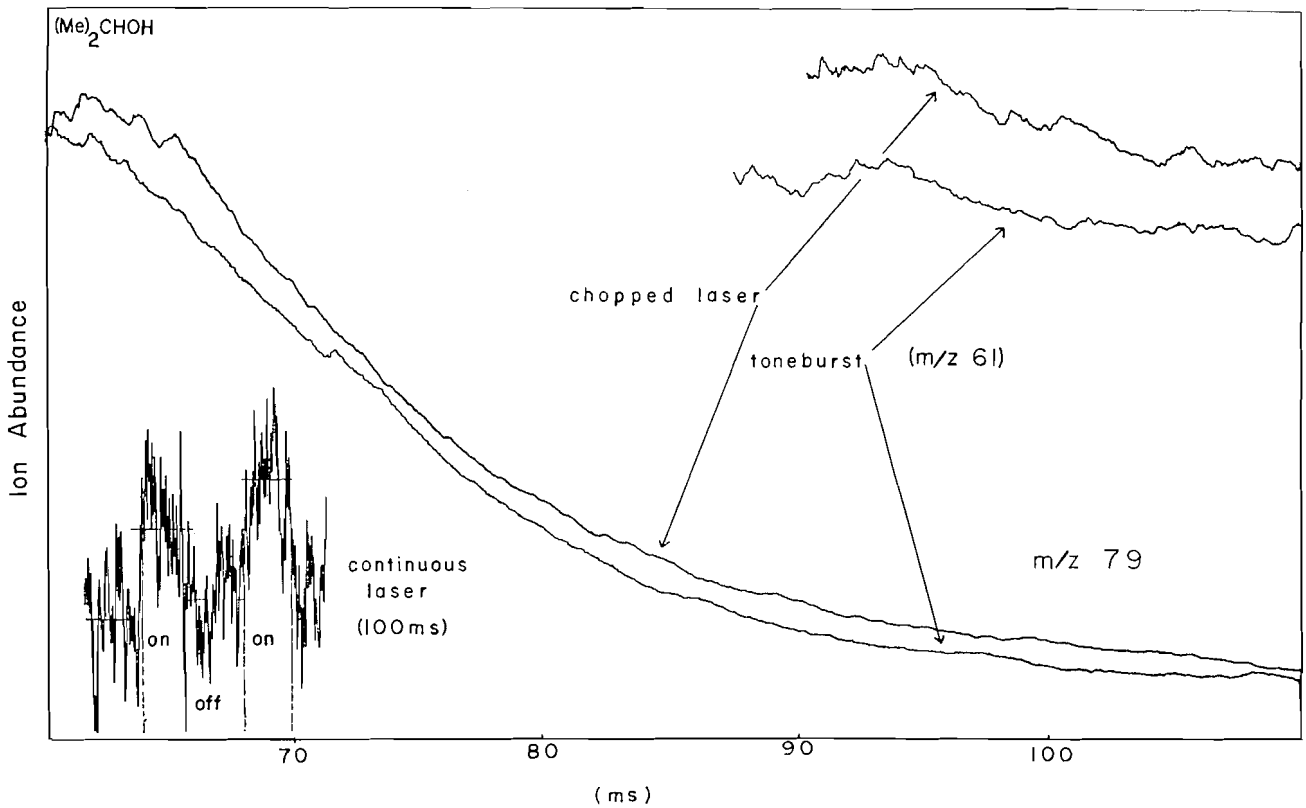

FIG. 5. Ion abundance versus storage time profiles of m/z 79. Conditions as for Fig. 2.

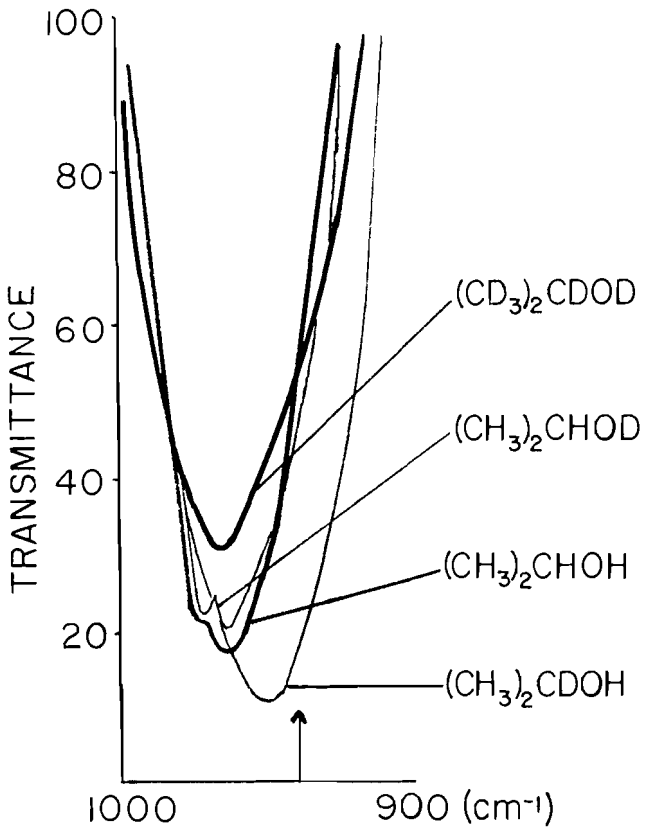

FIG. 6. Single photon infrared absorption spectrum in the range 1000 to 900 cm^{-1} for isopropanol, isopropan-d-ol, 2-d_1-isopropanol, and perdeuteroisopropanol. Vertical arrow marks laser wavelength.

matches closely that of m/z 61 marked toneburst in Fig. 4; this is as expected. The toneburst or resonance ejection of m/z 61 was initiated after 55 ms of storage. The traces in the top right hand corner of Fig. 5 are amplified by a factor of 6 to show more clearly the effect of chopped laser irradiation. The upper curves marked chopped laser show an enhancement of m/z 79 upon laser irradiation concurrent with resonance ejection of m/z 61. This effect is seen also upon continuous irradiation for 100 ms as shown in the inset in Fig. 5. Thus it appears that reaction [7] is operative, that photodissociation of the proton bound alcohol dimer under these operating conditions follows all three reaction channels described by reactions [5]–[7].

Multiphoton absorption by gaseous ions appears to occur at laser wavelengths corresponding to absorption in the single photon absorption ir spectrum. The ir absorption spectra in the vicinity of 944 cm^{-1} were obtained for isopropanol and its deuterated analogues, 2-d_1-isopropanol, isopropan-d-ol, and perdeuterated isopropanol, and are shown in Fig. 6. The spectra were obtained with a Perkin–Elmer 700 ir spectrophotometer under conditions of saturated vapour pressure of each alcohol and in a thermally equilibrated gas cell. Each of the isopropanols shows strong absorption at 944 cm^{-1}, hence each deuterated analogue was examined in turn in order to determine the relative weights for the reaction pathways corresponding to reactions [5]–[7]. The observations, obtained at 5.3 mPa, are reported in Table 1 as *changes* in ion abundance for each of the major ions, wrought initially by laser irradiation and subsequently by laser irradiation concurrent with resonance ejection of the appropriate proton (or D^+) bound alcohol dimer. The data for isopropan-d-ol are incomplete. The extent of photodissociation for each of the dimer ions formed from isopropanol, 2-d_1-isopropanol and perdeuterated isopropanol is in

[a]Change in ion abundance from that observed after 100 ms of storage to that observed after 100 ms of storage with laser irradiation during the final 50 ms. Parentheses indicate a decrease in ion abundance.

[b]As for footnote *a* but with resonance ejection of the appropriate proton bound alcohol dimer concurrent with laser irradiation.

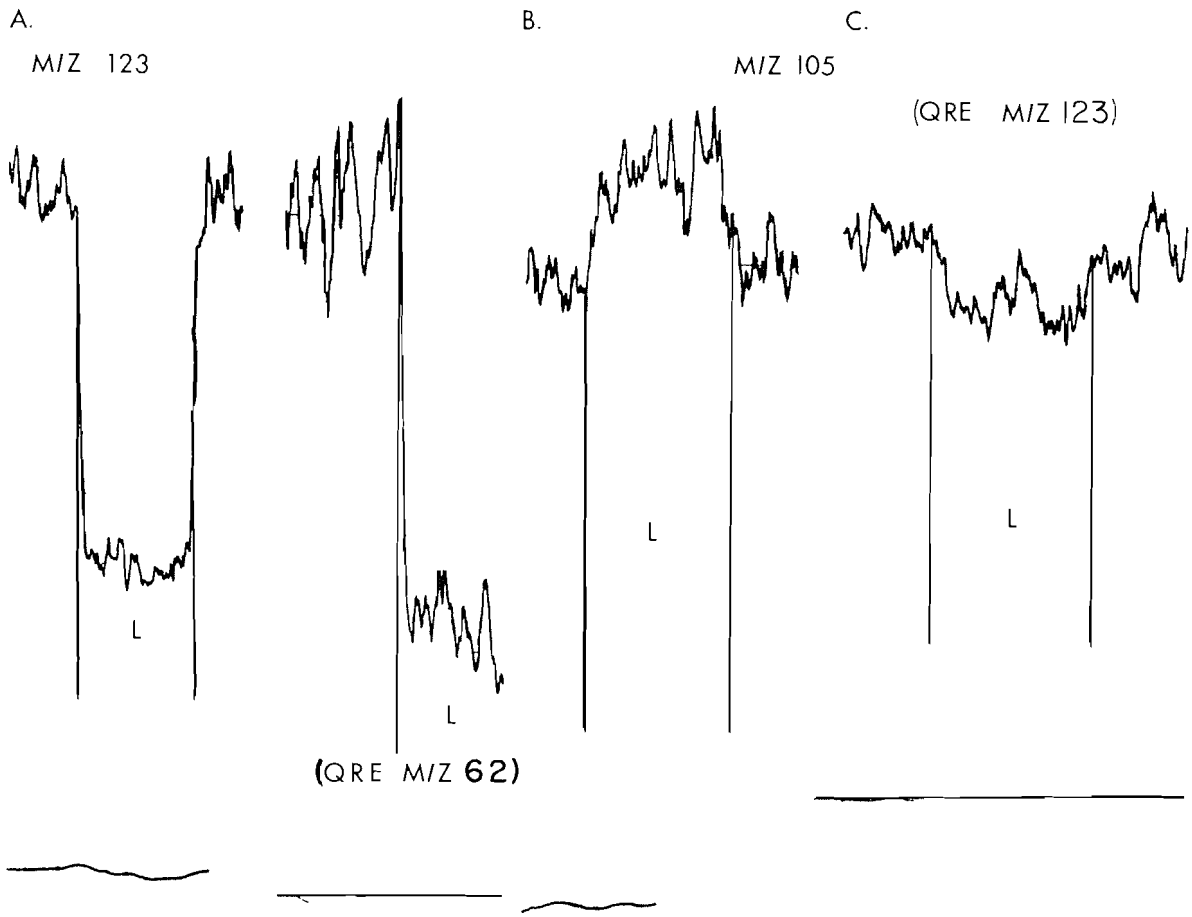

FIG. 7. Single ion monitored abundances of ions derived from 2-d_1-isopropanol, at 5.3 mPa. L refers to 50 ms of storage followed by 50 ms of CW CO_2 laser irradiation of 20 W cm^{-2} at 944 cm^{-1}. A: protonated dimer of 2-d_1-isopropanol, m/z 123, followed by irradiation concurrent with QUISTOR resonant ejection (QRE) of m/z 62; B: protonated ether, m/z 105; C: m/z 105, irradiated concurrently with resonant ejection of m/z 123. Baseline as indicated.

reverse order to that anticipated from the single photon absorption spectra shown in Fig. 6. The variation in the extent of photodissociation appears to be real in that photolysis of proton bound mixed alcohol dimers produces intermediate yields. This work will be reported in more detail when completed.

Zero change in ion abundance for m/z 118 in perdeuteroisopropanol was observed initially, and thus it appeared that [5] was not an available reaction channel in this system in contrast with isopropanol and 2-d_1-isopropanol. However, irradiation of m/z 118 in the absence of m/z 138 brought about a decrease in ion abundance as shown in Table 1. This behaviour is explained in the text following.

In all of the above experiments, it has been assumed that only photon absorption by the proton bound dimer is of importance. Photon absorption and subsequent photoexcitation of neutral molecules can be ignored as the residence time of neutrals in the laser beam is extremely short (~10 μs). Photoexcitation of protonated alcohol, m/z 61, can be ignored when m/z 61 is resonance ejected rapidly. Photoexcitation of the remaining species of importance, m/z 79 and m/z 103, was explored, together with the corresponding ions derived from the deuterated analogues.

In Fig. 7 are shown single ion monitoring traces of ions derived from 2-d_1-isopropanol. The two traces marked A are

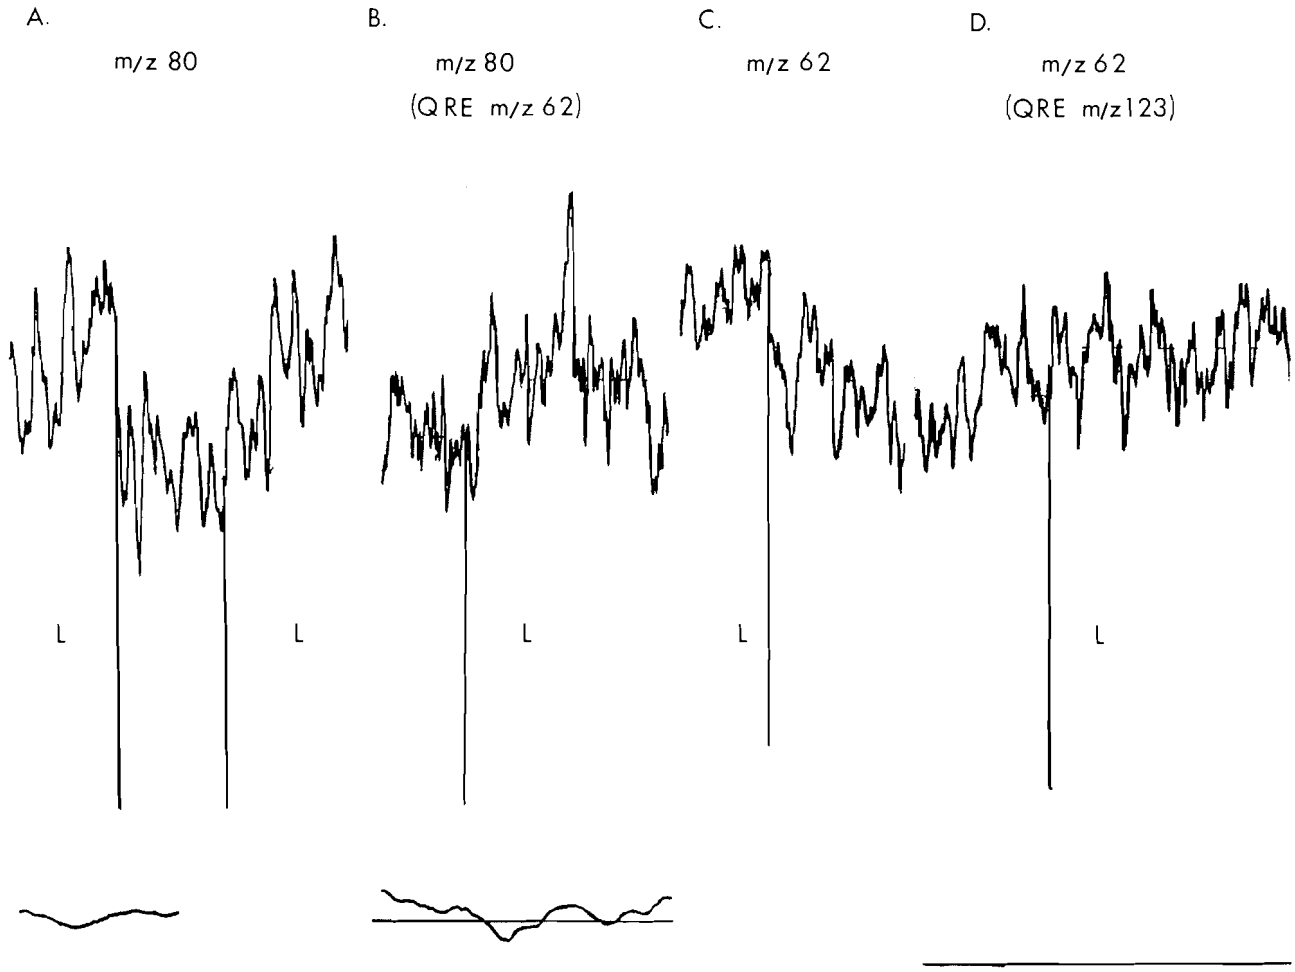

FIG. 8. Single ion monitored abundances of further ions derived from 2-d_1-isopropanol, at 5.3 mPa. A: m/z 80; B: m/z 80 with QRE of m/z 62; C: m/z 62; D: m/z 62 with concurrent QRE of m/z 123. Conditions as for Fig. 7.

for the proton bound alcohol dimer, m/z 123. It should be noted that the dimer contains two deuterium atoms, one from each alcohol molecule, and is proton, not deuterium, bound. In each case, the initial part of the trace corresponds to thermal conditions for 100 ms of storage while the parts marked L refer to 50 ms of storage followed by 50 ms of laser irradiation. In the first of the two traces marked A, some 55% dissociation of dimer, m/z 123, is observed; with resonance ejection of protonated alcohol, m/z 62, as shown in the second A trace, reactions [1] and [2] have been arrested and some 60% of dimer photodissociated. Trace B shows the anticipated increase in the protonated ether, m/z 105, with laser irradiation. Isotopic scrambling is not observed in the chemically activated proton bound dimer and reaction [5] results in the loss of H_2O rather than D_2O or HDO from m/z 123. As m/z 123 is the precursor of m/z 105, irradiation of the ion assembly in the absence of m/z 123 (wrought by resonance ejection) should not induce any change in the prevailing m/z 105 ion abundance. However, as can be seen from trace C obtained under the above conditions, a diminution in m/z 105 ion abundance is observed upon laser irradiation. Thus the increase in m/z 105 ion abundance in trace B is the net increase arising from the photoproduction [5] and the photodissociation process

$$[8]\quad \underset{m/z\ 105}{((CH_3)_2CD)_2OH^+} + n^{111}h\nu \longrightarrow \text{products}$$

Identification of the products of [8] was not possible, but this process affords an excellent example of the application of ion storage mode switching in the QUISTOR as discussed in the accompanying paper. Multiphoton dissociation of protonated diisopropyl ether has not been reported previously. However, the observation is not entirely unexpected as Beauchamp and co-workers (2*b*) have observed the ir laser photochemistry of protonated diethyl ether. They reported that the laser-induced process is

$$[9]\quad (C_2H_5)_2OH^+ + nh\nu \longrightarrow C_2H_5OH_2^+ + C_2H_4$$

rather than loss of alkane to form protonated acetaldehyde. Thus while multiphoton dissociation of m/z 105 may be anticipated, and the reaction analogous to [9] for protonated diisopropyl ether may be operative, the structure of m/z 105 remains to be verified. The m/z 105 ions observed here were formed from the alcohol dimer, and we have not examined the isomer formed by protonation of diisopropyl ether.

In Fig. 8 are shown results of examination of m/z 80 (note that the proton bound dimer apparently sheds C_3H_5D as expected) and the protonated alcohol, m/z 62. The parts of the traces marked L refer to 50 ms of storage followed by 50 ms of laser irradiation; the unmarked sections refer to 100 ms of thermal storage. The m/z 80 ion abundance, trace A, shows the expected increase in intensity with laser irradiation [7] and, similarly, an expected increase when m/z 62 is resonantly ejected. In trace C, where m/z 62 is monitored, the expected

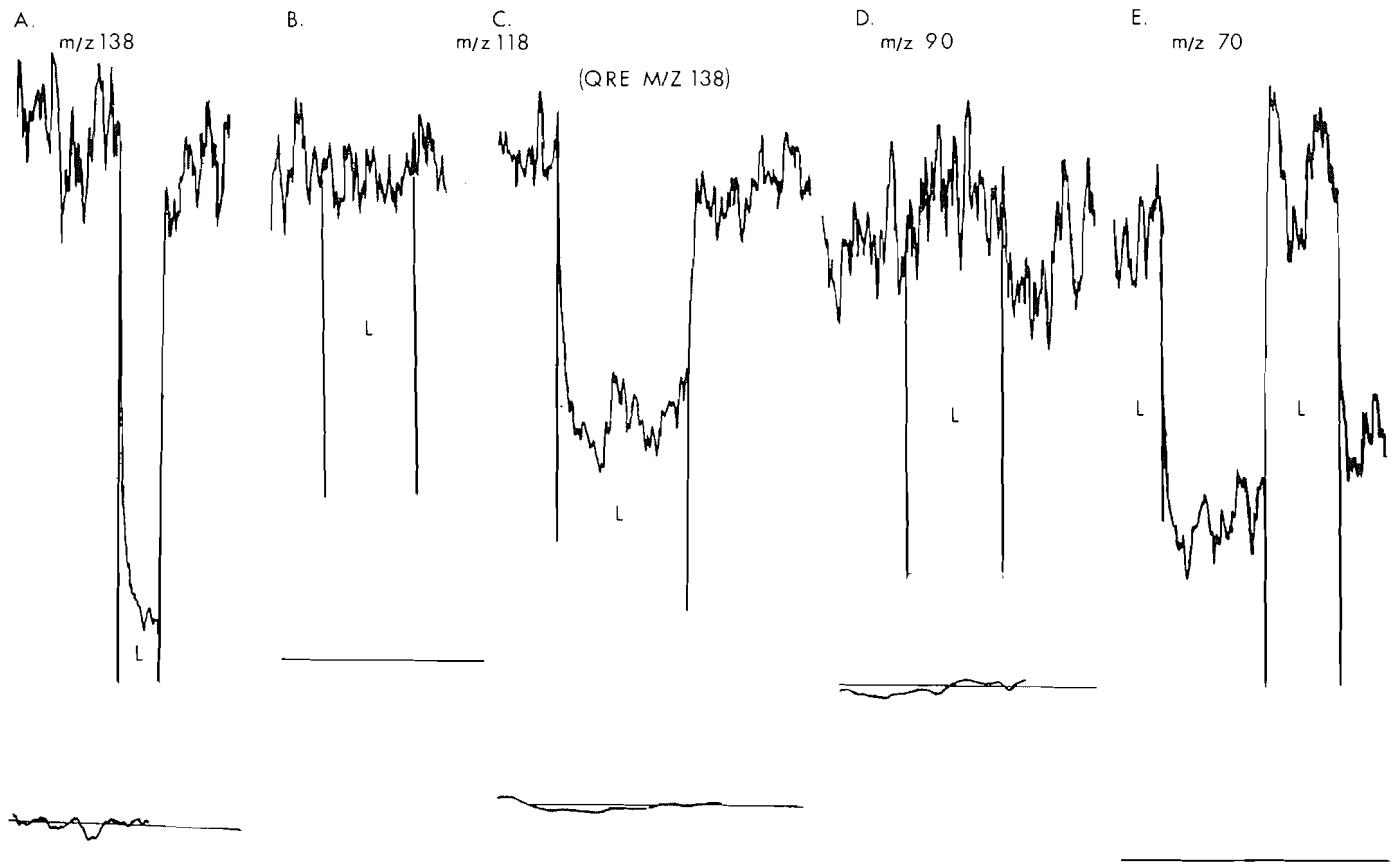

FIG. 9. Single ion monitored abundances of selected ions derived from perdeuteroisopropanol. A: m/z 138, the proton (D^+) bound perdeuterated alcohol dimer; B: m/z 118; C: m/z 118 with concurrent QRE of m/z 138; D: m/z 90; E: m/z 70. Conditions as for Fig. 7.

increase with laser irradiation is observed. Although the signal is very noisy in trace D in which m/z 62 is monitored, it appears that upon resonance ejection of m/z 123, thus removing the possibility of [6] occurring, laser irradiation induces a small signal enhancement which may be indicative that m/z 62 is a photoproduct of [8].

Of the four isopropanol analogues investigated, the proton (D^+) bound alcohol dimer most susceptible to multiphoton dissociation is that derived from perdeuteroisopropanol, m/z 138, as is shown in Table 1 and in trace A of Fig. 9 where approximately 70% of the dimer is dissociated. This evidence indicates that the majority of ions were irradiated by the narrow laser beam directed through the centre of the QUISTOR. The ion of m/z 118 (correspondng to m/z 103 protonated ether in the isopropanol system) was monitored as shown in traces B and C. In trace B, 50 ms of laser irradiation following 50 ms of thermal storage produced no obvious change in ion abundance from that observed after 100 ms of storage; lower, in trace C where the dimer, m/z 138, is ejected, laser irradiation of 50 ms duration following 50 ms of storage caused a reduction of signal intensity of approximately 42%. Thus, we conclude that the null change in trace B is due to almost exact compensation by [5] for the relatively high degree of photodissociation wrought by [8]. Traces D and E show the expected increases in ion abundance with laser radiation of m/z 90 (corresponding to m/z 79) and m/z 70 (corresponding to m/z 61), respectively.

Structure of m/z *79;* $(CH_3)_2CHOH \cdot H^+ \cdot OH_2$

The losses of the elements of C_3H_6 and H_2O by [7] and [5], respectively, from the proton bound alcohol dimer suggest that the ion formed by loss of C_3H_6, m/z 79, may have the structure of a proton bound mixed dimer of alcohol and water. In this event, m/z 79 should absorb ir photons from the laser via the alcohol moiety and, eventually, be photodissociated to regenerate protonated alcohol. Such a postulate may appear to be supported by the possibility of a reaction sequence of [5] and [9]. However, at 5.3 mPa pressure, as shown in trace A of Fig. 10, no change in ion abundance of m/z 79 was observed when irradiated in the absence of m/z 121 which was resonance ejected. Thus it is concluded that either the m/z 79 ion species is transparent to radiation at 944 cm^{-1}, which is unlikely as this would require a major change in hybridization, or the binding is much stronger than that of a proton bound alcohol—water dimer which is reported as 100 kJ mol^{-1} for $CH_3OH_2^+$—H_2O (10) and therefore of a different nature. The proton (D^+) bound mixed dimer of isopropan-*d*-ol with D_2O, m/z 83, was formed at a relatively low pressure of 0.67 mPa. Due to the considerably greater proton affinity of isopropan-*d*-ol (assumed to be equal to that of isopropanol) than that of D_2O, 816 kJ mol^{-1} cf. 690 kJ mol^{-1} (11), only a trace of the alcohol was added to D_2O, hence the partial pressure of the alcohol in the reaction chamber is not known. After 100 ms storage at 0.67 mPa, negligible proton (D^+) bound alcohol dimer was observed. While the signal intensity of m/z 83 was low and is shown in trace B of Fig. 10, the signal does appear to diminish with 50 ms of laser irradiation following 50 ms of storage compared to the signal intensity after 100 ms of storage. With the pressure restored to 5.3 mPa, the signal intensity of m/z 82 shows, in trace C of Fig. 10, a marked increase upon irradiation and

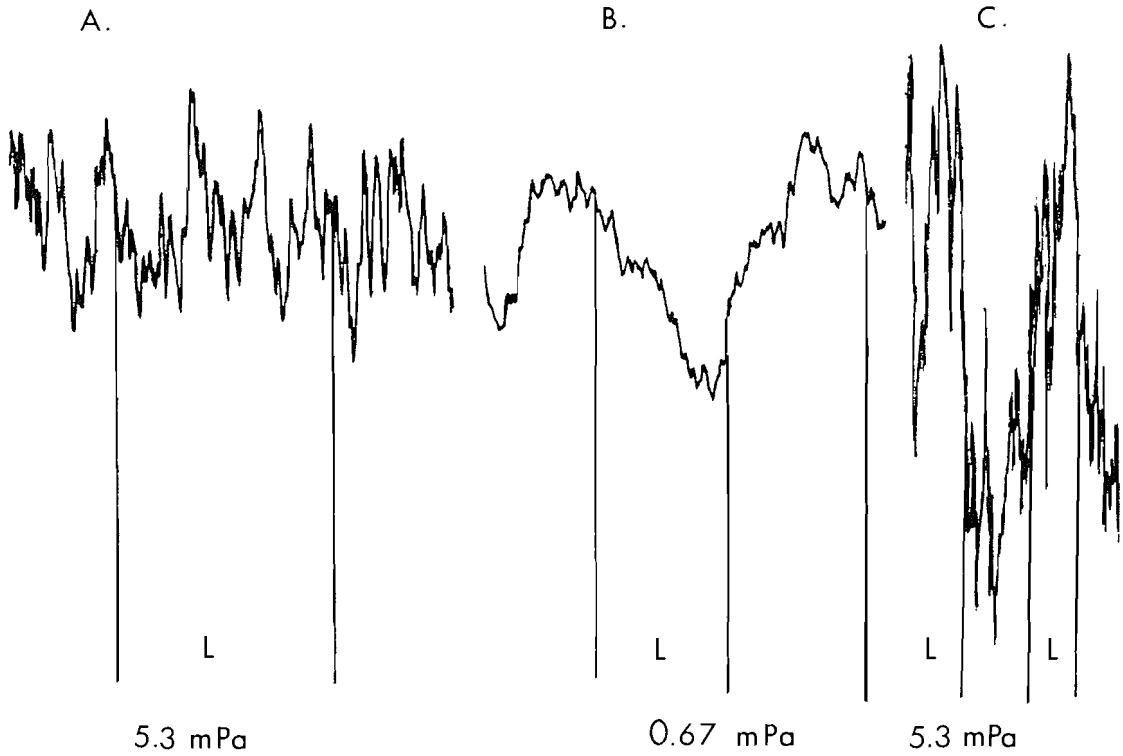

FIG. 10. Single ion monitored abundances of ions of the form $i\text{-}C_3H_7OH \cdot H^+ \cdot OH_2$. A: m/z 79 ions derived from isopropanol by [7] at 5.3 mPa with QRE of protonated dimer m/z 121; B: m/z 82 ions produced by clustering D_2O with $iso\text{-}C_3H_7OD_2^+$ at 0.67 mPa (N.B. only a minute trace of protonated dimer, m/z 124, was observed at this pressure); C: m/z 82 ion derived from $iso\text{-}C_3H_7OD$ by [7] at 5.3 mPa. Irradiation conditions as for Fig. 7.

photodissociation of the proton (D^+) bound alcohol dimer $(i\text{-}C_3H_7OD)_2D^+$ of m/z 124 which loses C_3H_6 by [7] to yield m/z 82. Thus it is concluded, principally from the results portrayed in traces A and B of Fig. 10, that the product ion of [7] differs in structure from that of a proton bound mixed dimer of alcohol and water. It is important to note that in the clustering of D_2O with $i\text{-}C_3H_7OD_2^+$, a mixed dimer of m/z 83 results, whereas alkene loss from the symmetrical dimer, $(i\text{-}C_3H_7OD)_2D^+$, results in an ion of m/z 82.

Let us consider a plausible structure for the proton bound isopropanol dimer m/z 121 and the possible mechanisms by which isomeric forms of m/z 79 may be produced. The m/z 121 ion may lose C_3H_6 in a concerted action involving 6 atoms, to yield I. Two different forms of rearrangement are then possible, the first rearrangement to yield II and IV produces an asymmetric ion of the form $R^+ \cdot H_2O \cdot H_2O$, whereas the alternative rearrangement produces the symmetric ion, III, $H_2O \cdot R^+ \cdot OH_2$. While structure III has been proposed previously (2*c*), a mechanism for its formation was not discussed.

Ion relaxation

Proton bound alcohol dimers formed initially by [1] in a chemically activated state, and observed at the expiry of a chosen trapping period, may be either radiatively stabilized under collision-free conditions or radiatively and collisionally stabilized at higher pressures. At an operating pressure of 5.3 mPa the time between ion–neutral collisions is approximately 0.38 ms, which is appreciable with respect to the normal storage and irradiation periods employed here. A crude experiment within the limitations of the equipment was attempted in which proton bound alcohol dimers were irradiated as a function of ion age, age being crudely synonymous with storage time, relaxation time, and average number of collisions

suffered by the ion. While primary ions are formed virtually instantaneously in 50 μs, the peak intensity of proton bound alcohol dimers is attained after 40–50 ms of storage leading to a distribution of ions at any given storage time. Nevertheless the distributions of ion ages will broaden with storage time from a narrow distribution initially for pure nascent ions. The distribution functions may be calculated from the ion abundance profiles with time, but this calculation has not been completed. Ideally, an irradiation period of several milliseconds should be used to probe the effect of ion relaxation on dissociation pathways but the chopping facility and the fluence of the CW CO_2 laser dictated a minimum irradiation period of 50 ms. Thus, proton bound alcohol dimers were irradiated for a constant period of 50 ms; irradiation was commenced initially after 5 ms of storage and subsequently delayed to longer storage times. Ions were mass analyzed at the conclusion of irradiation. From the results of each mass analysis, the reduction in signal intensity of the dimer ion and the changes in signal intensity of m/z 103, m/z 61, and m/z 79 due to [5]–[7], respectively, were noted. Photoinduced signal intensity changes obtained at a common amplification of detector signal indicated the degree to which each dissociative pathway was followed. In arriving at the m/z 103 signal intensity change, allowance was made for photodissociation of m/z 103 by determining the m/z signal intensity change with resonance ejection of the dimer ion. Photodissociation yields, expressed as a percentage of the total yield of photodissociation products, are plotted versus relaxation time and sampling time as shown in Fig. 11. The experiment is crude for the reasons expressed above and the scatter of the data points is appreciable, yet the observed behaviour may indicate a reconciliation of experimental findings reported here with those of Beauchamp (2*c*) which are shown as filled data points in Fig. 11. Let us assume that, on average, $(ROH)_2H^+$ requires an induction period of 35 ms of laser irradiation under the prevailing conditions of pressure and laser power in order to acquire the energy necessary, but not necessarily sufficient, for dissociation. As the time between successive collisions is 0.38 ms, the average number of collisions suffered by ions not detected (and presumed to have dissociated) at the shortest sampling time will range from 100–145 collisions, and from 210–250 collisions at the maximum sampling time. Thus the experiment encompasses a possible range of 100–250 collisions on average and a twofold range of radiative probabilities for nascent ions activated initially with some 125 kJ mol^{-1}. All those dissociative pathways [5]–[7] were observed.

At the shortest sampling (or relaxation) time the photodissociation yields of m/z 103 and m/z 61 were almost equal at approximately 50%. As sampling time was delayed, the photodissociation yield of m/z 103 increased at the expense of that for m/z 61; the yield of m/z 79 remained sensibly constant throughout at 4%. It is concluded that photoescalation of partially relaxed $[(ROH)_2H^+]^*$ may induce preferentially the reverse of [1]; the less the nascent ion is relaxed the fewer will be the number of photons required for reversal of [1]. The more relaxed the ion becomes, the greater is the dominance of [5] as a dissociation pathway. The invariance of the photodissociation yield of m/z 79 is suggested to be associated with an isomerization process. The dominance of [5] as a dissociative channel in Beauchamp's work is concluded to be due to near complete radiative relaxation during the relatively long (~1 s) storage time; the pressure region employed in ref. 2*c* corresponds to a collision frequency of 10 s^{-1}.

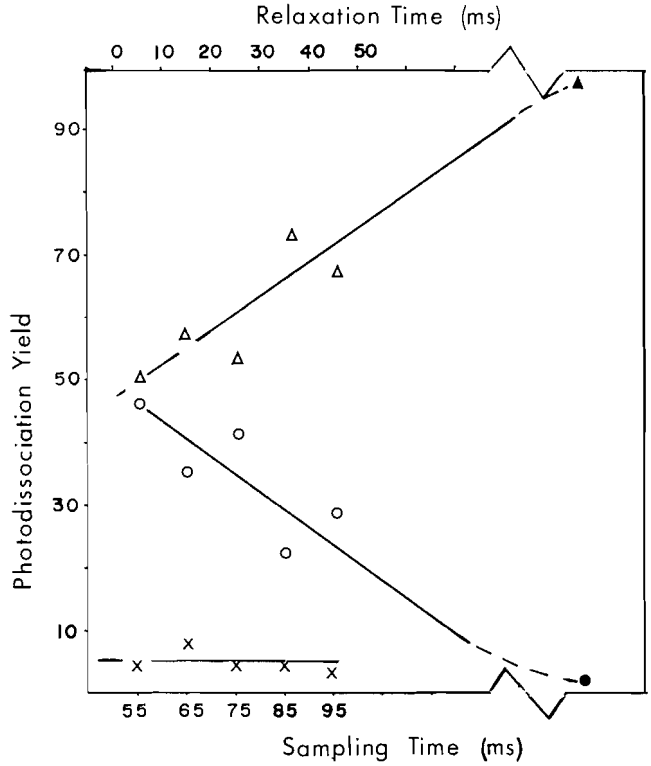

FIG. 11. Plot of photodissociation yield versus sampling time and relaxation time for the three multiphoton dissociation products of $(i\text{-}C_3H_7OH)_2H^+$. Relaxation time is defined as the period of ion storage from initiation of ion creation by electron impact to the commencement of laser irradiation. At the conclusion of 50 ms of irradiation the ions were mass analyzed. Sampling time refers to the total storage time and is equal to the relaxation time plus the irradiation time which was held constant at 50 ms. Relaxation time scale is proportional to the number of collisions suffered by each ion prior to irradiation, while sampling time is proportional to the number of collisions during the entire period of ion storage. 50 ms CW CO_2 laser irradiation of 20 W cm^{-2} at 944 cm^{-1}; pressure 5.3 mPa. △, m/z 103 product of [5]; ○, m/z 61 product of [6]; ×, m/z 79 product of [7]. △ and ○ which correspond to m/z 103 and m/z 61, respectively, were observed by Beauchamp at 4×10^{-2} mPa with a relaxation time of 500 ms and a sampling time of 950 ms.

There are several possible extensions of the present results which are either being explored in this laboratory or contemplated for study. Improved absorptivities of gaseous ions can be obtained by monitoring dissociation as a function of wavelength. Collisional and radiative relaxation of chemically activated ions may be probed by temporal variation of laser irradiation, and complemented by probing of resonance activated, i.e. selectively heated, ions. Individual ion species may be isolated in the QUISTOR and subsequently irradiated under total ion storage conditions in order to accumulate ionic photoproducts. The time scale of slow multiphoton absorption allows for radiative losses, hence ir spontaneous emission lifetimes may be studied.

Summary and conclusions

The ability to distinguish structural isomers of gaseous ions on the basis of ir absorbance is of great interest in that it would complement the capabilities of mass spectrometry. However, it is exceedingly difficult to observe ir absorption directly, due to the low densities of gaseous ions which can be assembled, e.g. the maximum number of ions which may be trapped simulta-

neously in the QUISTOR is $\sim 10^9$ ions based on the space charge. As the extent of multiphoton excitation depends on energy fluence rather than laser intensity, slow multiphoton induced dissociation can be effected in target molecules or ions irradiated under near collision-free conditions, provided that excitation rates exceed the rates for spontaneous emission. Thus slow multiphoton dissociation offers an indirect method for determining ir absorption spectra of gaseous ions and can be a source of ion structural information which previously was not obtainable. In addition, ir multiphoton excitation presents a novel method for ion fragmentation which can be employed as a further distinguishing criterion. Slow ir multiphoton dissociation of polyatomic gaseous ions constitutes a convincing demonstration of the incoherence of the process.

It is concluded that (*i*) slow multiphoton dissociation may be employed to determine the dissociation pathway of lowest activation energy provided that the photon-absorbing ions are well relaxed. (*ii*) Thermal dissociation pathways may be followed by partially relaxed or unrelaxed ions upon multiphoton absorption. (*iii*) Dissociation via the reaction channel with the lowest activation energy is always observed but not necessarily exclusively. (*iv*) Slow multiphoton dissociation may be employed to distinguish between isomers. (*v*) The ion formed by loss of H_2O from the proton bound alcohol dimer is itself photodissociative. (*vi*) While the ir absorption spectrum of gaseous ions may mimic the wavelength dependance of single photon absorption by neutrals, the order of relative absorbances by neutrals is not necessarily maintained with gaseous ions.

Received July 5, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

J. C. D. BRAND, U. D. DESHPANDE, A. R. HOY, and E. J. WOODS. Can. J. Chem. **61**, 846 (1983).

A previously-unknown ion-pair state of ICl has been identified and characterized in sequential transitions using polarization-labelling spectroscopy. This state is designated $1(^3P_1)$, indicating a state of axial electronic angular momentum $\Omega = 1$ correlating diabatically at dissociation with the states $I^+(^3P_1) + Cl^-(^1S_0)$ of the separated ions. The electronic energy and local potential constants for levels with $v = 1-7$ are (in cm^{-1}) $T_e = 45552.805(23)$, $\omega_e = 184.854(13)$, $\omega_e x_e = 0.6737(13)$, $B_e = 0.058898(42)$, and $\alpha = 2.485(93) \times 10^{-4}$, and the equilibrium bond distance is 3.231 Å.

J. C. D. BRAND, U. D. DESHPANDE, A. R. HOY et E. J. WOODS. Can. J. Chem. **61**, 846 (1983).

On a identifié un état de paire d'ions des composés ICl inconnu antérieurement et on l'a caractérisé dans des transitions séquentielles utilisant la spectroscopie de marquage par polarisation. On désigne cet état $1(^3P_1)$, indiquant un état du moment angulaire électronique axial $\Omega = 1$ corrélant diabatiquement à une dissociation avec les états $I^+(^3P_1) + Cl^-(^1S_0)$ des ions séparés. L'énergie électronique et les constantes de potentiel local des niveaux avec $v = 1-7$ sont de (en cm^{-1}) $T_e = 45552{,}805(23)$, $\omega_e = 184{,}854(13)$, $\omega_e x_e = 0{,}6737(13)$, $B_e = 0{,}058898(42)$ et $\alpha = 2{,}485(93) \times 10^{-4}$ et la distance d'équilibre de liaison est de 3,231 Å.

Introduction

With a few exceptions, the low-lying electronically-excited states of ICl are not well characterized. The transition from the ground state to the low-lying, case c $A\,^3\pi_1$ state has been analyzed extensively (1, 2), while the tangled O^+ states, B, B' are understood in principle (3) and have been the subject of comprehensive lifetime studies (4). Although constants of the $\Omega = 1$ E state have recently been determined by King *et al.* (5), no other sub-Rydberg states of the molecule are known at the present time. A critical summary of work published through 1976 is given in the monograph by Huber and Herzberg (6). It is worth noting that the band system $D-A$ in this monograph becomes $E-A$ according to the revised assignments of King and co-workers.

Polarization-sensitive laser methods offer a powerful means of studying excited states of molecules. Besides the drastic simplification compared to conventional absorption/emission spectra, these techniques also allow us to determine the electronic angular momentum of the excited state directly and unambiguously. This paper reports the identification and characterization of a previously unknown $\Omega = 1$ sub-Rydberg state of ICl lying ca. 0.8 eV higher than the E state. A search for this state was undertaken on the hypothesis that E is almost certainly the lowest-energy $\Omega = 1$ ion-pair state of ICl, correlating in a diabatic approximation with the ground states of the separated ions, $Cl^-(^1S) + I^+(^3P_2)$: since the $^3P_1$ excited state of I^+ lies about 0.9 eV higher than $^3P_2$ (7) the next-higher $\Omega = 1$ ion-pair state can be expected within roughly 1 eV of the E state. The energy and potential constants of the new state bear out this expectation; therefore we refer to the state, following the notation suggested by Tellinghuisen (8), as $1(^3P_1)$.

Experimental

The instrumentation used for polarization spectroscopy has been described elsewhere (9). In order to access the $1(^3P_1)$ state from the ground state of ICl, selected rotational transitions of the $A \leftarrow X$ system were pumped with a narrow-band laser and the $1(^3P_1) \leftarrow A$ transitions probed with a second, broadband laser. Energy and intensity (Franck–Condon) considerations then require that the pump laser be operated with R590(R6G), R610(RhB), or R640 dyes (10) as lasing media, using PTP (29100–29700 cm^{-1}) in the broadband probe. The XeCl excimer laser used to pump these dyes does not allow us to probe at frequencies higher than 29700 cm^{-1}. The signal transmitted through crossed polarizers was photographed in the 17-th order of a 3.4 m spectrograph using Kodak SA-1 emulsion, and the frequency measurements referred to an Fe/Ne hollow-cathode emission superimposed on the spectrum in the usual way. Development of the spectrum normally required $1-3 \times 10^3$ pump–probe pulse sequences, corresponding to a realtime exposure of ca. 20 μs.

The 20 cm sample cell contained ICl vapor in equilibrium with excess solid at 0°C. Commercial ICl (Eastman) was used without purification. Interference from I_2 transitions was minimal. The spectra were essentially unchanged after 10^3-10^4 pulses, thus the possible buildup of I_2 and Cl_2 during exposure has no significant effect. The cell location was chosen so that the (nominally) 8 ns pump and probe pulses arrived simultaneously at the sample.

Spectra of $I^{37}Cl$ were obtained without enrichment. Polarization-labelled spectra are sufficiently sparse that no interference occurs between transitions of the isotopes at natural abundance. $I^{35}Cl$ and $I^{37}Cl$ transitions were recorded in a ratio of about 2:1

Electronic assignment

The spectra recorded in this work were obtained using linearly-polarized pump and probe pulses, the two polarizations being oriented at 45° to one another. Typical signals recorded under these conditions are shown in Fig. 1. Each of these signals is a transition of the $1(^3P_1) \leftarrow A$ band system: selective labelling by the pump limits a band to just two transitions P(J) and R(J), where J is the rotational quantum number of the A-state level populated by the pump. It is an important diagnostic test that the Q-branch signal is weaker than P or R, irrespective of whether the transition pumped in the $A-X$ system belongs to a Q-branch or to P/R. In fact, unless J is small ($J \leq 5$), the Q-branch signals are below detection threshold and escape observation altogether. The P and R signals are accompanied by collision-induced satellites which extend over a considerable range of J when the parent signal is strong.

The intensity distribution has been derived recently in a

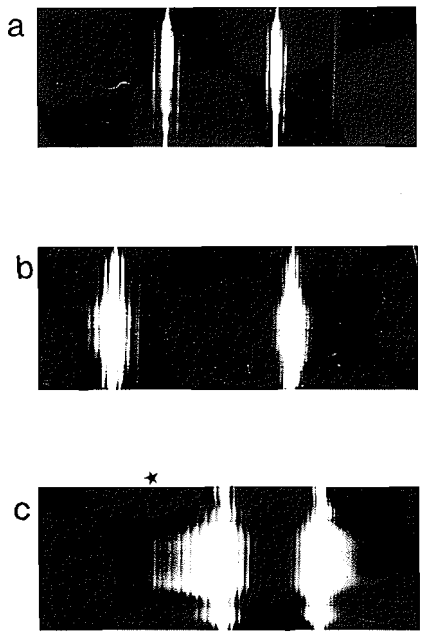

FIG. 1. Polarization spectra of the $1(^3P_1) \leftarrow A$ band system. (*a*) the Q-pumped, $v = 1-15$ band of $I^{35}Cl$: parent transitions, accompanied by weak $\Delta J = \pm 1$ collision-transfer satellites, are R30 (29418.66 cm^{-1}) and P30 (29411.58 cm^{-1}). (*b*) R-pumped 4–19 band of $I^{35}Cl$: parent transitions are R51 (29521.31 cm^{-1}) and P51 (29509.41 cm^{-1}). In this spectrum, and in (*c*) below, the saturation caused by the pump pulse is sufficiently high that the parent lines are reversed. (*c*) Q-pumped 3–17 band of $I^{35}Cl$: parents are P27 (29543.3 cm^{-1}) and R27 (29549.7 cm^{-1}). The weak feature marked * is the R-branch of another transition. Frequency increases towards the right in this diagram. The red-degradation of bands in the $1(^3P_1) \leftarrow A$ system is clearly shown by the distribution of collision satellites. These spectrograms are selected to illustrate the formation of collision satellites, and the parent transitions are broadened by overexposure.

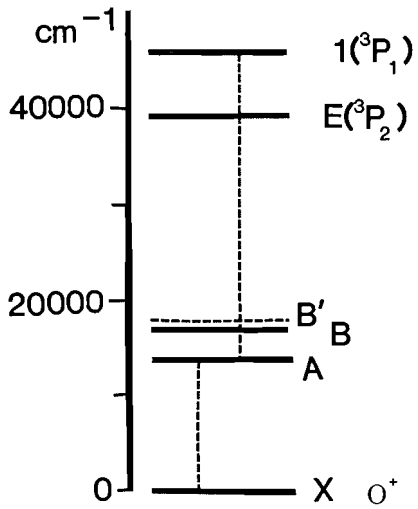

FIG. 2. Identified sub-Rydberg states of ICl. Vertical lines indicate the pump–probe sequence used in this work.

small signal approximation by Carlson *et al.* (11). In the ICl system the $A \leftarrow X$ pumped transition is $\Omega = 1 \leftarrow 0$; therefore, since the case *c* selection rules are $\Delta\Omega = 0, \pm 1$ the *final* state may have $\Omega = 0^{\pm}$, 1, or 2. When the probed transition is perpendicular, i.e., $0^- \leftarrow 1$, $0^+ \leftarrow 1$, or $2 \leftarrow 1$, the theoretical intensity distribution for all except small values of J indicates that for Q-branch pumping the Q-branch of the probed transition will be stronger than P or R in the last two cases. For the case $0^- \leftarrow 1$ the conditions are reversed, that is, pumping in a P- or R-branch will lead to a strong Q-branch, and vice versa. None of these possibilities describes the spectra in Fig. 1, where the P, R intensities far outweigh that of the Q-branch, irrespective of whether the pumped transition is P, Q, or R. (Finer details in these spectra are due to collision satellites and are discussed below.) The observed spectra correspond uniquely with a parallel, $\Omega = 1 \leftarrow 1$, transition between the intermediate and final states of the pump–probe sequence. Accordingly the final state can be identified unambiguously with a $\Omega = 1$ state. This assignment relative to that of other known sub-Rydberg states is shown schematically in Fig. 2.

[a] J refers to rotational levels of $v = 17$ in the intermediate, A state.

The abundance of collision-induced satellites at the moderate sample pressure of $\lesssim 4$ Torr was not expected. Assignments for the satellites seen in, for example, Fig. 1*c* are perfectly definite as shown by the compilation of A state combination differences in Table 1. It is worth noting in passing that analysis of the satellites enables us to assign the pumped transition without knowledge of the pump frequency. The intensity of the satellites falls off smoothly as ΔJ increases, though the rate at which intensity decreases is somewhat less on the low-frequency compared to the high-frequency side. Evidently this corresponds to a net trend to lower energy by collision transfer, as one expects intuitively. The collisions involved here are exceedingly weak, since a $\Delta J = 1$ transfer corresponds to $\Delta E \approx 2BJ \approx 3\ cm^{-1}$ at $J = 27$, which is much less than kT.

In Fig. 1*a*, the $\Delta J = 1$ satellite intensity is 10–12 times weaker than that of the parent line. If we can assume that T_1, the time-constant for J-changing collisions, and T_2, the constant for redistribution among M-sublevels of the same J, are such that $T_2 \gg T_1$ — which is supported by admittedly slender evidence from the spectrum of I_2 vapor (12) — the rate constant T_1^{-1} is calculated to be between one and two orders of magnitude greater than hard sphere. This value of T_1^{-1} is quite similar in magnitude to the rate constant for electronic self-quenching of the A state as reported some years ago by Holleman and Steinfeld (13). Although these two processes are physically distinct, it is natural to assume that the large cross-section implied in both cases is due to the field associated with the permanent electric moment. Since the selection rules for matrix elements of μ are $\Delta J = \pm 1$, $\Delta\Omega = 0$, $+ \leftrightarrow -$ we expect that the propensity rule for pure rotational transfers will be as shown in Fig. 3: this rule has been tacitly assumed in the second and fifth columns of Table 1. At present the data available do not distinguish whether the more remote satellites are populated directly or by a $\Delta J = \pm 1$ cascade.

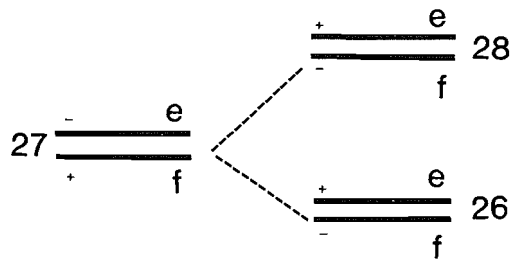

FIG. 3. Schematic representation of rotational relaxation in the A state of the $1(^3P_1) \leftarrow A \leftarrow X$ sequence. The pumped transition is identified with Q27 (see Fig. 1*c* and Table 1). $\Delta J = \pm 1$ collision transfers are assumed to obey a dipole propensity rule $\Delta\Omega = 0$, $+ \leftrightarrow -$. The Λ-type doubling is greatly exaggerated.

Potential function

The electronic energy and potential constants for the $1(^3P_1)$ state were determined from an all-lines, simultaneous least-squares fit of term values for $I^{35}Cl$ and $I^{37}Cl$ using a Dunham expansion. Local constants for $I^{35}Cl$ are summarized in Table 2. In the approximation that the potential function is identical for $I^{35}Cl$ and $I^{37}Cl$, as assumed in the refinement, the isotopic relationships are,

$$[1]\quad Y_{k,l}(37) = \rho^{l+k/2}\, Y_{k,l}(35)$$

where $\rho = 0.95765$ is the ratio of reduced masses.

Constants given by King *et al.* (5) for the E state of ICl are reproduced in Table 2 for comparison. The $1(^3P_1)$ and E states are in fact very similar, at least when compared to other states of the manifold: ω_e, for example, is 384 cm^{-1} in the X state and 420–445 cm^{-1} in Rydberg states whereas the frequencies for $1(^3P_1)$ and E are not only much smaller but fall within 10% of one another. This family likeness, which extends to r_e and other constants, indicates that both are ion-pair states I^+Cl^- as originally forecast by Mulliken (14) and tentatively confirmed by King *et al.* (5). An alternative notation for E is therefore $1(^3P_2)$.

Experience with the diatomic alkali halides shows that the potential function of an ion-pair state is described quite well by the "truncated-Rittner" model of Brumer and Karplus (15),

$$[2]\quad V(r) = T_\infty + A\exp(-br) - e^2/r - [\alpha(I^+) + \alpha(Cl^-)]e^2/2r^4 - C\,(I^+Cl^-)/r^6$$

Here, r is the ion–ion distance, the α's are ion polarizabilities, C/r^6 is the London approximation (16) to the van der Waals attraction,

TABLE 3. Parameters of the Rittner potential function

$$[3]\quad C(I^+Cl^-) = (3/2)\,\alpha(I^+)\alpha(Cl^-)\omega(I^+)\omega(Cl^-)/[\omega(I^+) + \omega(Cl^-)]$$

and A and b are parameters in an empirical term describing the short-range interaction. For dissociation into $I^+(^3P_1) + Cl^-(^1S_0)$ the $r = \infty$ term value T_∞, relative to $T_e = 0$ for the X state, can be calculated from the ionization potential of I_{atomic} (7), the electron affinity of Cl_{atomic} (17) and the dissociation energy of the X state. The ion polarizability for Cl^- is known (18) while that for I^+ can be estimated without serious error. If the ω's in [3] are identified with ionization potentials, the only two remaining parameters to be determined from the observed potential constants are A and b. The function [2] is therefore overdetermined in that five spectroscopic constants (Table 2) are available to fix two parameters.

The procedure followed is that A and b are first determined from the conditions $(dV(r)/dr)_e = 0$ and $(d^2V(r)/dr^2)_e = 4\pi^2c^2\omega_e^2\mu$. The complete potential curve can then be calculated. At $r = r_e$ the computed $V(r_e) \equiv T_e$ is in excellent agreement with the observed values of $Y_{0,0}$ (T_e), as shown in Table 3. Likewise the anharmonic part of $Y_{1,1}$ is proportional to the third derivative $(d^3V(r)dr^3)_e$, while $Y_{2,0}$ is determined by the third and fourth derivatives; here too the agreement is satisfactory though less good than for $Y_{0,0}$. The fact that the first five derivatives, $(d^nV/dr^n)_e$ for $n = 0$ through 4, are accounted for consistently affords definite physical evidence that the state in question is highly ionic in the region where r is not greatly different from r_e. However, extrapolation to a limit in which dissociation occurs into separated ions is a diabatic approximation. As Mulliken (14) has emphasized there are Rydberg states of atomic halogens lying below the $I^+(^3P_1) + Cl^-(^1S_0)$ asymptote: therefore at large r the curve will sidestep, in order to observe the non-crossing rule, to a channel leading to two neutral atoms one of which must be in a low-lying Rydberg state.

Photochemistry of acetylene

H. OKABE[1]

NASA/Goddard Space Flight Center, Laboratory for Extraterrestrial Physics, Astrochemistry Branch, Greenbelt, MD 20771, U.S.A.

Received July 5, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

H. OKABE. Can. J. Chem. **61**, 850 (1983).

Photochemical and fluorescence studies of acetylene initiated by absorption of light in the vacuum ultraviolet have been described. The photochemical primary process consists of (1) the formation of $C_2 + H_2$, (2) the production of $C_2H + H$, and (3) the formation of a metastable acetylene. The quantum yield of process (1) is about 0.1 and that of process (2) is 0.06 at 1849 Å and 0.3 at 1470 Å. The metastable acetylene either reacts with ground state acetylene to produce diacetylene or is deactivated by collisions with the walls, inert gases, or by fluorescence. A quasicontinuous emission is observed in the 4000 to 6000 Å region when acetylene is exposed to incident wavelengths below 1305 Å. This emission is ascribed to an electronically excited ethynyl radical. The rates of reaction $C_2H + H_2 \rightarrow C_2H_2 + H$ and $C_2H + RH \rightarrow C_2H_2 + R$ ($RH = CH_4$, C_2H_6, C_3H_8) have been measured. The photochemistry of acetylene in the Jovian and Titan atmospheres is briefly discussed.

H. OKABE. Can. J. Chem. **61**, 850 (1983).

On décrit les études de fluorescence et photochimiques de l'acétylène initiés par l'absorption de lumière dans l'ultraviolet sous vide. Le processus photochimique initial consiste (1) en la formation de $C_2 + H_2$, (2) en la production de $C_2H + H$ et (3) en la formation d'acétylène métastable. Le rendement quantique du premier processus est d'environ 0,1 et celui du 2e processus est de 0,06 à 1849 Å et de 0,3 à 1470 Å. L'acétylène métastable réagit soit avec l'acétylène à l'état fondemental pour produire le diacétylène ou est désactivé par suite des collisions avec les parois, les gaz inertes ou par fluorescence. On observe une émission quasi continue dans la région allant de 4000 à 6000 Å lorsqu'on expose l'acétylène à des longueurs d'ondes incidentes en dessous de 1305 Å. On attribue cette émission à un radical éthynyl excité électroniquement. On a mesuré les vitesses de réaction: $C_2H + H_2 \rightarrow C_2H_2 + H$ et $C_2H + RH \rightarrow C_2H_2 + R$ ($RH = CH_4$, C_2H_6, C_3H_8). On discute brièvement de la photochimie de l'acétylène dans les atmosphères de Jovian et de Titan.

[Traduit par le journal]

Introduction

Acetylene is one of the simplest hydrocarbons and as such it has been the subject of numerous photochemical studies in recent years (1). Major photochemical products are diacetylene, ethylene, hydrogen, and small amounts of vinylacetylene and benzene (2–4), while the Cd ($^3P_1$) sensitized reaction (5) produces benzene and vinylacetylene and the Hg ($^3P_1$) sensitized reaction (6) forms benzene, vinylacetylene, and hydrogen. On the other hand, the vacuum ultraviolet photolysis of acetylene in low temperature matrices has produced $C_2(X^1\Sigma_g^+)$ (7) and C_2H (7, 8) suggesting that the primary process may be: (1) $C_2H_2 \xrightarrow{h\nu} C_2 + H_2$; (2) $C_2H_2 \xrightarrow{h\nu} C_2H + H$. In addition to these reactions another gas phase process producing an electronically excited ethynyl radical, C_2H^*, is found (9, 10) below the incident wavelength 1305 Å.

The substantial production of metastable acetylene has also been suggested in the vacuum ultraviolet photolysis of acetylene (2, 3, 11). However, the quantum yields of these processes have not been determined. Acetylene has recently been detected in the Jovian (12) and Titan (13) atmospheres. It has been suggested (14) that acetylene plays an important role in the catalytic decomposition of hydrogen and methane in the planetary atmospheres.

Fluorescence from C_2H_2 has recently been detected in the spectral region 2500–3500 Å by light absorption near 2200 Å (15). Below 2000 Å no fluorescence arising from acetylene has been observed. This article describes some recent studies on (1) the quantum yield of the photochemical primary process of acetylene, (2) the reaction of ethynyl radical with H_2 and hydrocarbons, and discusses acetylene photochemistry in the Jovian and Titan atmospheres based on the results obtained from these studies.

Fluorescence and predissociation

The bond dissociation energy $D_0(H—C_2H)$ of 5.38 ± 0.05 eV has been determined by the author (16). This energy corresponds to the incident wavelength 2306 Å. Recently Abramson *et al.* (15) have found that even with 2207 Å excitation, 1900 cm^{-1} above the dissociation threshold, the fluorescence lifetime is of the order of 3 μs, indicating no dissociation of the excited acetylene occurs. At 2000 Å excitation, however, the fluorescence yield becomes 10^{-4} and at 1849 Å no fluorescence was seen (17). This weak predissociation is also observed in chloroacetylene fluorescence (1). The predissociation generally occurs much more rapidly above the dissociation threshold in triatomic molecules (SO_2, NO_2, CS_2) and in some four-atomic molecules (1) (formaldehyde, ammonia, thiophosgene). Fluorescence with vibrational structure has been observed by Brus (15) in the 2500–3500 Å region when acetylene in low temperature rare-gas matrices is irradiated by the ArF 1933 Å laser light.

Another quasicontinuous fluorescence has been observed by the author (9) and by Becker *et al.* (10), when acetylene is excited by incident wavelengths below 1305 Å. The fluorescence spectrum, shown in Fig. 1, lies in the 4000 to 6000 Å region with no apparent structure. Since both C_2H_2 and BrC_2H produce the similar quasicontinuum, it is most likely that this emission arises from an electronically excited C_2H (C_2H^*), and not from $C_2H_2^*$. Although the lifetime of fluorescence is 6 μs (10), similar to that excited by the incident wavelength, 2207

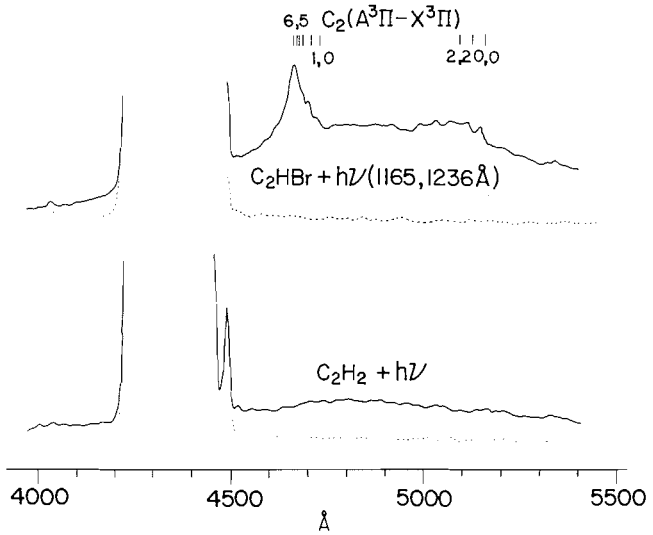

FIG. 1. The fluorescence spectrum produced from the photolysis of BrC_2H and C_2H_2 by the Kr lamp; the sample pressure is about 0.1 Torr; the resolution 10 Å; the broken lines indicate the background level; a large signal in the 4200 to 4500 Å region is due to the scattered emission lines from the lamp; from ref. 9.

Å (15), the fluorescence spectrum of the former (C_2H^*) is in the visible and quasicontinuous while the spectrum of the latter ($C_2H_2^*$) is in the ultraviolet and has vibrational structure.

From the threshold wavelength 1305 Å corresponding to $h\nu = 9.50$ eV for the production of C_2H^* from C_2H_2, in conjunction with the heat of reaction for $C_2H_2 \rightarrow C_2H + H$ (5.38 ± 0.05 eV), the author (9) obtained the electronic energy of C_2H, 4.11 ± 0.05 eV, corresponding to the incident wavelength, 3017 ± 40 Å. However, absorption or laser induced emission of C_2H has apparently not been found in this region. The long fluorescence lifetime indicates that the C_2H absorption may be too weak to detect.

Photochemical process

Primary process

Important progress has been made by Lange and Wagner (18) in understanding acetylene photochemistry. They have obtained the rate constant of the reaction

$$C_2H + C_2H_2 \rightarrow C_4H_2 + H$$

by measuring with the mass spectrometer the decay of C_2H and have obtained $k = 5 \times 10^{-11}$ cm^3 molec^{-1} s^{-1}. They have also found the product to be mainly diacetylene. Laufer and Bass (19) have also obtained the rate constant of 3×10^{-11} by measuring the rise time of C_4H_2 by absorption. Since the reaction is fast, the production of C_4H_2 by combination of C_2H may be neglected in the steady state photolysis of acetylene. Thus the quantum yield of process [1], where $C_2H_2^*$ means an initially formed singlet state,

$$[1] \quad C_2H_2 \xrightarrow{h\nu} C_2H_2^* \rightarrow C_2H + H$$

may be obtained from the quantum yield of diacetylene, $\phi_{C_4H_2}$. Amounts of diacetylene have been measured by absorption at 1642 Å, which corresponds to a strong Rydberg transition (see Fig. 2). The photolysis of acetylene has been performed at 1470 Å and 1849 Å, corresponding respectively to the transition to the Rydberg state and to the $\tilde{B}\ ^1B_u$ state ($v'_3 = 0$); see Fig. 3. The quantum yield of diacetylene at 1470 Å has been measured as a function of C_2H_2 pressure. The results are shown in Fig. 4. It can be seen that diacetylene is formed from the pressure independent process as well as the pressure dependent process. The quantum yield of the pressure independent process (direct dissociation) is 0.3. Higher yields of diacetylene at higher pressures of acetylene must arise from the reaction of a metastable acetylene, $C_2H_2^{**}$, with ground state acetylene (20).

$$[2] \quad C_2H_2^* \rightarrow C_2H_2^{**}$$
$$C_2H_2^{**} + C_2H_2 \rightarrow C_2H + C_2H_3$$
$$C_2H + C_2H_2 \rightarrow C_4H_2 + H$$

At low pressure of acetylene, $C_2H_2^{**}$ must be deactivated by wall collisions or by fluorescence.

$$C_2H_2^{**} \xrightarrow{\text{walls}} C_2H_2$$

The metastable acetylene can also be quenched by the addition of N_2 or He, resulting in the decrease of $\phi_{C_4H_2}$, as shown in Fig. 5. The quenching is not complete even by the addition of 400 times as much He or N_2 as acetylene at 1470 Å. When acetylene pressure is low (below 0.7 Torr), the addition of N_2 has no effect on the production of diacetylene since $C_2H_2^{**}$ does not contribute to the formation of diacetylene. At 1849 Å photolysis (21) $\phi_{C_4H_2}$ is also dependent on the pressure of acetylene. At the low pressure limit $\phi_{C_4H_2}$ is 0.06, 1/5 of that at 1470 Å. The results are shown in Fig. 6. The addition of N_2 or He reduces $\phi_{C_4H_2}$ to a constant value of 0.05, indicating that the quenching of $C_2H_2^{**}$ is complete above the partial pressure of 150 Torr N_2 or He (see Fig. 7). At 1849 Å, quenching of $C_2H_2^{**}$ requires less partial pressure of inert gas than at 1470 Å.

The state of metastable acetylene is not clear. Wetmore and Schaefer (22) calculate the low-lying triplet states to be *cis* $^3A_2$ (4.50 eV), *trans* ^3A_u (4.13 eV), *trans* ^3B_u (3.78 eV), and *cis* $^3B_2$ (3.43 eV). Since $C_2H_2 + C_2H_2 \rightarrow C_2H_3 + C_2H$ is endothermic by 3.91 eV, $C_2H_2^{**}$ must have energy above 3.91 eV to form C_4H_2. Hence it is probable that *cis* $^3A_2$ or *trans* ^3A_u is formed by absorption both at 1470 and 1849 Å. On the other hand, in the Hg and Cd sensitized reactions mainly *trans* ^3B_u, or *cis* $^3B_2$ may be formed, since in these reactions very little diacetylene is detected as a product (5, 6).

Another primary process is the production of molecular hydrogen

$$[3] \quad C_2H_2 \xrightarrow{h\nu} C_2H_2^* \rightarrow C_2 + H_2$$

The quantum yield of H_2 production is about 0.1 both at 1470 (20) and 1849 Å (21). The electronic state of C_2 is most likely to be $X^1\Sigma_g^+$ as indicated in the photolysis of acetylene in low temperature matrices (7). Little is known about the rate constant or products of the reaction $C_2\ X^1\Sigma_g^+$ with acetylene (23).

The sum of processes [1] and [3] is still much less than unity, indicating the substantial production of $C_2H_2^{**}$, process [2]. The quantum yield of diacetylene at 1849 Å (Fig. 6) increases to a maximum at about 10 Torr of acetylene and then decreases with further increase of acetylene, indicating the formation of another product, probably benzene, which has been detected by Tsukada and Shida (4). The reaction for benzene formation would be

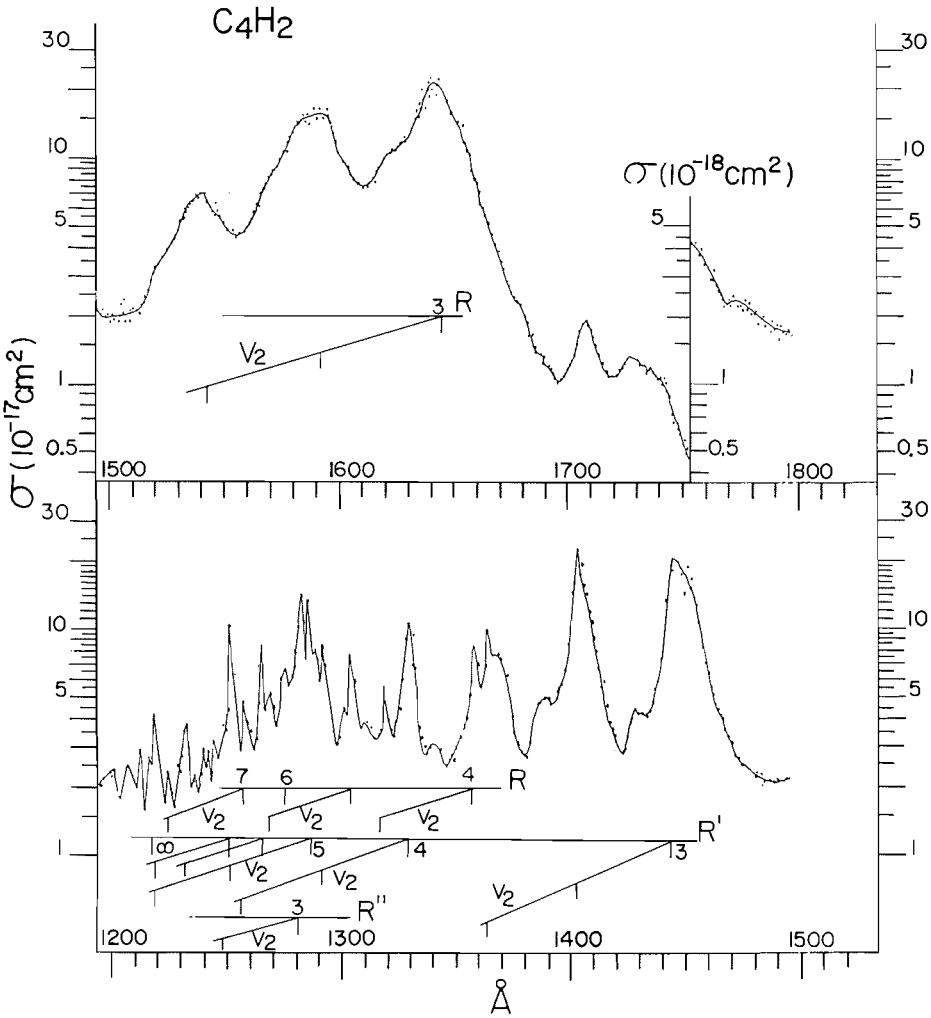

FIG. 2. Absorption cross sections of diacetylene in the 1200 to 1800 Å region. Almost all strong peaks observed belong to two Rydberg series R and R′ with associated ν_2 (C≡C) stretching vibration, leading to the ionization potential 10.18 eV at 1217 Å. Below 1300 Å a third Rydberg series R″ appears with associated ν_2 vibration. A strong peak at 1642 Å has been used for measuring the amounts of diacetylene produced (from ref. 20).

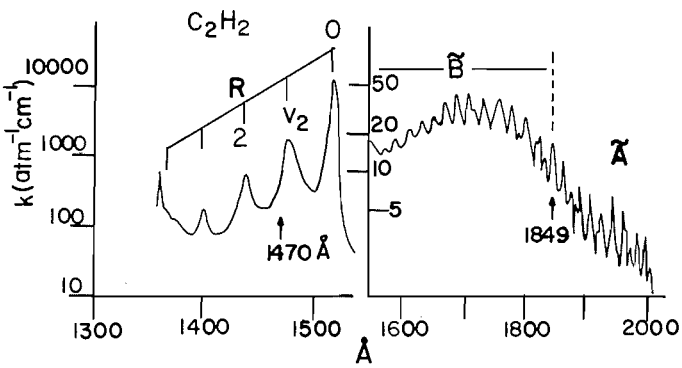

FIG. 3. Absorption coefficients, k, of acetylene in the 1400 to 2000 Å region; k is given in units of atmospheres and cm at 0°C, base e. At 1470 Å acetylene is excited to a Rydberg state, while at 1849 Å the B ^1B_u state, $\nu_3' = 0$ is formed; from ref. 28.

$$C_2H_2^{**} + 2C_2H_2 \rightarrow C_6H_6$$

Photolysis of C_2H_2–H_2, C_2H_2–hydrocarbon mixtures

Figure 8 shows $\phi_{C_4H_2}$ decreases with the addition of H_2, indicating the occurrence of the reaction (18)

[4] $C_2H + H_2 \rightarrow C_2H_2 + H$

in competition with the formation of diacetylene

[5] $C_2H + C_2H_2 \rightarrow C_4H_2 + H$

From reactions [4] and [5] we obtain

$$[6]\quad \phi^0_{C_4H_2}/\phi_{C_4H_2} = 1 + \frac{k_4(H_2)}{k_5(C_2H_2)}$$

where $\phi^0_{C_4H_2}$ is the quantum yield of diacetylene formation without H_2 and $\phi_{C_4H_2}$ is that with H_2. The plot, $\phi^0_{C_4H_2}/\phi_{C_4H_2}$ against $(H_2)/(C_2H_2)$ gives a straight line with the slope k_4/k_5, as shown in Fig. 9. The least-squares analysis of the plot gives $k_4/k_5 = 0.00775 \pm 0.00068$, that is, reaction [5] is 130 ± 11 times as fast as reaction [4]. Similar plots have been made for CH_4, C_2H_6, and C_3H_8. The results are given in Table 1. The rate constant of H abstraction by C_2H increases as $H_2 < CH_4 < C_2H_6 < C_3H_8$ and for propane the rate is one half as fast as that for acetylene.

Photochemistry of acetylene in the Jovian and Titan atmospheres

Acetylene has been detected in the Jovian atmosphere (12)

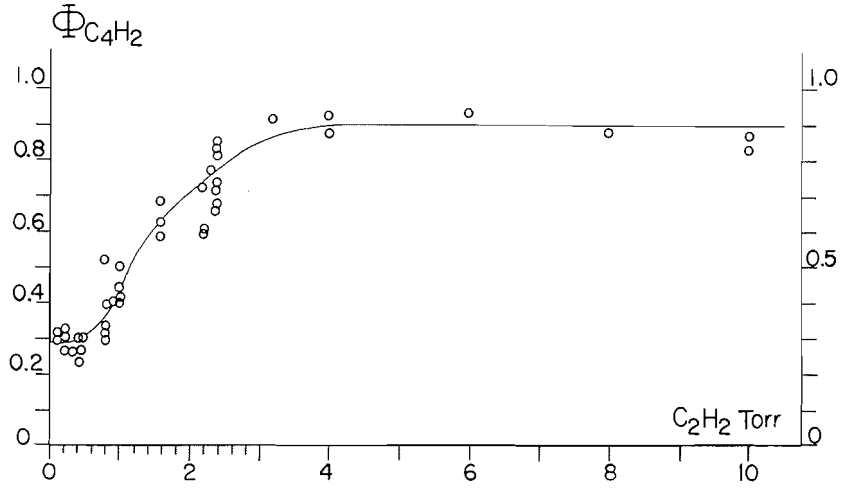

FIG. 4. The quantum yield of diacetylene formation $\phi_{C_4H_2}$ from acetylene photolysis at 1470 Å as a function of acetylene pressure; from ref. 20.

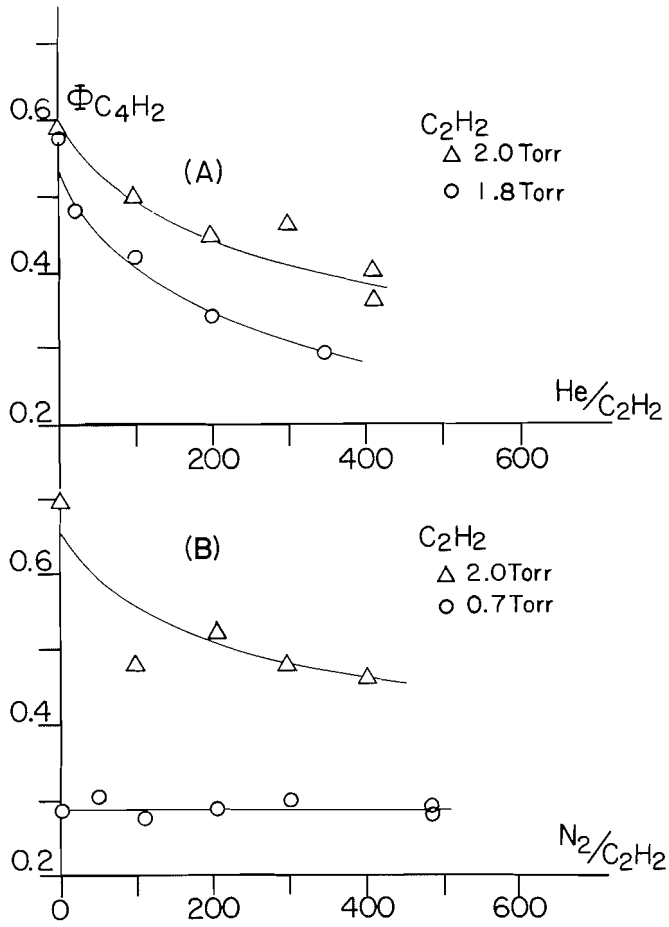

FIG. 5. The quantum yield of diacetylene formation in the 1470 Å acetylene photolysis as a function of (A) He pressure, (B) N_2 pressure; from ref. 20.

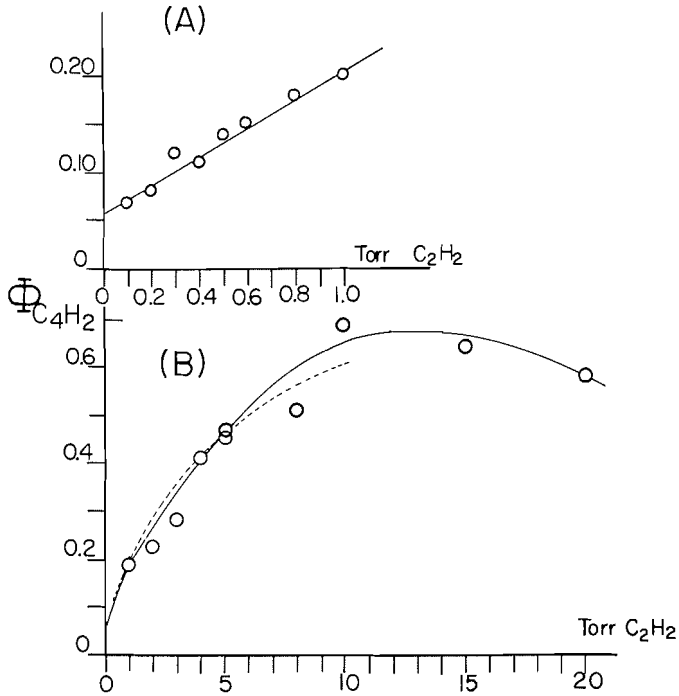

FIG. 6. The quantum yield of diacetylene as a function of acetylene pressure, λ = 1849 Å; from ref. 21.

and more recently in the Titan atmosphere (13). The reaction of C_2H produced from acetylene photolysis by absorption of solar radiation is mainly with H_2 in the Jovian atmosphere since H_2 is the most abundant species.

$$C_2H_2 \xrightarrow{h\nu} C_2H + H$$

$$C_2H + H_2 \rightarrow C_2H_2 + H$$

The two reactions correspond to the sensitized dissociation of H_2 by C_2H_2 since there is no net change in the concentration of acetylene. Acetylene absorbs solar radiation in the spectral region up to 2400 Å where the solar intensity is significantly greater than that below 1000 Å, the region of H_2 absorption. Hence the C_2H reaction plays an important role in the destruction of H_2. On the other hand, in the Titan atmosphere where methane is abundant, the production of C_2H from acetylene photolysis and the subsequent reaction with methane

$$C_2H_2 \xrightarrow{h\nu} C_2H + H$$

$$C_2H + CH_4 \rightarrow C_2H_2 + CH_3$$

is an important destruction mechanism of methane. Strobel estimates (14) that the destruction of CH_4 by the above mech-

anism is just as important as the photolysis of methane by solar radiation if the quantum yield for C_2H production from acetylene photolysis is 0.06 in the 1450–2000 Å region, the most effective wavelength region of solar radiation absorbed by acet-

ylene since radiation below 1450 Å is absorbed by methane. Table 2 shows the relative rates of C_2H with H_2 and hydrocarbons present in the Titan atmosphere. The main reaction route of C_2H is the destruction of CH_4 to form methyl radicals, which combine with each other to form ethane. Subsequently propane may be generated by the acetylene catalyzed dissociation of ethane. Small amounts of diacetylene found in the Titan atmosphere (13) are probably formed by $C_2H + C_2H_2$ as shown in Table 2.

It has been suggested that the photolysis of acetylene may produce $C_2X^1\Sigma_g^+$. It is known that $C_2X^1\Sigma_g^+$ reacts with H_2 and CH_4 (23). However, it is not known what products are formed from these reactions, the information needed for more detailed understanding of acetylene photochemistry of the Jovian and Titan atmospheres.

Received July 5, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

RONALD F. CHILDS, TINA DICLEMENTE, EUNICE F. LUND-LUCAS, TIMOTHY J. RICHARDSON, and CAROL V. ROGERSON. Can. J. Chem. **61**, 856 (1983).

The photoisomerizations of protonated 5-methylhex-3-en-2-one and 4-methylpent-2-enoic acid have been examined. In each case a relatively rapid *cis/trans* isomerization about the carbon–carbon partial double bond and a slower conversion to protonated dihydrofuran **2H** or protonated lactone **5H**, respectively, were observed. The transformation of the acyclic cations to the five-membered ring cations was shown to occur by a photo-initiated, intramolecular hydride shift from the γ to β carbon atom. This shift is fully in accord with an excited state twisting/charge localization model for the excited states of these systems. Control experiments and the thermal chemistry of these ions is described.

RONALD F. CHILDS, TINA DICLEMENTE, EUNICE F. LUND-LUCAS, TIMOTHY J. RICHARDSON et CAROL V. ROGERSON. Can. J. Chem. **61**, 856 (1983).

On a étudié les isomérisations photochimiques de la méthyl-5 hexèn-3 one-2 protonée et de l'acide méthyl-4 pentanoique-2. On a observé dans chaque cas une isomérisation *cis/trans* relativement rapide autour de la double liaison partielle carbone–carbone et une transformation plus lente en dihydrofurane protoné **2H** ou en lactone protonée **5H** respectivement. On montre que la transformation des cations acycliques en cations de type cycle à cinq chainons se produit par l'intermédiaire d'un glissement d'hydrure intramoléculaire initié photochimiquement à partir de l'atome de carbone en γ vers l'atome de carbone en β. Ce glissement est en parfait accord avec un modèle de localisation de charge déformant de l'état excité pour les états excités de ces systèmes. On décrit des expériences de vérification et la chimie thermique de ces ions.

Protonated α, β-unsaturated enones, enals, carboxylic acids, and imines undergo photoinduced *E/Z* isomerizations about the carbon–carbon and either carbon–oxygen or carbon–nitrogen partial double bonds (1–4). These photoisomerizations, which would appear to involve singlet states, proceed with high quantum efficiencies, e.g. eqs. [1] and [2], (3, 4).

[1] 
[2] 
The photoisomerizations shown in eqs. [1] and [2] parallel the *E/Z* isomerizations of the protonated Schiff base derivatives of retinal involved in the chemistry of vision (5). On the basis of molecular orbital calculations, Salem and Bruckmann (6) have suggested that twisting about the C(11)—C(12) double bond of the π,π* excited singlet state of the visual pigments is accompanied by a major change in charge distribution. This involves movement of the positive charge from the nitrogen atom, where it is largely centered in the ground state, to the other end of the molecule. A comparable charge redistribution could occur during the photoisomerization shown, for example, in eq. [1]. In this case a twisted excited state in which the positive charge is largely localized on the β-carbon might be expected, eq. [3].

[3] 
The twisted structure shown in [3] can be regarded as a secondary cation. If R were a substituent such as an isopropyl group, it is conceivable that a hydride shift from the γ to β carbon might occur. This would result in the formation of a tertiary cation which could subsequently undergo several possible dark reactions. These include bonding between the γ and β carbons to form a protonated cyclopropyl ketone, bonding of the carbon and oxygen atom with the formation of a furan derivative, or a reverse hydride shift to give the starting material. In order to examine such possibilities we have investigated the photoisomerizations of protonated 5-methylhex-3-en-2-one, **1H**, and 4-methyl-2-pentenoic acid.

Results

Protonation and thermal control experiments

The protonation of **1** and subsequent thermal isomerization to **2H** in a variety of acids has been reported by Brouwer *et al.* (7). We have found directly comparable results when using FSO_3H as the acid, eq. [4].

[4] 
1 **1H** **2H**

[1]Author to whom correspondence should be addressed.

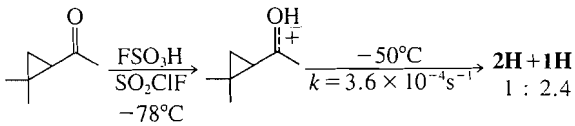
With FSO_3D as a solvent **1D** was observed to rearrange to **2D** with incorporation of a single deuterium at C3, eq. [5]. The selectivity of this deuterium incorporation was clearly shown in the ^1H nmr spectra of **2D**, where the signal due to the C3 proton was a broadened triplet of relative intensity one while the resonance attributed to the C4 protons was a doublet of relative intensity two. No deuterium incorporation could be detected in **1D** during the course of the isomerization and further deuterium exchange of **2D** was slow in FSO_3D at room temperature.

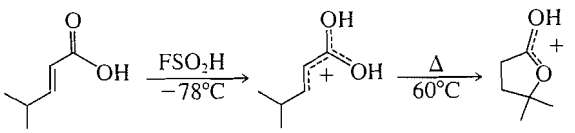
[5] 
1D **2D**

The protonated cyclopropyl ketone **3H** is a potential photoproduct of **1H**. Pittman and McManus (8) have reported that **3** very rapidly rearranges to **2H** when dissolved in 90% H_2SO_4. Using FSO_3H/SO_2ClF as the acid, it was possible to protonate **3** at −78°C and observe **3H**. The ^1H nmr spectrum of **3H** (Table 1) was consistent with its assigned structure (9). At −50°C, **3H** isomerized to a mixture of **2H** and **1H** in a ratio of 1:2.4.



3 **3H**

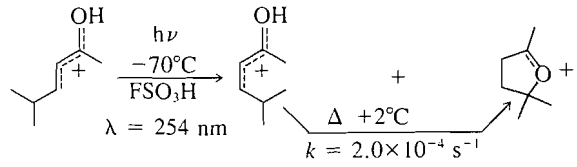
The acid **4** was cleanly protonated upon dissolution in FSO_3H to give **4H**. This cation was stable at room temperature, but on heating to 60°C partially isomerized to **5H**. This latter species was identified on the basis of the similarity of its ^1H nmr spectrum to that of **2H**. Other competing reactions of **4H** occurred at 60°C which limited the yield of **5H** obtained. These other products have not been fully characterized (10). In CF_3SO_3H these competing side reactions did not occur, and **4H** was cleanly converted to **5H**.



4 **4H** **5H**

Photoisomerizations of 1H and 4H

The uv spectrum of **1H** exhibited a strong absorption band with a maximum at 278 nm. Irradiation (254 nm) of a FSO_3H solution of **1H** at −70°C led to the formation of two products. The composition of the irradiated solutions was determined by low temperature ^1H nmr spectroscopy conducted directly on the irradiated solutions. The cation **2H** was identified as one of the photoproducts of **1H**. The second product formed and detected was **6H**, the *cis*-isomer of **1H**. The latter ion was readily identified by its ^1H nmr spectrum, Table 1, which displayed the characteristic coupling constant of 11 Hz between H(3) and H(4) (1). No thermal isomerizations of **1H** or **6H** occurred under the conditions used for this photoreaction. At higher temperatures, **6H** was found to isomerize thermally to **2H**, with a first order rate constant of 2.0×10^{-4} s^{-1} at +2°C ($\Delta G^{\ddagger}$ = 20.3 kcal/mol).



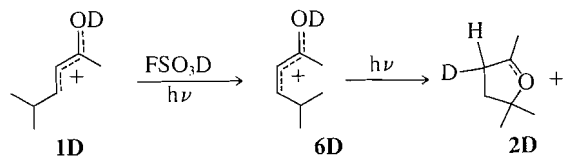
1H **6H** **2H**

The photoisomerization was followed as a function of time and the results are shown in Fig. 1.[2] As can be seen from this figure, the relative concentration of **6H** rose to a maximum after some five to six hours of irradiation and subsequently decreased to zero. The final and only product observed after 24 h irradiation was **2H**. As is usual with these photoreactions in FSO_3H, the material balance was excellent.

Careful examination of the ^1H nmr spectra obtained during the photoisomerization of **1H** failed to reveal any detectable (<10%) amounts of the protonated cyclopropyl ketone **3H**. While **3H** was shown to be thermally stable at −70°C, the temperature at which the photoreactions were carried out, it was found to photoisomerize to a mixture of **1H**, **2H**, and **6H** under the same conditions as used in the irradiation of **1H**.

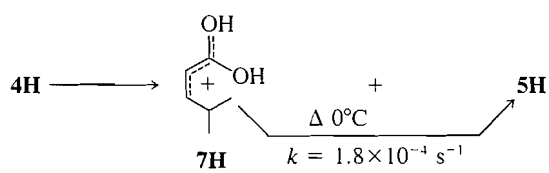
The quantum yield for the conversion of **1H** to **6H** was measured using a relative method and a value of 0.37 ± 0.05 (−70°C) found. Removing the dissolved oxygen in the FSO_3H solutions by sparging with argon had no apparent effect on the photochemical efficiency of this reaction.

Irradiation of **1D** in FSO_3D at −70°C led to the formation of **6D** and eventually **2D**. Deuterium incorporation at C3 of **2D** was clearly apparent from the ^1H nmr spectrum of the resulting solution. The resonance at 3.78 ppm attributed to the C3 proton appeared as a broadened triplet of only half the intensity of the doublet at 2.39 ppm associated with the methylene group on C4.



1D **6D** **2D**

The protonated carboxylic acid **4H** (λ_{max} = 240 nm) was irradiated at −70°C in FSO_3H (254 nm). The products were shown to be the *cis* isomer **7H** and protonated furan **5H** by ^1H nmr spectroscopy. As with the protonated ketone **1H**, the *cis* isomer **7H** was produced rapidly and **5H** less efficiently, Fig. 2. The *cis* isomer **7H** was shown to be thermally stable under the reaction conditions. At 0°C, **7H** isomerized to **5H**, $k=1.8\times10^{-4}$ s^{-1}; $\Delta G^{\ddagger}$ = 20.6 kcal/mol.



Discussion

The overall photochemical transformations of protonated ketone **1H** and acid **4H** are similar. These are relatively efficient

[2]This type of experiment assumes the lamp intensity to be constant.

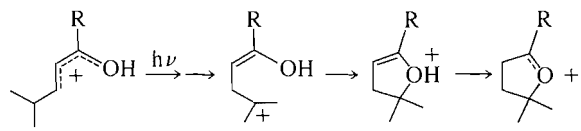
cis/trans isomerizations about the carbon–carbon partial double bonds and less efficient closures to the cyclic cations **2H** and **5H**, respectively. The thermal control experiments described above preclude the possibility that these reactions are thermally induced.

It has not been possible to observe emission from any of the protonated carbonyl compounds described, and there is no direct evidence for the nature of the excited state involved in these reactions. The absence of any effect of molecular oxygen on the reaction suggests that either singlet states or short lived triplet states are involved. Protonation of a carbonyl group raises the energy of n,π^* states, and π,π^* states are expected to be the lowest energy states (11).

The photochemically induced formation of these cyclic products from protonated α,β-unsaturated carbonyl compounds represents a new type of reaction characteristic of these systems. Other protonated enones studied previously have not undergone a comparable ring closure. For example, protonated pent-3-en-2-one or crotonic acid do not form cyclic cations even on prolonged irradiation. It is clear that the additional pair of methyl substituents on the cations **1H** and **4H** is important in facilitating this ring closure reaction.

The formation of protonated furan derivatives can be accounted for by a photochemically induced hydride shift from the tertiary γ-carbon to β-vinyl carbon. The tertiary cation so produced could then undergo reaction with the enol oxygen and lead eventually to the observed cyclic products.



R = CH_3 or OH

Such a pathway for the production of the protonated furan should proceed equally well from both the *cis* and *trans* carbon–carbon double bond isomers. This would indeed seem to be the case with the protonated acids **4H** and **7H**, Fig. 2, where **5H** is produced at the outset of the reaction; however, it is not the result which prevails with the protonated ketones **1H** and **6H**. It is apparent from the changes in composition which occur as the duration of irradiation is increased (Fig. 1) that a lag exists in the formation of **2H**. The relative concentration of **6H** reaches a maximum and then drops in such a way that the ratio of **1H** to **6H** approaches a constant value of 2:3. These observations are consistent with a mechanistic scheme in which a photoequilibrium is established between **1H** and **6H** and a somewhat less efficient photochemical conversion of **6H** to **2H**, eq. [6]. There is ample precedent for the establishment of

a photostationary state between the *cis* and *trans* isomers of a protonated enone (1, 3), and indeed the observed quantum yield for the conversion of **1H** to **2H** is very similar to that found for protonated 3-penten-2-one at the same temperature. However, the preferential conversion of **6H** rather than **1H** to **2H** raises questions about the hydride shift sequence proposed above.

[6] $$\mathbf{1H} \underset{254\ nm}{\overset{h\nu}{\rightleftharpoons}} \mathbf{6H} \longrightarrow \mathbf{2H}$$

The photochemical conversion of the *cis* isomer **6H** to **2H** suggests this reaction could proceed by a photo-initiated hydride transfer to oxygen, eq. [7]. Such a reaction, which may be compared to the photoenolization of the *cis* isomer of the unprotonated ketone (12) and other related enones (13), would produce the oxygen protonated dienol **8H**. This species would be expected to be very short lived in FSO_3H and be converted to **2H** by protonation C3, proton loss from oxygen, and further protonation at C4 (14). If a "photoenolization" type process were operative, then deuterium incorporation at both C3 and C4 of **2H** would be expected to occur when the reaction is carried out in FSO_3D. This is not the case, and in FSO_3D irradiation of **1D** leads only to **2D** in which a single deuterium atom is incorporated at C3. This result effectively excludes the "photoenolization" type reaction sequence and demonstrates that intramolecular migration of the hydrogen from the γ to β carbon must occur during the transformation of **6D** to **2D**.

[7] 
8H

The question remains as to why the photo-conversion of **6H** to **2H** is much more efficient than the comparable conversion of **1H** to **2H**. It is possible that a conformational difference exists between **1H** and **2H**. For bonding to occur between a positive centre at C5 and oxygen, it is essential that the C2—C3 bond have an *s-cis* configuration. On the basis of calculations reported for the π, π* excited state energy surfaces of acrolein (15), a substantial barrier to rotation about the C2—C3 bond of **1H** and **6H** would be expected in their singlet excited states. Thus the ground state conformation about the C2—C3 bond of **6H** and **1H** would be expected to be maintained in their excited states. Confirmation that the origin of the difference in the efficiency of conversion of **1H**, **6H** to **2H** derives from a ground state conformational effect is evident from the results obtained with the protonated acid. In this case, as has been pointed out above, the *trans* and *cis* isomers **4H** and **7H** are converted to **5H**. In these protonated acids the two oxygens on C1 remove the possibility of two conformations about the C1—C2 bond.

Definitive information on the ground state conformations of protonated enones is lacking. It is possible that **1H** prefers to exist in an *s-trans* conformation while **6H** could have a higher proportion of the *s-cis* conformer. Models indicate that **6H** is a highly congested cation in either conformation and it would seem unlikely that it is completely planar. This conclusion is supported by the anomalously high chemical shift observed for the C4 proton resonance of **6H** as compared to other comparable protonated enones and enals, indicating that the fraction of positive charge at C4 of **6H** is diminished relative to other protonated enones.

In conclusion, the results we have obtained indicate that a hydride shift from the γ to β carbon of an appropriately substituted protonated α,β-unsaturated carbonyl compound can occur on photo-excitation. The occurrence of this hydride shift is dependent on the substituents on the carbon. In the present cases two methyl groups on the γ-carbon allow this shift to occur in competition with the efficient *cis/trans* isomerizations about the carbon—carbon partial double bond. The occurrence of the hydride shift is apparent in the formation of protonated dihydrofuran derivatives, although the formation of a small amount of a protonated cyclopropyl ketone **3H** cannot be ruled out. At this stage it is not known whether the hydride shift is reversed thermally in competition with protonated dihydrofuran or protonated lactone formation. Deuterium labelled compounds are currently being prepared to investigate these possibilities. Overall we conclude that the occurrence of this hydride shift is consistent with the twisting/charge polarization model of the excited state of protonated carbonyl compounds.

Experimental

General

The ^1H nmr spectra were obtained on Varian EM-390 or Brucker WP-80 instruments. FSO_3H was distilled twice and checked by uv spectroscopy to ensure transparency in the 250 nm region before use. Samples were protonated by adding cooled FSO_3H to weighed amounts of **1** and **4** in nmr tubes cooled in Dry Ice—acetone. Solution was achieved by mixing the contents of the tubes with a thin glass rod.

Purification of 5-methyl-3-hexen-2-one, 1

Commercial samples of **1** (Aldrich Chemical Company) were found to be contaminated with 5-methyl-4-hexen-2-one (20%), and difficulty was experienced in separating the two isomers. The following procedure was adopted. A commercial sample of **1** (2 g) was dissolved in concentrated H_2SO_4 (10 mL) at 0°C and subsequently added to an excess of saturated $NaHCO_3$ solution with stirring at 0°C. The aqueous solution was extracted with CH_2Cl_2 (3 × 15 mL), the CH_2Cl_2 solution dried (K_2CO_3), and the solvent removed to give an oil. Purification by glpc using a Carbowax column gave pure **1**.

4-Methyl-2-pentenoic acid, 4

This acid was prepared from 5-methyl-3-hexen-2-one using a procedure identical to that used for the synthesis of 3-methylcrotonic acid from mesityl oxide (16). Yield 30%; ^1H nmr ($CDCl_3$) δ: 1.07 (6H, d, J = 6 Hz, CH_3), 2.43 (1H, m, C4H), 5.73 (1H d, J = 16, C2H), 7.03 (1H, d, d, J = 16 and 8 Hz, C3H).

Photoisomerizations

These were carried out using a Rayonet photoreactor (Southern New England Ultraviolet Co.) and 253.7 nm lamps. The samples, contained in 5 mm quartz nmr tubes, were cooled in a partially silvered quartz Dewar held at −70°C with a FTS Flexicool FC 2084P1 refrigeration unit. The reaction was followed by low temperature ^1H nmr spectroscopy.

Quantum yields were measured using the relative method described previously (3) with protonated 3-penten-2-one as an actinometer.

A kinetic study of the reactions of OH radicals with fluoroethanes. Estimates of C—H bond strengths in fluoroalkanes[1,2]

JEAN-PIERRE MARTIN[3] AND GEORGE PARASKEVOPOULOS

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received July 5, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

JEAN-PIERRE MARTIN and GEORGE PARASKEVOPOULOS. Can. J. Chem. **61**, 861 (1983).

A kinetic study of the reactions of OH radicals with a series of fluoroethanes in the gas phase is presented. OH radicals were generated by flash photolysis of H_2O vapor in the vacuum uv ($\lambda > 165$ nm) and were monitored in absorption by time-resolved attenuation of resonance radiation at 308.15 nm [$OH(A^2\Sigma^+ \rightarrow X^2\Pi)$]. The following absolute rate constants (in units of 10^9 cm^3 mol^{-1} s^{-1} at the 95% confidence limit) were determined at 298 K: $k_{CH_2FCH_2F} = 67.7 \pm 7.2$, $k_{CH_2FCHF_2} = 11.0 \pm 1.1$, $k_{CH_3CF_3} = 1.03 \pm 0.26$, $k_{CH_2FCF_3} = 3.10 \pm 0.35$, $k_{CHF_2CF_3} = 1.50 \pm 0.17$.

From a linear correlation of the present and previously published rate constants with bond dissociation energies, the following quantities (in kcal mol^{-1} at 298 K) were estimated to be: $D(CH_3CHF—H) = 96.3 \pm 1.5$, $D(CH_2FCHF—H = 98.8 \pm 1.0$, $D(CF_3CHF—H) = 103.5 \pm 1.0$, $D(CHF_2CF_2—H) = 103.0 \pm 1.5$, and $\Delta H_f^0(CH_3\dot{C}HF) = -18.7 \pm 1.6$, $\Delta H_f^0(CF_3\dot{C}HF) = -162.7 \pm 2.3$.

JEAN-PIERRE MARTIN et GEORGE PARASKEVOPOULOS. Can. J. Chem. **61**, 861 (1983).

Nous présentons une étude par cinétique en phase gazeuse des réactions entre les radicaux hydroxyles (OH) et une série d'éthanes fluorés. Les radicaux OH sont générés par photolyse-éclair de vapeur d'eau dans l'uv lointain ($\lambda > 165$ nm) et sont détectés par absorption résolue dans le temps de radiation en résonance à 308.15 nm [$OH(A^2\Sigma^+ \rightarrow X^2\Pi)$].

Nous obtenons les constantes de vitesse absolues suivantes, en unités de 10^9 cm^3 mol^{-1} s^{-1} à 298 K: $k_{CH_2FCH_2F} = 67.7 \pm 7.2$, $k_{CH_2FCHF_2} = 11.0 \pm 1.1$, $k_{CH_3CF_3} = 1.03 \pm 0.26$, $k_{CH_2FCF_3} = 3.10 \pm 0.35$, $k_{CHF_2CF_3} = 1.50 \pm 0.17$. Les écarts-type sont exprimés à un niveau de confiance de 95%.

A partir d'une corrélation linéaire entre la constante de vitesse et l'énergie de dissociation du lien C—H, nous évaluons les quantités suivantes, en kcal mol^{-1} à 298 K, comme suit: $D(CH_3CHF—H) = 96.3 \pm 1.5$, $D(CH_2FCHF—H) = 98.8 \pm 1.0$, $D(CF_3CHF—H) = 103.5 \pm 1.0$, $D(CHF_2CF_2—H) = 103.0 \pm 1.5$, $\Delta H_f^0(CH_3\dot{C}HF) = -18.7 \pm 1.6$, $\Delta H_f^0(CF_3\dot{C}HF) = -162.7 \pm 2.3$.

Introduction

There is considerable interest in the reactions of hydroxyl radicals with hydrocarbons and halocarbons, because of the important role that these reactions play in combustion and in the chemistry of the atmosphere. As a result, rate constants for reactions of OH radicals with a variety of classes of compounds have been determined for use in numerical modeling of these processes. The data, often verified in several laboratories (1), are of sufficient accuracy that empirical relationships may now be drawn between structure and reactivity (see, for example, ref. 2). Such relationships, when established, may allow estimates of rates to be made based on bond properties, and conversely, may also help in estimating needed bond properties from kinetic measurements.

In a previous paper (3), we have reported absolute rate constants for hydrogen abstraction by OH radicals from fluorocarbons, and have presented a linear correlation between the logarithm of the room-temperature rate constants and the corresponding C—H stretching frequencies for several alkanes and fluoroalkanes. In the case of CH_3CH_2F, with non-equivalent C—H bonds, the correlation indicated that hydrogen abstraction occurred mainly from the α position of CH_3CH_2F. This was later confirmed by product analysis (4).

In the present paper, we have extended our previous work to include the fluoroethanes and have explored correlations of rate constants with stretching frequencies and with bond dissociation energies. Thus, we report absolute rate constants at 298 K for the reactions of OH with CH_2FCH_2F, CH_2FCHF_2, CH_3CF_3, CH_2FCF_3, and CHF_2CF_3 in the gas phase; these were measured using the flash photolysis – resonance absorption technique. We also present and discuss empirical correlations of the rate constants for alkanes and fluoroalkanes from this and our previous work with the average stretching frequencies $\langle\nu_{C-H}\rangle$ of equivalent C—H bonds, and with bond dissociation energies. From the latter correlation we have estimated plausible values of the bond dissociation energies of $CH_3CHF—H$, $CH_2FCHF—H$, $CF_3CHF—H$, and $CHF_2CF_2—H$, and of enthalpies of formation in the gas phase at 298 K, for the radicals $CH_3\dot{C}HF$ and $CF_3\dot{C}HF$.

Experimental

The apparatus and experimental technique have been described in detail before (5, 6), and will be mentioned here briefly. The apparatus consists of a fast flash photolysis system coupled to a spectrophotometric detection system. Hydroxyl radicals were produced by flash photolysis of small pressures of water vapour (0.2–0.8) Torr in the vacuum uv ($\lambda > 165$ nm). The flash lamp was operated at discharge energies of 60 and 150 J. The OH concentration was monitored by following the time-resolved attenuation of the OH resonance radiation ($Q_1^{(3)}$ rotational line of the (0,0) band of the $A^2\Sigma^+ \rightarrow X^2\Pi$ transition) produced by a microwave discharge in a flowing low pressure Ar/H_2O mixture, as described before (5, 6). Signal averaging was used to improve the signal-to-noise ratio. Rate measurements were made in the range $(0.5–5) \times 10^4$ s^{-1}, by using 24–100 flashes.

The reactant gases were analyzed by gc/ms using a Finnigan gas chromatograph – mass spectrometer. Quantitative determinations of the impurities were made on 5-ft columns packed with Porapak QS or Porapak N and were based on peak areas. The purity levels (and the major impurities) were as follows: CH_2FCH_2F, 98.38% (CH_2FCHF_2,

1.53%; a pentafluorobutane isomer, 0.09%); CH_2FCHF_2, >99.50% (CO_2, trace; CHF_2CHF_2, 0.14%; an octafluorobutane isomer, 0.18%; a heptafluoroisobutane isomer, 0.15%); CH_3CF_3, 99.6% (CO_2, 0.005%; $CFClCH_2$, 0.40%); CH_2FCF_3, >99.7% (CO_2, trace; CH_3CF_3, 0.10%; CHF_2CF_3, 0.16%; CF_2ClCF_2Cl, 0.02%; CF_2CFCl, trace; $CHClCF_2$, trace; $CHClFCF_3$, trace; CH_2ClCF_3, trace); CHF_2CF_3, 99.24% (CH_3CF_3, 0.62%; CH_3CHF_2, 0.06%; CH_2FCF_3, 0.08%). The olefin impurity (CH_2CFCl) in CH_3CF_3 was completely removed by shaking the fluorocarbon for 1/2 hour with concentrated sulfuric acid containing a few crystals of $KMnO_4$. No significant olefin impurity was present in the other fluorocarbons because there was no difference in rate constants determined before and after treatment with H_2SO_4. The reagent gases and H_2O were subjected to several freeze–pump–thaw cycles and were further degassed at 77 K before each experiment. He >99.999% pure was used directly from the cylinder.

Results

Various aspects of the experimental conditions, procedure, and treatment of the data are given in refs. 5 and 6. The effect of multiple flashes (i.e. accumulation of reaction products) on the measured rates was tested by flashing a given mixture 2, 4, 8, 16, and 32 times and comparing the resulting rates. Although no significant difference was detected, only 8 flashes per mixture were used.

The initial OH concentration estimated from the initial absorption of the resonance radiation (5, 6) was $\sim(5-8) \times 10^{-12}$ mol cm^{-3} and $(1-2) \times 10^{-11}$ mol cm^{-3} for flash energies of 60 and 150 J respectively. The experiments were carried out under pseudo-first-order conditions with [fluoroethane] $\gg$ [OH]. The pseudo-first-order rate constant, k_I, was obtained from the slopes of the linear plots of ln [OH] against time (5, 6). The values of k_I obtained for varying fluorocarbon concentrations are related to the second-order rate constant, k_{II}, by the equation $k_I = \alpha + k_{II}$[fluorocarbon]. Plots of k_I against the fluorocarbon concentration are shown in Fig. 1 for all the fluorocarbons studied. The second-order rate constants, k_{II}, were evaluated from the slopes of these plots by weighted least-squares fits of the above equation to the points with weights $w = 1/\sigma^2$, where σ is the error in k_I evaluated as described before (5, 7). The small intercepts observed in Fig. 1 cannot be ascribed to a single predominant cause; their significance has been discussed in detail in refs. 5 and 6. The measured values of k_{II} are given in Table 1.

The experiments were done at pressures of 20–600 Torr depending on the amount of fluorocarbon required to obtain the desired rate. For the faster reactions the pressure was made up with He when necessary. The measured rates were found to be independent of pressure for all the fluorocarbons studied.

Evaluation of potential systematic errors

As discussed previously (5), the overall accuracy of our measurements, based on analysis of the flash period, electronic bandwidth, system linearity, and the analog-to-digital converter resolution, is ±5%. The principal potential sources of significant systematic errors are, therefore, secondary reactions of OH radicals (*a*) with radicals formed by photolysis of the reactant by the flash, (*b*) with the radical products of the initial reaction, and (*c*) with impurities which react with OH faster than the fluorocarbon reactant. Each of these possibilities will now be examined in detail.

The fluoroethanes are completely transparent to the photolysis light (9) ($\lambda > 165$ nm) and therefore no photodecomposition with consequent radical formation takes place.

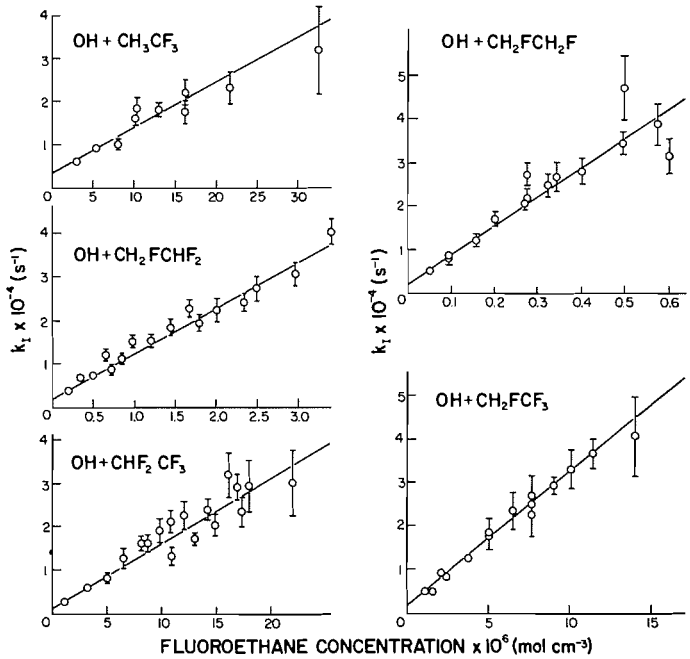

FIG. 1. Plots of pseudo-first-order rate constant, k_I, against the fluoroethane concentration.

[a]The indicated uncertainties are: for this work the 95% confidence limits calculated from the standard deviation and Student's *t* distribution (8), for ref. 10 those stated by the authors.

The maximum effect on the measured rates of the secondary reaction of OH with the radical product of the initial reaction was estimated by numerical simulation of the system (6). Assuming that $k_{OH+radical} \approx 1 \times 10^{14}$ cm^3 mol^{-1} s^{-1} (i.e., the collision rate) it was calculated that the measured rate constants would be increased as a result of the secondary reaction by 3.5% and 7% for [OH] $\approx 1 \times 10^{-11}$ mol cm^{-3} and [OH] $\approx 2 \times 10^{-11}$ mol cm^{-3}, respectively. That secondary reactions of OH with radicals were negligible was confirmed by experiments in which the measured rates were not affected within the experimental error, when the OH concentration was changed by a factor of 4, effected by varying both the pressure of H_2O (0.2–0.8 Torr) and the flash discharge energy (60 and 150 J).

In all the fluoroethanes studied (except CH_3CF_3), the small amounts of impurities react with OH slowly enough so as not to have any significant effect on the measured rate constants at the concentrations present. In the case of CH_3CF_3 the CH_2CFCl impurity (0.4%) caused a 20-fold increase in the rate until it

For personal use only.

was completely removed by treatment with concentrated sulfuric acid, as described in the previous section. As a precaution, we tested all the fluoroethanes studied for undetected olefinic impurities by measuring rates on samples treated with sulfuric acid. In all other cases no significant change in rate was found, indicating the absence of olefin contamination, or, in the case of CH_2FCF_3, that the traces of CF_2CFCl and $CHClCF_2$ present were too small to have any significant effect on the rate measurements.

Discussion

Comparison of rate constant values

Clyne and Holt (10) have reported rate parameters for four of the fluoroethanes studied in this work. They used the discharge flow technique with resonance fluorescence detection of OH. Their values are listed in Table 1 together with ours. With the exception of CH_3CF_3 for which the two determinations agree well, their values for CH_2FCF_3, CHF_2CF_3, and CH_2FCHF_2 are 1.4 to 2.7 times larger than ours. The obvious sources of systematic errors, discussed in the previous section, would all lead to an increase rather than a decrease of the measured rate constant. The reactions of OH with fluoroalkanes are comparatively slow and therefore the presence of even small amounts of fast reacting impurities could increase the observed rate constants. The detection in the present work of minute amounts of olefinic impurities in two fluoroethanes indicates the need for careful analysis and purification of the samples used for rate determinations. Some of the rate constants which appear too large in ref. 10 may have been affected by such impurities.

Correlation of rate constants with bond properties

Several attempts have been made to correlate rate constants for hydrogen abstraction by OH with various bond properties (2, 3, 11–13). A general expression (2) relating rate constants with temperature, molecular parameters, and bond dissociation energies (experimental or estimated), allows estimation of rate constants in many cases to within a factor of 3 but does not work well with halocarbons. Other, more specific correlations have also been examined (11–13), in which a function of the room temperature rate constant k (i.e. log k, log (k/n), log $(k/\sqrt{n})$, where n is the number of hydrogen atoms in the reacting molecule) has been correlated with the bond dissociation energy, D_{C-H}. Of these, a linear plot of log (k/n) at 300 K against D_{C-H} values for some simple saturated organics gives the better correlation (13).

We have presented, in a previous paper (3), a linear correlation between either the log $(k/\sqrt{n})$ or log k and the "isolated" stretching frequencies, ν^{is}_{C-H}, for several alkanes and fluoroalkanes (ν^{is}_{C-H} values are listed by McKean (14) and are obtained by substitution in the molecule of all hydrogens except one by deuterium). The two fluoroethanes studied in this work for which ν^{is}_{C-H} values are available, i.e., CH_3CF_3 (ν^{is}_{C-H} = 3010.0 cm^{-1} (15)), and CHF_2CF_3 (ν^{is}_{C-H} = 3000.7 cm^{-1}, measured in this laboratory on a Nicolet Model 7199 FTIR spectrometer), fit very well on the lines of both log k and log $(k/\sqrt{n})$ given in Fig. 3 of ref. 3.

Before proceeding further, it should be noted that in these correlations and those to be described below, which involve rate constants at one temperature, the assumption is made that for a homologous series of compounds the preexponential factors remain constant after correction for the number of equivalent C—H bonds, and that the difference in reactivity reflects differences in activation energies which can be correlated sometimes with bond properties. The preexponential factors (per C—H bond) reported by Greiner (16) for a series of alkanes are essentially constant. Furthermore, from the successful correlations (3, 13) involving alkanes and fluoroalkanes described above, it appears that the assumption is indeed justified for the reactions of OH with these compounds.

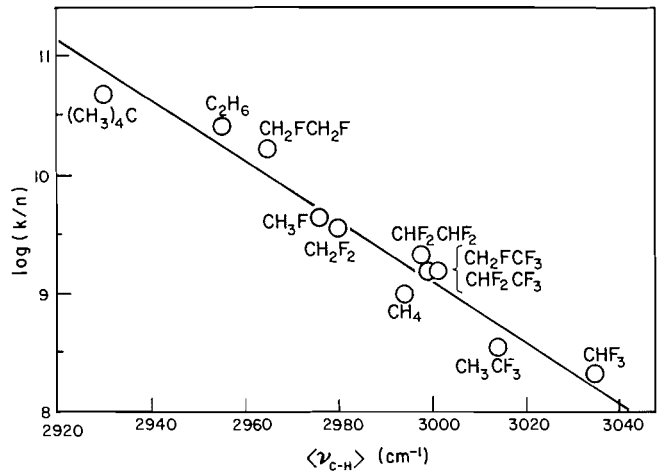

FIG. 2. Correlation of log (k/n) with the average stretching frequency $\langle\nu_{C-H}\rangle$ for selected alkanes and fluoroalkanes with equivalent C—H bonds. The straight line was obtained by least-square fits to the points except that for CHF_3 (see text): slope = $-2.56 \pm 0.25 \times 10^{-2}$, intercept = 85.8 ± 7.5.

CHF_2CF_3	9.18±0.05	3000.7	This work

[a]The rate constants were obtained in this laboratory (this work, refs. 3, 5, and 18) except for that of CHF_2CHF_2 which was taken from ref. 10.

[b]The average frequencies, $\langle\nu_{C-H}\rangle$, were calculated by averaging the C—H stretching frequencies from assigned spectra given in the references; the degeneracies were used as weights and the effects of *gauche* and *trans* isomers were taken into account when applicable.

Correlation of log (k/n) with average stretching frequencies

Correlations involving "isolated" stretching frequencies, although capable of distinguishing between non-equivalent C—H bonds, have limited predictive usefulness, because such frequencies are difficult to obtain experimentally, and hence are not available for many compounds. A potentially more useful correlation, from this point of view, may be with the average stretching frequencies $\langle\nu_{C-H}\rangle$ from a set of equivalent C—H bonds. The concept was introduced by Bernstein (17) who showed that it correlates with bond lengths and with bond dissociation energies. The $\langle\nu_{C-H}\rangle$ values are obtained by aver-

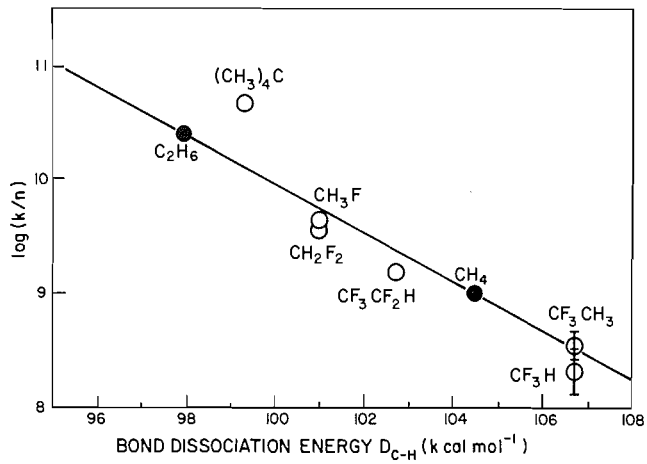

FIG. 3. Correlation of log (k/n) with the bond dissociation energy for selected alkanes and fluoroalkanes. The straight line was drawn connecting the points for CH_4 and C_2H_6 (see text).

aging (using the degeneracies as weights) the C—H stretching frequencies from assigned, gas phase, infrared, and Raman spectra of the corresponding compounds. In Fig. 2, log (k/n) is plotted against $\langle\nu_{C-H}\rangle$ for paraffins and fluoroparaffins with equivalent C—H bonds. The data used and their sources are given in Table 2. The plot is reasonably linear and allows estimates of rate constants to be made to within better than a factor of 2.

The value of ν_{C-H} for CHF_3 is known only approximately because of Fermi resonance (14, 21), the magnitude of which is uncertain (14). The value of $\nu_{C-H} = 2990\ cm^{-1}$ (14) used in our previous paper may have been too low due to too large a correction applied to ν_{C-H} (14). For this reason the point for CHF_3 was placed in Fig. 2 using the experimental value $\nu_{C-H} = 3035\ cm^{-1}$ (21) without correction. The point lies close to the straight line, but in view of the uncertainty involved, it was not used in determining the slope of the straight line in Fig. 2.

Correlation of log (k/n) with bond dissociation energies

Such a correlation is shown in Fig. 3, where log (k/n) is plotted against the bond dissociation energies, D_{C-H}, for alkanes and fluoroalkanes. The straight line in the figure was drawn connecting the points for CH_4 and C_2H_6 for which D_{C-H} values appear to be better established (26–28). The other points in the plot were placed using recommended D_{C-H} values. Although it is, perhaps, somewhat surprising that the alkanes and fluoroalkanes, which are not strictly homologous, fall on a single line in Fig. 3, the correlation seems to indicate that the fluorine atom does not substantially alter the reactivity of a C—H bond outside of its effect on D_{C-H}.

Estimates of bond dissociation energies were made using the correlation line in Fig. 3 and the experimental values of log (k/n), and are listed in Table 3 together with the recommended values in the literature. As may be seen in the table the estimated D_{C-H} values (except that for *neo*-C_5H_{12}) agree well with the literature values obtained from kinetic studies that involve different assumptions (26). The agreement supports the validity of the empirical correlation and hence the estimated bond dissociation energies of CH_3CHF—H, CH_2FCHF—H, CF_3CHF—H, and CHF_2CF_2—H for which there are no reported values. The $D(CH_3CHF—H) = 96.3$ kcal mol^{-1} was estimated using the rate constant of hydrogen abstraction from the α position of CH_3CH_2F which is 85% of the overall rate constant (3, 4).

TABLE 3. Comparison of estimated bond dissociation energies with literature values

Bond	D_{C-H} (kcal mol^{-1}) Estimated[a]	Literature value[b]	Reference
CH_3—H	—	104.5±1.0[c]	26, 27, 28
CH_3CH_2—H	—	98.0±1.0	26, 27
$(CH_3)_3CCH_2$—H	97.0±1.5	99.3±1.0	26
CH_2F—H	101.6±1.0	101.0±2.0	26, 29
CHF_2—H	102.0±1.0	101.0±2.0	26, 29
CF_3—H	107.6±1.5	106.7±1.0	30
CH_3CHF—H	96.3±1.5	—	—
CH_2FCHF—H	98.8±1.0	—	—
CF_3CH_2—H	106.7±1.5	106.7±1.1	31
CF_3CHF—H	103.5±1.0	—	—
CHF_2CF_2—H	103.0±1.5	—	—
CF_3CF_2—H	103.7±1.0	102.7±1.0	32

[a]The quoted uncertainties are approximate and are based on the 1 kcal uncertainty of D_{C-H} for CH_4 and C_2H_6.

[b]The literature values are usually recommended values based often on several determinations.

[c]The value of $D(CH_3—H)$ is based on critical reviews of the earlier data (26, 27) and on recent determinations (28).

The reported value $D(neo\text{-}C_5H_{11}—H) = 99.3$ kcal mol^{-1} (26) is significantly higher than that estimated from the correlation (97.0 kcal mol^{-1}); it is also higher than $D(C_2H_5—H) = 98.0$ kcal mol^{-1} (26, 27). On the basis of the activation energies for hydrogen abstraction from *neo*-C_5H_{12} and C_2H_6 by OH (1.68 and 2.45 kcal mol^{-1} (16), respectively) it may be expected that $D(neo\text{-}C_5H_{11}—H) < D(C_2H_5—H)$ and not the opposite. It could be that $D(C_2H_5—H)$ is substantially higher than reported (26, 27) (i.e. >99 kcal mol^{-1}); however, since the D_{C-H} value of ethane appears to be the better established (26, 27), there may be a need for reexamination of the D_{C-H} of neopentane.

The point for CHF_3 lies close to the straight line in Fig. 3. Thus, the present correlation does not support a suggestion made by Baulch and Campbell, in a recent review of gas-phase reactions of OH radicals (33), that the room temperature rate constant of OH + CHF_3 may be higher than the reported value (3) by about an order of magnitude.

From $D(CH_3CF_2—H) = 99.5 \pm 1.0$ kcal mol^{-1} reported by Pickard and Rodgers (34), it was estimated using the correlation that the rate constant for hydrogen abstraction from the α position of CH_3CHF_2 by OH is $\sim 1.23 \times 10^{10}$ cm^3 mol^{-1} s^{-1}. This corresponds to about 55–63% abstraction from the α position, based on the range of values of the total rate constant (3, 35), 2.23×10^{10} to 1.94×10^{10} cm^3 mol^{-1} s^{-1}.

Finally, from the estimated $D(CH_3CHF—H) = 96.3 \pm 1.5$ kcal mol^{-1} and $D(CF_3CHF—H) = 103.5 \pm 1.0$ kcal mol^{-1}, and the reported heats of formation in the gas phase at 298 K, $\Delta H_f^0(CH_3CH_2F) = -62.9 \pm 0.4$ kcal mol^{-1} (36), $\Delta H_f^0(CF_3CH_2F) = -214.1 \pm 2.0$ kcal mol^{-1} (36), and $\Delta H_f^0(H) = 52.1 \pm 0.001$ kcal mol^{-1} (27), we estimated the heats of formation of the radicals $\Delta H_f^0(CH_3\dot{C}HF) = -18.7 \pm 1.6$ kcal mol^{-1}, and $\Delta H_f^0(CF_3\dot{C}HF) = -162.7 \pm 2.3$ kcal mol^{-1}.

The photochemistry of phenanthrene-substituted molecules[1,2]

HOWARD E. ZIMMERMAN AND GUO-SHENG WU
The Chemistry Department, University of Wisconsin, Madison, WI 53706, U.S.A.

Received July 5, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

HOWARD E. ZIMMERMAN and GUO-SHENG WU. Can. J. Chem. **61**, 866 (1983).

The photochemistry of 3-methyl-3-(9-phenanthryl)-1-butene was examined as part of an investigation into the effects of having two π chromophores of widely different energies participating in a di-π-methane rearrangement. We observed both direct and sensitized reactivity with quantum yields $\phi^{DIR} = 0.043$ and $\phi^{SENS} = 0.053$. The primary reaction product from both direct and sensitized photolyses was 1,1-dimethyl-2-(9-phenanthryl)cyclopropane. However, in practice this product was obtained only from sensitized irradiations where it was almost completely unreactive. The triplet reactivity is unusual in that the typical free rotor decay exhibited by triplets does not lead to inhibition of di-π-methane reactivity in this case. This point is discussed. The intersystem crossing efficiency of the phenanthryl vinyl methane reactant was obtained from the sensitization of biacetyl phosphorescence by the phenanthrene derivative at varying biacetyl concentrations. This was $\phi_{isc} = 0.86$. This result and the bracketing relationships signify that essentially all of the direct irradiation rearrangement utilizes T_1. In addition, from these experiments, $^3k_{d(tot)}$ was determined as 5.8×10^3 s^{-1}. Similarly, $^3k_r = 250$ s^{-1} which is the slowest di-π-methane rearrangement encountered thus far. The rearrangement of the cyclopropane product to form 2-methyl-4-(9-phenanthryl)-1-butene was also investigated. $^1\phi$ was determined to be 0.091 and $^3\phi$ was determined as 0.00072. Thus the interesting contrast was encountered in which the di-π-methane rearrangement proceeds from the triplet while the rearrangement of the cyclopropane product proceeds most efficiently from the singlet.

HOWARD E. ZIMMERMAN et GUO-SHENG WU. Can. J. Chem. **61**, 866 (1983).

On a étudié la photochimie du méthyl-3-(phénanthryl-9-)-3 butène-1 comme un aspect de la recherche portant sur les effets de la presénce de deux chromophores π d'énergies très différentes participant à la transposition di-π-méthane. Nous avons observé les deux réactivités directe et sensibilisée avec des rendements quantiques $\phi^{DIR} = 0{,}043$ et $\phi^{SENS} = 0{,}535$. Le diméthyl-1,1 (phénanthryl-9)-2 cyclopropane et le produit primaire de réaction à partir de la photolyse directe et de la photolyse sensibilisée. Cependant, en fait, on obtient ce produit uniquement à partir des irradiations faites en présence de photosensibilisateurs où il est presque complètement inactif. La réactivité du triplet est inhabituelle en ce sens que la désintégration par centrifiguration libre typique exhibée par les triplets ne conduit pas à une inhibition de la réactivité du di-π-méthane dans ce cas. On discute de ce point. On retrouve l'efficacité du croisement intersystème du réactif phénanthrylvinyl méthane à partir de la sensibilisation de la phosphorescence du biacétyle par le dérivé du phénanthrène à des concentrations variables de biacétyle. Cette efficacité est de $\phi_{cis} = 0{,}86$. Ce résultat et la relation d'encadrement signifient qu'essentiellement toutes le transpositions par irradiation directe utilisent T_1. De plus, on a déterminé à partir de ces expériences que $^3k_{d(tot)}$ est de $5{,}8 \times 10^3$ s^{-1}. De la même façon, on a trouvé $^3k_r = 250$ s^{-1} ce qui correspond à la plus lente transposition di-π-méthane à jamais observée. On a également étudié la transposition du produit du cyclopropane qui donne le méthyl-2 (phénanthryl-9)-4 butène-1. On a trouvé que $^1\phi$ est de 0,091 et $^3\phi$ est de 0,00072. Ainsi, on a trouvé un contraste intéressant à savoir: la transposition di-π-méthane se produit à partir du triplet tandis que la transposition du produit du cyclopropane se fait d'une manière plus efficace à partir du singulet.

[Traduit par le journal]

Introduction

In our investigations dealing with the di-π-methane rearrangement (2*c*), we encountered some unusual effects in which the presence of a low energy π chromophore led to an unusually slow-reacting excited state in the di-π-methane rearrangement (2*a*). In pursuing the generality of this phenomenon, we have utilized phenanthryl-substituted systems. A system of particular interest was 3-methyl-3-(9-phenanthryl)-1-butene **1** because of the presence of the very low energy phenanthryl moiety and also because of the similarity of this reactant to the phenyl relative we had previously (3) investigated.

Results

Synthesis of photochemical reactants and potential photoproducts

The desired di-π-methane reactant **1** was synthesized as outlined in Scheme 1. Additionally, two potential photoproducts, 1,1-dimethyl-2-(9-phenanthryl)cyclopropane **2** and 3-methyl-3-(9-phenanthryl)-1-butene **3** were prepared, and these syntheses are included in Scheme 1. Details are to be found in the experimental section.

*Exploratory photolysis of the 3-methyl phenanthryl butene **1***

It was observed that direct irradiation under preparative conditions led to an isomeric phenanthryl butene **3**. Comparison with authentic material, synthesized as outlined in Scheme 2, showed this photoproduct to be 2-methyl-4-(9-phenanthryl)-1-butene **3**. Since mechanistic reasoning suggested that it was unlikely that this conversion was a one-step, single photon process, irradiations were carried out to shorter conversions. Indeed, under these conditions a new photoproduct dominated the reaction mixture. This proved identical with the synthetically prepared 1,1-dimethyl-2-(9-phenanthryl)cyclopropane **2**. These runs are outlined in Scheme 2 and the experimental section.

In contrast, xanthone sensitized irradiation of the phenanthryl vinyl methane **1** led cleanly to the dimethyl phenanthryl cyclopropane **2** with no observable secondary conversion to 2-methyl-4-(9-phenanthryl)-1-butene **3**. Again, note

[1]This is Paper 135 of our photochemical series. For Paper 134, see ref. 1.

[2]For Papers 128–133, see refs. 2*a*–*f*, respectively.

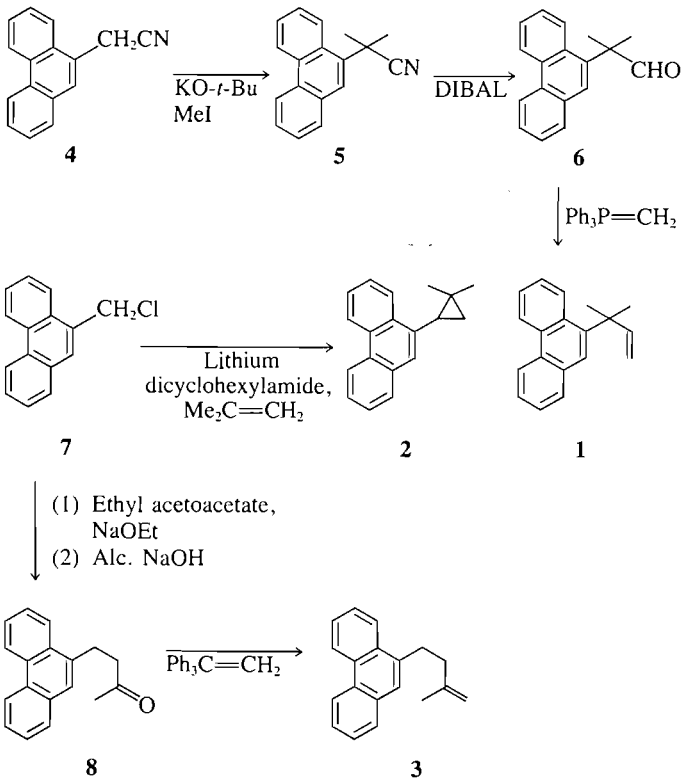


SCHEME 1. Synthesis of 3-methyl-3-(9-phenanthryl)-1-butene **1** and potential photoproducts **2** and **3**.

Scheme 2.

To confirm that direct irradiation of the dimethyl cyclopropane **2** did, indeed, give rise to the 2-methyl-4-(9-phenanthryl)-1-butene **3**, the direct photolysis of cyclopropane **2** was independently carried out and a facile conversion to **3** was observed as depicted in Scheme 2.

A further check (note the experimental section) showed that the direct irradiation of the 2-methyl butene **3** did not lead to its progenitors **1** and **2**.

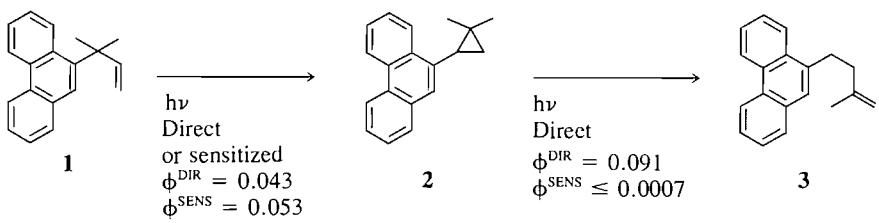
Still another control was the behavior of phenanthryl cyclopropane **2** on sensitization with xanthone. Only unreacted phenanthryl cyclopropane **2** was found, thus accounting for the sensitized photolyses of phenanthryl vinyl methane **1** giving only phenanthryl cyclopropane photoproduct **2**.

A summary of the photochemical rearrangements is given in Scheme 2.

Reactivity of the vinyl phenanthryl methane 1; quantum yield, rate, and intersystem crossing measurements

Quantum yields were determined using the Black Box apparatus (4) and electronic actinometer (5) described in our earlier publications. All quantum yields were determined with extrapolation to zero conversion, a procedure which proved to be necessary for meaningful efficiencies. Similarly suitable solution filters were used. Thus it was made certain that photoproducts were not absorbing any appreciable fraction of the light. A summary of the quantum efficiencies obtained is included in Scheme 2.

Additional experimental data needed for mechanistic purposes included the intersystem crossing efficiency of the phenanthryl vinyl methane **1** and the rate of decay of its triplet. The



SCHEME 2. Photochemical interconversions of phenanthryl-substituted systems.

method of Wilkinson and DuBois (6) and Sandros (7) has proven useful in our previous efforts (8).

We begin with eq. [1] which gives a linear relationship between the reciprocal of biacetyl phosphorescence and the reciprocal of concentration of biacetyl. Here ϕ_P is the observed phosphorescence emission of biacetyl sensitized by hydrocarbon **1**. BI refers to biacetyl, HC refers to the hydrocarbon, ${}^3k_{d(tot)}$ is the total rate of triplet decay by all processes, τ is the triplet lifetime of the hydrocarbon of interest, k_{ET} is the rate of triplet energy transfer to biacetyl, ϕ_{isc}^{HC} is the quantum yield of intersystem crossing of the hydrocarbon, and ϕ_P^{BI} is the phosphorescence efficiency of biacetyl. It can be seen from this equation that the intercept and slope of a plot of $1/\phi_P$ versus

$$[1] \quad 1/\phi_P = 1/\phi_P^{BI}\,[1/\phi_{isc}^{HC} + {}^3k_{d(tot)}^{HC}/\phi_{isc}^{HC}k_{ET}[BI]]$$

$1/[BI]$ are given as in eqs. [2*a*] and [2*b*]. Also the ratio of slope to intercept affords the ratio of the triplet decay rate to the bimolecular rate of energy transfer; note eq. [2*c*]. Here K is an instrumental constant, and REF refers to a reference compound

$$[2a] \quad \text{Intercept} = K(1/\phi_{isc}^{HC})$$

$$[2b] \quad \text{Slope} = K({}^3k_{d(tot)}^{HC}/\phi_{isc}^{HC}k_{ET})$$

$$[2c] \quad \text{Slope/intercept} = {}^3k_{d(tot)}^{HC}/k_{ET} = k_{ET}\,\tau$$

$$[2d] \quad \text{Intercept (HC)/intercept (REF)} = \phi_{isc}^{REF}/\phi_{isc}^{HC}$$

whose intersystem crossing efficiency is known.

For this treatment, biphenyl was used as a standard of known (7, 8) intersystem crossing efficiency. Here $\phi_{isc}^{REF} = 0.81$. Use of eq. [2*d*] led to a value of $\phi_{isc}^{HC} = 0.86$ for the phenanthryl vinyl methane **1**.

Similarly, eq. [2*c*] was utilized with the assumption that the rate of energy transfer is given by the rate of diffusion. This seems valid, since the triplet energy of biacetyl T_1(BI) is 56 kcal/mol compared with 66.5 kcal/mol observed for T_1 of the phenanthryl vinyl methane **1**. It has been noted (9) that triplet transfer processes which are 10 kcal/mol or more exothermic usually are diffusion controlled. Additionally, a bimolecular rate of diffusion of 2.3×10^{10} s^{-1} was calculated from the modified Debye equation (10).[3]

[3]The form $k_{diff} = 8RT/2000\,n$ was used.

TABLE 1. Summary of quantum yields and rates

Quantum yields

Compound	Additive	Quantum yield
Phenanthryl vinyl methane **1**	None	0.043
Phenanthryl vinyl methane **1**	Xanthone	0.053
Phenanthryl cyclopropane **2**	None	0.091
Phenanthryl cyclopropane **2**	Xanthone	≤0.0007

Triplet rates

Compound	Lifetime, μs	$^3k_{d(tot)}$, s^{-1}	ϕ_{isc}	^3k_r, s^{-1}
Biphenyl	28[a]	3.5×10^4	0.81[b]	
Phenanthryl vinyl methane **1**	170	5.8×10^3	0.86	250

[a]Compare ref. 7 which gives a value of 30 μs.
[b]Value taken from ref. 7.

This led to 0.17 milliseconds for the lifetime (τ) of the phenanthryl vinyl methane triplet ^{3}**1**. This corresponds to a rate of decay of $^3k_{d(tot)}$ of 5.8×10^3 s^{-1}.

Finally, with the total rate of decay of T_1 known and with the triplet quantum yield known (i.e. $\phi^{SENS} = 0.053$), it was possible to determine the rate of triplet rearrangement of **1** by use of the relation $^3k_r = {}^3k_{d(tot)}{}^3\phi$. This afforded $^3k_r = 250$ s^{-1}.

The various rate values obtained are summarized in Table 1.

Reactivity of the phenanthryl cyclopropane 2

As noted above, in the direct irradiations of the phenanthryl vinyl methane **1**, it was found that the intermediate phenanthryl cyclopropane **2** was observable only at low conversion. Additionally, independent checks starting with cyclopropane **2** revealed the facile direct rearrangement to afford the 2-methyl phenanthryl butene **3** and also the contrasting lack of reactivity of cyclopropane **2** in sensitized irradiations as suggested by the qualitative exploratory runs described above. Note Scheme 2.

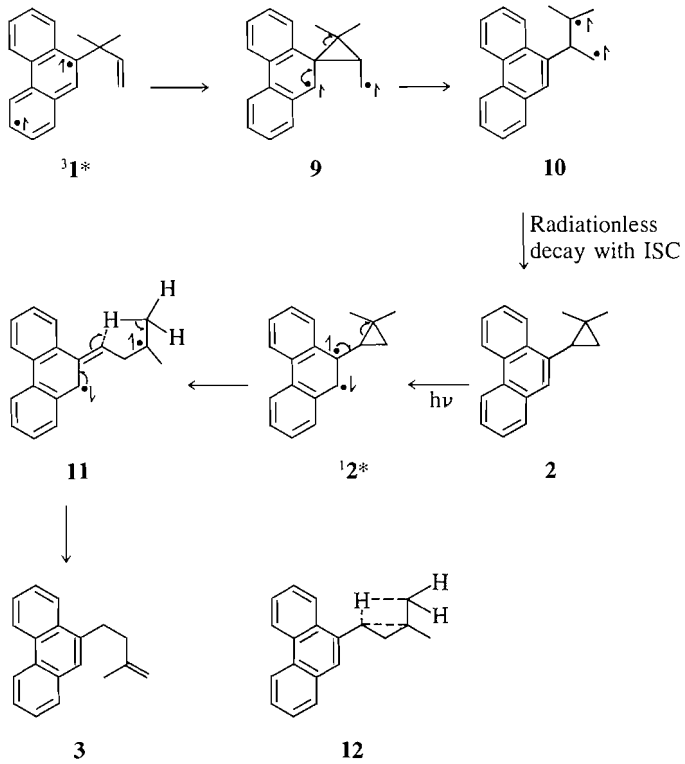
It was desired to obtain a quantitative measure of this behavior. Thus, the quantum yield in the direct irradiation of **2** was determined as 0.091. In xanthone sensitization runs, an upper limit was established as 0.0007 for the quantum yield. These results are included in Scheme 2 and Table 1.

Interpretative discussion

Gross rearrangement mechanisms

A number of aspects of the results deserve comment and interpretation. We begin with the structural details of the two rearrangements uncovered. The transformation of the phenanthryl vinyl methane **1** to the phenanthryl cyclopropane **2** is outlined in qualitative resonance terms in Scheme 3. Also, included in Scheme 3 is the mechanism suggested for the rearrangement of the phenanthryl cyclopropane (i.e. **2**) to afford the 2-methyl phenanthryl butene **3**.

Thus, excitation and intersystem crossing of the phenanthryl vinyl methane **1** affords its triplet ^{3}**1**, effectively the first reactant, as shown in Scheme 3. Application of the usual mechanism for the aryl–vinyl version of the di-π-methane rearrangement (2*c*, 11) to this system leads to the observed phenanthryl cyclopropane **2**.



SCHEME 3. Structural aspects of the rearrangement mechanisms.

Also, Scheme 3 outlines a mechanism for conversion of the phenanthryl cyclopropane **2** to the 2-methyl phenanthryl butene **3**. This involves opening of the benzylic bond of the three-membered ring regiospecifically to afford the more stable of two *a priori* possible diradicals, that is, to form diradical **11** in which one odd-electron center is stabilized by being tertiary. The alternative three-ring opening would afford a diradical with one electron center at a primary carbon. Intramolecular hydrogen transfer via a 5-membered ring transition state leads directly to the observed 2-methyl phenanthryl butene product **3**. An alternative mechanism (12, 13) has the ring opening and hydrogen transfer steps concerted so that, as the three-membered ring is in the process of opening, hydrogen transfer begins.[4] This mechanism involves the transfer of the locus of excitation (14)[5] from the phenanthryl moiety to the four-ring, four-electron Hückel cyclic array as depicted by structure **12** in Scheme 3. With a near HOMO–LUMO degeneracy in such an array (16), excitation flow in this direction does, indeed, become exothermic and favorable. Thus the ΔP elements (14, 15) become small for that part of the system which is most diradicaloid and has a local near degeneracy. This general point is discussed further below in connection with reaction multiplicity.

Multiplicity of the rearranging excited states

Having considered the gross, skeletal nature of the reaction

[4]For a summary of some known examples of the rearrangement, see ref. 12. For evidence of concertedness, note ref. 13.

[5]Note ref. 2*e* for a general discussion. For a specific example of energy flow during excited state reaction, see ref. 15.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

mechanisms, we turn to the reaction multiplicities. For the rearrangement of the phenanthryl vinyl methane **1** to afford the phenanthryl cyclopropane **2**, it is clear from the sensitization runs that the triplet when generated does react. Furthermore, the efficiency of the reaction originating with the triplet T_1 in such sensitization reactions proves to be somewhat greater (i.e. $\phi^{SENS} = 0.053$) than that in the direct irradiations ($\phi^{DIR} = 0.043$) where the initial species formed is S_1. At this point one may conclude that in the direct irradiation T_1 is a permissive species undergoing the rearrangement.

To proceed further we need to utilize the intersystem crossing efficiency ($\phi_{isc} = 0.86$) as determined (note Table 1). We use one ($2f$) of the two (1, $2f$) "bracketing relationships" which proved useful in our earlier studies. Note eq. [3]. Using

$$[3a] \quad {}^1\phi \leq \phi^{DIR} - \phi^{SENS}\,\phi_{isc}$$

$$[3b] \quad {}^1\phi \leq (0.043) - (0.053)(0.86) = 0.002$$

the experimentally observed values of the direct and sensitized irradiations and also the determined intersystem crossing efficiency, we conclude in eq. [$3b$] that the intervention of S_1 of phenanthryl vinyl methane **1** is vanishing and, therefore, that the observed photochemistry in the direct irradiations must derive from the triplet.

Contrasting with the photochemistry of the di-π-methane rearrangement of **1** is the photochemical rearrangement of the phenanthryl cyclopropane **2** to afford the 2-methyl phenanthryl butene **3**. Here it is clear that formation of the triplet of **2** by xanthone sensitization leads to no reaction, while the direct irradiation proceeds with a reasonable efficiency (i.e. $\phi^{DIR} = 0.091$). From this we can conclude that it is the singlet which successfully rearranges and that T_1 is unreactive. One likely rationale for the lack of reactivity of the triplet cyclopropane ^{3}**2** is occurrence of a reversible opening to form the triplet counterpart of diradical **11** of Scheme 3. The rearrangement of the singlet via a cyclic array such as defined by species **12** in Scheme 3 would proceed rapidly.

Such behavior would be another example of the exchange integral control of excited state reactivity by multiplicity (17). Thus, for cases with two possible routes along an excited state hypersurface, we have categorized these alternatives as "large K" and "small K" type reactions depending on the magnitude of the exchange integral and thus the singlet–triplet splitting at the critical points along the reaction coordinate. The general rule is that singlet excited states prefer small K reactions while triplets prefer large K mechanisms (17, 18).

In the present instance the singlet process is the cyclic process leading to the 2-methyl phenanthryl butene **3**. To the extent that this is a concerted process (12, 13), the result is in accord with our previous generalization that pericyclic processes tend to have small K values due to a "mismatch" of their highest bonding and lowest antibonding MO's. The triplet process is three-ring opening. Such openings tend to have large K values in analogy to the double-bond twisting case we discussed earlier. This situation is summarized in Fig. 1.

Still another point regarding three-ring opening of the phenanthryl cyclopropane **2** triplet is the analogy of this process to the common "free rotor" energy dissipation of triplets (8). In reversible three-ring opening a molecule breaks and reforms a bond which has both σ and π components, while in the standard free-rotor effect it is a purely π orbital which is reversibly broken. However the analogy is close.

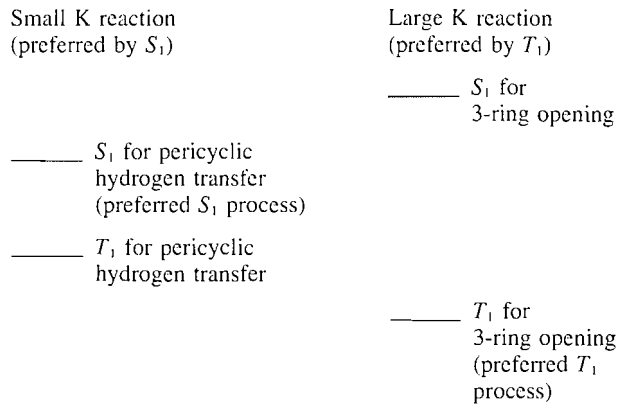


FIG. 1. Large K and small K control of reactivity of the cyclopropane **2**.

Another aspect of interest is the reaction of the phenanthryl vinyl methane **1** by way of T_1 even in the direct irradiations. This signifies that intersystem crossing of the vertical S_1 excited state is more rapid that any rearrangement of S_1. This has analogy in some of the barrelenes. For example, 2,3-naphthobarrelene rearranges, albeit by vinyl–vinyl rather than aryl-vinyl bridging, with analogous rapid intersystem crossing with T_1 being the reactive species in the di-π-methane process (19).

The rates of photochemical rearrangement and related processes

The most remarkable result encountered is the unusually slow rate of rearrangement of the phenanthryl vinyl methane triplet ^{3}**1**: $^3k_r = 250\ s^{-1}$. This is the most slowly rearranging excited state thus far encountered.

Parallel to this slow rate of rearrangement is a slow rate of decay, namely $^3k_{d(tot)} = 5.8 \times 10^3\ s^{-1}$. We note with interest that the decay rate is only slightly greater than the decay rate reported for the phenanthrene triplet itself where $^3k_{d(phen)} = 3 \times 10^3\ s^{-1}$ and τ(phen) = 333 μs (7). Thus, despite a very slow rate of decay, the quantum efficiency of the rearrangement is still reasonable. This is a particularly interesting phenomenon which extends to both singlet and triplet reactivity. Thus, although rates of decay of singlet and triplet excited states range from the present 250 s^{-1} to over $10^{12}\ s^{-1}$, quantum yields for a large variety of reactions remain in the range of 1.0–0.0001 due to the parallelisms between rates of reaction and decay. It appears that there is a fundamental reason for this parallelism. One likely rationale is that the same factors which are responsible for molecular reaction are also involved in molecular decay.

Finally, this is not the first example where particularly small rates of reaction and decay have been observed. In the photochemistry of the corresponding naphthyl vinyl methane ($2a$) the same type of behavior was encountered, except that it was the singlet which was involved. It appears that having a very low energy chromophore, as one of two which interact to rearrange, leads to a lifetime which is characteristic of that low energy chromophore and this type of behavior. Energy is available from the low energy chromophore and deliverable at the sites of bond alteration, but this delivery is slow. The overall excited state lifetime is dominated by the normal lifetime of the low energy chromophore.

Experimental

2-Methyl-2-(9-phenanthryl)propionitrile

To a solution of 10.0 g (89 mmol) of potassium *tert*-butoxide in

100 mL of anhydrous ether at −78°C was added a solution of 5.00 g (23 mmol) of 9-phenanthrylacetonitrile (20) and 19.0 g (134 mmol) of methyl iodide in 50 mL of anhydrous ether over 15 min under nitrogen. After an additional 1 hour at −78°C the mixture was stirred at room temperature for 1 hour. Addition of water, ether extraction of the organic phase, washing the organic layer successively with aqueous ammonium chloride, sodium thiosulfate, sodium chloride, and then drying over magnesium sulfate and concentrating *in vacuo*, followed by chromatography on silica gel and elution with hexane, afforded material which was recrystallized from hexane to yield 4.53 g (80%) of 2-methyl-2-(9-phenanthryl)propionitrile, mp 97–97.5°C.

The spectral data were: ir ($CHCl_3$): 3.27 (m), 3.36 (s), 3.40 (s), 3.48 (m), 4.42 (w), 4.46 (s), 5.85 (w), 6.25 (m), 6.53 (w), 6.67 (s), 6.89 (s), 7.19 (s), 7.24 (s), 7.30 (s), 7.94 (s), 8.48 (s), 8.55 (s), 10.0 (m), 10.4 (m), 10.9 (s), 11.2 (s), 13.9 (m), 15.4 (m), 16.1 (m) μ; nmr ($CDCl_3$) δ: 2.08 (s, 6H, 2 CH_3), 7.68–8.04 (m, 6H, arom), 8.68–8.96 (m, 3H, arom); ms *m/e* (245 calcd. for $C_{18}H_{15}N$): 246 (rel. abund. 5.2, M + 1), 245 (40.4, M), 230 (53.1, M − Me), 215 (9.3, M − 2Me), 205 (0.4, M − CH_2CN), 204 (11.1, M − CH_2CNH), 191 (2.7, M − C_3H_4N), 190 (1.1, M − C_3H_5N), 178 (20.3, phenanthrene), 55 (13.7, CH_3 + CH_2 + CN), 54 (0.2, C_3H_4N), 41 (26.4, MeCN), 40 (1.6, CH_2CN). *Anal.* calcd. for $C_{18}H_{15}N$: C 88.13, H 6.16; found: C 88.21, H 6.21.

2-Methyl-2-(9-phenanthryl)propionaldehyde

To 2-methyl-2-(9-phenanthryl)propionitrile (402 mg, 1.64 mmol) in 20 mL of anhydrous hexane at 0°C was added 2.0 mL (2.0 mmol) of 1 *M* diisobutylaluminum hydride in hexane, the mixture stirred for 20 min at 0°C, then 20 min at room temperature, and then refluxed for 24 h. Saturated ammonium chloride (20 mL) was added and the mixture stirred for 30 min followed by addition of 15 mL of 2% sulfuric acid and then hexane, filtration, ether extraction of the aqueous phase, washing the organic phase with brine and then water, drying, and concentrating. The residue was chromatographed on a 2 × 20 cm silica gel column. Elution with 500 mL of 5% ether in hexane followed by recrystallization from 50% aqueous ethanol afforded 213 mg (52%) of 2-methyl-2-(9-phenanthryl)propionaldehyde, mp 66–67°C, along with 83 mg of reactant.

The spectral data for the aldehyde were: ir ($CHCl_3$): 3.31 (s), 3.38 (s), 3.41 (s), 3.48 (s), 3.57 (m), 3.70 (m), 5.78 (s), 6.25 (m), 6.67 (m), 6.78 (s), 6.89 (s), 7.17 (m), 7.24 (m), 7.75 (s), 8.13 (m), 8.69 (m), 9.26 (m), 10.4 (m), 11.0 (s), 12.2 (m), 13.9 (m), 16.1 (m) μ; nmr ($CDCl_3$) δ: 1.64 (s, 6H, 2 Me), 7.64–7.98 (m, 6H, arom), 8.64–8.84 (m, 3H, arom), 9.80 (s, 1H, CHO); ms *m/e* (calcd. for $C_{18}H_{16}O$: 248.1200): 248.1199. *Anal.* calcd. for $C_{18}H_{16}O$: C 87.06, H 6.50; found: C 87.07, H 6.61.

3-Methyl-3-(9-phenanthryl)-1-butene

Ethereal methylenetriphenylphosphorane was prepared from reaction of 19.6 g (50.8 mmol) of methyltriphenylphosphonium bromide in 200 mL of anhydrous ether by addition of 40 mL (60 mmol) of 1.5 *M* n-butyllithium in hexane. After 4 h a solution of 12.4 g (50 mmol) of 2-methyl-2-(9-phenanthryl)propionaldehyde in 50 mL of anhydrous ether was added. Precipitation of triphenylphosphine oxide began immediately. After 2 hours of reflux the mixture was worked up by treatment with water, hexane extraction, washing with brine, water, drying over magnesium sulfate, concentration *in vacuo*, and chromatography on a 2.5 × 95 cm silica gel column packed with hexane. Hexane elution afforded 5.6 g of crude product which was recrystallized from 95% ethanol at low temperature to afford 4.7 g (38%) of 3-methyl-3-(9-phenanthryl)-1-butene, mp 28–29°C. In a second run 4.31 g (44%) of product was obtained from 9.84 g of reactant.

The spectral data were: ir ($CHCl_3$): 3.26 (m), 3.32 (m), 3.37 (s), 6.14 (m), 6.25 (m), 6.67 (m), 6.94 (m), 7.19 (m), 7.30 (w), 7.46 (w), 8.00 (m), 8.69 (w), 8.93 (w), 9.18 (w), 9.95 (s), 11.2 (s), 13.9 (m), 16.1 (m) μ; uv (EtOH) λ_{max}: 214 nm (log ε 4.48), 252 nm (log ε 4.75), 296 nm (log ε 4.00); nmr ($CDCl_3$) δ; 1.64 (s, 6H, 2 Me), 5.0–5.56 (m, 2H, $=CH_2$), 5.96–6.12 (m, 1H, —CH=), 7.60–7.92 (m, 6H, arom), 8.52–8.82 (m, 3H, arom); ms *m/e* (calcd. for $C_{19}H_{18}$: 246): 246 (15.9 rel. intensity, parent mass M), 231 (38.4, M − Me), 216 (47.0, M − 2 Me), 178 (100, phenanthrene). *Anal.* calcd. for $C_{19}H_{18}$: C 92.63, H 7.37; found: C 92.63, H 7.50.

4-(9-Phenanthryl)-2-butanone

To sodium ethoxide prepared from 690 mg (30 mmol) of sodium and 20 mL of absolute ethanol was added 5.2 g (40 mmol) of ethyl acetoacetate under nitrogen. This cloudy solution was then pumped into a suspension of 6.00 g (25.8 mmol) of 9-chloromethylphenanthrene (21) dissolved in 40 mL of absolute ethanol. After a 1.5 h reflux, 26 mL (80 mmol) of 3 *M* sodium hydroxide was added. This was followed by refluxing for 1.5 h more, and then stirring at room temperature for 2 h. Then 50 mL of 50% (v:v) phosphoric acid was added with stirring at room temperature for 5 h. Approximately 30 mL of ethanol was removed *in vacuo*, the residue was ether extracted, the extracts washed with bicarbonate, then water, dried over magnesium sulfate, and concentrated *in vacuo*. Silica gel chromatography gave 3.5 g (54%) of essentially pure 4-(9-phenanthryl)-2-butanone, mp 90–92°C. Recrystallization from hexane–acetone, hexane–benzene, and from 80% ethanol brought the mp to 94.5–95°C without appreciable loss.

The spectral data were: ir ($CHCl_3$): 3.26 (m), 3.38 (s), 3.43 (m), 3.50 (m), 5.76 (s), 6.67 (m), 7.25 (m), 8.47 (s), 8.55 (s), 9.57 (m), 11.2 (w), 12.3 (m), 13.7 (s) μ; nmr ($CDCl_3$) δ: 2.16 (s, 3H, Me), 2.84–3.00 (m, 2H, $CH_2C{=}O$), 3.32–3.50 (m, 2H, CH_2), 7.20–8.88 (m, 9H, arom); ms *m/e* (calcd. for $C_{18}H_{16}O$: 248): 249 (6.2, M + 1), 248 (53.2, M), 205 (40.6, M − acetyl), 191 (88.2, M − $MeCOCH_2$), 178 (19.0, phenanthrene), 71 (4.7, $MeCOCH_2CH_2$), 57 (24.9, $MeCOCH_2$), 43 (65.9, acetyl). *Anal.* calcd. for $C_{18}H_{16}O$: C 87.06, H 6.50; found: C 87.04, H 6.61.

2-Methyl-4-(9-phenanthryl)-1-butene

Methylenetriphenylphosphorane was prepared under nitrogen from 3.92 g (10.2 mmol) of methyltriphenylphosphonium bromide in 60 mL of anhydrous ether and 7.5 mL (11.1 mmol) of 1.5 *M* butyllithium in hexane. Following 4 h at room temperature, 2.48 g (10.0 mmol) of 4-(9-phenanthryl)-2-butanone in 25 mL of anhydrous benzene was added. Precipitation of triphenylphosphine oxide began at once. After overnight refluxing, water was added and the aqueous phase was hexane extracted. The extracts were washed with brine, water, dried over magnesium sulfate, concentrated *in vacuo*, and chromatographed on a 2 × 75 cm silica gel column, eluted with hexane, 1% ether, 2% ether, and 3% ether in hexane to give 1.90 g of 4-(9-phenanthryl)-1-butene which was recrystallized from hexane, benzene–hexane, and 95% ethanol to give 1.23 g (50%) of product, mp 40–40.5°C.

The spectral data were: ir ($CHCl_3$): 3.27 (s), 3.32 (w), 3.41 (s), 3.51 (w), 6.06 (s), 6.13 (w), 6.25 (w), 6.69 (m), 6.89 (s), 6.99 (m), 7.14 (w), 7.28 (w), 7.64 (w), 8.00 (m), 8.20 (m), 8.55 (w), 8.93 (w), 9.62 (m), 10.0 (m), 10.5 (m), 11.2 (s), 13.7 (s), 14.4 (m), 16.1 (m) μ; uv (EtOH) λ_{max}: 209 nm (log ε 4.60), 249 nm (log ε 4.75), 291 nm (log ε 3.90), 322 nm (log ε 3.35); nmr ($CDCl_3$) δ: 1.72 (s, 3H, Me), 2.36–2.44 (m, 2H, CH_2), 3.00–3.10 (m, 2H, CH_2), 4.76 (s, 2H, CH_2), 7.20–8.44 (m, 9H, arom); ms *m/e* (calcd. for $C_{19}H_{18}$: 246): 247 (3.8, M + 1), 246 (26.8, M), 231 (0.1, M − Me), 192 (12.8, M − $CH_2{=}CMeCH_2$ + 1), 191 (100, M − $CH_2{=}CMeCH_2$—), 178 (0.9, phenanthrene). *Anal.* calcd. for $C_{19}H_{18}$: C 92.63, H 7.37; found C 92.56, H 7.36.

1,1-Dimethyl-2-(9-phenanthryl)cyclopropane

Lithium dicyclohexylamide was prepared by slow addition of 15.3 mL (13.8 mmol) of 0.9 *M* methyllithium in ether to 2.50 g (13.8 mmol) of dicyclohexylamine in 5.0 mL of anhydrous ether and this base was transferred under nitrogen to the dropping funnel attached to a 150 mL flask. The apparatus had been carefully dried and a dry nitrogen atmosphere was initially used. The flask also was fitted with a Dry Ice condenser. With 2.50 g (11.0 mmol) of 9-chloromethylphenanthrene (21) in 5.0 mL of anhydrous ether in the flask, a gentle stream of isobutylene was passed into the flask with Dry Ice

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

–acetone cooling until 16 mL (165 mmol) of isobutene had been collected. A slight stream of isobutene was continued during the run. Then the lithium dicyclohexylamide solution was added with stirring at a rate to maintain gentle refluxing. This required 20 min. After an additional 20 min (longer reaction times led to lower yields) the mixture was treated with water, the solid which separated was washed with hexane, and the combined organic phase washed with 5% HCl, then with brine, water, dried over magnesium sulfate, concentrated *in vacuo*, and the residue chromatographed on a 1.5 × 70 cm silica gel column. Elution with hexane, followed by recrystallization from methanol afforded 0.734 g (27%) of 1,1-dimethyl-2-(9-phenanthryl)cyclopropane as white needles, mp 116–116.5°C.

The spectral data were: ir ($CHCl_3$): 3.27 (m), 3.32 (s), 3.36 (s), 3.40 (m), 3.48 (s), 4.16 (m), 6.25 (w), 6.54 (w), 6.90 (m), 6.99 (m), 7.19 (w), 7.35 (m), 7.64 (w), 8.20 (s), 8.62 (w), 8.94 (s), 9.26 (m), 9.52 (m), 10.5 (w), 12.8 (s), 14.8 (s), 15.7 (w) μ; uv (EtOH) λ_{max}: 210 nm (log ε 4.05), 252 nm (log ε 4.30), 300 nm (log ε 3.60); nmr ($CDCl_3$) δ: 0.72 (s, 3H, *cis*-Me), 0.8–1.0 (m, 2H, CH_2), 1.50 (s, 3H, *trans*-Me), 2.16–2.24 (m, 1H, CH), 8.64–7.48 (m, 9H, arom); ms *m/e* (calcd. for $C_{19}H_{28}$: 246): 247 (rel. abund. 21.9, M + 1), 246 (100, M), 231 (78.2, M − CH_3), 216 (29.8 M − 2Me), 204 (8.5, M − Me_2C), 203 (62.9, M − Me_2CH), 178 (13.7, phenanthrene). *Anal.* calcd for $C_{19}H_{18}$: C 92.63, H 7.37; found C 92.35, H 7.36.

General irradiation procedures

All irradiations were preceded by degassing with vanadous purified nitrogen for 1 hour and the photolyses were conducted under this atmosphere. Exploratory irradiations were carried out using a 450 W Hanovia medium pressure immersion lamp apparatus. Quantitative irradiations were performed using the Wisconsin Black Box apparatus described earlier (4). Light input was monitored with electronic actinometry (5). Potassium ferrioxalate (22) was used for calibration.

Exploratory direct photolysis of 3-methyl-3-(9-phenanthryl)-1-butene

A solution of 150 mg (0.61 mmol) of the methyl phenanthryl butene in 500 mL of *tert*-butyl alcohol was photolyzed for 2 hours through 1 mm of Corex using the preparative apparatus. Solvent removal *in vacuo* left 141 mg of material which was chromatographed on a 1.5 cm × 75 cm silica gel column. Elution with hexane and then 1% ether with 50 mL fractions gave 62 mg (41%) of starting material in fractions 4–7 and 33 mg (22%) of product in fractions 8–13. Stripping the column with 5% ether afforded 25 mg of unidentified products. The starting material was identified by nmr comparison with an authentic sample and the product was recrystallized to mp 39–40°C and proved to be identical with synthetically prepared 2-methyl-4-(9-phenanthryl)-1-butene.

In a run to shorter (1 hour) conversion, photolysis of 150 mg (0.61 mmol) afforded 97 mg of starting material, 21 mg of 2-methyl-4-(9-phenanthryl)-1-butene and 5 mg of unidentified material. The mass balance was 82% and the conversion was 14%.

Low conversion photolysis of 3-methyl-3-(9-phenanthryl)-1-butene; observation of di-π-methane product

Irradiation of 753 mg of 3-methyl-3-(9-phenanthryl)-1-butene in 500 mL of *tert*-butyl alcohol was carried out for 20 min through 1 mm of Corex, and work-up as above. Silica gel chromatography as well as thin layer chromatography proved ineffectual in separating the photoproduct. Chromatography using pentane on 1:1 silica gel – alumina and elution in 25 mL fractions gave fractions 11–13, which were recrystallized from methanol to afford 53 mg of 1,1-dimethyl-2-(9-phenanthryl)cyclopropane, mp 115–116°C, with spectral properties identical to those of authentically synthesized compound. Also, 604 mg of starting material was obtained from the early silica gel chromatography fractions and from fractions 4–8 of the alumina – silica gel chromatogram.

Direct photolysis of 1,1-dimethyl-2-(9-phenanthryl)cyclopropane

A solution of 150 mg of the cyclopropane in 500 mL of *tert*-butyl alcohol was irradiated for 2 hours through 1 mm of Corex. Chromatography on a 2.5 × 95 cm silica gel column packed with hexane but eluted with 1% ether in hexane and with 25 mL fractions gave 39 mg of reactant in fractions 3–7 after methanol recrystallization. Fractions 8–11 were recrystallized from benzene–hexane to afford 53 mg (35%) of 2-methyl-4-(9-phenanthryl)-1-butene, mp 38.5–40°C. This material proved spectrally identical with the authentic material described above.

Direct photolysis of 2-methyl-4-(9-phenanthryl)-1-butene; control run

Photolysis of 150 mg of the 2-methyl alkene for 1 hour through Corex (1 mm), followed by the usual work-up, afforded 130 mg of reactant, isolated by chromatography, and no isolable photoproducts.

Sensitized irradiation of 3-methyl-3-(9-phenanthryl)-1-butene

A solution of 87 mg (0.354 mmol) of the 3-methyl alkene together with 392 mg (2.0 mmol) of xanthone was irradiated in 250 mL of *tert*-butyl alcohol in the Black Box apparatus (4) utilizing the following filter: Cell 1, 0.2 *M* nickel sulfate hexahydrate in 10% sulfuric acid; Cell 2, 0.4 *M* cobalt sulfate in 10% sulfuric acid; Cell 3, 0.10 *M* stannous chloride dihydrate in 15% HCl. This combination gave λ_{max} for transmission at 345 nm and was opaque below 322 nm and above 385 nm; 3.29 meinsteins were absorbed. Then the photolysate was concentrated *in vacuo* and chromatographed on a 2.5 × 35 cm silica gel column. Hexane elution gave 82 mg of oil, and 10% ether gave 378 mg of xanthone. Chromatography of the oil on a 1:1 alumina–silica gel column packed and eluted with pentane with 50 mL fractions gave 59 mg of starting material by recrystallization of fractions 8–17 from 95% ethanol and 16.1 mg (18.5%) of 1,1-dimethyl-2(9-phenanthryl)cyclopropane, mp 114.5–116°C, by recrystallization of fractions 19–23 from methanol. The cyclopropane product proved identical in physical properties to authentic material described above.

Sensitized irradiation of 1,1-dimethyl-2-(9-phenanthryl)cyclopropane

A solution of 87 mg (0.354 mmol) of 1,1-dimethyl-2-(9-phenanthryl)cyclopropane and 392 mg (2.0 mmol) of xanthone in 250 mL of *tert*-butyl alcohol was irradiated in the Black Box apparatus (4) as described above using the same nickel–cobalt–stannous filter combination described previously for use with xanthone. Light output was monitored showing absorption of 3.075 meinsteins. Concentration *in vacuo* and chromatography on a 2.5 × 37 cm silica gel column gave with hexane elution 79 mg of the reactant cyclopropane, identified by its physical properties. Elution with 10% ether afforded 370 mg of xanthone. No further compounds could be observed.

Quantum yield determinations

These measurements were made on the Wisconsin Black Box apparatus (4). Direct irradiations were made using the following triple filter solution (filter A): Cell 1, 2 *M* nickelous sulfate hexahydrate in 10% sulfuric acid; Cell 2, 0.80 *M* cobalt sulphate heptahydrate in 10% sulfuric acid; Cell 3, 1.23×10^{-3} *M* bismuth chloride in 40% hydrochloric acid. This combination was opaque below 260 nm and above 300 nm. Sensitized irradiations used filter B: Cell 1, 0.50 *M* nickelous sulfate in 15% sulfuric acid; Cell 2, 2.0 *M* cobaltous sulfate in 5% sulfuric acid; Cell 3, 1.0 *M* cupric sulphate in 5% sulfuric acid. This combination had a transmission maximum at 337 nm (20%) and was opaque below 310 and above 375 nm. Electronic actinometry (5) was employed and calibration was with potassium ferrioxalate (22). Assays for reactant and products used a phenanthrene internal standard. A 4 × 240 mm hplc column packed with 5–10 μ spherical silica coated with C-18 reverse phase and 40% water in acetonitrile as the eluting solvent were employed. Ultraviolet scanning at 254 nm was used for detection. Planimetry was accomplished using a PDP-11/55 minicomputer along with a Bitpad (Summagraphics Co.) digitizer. For each quantum yield, determinations were made at several extents of conversion and a linear plot to zero conversion was made. Note Table 2 for details.

Fluorescence and phosphorescence measurements

These were made on an Aminco–Bowman spectrophotometer. Measurements were made with a series of diminishing slit openings to make certain that the results were slit independent. Wavelength inde-

pendence was assured by using a biphenyl standard. Degassing was accomplished with 10 freeze–thaw cycles using liquid nitrogen and 20 min pumping time per cycle. An arrangement was devised whereby the freeze–thaw operation was carried out in a separate tube and transferred to the square quartz cell at the end by inverting. The design assured no contact with grease or ground joints. This procedure avoided the common cracking of square quartz tubing on freeze–thaw. Biacetyl concentrations were varied in the range 10^{-5}–10^{-7} M with the phenanthryl vinyl methane at 2.24×10^{-3} M. Plots of biacetyl phosphorescence at 510 nm vs. $[BI]^{-1}$ were linear with biacetyl concentration low enough to preclude singlet energy transfer. The slopes and intercepts were determined at several slit settings and the results proved independent of this variable.

Over many years multiple investigations of the mechanism of the primary quantum conversion steps in natural photosynthesis have exposed the participation of some kind of manganese complex in the oxidation of water to molecular oxygen and the participation of a number of iron hemes in the electron transport chain between the two photosystems. It is almost certain that the participation of an iron–sulfur protein on the reduction side of the photosynthetic electron transfer scheme plays a role in the formation of reduced pyridine nucleotide through ferredoxin and in the evolution of hydrogen in plants deprived of CO_2 but having the hydrogenase present. The physical arrangement of the components is important as well, and the participation of at least one phase boundary (and probably two) in the same transport chain is likely. We have used this information to try to construct a synthetic chloroplast that would accomplish quantum conversion into stored energy in the form of intermediate oxidant and intermediate reductant. These could then be converted, respectively, into a useful oxidation product, or molecular oxygen, on the one hand, and molecular hydrogen, or a more useful reduction product, on the other.

MELVIN CALVIN. Can. J. Chem. **61**, 873 (1983).

Des recherches multiples échelonnées sur plusieurs années ont permis d'approfondir le mécanisme des étapes de la transformation quantique primaire lors de la photosynthèse naturelle et de mettre à jour la participation de certains complexes de manganèse lors de l'oxydation de l'eau en oxygène moléculaire et la participation d'un certain nombre d'hèmes de fer dans la chaîne de transfert d'électrons entre les deux systèmes photochimiques. Il est presque certain que la participation d'une protéine à base de fer-soufre du côté réduction du schéma de transfert photosynthétique d'électron joue un rôle dans la formation du nucléotide portant une pyridine réduite via la ferredoxine et dans l'évolution de l'hydrogène dans les plantes privées de CO_2 mais contenant l'hydrogénase. La disposition physique des composants est aussi importante et la participation d'au moins une phase limite (et probablement deux) dans la même chaîne de transport est probable. Nous avons utilisé cette information pour essayer de construire un chloroplaste synthétique qui pourrait accomplir cette transformation quantique en énergie de stockage sous la forme d'oxydant ou de réducteur intermédiaire. Ces derniers peuvent alors être transformés respectivement d'une part en un produit d'oxydation utile ou en oxygène moléculaire et d'autre part en hydrogène moléculaire ou en un produit de réduction plus utile.

Introduction

Artificial photosynthesis is a process that mimics the principles of green plant photosynthesis with a totally synthetic device (chemical system) that will capture the quanta from the sun and store them as stable chemicals (1–3). The primary problem of catching, converting, and storing visible light into stable chemical form involves devising a system in which the short-lived energy of a sensitizer can be stored in some stable chemical form, usually by a redox reaction in which an electron is transferred from one point to another point nearby. If energy is to be stored after the electron is transferred, the system must be in a higher energy stage than it was before, that is, the immediate products of the electron transfer reaction will have a great tendency to back-react. Therefore, two problems must be solved: (*1*) We must convert the excitation of the sensitizer (chlorophyll in the green plant) in a very short time to a pair of redox molecules neighboring to each other, which must be capable of back-reacting to give energy. (*2*) We must prevent that back-reaction from occurring, while the two objects are close to each other, until we can move and store them in far greater stability. The green plant has evolved over several billion years and accomplishes these steps with a high degree of efficiency. Our problem is to generalize from what we know of green plant quantum conversion to some physical-chemical principles and to construct an entirely synthetic device that will be successful in splitting the water molecule to yield reductant and oxidant, e.g., hydrogen and oxygen.

The natural material of the green plant in which these reactions occur in the chloroplast is a series of very thin membranes (about 40 Å thick) containing molecules of various types. The membrane is unsymmetrical, suggesting that what takes place in the membrane is a result of two different quantum acts, one on either side of the membrane.

Photosensitized electron transfer across bilayer membranes

Photoelectron transfer in nature, as represented in Fig. 1, shows that two quanta are absorbed in succession, and the quantum at 680 nm removes an electron from the water molecule through a manganese complex and raises that electron to a higher energy level, which is high enough to generate molecular hydrogen. The green plant, however, uses two quanta because the charge does not go directly from the first acceptor to NADPH, but rather goes through a series of downhill electron transfers with the generation of some ATP, the general energy currency of all living organisms. A second quantum then raises that electron again, whence it passes through a sequence of electron transferring agents such as iron–sulfur proteins, eventually reducing NADP to NADPH. The combination of NADPH formed here plus the ATP formed in the first quantum act together to reduce carbon dioxide to sugars. With this two-quantum process and the asymmetrical membrane structure as a model, its seems altogether reasonable that an early step in a synthetic quantum conversion process should be

[1]This manuscript represents a summary of the plenary lecture in the Symposium in Honor of H. E. Gunning. V. Physical Photochemistry, at the meeting of the Canadian Institute of Chemistry, Toronto, Canada, May 31, 1982.

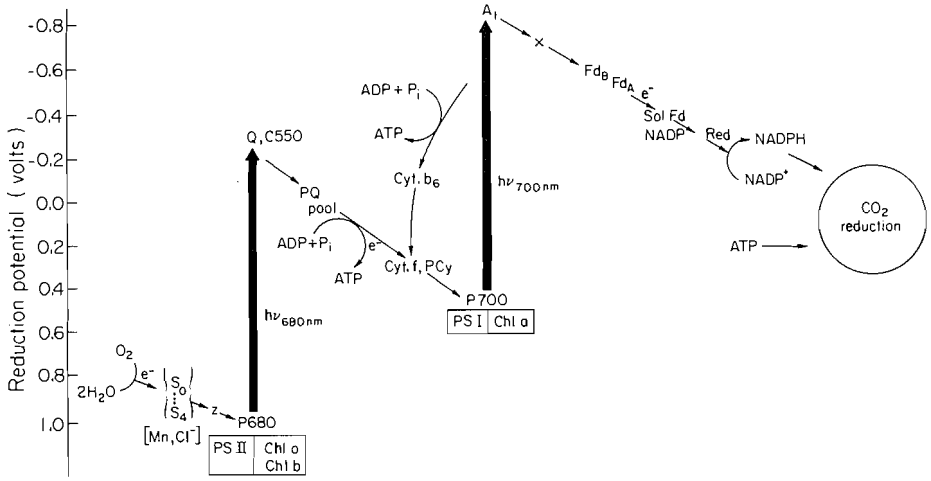

FIG. 1. Photosynthetic electron transfer scheme.

the transfer of an electron across a membrane.

It has been possible to construct a synthetic membrane with sensitizers on both sides and to demonstrate the passage of an electron from one side of the membrane to the other side (4, 5). The membrane consists of interfaces between phases, a water phase, an oil phase, and another water phase (6). Sensitizers have been placed on either side of the membrane at the interface between the water and oil phases. We have suggested as a basic physical principle that the electron must pass through the membrane. Before that happens, however, we must use the principles of photoelectron transfer across a phase boundary to stabilize the first reaction product of the quantum conversion act. The step would be the transfer of an electron from the donor to the acceptor at the phase boundary, i.e., separating the two phase boundary membranes into two separate parts. The transmission of an electron from the water phase, through the insulating membrane barrier to the other water phase, was demonstrated in vesicles using both synthetic and natural surfactant lipids (phospholipids). The synthetic lipids could be either dipolar or monopolar.

When we examined the natural system in the green plant we realized that chlorophyll, the sensitizer molecule, is actually a surfactant dyestuff. The chlorophyll has a hydrophylic head with a hydrophobic tail which is characteristic of surfactant structure. It was necessary to devise surfactant sensitizers more stable than the chlorophyll of the green plant. As one sensitizer molecule, we have used zinc porphyrin, which is more versatile and is capable of having a variety of substituent groups with both positive and negative charges, which can change the solubility function. The zinc porphyrin can also become a surfactant dyestuff by suitable adjustment of substituents. The synthetic electron acceptor, methylviologen or heptylviologen, was modeled after propylviologen sulfonate, a netural molecule, becoming a negative ion only after an electron is passed into it. When one electron is added to the heptylviologen, changing it from a dipositive to monopositive material, it becomes a free radical with a blue color which is stable by itself but not stable to oxygen. It is thus possible to monitor the color and measure the number of electrons transferred across a vesicle wall. The surfactant dyestuff on both sides of the membrane with the electron acceptor (heptylviologen) on the outside of the membrane is shown in Fig. 2. There is a donor system on the other side of the membrane which is irreversibly oxidized by Ru^{3+} to generate Ru^{2+} and oxidation products. An

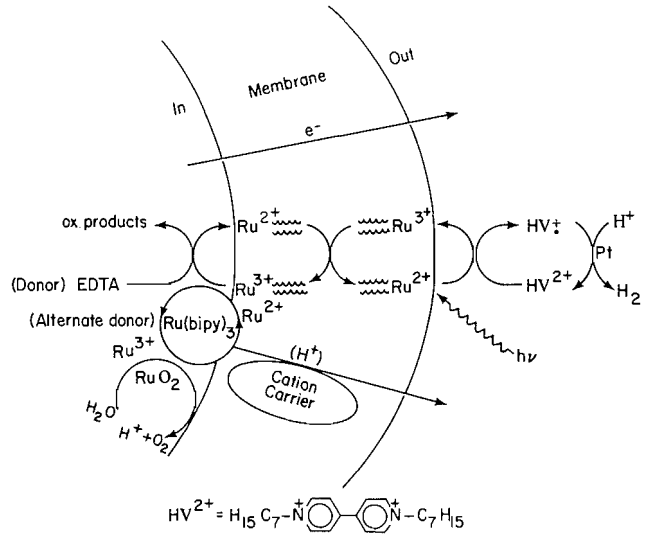

FIG. 2. Scheme for photosensitized electron transfer across a lipid vesicle wall.

alternative donor [$Ru(bipy)_3^{2+}$] has an oxidation potential (as $Ru(bipy)_3^{3+}$] high enough to produce oxygen from water, if there is a surface, such as ruthenium oxide (7), which can accumulate four positive charges. It is possible to make hydrogen on the other side of the membrane by providing a platinum surface to give the two-electron collection which is needed (2).

It is therefore possible to perform a photochemical electron transfer from the inside to the outside of the membrane, producing a reduction product on one side of the membrane and an oxidation product on the other side, which cannot back-react because the membrane prevents it. This is the basic, fundamental structure of the photosynthetic membranes in the green plant chloroplasts.

A number of experiments (8) were performed to test this idea (Fig. 3). A donor was placed on the inside of the membrane and an acceptor (methylviologen) on the outside. In the membrane (lower left), there is some surfactant acceptor present with a ruthenium surfactant sensitizer which produces a viologen radical on the outside; the reaction occurs rapidly at first and then gradually slows. The second experiment (upper) used methylviologen, without heptylviologen, and proceeded more slowly. In the third case (lower right) an electron carrier was

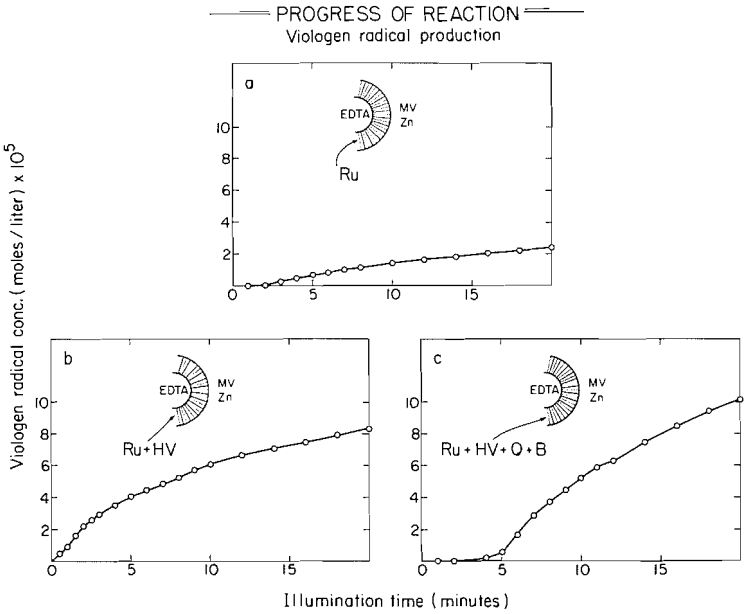

FIG. 3. Cofactors in photoelectron transfer reactions across a membrane sensitized by $Ru(bipy)_3$, EDTA as donor, MV or electron acceptor and Q *p*-benzoquinone as electron carrier, Zn^{2+} added on the outside to prevent any reaction with leaked EDTA.

added to the membrane which had little effect. This last experiment, together with the one without added carrier, did show that an electron carrier is not necessary to achieve electron transfer across a membrane.

The electron exchange between Ru^{2+} and Ru^{3+} across the membrane is an isoenergetic reaction, which is the reason electron tunneling occurs so readily. We have shown by kinetic arguments that this electron transport is the rate-limiting step in the overall reaction. If that is so, then it should be possible to accelerate electron transfer by putting the proper potential across the membrane by selectively adding ions (such as potassium and sodium) on the inside and outside of the membrane with an ionophore in the membrane, a molecule which allows only passage of potassium ions (9). By varying the concentration of ions in the membrane system the potassium ion can be made to flow through the membrane down a concentration gradient while the sodium will be unable to come back. This generates a positive charge on the outside and a negative charge on the inside of the membrane, accelerating electron transfer from the inside to the outside. This experiment can also be reversed, in which case the electron transfer is slowed down. Thus, the potential construction across the membrane helps to substantiate our hypothesis with respect to the mechanism by which the electron transfer is occurring.

Energy transfer on membrane surfaces

Recently (10) we have studied in greater detail the dynamics of the initial quenching reaction of $Ru(bipy)_3$, using the convenient ferricyanide ion in the bulk phase as the quencher (acceptor). A non-linear Stern–Volmer behavior indicated that a significant fraction of excited molecules was inaccessible to the quencher (Fig. 4). Treatment of the data by a modified Stern–Volmer plot showed that only 66% of the luminescent sensitizer molecules were accessible to the quencher (11). Presumably these were the sensitizers on the outside. When ferricyanide quencher was placed both inside and outside the vesicle, all the luminescent molecules were available for quenching and normal Stern–Volmer behavior was observed

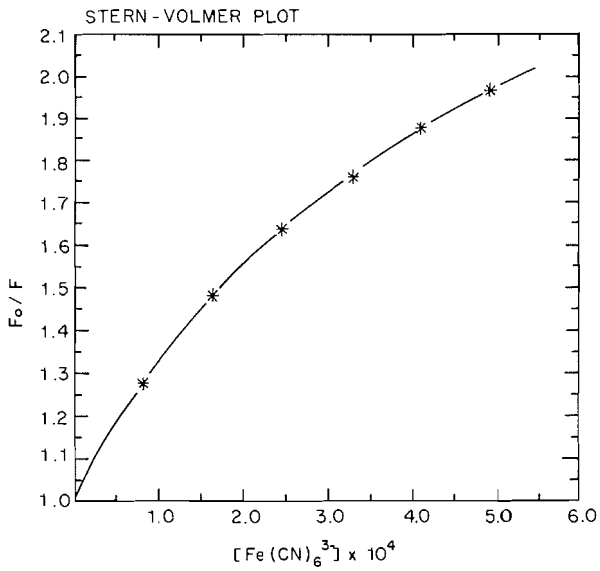

FIG. 4. Luminescence quenching of $Ru(bipy)_3^{2+}$ with quencher outside of vesicles only.

(Fig. 5). From the fraction of quenchable luminescence and the known thickness of the lipid bilayer and the assumption that the head groups of the sensitizer lie at the surfaces, the outer diameter of the vesicles could be computed to be about 350 Å.

We found that over a wide range of sensitizer concentration in the lipid the percent of quenchable luminescence remained constant at 66%, indicating that there was no energy exchange between sensitizers *across* the membrane during the excitation lifetime even when the number of transmembrane neighbors was greatly increased. On the other hand, increase in surface sensitizer concentration *did* result in larger quenching rate constants, suggesting that exciton coupling may be taking place among sensitizers on the same side of the membrane. By this mechanism, the effective surface area over which a particular excitation can interact with quencher is increased, and, therefore, in a diffusion-controlled quenching reaction, the quench-

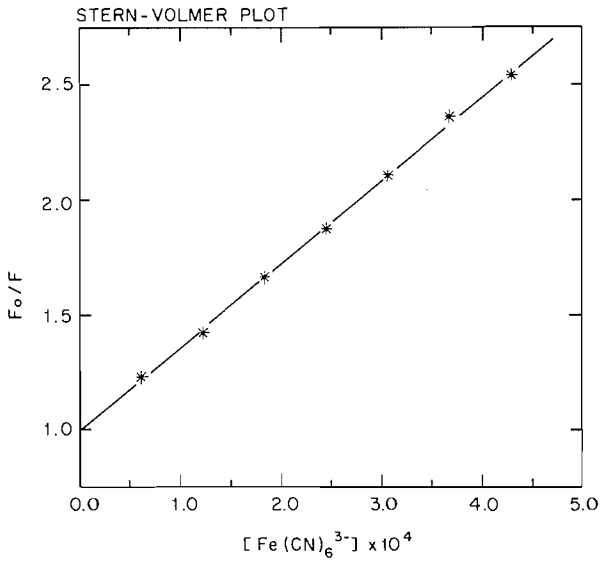

FIG. 5. Luminescence quenching of $Ru(bipy)_3^{2+}$ with quencher inside and outside of vesicles.

ing rate itself is increased.

Implications of this added excitation migration process in the overall dynamics of photosensitized electron transport are still being explored. However, our major conclusion is unchanged, namely, that the mechanism of electron transport through the vesicle wall is by charge exchange between surfactant $Ru(bipy)_3^{3+}$ and $Ru(bipy)_3^{2+}$ on opposite sides.

A method entirely independent of fluorescence was then used to check on our vesicle size determination. The vesicles were prepared in a buffer containing ^{14}C-labelled sucrose, which does not penetrate the bilayer. After gel filtration to remove the outside sucrose, the observed radioactivity of the vesicle suspension gave a measure of the total internal volume. Then from the total amount of lipid present and the known membrane thickness the average vesicle diameter could be computed to be about 500 Å, in fair agreement with the value obtained from the fraction of sensitizer that is quenchable. The two values could be made consistent by assuming either that the sensitizer head groups protrude from the lipid surfaces into the aqueous phases by about 15 Å or that the surface density of sensitizer on the inside is somewhat smaller than on the outside, perhaps because of the higher degree of curvature.

Photosensitized electron transfer in water-in-oil emulsions

It is also possible to transfer an electron across a single phase boundary in an emulsion (12) (Fig. 6). The photosensitizer used is zinc tetraphenylporphyrin sulfonate, a negatively charged material with four sulfonic acid groups, which is water soluble and will remain in a water droplet. The acceptor, methylviologen, is also water soluble. The donor, thiophenol, is in the interphase region. When this particular system is illuminated, the zinc–TPPS becomes excited, the excited state transfers an electron to the methylviologen which produces the blue color, the zinc–TPPS becomes oxidized, and the oxidized zinc–TPPS returns to the reduced form through the polar thiol group which concentrates at the water–toluene interface. When thiol is oxidized from sulfhydryl to disulfide, it moves away from the interface and is now oil soluble. Thus the separation of the oxidized product (disulfide) from the reduced product (viologen radical) is achieved by forming them in two separate phases.

The inner surface of the water droplet is surrounded by positively charged surfactants which affect the efficiency of this reaction. The positive charge attracts negatively charged zinc sensitizer but repels the positively charged electron acceptor. It is possible to use a neutral electron acceptor such as PVS, and to raise the quantum yield substantially.

Photosensitized electron transfer reactions in SiO_2 colloids

It occurred to us that it might be possible to use a surface potential to achieve separation, without having the charge go across the membrane boundary. It is possible to arrange the system in such a way that the surface potential of the interface will be the controlling factor in the efficiency of the electron transfer (13–15) if the right particles are used with the correct charge distribution and proper structure of donors/acceptors/sensitizers. We chose silica particles which are highly negatively charged to test this hypothesis, performing the experiments at pH 9 to be sure that the positive sensitizer is closely attached electrostatically to the negatively charged surface. The neutral electron acceptor, PVS, can approach either a positive or negative surface. When the sensitizer (Ru^{2+}) is illuminated and excited it can pass its electron to the neutral acceptor, creating a $PVS^{\cdot}$ radical which changes the charge on the ruthenium sensitizer from +2 to +3. The Ru^{3+} is held even more tightly to the negatively charged surface, and the electron acceptor, now negatively charged, is ejected from the field around the negative particles. Thus, the back-reaction of the two materials, which should energetically go back downhill, is prevented (Fig. 7). It is possible to regenerate the sensitizer by using a neutral donor. This reaction, using either positively charged ruthenium or zinc as sensitizer, is shown (Fig. 8) as a function of the light absorbed. The experimental data for the ruthenium (Fig. 8*a*) and for the zinc tetramethylpyridinium porphyrin (Fig. 8*b*) indicate that addition of silica particles prevents the back-reaction. A confirmation of this information was found through flash photolysis experiments which follow the first milliseconds of the reaction. The flash photolysis data show the amount of reduced methylviologen, and there is no question that the silica allows the reduction of the PVS while the negative surface prevents the reduced viologen from back-reacting with the oxidized ruthenium. The retardation of back-reaction can be modified by reducing the negative potential on the silica particles either by adding some salt or decreasing the pH; both of these changes increase the speed of the back-reaction.

We would like to move those electrons even further away from the silica particles by using another electron carrier. We have used PVS as a shuttle to reduce ferri- to ferrocyanide. The ferricyanide has three negative charges and ferrocyanide has four, and neither can approach closely the highly negative charged SiO_2 particles. It would be difficult to reduce directly ferri- to ferrocyanide because of the high potential energy of the negatively charged ferricyanide in the field of the silica particles. Therefore, the neutral PVS can be used as a shuttle because it can approach the silica particle. PVS is converted from a neutral to a negative molecule, is ejected from the negative field of the particle and reaches the ferricyanide and reduces it to ferrocyanide. The shuttle can then go back and accept another electron (Figs. 7 and 9). The same shuttle function occurs in the chloroplasts where the electron transfer chain pulls the electron further away from the initial sensitized membrane surface.

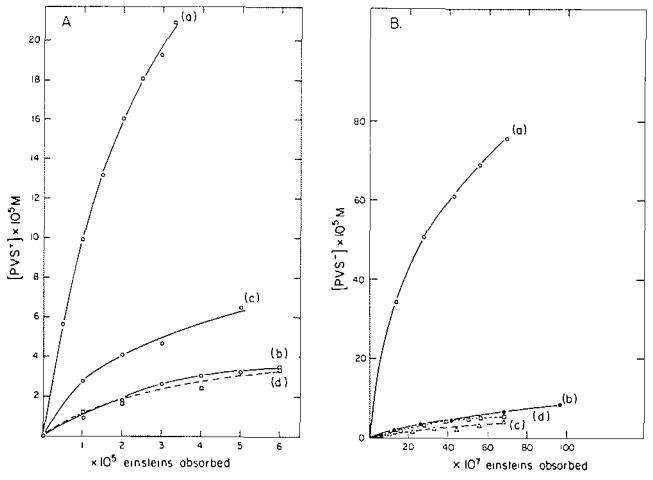

FIG. 8. Propylviologen radical, PVS^-, formation as a function of light absorbed, monitored by the increase of absorbance at $\lambda = 602$ nm ($\epsilon = 12500\ M^{-1}\ cm^{-1}$). (*A*) $Ru(bipy)_3^{2+}$ as sensitizer; (*a*) SiO_2 system; (*b*) homogeneous system; (*c*) micellar system; (*d*) NaLS micellar system with 0.1 *M* NaCl. (*B*) Zn—$TMPyP^{4+}$ and Zn—$TPPS^{4-}$ as sensitizers; (*a*) SiO_2 system with Zn—$TMPyP^{4+}$; (*b*) homogeneous system with Zn—$TMPyP^{4+}$; (*c*) SiO_2 system with Zn—$TPPS^{4-}$; (d) homogeneous system with Zn—$TPPS^{4-}$

As mentioned earlier, we can control the negative potential on the silica surface by adding salt to the environment, which reduces the negative surface potential, controlling what can approach the surface. Other surfaces, such as that of sodium laurylsulfonate micelles (Fig. 10) have surface potentials much lower than that of silica.The quantum yield, therefore, can be controlled by the negative charge of the particle upon which the reaction is occurring. Thus, PVS could be used as a shuttle between two different negatively charged particles, one of the negative particles generating hydrogen and the other generating oxygen (Fig. 11).

Device for photodecomposition of water

We have outlined two different methods for generating or building a device to separate water into its constituent parts using only synthetic materials for this purpose. We have also indicated how such a device can be constructed. We have already used vesicles which are spontaneously formed microspheres composed of phospholipids or synthetic lipids. These vesicles are 40 Å thick and the particle itself is 500 Å in diameter. It may also be possible to use synthetic membranes, which were developed for artificial kidneys or desalinization membranes, and spun in the form of hollow fibers (16). The hollow fibers are the sites for the sensitizers and the medium

through which the electrons can move. Our experiments used a hollow fiber originally synthesized for a desalinization membrane. We stained the fiber with oil-soluble porphyrin by swelling the fiber with an organic solvent (dioxane). The sensitizer (zinc tetraphenylporphyrin), when dissolved in the dioxane, penetrates the swollen fibers; the solvent is then washed out with water, leaving behind in the fiber the water-insoluble sensitizer. Therefore, it has been possible to create a stained fiber with a wall thickness of about 80 microns, containing a dyestuff which resists water. A substantial amount of sensitizer-dyestuff material is required in order to have one dyestuff molecule every 40 Å of fiber body. When an electron is removed from the outside of this hollow fiber, the hole may jump 40 Å each time to reach the other side.

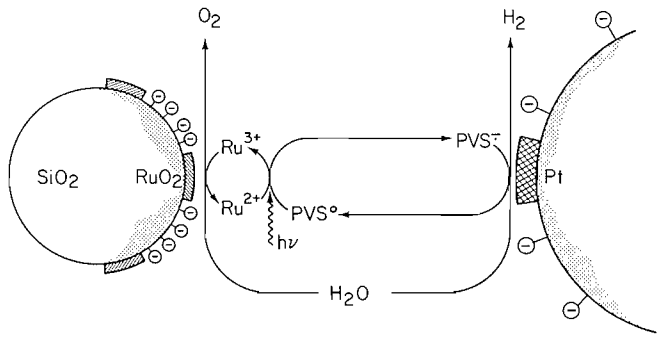

FIG. 11. Utilization of SiO_2 colloids in the photodecomposition of water.

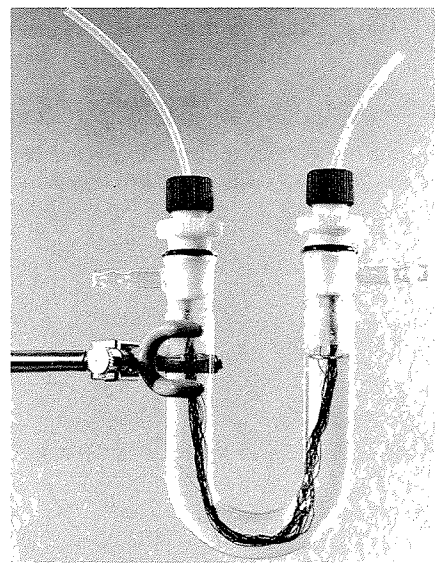

FIG. 12. Hollow fiber apparatus for photodecomposition of water.

The hollow fibers are mounted so the inside and outside can be reached separately (Fig. 12). In this prototype for the system, the inside of the hollow fibers is connected to the inside of the upper plastic tubes, and the outside is connected to the water layer which is accessible to the side-arms of the U-tubes.

With the hollow fiber (membrane) device for photoelectrochemically transferring electrons from one side to the other, it will be possible to place the catalyst for hydrogen production on one side and the catalyst for oxygen production on the other. The reactions have all been performed separately but not yet together in a single device.

Development of catalysts for artificial photosynthetic systems

Until recently, we have not used our knowledge of the natu-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

ral catalysts used by the green plants for the generation of hydrogen from water and generation of oxygen as a byproduct. We have used the phase boundary idea, the surfactant sensitizer idea, the photoelectron transfer idea, and the charge migration idea, but not what we know about the function of the natural catalysts that produce the final products in the plant.

The natural catalyst for molecular hydrogen in plants turns out to be an iron–sulfur cluster of four iron atoms and four sulfur atoms hanging in a protein by mercaptide groups of the cysteine residues of the polypeptide. It is possible to construct a synthetic iron–sulfur cluster that is the catalyst for hydrogen production and this has been done electrochemically but not yet photochemically (17). However, we have recently used synthetic iron–sulfur clusters to determine their photoelectron accepting capability. If one of the synthetic iron–sulfur clusters, tetra[alkyl(aryl)mercapto-μ_4-sulfido-iron], is placed in the water solution with the ruthenium or zinc sensitizer, it quenches the fluorescence of the sensitizer either by energy transfer or by accepting an electron from the excited sensitizer. We propose that the latter mechanism is the correct one (18). We have thus indicated a hydrogen-generating system which does not require platinum as a catalyst by using the iron–sulfur clusters.

Not as much is known, however, about the oxygen-generating catalyst. Manganese is indicated, and experiments over many years have sought to determine the state of that manganese. At one time, we felt it was a binuclear manganese compound, but more recent experiments indicate that the manganese must also be in a cluster, containing at least two manganese (perhaps four, in actuality) because it is necessary to move four electrons from the water to make molecular oxygen.

With the idea that the oxygen-generating catalyst contains two manganese atoms, we synthesized the type of molecule(s) which would have the required characteristics. Our first efforts involved manganese atoms on a rigid bridge-type connection; this turned out to be unsuccessful (19, 20). We then turned our attention to constructing a flexible binuclear manganese compound in which the manganese atoms could change the distance between each other. This can be explained as follows: two manganese porphyrin molecules hooked together by a flexible chain could be in solution; two water molecules could enter, changing the distance between the manganese atoms in the porphyrin molecules, closing the hook so to speak. Then the electrons would be removed via the manganese atoms and the two oxygen atoms could be brought together to make oxygen (21).

We have synthesized a mononuclear surfactant manganese compound (22), and inserted it into a thin membrane together with a zinc porphyrin. By photoexciting the zinc compound it was possible to eject an electron from the zinc to an aqueous viologen acceptor (23). The oxidized zinc in the membrane then extracts an electron from the nearby manganese, also in the membrane, indicating that it is possible to oxidize the manganese catalyst by sensitized oxidation. This is similar to the process used to reduce the iron–sulfur clusters (catalysts) on the hydrogen evolution side. The experimental basis for this observation is shown in Fig. 13. The data indicate that the back-reaction between the reduced acceptor (viologen in the water) and photo-oxidized catalyst in the membrane is inhibited. This inhibition occurs by (*1*) organizing the manganese compound and the photosensitizer (zinc porphyrin) on one side of a membrane interface (Fig. 14), while the acceptor resides in the aqueous phase; (*2*) making the membrane interface negatively charged; and (*3*) using a zwitterionic acceptor, propylviologen sulfonate, whose reduction product is then repelled from the membrane surface. These experiments suggest that the back-reaction between the oxidized zinc sensitizer and the reduced propylviologen sulfonate acceptor is retarded by the negatively charged membrane (Fig. 14).

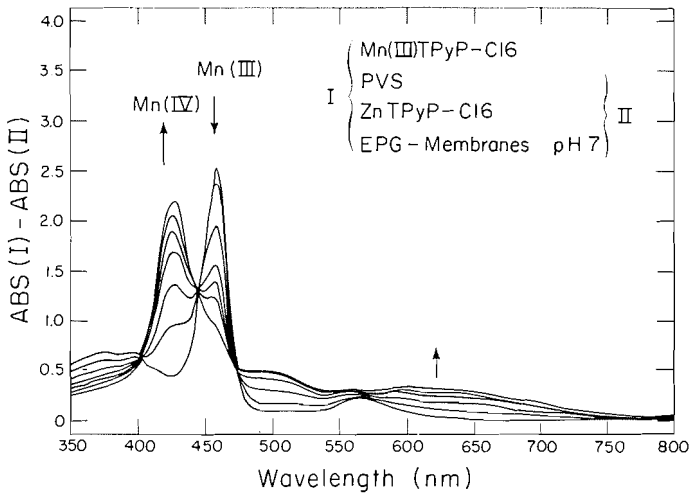

FIG. 13. Difference spectra between system I and system II after illumination.

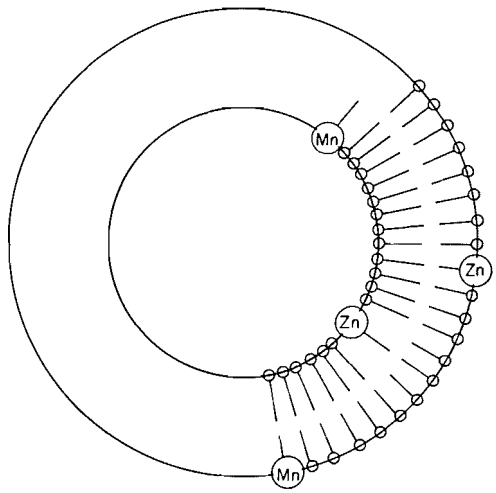

FIG. 14. Single unilamellar vesicle with diameter between 200 and 500 Å, prepared by sonication with indicated ratio between phospholipid and sensitizer of 86:3:1 with PVS added outside the vesicle. Phospholipid: MnTPyP-C16: ZnTPyP-C16 = 86:31; 10^{-3} *M* PVS outside, pH 7.

Conclusion

We can look forward to the creation of an artificial system for photosynthesis, using the principles of synthetic chloroplasts to mimic the way the green plant takes quanta to generate oxidizing power (oxygen) on one side of the membrane and reducing power (hydrogen) on the other. We have used analogues of most of the components of the natural photosynthetic system to achieve the synthetic chloroplasts: (*1*) The phase boundary concept, (*2*) the charge distribution idea, (*3*) electron transfer across the membrane via isoenergetic electron exchange (electron carriers), and (*4*) the use of two catalysts, one for the hydrogen evolution and the other for the oxygen evolution side. We have achieved, outside the green plant, all of

the parts of the natural system; it now remains to put them together into one device.

In our efforts to devise means for the photolysis of water using the light and creating hydrogen as a fuel, we have found that oxygen is generated as a byproduct. In actuality, molecular oxygen, because it is not a fuel, is not the material which is the most useful. It should be possible to use the electron transfer step sometime before molecular oxygen is formed to generate an intermediate oxidant such as a peroxide which is a more useful chemical reactant.

Therefore, it now appears that it will be possible to capture the energy of the sun for energy use (to make molecular hydrogen) and also for chemical use in the form of intermediate oxidants which are used in many chemical processes. The systems described accomplish both of the necessary requirements for a useful solar energy device: (*1*) The capture of the quantum and its conversion to some other energy form and (*2*) the storage of that energy for indefinitely long periods with the possibility of its recovery at will in some convenient form. The green plant has always performed these functions.

Molecular models for recombination and disproportionation of radicals[1]

SIDNEY W. BENSON

Hydrocarbon Research Institute, University of Southern California, Los Angeles, CA 90007, U.S.A.

Received July 5, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

SIDNEY W. BENSON. Can. J. Chem. **61**, 881 (1983).

The modified Gorin model of recombination as a long range interaction of weakly bound radicals, constrained only by steric forces, is rederived to give a collision impact parameter 11% larger than r_{max}, the separation at the centrifugal maximum. This larger impact parameter resolves some of the earlier difficulties with secondary and tertiary radicals. By imposing a new constraint, that the orientation of the radicals be such as to permit exchange forces to act, a new model is developed in which $k_r = 1/4\ Z_r\ \alpha$, where α represents the product of fractions of active surface areas of each radical available for bonding. Excellent agreement is obtained in estimating values of k_r.

Analysis of disproportionation is made to show that it cannot be described by the tight transition state but must also be governed by similar, long range exchange forces between the bond being attacked and the same "active surface" of the abstracting radical. Using an ad hoc radius for C$^{\cdot}\cdots$H—C equal to 4 Å it is possible to reproduce the data on alkyl radical disproportionation to within ±10%.

The model predicts a small decrease in rate of recombination with increasing temperature. This decrease is more pronounced for bulkier radicals and at higher temperatures (>900 K).

SIDNEY W. BENSON. Can. J. Chem. **61**, 881 (1983).

On a procédé à une nouvelle dérivation du modèle de recombinaison de Gorin modifé en tant qu'interaction à longue distance des radicaux faiblement liés et encombrés uniquement par des forces stériques dans le but de donner un paramètre d'impact collisionnel de 11% supérieur au r_{max}, la séparation au maximum centrifuge. Ce plus grand paramètre d'impact résoud quelques-unes des difficultés antérieures rencontrées avec les radicaux secondaires et tertiaires. En imposant une nouvelle contrainte, à savoir que l'orientation des radicaux doit être telle qu'elle permet aux forces d'échanges d'agir, on a mis au point un nouveau modèle dans lequel $k_r = 1/4\ Z_r\alpha$, où α représente le produit des fractions des surfaces actives de chaque radical disponible pour la liaison. On obtenu un excellent accord en évaluant k_r.

On a analysé la dismutation pour montrer qu'on ne peut pas la décrire par l'état de transition intime mais qu'elle doit aussi être gouvernée par des forces d'échange à longue distance semblables entre le lien attaqué et la même "surface active" du radical qui provoque l'élimination. En utilisant un rayon "ad hoc" pour C$^{\cdot}\cdots$H—C égal à 4 Å, il est possible de reproduire les données relatives à la dismutation des radicaux alkyles avec une marge d'erreur de ±10%.

Le modèle prédit une légère diminution de la vitesse de recombinaison quand la température augmente. Cette diminution est plus prononcée pour les radicaux encombrés et se manifeste à des températures plus élevées (>900 K).

[Traduit par le journal]

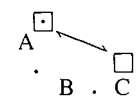
Introduction

Transition State Theory permits us to model chemical reactions as though we were modeling equilibria. That is, we can treat the metastable short-lived transition state complex as though it were a normal molecule. Almost two decades of testing such models against experimental data have seen the development of what are known as "tight" and "loose" transition states. The loose transition state was originally developed by Gorin (1) to describe the recombination of methyl radicals and has since been generalized to describe all radical–radical recombinations (2). The loose transition state resembles two weakly interacting radicals, with their active centers separated by $r^{\ddagger}$ about 2.6 to 3.2 times the normal bonding distance r_0. The relation employed has been derived (2) as:

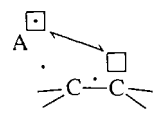
$$[1] \quad r^{\ddagger}/r_0 = (6V_0/RT)^{1/6}$$

where V_0 is the potential energy of the bond being formed and T is the absolute temperature. The distances so obtained for $r^{\ddagger}$ correspond, curiously enough, to van der Waals' distances for many molecules. At $r^{\ddagger}$ the recombining centers have a potential of interaction of about $RT/2$, a very weak interaction.

At the other end of the reaction spectrum is the tight transition state which has been found to characterize well the transition states[2] for metathesis reactions between molecules and radicals, at least for those reactions whose intrinsic activation energies exceed 1–2 kcal. With metathesis we include the addition of radicals or atoms to unsaturated systems which may be looked upon as the metathesis of π-bonds as opposed to σ-bonds which characterize atom transfers. From an electron point of view both metathesis and addition reactions are 3-center, 3-electron systems:



σ-Bond metathesis



π-Bond metathesis

The bonding distances in these reactions are taken as 0.3 Å larger than normal bond lengths and stretching and bending force constants are assumed to be 1/2 their normal values so that the corresponding frequencies are about 0.7 of their normal value.

[1]This work has been supported by grants from the National Science Foundation (CHE 7826623) and the U.S. Army Research Office (DAAG 27-76-G-0195).

[2]In general it is possible to predict the *A*-factors and their temperature dependence within an uncertainty of a factor of 2 or less. The chief uncertainty arises from the uncertainty in knowing whether one is dealing with a linear or bent transition state A$\cdots$B$\cdots$C.

In the present paper we will discuss a model for radical–radical interactions which will have characteristics of both the loose and tight transition states depending on whether we are considering recombination or disproportionation, respectively. What is most striking about these reactions is that they appear to have zero activation energy for both channels, recombination and disproportionation. Highly branched radicals such as *tert*-butyl appear to deviate from this general rule, showing a small decrease in rate of recombination with increasing temperature (6). Also striking about radical–radical reactions is that the rate constants generally fall between the limits of $10^{10.5}$ to $10^{8.0}$ L/mol-s, for all radical species. In fact, a mean value of $10^{9.5\pm0.5}$ would fit 90% of all systems studied.

Recombination of radicals; collision dynamics

Despite intensive efforts extending over a 30-year period, few if any radical–radical rate constants are known to better than a factor of 2 in accuracy. While recent studies show a greater reproducibility, they still show differences of this order between different experimental techniques (3). The most extensively studied system has been methyl recombination, for which 11 separate studies since 1967 yield values for k_r centered about $10^{10.4}$ L/mol-s near 300 K. Values range from $10^{10.38}$ to $10^{10.76}$ (3).[3] Studies at higher temperatures suggest a small decrease in k_r with increasing temperatures. This is difficult to separate from the fall-off in rate with pressure at temperatures above 900 K.

Because of the fact that k_r values are near collision frequencies, it has been useful to compare k_r with collision frequencies corrected for electronic degeneracies. If we write k_r in these terms:

$$[2] \quad k_r = g_e Z_r \alpha$$

then g_e is the ratio of electronic partition functions $g^{\ddagger}/g_1g_2$ for the transition state and radicals. It is usually equal to 1/4, corresponding to the spin factors for radicals which has spin 1/2 forming a singlet recombination product. Z_r is the collision frequency using $r^{\ddagger}$ (eq. [1]) for the collision diameter, while α is the steric factor for the collision and reflects the fact that, at the given separation of active centers $r^{\ddagger}$, not all angular orientations of both radicals are possible. In simple cases it is possible to calculate α directly (2) as a product of the fractions of the solid angles available to each species in the transition state. This modified Gorin model has been called "the restricted, free rotor model" and has been derived from an oversimple model of two point particles moving under the influence of central forces (2). The equation of motion for such a system can be described by:

$$[3] \quad E_0 = \frac{1}{2}\mu(\dot{r})^2 + E_0\frac{b^2}{r^2} - 2\frac{V_0 r_0^6}{r^6} = \frac{1}{2}\mu(\dot{r}_0)^2$$

where r is the radial separation of the point particles with initial relative kinetic energy E_0, impact parameter b, normal bond length r_0, and potential energy of dissociation V_0. E_0b^2/r^2 represents the centrifugal force in the polar trajectory; μ is the reduced mass of the system. The term in V_0 assumes that the valence forces can be represented by an r^{-6} potential at large distances.

In the usual derivation one calculates the forces by differentiation of the potential energy and calculates r_{max}, the separation at which the net force is zero. This is the centrifugal maximum in the potential function where the centrifugal and bonding forces are just equal. At smaller distances the bonding forces are larger, while at longer distances the repulsive centrifugal forces are dominant.

The trajectory described by eq. [3] (which neglects shorter range repulsive forces) is a complex, but smooth, path characterized for each initial set of values of E_0 and b by a distance of closest approach r_c. If, in the course of the trajectory, $r \leq r_{max}$ and $\dot{r}_{max} \leq 0$, then, since the forces are attractive in this region, $\dot{r}$ will remain negative and the trajectory will speed in towards the origin with increasing radical velocity. Note that, since we start with separated partices, $\dot{r}_0$ is initially negative. These trajectories resemble very much those for the Langevin Model for ion–molecule encounters which, in fact, historically provided the inspiration for the model (1). For real molecules the inclusion of short range repulsive forces in eq. [3] will prevent encounters at the origin.

While r_{max} is the minimum collision diameter required for a close encounter it is not the impact parameter for collision. One can calculate the latter by imposing two conditions on the collision. We want to know, for a given E_0, what impact parameter $b^{\ddagger}$ will satisfy the condition that $r_{max} \leq r_c$. On applying this to eq. [3], we find a result very similar to eq. [1]:

$$[4] \quad b^{\ddagger} = 1.5(V_0/E_0)^{1/6}$$

If we take $\langle E_0 \rangle = RT$, then

$$[5] \quad b^{\ddagger} = 1.5(V_0/RT)^{1/6}$$

Although functionally the same as eq. [1], the coefficient is about 11% larger and hence the cross section is about 23% larger.

While functionally of the correct form, eq. [5] does not represent the result of proper averaging of $b^{\ddagger}(E)$ over a Boltzman population. This latter is given by:

$$[6] \quad \langle b^{\ddagger}(E) \rangle = \int_0^{\infty} b^{\ddagger} P(E) dE$$

and using the appropriate P(E) (9)[4] we find:

$$[7] \quad \langle b^{\ddagger}(E) \rangle = 1.52\left(\frac{V_0}{RT}\right)^{1/6}$$

a result which differs from eq. [5] by about 1.5%

A somewhat larger correction is found when we take the proper average of Z_r over a Boltzman population. Z_r is given by (9):

$$[8] \quad Z_r = \pi(b^{\ddagger})^2 c_r$$

where c_r is the relative translational velocity of the colliding pair ($\dot{r}_\theta$ in eq. [2]). Replacing $b^{\ddagger}$ by its value from eq. [4] and setting $E_0 = 1/2\mu c_r^2$, we have:

$$[9] \quad Z_r = \pi(1.5)^2\left(\frac{2V_0}{\mu}\right)^{1/3}\langle c_r \rangle^{1/3}$$

The Boltzman average is then:

$$[10] \quad \langle Z_r \rangle = 2.25\left(\frac{2V_0}{\mu}\right)^{1/3}\langle c_r \rangle^{1/3}$$

[3] All the literature to the end of 1977 will be found in Vol. II; Vol. I summarizes data on radical metathesis.

[4] It can be shown that

$$\langle C^n \rangle = \left(\frac{2RT^{n/2}}{\mu}\right)\frac{\Gamma[(n+3)/2]}{\Gamma(3/2)}$$

$$[11] \qquad = \frac{2.25}{(\mu/2)^{1/2}}(V_0)^{1/3}(RT)^{1/6}(1.02)$$

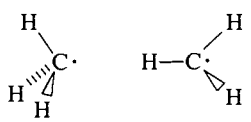
This result is 10% smaller than the result obtained by averaging c_r and $b^\ddagger$ separately and then substituting in eq. [8].

An observation on the dynamics of the encounter described by eq. [3] is appropriate. In the absence of any forces, $r_c = b^\ddagger$ is realized at $\theta = 90°$ when the particles pass each other. During this entire trajectory $r \geq b^\ddagger$. In the presence of attractive forces, r will become less than b at $\theta \doteq 90°$. We observe that $b^\ddagger = 1.11\ r^\ddagger$ marks the boundary line between close and distant encounters.

Methyl radical recombination

For CH_3 recombination, $\Delta H_r^\circ = -90.4$ kcal/mol at 300 K (4). Correcting this to 0 K and for zero point energy we find $V_0 = 96$ kcal so that $r^\ddagger$ (300 K) = 4.84 Å and $\langle b^\ddagger \rangle = 5.37$ Å. Using $g_c = 1/4$ we derive $Z_r = 2.8 \times 10^{11}$ L/mol-s and $k_r = 7.0 \times 10^{10}$. Comparing this with the experimental mean value of 2.4×10^{10} at 300 K we see that $\alpha = 0.34$, implying that 0.66 of all the possible geometric conformations of two CH_3 groups with carbon atoms 5.37 Å apart will not lead to recombination. At this separation, however, we can find that the hindered free rotor model gives no angular correction, that is, $\alpha = 1$. Using a 1.2 Å van der Waals' radius for H, we find that the methyl radicals can rotate freely at $b^\ddagger$ (C—C) = 5.37 Å. We could conclude that the potential function is incorrect and that the true $b^\ddagger$ (C—C) = 3.42 Å which would then give the observed k_r for $\alpha = 1$. This, however, is not an acceptable solution. At 3.42 Å, the methyl radicals are appreciably constrained in their orientation and α would have to be appreciably less than 1.

We should like to suggest an approximate solution to this dilemma for which again a relatively simple model may be adopted. The hindered free-rotor model is a necessary but not a sufficient condition for radical recombination. In order for recombination to occur, exchange forces must be operative between the two radicals. This in turn requires an overlap between the unoccupied electron orbitals. A conformation of two CH_3 radicals in which a H-atom lies along the line of centers, while not involving any van der Waals' repulsion at $b^\ddagger$, $b^\ddagger$ (C—C) = 5.37 Å, also does not permit orbital overlap



(noninteracting methyl radicals, $r = b^\ddagger$)

and thus cannot lead to the weak attraction required by the Gorin Model. Such an analysis suggests a modified model in which we draw a sphere centered on the free radical atom; for $\dot{C}H_3$ it is $\dot{C}$. The radius of this sphere is taken as $r = b^\ddagger/2$. We can now assign the surface of this sphere as active or inactive, depending on whether it is occupied by free electron density (active) or closed shell electrons (inactive). A critical collision for recombination is then considered to occur when two such spheres make contact with their active surfaces touching. In such configurations orbital overlap may occur. When these active areas are in contact, attraction is possible and recombination can take place.

If we represent by β the fraction of the "surface area" of the CH_3 radical of radius = 5.37/2 = 2.68 Å (centered at C) which is active, then $(1 - \beta)$ is the inactive fraction and $\alpha \leq \beta^2$. The inequality is used since, for radicals more complex than CH_3,

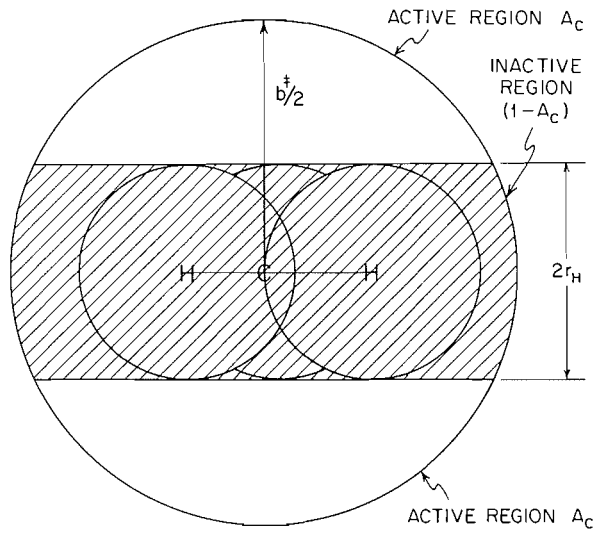


FIG. 1. Methyl radical in projection showing regions active and inactive (shaded) in recombination. r_H is the van der Waals' radius of the H atom; $b^\ddagger$ is the impact parameter for recombination. The third H atoms is behind the two shown.

nonbonded interactions between other portions of the radicals may inhibit contact between the active areas.[5] Using an experimental $\alpha = 0.34$ for CH_3 recombination, we can estimate the active area as $\beta = 0.66$ and the exluded region due to the H atoms $(1 - A) = 0.34$ of the surface area. Figure 1 shows such a sphere for $\dot{C}H_3$.

Is this physically reasonable? A simple model suggests that it is. If we take, as a model of the CH_3 radical, one which is planar so that the H-atoms form a belt around the center then we can project the area of this belt as a zone, symmetrical about the center of the sphere with a width equal to the van der Waals' radius of H of 1.2 Å. This belt subtends a zenith angle of approximately 27° about either side of the equator of this 2.68 Å sphere centered on C, and the zone would subtend 0.45 of the total surface area for $\beta = 0.55$ and $\alpha = 0.30$, in excellent agreement. If we assign to CH_3 a tetrahedral geometry and make the same calculation but assume we have two active areas, a large one with azimuth angle of 83° and a smaller one on the back of the CH_3 with azimuth angle of 44°, the total active area is 58% and $\alpha = 0.34$, not much different. Both models assume that front and back of the CH_3 radical are available for overlap and yield a recombination value differing by about 20% from the "best" observed value.

Baulch and Duxbury (5) have recently made a survey and analysis of k_r for CH_3 radicals and proposed a preferred value of log $k_r = 10.38$ in the range 250–420 K.

From an electron orbital point of view such a model corresponds to an orbital centered on carbon and occupied by a single electron. Pauli exclusion guarantees that this odd electron will be restricted to a volume in space outside the van der Waals' region occupied by the other bound electrons in the system, namely the electron-pairs in the adjacent C—H bonds. This would account for the "shadowing" effect of the neighboring bonds and the restriction of the "active" area or volume to that region in space available to the odd electron.

In Table 1 we list values for k_r taken from the literature together with calculated values of β^2 and α_{exp}. For two different

[5] This is because, at the cone angle of 80°, the axial H atoms are nearly in van der Waals' contact with each other.

[b] Calculated using $r^{\ddagger}$ (calcd) and $g_e = 1/4$. $Z_r = \pi(r^{\ddagger})^2\bar{v}/\sigma$ where $\bar{v}$ = relative velocity at 300 K and $\sigma = 2$ for identical radicals.
[c] From experimental data and eq. [2].
[d] Using dissociation rate constant of ref. 10, of a bond dissociation energy of 83.5 kcal/mol, and an estimated $\Delta S^{\circ}_{300} = -45 \pm 1.5$ eu to calculate k_r at 800 K.

radicals recombining, $\dot{R}_i$ and $\dot{R}_j$, we use the product $\beta_i\beta_j$.

tert-Butyl radical recombination

Among the lowest values observed for the rate of radical recombination is that for *t*-Bu. While some experimental values have shown an alarming spread, the most recent and direct measurements are centered about k_r (*t*-Bu) = 1×10^9 L/mol-s with an uncertainty of about a factor of 2 (3). We calculate $r^{\ddagger}$ = 5.19 Å using a value of V_0 estimated at about 77 kcal/mol. This gives $\langle Z_r \rangle = 3.6 \times 10^{10}$ L/mol-s and hence $\alpha = 0.028$ and $\beta = 0.16$. If we construct a bent model for *t*-Bu with a cone angle of 80°, about half-way between tetrahedral and a flat model, we estimate an active surface fraction β equal to 0.17. We do not include the back side of the *tert*-butyl but only the open side.[5] We also fix the geometry of the H-atoms as corresponding to three axial and six equatorial. This yields β^2 = 0.029, in excellent agreement with the experimental result. Volumes for ethyl and i-propyl may be calculated in similar fashion or else by interpolating the values of β between *tert*-butyl and methyl. Table 1 shows values estimated in this fashion. The agreement with experiment, as evidenced by the comparison of β^2 or $\beta_i\beta_j$ with α, is within the experimental uncertainty for all of these systems.

The effect of temperature on k_r is complex. Overall, the model would appear to predict an increase in k_r varying as $T^{1/6}$. This arises from an increased collision velocity going as $T^{1/2}$ and a decreased collision cross section going as $b^2 \propto T^{-1/3}$. In the range from 300 K to 600 K, over which most measurements have been made, the increase would come to a factor of $2^{1/6}$ = 1.12, too small an effect to be measured. However, as $b^{\ddagger}$ decreases, the collision radius decreases with it and the projected van der Waals' area of the bound atoms such as H in CH_3 becomes a larger part of the inactive surface. Hence β decreases and in the case of CH_3 radicals, which are simpler than most, we estimate a net decrease in recombination rate of the order of $T^{-1/6}$ or about 12% at 600 K.

For bulkier radicals such as *tert*-butyl the situation must be examined more closely. The collision radius we have calculated, of $5.19/2 \simeq 2.60$ Å at 300 K, is smaller than the largest van der Waals' dimension, which is about 3.20 Å. Thus the methyl groups project somewhat beyond the surface of our effective collision sphere and the calculated value of β^2 in Table 1 ignores this. In those conformations where these methyl boundaries touch each other there is an added van der Waals' constraint on the orientation for which a rough estimate reduces β^2 by about 8% at 300 K. At 600 K, with $b/2$ reduced by 12% to 2.32 Å, the van der Waals' repulsion is appreciably larger.

Some efforts have been made to measure CH_3 recombination in shock tubes near 1500 K. At this temperature b = 4.11 Å and $\beta^2 \leq 0.18$, a reduction of a factor of 3 in active area over that at 300 K. However, the effect on k_r is only a reduction of a factor of 2.3 because of the increase in collision rate. No firm data are available for comparison (8).

For many radicals, efforts have been made to deduce recombination rate constants from Arrhenius *A*-factors for the reverse reaction, measured at high temperatures, and the overall entropy change in the reaction. In the case of *tert*-butyl radicals, at 1000 K we deduce $b^{\ddagger}$ = 4.26 Å and there is now considerable restriction in the transition state, both on the mutual orientation of the two radicals and on their internal rotation. In parallel conformation the methyl groups on the opposing *t*-Bu radicals are only 5.3 Å apart (assuming tetrahedral geometry), yielding an effective active area of about 0.07 of the surface. The recombination rate would be reduced by a factor of about 6 compared to its value at 300 K. Data in the range 700–800 K suggest that this may be indeed the case (6).

Radical disproportionation; activation energy

Radical disproportionation is generally a very exothermic reaction with no activation energy and very large rate constants. One which has been well studied, relative to recombination, is that between C_2H_5 radicals. The ratio of rates of disproportionation to recombination, k_d/k_r is 0.14 over a very broad temperature range (3) and is also relatively insensitive to solvent or gas phase. The reaction is exothermic by 61 kcal/mol and if we adopt $k_r = 1 \times 10^{10}$ L/mol-s, then $k_d = 1.49 \times 10^9$ L/mol-s within the same accuracy with which k_r is known. Values for i-propyl and *tert*-butyl are somewhat higher, by factors of about 1.5 and 2 respectively (3). Since these are metathetical reactions, it is instructive to compare them with the known metathesis of radicals with molecules.

Most H-atom metathesis of alkyl radicals with hydrocarbons have intrinsic activation energies near 10 kcal, 90% of the known values lying within ±3 kcal of this number. They are not very sensitive to the exothermicity of the reaction except when $\Delta H \sim 0$, such as for $CH_3 + CH_4$, when they tend to reach maximum values near 14 or 15 kcal (3). Because C—H bond

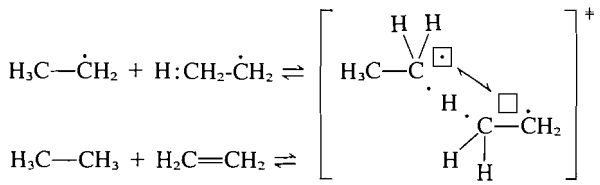
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

strengths lie in the range 84–105 kcal/mol, the exothermicities of metatheses are in the range 0–20 kcal/mol, considerably less than that for disproportionation.

It is of interest to try to understand the reason that radical disproportionations have zero activation energy. In the usual metathesis reaction, we change from the reactants in which we have two bonding electrons in the σ-bond being attacked to the tight transition state in which we have two one-electron bonds. Thus the number of bonding electrons is constant. The extra

$$\square \leftarrow\cdot\rightarrow \boxdot$$
$$A\cdot + B{:}C \rightleftharpoons [A\cdot B\cdot C]^{\ddagger} \rightleftharpoons A{:}B + C\cdot + \text{heat}$$

electron, initially on the attacking radical in the transition state is shared between the entering and leaving groups or atoms. It has been found that if either or both of these is a strong electrophile, the activation energy is thereby decreased (7). It has been suggested that the intrinsic activation energy in these reactions arises from the repulsion between the nonbonding electron and one of the two bonding electrons with which it has a similar spin orientation, essentially a type of triplet repulsion. The situation in disproportionation shows an interesting difference. Again, using two ethyl radicals, we can picture the electron distribution as:



The nonbonding electron can be displaced into an empty orbital associated with the near-neighbor carbon atom as shown, or even begin to participate in the formation of the π-bond, a bonding orbital. This near-neighbor carbon is thus acting as an electrophile and converting a nonbinding electron into a bonding electron. However one interprets such a model, it seems quite reasonable that the activation energy is lowered relative to metathesis and not surprising that it is zero, considering the large exothermicity of the overall reaction.

There are not too many cases reported of disproportionation between radicals involving transfer of atoms other than H. In the few cases that are known of Cl atom transfer, the activation energies reported are either zero or not more than 0.5 kcal (3). A number of reactions are classified as metatheses which are really radical recombinations followed by dissociation. Thus the reaction $H + HO_2 \rightarrow 2OH$, while overall involving O atom transfer, is really a radical recombination.

$$H + HO_2 \rightleftharpoons (HO_2H)^* \rightarrow 2OH$$

Radical disproportionation A-*factors*

The Arrhenius *A*-factor for disproportionation reactions turn out to be anomalously large compared to normal metathesis reactions. Thus, the tight transition state used to characterize metathesis yields *A*-factors of the order of 10^7 to 10^8 per H-atom, at least a factor of 10 lower than the values observed for disproportionation. If we calculate the *A*-factor for ethyl disproportionation by the usual procedure (Table 2), we estimate a value of $10^{7.9}$ L/mol-s, about a factor of 20 lower than the observed value.

Moreover, the usual tight transition state does not give us much flexibility. With 2 one-electron bonds in the C·H·C configuration, the neighboring groups attached to the carbon atoms are at most about 2.8 Å apart (using $r(C\cdot H) = 1.4$ Å) and hence very close to van der Waals' contact. Bending the C·H·C angle by 40° would achieve this if only H atoms were attached to the carbon atoms.

An even more dramatic view of these *A*-factors is afforded by the *A*-factor for the reverse reaction. In the case of ethyl disproportionation this would be the metathesis of C_2H_6 with C_2H_4:

$$C_2H_6 + C_2H_4 \rightarrow 2C_2H_5$$

The entropy increase in this reaction is 9.4 eu so that, using $10^{9.1}$ L/mol-s as the *A* factor for the reverse reaction, we calculate $A = 10^{11.2}$ L/mol-s! If we assign the two partners a collision diameter of 5 Å, the *A*-factor would correspond to the total collision rate at 300 K!

Transition state theory is of course a more sophisticated picture of collision theory. The low *A*-factors calculated for metathesis merely reflect the steric inhibition placed on a possible collision. One can make a direct collision calculation which demonstrates this. If we require a 1.4 Å separation in the C—H bond to be formed, then we can calculate the collision rate for such an event subject to steric constraints. For $2C_2H_5$, assuming 6 abstractable H atoms (3 on each ethyl), we can calculate $k_d = 3.8 \times 10^{10}\ \beta_H\beta_C$ L/mol-s (for singlet collision). Here $\beta_H\beta_C = \alpha$, the steric requirements on the possible orientation of each partner in the collision. If we allow each partner to undergo independent rotations about a fixed (C—H) collision geometry equal to an azimuthal deflection of 30°, we can calculate $\alpha = 4.5 \times 10^{-3}$ and $k_d = 1.8 \times 10^8$ L/mol-s. This is about 2.5 times larger than the transition state model because 30° is too high a flexibility for the assigned (C—H) contact distance. If we had restricted this to 24° we would have recovered the transition state result. It is still about a factor of 10 less than the observed k_d (C_2H_5).

All of these results imply that the interaction between two ethyl radicals must occur at larger separations than we have been calculating. We gain some idea by looking at the product ($\sigma^2 = \beta_H\beta_C$). The chosen values gave us a product 10 times too small. Hence $\sigma = \beta_i$ ($i = 1, 2$) must be increased about three-fold to reproduce the data. For example, if we make $r(C—H) = \sigma = 4.3$ Å, keeping β_i fixed or increasing both appropriately, we could reproduce k_d. At distances like 4.3 Å, however, van der Waals' interactions between hydrocarbons are negligible compared to *RT* and there is no reason why this distance should be significant. Let us suppose, however, that free radicals have a net dipole moment. If they are not exactly planar we would expect a net dipole along the electron orbital. Since the C—H bond has a small dipole moment we would then expect a dipole–dipole interaction which could be represented by:

$$[12] \quad E_{d-d} = \frac{2\mu_1\mu_2\cos\gamma}{r_{12}^3}$$

where γ is the azimuth angle between the C—H bond and the electron orbital dipole. Reasonable dipole moments for these would be 0.32 D for the C—H bond and 1.5 D for the C· moment. Let us assume that these are centered in the midpoint of the C—H bond and the carbon nucleus, respectively, and both oriented along their respective bond directions. Such an interaction is now relatively long range and begins to resemble the recombination model. We can look for the distance at which this interaction is of the order of *RT* at 300 K, assuming

[a] Data from ref. 3 except for $CH_3 + C_2H_5$ for which $k_d/k_r = 0.04$ is known and we have estimated k_r from the geometric mean law $k_{r12} = 2(k_{r11}k_{r22})^{1/2}$.
[b] Steric factors taken from Table 1 for radical recombination. Absolute fractions for each radical are shown in parentheses (from Table 1).

that $\gamma \leq 30°$. We find (eq. [3]) that $r_{12} \leq 2.75$ Å for a C···H distance of 2.20 Å which corresponds to a C···H···C distance of about 3.9 Å. At these larger distances there is much less steric inhibition and an azimuthal angle between the two ethyls of even up to 40° can be accommodated. In fact $r^{\ddagger}$ (C·H) = 2.2 Å, together with azimuthal angles of 40°, will reproduce k_d for ethyls.

In the absence of precise information on the Ċ moment let us proceed empirically. In Table 3 are collected some experimental data on alkyl radical disproportionations. We can represent k_d in the same way in which we treated k_r:

$$[13] \quad k_d = \frac{1}{4}Z_d\alpha = \frac{1}{4}Z_d\beta_C\beta_H$$

Z_d is a "hard sphere" collision rate $= \pi\sigma_d^2\,\bar{v} = \pi\sigma_d^2 (8RT/\pi\mu)^{1/2}$ in which μ is the reduced mass of the collision and σ_d the collision diameter. For nonidentical radicals two possible reactions are possible. Z_d includes the correction for the fact that disproportionation of two identical radicals can occur from either one through an asymmetric transition state. β_C and β_H are the fractions of solid angle available to the collision pair at the carbon radical (β_C) and abstracted H respectively. Without detailed knowledge, there are three parameters in eq. [13], σ_d, β_C, and β_H. We can reduce these by making a relative comparison.

Let us assume that in the cases listed in Table 3, the same number of H atoms in each CH_3 group are available for disproportionation and that β_H is a transferable constant for a methyl group. Ethyl, i-Pr, and *tert*-butyl then have β_H factors in the simple ratio 1:2:3 reflecting the number of available methyl groups. If we further assume that the dynamical, long range interaction is the same, then σ_d is the same for all pairs. By taking ratios of k_r for the different pairs relative to methyl, correcting for reduced masses and numbers of methyls, we can deduce ratios of β_R/β_{Me} which are shown in the 4th column of Table 3. In the last column of Table 3 are shown the ratios of fractions of surface, relative to CH_3, which are active in recombination. The two columns agree to within the experimental uncertainty.

This agreement suggests that the long range forces active in disproportionation are similar to the exchange forces active in recombination. This would help explain the fact that the ratios k_d/k_r show little temperature variation. The developing C—H bond would resemble a hydrogen bond with exchange character. A simple ad hoc model may then be constructed to reproduce the value of k_d.

Let us assume that at r(C···H···C) = 4.0 Å, the critical interaction is of the order of RT and that the same fraction of active area of the carbon center that we computed for recombination is also active in disproportionation. Then we can compute from the data in Table 3 that, for the methyl group, $\beta_H = 0.067$. This corresponds to a conical section of the methyl sphere with an azimuth angle of 30°, small enough to suggest that only one of the three H atoms is active in disproportionation. If all three were active, then for each the azimuth angle would be reduced to 17°. From a chemical point of view, it would be reasonable to expect attack on axial H-atoms which are in the *trans* position to the odd electron. This would facilitate π-bond formation.

Tin oxide and titanium dioxide semiconductor electrodes have been covalently modified by the attachment of functionalized olefins and arenes through surface silanation or via a cyanuric chloride linkage. The excited state and electrochemical properties of the molecules so attached are significantly affected by the semiconductor. Photocurrent measurements and time-resolved laser coulostatic monitoring have been employed to elucidate the mechanism of charge injection on these modified surfaces.

Introduction

Recently the harnessing of solar energy to catalyze kinetically inhibited processes or to drive endothermic reactions has become a widely sought goal. The most promising approaches to the solution of this problem involve photoredox reactions in which an electron is separated from an excited state donor. This electron–hole separation is inherently endothermic and a significant driving force for energy dissipative recombination exists. Only in specially designed systems can this tendency for recombination be sufficiently suppressed for net chemistry to be observed. Because the directional field which develops at an electrode–electrolyte interface can significantly assist such photoinduced electron transfers, these reactions are often accomplished in photoelectrochemical cells (1). The inherent band properties of semiconductors, together with band bending induced when such materials are placed in contact with an electrolyte, inhibit back electron transfer (2), so that electron–hole separation is most easily achievable at the surface of a semiconductor electrode.

There are two basic modes in which photoeffects can be observed at the semiconductor–electrolyte interface: band gap excitation of the semiconductor or sensitized irradiation of a dye molecule adsorbed or chemically attached to the surface of the semiconductor. The first method has been extensively investigated. Typically, band gap excitation leads to high quantum efficiencies for electron–hole separation, and the main limitation of this mode lies in the vexing dilemma imposed by requirements for both photostability and for utilization of large fractions of the incident solar light. That is, those durable semiconductor materials which can withstand extended use in photoelectrochemical cells (e.g., metal oxides) absorb efficiently only in the ultraviolet region of the spectrum and hence are incapable of capturing visible photons to initiate redox chemistry. Those materials which do absorb strongly throughout the solar spectrum (e.g., silicon, metal chalcogenides, sulfides, etc.) are not photostable under prolonged irradiation and require surface modification (as yet not well-defined) for extended use.

The second mode of inducing photoeffects in photoelectrochemical cells, sensitization, has also been limited by seemingly contradictory demands. On the one hand, efficient absorption of light by the sensitizer requires that substantial quantities of the absorptive dye be attached to the electrode surface, but if more than monolayer coverage is attained an insulating layer builds up and the vectorial component of the electrical field, which is required for the assisted electron–hole generation, is diminished dramatically.

Since surface modification is required for extended photoresponsiveness in either mode, we felt that a basic investigation of new synthetic procedures for attachment of photoresponsive molecules and of the effect of the attachment on the excited state properties of such molecules was required. We describe in this paper some of our recent efforts at studying photoredox processes at specifically tailored surfaces and how such modified semiconductors can be usefully employed in mechanistic investigations of charge generation at the photosensitive electrode–electrolyte interface.

Results and discussion

Four methods for attaching highly conjugated organic molecules to the semiconductor surface have been attempted in this study: silanation with tetrachlorosilane, e.g., eq. [1],

and the adsorption of preformed polymers onto a surface, e.g., eq. [4].

[4] 
4

Reasonable monolayer surface alteration (attachment of alcohols **5** and **6**) could be achieved using either the commonly

5 6

employed liquid phase procedure (dip silanation, ref. 3) or a gas phase silanation (4), followed by liquid phase attachment of the organic substrate. The usual techniques for the use of cyanuric chloride as a linking agent also proved effective.

Electrodes **1***a*, **1***b*, **2***a*, and **2***b* prepared in this fashion showed well-resolved waves characteristic of the electroactive organic compound when the well-washed electrodes were immersed in a nonaqueous electrolyte and studied by cyclic voltammetry. Examples of typical traces so obtained are shown in Figs. 1–3. Figure 1 represents the cyclic voltammetric trace of **5** as a 10^{-3} *M* solution in acetonitrile containing 0.1 *M* tetrabutyl ammonium perchlorate (TBAP). A similar reduction wave is evident in the scans of modified electrodes **1***a* (Fig. 2) and **2***a* (Fig. 3) in contact with inert electrolyte (TBAP), although the reversibility of the couple is significantly diminished. Such reduced reversibility will undoubtedly limit the functional lifetime of such a modified surface in photogalvanic operation unless a sacrificial redox system dissolved in the electrolyte can be employed to restore the original surface coverage.

Emission spectroscopy can also be used to establish the successful modification. Figure 4 shows the fluorescence spectrum of a dilute solution of **5** in ethanol. Comparison of this spectrum with that obtained on electrode **1***a* (Fig. 5) shows nearly identical band features, although some broadening and small shifts of the emission maxima have occurred on the surface.

In contrast to these successful surface modifications, our attempted electropolymerization of aryl-substituted vinyl monomers gave poor coverage. Although both methacryloyl chloride and methyl methacrylate could be effectively polymerized by applying a −3 V potential, arylated derivative **7**, prepared by esterification of methacryloyl chloride with **5**, gave no detectable evidence of electrode coating, eq. [3]. Murray and co-workers have similarly observed that cathodic polymerization fails unless the reduction center (i.e., the arene) is conjugated with the vinyl group (5).

Our initial suspicion that the polymerization was inhibited by substantial steric interference by the peri-hydrogens in **7** in the transition state for the chain lengthening step is probably incorrect since conventional solution phase initiation of the polymerization proceeds normally. If the polymer is preformed in solution and is fractionated to obtain relatively low molecular

weight cuts, the resulting sample can be applied, as a methylene chloride solution, to the electrode. Upon solvent evaporation, the polymer adheres and characteristic waves (Fig. 6) can be observed when scanned by cyclic voltammetry as described above. Redox couples (e.g., ferrocene) added to the electrolyte can be oxidized or reduced reversibly through this polymeric coating. Unfortunately, the polymer proved to be light sensitive, with deesterification occurring upon exposure to room light either in solution or at the electrode surface.

The electrodes so obtained were studied by monitoring improvements in sensitized photocurrents produced at the modified electrode compared with those observed with reversible adsorption of the sensitizing dye. For example, previous work in our laboratory has shown that anodic photocurrent can be observed if cyclooctatetraene dianions are excited at the surface of metal oxide electrodes in a photogalvanic cell (6). The net

chemistry observed can be summarized as in eq. [5].

[5] 
Here electron transfer from the dianion to the semiconductor is the primary photoprocess leading to the development of anodic current. Our projection that surface modification might influence the relative kinetics for energy dissipative back electron transfer vs. current producing dismutation was realized in our observation that more than order-of-magnitude enhancement (factors of 20–25-fold improvement) of sensitized photocurrents could be observed on **1***b* compared with those obtained on the native surface (7). Unfortunately, surface degradation during photogalvanic operation was more significant with **1***b* than with the native surface.

Laser-induced time resolved coulostatic measurements (8) reinforce the idea that surface modification does indeed influence the details of the kinetics of electron transfer at the surface of modified electrodes (9). Upon flash excitation of a native TiO_2 electrode in a photoelectrochemical cell, a coulostatic pulse rapidly develops (electron–hole pair formation) which ultimately decays back to its equilibrium value. We find that covalent modification of the semiconductor surface with non-electroactive molecules strongly influences the rate of this decay. Figure 7 illustrates the decay profiles for TiO_2 in native and silanized form. Clearly, the modification process itself diminishes the ability of the semiconductor to induce photoredox reactions, probably by introducing new surface states and/or recombination sites, unless the molecule attached is photo- or electroactive. Whether electroactive covalent modification will displace the surface states to positions outside the band gap or to where they are inacessible to the majority carrier (10) is at present still unknown.

Whether modification affects the intrinsic properties of the semiconductor was another question of interest. By determining the potential at which the onset of photocurrent begins (11, 12) or by characterizing the change in space-charge capacitance produced by the depletion layer at the surface of the semiconductor (13), we can define the band positions in native and in our unmodified electrodes. As in previous studies in our group (14), we find no dramatic alterations of band positions or interface energetics upon monolayer derivatization.

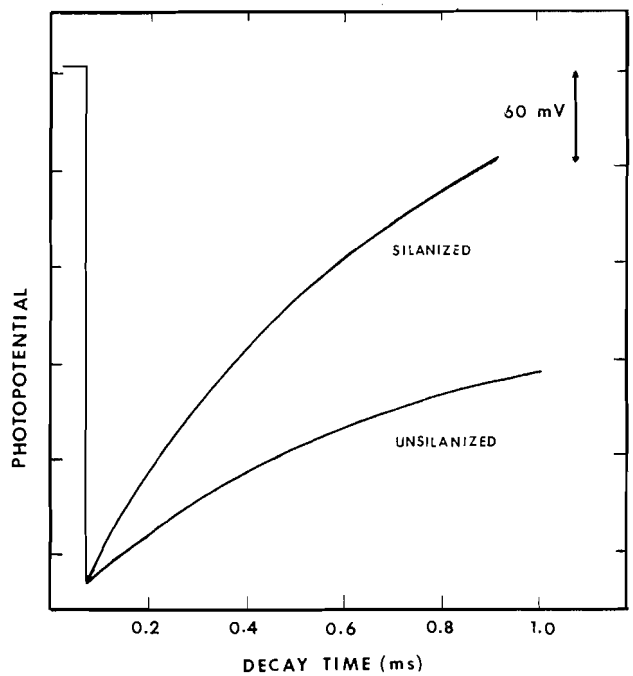

FIG. 7. Coulostatic decay profiles for native and silanized TiO_2.

Preliminary results show that the electroactive polymers described above, e.g., **4**, exert profound effects both on quantum yields for emission and on lifetime of dye molecules electrostatically adsorbed into the polymers. At least tenfold enhancement of both the fluorescence efficiency and the fluorescence lifetime are observed when highly absorptive oxocarbon dyes

are incorporated into polyvinylpyridine, a well-known electropolymerizable species, compared with normal solution phase properties. Such effects were also observed in our mechanistic investigation of sensitization (15) at modified semiconductor surfaces (16) and may be of significant importance to the general problem of expanding the photoresponsive region of stable semiconductors. Continuing effort within our research group is being directed toward the goal of systematically studying excited state properties of molecules confined within the double layer of such electrodes.

Experimental

General

Techniques for material purification, photocurrent measurements, and electrochemical analyses were identical to those previously reported (7). Experimental details relevant to the cyclic voltammograms shown in the figures are listed in the relevant captions. General techniques for electrode pretreatment and for surface modification by silanation or by employing cyanuric chloride as a linking agent have also been described elsewhere (7, 16). The fluorescence spectra reported here were obtained at room temperature in a Spex fluorometer either in the normal 90° mode (for solution phase measurements) or in the front face reflective mode (for measurements on surfaces). Laser coulostatic measurements were conducted on an apparatus nearly identical to that described by Perone *et al.* (8).

Compound 7

The acrylate monomer used in the polymerization studies was obtained by esterification of methacryloyl chloride (Aldrich) with 9-hydroxymethyl anthracene (17). To a solution of freshly distilled methacryloyl chloride (1 g, 0.01 mol) in dry tetrahydrofuran (THF) containing 100 mg pyridine was added dropwise 9-hydroxymethylanthracene (1.5 g, 0.007 mol). The resulting solution was heated under reflux for 45 min. The solvent and unreacted acid chloride were removed by distillation and the residue was recrystallized from petroleum ether.

Polymerization of **7** was attempted by applying a potential of −3 V (vs. SCE) to a SnO_2 or TiO_2 electrode immersed in a solution of **7** (0.02 *M*) in dry acetonitrile containing 0.1 *M* TBAP. After rinsing the electrode with freshly distilled solvent, the electrode was immersed in acetonitrile containing inert electrolyte. No evidence of a wave attributable to an anthracene derivative was evident.

Solution phase polymerization was accomplished, in collaboration with Professor S. E. Webber of this department, by heating a dilute solution of **7** in dry THF containing small quantities of azoisobutyronitrile. Details of the fractionation and polymer characterization will be published elsewhere. The fractionated polymer was dissolved in minimal methylene chloride and was applied to a tin oxide electrode. The solvent was allowed to evaporate and the resulting electrode was washed thoroughly with dry methylene chloride and acetonitrile. A cyclic voltammetric scan of the resulting electrode in acetonitrile containing TBAP showed a well-defined wave characteristic of an anthracene derivative.

Decay dynamics of aromatic thione triplet states in fluid solution[1]

A. SAFARZADEH-AMIRI, R. E. VERRALL, AND R. P. STEER

Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received July 5, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

A. SAFARZADEH-AMIRI, R. E. VERRALL, and R. P. STEER. Can. J. Chem. **61**, 894 (1983).

Phosphorescence emission and excitation spectra, quantum yields, and lifetimes of several aromatic thiones have been measured in fluid solution at room temperature. Excitation to any of the excited electronic states accessible in the near-uv and visible regions of the spectrum results in population of the lowest triplet state with near unit quantum yield. Triplets of relatively inflexible thiones decay non-radiatively with rate constants of the order of 10^5 s^{-1} whereas thiones capable of higher amplitude flexion or group rotation exhibit non-radiative decay constants $\geq 10^7$ s^{-1} at infinite dilution in aprotic solvents. Self-quenching occurs at diffusion-controlled rates.

A. SAFARZADEH-AMIRI, R. E. VERRALL et R. P. STEER. Can. J. Chem. **61**, 894 (1983).

On a mesuré l'émission par phosphorescence, les spectres d'excitation, les rendements quantiques et les temps de vie de plusieurs thiones aromatiques dans une solution fluide à la température ambiante. L'excitation de n'importe quel état électronique excité, accessible dans les régions du proche uv et visible des spectres, conduit à une population du plus faible état triplet avec un rendement quantique proche de l'unité. Les triplets des thiones relativement inflexibles se désintègrent d'une manière non radioactive avec des constantes de vitesse de l'ordre de 10^5 s^{-1} tandis que les thiones qui peuvent subir une flexion de plus grande amplitude ou une rotation de groupe ont des constantes de désintégration non radioactive de $\geq 10^7$ s^{-1} à dilution infinie dans des solvants aprotiques. L'arrêt automatique se produit à des vitesses contrôlées de diffusion.

[Traduit par le journal]

Introduction

Thiocarbonyl compounds exhibit a number of photochemical and photophysical properties which are unusual compared with those of compounds containing only first and second row elements (1–3). For example, as a consequence of their relatively large S_2–S_1 electronic energy gaps, some thiones fluoresce efficiently and react chemically from excited singlet states other than S_1 (1). The tetraatomic thiocarbonyl, thiophosgene, has been shown to undergo a unique excited singlet – excited singlet energy pooling reaction in the gas phase which can populate S_2 with high efficiency (4). There is also substantial evidence of strong spin–orbit coupling in thiones which leads to unusual physical and dynamic properties of their triplet states (5–7). Thus, thiones are among the few organic molecules which phosphoresce in fluid solution at room temperature.

The $T_1 \leftarrow S_0$ absorption in aromatic thiones in fluid solution is often spectrally distinct from other electronic absorption systems and has an oscillator strength which is only about one order of magnitude smaller than that of the corresponding $S_1 \leftarrow S_0$ transition (1). Thus T_1 may be populated either by direct absorption in the $T_1 \leftarrow S_0$ system or by intersystem crossing with high efficiency subsequent to excitation within the singlet manifold. Decay of the lowest triplet is dominated by intersystem crossing to the ground state, leading to small phosphorescence quantum yields and relatively short triplet lifetimes in either matrices at low temperature or in fluid solution. In dilute aprotic fluid solvents photochemical decay processes are minor (8) whereas self-quenching dominates at higher substrate concentrations (9, 10) and very rapid oxygen quenching dominates in air-saturated solutions (11).

To date the most detailed studies of the spectroscopy and photophysics of aromatic thiones in solution have been carried out on xanthione (XT, see Fig. 1). Absorption, emission, and excitation spectra of xanthione in fluid solution, in glasses, and in a Shpolskii matrix have been reported by Huber and coworkers (5, 12–14). These spectral studies and previous ODMR experiments (6) have been interpreted as indicating that the T_1 and T_2 states of xanthione are energetically very close and that the lowest triplet is of mixed $n,\pi^*-\pi,\pi^*$ character. Burland (7, 15) has shown that the triplet state of xanthione has a very large zero field splitting parameter, D (measured in a xanthone host at $T \geq 2$ K), and this has been taken as evidence in support of a mechanism of O_2–triplet thione quenching which involves strong "intramolecular" spin–spin coupling in the encounter complex (11).

The photochemical reactions of the triplet states of numerous aliphatic and aromatic thiones have been described previously (16–19). By contrast, the spectroscopic and photophysical properties of only a few aromatic thiones have been investigated. In this paper we present the results of studies of the spectroscopy and triplet state decay dynamics of seven aromatic thiones (Fig. 1) in fluid solution and examine the effects of molecular structure on these properties.

Experimental

1. Apparatus

Emission and emission excitation spectra were taken either on a single photon counting spectrofluorimeter previously described (20) or on a laser fluorimeter described below. An Optronics Laboratory 1000 W calibrated quartz-iodine lamp was used to obtain spectral correction factors for the detection system, according to the method of Parker (21). Emission quantum yields were determined using solutions of either quinine sulfate ($\phi_f = 0.55$ in 0.1 M H_2SO_4 (22)) or tetracene ($\phi_f = 0.17$ in cyclohexane (23)) as standards. Absorption spectra were taken on a Cary 118 spectrophotometer. All measurements were performed at a room temperature of 22°C.

Phosphorescence lifetimes were measured in the early stages of the work by a time-correlated single photon counting method similar to that described by Ware *et al.* (24) except that a free-running, N_2-filled

flash lamp was used as an excitation source. An argon-ion pumped, cavity-dumped, R6G dye laser was used for excitation later in the work, and a schematic diagram of this apparatus is shown in Fig. 2. A Spectra-Physics, Model 171, argon ion laser operating CW at 514.5 nm pumped a rhodamine 6G dye laser whose output was tuned by means of a birefringent filter. In the cavity-dumped configuration, the standard dye laser output coupler is removed, the cavity is lengthened, and pulsed output is obtained by means of an intra-cavity acousto-optic modulator. Average output powers of up to 200 mW, pulse widths of 12 ns, and pulse repetition rates between single shot and 4 MHz are obtainable with this system, which can also be used to synchronously pump the dye laser when the ion laser is mode-locked. In a typical experiment, an argon ion laser pump power of 2 W produced an average cavity-dumped output power of 2 mW at 582 nm and a repetition rate of 80 kHz. Samples were contained in a clear-sided 1 cm square quartz cell with provision for degassing, which intercepted the beam at Brewster's angle. Emission was collected with a telescope lens system, which, together with the cell, was enclosed in a light-tight box.

Start pulses were obtained by means of a beam splitter, photodiode and discriminator, and were delayed relative to stop pulses by means of appropriate lengths of coaxial cable. Emission was viewed in first order through a Jarrell-Ash, 0.75 m monochromator equipped with an 1800 l/mm holographic grating. A thermoelectrically cooled, red-sensitive RCA 31034 photomultiplier tube provided stop logic pulses, via a constant fraction discriminator, to an Ortec Model 473 biased TAC, the output of which was fed to a Northern, Model NS433, multichannel analyzer operating in the pulse height analysis mode. Deconvolution, background subtraction, and data analysis were performed on a time-shared DEC 2060 computer using standard programs. Single exponential phosphorescence decays with excellent statistical "goodness-of-fit" were obtained without exception.

2. Materials

2,2,3,3-Tetramethylindanthione (TMIT), 4-Br-2,2,3,3-tetramethylindanthione (4-Br-TMIT), 9,9-dimethylanthrathione (DMAT), 2,3,6,7-dibenzocycloheptane-1-thione (DBCHAT), and 2,3,6,7-dibenzocycloheptene-1-thione (DBCHET) were prepared from the corresponding ketones by treatment with P_2S_5 (25). 2,2,3,3-Tetramethylindanone was prepared by the method of Rothstein and Saboor (26) and was halogenated by a standard method (27) to give the 4-bromoketone. 2,6-Dimethyl-4H-1-benzthiopyran-4-thione (DMBTPT) was prepared from the corresponding ketone (28) by the method of Pederson *et al.* (29). *N*-Methylthioacridone (NMTA) was prepared as described previously (11). Solvents were purified by standard techniques and showed negligible luminescence under the conditions used to obtain emission spectra and lifetimes.

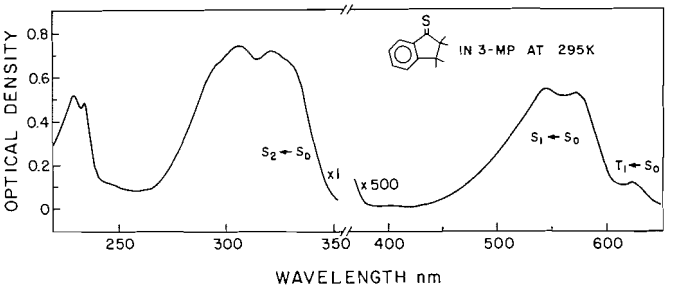

FIG. 3. Absorption spectrum of TMIT in 3-MP at 295 K.

Results

The uv-visible absorption spectrum of TMIT in 3-MP, shown in Fig. 3, is typical of many aromatic thiones in fluid solution at room temperature. The long wavelength absorption ($\lambda > 400$ nm) is due to two separate transitions both nominally of $n \rightarrow \pi^*$ character centered on the thiocarbonyl moiety. The lower energy absorption ($\epsilon_{max} = 3.8\ M^{-1}\ cm^{-1}$) is reasonably well-resolved from the higher energy absorption and is assigned (*vide infra*) as $T_1 \leftarrow S_0$ ($\tilde{a}^3A_2 \leftarrow \tilde{X}^1A_1$ in C_{2v} symmetry). The higher energy of these two long wavelength transitions has an ϵ_{max} of 20.0 $M^{-1}\ cm^{-1}$, an origin near 17240 cm^{-1} and is assigned as $S_1 \leftarrow S_0$ ($\tilde{A}^1A_2 \leftarrow \tilde{X}^1A_1$ in C_{2v}). This absorption is weakly structured in fluid solution at room temperature with distinct bands occurring 860 cm^{-1} and 2290 cm^{-1} to the blue of the 17240 cm^{-1} band. Structure in the $T_1 \leftarrow S_0$ absorption system is masked by the stronger $S_1 \leftarrow S_0$ absorption at room temperature, but structure in both systems becomes much more distinct in low temperature matrices. The first strong transition ($\lambda_{max} = 322$ nm, $\epsilon_{max} = 1.3 \times 10^4\ M^{-1}\ cm^{-1}$) lies in the near-uv and is overlapped by a second strong transition ($\lambda_{max} = 308$ nm) on the basis of its polarization spectrum. The spectral data for TMIT and the other thiones examined in this work are summarized in Table 1. Data for xanthione is provided for comparison (5, 12–14).

Excitation of all of these thiones except DBCHAT and DBCHET in either their weak visible absorption systems or their strong transitions in the near-uv–blue regions in degassed fluid solution at room temperature produces emission in the red and near infrared, assigned as $T_1 \rightarrow S_0$ phosphorescence (*vide infra*). DBCHAT and DBCHET emit too feebly for the emission to be observed at room temperature, but phosphorescence may be seen readily in a 3-MP glass at 77 K. A typical corrected spectrum, that of TMIT in degassed 3-MP at room temperature, is shown in Fig. 4. These spectra are qualitatively similar to the phosphorescence spectra of other aromatic thiones (5, 30–33). Identical phosphorescence spectra (albeit of varying intensities) were obtained by exciting in any of the weak visible or stronger near-uv absorptions. The corrected

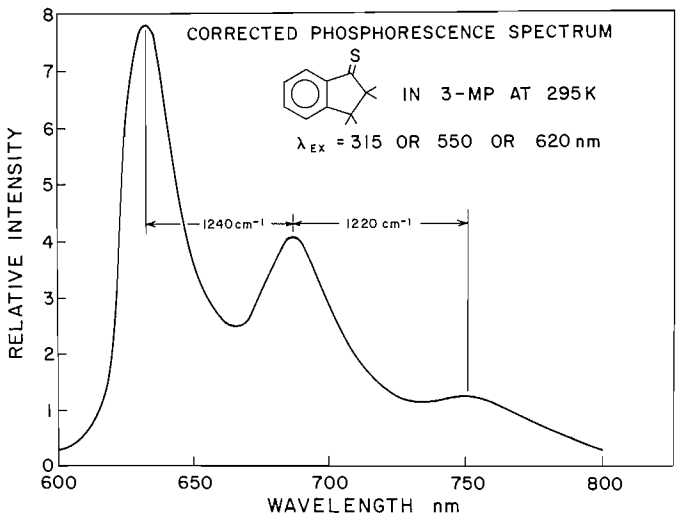

FIG. 4. Corrected phosphorescence emission spectrum of TMIT in 3-MP at 295 K.

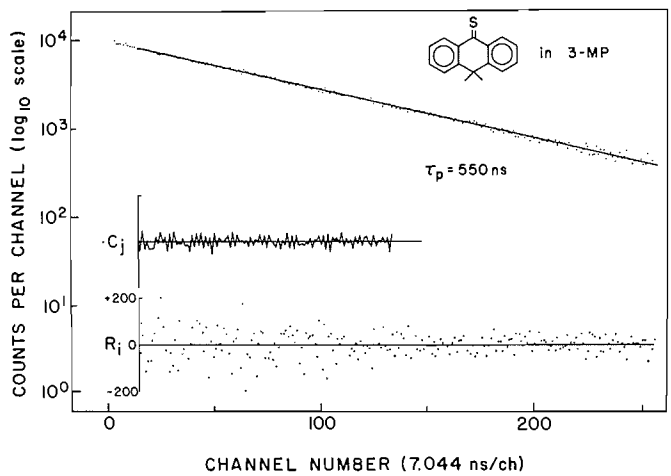

FIG. 5. Log_{10} (number of counts per channel) vs. channel number for DMAT in 3-MP at 295 K. Channel width 7.044 ns. R_i is the distribution of weighted residuals and C_j is the autocorrelation function, both plotted as a function of channel number. The solid line is computed from a single exponential decay function with phosphorescence lifetime of 550 ns.

phosphorescence excitation spectra follow the thione absorption spectra closely.

No emission identifiable as fluorescence from S_1 could be detected upon excitation either to S_1 or to higher singlets. However, excitation of most of these thiones in their strong uv–blue absorptions produced weak emission assignable as fluorescence from upper excited singlet states. The upper state decay dynamics of these thiones will be the subject of a forthcoming paper.

In fluid solution the quantum yield of phosphorescence decreases with increasing thione concentration due to self-quenching. Measurement of phosphorescence quantum yields and lifetimes as a function of thione concentration gave data which fit the Stern–Volmer relationship

$$[1] \qquad \frac{\phi_p^0}{\phi_p} = 1 + k_q \tau_p^0 [T]$$

where ϕ_p^0 and ϕ_p are the phosphorescence quantum yields at infinite and finite dilution respectively, k_q is the bimolecular self-quenching rate constant, τ_p^0 is the phosphorescence lifetime at infinite dilution, and [T] is the molar concentration of thione. Typical lifetime data, obtained with the laser excited, time-correlated single photon counting method, are presented in Fig. 5. In this figure R_i is the distribution of weighted residuals and C_j is the autocorrelation function (34). Excellent fits of the data to a single exponential decay law were observed in all cases. Values of k_q and τ_p^0 were obtained by measuring the slope and intercept, respectively, of

$$[2] \qquad \frac{1}{\tau_p} = \frac{1}{\tau_p^0} + k_q [T]$$

where τ_p is the observed phosphorescence lifetime at finite thione concentration. A typical plot, for NMTA in 3-MP at 295 K, is shown in Fig. 6. Table 2 gives values of ϕ_p^0 and τ_p^0 for the several thiones investigated in this study, together with calculated values of the rate constants for the first order radiative, k_{r,T_1}, and non-radiative, k_{nr,T_1}, decay of T_1 in 3-MP at 295 K.

The role of the solvent in determining the triplet decay rate and mechanism was investigated for NMTA and for TMIT. A linear relationship between k_q and the reciprocal of the solvent viscosity at constant temperature was observed, as illustrated for NMTA in Fig. 7. Benzene appears to be a somewhat exceptional solvent, having a value of k_q which is about 50% smaller

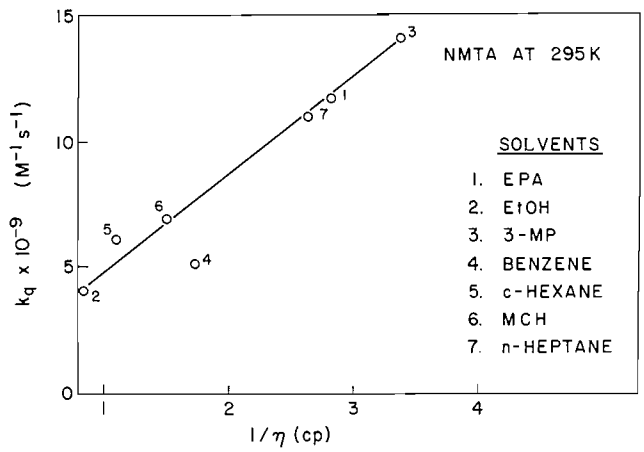

FIG. 7. k_q vs. η^{-1} for NMTA in various solvents.

than expected. There is some evidence of ground state NMTA–benzene interaction, however, because an isosbestic point at 464 nm appears in absorption spectra of NMTA in cyclohexane as a function of added benzene concentration. This point was not pursued further in this work, but may be of relevance in explaining the difference between the S_2 lifetime of xanthione in benzene (12 ps (35)) compared with 3-MP (60 ps (14)).

Phosphorescence spectra of TMIT and 4-Br-TMIT were also measured in *n*-chlorobutane and *n*-bromobutane. The spectra show loss of structure in the halobutane solvents, but are otherwise similar to spectra in 3-MP. Quantum yields of phosphorescence are nearly identical in all three solvents.

Photochemical reactions of the thiones were monitored by measuring the decrease in optical density in the strong uv–blue absorption of the thione. No evidence of significant photochemical reaction was observed when these thiones were illuminated in their weak, visible absorption systems in degassed, aprotic solvents at room temperature for thione concentrations up to 10^{-4} *M*. In oxygenated solutions the corresponding ketone is produced photochemically. NMTA is one of the most photoreactive thiones and the production of *N*-methylacridone in this system could be monitored by the growth of absorption in the spectral window near 400 nm between the thione $S_2 \leftarrow S_0$ and $S_3 \leftarrow S_0$ absorption systems. Evidence that thione triplets abstract hydrogen from hydrogen-donating solvents and addends has been obtained by Huber *et al.* (5, 8) for xanthione and by de Mayo and co-workers (18), for other thiones. Similar evidence is available from measurements of thione triplet lifetimes as a function of the nature of the solvent in the present work. Lifetimes are generally shorter in protic than aprotic solvents, whereas in aprotic solvents the product of the square of the solvent refractive index and the phosphorescence lifetime at infinite dilution is constant.

Discussion

The absorption spectra of the aromatic thiones examined in this study are similar to those of other aromatic thiones in fluid solution previously reported (5, 30, 31, 33). The longest wavelength absorption is assigned to the direct T_1 $^3(n,\pi^*) \leftarrow S_0$ transition and appears as a weak, but spectrally resolved band in TMIT, 4-Br-TMIT, NMTA, and DMBTPT as it does in xanthione (5). The oscillator strength of this transition lies between 1×10^{-5} and 3×10^{-5} for these thiones. The assignment is made on the basis of the magnitude of the oscillator strength, the overlap of this band with the highest energy band in the emission (phosphorescence) spectrum, the blue shift of this band in more polar solvents, and the decay characteristics of the (triplet) excited state produced on absorption (*vide infra*) as well as their polarization spectra (36). In the other thiones studied, the nearby $S_1 \leftarrow S_0$ transitions are substantially stronger, perhaps owing to the greater flexibilities of these molecules, and the weaker $T_1 \leftarrow S_0$ transitions are not distinct in the absorption spectra. Their approximate triplet energies can nevertheless be discerned from their phosphorescence emission and, in some cases, excitation spectra in glasses at 77 K. The relatively large oscillator strength of the $T_1 \leftarrow S_0$ transition compared, for example, with the corresponding ketones, may be ascribed in part to efficient spin–orbit coupling (37) which prevails in aromatic thiones.

The $S_1 \leftarrow S_0$ absorptions lie to slightly higher energies in the visible and have oscillator strengths about an order of magnitude larger than those of the corresponding $T_1 \leftarrow S_0$ transi-

tions (when the latter are spectrally distinct). From their intensities, energy, and behavior as a function of solvent polarity, these transitions are clearly forbidden by electric dipole selection rules and are of $n \rightarrow \pi^*$ character. Each is well-separated from the first strong electric-dipole-allowed $\pi \rightarrow \pi^*$ transition in the near-uv–blue. The approximate $S_2 - S_1$ energy gaps, calculated from energy differences between the absorption maxima of the $S_2 \leftarrow S_0$ and $S_1 \leftarrow S_0$ systems, vary from ca. 5000 cm^{-1} for NMTA to ca. 12,200 cm^{-1} for TMIT.

Emission in the red and near-infrared regions of the spectrum may be excited in any of the visible or near-uv–blue absorption systems. The emission is assigned as $T_1 \rightarrow S_0$ phosphorescence on the basis of (*i*) a comparison of the measured radiative rate constants for T_1 (Table 2) with approximate values calculated from the $T_1 \leftarrow S_0$ integrated absorption coefficient (38), (*ii*) the observation that the emission is quenched at a near diffusion-controlled rate by molecular oxygen and by anthracene whose triplet energy (42.7 kcal mol^{-1} (39)) is lower than or approximately equal to those of the thiones examined in this study, (*iii*) the spectral properties of the emission, and (*iv*) comparisons with other aromatic thiones of similar structure known to phosphoresce (5, 30, 31, 33).

The only other possible interpretation of the emission and absorption data is that the long wavelength weak absorption is part of the $S_1 \leftarrow S_0$ system and that the emission observed is $S_1 \rightarrow S_0$ fluorescence. However, all available photochemical and photophysical evidence from other systems (1) indicates that the S_1 states of aromatic, aliphatic, and aralkyl thiones in fluid solution are very short-lived and cannot be identified with emitting states having lifetimes in the microsecond range, such as those observed in this work. Only tetraatomic thiones such as H_2CS and Cl_2CS in the gas phase are known (1) to fluoresce from S_1 with high quantum yields ($\phi_f \rightarrow 1$). By contrast the lowest excited singlet states of several larger organic thiones in solution have been shown to decay very rapidly via intersystem crossing to T_1 ($\phi_{isc} \rightarrow 1$). The lifetime of xanthione S_1, for example, has previously been estimated to be $<10^{-11}$ s (13, 35).

Vibrational structure in the corrected phosphorescence spectra of all the thiones examined in the present study is poorly resolved in fluid solution at room temperatures, but does exhibit a characteristic peak-to-peak separation of ca. 1200 to 1300 cm^{-1}. This frequency has previously been ascribed to the thione ground state C—S stretching mode. However, recent work by Mahaney and Huber on xanthione in a Shpolskii matrix (14) has demonstrated that the vibrational bands observed in the room temperature spectrum undoubtedly result from the superposition of several closely spaced vibrational features, and that the features of greatest intensity are due to ring vibrations. Only gross vibrational features are observable in the room temperature spectra, and a discussion of vibrational assignments will not be pursued further here.

The corrected phosphorescence excitation spectra very closely resemble the absorption spectra throughout the visible and near-uv regions. The implication of this observation is that the emitting state is T_1 and the quantum yield of triplet formation is very nearly equal to unity, regardless of whether T_1, S_1 or higher singlets are populated initially. In dilute, degassed solutions employing aprotic solvents, there is no evidence of significant photochemical activity for any of the thiones, regardless of excitation wavelength, in agreement with a previous observation for xanthione (8) in which the quantum yield of xanthione disappearance in 3-MP at room temperature was found to be 0.005. The quantum yield of fluorescence from S_1 is too small to be measured ($\phi_f(S_1 \rightarrow S_0) < 10^{-4}$), and from S_2 is no more than 2.4% (36). The phosphorescence lifetime of a 7.13×10^{-5} *M* solution of TMIT was 1.03 μs when excited into S_1 at 582 nm and 1.04 μs when excited into T_1 at 627 nm.

These observations are all consistent with the suggestion that the quantum yield of triplet formation is 1.0 regardless of excitation wavelength. Moreover, at fixed thione concentration over both visible absorption systems the equality

$$[3] \qquad I_{p,S}/I_{p,T} = \epsilon_S L_S/\epsilon_T L_T$$

holds within an estimated experimental error of ±15%. Here $I_{p,S}/I_{p,T}$, ϵ_S/ϵ_T and L_S/L_T are the ratio of the measured phosphorescence intensity at a fixed emission wavelength excited in the $S_1 \leftarrow S_0$ absorption to that excited in the $T_1 \leftarrow S_0$ absorption, ϵ_S/ϵ_T is the ratio of the molar extinction coefficient at the wavelengths of excitation in the singlet system to that in the triplet system, and L_S/L_T is the ratio of the excitation intensity at the wavelength of excitation in the singlet system to that in the triplet system respectively. The suggestion that $\phi_{isc}(S_1 \rightarrow T_1) = 1.0$ for the aromatic thiones investigated in this study is in complete accord with the results of previous work on similar systems (1). An upper limit of 10^{-4} for the quantum yield of $S_1 \rightarrow S_0$ fluorescence may be established from the sensitivity of the emission detection system used in the present work. Using S_1 radiative lifetimes estimated from the integrated absorption coefficients (37, 38) of the $S_1 \leftarrow S_0$ transitions, lower limits of the rate constants for the non-radiative decay of S_1 (i.e. for $k_{isc}(S_1 \rightarrow T_1)$ may be obtained. These values are given in Table 2 and indicate that the S_1 lifetimes must be no longer than of nanosecond duration and may be much shorter. By comparison a rate constant of $S_1 \rightarrow T_1$ intersystem crossing in excess of 10^{11} s^{-1} has been estimated for xanthione (35) in benzene.

The S_1–T_1 energy gaps of the tetraatomic thiones, whose $S_1 \rightarrow S_0$ fluorescence quantum yields approach unity in the gas phase, are very similar to the S_1–T_1 energy gaps of the aromatic thiones studied here; ca. 1000–2000 cm^{-1}. The electronic matrix elements coupling the S_1 and T_1 states are therefore expected (40) to be similar for the two groups of compounds. The vast difference in their behavior may therefore be ascribed to the much larger density of accepting vibronic states in the triplet manifolds of the larger thiones and to the irreversible decay rate enhancing influence of the solvent.

Both the magnitude of k_q and its variation with the solvent viscosity indicate that the self-quenching process is diffusion controlled. In degassed, aprotic solvents at room temperature, quantum yields of thione disappearance are estimated to be <0.01. Thus concentration quenching is the only important intermolecular decay pathway at the thione triplet concentrations encountered in this study. A similar result has also been obtained for the self-quenching of xanthione (9) and for the quenching of triplet xanthione by other thiones (10).

It is interesting to note that, based on the data presented here, at the higher triplet concentrations obtainable on thione $S_1 \leftarrow S_0$ or $T_1 \leftarrow S_0$ excitation with pulsed-laser systems, triplet–triplet interaction could be responsible for a significant fraction of the intermolecular triplet decay processes in fluid solution. Because many of these same thiones also fluoresce from S_2 with quantum yields of the order of 1%, and have S_2–S_0 energy gaps which are almost invariably less than twice their T_1–S_0 energy gaps, these systems are well-suited for

For personal use only.

studying the $2T_1 \rightarrow S_2 + S_0$ triplet–triplet annihilation process. This work is in progress.

The variation in k_r and k_{nr} of the triplet states with thione structure is difficult to interpret definitively on the basis of the data presently at hand. Nevertheless, a qualitative interpretation appears to be possible. Relatively rigid aromatic thiones such as xanthione, TMIT, NMTA, and DMBTPT exhibit relatively small $S_1 \leftarrow S_0$ extinction coefficients, $T_1 \leftarrow S_0$ absorption systems which are resolved from the $S_1 \leftarrow S_0$ absorptions, and triplet non-radiative decay constants of the order of 10^5 s^{-1} (sufficiently small that phosphorescence quantum yields of the order of 1% are observed in fluid solution at room temperature). On the other hand, thiones such as DBCHAT and DBCHET which are capable of higher amplitude ring bending vibrations, or which are capable of unrestricted rotations of groups α to the C=S group such as thiobenzophenone and the aralkyl thiones studied by Hui *et al.* (33) show substantially higher $S_1 \leftarrow S_0$ extinction coefficients, $T_1 \leftarrow S_0$ absorptions which are generally not resolved from the $S_1 \leftarrow S_0$ absorptions at room temperature, and exhibit triplet non-radiative decay constants which are large enough ($>10^7$ s^{-1}) to dominate totally the triplet decay process. No phosphorescence is seen from this latter group of compounds in fluid solution at room temperature, but weak phosphorescence may be observed in matrices at low temperature. These observations suggest that the interaction of the S_1 state with upper singlets via symmetry breaking ring vibrations and perhaps group rotations may be responsible for the major part of the intensity of the electric dipole forbidden $S_1 \leftarrow S_0$ absorption, and that these same vibrations and rotations may be responsible for promoting the non-radiative decay of the thione triplets. Similar observations on a limited number of aromatic thiones have been made by Serafimov *et al.* (31).

The decay parameters of triplet TMIT and 4-Br-TMIT were measured in both hydrocarbon and heavy atom-containing solvents in order to examine the influence of both internal and external heavy atom perturbations on triplet thione decay dynamics. The $T_1 \leftarrow S_0$ molar extinction coefficient at λ_{max} is slightly larger for 4-Br-TMIT than for TMIT itself, indicative of greater spin–orbit coupling in the molecule containing the heavy atom, as expected (37). However, the measured intrinsic radiative lifetime (k^{-1}_{r,T_1}) for TMIT is slightly shorter than for 4-Br-TMIT in hydrocarbon solvents, whereas the rate constant for the non-radiative decay of triplet TMIT is slightly smaller than that for 4-Br-TMIT. Aside from broadening the emission and absorption spectra, the use of heavy-atom-containing solvents had little effect on the decay dynamics. These effects are seemingly inconsistent with expectations based upon the results of similar experiments with aromatic hydrocarbons and ketones (37). Unkown at present are the extent to which the $T_1 \leftarrow S_0$ absorption system is buried under the $S_1 \leftarrow S_0$ absorption, and the location and influence of other nearby triplet states. In xanthione there is evidence (6, 7, 14) that T_2, nominally $^3(\pi,\pi^*)$, lies very close in energy to T_1, nominally $^3(n,\pi^*)$, and that T_1 therefore has a large component of $^3(\pi,\pi^*)$ character. The location of higher energy triplet states in these thiones and the spectroscopic disentangling of the $S_1 \leftarrow S_0$ and $T_1 \leftarrow S_0$ transitions are under further investigation.

Photovoltaic properties of CdS/phthalocyanine heterojunction cells[1]

A. M. Hor and R. O. Loutfy

Xerox Research Centre of Canada, 2480 Dunwin Drive, Mississauga, Ont., Canada L5L 1J9

Received July 8, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

A. M. Hor and R. O. Loutfy. Can. J. Chem. **61**, 901 (1983).

Photovoltaic heterojunction solar cells formed between *n*-type cadmium sulfide, CdS, and various p-type phthalocyanines (Pc) such as H_2Pc, ZnPc, MgPc, CuPc, MnPc, PbPc, and VOPc were investigated. The cells were prepared by electrodepositing thin CdS films onto conducting indium-tin oxide (ITO) followed by sequential vacuum deposition of the phthalocyanines and gold layers. Among the seven phthalocyanines studied, ZnPc and MgPc exhibited the highest photovoltaic activity. Some optimization work was done for both the ZnPc and MgPc heterojunction devices. The optimum thickness of CdS and phthalocyanines was found to be 500 and 850 Å, respectively. Under an illumination of 50 mW cm^{-2}, the photovoltaic characteristics of the ITO/CdS/ZnPc/Au cell were: V_{oc} = 0.54 volts, J_{sc} = 285 μA cm^{-2}, and η = 0.10%, while the ITO/CdS/MgPc/Au cell delivered V_{oc} = 0.46 volts, J_{sc} = 231 μA cm^{-2}, and η = 0.066%.

A. M. Hor et R. O. Loutfy. Can. J. Chem. **61**, 901 (1983).

On a étudié les cellules solaires photovoltaïques à jonction hétérogène entre le sulfure de cadmium (CdS) de type-*n* et plusieurs phtalocyanines (Pc) de type-*p*, telles H_2Pc, ZnPc, MgPc, CuPc, MnPc, PbPc et VOPc. On a préparé les cellules par dépôt électrolytique de films minces de CdS sur l'oxyde conducteur d'indium et d'étain (OIT) suivi de dépôts successifs sous vide de couches de phtalocyanines et d'or. Parmi les 7 phtalocyanines étudiées, la ZnPc et la MgPc montrent la plus forte activité photovoltaïque. On a réalisé quelques travaux d'optimisation pour les deux dispositifs d'hétérojonction: ZnPc et MgPc. On a trouvé que l'épaisseur optimum de CdS et des phtalocyanines est respectivement de 500 et de 850 Å. Sous une illumination de 50 mW/cm^2, les caractéristiques photovoltaïques de la cellule OIT/CdS/ZnPc/Au sont de: V_{oc} = 0,54 volt, J_{sc} = 285 μA cm^{-2} et η = 0,10% tandis que la cellule OIT/CdS/MgPc/Au donne V_{oc} = 0,46 volt, J_{sc} = 231 μA cm^{-2} et η = 0,066%.

[Traduit par le journal]

Introduction

Phthalocyanines (Pc) have been recognized as an important class of organic semiconductive and photoconductive materials. These substances have found applications in the fields of reprography (1–4), organic photovoltaic cells (5–7), and more recently as infrared dyes in optical storage systems (8). One of their important potential uses will be as photocatalyst and spectral sensitizer in solar energy conversion.

Ghosh *et al.* (6) had investigated photovoltaic devices made of Al/magnesium phthalocyanine (MgPc)/Ag and observed an open-circuit voltage of 0.90 V and a short-circuit current of 9.5×10^{-8} A under an unspecified light intensity. From their measurements of capacitance–voltage ($C-V$) characteristics and action spectra, they confirmed the presence of a Schottky barrier at the Al/MgPc interface. A photovoltaic efficiency of 0.01% was quoted for the cell illuminated with a monochromatic light of 690 nm.

Later, Fan and Faulkner (7) reported their results for metal-free phthalocyanine (H_2Pc) and zinc phthalocyanine (ZnPc) cells with In and Al as blocking electrodes and Au as an ohmic contact. Cells with Al electrodes exhibited a power conversion efficiency 2 to 3 orders of magnitude lower than those with In electrodes. This was attributed to the presence of an insulating Al_2O_3 layer at the Al/Pc interface. Their best cell of In/ZnPc/Au had a conversion efficiency of 0.023% at a low light intensity of 2 mW cm^{-2} though an estimated quantum efficiency of 14.2% was claimed.

Both groups used phthalocyanines purchased from commercial suppliers without further purification. Also the thickness of the Pc films in their cells, i.e. 1500 Å in ref. 6 and 3000 Å in ref. 7, were much larger than the sum of the Schottky barrier width and diffusion length of minority carriers (electrons) or excitons which were estimated to be about 300 Å and 150 Å respectively (6). Uncontrolled impurities and incompatible thickness certainly have detrimental effects on the cell performance.

Recently, Wagner and Loutfy (9) employed a novel heterojunction cell in which the barrier electrode was an electrodeposited CdS film. CdS film can transmit more than 70% of light above 500 nm and thus does not interfere with the absorption of Pc in the visible region. More important, it is a n-type semiconductor with a Fermi level E_f = ~4.0 eV which is suitable for interfacing with phthalocyanines (E_f ~ 4.6 to 4.8 eV) to produce a reasonable built-in potential of 0.7 V at their junction. From their capacitance–voltage data of various CdS/MgPc cells they found that the barrier width was not sensitive to the thickness of CdS and hence concluded that the band bending or built-in potential essentially occurred within the Pc. Interestingly, these solid state devices were found to be very stable.

The main objectives of this work are: (*i*) to evaluate the effectiveness of various Pc in CdS/Pc photovoltaic cells, and (*ii*) to optimize the cell performance for the most promising phthalocyanines.

Experimental

Materials

A series of Pc including H_2Pc, MgPc, ZnPc, vanadyl phthalocyanine (VOPc), copper phthalocyanine (CuPc), lead phthalocyanine (PbPc), and manganese phthalocyanine (MnPc) have been studied in this work. They were purchased from Eastman Kodak and they were purified by sublimation. Indium-tin-oxide (Nesatron) glass plates were obtained from Pittsburg Glass Corp. with a sheet resistance of 70 Ω/square and optical transmission >83%. All other chemicals were obtained from common commercial sources.

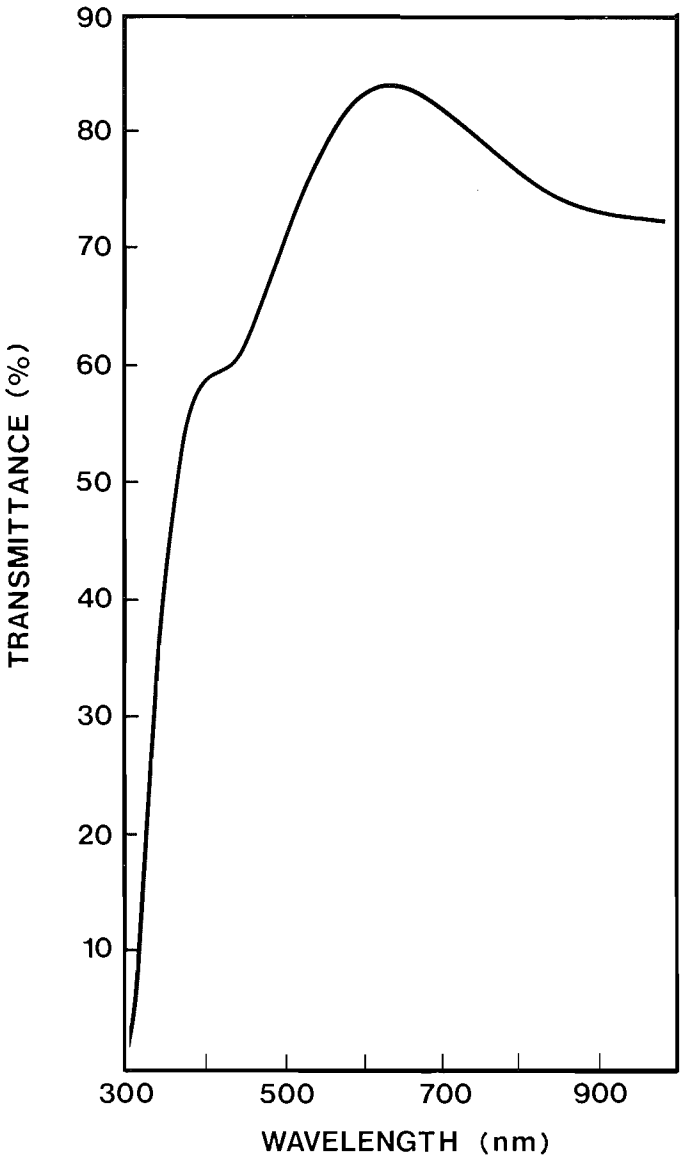

FIG. 1. Transmission spectrum of CdS (1600 Å) on Nesatron.

Device fabrication

Thin films of CdS were cathodically deposited (10) onto the Nesatron substrate from a solution of 400 mL dimethyl sulfoxide (DMSO) containing 0.6 g of sulfur and 1.0 g of cadmium chloride. The thickness of CdS films formed depended on the duration of electrodeposition. Figure 1 shows the transmission spectrum of a CdS film (1600 Å thick) deposited on the Nesatron. Above 500 nm it can transmit more than 70% of the incident light. The CdS-coated Nesatron substrates were cut into 2 in. × 2 in. square slides. A thin film of the phthalocyanine material was vacuum deposited onto the CdS-coated Nesatron. The deposition was carried out in a Balzer's vacuum coater at a base pressure of less than 10^{-6} mbar. Finally a Au electrode of 400 Å thickness was deposited onto the Pc film to complete the cells as shown in Fig. 2.

Measurements

All the measurements performed on the cells were carried out in air. The current–voltage ($J-V$) measurements were made by biasing the cells with an EG&G Polarographic Analyser Model 174A. Current and voltage readings were monitored by our data acquisition system built from a HP 9845B computer. The light source was a 1 kW Oriel Solar Simulator and light intensities were measured by a Karl Lambrecht light probe. Optical absorption spectra were recorded on a

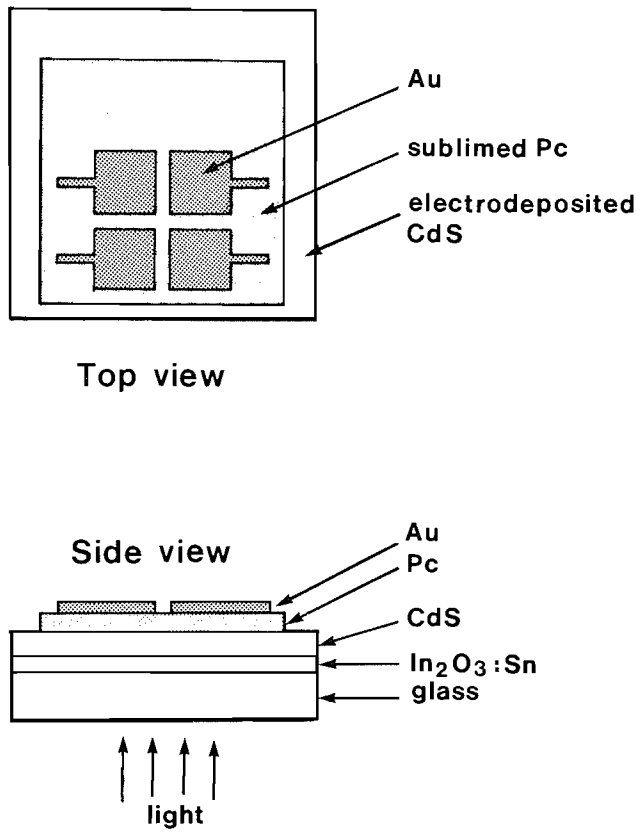

FIG. 2. Structure of a CdS/Pc heterojunction cell.

Cary 17 spectrophotometer. The light source for action spectrum measurements consisted of a 150-W Xe lamp and a $\frac{1}{4}$-m Jarrel Ash monochromator. The action spectra of the device were measured as described previously (11).

Results and discussion

1. *Dark* J–V *curve*

All Cds/Pc heterojunction cells display a rectifying behaviour in the dark. The dark $J-V$ curve of a typical CdS/MgPc cell is shown in Fig. 3. In the forward bias mode the Au electrode was polarized positive with respect to the CdS electrode.

2. *Action spectra*

In Fig. 4 the photocurrent action spectra of a typical CdS/MgPc heterojunction cell illuminated through the CdS and Au electrodes respectively are shown together with the absorption spectrum of a MgPc film deposited on a glass slide. A better agreement is seen between the optical absorption and the action spectrum obtained from illuminating the CdS electrode, verifying that the photoactive junction is situated at the interface between CdS and MgPc. Similar results were observed for other phthalocyanines.

3. *Comparison of various CdS/Pc cells*

In order to compare the performance of various cells a standardized cell structure was adopted which consisted of 1600 Å of CdS, 700 Å of Pc, and 400 Å of Au. These values were chosen on the basis of the optimal results reported in ref. 9. The cells were illuminated through the CdS electrode with simulated solar light of 50 mW cm^{-2}. Figure 5 shows the light $J-V$ curve of a CdS/MgPc device from which the characteristic photovoltaic parameters like open-circuit voltage V_{oc}, short-

circuit current J_{sc}, fill factor f.f., and conversion efficiency η can be evaluated. The results obtained from various cells are presented in Table 1. Among these cells MnPc hardly showed any photovoltaic activity. For all other cells the V_{oc} varied over a range from 0.41 to 0.55 V but the J_{sc} varied by a factor of ~3.5. The low fill factor usually observed in organic photovoltaic devices is attributed to the large series resistances derived from both CdS and Pc.

The magnitude of V_{oc} depends on the extent of band bending in the Pc at the CdS/Pc interface, hence on the difference in energy between their Fermi levels. Unfortunately, there are no reliable values for Fermi levels of Pc in the solid state and therefore we cannot explain, in a straightforward manner, the trend of V_{oc} observed for the Pc cells. Since Pc are p-type semiconductors with the top of the valence band located at about 5.0 eV with respect to the reference vacuum level, their Fermi levels may lie a fraction of an eV above the valence band. The exact location of the Fermi level within the band gap

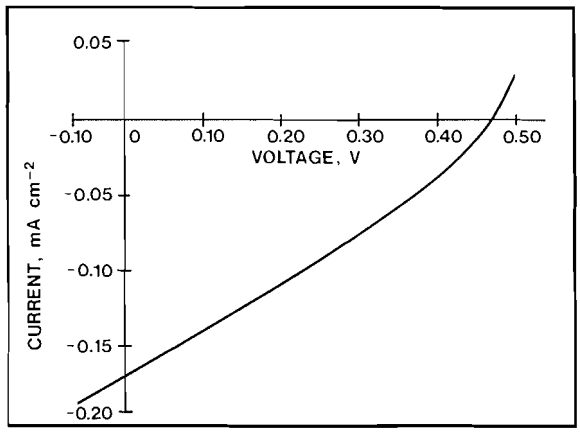

FIG. 5. Current–voltage curve of a CdS/MgPc cell under 50 mW/cm^{-2} of illumination.

of a semiconductor is known to be affected by several factors: impurity concentrations, surface states, etc. The observed V_{oc} values for all cells except MnPc suggested that their Fermi levels are at ~4.7 eV. The crystal ionization potential of MnPc has been estimated to be 4.16 eV (12) which can be considered as equivalent to the location of the top of the valence band. Obviously, interfacing MnPc with CdS would not produce any band bending in Pc and this may explain why no photovoltaic activity was observed from MnPc cells.

For these Pc cells, their photocurrents increased linearly with light intensity but the V_{oc} increased only logarithmically. This behaviour is illustrated by the data plotted in Figs. 6 and 7 for a ZnPc cell. The photocurrent J_{sc} and V_{oc} therefore can be analysed with the aid of the diode equation

$$V_{oc} = \frac{n\,kT}{q} \ln\left(\frac{J_{sc}}{J_0} + 1\right)$$

where kT = 0.025 eV at room temperature, q = electronic charge, n = diode factor, and J_0 = reverse saturation current.

The value of n was obtained from the slope of the plot of V_{oc} vs. log J_{sc}, and J_0 was then calculated from the diode equation. The values of n and J_0 are also included in Table 1. The reverse saturation current J_0 decreases as the value of n approaches one, and this appears to be consistent with the picture that a better diode would have a smaller leakage current. However, low J_0 and small n did not lead to good performance for H_2Pc, CuPc, and VOPc cells. This implies that the rectifying property at the junction, measured by the magnitude of n and J_0, is not the dominant factor in governing the performance of the photovoltaic devices studied. Probably, the carrier-generation efficiency is more important.

The photocarrier generation process in organic materials is very complex (13). The absorption of a photon creates an exciton rather than free carriers. The excitons can migrate from molecule to molecule or thermalize to form bound electron-hole pairs at impurity centers, defects, or interfaces. The electron-hole pair may terminate its life through recombination or dissociation into free carriers. The dissociation step is generally favored in the region of high electric field which happens to be near the CdS/Pc interface in our heterojunction cells. Some free carriers may be lost through trapping or recombination and only those which reach the collecting electrodes will contribute to the observed photocurrent. Our experimental data indicate that the conversion efficiencies of the CdS/Pc heterojunction cells decrease in the following order: ZnPc >

MgPc > H_2Pc > VOPc, PbPc, CuPc > MnPc. In view of the complex nature of various processes involved in the photocarrier generation, a simple explanation for the observed trend is very unlikely. An attempt to rationalize the conversion efficiencies of Al/Pc solar cells in terms of the oxidation potentials of Pc's was also unsuccessful (14).

According to the results listed in Table 1, we can single out ZnPc and MgPc as the most promising candidates for further investigation.

4. *Optimization of MgPc and ZnPc cells*

The optimization of MgPc and ZnPc cells was carried out by adjusting the film thickness of both CdS and Pc. For MgPc cells, the thickness of CdS was varied from 500 Å to 1600 Å and that of MgPc from 700 to 1200 Å. Table 2 summarizes the photovoltaic data obtained from a series of MgPc devices studied. Although cells with CdS thinner than 500 Å had been fabricated, serious electrical shortings did not allow any meaningful investigation. The shorting problems were most likely due to the presence of large imperfections in the very thin CdS films. The photovoltaic performance of MgPc cells remained almost constant when the CdS films ranged from 500 Å to 1000 Å and the MgPc film from 850 Å to 1200 Å. The best MgPc cell, which was fabricated with 850 Å of MgPc and 500 Å of CdS, had the following characteristics: V_{oc} = 0.462 V, J_{sc} = 231 μA cm^{-2}, η = 0.066% at an illumination of 50 mW cm^{-2}.

For the optimization of ZnPc cells, the CdS film was held constant at 500 Å while the ZnPc film was varied from 700 to 1200 Å. The results are presented in Table 3. The performance of the ZnPc cells was more sensitive to the thickness of the organic layer. The best ZnPc cell consisted of 850 Å ZnPc and 500 Å CdS and its photovoltaic characteristics were V_{oc} = 0.534 V, J_{sc} = 285 μA cm^{-2}, and η = 0.10% under the same illumination.

η, %	0.070	0.10	0.040

*Cell configuration: Nesatron/CdS/ZnPc/Au (400 Å).

Thus, for both MgPc and ZnPc cells, the optimum thickness of Pc films is 850 Å. Since the width of the Schottky barrier has been determined to be ~500 Å in Pc (9), one can estimate that the diffusion length of excitons in Pc is ~350 Å which agrees reasonably well with Fan and Faulkner's value of 200 Å (7). The absorptions of light both inside and outside the barrier region contribute to the generation of photocurrent.

Conclusion

Among the seven Pc's studied in this work, ZnPc and MgPc show the greatest promise. At present, the only optimization done was related to the effect of film thickness of CdS and Pc. Future work will involve the improvement of their photoconducting characteristics which can only be gained by varying the fabrication conditions.

Energy partitioning in some atom/radical reactions found in atmospheric pollution systems[1]

D. J. DONALDSON AND J. J. SLOAN

National Research Council of Canada, Division of Chemistry, 100 Sussex Drive, Ottawa, Ont., Canada K1A 0R6

Received July 12, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

D. J. DONALDSON and J. J. SLOAN. Can. J. Chem. **61**, 906 (1983).

A modification of the arrested relaxation infrared chemiluminescence technique has been used to study the energy disposal in two atom–radical reactions. Vinyl and formyl radicals were generated chemically and their subsequent reactions with O atoms (in the case of vinyl) and F atoms (in the case of formyl) were followed. Product CO emission was observed in the system O/C_2H_3. Emission from both CO and HF was seen in the F/HCO system. The O/C_2H_3 reaction gives rise to substantially higher excitation in the CO product than does the F/HCO case. In each case, bound intermediates may be formed; the differences in energy diposal are discussed in terms of the possible influence of these intermediates.

D. J. DONALDSON et J. J. SLOAN. Can. J. Chem. **61**, 906 (1983).

On a utilisé une modification de la technique de chémiluminescence infrarouge de relaxation à l'arrêt pour étudier le dégagement d'énergie des deux réactions du type atome–radical. On a produit chimiquement des radicaux vinyle et formyle et on a suivi leurs réactions avec les atomes d'oxygène (dans le cas du vinyle) et avec les atomes de fluor (dans le cas du formyle). On a observé une émission de CO produit par le système O/C_2H_3. On a noté une émission à la fois de CO et de HF par le système F/HCO. La réaction du O/C_2H_3 donne lieu à une excitation nettement plus forte dans le CO produit que dans le cas du F/HCO. Il peut se former dans chaque cas des intermédiaires liés; on discute des différences de dégagement d'énergie en fonction de l'influence possible de ces intermédiaires.

[Traduit par le journal]

Introduction

The atmospheric chemical system involves many hundreds of reactions (1–5). These frequently occur in interconnected cycles, in which the products of a previous step are the reagents of a subsequent one. Since the rates of most reactions depend sensitively on the energy content of their reagents, this interdependence makes it important to understand the energy partitioning in such a system.

A great deal of work has been done on the measurement of energy partitioning in atom/molecule reactions and many excellent reviews of this subject exist (6, 7). However, a large fraction of the reactions important to atmospheric chemistry involve free radicals as either reagents or products (4) and the measurement of energy partitioning in such reactions is much more difficult. Although laser induced fluorescence techniques have made total rate measurements possible for many of these atom/radical reactions (8–10), energy partitioning measurements, which yield reaction rates as a function of internal energy of the products, can be made for only a very few radical systems (for example those involving OH).

We have constructed a machine, based on a low pressure infrared chemiluminescence apparatus, designed to measure energy partitioning in many simple atom/radical reactions which are important to the chemistry of tropospheric pollution. In previous work with this apparatus, we have reported measurements on the reactions of F atoms with OH (11), HNF (12), and C_2H_3 (13) radicals. Studies of F atom reactions with HS and NH_2 are also under way. In the following, we report our energy partitioning measurements on the reactions of O atoms with C_2H_3 radicals, and of F atoms with CHO radicals.

Experimental

The apparatus is based on a low pressure infrared chemiluminescence machine which has been described in detail previously (14). Recent modifications to the machine described in ref. 14 include the substitution of a Varian VHS 400 (8000 L/s) diffusion pump for the previous one, and the substitution of a homemade high conductance (38 cm inside diameter) cryobaffle for the one described in ref. 14. The new cryobaffle is not optically dense, but retains nearly two thirds of the pumping speed of the diffusion pump, at some expense in backstreaming.

A cross sectional sketch of the cylindrical vacuum chamber in which the reactions occur is shown in Fig. 1. A cylindrical liquid nitrogen reservoir, shown as the dotted area in the figure, is suspended from the top of the chamber. A series of copper vanes is suspended vertically from the underside of this reservoir. These are arranged in

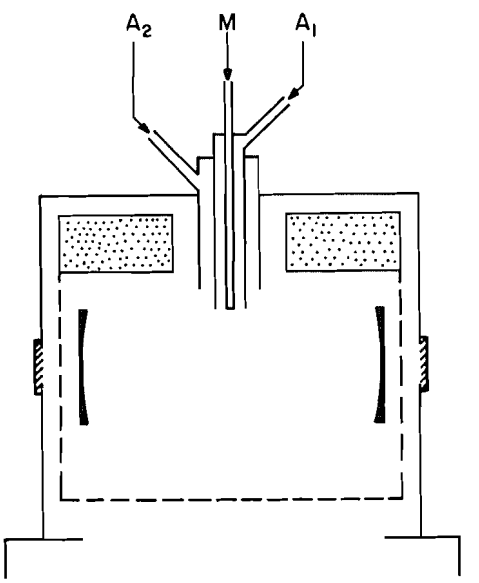

FIG. 1. Cross sectional sketch of the vacuum chamber showing three concentric reagent inlet tubes at top centre. M: vertically adjustable inlet tube for molecular reagent. FIG. 2. A segment of the spectrum of the high-v' HF produced in reaction [1].

a radial pattern such that they effectively enclose the volume indicated by the dashed line in the figure. A reactor consisting of three concentric glass tubes is fixed to the lid of the vacuum chamber. The reactor, which is based on a previous design (15), is used to form the radical being studied in a chemical reaction between the molecular precursor M (which effuses through holes drilled radially in the wall of the central tube near its tip) and A_1, an atomic reagent. In the experiments reported here, A_1 is an F atom generated in a 2450 MHz, 100 watt microwave discharge in SF_6. For the vinyl radical studies, the molecular precursor, M, is C_2H_4, and the vinyl radicals are produced in the reaction:

$$[1]\quad F + C_2H_4 \rightarrow C_2H_3 + HF(v' \leq 2)\ \Delta H_0^0 = -29 \text{ kcal mol}^{-1}$$

Formyl radicals are produced if the precursor, M, is formaldehyde:

$$[2]\quad F + H_2CO \rightarrow HCO + HF(v' \leq 4)\ \Delta H_0^0 = -49 \text{ kcal mol}^{-1}$$

The location of the tip of the M injector, and thus the extent of these precursor reactions, can be adjusted from a position about 5 cm inside the A_1 tube to about 3 cm beneath its outlet.

Following the precursor reaction, the radicals mix with atoms A_2, which are added via the outermost of the three concentric tubes. For the $O + C_2H_3$ studies, A_2 is an oxygen atom formed in a second 2450 MHz, 100 watt discharge in O_2. In this case the following reaction occurs:

$$[3]\quad O + C_2H_3 \rightarrow CO(v' \leq 22) + CH_3\ \Delta H_0^0 = -120 \text{ kcal mol}^{-1}$$

For the formyl radical study (precursor reaction [2]), atom A_2 is a second F-atom, and the ensuing reaction is:

$$[4]\quad F + HCO \rightarrow CO(v' \leq 21) + HF(v' \leq 14)\ \Delta H_0^0 = -115 \text{ kcal mol}^{-1}$$

The indicated product vibrational states (v') in reactions [1] to [4] are the maximum levels which can be formed from the indicated exoergicities in each case. These were observed for reactions [1] and [2], but not for reactions [3] and [4], for reasons to be discussed shortly.

Results

1. *The $O + C_2H_3$ reaction*

For this system, the precursor reaction [1] has been extensively studied previously (16–18). It is known that this reaction partitions about 60% of the available energy into HF vibration and rotation. Therefore the vinyl radical receives a relatively small amount of the reaction energy. Reaction [1] has also been measured in this laboratory in connection with a study of the F + C_2H_3 reaction (19). It was shown that under the conditions of the F/C_2H_3 study, which are the same as those of the present experiments, the small amount of excitation energy partitioned into the vinyl radical by reaction [1] must be lost in collisions with the parent C_2H_4 before the former undergoes secondary processes such as reaction [3]. It is therefore assumed in the following that the C_2H_3 reagent in [3] has been thermalized to the temperature of the C_2H_4 (300 K).

The reaction of the C_2H_3 radicals with the F-atoms not consumed in reaction [1] provides a convenient means to monitor the concentration of the C_2H_3 radical in the present study. The F + C_2H_3 reaction, which was analysed in ref. 19, is about 98 kcal mol^{-1} exoergic, and thus can populate HF vibrational levels up to $v' = 11$. Its precursor (reaction [1]) is 29 kcal mol^{-1} exoergic, and can only populate HF levels up to $v' = 3$. Therefore, all emission from HF($v' \geq 3$) must come from the reaction of C_2H_3 radicals. A segment of the emission from high-v' HF recorded in the present experiments is shown in Fig. 2. For reasons discussed in ref. 19, HF($v' = 9$) was the highest level observed in the F/C_2H_3 system. However, the emission shown in Fig. 2 serves to demonstrate that the vinyl radicals were present in high concentration.

When O atoms are added to the F/C_2H_4/C_2H_3 system via the outer reactor tube (A_2 in Fig. 1), CO emission is observed. A sample of this emission appears in Fig. 3. In this figure, the band origins for the various vibrational levels CO($v' = 1$–7) are indicated. The lower trace is recorded if no F atoms are present in the system, and shows weak emission from CO($v' = 1, 2$) only. The upper trace, shown with the same vertical gain as the lower, appears when F atoms (and hence C_2H_3 radicals) are present. In this case, strong emission from all the indicated CO levels is observed. This is a lower limit to the maximum CO level produced, however, because the infrared detector used (InSb) becomes quite insensitive below about 1950 cm^{-1}.

The upper spectrum shows that highly vibrationally excited CO is produced in reaction [3]. The limit imposed by the present detector prevents the determination of the maximum excitation, and of the accurate population distribution. A HgCdTe detector which is sensitive at longer wavelengths than

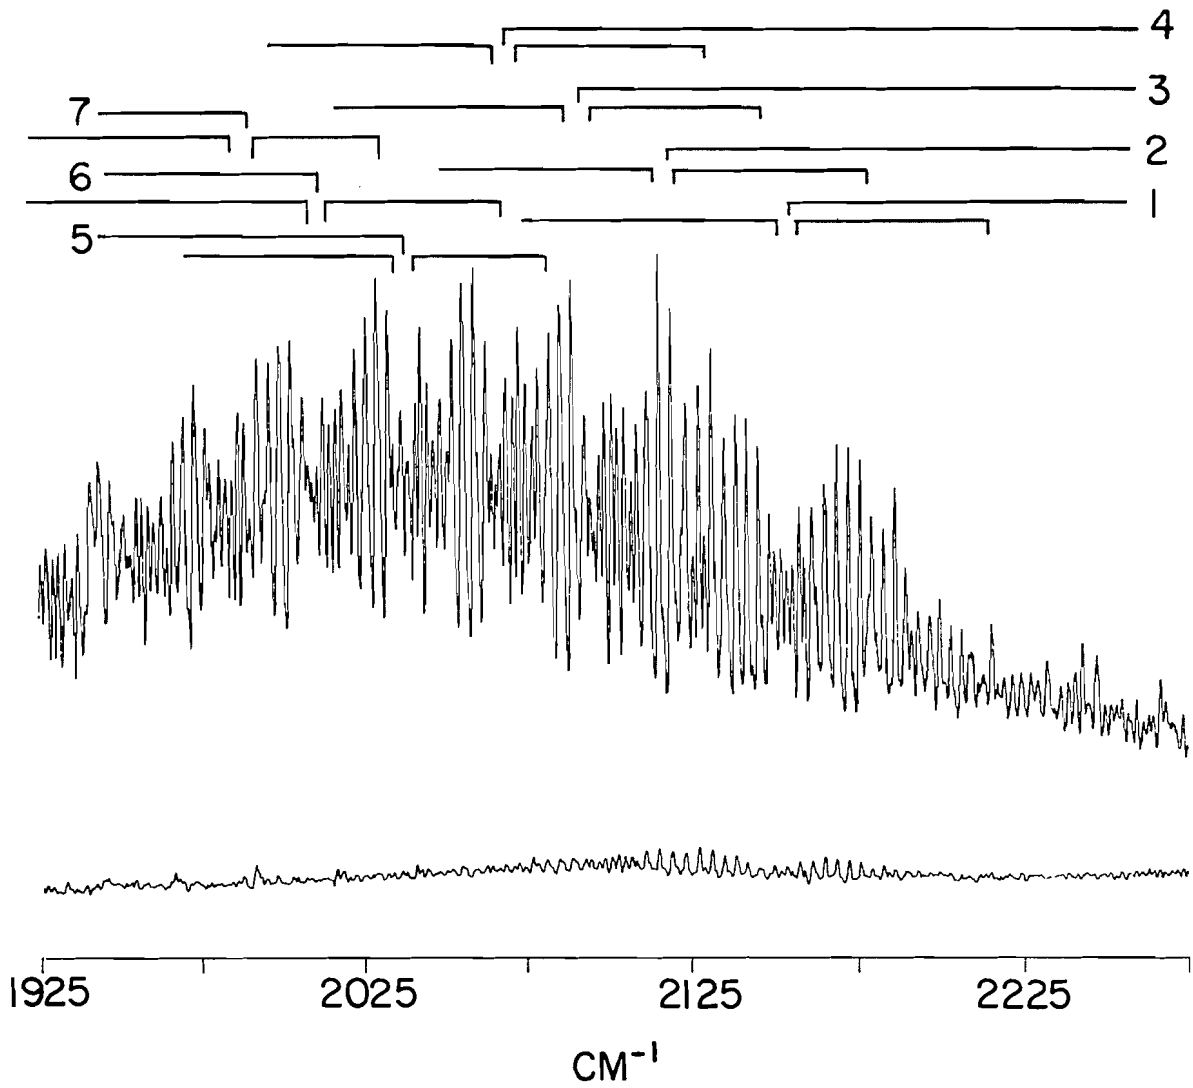

FIG. 3. CO emission from O/C_2H_3 system. Lower trace: F atom discharge off. Upper trace: F atom discharge on. Same reagent flows and vertical gain in each case.

the InSb detector will be installed to make these measurements. The emission in the lower trace originates in the O/C_2H_4 system. The latter reaction has been extensively studied (20–23), and it has been concluded that the major channel is a substitution producing hydrogen and a vinoxy radical: $O + C_2H_4 \rightarrow H + C_2H_3O$. We believe the CO signal shown in the lower trace of Fig. 3 is due to the decomposition of the vinoxy radical produced in this reaction, possibly in a collision-assisted process. Assuming room temperature reagents, the process $O + C_2H_4 \rightarrow C_2H_3O + H \rightarrow CO + CH_3 + H$ releases about 14–16 kcal mol^{-1} to the products. This is enough to create $CO(v' = 2)$, as observed in the lower trace of Fig. 3.

2. The F + HCO reaction

The precursor reaction [2] for this system has also been studied extensively (24, 25) and the HF vibrational distribution has been determined. This reaction also channels a large fraction – about 57% (25) – of its available energy into the HF product. The exoergicity of reaction [2] is 48.6 kcal mol^{-1}. This is enough to populate the product HF up to the $v' = 4, J' = 13$ level. The HF distribution measured in previous experiments (25) on this reaction peaks strongly in $v' = 3$ and shows substantial population to the maximum allowed level.

In the present experiments, this previously-observed HF distribution can be reproduced by choosing low reagent flows (SF_6: 1.0 μmol s^{-1}; H_2CO: 0.5 μmol s^{-1}) and extending the injector tip 3 cm outside the end of the A_1 tube. The resulting distribution is shown in Fig. 4 (squares). The maximum energetically allowed level for reaction [2] is indicated by an arrow.

When the reagent flows are increased (total SF_6: 2.8 μmol s^{-1}; H_2CO: 1.7 μmol s^{-1}), the injector tip is withdrawn 7 mm inside the A_1 tube, and F atom discharges are run in both tubes A_1 and A_2, the HF distribution indicated by the circles in Fig. 4 was obtained. Here, the $HF(v' \leq 4)$ which is predominantly created in the precursor reaction [2] has begun to be vibrationally deactivated. Concurrently, emission from levels $HF(v' \geq 5)$ has appeared. The latter levels can be created only in reaction [4]. The triangular points show the populations of the levels $v' \geq 5$ scaled up by a factor of 10., This shows that the latter distribution decreases rapidly with increasing vibrational excitation, in contrast to that of the $v' \leq 4$ levels.

A portion of the HF spectrum from which the upper levels (circular points) in Fig. 4 were calculated is reproduced in Fig. 5. Only transitions from levels not accessible to reaction [2] – $HF(v' \geq 5)$ – are assigned. This illustrates the signal-to-noise ratio obtained in the data for these particular experiments.

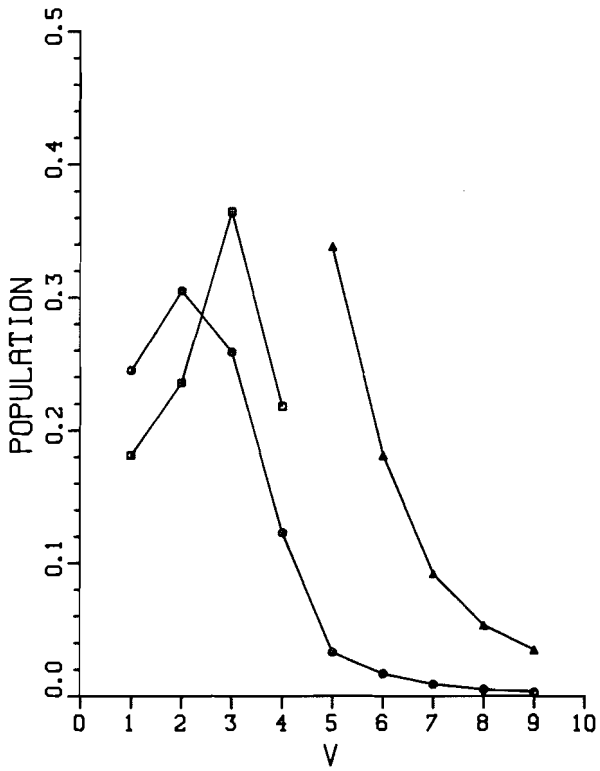

FIG. 4. HF vibrational distributions from $F/H_2CO/HCO$ system. □: Low reagent flows, injector fully extended. ○: Increased reagent flows, injector partially withdrawn. △: Vertical gain increased by 10×.

Under the conditions of increased reagent flows and double F atom discharges just described, emission was recorded from CO as well as from HF. The CO emission is shown in Fig. 6. The band origins for levels up to $v' = 4$ are indicated as before. The CO emission intensity decreases smoothly with increasing vibrational level until it blends with the noise. However, in the spectrum displayed in Fig. 6, emission from all levels up to and including $v' = 5$ could be unambiguously assigned. This CO emission intensity responds to changes in the experimental conditions (reagent flows and injector location) in the same way as that of the HF($v' \geq 5$) emission shown in Fig. 5. Additionally, the CO emission does not appear without the higher-flow conditions which gave the intense HF($v' \geq 5$) emission just described. The origin of the CO emission is therefore believed to be the same as that of the HF($v' \geq 5$), reaction [4].

Discussion

The atom/radical reactions [3] and [4] both give rise to easily-detectable CO fundamental emission. These are secondary reactions in the sense that each requires a reagent which is generated in a previous reaction in the flowing gas mixture. In order to be observable in the conditions of the present experiment (total pressure in the reaction zone about 10^{-2} Torr, total residence time of the flowing gases about 0.2 ms), these reactions must be very fast, with cross sections at least gas kinetic.

In spite of superficial similarities, however, these reactions appear to differ in some more fundamental respects. Comparison of the CO emission spectrum in Fig. 3 (from reaction [3]) with that shown in Fig. 6 (from reaction [4]) shows that the former creates much more vibrational excitation in the CO than the latter, even though the reactions have approximately the same exoergicity. (The value of ΔH_0^0 shown in eq. [3] is based on $\Delta H_{0,f}^0$ (g) of C_2H_3 = 69 kcal mol^{-1} (26). However, this may be as much as 10 kcal mol^{-1} too high (27).) A quantitative determination of the difference in the CO excitation created by these reactions cannot be made until the extent of the CO excitation in reaction [3] is known. However, it is clear from the figures that this difference is significant.

We have previously shown (19) that the measured HF distribution for the reaction $F + C_2H_3 \rightarrow HF + C_2H_2$ agrees with that predicted by a phase space calculation (28) which yields the distribution expected from the statistical decomposition of a microcanonical system consisting of the energized intermediate (vinyl fluoride) having the transition state geometry calculated

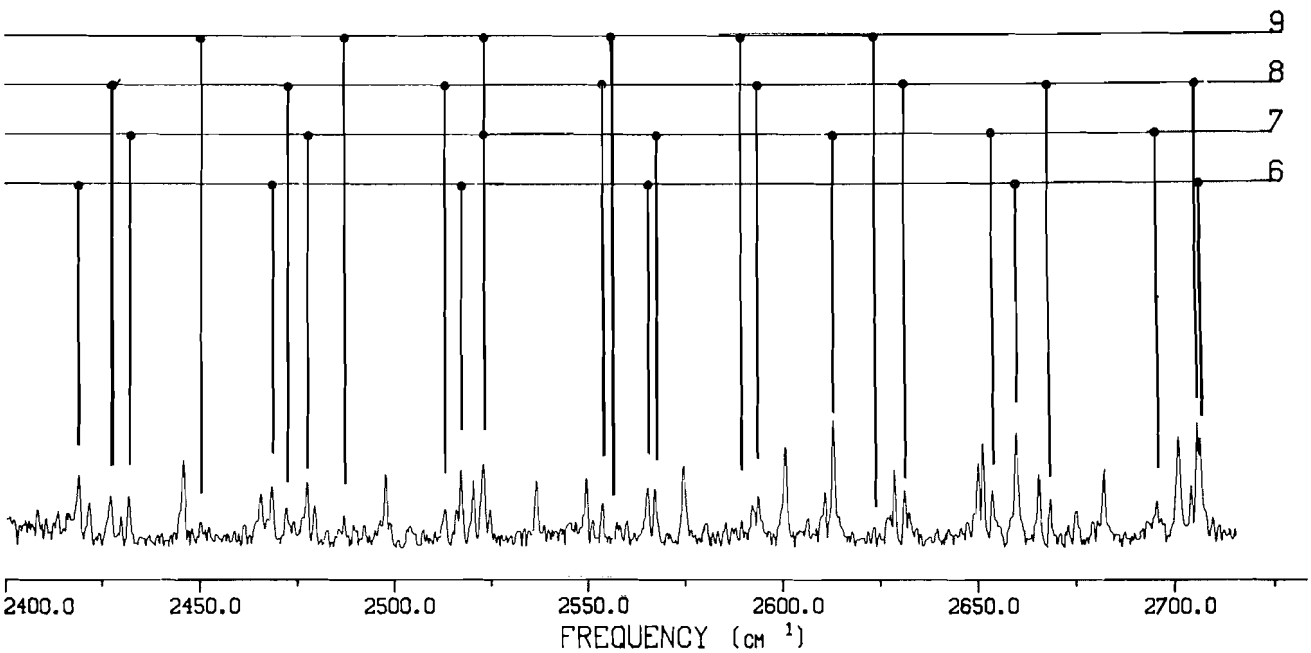

FIG. 5. High-v' HF emission from $F/H_2CO/HCO$ system. Only levels $v' > 5$ have been indicated.

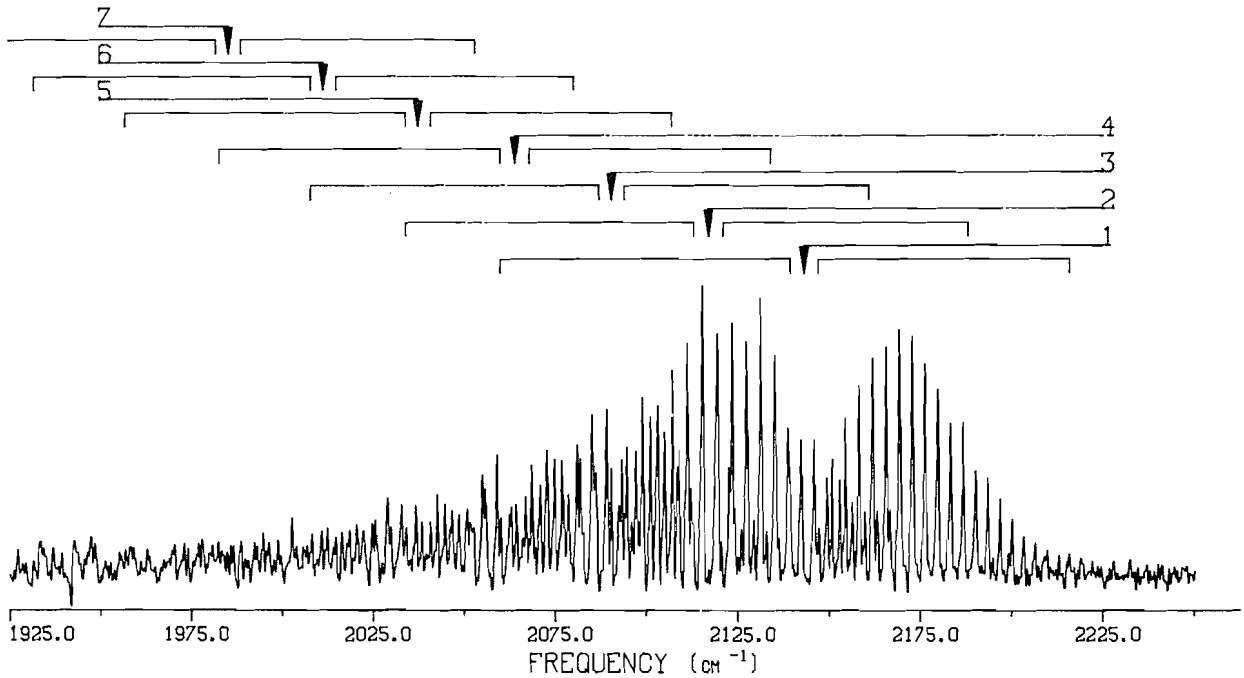

FIG. 6. CO emission from $F/H_2CO/HCO$ system. Band origin, R branch (to the left) and P branch (to the right) for transitions from the first four vibrational levels have been indicated.

in ref. 29. The F/C_2H_3 reaction resembles the F/HCO reaction in that the assumed intermediate in both cases is a strongly bound, closed shell molecule in which decomposition to products requires the unimolecular elimination of HF. A preliminary calculation has been done on the F/HCO system, and the result was found to agree roughly with high-v' distribution measured in reaction [4]. However, the quality of the experimental data is not yet high enough to permit a final conclusion to be made on this point.

The fact that the HF distributions from either of these reactions (F/C_2H_3 or F/HCO) would be found to be statistical is somewhat surprising in view of the very large exoergicity of both reactions. The total energy of the vinyl fluoride intermediate is about 100 kcal mol^{-1} above the HF + C_2H_2 products, and the HFCO is about 116 kcal mol^{-1} above separated HF + CO. In the former case, this is 20–30 kcal mol^{-1} (29) and in the latter, it is 40–50 kcal mol^{-1} (28) above the calculated minimum exit channel barrier. In view of this, it seems surprising that the potential energy well representing the intermediate, although very deep, should have any influence at all, since the RRKM lifetime of such a highly energized species would be very short indeed.

In Figs. 3 and 6 it was seen that the energy partitioned into the CO product of the O + C_2H_3 reaction was much greater than for the case of the F/HCO reaction. In the former case, the intermediate vinoxy radical is about as highly energized as the HFCO is in the latter reaction. The total energy of the O/C_2H_3 system, including that of the reagents, is about 120 kcal mol^{-1}. The minimum barrier to decomposition of the vinoxy radical to CO and CH_3 is not known, but it is likely to be much less than that of the HFCO and vinyl fluoride systems, because in the O/C_2H_3 case the intermediate is a radical which requires only a hydrogen atom migration before decomposition. If the exit channel barrier to C_2H_3O decomposition is somewhat lower than those of the other two reactions, the nonstatistical CO distribution may simply imply that the vinoxy system does not remain in the vicinity of the intermediate well in the potential energy surface as long as the F atom systems do.

Further work on these systems is under way. Accurate measurements of the CO energy distributions for reactions [3] and [4] will be made, and the extent to which these differ from completely statistical distributions will be determined. This information will also permit the complete determination of the energy partitioning in the F + HCO reaction, since it will involve direct measurement of the energy content of all products.

D. J. DONALDSON, J. S. WRIGHT, and J. J. SLOAN. Can. J. Chem. **61**, 912 (1983).

The hydroxyl radical is generated in various vibrational states by three reactions: $F + H_2O \rightarrow HF + OH$ ($v = 0$), $H + NO_2 \rightarrow NO + OH$ ($v \leq 3$), and $H + O_3 \rightarrow O_2 + OH$ ($v = 7-9$). The OH so produced reacts with F atoms according to $F + OH(v) \rightarrow HF(v') + O$. The vibrational populations of OH and HF are obtained by the low pressure infrared chemiluminescene technique.

D. J. DONALDSON, J. S. WRIGHT et J. J. SLOAN. Can. J. Chem. **61**, 912 (1983).

On forme le radical hydroxyde sous différents états vibrationnels au moyen de trois réactions: $F + H_2O \rightarrow HF + OH$ ($v = 0$), $H + NO_2 \rightarrow NO + OH$ ($v \leq 3$) et $H + O_3 \rightarrow O_2 + OH$ ($v = 7-9$). Le radical OH ainsi produit réagit avec les atomes de fluor selon l'équation: $F + (OH)(v) \rightarrow HF(v') + O$. On a obtenu les populations vibrationnelles du OH et de HF par la technique de chimiluminescence par infrarouge à faible pression.

[Traduit par le journal]

Introduction

Reactions of the hydroxyl radical play an important role in atmospheric photochemistry (1, 2). In the upper atmosphere OH is produced in vibrationally excited states by the reaction of hydrogen atoms with ozone. Emission from these states is considered to be the major source of the Meinel OH bands (3).

The laboratory study of reactions of vibrationally excited OH began with the work of Coltharp *et al.* (4) and Streit and Johnston (5) on $OH(v) + O_3$. Spencer and Glass (6) produced OH ($v = 1$) in high yield and studied its reactions with a variety of molecules. In a paper closely related to the present one, Blackwell *et al.* (7) prepared OH in two vibrational distributions by reaction with $H + O_3$ and $H + NO_2$, and reacted the OH (v) with atomic chlorine to produce vibrationally excited HCl. Infrared emission from the HCl was monitored and converted into product populations, using an infrared chemiluminescene technique similar to the present one.

In this paper we report the results of a low pressure ir chemiluminescence study of the reaction of F + OH, where the OH is prepared in three different pre-reactions:

[PR1] $F + H_2O \rightarrow HF + OH$ ($v = 0$), $\Delta H^\circ_O = -17.4$ kcal/mol

[PR2] $H + NO_2 \rightarrow NO + OH$ ($v = 0-3$), $\Delta H^\circ_O = -28$ kcal/mol

[PR3] $H + O_3 \rightarrow O_2 + OH$ ($v = 7-9$), $\Delta H^\circ_O = -77.1$ kcal/mol

The OH so prepared then reacts with atomic fluorine:

[R1,R2,R3] $F + OH(v) \rightarrow HF(v') + O(^3P)$, $\Delta H^\circ_O = -33.7$ kcal/mol

This reaction will be labelled [R1], [R2], [R3], according to whether the OH reagent has been prepared by reaction [PR1], [PR2], or [PR3]. In addition to [R1]–[R3], reaction [PR3] can provide enough reagent excitation to populate excited electronic states or rearrangement channels of the products, including

[R4] $F + OH \rightarrow HF + O(^1D)$, $\Delta H^\circ_O = +11.7$ kcal/mol

[R5] $F + OH \rightarrow HF + O(^1S)$, $\Delta H^\circ_O = +63$ kcal/mol

[R6] $F + OH \rightarrow OF + H$, $\Delta H^\circ_O = +48.9$ kcal/mol

In the following, the effect of OH reagent excitation on the observed HF product excitation will be presented.

Experimental

These experiments were carried out in an arrested relaxation infrared chemiluminescence apparatus which has been described previously (8). It was fitted with an adjustable reagent inlet device in which the OH reagent was produced. In experiments with H_2O and NO_2, the vessel walls were cooled with liquid nitrogen. In experiments involving ozone, the coolant was a Dry Ice/methanol slurry, in order to avoid condensing liquid ozone inside the system. Fluorine atoms were generated in a 100 W, 2450 MHz discharge in CF_4 gas (Matheson, 99.7%). Hydrogen atoms were obtained from H_2 gas in the same way. NO_2 was vacuum distilled from a cylinder and stored at −80°C until used. Ozone was generated in a manner described previously (9) and stored over silica gel at −80°C until used.

The adjustable reagent inlet which was used to generate OH for the case of reaction [PR1] was similar to that used in a previous study with this system by Sloan *et al.* (ref. 10, hereafter Paper I). Briefly, it consists of a 6 mm diameter quartz tube inside a 25 mm diameter Teflon tube. H_2O is admitted to the quartz tube which is sealed at its end, except for small holes through which the vapour escapes laterally. F atoms flow down the Teflon tube and reaction [PR1] occurs at the mixing point which can be adjusted vertically over a range of about 5 cm. The pressure in this mixing region is estimated to range from about 1 mTorr to 10 mTorr. As discussed in I, the OH from [PR1] is all formed in the $v = 0$ state. This result, which was reported in I, has been confirmed by repeated experiments. The secondary reaction [R1] also occurs within and below this mixing region.

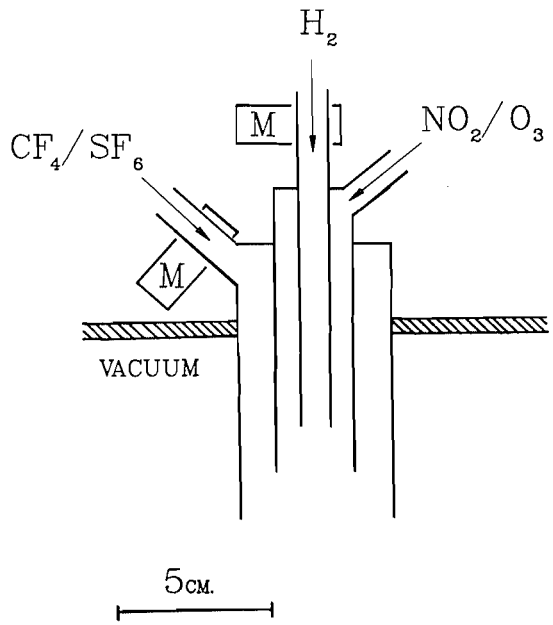

FIG. 1. Geometry of reagent inlet for NO_2 and O_3 experiments. F-atoms and H-atoms form as CF_4 and H_2 pass microwave discharges, labelled M.

The reagent inlet used in the O_3 and NO_2 experiments is shown in Fig. 1. It consists of three concentric quartz or Pyrex tubes, all of which are Teflon-coated. The H-atoms generated in the discharge flow down the inner tube and react with the NO_2 or O_3 which is admitted via the middle tube. F-atoms pass down the outer tube and encounter the OH (v) formed in reactions [PR2] and [PR3]. The F + OH (v) reaction occurs in the low-pressure region beneath the reactor inlets (the pressure rapidly drops to about 10^{-5} Torr in the centre of the vacuum chamber). For this reason the product HF from this reaction suffers virtually no vibrational energy transfer collisions.

Results

The results from the experiments using [PR1] are shown in Fig. 2 (10). The vibrational distribution of OH produced from reaction [PR1] is indicated as a single spike at $v = 0$. Because the activation energy for reaction [R1] is expected to be zero, the total energy available to products is about 34 kcal/mol (indicated as E'_{TOT}, Fig. 2). This is sufficient to populate HF ($v' \leq 3$). Reaction [PR1] also produces HF in states $v' = 0$ and 1; this cannot be separated from the contribution to these levels produced by reaction [R1]. The observed HF population in levels 0 and 1 is therefore due to reactions [PR1] and [R1], whereas for levels 2 and 3 it originates only from reaction [R1].

The result, shown in Fig. 2 and described in more detail in ref. 10, demonstrates that the reaction with ground state OH produces internally excited HF with vibrational energy up to the limit of the energy available (E'_{TOT}). However, the highest HF vibrational levels have smaller populations than the lower ones; the product excitation decreases with increasing vibrational level.

The reagent inlet configuration shown in Fig. 1 was used to explore the effect of OH vibrational excitation. For intermediate levels (up to OH ($v = 3$)), [PR2] was the source of vibrationally excited OH. The H-atoms for [PR2] were produced in a microwave discharge in H_2 (indicated as M in Fig. 1). However some undissociated molecular H_2 remains after such a discharge, and some vibrationally excited H_2 is produced in the high temperature plasma. As a result, the reaction between

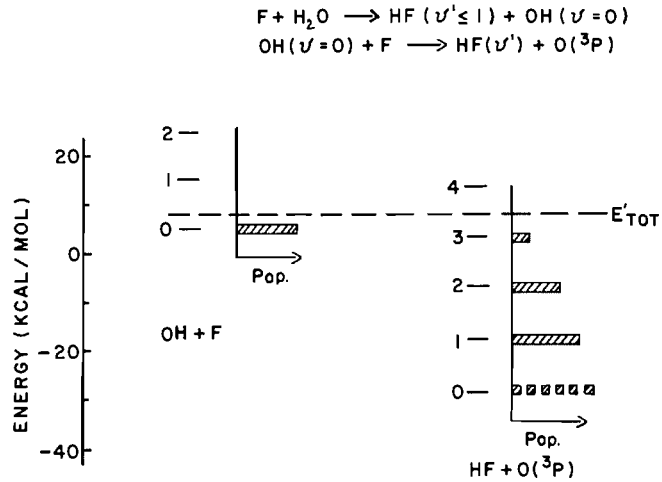

FIG. 2. Vibrational populations (hatched bars) at each quantum level for OH and HF. The population in HF ($v' = 0$) is unknown, as indicated by the dashed bar.

F-atoms and the remaining ground state H_2 produces HF with vibrational excitation up to $v' \leq 3$, while that with the vibrationally excited H_2 produces detectable amounts of HF ($v' \leq 4$). These HF emission spectra could be measured with both microwave discharges operating but with the NO_2 (and hence the OH) absent from the reactor. This provides a means whereby the HF populations produced by these interfering reactions could be determined, and subsequently subtracted from those measured with the OH reagent present.

In order to obtain the most accurate distributions for this subtraction, experiments were carried out in which CO_2 was substituted for the NO_2 in the reactor inlet. CO_2 was chosen for this purpose because it is not chemically reactive in this system, and it mimics, at least approximately, the vibrational deactivation (of HF) and the gas dynamic (e.g. momentum transfer) properties of NO_2. The HF vibrational distribution measured in the CO_2 "blank" experiment is indicated as squares in Fig. 3b. For the levels HF ($v' \leq 3$) the populations are within 5% of those produced by the F + H_2 reaction alone (11); the small difference arises from some deactivation and a small contribution fom the vibrationally excited H_2 reaction.

The small population in HF ($v' = 4$) is entirely due to the reaction with vibrationally excited H_2. Several experiments were carried out which explored the effect on the $v' = 4$ population of H_2 flow, added rare gas, differing F-atom precursors (SF_6 and CF_4), and an added HF deactivator, such as CO_2. These showed that while the vibrationally excited H_2 could not be completely eliminated, its effect, as judged by the HF ($v' = 4$) population, was reproducible for a given H_2 flow. As a result, a set of conditions was chosen which provided adequate H-atom concentrations with a known background HF population from the interfering reactions.

When NO_2 was substituted for CO_2 in the experiment,OH emission from the H + NO_2 reaction was observed. The OH distribution obtained under the flow conditions chosen for this study is shown in Fig. 3a. In this experiment, only the vibrationally excited OH could be determined, since the measurement is based on emission spectroscopy, but [PR2] also forms OH in its ground vibrational state. Under collision-free conditions the OH ($v = 0$) and OH ($v = 1$) levels are formed in approximately equal amounts by [PR2] (12). However, in the conditions of the present experiment, some deactivation of the

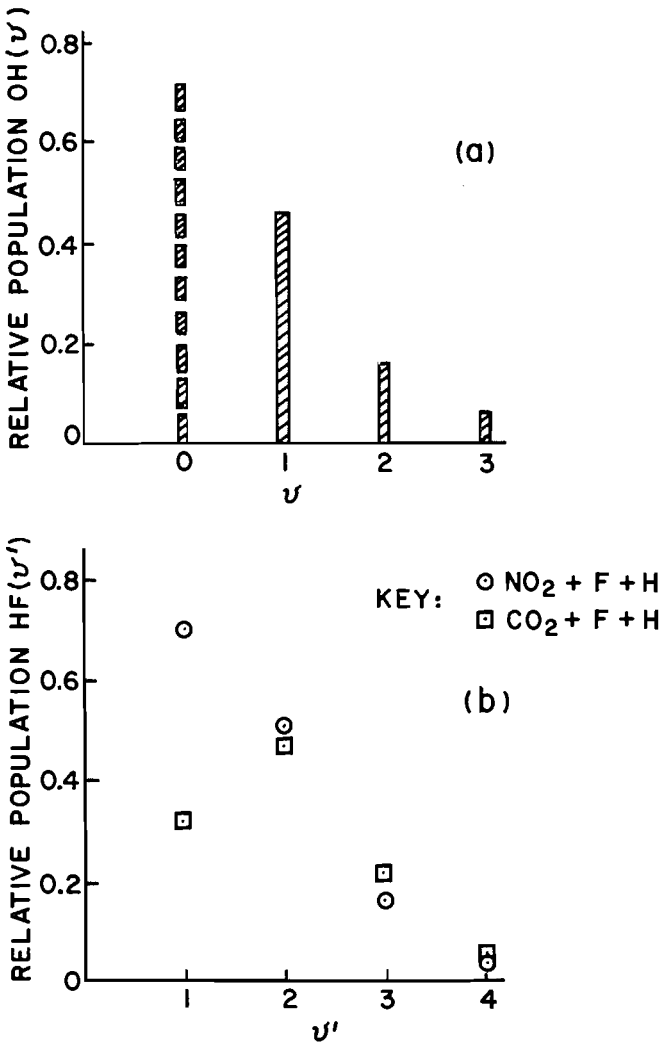

FIG. 3. (a) Vibrational populations of OH from H + NO_2 → OH (v) + NO. The dashed bar indicates an unknown, but probably large population in $v = 0$. (*b*) Vibrational populations of HF from two experiments: F + H + NO_2 (circles), F + H + CO_2 (squares).

vibrationally excited OH by NO_2 would be expected (9, 13). Rough calculations, based on the amount by which the observed OH ($v \geq 1$) distribution is collisionally deactivated (9, 12), suggest that the $v = 0$ population is between about 1 and 3 times that of the $v = 1$ level.

The effect of the OH (v) produced in [PR2] is shown by the circles in Fig. 3. In this case there is a substantial increase in the population of HF ($v' = 1$) and a small increase in that of HF ($v' = 2$) over those measured in the CO_2 "blank" experiment. The combined error in the two experiments are large, about 5%, for each vibrational level. Thus the remaining populations are, within this uncertainty, unchanged by the reaction with NO_2. Comparison of these results with those shown in Fig. 2 for the F + OH ($v = 0$) reaction shows that modest excitation of the OH (mostly to the $v = 1$ level) does not lead to any measurable increase in the product HF excitation.

Figure 4 shows the result of substantial vibrational excitation in the OH reagent. In this case the OH (v) was produced by reaction [PR3]. The same interferences from the F + H_2 reactions occurred in this case as well, and contributed to the observed HF ($v \leq 4$) populations. The HF ($v' \leq 3$) levels have been omitted from the figure for this reason. The reaction with

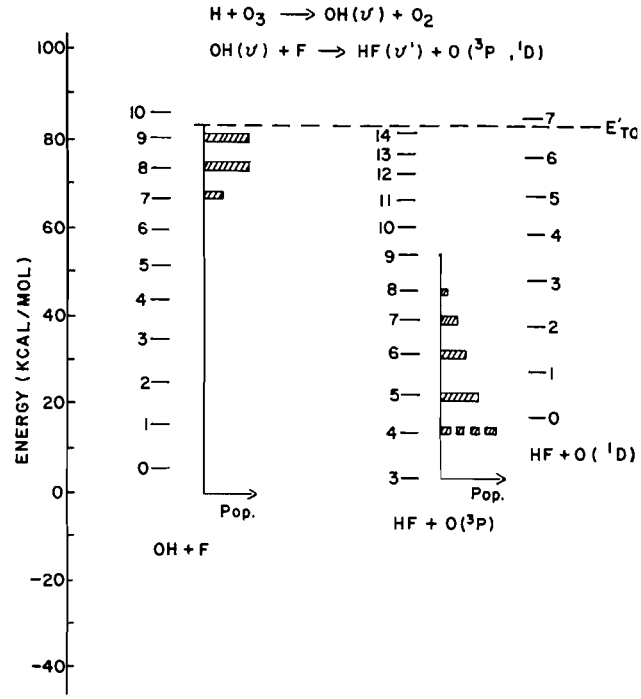

FIG. 4. Vibrational populations (hatched bars) for reagent OH ($v = 7-9$) and product HF ($v' \leq 8$). The dashed bar at HF ($v' = 4$) indicates that the levels $v' \leq 4$ may also be populated from the F + H_2 reaction. Also shown (at right) is the vibrational manifold for HF on the excited electronic surface HF + O (^1D).

vibrational excited H_2 contributes about 5% to the population of the $v' = 4$ level, which has been shown as a dashed bar to indicate this uncertainty.

It is clear from Fig. 4 that substantial (up to $v = 9$) vibrational excitation of the OH has resulted in a comparable increase in the vibrational excitation of the HF product. An increase in the maximum excitation of the OH reagent by about 50 kcal mol^{-1} (from $v = 3$ to $v = 9$) results in a nearly equal increase in the maximum observed HF product excitation (from $v' = 2$ to $v' = 8$).

Discussion

The electronic state correlation diagram, obtained for the FOH system by a combination of known thermochemistry and *ab initio* calculations reported in Paper I, is reproduced here and shown in Fig. 5.

Progress across the potential energy surface is indicated by the angle θ which changes from 90° (reagents) to 0° (products) during the course of the reaction. Inspection of Fig. 5 shows that two states, $^3\Pi$ and $^3\Sigma^-$, directly correlate ground state reactants F (^2P) + OH ($^2\Pi$) to ground state products HF ($^1\Sigma^+$) + O (^3P). However, the triplet barrier of ca. 12 kcal/mol cannot be surmounted by reaction [R1]. As discussed in I, an alternative path involving formation of the $^1A'$ HOF complex, followed by a crossing to the triplet surface in the exit channel (dashed circle) is required to explain the observed HF product formation in $v' \geq 1$. The presence of the HOF potential well and the presence of an exit channel barrier near the surface crossing would increase the lifetime of the HOF complex. As discussed in Paper I, if the complex is long-lived, the energy should be partitioned statistically among the product degrees of freedom. This is consistent with the distribution shown in Fig. 2. The results obtained with [PR2] show that modest

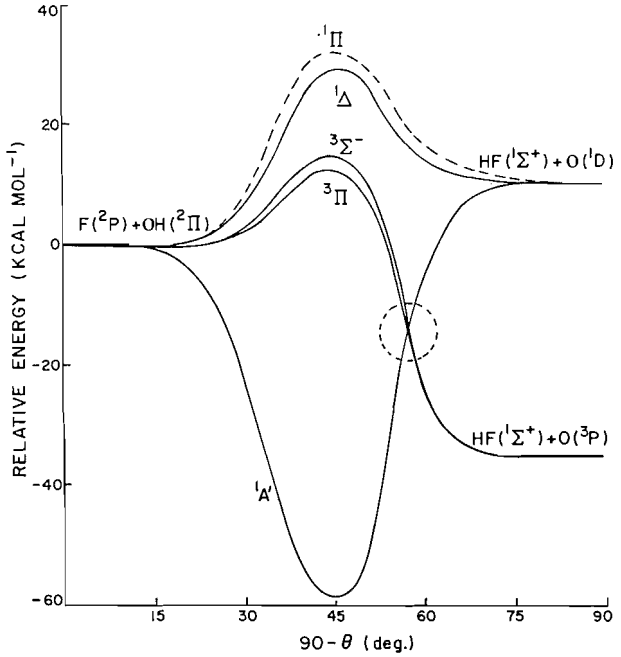

FIG. 5. Electronic state correlation diagram for the FOH system, taken from Paper 1.

vibrational excitation of the OH reagent (mostly to OH (v = 1)) does not appear to modify the dynamics of the reaction measurably. However, a substantial increase in vibrational excitation of the OH reagent causes a comparable increase in the maximum observed HF product excitation. This result is qualitatively the same as that obtained from the Cl + OH reaction reported in ref. 7. In that case, however, the reaction between the ground state reagents is virtually thermoneutral, and hence an increase in the energy of the reagent to a certain level led to an increase in the product energy to the same (absolute) level.

While the two reactions exhibit the same qualitative behaviour (increased reagent vibrational excitation leads to an increase by a comparable amount in the product vibrational excitation), the exoergicity of the FOH reaction makes a direct comparison difficult. The F + OH (v = 0) reaction, although substantially exoergic, does not efficiently partition its reaction energy into product vibration. It was suggested in ref. 10 that this may be an indication that a relatively long-lived FOH intermediate is formed. However, when the OH has substantial vibrational excitation, this excess reagent energy appears to be partitioned efficiently into product vibration. This suggests there is a difference in the efficiency with which reaction exoergicity and excess reagent energy are partitioned into product vibration. Such a difference would necessarily require non-statistical energy partitioning, and hence a change from the statistical behaviour of the reaction with OH (v = 0).

A second interpretation is possible for this observation; it is suggested by the third column of energy levels in Fig. 4. The product oxygen atom may be formed in its first electronically excited state, O (^1D), as indicated by the direct correlation shown in Fig. 5. If this occurs, only enough energy remains to excite the HF up to the v' = 6 level. If most of the reaction goes via this channel, then the large populations in levels HF ($v' \leq 6$) would imply substantial population up to the maximum thermochemically allowed limit. This, in turn would indicate a direct, non-ergodic reaction in which a large amount of the reaction exoergicity is partitioned into product vibration.

To distinguish between these two possibilities is an exceedingly difficult experimental problem; it is impossible with apparatus which is presently available. Substantial modifications to the apparatus are presently being carried out. It is hoped that these will decrease the uncertainty in the measured populations and present a clearer result in which the small differences in population predicted by the two models may be resolvable.

Concurrently, classical trajectory studies of the reactions on the various potential energy surfaces are also being carried out to better quantify the precise shapes of the distributions expected from the different possible reaction dynamics. It is hoped that these efforts will reveal the origins for the effect reported here. Presently, however, it can be concluded that the reaction with vibrationally cold OH gives low product vibrational excitation, a result which is consistent with the formation of a long-lived intermediate. In contrast to this, vibrational excitation in the reagent is channelled fairly efficiently into vibration in the product, a result which implies that the reaction with the vibrationally excited reagents is a direct process.

A search for a gas-phase free-radical inversion displacement reaction at a saturated carbon atom[1]

R. A. BACK

Chemistry Division, National Research Council of Canada, 100 Sussex Drive, Ottawa, Ont., Canada K1A 0R9

Received July 12, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

R. A. BACK. Can. J. Chem. **61**, 916 (1983).

Five thermal and photochemical reaction systems have been examined in an attempt to detect or to place upper limits on the rates of the simple inversion reaction, $CH_3 + CH_4 \rightarrow C_2H_6 + H$, and its reverse. No positive evidence was obtained for the occurrence of these reactions. An upper limit for the rate constant for the forward reaction of 0.063 M^{-1} s^{-1} at 802 K was obtained from the thermal decomposition of methane, and upper limits of 0.044 and 0.14 at 823 and 983 K respectively were estimated from the thermal decomposition of ethane. Other systems examined were the thermal decomposition of azomethane in the presence of methane, and the mercury-photosensitized decompositions of methane and ethane, which were complicated by unexpected side reactions.

R. A. BACK. Can. J. Chem. **61**, 916 (1983).

On a étudié cinq systèmes de réaction thermique et photochimique dans le but de déceler ou de situer les limites supérieures des vitesse de la réaction d'inversion simple: $CH_3 + CH_4 \rightarrow C_2H_6 + H$ et de la réaction inverse. On n'a pas obtenu la preuve formelle de l'existence de ces réactions. On a obtenu une limite supérieure pour la constante de vitesse de la réaction directe de 0,063 M^{-1} s^{-1} à 802 K à partir de la décomposition thermique du méthane et on a évalué des limites supérieures de 0,044 et de 0,14 à 823 et 983 K respectivement. On a examiné d'autres systèmes tels: la décomposition thermique de l'azométhane en présence de méthane et les décompositions photosensibilisées par le mercure, du méthane et de l'éthane. Ces décompositions se sont compliquées par la présence des réactions secondaires non prévues.

[Traduit par le journal]

Introduction

No simple free-radical displacement inversion reaction at a saturated carbon atom has apparently ever been observed. A large potential-energy barrier can be expected for such a reaction, and a knowledge of its activation energy and frequency factor is important to an understanding of the reaction dynamics, and more practically, to determine whether inversion reactions might be significant in particular reaction systems. The prototype

[1] $H + CH_4 \rightarrow CH_4 + H$

in which an H-atom approaches the carbon atom along one of the C—H axes, displacing the H-atom from the opposite side, would lead to isotopic exchange. This would be almost impossible to detect, however, in competition with the efficient methyl-radical chain reaction which leads to the same result (1). Inversion reactions of more practical interest are

[2] $CH_3 + CH_4 \rightarrow C_2H_6 + H$

and its reverse,

[3] $H + C_2H_6 \rightarrow CH_3 + CH_4$

Reaction [2] was suggested almost 50 years ago as a possible chain propagation step in the thermal decomposition of methane (2), for reasons that are no longer valid, and recent studies of this system (3) concluded that there was no evidence for its occurrence at temperatures down to 1000 K. The initial stages of the methane decomposition appear to be accounted for by the simple non-chain mechanism,

[4] $CH_4 \rightarrow CH_3 + H$

[5] $H + CH_4 \rightarrow H_2 + CH_3$

[6] $2CH_3 \rightarrow C_2H_6$

Reaction [4] is rate-controlling, and the rate $R = 2k_4[CH_4]$. If reaction [2] were important, a chain reaction would ensue, yielding $H_2 + C_2H_6$, the same products as before:

[2] $CH_3 + CH_4 \rightarrow C_2H_6 + H$

[5] $H + CH_4 \rightarrow H_2 + CH_3$

Net reaction $2CH_4 \rightarrow H_2 + C_2H_6$

It can be easily shown that the rate expression then becomes

$$R = 2k_4[CH_4] + 2k_2(k_4/k_6)^{1/2}[CH_4]^{3/2}$$

Activation energies associated with the non-chain and chain process would be E_4 and $(E_2 + \frac{1}{2}E_4 - \frac{1}{2}E_6)$ respectively. Taking $E_4 = 107.6$ (3) and $E_6 = 0$, it can be seen that if E_2 is less than 54 kcal/mol, the second term will have a lower activation energy than the first and might be expected to become important at sufficiently low temperatures. Conversely, if E_2 exceeded 54 kcal/mol the chain reaction could become important at high temperatures. It could also become important at much higher temperatures when the dissociation of ethane (the reverse of reaction [6]) becomes fast, essentially preventing the removal of methyl radicals by reaction [6] and allowing their concentrations to build up to very high values. In fact, it has been suggested that this occurs in the decomposition of methane in a shock tube at temperatures from 2000 to 2500 K (4).

In the present study, the following systems were examined in an attempt to detect reaction [2] or to place upper limits on its rate: (*1*) the thermal decomposition of methane; (*2*) the mercury-photosensitized decomposition of methane; (*3*) the thermal decomposition of azomethane in the presence of methane; (*4*) the thermal decomposition of ethane; (*5*) the mercury-photosensitized decomposition of ethane. The first

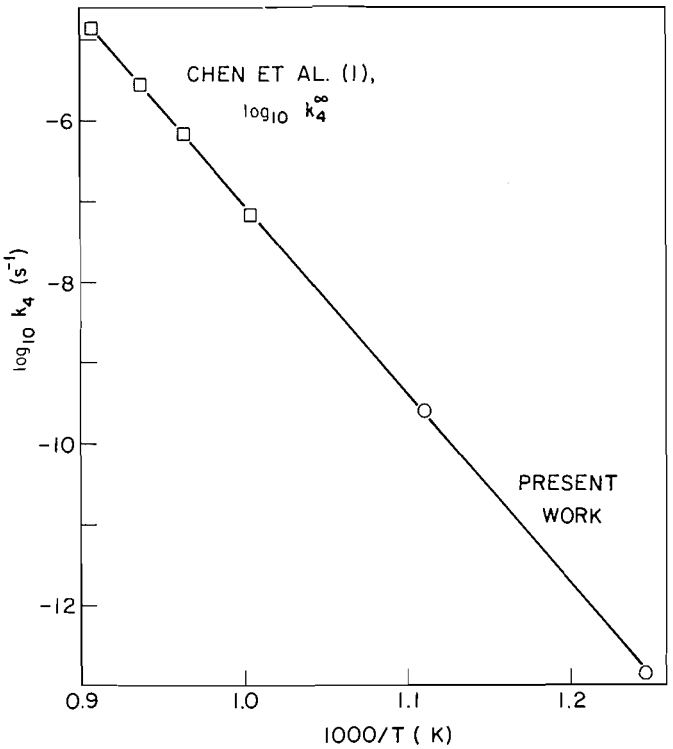

FIG. 1. Arrhenius plot of k_4, the first-order rate constant for the dissociation of methane.

three systems involve reaction [2] directly, the last two indirectly through reaction [3] to which it can be related thermochemically.

The thermal decomposition of methane

Previous studies in this laboratory (3) established that the initial stages of the decomposition from 995 to 1103 K are well accounted for by reactions [4], [5], and [6], with reaction [4] exhibiting some unimolecular pressure dependence, and no evidence for the occurrence of reaction [2]. The present experiments have extended these measurements to 899 and 802 K at pressures of about 1000 Torr where k_4 should be close to its high-pressure limit. Methods were similar to those used previously (3), with the quartz reaction vessel conditioned before each experiment by admitting air at the pyrolysis temperature for several hours to remove any carbon deposit. Without this conditioning, high and irregular rates were obtained, and it is clear that surface effects are more serious at these lower temperatures. Experiments in unconditioned sealed Pyrex vessels at pressures up to 10 atm also gave erratic results. Data from the conditioned vessel are shown in Fig. 1 together with the earlier data of Chen *et al.* (1), and it is clear that they are in close agreement with an extrapolation of k_4^∞ from the latter; i.e., there is no evidence for the occurrence of reaction [2]. Reaction times needed at 802 K to give measureable C_2H_6 were several months, and it seems impractical to extend these measurements to still lower temperature.

No ethylene was observed in any of these experiments, as would have been expected if secondary decomposition of ethane were occurring, and there is no reason to doubt that initial primary yields of ethane, and hence initial rates of reaction [4], were measured. It can be estimated that if reaction [2] had occurred to an extent 10% that of reaction [4] at our lowest temperature, we should have detected an enhanced rate of ethane formation. From this, an upper limit of $k_2 = 0.063\ M^{-1}\ s^{-1}$ can be estimated, taking a value of $k_6 = 4 \times 10^{10}\ M^{-1}\ s^{-1}$. If a frequency factor of $10^{10}\ M^{-1}\ s^{-1}$ is assumed, this corresponds to a lower limit of about 40 kcal/mol for E_2.

In their shock-tube studies Tabayashi and Bauer (4) found that values of $A_2 = 8 \times 10^{10}\ M^{-1}\ s^{-1}$ and $E_2 = 40$ kcal/mol in their reaction model gave the best fit to their data. These parameters give a value of $k_2 = 0.92\ M^{-1}\ s^{-1}$ at 802 K, about 15 times higher than our estimated upper limit.

The mercury-photosensitized decomposition of methane

This system merely substitutes a new initiation step,

[7] $Hg(^3P_1) + CH_4 \rightarrow Hg(^1S_0) + CH_3 + H$

for reaction [4] in the pyrolysis mechanism, permitting an extension of the measurements to lower temperatures at which the purely thermal reaction is too slow. Using methods similar to those used previously (5), the decomposition was studied at temperatures from 553 to 863 K, thus overlapping both the thermal decomposition studies and our earlier mercury-photosensitized experiments (5). Quantum yields of ethane at several temperatures are shown in Fig. 2 as a function of methane concentration. These data are in essential agreement with our earlier studies, with quantum yields rising with increasing pressure and temperature. If reactions [7], [5], and [6] were quantitative, the quantum yield should have been unity, independent of temperature and pressure. The observed values, and their variation, probably reflect as before an incomplete and temperature-dependent quenching of $Hg(^3P_1)$ in reaction [7], with perhaps some loss of CH_3, and thence C_2H_6, by the incomplete suppression of the combination reaction,

[8] $CH_3 + H \rightarrow CH_4$

For our present purposes, the important observations are that the quantum yield of ethane is always less than unity and shows no sharp upward trend with temperature as might be expected from the onset of a chain reaction, propagated by reaction [2], with an activation energy in the 20–50 kcal/mol range (cf. the mercury-photosensitized decomposition of ethane at high temperature (6) in which a chain decomposition is propagated by the decomposition of the ethyl radical). An activation energy of about 6 kcal/mol can be estimated from Fig. 2 at a methane concentration of $8 \times 10^{-3}\ M$, much too low for the inversion reaction. Because of uncertainties in the efficiencies of reactions [5], [6], and [7], it is impossible to calculate a meaningful upper limit for reaction [2] from this system, but there is no positive evidence for its occurrence.

The thermal decomposition of azomethane in the presence of methane

In this system again a new initiation step,

[9] $C_3NNCH_3 \rightarrow 2CH_3 + N_2$

is substituted for reaction [4] in the methane pyrolysis. In pure azomethane this is followed by the reaction

[10] $CH_3 + CH_3NNCH_3 \rightarrow CH_4 + CH_3NNCH_2$

and reaction [6]. Subsequent reactions of CH_3NNCH_2 and other radicals with azomethane lead to a short-chain reaction with a chain length of 2 or 3, yielding N_2, CH_4, C_2H_6, and some higher products (7). With methane present, this chain may be partly suppressed by the reversal of reaction [10].

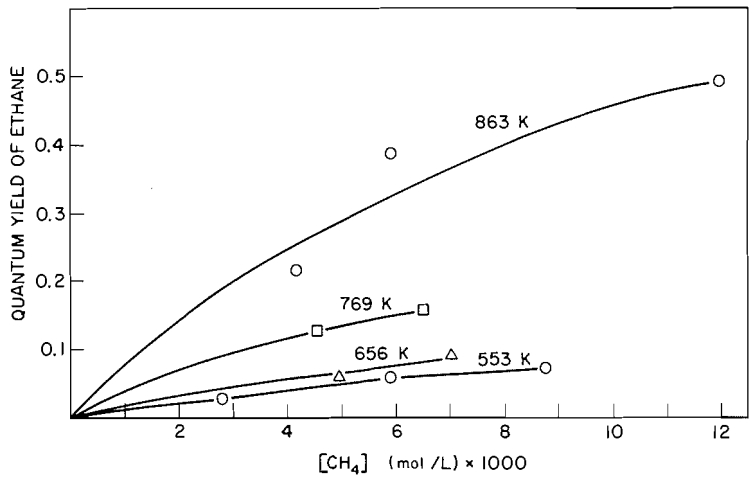

FIG. 2. Quantum yields of ethane vs. methane concentration in the mercury-photosensitized decomposition of methane.

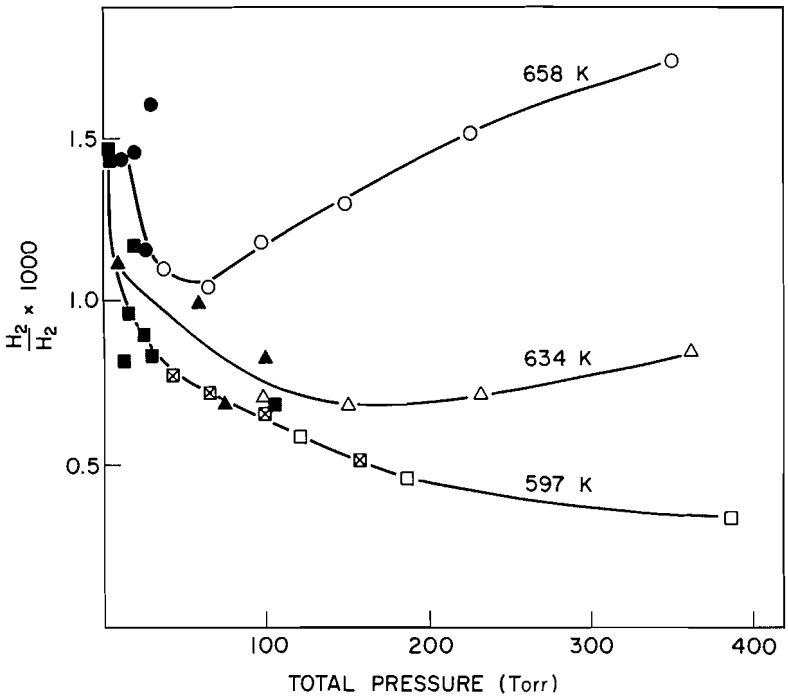

FIG. 3. Variation with pressure of the product ratio H_2/N_2 in the thermal decomposition of azomethane in the presence of CH_4 and CO_2. ●▲■ = pure azomethane; ○△□ = added CH_4; ⊠ = added CO_2. Pressures of CO_2 have been multiplied by an efficiency factor of 0.3.

If to this mechanism we now add the inversion reaction, [2], followed by reaction [5] the net result would be, as in the methane pyrolysis, a chain reaction yielding H_2 and C_2H_6. Formation of H_2 has not been reported in previous studies of the pyrolysis of azomethane alone, and its appearance on the addition of CH_4 at temperatures at which reaction [4] is negligible should be a sensitive indicator of reaction [2].

The decomposition of azomethane was studied in a static system at temperatures of 597, 634, and 658 K, both alone and in the presence of methane. Yields of N_2 and H_2 were measured by gas chromatography on a silica gel column at room temperature with argon carrier gas, which gave a good sensitivity for hydrogen on a thermal conductivity detector. Pressures of azomethane ranged from about 1 to 100 Torr and the extent of decomposition was between 10 and 50%, based on nitrogen yields.

Hydrogen, previously unreported, was found to be a very minor product in the decomposition of azomethane itself, with yields between about 0.08 and 0.16% of the N_2 at the lowest pressures employed. The H_2/N_2 ratio decreased with increasing pressure of azomethane at all three temperatures. At 597 K, the addition of CH_4 caused a further *decrease* in the ratio; at the higher temperatures, an initial decrease was followed by a slight increase in H_2/N_2 at 634 K and by a larger increase at 658 K. These results are shown in Fig. 3 where the H_2/N_2 ratio is plotted against total pressure.

The source of H_2 from the azomethane decomposition is not clear. The pressure dependence suggests collisional stabiliza-

For personal use only.

tion of an excited intermediate, and to test this possibility experiments were done at 597 K with CO_2 added to azomethane. The results are also shown in Fig. 3; again the H_2/N_2 ratio was reduced and if an efficiency for CO_2 of 0.3 relative to CH_4 is assumed, the data coincide with those for the addition of CH_4. One possible source of H_2 is the decomposition of excited ethane formed by methyl combination,

[11] $2CH_3 \rightarrow C_2H_6^* \rightarrow H_2 + C_2H_4$

[12] $\rightarrow H + C_2H_5$

Reaction [12] requires an additional 11 kcal/mol above the combination energy, while reaction [11] probably requires rather less but would have a lower frequency factor. While for most purposes the combination of methyl radicals can be regarded as pressure-independent at the pressures and temperatures employed, the occurrence of 0.1% dissociation via reaction [11] or [12] is not impossible. Further studies are planned to test this explanation of the production of H_2 from azomethane, which must for the moment remain tentative.

The increase in the H_2/N_2 ratio on the addition of CH_4 at 658 K shows the right kinetics for production of H_2 by the inversion reaction, [2], followed by [5]. Assuming reactions [11] and [12] to be roughly independent of temperature, and reaction [2] to be negligible at 597 K, then subtracting the curve at 597 K from that at 658 K in Fig. 3 should give an approximate measure of the contribution of reaction [2] to the hydrogen yield at the higher temperature. From steady-state kinetics based on a simplified mechanism comprising reactions [2], [5], [6], and [9], it can be shown that the ratio

$$H_2/N_2 = k_2[CH_4]/k_6k_9[CH_3NNCH_3]$$

from which a value of $k_2 = 186\ M^{-1}\ s^{-1}$ may be estimated at 658 K. This is an impossibly high value, since from the methane pyrolysis we have already established an upper limit for k_2 at 802 K of 0.032 and it must be concluded that reaction [2] is not the cause of the increase in H_2/N_2 at 658 K when methane is added to azomethane. The absolute yield of H_2 is small, and some very minor secondary reactions could be responsible, but these are still enough to make measurements of k_2 in this system impossible.

The thermal decomposition of ethane

This system and the following one are chosen to provide evidence for the occurrence of reaction [3], the reverse of [2], rather than reaction [2] itself. The thermochemistry of the equilibrium is well established, with $\Delta S^0 = -8.5$ cal/mol degree, $\Delta H^0 = 15.8$ kcal/mol, and $\Delta C_p = 1.3$ cal/mol deg for reaction [2]. Reaction [3] will thus have an activation energy about 16 kcal/mol lower than reaction [2], and a higher frequency factor, and would appear to be more easily detected, with $k_3/k_2 = 4 \times 10^5$ at 1000 K.

The thermal decomposition of ethane in a static system at temperatures between 550 and 620 K follows to a good approximation the free-radical chain mechanism (8),

[13] $C_2H_6 \rightarrow 2CH_3$

[14] $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$

[15] $C_2H_5 \rightarrow C_2H_4 + H$

[16] $H + C_2H_6 \rightarrow H_2 + C_2H_5$

[17] $2C_2H_5 \rightarrow C_4H_{10}$ (or $C_2H_4 + C_2H_6$)

Reactions [15] and [16] constitute a chain reaction forming $H_2 + C_2H_4$, the major products of the decomposition.

If the inversion reaction,

[3] $H + C_2H_6 \rightarrow CH_3 + CH_4$

occurred, followed by reactions [14] and [15], the result would be a new chain reaction operating in parallel to the previous one, yielding $2CH_4 + C_2H_4$. The thermal decomposition of ethane has been very thoroughly studied, and we have done no new experiments on this system. Methane is a product, but it has always been attributed to reactions [13] and [14], and its yield has in fact been used to measure the rate of reaction [13]. From the data of Lin and Back (8), who measured both CH_4 and H_2, and thereby the rates of chain initiation and propagation respectively, kinetic chain lengths of 150 and 125 can be estimated at 823 and 893 K at pressures of about 300 Torr of ethane. If we estimate somewhat arbitrarily that 10% additional formation of methane by reaction [3] could have been detected, then reaction [3] could have been no more than a fraction $(0.1/(2 \times \text{chain length}))$ of the rate of the propagation step, [16], with which it is in direct competition. Rate constants for reaction [16] of 3.0×10^8 and $3.7 \times 10^8\ M^{-1}\ s^{-1}$ can be estimated from the literature (9) for temperatures of 823 and 893 K respectively, from which upper limits of $k_3 = 1.48$ and $2.01 \times 10^5\ M^{-1}\ s^{-1}$ can be calculated. Finally, from the thermodynamic relations between k_2 and k_3, upper limits for k_3 of 0.044 and 0.14 $M^{-1}\ s^{-1}$ at 823 and 893 K respectively can be estimated; these are slightly lower than the upper limits obtained from the methane decomposition, which gave a limit of 0.063 $M^{-1}\ s^{-1}$ at 802 K.

The mercury-photosensitized decomposition of ethane

As with methane, mercury photosensitization substitutes a new radical source in the ethane decomposition (6, 10),

[18] $Hg(^3P_1) + C_2H_6 \rightarrow Hg(^1S_0) + C_2H_5 + H$

replacing reaction [13]. At temperatures at which the latter is negligible, the inversion reaction, [3], followed by [14], becomes the only source of CH_4, which should therefore be a sensitive indicator of its occurrence. An interfering source of methyl radicals (and thence methane) which must be avoided is the "cracking" reaction,

[19] $H + C_2H_5 \rightarrow C_2H_6^* \rightarrow 2CH_3$

This can be minimized (10) by working at low light intensity (which gives low concentrations of H and C_2H_5) and high ethane pressure, which reduces the concentration of H by enhancing its removal in reaction [16]. Experimental methods were similar to those used in methane. Product analysis was done either by removing all the noncondensible gases through a trap at −196°C, and measuring H_2 and CH_4, or by simply analysing a small portion of the reaction mixture for CH_4 and n-C_4H_{10}, using gas chromatography in both cases.

In experiments at 298 K, as the light intensity was reduced and ethane pressure increased, the ratio CH_4/C_4H_{10} fell to values less than 0.002, showing that reaction [19] could be almost completely suppressed. The decomposition under these conditions should follow to a good approximation the simple mechanism consisting of reactions [18], [16], and [17]. If now the temperature is increased until reaction [3] begins to compete with reaction [15], the ratio of rates will be given by $R_3/R_{16} = CH_4/2C_4H_{10}$ (neglecting the disproportionation of ethyl radicals). Experiments were done at 498 and 556 K and pressures

of a few hundred Torr, and unexpectedly large yields of methane were found, with values of CH_4/C_4H_{10} about 0.6 and 1.4 respectively, much too high for the methane to be coming from reaction [3]. Measurements of the CH_4/H_2 ratio confirmed the large yields of methane. The source of this methane is not clear; production of $2CH_3$ in a temperature-dependent primary dissociation, which might have been missed in earlier studies (5, 10), is one possibility, and experiments to test this are planned. For the present purposes, the production of methane, by whatever means, frustrates for the moment the attempt to use this system to detect the inversion reaction.

Concluding remarks

We have examined five systems which showed some promise of detecting or putting upper limits on the inversion reactions, [2] and [3]. There is no positive evidence in any of these systems for the occurrence of these reactions. The lowest upper limits for their rates are derived from the thermal decompositions of methane and ethane at 802, 823, and 893 K. Attempted measurements in two of the more promising systems, the azomethane–methane decomposition and the mercury-photosensitized decomposition of ethane, failed because of the unexpected formation, from other sources, of H_2 and CH_4, respectively, the products which it was hoped would be sensitive indicators of the inversion reactions. Addition of excess H_2 to the ethane–Hg system, for example, may be a way to ensure that H-atoms are the only primary products. Finally, the reaction of H-atoms (produced by mercury photosensitization) with cyclopropane or cyclobutane in an inversion reaction analogous to reaction [3], should yield *n*-propyl or *n*-butyl radicals with an activation energy much reduced by the release of ring strain energy, and perhaps offer the best hope of observing such an inversion reaction. It is worth noting, in a symposium honoring Professor Gunning, that the mercury-photosensitized reactions in which he pioneered can still be very useful in kinetic studies of free-radical reactions.

Quenching of $O_2(c^1\Sigma_u^-)v = 0$ by $O(^3P)$, $O_2(a^1\Delta_g)$, and other gases

REX D. KENNER AND ELMER A. OGRYZLO

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V8T 1W5

Received July 13, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

REX D. KENNER and ELMER A. OGRYZLO. Can. J. Chem. **61**, 921 (1983).

Spectroscopic and kinetic results for the quenching of $O_2(c^1\Sigma_u^-)$ are presented, including the first reported laboratory observation of gas phase emission from vibrational levels greater than zero for this state. In addition, the absolute rate constants for quenching of the lowest vibrational level by $O(^3P)$, $O_2(a^1\Delta_g)$, $O_2(X^3\Sigma_g^-)$, CO_2, SF_6, HE, and Ar are given. These results are compared with the results of atmospheric modeling studies. Qualitative evidence is presented for the formation of $O_2(a^1\Delta_g)$ and $O_2(a^1\Sigma_g^+)$ in the quenching of this state.

REX D. KENNER et ELMER A. OGRYZLO. Can. J. Chem. **61**, 921 (1983).

On présente les résultats spectroscopiques et cinétiques de la rupture du $O_2(c^1\Sigma_u^-)$ en incluant les premières observations de laboratoire publiées sur l'émission en phase gazeuse à partir de niveaux vibrationnels de cet état supérieure à zéro. De plus, on donne les constantes de vitesse absolue pour le piégage du niveau vibrationnel le plus bas par $O(^3P)$, $O_2(a^1\Delta_g)$, $O_2(X^3\Sigma_g^-)$, CO_2, SF_6, He et Ar. On a comparé ces résultats avec les résultats d'études de modèles atmosphériques. On présente des preuves qualitatives de la formation de $O_2(a^1\Delta_g)$ et de $O_2(a^1\Sigma_g^+)$ lors du piégeage de cet état.

Oxygen is the second most abundant element in the Earth's atmosphere and is responsible for much of the visible and ultraviolet emission from the upper atmosphere (1–5). On the dark side of the Earth the principal energy source for these emissions is the recombination of atoms generated by photodissociation during the day (6). Six bound states arising from the recombination of two ground state oxygen atoms have now been observed, both in the Earth's nightglow (1–5) and in the laboratory (7–10). While the kinetics of the lower two excited singlet states of O_2, $O_2(a^1\Delta_g)$ and $O_2(b^1\Sigma_g^+)$, are relatively well understood (11), only recently has much progress been made in understanding the three higher metastable states: $O_2(A^3\Sigma_u^+)$, $O_2(c^1\Sigma_g^-)$, and $O_2(A'^3\Delta_u)$. Note the redesignation of the $(^3\Delta_u)$ state as A' rather than C (12). Detailed spectroscopic investigations of these three u-states were first reported by Herzberg (13, 14) and the transitions between them and the ground state, $O_2(X^3\Sigma_g^-)$ are referred to as the Herzberg I, II, and III systems respectively.

Emission of the Herzberg I system was first seen in the laboratory by Broida and Gaydon (15) in oxygen afterglows. Three subsequent laboratory studies (16–18) have reported values for the composite emission rate constant, k_A, in the expression

$$I_A = k_A[O]^2[M]/[O_2]$$

A fourth study (19) reported absolute rate constants for reactions with $O(^3P)$, O_2, and Ar. Subsequent work in this laboratory has refined these rate constants as well as extending the list of quenchers investigated.[1]

The $O_2(A'^3\Delta_u)$ state is much less well understood. Transitions to this state were first observed as diffuse triplets in the high pressure absorption of molecular oxygen by Wulf (20) and Finklnburg and Steiner (21). These absorptions were subsequently seen by Herzberg (14) who, using a very long pathlength, observed fragments of two weak triple-headed bands at pressures of several atmospheres. More recently, emission from the $O_2(A')$ state has been reported in matrix isolation studies in N_2 and rare gas hosts at low temperatures (22–25). In the gas phase, two emission systems, $A' \rightarrow X$ and $A' \rightarrow a$, have been identified by Slanger (4, 10) who observed them in helium–oxygen afterglows as well as in NO-titrated afterglows. He also identified these transitions in the spectrum of the nightglow of Venus (26) and confirmed the earlier suggestion by Chamberlain (27) that some of the features of the Earth's nightglow could be explained by $A' \rightarrow a$ transitions (5).

Until the advent of exploration of the nearby planets of our solar system, little was known about the $O_2(c^1\Sigma_u^-)$ state. Herzberg (14) had analyzed six bands observed in long-path absorption and two very weak bands were observed by Degen (28) in argon–oxygen afterglows. From his rotational analysis of these emission bands and Herzberg's absorption results, Degen was able to determine the molecular constants and construct a Delandres table for the $c \rightarrow X$ transition (28).

When the Russion spacecrafts Venera 9 and 10 recorded the visible nightglow of Venus, a simple system of eleven emission bands was found (29). This sequence was first correctly identified by Lawrence *et al.* (30) as the $v' = 0$ sequence of the $c \rightarrow X$ transition. These workers were also able to reproduce the spectrum in the laboratory by adding carbon dioxide to a helium–oxygen afterglow (30). It should be noted that the Venusian atmosphere contains large amounts of carbon dioxide (31).

Later, Slanger (10) and Kenner *et al.* (32) showed that carbon dioxide was not essential for the observation of these bands. The latter authors (32) showed that with the appropriate conditions, the Herzberg II band system could be made the dominant visible emission in an argon–oxygen afterglow. They also found that several gases other than carbon dioxide, notably some chlorofluorocarbons, were effective in enhancing the Herzberg II emission relative to that of the other states of O_2. In 1953 Herzberg (14) suggested that some of the features of the Earth's nightglow could be due to emission from the $O_2(c)$ state and this has now been confirmed by Slanger (5).

Much of the current interest in the $O_2(c)$ state derives from an attempt to explain the strong emission line at 557.7 nm emitted by atomic oxygen, $O(^1S)$ in the Earth's nightglow

(33). Llewellyn and co-workers (34) have proposed that energy transfer from the higher vibrational levels of $O_2(c)$ is the source of this excitation energy.

[1] $\quad O_2(c)v > 1 + O(^3P) \rightarrow O_2(X) + O(^1S)$

In addition, they have proposed (35) that O_2 quenching of this state is the source of $O_2(b)$ in the upper atmosphere. To verify these hypotheses it is necessary to have a much better understanding of the initial states formed in the atom recombination and of the rates of vibrational relaxation and quenching for the states involved.

The kinetics of the $O_2(c)$ state in the gas phase have been investigated in only one laboratory study. Kenner *et al.* (32) have shown, by comparison with the Herzberg I emission, that in an argon–oxygen afterglow the emission intensity from the lowest vibrational level of $O_2(c)$ is first order in O, second order in M and inversely proportional to O_2:

$$I_c = k_c[O][M]^2/[O_2]$$

In the present paper are reported the first measurements of the absolute rate constants for quenching of the zero vibrational level of $O_2(c^1\Sigma_u^-)$, as well as some qualitative observations about its formation following surface-catalyzed recombination of oxygen atoms.

Experimental

The method used to determine the quenching constants for $O_2(c)$ has been developed in this laboratory and was used in previous studies on $O_2(A)$ and $O(^1S)$ (36). It is based on the work of Harteck and co-workers (37–40) on surface-catalyzed emission in which a nickel surface is used to catalyze the recombination of oxygen atoms. Mannella and Harteck (39) reported the strong catalysis of the $O_2(A)$ and $O_2(b)$ emissions by this method and Kenner and Ogryzlo (36) have reported the additional observation of $O_2(A')$, $O_2(c)$, and $O(^1S)$ emissions. With the formation of the excited states on the nickel surface, the flow along the tube becomes a time axis and the rate of decay of the species under investigation can be measured as a function of the concentrations of various quenching species.

The apparatus consisted of a fairly conventional discharge flow system with a 38 mm diameter flow tube approximately 75 cm long (Fig. 1). The discharge was excited by a 2.45 GHz microwave generator through a quarter-wave cavity. The gas flows to the system were controlled by needle valves and monitored with calibrated flowmeters; pressures were measured with capacitance manometers. A 1000 L/min (STP) pumping system gave linear flow rates of about 12 m/s at the pressures used in these experiments (2–4 Torr).

The atomic oxygen concentration was determined by adding a measured amount of NO and measuring the intensity of the resulting NO_2 emission. (The light fiber used for this intensity measurement was connected to the monochromator stage in line with the monochromator entrance slit and is not shown in Fig. 1). The $O_2(a)$ concentration was determined from its emission intensity at 1.27 μm as measured with a calibrated intrinsic germanium detector. Separate experiments showed that $O_2(a)$ remained essentially constant down the flowtube under the operating conditions used in these experiments.

Argon was purified by passage through a titanium-filled furnace at 800 K; helium by passage through a liquid nitrogen-cooled trap filled with activated charcoal. Ultra high purity oxygen was used as recieved, as were all other gases (with the exception of NO, which was vacuum distilled).

Decay curves were collected using the movable monochromator and photomultiplier. The output of this photomultiplier was connected to a photon counter and interfaced with a microcomputer. The monochromator wavelength scan and the drive screw for the monochromator stage were driven by stepping motors which were also interfaced with the computer. The data were collected by determining the count rate at each of a number of fixed points along the flowtube; the results were stored on disk for later treatment using any of several programs. Experimental decay rates were determined using a regression analysis of the semilog plots of the data. The value of the intercept of this plot was also determined (the position of the nickel screen being taken as zero time) and should represent the total amount of $O_2(c)v = 0$ formed.

Results

In the matrix studies of Goodman and Brus (23), a risetime was observed for the emission from $O_2(c)v = 0$ following photoexcitation of the $v = 6$ level of $O_2(A')$. In the present system, one can observe a risetime associated with the emission from $O_2(c)v = 0$ following surface-catalyzed atom recombination. This is illustrated in Fig. 2. The apparent risetime associated with the $O_2(A)v = 0$ is an artifact of the experimental system. Clearly, the $O_2(c)v = 0$ is peaking later with a slower decay than is the $O_2(A)v = 0$. This difference can be increased by using argon instead of helium as the carrier gas, or by reducing the concentration of the quenching species.

In Fig. 3 are shown two spectra taken in an argon system and

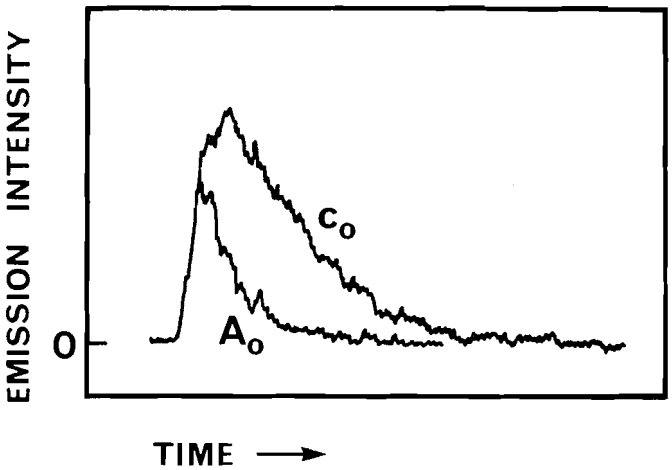

FIG. 2. Emission intensity as a function of time for two bands in the emission from surface-catalyzed recombination of O-atoms in helium. Upper curve: $O_2(c^1\Sigma_u^-)v = 0$; Lower curve: $O_2(A^3\Sigma_u^+)v = 0$

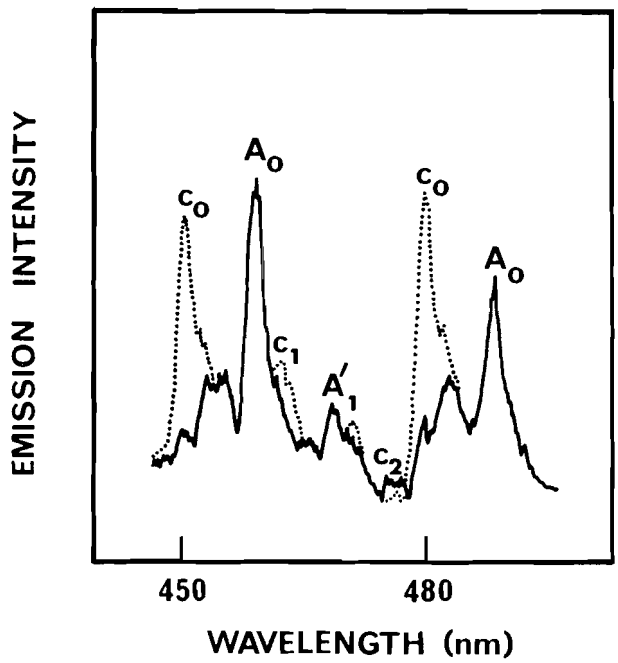

FIG. 3. Emission intensity as a function of wavelength from surface-catalyzed recombination of O-atoms in argon. Solid spectrum measured at the nickel surface. Dotted spectrum measured approximately 1.6 milliseconds downstream of the nickel and normalized to the solid curve using the A_0 peak (intensity of dotted curve approximately doubled in this normalization).

normalized by the $O_2(A)v = 0$ peaks (the intensity of the solid spectrum is divided approximately by two). The solid curve is taken at the nickel surface and shows only a small emission intensity from the $O_2(c)v = 0$. In the dotted curve, taken approximately 1.6 ms downstream of the nickel, the $O_2(c)v = 0$ bands are very prominent. In addition, close examination of the spectrum shows that the $O_2(c)v = 1$ and $v = 2$ are present and that the $v = 2$ level decays relative to $O_2(A)v = 0$ while the $v = 1$ increases. Spectra taken at even later times show emission exclusively from the zero level of $O_2(c)$, as do those of conventional O-atom recombination with added carbon dioxide (30).

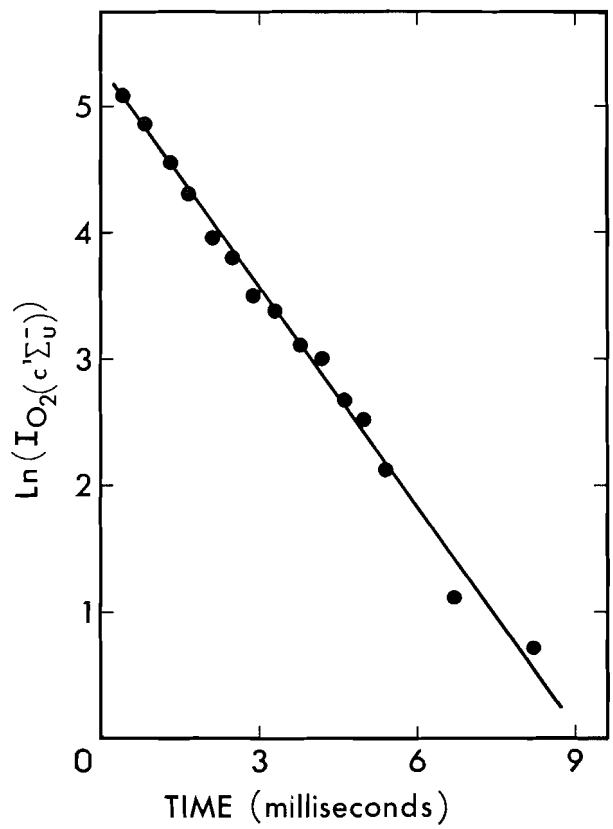

FIG. 4. Typical semilog decay curve determined using peak intensity in argon at 2.5 Torr total pressure.

The kinetic data were collected by measuring the intensity of the emission of $O_2(c)v = 0$ at fixed points along the flowtube. This was done in two ways. First, a small region of the spectrum was scanned at each point; the resulting peaks were integrated and fitted to an exponential decay. Second, only the peak intensity was measured at each point, followed by a similar fitting technique. Since the two methods gave similar results, only the second was used for most of the data reported here. A typical decay curve is shown in Fig. 4.

In the present apparatus the concentration of the oxygen atoms can be varied at constant $[O_2]$ by changing the power applied to the microwave discharge and/or by varying the flow through the discharge by use of the discharge bypass. These changes also affect the concentration of the $O_2(a)$. The range of concentrations of either of these species which could be obtained while holding the other constant was quite small, so it was decided to vary both over the full range available and use multiple regression analysis to extract the rate constants. This method still leads to larger uncertainties than one would like due to partial correlation between the two concentrations.

Working with argon as the carrier gas at 2.50 Torr, the concentrations of O and $O_2(a)$ were varied from 0.50 to 8.1 $\times$ 10^{13} and 0.40 to 1.9 $\times$ 10^{13} molecules cm^{-3} respectively. The resulting rate constants with uncertainties are:

[2] $O_2(c)v = 0 + O(^3P) \rightarrow$ quenched products

$k_2 = (5.9 \pm 0.6) \times 10^{-12}$

[3] $O_2(c)v = 0 + O_2(a) \rightarrow$ quenched products

$k_3 = (6.0 \pm 2.4) \times 10^{-12}$

[b] This paper.
[c] All units are cm^3 molecule^{-1} s^{-1}.
[d] Indicated error limits are the 1σ statistical uncertainties.

in units of cm^3 molecule^{-1} s^{-1}. The intercept is 53 ± 21 s^{-1}, which is the sum of all other quenching rates in the system. These other rates would include quenching by oxygen, argon, and walls. The values found in a previous study for $O_2(A)$ are listed for comparison in Table 1.

Similar experiments were conducted in helium at a pressure of 3.00 Torr and the total experimentally measured decay rate was found to be very much faster. This leads to larger uncertainties in the exponential fits and in the resulting rate constants. The results were

$$k_2 = (4.4 \pm 2.2) \times 10^{-12}$$

$$k_3 = (12.5 \pm 6.4) \times 10^{-12}$$

in units of cm^3 molecule^{-1} s^{-1} with an intercept of 576 ± 178 s^{-1}. These rate constants agree, within the listed uncertainties, with those determined in argon. The intercept is, however, approximately ten times larger. Given that the O_2 concentrations were similar and assuming no change in the rate of wall quenching, this implies that helium is a much better quencher of $O_2(c)v = 0$ than is argon.

With the rate constants for O and $O_2(a)$ quenching measured, that for O_2 could be determined. For these experiments, the gas flows through the discharge and the power applied to the discharge were kept approximately constant. Oxygen was then added after the discharge through the first fixed inlet. The oxygen atom concentration was monitored upstream of the nickel screen and was found to remain constant within experimental error. The oxygen atom concentration downstream of the nickel did, however, vary a little and the concentration of the $O_2(a)$ was slightly reduced by the addition of O_2.

Using the previously obtained rate constants, the experimental decay rate, k_{exp}, could be corrected for these changes and from the slope of a plot of $k_{corr} = k_{exp} - k_2[O] - k_3[O_2(a)]$ as a function of $[O_2]$ (see Fig. 5), one obtains $k_4 = 3 \times 10^{-14}$ cm^3 molecules^{-1} s^{-1} for

[4] $O_2(c)v = 0 + O_2 \rightarrow$ quenched products

The intercept on this plot is 15 s^{-1} which indicates that the combined wall and argon quenching is quite small. This is in sharp contrast with the results for $O_2(A)$ which is quenched by walls with unit efficiency (19).

The rate of quenching by three other gases was also investigated. These gases were carbon dioxide, sulfur hexafluoride, and nitrous oxide. The carbon dioxide was of particular interest since it is known that the $O_2(c)v = 0$ is enhanced by the addition of this gas in a conventional atom recombination experiment (10, 30). In this case, no quenching could be detected within experimental error and only an upper limit to the quenching rate constant could be estimated. This limit is shown in Table 1. The intercepts of the semilog plots of the decay curves were found to increase in an almost linear fashion with increasing carbon dioxide concentration, which implies an increased production of $O_2(c)v = 0$ with added carbon dioxide.

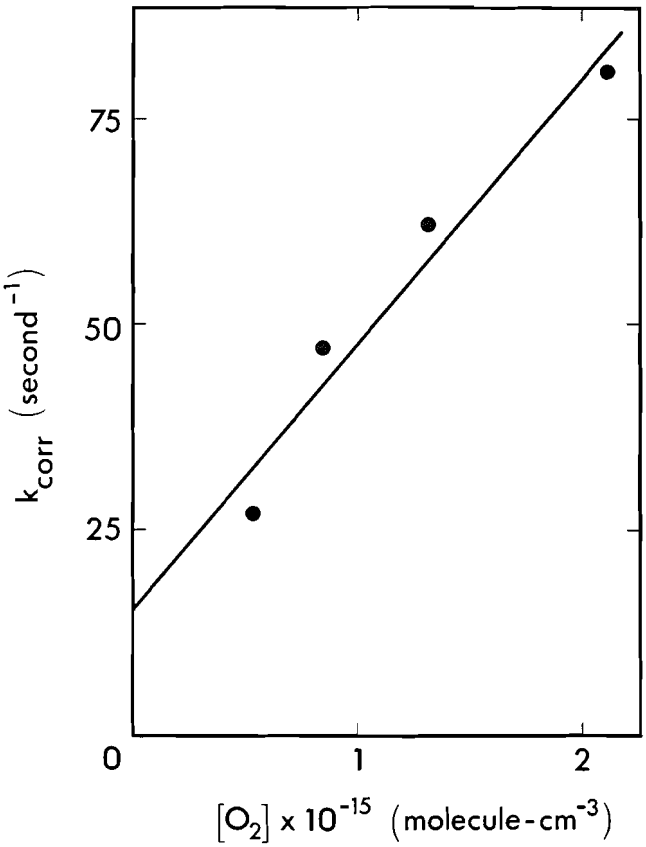

FIG. 5. A plot of k_{corr} as a function of molecular oxygen concentration $k_{corr} = (k_{exp} - k_0[O] - k_a[^1\Delta])$. The slope of the line gives $k_{O_2} = 3 \times 10^{-14}$ cm^3 molecule^{-1} s^{-1}.

Both sulfur hexafluoride and nitrous oxide were found to be good quenchers of $O_2(c)v = 0$ (see Table 1). When nitrous oxide was used as the quencher, the intercepts of the semilog decay plots were found to increase slightly with increasing N_2O concentration.

In contrast, even though sulfur hexafluoride enhances the intensity of the Herzberg II emission relative to that of the Herzberg I in argon–oxygen afterglows,[2] the intercepts of the semilog decay plots decrease with increasing SF_6 concentration.

Discussion

From the spectra of the surface-catalyzed emission, one can identify emission bands from the first six vibrational levels of $O_2(A)$, the first six levels of $O_2(A')$, but only the lowest three levels of $O_2(c)$ (19, 20, 36, 39). It should be noted that all three of these levels of $O_2(c)$ are at equal or lower energy than the

zero level of $O_2(A')$ (4, 28). There is no evidence in the present system to suggest that the upper levels of $O_2(c)$ are populated in the surface-catalyzed recombination.

It therefore remains possible that recombination occurs principally into the triplet manifold ($(O_2(A)$ and $O_2(A')$) followed by intersystem crossing to the $O_2(c)$ state from the lowest level of $O_2(A')$, as suggested by Kenner *et al.* (32).

A similar conclusion can be reached from the matrix isolation studies (22, 23, 25) where, in the absence of a heavy atom effect, emission is observed only from $O_2(A')v = 0$ in cases where $O_2(c)v = 2$ lies above $O_2(A')v = 0$ and only from $O_2(c)v = 0$ if $O_2(c)v = 2$ lies below $O_2(A')v = 0$. An exception to this is the work of Schoen and Broida (41) who used electron bombardment as the excitation source. It has been suggested (42) that $O_2(c)$ is formed preferentially by this method.

The detailed path of vibrational relaxation in these electronically excited states is not known so it is difficult to draw any quantitative conclusions from the observed risetimes. Qualitatively, as one would expect, the risetime is observed to increase in the presence of low quencher concentrations.

The rate constants measured in this study are summarized in Table 1, with those for $O_2(A)v = 2$ shown for comparison. Also included are estimates for quenching by argon and helium derived from the intercepts of the $O/O_2(a)$ multiple regression fit assuming no wall quenching. The error limits for these rate constants are difficult to estimate. The O-atom concentration and the $O_2(a)$ concentration were ultimately based on the absolute rate constant for the NO + O reaction and the relative spectral distribution of this emission. This rate constant has an estimated uncertainty of ±30% (43) and the relative intensity at 1.27 μm is uncertain by a factor of about two (44). Other sources of error should have been small (see, however, ref. 45). At the flow rates used here no corrections should be needed for flow parameters and the plug flow approximation should be justified (46). The uncertainties listed for the O and $O_2(a)$ quenching rate constants are the 1σ statistical uncertainties. All values given for $O_2(c)v = 0$ should be good to within ±50% and those given for $O_2(A)v = 2$ better than that.[1]

The rate constants for quenching of $O_2(c)$ have not been measured directly before. Some of them have, however, been estimated in computer modeling of the upper atmosphere. Greer *et al.* (35) have proposed

[5] $O_2(c) + O \rightarrow$ quenched products

$$k_5 = 3 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

[6] $O_2(c) + O_2 \rightarrow$ quenched products

$$k_6 = 5 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

Both of these values are larger than those found here but they refer to the Earth's upper atmosphere where $O_2(c)$ shows a high vibrational excitation with the level of maximum population being $v' = 7$ according to Slanger (5). Quenching of these upper levels, at least in the case of O, could be faster than that for the zeroth level due to additional product channels (see later discussion).

In the study by Krasnopolsky (47), he reports

$$k_5 = 2.5 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

$$k_6 = 1 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

[7] $O_2(c) + M \rightarrow$ quenched products

$$k_7 = 1 \times 10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}, \text{ M–Ar, He}$$

These values were derived using the nightglow results from Venus and therefore pertain to $v = 0$ (30). The O quenching constant is smaller than the one reported here but the difference could be a temperature effect since the temperature of the emitting layer on Venus is about two hundred Kelvin (31), whereas the laboratory measurements were done at room temperature.

The rate constants for the quenching of $O_2(c)v = 0$ are all smaller than the corresponding values for quenching of $O_2(A)v = 2$ (see Table 1). For both states the rate constants for quenching by $O(^3P)$ and $O_2(a)$ are larger than those for any other quenchers. This difference can probably be attributed to more favorable energy transfer pathways in the case of the $O_2(A)$ state.

Greer *et al.* (35) have suggested that $O(^1S)$ is formed in the quenching of $O_2(c)v > 1$ by $O(^3P)$ (reaction [1]). However, this pathway is energetically unavailable to the zeroth vibrational level (reaction [2]). Since the formation of $O(^1S)$ in the quenching of $O_2(A)$ is an energetically accessible and spin-allowed product channel for reaction [8],

[8] $O_2(A) + O(^3P) \rightarrow$ quenched products

the difference in the values of the rate constants for reactions [2] and [8] could be due partly to the addition of the $O(^1S)$ product channel in reaction [8].

Similar arguments appear to be applicable for processes involved in quenching by $O_2(a)$. Consider the following three processes for which rate constants are now available:

[9] $O(^1S) + O_2(a) \rightarrow$ quenched products

$$k_g = 2 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ (36, 48)}$$

[10] $O_2(A) + O_2(a) \rightarrow$ quenched products

$$k_{10} = 8 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \text{ (footnote 1)}$$

$O_2(c) + O_2(a) \rightarrow$ quenched products

$$k_3 = 6 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

For the first, $O_2(a)$ quenching of $O(^1S)$, Slanger and Black (49) have found that a major product channel involves energy transfer to $O_2(a)$ with $O(^1S)$ relaxing to $O(^3P)$. The $O_2(a)$ is excited in a vertical transition to one of the higher u-states in the vicinity of the dissociation limit and is in part dissociated.

In the second process, a similar energy transfer to $O_2(a)$ can take place. However, those transitions of $O_2(A)$ with sufficient energy to excite $O_2(a)$ to the higher u-states or to lead to its dissociation are not vertical transitions. These transitions will therefore have a lower probability than the corresponding reaction involving $O(^1S)$ and thus the smaller rate constant is not unexpected.

For the third process, $O_2(a)$ quenching of $O_2(c)v = 0$, the total energy is insufficient for dissociation. The extra energy required would reduce the rate constant for dissociation by at least a factor of thirty, virtually eliminating this product channel. In addition, the Franck–Condon factors for the energy pooling process would be even less favorable than those for $O_2(A)$ and a further reduction in the quenching rate constant is quite reasonable.

The failure to detect any quenching of $O_2(c)v = 0$ by carbon dioxide is consistent with the observation of strong emission from this state in the nightglow of Venus (29). The fact that the total production of $O_2(c)v = 0$ increases with increasing CO_2 concentration indicates that CO_2 is competing with some loss process of the precursor state or states of $O_2(c)v = 0$. An

analysis of the effect of carbon dioxide on the risetime for $O_2(c)v = 0$ could be important in determining the identity of these precursor states.

In conclusion, two other qualitative observations are worth noting. First, in an experiment designed to test the prediction of Greer *et al.* (35) that $O_2(b)$ is formed in the O_2 quenching of $O_2(c)$, oxygen was added through a movable inlet downstream of the nickel screen into the region of the surface-catalyzed emission. When the $O_2(b)$ was monitored as a function of distance along the flow tube, a localized rise in the $O_2(b)$ was found just downstream of the O_2 addition. This would seem to be direct confirmation of the predicted mechanism.

Secondly, it was observed that the concentration of the $O_2(a)$, measured downstream of the nickel screen, increased slightly when carbon dioxide was added. This would be the expected result if the suggestion of Llewellyn and Solheim (50) that O quenching of $O_2(c)v = 0$ leads to $O_2(a)$ is correct, since carbon dioxide increases the yield of $O_2(c)v = 0$.

Atmospheric temperature inversions frequently trap pollutants in the urban atmospheres of Alberta leading to photochemical air pollution. Peroxyacetyl nitrate (PAN) was monitored, for the first time in Alberta, from November 1980 to August 1981 at the University of Calgary using electron capture gas chromatography. Measurements were made at one-half-hour intervals from July, 1981 to February, 1982 at a downtown location. Maximum PAN concentrations were recorded at the University and downtown sites on August 14 at 1400 h, 1981 and the values were 2.4 and 6.6 ppb, respectively. In each case the maximum PAN peak coincided with the afternoon peak in ozone concentrations, 79 ppb at the University and 59 ppb at the downtown site. Surprisingly, a high value of 2.3 ppb PAN was recorded at the University during January of 1981 giving rise to questions regarding the influence of low temperatures and solar radiation on the photochemical formation of PAN. Calculations employing a simple photochemical model for PAN and ozone formation have been carried out and comparisons made between the observed and the computed values.

E. PEAKE et H. S. SANDHU. Can. J. Chem. **61**, 927 (1983).

Les inversions de température atmosphérique piègent fréquemment les agents polluants dans les atmosphères urbains de l'Alberta conduisant ainsi à une pollution photochimique de l'air. On décelé le nitrate de peroxyacétyle (NPA) pour la première fois en Alberta du mois de novembre 1980 au miois d'août 1981 à l'université de Calgary en utilisant un chromatographe en phase gazeuse à capture électronique. On a effectué les mesures à des intervalles d'une demi-heure du mois de juillet 1981 au mois de février 1982 en un point du centre ville. On a enregistré les concentrations maximales en NPA le 14 août 1981 à 14 h tant à l'université qu'au centre ville alors que les valeurs observées étaient respectivement 2,4 et 6,6 ppb. Dans chaque cas, la concentration maximale de NPA coincide avec le pic dans les concentrations d'ozone de l'après-midi soit 79 ppb à l'université et 59 ppb au centre ville. D'une façon surprenante, le fait qu'on ait enregistré à l'université une concentration de NPA aussi élevée que 2,3 ppb durant le mois de janvier 1981 remet en question l'influence des faibles températures et de la radiation solaire sur la formation photochimique du NPA. On a effectué des calculs en utilisant un modèle photochimique simple pour la formation du NPA et de l'ozone et on a comparé les valeurs observées avec celles obtenues par le calcul.

[Traduit par le journal]

Introduction

Peroxyacetyl nitrate (PAN) and ozone are the two important secondary photochemical air pollutants found in the urban atmosphere (1–3). Of the two, PAN is the more useful indicator of photochemical reactions in polluted air as, unlike ozone, it appears to have no large natural source (2–7). Both are strong oxidants which are phytotoxic in high concentrations (8, 9), and can affect human health (3). PAN is a strong eye irritant and has been cited as a possible etiological agent in the high incidence of skin cancer observed in tropical regions as compared to temperate ones (10–12).

Previous studies of PAN have related its occurrence to primary pollutants such as nitrogen oxides and hydrocarbons (13–15). The formation of PAN in the polluted atmosphere is believed to be initiated by the photooxidation of hydrocarbons leading to aldehydes and, subsequently, peroxyacyl radicals. These radicals in turn react with nitrogen oxides to form peroxyacetyl nitrate and lesser amounts of peroxypropionyl nitrate (2, 15, 16). The concentration of PAN in the urban atmosphere is influenced not only by solar radiation but also by the magnitude of primary pollutant emissions and meteorological parameters such as temperature, mixing volumes, and ventilation rates.

Ozone measurements for Alberta cities and computer modelling of photochemical air pollution under Alberta climatic conditions have been reported previously (17–20). Although theoretical calculations are available, no field observations have been made so far of PAN concentrations in the Alberta atmosphere to validate the existing models. In general, information on PAN concentrations for other Canadian cities is lacking. To our knowledge, the only study presently underway is in Simcoe, Ontario (21).

For the past decade Alberta has undergone the highest rate of economic growth of any Canadian province. As a consequence the major cities of Calgary and Edmonton have undergone a rapid increase in population. Each is expected to double its population by the year 2000. Despite advances in pollution control technologies, increased emission of pollutants, such as nitrogen oxides and hydrocarbons from industrial and transportation sources, are to be expected. Already concentrations of nitrogen oxides in Alberta's cities are amongst the highest in Canada during winter months (18).

Another important factor in PAN and ozone formation is the

effect of climate. Calgary is in the northern cool temperate zone. It is located at a latitude of 51°N, an elevation of 1050 m, 650 km from the Pacific Ocean, and 100 km east of the Continental Divide created by the Rocky Mountains. Mean daily temperatures range from 10.9°C in July to −10.6°C in January. Average mixing heights are about 2100 m in summer and 360 m in the winter. Mixing heights are often much less than the average and vary greatly as Calgary is subject to temperature inversions and to chinook phenomena.

Measurements of PAN have been made in European cities situated at similar northern latitudes but PAN concentrations have not been reported for cities with the cold, dry, continental climate of Alberta. The cities of Calgary and Edmonton, separated by 300 km and with no other major city within 500 km, can be considered isolated area sources of pollutants. This provides an opportunity to study PAN formation and degradation under cold, dry, climatic conditions.

In 1980 a research program was initiated by the Alberta Department of the Environment to understand, predict, and ultimately control photochemical air pollution. The objectives of this program are: (1) to measure the present rural and urban concentrations of peroxyacetyl nitrate; (2) to establish the relationship among PAN, ozone, and major primary pollutants such as nitrogen oxides, hydrocarbons, and carbon monoxide under Alberta climatic conditions; (3) to compare PAN and ozone concentrations in Alberta with those of other regions; and (4) to identify the role of PAN in the long-range transport of air pollutants.

Experimental

Analysis of PAN in the ambient atmosphere

PAN was measured by gas chromatography at two locations in Calgary and at a single site in the Kananaskis Valley, 70 km to the west of Calgary. One Calgary sampling site was located in the city center at Alberta Environment's air quality monitoring station. The second site was at The University of Calgary, 6 km northwest of the city center.

The gas chromatograph used at the University was a Tracor model 560, and at the downtown and Kananaskis sites a Varian model 3700. Both instruments were equipped with nickel 63 electron capture detectors. The chromatographic column was a 1 m by 1.5 mm inside diameter glass column packed with 5% Carbowax 600 on Chromosorb W, High Performance, 80/100 mesh (Chromatographic Specialties). The carrier gas was nitrogen with a flow rate of 50 mL per minute. The detector temperature was 80°C and the oven and injection port temperatures were 33°C. Samples were manually introduced into the Tracor instrument using a 5 mL gas tight syringe. The Varian chromatograph was equipped with an automated gas sampling system. This system consisted of a Valco gas sampling valve with air actuator and air switch, a 5 mL Teflon sample loop, a Reciprotor pump, and a Valco digital valve sequence programmer. A Hewlett Packard model 3390 integrator was activated by the sequence programmer to report results. A 2 m by 6.4 mm Teflon tube connected the gas chromatograph to an Ace glass manifold used to introduce ambient air into Alberta Environment's air monitoring station.

Samples were taken and automatically analyzed every 30 minutes, 24 hours per day, at the downtown sampling site from July 12, 1981 to April 7, 1982. At the University, samples were taken during working hours only, generally 0700 to 1600 h Mountain Standard Time, each week day from November 19, 1980 to August 30, 1981. Preliminary sampling of PAN at the Kananaskis station began in April of 1982 and is continuing.

Synthesis of PAN and instrument calibration

Hazard

PAN and ethyl nitrite are explosive. Workers should be protected by shields, gloves, and goggles.

A series of PAN standards with concentrations of 0.1 ppb to 20 ppb PAN in dry air were generated to calibrate the gas chromatograph electron capture detectors. The generation of these standards presented a number of problems. PAN is highly reactive in the vapor form and explosive as a liquid. Great care is required during PAN synthesis and the standards, once prepared, degrade rapidly.

At least five reactions have been used to synthesize PAN (22−25) but the most convenient is the photolysis of ethyl nitrite in oxygen (25).

The first step in PAN synthesis was the preparation of ethyl nitrite:

$$C_2H_5OH + H_2SO_4 \rightarrow C_2H_5OSO_2OH + H_2O$$

$$C_2H_5OSO_2OH + NaNO_2 \rightarrow C_2H_5ONO + NaHSO_4$$

Ethyl nitrite was synthesized by the addition of 5.5 mL of cooled sulphuric acid to 5.7 mL of cooled ethanol in a 50 mL Erlenmeyer flask immersed in an ice bath. The flask was fitted with a one-hole stopper and connected with a Teflon tube to a U-shaped glass trap cooled in a Dry Ice − acetone bath. Upon addition of 6.9 g of sodium nitrite to the Erlenmeyer flask, ethyl nitrite vapor passed through the tube and was retained by the trap. Once the reaction was complete the Teflon stopcocks on the trap were closed and the trapped ethyl nitrite was stored at 0°C until used in the synthesis of PAN (note, ethyl nitrite boils at 17°C).

A simple, inexpensive system was devised for the preparation of the small quantity of PAN required in the calibration of the gas chromatographs. PAN was synthesized in a 2-L Teflon bag by the photolysis of ethyl nitrite in an oxygen atmosphere:

$$C_2H_5ONO + 2O_2 \xrightarrow{h\nu} CH_3\overset{\overset{O}{\|}}{C}OONO_2 + H_2O$$

The trap was warmed (both stopcocks open) to produce ethyl nitrite vapor, 0.25 mL of which was injected into the Teflon bag containing oxygen. The bag was irradiated with a 20 watt "mineral light" from which the filter had been removed to allow passage of all wavelengths of ultraviolet light. Injections of ethyl nitrite vapor were repeated every 15 minutes over a 3-hour period. PAN was transferred into a glass trap cooled in a Dry Ice − acetone bath by gently squeezing the bag, forcing the PAN vapor through a Teflon tube into the trap. The PAN was then transferred into an infrared gas cell by evacuating the cell and connecting it to the trap which was gently warmed to room temperature. From the infrared spectrum the concentration of PAN in the cell was calculated with an absorptivity of 13.9×10^4 ppm^{-1} m^{-1} at 8.30 micron. This band is one of the more intense in the spectrum of PAN and is free from interferences from PAN decomposition products (26).

Standards for the calibration of the gas chromatograph were made by diluting PAN vapor (0.005 to 0.5 mL) from the infrared cell into a measured volume of air in a 50-L Teflon bag (0.1 to 20 ppb). A linear response was obtained with concentrations of PAN up to 20 ppb. A detection limit of 0.03 ppb and a precision of 0.03 ppb at 1 ppb was obtained for ambient air samples with the Tracor model 560 gas chromatograph. The Varian 3700 gas chromatograph was far less sensitive to PAN than the Tracor model 560. The sensitivity of the system was also limited by the ability of the integrator to discriminate between instrument noise and the onset of a chromatographic peak. These factors combined to give a detection limit of 0.2 ppb.

Results and discussion

PAN concentrations in the Calgary atmosphere

Mean concentrations of PAN in Calgary are lower than those reported for major cities in the southern United States (Tables 1−3) (27). The overall mean concentration of PAN at the University of Calgary from 0800 to 1700 h, December 1, 1980 to August 31, 1981, was 0.22 ppb. At the downtown site, where one-half-hour samples were taken 24 hours per day from

*n = number of days with observations.

July 12, 1981 to February 28, 1982, the mean concentration of PAN was 0.14 ppb. The mean daily maxima at the University was 0.38 ppb whereas at the downtown location it was somewhat higher, 0.59 ppb. The maximum concentrations of PAN measured at the University and downtown were 2.4 and 6.6 ppb, respectively.

Most previous studies of PAN in the urban atmosphere have been carried out over shorter time periods, generally a few weeks. During the summer months in Houston, Texas, mean daytime PAN concentrations of about 1.0 ppb with a maximum of 15.6 ppb were recorded (28). For a one month period from mid-July to mid-August, 1973, Spicer (29) reported an average of 1.8 ppb PAN in St. Louis, Missouri, with daily maxima averaging 4.6 ppb and a maximum of 19 ppb. By comparison, the August 1981 mean for downtown Calgary was 0.49 ppb, the mean daily maximum was 2.1 ppb, and the maximum recorded was 6.6 ppb. Calgary's atmospheric concentrations of PAN are similar to those reported for northern European cities: Riso, Denmark; Goteborg, Sweden; Delft, Netherlands; Essen, West Germany; and Harwell, England (Table 4). They are far lower than levels measured in the Los Angeles basin where long term studies have been carried out. The yearly average at Riverside, California, for 1980 during the hours of 0800 to 2000 was 4.9 ppb, and the highest concentration recorded was 41.6 ppb (27).

At first glance it would appear that PAN concentrations, as given by the overall mean concentrations in Tables 1 and 2, were higher at the University than at the downtown sampling site, 0.22 ppb versus 0.14 ppb. However, the University data included only daytime readings when PAN concentrations are expected to be highest, whereas the downtown data were taken over a full 24-hour period. PAN concentrations were actually higher at the downtown location. For example on August 14, 1981 between the hours of 0800 and 1600 the mean PAN concentration at the downtown site was 2.0 ppb versus 0.84 ppb at the University. On 15 days during July and August, 1981, PAN was measured simultaneously at both stations. The mean concentration over these periods was 1.3 ppb at the downtown location and 0.57 ppb at the University, a 2.2-fold greater concentration at the downtown site. It was during this period that the maximum concentrations of PAN were recorded at both the University and downtown locations, 2.4 ppb and 6.6 ppb on August 14, again, more than a 2-fold greater concentration downtown. These PAN concentrations are believed to be too low to injure plants or to present a health problem to man except possibly for some highly susceptible allergic individuals (3).

Diurnal variations in PAN concentrations

The diurnal pattern of PAN concentrations in the Calgary atmosphere is illustrated in Fig. 1 for the University location, and Fig. 2 for the downtown Calgary sampling site. PAN generally starts forming between 0700 and 0800 h in the Calgary area during the summer months. The peak PAN concentration is usually achieved by 1200 or 1300 h although on occasion the afternoon peak may be delayed until as late as 1500 h. On days with comparable data, the afternoon maximum in the PAN concentrations occurred at about the same time at both the downtown and University of Calgary locations. This is in contrast to the situation at Riverside, California, where oxidants which are generated locally reach a maximum by 1000 or 1100 h but in addition a "smog front", advected from Los Angeles, produced a second maximum at about 1500 h (27). The spacing between the downtown and University of Calgary sampling sites is relatively small, only 6 km, and such a "front" effect caused by movement from the downtown area to the University may not be distinguishable.

Factors influencing PAN formation

PAN is believed formed in the urban atmosphere by those hydrocarbons which yield acetylperoxy radicals upon photooxidation. Peroxyacyl radicals react with nitrogen oxides to form peroxyacyl nitrates (2, 16). Thus a close relationship might be expected to exist between the occurrence of the primary pollutants, nitrogen oxides and hydrocarbons, with that of the secondary pollutants, ozone and PAN. Such a relationship is well known for the nitrogen oxides and ozone; nitric oxide is oxidized to nitrogen dioxide leading to the formation of ozone (3). It is not the absolute amount of nitrogen oxides which controls the abundance of ozone but rather the ratio of the nitrogen dioxide to nitric oxide. The mechanisms of PAN formation are quite different from those of ozone. PAN is the terminal product of a chain of free radical reactions whereas, with ozone, the generation process is self perpetuating.

In Calgary, the primary pollutants, nitrogen oxides, carbon monoxide, and hydrocarbons, show similar diurnal concentration patterns (Fig. 3). The maximum concentration of each

occurs at the same time on a given day. The hydrocarbon concentrations, however, show far less variation than do the carbon monoxide and nitrogen oxides, with sufficient hydrocarbons available at all times to participate in the formation of peroxyacyl radicals.

As shown by the monthly means in Tables 1 and 2 the highest concentrations of PAN occurred in May and August. This may be explained on the basis of solar radiation intensity and duration, temperature, and pollutant concentrations (Table 5). In the winter months concentrations of primary pollutants are high but the intensity and duration of solar radiation and the atmospheric temperature are low. Conversely, during the summer, solar radiation reaches its maximum intensity and duration and temperatures are highest, but pollutant concentrations are low. During spring and autumn months the possibility exists for the simultaneous occurrence of high levels of pollutants together with high solar radiation and temperatures resulting in the generation of PAN. Thus solar radiation is

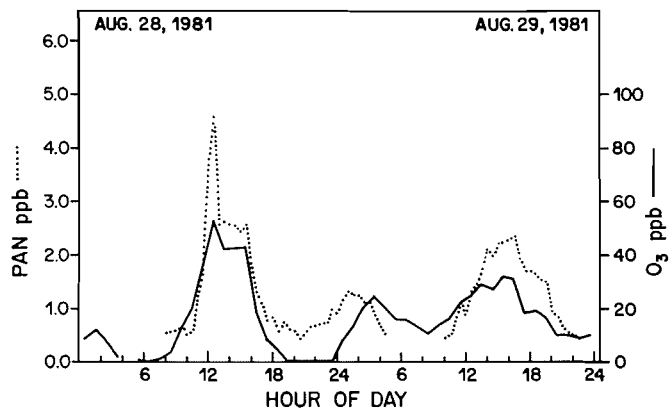

FIG. 2. Ozone and PAN concentrations in downtown Calgary, August 28 and 29, 1981.

believed to be the limiting factor in the formation of PAN during the winter months in Calgary (51°N) whereas the abundance of the primary pollutants, the precursors of PAN, is the limiting factor in the summer months. This is in contrast to the Los Angeles basin (31°N) where evidence suggests that solar radiation is not a limiting factor (41).

Temperature is one of the factors which influence the rate of PAN generation. Most PAN measurements have been made in the southern United States where temperatures are warm. Other measurements of PAN have been made mostly during the summer months in the more northerly United States and in Europe. PAN was found in Calgary, however, on several days when the temperature did not exceed 0°C. The highest PAN concentrations recorded at the University of Calgary were 2.4 ppb on August 14 and 2.3 ppb on January 27. The maximum temperature on August 14 was 27°C; on January 27 it was only +1°C. On March 7, 1982 the maximum temperature was −4°C but 1.5 ppb PAN was recorded in downtown Calgary.

These findings confirm the results of modelling studies of a

general photochemical air pollution system carried out by Bottenheim *et al.* (19). The model showed lower rates of product formation under winter conditions due to solar altitude rather than temperature. The rate of primary formation of major radicals, HO, HO_2, and RO_2, together with their participation in several chain length reactions, are the driving forces in these systems. Primary formation of these radicals is largely unaffected by temperature. Chain lengths are dependent upon the activation energies of the reactions involved, which are generally small, thus temperature has little influence. Conversely solar attitude is expected to have a much greater effect since these radicals are produced primarily by photochemical reactions (19).

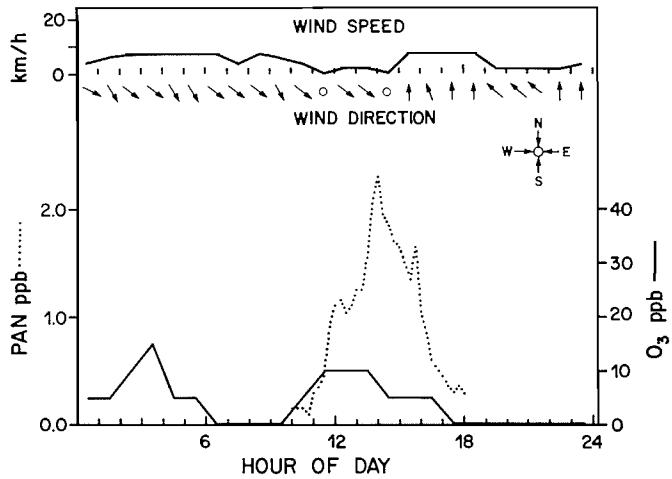

FIG. 4. Ozone and PAN concentrations and wind speed and direction at The University of Calgary, January 27, 1981.

Ozone–PAN relationships

The photochemical oxidants, PAN and ozone, are generated by related photochemical processes, each usually reaching maximum concentrations simultaneously in the early afternoon.

The peak afternoon concentration of PAN is much less than the corresponding ozone maximum. During episodes with high concentrations of photochemical smog in Los Angeles or in Japan, ozone/PAN ratios of 10 have been reported (8, 38). In Europe, ratios are commonly 50 (4, 43, 44). In downtown Calgary, ratios as low as 1 were measured (Table 6). Such low ratios occurred when the background concentration of ozone was first suppressed by nitrogen oxides followed by photochemical ozone and PAN formation. Ozone/PAN ratios at the University were generally higher than downtown. On August 14, the day of maximum PAN concentrations both downtown and at the University, the ratio was 33 at the University compared with 9 downtown. The mean ratio for fourteen days when PAN was measured both at the University and downtown was 65 at the University and 21 downtown. Overall ozone concentrations are higher at the University than downtown (means for 1981 of 18.3 ppb and 10.3 ppb respectively) reflecting the University location upwind of the major transportation sources of nitrogen oxides. Downtown Calgary ozone concentrations are suppressed by nitric oxide emissions. On days of relatively high pollution, during the winter months, low ozone/PAN ratios may result, even at the University, from suppression of ozone by nitric oxide rather than from high PAN concentrations. For example, on January 27, a ratio of 4 was measured at the University. The PAN concentration was 2.3 ppb while the ozone concentration was only 10 ppb.

Comparison of the primary pollutant concentrations, with the corresponding ozone and PAN concentrations, showed the generation of ozone and PAN after a decline in the overall concentration of nitrogen oxides which corresponded to the conversion of NO to NO_2 (Figs. 2 and 3). In some cases, however, PAN maxima occurred coincident with maximum concentrations of the primary pollutants. On January 27, 1981, high nitrogen oxide concentrations were recorded at the University, and the maximum PAN concentration of 2.3 ppb occurred simultaneously with a maximum of 410 ppb nitrogen oxides (Figs. 4 and 5), both NO and NO_2 reaching a maximum at that time.

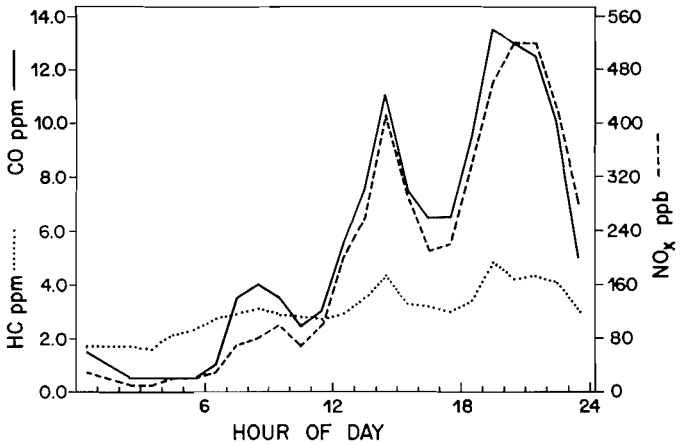

FIG. 5. Concentrations of hydrocarbons, carbon dioxide, and nitrogen oxides at The University of Calgary, January 27, 1981.

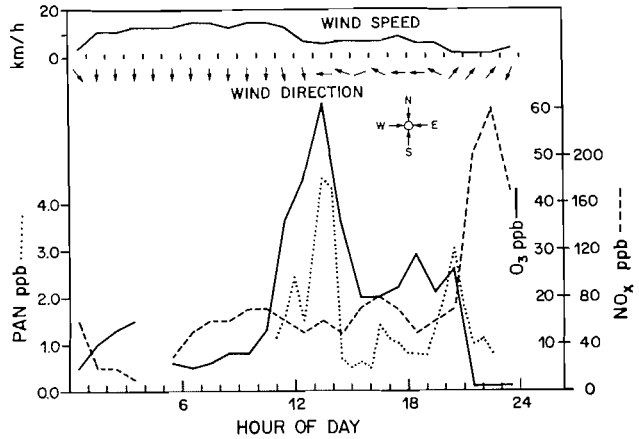

FIG. 6. Ozone, PAN, and nitrogen oxide concentrations and wind speed and direction in downtown Calgay, August 28, 1981.

Generally only one peak in the PAN concentration occurred each day, usually during the afternoon, but on occasion a second peak occurred later in the day. On August 28 a secondary PAN maximum occurred at 2400 h (Fig. 6). This would suggest either that sufficient peroxyacyl radical existed to allow the generation of PAN to proceed after dark (16) or that an air mass moved from the downtown area of the city during the afternoon and returned in the evening to produce a second PAN peak. Air moves along the river valley in Calgary in response to adiabatic heating and cooling.

Persistence and long range transport of PAN

If the two maxima in PAN concentration were the result of air mass movement, the relative concentrations of PAN, 4.5 ppb at 1130 h and 3.0 ppb at 2030 h, are of interest. As the downtown sampling site is centrally located, it is assumed that the maximum PAN concentrations occur at that location. Therefore the maximum loss of PAN by a combination of chemical reactions in the atmosphere and interaction with surfaces during the 9-hour period was about 33%. In all likelihood there would be some mixing of the air mass and dilution of the PAN, therefore the rate of PAN destruction would be less than 33%.

PAN and ozone decay rates have been measured over grass, soil, and water. Deposition velocities of PAN over grass and soil were similar, 0.21 and 0.26 cm/s, but were considerably lower over water, 0.02 cm/s (5, 45). These rates indicate that surface chemical reaction is the major mechanism of PAN removal from the atmosphere rather than gas phase reactions with other pollutants such as nitric oxide (46). Surface reactions are also believed to be responsible for the daily cycle in atmospheric ozone concentrations (47). The deposition velocity of ozone is about 3 times greater than that of PAN over grass and about 6 times greater over soil. Thus PAN is more persistent in the atmosphere than ozone. Although PAN in the Calgary atmosphere generally decreased rapidly in concentration during the late afternoon, it would sometimes persist overnight. It should be emphasized that a decline in PAN concentration may not mean that the PAN was degraded; it may simply mean that an unpolluted air mass has replaced the polluted air or that the mixing height has increased. In the Los Angeles basin, where very large polluted air masses may be expected, PAN averaged 17.7 ppb over one 18-day period with readings as high as 26 ppb at midnight (27).

On several days the maximum PAN concentrations occurred after a change in wind direction which may have signaled the breakup of the temperature inversion (Figs. 1, 4, and 6). Should the breakup of the nocturnal temperature inversion have preceded the occurrence of the PAN maximum it would support the thesis that PAN degrades primarily by contact with surfaces (43). Presumably PAN would persist above the thermal inversion whereas the PAN below the temperature inversion would be degraded. At the breakup of the inversion, air containing higher concentrations of PAN would be brought to ground level.

Calgary is located about 100 km east of the Rocky Mountains with no large city within 650 km to the west, the direction of the prevailing winds. Edmonton, the nearest major city, is 300 km to the north. Thus, Calgary is isolated from major urban sources of air pollution. To determine the quality of air approaching Calgary, monitoring of PAN and ozone was begun in April of 1982 in the Kananaskis Valley on the edge of the Rocky Mountains 70 km west of Calgary. Preliminary results periodically show the presence of PAN in concentrations up to 0.5 ppb. It seems unlikely that the observed PAN was generated locally from anthropogenic pollutants. Generation from local natural emissions may be possible (48) but long range transport is the most likely mechanism.

Recent studies in northern Sweden (56–58°N) have shown transport of PAN for about 1000 km in air masses moving mainly over the sea (29). The source of PAN in southern Scandinavia is probably Great Britain or the central continent. PAN is more stable over water than over land and the sources of pollutants in industrialized Great Britain and Europe are large. In contrast, there are no large sources of pollutants on the North American continent to the northwest of Calgary and sources to the west and southwest are small in comparison with those of Europe. If Vancouver or Seattle, the only major cities to the west, were the source, PAN or its precursors would be transported 650 km over land before reaching the Kananaskis sampling site. Deposition velocities of PAN are about 10 times greater over land than over water (45). In order for PAN to reach the Kananaskis site it must be transported at such an altitude that there is no easy contact with the ground. To the west of Calgary are five mountain ranges with peaks up to 3800 m high. On the eastern edge of the mountains, air from higher altitudes sweeps down to the plains. In this zone PAN, which may have been transported thousands of kilometers or

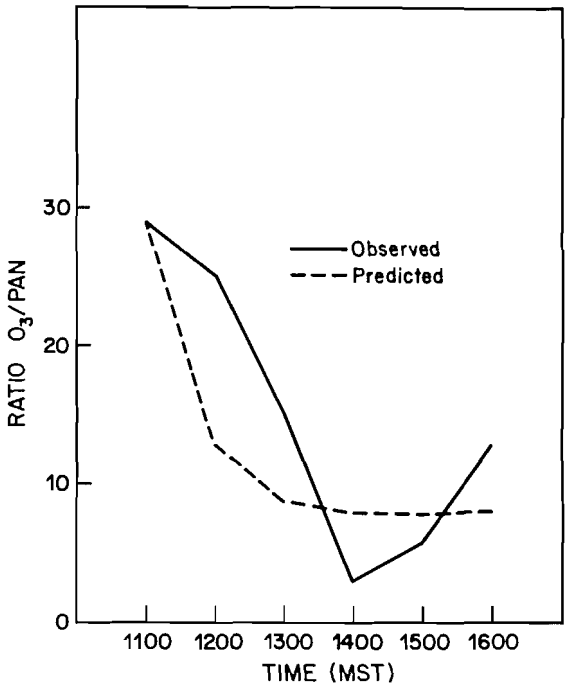

FIG. 7. Predicted ozone/PAN ratios (19) and observed ratios for downtown Calgary, August 14, 1981. Initial conditions for computation; ozone 29.0 ppb, PAN 1.0 ppb, NO 0.01 ppm, NO_2 0.08 ppm, paraffinic hydrocarbons 1.76 ppm, olefinic hydrocarbons 0.44 ppm, aromatic hydrocarbons 0.44 ppm, temperature 20.0°C, relative humidity 47%.

perhaps existed in the upper atmosphere naturally or as a result of anthropogenic pollutants, may be brought to ground level. The Kananaskis sampling site located on the eastern slopes of the Rocky Mountains is in a position to intercept and monitor this air.

Model calculations

Bottenheim *et al.* (19) studied the effect of temperature and solar altitude variation on the chemical processes which take place in a general photochemical air pollution system at 60°N latitude. Eleven photochemical and 100 dark reactions of 11 initial reactants were considered. The assumption of no atmospheric dilution of products and reactants was employed in these computations. Ambient air pollutant concentrations measured at 1100 h and appropriate photochemical rate parameters for Calgary's solar altitudes for August 14 were used in our computations. The calculated O_3/PAN ratio is displayed as a function of time in Fig. 7 along with initial pollutant concentrations, temperature, and relative humidity values.

Observed O_3/PAN values for the same day are also shown in Fig. 7. Considering the assumptions of no dilution of reactants and products in the model, the trend in the observed ratios is reasonably predicted by the computations. Further work is underway to improve the model in the light of these observations.

Acknowledgements

We express our appreciation to the Alberta Department of the Environment for their financial support and to the many members of the Department who cooperated on this project, in particular, T. J. Spackman and D. D. Bensler for providing technical information and assistance often on very short notice, M. Choukalos for his help in computing, and G. R. Peck and the staff of the Pollution Control Division for their patience and efficiency in answering our many requests for information and data. We also thank the staff of the Kananaskis Centre for Environmental Research for conducting analyses, and collecting and compiling data. We especially thank M. A. MacLean, D. R. Connery, L. Dunne, and D. Patton for their invaluable assistance and E. C. Rhodes of The University of Calgary Geography Department for supplying meteorological data. Lastly, we thank P. J. Temple and O. C. Taylor of the Statewide Air Pollution Research Center, University of California, Riverside, for providing us with an advance copy of a manuscript recently submitted for publication (27).

Factors affecting product formation in the photolysis of α-spirocyclopropyl ketones

PETER YATES AND PATRICK HUGH HELFERTY[1]

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received July 13, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

PETER YATES and PATRICK HUGH HELFERTY. Can. J. Chem. **61**, 936 (1983).

Photolysis of spiro[2.5]oct-7-en-4-ones results in exclusive β-cleavage in methanol to give 2-ethenylcyclohex-2-en-1-ones and in hydrocarbon solvents to give (*E*)- and (*Z*)-2-ethylidenecyclohex-3-en-1-ones. The solvent effect is ascribed to the role of methanol in stabilizing trienol intermediates and engendering their intermolecular ketonization. Photolysis of 8-methylenespiro[2.5]octan-4-ones in methanol gives 2-ethenylcyclohex-2-en-1-ones and bicyclo[4.3.0]non-1(6)-en-2-ones; irradiation in methanol-*O-d* indicates that the former type of product is formed mainly via a trienol intermediate. Photolysis of 8-methylenespiro[2.5]octan-4-ones in benzene gives 2-ethenylcyclohex-2-en-1-ones together with (*E*)- and (*Z*)-2-ethylidene-3-methylenecyclohexan-1-ones; the latter undergo photoconversion to the former during the irradiation. 6,6-Dimethylspiro[2.4]-heptan-4-one on photolysis in methanol undergoes α-cleavage to give 4-methoxy-7,7-dimethyl-5-oxaspiro[2.5]octane as the major product, whereas under the same conditions 6,6-dimethylspiro[2.5]octan-4-one is reduced to the corresponding alcohol and 6,6,8-trimethylspiro[2.5]octan-4-one undergoes β-cleavage to give 2-ethyl-3,5,5-trimethylcyclohexan-1-one as the major primary product; this trichotomy is interpreted in terms of ring-size and steric factors.

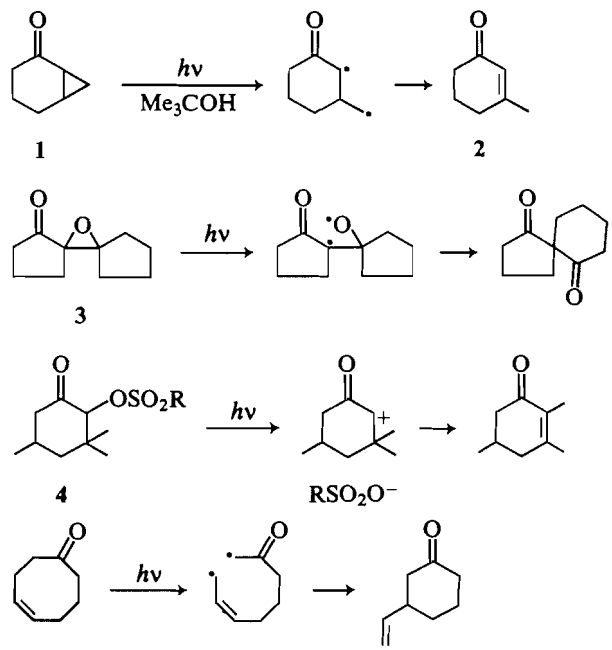
PETER YATES et PATRICK HUGH HELFERTY. Can. J. Chem. **61**, 936 (1983).

La photolyse des spiro[2.5] octène-7 ones-4 dans le méthanol donne par suite d'un clivage exclusif en β,,les éthényl-2 cyclohexène-2 ones-1 et dans les solvants hydrocarbonés, elle conduit aux éthylidène-2 cyclohexène-3 ones-1 (*E*) et (*Z*). On attribue l'effet de solvant au rôle du méthanol dans la stabilisation des intermédiaires triénol dont il provoque la cétonisation intermoléculaire. La photolyse des méthylène-8 spiro[2.5] octanones-4 dans le méthanol conduit aux éthényl-2 cyclohexène-2 ones-1 et aux bicyclo[4.3.0] nonène-1(6) ones-2. L'irradiation dans le méthanol-*O-d* indique que le premier type de composé se forme principalement via un intermédiaire triénol. La photolyse des méthylène-8 spiro[2.5] octanones-4 dans le benzène donne les éthényl-2 cyclohexène-2 ones-1 ainsi que les éthylidène-2 méthylène-3 cyclohexanones-1 (*E*) et (*Z*). Les derniers composés subissent une conversion photochimiques pendant l'irradiation. La diméthyl-6,6 spiro[2.4] heptanone-4, par photolyse dans le méthanol, subit une clivage α en donnant comme produit principal la méthoxy-4 diméthyl-7,7 oxa-5 sprio[2.5] octane, tandis que dans les mêmes conditions la diméthyl-6,6 spiro[2.5] octanone-4 est reduit à l'alcool correspondant et la triméthyl-6,6,8 spiro[2.5] octanone-4 subit un clivage β donnant comme produit principal la éthyl-2 triméthyl-3,5,5 cyclohexanone-1. On interprète cette trichotomie en fonction de la dimension du cycle et de facteurs stériques.

[Traduit par le journal]

Cycloalkanones have been found to give a wide variety of products upon ultraviolet irradiation in solution. But the primary chemical processes leading to these products are relatively few. The most important of these reactions are α-cleavage (Norrish type 1 reaction) (1–3) and intramolecular or intermolecular hydrogen abstraction (1, 3). β-Cleavage has also been observed in the case of certain structural types. Examination of cases where β-cleavage occurs suggests that two of the structural factors that favor such cleavage are (*i*) relief of ring strain and (*ii*) stabilization of a developing biradical or zwitterion or their equivalents (3). Thus, the β-cleavage of α,β-cyclopropyl ketones (e.g. **1** (4)) and α,β-epoxy ketones (e.g., **3** (5)) can be attributed to the former factor, and that of α-sulfonyloxy ketones (e.g., **4** (5)) and cyclooct-4-en-1-one (**5**) (6) to the latter (Scheme 1).[2]

In the case of cyclopropyl ketones it has been shown that alkyl substitution on the cyclopropane ring favors β-cleavage (4, 7),[3] which is also favored if the σ* orbital of the bond undergoing cleavage can overlap efficiently with the π* orbital of the carbonyl group (1). A combination of these factors has been invoked to account for the preference for cleavage of one cyclopropyl bond rather than another (1, 3, 4). However, additional factors must also contribute to the relative yields of α- and β-cleavage products. Thus, in *tert*-butyl alcohol compound



SCHEME 1

[1]Present address: Research Department, Imperial Oil Ltd., Sarnia, Ont.

[2]Although it is probable that these types of reactions often proceed via diradical or zwitterionic intermediates or their equivalents (3), it is not excluded that in some cases they are concerted (3, 6).

[3]Such substitution can also provide another pathway for β-cleavage, i.e., Norrish type 2 reaction (4, 7).

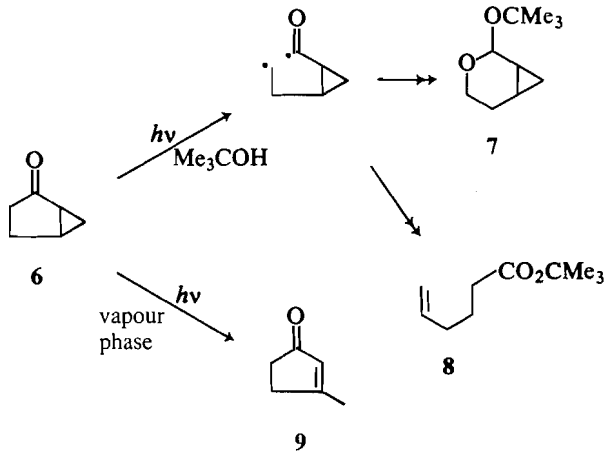
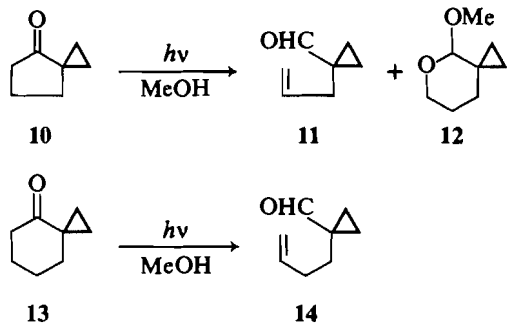


SCHEME 2

6, unlike **1**, gives the α-cleavage products **7** and **8**, although in the vapor phase it gives the β-cleavage product **9** analogous to **2** (8) (Scheme 2). Further the α-spirocyclopropyl ketones **10** and **13** on irradiation in methanol give only α-cleavage products (9, 10) (Scheme 3),[4] although it would appear that the β-cyclopropyl bonds are as favorably disposed for β-cleavage as the cyclopropyl bond in **1** that undergoes β-cleavage in *tert*-butyl alcohol.

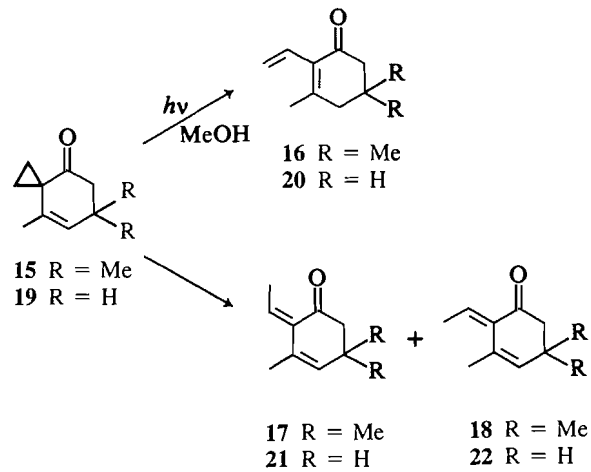


SCHEME 3

We report now on an investigation of the products formed on ultraviolet irradiation of several β,γ-unsaturated α-spirocyclopropyl ketones. It was anticipated that the presence of the ethylenic double bond would provide a second factor favoring β-cleavage (*vide supra*) and that this would be the sole primary chemical process. We also describe studies of the products formed on irradiation of three substituted derivatives of **10** and **13**, which relate to another interesting dichotomy – although both **10** and **13** upon irradiation in methanol undergo exclusive α-cleavage, **10** gives both the enal **11** and the acetal **12** as primary products, while **13** gives exclusively the enal **14**.

Photolysis of spiro[2.5]oct-7-en-4-ones

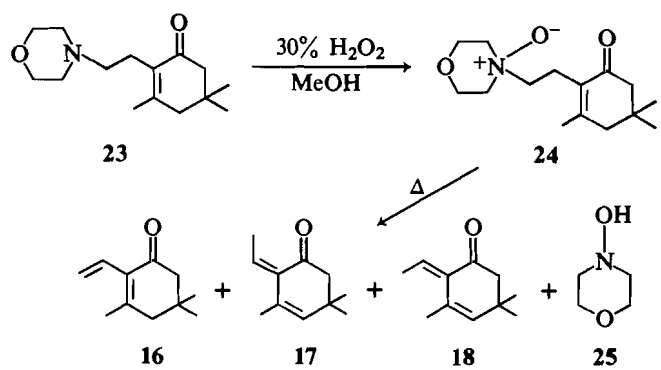
Irradiation of 6,6,8-trimethylspiro[2.5]oct-7-en-4-one (**15**) (12) in methanol through Pyrex or quartz gave 2-ethenyl-3,5,5-trimethylcyclohex-2-en-1-one (**16**) (Scheme 4). As the reaction proceeded the rate of product formation decreased (cf. ref. 5);[5] this is attributed to competitive uv absorption by the product,



SCHEME 4

which can readily dissipate its excitation energy by *cis–trans* isomerization about the vinyl double bond without net chemical change. Irradiation of **15** in benzene or hexanes through quartz gave a 2:1 mixture of (*Z*)-(**17**) and (*E*)-2-ethylidene-3,5,5-trimethylcyclohex-3-en-1-one (**18**) together with unconsumed **15**; no **16** was observed in the product mixture. Irradiation of **17** in benzene gave a 2:1 mixture of **17** and **18**. Photolysis of **15** through quartz in a 9:1 mixture of benzene and methanol gave **16** (35%), **17** (10%), and **18** (5%) together with unconsumed **15** (47%). Irradiation of **16** in benzene and of a mixture of **17** and **18** in methanol returned starting material only, demonstrating that **16** and the ethylidene compounds do not interconvert photochemically. Photolysis of 8-methylspiro[2.5]oct-7-en-4-one (**19**) (12, 13) gives analogous results, with formation of 2-ethenyl-3-methylcyclohex-2-en-1-one (**20**) in methanol and a mixture of (*Z*)-(**21**) and (*E*)-2-ethylidene-3-methylcyclohex-3-en-1-ones in hydrocarbon solvents.

The structures of the dienones **16**–**18** and **20**–**22**, like those of the other products isolated in the present work, were assigned on the basis of spectroscopic data (see Experimental). In the cases of **16**–**18** the assignments were confirmed by comparison with samples obtained by independent synthesis from 3,5,5-trimethyl-2-(2-(4-morpholinyl)ethyl)-2-cyclohexen-1-one (**23**) (12) by the route shown in Scheme 5. Treatment of **23** with hydrogen peroxide gave amine oxide **24**,



SCHEME 5

[4]Additional products are formed by subsequent reactions of **11** and **14**. In n-hexane **10** gives a trace of the β-cleavage product, 2-ethylcyclopentanone, and **13** gives **14** and the β-cleavage product, 2-ethylcyclohexanone in a ~4:1 ratio (11).

[5]Product formation on irradiation of β,γ-unsaturated α-spirocyclopropyl ketones in methanol through Pyrex generally stopped after ~30% conversion to products. Analogous irradiation through quartz stopped after ~60% conversion to products.

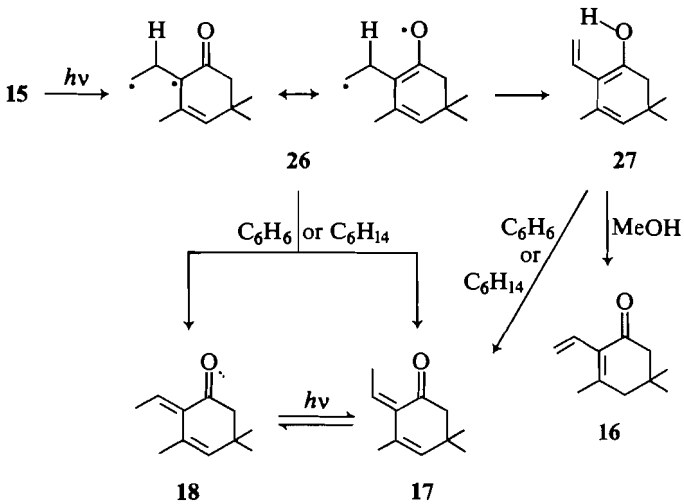
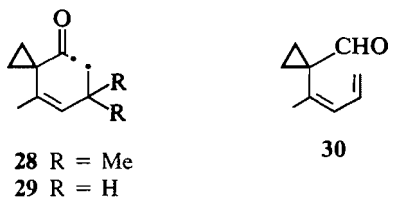
which on being heated at 105°C underwent Cope elimination of *N*-hydroxymorpholine (**25**) to give a 4:1 mixture of **16** and **17** and a small amount of **18** (~2%). The ethylidene compounds **17** and **18** are considered to be formed from **24** via isomerization of **16**, perhaps catalyzed by **25**.

We propose that the effect of solvent on the photochemistry of the spiro compounds **15** and **19** can be interpreted in terms of reaction pathways of the type shown for **15** in Scheme 6. Initial β-cleavage gives the biradical **26**, which is converted to the trienol **27** by a 1,4 hydrogen shift. In methanol the trienol ketonizes intermolecularly by proton transfer to and from the solvent to give **16**, the only observed product in this solvent. If trienol **27** is formed in hydrocarbon solvents proton transfer would proceed intramolecularly to give **17**, which would photoequilibrate to the observed product mixture of **17** and **18**. However, in the latter solvents formation of **27** from the biradical **26** would be less favorable than in methanol and it is considered that **17** and **18** are also formed directly from **26** via 1,2 hydrogen transfer.



SCHEME 6

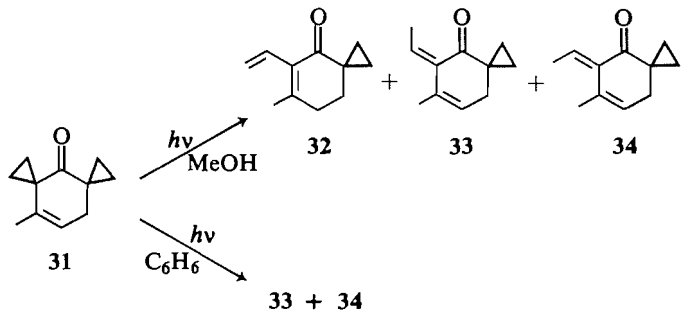
The nature of the excited state(s) leading to the reaction products was not investigated, but analogous products have been observed to be formed previously from both the $n \rightarrow \pi^*$ singlet and triplet states of α-cyclopropyl ketones (14). As anticipated (*vide supra*), the presence of the ethylenic double bond exerts a striking effect on the course of the photolyses. Photolysis of the corresponding saturated α-spiro cyclopropyl ketone **13** in methanol gives as the only primary product the enal **14**, formed via α-cleavage (9) (Scheme 3). Although analogous α-cleavage of **15** would give the biradical **28** in which enal formation would be blocked by the geminal methyl groups, in the case of **19** such cleavage would give the biradical **29** in which it would be expected that facile intramolecular hydrogen transfer would occur to give **30**. The fact that both **15** and **19** give only β-cleavage products and no α-cleavage products could be due to facilitation of the former process by a change in the excitation process resulting from the presence of the ethylenic double bond and/or by the stabilization by the latter of the transition state involved in the cleavage of the cyclopropyl ring. That the latter factor plays an important role is suggested by the allylic relationship of the ethylenic double bond to one of the developing radical centers in the transition state for the formation of biradicals of type **26** by β-cleavage.



28 R = Me
29 R = H

30

Additional evidence for the involvement of the ethylenic double bond was forthcoming from a study of the photolysis of dispiro compound **31** (12). This gave products **32**–**34** analogous to those obtained from **15** and **19** (Scheme 7). Only

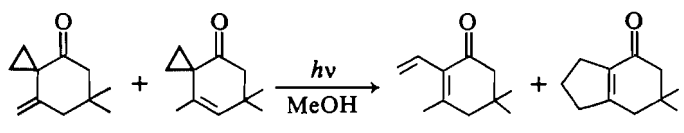


SCHEME 7

products resulting from cleavage of the cyclopropyl ring conjugated with the ethylenic double bond were detected, confirming the importance of the role of the latter in the β-cleavage reactions. An interesting difference in the case of **31** from those of **15** and **19** was the fact that its photolysis in methanol in quartz led to all three types of product **32**–**34**, whereas only a product of type **32** was obtained from **15** and **19** under these conditions. This may reflect an increase in the energy of the transition state leading from the biradical analogous to **26** to the trienol analogous to **27** (cf. Scheme 6) relative to the energy of those leading directly from the former to **33** and **34** because of reduced conjugative interaction between the carbonyl group and the remaining cyclopropyl ring. In benzene only the ethylidene compounds **33** and **34** were formed in analogy with the results for **15** and **19**.

Photolysis of 8-methylenespiro[2.5]octan-4-ones

Our initial work on the photochemistry of the 8-methylenespiro[2.5]octan-4-ones was carried out on mixtures of these compounds with the corresponding 8-methylspiro[2.5]oct-7-en-4-ones; it was later found possible to isolate pure samples of the former and examine them separately (12). Irradiation of a 4:1 mixture of *exo* and *endo* spiro ketones **35** and **15** in methanol gave a 5:3 mixture of **16** and 4,4-dimethylbicyclo[4.3.0]-non-1(6)-en-2-one (**36**) together with unconsumed **35** and **15** (Scheme 8). Compound **36** must be formed from **35** since none of it is formed on irradiation of **15**. Further, the amount of **36** formed was less than that of **35** consumed and the amount of **16** formed was greater than that of **15** consumed, demonstrating that **35** also gives rise to **16** (*vide infra*).



SCHEME 8

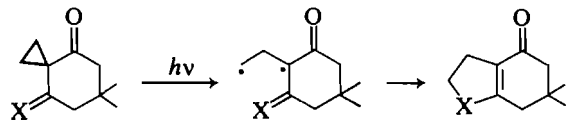
For personal use only.

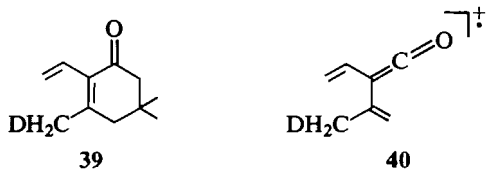
The formation of **36** on irradiation of **35** is analogous to previously reported photochemical vinylcyclopropane–cyclopentene rearrangements of unsaturated cyclopropyl carbonyl compounds (15). It also appears to have a close resemblance to the formation of the dihydrofuran **38** on irradiation of the spiro dione **37** (16) and may be formulated as occurring in analogous fashion (Scheme 9).



35 X = CH_2 **36** X = CH_2
37 X = O **38** X = O

SCHEME 9

In order to elucidate the mechanism of formation of **16** from **35**, the latter was irradiated in methanol-*O*-*d*. After 4 hours an 11:1 mixture of **16** and **36** together with unconsumed **35** was obtained (confirming that **16** was formed from both **35** and **15** when the mixture of the two was irradiated in methanol). ^{1}H nuclear magnetic resonance and mass spectroscopic analysis showed that the **16** formed in methanol-*O*-*d* was a 9:1 mixture of **16**-3′-*d* (**39**) and unlabelled **16**. Thus in its ^{1}H nmr spectrum the allylic methyl signal (δ 2.00) was broader than the corresponding signal in the spectrum of unlabelled **16** and the ratio of its area to that of the signal of the geminal methyl groups (δ 1.05) was 2.1:6. In its mass spectrum peaks at *m/e* 165, 109,

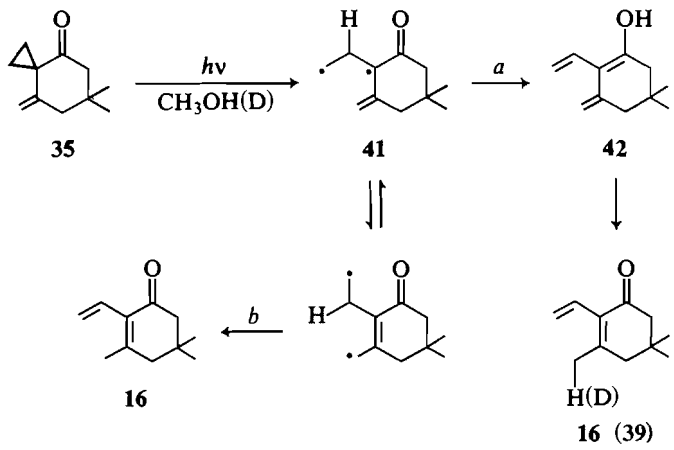


39 **40**

and 81 with relative abundances of 62, 66, and 100, respectively, replaced peaks of unlabelled **16** at *m/e* 164, 108, and 80 with relative abundances of 64, 68 and 100, respectively. The *m/e* 109 peak in the spectrum of **39** can readily be interpreted as arising from **40**, the product of a retro-Diels–Alder fragmentation of the molecular ion. Examination of the ^{1}H nmr and mass spectra of unconsumed **35** after irradiation in methanol-*O*-*d* for 4 hours and of **16** recovered after irradiation in methanol-*O*-*d* under identical conditions showed that only minor amounts (<10%) of deuterium were incorporated.

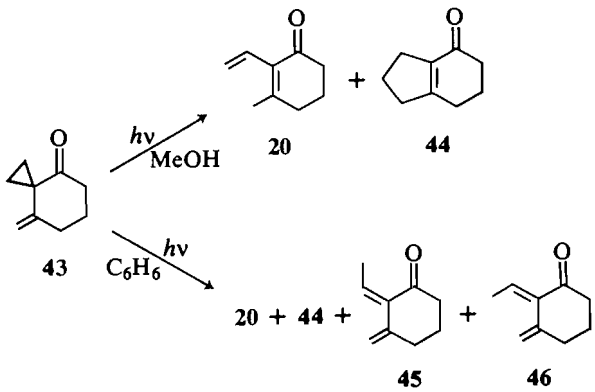
These results show that there are two mechanisms for the photoconversion of **35** to **16**. One is analogous to that postulated for the formation of **16** from **15** (route *a* in Scheme 10); ketonization of the trienol **42** in methanol-*O*-*d* would lead to the introduction of deuterium as in **39**. The other involves a 1,4-hydrogen shift to carbon rather than oxygen in the biradical **41** (route *b* in Scheme 10) and would account for the formation of unlabelled **16**.

Irradiation of a 1.1:1 mixture of the *exo* and *endo* spiro ketones **43** and **19** in methanol gave products **20** and **44** analogous to those obtained from the mixture of **35** and **15** (Scheme 11), and it could be demonstrated that **20** is formed from both **43** and **19**. Irradiation of **43** in benzene through quartz gave in addition to compounds **20** and **44** the two ethylidene compounds **45** and **46** (Scheme 11); the amounts of **45** and **46**



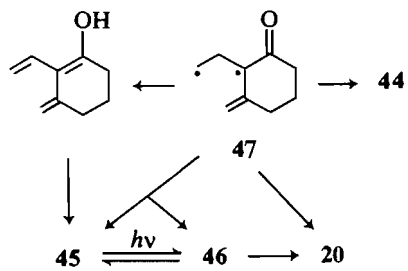
35 **41** **42**
16 **16** (39)

SCHEME 10



20 **44**
43
45 **46**

SCHEME 11

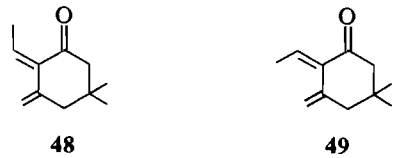


47
45 **46** **20** **44**

SCHEME 12

reached a maximum early in the photolysis and then decreased. These products are considered to be derived from the initially formed biradical **47** as outlined in Scheme 12. The formation of **45** and **46** on irradiation of **43** in benzene is analogous to the formation of ethylidene compounds on similar irradiation of **15** and **19**. The formation of **20** under these conditions finds no analogy in the cases of **15** and **19**; it is attributable to isomerization of **46** and perhaps also to direct hydrogen transfer in the biradical **47**.

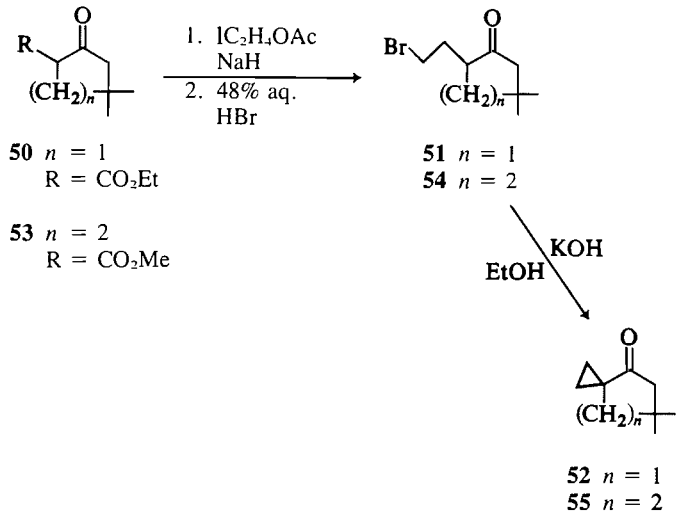
A preliminary examination of the photolysis of **35** in benzene clearly indicated that it behaved in analogous fashion to **43** in this solvent. In addition to **16** and **36**, the products formed in methanol, two other products were formed whose amounts reached a maximum early in the photolysis and then decreased. These were not characterized but their gc retention times were similar to those of **45** and **46** and they are considered to be the analogous ethylidene compounds **48** and **49**.



48 **49**

Preparation and photolysis of spiro[2.4]- and spiro[2.5]-alkan-4-ones

6,6-Dimethylspiro[2.4]heptan-4-one (**52**) and 6,6-dimethylspiro[2.5]octan-4-one (**55**) were prepared by the route shown in Scheme 13. Alkylation of **50** and **53** (17) with iodoethyl acetate (cf. ref. 18) followed by treatment with 48% hydrobromic acid gave **51** and **54**, respectively, which with ethanolic potassium hydroxide gave **52** and **55**, respectively.[6] 6,6,8-Trimethylspiro[2.5]octan-4-one (**56**) was prepared by hydrogenation of a mixture of **15** and **35** (12).



50 $n = 1$, R = CO_2Et

53 $n = 2$, R = CO_2Me

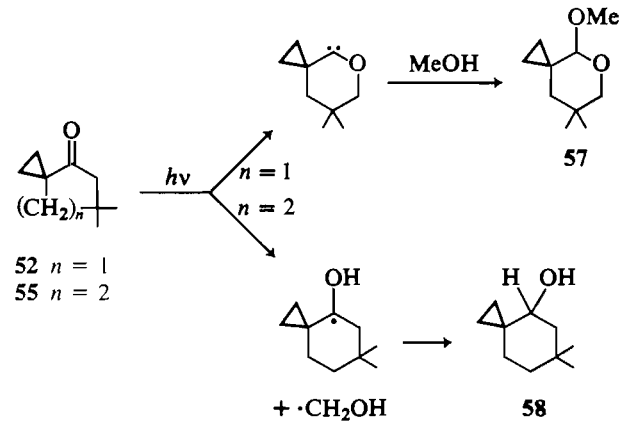
51 $n = 1$
54 $n = 2$

52 $n = 1$
55 $n = 2$

SCHEME 13

Irradiation of **52** in methanol for 8 hours gave a single major product (85%), which was identified as the cyclic acetal **57**, and 5% of unconsumed **52**. Irradiation of **55** in methanol for 13 hours also gave a single major product (72%), which was identified as the reduction product **58**; this was confirmed by its oxidation to **55**. Peaks at 5.76 μm and δ 3.60 (m) in the ir and ^1H nmr spectra, respectively, of the crude photolysate, suggested the presence of a minor amount of a methyl ester; no evidence was obtained for the presence of a cyclic acetal analogous to **57**. The major products from **52** and **55** are considered to arise by the routes shown in Scheme 14 (cf. refs. 2, 9, 10).[7]

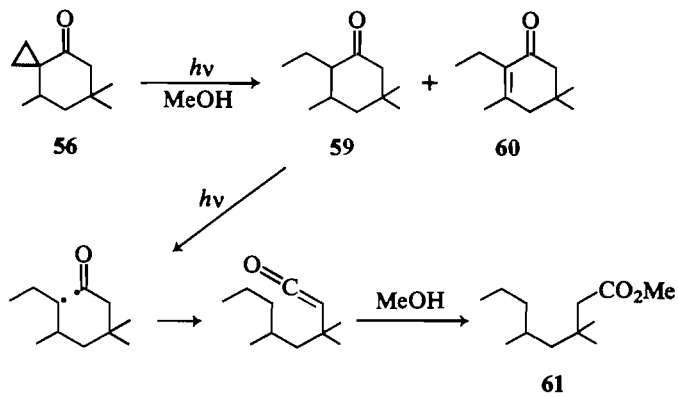
Irradiation of **56** in methanol through Pyrex for 21 hours gave two major products and at least eight minor products. One of the former was identified as **59** and one of the minor products as **60** by comparison of their ir and ^1H nmr spectra and gc retention times with those of authentic samples. Compound **60** was prepared by ethylation of isophorone (12, 20) and compound **59** was obtained by hydrogenation of **60** (12, 21). The other major product, which was not obtained free of **59**, is assigned structure **61** and is considered to be formed by further photolysis of **59** (Scheme 15). The formation of such a ketene-derived product from the cyclohexanone **59** is expected, and indeed the gc retention time of the major product formed on photolysis of **59** in methanol was the same as that of the product from **56** and its ir and ^1H nmr corresponded to those features of the spectra of the mixture of the latter product and **59** that are attributable to **61**. Further photolysis of **60** is not a significant source of products in the photolysate from **56** since upon irradiation in methanol through Pyrex for 25 hours **60** gave, in addition to unconsumed starting material, only one product (8%), which had the same gc retention time as a minor component (<1%) of the photolysate from **56**.



52 $n = 1$
55 $n = 2$

57 **58**

SCHEME 14



56 **59** **60** **61**

SCHEME 15

The formation of **59** from **56** may occur in two fashions (Scheme 16); by initial β-cleavage to give the biradical **62** followed by two successive intermolecular transfers of hydrogen atoms or by initial intermolecular hydrogen transfer, as proposed in the case of **55**, followed by cyclopropane ring opening and a second such transfer (cf. ref. 22). The biradical **62** also can serve as the source of **60** via several routes, two of which are indicated in Scheme 16: 1,4 intramolecular hydrogen transfer would give **60** directly, while 1,5 transfer would give the biradical **63**, which could give **60** via a 1,2 transfer (cf. ref. 4).

Discussion and summary

All of the photochemical reactions of the β,γ-unsaturated spiro α-cyclopropyl ketones investigated here can be most

[6]Attempted preparation of **52** by a route modeled on an earlier synthesis of spiro[2.4]heptan-4-one (**10**) (19) foundered on the low regioselectivity of the formation of 4,4-dimethyl-1-(trimethylsiloxy)-cyclopentene from 3,3-dimethylcyclopentanone.

[7]A referee has kindly suggested that the fact should be pointed out that reaction of a cyclic ketone to give a ring-expanded acetal via an oxacarbene intermediate (2) has been termed the Yates Rearrangement by others; we are happy to do so.

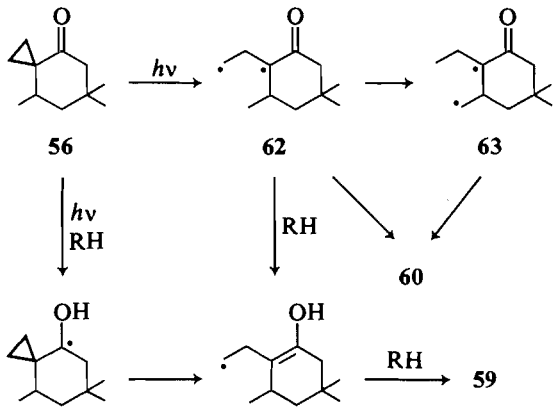
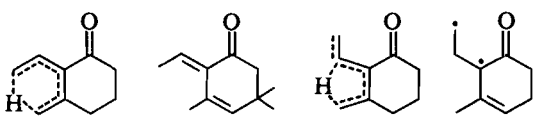


SCHEME 16

readily interpreted in terms of initial β-cleavage to give a biradical intermediate. This exclusive β-cleavage is in accord with expectation based on the view that such cleavage is favored both by release of ring strain and by conjugative stabilization of the developing biradical. Although it is well known that α-cleavage is reversible (1, 2), it seems unlikely that reversible α-cleavage is competing with β-cleavage in the present cases, since compound **19** fails to give the dienal **30** (*vide supra*). The interesting solvent effect on the nature of the products formed from the biradical intermediates can be interpreted consistently in terms of the previously proposed role of methanol in favoring the formation of trienols of type **27** from the biradicals in providing an intermolecular pathway for their subsequent ketonization to 2-ethenylcyclohex-2-en-1-ones. The fact that in the cases of the *exo* compounds **35** and **45** such products are formed in hydrocarbon solvents, in addition to 2-ethylidene compounds of type **46**, while the *endo* compounds **15** and **19** give only 2-ethylidene compounds of type **18** is readily explicable in terms of their formation by further reaction of the 2-ethylidene compounds of type **46** via a 1,5-sigmatropic shift of hydrogen (cf. **64**). Such a shift could occur either thermally in suprafacial fashion or photochemically in antarafacial fashion (23) but would be geometrically impossible in 2-ethylidene compounds of type **18**. As noted previously, 2-ethenylcyclohex-2-en-1-ones could also be formed by hydrogen transfer in biradicals of type **47** (cf. **65**), a process which again is not geometrically feasible in the biradicals formed from the *endo* compounds **15** and **19** (cf. **66**).



64 **18** **65** **66**

The photochemistry of the three saturated α-cyclopropyl ketones **50**, **53**, and **56** shows a remarkable trichotomy of reactivities. Compound **50** undergoes α-cleavage, **53** is reduced without cleavage, and **56** undergoes β-cleavage. The formation of the oxacarbene-derived acetal **57** as the major product from **50** is in accord both with the earlier observation that the parent spiro[2.4]heptan-4-one (**10**) gives the enal **11** together with the oxacarbene-derived product **12** (9, 10) and with the proposal that oxacarbene formation occurs *faute de mieux* (2), since the geminal substitution in **50** precludes enal formation. The failure of **53** to form an analogous product seems unlikely to be due to inhibition of α-cleavage, but reflects rather that such cleavage is reversible (*vide supra*) and that reclosure of the resulting biradical to a seven-membered cyclic oxacarbene is unfavorable entropically.[8] The fact that **56** undergoes β-cleavage but **53** does not is ascribed to the steric interaction of the 8-methyl group of **56** with the cyclopropyl ring. This interaction will be ameliorated if the cyclopropane ring undergoes cleavage and we consider this to be the driving force for such β-cleavage, a consideration that applies whichever of the two routes proposed for the formation of the major product (Scheme 16) is operative. Finally it may be noted that β-cleavage of the cyclopropane ring in α-spirocyclopropyl ketones has also been observed to be a reversible reaction (7, 24) and thus the occurrence of such reversible cleavage cannot be excluded in the cases of **50** and **53**. The fact that only **56** gives products resulting from β-cleavage could then be ascribed to retardation of reclosure resulting from the steric interaction referred to previously.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The ir spectra were taken in $CHCl_3$ solution and the ^1H and ^{13}C nmr spectra in $CDCl_3$ solution unless otherwise specified. The uv spectra were taken in 95% ethanol and/or hexane solution as indicated. Gas chromatographic (gc) analyses were carried out on a Varian 2700 gas chromatograph, equipped with a flame ionization detector. The temperatures of the in-column injector and detector were set at 260°C and 335°C, respectively; oven temperatures ranging from 90°C to 120°C were used. The flow rate of the carrier gas (nitrogen) was maintained at 30 mL/min. Unless otherwise indicated, a 6-ft glass column (od 1/8 in., id 2 mm) packed with 3% OV-101 on Chromosorb G(HP), 80/100 was utilized. The only other column used was a 6-ft glass column (od 1/8 in., id 2 mm) packed with 3% OV-17 on Chromosorb W(HP), 80/100. The relative intensities and retention times were determined with a Varian Chromatography Data System 111C; since in some cases there was peak overlap and the relative intensities are uncorrected for variation in the response factors, the relative product yields given are approximate only. Preparative gc separations were carried out on a Varian GC 920 gas chromatograph, equipped with a thermal conductivity detector. The temperatures of the in-column injector and detector were set at 245°C and 260°C, respectively; an oven temperature of 120°C was utilized. The flow rate of the carrier gas (nitrogen) was maintained at 40 mL/min. A 6-ft aluminum column (3/8 in. od) packed with 5% OV-101 on Chromosorb G(HP), 80/100 was utilized. Analytical thin-layer chromatography (tlc) was carried out on 70 × 20 × 0.25-mm silica gel LK6F plates from Whatman Inc. Preparative tlc was carried out on 20 × 20-cm plates coated with a 1-mm or 2-mm layer of silica gel or neutral alumina and activated at 150°C for 30 min prior to use. Column chromatography was performed on silica gel (Grace-Davison, grade 923, 100/200. Organic solutions were dried over anhydrous $MgSO_4$ and concentrated on a rotary evaporator under water aspirator pressure. Photolyses were carried out with a Hanovia 450-W medium-pressure mercury arc lamp type 679 A36 surrounded by a quartz water-cooling jacket. All photolysis solutions were flushed with a stream of dry nitrogen for 30 min immediately prior to irradiation.

Photolysis of 6,6,8-trimethylspiro[2.5]oct-7-en-4-one (15) in methanol. Formation of ethenyl compound 16

Spirooctenone **15** (12) (100 mg, 0.610 mmol) in methanol (10 mL) was irradiated through Pyrex for 23 h. Gas chromatographic analysis after 2, 6, and 23 h showed the formation of only one product to the

[8]Alternatively, as suggested by Professor Keith Yates, closure to the oxacarbene may occur, but because of the unfavorable geometry of a seven-membered cyclic oxacarbene this reaction may be readily reversible.

extent of 10, 19, and 32%, respectively, having the same retention times as **16** (*vide infra*). The ^{1}H nmr and ir spectra of the photolysate confirmed the presence of unconsumed **15** and ethenyl compound **16**.

*Photolysis of **15** in benzene. Formation of ethylidene compounds **17** and **18***

Spirooctenone **15** (109 mg, 0.665 mmol) in benzene (11 mL) was irradiated through quartz for 19 h. The gc analysis showed the presence of unconsumed **15** (82%) together with two photoproducts in a 2:1 ratio, having retention times identical to those of **17** and **18** (*vide infra*). The ^{1}H nmr and ir spectra of the photolysate confirmed the presence of unconsumed **15** and *Z*- and *E*-ethylidene compounds **17** and **18**.[9]

*Photolysis of **15** in hexanes. Formation of ethylidene compounds **17** and **18***

Spirooctenone **15** (109 mg, 0.665 mmol) in hexanes (10 mL) was irradiated through quartz for 18 h. The gc analysis showed the presence of **15** (81%) together with ethylidene compounds **17** and **18** in a 2:1 ratio. The ^{1}H nmr and ir spectra of the photolysate confirmed the presence of these compounds.

*Photolysis of **15** in 10% methanol in benzene. Formation of **16**, **17**, and **18***

Spirooctenone **15** (140 mg, 0.854 mmol) in 10% methanol in benzene (14 mL) was irradiated through quartz for 24 h. The gc analysis revealed the presence of unconsumed **15** (47%) together with ethenyl compound **16** (35%), *Z*-ethylidene compound **17** (10%), and *E*-ethylidene compound **18** (5%). The ^{1}H nmr and ir spectra of the photolysate confirmed the presence of these compounds.

*Preparation of 2-ethenyl-3,5,5-trimethylcyclohex-2-en-1-one (**16**) and (Z)-2-ethylidene-3,3,5-trimethylcyclohex-3-en-1-one (**17**) from **23***

A solution of **23** (12) (7.30 g, 29.1 mmol) in methanol (30 mL) was cooled in an ice bath and 30% aqueous hydrogen peroxide (10.0 mL, 158 mmol) was added over 30 min. The solution was allowed to warm to room temperature and was stirred for 68 h after which platinum black (prepared by warming together potassium tetrachloroplatinate, sodium acetate, and formic acid followed by centrifugation to collect the precipitate) was added. When gas evolution was complete the solution was centrifuged and the supernatant solution was removed. The catalyst was washed with methanol, the suspension was centrifuged, and the supernatant solutions were combined and concentrated in a 25-mL round-bottomed flask. The flask, fitted with a vacuum-distillation assembly, was submerged in an oil bath and the pressure was reduced (12 Torr). The oil bath was heated from 25° to 120°C at ~2°C/min and held at 120°C for 20 min during which time a colorless liquid, bp 81°–88°C (12 Torr), distilled. The oil bath was heated at ~1°C/min to 150°C and a liquid, bp 88°–97°C (12 Torr) distilled, after which the still-head temperature dropped. The viscous pot material was transferred to a molecular still and heated at 100°C (0.025 Torr) to recover unconsumed **23** (695 mg, 9.5%). The ^{1}H nmr spectrum of the combined earlier distillates (5.25 g) showed that they contained a mixture of **16**, **17**, and *N*-hydroxymorpholine (**25**). This mixture was dissolved in ether, washed with 0.1 *N* hydrochloric acid and water, dried, and concentrated to give a mixture (~4:1 by gc analysis) of 2-ethenyl-3,5,5-trimethylcyclohex-2-en-1-one (**16**) and (*Z*)-2-ethylidene-3,5,5-trimethylcyclohex-3-en-1-one (**17**) (3.31 g, 69%, 79% based on recovered **23**). This mixture (2.00 g) was chromatographed on silica gel with 20% ether in hexanes; **17** (356 mg) was eluted first, followed by a small amount of its *E* isomer **18** (22 mg). and then **16** (1.59 g). The last was molecularly distilled at 95°C (12 Torr) to give pure **16** (1.45 g); ir λ_{max}: 3.42(w), 6.02, 6.18(w) μm; uv λ_{max} (ε) (95% ethanol): 220 (8890), 259 (8460) nm; ^{1}H nmr δ: 1.05 (s, 6H), 2.00 (s, 3H), 2.27 (s, 4H), 5.2–5.6 (m, 2H), 6.1–6.7 (m, 1H); ^{1}H nmr δ (C_6D_6): 0.75 (s, 6H), 1.60 (br s, 3H), 1.73 (br s, 2H), 2.08 (s, 2H), 5.36 (dd, J = 3, 11 Hz, 1H), 5.78 (dd, J = 3, 18 Hz, 1H), 6.61 (br dd, J = 11, 18 Hz, 1H); ^{13}C nmr δ: 198.6, 154.4, 132.2, 129.9, 119.9, 51.9, 47.6, 32.6, 28.3, 22.2; *m/e*: 164 (64), 80 (100). *Anal.* calcd. for $C_{11}H_{16}O$: C 80.44, H 9.82; found: C 80.29, H 9.85.

Molecular distillation of the *Z*-ethylidene compound at 95°C (12 Torr) gave pure **17** (331 mg); ir λ_{max}: 3.49 (m), 5.94, 6.12 (w), 6.26 (m) μm; uv λ_{max} (ε) (hexanes): 221.5 (12 000), 268 (5600), 322 (128) nm; uv λ_{max} (ε) (95% ethanol): 223 (10 000), 279 (3760) nm; ^{1}H nmr δ: 1.08 (s, 6H), 1.82 (d, J = 1.2 Hz, 3H), 2.17 (dd, J = 7.5 Hz, 0.85 Hz, 3H), 2.41 (s, 2H), 5.54 (m, 1H), 6.06 (qd, J = 7.5 Hz, 0.85 Hz, 1H); ^{13}C nmr δ: 202.2 (s), 135.9 (d), 134.8 (s), 132.4 (d), 131.1 (s), 55.2 (t), 35.6 (s), 29.6 (q), 19.5 (q), 15.8 (q); *m/e*: 164 (44), 149 (100). *Anal.* calcd. for $C_{11}H_{16}O$: C 80.44, H 9.82; found: C 80.22, H 9.79.

*Photolysis of **17**. Preparation of (E)-2-ethylidene-3,5,5-trimethylcyclohex-3-en-1-one (**18**)*

Z-Ethylidene compound **17** (300 mg, 1.83 mmol) was dissolved in benzene (30 mL) and irradiated through Pyrex for 1 h. Gas chromatographic analysis after 30 min and after 1 h showed the product to be a 2:1 mixture of **17** and **18**. Evaporation of the solvent followed by preparative tlc (20% ether in hexanes) gave **17** (183 mg) and its *E* isomer **18** which was molecularly distilled at 95°C (12 Torr) to give pure (*E*)-2-ethylidene-3,5,5-trimethylcyclohex-3-en-1-one (**18**; 89 mg, 30%, 76% based on recovered **17**); ir λ_{max}: 3.41 (m), 5.92, 6.12 (m), 6.26 (m) μm; uv λ_{max} (ε) (hexanes): 224 (8640), 269 (5750), 318 (sh, 162), 330 (148), 344 (109), 354 (52) nm; uv λ_{max} (ε) (95% ethanol): 224 (8000), 277 (3790) nm; ^{1}H nmr δ: 1.08 (s, 6H), 2.03 (d, J = 7.5 Hz, 3H), 2.10 (d, J = 2 Hz, 3H), 2.36 (s, 2H), 5.62 (m, 1H), 6.75 (qd, J = 7.5 Hz, 1.9 Hz, 1H); ^{13}C nmr δ: 201.1, 139.2, 134.4, 132.6, 130.8, 52.2, 33.8, 29.3, 23.0, 15.5; *m/e*: 164 (40), 149 (100). *Anal.* calcd. for $C_{11}H_{16}O$: C 80.44, H 9.82; found: C 80.21, H 9.83.

*Irradiation of **16** in benzene*

Compound **16** (75 mg, 0.457 mmol) was dissolved in benzene (7.5 mL) and irradiated through Pyrex for 17 h. Evaporation of the solvent returned unconsumed **16** (by gc and ^{1}H nmr spectroscopic analysis). None of the ethylidene compounds **17** and **18** were present.

*Irradiation of **17** and **18** in methanol*

A 2:1 mixture of **17** and **18** (30.0 mg, 0.18 mmol) was dissolved in methanol (3.0 mL) and irradiated through Pyrex for 2.5 h. The gc analysis of the photolysate showed that it was a 1.9:1 mixture of **17** and **18** containing none of ethenyl compound **16**.

*Photolysis of 8-methylspiro[2.5]oct-7-en-4-one (**19**) in methanol. Formation of ethenyl compound **20***

Spirooctenone **19** (12) (37.3 mg, 0.274 mmol) was dissolved in methanol (3.7 mL) and irradiated through Pyrex for 6.5 h. Gas chromatographic analysis after 3.5, 5.5, and 6.5 h showed the formation of only one product to the extent of 18, 20, and 24%, respectively, having the same retention time as **20** (*vide infra*). This solution was then irradiated through quartz for 5.5 h. Gas chromatographic analysis after 2, 3.5, and 5.5 h showed that **20** was present to the extent of 44, 51, and 63%, respectively, together with unconsumed **19**. The ^{1}H nmr spectrum of the photolysate confirmed the presence of unconsumed **19** and ethenyl compound **20**.

*Photolysis of **19** in benzene. Preparation of (Z)- and (E)-2-ethylidene-3-methylcyclohex-3-en-1-one (**21** and **22**)*

Spirooctenone **19** (1.28 g, 9.41 mmol) was dissolved in benzene (125 mL) and irradiated through quartz for 6 h. The gc analysis of the crude photolysate showed the presence of unconsumed **19** (82%) together with two photoproducts (12% and 6%) having retention times different from that of **20**. The oil obtained on evaporation of the solvent was chromatographed on silica gel (100 g) with 10% ether in hexanes and the eluate was separated into five fractions. The first band eluted was shown by gc analysis to contain the major photoproduct.

[9]Individual structural assignments for **17** and **18** and other such pairs of *Z* and *E* isomers were made on the basis of a detailed analysis of their spectra, which will be discussed elsewhere.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

Preparative tlc (10% ether in hexanes, 3 elutions) of the oil obtained on evaporation of the solvent, followed by molecular distillation at 75°C (12 Torr), gave (*Z*)-2-ethylidene-3-methylcyclohex-3-en-1-one (**21**; 82.2 mg, 6.4%); ir λ_{max}: 3.46 (m), 5.93, 6.09 (w), 6.27 (m) μm; uv λ_{max} (ε) (hexanes): 223 (9060), 269 (4460), 324 (sh, 90) nm; ^{1}H nmr δ: 1.82 (d, J = 2 Hz, 3H), 2.10 (d, J = 8 Hz, 3H), 2.3−2.6 (m, 4H), 5.65 (m, 1H), 5.98 (q, J = 8 Hz, 1H); ^{13}C nmr δ: 201.7, 135.3, 134.0, 131.8, 124.3, 40.4, 24.8, 19.5, 15.8; *m/e*: 136 (100), 121 (32). *Mol. Wt.* calcd. for $C_9H_{12}O$: 136.0888; found (ms): 136.0882.

The second and fourth fractions contained mixtures of **19** and **21** and of **19** and the minor photoproduct, respectively, whereas the third fraction contained only unconsumed **19**. Gas chromatographic analysis of the oil obtained on evaporation of the fifth fraction (33.0 mg) showed that it was primarily (85%) the minor photoproduct together with unconsumed **19** (15%). Preparative tlc (10% ether in hexanes, 3 elutions) of this fraction followed by molecular distillation at 80°C (12 Torr) gave (*E*)-2-ethylidene-3-methylcyclohex-3-en-1-one (**22**; 26.4 mg, 2.1%); ir λ_{max}: 3.42 (w), 5.92, 6.11 (w), 6.27 (m) μm; uv λ_{max} (ε) (hexanes): 224 (6900), 270 (4300), 316 (sh, 220), 330 (sh, 140), 342 (sh, 115) nm; ^{1}H nmr δ: 2.07 (d, J = 8 Hz) and 2.15 (m) (6H), 2.3−2.6 (m, 4H), 5.84 (m, 1H), 6.77 (qd, J = 8 Hz, 1.5 Hz, 1H); ^{13}C nmr δ: 201.6, 135.6, 133.7, 132.4, 127.8, 37.1, 22.9, 22.8, 15.4; *m/e*: 136 (100), 121 (51). *Mol. Wt.* calcd. for $C_9H_{12}O$: 136.0888; found (ms): 136.0861.

*Photolysis of **21** in benzene. Formation of **22***

Z-Ethylidene compound **21** (28.2 mg, 0.207 mmol) was dissolved in benzene (2.8 mL) and irradiated through quartz for 45 min. The gc analysis of the photolysate showed that it was a mixture of **21** (65%) and its *E* isomer **22** (35%). The ^{1}H nmr spectrum of the photolysate confirmed the presence of **21** and **22**.

*Photolysis of 8-methyldispiro[2.1.2.3]dec-8-en-4-one (**31**) in methanol. Preparation of 5-ethenyl-6-methylspiro[2.5]oct-5-en-4-one (**32**) and formation of **33** and **34***

Dispirodecenone **31** (12) (800 mg, 4.94 mmol) was dissolved in methanol (80 mL) and irradiated through quartz for 8 h. The gc analysis of the photolysate showed that it was a mixture of unconsumed **31** (44%) together with one major (45%) and two minor (6% and 4%) photoproducts. The gc retention times of the minor photoproducts were identical to those of ethylidene compounds **33** and **34**, obtained by irradiation of **31** in benzene (*vide infra*). The ^{1}H nmr spectrum of the photolysate confirmed the presence of the ethylidene compounds. Column chromatography of the photolysate on silica gel (100 g) with 3% ether in hexanes gave two fractions. The first band eluted was shown by gc analysis to contain unconsumed **31** together with **33** and **34**. Preparative tlc of the oil obtained on evaporation of the solvent from the second fraction, followed by molecular distillation at 90°C (12 Torr), gave 5-ethenyl-6-methylspiro[2.5]oct-5-en-4-one (**32**; 207 mg, 26%): ir λ_{max}: 3.43 (m), 6.04, 6.30 (w) μm; uv λ_{max} (ε) (hexanes): 254 (5630), 314 (sh, 76) nm; ^{1}H nmr δ: 0.55−0.98 (m, 2H), 0.98−1.43 (m, 2H), 1.78 (br t, J = 6.5 Hz, 2H), 2.10 (s, 3H), 2.2−2.6 (m, 2H), 5.2−5.6 (m, 2H), 6.2−6.8 (m, 1H); ^{1}H nmr δ (C_6D_6): 0.2−0.7 (m, 2H), 0.9−1.5 (m, 4H), 1.66 (d, J = 4 Hz, 3H), 1.8−2.2 (m, 2H), 5.2−5.9 (m, 2H), 6.4−7.0 (m, 1H); ^{13}C nmr δ: 197.1, 156.1, 133.6, 130.5, 119.5, 31.8, 30.2, 25.9, 22.4, 16.1; *m/e*: 162 (100). *Anal.* calcd. for $C_{11}H_{14}O$: C 81.44, H 8.70; found: C 81.18, H 8.75.

*Photolysis of **31** in benzene. Preparation of (Z)- and (E)-5-ethylidene-6-methylspiro[2.5]oct-6-en-4-one (**33** and **34**)*

Dispirodecenone **31** (275 mg, 1.70 mmol) was dissolved in benzene (28 mL) and irradiated through quartz for 8 h. The gc analysis of the photolysate showed that it was a mixture of unconsumed **31** (82%) and ethylidene compounds **33** (11%) and **34** (7%). None of the ethenyl compound **32** formed on irradiation of **31** in methanol was present. The oil obtained on evaporation of the solvent was subjected to preparative tlc (5% ether in hexanes, 3 elutions). Molecular distillation of the oil from the first band at 90°C (12 Torr) gave (*Z*)-5-ethylidene-6-methylspiro[2.5]oct-6-en-4-one (**33**; 24.2 mg, 9%); ir λ_{max}: 3.46 (m), 5.98, 6.08 (sh), 6.29 (m) μm; uv λ_{max} (ε) (hexanes): 222 (10 300), 277 (5500), 323 (sh, 180) nm; ^{1}H nmr δ: 0.48−1.08 (m, 2H), 1.08−1.47 (m, 2H), 1.88 (m, 3H), 2.17 (d, J = 8 Hz, 3H), 2.33 (m, 2H), 5.55 (m, 1H), 6.12 (q, J = 8 Hz, 1H); ^{13}C nmr δ: 201.4, 134.7, 134.3, 133.7, 123.6, 33.6, 27.1, 20.2, 19.4, 16.5; *m/e*: 162 (45), 147 (49), 134 (100). *Mol. Wt.* calcd. for $C_{11}H_{14}O$: 162.1045; found (ms): 162.1045.

The second band contained unconsumed **31**. The oil obtained from the third band was molecularly distilled at 90°C (12 Torr) to give (*E*)-5-ethylidene-6-methylspiro[2.5]-oct-6-en-4-one (**34**; 14.6 mg, 5%); ir λ_{max}: 3.44 (m), 5.96, 6.12 (w), 6.27 (m) μm; uv λ_{max} (ε) (hexanes): 220 (3020), 262 (1880), 318 (sh, 111) nm; ^{1}H nmr δ: 0.57−1.02 (m, 2H), 1.02−1.47 (m, 2H), 2.01 (d, J = 8 Hz) and 2.12 (m) (8H), 5.87 (m, 1H) and 6.67 (qd, J = 8 Hz, 1 Hz, 1H); ^{13}C nmr δ: 201.0, 136.8, 133.0, 132.1, 126.6, 32.6, 25.1, 22.6, 20.0, 15.7; *m/e*: 162 (40), 147 (100), 134 (23). *Mol. Wt.* calcd. for $C_{11}H_{14}O$: 162.1045; found (ms): 162.1042.

*Photolysis of **33** in benzene. Formation of **34***

Z-Ethylidene compound **33** (30.1 mg, 0.186 mmol) was dissolved in benzene (3.0 mL) and irradiated through quartz for 30 min. The gc analysis of the photolysate showed that it was a mixture of **33** (62%) and its *E* isomer **34** (38%). The ^{1}H nmr spectrum of the photolysate confirmed the presence of **33** and **34**.

*Photolysis of a mixture of 6,6-dimethyl-8-methylenespiro[2.5]octan-4-one (**35**) and **15** in methanol. Preparation of 4,4-dimethylbicyclo[4.3.0]non-1(6)-en-2-one (**36**) and formation of **16***

A 4:1 mixture of spiro ketones **35** and **15** (12) (5.00 g, 30.5 mmol) in methanol (500 mL) was irradiated through quartz for 23 h. The gc analysis of the photolysate showed that it contained **35** (48%), **15** (14%), **16** (24%), and **36** (14%). The photolysate was chromatographed on silica gel (500 g) with 20% ether in hexanes. Spiro ketones **35** and **15** (2.28 g, 46%) were eluted together, folowed by ethenyl compound **16** (928 mg, 19%). The third band (549 mg, 11%) contained **36**, which was shown by gc analysis to be 86% pure. This material (225 mg) was purified by preparative tlc on alumina with 30% ether in hexanes and molecularly distilled at 110°C (12 Torr) to give 4,4-dimethylbicyclo[4.3.0]non-1(6)-en-2-one (**36**; 178 mg); ir λ_{max}: 3.42 (w), 6.05, 6.10 (sh) μm; uv λ_{max} (ε) (95% ethanol): 250 (5750) nm; ^{1}H nmr δ: 1.08 (s, 6H), 1.7−2.2 (m, 2H), 2.23 (s, 4H), 2.3−2.8 (m, 4H); ^{13}C nmr δ: 197.4, 163.4, 136.4, 51.8, 41.0, 37.8, 35.1, 28.8, 28.6, 21.8; *m/e*: 164 (29), 108 (100); *Mol. Wt.* calcd. for $C_{11}H_{16}O$: 164.1201; found (ms): 164.1201.

*Photolysis of **35** in methanol-O-d. Incorporation of deuterium into **16***

Spirooctanone **35** (12) (76.6 mg, 0.467 mmol) in methanol-*O-d* (7.0 mL) was irradiated through quartz. Gas chromatographic analysis at hourly intervals showed the formation of **16** and **36**. After 4 h the solution contained 60% **35**, 21% **16**, and 19% **36**. Evaporation of the solvent followed by preparative tlc on silica gel with 20% ether in hexanes separated the mixture into three components. The first compound eluted was unconsumed **35** (33.6 mg, 44%), which was analyzed for deuterium content by ^{1}H nmr and mass spectroscopy. The ^{1}H nmr spectrum showed no evidence for significant deuterium incorporation. The parent ion peak in the mass spectrum occurred at *m/e* 164; M + 1/M was 19% (observed for unirradiated **35** M + 1/M: 14%; calcd.: 12%). The oil isolated from the middle band was molecularly distilled at 95°C (12 Torr) to give a colorless liquid (13.9 mg, 18%) having ^{1}H nmr spectra in $CDCl_3$ and C_6D_6 corresponding to those of unlabelled **16**, with the following exceptions: the peak at δ 2.00 (in $CDCl_3$) was broader and its area corresponded to 2.1 rather than 3.0 proton relative to the six-proton peak at δ 1.05; the peak at δ 1.60 (in C_6D_6) was broader and its area corresponded to 2.1 rather than 3.0 protons relative to the six-proton peak at δ 0.75. Its mass spectrum had peaks at *m/e* 166 (20), 165 (62), 164 (13), 109 (66), and 81 (100).

*Irradiation of **16** in methanol-O-d*

Ethenyl compound **16** (30.0 mg, 0.183 mmol) in methanol-*O-d* (3.0 mL) was irradiated through quartz for 4 h. Evaporation of the solvent and examination of the residue by ^{1}H nmr spectroscopy (C_6D_6)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

showed that significant amounts of deuterium (>5%) had not been incorporated at any position in the starting material (peak areas were compared to that of the six-proton peak at δ 0.75). The parent ion peak in its mass spectrum occurred at *m/e* 164; M + 1/M was 26% (observed for unirradiated **16** M + 1/M: 19%; calcd.: 12%.

*Photolysis of a mixture of 8-methylenespiro[2.5]octan-4-one (**43**) and **19** in methanol. Preparation of 2-ethenyl-3-methylcyclohex-2-en-1-one (**20**) and bicyclo[4.3.0]non-1(6)-en-2-one (**44**)*

A mixture of spiro ketones **43** (52%) and **19** (48%) (12) (1.37 g, 10.1 mmol) was dissolved in methanol (137 mL) and irradiated through quartz for 8 h. The gc analysis of the photolysate showed that it was a mixture of **20** (21%) and **44** (3%), together with unconsumed **43** (41%) and **19** (35%). Evaporation of the solvent gave an oil (1.14 g) which was chromatographed on silica gel (100 g) with 20% ether in hexanes. The first band eluted (826 mg, 60%) consisted of a mixture of **43** and **19**. The oil obtained from the second band was molecularly distilled at 80°C (12 Torr) to give 2-ethenyl-3-methylcyclohex-2-en-1-one (**20**; 168 mg, 12%); ir λ_{max}: 3.43 (m), 6.04, 6.21 (m) μm; uv λ_{max} (ε) (hexanes): 222 (6120), 252.5 (5950), 325 (51) nm; ^{1}H nmr δ: 1.7−2.2 (m) and 2.07 (s) (5H), 2.2−2.6 (m, 4H), 5.3−5.7 (m, 2H), 6.1−6.8 (m, 1H); ^{1}H nmr δ (C_6D_6): 1.1−2.0 (m) and 1.63 (s) (7H), 2.17 (br t, *J* = 6 Hz, 2H), 5.37 (dd, *J* = 3 Hz, 11 Hz, 1H), 5.69 (dd, *J* = 3 Hz, 18 Hz, 1H), 6.59 (dd, *J* = 11 Hz, 18 Hz, 1H); ^{13}C nmr δ: 197.8 (s), 156.6 (s), 133.2 (s), 130.0 (d), 119.6 (t), 38.1 (t), 33.2 (t), 21.9 (q), 21.7 (t); *m/e*: 136 (100). *Mol. Wt.* calcd. for $C_9H_{12}O$: 136.0888; found (ms): 136.0895.

The mobile phase was changed to 1:1 ether−hexane and a third band was eluted. The oil obtained by evaporation of the solvent was molecularly distilled at 85°C (12 Torr) to give bicyclo[4.3.0]non-1(6)-en-2-one (**44**; 29 mg, 2%; 87% pure by gc): ir λ_{max}: 3.44 (m), 6.04, 6.12 (sh) μm (lit. (25) ir λ_{max} (neat): 6.00 μm); *m/e*: 136 (54), 108 (100). *2,4-Dinitrophenylhydrazone*: mp 248−249°C (lit. (25) 247−247.5°C).

*Irradiation of **43** in benzene*

Spiro ketone **43** (12) (132 mg, 0.971 mmol) in benzene (13 mL) was irradiated through quartz. Gas chromatographic analysis after 3 h showed the presence of unconsumed **43** (8.9 min, 57%), ethenyl compound **20** (15.7 min, 12%), and bicyclic compound **44** (23.3 min, 13%) together with two other photoproducts (**45** and **46**; 11.5 min and 12.7 min, 17%). The ^{1}H nmr spectrum of the oil obtained by evaporation of the solvent had multiplets at δ 4.87 and 5.18, and quartets at δ 6.20 (*J* = 7.5 Hz) and 6.71 (*J* = 7 Hz) in addition to peaks attributable to **43**, **20**, and **44**. The oil was redissolved in benzene (13 mL) and irradiated through quartz for 8 h (total 11 h). The gc analysis showed that, as the reaction proceeded, the proportion of **43**, **45**, and **46** decreased and that of **20** and **44** increased such that after 11 h the mixture contained 30% **43**, 25% **20**, 33% **44**, and 12% **45** and **46**. The ^{1}H nmr spectrum of the photolysate confirmed the presence of **43**, **20**, and **44**.

*Irradiation of **35** in benzene*

Spiro ketone **35** (25.0 mg, 0.152 mmol) in benzene (2.5 mL) was irradiated through Pyrex for 5 h. The gc analysis showed the presence of unconsumed **35** (9.6 min, 72%), ethenyl compound **16** (14.4 min, 6%), and bicyclic compound **36** (21.3 min, 7%) together with two other photoproducts (**48** and **49**, 10.4 min (6%) and 13.5 min (6%)). Thereafter the proportion of **48** and **49** decreased and that of **16** and **36** increased such that after 4 h gc analysis indicated that the solution contained 62% **34**, 2% **48**, 3% **49**, 16% **16**, and 16% **36**. The ^{1}H nmr spectrum of the photolysate confirmed the presence of **35**, **16**, and **36**.

*Preparation of 6,6-dimethylspiro[2.4]heptan-4-one (**52**)*

Ethyl 4,4-dimethyl-2-oxocyclopentanecarboxylate (17) (**50**; 1.40 g, 7.62 mmol) was added to toluene (distilled from calcium hydride, 30 mL) and sodium (224 mg, 9.81 mmol) and the resulting mixture was boiled under reflux. After 1 h, 2-iodoethyl acetate (2.74 g, 12.8 mmol) was added and the mixture was boiled under reflux for 10 h (18). After cooling, 0.2 *N* hydrochloric acid (10 mL) was added, the layers were separated, and the aqueous layer was extracted with toluene (3 × 10 mL). The combined organic solutions were washed with saturated aqueous sodium bicarbonate, dried, and evaporated. Unconsumed starting materials were removed by distillation (60°−110°C (12 Torr)). The residue (1.13 g) was heated with 48% hydrobromic acid (9.5 mL) on a steam bath for 2 h. The solution was neutralized with sodium bicarbonate and extracted with ether (3 × 15 mL). The combined extracts were washed with water, dried, and evaporated to give an oil (**51**, 681 mg); ir λ_{max}: 5.78 μm; ^{1}H nmr δ: 3.50 (m). This was dissolved in 30% ethanolic potassium hydroxide (7.0 mL) and the solution was boiled under reflux for 3 h. After cooling, the solution was neutralized with 0.2 *N* hydrochloric acid and extracted with ether (3 × 15 mL). The combined extracts were washed with saturated aqueous sodium chloride and dried, and the solvent was evaporated giving an oil which was molecularly distilled at 75°C (12 Torr) to give 6,6-dimethylspiro[2.4]heptan-4-one (**52**; 214 mg, 20% based on **50**); ir λ_{max}: 3.40 (m), 5.81 μm; ^{1}H nmr δ: 0.88 (m, 2H), 1.1−1.4 (m) and 1.20 (s) (8H), 1.88 (s, 2H), 2.23 (s, 2H); ^{13}C nmr δ: 219.0 (s), 53.8 (t), 46.2 (t), 35.2 (s), 29.3 (s), 28.6 (q), 17.8 (t); *m/e*: 138 (62), 123 (100). *Mol. Wt.* calcd. for $C_9H_{14}O$: 138.1045; found (ms) 138.1024.

*Preparation of 6,6-dimethylspiro[2.5]octan-4-one (**55**)*

Methyl 4,4-dimethyl-2-oxocyclohexanecarboxylate (17) (**53**: 13.1 g, 71.2 mmol) was added to toluene distilled from calcium hydride (250 mL) and sodium (1.80 g, 78.3 mmol) and the resulting mixture was boiled under reflux. After 1 h, 2-iodoethyl acetate (27.2 g, 127 mmol) was added and the mixture was boiled under reflux for 10 h (18). After cooling, 0.2 *N* hydrochloric acid (50 mL) was added, the layers were separated, and the aqueous layer was extracted with toluene (3 × 40 mL). The combined organic solutions were washed with saturated aqueous sodium bicarbonate, dried, and evaporated. Unconsumed starting materials were recovered by distillation (bp 60°−110°C (12 Torr)). The residue (6.10 g) was heated with 48% hydrobromic acid (35 mL) on a steam bath for 3 h. The acidic solution was neutralized with sodium bicarbonate and extracted with ether (4 × 30 mL). The combined extracts were washed with water, dried, and evaporated to give an oil (**54**; 5.12 g); ir λ_{max}: 5.87 μm; ^{1}H nmr δ: 3.48 (t). This oil was dissolved in 30% ethanolic potassium hydroxide (70 mL), and the solution was boiled under reflux for 3 h. After cooling, the solution was neutralized with 0.2 *N* hydrochloric acid and extracted with ether (4 × 50 mL). The combined extracts were washed with saturated aqueous sodium chloride and dried, and the solvent was evaporated to give an oil (2.26 g). Column chromatography of this material on silica gel with 2:1 hexanes and ether followed by molecular distillation at 80°C (12 Torr) gave 6,6-dimethylspiro[2.5]octan-4-one (**55**; 1.60 g, 15% based on **53**); ir λ_{max}: 3.45 (m), 5.93 μm; uv λ_{max} (ε) (hexanes): 285 (36) nm; ^{1}H nmr δ: 0.61 (m, 2H), 1.05 (s) and 1.15 (m) (8H), 1.6−1.8 (m, 4H), 2.20 (s, 2H); ^{13}C nmr δ: 211.3 (s), 53.6 (t), 37.0 (t), 33.6 (s), 30.6 (t), 28.9 (q), 27.5 (s), 17.2 (t); *m/e*: 152 (34), 96 (100). *Anal.* calcd. for $C_{10}H_{16}O$: C 78.90, H 10.59; found: C 78.78, H 10.58.

*Photolysis of 6,6-dimethylspiro[2.4]heptan-4-one (**52**). Formation of 4-methoxy-7,7-dimethyl-5-oxaspiro[2.5]octane (**57**)*

Spiroheptanone **52** (167 mg, 1.21 mmol) was dissolved in methanol (17 mL) and irradiated through Pyrex. Gas chromatographic analysis after 8 h showed the presence of unconsumed **52** (5%), a major photoproduct (85%), and a minor photoproduct (10%). Evaporation of the solvent gave an oil that was shown by ^{1}H nmr and ir spectroscopy to be primarily **57**. Preparative gc of a portion of this oil gave 4-methoxy-7,7-dimethyl-5-oxaspiro[2.5]octane (**57**); ir λ_{max}: 3.43 (m), 9.14, 9.73 μm; ^{1}H nmr δ: 0.1−0.7 (m, 4H), 0.89 (s) and 1.13 (s) and 0.7−1.3 (m) (8H), 3.14 (dd, *J* = 11 Hz, 2 Hz, 1H), 3.40 (s, 3H), 3.59 (br d, *J* = 11 Hz, 1H), 3.67 (m, 1H), 3.80 (s, 1H); *m/e*: 170 (1), 155 (7), 142 (76), 139 (15), 83 (100). *Mol. Wt.* calcd. for $C_{10}H_{18}O_2$: 170.1307; found (ms): 170.1289.

*Photolysis of 6,6-dimethylspiro[2.5]octan-4-one (**55**). Formation of 6,6-dimethylspiro[2.5]octan-4-ol (**58**)*

Spirooctanone **55** (350 mg, 2.30 mmol) in methanol (35 mL) was irradiated through Pyrex for 8 h. Gas chromatographic analysis showed the presence of unconsumed **55** (retention time 7.0 min), a major photoproduct **58** (retention time 7.2 min) (**55** + **58** = 88%),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

and a minor photoproduct (6%). Several other products, each less than 3%, were also present. This oil (280 mg) was redissolved in methanol and irradiated through Pyrex for 5 h. The gc analysis and ir and ^{1}H nmr spectroscopy of the photolysate showed that <5% of **55** remained. The gc analysis showed the presence of the major photoproduct **58** (72%), a minor photoproduct (11%), and nine other minor photoproducts (1−4% each). A portion of this product was chromatographed on a 1-mm silica gel plate (20% ether in hexanes). A low R_f band was isolated and was shown by gc analysis to contain 87% of **58**; ir λ_{max}: 2.87 μm; ^{1}H nmr δ: 0.1−0.7 (m, 4H), 0.7−1.6 (m) and 0.97 (s) and 1.03 (s) (12 H), 2.37 (br s, 1H; absent after treatment with D_2O), 3.1−3.7 (m, 1H); *m/e*: 154 (11), 136 (55), 121 (100). *Mol. Wt.* calcd. for $C_{10}H_{18}O$: 154.1358; found (ms): 154.1352.

Oxidation of 58. Formation of 55

The remainder of the oil from the photolysis of **55** (*vide supra*) (150 mg) was dissolved in methylene chloride (1.0 mL) and the solution was added to a suspension of pyridinium chlorochromate (221 mg, 102 mmol) in methylene chloride (3.0 mL). The resulting mixture was stirred at room temperature under nitrogen for 2 h, after which ether (5.0 mL) was added and the supernatant solution was decanted from the black gum. The gum was washed with ether (3 × 3.0 mL) and the combined washings and supernatant solution were passed through a pad of Florisil. Evaporation of the solvent gave an oil (117 mg) that was shown by gc analysis and by ^{1}H nmr and ir spectroscopy to be **55**.

Photolysis of 6,6,8-trimethylspiro[2.5]octan-4-one (56). Formation of 2-ethyl-3,5,5-trimethylcyclohexan-1-one (59), 2-ethylisophorone (60), and methyl 3,3,5-trimethyloctanoate (61)

Spirooctanone **56** (12) (208 mg, 1.86 mmol) was dissolved in methanol (31 mL) and irradiated through Pyrex. The gc analysis after 13 h showed the presence of unconsumed **56** (retention time 11.2 min, 54%), two major products (retention times 8.6 min (**59**; 19%) and 14.7 min (**61**; 14%)), and six minor products (1−4% each). Irradiation for a further 8 h (total 21 h) gave a mixture that contained **56** (48%), **59** (18%), **61** (17%), and seven minor products (1−5% each). The gc analysis on OV-17 on which the peaks of **56** and **60** do not overlap showed the presence of a minor component (8%), the retention time of which was identical to that of 2-ethylisophorone (**60**) (12, 20). The retention times of the major products were identical to those of 2-ethyl-3,5,5-trimethylcyclohexan-1-one (**59**) (12, 21) and of methyl-3,3,5-trimethyloctanoate (**61**), the major product formed on irradiation of **59** in methanol (*vide infra*). The photolysate from the irradiation of **56** was chromatographed on a 2-mm silica gel plate (20% ether in hexanes) to give an oil (R_f 0.62) that was shown by gc analysis to contain primarily the two major photoproducts. Comparison of the ir and ^{1}H nmr spectra of this oil with those of **59** and of the major product formed on irradiation of **59** confirmed the presence of **59** and **61**. A second band (R_f 0.48) was isolated and was shown by gc analysis and by ir and ^{1}H nmr spectroscopy to be unconsumed **56**. A third band (R_f 0.38) was shown by gc analysis and by ir and ^{1}H nmr spectroscopy to be primarily 2-ethylisophorone (**60**).

Irradiation of 59. Formation of 61

Ketone **59** (12, 21) (28.8 mg, 0.171 mmol; ir λ_{max}: 5.88 μm) was dissolved in methanol (3.0 mL) and irradiated through Pyrex. The gc analysis after 3 h showed the presence of a minor amount of unconsumed **59** (retention time 8.6 min) together with one major product (retention time 14.7 min). Evaporation of the solvent gave an oil having the following spectroscopic features corresponding to those assigned to **61** in the spectra of the mixture of **61** and **59** obtained from the photolysis of **56**: ir λ_{max}: 5.77 μm; ^{1}H nmr δ: 0.7−1.5 (m), 1.02 (s), 2.18 (s), 3.62 (s). The gc retention times of all of the minor products corresponded to those of minor products formed on photolysis of **56**.

The decomposition of NO, photosensitized by $Hg6^3P$ atoms, leads to N_2 and N_2O. The decomposition rate is enhanced by the silanes Me_2SiF_2 and $MeSiF_3$. A mechanism is proposed involving the formation of complexes of the silanes with electronically-excited NO.

T. N. BELL, G. SOTO-GARRIDO et A. G. SHERWOOD. Can. J. Chem. **61**, 946 (1983).

La décomposition du NO, photosensibilisée par des atomes de $Hg6^3P$, conduit au N_2 et au N_2O. Les silanes du type Me_2SiF_2 et $MeSiF_3$ augmentent la vitesse de décomposition. On propose un mécanisme qui implique la formation de complexes des silanes avec le NO excité électroniquement.

Introduction

The $Hg(6^3P_1)$ photosensitized decomposition of NO has been studied by several workers (1–5) and a mechanism proposed by Strausz and Gunning involves the formation of $^4\pi NO$ molecules (designated NO*) in the quenching reaction of Hg* with NO.

[1] $Hg + h\nu \rightarrow Hg^*$

[2] $Hg^* + NO \rightarrow NO^*$

[3] $NO^* + NO \rightarrow 2NO$

[4] $NO^* + NO \rightarrow N_2O_2^*$

[5] $N_2O_2^* \rightarrow N_2 + O_2$

[6] $N_2O_2^* + NO \rightarrow N_2O + NO_2$

Our interest in adding methyl fluoro silanes was to determine if collisions with $NO(^4\pi)$ would cause C—Si bond cleavage to yield fluorosilyl radicals. No evidence of such a photosensitized reaction was found. Instead, it was found that the silanes enhanced the decomposition of NO in forming N_2 and N_2O.

Experimental

A gas-circulating, closed reaction system was used, whereby the reactants were pumped over a pool of liquid Hg, held at 50°C through a condenser kept at 25°C, then through a reaction vessel made of Suprasil. The total volume of the circulatory reaction system was 238 mL and, of this, the 1 cm path-length reaction vessel had a volume of 36.6 mL. A low pressure mercury lamp was used to generate the 2537 Å resonance line. The 1849 Å resonance line was removed with a Vycor 7910 filter.

A conventional vacuum line, containing metering, dosing, and fractionating systems, was connected to the reaction system. Analyses were carried out by gas chromatography and mass spectrometry.

Reproducibility of results was obtained by washing the detachable cell with nitric acid, followed by thorough drying between each experimental run.

Materials

Nitric oxide, obtained from Matheson Company, was distilled at low pressure through a liquid-oxygen-cooled trap. $MeSiF_3$ and Me_2SiF_2, obtained from PCR Research Chemicals, Inc., were degassed and distilled, the reagents being collected at −160°C and −130°C, respectively. SiF_4, from Matheson Company, was degassed and distilled. The purified reagent was collected at −160°C.

Results

Initial experiments were carried out to determine the quenching cross section of $MeSiF_3$ for $Hg6^3P_1$ by the chemical method (6). These results indicated a quenching cross section too small for accurate measurement but certainly lower than the value of 0.19 Å^2 reported for Me_2SiF_2 (7).

Since the quenching cross section of NO for $Hg6^3P_1$ is 24.7 Å^2 (8), quenching of NO–silane mixtures will be predominantly by NO.

Quantitative measurements of product yields were restricted to N_2 and N_2O, since the other major product, NO_2, reacts with mercury to give involatile products.

Reaction times were chosen so that the extent of decomposition of NO was generally less than 1%, although up to 3% decomposition was necessary in runs with low NO concentrations.

The mercury photosensitized decomposition of *n*-butane–N_2O mixtures was used for actinometry (6).

In all cases, the reaction of NO–silane mixtures results in no measurable consumption of silane and no products additional to those formed in the NO/Hg systems.

The effect of light intensity is shown in Table 1. Quantum yields are, within experimental error, independent of light intensity.

Experiments were carried out to determine the effect of composition of the reaction mixture on the product quantum yields. The results are given in Table 2 for $MeSiF_3$–NO mixtures and in Table 3 for Me_2SiF_2–NO mixtures. Experiments were also done with SiF_4–NO mixtures but it appeared that the presence of SiF_4 had only a small effect on the yields of N_2O and N_2.

The data in Tables 2 and 3 show that the quantum yields of N_2 and N_2O increase markedly with increasing pressures of $MeSiF_3$ and Me_2SiF_2 for a fixed pressure of NO. When the silane is kept constant and NO increased, the quantum yield of N_2O decreases in both cases while that of N_2 increases markedly for Me_2SiF_2 and slightly for $MeSiF_3$.

The magnitude of these observed effects is such that the enhanced decomposition of NO caused by the silanes is in the order $Me_2SiF_2 > MeSiF_3 \gg SiF_4$.

Discussion

The data in Tables 1, 2, and 3 indicate that the quantum yields of N_2 and N_2O are markedly increased by the presence

of the silanes $MeSiF_3$ and Me_2SiF_2 but are unaffected by light intensity.

Strausz and Gunning (5), in their study of the $Hg(6^3P_1)$ + NO reaction, found that the sum of the quantum yields of N_2 and N_2O were independent of NO pressure in the complete quenching region. This observation clearly indicates that their mechanism, reactions [1] to [6], cannot also include the regeneration of NO from the excited dimer N_2O_2* by either a unimolecular dissociation or by reaction with NO.

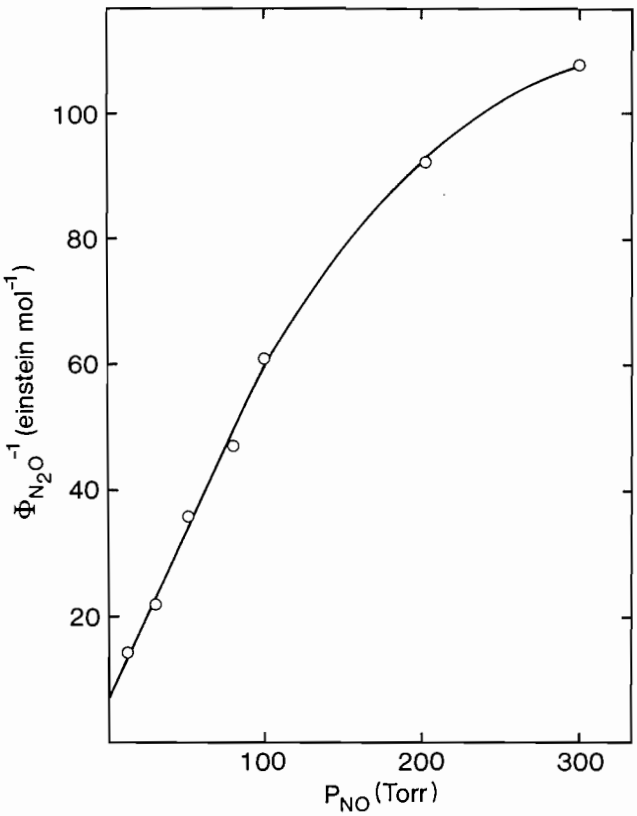

FIG. 3. Plot of reciprocal of quantum yield of N_2O vs. NO pressure. P_{MeSiF_3} = 100.2 Torr.

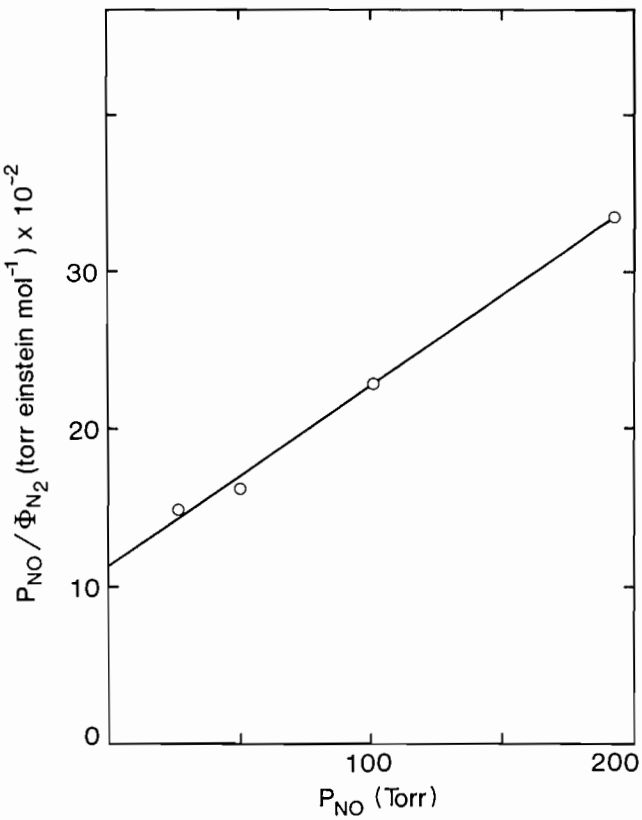

FIG. 4. Plot of P_{NO}/Φ_{N_2} vs. NO pressure. $P_{Me_2SiF_2}$ = 50.5 Torr.

The effect of added silanes cannot be a result of reaction of the silanes with N_2O_2* since this would not increase the yields of N_2 and N_2O. It seems likely that the silanes intervene in the mechanism through competition with reactions [3] and [4]. The data are consistent with an interpretation involving the formation of two different silane–NO complexes, each initiating a set of steps to yield one of the products of the reaction. The nature of these two complexes is conjectured upon later. They are designated SilNO† and SilNO†† in the proposed mechanism, where SilNO† leads to N_2 and SilNO†† leads to N_2O and where Sil represents either $MeSiF_3$ or Me_2SiF_2.

[7] $NO^* + Sil \rightarrow SilNO\dagger$

[8] $\rightarrow SilNO\dagger\dagger$

If these complexes are not interconvertible, their fates may be considered independently.

[9] $SilNO\dagger \rightarrow Sil + NO$

[10] $SilNO\dagger + NO \rightarrow Sil + N_2 + O_2$

[11] $SilNO\dagger + NO \rightarrow Sil + 2NO$

[12] $SilNO\dagger + Sil \rightarrow 2Sil + NO$

A steady state treatment of this mechanism yields the following expression for the quantum yield of N_2. The yield of N_2 by reaction [5] has been ignored because of the very low quantum yield for N_2 in the absence of silanes (5),

[*a*] $$\Phi_{N_2} = \frac{k_7k_{10}\,[Sil][NO]}{\{(k_3+k_4)[NO]+(k_7+k_8)[Sil]\}\{k_9+(k_{10}+k_{11})[NO]+k_{12}[Sil]\}}$$

The following reactions of the second complex are similarly considered.

[13] $SilNO\dagger\dagger \rightarrow Sil + NO$

[14] $SilNO\dagger\dagger + NO \rightarrow SilN_2O_2\dagger\dagger \xrightarrow{NO} Sil + N_2O + NO_2$

[15] $SilNO\dagger\dagger + NO \rightarrow Sil + 2NO$

[16] $SilNO\dagger\dagger + Sil \rightarrow 2Sil + NO$

A steady state treatment of these steps yields the following expression.

[*b*] $$\Phi_{N_2O} = \frac{k_8k_{14}\,[Sil][NO]}{\{(k_3+k_4)[NO]+(k_7+k_8)[Sil]\}\{k_{13}+(k_{14}+k_{15})[NO]+k_{16}[Sil]\}}$$

Tables 2 and 3 indicate differences between the effects of $MeSiF_3$ and Me_2SiF_2; thus, the two compounds are discussed separately.

$MeSiF_3$

The dependence of product quantum yields on reactants given in Table 2 requires modification to the above derived rate equations for Φ_{N_2} and Φ_{N_2O}. When the total data are considered together, the terms which must be dropped in order to fit the quantum yields to consistent and complementary kinetic schemes are self-selective.

Thus, $(k_7 + k_8)$[Sil] must be neglected in eq. [*a*] relative to $(k_3 + k_4)$[NO] and $(k_{10} + k_{11})$[NO] must be $\ll k_9 + k_{12}$[Sil]. These considerations reduce the equation for Φ_{N_2} to

$$\Phi_{N_2} = \frac{k_7k_{10}}{(k_3+k_4)}\,\frac{[Sil]}{(k_9+k_{12}[Sil])}$$

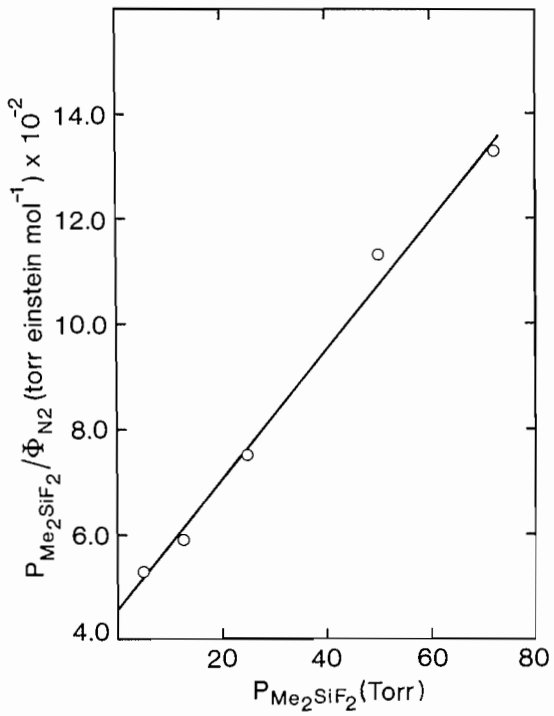

FIG. 5. Plot of $P_{Me_2SiF_2}/\Phi_{N_2}$ vs. Me_2SiF_2 pressure. P_{NO} = 100.7 Torr.

from which

$$\Phi_{N_2}^{-1} = \frac{(k_3 + k_4)}{k_7 k_{10}}\left(\frac{k_9}{[Sil]} + k_{12}\right)$$

As can be seen from Fig. 1, a plot of $\Phi_{N_2}^{-1}$ vs. $P_{MeSiF_3}^{-1}$ is a straight line and from the slope and intercept

$$k_9/k_{12} = 6.5 \times 10^{-3} \text{ mol L}^{-1}$$

The main fate of NO* is its deactivation to NO, both in the presence and absence of silane.

Since the conclusion that $(k_3 + k_4)[NO] \gg (k_7 + k_8)[Sil]$ has already been made in the $MeSiF_3$–NO system, the equation for Φ_{N_2O} is reduced to

$$\Phi_{N_2O} = \frac{k_8 k_{14}}{(k_3 + k_4)} \frac{[Sil]}{\{k_{13} + (k_{14} + k_{15})[NO] + k_{16}[Sil]\}}$$

A plot of Φ_{N_2O} vs. P_{MeSiF_3}, at constant P_{NO} (Fig. 2), is a straight line with zero intercept which indicates that $k_{16}[Sil]$ is negligible and so

$$\Phi_{N_2O} = \frac{k_8 k_{14}}{(k_3 + k_4)} \frac{[Sil]}{\{k_{13} + (k_{14} + k_{15})[Sil]\}}$$

or

$$\Phi_{N_2O}^{-1} = \frac{(k_3 + k_4)}{k_8 k_{14}} \frac{k_{13} + (k_{14} + k_{15})[NO]}{[Sil]}$$

Figure 3 shows that $\Phi_{N_2O}^{-1}$ is a linear function of P_{NO} at low pressures of NO. The fall-off of the graph at high NO pressures indicates that, as P_{NO} is increased beyond about 150 Torr, the yield of N_2O from reaction [6] becomes a significant source of N_2O which was not considered in the derivation of the equation for Φ_{N_2O}.

From the values of slope and intercept from Fig. 3 we have

$$\frac{k_{14} + k_{15}}{k_{13}} = 1.1 \times 10^3 \text{ mol L}^{-1}$$

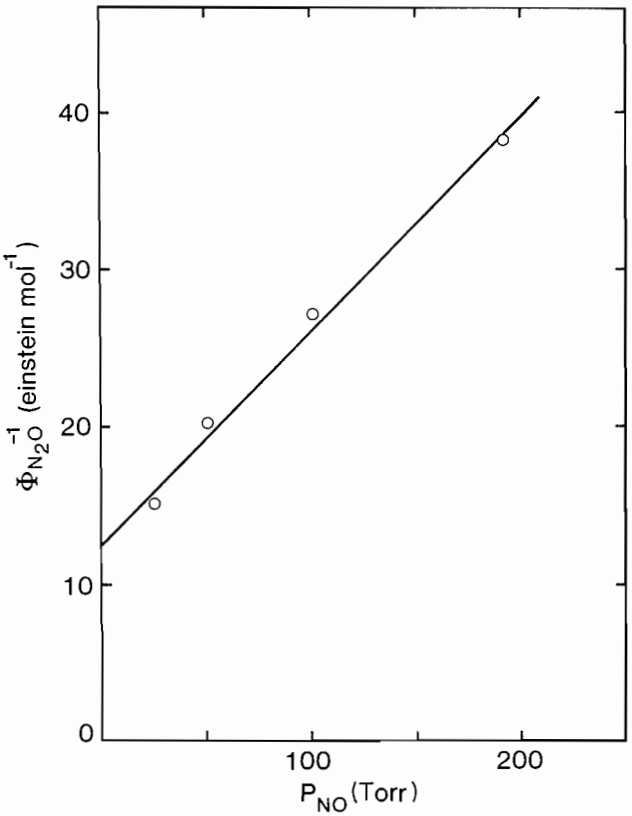

FIG. 6. Plot of reciprocal of quantum yield of N_2O vs. NO pressure. $P_{Me_2SiF_2}$ = 50.5 Torr.

Me_2SiF_2

In the case of Me_2SiF_2, there is a distinct dependence of Φ_{N_2} on the NO pressure. This would suggest that, in this case, $(k_7 + k_8)[Sil]$ is not negligible, compared with $(k_3 + k_4)[NO]$. Both terms are thus retained in the kinetic expression.

Retaining our arguments that $k_9 + k_{12}[Sil] \gg (k_{10} + k_{11})[NO]$ leads to a kinetic expression in agreement with experiment, provided $k_{12}[Sil]$ is sufficiently small and can be neglected relative to k_9; i.e., unimolecular dissociation of SilNO† is much faster than collisional deactivation by silane.

Thus, the expression for Φ_{N_2} becomes

$$\Phi_{N_2} = \frac{k_7 k_{10}[Sil][NO]}{k_9\{(k_3 + k_4)[NO] + (k_7 + k_8)[Sil]\}}$$

or

$$\frac{[NO]}{\Phi_{N_2}} = \frac{k_9}{k_7 k_{10}}\left\{(k_3 + k_4)\frac{[NO]}{[Sil]} + (k_7 + k_8)\right\}$$

A plot of P_{NO}/Φ_{N_2} versus P_{NO} at constant $P_{Me_2SiF_2}$ is a straight line and is shown in Fig. 4.

The appropriate equation for the dependence of Φ_{N_2} on [Sil] is

$$\frac{[Sil]}{\Phi_{N_2}} = \frac{k_9}{k_7 k_{10}}\left\{(k_3 + k_4) + (k_7 + k_8)\frac{[Sil]}{[NO]}\right\}$$

A plot of $P_{Me_2SiF_2}/\Phi_{N_2}$ vs. $P_{Me_2SiF_2}$ is a straight line and is shown in Fig. 5.

The formation of N_2O in the Me_2SiF_2/NO case must be in accord with the requirement for N_2 formation; i.e., $(k_7 + k_8)[Sil]$ is not negligible relative to $(k_3 + k_4)[NO]$.

The kinetic data then will fit with a kinetic expression, where

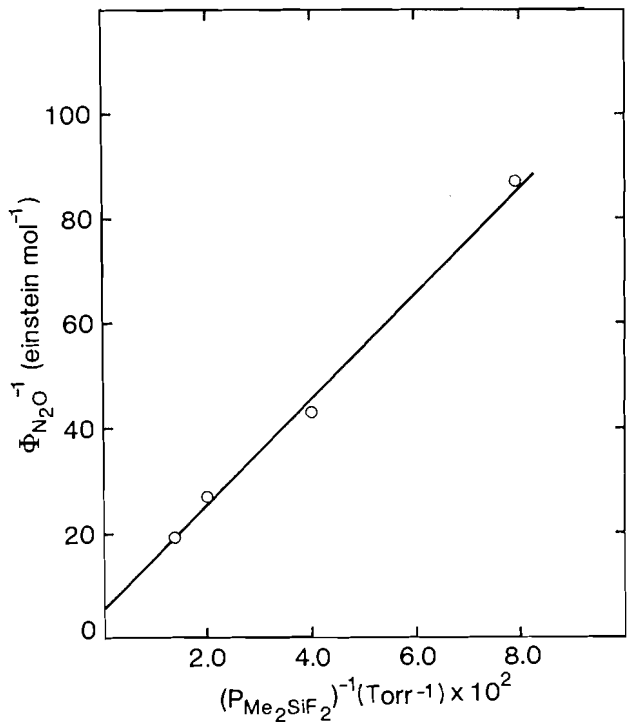

FIG. 7. Plot of reciprocal of quantum yield of N_2O vs. reciprocal of Me_2SiF_2 pressure. P_{NO} = 100.7 Torr.

deactivation and product formation via [15] and [14] are more important than the unimolecular decomposition of SilNQ††.

In such a case, the kinetic expression becomes

$$\Phi_{N_2O} = \frac{k_8 k_{14}[\text{Sil}]}{(k_{14} + k_{15})\{(k_3 + k_4)[\text{NO}] + (k_7 + k_8)[\text{Sil}]\}}$$

and

$$\Phi_{N_2O}^{-1} = \frac{k_{14} + k_{15}}{k_8 k_{14}}\left\{(k_3 + k_4)\frac{[\text{NO}]}{[\text{Sil}]} + (k_7 + k_8)\right\}$$

Figure 6 indicates that the plot of $\Phi_{N_2O}^{-1}$ vs. P_{NO}, at constant $P_{Me_2SiF_2}$, is linear, in agreement with the above expression.

Figure 7 is a plot of $\Phi_{N_2O}^{-1}$ vs. $P_{Me_2SiF_2}^{-1}$. It is also linear. The datum point for the lowest value of $P_{Me_2SiF_2}$ is not plotted. It lies far beyond the portion of the graph shown and the value of Φ_{N_2O} would be considerably larger than would be given by the straight line. Again, we conclude this is due to the increased importance of reaction [6] as a source of N_2O at low Me_2SiF_2 pressures.

Values of the ratio $(k_7 + k_8)/(k_3 + k_4)$ can be obtained from the slopes and intercepts of the four graphs of data from the Me_2SiF_2–NO system. The values are 2.0, 2.8, 1.8, and 0.5, respectively. The low value is derived from Fig. 7 and is the most uncertain, due to the small value of the intercept.

The mechanism proposed involves the formation of two non-interconvertible complexes of NO with silane.

If the reactive NO species were simply a vibrationally excited ground electronic state molecule, we would expect strong collisional deactivation with all species and it is hard to envisage vibrational deactivation together with complex formation. Further, we would anticipate interconversion of SilNO† and SilNO†† through the vibrational cascade, not in accord with the experimental kinetics.

We find the idea of a complex with $^4\pi$NO much more appealing and in line with the Strausz–Gunning proposal for the Hg-sensitized decomposition of NO itself. The $^4\pi$ state of NO lies 108 kcal above the ground state (9), permitting maximum vibrational excitation to $v = 1$; hence the two complexes must be structurally, rather than energetically, different.

The ability of Si to expand its coordination number to five, through the use of *d* orbitals, accounts for much of its chemistry different to that of carbon. In the present instance, we propose the two complexes are formed through Si—N and Si—O bonding; viz., Si—N—O and Si—O—N. We do not, however, conjecture which one leads to N_2 and which to N_2O.

Theoretical calculation by P. G. and K. A. Perkins[1] has indicated that, indeed, a minimum of the potential energy does occur in the interaction of silanes with NO in the ground state. This minimum of the potential lies between 3.0 and 3.5 angstroms separation distance. The complexes Si—N—O, for SiF_4, $MeSiF_3$, and Me_2SiF_2, lie energetically 2.7, 2.5, and 2.7 kcal below the ground state molecules, while the Si—O—N systems are 3.0, 3.4, and 4.5 kcal, respectively, below the ground state molecules.

In the quartet state, the only estimates available at this time are that SiF_4—NO lies 1.6 and SiF_4—ON 2.6 kcal below the separated molecules SiF_4 and $^4\pi$NO.[2]

Conclusions

The same mechanism yields rate equations in accord with experiment for the $MeSiF_3$—NO and the Me_2SiF_2—NO cases. Differences are due to differences in values of the rate constants.

The reactions in which the complexes are formed, reactions [7] and [8], are faster in the Me_2SiF_2 case. Indeed, they appear competitive with the deactivation reaction [3].

In both cases, a small fraction of the SilNO† complexes react to form N_2. Most dissociate to re-form Sil and NO. In the $MeSiF_3$ case, deactivating collision with Sil is also important.

Deactivation of SilNO†† by collision with Sil is of negligible importance in both the $MeSiF_3$ and Me_2SiF_2 cases. In the $MeSiF_3$ case, unimolecular dissociation to yield Sil + NO competes with reactions with NO, i.e., reactions [14] and [15]. In the Me_2SiF_2 case, the most important reactions of SilNO†† are those with NO. The data do not provide an estimate of the relative importance of [14] and [15] but [15] must be significant since, even in the Me_2SiF_2 case, where complex formation competes with the reaction [3], the quantum yield of N_2O is small.

Rotational relaxation of the $A^1\pi(v' = 13, J' = 13^+)$ state of $^{13}C^{16}O$ by various gases[1]

A. C. VIKIS[2]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received July 13, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

A. C. VIKIS. Can. J. Chem. **61**, 952 (1983).

Rotational relaxation of the $A^1\pi$ ($v' = 13, J' = 13^+$) state of $^{13}C^{16}O$ was studied in the presence of H_2, D_2, He, Ne, Ar, Xe, N_2, CO, $^{13}C^{16}O$, and $^{12}C^{18}O$. The rotational relaxation cross sections $\Sigma\sigma_{13\to J'}$, in $cm^2 \times 10^{16}$ and in the above order, were: 19 ± 1, 27 ± 1, 23 ± 1, 32 ± 1, 55 ± 2, 14 ± 1, 43 ± 3, 69 ± 5, 23 ± 1, and 100 ± 15. The rotational relaxation probabilities per gas-kinetic collision correlate with the square root of the reduced mass, except for Xe and the CO isotopic molecules. The latter molecules have several electronic states accessible at this energy. Their rotational relaxation cross sections depend on the magnitude of their respective electronic quenching cross sections, in a manner indicating preemption by fast electronic–electronic energy transfer.

A. C. VIKIS. Can. J. Chem. **61**, 952 (1983).

On a étudie la relaxation vibrationnelle de l'état $A^1\pi$ ($v' = 13, J' = 13^+$) du $^{13}C^{16}O$ en présence des gaz suivants: H_2, D_2, He, Ne, Ar, Xe, N_2, CO, $^{13}C^{16}O$ et $^{12}C^{18}O$. Les sections droites de relaxation vibrationnelle $\Sigma\sigma_{13\to J'}$ en $cm^2 \times 10^{16}$ sont, dans l'ordre des gaz mentionnés ci-dessous: 19 ± 1, 27 ± 1, 23 ± 1, 32 ± 1, 55 ± 2, 14 ± 1, 43 ± 3, 69 ± 5, 23 ± 1 et 100 ± 15. On a établi une corrélation entre les probabilités de relaxation rotationnelle par collision cinétique des gaz et la racine carrée de la masse réduite, sauf pour les molécules isotopiques de Xe et de CO. Ces dernières molécules ont plusieurs état électroniques accessibles à ce niveau d'énergie. Les sections droites de relaxation vibrationnelle dépendent de l'ordre de grandeur de leurs sections droites respectives de piégeage électronique d'une façon qui suggère une élimination préalable par transfert rapide d'énergie électronique–électronique.

Introduction

Energy transfer from excited molecules in collisions with other molecules has been studied extensively because of the importance of such processes in chemical reactions and in lasers. Experimental and theoretical results have been summarized in several review articles (1–5) and in the books by Herzfeld and Litowitz (6) and Cottrell and McCoubrey (7). The bulk of the early data were obtained for ground electronic states, using techniques which yielded cross sections averaged over several vibrational and rotational states. Selective excitation of single molecular states can be achieved with monochromatic radiation from lasers or intense atomic resonance-lamps. Energy transfer from a selected state to others, monitored spectroscopically, can yield detailed cross sections which can be compared more easily with theoretical predictions. State detailed experiments (8–14) provided valuable information on how the dynamics and kinematics of the colliding pair affect the efficiency of energy transfer, and on how interconversion of energy among the various degrees of freedom occurs.

In this work the rotational relaxation of the $J' = 13^+$ state of $^{13}C^{16}O(A^1\pi, v' = 13)$ was studied in the presence of various gases. Selective excitation of this state, using sharp and unreversed radiation (123.58 nm) emitted by a krypton resonance-lamp, was demonstrated in a previous study (15). This fortuitous coincidence was used to enrich carbon-13 in the CO_2 and C_3O_2 products of the reaction of excited $^{13}C^{16}O$ with ground state CO (16, 17). Energy transfer from this state was studied for its own merits and also to assess the extent of destruction of the initial isotopic selectivity in the presence of high pressures of natural isotopic abundance CO, needed for practical reaction yields.

The electronic relaxation data for this state have already been reported in the literature (18). Even though $^{13}C^{16}O$ was also vibrationally excited, no detectable vibrational relaxation was observed due to the low cross sections for this process and the short lifetime (<10 ns) of the state with respect to emission and electronic quenching. Rotational relaxation cross sections were determined from measurements of the emission intensities of the parent $J' = 13^+$ state and the J' states populated by collisions with other molecules.

Experimental

The spectroscopic apparatus employed in this work was described elsewhere (15). Light source #2 (15) which emitted sharp and unreversed Kr resonance radiation (123.58 nm) was used. This radiation was absorbed selectively by the Q(13) transition of the $^{13}C^{16}O$ $A-X$ (13,0) band populating the $J' = 13^+$ component of the Λ-type doublet. The $A-X$ (13,21) band fluorescence at 237 nm was monitored in these experiments.

In the absence of rotational relaxation, selection rules applicable to this system (19) allow only a single Q(13) transition to be observed in fluorescence. Resolution of the Q(13) fluorescence from the relaxed fluorescence could be achieved with a spectrometer band width of 0.08 nm (Fig. 1). The ratio of the unrelaxed to the relaxed populations, $N(13^+)/\sum_{J'\neq 13^+} N(J')$, is equal to $2.0I_{Q(13)}/(\sum_{J'\neq 13^+} I(J') + 4.2I_{P(14)} + 3.9I_{R(12)}$, where the factors 2.0, 4.2, and 3.9 correspond to the degeneracy $(2J' + 1)$ divided by the rotational line strengths, $S_{J'}$, of the Q, P, and R transitions, respectively. In the present experiments the P(14) and R(12) transitions are not resolved from the rest ($J' \neq 13$) of the relaxed states. Therefore, the ratio $N(13^+)/\sum_{J'\neq 13^+} N(J')$ is approximated with $2.0I_{Q(13)}/\int_{J'\neq 13^+} I(J')$, where the denominator is the integrated intensity from all J' states except $J' = 13^+$. This approximation does not introduce a significant error because the intensities of the P(14) and R(12) transitions are not a significant

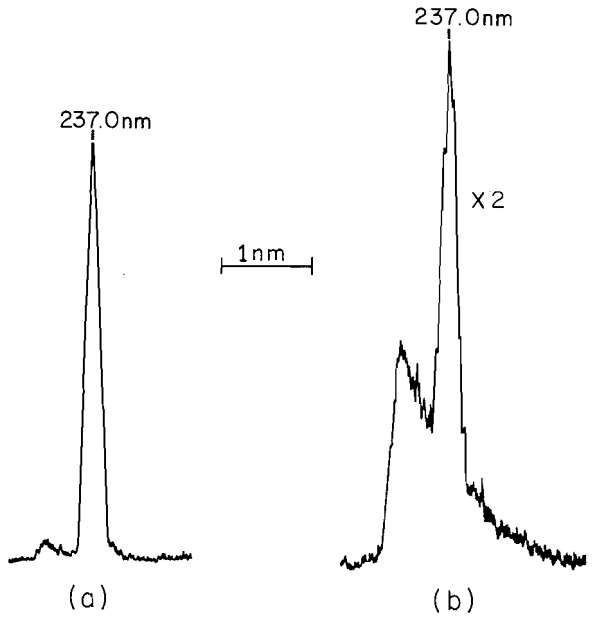

FIG. 1. (*a*) The $^{13}C^{16}O$ $A-X$ (13,21) band in the presence of 69 Pa $^{13}C^{16}O$, only; (*b*) the $^{13}C^{16}O$ $A-X$ (13,21) band in the presence of 69 Pa $^{13}C^{16}O$ and 2.5 kPa Ne.

fraction of the total relaxed intensity. It is shown later in this paper that the relaxed population of the $J' = 13$ state is ~12% of the total relaxed population. Also, within the narrow frequency range of the spectrum, corrections for the frequency dependence of emission and for the spectral response of the equipment were negligible.

The various gases and their purity, according to the manufacturer, were: Merck, Sharpe and Dohme ^{13}CO (92 atom% ^{13}C); Stohler Isotope Chemicals $C^{18}O$ (99 atom% ^{18}O); Matheson research grade CO (99.99% minimum), H_2 (99.9995%), He (<2 ppm impurities), Xe (99.9995% minimum); Airco research grade Ne (27 ppm He, <2 ppm of other impurities), Ar (<2 ppm impurities), N_2 (<2 ppm impurities); Bio-Rad D_2 (99.65 mol% D_2), N_2 (<24 ppm, O_2 <1 ppm).

In each experiment the partial pressure of $^{13}C^{16}O$ was kept constant at 66.7 ± 1.3 Pa. The various gases were added from their reservoirs to $^{13}C^{16}O$ through a needle valve. Pressures in the 0–133 Pa range were measured with an MKS (type-77 Baratron) pressure gauge. Higher pressures (up to 1.33 kPa) were measured with a Wallace and Tiernan mechanical pressure gauge.

Results

A higher resolution spectrum of the (13,21) emission band, obtained in the presence of 2.15 kPa of He, is shown in Fig. 2. Emission from J' levels other than $J' = 13^+$ was observed under these conditions. These levels were populated by both positive and negative $\Delta J'$ transitions. P and Q transitions originating from $J' > 12$ were sufficiently resolved to derive their relative population. The population of the rest of the rotational levels was obtained by computer simulation of the spectrum. The triangular distribution, shown in the insert of Fig. 2, seems to fit best the observed spectrum in this case.

From comparison of computed and observed spectra, it was concluded that all P, Q, and R transitions originating from relaxed levels are present, i.e., that collisions transfer molecules from the originally populated positive level of the $J' = 13^+$ Λ-type doublet to both positive and negative components of the other J' states. If an optical-like selection rule (+ ↔ −, + ↔ +, − ↔ −) (19) were obeyed in this collisional energy transfer case, no odd-numbered P, Q, and R transitions would have been observed except for Q(13). Transitions originating from P(21), P(19), P(17), P(15) + Q(19), and P(13) + Q(17) are well resolved and definitely present in the spectrum of Fig. 2. Optical-like propensities have been observed in other cases of rotational energy transfer (10).

Because of insufficient resolution, detailed cross sections, $\sigma_{13\to J'}$, were not determined. Instead, rotational relaxation cross sections, $\sigma_R = \sum\sigma_{13\to J'}$, were determined from the Q(13) intensity relative to the total intensity of the rest of the band, as a function of foreign-gas pressure. The steady-state ratio of the unrelaxed population ($J' = 13^+$, shown below by CO*) divided by the relaxed population ($J' \neq 13^+$, shown by CO′), as a function of foreign gas, M, was derived from the following mechanism:

[1] $CO + h\nu(\lambda = 123.58\ nm) \rightarrow CO^*$

[2] $CO^* + CO \rightarrow CO' + CO$

[3] $CO^* + CO \rightarrow$ electronic quenching products

[4] $CO^* + M \rightarrow CO' + M$

[5] $CO^* + M \rightarrow$ electronic quenching products

[6] $CO' + CO \rightarrow$ electronic quenching products

[7] $CO' + M \rightarrow$ electronic quenching products

[8] $CO^* \rightarrow CO + h\nu^*$ (unrelaxed emission)

[9] $CO' \rightarrow CO + h\nu'$ (relaxed emission)

In the above mechanism chemical reaction and electronic quenching to the ground and/or other electronic states were grouped together.

Repopulation of the unrelaxed state, due to collisional transfer from relaxed states (the reverse of [2] and [4]) was neglected in this analysis. If this effect were significant, rotational relaxation would be underestimated. An upper limit to the fraction of population of the unrelaxed state, which could be attributed to transfer from relaxed states, can be estimated from the relative populations of unrelaxed vs. relaxed states and the population distribution in the relaxed state. From the relaxed state population distribution given in Fig. 2 (triangular distribution in insert), the relaxed population for $J' = 13$ is ~10% of the total relaxed population. For the same experiment, the ratio of unrelaxed to total relaxed population calculated from the quenching curve is equal to 0.8. Thus, not more than ~12% of the population of the unrelaxed state can be attributed to transfer from relaxed states. This estimate is an upper limit, because a fraction of the relaxed population of $J' = 13$ is due to transfer from the unrelaxed component of the Λ-type doublet. At lower pressures, where the majority of data were obtained, collisional repopulation of the unrelaxed state would be even less important.

The steady-state ratio [CO*]/[CO′], derived from this mechanism, is:

$$[10]\quad [CO^*]/[CO'] = (1/\tau + k_6[CO] + k_7[M])/(k_2[CO] + k_4[M])$$

where τ is the radiative lifetime of the $A^1\pi$ state. With the exception of Xe, eq. [10] can be approximated by eq. [11] at the low and constant [CO] used in these experiments.

$$[11]\quad [CO^*]/[CO'] = k_7/k_4 + (1/\tau + k_6[CO])/k_4[M]$$

For Xe, $k_7[M] \sim (1/\tau + k_6[CO])$ and $k_4[M] \sim k_2[CO]$; therefore, the Xe data were fitted to eq. [10].

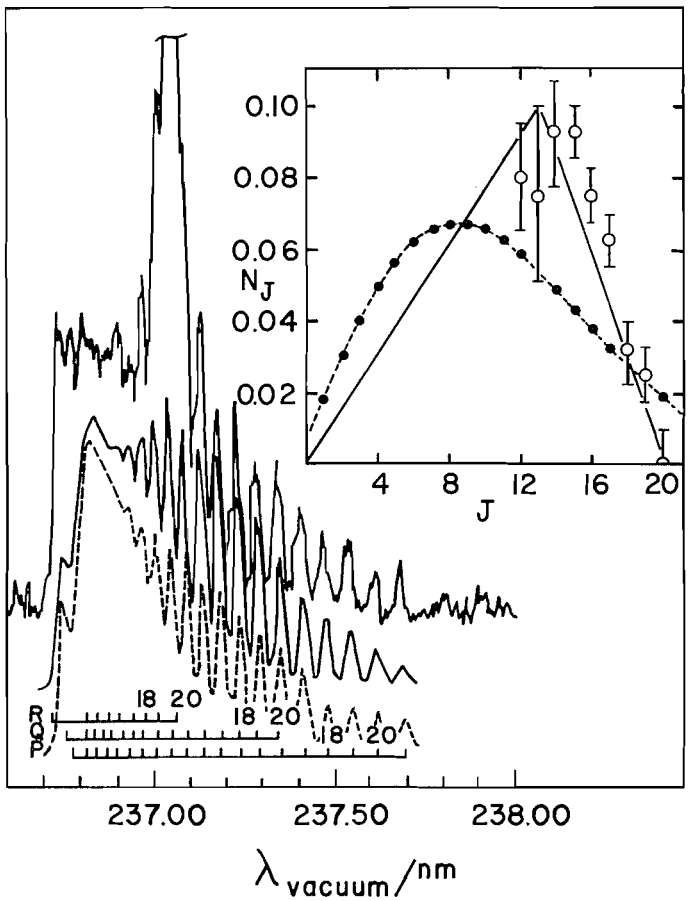

FIG. 2. The $^{13}C^{16}O$ $A-X$ (13,21) band (upper spectrum) at higher resolution in the presence of 190 Pa $^{13}C^{16}O$ and 2.1 kPa He. The insert gives the rotational population distribution for: (*a*) ○, determined from peak heights of resolved rotational transitions (upper spectrum); (*b*) —, corresponding to middle computed spectrum; (*c*) ·-·-·-·, Boltzmann distribution (T = 300 K) corresponding to lower computed spectrum.

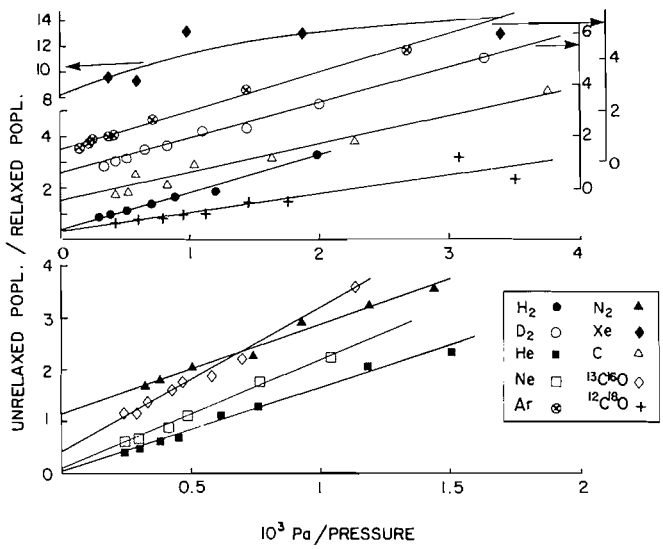

FIG. 3. Linear least-squares fits of rotational relaxation data for various molecules.

Graphs of [CO*]/[CO′] vs. $[M]^{-1}$ are shown in Fig. 3 for the various gases studied. The rotational relaxation rate constant, k_4, was determined from the slopes, $(1/\tau + k_6[CO])/k_4$, of these plots using τ = 10 ns and $k_6 = 7.83 \times 10^{11}$ dm^3 mol^{-1} s^{-1} (18).[3] The rotational relaxation cross sections, defined as $\sigma_R = k_4/\bar{c}$, are given in Table 1. The "hard-sphere" collision cross sections, $\sigma_{HS} = \pi\sigma^2_{CO^*-M}$, are also listed in Table 1 for comparison. Lennard–Jones potential parameters (22) derived from gas-viscosity data were used for σ_{CO^*-M}, assuming that $\sigma_{CO^*-M} = (\sigma_{CO^*} + \sigma_M)/2$. The σ_{CO^*} was approximated (9) with $\sigma_{CO} + \Delta r$, where Δr = 0.025 nm is the difference in bond lengths between the $X^1\Sigma^+$, v'' = 0 and $A^1\pi$, v' = 13 states of CO. Rotational relaxation probabilities, σ_R/σ_{HS}, are given in column 4 of Table 1 and are also plotted in Fig. 4 against the square root of the reduced mass of the CO*–M collision pair.

TABLE 1. Rotational relaxation (σ_R) and hard sphere (σ_{HS}) cross sections for $^{13}C^{16}O$ ($A^1\pi$, v' = 13, J' = 13$^+$) and various gases*

Molecule	σ_R (cm^2 × 10^{16})	σ_{HS} (cm^2 × 10^{16})	σ_R/σ_{HS}	$\mu^{1/2}$ (g$^{1/2}$ mol$^{-1/2}$)
H_2	19±1	38	0.50	1.37
D_2	27±1	38	0.71	1.87
He	23±1	34	0.67	1.87

N_2	43±3	47	0.93	3.77
Ar	55±2	43	1.3	4.10
Xe	14±1	52	0.27	4.87
CO	69±5	47	1.5	3.77
$^{13}C^{16}O$	23±1	47	0.48	3.81
$^{12}C^{18}O$	100±15	47	2.1	3.84

*The errors correspond to one standard deviation.

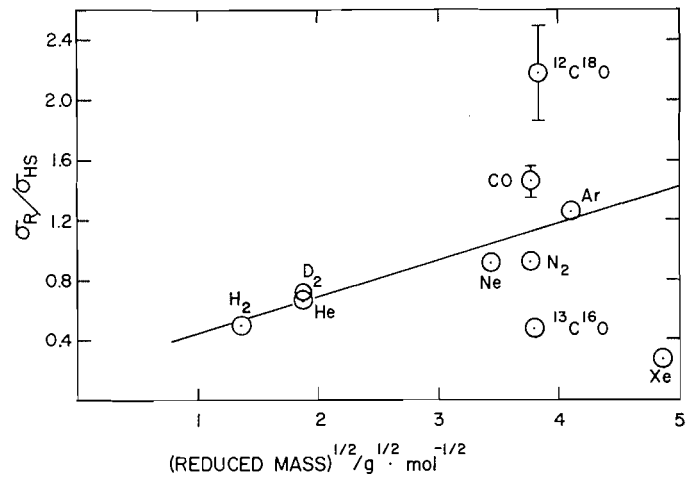

FIG. 4. Rotational relaxation probabilities ($\propto \sigma_R/\sigma_{HS}$) plotted against the square root of the reduced mass for the system $^{13}C^{16}O$ ($A^1\pi$, v' = 13, J' = 13) – various gases.

Discussion

In general the rotational relaxation cross section observed for $^{13}C^{16}O$ ($A'\pi$, v' = 13, J' = 13$^+$) are large, indicating an efficient energy-transfer process. This is in line with other experimental and theoretical evidence (6–9, 11, 14) on rotational ↔ translational energy transfer when the energy to be transferred is of the order of, or less than, kT.

[3]The natural lifetime of the $A^1\pi$, v' = 13 state of $^{13}C^{16}O$ has not been determined. The natural lifetime of the first seven vibrational levels of the $^{12}C^{16}O$ ($A^1\pi$) state varies from 9.0 ns to 10.5 ns (20, 21). Due to these uncertainties a natural lifetime of 10 ns was assumed.

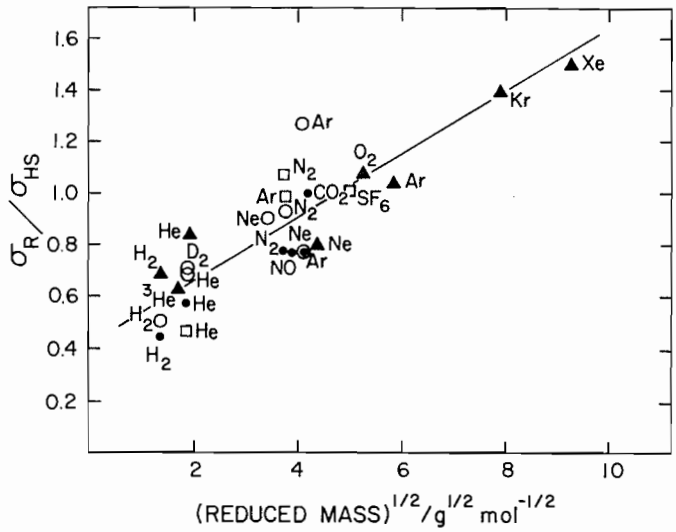

FIG. 5. Rotational relaxation probabilities ($\propto \sigma_R/\sigma_{HS}$) plotted against the square root of the reduced mass for the systems: ○, $^{13}C^{16}O$ ($A^1\pi$, $v' = 13$, $J' = 13$) − M; □, NO ($X^2\pi$, $v'' = 12$, $J'' = 2$) − M; ●, NO ($A^2\Sigma^+$, $v' = 1$, $K' = 13$) − M; ▲, I_2 ($B^3\pi_{0u^+}$, $v' = 25$, $J' = 34$) − M.

Also, for collisions between molecules which interact weakly and when $\Delta E \lesssim kT$ the rotational translational energy transfer probability varies proportionally with the square root of the reduced mass (9, 11). This mass effect was attributed (9, 23) to the relative momentum ($\bar{p} = \mu v \propto \mu^{1/2}$) of the collision. With the exception of Xe and the CO isotopic molecules, which are discussed below, the rest of the molecules studied conform well with this trend. Subtle changes in the dynamics (potential energy) of the collision are apparently unimportant, as far as the total rotational relaxation cross section is concerned. This is evidenced by the close similarity in both trend and magnitude (Fig. 5) between the present data and those for I_2 ($B^3\pi_{0u^+}$, $v' = 25$, $J' = 34$) (9), NO ($X^2\Sigma^+$, $v' = 1$, $K' = 13$) (8), and NO ($X^2\pi$, $v'' = 2$, $J'' = 10\frac{1}{2}$) (14).

The rather low cross section by Xe and the large variation between the cross sections by the three CO isotopic molecules are prominent. These molecules have electronic states accessible at this energy. Transfer from the $A^1\pi$ state to another electronic state can compete with rotational relaxation within the $A^1\pi$ state rotational manifold. Efficient electronic energy transfer to Xe ($^1P_1$, $^3P_{0,1,2}$) states must be the reason for the much larger electronic-quenching cross section by Xe (1.4×10^{-14} cm^2) (18) compared to the one by Ar (3.23×10^{-16} cm^2) (18). Argon has no accessible electronic states at this energy. Large electronic-quenching cross sections by Xe were also observed (24, 25) for the $A^1\pi$ state of $^{12}C^{18}O$ ($v' = 9$), $^{12}C^{16}O$ ($v' = 9$), and $^{12}C^{16}O$ ($v' = 14$). The Xe electronic-quenching cross sections for these states, compared to those by Kr given in parentheses, in the above order were: 110 (42), 91 (23), 170 (23) (cm$^2 \times 10^{16}$). Krypton has no electronic states accessible at these energies.

The variation of the rotational relaxation cross sections by the CO isotopic molecules must also be due to competition between rotational relaxation and electronic quenching. The electronic-quenching cross sections of the $^{13}C^{16}O$ ($A^1\pi, v' = 13$, $J' = 13$) state (18) (compared to the rotational ones given in parentheses) by $^{12}C^{16}O$, $^{13}C^{16}O$, and $^{12}C^{18}O$ are 57 (69), 198 (23), 38 (100) cm$^2 \times 10^{16}$, respectively. Preemption of the rotational relaxation channel by the more efficient electronic-quenching channel is most evident in the $^{13}C^{16}O$ case. The variation in the electronic-quenching cross sections which is assumed responsible for the rotational relaxation anomalies, was attributed (18) to electronic−electronic energy transfer processes from the $A^1\pi$ state to one or more of the electronic states ($A^3\pi$, $a'^3\Sigma^+$, $d^3\Delta_i$, $e^3\Sigma^-$, $I^1\Sigma^-$, $D^1\Delta$) accessible at this energy (26). Transfer of the system to another potential energy surface would depend on the symmetry of the states involved and on resonance (19). The latter depends heavily on isotopic substitution. Other large variations in electronic energy transfer involving isotopic combinations of the $A^1\pi$ state of CO have been observed (24, 25, 27) and support the above argument.

Reaction topology of excited state potential energy hypersurfaces

PAUL G. MEZEY

Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received July 13, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

PAUL. G. MEZEY. Can. J. Chem. **61**, 956 (1983).

Topology ("rubber geometry") is an exceptionally suitable mathematical framework for a global quantum chemical description of the fundamental relations between nonrigid molecular systems, chemical reactions, and many photochemical processes. In Reaction Topology the concept of nuclear geometry is replaced by open subsets of an abstract nuclear configuration space ^{n}R. The ground and various excited state energy expectation value functionals induce a sequence of topologies in the nuclear configuration space ^{n}R, leading to a consistent topological description of molecular structure, excimers, exciplexes, and reaction mechanisms. Utilizing earlier results on topological properties of the abstract nuclear charge space ^{n}Z, a theorem is proven on the ordering of excited state potential energy hypersurfaces for sequences of isoelectronic molecules.

PAUL. G. MEZEY. Can. J. Chem. **61**, 956 (1983).

La topologie ("géométrie de caoutchouc") est un cadre mathématique exceptionnellement adéquat pour une description de la chimie quantique globale des relations fondamentales entre les systèmes moléculaires non rigides, les réactions chimiques et plusieurs processus photochimiques. Dans la topologie des réactions, on remplace le concept de géométrie nucléaire par des sous ensembles ouverts de configurations spaciales nucléaires abstraites, ^{n}R. Les valeurs fonctionnelles attendues pour les énergies de l'état fondamental et de divers états excités induisent une suite de topologie dans les configurations spatiales nucléaires, ^{n}R, conduisant à une description topologique cohérente de la structure moléculaire, des excéplex et des mécanismes de réaction. Utilisant des résultats antérieurs sur les propriétés topologiques de charge spatiale nucléaire abstraite, ^{w}Z, on démontre un théorème sur la façon d'ordonner les hypersurfaces d'énergie potentielle des états excités pour des séquences de molécules isoélectroniques.

Introduction

In most experimental and theoretical studies on photochemical processes the investigation is usually restricted to small domains of selected potential energy surfaces, and relatively little is known about the global properties of the corresponding energy expectation value functionals. There are good reasons for this. On the one hand, it is difficult to obtain reliable experimental information on molecular conformations which lie far from the equilibrium nuclear configurations. On the other hand, theoretical calculations of reasonably complete potential energy hypersurfaces are extremely costly even for the smallest of molecules. There is, however, a continuous and rather spectacular progress in computing capabilities where, significantly, it is the software development which lags behind the development of computer hardware. Without a doubt, the accelerating development of computing capabilities is expected to continue, paving the way for global analyses of potential surfaces of more and more complex molecules. Meanwhile, advanced mathematical methods which may simplify the global analysis are also expected to find more applications. Most advanced of the geometrical models is the theory of the intrinsic reaction coordinate, developed by Fukui (1,2), and Tachibana and Fukui (3,4). The intrinsic reaction coordinate represents the link between earlier geometrial models and the topological model discussed in the present study.

In recent years several studies have been carried out on the applications of topology and manifold theory to the problems of potential energy hypersurfaces (5–13). The theory of topological manifolds and differential topology (14, 15), as applied to energy expectation value functionals, leads to Reaction Topology, a topological – quantum mechanical model of conformational and reaction processes of molecules, and a mathematical framework for computer-aided quantum chemical synthesis design.

Consider a system of N nuclei and k electrons in a specified electronic state. In the Born–Oppenheimer model the energy expectation value functional $E(\boldsymbol{r})$ can be regarded as an energy hypersurface defined over an abstract nuclear configuration space $^{n}\tilde{R}$. We shall assume that this nuclear configuration space has the following properties.

(i) Over a subset ^{n}R of $^{n}\tilde{R}$

$$[1] \quad {}^{n}R \subset {}^{n}\tilde{R}$$

the energy expectation value functional $E(\boldsymbol{r})$

$$[2] \quad \boldsymbol{r} \in {}^{n}R$$

is a twice continuously differentiable functional.[1]

(ii) Furthermore, we shall assume that the negative gradient

$$[3] \quad -\boldsymbol{g}(\boldsymbol{r}),\ \boldsymbol{r} \in {}^{n}R$$

corresponds to the laboratory frame forces of relaxation acting upon the nuclei. The above conditions are equivalent to those in the definition of the intrinsic reaction coordinate as defined by Tachibana and Fukui (3,4).

As a consequence of the above conditions, at every noncritical point $\boldsymbol{r} \in {}^{n}R$ the steepest descent path $P_{\boldsymbol{r}}$ is well defined with respect to the energy hypersurface $E(\boldsymbol{r})$ of the given electronic state. Furthermore, the above conditions and the boundedness of the energy hypersurface $E(\boldsymbol{r})$ also imply that this path $P_{\boldsymbol{r}}$ has a unique extremity $\boldsymbol{e}\ (P_{\boldsymbol{r}})$ which is a critical point of $E(\boldsymbol{r})$:

[1]Throughout this paper we shall assume differentiability of $E(\boldsymbol{r})$. Note that this condition is not necessarily valid for more general hypersurfaces and in certain domains, denoted by D_{excl}, $E(\boldsymbol{r})$ is not well defined. For a treatment of more general hypersurfaces and for the description of D_{excl}, see refs. 5, 6, and 8.

[4] $\boldsymbol{e}(P_r) = \boldsymbol{c}^{(\lambda,i)} \in {}^nR$

[5] $\boldsymbol{g}(\boldsymbol{c}^{(\lambda,i)}) = \boldsymbol{0}$

Here we use similar notations as in refs. 5–13: λ is the number of negative eigenvalues of the Hessian matrix $H(\boldsymbol{c}^{(\lambda,i)})$ of second derivatives of $E(\boldsymbol{r})$, expressed at the critical point $\boldsymbol{c}^{(\lambda,i)}$. λ is referred to as the critical point index of $\boldsymbol{c}^{(\lambda,i)}$, whereas i is an index of ordering.

Consider the set P of all steepest descent paths of $E(\boldsymbol{r})$ in ${}^nR$:

[6] $P = \{P_r\}$

Set P is partitioned into equivalence classes $P^{c(\lambda,i)}$ according to the extremities of the paths:

[7] $P = \bigcup_{\lambda,i} P^{c(\lambda,i)}$

The $P^{c(\lambda,i)}$ equivalence class is defined as

[8] $P^{c(\lambda,i)} = \{P_r : \boldsymbol{e}(P_r) = \boldsymbol{c}^{(\lambda,i)}\}$

Since there is a one-to-one correspondence between each noncritical point $\boldsymbol{r} \in {}^nR$ and steepest descent path $P_r \in P$, the equivalence class partitioning of P, eq. [7], implies an equivalence class partitioning of ${}^nR$:

[9] ${}^nR = \bigcup_{\lambda,i} C^{c(\lambda,i)}$

Sets $C^{c(\lambda,i)}$ are referred to as catchment regions and are defined by

[10] $C^{c(\lambda,i)} = \{\boldsymbol{c}^{(\lambda,i)}, \boldsymbol{r}, \boldsymbol{r} : P_r \in P^{c(\lambda,i)}, \boldsymbol{r} \in {}^nR\}$

Note that each critical point $\boldsymbol{c}^{(\lambda,i)}$ belongs to its own catchment region. Alternatively, one could regard the critical points as degenerate "single point paths," thus elements of the corresponding $P^{c(\lambda,i)}$ equivalence classes.

The family of catchment regions,

[11] $\mathbf{C}' = \{C^{c(\lambda,i)}\}$

forms a cover of the entire space ${}^nR$. Similarly, the family of closures of catchment regions, where the closure refers to the metric topology $\mathbf{T}$ on ${}^nR$,

[12] $\mathbf{C}'' = \{\bar{C}^{c(\lambda,i)}\}$

is also a cover of the nuclear configuration space:

[13] ${}^nR = \bigcup_{\lambda,i} \bar{C}^{c(\lambda,i)}$

Evidently, the family $\mathbf{C}$ defined as

[14] $\mathbf{C} = \mathbf{C}' \cup \mathbf{C}''$

is also a cover for ${}^nR$.

Families $\mathbf{C}'$, $\mathbf{C}''$, and $\mathbf{C}$ are defining subbases for three topologies, $\mathbf{T}_{C'}$, $\mathbf{T}_{C''}$, and $\mathbf{T}_C$, respectively, on the nuclear configuration space ${}^nR$. Finite intersections of elements of $\mathbf{C}'$, $\mathbf{C}''$, and $\mathbf{C}$ form proper bases for topologies $\mathbf{T}_{C'}$, $\mathbf{T}_{C''}$, and $\mathbf{T}_C$, respectively, and for either of C', C'', or C, the three criteria of topology are fulfilled:

[15] (i) ${}^nR, \emptyset \in \mathbf{T}_X$ ($X = C'$, C'' or C)

[16] (ii) $\bigcup_{\beta} T_\beta \in \mathbf{T}_X$ if each $T_\beta \in \mathbf{T}_X$

[17] (iii) $\bigcap_{j=i}^{m} T_j \in \mathbf{T}_X$ if each $T_j \in \mathbf{T}_X$, m is finite

It has been demonstrated earlier that the concept of catchment regions gives a topological definition of molecular structure and reaction mechanism (5, 6, 8). Points from a given catchment region, i.e. from equivalence class $C^{c(\lambda,i)} \subset {}^nR$, are physically equivalent in the following sense: an ideal, "vibrationless relaxation" of the nuclear geometry from any of these points leads to the *same* extremity $\boldsymbol{c}^{(\lambda,i)}$, i.e. to the same distinguished point of the catchment region. Since any distortion of nuclear geometry within the catchment region $C^{c(\lambda,i)}$ retains the reference to the same critical point $\boldsymbol{c}^{(\lambda,i)}$, these distortions are not large enough to be regarded as chemical changes. In the topological representation of ${}^nR$ the identity of chemical structures is considered unchanged when geometry variations are confined to one catchment region. The topological molecular structure is defined as a catchment region, i.e. a $\mathbf{T}$-open set of defining subbase $\mathbf{C}$ of topology $\mathbf{T}_C$.

For all stable molecular structures the critical point index $\lambda = 0$, that is, the corresponding $\mathbf{T}_C$-open catchment regions are those of *minima* on the energy hypersurface. For all transition structures[2] ("transition states") the critical point index $\lambda = 1$, i.e. the corresponding $\mathbf{T}_C$-open catchment regions are those of saddle points with one negative canonical curvature. Structures with $\lambda \geq 1$ are unstable and those with $\lambda > 1$ are of lesser importance (1).

Relations between catchment region topologies of ground and excited electronic states

Consider a sequence of electronic states, a_1, a_2,..., a_s and the respective energy hypersurfaces $E^{(1)}(\boldsymbol{r})$, $E^{(2)}(\boldsymbol{r})$,..., $E^{(s)}(\boldsymbol{r})$, defined over ${}^nR$. The corresponding catchment region topologies $\mathbf{T}_C{}^{(1)}$, $\mathbf{T}_C{}^{(2)}$,..., $\mathbf{T}_C{}^{(s)}$ are defined in terms of subbases $\mathbf{C}^{(1)}$, $\mathbf{C}^{(2)}$,..., $\mathbf{C}^{(s)}$, respectively.

In any one of the resulting topological spaces $({}^nR,\mathbf{T}_C{}^{(1)})$, $({}^nR,\mathbf{T}_C{}^{(2)})$,..., $({}^nR,\mathbf{T}_C{}^{(s)})$ the general results on the topological properties of molecular structures, reaction mechanisms, and reaction networks (5–8) are equally applicable. We show now that the topological properties of the entire sequence of electronic states a_1, a_2,..., a_s can be described collectively within a *single* topological space. Family $\mathbf{C}^{(1,2,\ldots,s)}$, given as

[18] $\mathbf{C}^{(1,2,\ldots,s)} = \bigcup_{l=1}^{s} \mathbf{C}^{(l)}$

is a defining subbase for a unique topology $\mathbf{T}_C{}^{(1,2,\ldots,s)}$ on the nuclear configuration space ${}^nR$. Due to the construction of subbase $\mathbf{C}^{(1,2,\ldots,s)}$ topology $\mathbf{T}_C{}^{(1,2,\ldots,s)}$ is finer than any of the $\mathbf{T}_C{}^{(l)}$ topologies, i.e. for the respective topological spaces the following relation holds:

[19] $({}^nR, \mathbf{T}_C{}^{(l)}) \subset ({}^nR, \mathbf{T}_C{}^{(1,2,\ldots,s)})$

[20] $l = 1, 2,\ldots, s$

That is, any chemical structure or reaction mechanism of any of the energy hypersurfaces $E^{(l)}(\boldsymbol{r})$ being a $\mathbf{T}_C{}^{(l)}$-open set of the $({}^nR, \mathbf{T}_C{}^{(l)})$ topological space, ($l = 1, 2,\ldots, s$), is also a $\mathbf{T}_C{}^{(1,2,\ldots,s)}$-open set of the $({}^nR,\mathbf{T}_C{}^{(1,2,\ldots,s)})$ topological space. Consequently, all relations between chemical structures or reaction mechanisms in electronic states a_1, a_2,..., a_s of the system of N nuclei and k electrons can be described by *intersection and inclusion relations* between $\mathbf{T}_C{}^{(1,2,\ldots,s)}$-open sets of topological space $({}^nR,\mathbf{T}_C{}^{(1,2,\ldots,s)})$. Such intersection relations can be represented by intersection graphs, which graphs have been utilized earlier for the analysis of reaction networks defined for a single energy hypersurface (8). In special cases

[2]We prefer using the term "transition structure", as suggested by J. A. Pople, rather than the more conventional term "transition state".

where intersection relations are replaced by inclusion relations, as has been the case for level set topologies (5*c*), a concise description of these relations can be given in terms of incidence matrices.

Consider now the simplest nontrivial case of $s = 2$, i.e. a *pair* of energy hypersurfaces, $E^{(1)}(\boldsymbol{r})$ and $E^{(2)}(\boldsymbol{r})$, where a_1 is the electronic ground state and a_2 is an excited electronic state. Consider further a molecular structure $C^{c(\lambda,i,1)}$, with respect to $E^{(1)}(\boldsymbol{r})$, and another one, structure $C^{c(\lambda',i',2)}$, with respect to $E^{(2)}(\boldsymbol{r})$, where the third index in the superscript refers to the electronic state. Both catchment regions are open sets in the topological space $({}^{n}R, \mathbf{T}_C^{(1,2)})$:

[21] $C^{c(\lambda,i,1)} \in \mathbf{T}_C^{(1,2)}$

and

[22] $C^{c(\lambda',i',2)} \in \mathbf{T}_C^{(1,2)}$

Consequently, intersection and inclusion relations between them are topological relations in space $({}^{n}R, \mathbf{T}_C^{(1,2)})$.

There are five distinct possibilities:

[23] (*i*) $C^{c(\lambda,i,1)} \cap C^{c(\lambda',i',2)} = \phi$

[24] (*ii*) $C^{c(\lambda,i,1)} \cap C^{c(\lambda',i',2)} \neq \phi$

where

[25] $C^{c(\lambda,i,1)} \not\supset C^{c(\lambda',i',2)}$

and

[26] $C^{c(\lambda,i,1)} \not\subset C^{c(\lambda',i',2)}$

[27] (*iii*) $C^{c(\lambda,i,1)} \supset C^{c(\lambda',i',2)}$

where

[28] $C^{c(\lambda,i,1)} \not\subset C^{c(\lambda',i',2)}$

[29] (*iv*) $C^{c(\lambda,i,1)} \subset C^{c(\lambda',i',2)}$

where

[30] $C^{c(\lambda,i,1)} \not\supset C^{c(\lambda',i',2)}$

[31] (*v*) $C^{c(\lambda,i,1)} = C^{c(\lambda',i',2)}$

These five cases are shown schematically in Fig. 1.

Consider the special case of

[32] $\lambda = \lambda' = 0$

i.e. the relation between two stable molecules $C = C^{c(0,i,1)}$ and $C' = C^{c(0,i',2)}$ on the two energy hypersurfaces $E^{(1)}(\boldsymbol{r})$ and $E^{(2)}(\boldsymbol{r})$. An $a_1 \rightarrow a_2$ electronic excitation of molecule C cannot lead directly to C' in case (*i*), and can lead only to C' in cases (*iv*) and (*v*). In cases (*ii*) and (*iii*) C' is only one of the possible products. Note that for polyatomic systems cases (*i*)–(*iv*) are the most common and case (*v*), i.e. exact coincidence of C and C', is unlikely. However, for diatomic molecules case (*v*) is rather common, since whenever the two states a_1 and a_2 are nondissociative, the following relations are valid between the topological spaces over the nuclear configuration space ${}^{1}R$:

[33] $\mathbf{T}_C^{(1)} = \mathbf{T}_C^{(2)} = \mathbf{T}_C^{(1,2)} = \{\phi, {}^{1}R\}$

that is,

[34] $({}^{1}R, \mathbf{T}_C^{(1)}) = ({}^{1}R, \mathbf{T}_C^{(2)}) = ({}^{1}R, \mathbf{T}_C^{(1,2)})$

Relation [33] is a simple consequence of the usual shapes of Morse potentials.

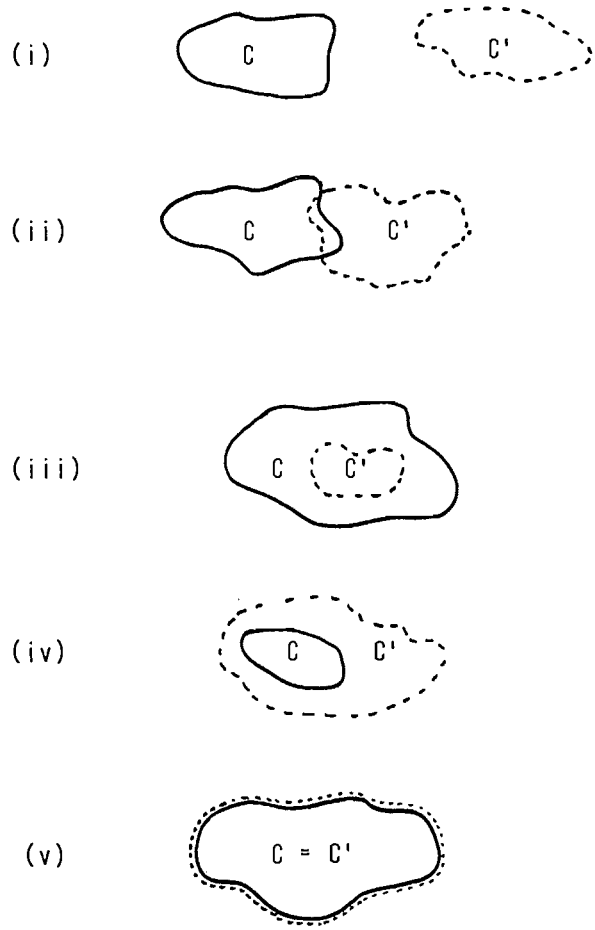

FIG. 1. The five topologically distinct cases, (*i*)–(*v*), for the relative positions of catchment regions $C = C^{c(\lambda,i,1)}$ and $C' = C^{c(\lambda',i',2)}$ of electronic states a_1 and a_2, respectively.

An $a_2 \rightarrow a_1$ de-excitation from structure C' can lead only to C in cases (*iii*) and (*v*). In cases (*ii*) and (*iv*) C is only one of the possible products, whereas in case (*i*) the de-excitation cannot lead directly to C. If chemical structure C is a single molecule (e.g. not a pair of dissociated fragments), then in cases (*iii*) and (*v*) C' *cannot* be an excimer (or exciplex). On the other hand, if case (*i*), that is relation [23], is valid for the given set C', $C' \in \mathbf{T}_C^{(2)}$ and for *every* $C \in \mathbf{T}_C^{(1)}$ where $C = C^{c(0,i,1)}$, then C' is an excimer (or exciplex) of electronic state a_2.

Photochemical relations in the abstract nuclear charge space ${}^{w}Z$. A topological "ordering rule" for the electronic states of isoelectronic molecules in product space ${}^{w}Z \otimes {}^{n}R$

We shall apply two theorems (12) on the topological properties of the abstract nuclear charge space ${}^{w}Z$ to obtain an ordering rule for excited state electronic energy hypersurfaces of isoelectronic molecules.

Space ${}^{w}\tilde{Z}$ has been defined (12) as

[35] ${}^{w}\tilde{Z} = \{z,\ z : z_i$ is the charge of the i-th nucleus, $i = 1,\ldots, w\}$

and usually a subset ${}^{w}Z$ of ${}^{w}\tilde{Z}$,

[36] ${}^{w}Z = \{z,\ z : z_i \geq 0\ (i = 1,\ldots, w),\ z \in {}^{w}Z\}$

is considered. Level sets of the electronic energy functional

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

$E_e(\boldsymbol{r},z)$ in ^{w}Z are defined for any fixed $\boldsymbol{r} \in {}^{n}R$ and energy value E^0 as

[37] $F_{E^0}(\boldsymbol{r}) = \{z, z : E_e(\boldsymbol{r},z) \geq E^0, z \in {}^{w}Z\}$

The first theorem of ref. 12 states that all such level sets in ^{w}Z are *convex* sets for *any* fixed $\boldsymbol{r} \in {}^{n}R$.

The second theorem of ref. 12 states that the electronic energy of molecule $M^{(1)}$ of nuclear charges $z^{(1)}$ is higher than that of molecule $M^{(2)}$ of nuclear charges $z^{(2)}$ ($M^{(2)}$ isoelectronic with $M^{(1)}$), if $z^{(2)}$ lies *outside* of a hypercube $C^0 \subset {}^{w}Z$ having one vertex the origin, and $z^{(1)}$ lies *within* a pyramid $P^0 \subset C^0$ with apex the origin.[3] Theorem 2 is valid for *any* geometries $\boldsymbol{r}^{(1)}$, $\boldsymbol{r}^{(2)} \in {}^{n}R$ if the electronic state considered is the *lowest* of a given manifold, i.e. the electronic wavefunctions $\psi^{(1)}$ and $\psi^{(2)}$ are variational.

It has been demonstrated earlier on many examples that the convexity theorem alone is often sufficient to establish electronic energy inequalities between molecules (9, 10, 12). Here we shall propose a trivial and a somewhat less trivial extension of these inequalities.

A simple *"rule of ordering"* for electronic hypersurfaces can be derived for isolectronic molecules $M^{(1)}$, $M^{(2)}$,..., $M^{(t)}$, fulfilling the conditions of Theorem 1 or Theorem 2.

Theorem: Consider a sequence of isoelectronic molecules $M^{(1)}$, $M^{(2)}$,..., $M^{(t)}$, and a sequence of electronic states a_1, a_2,..., a_s, all of which are the *lowest* of a given electronic manifold.

(*i*) If convexity of level sets in ^{w}Z implies the

[38] $E_e^{(1)} \geq E_e^{(2)} \geq \ldots \geq E_e^{(t)}$

order of electronic energies for a fixed geometry $\boldsymbol{r} \in {}^{n}R$ and for one of the electronic states, a_l ($1 \leq l \leq s$), then the ordering [38] is valid at *any* other geometry $\boldsymbol{r}' \in {}^{n}R$ and for any of the electronic states a_1, a_2,..., a_s.

(*ii*) If the sequence of points $z^{(1)}$, $z^{(2)}$,..., $z^{(t)}$ in ^{w}Z is such that the pyramid–cube separation applies for adjacent point pairs in the above order, in one of the electronic states a_l, then the ordering [38] is valid in any of the electronic states a_1, a_2,... a_s for *arbitrary geometries* $\boldsymbol{r}^{(1)}$, $\boldsymbol{r}^{(2)}$,..., $\boldsymbol{r}^{(t)} \in {}^{n}R$.

The proof of part (*i*) follows directly from Theorem 1 of ref. 12, since this theorem is applicable at any *common* geometry $\boldsymbol{r} \in {}^{n}R$. Since the electronic wavefunctions are variational for each of the a_1, a_2,..., a_s electronic states, ordering [38] is valid for any one of these states.

The proof of part (*ii*) follows from a repeated application of Theorem 2, ref. 12, on the sequence of point pairs $z^{(1)},z^{(2)}$; $z^{(2)},z^{(3)}$;..., $z^{(t-1)},z^{(t)}$. Since the above theorem gives a geometry-independent inequality for electronic energies, ordering [38] is valid for any *independent* choice of geometries $\boldsymbol{r}^{(1)}$, $\boldsymbol{r}^{(2)}$,..., $\boldsymbol{r}^{(t)}$ in any of the electronic states a_1, a_2,..., a_s.

Rephrased in terms of hypersurfaces, result (*i*) states that the electronic energy hypersurface $E_e(\boldsymbol{r})$ of molecule $M^{(j)}$ lies above that of $M^{(j')}$ over the entire ^{n}R if $j < j'$ in the sequence. Result (*ii*) is much stronger: if the conditions are fulfilled, then the *lowest* point of the electronic energy hypersurface $E_e^{(j)}(\boldsymbol{r})$ of molecule $M^{(j)}$ lies *above*[4] the *highest* point of the electronic energy hypersurface $E_e^{(j)}$ of $M^{(j')}$ if $j < j'$. Examples for cases (*i*) and (*ii*) are shown in Fig. 2.

[3] All but one of the faces of P^0 lie on the faces of C^0.

[4] In the special case of equality in [38] the lowest value of $E_e^{(j)}(\boldsymbol{r})$ may coincide with the highest value of $E_e^{(j')}(\boldsymbol{r})$.

Note that the result of Theorem 2, quoted above, can be further strengthened if geometry variations are restricted to various catchment regions $C^{c(\lambda,i)}$ of the nuclear configuration space (12), which restriction implies a constraint on homotopical variations of boundary sets of E_{E^0} level sets within cube C^0.

It has been shown (12), that for such limited geometry variations the boundary sets of level sets F_{E^0} are confined to a subset $T^{0(1)}$ of the closure of the relative complement T^0 of the pyramid P^0 in cube C^0:

[39] $T^{0(1)} \subset \overline{T^0} = \overline{C^0 \backslash P^0}$

This set $T^{0(1)}$, characteristic to a given catchment region of the nuclear configuration space ^{n}R, generates a partitioning of $\overline{T^0}$:

[40] $\overline{T^0} = \bigcup_{j=1}^{m} T^{0(j)}$, $m \geq 3$,

where $T^{0(2)}$ contains the center of cube C^0 and $T^{0(3)}$ contains the corner of C^0 with the longest distance from the origin (as measured in the metric topology $\mathbf{T}$ of ^{w}Z). For *any* two geometries within the catchment region,

[41] $\boldsymbol{r}^{(1)}, \boldsymbol{r}^{(2)} \in C^{c(\lambda,i)}$

and for any two points $z^{(1)}, z^{(2)} \in {}^{w}Z$ fulfilling conditions

[42] $z^{(1)} \in P^0 \cup T^{0(2)}$

and

[43] $z^{(2)} \in T^{0(3)} \cup ({}^{w}Z \backslash C^0)$

the inequality

[44] $E(\boldsymbol{r}^{(1)},z^{(1)}) \geq E_e(\boldsymbol{r}^{(2)},z^{(2)})$

applies.

The above result can be combined with the ordering rule and one can obtain a sequence of inequalities for the electronic energy functional $E_e(\boldsymbol{r},z)$ defined on the product space $^{n}R \otimes {}^{w}Z$. Taking the simplest nontrivial case of $t = 2$, in the $({}^{n}R,\mathbf{T}_C^{(1,2)})$ topological space, the union $C^{(1,2)}$ of catchment regions $C^{c(\lambda_1,i_1,l)}$ and $C^{c(\lambda_2,i_2,l)}$ of molecular structures $M^{(1)}$ and $M^{(2)}$ is an open set:

[45] $C^{(1,2)} \in \mathbf{T}_C^{(1,2)}$

where

[46] $C^{(1,2)} = C^{c(\lambda_1,i_1,l)} \cup C^{c(\lambda_2,i_2,l)}$

and

[47] $l = 1$ or 2

If the subsets $T^{0(1)}$, $T^{0(2)}$, and $T^{0(3)}$ of hypercube C^0 are defined with respect to set $C^{(1,2)}$, then relations [42] and [43] are sufficient to estabish the ordering

[48] $E_e^{(l)}(M^{(1)}) \geq E_e^{(l)}(M^{(2)})$

for both electronic states a_1 and a_2. Note that this result is stronger than the ordering relation obtained directly from Theorem 2, since here conditions [42] and [43] are less restrictive than the pyramid–hypercube separation of points $z^{(1)}$ and $z^{(2)}$.

Example:

We shall illustrate the application of the ordering rule, case (*ii*), on the following sequence of chemical systems:

$$M^{(1)} = \begin{matrix} COO^- \\ | \\ COO^- \end{matrix} + H_2O$$

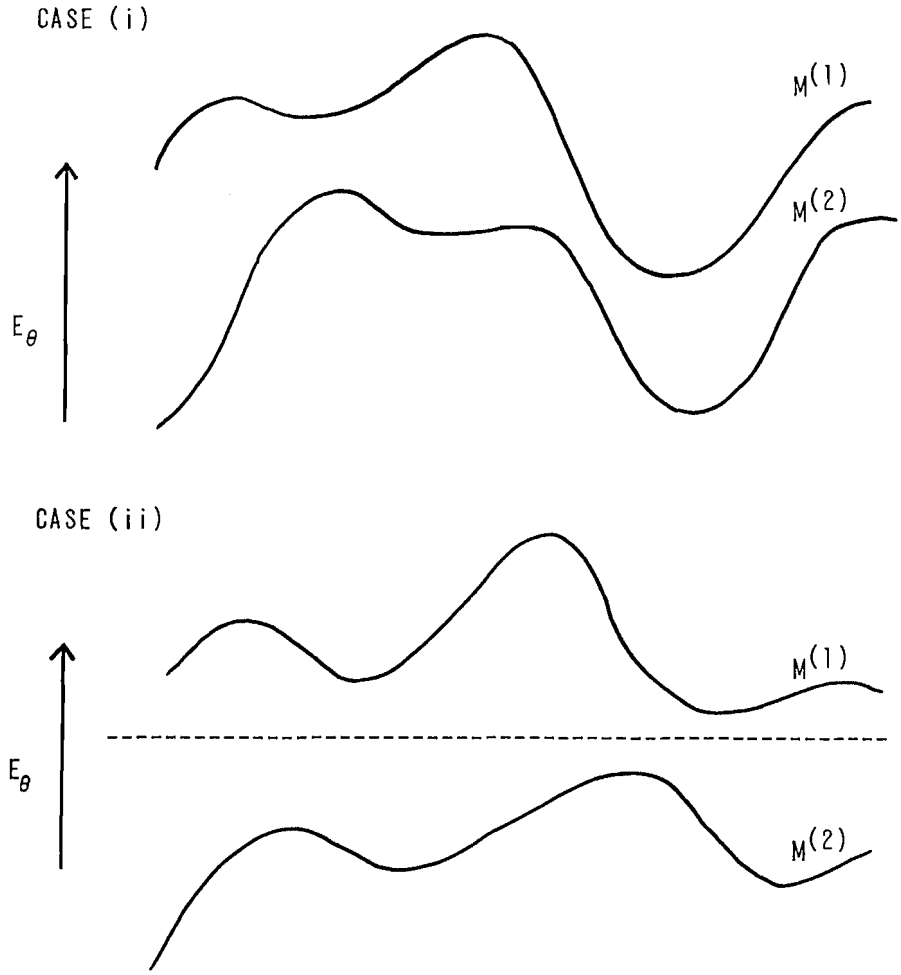

FIG. 2. The ordering rule, based on convexity of level sets of space ^{n}Z in case (*i*), implies that the electronic energy hypersurface of molecule $M^{(1)}$ lies above that of molecule $M^{(2)}$. A pyramid–hypercube separation of nuclear charge vectors $z^{(1)}$ and $z^{(2)}$ in ^{n}Z (see text for details) in case (*ii*) implies a stronger constraint, i.e. the existence of a constant energy value separating the two hypersurfaces. Both cases (*i*) and (*ii*) apply to any electronic state of sequence $a_1, a_2, \ldots, a_s$, which are the lowest states in their respective electronic manifolds.

$M^{(2)} = CsH$

$M^{(3)} = La^{+}$

Let us assume that the electronic states a_1, a_2, and a_3 are the lowest singlet, triplet, and quintuplet states, respectively. Not that case (*ii*) corresponds to the stronger conditions, consequently these systems also serve as examples for case (*i*).

Furthermore, the dimensions of both ^{n}Z and ^{n}R can be chosen such that they accommodate the largest chemical system, in our case $M^{(1)}$. For the rest of the chemical systems "dummy nuclei" with zero nuclear charges can be added in order to make up for the "missing" dimensions.

The above systems are isoelectronic ($k = 56$). Point $z^{(1)} \in {}^{9}Z$ falls within the largest pyramid $P^0 \subset C^0$ with apex the origin:

$$z^{(1)} \in P^0$$

where hypercube C^0 has the edge length of 54.5 protonic charge units, whereas point $z^{(2)}$ lies in the complement of C^0:

$$z^{(2)} \in ({}^{9}Z \setminus C^0)$$

On the other hand,

$$z^{(2)} \in P^{0'}$$

where pyramid $P^{0'} \subset C^{0'}$ is the largest pyramid in hypercube $C^{0'}$, the latter having an edge length of 56.5 protonic charge units. Point $z^{(3)}$ lies outside of both cubes,

$$z^{(3)} \in ({}^{9}Z \setminus C^{0'})$$
$$(C^0 \subset C^{0'})$$

Consequently, for both pairs $z^{(1)}, z^{(2)}$, and $z^{(2)}, z^{(3)}$ there exists a pyramid–cube separation in the 9-dimensional nuclear charge space ^{9}Z, and the ordering rule is applicable:

$$E_e(M^{(1)}) \geq E_e(M^{(2)}) \geq E_e(M^{(3)})$$

in *all three* electronic states a_1, a_2, and a_3. That is, the electronic energy hypersurfaces $E_e^{(j)}(\boldsymbol{r})$, ($j = 1, 2, 3$) must be separated by constant energy values over the entire nuclear configuation space ^{n}R, for each of the a_1, a_2, and a_3 electronic states.

Photolyse du méthyl-3-butène-1 et du méthyl-2-butène-1 à 185 nm

DANIELLE HOUDE, HÉLÈNE DESLAURIERS ET GUY J. COLLIN[1]

Département des Sciences fondamentales, Université du Québec à Chicoutimi, Chicoutimi (Qué.) Canada G7H 2B1

Reçu le 19 juillet 1982

Cet article est dédié au Professeur Harry E. Gunning à l'occasion de son 65e anniversaire

DANIELLE HOUDE, HÉLÈNE DESLAURIERS et GUY J. COLLIN. Can. J. Chem. **61**, 962 (1983).

Nous avons étudié la photolyse du méthyl-3-butène-1 (M3B1) et du méthyl-2-butène-1 (M2B1) à 185 nm en phase gazeuse. Les processus primaires de fragmentation observés confirment la prépondérance de la fragmentation via la rupture de la liaison β(C—C) avec formation concomitante de radicaux méthyles et soit de radicaux α-méthallyles (cas du M3B1) soit de radicaux β-méthallyles (cas du M2B1). La comparaison de ces deux systèmes inspire une méthode très primitive quant à la détermination de l'énergie supportée par les radicaux méthallyles: 48% des radicaux C_4H_7* ainsi produits ont une énergie interne entre 42 et 58 kcal mol^{-1} à 185 nm. D'autres comparaisons sont faites avec ce qui a été observé précédemment à 163 et à 174 nm. Ces observations confirment la conclusion que l'énergie du photon est très probablement distribuée de façon statistique dans le tissu vibrationnel de la molécule photoexcitée avant sa fragmentation.

DANIELLE HOUDE, HÉLÈNE DESLAURIERS, and GUY J. COLLIN. Can. J. Chem. **61**, 962 (1983).

The gaseous photolysis of 3-methyl-1-butene (M3B1) and of 2-methyl-1-butene (M2B1) has been studied at 185 nm. The observed primary fragmentation processes of the photoexcited molecules confirm the leading role of the β(C—C) bond rupture, with formation of methyl radicals and either α-methallyl radicals (M3B1 system) or β-methallyl radicals (M2B1 system). The comparison of the two systems suggests a very simple method to evaluate the energy content of the methallyl excited radical: 48% of C_4H_7* radicals so produced have an energy content of 50 ± 8 kcal mol^{-1} at 185 nm. Other comparisons have been made with results previously obtained at 163 and 174 nm. These observations support the idea that the energy of the incident photon is very likely distributed among the vibrational frame of the photoexcited molecule before the occurrence of fragmentation processes.

Introduction

La photolyse du méthyl-2-butène-1 (M2B1) et du méthyl-3-butène-1 (M3B1) dans la région de l'ultraviolet sous vide a déjà fait l'objet d'études à différentes longueurs d'onde. À 147 nm, à 123,6 et à 104,8−106,7 nm, les produits principaux sont l'allène et le radical méthyle dans le cas du M2B1 (1) et le butadiène-1,3 et le radical méthyle dans le cas du M3B1 (2). Il faut mentionner en outre une isomérisation importante: formation de méthyl-2-butène-2 aux plus courtes longueurs d'onde, c'est-à-dire à des énergies supérieures aux potentiels d'ionisation du monomère et probablement associée à la photoionisation. À 174 et à 163 nm, la fragmentation observée a été expliquée sur la base de la rupture presque quantitative de la liaison C—C située en position β par rapport à la double liaison, suivie d'une importante fragmentation secondaire des radicaux α-méthallyles en butadiène-3 et un atome d'hydrogène (cas du M3B1) ou des radicaux β-méthallyles en allène et un radical méthyle (cas du M2B1) (3).

À 185 nm, les triméthyléthylène (méthyl-2-butène-2; M2B2) et tétraméthyléthylène ont montré un comportement similaire avec en outre formation d'isomères (4, 5). Le présent rapport a pour but de vérifier à 185 nm la validité du mécanisme réactionnel de fragmentation proposé à plus courtes longueurs d'onde. D'autre part, il est également pertinent de vérifier l'apparition éventuelle d'isomères, tout en poursuivant notre effort de réflexion sur la distribution de l'énergie dans la molécule photoexcitée (1−3).

Méthode expérimentale

Les techniques expérimentales utilisées ont été déjà abondamment décrites dans la littérature (1−5). Les méthylbutènes sont des produits A.P.I. de pureté moléculaire supérieure à 99,9%. L'analyse du M2B1 révèle les impuretés suivantes: méthyl-2-butène-2: 103 ± 3 ppm (échantillon A) ou 340 ± 10 ppm (échantillon B); butadiène-1,3: 1,2 ppm (A) ou 4 ppm (B). Celle du M3B1 montre la présence du butadiène-1,3 (2,0 ± 0,2 ppm), isoprène (0,6 ppm) et méthyl-2-butène-2 (3,8 ± 0,3 ppm). L'analyse du DI (Merck, Sharp, and Dohme of Canada) montre la présence de benzène: 300−500 ppm. Celle du D_2S montre de faibles signaux correspondants au méthane (20 ppm) et à l'acétylène (35 ppm).

Les analyses ont été réalisées par chromatographie en phase gazeuse (double flammes ionisantes). La lampe utilisée est une lampe à mercure "basse pression" achetée chez Philipps. Elle est vérifiée à l'aide d'un monochromateur d'un demi-mètre McPherson. L'actinométrie est réalisée en utilisant la photolyse de l'éthylène ($\Phi(C_2H_2)$ = 0,50) (6, 7).

Résultats

Les résultats exprimés sous la forme des rendements quantiques sont présentés dans les tableaux et figures qui accompagnent la discussion. À ces résultats il importe d'ajouter les remarques suivantes: (a) Les coefficients d'absorption de la lumière ont été mesurés à 185 nm: ϵ_{DI} = 140 ± 10% (8), ϵ_{D_2S} = 800 ± 5% (9), et $\epsilon_{M3B1} = \epsilon_{M2B1}$ = 7000 ± 15% L $mol^{-1}cm^{-1}$ (10). (b) En présence d'oxygène (10%) ou d'oxyde nitrique (5%), aucun produit, entre 133 et 16000 N m^{-2} (1−150 Torr), sauf le butadiène-1,3 (Fig. 1) et l'allène (Fig. 3), n'a un rendement quantique supérieur à 0,01. Ces mêmes rendements quantiques sont peu ou pas affectés par la variation de pression. (c) Nous n'avons pas pu mesurer de façon convenable la formation d'isomères provenant de la photolyse directe de chacun des deux monomères. Dans le cas du méthyl-2-butène-1, étant donné le niveau d'impuretés dans l'échantillon A, les rendements quantiques Φ(M3B1) et Φ(M2B2) sont inférieurs à 0,01 quelle que soit la pression du monomère. Aucun autre isomère n'a pu être mis en évidence. Dans le cas du méthyl-3-butène-1, la formation du M2B2 est plus évidente bien que l'incertitude expérimentale soit appréciable (Tableau 1).

Discussion

La fragmentation de la molécule photoexcitée

La photodécomposition des M3B1 et M2B1 à 185 nm est similaire à celle déjà observée à 163 nm que ce soit en l'absence ou en présence d'additifs: tableaux 1–4 (3). On ne rediscutera pas ici en détails cette photodécomposition si ce n'est pour en relever les principales caractéristiques et différences. Tout d'abord, dans les systèmes purs ou en présence d'oxygène ou d'oxyde nitrique ajoutés en vue d'éliminer la formation de produits via les recombinaisons radicalaires possibles, les rendements quantiques mesurés à 185 nm sont en première approximation les mêmes ou plus faibles que ceux mesurés à 163 nm. Dans les systèmes purs, le produit dont le rendement est le plus élevé est l'éthane. Conformément à la discussion présentée à 163 nm (3), et étant donnée l'absence de butane normal d'une part et la disparition de ce produit en présence soit d'oxygène, soit d'oxyde nitrique d'autre part, l'éthane est très probablement le résultat de la recombinaison des radicaux méthyles. On note aussi la formation importante de méthane (Tableaux 2 et 4), lorsque la photolyse a lieu en présence soit de D_2S, soit de DI:

[1] $CH_3 + RD \rightarrow CH_3D + R$ (où R ≡ I ou DS)

L'addition de D_2S ou de DI entraîne des modifications majeures sur la formation des produits (Tableaux 2 et 4). Cependant l'usage de l'un ou l'autre de ces deux additifs ne permet une interprétation très quantitative des résultats. Tout d'abord D_2S n'intercepte pas, ou mal, les radicaux allyliques de telle sorte que les radicaux α-méthallyles éventuellement formés dans le M3B1 ne sont pas interceptés. Lorsque le taux de

[b]Produits dont les rendements sont inférieurs à 0,008 en présence de 10% d'oxygène ou d'oxyde nitrique.
[c]$C_2H_2/C_2H_4 \leq 0,1$.
[d]Produits peu ou pas affectés par la présence d'oxygène ou d'oxyde nitrique.
[e]C_6H_{12} ≡ méthyl-2-pentène-1 + éthyl-2-butène-1 en quantités similaires.
[f]C_6H_{14} ≡ diméthyl-2,2-butane.

conversion s'élève, les radicaux α-méthallyles entrent en compétition avec le deutérium sulfuré pour intercepter les radicaux méthyles, et l'on assiste à la formation de pentène-2 (Tableau 2). On sait en outre que le radical HS s'additionne probablement rapidement sur le butadiène-1,3 (11, 12). Ce dernier produit est alors consommé probablement dans un mécanisme en chaîne radicalaire.

De son côté l'iodure d'hydrogène est un bien meilleur intercepteur vis-à-vis des radicaux allyliques que l'hydrogène sulfuré (13):

[2] $CH_3\dot{C}HCH{=}CH_2 + DI \rightarrow$ 1- ou 2-$C_4H_7D + I$

[3] $CH_2{=}C(CH_3)\dot{C}H_2 + DI \rightarrow$ iso-$C_4H_7D + I$

Rappelons que les atomes d'iode ne sont pas insensibles à la présence du monomère insaturé (14, 15). Dans le cas particulier du M2B1 on observe une isomérisation du monomère avec production du M2B2 dans un mécanisme en chaîne radicalaire avec probablement apparition importante d'isopentane. En outre le dépôt d'iode sur la fenêtre inhérent à l'usage de DI, comme celui de soufre dans le cas de l'utilisation de D_2S, diminue sensiblement la précision expérimentale. On peut cependant qualitativement à partir des tableaux 2 et 4 confirmer la présence de radicaux α- et β-méthallyles.

L'analyse du tableau 1 permet de rationnaliser simplement la fragmentation du M3B1 selon le mécanisme déjà proposé à 163 nm (Fig. 1):

[4] M3B1 + $h\nu \rightarrow$ M3B1**

[5] M3B1** $\rightarrow CH_3\cdot + CH_3CH{=}C\dot{H}CH_2$* ou $CH_3\dot{C}HCH{=}CH_2$*
$\Delta H = 69$ kcal mol^{-1} (16)

[6] $CH_3\dot{C}HCH{=}CH_2$* ou $CH_3CH{=}C\dot{H}CH_2$* $\rightarrow$ H + $CH_2{=}CHCH{=}CH_2$
$\Delta H = 49$ kcal mol^{-1}
$E_A = 50,4$ kcal mol^{-1} (17, 18)

[7] $CH_3\dot{C}HCH{=}CH_2^* \xrightarrow{M} CH_3\dot{C}HCH{=}CH_2$ ...

On peut estimer le rendement quantique des radicaux α-méthallyles en considérant toutes leurs réactions possibles:

[A] $\Phi([5]) = \Phi(C_4H_6\text{-}1,3) + \Phi(C_5H_{10}\text{-}2) + \Phi(C_8H_{14})$

En effet les radicaux méthallyles stabilisés (issus de la réaction [7]) peuvent se recombiner ou dismuter entre eux (19) ou avec les radicaux méthyles (20). Si l'on sait mesurer le pentène-2, il faut aussi évaluer la fraction de la recombinaison méthyle + α-méthallyle qui reforme le monomère (20). Quant au C_8H_{14}, produit non analysé, on peut aussi l'estimer via la relation suivante (21):

[B] $$\frac{\Phi(CH_3 + \alpha\text{-}C_4H_7)}{\Phi(CH_3 + CH_3)^{\frac{1}{2}} \cdot \Phi(\alpha\text{-}C_4H_7 + \alpha\text{-}C_4H_7)^{\frac{1}{2}}} = 2,0$$

L'utilisation de cette équation de concert avec les remarques précédentes montre que le rendement de la réaction [5] est tel que: $\Phi([5]) = \Phi([7]) + \Phi(\text{butadiène-1,3}) = 0,8 \pm 0,2$ à toute pression entre 130 et 20 000 N m^{-2} (1 à 150 Torr). De la même manière, on peut estimer le rendement en radicaux méthyles: $\Phi(CH_3) = 0,85 \pm 0,10$ (3). On en conclut que la principale sinon la seule réaction importante de fragmentation de la molécule parente photoexcitée est la réaction [5]. Il s'ensuit que le système à 185 nm est beaucoup moins complexe qu'à 163 nm et que le radical méthyle a essentiellement la possibilité de réagir avec lui-même ou avec le radical α-méthallyle. Par exemple, le rendement en atomes d'hydrogène semble moins élevé à 185 nm qu'à 163 nm: la comparaison des rendements Φ_{DI}(iso-C_5H_{12}) confirme cette assertion.

Il faut aussi noter la formation d'isoprène qui pourrait être le résultat du mécanisme suivant (Fig. 2):

[8] M3B1** $\longrightarrow$ H + $(CH_3)_2\dot{C}CH{=}CH_2$*

[9] $(CH_3)_2\dot{C}CH{=}CH_2$* $\longrightarrow$ H + iso-C_5H_8

[10] $(CH_3)_2\dot{C}CH{=}CH_2^* \xrightarrow{(M)} (CH_3)_2\dot{C}CH{=}CH_2$

La rupture du β(C—H) serait donc faiblement en compétition avec la rupture β(C—C): $\Phi_0(C_5H_8) = 0,01$. Ce mécanisme a été observé dans le cas de la photolyse du M2B2 (22), et est probablement responsable en partie de la formation de l'isopentane en présence de D_2S ou de DI ou du diméthyl-2,3-butane dans le système pur.

L'alternative est d'admettre une élimination moléculaire d'hydrogène. Si tel est le cas, la figure 2 permettrait d'évaluer le temps de vie de la molécule photoexcitée. En effet l'interception de la droite avec l'axe des pressions permet d'évaluer la constante de vitesse de la réaction [11]: $k_{11} \simeq 2 \times 10^9$ s^{-1}. Cette constante de vitesse permettrait à son tour d'évaluer le temps de vie de la molécule photoexcitée à 5×10^{-10} s. C'est un temps comparable à celui mesuré dans le cas de la photolyse de l'hexène-1 à 184,9 nm (23). Ce mécanisme n'exclut cependant pas le précédent.

[11] M3B1** $\rightarrow H_2$ + iso-C_5H_8

[12] M3B1** + M3B1 $\rightarrow$ 2 M3B1

La situation est similaire dans le cas du méthyl-2-butène-1 et ne commande pas d'autres discussions (3). Il faut cependant rappeler l'importance de la formation de radicaux méthyles — formation de méthane en présence de D_2S ou de DI et d'éthane dans le produit pur — et de radicaux β-méthallyles — formation d'isobutène en présence de DI.

[13] $CH_2{=}C(CH_3)CH_2CH_3 + h\nu \rightarrow CH_2{=}C(CH_3)CH_2CH_3$**

[14] $CH_2{=}C(CH_3)CH_2CH_3$** $\rightarrow CH_3 + CH_2{=}C(CH_3)\dot{C}H_2$*
$\Delta H = 71$ kcal mol^{-1} (24)

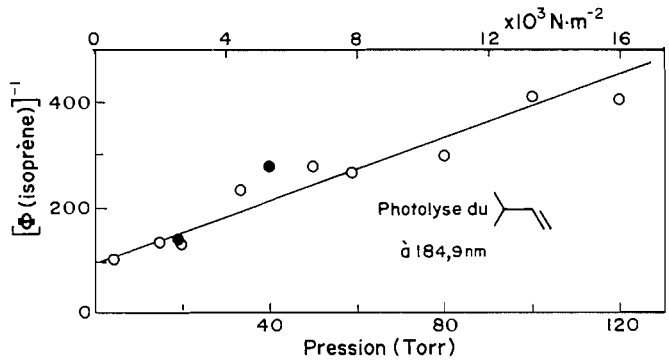

FIG. 2. Courbe de Stern–Volmer relative à la formation d'isoprène dans la photolyse du mélange M3B1/O_2 (100:10), ○; et du mélange M3B1/NO (100:5), ●.

[15] $CH_2{=}C(CH_3)\dot{C}H_2{}^* \xrightarrow{k_d} CH_2{=}C{=}CH_2 + CH_3$
ΔH = 49 kcal mol^{-1}
E_A = 56 kcal mol^{-1} (17)

[16] $CH_2{=}C(CH_3)\dot{C}H_2{}^* \xrightarrow{k_s[M]} CH_2{=}C(CH_3)\dot{C}H_2$

L'effet de la pression est aussi similaire à celui observé à plus courtes longueurs d'onde. L'effet le plus important porte sur la formation de l'allène (cas du M2B1) et du butadiène-1,3 (cas du M3B1). Les rendements quantiques de ces deux produits formés dans les réactions [5]–[7] et [14]–[16] sont susceptibles de suivre la loi de Stern–Volmer. Par exemple, dans le cas du M2B1 (Fig. 3),

[C] $[\Phi(\text{allène})]^{-1} = [\Phi_0(\text{allène})]^{-1} + [\Phi_0(\text{allène})]^{-1} k_s[M]/k_d$

où Φ_0 est le rendement du produit à pression nulle. Les figures 1 et 3 montrent la bonne linéarité obtenue pour les droites de Stern–Volmer. Ces droites permettent d'obtenir non seulement le rendement des produits à pression nulle, mais encore, via l'interception de la droite avec l'axe des abcisses, le rapport $-k_s/k_d$. En faisant l'hypothèse d'une unique collision pour stabiliser l'intermédiaire activé, c'est-à-dire en utilisant cette réaction de stabilisation comme horloge interne, on peut déterminer la constante de vitesse d'ordre 1 de la réaction de fragmentation du radical méthallyle. Cette particularité a été utilisée, via un calcul RRKM, pour évaluer l'énergie interne des méthallyles excités qui se fragmentent (25). Les résultats obtenus ne valent que pour les radicaux qui obéissent au mécanisme de Stern–Volmer. Ils ne permettent donc pas d'avoir une quelconque idée de l'énergie supportée par la majorité des $C_4H_7{}^*$ qui ne se fragmentent pas.

La distribution de l'énergie dans les fragments primaires

Il faut mentionner ici les différences ou ressemblances avec celles observées à plus courtes longueurs d'onde (Tableau 5). Tout d'abord, alors que la fragmentation primaire de la liaison β(C—C) devient la principale sinon la seule rupture primaire, il y a de moins en moins de ruptures secondaires du radical β-méthallyle avec l'accroissement de la longueur d'onde (Tableau 5). À 185 nm, à pression nulle, le rendement quantique de l'allène est de 0,04: il est donc tentant d'en déduire que le rendement des radicaux β-méthallyles activés qui ont au moins l'énergie interne suffisante pour permettre le passage au-dessus de la barrière de potentiel relatif à la réaction [12] est

[a]Les données sont déterminées à partir des droites Stern–Volmer [C]; r^2 est le coefficient de corrélation, $a \equiv \Phi_0^{-1}$ et $b \equiv \Phi_0^{-1}\, k_s/k_d$.

[b]Les rendements quantiques n'ont pas été exactement mesurés (3).

de 0,04: E_{int} = 56 kcal mol^{-1}. Il s'ensuit, comme on l'a mentionné plus haut, qu'il est difficile d'obtenir une idée convenable de la distribution de l'excédent de l'énergie du photon dans la molécule photoexcitée puisqu'on n'a aucune idée de l'énergie supportée par 96% des radicaux β-méthallyles.[2] La situation semble un peu plus favorable dans le cas du butadiène-1,3 puisqu'à 185 nm environ 24% des radicaux α-méthallyles se fragmentent. En d'autres termes, le rendement des radicaux α-méthallyles qui ont l'énergie interne suffisante pour passer par-dessus la barrière de potentiel de la réaction [6] est voisin de 0,24: E_{int} = 50,4 kcal mol^{-1}. Ainsi l'importance de la fragmentation secondaire est plus grande dans le cas du M3B1 que dans celui du M2B1. Il est pertinent d'essayer de comprendre le pourquoi de cette différence. En fait ces deux systèmes sont très semblables. Les spectres d'absorption sont insuffisamment bien connus pour que l'on puisse sortir une quelconque différence entre 130 et 190 nm. Les deux molécules isomères absorbent à 185 nm avec formation concomitante d'une molécule excitée π,π* (26). On ne peut guère dire plus sur ce qui peut se passer entre l'absorption du photon et la fragmentation primaire, celle qui donne naissance au radical méthallyle. On peut raisonnablement penser que le cheminement de l'énergie dans les tissus électronique et vibrationnel des deux molécules est semblable. Dans les deux cas, il y a rupture primaire du lien β(C—C), tout comme dans les autres alcènes, et en particulier comme dans celui du *cis*-pentène-2 (3). Thermodynamiquement les différences sont vraiment mineures sauf peut-être entre les réactions secondaires de fragmentation des radicaux α- et β-méthallyles. Alors que les enthalpies sont les mêmes, la barrière de potentiel relative à l'addition du radical méthyle sur l'allène, $E_A(CH_3 + CH_2{=}C{=}CH_2)$ égale 8,1 kcal mol^{-1} (17) tandis que celle

[2]Pour la simplicité de la compréhension on a supposé implicitement que la fragmentation primaire de la liaison β(C—C) est quantitative à 185 nm.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

relative à l'addition d'un atome d'hydrogène sur le butadiène-1,3 est de 1,3 kcal mol^{-1} (17). Cette différence entraîne une différence similaire dans l'énergie d'activation des processus inverse de fragmentation. Ainsi, si cette approche est correcte, le fait est que l'énergie requise pour la fragmentation du radical α-méthallyle requiert 7 kcal mol^{-1} d'énergie en moins. Puisqu'à 174 et à 163 nm, le comportement des radicaux α-méthallyles obtenus soit à partir du M3B1, soit à partir du *cis*-pentène-2 est le même, cela n'infirme pas cette approche. En considérant la photolyse des C_5H_{10} comme un même système on peut en déduire qu'à 185 nm 4% des radicaux C_4H_7* ont une énergie interne d'au moins 57 kcal mol^{-1}, que 24% ont au moins 50,4 et donc que 76% ont moins que 50,4 kcal mol^{-1}. À 174 nm, l'énergie du photon s'est enrichie de quelque 8 kcal $einstein^{-1}$. En faisant les hypothèses grossières que (a) le fragment primaire méthyle emporte à 174 nm la même énergie qu'à 185 nm et (b) l'énergie de recul des deux fragments primaires l'un par rapport à l'autre est similaire à ces deux longueurs d'onde, l'augmentation de 8 kcal mol^{-1} entraîne qu'à 174 nm, 14% des fragments C_4H_7* ont plus de 57 kcal mol^{-1}, 48% ont plus de 50,4 et donc 52% ont moins de cette valeur. L'enrichissement de 8 kcal mol^{-1} a donc déplacé 24% des radicaux C_4H_7* de la tranche la moins énergétique vers la tranche intermédiaire (celle comprise entre 50,4 et 57 kcal mol^{-1}). De son côté la tranche supérieure s'est gonflée de 4 à 24% du total. Par comparaison, on est donc amené à proposer qu'à 185 nm, 48% des radicaux C_4H_7* ont une énergie interne comprise entre 42 et 57 kcal mol^{-1}. Si l'on admet une distribution statistique de l'énergie du photon à travers le tissu vibrationnel de la molécule avant la fragmentation primaire, on devrait trouver une énergie moyenne voisine de 59 kcal mol^{-1} (25). Compte tenu des hypothèses faites, et surtout du caractère simpliste de ce raisonnement, on ne peut qu'être conduit à admettre cette distribution statistique de l'énergie du photon. En effet, la plus grande faiblesse de cette approche réside dans l'hypothèse faite que nécessairement si la fragment C_4H_7* a une énergie interne tout juste supérieure à ce qui est requis par la barrière de potentiel, il se fragmentera. Compte tenu de l'échelle de pression étudiée, il faut certainement déplacer les tranches énergétiques proposées de plusieurs kcal vers les valeurs supérieures pour avoir une vue plus réaliste.

Il serait aventureux de poursuivre la comparaison avec ce qui est obtenu à 163 nm. Cependant, ces comparaisons grossières confirment que le radical C_4H_7* libéré dans le processus primaire de fragmentation a une énergie relativement importante, distribuée largement autour de 55 ± 20 kcal mol^{-1}. On peut donc inférer une large distribution de l'énergie dans la molécule avant la rupture primaire.

Remerciements

Nous voulons remercier particulièrement le Conseil de Recherche en Sciences Naturelles et en Génie (CRSNG) de même que le Fonds FCAC pour l'aide apportée tout au long de ce projet.

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

D. L. SINGLETON, R. S. IRWIN, and R. J. CVETANOVIĆ. Can. J. Chem. **61**, 968 (1983).

The mechanism of the reaction of ground state oxygen atoms, $O(^3P)$, with CH_3SSCH_3 was studied by analysis of the final products. Oxygen atoms were generated by mercury photosensitized decomposition of N_2O such that $[CH_3SSCH_3] \gg [O]$. The only detected product was $CH_3S(O)_2SCH_3$, which accounted for close to 70% of the oxygen atoms reacted. Isomerization of small amounts of *cis*- or *trans*-2-butene added to the reaction mixture indicated the presence of CH_3S radicals. The results are consistent with the primary reaction $O + CH_3SSCH_3 \rightarrow CH_3SO + CH_3S$. The effect of small amounts of CH_3SH and H_2S on the yields of $CH_3S(O)_2SCH_3$ and the products formed provide further information on the nature of the secondary chemistry. A comprehensive reaction mechanism has been proposed.

D. L. SINGLETON, R. S. IRWIN et R. J. CVETANOVIĆ. Can. J. Chem. **61**, 968 (1983).

On a étudié, par l'analyse des produits finaux, le mécanisme de la réaction des atomes d'oxygène à l'état fondamental, $O(^3P)$, avec le CH_3SSCH_3. On génère les atomes d'oxygène par la décomposition photosensibilisée par le mercure du N_2O de telle sorte que $[CH_3SSCH_3] \gg [O]$. Le seul produit détecté est le $CH_3S(O)_2SCH_3$ qui compte presque pour 70% des atomes d'oxygène qui ont réagi. L'isomérisation de petites quantités de butène-2 *cis* et *trans* ajoutées au mélange réactionnel indique la présence de radicaux CH_3S. Les résultats sont en accord avec la réaction initiale $O + CH_3SSCH_3 \rightarrow CH_3SO + CH_3S$. L'effet de petites quantités de CH_3SH et de H_2S sur les rendements en $CH_3S(O)_2SCH_3$ et les produits formés fournissent une information plus poussée sur la nature de la chimie secondaire. On propose un mécanisme global de réaction.

[Traduit par le journal]

Introduction

Studies of the mechanisms of the gas phase reactions of oxygen atoms with thiols and organic sulfides indicate attack at the sulfur atom (1–3) with the formation of an energy rich adduct which subsequently fragments or which might be stabilized by collisions. We have recently carried out an extensive study of the kinetics (4) and mechanisms (5) of oxygen atom reactions with several organic sulfur compounds including CH_3SH, C_2H_5SH, CH_3SCH_3, and CH_3SSCH_3. From a detailed analysis of products observed in the reaction of single organic sulfur compounds and their mixtures (5), it was possible to arrive at substantial quantitative information on the primary and secondary reaction mechanisms. In the case of $O + CH_3SH$, the following reaction channels and their relative importance were indicated:

$$\begin{aligned} O + CH_3SH &\rightarrow CH_3 + HSO \ (60\%) \\ &\rightarrow H + CH_3SO \ (30\%) \\ &\rightarrow OH + CH_3S \ (10\%) \end{aligned}$$

For the reaction with methyl sulfide, our analysis of the stable products indicated that the major channel is

$$O + CH_3SCH_3 \rightarrow CH_3 + CH_3SO \ (>95\%)$$

There was no evidence of stabilization of a $CH_3S(O)CH_3$ adduct even at 1200 Torr.

In the $O + CH_3SSCH_3$ reaction, no volatile products were formed, and it was possible only to suggest by analogy with the thiol and sulfide a reaction mechanism with the following primary steps,

$$[1a] \quad O + CH_3SSCH_3 \rightarrow CH_3S + CH_3SO$$

$$[1b] \quad O + CH_3SSCH_3 \xrightarrow{[M]} CH_3S(O)SCH_3$$

In either case, on the basis of the postulated secondary reactions, it was expected that $CH_3S(O)_2SCH_3$ would be the final stable oxidation product. However, it was not possible to analyze for this compound by the analytical technique used, and the postulated mechanism was only tentative.

The present work was initiated to determine the products of the $O + CH_3SSCH_3$ reaction by an analytical procedure capable of recovering less volatile oxidation products. Also, several experiments were done to determine whether the reaction proceeded exclusively by addition–stabilization, reaction [1*b*], or whether fragmentation (or direct displacement), reaction [1*a*], occurred.

Experimental

Oxygen atoms were generated by mercury photosensitized decomposition of N_2O in a cylindrical quartz reaction cell (54 mm od × 81 mm) containing a few drops of mercury. Two short tubes fitted with septa extended from the side of the cell, which allowed the cell to be flushed with N_2O at atmospheric pressure and the reactants to be introduced by syringe. The source of the 253.7 nm radiation was a low pressure mercury lamp. A Corning 9-54 filter[3] removed the

184.9 nm line, and a neutral density filter reduced the intensity to acceptable levels. A rotating Teflon coated magnet agitated the mercury surface to help maintain a saturated vapor pressure of mercury. After irradiation, 0.5 cm^3-atm of propane was added as an internal standard, and aliquots were withdrawn by syringe and analyzed by gas chromatography with either thermal conductivity or flame ionization detection. A 1/8-in × 5-ft stainless steel column packed with Porapak QS was used for most analyses, and temperature programming up to 220°C was required. Analyses of *cis*- and *trans*-2-butene were done by gas chromatography on a 1/8 in × 10 ft column of Carbopak + 0.19% picric acid at room temperature. Analyses of N_2 and CH_4 were not made. After analysis of the gas phase, 1 cm^3 of acetone was injected into the reaction cell to dissolve any products adhering to the walls. Aliquots of the acetone solution were withdrawn by syringe and analyzed by gas chromatography using the Porapak QS column and the acetone as an internal standard. Response factors for the detectors were determined with standard mixtures. The response factor for $CH_3S(O)_2SCH_3$ determined for standard mixtures of 4 μmol and 40 μmol in 1 cm^3 of acetone showed a difference of about 16%, indicating that a small amount was lost on the chromatographic column at lower concentrations. The response factors were reproducible, and the appropriate values were used in the experiments.

Results

As in the previous work (5), no volatile products were detected in the O + CH_3SSCH_3 reaction. However, the product methyl methanethiosulfonate, $CH_3S(O)_2SCH_3$, was identified in the acetone used to rinse the reaction cell. Identification of the product was established by comparison of its gas chromatographic retention time with an authentic sample and by its mass spectrum obtained by gas chromatography – mass spectrometry. It was not formed in the absence of photolysis. In Table 1 the yield of $CH_3S(O)_2SCH_3$ is given as a function of reaction time. The yield increases linearly with time, as is evident in Fig. 1, indicating that it is not formed as a result of secondary oxygen atom reactions.

A series of experiments was done to determine the yield of $CH_3S(O)_2SCH_3$ per oxygen atom reacted, $\phi[CH_3S(O)_2SCH_3]$. The rate of production of oxygen atoms was determined by measuring the addition products, 1,2-epoxybutane, butanal, and 2-butanone produced in the O + 1-butene reaction at 1 atm of N_2O and ~30 Torr of 1-butene. Earlier measurements indicated that these products account for ~85% of the oxygen atoms reacted. The actinometry was done immediately before or after a measurement of the yield of $CH_3S(O)_2SCH_3$. The average value of $\phi[CH_3S(O)_2SCH_3]$ for 3 pairs of experiments was 0.34 ± 0.09, where the uncertainty is the 95% confidence interval. Thus the measured yield of $CH_3S(O)_2SCH_3$ accounts for close to 70% of the oxygen atoms reacted.

In order to determine whether the reaction proceeds solely by way of addition–stabilization as in reaction [1*b*], or whether reaction [1*a*] occurs to any extent, some experiments were done with small amounts of *cis*- or *trans*-2-butene added to the reaction mixture. Any CH_3S radicals formed in reaction [1*a*] would be expected to isomerize the olefin (6). The results in Table 2 indicate that isomerization occurs, and that the olefin does not significantly alter the yield of $CH_3S(O)_2SCH_3$. It was calculated that less than 6% of the oxygen atoms react with the olefin initially, but at long reaction times this would increase as the consumption of disulfide increases. This accounts for the trend in the amount of recovered butenes in Table 2. As the irradiation time increases, the mole fraction of *cis*-2-butene approaches the equilibrium value of 0.24 at 298 K, as shown in Fig. 2.

Addition of CH_3SH to the N_2O, Hg, CH_3SSCH_3 reaction mixture results in diminished yields of $CH_3S(O)_2SCH_3$, although less than 10% of the oxygen atoms react with CH_3SH in the experiment with the highest concentration of CH_3SH. The results are given in Table 3. The consumption of CH_3SSCH_3 is not as great as in the absence of CH_3SH, and in most cases the final amount of CH_3SSCH_3 exceeds the initial amount, i.e., CH_3SSCH_3 is actually formed from the added CH_3SH in the course of the reaction as has been observed in our earlier work (5). Addition of 80 μmol of CH_3SH decreases the yield of $CH_3S(O)_2SCH_3$ to about 30% of its value in the absence of CH_3SH. Complete suppression, however, is not approached until as much as 400 μmol of CH_3SH is added.

The recovery of the CH_3S groups (i.e., the mass balance) calculated from the analytical data is 86% in the absence of CH_3SH, and varies from 76% to 119%, with an average of 99 ± 5%, when CH_3SH is added to the reaction mixture, as seen in Table 3. The average value of $\Delta CH_3SH/\Delta CH_3S(O)_2SCH_3$ is 4.6 ± 0.5, where the uncertainty is the standard deviation of the mean, and $\Delta CH_3S(O)_2SCH_3$ is the difference between the yields with CH_3SH absent and present. The two runs in which CH_3SH was absent in the products and the run with the large initial amount of CH_3SH of 400 μmol were excluded from the average.

When H_2S is added to the reaction mixture of N_2O, Hg, and CH_3SSCH_3, the thiol CH_3SH appears as a product, as seen in

[b]nd = not determined.

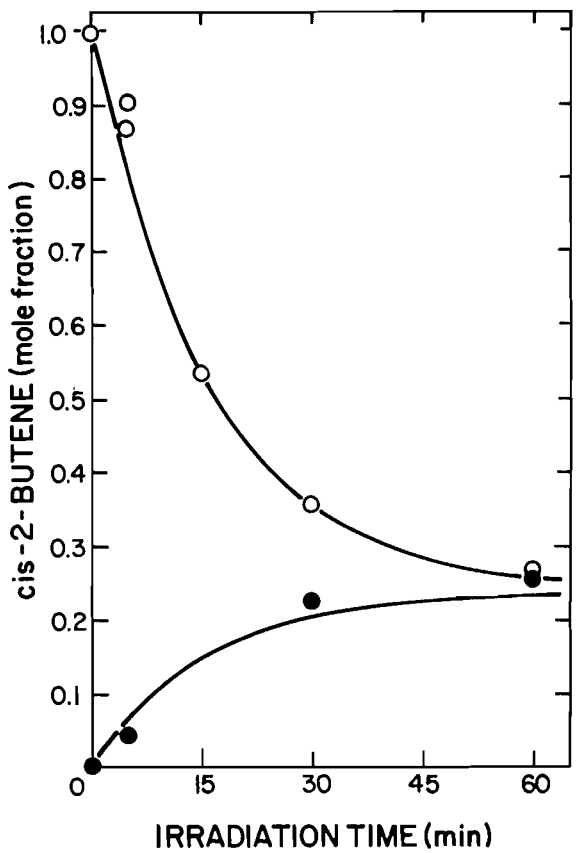

FIG. 2. Mole fraction of *cis*-2-butene as a function of irradiation time. Small amounts of either *cis* (○) or *trans* (●) isomer were added initially to the N_2O, Hg, CH_3SSCH_3 reaction mixture. The solid lines are the results of a steady state calculation.

Table 4. Also, H_2S and CH_3SSCH_3 are consumed, and the yield of $CH_3S(O)_2SCH_3$ is depressed in a similar fashion as in the experiments with CH_3SH initially added. The observed mass balance of the CH_3S group is not as good as in Table 3, with values of only 74% to 93%, and an average of 86 ± 3%. Although there was a very slow dark reaction between H_2S and CH_3SSCH_3 which formed CH_3SH, the correction to the measured yields of CH_3SH in the photolysis experiments due to the dark reaction was small, ranging from 7% to 12%.

Discussion

The notable feature of our previous study of the O + CH_3SSCH_3 reaction was the lack of any detectable volatile product (5). It was nevertheless possible to postulate tentatively a basic reaction mechanism by analogy with the O + CH_3SH and O + CH_3SCH_3 reactions studied at the same time, for which more experimental information on the products formed could be obtained. The postulated mechanism consisted of reactions [1]–[7] in Table 5, excluding disproportionation reactions. It was consistent with the absence of volatile products and also with the large consumption of CH_3SH and its partial conversion to CH_3SSCH_3 when CH_3SH was added in small amounts to the reaction mixture.The mechanism predicted formation of $CH_3S(O)_2SCH_3$, unobserved at the time, as the final stable product. The results of the present study confirm the formation of this compound as the major product and provide additional information on the reaction mechanism. The set of reactions listed in Table 5 includes the basic mechanism (reactions [1]–[7]) and a number of other reactions considered in connection with the additional experimental results obtained in the present work.

It was suggested previously (5) that some stabilization of the adduct could occur in reaction [1*b*]. The S—S bond in $CH_3S(O)SCH_3$ is 46 kcal/mol, and the S—O bond is about 80 kcal/mol. A simple RRK calculation indicates a lifetime similar to that calculated for the adduct in the O + CH_3SCH_3 reaction, i.e., about 10^{-10} s. Since the calculated lifetime of the initially formed $CH_3S(O)SCH_3$ is very small and is similar to that for $CH_3S(O)CH_3$ formed in the O + CH_3SCH_3 reaction, in which experiments showed (5) that stabilization is not important at 1 atm, it is likely that k_{1b}/k_{1a} is very small in our experiments.

The experiments in which *cis*- or *trans*-2-butene are isomerized provide evidence of significant formation of CH_3S radicals. The solid lines in Fig. 2 are calculated from a steady state expression having the functional form $X - X_{eq} = a \exp(-bt)$, where X is the mole fraction of *cis*-2-butene, X_{eq} is the value at equilibrium, and t is the irradiation time. It was assumed in the derivation that reaction [1*b*] was negligible, and that CH_3S radicals were consumed only in reaction [2]. The parameter b can be shown to be related to the equilibrium constant for *trans*- and *cis*-2-butene, the rate constants for reversible complex formation of CH_3S with the butenes, the rate constant for recombination of CH_3S radicals, and the rate of light absorption.

[a]67 μmol of CH_3SSCH_3 were present initially. Irradiation time = 30 min; T = 24°C; MSSM = CH_3SSCH_3, etc.
[b]ΔMS(O)$_2$SM = 10.7 − amount of MS(O)$_2$SM in column 7.

The value of b which gives a reasonable fit to the experimental points is about 50% of that calculated using the rate constants in ref. 6. Although this may suggest that reaction [1b] is not negligible, the simplicity of the model calculation, the uncertainty in the rate constants, and the scatter of the data do not allow its quantitative determination.

The basic mechanism in Table 5 predicts a value of $\phi[CH_3S(O)_2SCH_3] = 0.5$ if disproportionation reactions are negligible. The lower value of 0.34 observed experimentally could be accounted for by assuming for reactions [3] and [4] the following disproportionation steps (written with their approximate[4] ΔH values in kcal/mol).

$$[3d_1]\quad CH_3SO + CH_3S \rightarrow CH_3SOH + CH_2S \quad -40$$

$$[3d_2]\quad CH_3SO + CH_3S \rightarrow CH_2SO + CH_3SH \quad -37$$

$$[4d_1]\quad CH_3SO + CH_3SO \rightarrow CH_2SO + CH_3SOH \quad -20$$

No experimental values for these disproportionation/recombination ratios appear to be available. If these are the only additional channels responsible for loss of oxygen atoms, the disproportionation reactions would account for 32% of the oxygen atoms, leading to an overall ratio of disproportionation/recombination of 0.47 for reactions [3] and [4]. For comparison, although earlier studies indicated a disproportionation/recombination ratio of 0.4 for CH_3S radicals (8), later work suggests that disproportionation is insignificant (9, 10).

The following alternative (or additional) pathway for loss of oxygen atoms can be postulated by analogy with the observation that aryl sulfinyl radicals, ArSO, can disproportionate in solution (11) to $ArSO_2$ and ArS, and the former radicals can, through a series of reactions, lead to a sulfonic anhydride (12).

$$[4d_2]\quad CH_3SO + CH_3SO \rightarrow CH_3SO_2 + CH_3S$$

$$CH_3SO_2 + CH_3SH \rightarrow CH_3SO_2H + CH_3S$$

$$CH_3SO_2H \rightarrow CH_4 + SO_2$$

The last two reactions are based, by analogy, on the report (13) that Cl_3CSO_2 can abstract hydrogen from $C_6H_{11}SH$ to give Cl_3SO_2H, which then decomposes into Cl_3CH and SO_2. This alternative pathway could, if valid, also account for the larger than expected yields of CH_4 in our earlier experiments (5) with CH_3SSCH_3/CH_3SH mixtures. It was found then that the yields of CH_4, although small, were about 2−10 times greater than could be explained by the minor secondary reaction of oxygen atoms with CH_3SH. (It should be pointed out that any CH_3SO_2 radicals formed in reaction [4d_2] would then also contribute to the isomerization of the 2-butenes in the experiments summarized in Table 2 (14).)

In another study, however, Block and O'Connor (15) found equal amounts of $CH_3S(O)_2SCH_3$ and CH_3SSCH_3 in the photochemical disproportionation of $CH_3S(O)SCH_3$ dissolved in either CH_2Cl_2 or C_6H_6, in contrast to the thermal disproportionation of $C_6H_5S(O)SC_6H_5$ for which the disulfide/

[4]Based on the similarity of $D(CH_3OO - H)$ and $D(HOO - H)$, the value of $D(CH_3SO - H)$ was estimated to be equal to $D(HSO - H)$, which was obtained from data in ref. 7.

TABLE 5. Elementary reactions involved in the reaction of $O(^3P)$ with CH_3SSCH_3, with mixtures of CH_3SSCH_3 and CH_3SH, and with mixtures of CH_3SSCH_3 and H_2S

	A. Basic reactions involved in the O + CH_3SSCH_3 reaction	
[1*a*]	$O(^3P) + CH_3SSCH_3$	$\rightarrow CH_3S + CH_3SO$
[1*b*]	$O(^3P) + CH_3SSCH_3$	$\xrightarrow{[M]} CH_3S(O)SCH_3$
[2]	$CH_3S + CH_3S$	$\rightarrow CH_3SSCH_3$
[3]	$CH_3S + CH_3SO$	$\rightarrow CH_3S(O)SCH_3$
[3*d*$_1$]	$CH_3S + CH_3SO$	$\rightarrow CH_2S + CH_3SOH$
[3*d*$_2$]	$CH_3S + CH_3SO$	$\rightarrow CH_3SH + CH_2SO$
[4]	$CH_3SO + CH_3SO$	$\rightarrow CH_3S(O)OSCH_3 \rightarrow CH_3S(O)_2SCH_3$
[4*d*$_1$]	$CH_3SO + CH_3SO$	$\rightarrow CH_2SO + CH_3SOH$
[5]	$2CH_3S(O)SCH_3$	$\rightarrow CH_3S(O)_2SCH_3 + CH_3SSCH_3$
	B. Major additional reactions involving CH_3SH	
[6]	$CH_3SH + CH_3S(O)SCH_3$	$\rightarrow CH_3SSCH_3 + CH_3SOH$
[7]	$CH_3SH + CH_3SOH$	$\rightarrow CH_3SSCH_3 + H_2O$
[8]	$CH_3SH + CH_3S(O)OSCH_3$	$\rightarrow CH_3S(O)SCH_3 + CH_3SOH$
[9]	$CH_3SH + CH_3SO$	$\rightarrow CH_3SOH + CH_3S$
[10]	$CH_3SOH + CH_3SOH$	$\rightarrow CH_3S(O)SCH_3 + H_2O$
	C. Major additional reactions involving H_2S	
[11]	$H_2S + CH_3S(O)SCH_3$	$\rightarrow CH_3SSH + CH_3SOH$
[12]	$H_2S + CH_3SOH$	$\rightarrow CH_3SSH + H_2O$
[13]	$H_2S + CH_3S(O)OSCH_3$	$\rightarrow CH_3SOH + CH_3S(O)SH$
[14]	$H_2S + CH_3SO$	$\rightarrow SH + CH_3SOH$
[15]	$H_2S + CH_3S$	$\rightarrow SH + CH_3SH$
[16]	$SH + CH_3SH$	$\rightarrow H_2S + CH_3S$
[17]	$SH + CH_3S$	$\rightarrow CH_3SSH$
[18]	CH_3SSH	$\rightarrow CH_3SH + S$
[19]	$S + CH_3SSCH_3$	$\rightarrow CH_3SS + CH_3S$

thiosulfonate ratio was greater than 1 (12). The results of Block and O'Connor suggest that under their conditions CH_3SO_2 radicals react only with CH_3S. It is clear that more information is needed on the reactions of these radicals.

The depletion of $CH_3S(O)_2SCH_3$ when small amounts of CH_3SH are added to the reaction mixture is consistent with reactions [6] and [7]. Addition of CH_3SH *after* irradiation of the N_2O, Hg, CH_3SSCH_3 mixture has no effect on the yield of $CH_3S(O)_2SCH_3$. Therefore CH_3SH must react with an intermediate such as $CH_3S(O)SCH_3$ formed in reaction [3], and not with $CH_3S(O)_2SCH_3$. But because addition of 400 μmol of CH_3SH leads to nearly complete depletion of $CH_3S(O)_2SCH_3$, CH_3SH must react also with the intermediate product of reaction [4], i.e.,

[8] $CH_3SH + CH_3S(O)OSCH_3 \rightarrow CH_3SOH + CH_3S(O)SCH_3$

Alternatively, the CH_3SH could potentially intercept the CH_3SO radical directly,

[9] $CH_3SH + CH_3SO \rightarrow CH_3SOH + CH_3S$

and prevent the formation of $CH_3S(O)_2SCH_3$ before reactions [3] and [4] occur. However, in estimating the rate constant of reaction [9] it should be remembered that this reaction may be endothermic (estimated $\Delta H = +9 \pm 10$ kcal/mol).

The basic mechanisms in Table 5 for the case with CH_3SH added to the reactants predict that $\Delta CH_3SH/\Delta CH_3S(O)_2SCH_3 = -4$. The experimental results in Table 3 average -4.6 ± 0.5 (neglecting runs 133, 130, and 137 for which the analytical error is large), which is in reasonable agreement with the predicted value in view of the precision with which this ratio can be determined.

Addition of H_2S to the N_2O, Hg, CH_3SSCH_3 reaction mixture decreases the yield of $CH_3S(O)_2SCH_3$ in a similar manner. Thus, H_2S must react with $CH_3S(O)SCH_3$ analogously to CH_3SH i.e.,

[11] $H_2S + CH_3S(O)SCH_3 \rightarrow CH_3SSH + CH_3SOH$

[12] $CH_3SOH + H_2S \rightarrow CH_3SSH + H_2O$

Also, because addition of 80 μmol of H_2S causes the yield of $CH_3S(O)_2SCH_3$ to be so small as to be undetectable, either one or both of reactions [13] and [14] (the analogs of reactions [8] and [9]) must occur, although reaction [14] may be endothermic.

[13] $H_2S + CH_3S(O)OSCH_3 \rightarrow CH_3SOH + CH_3S(O)SH$

[14] $H_2S + CH_3SO \rightarrow CH_3SOH + SH$

The fate of CH_3SSH is likely to be decomposition on the walls, as postulated in a different reaction sequence (16).

[18] $CH_3SSH \xrightarrow{\text{wall}} CH_3SH + S$

although it could conceivably react with H_2S, ultimately yielding the same products as reaction [18],

$CH_3SSH + H_2S \rightarrow CH_3SH + HSSH$

$HSSH \xrightarrow{\text{wall}} H_2S + S$

In either case, the formation of CH_3SH indicated in Table 4 would be accounted for. This reaction scheme, outlined in Table 5 predicts the ratios $-\Delta H_2S/\Delta CH_3S(O)_2SCH_3 = \Delta CH_3SH/\Delta CH_3S(O)_2SCH_3 = 4$, where ΔH_2S and ΔCH_3SH

are the consumption of reactant H_2S and the yield of product CH_3SH, and $\Delta CH_3S(O)_2SCH_3$ is the net difference in the yield of $CH_3S(O)_2SCH_3$ caused by adding H_2S to the reaction mixture. The observed ratios are $1.8 < -\Delta H_2S/\Delta CH_3S(O)_2SCH_3 < 3.3$ and $0.9 < \Delta CH_3SH/\Delta CH_3S(O)_2SCH_3 < 1.6$, with the ratios increasing with increasing H_2S. These ratios are smaller than the simple mechanism predicts because the product CH_3SH will compete with H_2S in reactions [6]–[9]. With increasing concentrations of H_2S, CH_3SH would be less competitive, and the ratios should increase, as observed. This mechanism is further supported by the observation that the consumption of CH_3SSCH_3 decreases when small amounts of H_2S are present, compared with the experiments where H_2S is absent, indicating that CH_3SSCH_3 is regenerated by reactions of the product CH_3SH in reactions [6] and [7].

The enhanced complexity of the O + CH_3SSCH_3 reactions with CH_3SH or H_2S added to the reaction mixture evidently requires inclusion of additional elementary steps in the reaction mechanism. The extended mechanism is summarized in Table 5. Its plausibility has been tested by computer simulation (17, 18) of the experimentally observed trends of product yields for different concentrations of reactants. Literature values of the required rate constants were used whenever available. However, for a number of reactions the rate constants are not known, and some plausible values had to be assumed. Thus, for the very fast radical–radical reactions, the statistical ratios $(k_3 + k_{3d_1} + k_{3d_2}) = 2k_2 = 2(k_4 + k_{4d_1} + k_{4d_2}) = 2k_{17}$ are adopted as was done previously (5). Sensitivity tests showed that appreciable variations in the absolute values of these and some of the other rate constants had only a minor effect on the results. The unknown disproportionation/recombination ratios (such as k_{3d_1}/k_3, k_{3d_2}/k_3, k_{4d_1}/k_4) were treated as curve fitting parameters as were also the rate constants for some other reactions shown to have an appreciable effect on the results. Whenever possible, the adopted values were scrutinized for thermodynamic and kinetic plausibility. The reactions O + CH_3SH and O + H_2S were included in the simulations but are not listed in Table 5 because they did not contribute significantly to the consumption of oxygen atoms.

The results of the computer simulation for the reactions in the presence of H_2S and CH_3SH, respectively, are presented in Figs. 3 and 4 in the form of standardized (per oxygen atom reacted) rate curves as a function of the initial concentration of the added compound (H_2S or CH_3SH).

The agreement between the computer simulated curves in Fig. 3 for $CH_3S(O)_2SCH_3$, CH_3SH, $-\Delta CH_3SSCH_3$, and ΔH_2S and the trends in the corresponding experimental points plotted is quite good in view of some unavoidable analytical error. No experimental data were obtained for H_2O and CH_2SO. The plot illustrates well the effect of H_2S addition to CH_3SSCH_3 on the character of the oxidation reaction products, which change from the oxygenated sulfur organics ($CH_3S(O)_2SCH_3$, CH_2SO) to water as the amount of added H_2S is increased, although the fraction of oxygen atoms reacting with the much less reactive H_2S remains very small.

Figure 4 shows the computer simulated rate curves for $CH_3S(O)_2SCH_3$, H_2O, CH_2SO, ΔCH_3SSCH_3, and ΔCH_3SH as a function of the amount of CH_3SH added. The experimental points are plotted only for $CH_3S(O)_2SCH_3$. Measurements have been made also for ΔCH_3SSCH_3 and ΔCH_3SH, but because of the large analytical uncertainty of the data (listed in Table 3) they are not plotted in Fig. 4. The data nevertheless illustrate

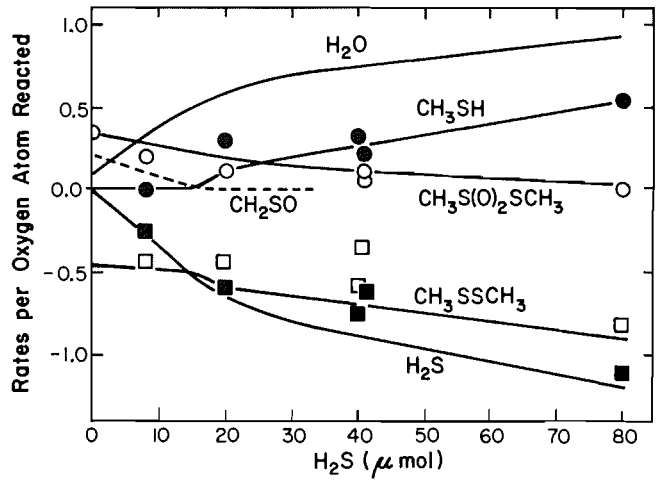

FIG. 3. Rate of product formation per oxygen atom reacted as a function of the initial amount of H_2S present. The lines are the results of computer simulations using the reactions in Table 5 and the experimental conditions in Table 4. The experimental results are indicated by symbols: ○ $CH_3S(O)_2SCH_3$; ● CH_3SH; □ CH_3SSCH_3; ■ H_2S.

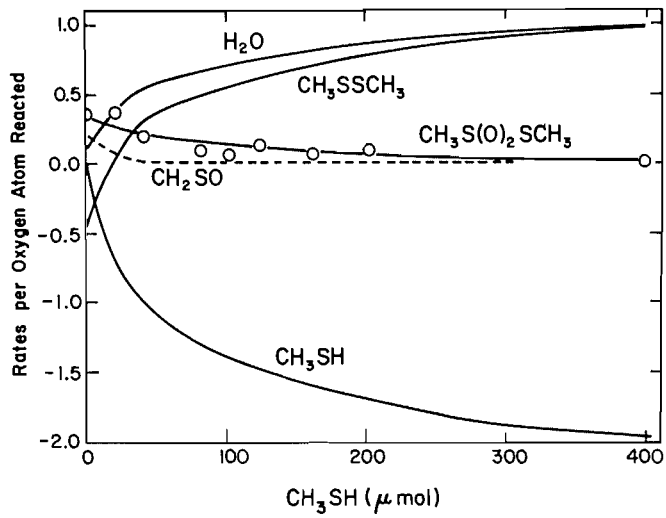

FIG. 4. Rate of product formation per oxygen atom reacted as a function of the initial amount of CH_3SH present. The lines are the results of computer simulations using the reactions in Table 5 and the experimental conditions in Table 3. ○ experimental yields of $CH_3S(O)_2SCH_3$.

clearly formation of CH_3SSCH_3 in the system at the expense of a large consumption of CH_3SH, although in this case also the fraction of oxygen atoms reacting with CH_3SH remains small. At sufficiently large CH_3SH addition, the net effect is the CH_3SSCH_3 catalyzed oxidation by oxygen atoms of two molecules of CH_3SH to form one molecule of CH_3SSCH_3 and one molecule of H_2O.

The computer simulations carried out demonstrate the plausibility of the mechanism summarized in Table 5. However, they do not eliminate the possibility of some variation of details, as for example the finer details of secondary chemistry in the presence of H_2S. Also, the question of the ratio k_{1a}/k_{1b} remains quantitatively unresolved, although the low $\phi[CH_3S(O)_2SCH_3] = 0.34$ measured in this work requires at least a substantial free radical formation in reaction [1*a*]. (Computer simulation with reaction [1*b*] alone predicts $\phi[CH_3S(O)_2SCH_3] = 0.5$, as expected.) This question reduces

to the effectiveness of collisional stabilization under different experimental conditions.

An addition–fragmentation–stabilization viewpoint has been applied originally to O + olefin reactions (19) and more recently by Lee *et al.* (1) to O + CH_3SCH_3 and by Slagle *et al.* (2) to O + CH_3SH and O + CH_3SCH_3 reactions. The most direct evidence of adduct formation was the detection of CH_3SOH^+ ions in the photoionization – mass spectrometry analysis of the products from high intensity crossed beams of oxygen atoms and CH_3SH (2). Supportive evidence for adduct formation was the similarity between the correlation of activation energies with ionization potentials of the sulfur compound (20) and the analogous correlation for O + olefin reactions which proceed by a major addition channel. Also, the curvature of the Arrhenius plots of O + thiol reactions (4, 20) and the negative Arrhenius activation energy for O + CH_3SCH_3 (1, 4, 20) are reminiscent of the O + olefin reactions (21). The correlation and behaviour of the Arrhenius parameters, however, cannot be considered as conclusive evidence.

Additional information on the nature of these reactions was provided by Tevault *et al.* (22), who photolyzed O_3 in an argon matrix at 10 K in the presence of CH_3SH or CH_3SCH_3 and analyzed the products by infrared spectroscopy. For O + CH_3SH, the products were consistent with fragmentation of a $CH_3S(O)H$ adduct in a matrix cage followed by recombination of the radical fragments. The products $CH_3S(O)H$, CH_3SOH and CH_3OSH were identified. In the CH_3SCH_3 reaction, only $CH_3S(O)CH_3$ was detected (as well as $CH_3S(O)_2CH_3$, presumed formed by stepwise addition of oxygen atoms to CH_3SCH_3). The presence of CH_3SOCH_3, which could have been formed by recombination of any CH_3 and CH_3SO radicals generated in the primary reaction, was not apparent. This molecule would have produced a band at 1084 cm^{-1} (C—O absorption), which may be at least partially obscured by the strong S=O band at 1091 cm^{-1}, and a band at about 767 cm^{-1} (S—O absorption), but no significant absorption is evident in this region in their Fig. 1. They interpreted their results as indicating that the adduct is stabilized for O + CH_3SCH_3 under their conditions, but that extensive fragmentation occurs for O + CH_3SH, in accord with the number of vibrational modes.

In our previous study (5) of the O + CH_3SCH_3 reaction, even at 1200 Torr at least 95% of the reaction results in breakage of the C—S bond. If $CH_3S(O)H$ were to be formed in our study of the O + CH_3SH reaction, it would not have been detected because of its instability. In view of the failure to stabilize any $CH_3S(O)CH_3$ adduct even at 1200 Torr in the O + CH_3SCH_3 reaction, it seems unlikely that a $CH_3S(O)H$ adduct would be important under our experimental conditions, and even less important at the very low pressures of molecular beam studies.

Further work is necessary to determine more quantitatively under a range of experimental conditions the relative importance of an addition–stabilization–fragmentation mechanism and a direct displacement ("pressure independent fragmentation") mechanism analogous to that occurring in the reaction of oxygen atoms with olefins (19) and possibly in the reaction of hydrogen atoms with organic sulfur compounds (16, 23). Further theoretical calculations would be expected to provide insight into the nature of the potential energy surfaces involved in such reactions.

Subpicosecond laser spectroscopy: strong field effects on molecular photophysics and dynamics

E. QUITEVIS, P. M. KROGER, C. KALPOUZOS, AND G. A. KENNEY-WALLACE

Picosecond Laser Laboratory, Lash Miller Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received August 10, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

E. QUITEVIS, P. M. KROGER, C. KALPOUZOS, and G. A. KENNEY-WALLACE. Can. J. Chem. **61**, 975 (1983).

The possible role of strong field effects is discussed in the context of picosecond relaxation and reaction in polyatomic systems. The picosecond pulse diagnostics from an argon-ion synchronously pumped dye laser are then outlined in terms of cavity detuning and laser pumping parameters. A profile of auto-correlation data on ensemble-averaged pulses and streak camera data on single pulses is presented, from which the domain of stable, single pulse operation can be deduced. Finally data are presented on the photoionization and energy relaxation of pyrene in alcohols and micelles, and for the reorientational dynamics of liquid chlorobenzene, which illustrate different consequences of strong field phenomena in dense media.

E. QUITEVIS, P. M. KROGER, C. KALPOUZOS et G. A. KENNEY-WALLACE. Can. J. Chem. **61**, 975 (1983).

On discute du rôle que pourrait jouer des effets de champ fort dans le contexte de relaxation et de réaction de l'ordre de la picoseconde dans des systèmes polyatomiques. On décrit une méthode de diagnostique par impulsion de l'ordre de la picoseconde basée sur un laser à colorant activé d'une façon synchrone par de l'argon, en fonction d'un désajustement de la cavité et des paramètres de pompage du laser. On présente une courbe des données d'autocorrélation pour des impulsions ajustées au niveau de l'ensemble des données d'une caméra "streak camera" relatives aux impulsions uniques; à partir de ces données, on peut déduire le domaine d'opération stable d'un impulsion unique. Finalement on présente les données sur la photoionisation et sur la relaxation d'énergie du pyrène dans des alcools et des micelles et sur la réorientation dynamique du chlorobenzène liquide, qui illustrent les différentes conséquences du phénomène de champ fort dans les milieux denses.

I. Introduction

The dramatic impact of tunable laser spectroscopy on our understanding of energy levels and dynamics in polyatomic molecules has shaped many of the contemporary theoretical attitudes towards the description of energy relaxation, energy transfer, and chemical reaction from electronically excited states (1). Picosecond laser spectroscopy (2) has opened up the realm of earliest events for polyatomic molecules, in which these central issues in photophysics and photochemistry can be directly examined during the lifetime of the event. Whether in condensed media, where the number density of molecules, intermolecular forces and torques, and collisional events become the determining factors, or isolated in the gas phase and characterised by a high density of states, molecular systems are a natural target for such fundamental studies of efficient and rapid inter- and intramolecular energy flow, using ultrashort laser pulses. Yet as we begin to explore laser-induced relaxation and reaction channels in molecules at shorter and shorter times, other issues arise which are unique to laser spectroscopy in the subpicosecond domain. These concern the preparation of optically excited states, local field effects, and nonlinear phenomena, to name a few specific examples, and the precision of measurement in general, as we approach the transform limits.

We present in this paper new spectroscopic and dynamic results selected to address strong field effects in particular from three different, ongoing research projects on multiphoton photoionization and electron transfer (3–5), on laser-induced photophysics and energy transfer (5, 6), and on the molecular dynamics of nonlinear optical phenomena in liquids (4, 7–9). Any problem of photochemical dynamics is really one of describing the photophysics (relaxation) and photochemistry (reaction) as competing channels, under precise conditions of the radiation field. Associated with all of these experiments is the need to fully characterise the laser pump and probe pulses, thus we outline new results from a comprehensive study of pulse generation and diagnostics that we have undertaken.

II. Optical interactions in the picosecond and femtosecond domain

A measurement using ultrashort laser pulses, whether information is recorded in time or frequency space, carries through a corresponding uncertainty that is a natural limitation to the interpretation of the experimental result. The limitation of subpicosecond measurements thus begins to appear in the energy resolution of the molecular event under study, through the simple relationship $\Delta E \Delta t \sim \hbar$. In picosecond (ps) and femtosecond (fs) laser spectroscopy, it makes little sense to try to distinguish the individual dynamical behavior of two close lying vibrational levels when the linewidth or frequency uncertainty of the subpicosecond laser pulse is greater than the frequency difference between the levels of interest. On the other hand, precisely such a situation can lead to the observation of interference effects when the two levels are *coherently* excited. This is the experimental prerequisite for studying quantum beats in the fluorescence decay of polyatomic molecules (10, 11). A pulse duration of 0.01 ps or 10 fs has associated with it an energy uncertainty corresponding to several eV or half the energy of a typical chemical bond. The shorter the duration of these visible laser pulses, the "whiter" they become. Therefore the region 10^{-13} to 10^{-9} s will probably remain the most productive in terms of new insights into dynamical theories or chemical kinetics and molecular energy transfer, because even if future advances in laser technology did allow us to probe and record even faster events, the uncertainty in the energy will be comparable to or greater than the energy measurement itself. For photochemistry, the time barrier beyond which our *current* questions begin to lose their practical significance is 10^{-13} s.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

Nevertheless, we cannot anticipate the future results of the current picosecond and the most recent femtosecond (12) studies, and so new phenomena, requiring new theories rather than modified old theories, may be awaiting us. We will now briefly examine two specific areas which could constitute a source of new phenomena or new techniques.

(a) Laser pulses: profiles and propagation

Ideally, ps and fs experiments are performed with transform limited pulses, for which a theoretical limit on the product $\Delta\nu\Delta t$ can be established for a given temporal laser pulse profile, and hence the fwhm linewidth $\Delta\bar{\nu}$ cm^{-1} can be calculated. The significant difference between the bandwidth product of various pulse shapes, namely 0.4413 for Gaussian, 0.3148 for sech^2, and 0.1420 for an exponential (symmetric) intensity $I(t)$ profiles, immediately poses the problem of how one can determine $I(t)$, a topic addressed in the Experimental section. A Gaussian laser pulse of duration 0.3 ps at $\lambda = 600$ nm thus has a linewidth of 26 cm^{-1} and, if on resonance, the pulse will excite a subset of states within the molecule corresponding to that bandwidth. This raises the question of state-selective preparation as a feasible approach for studies of the earliest events in molecular photophysics at times $\ll 10^{-12}$ s. However, even if these ultrashort pulses were to propagate in transparent media, dispersion effects still play an important role and pulse broadening must be taken into account for every optical path in the system. Group velocity (V_g) must be used to calculate the propagation times of various frequency ($\omega = 2\pi\nu$) components of a laser pulse or of an absorption or emission spectrum. Low frequencies travel faster than high frequencies for $\lambda < 1.5$ μ and thus dispersion effects ($\partial V_g/\partial\lambda = \partial^2 k/\partial\omega^2$) are particularly limiting when trying to take (for example) simultaneous infrared and near-uv absorption data. Furthermore, it is not possible to spatially focus pulses of different frequency to exactly the same focal volume, nor to collect information at identically the same time from an image of finite size, since there will be an intrinsic uncertainty associated with the transit time of photons from different points on the image. A 100 μ image represents a ~0.3 ps limitation. Dispersion in quartz is such that a 600 nm, 100 fs pulse of 100 cm^{-1} bandwidth would experience 40 fs delay on propagating through a 1 cm lens. Every optical element leaves its imprint on the pulse characteristics.

Clearly, to do femtosecond spectroscopy, which we define operationally as the domain below 0.5 ps, we must first address fundamental issues of pulse propagation and optical measurements that are an integral part of the interactions of laser radiation with atoms and molecules. The nonlinear polarization interactions as well as dispersion are of paramount interest, and we will now briefly examine some of these in the more general context of strong field effects.

(b) Strong field effects

The strong field effects we wish to briefly summarise here are (*i*) the transient, laser $\boldsymbol{E}$ field-induced orientational alignment, studied as the ps optical Kerr effect, (*ii*) the static $\boldsymbol{E}$ field-gradient induced shifts in molecular energy levels, and (*iii*) the laser $\boldsymbol{E}$ field dressed-states concept in laser-induced chemistry.

(*i*) The nonlinear polarization (P) in dense media resulting from interaction with intense laser pulses is usually written as

$$[1] \quad P_i = \chi^{(1)}_{ij}E + \chi^{(2)}_{ijk}E_jE_k + \chi^{(3)}_{ijkl}E_jE_kE_l$$

an expansion in higher orders of the electric field (E^n) and the susceptibilities $\chi^{(n)}$ of the molecular system, as derived from a perturbation theory approach (13). While this expression does not explicitly include the time-dependence (8, 9, 15) of the medium susceptibility response nor of the laser pulse, it is illustrative of the origin of the nonlinear, strong field effects that we first discuss. The second-order term, which vanishes for isotropic material, describes the second harmonic generation (SHG) which is generally employed to measure ps pulse durations through second order autocorrelation techniques. Based on nonlinear sum or difference frequency mixing in biaxial crystals, for which no inversion centre of symmetry exists, SHG, or its higher order analogs, are the major source of information on laser pulse durations at times <50 ps. No electronic devices can match in speed such electronic polarization, which follows instantaneously the laser pulse intensity profile. We will return to SHG in the experimental section, but turn now to the third-order term $\chi^{(3)}_{ijkl}$, through which the laser field-induced orientational alignment occurs. The optical Kerr effect (OKE), frequently used as an ultrafast optical shutter technique (14), refers here to the transient birefringence $\delta n(t)$ induced in a system comprising non-spherically symmetric molecules, subjected to an intense ps laser pulse. The nonlinear polarization, third-order in the electric field, can be envisaged as a time-dependent, nonlinear refractive index (n_2) of the molecular system which relaxes after the laser pulse is over with a lifetime characteristic of the intrinsic orientational dynamics (τ_d) of the system. During the passage of the laser pulse, the molecules align such that the molecular axis of maximum polarizability is parallel to the propagating electric field vector. Of prime interest to us is the time-dependence of the rise and decay of the Kerr transients in response to the polarization selectivity of the $\chi^{(3)}$ coefficients and the fundamental molecular dynamics and time-dependent contributions to $\chi^{(3)}$ (7, 8, 15). Furthermore, we propose the possibility of using such laser-imposed orientational alignments to enhance or frustrate chemical reactions or energy transfer processes in which the geometry, or relative alignment of the molecules, is a deterministic factor on the time scale of the actual event.

(*ii*) While OKE is a transient external field phenomenon, clearly there are local, non-averaged internal field effects arising from polarizability fluctuations with which to contend on the ps time scale and this subject will be discussed elsewhere. One "local" field case, however, is of singular importance and that refers to the presence of a non-trivial field gradient, usually due to the presence of a charged interface. A few mV extending over several angstroms constitutes a field of about 10^5 V cm^{-1} and surface potentials of 100 mV are not unknown in biological interfaces. By analogy with Stark promoted field ionization of Rydberg states in atoms, we have proposed (3) that in molecules in close proximity to charged interfaces in micelles and vesicles, static, internal field gradient effects could lead to electron tunneling, to lowering of ionization potentials, or to the coupling of normally energetically disallowed processes by virtue of lowering the potential energy barriers. The influence of fields on charge detrapping in inorganic semiconductors (16) or the Poole–Frenkel effect, and the Schottky model of electron emission, touch upon similar concepts in solid state physics (17). More recently, the idea of using charged interfaces to assist the separation of ionic photoproducts in photosensitized electron transfer in aqueous media has been discussed (18) and data have been reported (18, 19) to show that quantum yields and kinetics have been correlated at least qualitatively with the surface charge and potential of micelles and the colloidal semi-

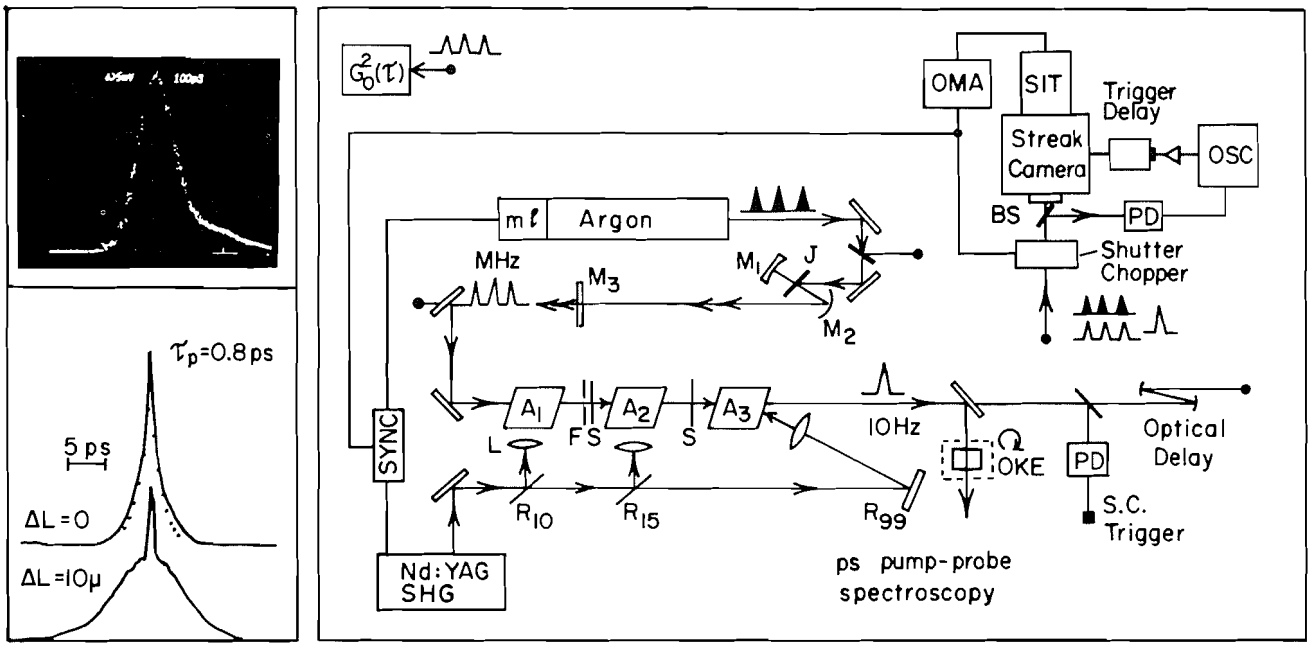

FIG. 1. Schematic of SML oscillator–amplifier dye laser system for picosecond absorption and emission studies, utilising a streak camera coupled to a SIT vidicon tube and optical multichannel analyser (OMA). See text for discussion and details on pulse diagnostics shown as inserts.

conductor material, SiO_2.

Picosecond laser spectroscopy allows us to directly examine these phenomena via a study of photoionization, electron transfer, and trapping processes across the interface. The results are of pivotal importance not only for basic understanding of these classic interfacial systems, but also for designing schemes which will produce rather practical and efficient solar energy cells.

(*iii*) The third, strong field effect refers to the dressed state concept, which has stimulated much theoretical interest in the description of potential energy surfaces within an intense laser radiation field (20). In principle, the molecular electronic state dressed (21) by an energy $\hbar\omega$, a quantum of the laser field, can couple to another electronic state to produce new reaction or relaxation channels otherwise inaccessible to the molecule. Thus the field can both distort the potential energy surfaces and, when two states can be coupled by photon exchange with the field, shift two potential energy surfaces with respect to each other, leading to new degeneracies. The intensity dependent effects we observe for laser-induced electron transfer originating from electrons in alcohol clusters (5) may well include type (*iii*) contributions. However, for the purposes of the present paper, we will focus on types (*i*) and (*ii*).

III. Experimental

(a) Pulse diagnostics and interpretation

Over the past year there have been some dramatic advances (12, 22, 23) in the generation of femtosecond laser pulses at 615 nm — the limit being 30 fs (22) at time of writing — and in obtaining significantly shorter subpicosecond pulses in general. By employing ring configurations for the dye laser, and using the colliding-pulse model (22) to determine the transit distances and times in the cavity for the counter-propagating pulses, it should be possible to gain a factor of at least 3 for the *tunable* pulses and to approach 300 fs.

Whatever the actual duration of the pulse, it is the pulse diagnostics which we emphasize here as the key to definitive and quantitative interpretation of the data. Figure 1 illustrates the oscillator–amplifier tunable dye laser system, which we have built for absorption and emission studies on the picosecond and subpicosecond time domain and whose pulse characteristics we describe here. The synchronously mode-locked (SML) dye laser oscillator is presently operating in a linear, extended cavity configuration and can generate pulses at 82 MHz of ≥0.8 ps with an average power of 150 mW, tunable from 580–620 nm. Full details of its operation and the 3-stage amplification, which is driven by the second harmonic output at 530 nm from a Q switched Nd:YAG laser operating at 10 Hz to generate trains of dye laser pulses ~800 μJ/pulse at 10 Hz in the visible, have been given elsewhere (4, 24); only the salient details will be repeated here.

We have measured the temporal profiles for both the pulse ensemble and a single pulse selected from the ensemble. Autocorrelation traces are inherently a part of an ensemble-averaged nature and thus may contain contributions from a distribution of pulse shapes. We employ our speaker–autocorrelator system (24) as a permanent on-line monitor to measure, in real time, the background-free second-order autocorrelation function ($G_o^{(2)}(\tau)$) of the unamplified pulses emerging at 82 MHz from the output coupler of the dye laser. A step-by-step measurement of $G_o^{(2)}(\tau)$ is taken for amplified pulses at 10 Hz, using translation stages capable of electronically-controlled ±1 μ precision to determine the delay time (τ) within ±35 fs in one arm of the correlator.

In order to determine the true single pulse profiles, we have taken unamplified and amplified pulse measurements using an Imacon 500 (Hadland Co.) streak camera, coupled to a 20/30 intensifier, with a minimum slit width of 25 μ, maximum streak speed of 20 ps/mm, and an intrinsic technical response time of 0.75 ps for a threshold flux of ~10^5 photons/event at the slits. In practice, before this minimum response of the camera can be fully evaluated, significant electronic triggering/synchronization has been necessary to coordinate the multiple functions of this laser oscillator–amplifier system. We summarise the main sequence of events below.

The intensifier is coupled via a f/1.2 1:2 lens to a SIT vidicon detector and OMA 2 system (P.A.R., Corp.) which can be operated to automate data acquisition and storage. Single shot measurements are made by passing the argon ion or dye laser beam through a chopper–shutter arrangement which produces one 60 μs burst of pulses upon command from the OMA. A fraction of this burst is diverted to a PIN diode (PD), the output of which is connected to a Tektronix 7904 (500 MHz) oscilloscope (OSC). The +GATE output of OSC, which is synchronized to the sweep, is amplified to give an 18 V pulse with a risetime of 0.5 V/ns which triggers the streak

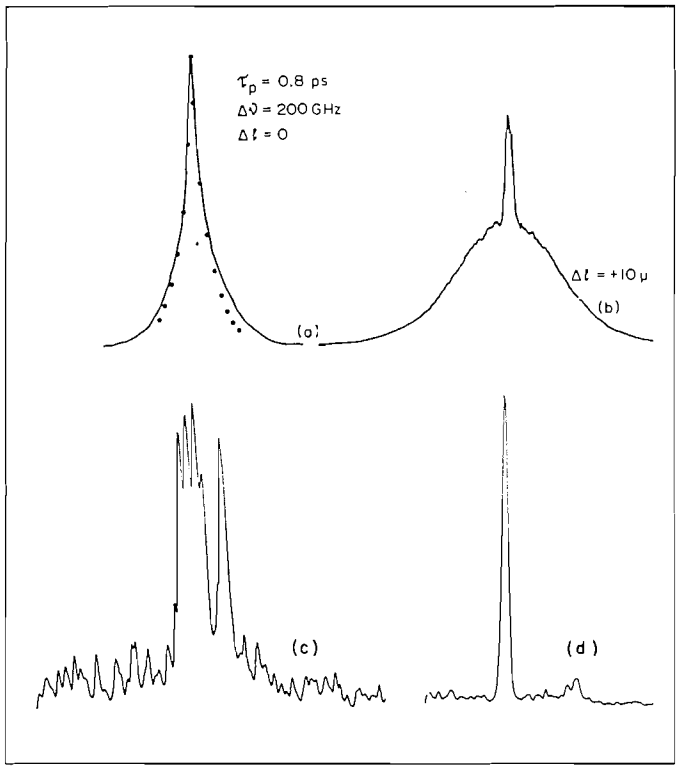

FIG. 2. Comparison of autocorrelation ensemble traces (*a*, *b*) and streak camera single pulse traces (*c*, *d*) for SML dye laser pulses as a function of cavity detuning. See text for details.

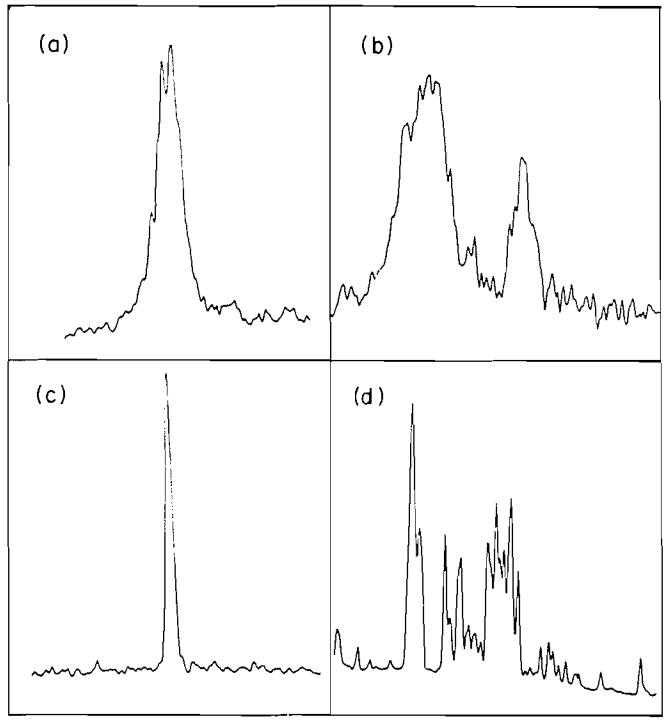

FIG. 3. Dependence of dye pulse profiles (*c*, *d*) on Ar^+ pump laser profiles (*a*, *b*) and cavity parameters. See text for details.

camera through an electronic delay. The trigger level on OSC is adjusted to select pulses from the burst and control jitter of streaks. Time calibration is accomplished with solid etalons.

Figure 2 illustrates the general effect of dye laser cavity detuning by 10 μ as revealed by the autocorrelation trace and the streak camera trace of the oscillator pulse. The effects of detuning on measurements of $G_o^{(2)}$ on synchronously-pumped dye laser systems have been reported earlier by us (24) and by others (25–27), but we are aware of only two other reports (26, 27) which have *compared* these effects with streak camera traces in the single shot mode, using a somewhat slower streak camera. Reproduced here to indicate that indeed apparent single pulse $G_o^{(2)}$ traces can actually include a major, if not dominant contribution, from multiple pulse structure, are selected data from a comprehensive survey of such effects that we are completing for the tunable SML laser system.

Trace (*a*) is obtained under optimum conditions, can be fitted (black dots) to an exponential pulse shape yielding τ_p = 0.8 ps ($\Delta\nu$ = 200 GHz) and is usually accepted as a "good" single pulse profile, while trace (*b*) represents the partial mode-locking case, which is seen following an increase in the dye laser cavity length of 10 μ. Under identical experimental conditions, the streak camera traces show that there is a significant population of multiple pulse structures, as typified in (*c*), hidden in the trace (*a*). In fact, the additional intensity in the wings of (*a*) above the theoretical fit is indeed a signature of some broader pulses within the ensemble. The pulse burst of (*c*) has a measured fwhm of 75.2 ps, with many narrower components. (This value is not corrected for streak camera resolution.) The analogous trace after detuning in (*d*) shows only single pulses with negligible satellite structures corresponding to the measured fwhm of (*b*), namely 10.3 ps.

The cavity detuning is not the sole parameter for determining single versus multiple pulse structure. If we can assign a probability P to the appearance of single pulses and thus $(1 - P)$ to the appearance of multiple structures, then for trace (*b*) $P \sim 1$, while for trace (*a*) $P < 1$ and has a weighted ratio of contributions from (*c*) and (*d*) type profiles. P is a complicated function related to the gain profile and at present we merely state $P = f(\omega,\omega_t,\omega_{ml},\nu_{ml},\Delta l,l...)$, where ω = average pumping power of argon ion laser, ω_t is the power threshold for the dye laser, ω_{ml} is the rf power, ν_{ml} the acousto-optic mode-locker frequency, and l the dye laser cavity length. We have separated out the intrinsic hydrodynamic behaviour of the ~300 μ thick dye jet, because although it is of most importance to the absolute duration and coherence quality of the subpicosecond laser pulses.

What determines the value of P in empirical terms? The four profiles in Fig. 3 illustrate the change in the Ar^+ pulse and the SML dye laser pulse as the laser operating conditions are varied. Trace (*a*) is a streak camera record of a single Ar^+ pulse (fwhm = 117 ps) from the 514 nm laser line just above threshold at 30 A, at W = 650 mW, and ν_{ml} = 41.1215 MHz, where P = 1 for single Ar^+ pulses. When l was adjusted to give good $G_o^{(2)}(\tau)$ traces (no wings), single pulse dye laser performance ($P \sim 1$) was obtained. Trace (*c*) (fwhm = 12 ps) is a typical streak camera record of such pulses. Increasing the ion current to 31 A where W = 800 mW and ν_{ml} = 41.1225 MHz lead to the Ar^+ double pulses seen in (*b*) with 259 ps separation between the major peaks. It is not surprising that under such conditions dye laser performance degrades to the trace in (*d*), a pulse burst of 168 ps where $P \sim 0.3$, even while cavity matching (Δl = 0) is maintained. One must be cautious in assessing true Ar^+ pulse shapes from ultrafast photodetectors and sampling techniques whose total response time averages out the vital information on the pulse substructure. The photograph inset to Fig. 1 shows such a photodiode signal of the argon ion pulse, where the diode total rise and fall time was specified to be 120 ps. There are three important conclusions from our studies so far which have general implications for all SML systems. (*1*) SML systems can generate multiple structure dye pulses with rather small changes in laser operating parameters. Single pulse operation is a very sensitive function of many variables. (*2*) These pulse bunches cannot be obviously recognized through autocorrelation traces, which averaged over millions of pulses could contain pulses of duration from typically 1 ps to 30 ps. This is because $G_o^{(2)}$ autocorrelation techniques based on second harmonic generation, while capable of indicating ultrafast subpicosecond and femtosecond components, are nevertheless fated to be symmetric in temporal profile and such pulse bunching appears as a somewhat dispersed contribution to the wings of the signal. (*3*) Streak camera traces reveal asymmetric and pulse

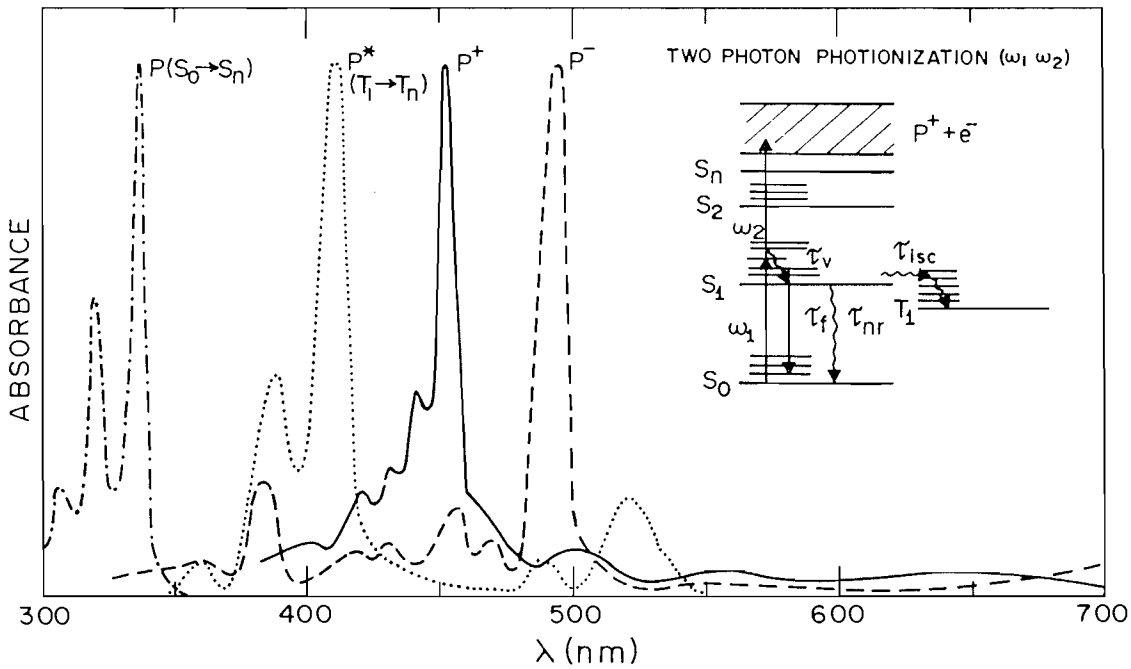

FIG. 4. Two photon photoionization of pyrene at $(\omega_1 + \omega_2)$ and competing intramolecular relaxation processes involving S_1, T_1 levels. Transient absorption spectra of the ions (P^+, P^-) and triplet [$P^*(T_1 \rightarrow T_n)$] are shown for comparison with singlet [$P^*(S_1 \rightarrow S_n)$] in Fig. 5. See text for discussion.

bunching or multiple structure very clearly, but nevertheless, at the present time, they cannot readily break the time barrier for subpicosecond resolution on a single shot on several technical accounts. These conclusions support earlier observations (26, 27) but indicate single pulse performance and the factor P to be a more sensitive function of cavity parameters than previously supposed. Such pulse diagnostics are the true beginning of reliable interpretations in photophysics and photochemistry, and for experiments exploiting excited states as probes of molecular and chemical dynamics. We have now succeeded in determining the domain of operating stability for single pulses from our SML oscillator–amplifier system and can deconvolute where necessary the excitation function from the dynamics of the molecular response under investigation.

(b) Picosecond and femtosecond pump-probe spectroscopy

Following excitation with a pump laser pulse, a weaker probe pulse (often of different frequency) monitors the transient absorbance, A. The intrinsic time resolution of an event is determined by varying the difference (τ) in arrival times of the pump and probe laser pulses, at both the sample and the detector. For recording the full optical absorption spectrum of ps transients, a ps continuum (28) is used in conjunction with a monochromator and calculations made for group velocity corrections and the SIT vidicon detector response of A (τ) where appropriate (4). For the photophysical studies both kinetics at single wavelengths and spectra were recorded for the transients following one or two photon laser excitation. For the pyrene absorption data reported here, purified and recrystallized pyrene (P) was used to prepare $\sim 10^{-4}$ M solutions in alcohols (distilled-in-glass quality) contained in 1, 2, or 10 mm pathlength quartz cells. Excitation and relaxation schemes are shown as an inset in Fig. 4. The amplified pulses at 615 nm were frequency-doubled to generate ω_1 (λ = 307 nm), which is absorbed strongly by pyrene undergoing a $S_0 \rightarrow S_2$ (^1L_a) transition, $\epsilon_{307} = 1.2 \times 10^4 M^{-1}\,cm^{-1}$. In other experiments, the 355 nm from the Nd:YAG laser was used to create population in the first excited singlet via excitation of a much weaker transition, $S_0 \rightarrow S_1$ (^1L_b) for which $\epsilon_{355} = 3.2 \times 10^2 M^{-1}\,cm^{-1}$. Subsequent excitations were for $\omega_1 = \omega_2$, or ω_2 tunable with $\lambda \geq 355$ nm. At these concentrations there was no evidence of excimer formation.

In the nonlinear optical experiments, chlorobenzene (spectroscopic grade) was used as a Kerr active medium and the measurements made in a collinear geometry for pump (ω_2) and probe (ω_1) pulses, as shown in the inset to Fig. 6*a*. The time-dependent transmission $T(\omega_1)$ of ω_1 through the Kerr cell contained within crossed polarizers (P_1, P_2) was measured during and after the passage of 300 fs pulses at 615 nm ($\omega_1 + \omega_2$). A double beam configuration was used as previously described (8) in order to normalise the data for laser pulse intensity fluctuations against the calibrated response from a CS_2 cell, where $n_2 = 2 \times 10^{-11}$ esu. The transmission of ω_1 through P_2 was detected by a fast photodiode coupled directly to a computer for the case of W_2 as linear and as circular polarized light, by manipulating a combination of wave plates and polarization rotators (represented by λ/n) at the entrance to the cell. Extreme care was taken to ensure the quality of polarized light and the absence of elliptical components in both ω_1 and ω_2, using techniques described earlier (8).

Organic molecular photophysics and dynamics

(a) Picosecond photophysics of pyrene

The influence of molecular motion such as vibration or rotation on the outcome of a chemical event depends on whether or not the nuclear kinetic energy terms can couple potential energy surfaces leading to new intramolecular relaxation or reaction channels. Such motion can enhance or impede the efficiency of the reactive channel. Multiphoton photoionization (29, 30) involving real intermediate stages S_1, S_2..., and thus sequential excitation to a higher S_n, level competes with vibronic relaxation (τ_v, τ_{nr}) intersystem crossing (τ_{isc}) and the onset of radiative relaxation (τ_f) from states already populated via ω_1, as shown for pyrene in Fig. 4 (inset). Tunable laser studies (3) of the multiphoton ionization mechanisms and measurement of the photoionization thresholds (IP) of molecules embedded in a range of environments can thus lead to important insights not only of intramolecular energy relaxation, but also of (*i*) the influence of intermolecular interactions, local fields, and phase density on the lowering of ionization potentials, (*ii*) the existence of molecular Rydberg states, and (*iii*) geminate ion recombination, electron trapping, and transfer processes. We

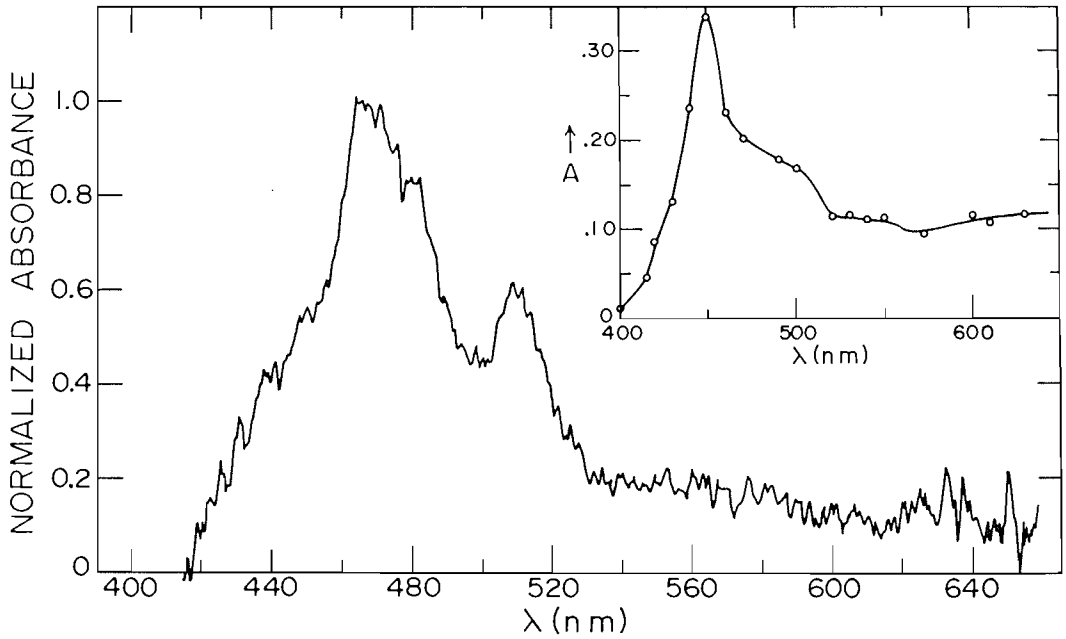

FIG. 5. Picosecond transient absorption: spectrum recorded at 2 ps in 10^{-4} *M* pyrene in ethanol following $S_o \rightarrow S_2$ excitation at 307 nm. Insert shows spectrum of P*($S_1 \rightarrow S_n$) recorded at 20 ns for 8×10^{-5} *M* pyrene in methanol, following $S_o \rightarrow S_1$ excitation at 347 nm.

report here the ps photophysics of pyrene in polar liquids as a prelude to ps photoionization studies of field-induced ionization and electron transfer in micelles.

Figure 4 shows the transient absorption spectra recorded in the $10^{-9}-10^{-6}$ s time domain following the two photon uv photoionization of pyrene in methanol at 355 nm and 347 nm (29). Note the relatively clear spectral separation of the radial ions P^+, P^-, and the triplet P*(T_1). The nanosecond spectrum of the singlet P*(S_1) and P^+ appear as an inset in Fig. 5, which shows the transient absorption spectrum in pyrene ethanol solutions following excitation with 300 fs pulse at 307 nm (31). The transient absorption was measured from 400 nm to 900 nm at 2 ps up to 50 ps delay, and within experimental resolution there were no significant spectral shifts, only loss of intensity over this interval. Absorption maxima occurred at 470 nm and 510 nm, corresponding to the singlet−singlet absorption at ns times (29). Under these experimental conditions, there was no evidence for the characteristic e_s^- absorption or the P^+ cation, which has a peak at 450 nm, and thus we conclude that only excited states have been formed. Furthermore, the triplet absorption ($^3P^*$) at 415 nm which grows significantly in $\sim 2 \times 10^{-6}$ s, is not apparent at these early times, eliminating suggestions of ultrafast triplet formation from this higher excited state of pyrene. The fact that the ps spectral profile of the P*($^1S_1 \rightarrow {}^1S_n$) transition is reminiscent of that measured in ns following 347 nm laser excitation of pyrene in cyclohexane (29), suggests that vibronic relaxation within the singlet manifold is very fast. However, current streak camera experiments designed to measure the ps fluorescence rise and decay in pyrene will confirm these qualitative observations and establish quantitative relaxation rates for $S_n \rightarrow S_1$ intramolecular radiationless transitions as a function of excess energy in the molecule. These are also important data for models of photoionization and electron transfer originating from high lying singlet states in pyrene in alcohols. The nature and lifetime of the ionizing state could well be important considerations in the interpretation of experiments which seek to measure the electron localization and solution time through the time-dependent appearance of e_s^- absorption (32−35). Clearly the pyrene photoionization step must be very efficient, and the lifetime of the ionizing state short, in order to complete effectively against ps vibronic relaxation. For electron localization times of 10^{-12} s, a lifetime of $\leq 10^{-12}$ s may determine the electron trapping rate.

The ionization potential of pyrene in a series of alcohols and micelles has been measured for ns times in double-pulse, tunable laser spectroscopy (3). The reduction in IP observed, from 7.7 eV in the gas phase to 6.6 eV in methanol, for example, is in agreement with the trends recently observed for other aromatic molecules such as benzene (30), and both sets of studies invoke the possibility of high-lying Rydberg states as the doorway states to ionization. Furthermore, this decrease of about 1.1 eV is within the 1.0−1.5 eV decrease commonly observed in photoemission studies of aromatic molecules in thin films, a shift assigned to valence electron interactions in the disordered media (36). While Rydberg states and valence states of gas phase atoms and small molecules exhibit different spectral features, discernible by observing the effects of perturber gases on the linewidth of the transitions, the number density of the condensed systems automatically ensures the high pressure limit and masks such distinctions. Nevertheless, ps emission and absorption studies of the onset of photoionization can provide quantitative dynamical data on the role of the *environment* in modifying the energetics and dynamics of the guest molecule. In a micelle, the charged interface could well be modelled as a type (*ii*) strong field effect. In sodium dodecyl sulphate micelles (SDS), which have a negative surface potential of about −85 mV and a radius of ~30 Å, the IP of pyrene is apparently lowered to 5.4 eV (3). This value was also later deduced from indirect measurements of the IP in cw illumination and conductivity experiments (37). Calculations of the polarization energies of the cation via the Born approximation and of V_o, the bottom of the conduction band for the excess, quasifree electron, are approximate but nevertheless cannot account for the further substantial decrease in IP on going from methanol to an aqueous SDS micelle (3). The unique contribution from the micelle could well be the charged

interface, which leads to a distortion of the Coulomb potential and lowering of the effective barrier to ionization. The effect of the field gradient cannot be established quantitatively in the absence of a thorough understanding of the complex phase transitions and structural dynamics of these micelles, which are highly sensitive to the presence of a perturbing guest (5*a*), and it is from this perspective that we are now pursuing these interface studies in the picosecond domain.

(b) Femtosecond nonlinear optical responses

While several incoherent and coherent, linear and nonlinear optical techniques are employed to extract dynamical information on orientational relaxation times, vibrational relaxation (T_1), dephasing (T_2), and field-induced nonlinear phenomena, the motivation and results can all be traced back to a single, very basic question. What is the microscopic dynamical description of a liquid? Liquids can be viewed a structureless fluid with continuum, bulk properties at one extreme, which anticipates hydrodynamic behaviour (38), or, at the other extreme as molecular or (atomic) systems within which collisions, spatial correlations, and high frequency fluctuations in local properties determine the dynamics and structure. The latter approach is closely reminiscent of kinetic theory. Picosecond and femtosecond laser spectroscopy has a unique role to play in probing the nature of molecular dynamics of liquids in real time and testing such theories. We present here new results on the orientational dynamics in chlorobenzene ($n_2 = 6 \times 10^{-12}$ esu) at 300 K as illustrative of the optical Kerr effect and polarization memory (9) in liquids at femtosecond times. These data are part of a fs study on temperature dependence of rotational motion in CS_2 and C_6H_5Cl (8).

The transmission (T) of the optical Kerr shutter in the collinear geometry (8) described for Fig. 6 corresponds to:

$$T(\omega_1) \propto \int_{-\infty}^{+\infty} I\omega_1(t - t^1) \sin^2 \left\{\frac{\delta\phi(t)}{2}\right\} dt$$

for linearly polarized pump and probe pulses, where for small phase (ϕ) shifts:

$$\delta\phi(t) = \frac{2\pi}{\lambda_1}\delta n(t)\text{: } \delta\phi(t) \propto I\omega_2(t)$$

The peak transmission in Fig. 6(*a*) occurs at zero time delay ($t^1 = 0$), or total overlap of the 300 fs pump and probe pulses, and rapidly relaxes over about 20 ps. The decay has both fast and slow exponential components, the latter displaying a time constant of 12 ± 1 ps which can be assigned to the orientational relaxation time of chlorobenzene via collisional and diffusional events. This is in good agreement with $\tau = 11.1$ ps, measurements obtained from dielectric relaxation (39), and reflects the predominance of collective motions, as also observed in depolarized laser light scattering techniques (38). The fast component, which seems to follow the laser pulse profile, we assign to electronic nonlinear polarization with perhaps some vibrational contributions to $\chi^{(3)}$ too. In Fig. 6(*b*) is shown the transmission recorded for circular pump (ω_2) and linear probe (ω_1) pulses, in which the fast component clearly dominates. (The same transmission function was measured despite differences in the phase shift $\delta\phi(t)$ anticipated for the circular case (9).) The fwhm of this signal is ~300 fs and together with recent fs CS_2 data (8, 23) represents the fastest optical responses recorded to date in any liquid.

A full interpretation of these effects must take into account the simultaneous superposition of coherently scattered electric fields and polarization in the molecular ensemble, but this will be addressed in a future paper. In brief, we have shown theoretically that such polarization selectivity should reveal the only electronic Kerr response, which will be enhanced close to a two-photon resonance (15). However, since $\omega_1 = \omega_2$ in this experiment, it is also possible that some degenerate four wave mixing (8, 9, 13, 40, 41) is taking place. Thus the amplitude of the transmission signal must be studied in a tunable probe experiment before a definitive measurement of the magnitude

of $\chi^{(3)}_{elec}$ is established. Nevertheless, both effects find their roots in electronic hyperpolarization and if we deconvolute the electronic temporal contribution from that in Fig. 6(*a*) containing the molecular part too, it is clear that there is an asymmetry in the temporal response of the orientational component. Chlorobenzene is not a symmetric top and it is possible that anisotropic diffusional components are quire *E*-field sensitive. The rise time is faster than the decay, implying that the reorientation response of the molecules to the sudden imposition of a strong field is faster than the ~12 ps relaxation of the alignment when the field is off. This demonstrates that indeed strong field effects can influence molecular orientation via a memory of the prior statistical structure and interactions of the liquid. This memory becomes impressed upon the polarization properties of the transmitted later pulses. It is possible that intracavity Kerr experiments (4, 7) will reveal a sharper asymmetry in the orientational transients. With fs laser pulses, we can begin to probe spatial correlations in liquids on time scales approaching a relatively small number of collisional events and characterise the behaviour of the memory kernel or the correlation function of the random forces in liquids.

We are continuing these theoretical and experimental studies in order to examine the impact of these strong field and orientational effects on chemical dynamics for systems undergoing sterically specific reactions, isomerization, or dipole–dipole Forster energy transfer with prerequisite molecular alignments.

Deviations from the $O_3-NO-NO_2$ photostationary state in tropospheric chemistry

JACK G. CALVERT and WILLIAM R. STOCKWELL

National Center for Atmospheric Research, P. O. Box 3000, Boulder, CO 80307, U.S.A.[1]

Received August 26, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

JACK G. CALVERT and WILLIAM R. STOCKWELL. Can. J. Chem. **61**, 983 (1983).

A theoretical study of the magnitude and origin of deviations in the photostationary state relation, $[O_3]_t[NO]_t/[NO_2]_t \simeq (k_1/k_3)_t[I]$ has been carried out by computer simulation. Various homogeneous tropospheric mixtures were chosen with initial pollutant concentrations varied from those of highly polluted to very clean atmospheres. Even for the homogeneous conditions assumed here, strong negative deviations were observed ($[O_3]_t[NO]_t/[NO_2]_t < (k_1/k_3)_t$ for many of the conditions chosen. Failure of [I] in many cases resulted largely from the non-zero value of $d[O_3]/dt$. Many other factors, including significant rates of O_3 reaction with NO_2, alkene, HO_2, HO, and ozone photolysis, contribute significantly to the deviations seen in several cases considered.

JACK G. CALVERT et WILLIAM R. STOCKWELL. Can. J. Chem. **61**, 983 (1983).

Faisant appel à une simulation à l'aide de l'ordinateur, on a étudié théoriquement l'ampleur et l'origine des déviations de la relation de l'état stationnaire $[O_3]_t[NO]_t/[NO_2]_t \simeq (k_1/k_3)_t[I]$. On a choisi plusieurs mélanges troposphériques homogènes avec diverses concentrations initiales en polluant allant des atmosphères très polluées à des atmosphères très propres. Même dans les conditions homogènes utilisées dans ce travail, on a observé des fortes déviations négatives ($[O_3]_t[NO]_t/[NO_2]_t < (k_1/k_3)_t$ pour plusieurs des conditions choisies. Dans plusieurs cas, l'insuffisance de la relation [I] provient principalement de la valeur de $d[O_3]/dt$ différente de zéro. Plusieurs autres facteurs incluant les vitesses appréciables des réactions de O_3 avec le NO_2, l'alcène, le HO_2, le HO et la photolyse de l'ozone, contribuent de façon significative aux déviations observées dans plusieurs des cas considérés.

[Traduit par le journal]

Introduction

It has been recognized for many years that in a sunlight-irradiated, polluted troposphere reactions [1]–[3] are the dominant fates of the NO, O_3, and NO_2. For these conditions relation [I] is expected to hold reasonably well at any time t.

[1] $NO_2 + h\nu \rightarrow O + NO$

[2] $O + O_2 + M \rightarrow O_3 + M$

[3] $O_3 + NO \rightarrow NO_2 + O_2$

[I] $[NO]_t[O_3]_t/[NO_2]_t \simeq (k_1/k_3)_t$

There are a variety of qualitative studies which have helped define the conditions under which relation [I] holds or for which deviations are large. Both experiment and theory suggest that for conditions of high air pollution (high [NO] and strong sunlight) relation [I] is followed reasonably well (1–16). Large positive deviations of $[NO]_t[O_3]_t/[NO_2]_t$ from $(k_1/k_3)_t$ observed by Calvert for the early morning hours in Los Angeles (12) were attributed to the large heterogeneity of the morning air masses. It was suggested that pockets of NO-rich air that originated from pollution sources near ground level mixed turbulently with pockets of older O_3-rich air that came from aloft. It was reasoned that although the photostationary state relation [I] may apply reasonably well in each pocket, an apparent deviation from [I] may occur from the use of averaged values of [NO] and $[O_3]$. These are measured by the aircraft during some finite time period during which many diverse pockets are sampled. For these conditions the product $\langle[NO]\rangle\langle[O_3]\rangle$ must be greater than the true $[NO][O_3]$ product in each small pocket of air. This reasoning appears to be consistent with the results of more quantitative consideration of this phenomenon by Seinfeld (17), Feigley (18), Chock and Kumar (19), and Bilger (14).

It has been recognized by several workers that deviations from relation [I] may be anticipated even for well mixed, homogeneous air masses (1, 7, 10–12, 16, 20–22). These cases involve conditions for which either the rates of reactions of O_3 with other species (NO_2, alkene, etc.) may become competitive with that for reaction [3], or the steady-state assumption may not be justified because of a rapid change in sunlight intensity (early or late in the day, cloud development, etc.) or NO, NO_2, or O_3 concentrations. However, the general consensus in the existing literature is that relation [I] describes reasonably well the interrelationship of the [NO], $[O_3]$, and $[NO_2]$ data for the highly polluted and the moderately polluted troposphere.

The present work was initiated to better characterize the extent of the deviations from relation [I] for homogeneous tropospheric air masses with various degrees of contamination and to determine the magnitude and the reasons for its failure. Stedman and co-workers (16, 20, 21) have made an interesting suggestion that deviation of $[O_3]_t[NO]_t/[NO_2]_t$ from $(k_1/k_3)_t$ observed in the relatively clean tropospheric air may result largely from the importance of the reaction $HO_2 + O_3 \rightarrow HO + 2O_2$ for these conditions. We will test this hypothesis in this study. In addition, we will attempt to define those conditions where relation [I] is an adequate representation of the O_3, NO, NO_2 data. Such information is valuable to modelers in their attempts to simplify tropospheric simulations.

Discussion

In this work we have used a seemingly realistic reaction scheme (Table 1) to computer simulate the homogeneous chemistry which occurs in synthetic polluted atmospheres. The chemical reaction mechanism employed should describe well the interactions between the inorganic and carbonyl species.

$CH_3COO_2H + h\nu \rightarrow CH_3O_2 + CO_2 + HO$	4.07×10^{-4} [b]
$CH_4 + HO \rightarrow H_2O + CH_3O_2$	1.14×10

[a] Units: second order constants, $ppm^{-1}\ min^{-1}$; first order, min^{-1}; third order, $ppm^{-2}\ min^{-1}$; pressure, 1 atm, temperature, 25°C.

[b] These rate constants vary with time to simulate the solar variation; the number shown is the value for 1200 h ($Z = 16.9°$, sea level, assumed 0.20 albedo).

Some shortcuts were adopted in the hydrocarbon reaction sequence adopted here in order to maintain some degree of control over the computer time for the simulations. Thus we have used only three hydrocarbon species, CH_4, "alkene", and "alkane". The reaction rate constants for HO and O_3 reactions with the alkene and alkane were adjusted averages (weighted by concentration, reactivity) which were derived from typical alkene, alkane, and aromatic hydrocarbon composition data from urban areas. The subsequent chemistry of the alkene and alkane was made to mimic that for propylene and propane,

respectively; thus CH_2O, CH_3CHO, and acetone (ketone) appear as the only carbonyl products. The sunlight intensity and the photolysis constants were picked to simulate a clear day in summer (July 1) at 40°N latitude, near sea level (temperature, 25°C). A surface albedo of 0.20 was assumed. The photolysis constants were varied to match reasonably well the diurnal variation of the sun through relation [II]:

$$[II]^2 \quad (k_x)_t = \exp\{\ln (k_x)_{noon}/\sin[(t - a)\pi/b]\}$$

Here $(k_x)_t$ is the apparent first-order rate constant for a given photochemical reaction x at time t (measured from midnight of the given day); a is the time for sunrise (0500, 300 min), and b is the time from sunrise to sunset (840 min). The $(k_x)_{noon}$ values for the eighteen different photochemical reactions in the simulation are shown in Table 1. All aspects of the mechanism chosen are based on current knowledge of the chemistry of these systems, but in those cases where experimental rate data are not available (e.g., the absolute rate constants for the reactions of the Criegee intermediates, CH_2O_2 and CH_3CHO_2), estimates were made using appropriate thermochemical and kinetic methods together with relative rate constant information. In most cases we have not included source terms for the pollutants, dilution of the reacting mixture, and ground loss of the reactants and products. The effects of adding these features are investigated in additional simulations as part of this study. Computer simulations were made using a variety of initial pollutant concentrations which are representative of a range of conditions from a highly polluted to a relatively clean tropospheric air mass. These initial concentrations are summarized in Table 2. The reactant, product − time distributions need not be considered here in detail, but they appear to be in qualitative accord with field data for conditions of similar pollutant contamination. Of special interest in the consideration of deviations from relation [I] are the reactants O_3, NO, NO_2, and alkene. A few examples of the time dependence during the daylight hours for cases *A*, *C*, *G*, and *H* can be seen in Figs. 3*a*, 4*a*, 8*a*, 11*a*–*c*, 13*a*, and 14*a*. Our analysis of these and other product and radical concentrations for cases *A*–*H* and other cases suggests that the present mechanism does a reasonably good job of simulating the gas phase chemistry of the troposphere, and our use of this mechanism to test for deviations from relation [I] should provide meaningful results.

The major reactions which control the ozone level in these simulations are as follows:

[1] $NO_2 + h\nu \rightarrow O + NO$

[2] $O + O_2 + M \rightarrow O_3 + M$

[3] $O_3 + NO \rightarrow O_2 + NO_2$

[4] $O_3 + h\nu \rightarrow O(^1D) + O_2$

[5] $O_3 + h\nu \rightarrow O + O_2$

[6] $O(^1D) + H_2O \rightarrow 2HO$

[7] $O(^1D) + M \rightarrow O + M$

[8] $O_3 + \text{alkene} \rightarrow \text{products}$

[9] $NO_2 + O_3 \rightarrow NO_3 + O_2$

[10] $HO + O_3 \rightarrow HO_2 + O_2$

[2]The function II is only for values in $\ln (k_x)_{noon} < 0$, for $\ln (k_x)_{noon} \geq 0$ a different function of similar form was used.

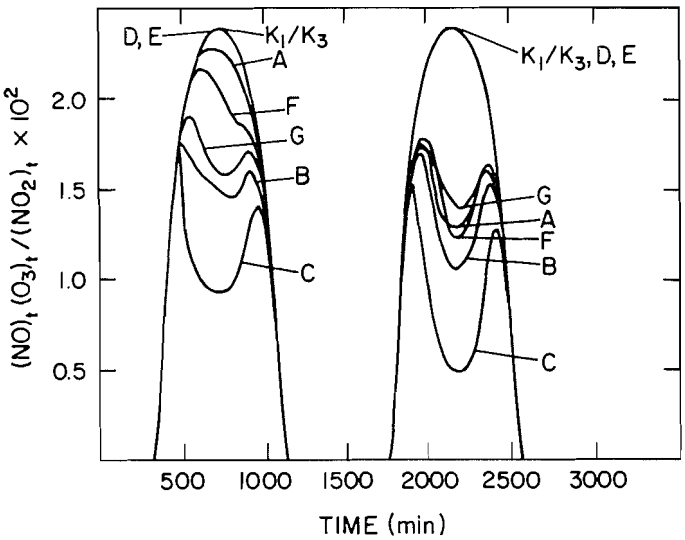

FIG. 1. Plot of the function $[O_3]_t[NO]_t/[NO_2]_t$ and $(k_1/k_3)_t$ for various times during a series of two-day computer simulations of the chemistry of tropospheric mixtures of varied pollutant composition; initial concentrations for the various cases A–G are given in Table 2.

[11] $HO_2 + O_3 \rightarrow HO + 2O_2$

Reaction [5] forming ground state $O(^3P)$ atoms is followed by an almost quantitative reformation of O_3 through reaction [2], so it is an insignificant O_3 loss mechanism in the lower troposphere. However, that fraction (Q) of the $O(^1D)$ formed in reaction [4] which ultimately reacts with H_2O, $Q = k_6[H_2O]/(k_6[H_2O] + k_7[M])$, results in O_3 loss. If we neglect dilution of the air mass and O_3 ground loss, then the rate of ozone generation in the system will be given by relation [III]:

$$[III] \quad \frac{d[O_3]}{dt} = k_1[NO_2] - [O_3][NO]k_3 - [O_3]k_4Q - [O_3][\text{alkene}]k_8 - [O_3][NO_2]k_9 - [O_3][HO]k_{10} - [O_3][HO_2]k_{11}$$

This relation can be recast into the form [IV] which reflects more directly the relation to the simplified steady state relation [I]:

$$[IV] \quad \frac{[O_3]_t[NO]_t}{[NO_2]_t} = \frac{(k_1)_t}{(k_3)_t}\left[1 + \frac{1}{(k_3)_t[NO]_t} \times \left\{\frac{k_4k_6[H_2O]_t}{k_6[H_2O]_t + k_7[M]_t} + k_8[\text{alkene}] + k_9[NO_2]_t + k_{10}[HO]_t + k_{11}[HO_2]_t + \frac{d[O_3]_t}{dt[O_3]_t}\right\}\right]^{-1} = (k_1/k_3)_tP$$

As we would expect the value of the function P approaches unity, and the relation [I] applies well, when $(k_3)_t[NO]_t$ is large compared to the other terms in relation [IV], that is, when reaction [3] is the dominant O_3 loss term. Of course deviations from [I] occur when alternative pathways of O_3 reaction become significant.

The instantaneous values of the function $[O_3]_t[NO]_t/[NO_2]_t$ were calculated as a function of time in the computer simulation of several one and two day scenarios using a range of typical impurity concentrations common in the troposphere. The magnitude of the deviations from the relation [I] were

TABLE 2. Initial concentrations of the pollutants for the simulations of various sunlight-irradiated tropospheric mixtures[a]

Pollutant	Concentration, ppb for the case shown							
	A	B	C	D	E	F	G	H

50% 1.56×10^7								
100% 3.12×10^7								

[a]These concentrations were assumed to be present at sunrise (0500) in simulations A–H shown.

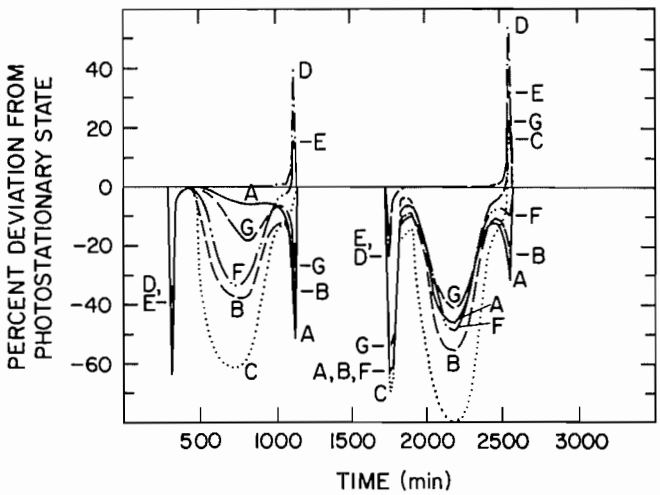

FIG. 2. Plot of the percentage deviation of the $[O_3]_t[NO]_t/[NO_2]_t$ function from $(k_1/k_3)_t$ for various times during a series of two-day computer simulations of the chemistry of various polluted tropospheric air masses; initial compositions are shown in Table 2.

calculated, and the contribution of each term of relation [IV] to this deviation was estimated. By "term" we refer to the individual terms within the { } signs multiplied by the quantity $1/(k_3)_t[NO]_t$. These deviations are seen in Fig. 1 for each of the initial conditions *A*–*G* (50% relative humidity) described in Table 2. Only in cases *D* and *E*, at the highest nitric oxide-to-hydrocarbon ratio, does the $[O_3]_t[NO]_t/[NO_2]_t$ time variation follow $(k_1/k_3)_t$ very closely during most of the daylight hours. In all other cases strong deviations are apparent. The percent deviation between the two terms at various times is shown in Fig. 2. Note that in all cases there is a strong negative deviation during the early morning hours. In the late afternoon hours all cases but *C* (first day) show another strong deviation, in some cases positive, some negative. The origin of the deviations has been determined from a detailed computer analysis of the systems. We will consider several of these cases which illustrate the results for different tropospheric mixtures.

(*a*) *The Highly Polluted Troposphere with a Relatively Low RH/NO_x Ratio, Case* A

The mixture chosen to represent highly polluted tropospheric air, case *A* (Table 2), has a relatively low hydrocarbon-to-nitrogen oxides ratio (5), which is typical of the early morning

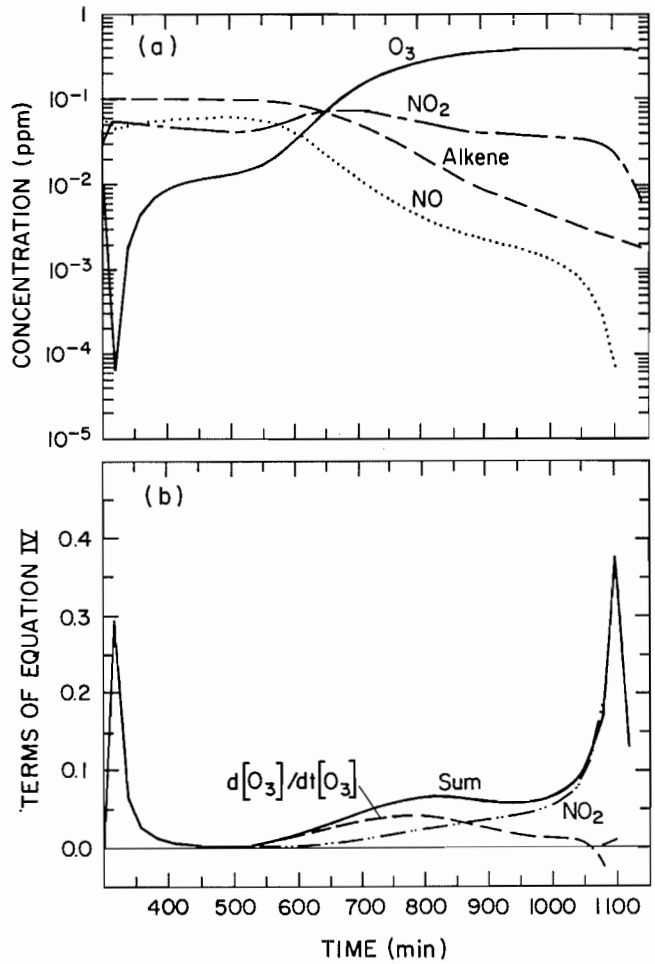

FIG. 3. (*a*) The time dependence of the various reactant concentrations during the first day of a computer simulation of the chemistry of a highly polluted tropospheric air mass (case *A*); (*b*) the magnitude of the individual terms of function [IV] and the sum of these terms for various times; the symbols shown with each curve give the reactant involved in the corresponding term in relation [IV].

urban air masses. During day 1 of this scenario, significant levels of ozone develop (about 0.39 ppm) late in the day; see Fig. 3*a*. In our simulation we have intentionally started the first morning with an imbalance in the $NO-NO_2-O_3$ mixture (with respect to relation [I]) which would be typical of the freshly mixed ozone-rich, older air from aloft and the NO-rich air from the early morning human activity near ground level. One sees a rapid decrease in the O_3 and NO as reaction [3] occurs forming NO_2. As the sunlight intensity increases, the hydrocarbons and aldehydes are oxidized, NO is converted to NO_2, and ozone development occurs; see Fig. 3*a*. The deviations from the steady state relation [I] for this case *A* are relatively small during most of the first day, but they become more serious the second day; see Figs. 1 and 2. Deviations seen near sunrise and sunset are the expected result of the rapidly changing concentrations of ozone, NO, and NO_2; for such conditions the steady-state relation [I] cannot be fulfilled at the very low NO_2 photolysis rates characteristic of the low solar flux at these hours.

In Fig. 3*b* we can learn the origin of the deviations seen from the plot of the magnitude of the individual terms of relation [IV]. The last term in relation [IV] involving $d[O_3]/dt[O_3]/k_3[NO]$ is the dominant source of the deviation during most of the day; in the afternoon hours, the third term of [IV] resulting from the O_3-NO_2 reaction [9] becomes important. At this time [NO] becomes very low and $[NO_2]$ relatively high. No other terms in [IV] are significant here.

Concentrations of reactants during the nighttime hours are not shown, but those starting with the sunrise the second day are plotted in Fig. 4*a*. The NO level is extremely low initially, although it climbs somewhat as NO_2 photolyzes to form NO. As a result reactions other than [3] are important in O_3 loss, and the second day deviations from relation [I] are much larger; Figs. 1 and 2. Several terms in relation [IV] cause the deviations in this case; see Fig. 4*b*. Large positive terms in [IV] come from both the HO_2-O_3 reaction [11] and the O_3 photolysis in process [4] followed by [6]; a large negative term results from the last term of [IV] involving $d[O_3]/dt[O_3]$. A smaller but observable contribution from the HO-reaction can be seen as well. Negative deviations of $[O_3]_t[NO]_t/[NO_2]_t$ from $(k_1/k_3)_t$ of the magnitude seen here for day 2 of case *A* have been observed in polluted tropospheric air masses by Kewley and Post (15) in the Sydney, Australia airshed, and by Stedman *et al.* (20) in Claremont, California. Both these groups have used alternative explanations to those advanced here in the explanation of these deviations.

We can see in Fig. 5 the effect of different humidities on the magnitude of the stationary state deviations starting with the initial *A* mixture composition. Note here that the deviations from relation [I] become larger with increasing humidity. From Fig. 6 it is apparent that the larger error enters by way of the increased significance of the $d[O_3]/dt[O_3]$ term. Other terms make observable contributions during the time near sunrise and sunset.

Real atmospheric mixtures of impurities have some degree of dilution as the dirty air mass diffuses turbulently into cleaner air, and the emission of new impurities into the air mass usually occurs as well near urban environments. To observe the effects of these more realistic conditions on the magnitude of the deviations from relation [I], we have made runs with case *A* initial conditions but with the inclusion of dilution of the reacting mixture (10^{-4} min^{-1}) and continued addition of new impurities (NO, NO_2, and alkene at 1.25×10^{-4}, 4.18×10^{-5}, and 1.67×10^{-4} ppm min^{-1}, respectively). These results are

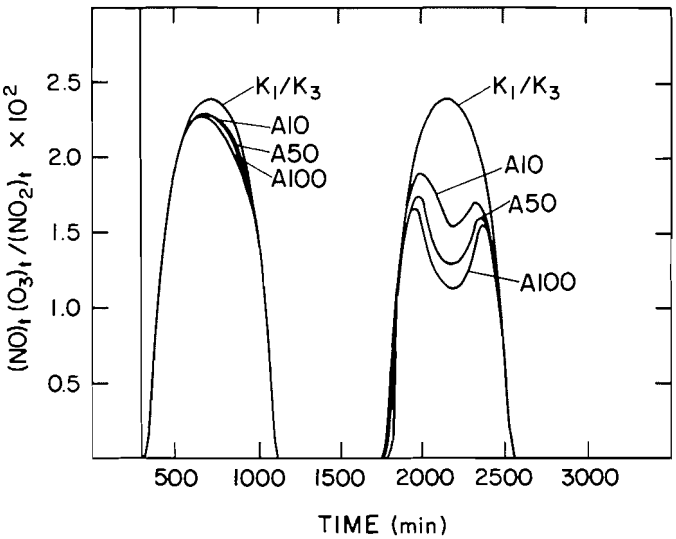

FIG. 5. The effect of humidity on the deviations of $[O_3]_t[NO]_t/[NO_2]_t$, from $(k_1/k_3)_t$, for a two-day computer simulation of the chemistry of a highly polluted tropospheric air mass (case *A*).

summarized in Figs. 7*a* and 7*b*. As one might expect a smaller deviation is seen for this case as a result of the higher NO levels

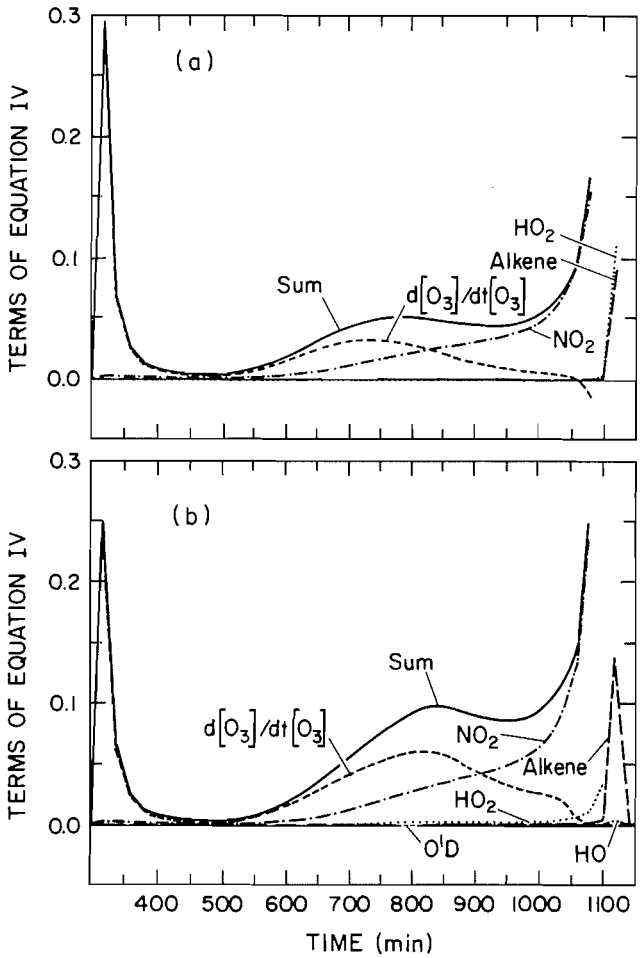

FIG. 6. The magnitude of the individual terms of the function [IV] and the sum of these terms for various times in the simulation of the highly polluted air mass (case *A*) for: (*a*) 10% and (*b*) 100% relative humidity. Compare with the similar results for case *A* at 50% relative humidity in Fig. 3*b*.

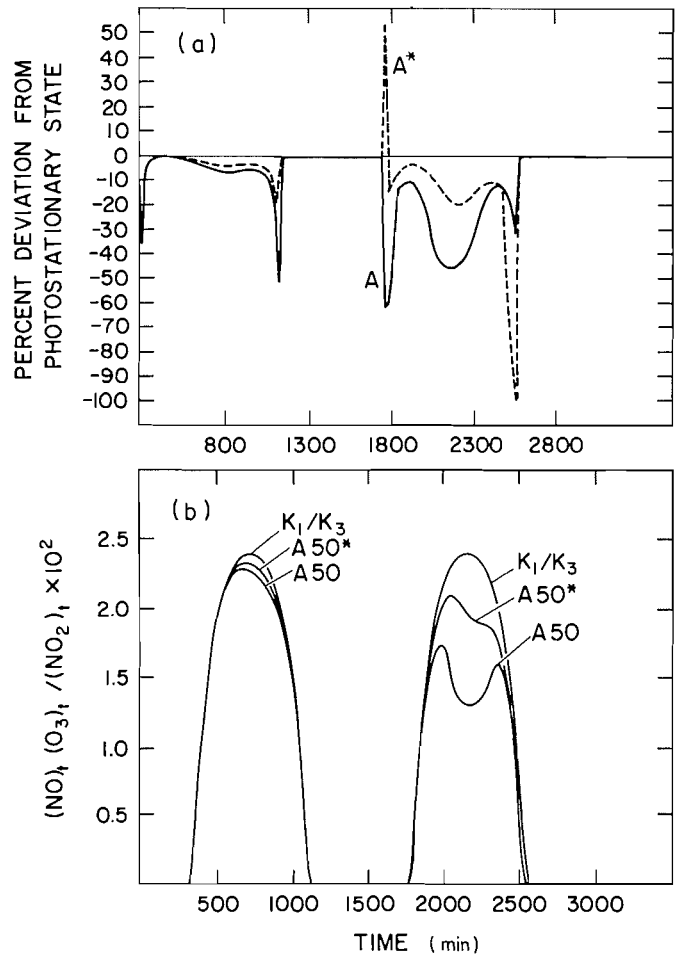

FIG. 7. (*a*) The percentage deviation of the $[NO]_t[O_3]_t/[NO_2]_t$ from $(k_1/k_3)_t$ for various times for the two scenarios of Fig. 7*a*. (*b*). Plot of the functions $[NO]_t[O_3]_t/[NO_2]_t$ and $(k_1/k_3)_t$ for various times during the computer simulation of the chemistry for case *A* (50% relative humidity) and with (A50*) and without (A50) pollutant dilution and continued pollutant additions.

maintained through continued NO emissions and the resulting enhanced rate of the $NO-O_3$ rate compared to other competitive O_3 reactions. It appears that for the highly polluted troposphere, the approximate relation [I] may apply reasonably well (within 20%) during the bulk of the daylight hours even over a several day period, provided that NO_x sources maintain a modest level of NO during the daylight hours. The use of relation [I] in simplifying computer simulations of highly polluted tropospheric mixtures such as case *A* at low RH/NO_x ratios, appears to be justified.

(*b*) *The Highly Polluted Troposphere at Very High RH-to-NO_x Ratio, case* C

In all of the studies made here the deviation from the relation [I] is greatest for case *C*. At the low levels of NO present in this case together with the high levels of impurities such as the hydrocarbons and aldehydes, the O_3 loss by reactants other than NO becomes very significant (Fig. 8*b*) from the onset of the simulation. The NO is titrated to NO_2 by O_3 during the early morning and late evening hours (Fig. 8*a*), and the O_3-NO_2 reaction leads to large positive deviations. The rate of change of ozone with time (last term of relation [IV]) leads to a much larger negative deviation at these times. During the vast portion of the daylight hours this same term is the source of the largest positive deviation. Smaller but significant deviations result from the O_3 loss by HO_2, O_3 photolysis, and alkene reactions. Obviously one cannot use relation [I] in simplifying tropospheric simulations for dirty air masses at high RH/NO_x ratios.

(*c*) *The Troposphere with Rather Low Pollution Levels, case* G

In this case NO_x, RH, RCHO, and SO_2 levels are only one-hundredth of those of the highly polluted troposphere (case *A*). Deviations from relation [I] are significant but not as serious as in case *C*; see Figs. 1 and 9. Again the deviations are sensitive to the humidity with the highest deviation occurring at the highest humidity; Fig. 9. In Fig. 10 we observe that during the first day events for case *G* the non-zero $d[O_3]/dt[O_3]$ term is the major error source for all humidities, but the loss of O_3 through its photolysis, and by its reactions with HO_2, HO, and NO_2 reactions becomes increasingly important for increased humidity. The results observed for the second day of case *G* at 100% relative humidity are interesting. NO is very low during the second day of case *G* (Fig. 11*c*), and the deviation seen during the day results from the sum of a large positive deviation from ozone loss by photolysis, a nearly equal term of negative sign from $d[O_3]/dt[O_3]$, and very significant positive terms which come from the HO_2 and HO reactions with O_3 (Fig. 11*d*). Obviously the deviation in this case results from

several significant contributing terms in relation [IV]; no single term dominates.

(*d*) *The Very Clean Tropospheric Air, case* H

To test the hypothesis of Stedman *et al.*, a five day scenario was studied using initial pollutant concentrations which are representative of very clean tropospheric air. The deviations of the $[NO]_t[O_3]_t/[NO_2]_t$ function from $(k_1/k_3)_t$ for this case can be seen in Fig. 12. After the first day little further change in the extent of the deviation can be seen. We have analyzed the origin of this deviation for the third and fourth days. The concentrations of O_3, NO, NO_2, and alkene during these

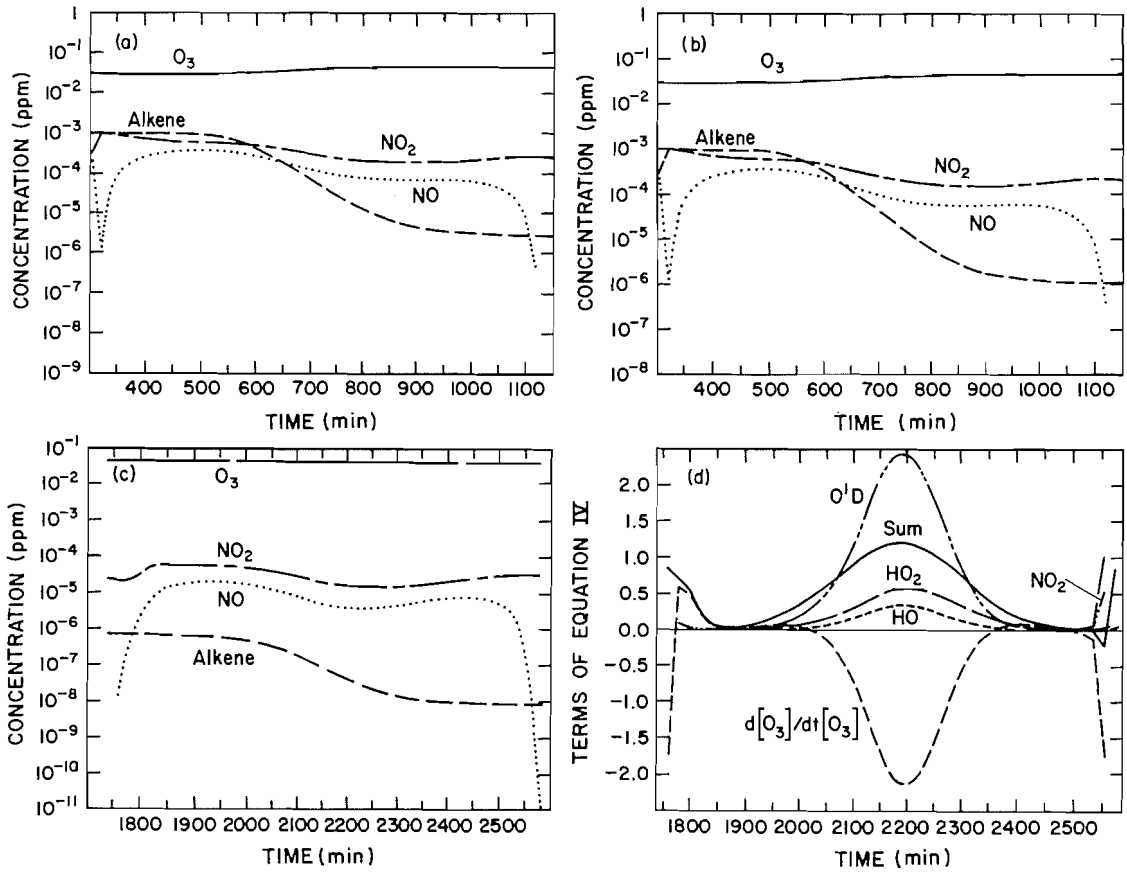

FIG. 11. The time dependence of various reactant concentrations during the computer simulation of the chemistry of a relatively clean tropospheric air mass (case *G*): (*a*) day 1, 50% relative humidity; (*b*) day 1, 100% relative humidity; (*c*) day two, 100% relative humidity.

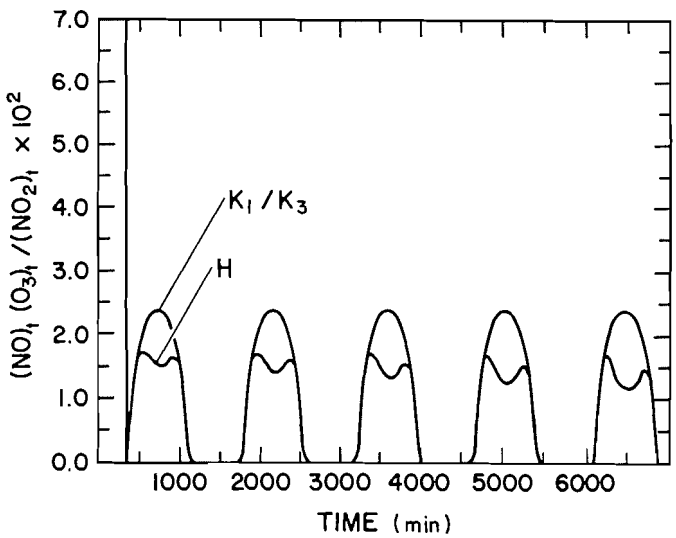

FIG. 12. Plot of the function $[NO]_t[O_3]_t/[NO_2]_t$ and $(k_1/k_3)_t$ versus time for a five-day simulation of the chemistry of a very clean tropospheric air mass (case *H*, 50% relative humidity).

periods are shown in Figs. 13*a* and 14*a*. The origin of the deviations are summarized in Figs. 13*b* and 14*b*. In each of these cases there is a near balance between the large negative term resulting from $d[O_3]/dt[O_3]$ and the positive term for O_3 loss by photolysis; O_3 loss from both HO_2 and HO reactions give relatively large positive terms. Note that near midday on the fourth day the total deviation is close to that for the HO_2-O_3 term alone; although other terms contribute significantly to the total deviation, a fortuitous near cancellation of the other terms results for this case. For this special case the suggestion of Stedman *et al.* (16, 20, 21) that observed deviations from [I] in relatively clean tropospheric air masses may reflect the occurrence of the HO_2-O_3 reaction is borne out. Note that during day 3 of case *H* this is not the case.

In most of the cases considered here several significant terms of relation [IV] control the deviation from the $O_3-NO-NO_2$ photostationary state. By far the largest term in most cases considered here is the last term of relation [IV] containing the $d[O_3]/dt[O_3]$ function. Several conclusions can be made in view of the present work. (*1*) The approximate steady-state relation applies well for NO-rich, highly polluted air masses at low RH/NO_x ratios. For this condition modellers will find that the use of relation [I] in the simplification of simulations is justified. (2) It is apparent that, in general, one cannot simply equate non-conformity of the O_3, NO, NO_2 concentration data to relation [I] with the influence of the HO_2-O_3 reaction alone; a reasonable interpretation can be made only through a knowledge of the level of all the potential O_3 reactant concentrations (NO, NO_2, alkene, HO_2, HO) as well the rate of change of O_3 with time; with this information in hand an investigator can make a meaningful interpretation of the magnitude of the several terms in relation [IV] and the extent of the deviation from [I]. We must conclude that the inference that HO_2 concentrations in the clean troposphere can be estimated from the measured deviations of $[O_3]_t[NO]_t/[NO_2]_t$ from $(k_1/k_3)_t$ is not of general validity, although there can be special circumstances where this appears to be a reasonably accurate hypothesis.

A simple, banded absorption spectrum has been detected by photochemical modulation spectroscopy in Hg-photosensitized reactions forming vinyl radicals. It starts at 499.5 nm, reaches maximum intensity ($\epsilon \approx 30\ M^{-1}\ cm^{-1}$) around 400 nm, and contains progressions of 1200 and 920 cm^{-1} vibrations. These features are compatible with the electronic structure, equilibrium geometries, and energies of the $^2A'$ ground and $^2A''$ first excited states of vinyl which were determined by *ab initio* SCF calculations. The upper state of the observed transition is analogous to the $\tilde{C}$ state of the isoelectronic formyl radical.

H. E. HUNZIKER, H. KNEPPE, A. D. MCLEAN, P. SIEGBAHN et H. R. WENDT. Can. J. Chem. **61**, 993 (1983).

Faisant appel à la spectroscopie de modulation photochimique, on a observé un spectre simple de bandes d'absorption lors des réactions photosensibilisées par le mercure conduisant à la formation de radicaux vinyles. Le spectre s'étale de 499,5 nm pour atteindre son maximum d'intensité ($\epsilon \approx 30\ M^{-1}\ cm^{-1}$) autour de 400 nm et contient des progressions de vibrations à 1200 et à 920 cm^{-1}. Ces caractéristiques sont compatibles avec la structure électronique, les géométries d'équilibre et les énergies de l'état fondamental $^2A'$ et du premier état excité $^2A''$ du vinyle que l'on a déterminé par des calculs *ab initio* de champ autocohérent. L'état supérieur de la transition observée est analogue à l'état $\tilde{C}$ du radical formyle isoélectronique.
[Traduit par le journal]

Introduction

It is surprising that a small hydrocarbon radical as common as vinyl has not yet been detected optically. Observation of this species has previously been accomplished only by mass spectroscopy (1) and electron spin resonance (2). The latter technique has been used to study reactions of substituted vinyl radicals in the liquid phase. Mass spectrometric detection of vinyl in gas phase reactions has been very limited (1, 3) and little is known about bimolecular rate processes involving the radical (4). This is unfortunate since vinyl radicals play a role in many chemical reactions, especially free radical addition to, and polymerization of, acetylenes. The simplest reaction of this type, reversible addition of H-atoms to acetylene, has been of interest to kineticists investigating falloff behavior of addition reactions (5). We have used this well-studied reaction as the basis of a search for the vinyl optical spectrum. The search was guided by *ab initio* SCF calculations for the ground and first excited electronic states of the radical. We hope that our identification of a visible spectrum of vinyl will be useful in future measurements of its gas phase reactivity.

Ab initio electronic structure calculations

SCF calculations show that the vinyl radical is planar in both its $1a'^2 \ldots 6a'^2 7a'^1 1a''^2, {}^2A'$ ground state and $1a'^2 \ldots 6a'^2 7a'^2 1a''^1, {}^2A''$ lowest excited state. The excitation moves one of the C—C π-bonding electrons into the in-plane orbital which is singly occupied and localized on the radical center in the ground state. In calculations with a basis set of double-zeta quality (6), the optimized geometries shown in Fig. 1 were determined. The largest relaxation effects following excitation are the expected lengthening of the C—C bond, 1.323 Å to 1.455 Å, and a change in the CCH angle at the radical center from 135° to 105°. The bond lengths shown in Fig. 1 are probably reliable to within 0.02 Å. These simple SCF calculations have taken advantage of compensating errors arising from lack of completeness in the basis set and neglect of correlation effects.

Excitation energies were computed with correlated wavefunctions at the geometries of Fig. 1. The wavefunctions, for both states, are CI expansions in a configuration state function (CSF) space of the dominant SCF configuration plus single and double replacement CSF's generated by replacing occupied orbitals in the dominant configuration by SCF unoccupied orbitals. Double replacement CSF's are restricted to those spanning the interacting space defined by McLean and Liu (7). In these correlated calculations the orbitals were expanded in a double-zeta plus polarization basis; one *d*-type function was added to each carbon and one *p*-type function to each hydrogen.

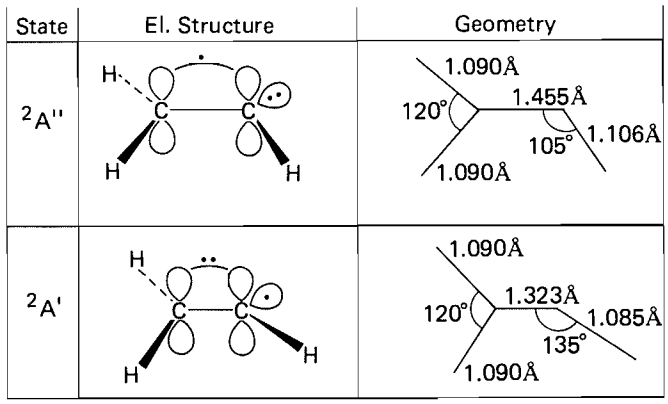

FIG. 1. Qualitative electronic structures and computed SCF geometries of the $^2A'$ ground state and $^2A''$ first excited state of vinyl radical.

The vertical excitation energy thus calculated is 3.24 eV, and the adiabatic excitation energy is 2.37 eV.

Photochemical modulation experiments

The optical absorption spectrum of the radical was measured by modulation spectroscopy of Hg-photosensitized reactions. An apparatus similar to one described previously was used (8), except that for the vinyl experiments it was equipped with a 12-pass White cell (9) affording a 2.4 m absorption path

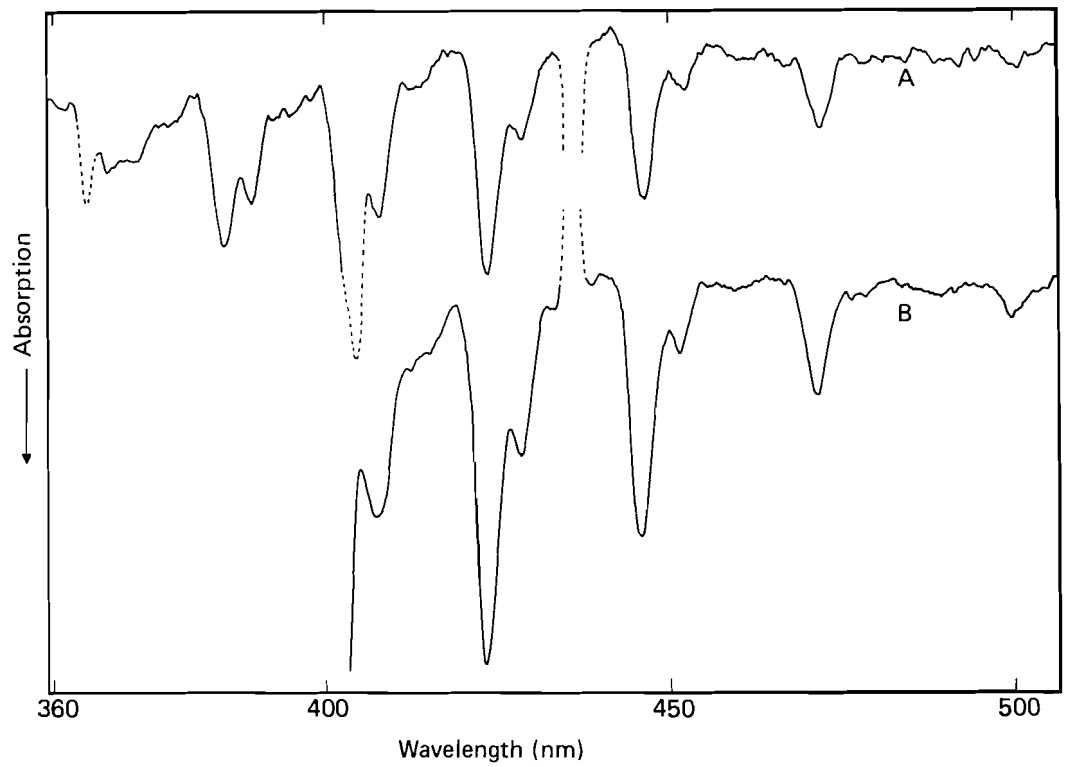

FIG. 2. Absorption spectrum of vinyl radical at 1.6 nm resolution. Reaction [3] was the H-atom source for Trace A (with RH = C_2H_6), and reaction [2] for Trace B. Dotted regions indicate interference by HgH absorption bands and Hg I straylight lines. The molar extinction coefficient at the 423.2 nm band maximum is approximately 30 L/mol cm (see text).

length, and with a cooled Si photodetector.[1] The photolysis source, an rf-excited, low pressure Hg arc, was modulated at 270 Hz and provided an average excitation rate of about 10^{-5} mol/L s inside the flow reactor. Experiments were carried out at 310 K and 1 atm total pressure, where the reaction

[1] $H + C_2H_2 + M \rightarrow C_2H_3 + M$

can be assumed to be in its high pressure limit with the polyatomic third bodies, M, used (5). H atoms were generated either by Hg-photosensitized decomposition of H_2,

[2] $Hg(6^3P_1) + H_2 \rightarrow 2\,H + Hg(6^1S_0)$

or of ethane or propane (RH),

[3] $Hg(6^3P_1) + RH \rightarrow H + R + Hg(6^1S_0)$

While reaction [2] yields more H-atoms and a larger vinyl signal, it also generates HgH as an intermediate (10) whose strong absorption spectrum interferes with that of vinyl below 405 nm. In this wavelength region reaction [3] is more useful since little HgH is formed and interference can be minimized by phase adjustment, making use of the shorter lifetime of HgH. Acetylene concentrations were approximately optimized for vinyl production, avoiding the possible side reactions $Hg(6^3P_1) + C_2H_2$ and H + RH. Accordingly 5 Torr of C_2H_2 were used with RH = C_3H_8 and 0.5 Torr with C_2H_6. With H_2 (used diluted, 1:30, in CH_4, which was the third body in this case) some removal of Hg was noted, increasing with C_2H_2 partial pressure and probably due to reaction of HgH with C_2H_2. Low C_2H_2 pressures (0.5 to 1 Torr) were therefore used.

Transient absorption spectra obtained with reactions [2] and [3] as H-atom sources are shown in Fig. 2, and positions of the band maxima are listed in Table 1. The phase shift of the transient absorption signal relative to the modulated photolysis light was about 45° at high acetylene concentrations, where reaction [1] is fast enough to contribute little to the shift. This corrresponds to a transient lifetime of about 1 ms which is expected when the decay occurs by radical–radical reactions. The bimolecular rate constant for the vinyl–vinyl reaction cannot be easily derived from this observation since vinyl–alkyl and vinyl–H encounters also contribute.

The 423.2 nm band was examined for rotational structure at twice the resolution of Fig. 2, but no clear evidence of structure was found. It was hoped that some K-subbands (11) could be detected on the long wavelength side of the band, where the geometries of Fig. 1 predict the subband spacings to become comparable with the 45 cm^{-1} resolution. No definite conclusion is possible as to whether the rotational structure is sharp or diffuse. The latter could be the case since the upper state lies above the H–C_2H_2 dissociation limit (770 nm) (12), although adiabatic dissociation into $C_2H_2(\tilde{X})$ + $H(^1S)$ is symmetry forbidden.

Experiments were also carried out using D_2 instead of H_2, and replacing C_2H_2 by C_2HD or C_2D_2. Spectra resembling those of Fig. 2, with ill-defined changes in the $v_2' = 1$ series, were obtained. It appeared that H–D exchange and increased polymer formation, the latter being especially severe in the C_2D_2/D_2 case, made it difficult to obtain clear-cut results with deuterated reactants.

In order to support the assignment of the observed spectrum the reaction

[4] $Hg(6^3P_1) + (C_2H_3)_2O \rightarrow Hg(6^1S_0) + C_2H_3 + C_2H_3O$

was investigated as an alternate vinyl source. Direct photolysis

*Estimated position.

of divinyl ether is known to produce vinyl and "vinoxy" (α-oxo-ethyl) radicals (3). Several of the stronger bands of Fig. 2 were observed with reaction [4] together with the spectrum of C_2H_3O which starts at 347.7 nm (13). Hg-photosensitized decomposition of divinyl ether does not appear to proceed uniquely by reaction [4] since other transients absorbing in the region of the vinyl spectrum are also formed.

Since extinction coefficients for the "vinoxy" radical were determined previously (13), the divinyl ether experiment yields a direct estimate of the extinction of the vinyl bands, provided the two radicals are formed in a 1:1 ratio as in reaction [4]. $\epsilon = 24$ L/mol cm was thus obtained for the maximum of the 423.2 nm band. This value was checked by generating vinyl and "vinoxy" radicals separately, the former with reactions [1] and [3] ($RH = C_3H_8$) and the latter by Hg-photosensitized decomposition of methyl vinyl ether (13), under otherwise identical experimental conditions. Comparison of the absorption signals yielded a value of $\epsilon = 30$ L/mol cm based on an H-atom yield of 0.77 from propane (14). (With a yield of 1.0, $\epsilon = 24$ L/mol cm is obtained.) Including the uncertainty of the "vinoxy" reference, we estimate $\epsilon = (27 \pm 12)$ L/mol cm for the 423.2 nm band maximum at 1.6 nm resolution.

Discussion

The features of the observed absorption spectrum, Fig. 2 and Table 1, agree with the *ab initio* predictions for vinyl. From the equilibrium geometries of Fig. 1 we expect to see progressions of the upper state C—C stretching and CCH bending vibrations in the $^2A''-{}^2A'$ electronic transition. Two progressions with $\nu_1 \approx 1200$ cm^{-1} and $\nu_2 \approx 920$ cm^{-1} are indeed observed. These values are in reasonable agreement with those expected for C$\dot{-}$C and C$\dot{-}$C—H partial-bond stretching and bending motions, respectively,[2] as required by the upper state electronic structure. Similar frequencies have been found for the $\tilde{C}$ state of HCO where the corresponding modes give rise to intervals of 1200 cm^{-1} and 960 cm^{-1} (15). HCO is isoelectronic with C_2H_3 and the electronic structure of its $\tilde{C}$ state is analogous to that of the $^2A''$ state of C_2H_3 (16).

We cannot be certain whether the first band observed at 20 020 cm^{-1} is the 0–0 transition but it is not far from the predicted, adiabatic excitation energy, 18 300 cm^{-1}. The Franck–Condon maximum of the band system is located near the 24 815 cm^{-1} band which is again in reasonable agreement with the calculated, vertical excitation energy of 26 100 cm^{-1}. Since the matrix elements determining the strength of this $\pi \rightarrow n$ transition in vinyl are qualitatively similar to those of $n \rightarrow \pi^*$ transitions in aldehydes and ketones, we expect extinction coefficients of the same order of magnitude, i.e. $\epsilon(\text{max}) \approx 20$ L/mol cm (17). The observed value, $\epsilon(\text{max}) \approx 30$ L/mol cm, agrees with this expectation.

Conclusion

We have observed a transient absorption spectrum whose presence and kinetics in two simple reaction systems make it likely that it belongs to the vinyl radical, C_2H_3. While we were unable to obtain rotational and isotopic information, close agreement of the observed spectrum with *ab initio* predictions strongly favors its assignment to the $^2A''-{}^2A'$ lowest electronic transition of vinyl radical.

Acknowledgments

We want to thank Dr. J. Weber for assisting with the calculations, and Dr. J. V. Michael and Dr. B. Liu for helpful discussions.

The intermediate formation of ketocarbenes and the conformational control in the Wolff rearrangement of α-diazoketones

MANUEL TORRES, JUAN RIBO, ALLAN CLEMENT, AND OTTO P. STRAUSZ
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 23, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

MANUEL TORRES, JUAN RIBO, ALLAN CLEMENT, and OTTO P. STRAUSZ. Can. J. Chem. **61**, 996 (1983).

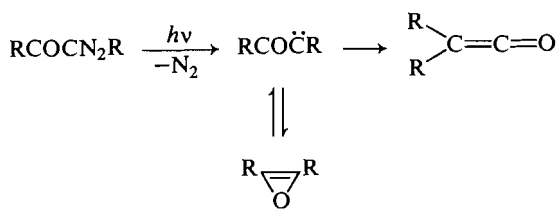
The conformational control of the Wolff rearrangement (WR) has been studied by means of a comparative study of the low temperature photolysis of argon-matrix isolated α-diazo ketones, **1**, and of vinylene thioxocarbonates, **2**. Under these conditions the *s-E*, *s-Z* conformational equilibrium of **1** will be hindered whereas **2** has a fixed *s-Z* conformation. The results indicate that the conformational control observed in the WR of α-diazo ketones is not per se a proof for a concerted mechanism and that a mechanism involving a ketocarbene intermediate is the most reasonable.

MANUEL TORRES, JUAN RIBO, ALLAN CLEMENT et OTTO P. STRAUSZ. Can. J. Chem. **61**, 996 (1983).

On a étudié le contrôle conformationnel de la transposition de Wolff (TW) au moyen d'une étude comparative de la photolyse à basse température des α-diazo cétones **1** et des thioxocarbonates de vinylène **2**, isolés dans une matrice d'argon. Dans ces conditions, l'équilibre conformationnel *s-E*, *s-Z* du composé **1** sera empêché tandis que le composé **2** a une conformation *s-Z* fixe. Les résultats indiquent que le contrôle conformationnel observé dans la TW des α-diazo cétones n'est pas en soi une preuve de l'existence d'un mécanisme concerté et qu'un mécanisme impliquant un cétocarbène comme intermédiaire est plus raisonnable.

[Traduit par le journal]

The Wolff rearrangement (WR) of α-diazo ketones and α-diazo esters to ketenes can be brought about either photolytically, thermally, or catalytically and ketocarbenes are generally thought to be implicated as short-lived reactive intermediates in the photochemical and thermal reactions (1–12).



Unambiguous evidence for the intermediacy of ketocarbenes and carbalkoxycarbenes came from the detection of oxirenes as reactive intermediates in the WR (4, 10, 11) kinetic studies (7) as well as from the effects of the substituent upon nitrogen elimination (6). Moreover, molecular orbital computations predict a prohibitively high energy requirement for concerted nitrogen elimination (12). Also, the low temperature stabilization and direct esr detection of a series of triplet state ketocarbenes from the photolysis of α-diazo ketones has been reported (13–18). These observations are in agreement with molecular orbital predictions of a triplet ground state for these species, with a small singlet–triplet energy separation (19).

A concerted mechanism for the WR would be in clear contradiction to the now well established transient formation of oxirene in a large number of photochemical WR (for a recent review, see ref. 20). Recently, however, Kaplan and Mitchell (21) have restated an earlier suggestion (22) of an alternative concerted mechanism for the decomposition WR sequence of those α-diazo ketones in which the intermediacy of oxirene was not detected. The α-diazo ketones may exist as two rotational isomers of the type *s-E* and *s-Z* and the proposed mechanism is based on the conformational control observed in the photolysis and thermolysis of some α-diazo ketones. Accordingly, for α-alkyl α-diazo ketones, the *s-E* conformer leads preferentially to 1,2-hydrogen or alkyl migration whereas the *s-Z* conformer undergoes a concerted WR to the ketenes. A similar concerted approach has been proposed by Roth and Manion (23) based on CIDNP studies on α-diazoacetone. Direct photolysis of α-diazoacetone, which is known to undergo a WR to methylketene, failed to generate any nuclear spin polarization, whereas the triplet photosensitized reaction resulted in the observation of radical pairs derived from both triplet and singlet acetylmethylene. Tomioka *et al.* (24) have also advocated the occurrence of a concerted mechanism on the basis of their studies on the direct and triplet sensitized photolysis of α-diazo ketones in alcohols. The latter authors, however, were forced to invoke at least the partial participation of a nonconcerted mechanism via a ketocarbene intermediate to explain the experimental results.

Recently we have reported new source compounds for the study of the ketocarbene–ketene rearrangement, namely vinylene thioxocarbonates (25). This class of compounds features a rigid *s-Z* stereochemistry and hence comparison of their photolysis products with those of the analogous diazo ketones allows a better elucidation of the conformational effects associated with the WR. We wish to report here such a comparative study on the low temperature argon-matrix photolysis (coupled with ir spectroscopy) of α-diazo ketones **1** and on vinylene thioxocarbonates **2**. Under these conditions the conformational equilibrium of **1** will be hindered.

At room temperature 3-diazo-2-butanone, **1***a*, exists as a mixture of the *s-Z*, *s-E* conformers in equilibrium (26), and has been reported to lead to 100% oxirene formation in the gas-phase photolysis (11). Photolysis of argon-matrix isolated **1***a* using λ = 254 nm radiation resulted in the formation of dimethylketene, **3***a*, the WR product, and methylvinylketone, **4***a*, via 1,2-hydrogen shift; the latter is formed mostly in the *s-Z* conformation. Methylvinylketone, **4***a*, is known to exist in an *s-E*, *s-Z* equilibrium favouring the *s-E* conformation. Irradiation of **4***a* in an argon-matrix resulted in a change in the conformers' ratio leading to a photostationary state characterized by an increase in the *s-Z* conformer (27). The fact that the

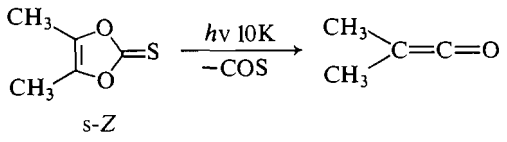
s-Z *s-E* 3*a* *s-Z*

1*a* 4*a*

methylvinylketone, 4*a*, obtained in the argon-matrix photolysis of 1*a* is formed in an *s-Z*/*s-E* ratio larger than expected from a photostationary state clearly suggests that it is formed from the *s-E* conformation of 1*a*. Photolysis, on the other hand, of dimethylvinylene thioxocarbonate 2*a* under the same conditions and using either λ = 270 or 254 nm radiation resulted in the exclusive formation of ketene 3*a* and no vinylmethylketone

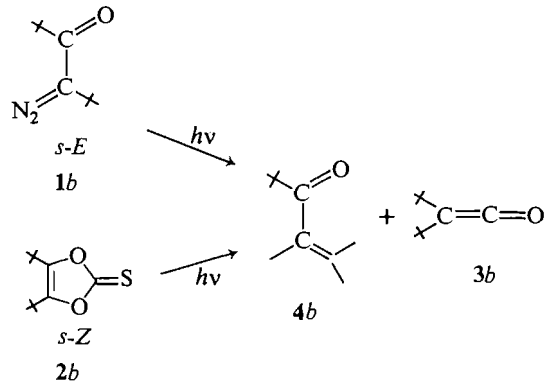


s-Z

2*a* 3*a*

4*a* could be detected. Although these results clearly indicate an *s-Z* preferred conformation for the WR, it is, however, difficult to visualize a concerted process for the COS elimination and ketene formation in the case of 2*a*.

Since the methyl group does not impose a strong steric hindrance we have carried out parallel studies for the bis(tert-butyl) substituted diazoketone and vinylene thioxocarbonate, 1*b* and 2*b* respectively, using λ = 254 nm radiation in both cases. The results showed the formation of α,β unsaturated ketone 4*b* and only traces of ketene 3*b* for the case of 1*b* and the formation of 3*b* and traces of 4*b* in the case of 2*b*. Although these results again parallel those of Kaplan and Mitchell (21), it is still difficult to visualize a concerted process for the formation of 3*b* from 2*b*.



s-E *s-Z*

1*b* 2*b* 4*b* 3*b*

Finally, to confirm the transient formation of oxirene even under matrix conditions, and hence of ketocarbene, in the photolysis of 1*a*, we have carried out the photolysis of 1*a* ^{13}CO labelled under identical conditions as described above. Under these conditions no scrambling of the diazo ketone itself prior to nitrogen elimination was observed, in agreement with Blaustein and Berson (28). From the ir spectrum it could be estimated that the vinylmethylketone 4*a* was formed with ~5% scrambling whereas the dimethylketene 3*a* was formed with ≃30% scrambling. These results indicate that most of the ketene 3*a* is formed through a path that involves oxirene whereas 4*a* is not, and that the total oxirene formation, ~70% in argon-matrix conditions, is comparable to the reported 100% and 70% oxirene formation in the gas and solution phase, respectively (11).

From these results it can be concluded that of the two competing reactions that can take place upon photolysis of 1 and 2, the 1,2-hydrogen or alkyl shift and the WR, the former occurs preferentially from the *s-E* conformation and the latter from the *s-Z* conformation of the precursor. A concerted mechanism is difficult to envisage for the photolysis of vinylene thioxocarbonates 2 and, according to the ^{13}C labelling experiments, oxirene and ketocarbene are involved in the argon-matrix photolysis of 1*a*. Therefore, the observed conformational control must originate in the ketocarbene, that is, the conformational identity of the diazoketone must be preserved in the ketocarbene. Although *ab inito* MO calculations for the parent formylmethylene predict a geometry in which the methylene hydrogen lies perpendicular to the HCO plane with the consequent loss of *s-E*, *s-Z* conformational identity, the presence of substituents may change the situation and in fact, for 1*a*, three minima for the *s-E*, *s-Z*, and the perpendicular conformations are predicted.[1]

Preservation of the diazo ketone geometry in the ketocarbene is not unusual. We have observed in esr studies of triplet ketocarbenes that the conformation of the most abundant triplet is the same as the conformation of the diazo ketone precursor as determined by X-ray crystallography (29). Since it can be assumed that the triplet ketocarbene is formed most likely from the singlet ketocarbene via ISC then it follows that if the geometry is preserved in the triplet ketocarbene it must also be preserved in the singlet ketocarbene.

The fact that triplet sensitized decomposition of α-diazo ketones give rise to singlet ketocarbene reactions such as O—H insertion, but not necessarily to WR products (23) can be explained on the basis of the low vibrational energy content of the thermally populated singlet, which will favour the decay reaction requiring lower activation energy. Although *ab initio* MO calculations predict no activation energy for the ketocarbene–ketene rearrangement in the parent formylmethylene and only a small activation energy for the ketocarbene–oxirene ring closure, substituents will probably exert marked effects and could conceivably reverse the order.

In summary we have established that the conformational control of the WR of α-diazo ketones is also observed in cases such as the argon-matrix photolysis of 3-diazo-2-butanone in which oxirene, and hence a nonconcerted mechanism, is detected and in vinylene thioxocarbonates for which a concerted mechanism seems most unlikely. Therefore the conformational control in the decomposition WR of α-diazo ketones is not proof per se for the occurrence of a concerted mechanism and can be explained via ketocarbene intermediate.

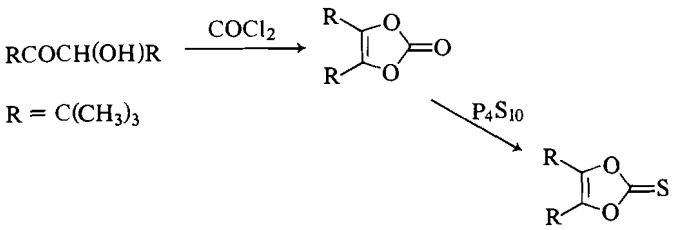
cycle-helium refrigeration system coupled to a high vacuum line was employed as described before (30). The light source was a 140 W Hanovia 30620 medium pressure mercury lamp equipped with a Vycor filter or a 270 nm interference filter, alternatively a low pressure mercury resonance lamp equipped with a Vycor filter was also used. Mass spectra were recorded on Metropolitan Vickers MS-12 and MS-50 spectrometers at an ionization potential of 70 eV, ir spectra were obtained on a Nicolet 7199 FT infrared spectrophotometer, and nmr spectra were recorded on Varian Associates Models A-60 and HR-100 spectrometers using TMS as internal standard. Values are given in δ units.

3-Diazo-2-butanone, **1***a* (31); 3-diazo-2-butanone ^{13}CO (11), 3,4-dimethylvinylenethioxocarbonate **2***a* (32), and 2,2,5,5-tetramethyl-4-diazo-3-hexanone **1***b* (33) were prepared according to described procedures.

4,5-Bis(*tert*-butyl)vinylenethioxocarbonate, **2***b*, was prepared according to the following sequence. 4,5-Bis(*tert*-butyl)vinylene



carbonate was prepared by reaction of pivaloin (21) with phosgene in the presence of dimethylaniline; ir (CCl_4): 1830 cm^{-1} (C=O); nmr (CCl_4): 1.31 (s); ms *m/e* (%): 198 (18), 183 (35), 97 (11), 69 (27), 57 (100). *Exact Mass* measured by high resolution mass spectrometry: 198.1257 ($C_{11}H_{18}O_3$). 4,5-Bis(*tert*-butyl)vinylene carbonate was subsequently converted to **2***b* by reaction with P_4S_{10}; mp 55–56°C; ir (CCl_4): 1325 cm^{-1} (C=S); nmr (CCl_4): 1.3 (s); ms *m/e* (%): 214 (100), 97 (69), 83 (15), 69 (97), 57 (89), 41 (39). *Exact Mass* measured by high resolution mass spectrometry: 214.1029 ($C_{11}H_{18}O_2S$). *Anal.* calcd. for $C_{11}H_{18}O_2S$: C 61.62, H 8.47, S 14.97%; found: C 61.46, H 8.52, S 15.01%.

On the chemistry of metastable species

E. F. HILINSKI, S. V. MILTON, C. RAMANA,[1] AND P. M. RENTZEPIS
Bell Laboratories, Murray Hill, NJ 07974, U.S.A.

Received December 1, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

E. F. HILINSKI, S. V. MILTON, C. RAMANA, and P. M. RENTZEPIS. Can. J. Chem. **61**, 999 (1983).

The mechanisms of a variety of chemical, physical, and biological processes are now understood more clearly as a result of picosecond spectroscopic studies. The identification of metastable species and transient states and the measurement of their formation and decay kinetics are made possible by means of picosecond emission and absorption spectroscopy. The data from these studies provide detailed mechanistic information about a reaction as it evolves. In this paper, we describe a laser system used for picosecond spectroscopy along with several chemical applications of picosecond absorption and emission spectroscopy performed in our laboratories. These include studies on the photochemical generation of trimethylenemethane biradicals from azo compounds, excited-state relaxation dynamics of *p*-dimethylaminobenzonitrile, and photodissociation of haloaromatic compounds.

E. F. HILINSKI, S. V. MILTON, C. RAMANA et P. M. RENTZEPIS. Can. J. Chem. **61**, 999 (1983).

Les études spectroscopiques de l'ordre de la picoseconde permettent de mieux saisir les mécanismes de divers processus chimiques, physiques et biologiques. L'identification des espèces métastables et des états de transition, la mesure de leur formation et les cinétiques de la désintégration sont rendues possibles au moyen de spectroscopie d'émission et d'absorption de l'ordre de la picoseconde. Les données recueillies à partir de ces études fournissent une information détaillée sur le mécanisme de la réaction. Dans ce travail nous décrivons un système de laser utilisé pour la spectroscopie de l'ordre de la picoseconde ainsi que les applications chimiques de cette spectroscopie réalisées dans nos laboratoires. Ceci comprend les études sur la production photochimique des biradicaux triméthylène-méthane à partir des composés azo, les dynamiques de relaxation de l'état excité du *p*-diméthylaminobenzonitrile et la photodissociation des composés haloaromatiques.

Introduction

Our understanding of chemical and biological reactions is based upon a knowledge of the sequence of events which transpires when one substance is transformed into another in a process induced by some external agent such as heat, light, or a chemical reagent. Many methods are available to the physical chemist for the elucidation of a reaction mechanism. Of these, picosecond spectroscopy has provided a means for identifying intermediates in reactions and measuring their formation and decay kinetics. The best time resolution of course will enable the greatest amount of detailed information to be obtained about a reaction and will therefore permit the best understanding of the microscopic events involved in the conversion of one species into another.

Direct observation of the ultrafast events involved in many chemical and biological reactions is provided by absorption, emission, and lately Raman spectroscopy with picosecond time resolution. Technological advances in lasers and optical detection systems have improved the original capabilities of picosecond spectroscopy and expanded its application to a wide variety of mechanistic problems. Currently several types of picosecond laser systems with time resolution of less than one picosecond to several picoseconds exist which can be used to monitor the dynamics of a photoinitiated chemical reaction while it is occurring.

We will briefly describe an experimental apparatus used for picosecond spectroscopy. Several applications of picosecond emission and absorption spectroscopy to mechanistic chemical problems which were performed in our laboratories will be presented. These include studies on the photochemical generation of trimethylenemethane biradicals from azo compounds, excited-state relaxation dynamics of *p*-dimethylaminobenzonitrile, and photodissociation of haloaromatics.

Experimental

Most commonly used picosecond laser systems currently rely on either solid-state oscillators or synchronously pumped dye lasers to generate picosecond light pulses initially. Passively mode-locked Nd^{3+}:YAG oscillators were the sources of the picosecond pulses used in the studies to be discussed later in this paper. This type of laser system has been described previously (1*a*,*b*). More recently, synchronously pumped dye laser systems have become popular as a result of their wavelength tunability and their capability of generating shorter pulses. While specific details of various laser systems differ, both the solid-state and synchronously pumped dye laser systems, in general, are the same after pulse generation and amplification has been accomplished. Because of their basic similarities, only a discussion of a synchronously pumped dye laser system will be described here.

The picosecond laser system illustrated in Fig. 1 is composed of an actively mode-locked argon ion laser which generates a train of 150-ps full-width-at-half-maximum (FWHM), 514.5-nm pulses at a repetition rate of 123 MHz. These pulses pump a ring dye laser which generates ~1-ps FWHM pulses with an average power of ~100 mW. Depending upon the dye used as a lasing medium, a wide range of wavelengths is available from the ring laser. The quality of the pulses is monitored by means of a background-free autocorrelator (1*c*).

On the basis of the specific requirements of a particular chemical or biological study, the train of low-energy ps-pulses emerging from the ring dye laser can be used directly or can be amplified by as much as $\sim 10^6$ times by means of flowing dye cells pumped by 10-ns pulses of the second harmonic, 532 nm, of a Nd^{3+}:YAG laser. The amplified pulse can then be used directly or now possesses sufficient energy to be converted, by means of frequency-doubling crystals and/or stimulated Raman scattering, to wavelengths other than the one originally generated by the ring laser. Appropriate direction and splitting of this

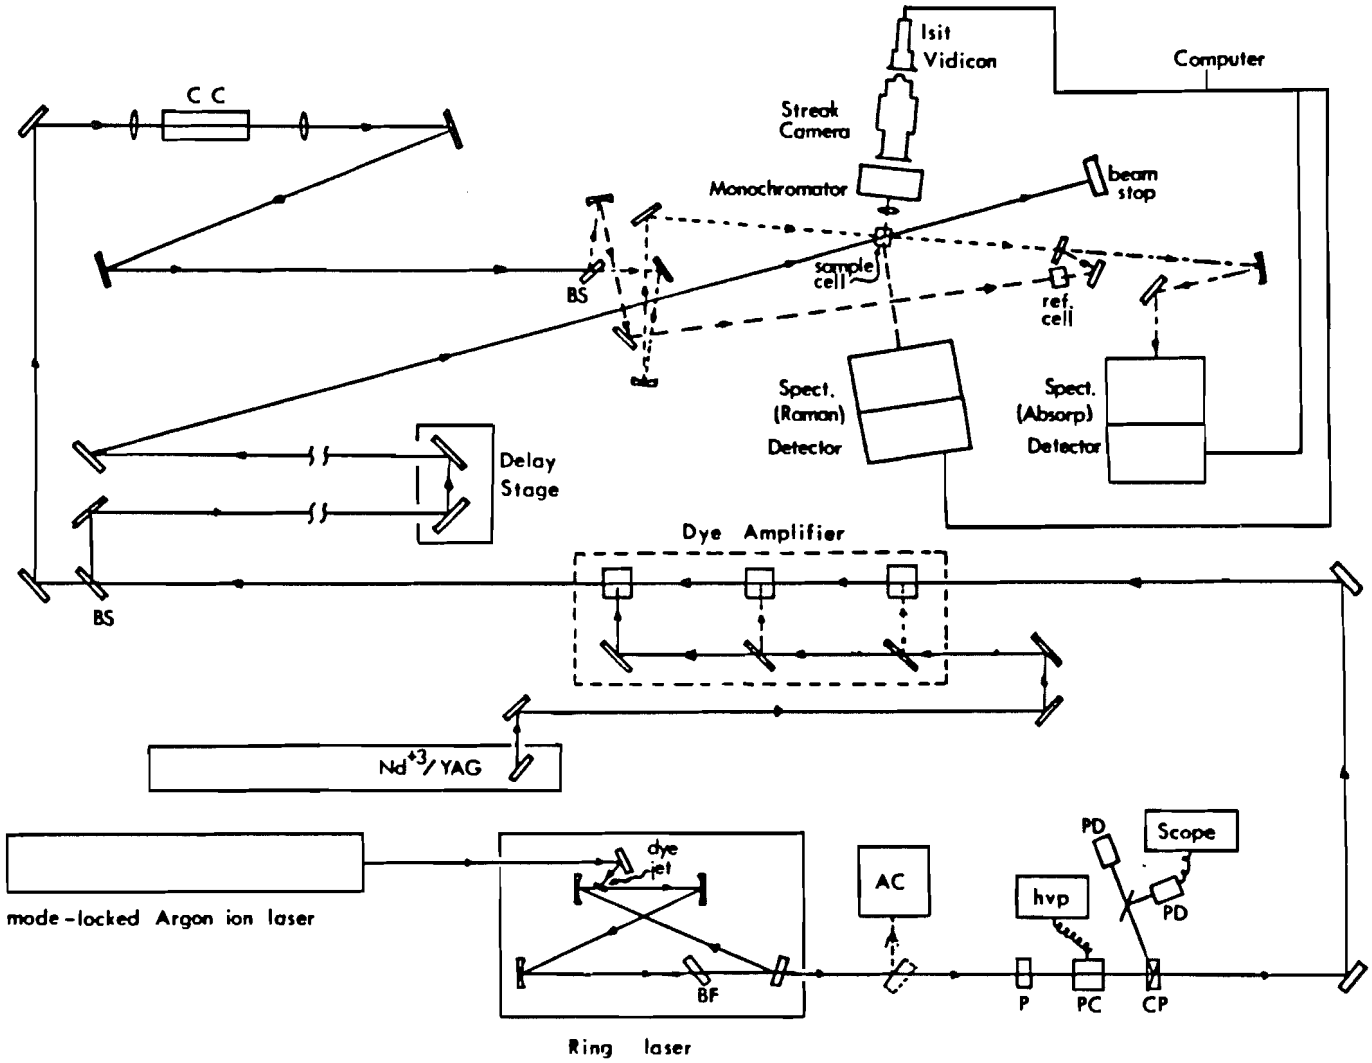

FIG. 1. Schematic diagram of a synchronously pumped dye laser system. AC: autocorrelation, P: polarizer, PC: Pockels cell, CP: crossed polarizer, bvp: high-voltage pulser, PD: photodiode, BS: beam splitter, CC: continuum cell.

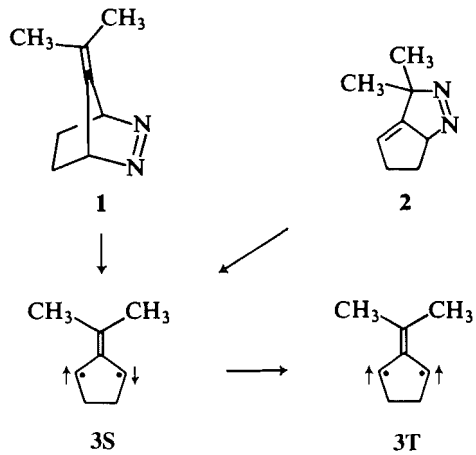
ps pulse, as illustrated in Fig. 1, permits the detection and recording of the spectra of transient intermediates and measurement of their lifetimes by means of picosecond emission, absorption, and Raman spectroscopy.

Transient intermediates of a TMM derivative

A molecular species which has recently been studied by means of picosecond emission spectroscopy is the trimethylenemethane (TMM) derivative, 2-isopropylidenecyclopentane-1,3-diyl (**3**) (2). Many experimental and theoretical studies have been performed on the TMM biradical (3). Past spectroscopic studies have employed electron paramagnetic resonance to study the triplet ground-state of TMM (3*c*,*d*). Direct spectroscopic and kinetic information has been obtained only very recently by Kelley *et al.* (2) using picosecond fluorescence spectroscopy. Prior to this direct observation, evidence for the existence of singlet 2-isopropylidenecyclopentane-1,3-diyl (**3S**) was based upon the kinetic argument of Mazur and Berson (4).

Kelley *et al.* (2) observed the decay kinetics and emission spectra of transients generated by excitation of diazenes **1** and **2** with a 25-ps FWHM, 266-nm pulse in hexane solution at room temperature and in argon and xenon matrices at 4.2 K.



In hexane solution at room temperature, the fluorescence decay kinetics of both diazenes were found to exhibit biexponential decays with lifetimes, τ_1 and τ_2, of 38 ps and 280 ps for **1** and of 25 ps and 310 ps for **2** (Fig. 2). The short-lifetime components were assigned to emission from the predissociative states of **1** and **2**. The longer-lived component ($\tau \cong 300$ ps) was attributed to emission from an excited singlet

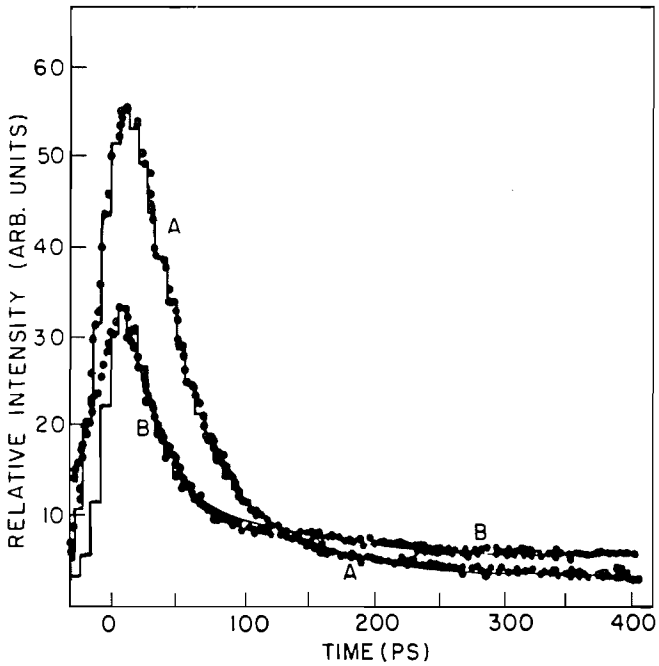

FIG. 2. Fluorescence intensity (>310 nm) versus time for diazene **1** (A) and diazene **2** (B) in hexane at room temperature. Solid lines are calculated biphasic curves with decay times of 38 ps and 280 ps for **1** and of 25 ps and 310 ps for **2**. No relationship between the two curves is implied since the curves are not normalized. (From ref. 2.)

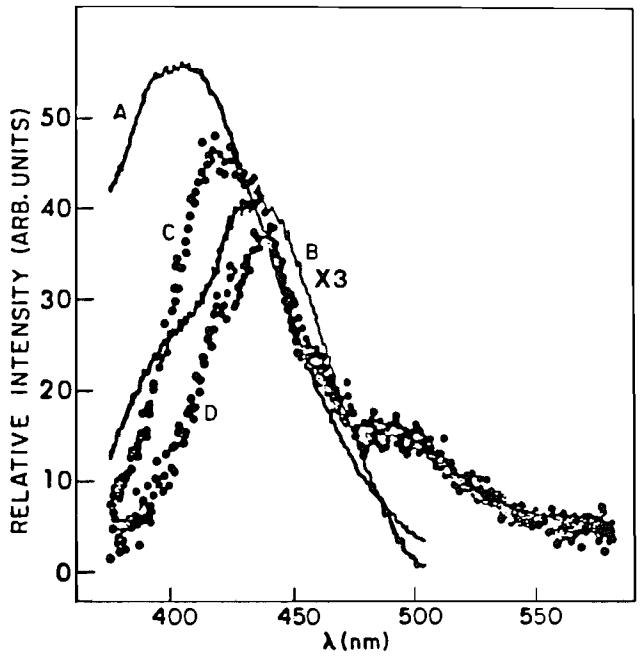

FIG. 3. Relative fluorescence intensity versus wavelength taken in hexane solution at room temperature. Spectra were recorded under the following conditions: (A) diazene **1**, fluorimeter; (B) diazene **2**, fluorimeter; (C) diazene **1**, laser-induced; (D) diazene **2**, laser-induced. Spectra A and B are normalized with respect to each other by multiplying the amplitude of B by a factor of three. (From ref. 2.)

state of the TMM biradical (**3S***). Room-temperature laser-induced emission spectra obtained by photolysis of either diazene was dominated by fluorescence from **3S***. In contrast, the laser-induced emission spectra obtained by photolysis of **1** or **2** in inert-gas matrices at 4.2 K were dominated by emission originating from the azo chromophores of the starting diazenes (Fig. 3). Kelley *et al.* (2) concluded that photochemical deazetation was partially suppressed under the conditions of matrix isolation and low temperature.

Biphasic fluorescence decays in argon matrices at 4.2 K were observed for **1** and **2**. The lifetimes of shorter-lived components (τ_1 = 5.0 ns and τ_1 = 3.1 ns for **1** and **2**, respectively) indicated a considerable increase from the room-temperature predissociative lifetimes. However, the predissociative lifetime of **1** remained longer than the corresponding value of **2**. The observed fluorescence lifetimes of the long-lived components ($\tau_2 \cong 30$ ns) of **1** and **2** correspond to the lifetime of **3S*** and are in accord with the expected natural radiative lifetime of **3S*** (5).

In xenon matrices at 4.2 K, monoexponential decays were observed for both **1** and **2** with identical lifetimes of 6.5 ns. The emission spectra of **1** or **2** in xenon matrices were very similar. This similarity was interpreted as indicating the occurrence of an isomerization of **2** → **1** which was fast compared to fluorescence decay. Little, if any, emission from **3S*** was observed in Xe matrices. This indicated that the lifetime **3S*** was <10 ns and supported the hypothesis that the major decay pathway for **3S*** was intersystem crossing to a triplet state, a process expected to be enhanced in the presence of the heavy atom, xenon.

The picosecond data obtained by Kelley *et al.* (2) provided direct evidence of the mechanism of predissociation and radical formation along with an identification of the several species by means of emission spectroscopy.

Relaxation dynamics of photoexcited *p*-dimethylaminobenzonitrile

Another problem of interest studied by means of picosecond spectroscopy is the anomalous dual fluorescence of *p*-dimethylaminobenzonitrile (DAB) in polar solvents. Many studies besides those utilizing picosecond spectroscopy have attempted to interpret the nature and kinetics of this anomalous phenomenon (6–10). The two fluorescence bands have been designated the *a* and *b* bands. The maxima of the *b* band occurs at ~350 nm in both polar and nonpolar solvents and exhibits an exceptionally large red shift of ~6000 cm^{-1} from the intense first absorption band at 295 nm. A highly polar excited state is believed to be responsible for the *a* band which has a fluorescence maxima at 470 nm in polar solvents. Both fluorescence bands are polarized parallel to the plane of the benzene ring (11). Recent steric evidence (12) favors the identification of the emitting state, a^*, with a strongly dipolar twisted internal charge-transfer singlet state, ^{1}(TICT), which relaxes torsionally to a conformation in which the phenyl ring and dimethylamino group are mutually perpendicular. These studies (11, 12) have also demonstrated that these emission bands do not correspond to the first absorption band of DAB, nor do they correspond to low-lying $^1(\pi,\pi^*)$ states.

High-pressure oxygen fluorescence quenching studies (13, 14) in acetonitrile suggest a consecutive rather than competitive formation of b^* and a^*, i.e. ground state $\xrightarrow{h\nu}$ $(X\rightarrow)$ $b^* \rightarrow a^*$. Results from previous studies (10, 12, 15) have shown that in most cases the activation energy for the $b^* \rightarrow a^*$ process follows closely the solvent viscosity, which suggest that the formation of the relaxed a^* state is viscosity-controlled. Using a reversible $b^* \rightleftarrows a^*$ kinetic model and results from the quenching experiments (13, 14), a reaction half-life as short as ~2 ps for DAB in methylene chloride is revealed. Alternatively, since

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

the solvent reorientation time of acetonitrile is ~1.5 ps (16), the fluorescence lifetime in this solvent (estimated to be ~10 ps) (13) appeared to be limited by the rate of internal rotation and not solvent viscosity.

Advances in the past decade in picosecond spectroscopy and streak camera technology now allow direct measurements of fluorescence decay rates which do not rely on a previously assumed kinetic model. Struve and Rentzepis (17), using a picosecond time-resolved CS_2 shutter apparatus, observed an ~40-ps risetime for the a^* fluorescence of DAB at ~470 nm in methanol, ethanol, and n-butanol, and a longer risetime in the more viscous cyclohexanol. More recently, Huppert *et al.* (18) have measured the a^* fluorescence risetimes and a^* formation kinetics of DAB by both direct measurement and by monitoring the b^* fluorescence decay rates. These results, which were not directly obtainable before (17, 19) because of picosecond spectrometer limitations, were obtained when Huppert *et al.* (18) used the fourth harmonic (266 nm, 20 ps FWHM) of a Nd^{3+}:YAG laser for sample excitation and a streak camera for detection of the ultrafast picosecond events.

With appropriate filters, both the a^* and b^* fluorescences could be observed and measured independently. The b^* state fluorescence was found to be biphasic and appeared within the pulse-width of the laser (risetime, $\tau_r^b < 10$ ps). This was true for all linear alcohols except methanol where τ_f^b was within the time resolution of the experiment. The long-component fluorescence lifetime was found to be linearly related to the respective solvent viscosity (Fig. 4). Pulse-limited fluorescence decay was also observed for the polar aprotic solvents, acetonitrile, *N*,*N*-dimethylformamide, and dimethyl sulfoxide, whose room-temperature viscosities are less than 2.5 cP. The fluorescence of the b^* state in the nonpolar aprotic solvents, methylcyclohexane and diethyl ether, showed no viscosity dependence (τ_f^b = 1.8 ns and 3.2 ns, respectively, at 25°C) and, as was known previously (6, 7), no a^* fluorescence was observed. It was further found by Huppert *et al.* (18) that the a^* fluorescence risetimes are the same as the b^* fluorescence decays within experimental error in the solvents, 1-pentanol, 1-hexanol, 1-decanol, and 1-dodecanol (Fig. 5). These results further confirmed that the b^* state is the kinetic precursor to the a^* state in many polar solvents as was previously concluded from the fluorescence quenching data (13). The a^* decay times were found to exhibit a marked temperature dependence and were measured to be single exponential with lifetimes of τ_f^a = 3.6 ns, 3.4 ns, 3.7 ns, and 1.4 ns in 1-dodecanol, 1-hexanol, acetonitrile, and methanol, respectively. This temperature dependence was attributed to a thermally activated nonradiative process. A similar observation for the TICT state of *p*-anthryl derivatives of dialkylanilines has also been reported elsewhere (20). The study by Huppert *et al.* (18) also revealed for the first time the biexponential character of the a^* risetimes and b^* decays. The short-time components were interpreted as reflecting the microscopic solvent reorientation required for solvation of the polar species, while the long-time component was attributed to the normal decay and risetimes of the bands.

Photodissociation of haloaromatics

Recent picosecond studies, by Struve and co-workers (21) and Huppert *et al.* (22), on the photodissociation of haloaromatics demonstrate the tremendous potential of picosecond spectroscopy for determining the detailed course of a reaction, specifying intermediate electronic states and the energy dissipation channels involved.

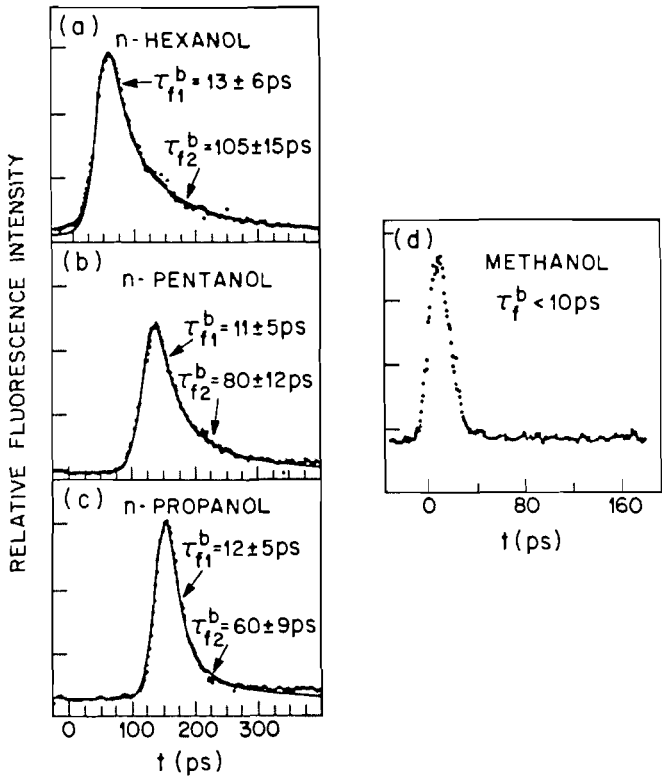

FIG. 4. Time-resolved b^* fluorescence intensities of $\sim 10^{-4}$ *M* solutions of DAB excited by 266-nm excitation pulses in 1-hexanol, 1-pentanol, 1-propanol, and methanol at 20°C. Each trace was averaged over five to eight laser pulses. (From ref. 18.)

Haloaromatics are known to photodissociate to the parent aromatic and halogen radicals. Ermolaev and Svitashev (23) have studied intersystem crossing from the excited singlet to a lower-lying triplet state by observing room-temperature fluorescence and low-temperature phosphorescence in rigid glasses. The quantum yields vary from $\phi_f < 0.0005$ and $\phi_p = 0.38$ for 1-iodonaphthalene to $\phi_f = 0.3$ and $\phi_p = 0.058$ for 1-chloronaphthalene. Phosphorescence spectra of some haloaromatics, studied by Pavlopous and El-Sayed (24), contain at least two "subspectra," which differ in their polarization, and are enhanced by heavy-atom substitution.

Pavlopoulos and El-Sayed (24) measured triplet decay rates by observation of $T_n \leftarrow T_1$ absorption for naphthalene, anthracene, and phenanthrene and their halogen derivates in cyclohexane and viscous paraffin (η = 170 cP) solutions at room temperature. Iodonaphthalene showed no $T_n \leftarrow T_1$ absorption while the bromo- and chloro-compounds showed maxima at 425 nm. They attributed the absence of triplet absorption in iodonaphthalene to either a low intersystem crossing probability or to a triplet lifetime less than 10^{-5} s. Sandros and Backstrom (25, 26) estimated the triplet lifetimes of 1-iodo- and 2-iodonaphthalene to be 10 ns and 1100 ns, respectively. Studies by Wilkinson (27) and Levy *et al.* (28) have shown that energy dissipation from the triplet state occurs by dissociation of the carbon–halogen bond, but that dissociation may occur from the singlet state as well. Temperatured dependence of the triplet lifetimes of 1-iodonaphthalene, 2-iodonaphthalene, and 4-iodobiphenyl was studied by Grieser and Thomas (29) using pulse radiolysis. The lifetimes were found to correlate well with the expression $\ln\left(\frac{1}{\tau}\right) = -E_a/RT + \ln A$. They attributed

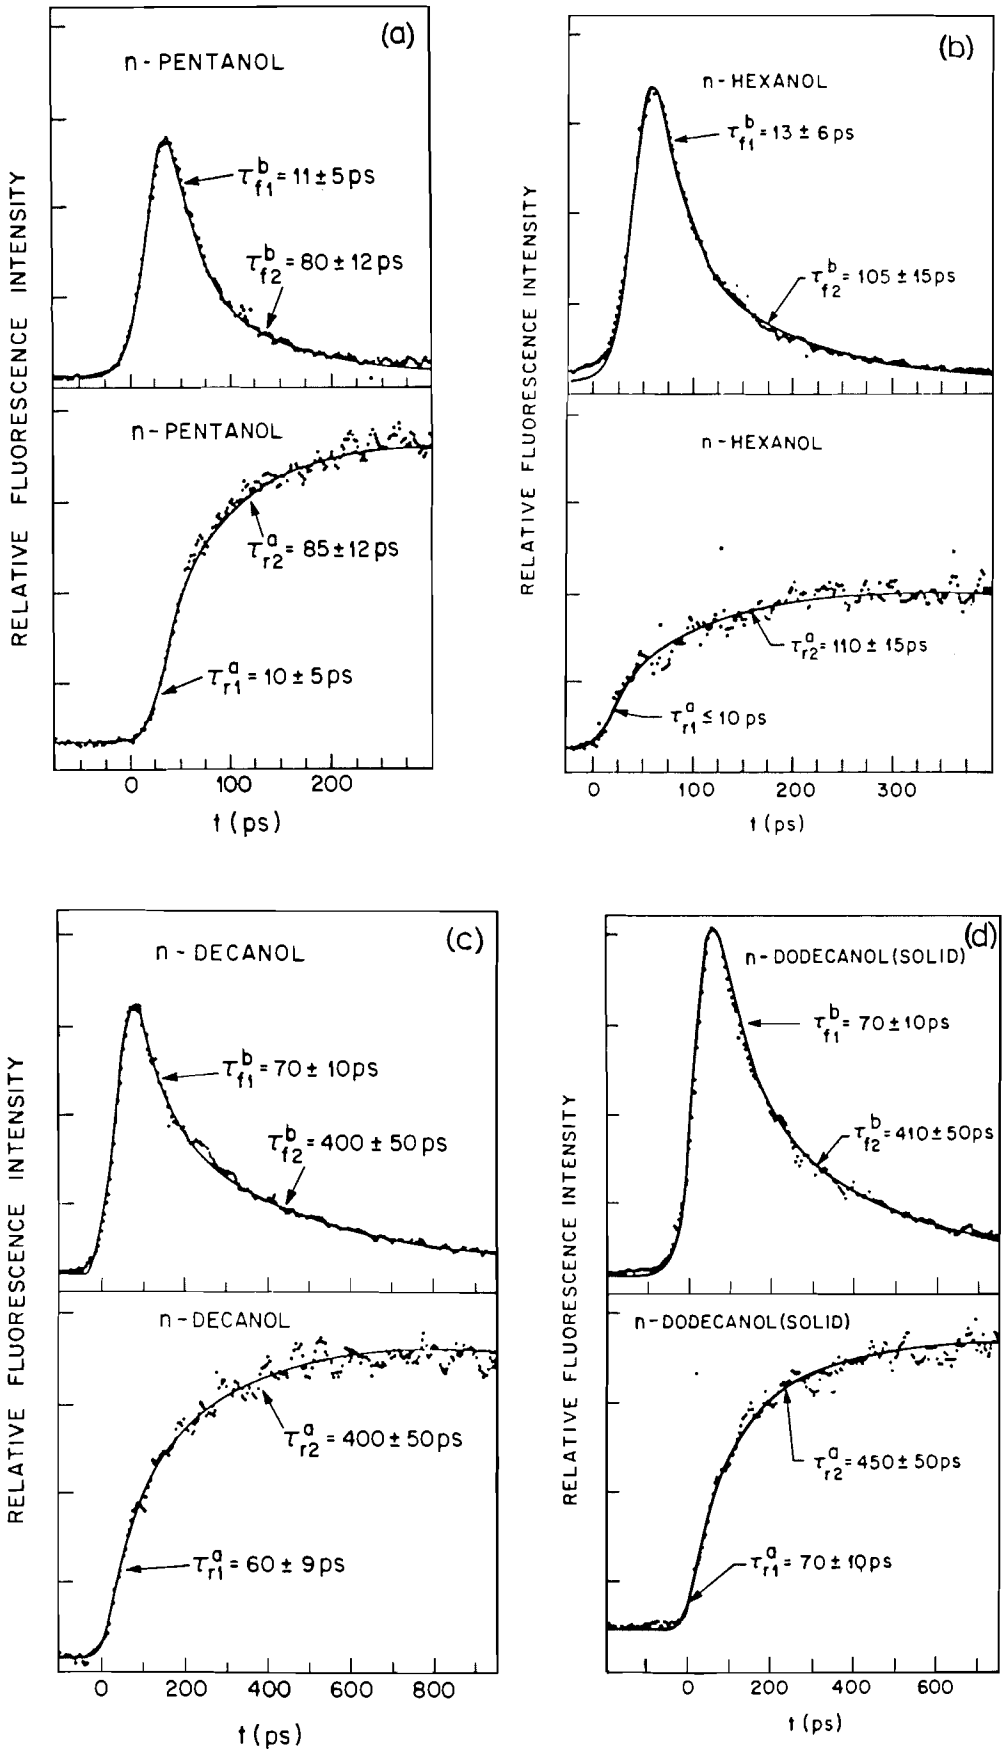

FIG. 5. Comparison of b^* fluorescence decay times τ_f^b to a^* fluorescence risetimes τ_r^a for DAB in (a) 1-pentanol; (b) 1-hexanol; (c) 1-decanol; (d) 1-dodecanol all at 20°C. (From ref. 18.)

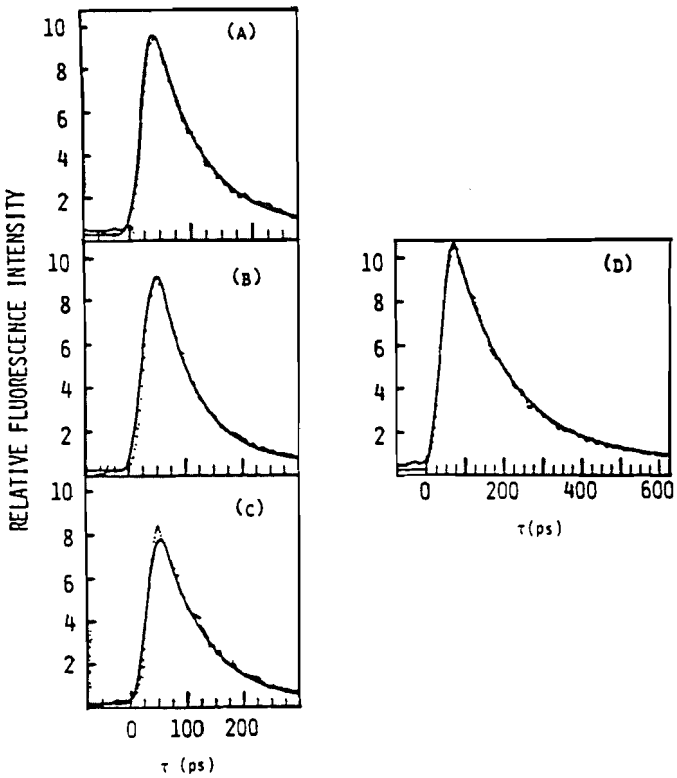

FIG. 6. Time-resolved emission of bromonaphthalenes in hexane at room temperature resulting from excitation by a 266-nm, 20-ps pulse. The emission is within the range of 310−550 nm. Plots of emission intensity vs. time (ps) for: (a) 1-bromonaphthalene; (b) 1-bromo-2-methylnaphthalene; (c) 1-bromo-4-methylnaphthalene; (d) 2-bromonaphthalene. (From ref. 22.)

this unusual dependence of lifetime on temperature to a crossing of the potential energy surfaces of the triplet state and the $T(\sigma,\sigma^*)$ dissociative state.

Saigusa *et al.* (30) measured the intersystem crossing (ISC) rates from the lowest excited singlet by picosecond emission spectroscopy. They found the ISC rates for 1-chloro- and 1-bromonaphthalene to be $(5.9 \pm 0.8) \times 10^8$ s^{-1} and $(1.5 \pm 0.3) \times 10^{10}$ s^{-1}, respectively. 1-Iodonaphthalene, as a result of its short lifetime, fluoresced only weakly, and its ISC rate could not be measured.

Haloaromatic photodissociation has also been studied in molecular beams by Bersohn and co-workers (31, 32). They estimated dissociation rates by determining β, the anisotropy parameter characterizing angular distribution of photofragments. The lifetimes of iodobenzene, 1-iodonaphthalene, and 2-iodonaphthalene were found to be ~0.5 ps. The lifetime of methyliodide is an order of magnitude smaller, 0.07 ps. The analogous aryl bromides were found to have lifetimes 2 orders of magnitude longer. They concluded that photodissociation occurs by intersystem crossing to the triplet state localized in the halogen bond: $S_0 \rightarrow S_2(\pi,\pi^*) \rightarrow S_1(\pi,\pi^*) \rightarrow T(\sigma,\sigma^*) \rightarrow$ fragments.

The bromoaromatics display an unusually long lifetime compared to the iodo-analogs, if intersystem crossing from $S(\pi,\pi^*)$, and therefore spin-orbit coupling, is the dominant parameter. Spin-orbit coupling energy is proportional to the $^2P_{3/2}-^2P_{1/2}$ fine structure splitting of the ground-state halogen atom. The lifetime of the bromoaryl should be longer by the square of the iodo−bromo splitting ratio. The bromoaryl lifetimes are approximately 10-fold longer − too long for spin-orbit coupling to be the dominant parameter. Bersohn reconciled this by including predissociation from the S_1 as another dissociation channel.

TABLE 1. Room temperature (~20°C) fluorescence lifetimes of haloaromatics in hexane for laser excitation at a given wavelength (λ_{ex}) (from ref. 22)

Sample	λ_{ex} (nm)	τ_f (ps)
4,4-Dibromobiphenyl	265	30
4-Bromobiphenyl	265	35
1-Bromonaphthalene	265	75
1-Bromo-4-methylnaphthalene	265	80
1-Bromo-2-methylnaphthalene	265	72
2-Bromonaphthalene	265	150
1-(Chloromethyl)naphthalene	265	490
2-(Bromomethyl)naphthalene	265	*
1-Chloronaphthalene	265	2400
2-Chloronaphthalene (zone refined >99%)	265	3300
2-Chloronaphthalene	265	3500
9-Bromoanthracene	355	100
9,10-Dibromoanthracene	355	1300
2-Iodoanthracene	265	14
9-Iodoanthracene	265	35
2-Iodoanthracene	355	17
9-Iodoanthracene	355	55

*Not detected.

The picosecond absorption and emission studies by Huppert *et al.* (22) clarify the mechanism of photodissociation of a number of haloaromatics. Their fluorescence measurements showed the expected heavy-atom effect due to spin-orbit coupling. Lifetimes of the chloronaphthalenes were the longest, 2.4 and 3.3 ns for 1-chloronaphthalene and 2-chloronaphthalene, respectively. The 1-bromo and 2-bromo compounds (see Fig. 6) had lifetimes of 75 ps and 150 ps, respectively. Iodo-substituted compounds had the shortest lifetimes, 14 ps and 35 ps for 2-iodoanthracene and 9-iodoanthracene, respectively. They found that the intersystem crossing rate is heavily influenced by the position of the substituent on the ring, as well as its spin-orbit couplings, as shown clearly by the lifetime data for 1- and 2-halonaphthalenes, 2- and 9-iodoanthracenes (see Table 1 for a summary of the fluorescence data).

Prompt risetimes and the absence of unrelaxed fluorescence ($\tau \cong 5$ ps) after excitation indicates that vibrational relaxation from hot S_1 levels to $S_1(v = 0)$ occurs within 5 ps. Fluorescence decay studies show the S_1 relaxation rate, but transient absorption spectra are needed to determine the identity of the several states involved in the relaxation process. Transient absorption spectra showing $S_n \leftarrow S_1$ disappearance and $T_n \leftarrow T_1$ appearance (see Fig. 7) give unequivocal proof of the dissociation pathway. Huppert *et al.* (22) concluded that photodissociation of these haloaromatics proceeds by fast relaxation from upper S_1 vibrational levels (6,000 cm^{-1} excess vibrational energy) to $S_1(v = 0)$ and intersystem crossing to an upper $T_1(v > 0)$ state. Fast vibrational relaxation to $T_1(v = 0)$, is followed by predissociation of a $T(\sigma,\sigma^*)$ state. Halo-substitution of the methyl group of the aromatics increased the intersystem crossing and predissociation rates which further supported Bersohn's proposals (31, 32). Though picosecond studies have provided detailed mechanistic information on the photodissociation of haloaromatics, questions remain, since,

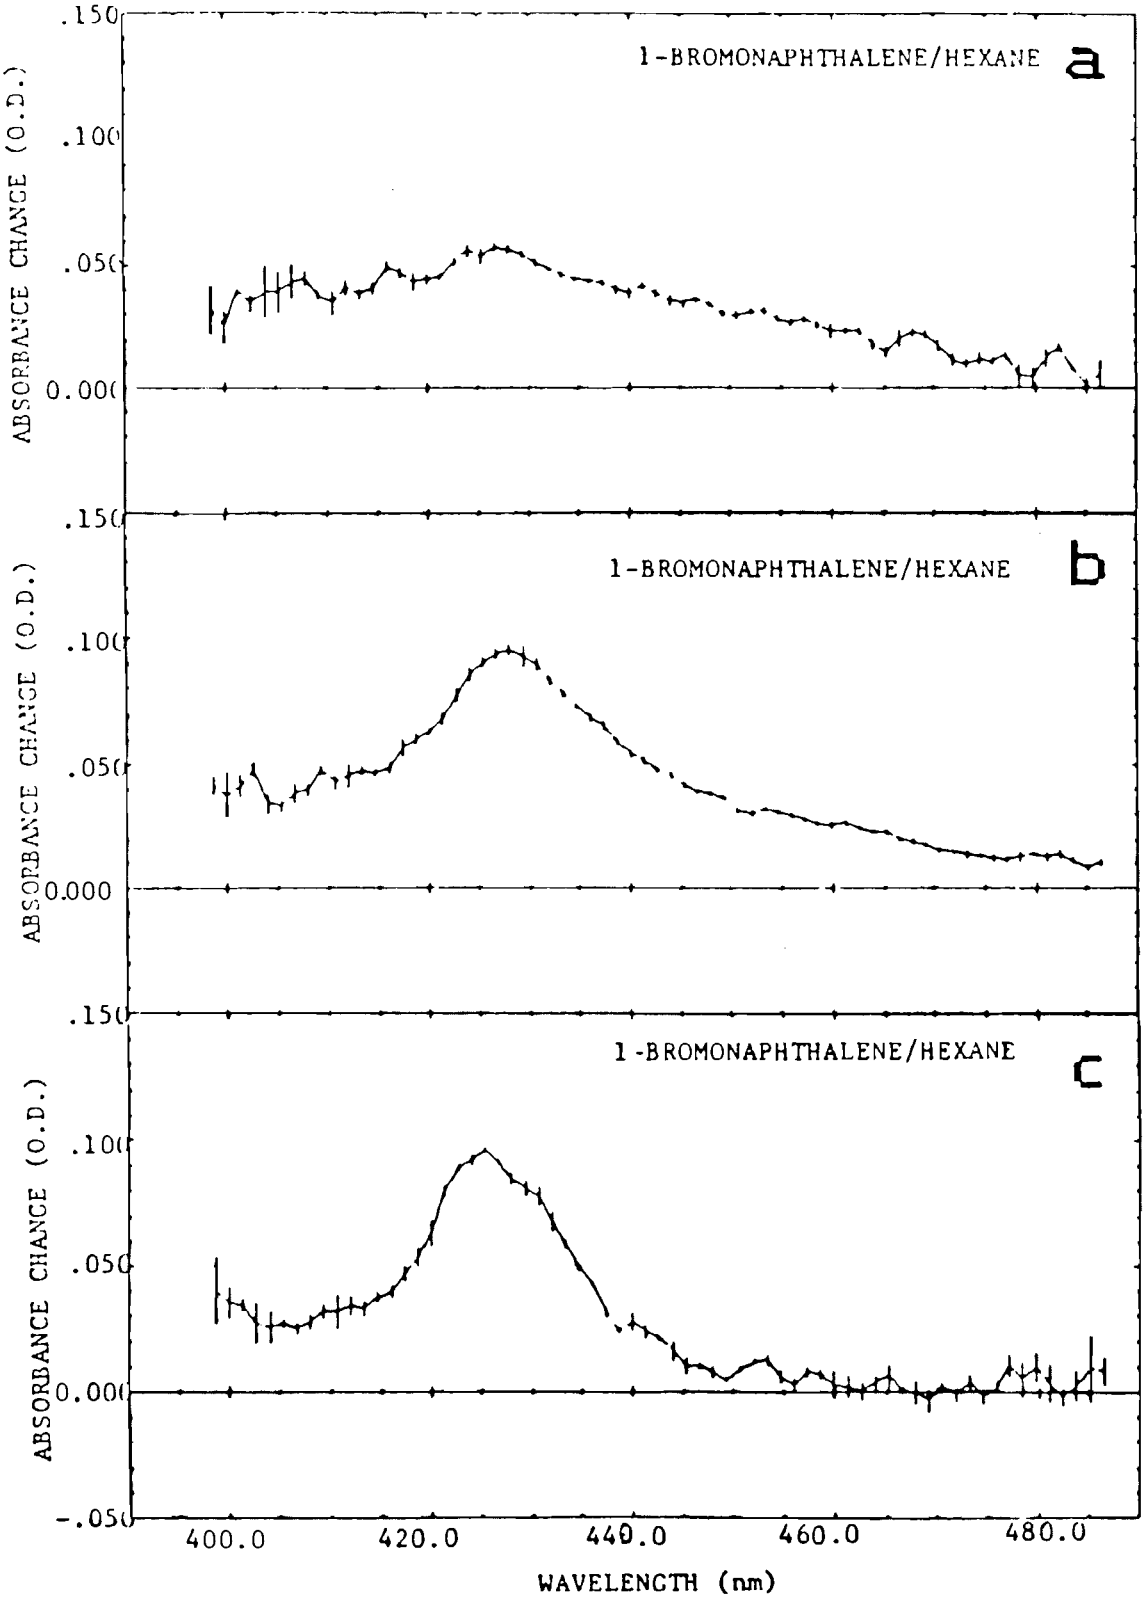

FIG. 7. Transient absorption spectra of 1-bromonaphthalene in hexane at room temperature excited with a 266-nm ps pulse, recorded (a) 25 ps after excitation; (b) 100 ps after excitation, (c) 500 ps after excitation. (From ref. 22.)

for example, Struve and co-workers have interpreted their data from picosecond studies of iodoanthracene differently (21).

Conclusion

From the examples of photoinitiated organic reactions discussed here, it is apparent that picosecond absorption spectroscopy and picosecond emission spectroscopy have provided data about the events which occur on this ultrafast time scale and which determine the path a reaction takes on its way to completion. Whether it be simply the mechanism of relaxation

from an excited state, as in the case of *p*-dimethylaminobenzonitrile, or an actual chemical change which takes place within a molecule, as in the studies of the photodissociation of haloaromatic or azo compounds, picosecond spectroscopy enables one to detect the intermediates involved and measure their kinetics in such a way as to give a detailed understanding of the mechanism of the occurring process. As picosecond Raman spectroscopy becomes a better-developed investigative tool, the structural information which it yields will enhance our understanding of chemical reactions at the molecular level and, in addition to general advances in technology, will increase the number of applications of picosecond spectroscopy to mechanistic chemical, physical, and biological problems.

The use of insoluble benzoylated polystyrene beads (polymeric benzophenone) in photochemical reactions

JOSÉ LUIS BOURDELANDE, JOSEP FONT, AND FRANCISCO SÁNCHEZ-FERRANDO

Departament de Química Orgànica, Facultat de Ciències, Universitat Autònoma de Barcelona, Bellaterra, Spain

Received March 8, 1982[1]

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

JOSÉ LUIS BOURDELANDE, JOSEP FONT, and FRANCISCO SÁNCHEZ-FERRANDO. Can. J. Chem. **61**, 1007 (1983).

Friedel–Crafts benzoylation of 2%-divinylbenzene (DVB) cross-linked polystyrene beads yielded insoluble polymeric analogs of benzophenone which were used as sensitizers in the |2 + 2| photocycloaddition of cyclohexene to maleic anhydride and in the $E-Z$ isomerization of (*E*)-1,3-pentadiene and methyl (*E*)-2,2-dimethyl-3,5-hexadienoate. In the first reaction, the use of the polymer-anchored sensitizers resulted in the separation of polymer-attached by-products by simple filtration, although the yield of photoadducts was less than three quarters of that obtained when using benzophenone itself, and the recovered polymers could not be reused. In the photoisomerizations, the compositions of the photostationary states reached when using the polymeric sensitizers (now reusable) were shown to depend on the degree of functionalization of the polymers via steric hindrance to the energy transfer process. Intrapolymerically sensitized $E-Z$ photoisomerization was also demonstrated on a polymer containing benzophenone and diene units. Photooxidation of secondary alcohols (isopropanol, cyclohexanol) to ketones and photooxygenation of 2,3-dimethyl-2-butene to 2,3-dimethyl-3-buten-2-yl hydroperoxide (in the presence of oxygen) were other reactions for which polymeric benzophenones could be used.

JOSÉ LUIS BOURDELANDE, JOSEP FONT et FRANCISCO SÁNCHEZ-FERRANDO. Can. J. Chem. **61**, 1007 (1983).

La benzolation selon Friedel et Crafts d'une résine de polystyrène réticulée à 2% de divinylbenzène (DVB) donne des polymères insolubles analogues de la benzophénone qu'on utilise comme sensibilisateur dans la photocycloaddition du type |2 + 2| du cyclohexène sur l'anhydride maléique et dans l'isomérisation du type $E-Z$ du pentadiène-1,3 (*E*) et du diméthyl-2,2 hexadiène-3,5 oate de méthyle (*E*). Dans la première réaction, l'utilisation d'un sensibilisateur fixé sur un polymère conduit à une séparation des produits secondaires fixés sur le polymère par simple filtration, bien que le rendement en photoadduits représente moins de 75% de celui que l'on obtient en utilisant la benzophénone elle-même et bien que les polymères récupérés ne soient pas réutilisables. Dans le cas des photoisomérisations, on montre que les compositions des états photostationnaires atteints lorsqu'on utilise les sensibilisateurs fixés sur un polymère (non réutilisable) dépendent du taux de fonctionnalisation des polymères via l'encombrement stérique qui gène le processus de transfert d'énergie. On a aussi démontré qu'un polymère contenant une benzophénone et un diène peut provoquer une photoisomérisation $E-Z$ sensibilisée à l'intérieur du polymère. La photoxydation des alcools secondaires (isopropanol, cyclohexanol) en cétones et la photoxygénation du diméthyl-2,3 butène-2 en hydroperoxyde de diméthyl-2,3 butène-3 yle-2 (en présence d'oxygène) sont d'autres réactions où il est possible d'utiliser des benzophénones fixées sur un polymère.

Introduction

The well developed concept of solid-phase synthesis (1), i.e., the attachment of a reactant to an insoluble matrix (polymeric or inorganic) prior to its reaction (now in heterophase) with soluble reactants, offers the following possibilities when applied to photochemical reactions: (*i*) anchored substrate, soluble photoreagent (or sensitizer); (*ii*) anchored photoreagent, soluble substrate; (*iii*) both substrate and photoreagent anchored. We (2) and others (3) have described the photohalogenation of anchored *n*-alkanoic acids as an example of case (*i*). The present paper deals mainly with case (*ii*), although an example of case (*iii*) is also presented. Both cases offer great interest, since many of the current approaches to chemical storage or utilization of the energy of sunlight depend on the use of photoredox reagents or sensitizers physically adsorbed or chemically bound to solid insoluble particles of inorganic oxides or organic polymers, in order to produce separation of the individual reacting species involved in each step of the process (4). Actually, some insoluble polymeric (or polymer-bound) photosensitizers have been known for some time. After the pioneering work of Leermakers and James (5) on the use of polyvinyl phenyl ketone, prepared by bulk polymerization of the corresponding monomer, other authors used the solid phase concept and attached known sensitizers to insoluble resins, usually cross-linked polystyrene beads. Several resin-bound photosensitizers have been developed and tested, mainly by Neckers and co-workers, including both soluble and insoluble polystyrylmethyl 4-benzoylbenzoate (6), soluble poly(*p*-(trifluorovinyl)benzophenone) and poly(*p*-(trifluorovinyl)acetophenone) (7), rigid polydivinylbenzophenone (8), and the very useful P-Rose Bengal (9), which is the reagent of choice for the sensitized photochemical generation of singlet oxygen.

Benzophenone **1** is well known in organic photochemistry. With its convenient triplet energy of 288 kJ mol^{-1}, it sensitizes many photochemical reactions, such as |2 + 2| photocycloadditions and $Z-E$ photoisomerization of suitable alkenes. In addition, it can also act as a photoreagent, for instance in cycloadditions with alkenes (Paterno–Buchi reaction), or as photooxidant by hydrogen atom abstraction from appropriate donors. One polymeric analog of benzophenone, namely poly-*p*-styrylmethyl 4-benzoylbenzoate **2**, was found by Neckers to sensitize |2 + 2| photocycloadditions (6). However, in later work by the same group, some doubts were cast on this polymer as a true solid phase sensitizer (10). Another more closely related insoluble polymeric analog of **1**, namely polystyryl 4-(*N*,*N*-dimethylamino)phenyl ketone, was found to

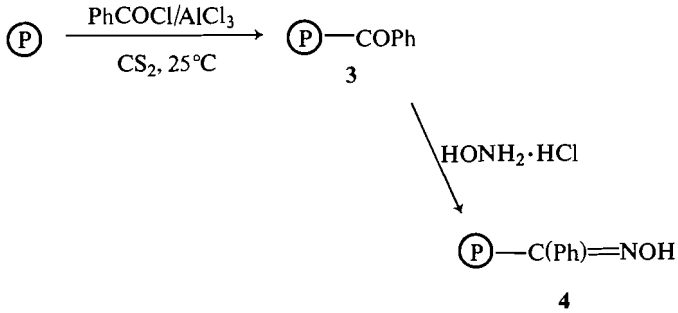
sensitize the norbornadiene-quadricyclane photoisomerization with the same quantum yield as soluble 4-(*N*,*N*-dimethylamino)benzophenone, although at slightly slower rates (11). Quite surprisingly, the simplest polymeric analog of benzophenone, i.e., poly-*p*-styryl phenyl ketone **3**, has not been evaluated in photochemical reactions "because of the problem with $AlCl_3$ incorporation when polystyrene–divinylbenzene beads are benzoylated under Friedel–Crafts conditions" (6), in spite of the recorded successful uses of **3** in other types of reactions (12–14).

The purpose of the present work is to fill this gap by describing the preparation of $AlCl_3$-free cross-linked poly-*p*-styryl phenyl ketone **3** (polymeric benzophenone) and its use as sensitizer in the $|2 + 2|$ photocycloaddition of cyclohexene and maleic anhydride, and in the *E*–*Z* photoisomerization of two soluble conjugated dienes and one polymer-bound diene. Also described is the use of **3** in the photooxidation of two secondary alcohols and in the photooxygenation of an alkene to the corresponding hydroperoxide. Preliminary communications have been published on some of these subjects (15, 16).

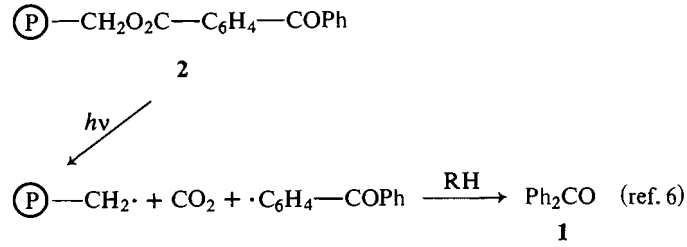
Preparation and characterization of polymeric benzophenones

Beads of a (98:2) copolymer of styrene and divinylbenzene (DVB) were benzoylated by reaction with benzoyl chloride in carbon disulfide in the presence of $AlCl_3$ (17), a method which is also used for the benzoylation of soluble polystyrene (18). The degree of functionalization to be achieved was limited by the amount of benzoyl chloride and $AlCl_3$ used. The resulting polymeric benzophenones were thoroughly washed with a series of solvents and shown to be free of $AlCl_3$ by elemental analysis. The degree of functionalization was determined by conversion into the corresponding polymeric oximes **4** and elemental analysis for nitrogen in these derivatives.



The three polymeric benzophenones prepared in this way were shown to contain 0.95, 2.2, and 3.2 mequiv. g^{-1} of carbonyl group. This can also be expressed as 11%, 29%, and 50% functionalization of the phenyl groups of the original polystyrene. For convenience, we shall refer to these three polymeric benzophenones as P-11, P-29, and P-50, respectively.

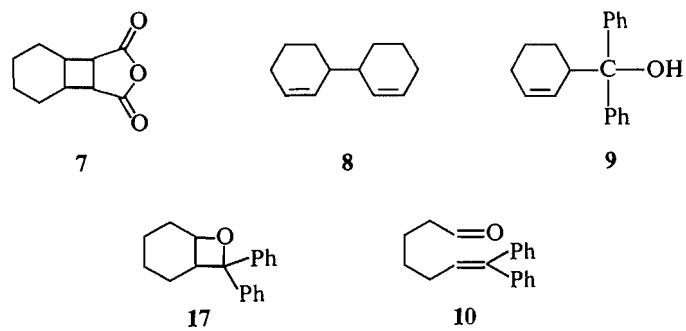
The photostability of all three polymers was checked by irradiation ($\lambda > 290$ nm) for 15 h in benzene or acetonitrile under nitrogen. This very prolonged irradiation released in soluble form less than 0.1% of a nonvolatile material which showed no peak of benzophenone by glc. The recovered irradiated polymers showed ir spectra almost identical to those of the starting materials, except for a very small broad absorption in the associated hydroxyl region. Furthermore, very little loss of activity was found when using P-29 pre-irradiated for 14 h in *Z*/*E* photoisomerizations (Fig. 2, curves 12 and 13). These data imply the occurrence of some (although very little) photodegradation of the polymers by backbone hydrogen atom abstraction, followed by cross-linking. Thus, P-11, P-29, and P-50 were shown to be rather photostable in the absence of substrates. These results should be compared with those obtained by Neckers (10) when evaluating his ester-type polymeric benzophenone **2** (6), which clearly showed the occurrence of up to 50% photodecarboxylation with release of up to 20% free benzophenone during irradiation for 6 h.



Polymeric benzophenones as sensitizers

(a) *Sensitized $|2 + 2|$ photocycloaddition of cyclohexene and maleic anhydride*

The photocycloaddition between cyclohexene **5** and maleic anhydride **6** gives mixtures of diastereomeric bicyclo|4.2.0|-octane-7,8-dicarboxylic anhydrides **7** and can be performed by unsensitized direct irradiation of the charge-transfer complex between **5** and **6** (19) or under sensitization by benzophenone **1** (20). We now describe the use of polymeric benzophenones as sensitizers for this reaction, the results being compared with those obtained when using **1** in the same conditions. In our hands, some by-products to be expected in the reaction sensitized by **1** were bi-2-cyclohexen-1-yl **8**, cyclohex-2-enyldiphenylmethanol **9**, and 7,7-diphenyl-6-heptenal **10**, as well as benzopinacol **11** and benzhydrol **12**. Of course, by-products of types **9**–**12**, if formed, could not be released to the solution when using the polymeric sensitizers P-11, P-29, or P-50. Thus, after filtration, the crude reaction mixture contained only adducts **7** and by-product **8**, besides starting materials.



Formation of **7** as a function of irradiation time was determined by glc. The results are given in Fig. 1. As seen in this figure, the polymeric sensitizers were less efficient than **1**, and since the "concentrated" P-50 gave lower yields of **7** than the "diluted" P-11, steric hindrance is likely to play a major role. We conclude that energy transfer to the bulky charge-transfer complex between **5** and **6** is more sterically hindered when using the more highly functionalized polymeric sensitizer.

Other factors being the same, yields of **7** increased when performing these reactions in the presence of acetonitrile as a cosolvent, probably due to the low solubility of maleic anhy-

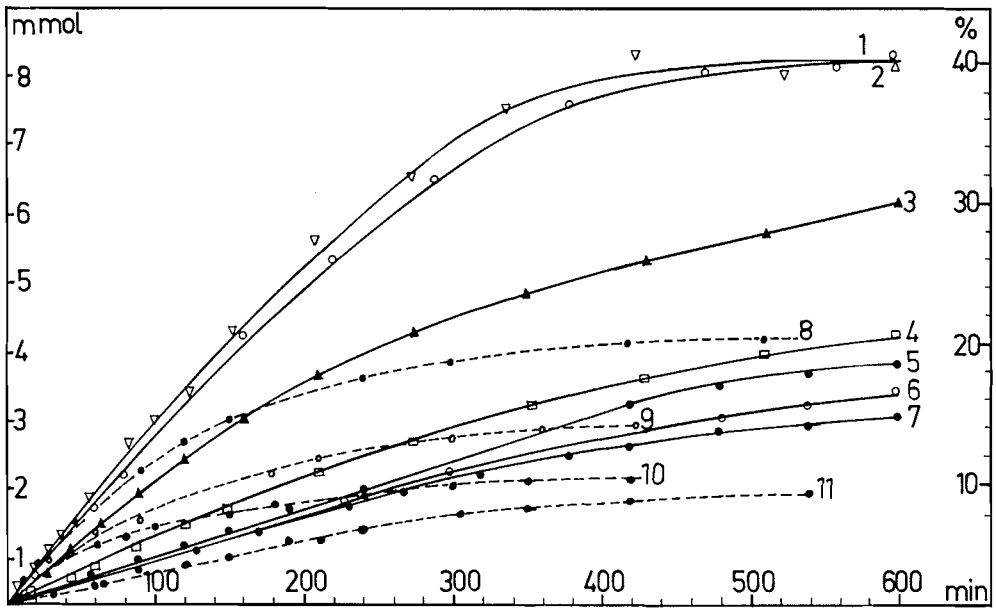


FIG. 1. Photocycloaddition of cyclohexene **5** and maleic anhydride **6**. Solid lines: yields of adducts **7** upon irradiation of **6** (2 g, 20.4 mmol) and **5** (10 mL) in acetonitrile (20 mL) in the presence of: curve 1, Ph_2CO (273 mg, 1.5 mmol); curve 2, Ph_2CO (273 mg, 1.5 mmol) and unfunctionalized polystyrene (2.38 g); curve 3, P-11 (2.7 g, 2.56 mequiv.); curve 4, P-50 (470 mg, 1.5 mequiv.); curve 5, unfunctionalized polystyrene (2.38 g); curve 6, no carbonyl compound; curve 7, P-11 recovered from experiment 3 (curve 3). Dashed lines: yields of adducts **7** upon irradiation of **6** (2 g, 20.4 mmol) in **5** (30 mL) in the presence of: curve 8, Ph_2CO (273 mg, 1.5 mmol); curve 9, P-11 (2.7 g, 2.56 mequiv.); curve 10, P-50 (470 mg, 1.5 mequiv.); curve 11, no carbonyl compound.

dride in cyclohexene.

Formation of the oxidative dimer **8** shows the photooxidizing ability of **1** and its polymeric analogs (see below).

The polymeric benzophenones recovered after their use in these sensitized cycloadditions did not show the original ketone carbonyl band in their ir spectra, bands at 1700–1780 (broad) and 1860 cm^{-1} as well as some associated hydroxyl bands at 3100–3600 cm^{-1} being observed instead. These recovered polymers could not be reused, and their 1780–1860 cm^{-1} bands, so similar to those of succinic anhydride, were taken as a clear indication of the anchoring of part of the maleic anhydride to the phenyl rings of the polymer units by $|2 + 2|$ photocycloaddition followed by conventional Diels–Alder cycloaddition, a process known to happen for benzene (21) and soluble polystyrene (22).

Attempts to determine the amount of polymer-bound maleic anhydride (by formation of the corresponding *p*-bromophenacyl ester, followed by Br analysis) failed, since most anhydride survived the treatment, as shown by ir.

(b) *Sensitized* E–Z *photoisomerization of conjugated dienes*

The *E–Z* photoisomerization of (*E*)-1,3-pentadiene, (*E*)-**13**, sensitized by **1**, is a well-known process (23) characterized by the triplet energies of substrate (*E*)-**13** (247 kJ mol^{-1}), product (*Z*)-**13** (238 kJ mol^{-1}), and sensitizer **1** (288 kJ mol^{-1}), and by a photostationary *Z/E* ratio of 0.82 ± 0.04 when using sensitizers having triplet energies well above those of the dienes, as is the case with **1**. We have performed this photoisomerization using polymeric benzophenones instead of **1**. The *Z/E* ratio was determined by glc as a function of irradiation time. The photoisomerization of methyl (*E*)-2,2-dimethyl-3,5-hexadienoate, (*E*)-**14**, prepared by known procedures (24), was also examined. The results of both series are given in Fig. 2. As shown in this figure, photostationary states were reached slightly more slowly when using polymeric benzophenones as sensitizers instead of **1**. The polymeric sensitizers could be reused without producing changes in the composition of the photostationary states, although these states were approached at somewhat smaller rates.[2] One important feature of the polymeric sensitizers was the decrease in the photostationary *Z/E* ratio which went along with the increase in the degree of functionalization of the polymer, clearly shown in the case of **14**. This effect appears to be of steric nature. Indeed, steric hindrance to energy transfer from triplet sensitizer to ground state alkene results in an increased photostationary proportion of the alkene isomer having the higher triplet energy (25). In our case such an effect should favour (*E*)-**13** over (*Z*)-**13**, according to the known triplet energies of these two isomers, and we assume that analogously (*E*)-**14** would also be favoured over (*Z*)-**14** . In the case of **13** this steric hindrance to energy transfer was operative only when using the more concentrated polymeric sensitizer, P-50. On the somewhat bulkier diene **14**, even the lightly functionalized polymer P-11 showed this effect. We therefore conclude that increasing the degree of functionalization of the polymeric benzophenones affects the photostationary *Z/E* ratios via steric hindrance of the energy transfer step. The same effect on the photostationary Z/E ratios can be obtained by means of the use of sensitizers with lower triplet energy, particularly if this energy approaches that of the phantom triplet of the alkene

[2]A referee points out that light transmittance/reflectance of the polymer beads changes on swelling in aromatic solvents, and that any change in this transmittance/reflectance ratio would affect the absorption of light and therefore the rate of the photochemical reaction. Nevertheless, the only type of reactions performed in benzene were these photoisomerizations and, although some changes could be observed in the *rates* of these reactions, the major finding was the change in the *composition* of the photostationary states, an effect which cannot be due to changes in transmittance/reflectance ratio.

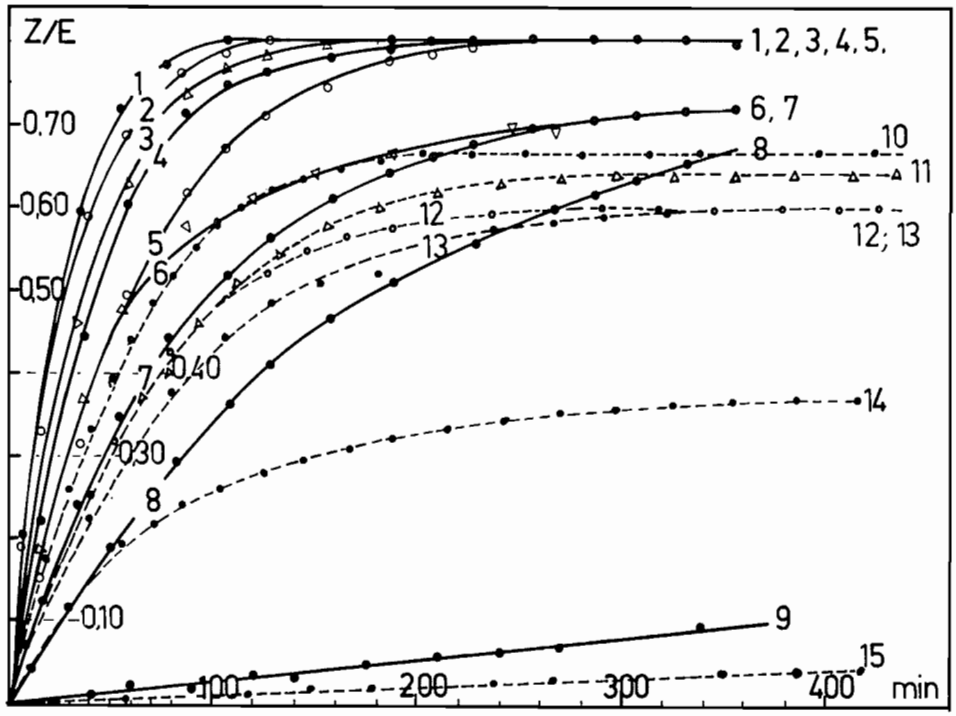

FIG. 2. $E-Z$ photoisomerization of conjugated dienes. Solid lines: Z/E ratio vs. irradiation time upon irradiation of (E)-**13** (0.20 mL, 135 mg, 2.0 mmol) in benzene (30 mL) in the presence of: curve 1, Ph_2CO (18 mg, 0.1 mmol); curve 2, P-11 (180 mg, 0.17 mequiv.); curve 3, Ph_2CO (9 mg, 0.05 mmol); curve 4, P-11 (90 mg, 0.085 mequiv.); curve 5, P-11 (90 mg) recovered from experiment 2; curve 6, P-50 (31 mg, 0.1 mequiv.); curve 7, P-50 (15 mg, 0.05 mequiv.); curve 8, P-50 (15 mg) recovered from experiment 6; curve 9, unfunctionalized polystyrene (161 mg). Dashed lines: Z/E ratio vs. irradiation time upon irradiation of (E)-**14** (462 mg, 3 mmol) in benzene (30 mL) in the presence of: curve 10, Ph_2CO (27 mg, 0.15 mmol); curve 11, P-11 (173 mg, 0.16 mequiv.); curve 12, P-29 (78 mg, 0.17 mequiv.); curve 13, P-29 (78 mg) preirradiated in benzene for 14 h; curve 14, P-50 (47 mg, 0.15 mequiv.); curve 15, no carbonyl compound.

(26). According to our results, we suggest the use of polymeric benzpohenones with an appropriate degree of functionalization as an alternative to lower triplet sensitizers for increasing the photostationary proportion of the olefin having the highest triplet energy.

(c) *The intrapolymerically sensitized* Z/E *isomerization of a resin-bound diene*[3]

The very encouraging results obtained in the isomerization of soluble dienes (above) suggested to us the feasibility of a similar intrapolymeric reaction, for which a difunctional polymer, containing both the sensitizer benzophenone and the diene units covalently linked to the same polymer lattice, was required. This type of reaction was already mentioned by us some years ago (2*a*).

There is little precedent in the literature of intrapolymeric reactions in insoluble difunctional polymers. One example is the directed mixed ester condensation of two acids (one of them non-enolizable in great excess) bound to a common polymer backbone, reported by Kraus and Patchornik in 1971 (27). Another example is the polymeric triphenylphosphine ligand containing both nickel and rhodium used by Pittman and Smith as a difunctional catalyst for sequential telomerization and hydrogenation reactions (28). In both cases the two different functional groups were introduced in a random array. A different approach was used by Leznoff and co-workers (29), who prepared difunctional polymers containing proximally located trityl and benzoyl chloride units by quenching polymeric phenyllithium with 4-benzoylphenyl ethyl carbonate and used these difunctional resins in the synthesis of insect sex attractants. In these three papers the feasibility of intrapolymeric reactions (transfer of substrate from one catalytic site to another, double binding of difunctional substrates, or actual bond formation between two different attached moieties) was demonstrated.

From the photochemical site, there is also precedent for the intramolecular energy transfer within a dichromophore, as demonstrated by Cowan and Baum for a series of phenyl ω-benzylidenealkyl ketones (30), in which light initially excited the acetophenone chromophore, which after intersystem crossing to the triplet state underwent energy transfer to the β-alkylstyrene moiety in an intramolecular process. The resulting triplet β-alkylstyrene moiety ultimately underwent Z/E isomerization (30), in what amounts to an intramolecularly sensitized photoisomerization.

We therefore tried the intrapolymeric reaction corresponding to photoisomerization of the soluble diene **14**, an excellent model which could be bound to chloromethylated resins as a benzylic ester. Two such difunctional polymers **15** were prepared by the sequence shown.

In the first step, the appropriate polymeric benzophenone (P-11 or P-29) was chloromethylated essentially as described by Merrifield for polystyrene (31), the only modification being the use of polymeric benzophenones precoordinated with $SnCl_4$ at all their carbonyl groups. The resulting chloromethylated polymers were analyzed for chlorine content and were then treated with (E)-2,2-dimethyl-3,5-hexadienoic acid **16** (24) in

[3]We gratefully thank a referee for his suggestions, particularly helpful in this section.

15*a* (n = 11%, m = 11%)

15*b* (n = 29%, m = 13%)

the presence of triethylamine, giving the desired difunctional polymers **15**, which were shown to be devoid of chlorine by elemental analysis. We assumed that the degree of ester functionalization of polymers **15** was the same as the chloromethyl contents of their immediate precursors. In this way, difunctional polymers **15***a* and **15***b* were prepared.

Both polymers released only the *E* diene ester (*E*)-**14** when transesterified with refluxing methanolic hydrochloric acid in dioxane (2). This shows the configurational stability of the double bond towards the transesterification conditions. On the other hand, the transesterification was far from complete, as shown by the low (<8%) yields of (*E*)-**14** obtained and by the prominent ester carbonyl absorption at 1725 cm^{-1} in the ir spectra of the recovered transesterified polymers. Other de-anchoring methods tested gave even worse results. Thus, neither sodium methoxide in anhydrous methanol – dioxane 1:1 at reflux nor sodium iodide in dioxane–acetone 1:6 at reflux, followed by treatment of the evaporated filtrate with diazomethane, gave the diene ester *E*-**14** (glc). One possible reason for the failure of the transesterification reaction could be the steric hindrance to attack at the ester carbonyl imposed by the neighbouring *gem*-dimethyl group (cf. ref. 2, where polymeric *n*-alkanoates were cleanly de-anchored by acid transesterification), coupled with instability of the diene esters **14** to prolonged heating. Actually, acid **16** is reported to polymerize spontaneously at room temperature within a few days, while it decarboxylates to 5-methylhexa-1,4-diene under pyrolytic conditions (24).

The difunctional polymers **15***a* and **15***b* were irradiated in benzene for up to 5 h. Bearing in mind the photodecarboxylation of **2** referred to above, we checked for the possible release of esters **14** or other derived compounds by glc on the filtrate after irradiation, but no peaks other than those of solvents were found. To make sure that no nonvolatile acids such as **16** had been released during irradiation, the filtrate was refluxed with methanolic hydrochloric acid in dioxane, and again glc showed the absence of esters **14**.

De-anchoring of the pendant ester groups from the irradiated difunctional polymers by refluxing them in methanolic hydrogen chloride in dioxane was quite incomplete even after long periods. However, this transesterification released not only

[a]The difunctional polymers **15** (300 mg) were irradiated in benzene (30 mL) under nitrogen bubbling.

[b]Irradiation for more than 2 h, followed by transesterification, resulted in very noisy chromatogrammes for the transesterification filtrates, in which peaks of esters **14** could no longer be resolved from background noise.

[c]The irradiated polymers were transesterified by refluxing them in a solution of 2 mL saturated methanolic HCl in 2 mL dioxane.

[d]Overall amount of esters **14** in the transesterification filtrate.

ester (*E*)-**14** but also (*Z*)-**14** (glc), undoubtedly formed from the polymeric esters **15** in a photoisomerization intrapolymerically sensitized by nearby benzophenone units. The results from these experiments are given in Table 1. From the data shown in this table we were unable to establish the photostationary Z/E ratio because of (*i*) the low yield of the transesterification step, and (*ii*) the dispersion of the experimental Z/E values. Nevertheless, the presence of (*Z*)-**14** in the transesterification mixtures proves unmistakably the occurence of the intrapolymerically sensitized $E-Z$ isomerization in what, to the best of our knowledge, appears to be the first example of such a process.

Polymeric benzophenones as photooxidizing reagents

Triplet benzophenone is known to abstract hydrogen atoms from suitable donors R—H, yielding hydroxybenzhydryl radicals $HOPh_2C\cdot$ (which ultimately couple to give benzopinacol) and radicals R· which can undergo further reactions, such as dimerization to R—R (cf. **8**) or loss of a second hydrogen atom, giving an unsaturated compound (i.e., oxidation of secondary alcohols to ketones). We have checked the photooxidizing ability of polymeric benzophenones in both types of reactions as described below.

(a) *Oxidative photodimerization of cyclohexene*

Previous work by Bradshaw (32) has shown that photolysis of benzophenone **1** in cyclohexene **5** gives oxetane **17** (13%), benzopinacol (47%), alcohol **9** (27%), and dimer **8** (6%). As mentioned above, some of these compounds were found as by-products of the photocycloaddition of **5** and **6** sensitized by **1**. We therefore investigated the products of the irradiation of **1** and its polymeric analogs in the presence of **5** but without added **6**. When using **1**, in our conditions (Pyrex equipment, 125 W lamp), the following compounds were isolated: benzopinacol (6.5%), alcohol **9** (9%), dimer **8** (26%), and aldehyde **10** (12%) (all yields relative to initial benzophenone). No oxe-

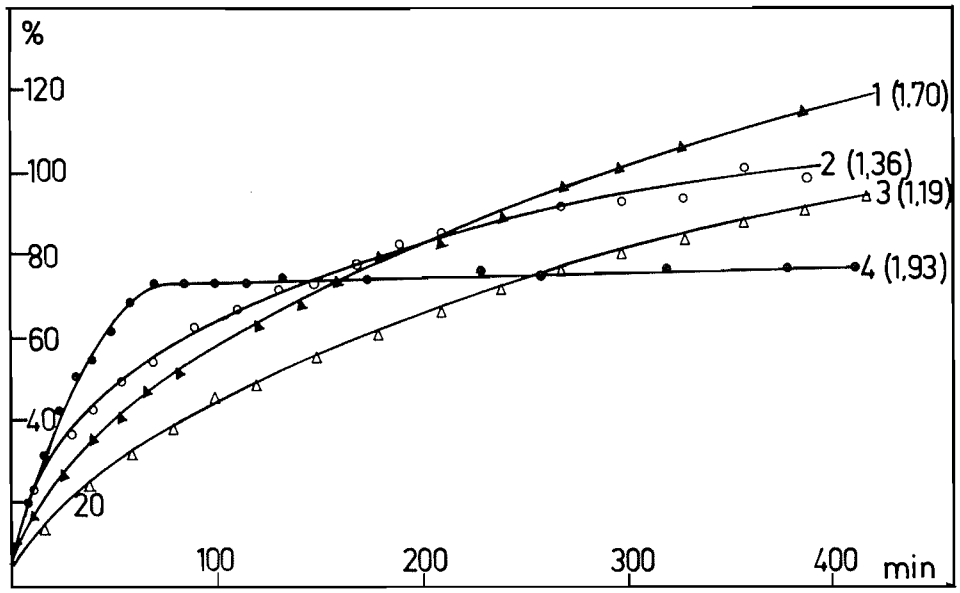

FIG. 3. Photooxidation of cyclohexanol. Yields (mmol cyclohexanone per mequiv. starting carbonyl compound) of cyclohexanone formed upon irradiation of cyclohexanol (10 mL) in CH_2Cl_2 (20 mL) in the presence of: curve 1, P-29 (0.64 g, 1.4 mequiv.); curve 2, P-11 (1.4 g, 1.3 mequiv.); curve 3, P-50 (390 mg, 1.25 mequiv.); curve 4, Ph_2CO (455 mg, 2.5 mmol). A complementary blank experiment, in which the irradiation was performed in the absence of any added carbonyl compound, gave a linear increase of the amount of cyclohexanone vs. irradiation time, with formation of 48 mg (0.5 mmol) after 7.5 h. Figures in parentheses give the mmol of cyclohexanone after 7.5 h irradiation.

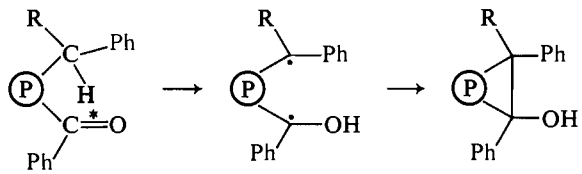
tane **17** was found, although it was probably the precursor of aldehyde **10**. Formation of **8** was measured by glc as a function of irradiation time under sensitization by **1**, P-11, and P-50. The results reported elsewhere (15), showed that **1** was much more effective than P-11 or P-50 in promoting oxidative dimerization of **5** to **8**, while both polymeric benzophenones showed similar effectivities, particularly on a stoichiometric basis. The presence of acetonitrile as a cosolvent caused a decrease in the amount of **8** formed, probably due to the lower concentration of **5**.

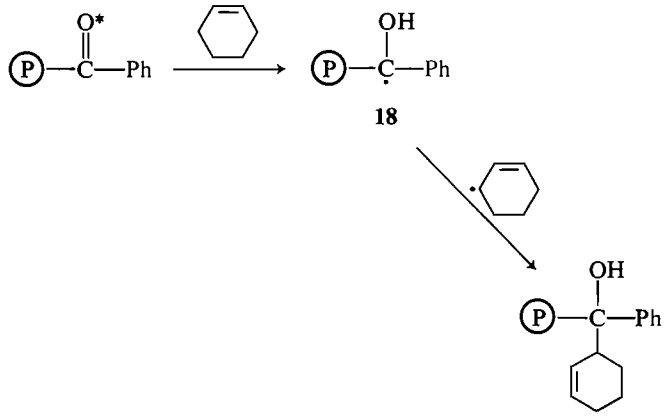
The ir spectrum of a recovered polymer showed no carbonyl band. Instead, an associated hydroxyl band was present, and of course these recovered polymers could not be reused. This could conceivably be taken as an indication of the occurrence of a photoinduced additional cross-linking mechanism, known to take place in **2** (10), which starts by intrapolymeric hydrogen abstraction from benzylic positions, yielding macrodiradicals which ultimately collapse to a new C—C bond.



However, as described above, polymeric benzophenones themselves were shown to be rather stable towards irradiation. Finally, comparison of the ir spectra of polymers recovered from these photodimerizations and that of alcohol **9** supports the conclusion that most of the polymeric hydroxybenzhydryl radicals **18**, being unable for steric reasons to dimerize to a polymeric benzopinacol analog, collapse with cyclohexenyl radicals to end up as alcohols **19**, the polymeric analogs of **9**.

(b) *Photooxidation of secondary alcohols*

The photooxidation of secondary alcohols to ketones is one of the oldest applications of organic photochemistry. The well-



known benzopinacol mechanism of this reaction (33) requires the consumption of two moles of **1** per mole of ketone formed.

We have used polymeric benzophenone for the photooxidation of isopropyl alcohol **20** and cyclohexanol **21**. The results for **21** are given in Fig. 3, while similar results were obtained for **20**. As seen in this figure, the yield of ketone obtained, based on initial photooxidizing reagent, was higher than the 50% allowed by the stoichiometry of the benzopinacol mechanism, even after correction for the ketone formed in the blank experiments (except for the reaction between **20** and **1**, not shown in the figure, for which a 50% yield was obtained). For polymeric benzophenones, collapse of macroradicals **18** to a polymeric equivalent of benzopinacol should be sterically hindered, thus opening up the possibility of the alternative benzhydrol mechanism:

$$Ph—CO—Ph + h\nu \longrightarrow Ph—CO^*—Ph$$

$$Ph_2CO^* + R^1R^2CHOH \longrightarrow Ph_2(OH)C\cdot + R^1R^2(OH)C\cdot$$

$$Ph_2(OH)C\cdot + R^1R^2(OH)C\cdot \longrightarrow Ph_2CHOH + R^1R^2CO$$

$$Ph_2CO + R^1R^2CHOH + h\nu \longrightarrow Ph_2CHOH + R^1R^2CO$$

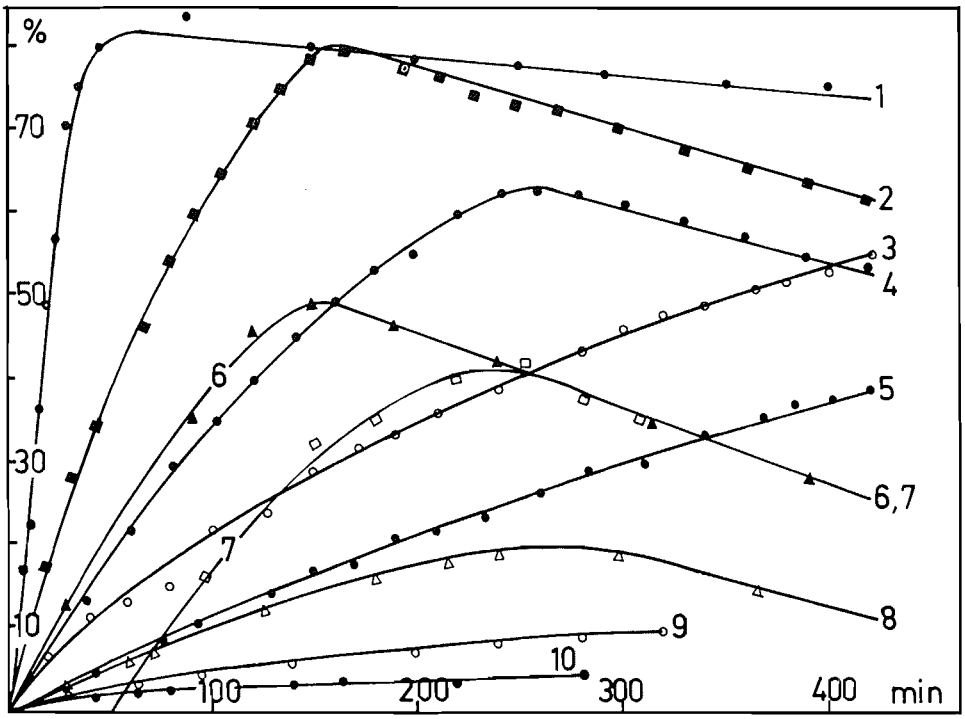

FIG. 4. Photooxygenation of 2,3-dimethyl-2-butene **22**. Yields of hydroperoxide **23** upon irradiation of **22** (0.42 mL, 340 mg, 4 mmol) in CH_2Cl_2 (30 mL) under oxygen bubbling in the presence of: curve 1, Rose Bengal (356 mg, 0.3 mmol; MeOH (ref. 36) instead of CH_2Cl_2 as solvent); curve 2, P-50 (94 mg, 0.3 mequiv.); curve 3, P-29 (156 mg) recovered from experiment 4; curve 4, P-29 (156 mg, 0.34 mequiv.); curve 5, P-11 (335 mg, 0.32 mequiv.); curve 6, P-29 (780 mg, 1.7 mequiv.; only 0.38 mL **22** used); curve 7, P-50 (94 mg, 0.3 mequiv.; 93 mg of 2,6-di-*tert*-butyl-*p*-cresol were also added; formation of **23** started after complete exhaustion of this radical inhibitor); curve 8, Ph_2CO (273 mg, 1.5 mmol); curve 9, no carbonyl compound (only 0.38 mL **22** used); curve 10, unfunctionalized polystyrene (102 mg).

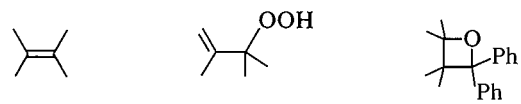
This benzhydrol mechanism is known not to occur in the reaction between **20** and **1** (33). However, the results of our experiments (Fig. 3, curve 4) force us to conclude that this mechanism was operative (at least in part) in the reaction between **21** and **1**, although the second hydrogen transferred from cyclohexanol was possibly the α rather than the hydroxyl hydrogen.

The polymers recovered from these reactions no longer exhibited the carbonyl band in their ir spectra, and obviously could not be reused.

Photooxygenation of 2,3-dimethyl-2-butene

Irradiation of either benzophenone or polymeric benzophenones in solutions of 2,3-dimethyl-2-butene **22** in dichloromethane under oxygen bubbling resulted in the formation of 2,3-dimethyl-3-buten-2-yl hydroperoxide **23**, as shown by glc (Fig. 4). Unlike the singlet oxygen mediated reaction brought about by dyes such as Rose Bengal (Fig. 4, curve 1), formation of hydroperoxide **23** in the presence of **1** or its polymeric analogs is a radical reaction, inhibited by 2,6-di-*tert*-butyl-*p*-cresol (Fig. 4, curve 7). Effectivity in promoting formation of **23** increased in the order **1** ≪ P-11 < P-29 < P-50. When using soluble benzophenone **1**, most starting alkene **22** underwent a photocycloaddition with **1** (Paterno–Buchi reaction) to give 4,4-diphenyl-2,2,3,3-tetramethyloxetane **24**, a reaction which should be sterically hindered when using the polymeric benzophenones. This steric hindrance, which should be more acute for the more highly functionalized polymers, is probably responsible for the observed order of effectiveness in the formation of hydroperoxide **23**.



22 **23** **24**

Polymers recovered from these irradiations could be reused (Fig. 4, curve 3) and showed a broad range of carbonyl bands in their ir spectra (1770–1690 cm^{-1}), besides the expected band for the benzophenone-like carbonyl at 1665 cm^{-1}. Polystyrene is known (34) to degrade to carbonyl compounds under photooxygenation. Therefore, a similar process could originate the new carbonyl bands in the recovered polymers.

Conclusion

As seen in the preceding sections, insoluble poly-*p*-styryl phenyl ketones **3** (polymeric benzophenones) could be used as sensitizers or as photooxidizing reagents instead of benzophenone **1** itself. The sometimes noticeable differences between the results obtained with the two kinds of carbonyl compounds could be interpreted in terms of steric effects. Thus, steric hindrance to the energy transfer step, greater for the more highly functionalized polymeric benzophenones, resulted in a diminished efficiency of **3** in the photocycloaddition between cyclohexene and maleic anhydride, and in changes in the photostationary *Z*/*E* ratios from photoisomerization of olefins. On the other hand, steric hindrance of secondary reactions resulted in some cases in an increased efficiency of the polymeric benzophenones. For instance, we can quote that steric hindrance of formation of the polymeric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

analog of benzopinacol went along with an increase in the yield of ketones for the photooxidation of secondary alcohols.

Experimental

The polystyrene used was a (98:2) copolymer of styrene–DVB, 200–400 mesh, purchased from Eastman–Kodak. Prior to its use, polystyrene (150 g) was sequentially washed with: ethanol–dioxane–water (30:4:1, v/v/v), 5 L; ethanol, 300 mL; ethanol–dioxane (2:1), 300 mL; ethanol–dioxane (1:1), 300 mL; dioxane, 1 L; dioxane–ether (1:1), 500 mL; dioxane–ether (1:2), 500 mL; and ether, 1 L. Drying (80°C, 2 Torr) to constant weight (149.5 g) over P_2O_5 gave a product with the following elemental analysis: C 92.34, H 7.99%.

Irradiations were performed in a small convential photochemical reactor, consisting of a three-necked 100 mL reaction vessel and a water-jacketed Pyrex immersion well, using a medium-pressure 125 W mercury lamp (Philips HPK-125), usually under a nitrogen atmosphere and with magnetic stirring. Except for irradiations under oxygen bubbling, nitrogen was bubbled through the solutions or suspensions to be irradiated for 30 min before switching the lamp on. For very volatile substrates, instead of nitrogen bubbling through the stirred mixtures, a nitrogen stream was passed very slowly over the reacting mixtures during irradiation. Except where otherwise stated, water was used for refrigeration of the immersion well jacket. Irradiations were stopped for taking aliquots (~50 μL) and resumed immediately after.

Gas–liquid chromatographic analyses were performed on a Perkin–Elmer Sigma 10 instrument, under fid detection, using the internal standard method. Results are the mean values of at least three nondeviating injections.

Polymeric benzophenones

P-11

To a stirred slurry of polystyrene (30.4 g, 291 mequiv.) and $AlCl_3$ (6.0 g, 45 mmol) in CS_2 (400 mL) was added dropwise a solution of benzoyl chloride (4.84 g, 34 mmol) in CS_2 (250 mL) over a 7 h period. After stirring overnight and filtering, the crude benzoylated polymer was washed with: 0.5 *M* HCl – dioxane (5:2), 4 L; water–dioxane (4:1), 4 L; water–dioxane (3:1), 1.5 L; water–acetone–dioxane (3:1:1), 1.5 L; water–acetone–dioxane (1:3:1), 2 L; acetone–dioxane (1:1), 500 mL; methanol–acetone–dioxane (1:1:1), 500 mL; methanol–dioxane (2:1), 500 mL; methanol–dioxane (1:2), 500 mL; methanol–dioxane (1:3), 500 mL; dioxane, 500 mL; dioxane–ether (2:1), 500 mL; dioxane–ether (1:1), 500 mL; dioxane–ether (1:2), 500 mL; dioxane–ether (1:3), 500 mL; ether, 1 L. The washed polymer was dried (80°C, 2 Torr) over P_2O_5 until constant weight. Yield, 33.0 g; ir (KBr): 1655 cm^{-1}. Elemental analysis: C 90.18, H 7.42%, Cl negative.[4]

Oxime of P-11

A suspension of P-11 (300 mg) in a solution of $NH_2OH \cdot HCl$ (3 g) and NaOH (5.6 g) in a mixture of ethanol (40 mL), dioxane (25 mL), and water (2 mL) was refluxed for 3 h. The mixture was then poured into 200 mL of a (1:1) mixture of 2 *N* HCl and dioxane containing 50 g of crushed ice, stirred for 30 min, and filtered. This washing was repeated twice. The acid-washed polymeric oxime was then washed with the sequence of solvents described above for the washing of P-11, from water–dioxane to ether, using 200 mL of each solvent or solvent mixture. Drying (80°C, 2 Torr) over P_2O_5 afforded 280 mg of the oxime of P-11. Infrared (KBr): 3700–3150 (broad) and 1600 cm^{-1}. Elemental analysis: C 90.08, H 7.22, N 1.31%, Cl negative.[4]

P-29 was prepared from 30.4 g (291 mequiv.) polystyrene and 15 g (112 mmol) of $AlCl_3$ in 400 mL CS_2 by addition of 12.1 g PhCOCl (86 mmol) in 200 mL CS_2. Yield: 37.5 g; ir (KBr): 1655 cm^{-1}. Elemental analysis: C 90.05, H 6.87, Cl negative.[4] Its oxime was prepared from 500 mg of P-29. Yield, 490 mg; ir (KBr): 3700–3150 (bd) and 1600 cm^{-1}. Elemental analysis: C 87.07, H 6.87, N 3.06%, Cl negative.[4]

P-50 was prepared from 26.0 g (249 mequiv.) polystyrene and 17 g (127 mmol) $AlCl_3$ in 250 mL CS_2 by addition of 20 g (142 mmol) PhCOCl in 125 mL CS_2. Yield, 38.0 g; ir (KBr): 1655 cm^{-1}. Elemental analysis: C 88.40, H 6.47%, Cl negative.[4] Its oxime was prepared from 320 mg of P-50. Yield, 310 mg; ir (KBr): 3700–3150 (bd) and 1600 cm^{-1}. Elemental analysis: C 84.19, H 6.68, N 4.23%, Cl negative.[4]

Stability towards irradiation

(a) A stirred suspension of P-29 (1.50 g, 3.29 mequiv.) in benzene (30 mL) was irradiated for 15 h under nitrogen. After filtration, the polymer was washed with benzene, benzene–ether, and ether and finally dried (80°C, 1 Torr) over P_2O_5 to constant weight (1.45 g). Infrared (KBr): 3600–3450 (very weak), other bands as in P-29. Evaporation of combined filtrate and washings gave 1.5 mg of an oil which , analyzed by glc, showed only peaks of retention time much higher than benzophenone. The ir spectrum of this oil, however, closely resembled that of benzophenone.

(b) Irradiation of P-50 (468 mg, 1.5 mequiv.) in acetonitrile (30 mL) for 10 h under nitrogen gave 430 mg of washed and dried polymer, similar to that described above, while the combined filtrates and washings showed no peaks other than those of the solvents by glc.

Photocycloaddition of cyclohexene and maleic anhydride

Materials

Cyclohexene was stirred overnight over neutral alumina, then refluxed over sodium for 24 h in a nitrogen atmosphere, and finally distilled over sodium under a slow nitrogen stream, bp 83°C. Acetonitrile was distilled twice over P_2O_5, bp 81°C. Maleic anhydride was recrystallized from chloroform and sublimed (70°C/14 Torr) before use, mp 58°C. Cycloadducts **7**, required as standards for quantitative glc determinations, were independently prepared following the method of Robson *et al.* (19).

Irradiations

The compositions of the mixtures to be irradiated are given in the caption of Fig. 1.

Analysis

Aliquots were analyzed by glc, using a 2 m × 1/8 in. column packed with 3% SE-30 on Chromosorb W-AW-DMCS (80–100 mesh) at 80–164°C (rate 3.5°C min^{-1}), then at 164–250°C (rate 10°C min^{-1}), and then 250°C (isotherm.) for 6 min, with nitrogen (25 mL min^{-1}) as the carrier gas. The internal standard used was diethyl adipate. Peaks for the individual stereoisomers of cycloadducts **7** could not be resolved completely, and therefore the overall envelope of cycloadducts **7** was integrated as a whole.

By-products

A peak from by-product **8** was detected in all the irradiations performed. Other peaks, from by-products **9** and **10**, were detected in irradiations in which benzophenone was used as sensitizer. The isolation and identification of these by-products is described under oxidative photodimerization of cyclohexene (see below).

Sensitized E–Z *photoisomerization of conjugated dienes*

Materials

(*E*)-1,3-pentadiene was purchased from Merck, showed a single peak in glc, and was used without further purification. Methyl (*E*)-2,2-dimethyl-3,5-hexadienoate was prepared following the procedure of Bigley and Weatherhead (24) and showed a single peak in glc. Thiophene-free benzene was used.

Irradiations

The compositions of the mixtures to be irradiated are given in the caption of Fig. 2.

Analysis

For 1,3-pentadiene irradiations, aliquots were analyzed by glc, using a 5.5 m × 1/8 in. column packed with 20% oxydipropionitrile

[4]A 15–20 mg sample was analyzed. Lower limit of detection is ≃ 0.5% Cl.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

on Chromosorb P (80–100 mesh) at 70°C (isotherm.), with nitrogen (5 mL min^{-1}) as the carrier gas. The internal standard method was not used, since only *Z*/*E* ratios were determined. Equal response factors were assumed for both isomers. For methyl 2,2-dimethyl-3,5-hexadienoate irradiations, glc analyses were performed on a 2 m × 1/8 in. column, packed with 10% Carbowax 20M on Chromosorb W-HP (80–100 mesh) at 60–150°C (rate 3°C min^{-1}), with nitrogen (25 mL min^{-1}) as the carrier gas. No internal standard was used, since only *Z*/*E* ratios were determined. Equal response factors were assumed for both isomers.

Product identification

With both types of (*E*)-diene substrates, the peaks assigned to the *Z* isomers in glc analysis were confirmed by gc/ms to correspond to isomers of the starting materials.

Intrapolymerically sensitized E–Z *photoisomerization of difunctional polymers* ***15****a and* ***15****b*

Chloromethylation of P-29

To a stirred suspension of 2 g (4.4 mequiv.) of P-29 in anhydrous $CHCl_3$ (25 mL), kept at 0°C, was added 0.45 mL (1.0 g, 3.8 mmol) of $SnCl_4$ and, after 1 h, a solution (at 0°C) of 0.2 mL (0.44 g, 1.7 mmol) of $SnCl_4$ in 1.3 mL (1.4 g, 17 mmol) of methyl chloromethyl ether was added dropwise. After stirring at 0°C for another 30 min, the polymer was filtered and washed three times with 3 *N* HCl – dioxane (1:3), followed by the sequence described under benzoylation of polystyrene (see above). The polymer was then dried (100°C, 2 Torr) over P_2O_5 until constant weight. Yield, 2.1 g. Elemental analysis: C 87.15, H 6.68, 3.17%.

Chloromethylation of P-11 (2.0 g, 2.1 mequiv.) by methyl chloromethyl ether (1.3 mL, 1.4 g, 17 mmol) and $SnCl_4$ (0.4 mL, 0.9 g, 3.4 mmol overall) as above yielded 1.95 g of chloromethylated P-11. Elemental analysis: C 87.73, H 6.78, Cl 3.14%.

Difunctional polymer ***15****a*

A mixture of chloromethylated P-11 (1.4 g, 1.2 mequiv. CH_2Cl), (*E*)-2,2-dimethyl-3,5-hexadienoic acid **16** (21) (1.2 g, 8.6 mmol), and 1.4 mL (10 mmol) triethylamine was refluxed for 44 h. After filtration and washing as described above for the chloromethylated polymers, the product was dried (100°C, 1 Torr) over P_2O_5 for 20 h. Yield, 1.45 g; ir (KBr): 1725 and 1655 cm^{-1}. Elemental analysis: Cl negative, N negative.

Difunctional polymer ***15****b* was prepared similarly from 1.9 g (1.7 mequiv. CH_2Cl) of chloromethylated P-29. Yield: 1.9 g; ir (KBr): 1725 and 1655 cm^{-1}. Elemental analysis: Cl negative, N negative.

Transesterification of difunctional polymers ***15***

A suspension of **15***a* (300 mg, 0.26 mequiv. ester) in 2 mL dioxane and 2 mL saturated methanolic HCl was refluxed for 20 h. Aliquots taken after 7 h and 20 h were neutralized by addition of solid $NaHCO_3$, filtered, and analyzed for their contents in esters **14** by means of glc (see above, under sensitized *E*–*Z* photoisomerization of conjugated dienes, for the chromatographic conditions). Only the peak of (*E*)-**14** was detected. The transesterification yields measured using diethyl adipate as internal standard were 4% (7 h) and 7% (20 h). The remaining polymer was washed and dried (70°C, 1 Torr) to constant weight (280 mg), and showed ir bands (in KBr) at 1725 and 1655 cm^{-1}. The same treatment, applied on **15***b*, gave transesterification yields of 3% (1 h reflux), 7% (5 h), and 6% (20 h), without a peak for (*Z*)-**14**.

Irradiation of ***15***

A stirred suspension of **15***a* (300 mg) in benzene (30 mL) was irradiated under nitrogen bubbling for 1 h (longer irradiation resulted in the release of smaller amounts of esters **14** after transesterification). After filtering and washing (the washings were shown by glc to be devoid of esters **14**), the irradiated polymer was transesterified as described above, and the amount of ester (*E*)- and (*Z*)-**14**, as well as their ratio, was determined by glc. The results are given in Table 1, together with the conditions and results of other irradiations of difunctional polymers **15**.

Oxidative photodimerization of cyclohexene

Reaction of cyclohexene ***5*** *and benzophenone* ***1*** *under irradiation*

A stirred solution of **1** (2 g, 11 mmol) in cyclohexene (30 mL, 24.3 g) was irradiated for 4 h. On addition of hexane, benzopinacol (260 mg, 6.5%) crystallized out (mp 185–186°C). After filtration and removal of solvents the residue was chromatographed on silica gel, giving the following fractions.

Bi-2-cyclohexen-1-yl ***8****, eluted with hexane*

Yield 0.23 g (26% yield given according to the stoichiometry: 2 moles of **1** reacting with 2 moles of **5** to give one mole of **8**; the yield quoted is relative to initial **1**). The compound showed a single peak in glc, and showed spectra identical to those described by Strausz *et al.* (35).

2-Cyclohexen-1-yldiphenylmethanol ***9****, eluted with hexane–* CH_2Cl_2 *(3:1)*

Yield, 269 mg (9%). Its nmr spectrum was identical to that described by Bradshaw (32).

7,7-Diphenyl-6-heptenal ***10****, eluted with hexane–* CH_2Cl_2 *(1:1)*

Yield, 350 mg (12%); oil; ir (film): 3090, 3060, 2975, 2900, 2750, 1720, 1600, 1495, 1450, and 750 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.3–2.7 (m, 8H), 6.1 (t, J = 7 Hz, 1H), 7.3 (m, 10H), and 9.85 (t, J = 1.5 Hz, 1H); ms at 70 eV, *m*/*e* (%): 264 (M, 26), 246 (7), 236 (17), 193 (93), 115 (100), 91 (44), and lower *m*/*e*.

Oxidative photodimerization of ***5*** *using polymeric benzophenones*

A stirred suspension of P-11 (2.7 g, 2.6 mequiv.) in cyclohexene (30 mL) was irradiated under nitrogen for 10 h. The amount of **8** formed was measured by analyzing aliquots by glc, with diethyl adipate as internal standard, under the chromatographic conditions described above for determination of cycloadducts **7**. The results were given in a preliminary communication (15).

Photooxidation of secondary alcohols

A suspension of P-11 (2.8 g, 2.7 mequiv.) in a solution of isopropyl alcohol or cyclohexanol (10 mL) in CH_2Cl_2 (20 mL) was irradiated for 7.5 h. The amount of ketone formed was measured by glc. Analytical conditions used when isopropyl alcohol was the substrate: 2 m × 1/8 in. column packed with 10% Carbowax 20M on Chromosorb W-HP (80–100 mesh), with nitrogen (8 mL min^{-1}) as the carrier gas, at 60°C (isotherm., 1 min), then 60 to 90°C (rate 5°C min^{-1}). Toluene was used as the internal standard. Analytical conditions used when cyclohexanol was the substrate: same column; nitrogen flow rate, 15 mL min^{-1}; temperatures: 60°C for 1 min, then 60–70°C (rate 5°C min^{-1}), then 70–110°C (rate 20°C min^{-1}), then 110°C for 3 min, then 110–150°C (rate 40°C min^{-1}), and finally 150°C for 3 min.

Photooxygenation of 2,3-dimethyl-2-butene ***22***

A stirred suspension of P-50 (95 mg, 0.3 mequiv.) in a solution of **22** (340 mg, 4.0 mmol) in CH_2Cl_2 (30 mL) was irradiated under oxygen bubbling for 7 h. Aliquots were analyzed by glc, using a 2 m × 1/8 in. column packed with 3% SE-30 on Chromosorb W-AW-DMCS (80–100 mesh), with nitrogen (5 mL min^{-1}) as the carrier gas, at 40°C for 2 min, then 40–90°C (rate 40°C min^{-1}), then 90°C for 3 min. Hydroperoxide **23**, independently prepared by a published procedure (36), was determined quantitatively, using toluene as the internal standard, for monitoring the progress of the reaction. Results are given in Fig. 4, as well as the compositions and results of other irradiations performed. In operations in which benzophenone **1** was used (Fig. 4, curve 8), a very late peak (beyond benzophenone), integrating for most of the reaction mixture, was identified (gc/ms) as 4,4-diphenyl-2,2,3,3-tetramethyloxetane **24** by comparison with the published mass spectrum (37) of this compound.

Ligand exchange in the rhenium–quinone radical complexes: kinetics and mechanism

KATHERINE A. M. CREBER AND JEFFREY K. S. WAN
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received July 12, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

KATHERINE A. M. CREBER and JEFFREY K. S. WAN. Can. J. Chem. **61**, 1017 (1983).

The substitution of the labile carbonyl groups of the rhenium–quinone radical complexes by nitrogen, phosphorus, arsenic, antimony, and oxygen donor ligands was observed. The extent of substitution was evidenced from esr spectra, while the configuration of the ligands about the rhenium centre was deduced from infrared absorption spectra. Rate data was obtained for the mono-substitution reaction which can be best interpreted in terms of concurrent major dissociative (D) and minor dissociative interchange (I_d) pathways. The relative thermodynamic stability of a number of substituted rhenium–quinone radical complexes was also investigated by competitive ligand exchange reactions.

KATHERINE A. M. CREBER et JEFFREY K. S. WAN. Can. J. Chem. **61**, 1017 (1983).

On a observé la substitution des groupes carbonyles labiles des complexes radicalaires de rhénium–quinone par des ligands donneurs d'azote, de phosphore, d'arsenic, d'antimoine et d'oxygène. On a mis en évidence le degré de substitution à l'aide des spectres de rpe tandis qu'on a déduit la configuration des ligands autour du centre rhénium à partir des spectres d'absorption infrarouge. On a obtenu les données de vitesse pour la réaction de mono-substitution que l'on peut avantageusement interpréter en fonction d'un schéma d'interchange dissociatif principal D et d'un interchange dissociatif secondaire (I_d) concurrents. On a également étudié la stabilité thermodynamique d'un certain nombre de complexes radicalaires de rhénium–quinone substitués en faisant appel à des réactions compétitives d'échange de ligand.

Introduction

Transition metal organometallic free radicals have received a considerable amount of attention in recent years, as they are known to have catalytic applications (1–3), as well as their potential to act as models for biological systems (4–7). The difficulty in studying these radicals is that they are usually very unstable and short-lived, making them very difficult to isolate. For example, the only 17-electron species for which a solid state crystal structure has been reported is $Mn(CO)(\eta^4\text{-}C_4H_6)$ (8).

Transition metal carbonyl radicals are easily formed by homolysis of metal–metal bonds, which can readily be accomplished by photolysis. These radical complexes are known to be very labile toward substitution (9). Hence, this type of organometallic radical complex offers an excellent opportunity for the study of organometallic radical reactions. In particular, the manganese and rhenium complexes have been examined by several groups with the aim of establishing a general mechanism for the substitution reactions of metal carbonyl radical complexes. While early controversy centered around the debate of a perfectly dissociative or an associative mechanism (10–14), recent consensus (15–17) emerged indicates that both mechanisms can be concurrently operative. Nevertheless, many of the metal carbonyl radicals are not totally stable in solution and they cannot be isolated for kinetic studies in the pure form. Thus, the recombination of the metal carbonyl radicals must be taken into consideration in the overall kinetic schemes (15).

In our earlier development of the HPLC-esr techniques (18, 19), we have found that *ortho*-quinones uniquely form very stable radical complexes with the rhenium carbonyls which can be isolated by the HPLC-esr technique for spectroscopic studies. However, a similar experiment with manganese carbonyls produced the radical complexes which decomposed while being eluted through a HPLC column. Since the rhenium carbonyl – quinone radical complexes undergo slow substitution reactions with a number of organometal donors (20–22), it follows that one could design kinetic experiments using the pure radical complexes. Furthermore, we have demonstrated (20, 21) that the ligand substitution reactions involving optically active organometals and/or optically active quinones led to the isolation of some interesting optically active radical complexes. These reactions are potentially highly stereo-specific and enantio-selective, it is important that some kinetics and mechanistic information of these rhenium carbonyl – quinone radical complexes involved in the substitution reactions be delineated.

Experimental

The HPLC-esr instrumentation has been previously described (18, 19).

The infrared absorption spectra were recorded on a Perkin-Elmer 598 spectrometer. The samples were run as chloroform solutions in NaCl cells having a path length of 0.25 cm.

A Perkin-Elmer 552 spectrometer was used for the kinetic runs. A specially constructed temperature accessory held the averaged sample temperature constant to ±0.1°C, within the temperature range 20–50°C. For the kinetic runs, the wavelength maximum of the DTBQ$^{\bullet}$—$Re(CO)_4$ radical complex (λ_{max} = 510 nm) was monitored at regular time intervals and the absorbance readings recorded.

The ligands triphenylphosphine (Aldrich), triphenylarsine (Aldrich), triphenylantimony (Aldrich), triphenylphosphite (Aldrich), triethylamine (Baker), pyridine (BDH), and dimethylsulphoxide (Baker) were found to be spectroscopically pure and were used as received. 3,5-Di-*t*-butyl-*o*-quinone was supplied by Aldrich and decacarbonyldirhenium was supplied by Strem.

Results and discussion

1. Kinetics and mechanism of the CO substitution reactions of DTBQ$^{\bullet}$—Re(CO)$_4$

The kinetics of the following reaction were investigated

$$[1]\quad DTBQ^{\bullet}\text{—}Re(CO)_4 + L \xrightarrow[\text{benzene}]{\text{dark}} DTBQ^{\bullet}\text{—}Re(CO)_3L + CO$$

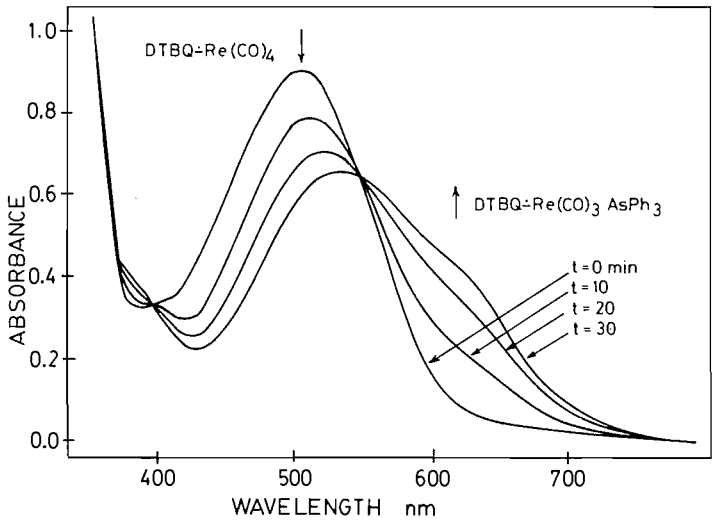

FIG. 1. Visible absorption spectrum of DTBQ—$^{\bullet}$—Re(CO)$_4$ in benzene at 25°C before and after the addition of a ten-fold excess of $AsPh_3$.

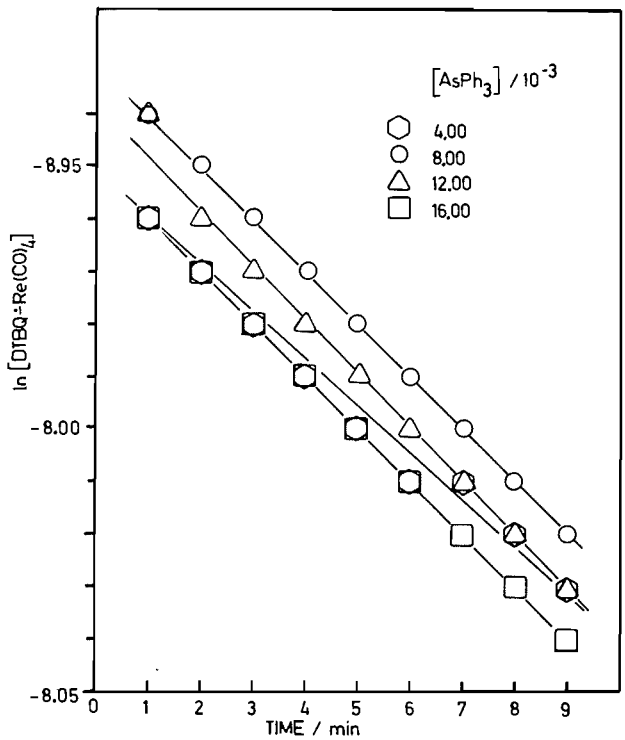

FIG. 2. Plot of ln [DTBQ—$^{\bullet}$—Re(CO)$_4$] vs. time for the reaction of DTBQ—$^{\bullet}$—Re(CO)$_4$ with $AsPh_3$ in benzene at 25°C.

where L represents PPh_3, $AsPh_3$, $SbPh_3$, and $P(OPh)_3$. The reaction was studied under pseudo-first order conditions, with the ligand (L) concentration being at least ten-fold in excess. The progress of the reaction was followed by visible absorption spectroscopy. In particular, the band at 510 nm, which corresponds to the $\pi \rightarrow \pi^*$ transition of the unsubstituted complex (18), was monitored at regular time intervals. Figure 1 shows a typical run where the entering ligand was $AsPh_3$.

The rate equation for reaction [1] can be written as a two-term rate law (15):

[2] Rate = $(k_1 + k_2[L])$[DTBQ—$^{\bullet}$—Re(CO)$_4$]

The rate constant k_1 is related to the first-order dissociative step while the rate constant k_2 describes the concurrent dissociative interchange process between the radical complex and the ligand. In our systems using pure DTBQ—$^{\bullet}$—Re(CO)$_4$ as well as the ligands to be substituted, it is possible to vary *independently* the initial concentrations of both reactants and to monitor the concentration of the DTBQ—$^{\bullet}$—Re(CO)$_4$ independently as a function of time.

For pseudo-first order treatment (which is valid for an initial concentration of the ligand being much higher than the radicals), eq. [2] can be rewritten as

[3] Rate = k'[DTBQ—$^{\bullet}$—Re(CO)$_4$]

where $k' = (k_1 + k_2[L])$. In our experiments, both the initial concentration of the radical complex, $[DTBQ—^{\bullet}—Re(CO)_4]_0$, and the instant concentration [DTBQ—$^{\bullet}$—Re(CO)$_4$], are monitored by either or both optical and esr measurements.

A plot of ln [DTBQ—$^{\bullet}$—Re(CO)$_4$], vs. time for the reaction with $AsPh_3$ at 25°C is shown in Fig. 2. The value of k' (slope = $-k'$) obtained at different experimental conditions are given in Table 1. A plot of log k' vs. log [L] indicates that within the experimental range of ligand concentrations the value of k' does not vary with [L]. Thus, it can be concluded that the reaction is first order, under the experimental conditions.

In order to obtain an approximate parameter for the Arrhenius activation energy, we assumed that the pre-exponential factor and the activation energy are constant over the experimental temperature range. The Arrhenius plots obtained for the four radical complexes studied are shown in Fig. 3 and the data obtained from the least squares analysis are given in Table 2. The k' values used in the plots are the average of all ligand concentrations at the particular temperature.

The thermodynamic parameters $\Delta H^{\ddagger}$ (enthalpy of activation), $\Delta S^{\ddagger}$ (entropy of activation), and $\Delta G^{\ddagger}$ (free energy of activation), were obtained from the following equations:

[4] $E_a = \Delta H^{\ddagger} + RT$

[5] $A = \frac{ekT}{h} \exp \frac{(\Delta S^{\ddagger})}{R}$

[6] $\Delta G^{\ddagger} = \Delta H^{\ddagger} - T\Delta S^{\ddagger}$

where k is the Boltzman constant and all other parameters have their usual meaning. Table 3 gives the thermodynamic parameters for the various substitution reactions of DTBQ—$\overset{\bullet}{}$—Re(CO)$_4$.

Before discussing the mechanistic implications of the data obtained in this study, it is important that several concepts be made clear. The dissociative (S_N1, five-coordinate intermediate and rate of substitution independent of entering ligand) and associative (S_N2, seven coordinate intermediate and rate of substitution strongly dependent upon the nature and concentration of the entering ligand) mechanisms are extremes. Rarely is a mechanism a clear cut example of either an associative or dissociative mechanism. Tobe (23) has clearly described the extremes, as well as an intermediate case, known as an interchange mechanism. Both a dissociative interchange, I_d, and an associative interchange, I_a, are described. The main feature of the $I_{a,d}$ mechanism is that it is assigned when no evidence for an intermediate can be found, with the assumption that it is very short-lived.

The results of the study of the substitution of a CO group of DTBQ—$\overset{\bullet}{}$—Re(CO)$_4$ indicate that the reaction is mainly a dissociative process, with the loss of the CO group being the rate determining step. The lack of variation in the rate constants at

[a]The k's at each temperature are the averaged values of the individual k's at different ligand concentrations as reported in Table 1.

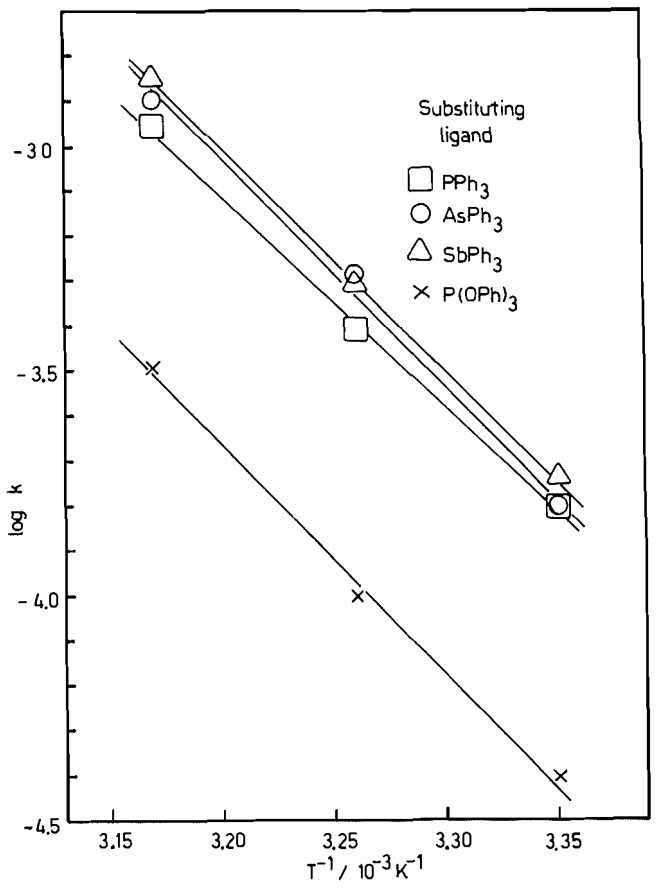

FIG. 3. Plot of log k vs. T^{-1} for the carbonyl substitution reactions of DTBQ$^{\bullet-}$—Re(CO)$_4$ by PPh_3, $AsPh_3$, $P(OPh)_3$, and $SbPh_3$.

differing ligand concentrations and the very small variation in the rates when different ligands were used is indicative of a dissociative mechanism. A similar, though associative, reaction involving the exchange of a CO group for various phosphine ligands on an iron–carbonyl complex was reported, having rate constants for the different phosphine ligand reactions which varied by as much as four orders of magnitude

TABLE 3. Thermodynamic parameters of the substitution reactions of DTBQ$^{\bullet-}$—Re(CO)$_4$ in benzene at 25°C

Ligand	$\Delta H^{\ddagger}$ (kJ/mol)	$\Delta S^{\ddagger}$ (J/mol)	$\Delta G^{\ddagger}$ (kJ/mol)
PPh_3	85.4±5.5	−31.8±16.5	95.1±5.5
$AsPh_3$	89.5±6.5	−19.7±20.0	95.3±6.5
$SbPh_3$	89.5±5.7	−16.3±17.0	94.5±5.7
$P(OPh)_3$	91.2±5.2	−23.0±16.0	97.9±5.2

(24).

The reactions at 25°C all had very small negative $\Delta S^{\ddagger}$ values. A large, negative value would be indicative of a purely associative mechanism, while a large positive value would indicate that the mechanism is purely dissociative in nature. In view of the error likely in the $\Delta S^{\ddagger}$ values (8 J mol^{-1} deg^{-1}) and their closeness to zero, it is reasonable to assume that the entering ligand probably approaches the radical complex within some defined distance before the dissociation of the CO group occurs.

Further evidence for the dissociative nature of the substitution reaction comes from the study of the reaction in benzene solutions which were saturated with carbon monoxide. For the three cases studied at 25°C, where the entering ligands were PPh_3, $AsPh_3$, and $SbPh_3$, the rate constants were found to be smaller by a factor of ten in the CO-saturated solutions than in the nitrogen-degassed solutions normally employed.

From the evidence accumulated here, it can be concluded that the mechanism which best describes the reaction is a dissociative reaction, with the loss of CO being the rate-determining step and with a small degree of I_d contribution between the ligand and the unsubstituted radical before CO dissociation occurs. A general scheme representing the reaction system and as suggested by a referee is given below:

[7] DTBQ$^{\bullet-}$—Re(CO)$_4$ ⇌ DTBQ$^{\bullet-}$—Re(CO)$_4$ + CO
DTBQ$^{\bullet-}$—Re(CO)$_4$ + L → DTBQ$^{\bullet-}$—Re(CO)$_4$L } D mechanism for major path

and

DTBQ$^{\bullet-}$—Re(CO)$_5$ + L → DTBQ$^{\bullet-}$—Re(CO)$_4$L + CO; I_d mechanism for minor path

DTBQ$^{\bullet-}$—$Re(CO)_3pY$	C_{3v}	1990 (s, A_1); 1911 (s, E); 1892 (s, E)
DTBQ$^{\bullet-}$—$Re(CO)_2[P(OCH_3)_3]_2$	C_{2v}	1935 (s, A_1); 1878 (s, B_1)

2. Substitution of ligands other than CO in the DTBQ—Re(CO)$_3$L radical complex

The exchange of ligands, other than CO, in radicals of the type DTBQ$^{\bullet-}$—$Re(CO)_3L$ by other ligands of similar type has also been investigated. Qualitative experiments, monitored by esr, were performed in which an excess of ligand, L′, was added to a toluene solution of a previously CO-substituted radical complex, as shown below:

[8] DTBQ$^{\bullet-}$—$Re(CO)_3L$ + L′ → DTBQ$^{\bullet-}$—$Re(CO)_3L'$ + L

Several interesting observations were made during the course of the reactions. When NEt_3 was the originally substituted ligand, the replacement of NEt_3 by $AsPh_3$ or $SbPh_3$ was very much faster than the substitution of CO in DTBQ$^{\bullet-}$—$Re(CO)_4$ by $AsPh_3$ or $SbPh_3$. Radical complexes substituted with pyridine, however, did not react with $AsPh_3$ or $SbPh_3$.

The results of this study can be summarized by listing the ligands in decreasing order of their ability to displace another ligand lower in the series. The series is:

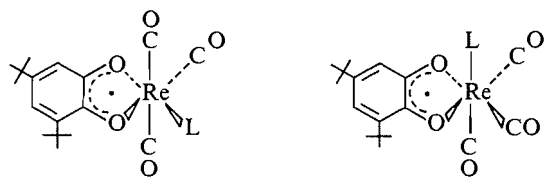
$$PPh_3 > py > DMSO \approx AsPh_3 > SbPh_3 > NEt_3$$

It is clear from this series and the kinetic results of the previous section that the thermodynamic stability of a radical complex is not necessarily related to the rate of its formation.

The position of the substituting ligand in the octahedral radical complexes was investigated. In metal–quinone complexes, axial substitution (where the bidentate quinone defines the plane) has been reported for rhodium (25–27) and ruthenium (25) complexes, while equatorial substitution has been reported for platinum (25), palladium (25), and iridium (25–27) complexes, where PPh_3 was the entering ligand. Alberti *et al.* (28) have reported equatorial substitution of two triethylphosphite ligands on a manganese–quinone radical complex at 0°C which thermally rearranged to axial positions when the temperature was raised to 60°C. These results were based on esr data and the idea that an equatorial P atom is expected to have a smaller hyperfine coupling constants. This is due to the less efficient transmittance of spin density through the metal atom than an axial position where a direct overlapping with the unpaired spin π-orbitals of the quinone can occur.

Although positive esr data can provide information on the probable configuration, confirmation by another technique is, of course, valuable. Infrared absorption, particularly in the carbonyl region of the pure radical complex, was used to determine the configuration of the CO groups, and hence the other ligands, about the rhenium centre. Table 4 gives the carbonyl stretching frequencies and band assignments of the radical complexes. Again we were taking advantage of the valuable HPLC-esr technique which provides the pure radical complex (without the presence of parent compounds) which could mask the CO absorption region. The ir assignments were made assuming that the ligands were point charges (29), since they all have similar bonding properties (i.e., all are σ-donors and π-acceptors). It should be *emphasized* that the "point-charge" model is at best an approximation as the radical complexes will in fact exhibit some distortion from the ideal geometry. Nevertheless, the absorption of the CO groups is very strong in these complexes, making the resolution of the number of bands more unambiguous. Furthermore, the ir results are also consistent with the esr assignments.

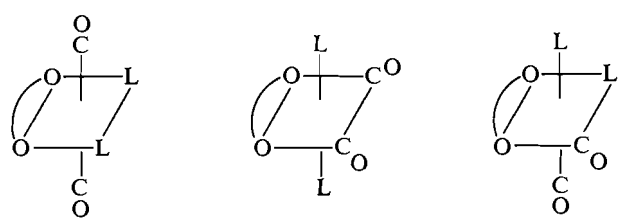
The monosubstituted radical complexes could have been either of the two conformations shown below.



C_{2v} C_{3v}

The C_{2v} complex, with the ligand *trans* to the quinone, is expected to exhibit two bands in the carbonyl region, (A_1 + B_1). The C_{3v} complex should also exhibit two bands (A_1 + E), however, if the axial ligands are not identical, as is the case here, then the E band is expected to broaden or split as the symmetry of the molecule changes to C_5 (30). From the examination of the ir carbonyl bands, it can be concluded that the C_{3v} structure is the correct one for all of the monosubstituted radical complexes which were studied. This is in agreement with the rather large (~25 G) phosphorus coupling constants which were observed (21, 22).

There are three possible structures for the disubstituted rhenium radical complexes shown below.



I (D_{4h}) II (C_{2v}) III (C_{2v})

The D_{4h} structure should exhibit only one ir band in the CO region (A_{2u}), hence can be ruled out as a possible structure. The esr spectrum showed that the two phosphite ligands were equiv-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

alent, so that structure **III** can be eliminated. Structure **II** with *trans* phosphite ligands should have an ir spectrum with two bands of equal intensity ($A_1 + B_1$), which is exactly what was observed. The structure of the bisubstituted rhenium–quinone radical complexes can thus be assigned structure **II**.

Though the thermodynamically most favourable position for the substituting ligands has been shown to be in axial positions, this does not necessarily mean that the original CO group lost was in an axial position. It is well known that intramolecular rearrangement in transition metal carbonyl complexes can be very rapid (31). We were unable to observe a phosphorus ligand in an equatorial position, even when the complex was formed at 0°C.

Rotationally resolved photofragment fluorescence from $OH(A^2\Sigma^+)$ following the coherent two-photon excitation of H_2O with a KrF laser (248 nm), is reported and the dynamics of the dissociation process are discussed. Fluorescence from $CN(B^2\Sigma^+)$ following two-photon excitation of ICN is also described. In both cases the energy distribution in the photofragments is shown to differ significantly from that observed with single-photon excitation at closely similar energies.

Two further examples of multiphoton excitation, involving CS_2 and SO_2, are briefly discussed. In these cases absorption of a further photon, by fragments produced in the primary step, gives rise to strong laser-induced fluorescence.

R. J. DONOVAN, C. FOTAKIS, A. HOPKIRK, C. B. MCKENDRICK et A. TORRE. Can. J. Chem. **61**, 1023 (1983).

On rapporte la fluorescence de photofragment résolue rotationnellement à partir de $OH(A^2\Sigma^+)$ après excitation par deux photons cohérents de l'eau à l'aide d'un laser au KrF (248 nm) et on discute des dynamiques du processus de dissociation. On décrit également la fluorescence provenant de $CN(B^2\Sigma^+)$ qui suit l'excitation du ICN par deux photons. Dans les deux cas on montre que la distribution d'énergie des photofragments diffère de façon significative de celle observée lors d'une excitation à l'aide d'un photon unique à des énergies très semblables.

On discute brièvement de deux autres exemples d'excitations par multiphoton qui impliquent le CS_2 et le SO_2. Dans ces cas l'absorption d'un autre photon, par les fragments produits dans la première étage, donne lieu à une forte fluorescence induite par un laser.

[Traduit par le journal]

Introduction

The use of high power ultraviolet lasers to induce multiphoton excitation and bring about photochemical change offers a number of advantages over conventional techniques. Firstly, states which lie at energies equivalent to those for single-photon transitions in the vacuum ultraviolet can be populated without having to contend with the many practical difficulties associated with the evacuation of the optical path and the handling of materials that are transparent at vacuum ultraviolet wavelengths (the transmission of such materials is rapidly degraded by the slightest contamination and they are also susceptible to radiation damage). Secondly, the selection rules for multiphoton excitation differ from those for single-photon excitation and this allows access to a whole new range of electronically excited states. This point is well illustrated by the simplest of multiphoton excitation processes, i.e. two-photon excitation. The selection rules for two-photon excitation are equivalent to those for Raman scattering and thus complement the normal electric dipole selection rules.

A third difference which has not yet been much exploited is the ability to excite samples homogeneously that would otherwise be optically thick for single-photon absorption in the vacuum ultraviolet. Thus, using multiphoton excitation, a homogeneous distribution of radicals can be produced in systems where high reagent concentrations would render the sample opaque to vacuum ultraviolet radiation. The latter principle can be further exploited for the excitation and detection of atoms which by virtue of their high peak extinction coefficients become optically thick at very low concentrations.

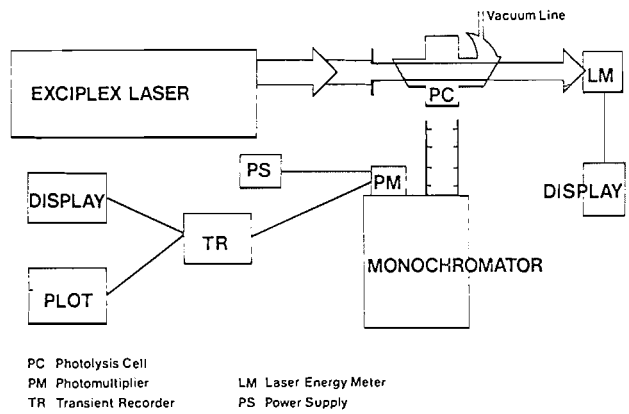

FIG. 1. Experimental arrangement for observing photofragment fluorescence and multiphoton excitation.

In the work presented below we demonstrate how a simple excimer laser can be used to induce multiphoton transitions in a number of small molecules and discuss the various mechanisms involved. The first example considered, that of the coherent two-photon excitation of H_2O, is the most clearly understood. We then discuss the two-photon excitation of ICN which involves a repulsive intermediate state at resonance with the first photon. Finally, we discuss two examples in which the primary photofragments are excited by absorption of a further photon from the laser pulse and give rise to strong *laser-induced* fluorescence spectra.

Experimental

The experimental arrangement (see Fig. 1) was similar in principle to that described previously (1) but differed in a number of important respects. For the multiphoton excitation of water the excimer laser used was a Lambda Physik EMG 201; this laser is capable of deliv-

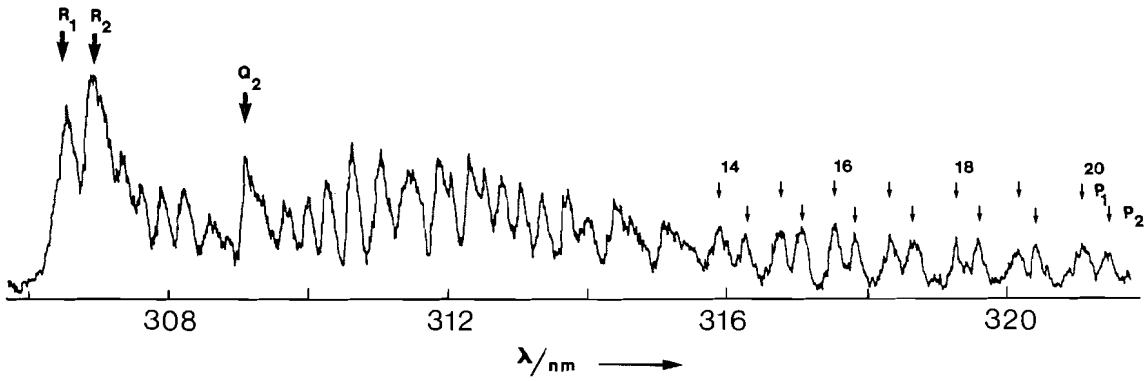

FIG. 2. Photofragment fluorescence from OH($A^2\Sigma^+$, $v' = 0 \rightarrow X^2\Pi$, $v'' = 0$) following two-photon excitation of H_2O (P_{H_2O} = 1.5 kN m^{-2}) with a KrF laser (248 nm). The heads of the R_1, R_2, and Q_2 branches, together with the resolved rotational lines of the P_1 and P_2 branches, are indicated by arrows.

ering 1 J per pulse on the KrF line at 248 nm. The laser output was focussed into the photolysis cell with a quartz lens of focal length 10 cm. The OH photofragment fluorescence was monitored at right angles to the laser beam and was dispersed with a Monospek 500 monochromator used in the second order. The observations on SO_2 excitation were also made with this arrangement.

The work with ICN and the other molecules discussed below was carried out with a Lambda Physik EMG 500 laser and an experimental arrangement that has been described previously (1, 2).

Results and discussion

(i) *Two-photon excitation of water*

The only photofragment fluorescence observed when water was subjected to the focussed output of the KrF laser was readily identified as due to OH($A^2\Sigma^+ \rightarrow X^2\Pi$). The intensity of the emission was found to increase slowly with increasing vapour pressure of water and at 1.5 kN m^{-2} pressure the intensity was sufficient to allow rotational structure to be resolved for levels with $K \geq 14$ (see Fig. 2). The spectrum could still be observed for pressures as low as 67 N m^{-2} and was essentially identical to that at the highest pressures. This is consistent with the large ratio for the cross-sections for electronic quenching versus rotational relaxation of OH($A^2\Sigma^+$) by water (3).

Water is completely transparent at 248 nm (i.e. for single-photon absorption) and as there is insufficient energy to dissociate the molecule we can be certain that this photofragment fluorescence must result from a coherent two-photon process or a higher order process. The intensity of the OH($A^2\Sigma^+$) fluorescence was found to increase quadratically with the laser intensity (1) which supports the two-photon mechanism.

The populations of the K levels, for K = 14–20, were readily determined using the known line strengths, as the P_1 and P_2 branches associated with these higher levels are clearly resolved. Careful analysis of the sharper features at shorter wavelength, several of which are blends of only two lines, allows a reasonable estimate to be made of populations below K = 14. These populations can then be fed into a computer program which simulates the fluorescence spectrum. Small adjustments are made to the populations until a good fit between the experimental and simulated spectrum is obtained. The best fit to the data in Fig. 2 was achieved with a distribution that peaked at about K = 16 and declined slowly up to K = 20. Below K = 16 the populations are fairly constant. This distribution is clearly very different to the one observed following single-photon excitation of H_2O at 123.6 nm where a monotonically

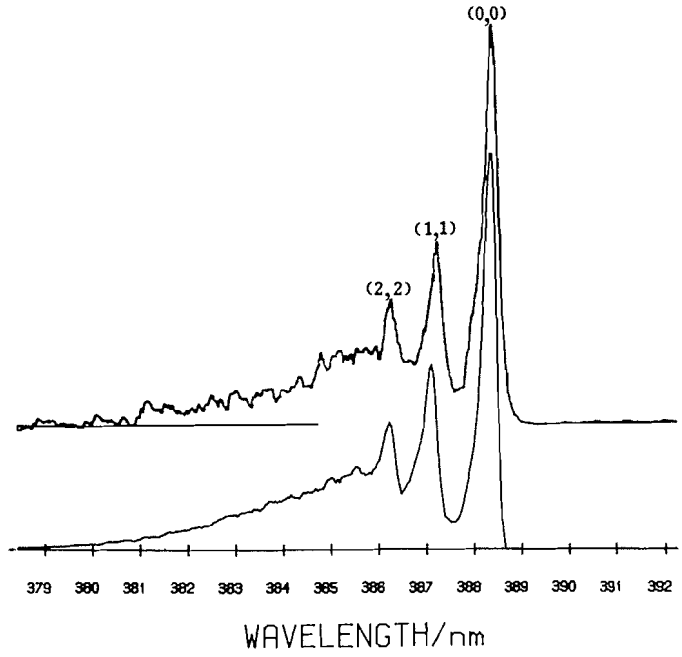

FIG. 3. Photofragment fluorescence from CN($B^2\Sigma^+ \rightarrow X^2\Sigma^+$) following two-photon excitation of ICN (P_{ICN} = 24 N m^{-2}) with a KrF laser (248 nm). The upper trace is the experimental spectrum and the lower trace a computer simulation.

rising population of K levels, up to the maximum possible level (i.e. K = 20), is observed (4). The rotational distribution produced by two-photon excitation is thus somewhat cooler than that produced by single-photon excitation but the OH($A^2\Sigma^+$) fragment still receives a considerable amount of angular momentum.

The different rotational distributions observed following single-photon and two-photon excitation suggest that different upper electronic states could be involved in the two absorption processes. In the case of single-photon excitation both the bound $\tilde{C}^1B_1$ and the repulsive $\tilde{B}^1A_1$ states are populated. The $\tilde{C}^1B_1$ state is known to be mixed with a close lying $^1A_2$ state, forming a Rydberg complex, and is also predissociated by the $\tilde{B}^1A_1$ state (5). Transitions to the $^1A_2$ state are forbidden for single-photon absorption, but allowed for two-photon absorption. Thus two-photon excitation of H_2O can directly populate the $^1A_2$ state which may therefore play a more important role in the two-photon process. As the $^1A_2$ state does not correlate

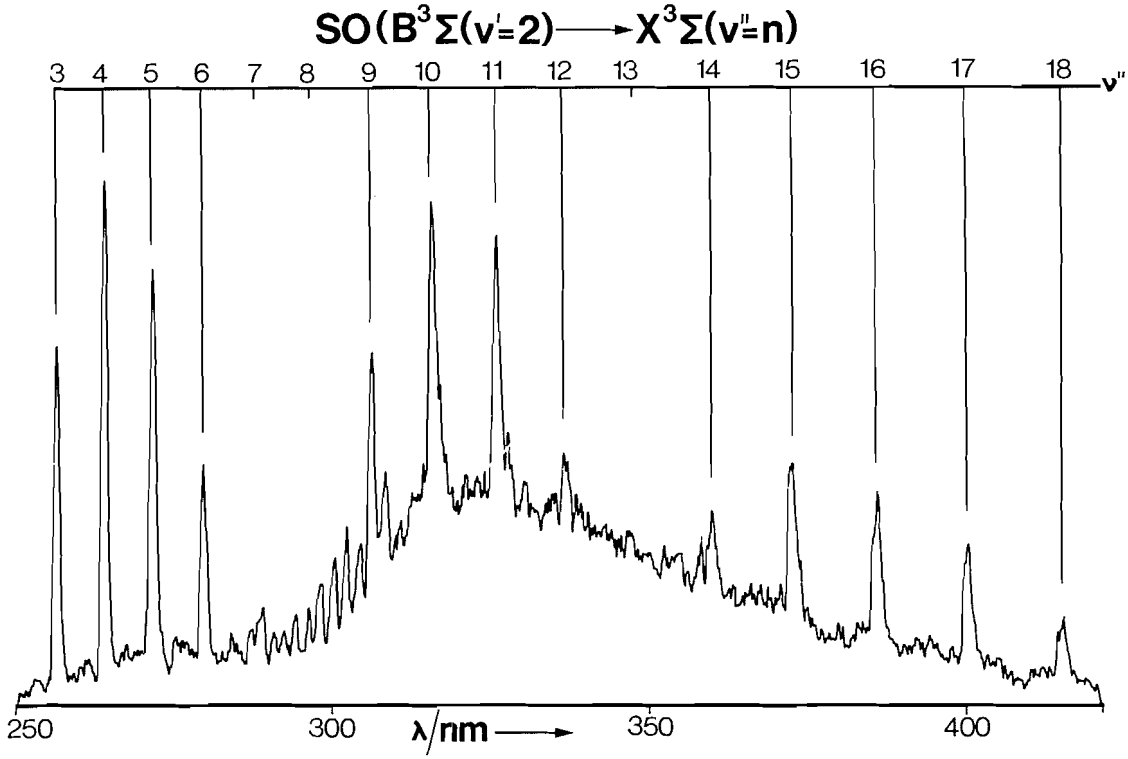

FIG. 4. Laser-induced fluorescence spectrum from SO following two-photon excitation of SO_2 (P_{SO_2} = 1.33 kN m^{-2}) with a KrF laser (248 nm). The broad continuous emission is due to fluorescence from SO_2 and the structure observed in the region 290–310 nm is due to *reabsorption* of this fluorescence by SO_2.

TABLE 1. Vibrational distributions (N_v/N_0) for CN($B^2\Sigma^+$) following two-photon and single-photon excitation of ICN

v'	Two-photon excitation ($\frac{1}{2}$ × 248 nm)	Single-photon excitation* (123.6 nm)
0	1.0	1.0
1	0.4	0.77
2	0.2	0.75
3	~0.1	0.52
4	<0.1	0.54

directly with OH($A^2\Sigma^+$), crossing to the $\tilde{B}\,^1A_1$ state is still required. If this crossing occurs in a different region of the hypersurface to that for the $\tilde{C}\,^1B_1$ state, as is likely to be the case, the dynamics of the dissociation process and the energy distribution in the products will differ from those for the single-photon excitation process, despite the similar total energies involved. We intend to examine this proposal in more detail in the future using the output of a tunable line-narrowed KrF laser.

(ii) *Two-photon excitation of ICN*

The photochemistry of the cyanogen halides has attracted considerable experimental and theoretical interest (6). Vacuum ultraviolet photolysis produces electronically excited (*A* and *B* state) CN radicals and this has facilitated the study of the photodissociation dynamics. The vibrational and rotational energy distribution in the CN radical has been shown to be very sensitive to the nature of the ICN state populated. In general the discrete (Rydberg) spectral features give rise to hot vibrational and rotational distributions, while the underlying continuum gives rise to a cold distribution (7).

In a recent study using two-photon excitation at 248 nm (KrF laser) we have shown (2) that CN($B^2\Sigma^+$) is formed with a relatively cold vibrational distribution (see Fig. 3) although the spectrum of ICN at 124 nm is dominated by a *discrete* transition to the $8s\sigma(^3\Pi)$ Rydberg state. This contrasts sharply with the hot distribution observed by Ashfold and Simons following single-photon excitation at 123.6 nm (Table 1). It was suggested by Hopkirk and Donovan (2) that this difference could result from the population of different electronic states of ICN by two-photon excitation, however, an alternative mechanism involving sequential excitation via a repulsive intermediate state could not be ruled out. The latter mechanism is expected to lead to a broader and cooler distribution of vibrational states, as the sequential pumping process can in principle sample a wide range of I—CN internuclear separations during dissociation on the repulsive intermediate surface. However, the probability of a molecule absorbing a second photon during this dissociation process is rather small, as the lifetime in the repulsive state will be $<10^{-12}$ s.

(iii) *Laser-induced fluorescence following multiphoton excitation and fragmentation*

Two-photon excitation of CS_2 with a KrF laser at 248 nm produces CS radicals in both the ground and excited $A^1\Pi$ electronic states (8). Ground electronic state radicals are formed in a range of vibrational levels and those in the $v'' = 2$ level absorb a further 248 nm photon, via the (2,2) band of the CS($A \leftarrow X$) system, leading to strong laser-induced fluorescence, viz:

$$CS_2 + 2h\nu\ (248\ \text{nm}) \rightarrow CS(X^1\Sigma^+, v'' = n) + S$$

$$CS(X^1\Sigma^+, v'' = 2) + h\nu\ (248\ \text{nm}) \rightarrow CS(A^1\Pi, v' = 2)$$

$$CS(A^1\Pi, v' = 2) \rightarrow CS(X^1\Sigma^+, v'' = n) + h\nu(248\text{–}290\ \text{nm})$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

A further example is seen in the two-photon *sequential* excitation of SO_2 at 248 nm which leads to the formation of SO in its ground electronic state, viz:

$$SO_2 + h\nu \rightarrow SO_2(\tilde{B}^1B_1)$$

followed by

$$SO_2(\tilde{B}^1B_1) + h\nu \rightarrow SO_2(\tilde{G}) \rightarrow SO + O$$

SO radicals produced in the $v'' = 2$ level then absorb a further photon (9, 10) which results in strong laser-induced $SO(B \rightarrow X)$ fluorescence (see Fig. 4), viz:

$$SO(X^3\Sigma, v'' = 2) + h\nu\ (248\ nm) \rightarrow SO(B^3\Sigma, v' = 2)$$

$$SO(B^3\Sigma, v' = 2) \rightarrow SO(X^3\Sigma, v'' = n) + h\nu\ (248-450\ nm)$$

A weaker contribution to this fluorescence from $SO(A^3\Pi_2, v' = 11)$ is also observed at the shorter wavelengths (11).

Conclusions

The main conclusion to be drawn from the above work is that the use of high power ultraviolet lasers allows the facile production of a range of electronically excited species which can now be readily studied using conventional time-resolved kinetic techniques. It should also be apparent that in most cases the detailed mechanism by which multiphoton excitation occurs is unclear and that much remains to be done in this new realm of photochemistry.

Radical cations of strained ring hydrocarbons. Cyclopropane derivatives

HEINZ D. ROTH AND MARCIA L. MANION SCHILLING
Bell Laboratories, Murray Hill, NJ 07974, U.S.A.

Received July 27, 1982

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

HEINZ D. ROTH and MARCIA L. MANION SCHILLING. Can. J. Chem. **61**, 1027 (1983).

A series of radical cations has been generated from various cyclopropane derivatives by photoinitiated electron transfer to chloranil. Nuclear spin polarization effects observed during these reactions have been interpreted as evidence for the structure of these intermediates. Tri- and tetraalkylsubstituted cyclopropanes (**1**, **3**, **4**) form "trimethylene" radical cations in which the most highly substituted carbon–carbon bond is broken (or weakened). The benzocyclopropanorbornene (**12**) forms a radical cation in which spin and charge are located in the benzenoid ring; the tertiary cyclopropane protons are coupled by a homohyperconjugative interaction; otherwise, the cyclopropane ring is unaffected. To the radical cation derived from bismethanoparacyclophane (**17**) a trimethylene structure is assigned in which the benzylic carbons are pyramidal. Finally, benzonorcaradiene (**20**) forms a radical cation in which the two secondary–tertiary bonds are lengthened and in which the methylene group bears spin density.

HEINZ D. ROTH et MARCIA L. MANION SCHILLING. Can. J. Chem. **61**, 1027 (1983).

On a produit une série de cations radicalaires à partir de divers dérivés du cyclopropane en utilisant un transfert d'électron photoinduit sur le chloranil. On a interprété les effets de polarisation de spin nucléaire observés dans ces réactions comme une preuve de structure de ces intermédiaires. Les cyclopropanes portant des substituants tri et tétraalkyles (**1**, **3**, **4**) forment des cations radicalaires "triméthylène" dans lesquels la liaison carbone–carbone la plus substituée est rompue (ou affaiblie). Le benzocyclopropanorbornène (**12**) forme un cation radicalaire dans lequel le spin et la charge sont localisés dans le cycle benzénique; les protons tertiaires du cyclopropane sont couplés par une interaction homohyperconjuguée sans quoi le cycle cyclopropane n'est pas affecté. Au cation radicalaire provenant du biméthanoparacyclophane (**17**) on a attribué une structure triméthylène dans laquelle les carbones benzyliques sont pyramidaux. Finalement le benzonorcaradiène (**20**) forme un cation radicalaire dans lequel deux liaisons secondaire–tertiaires sont allongées et dans lequel le groupe méthylène porte la densité de spin.

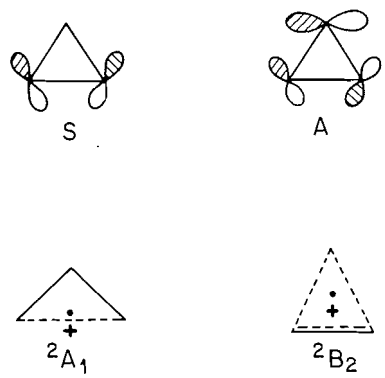
For several years we have been interested in photoinitiated electron transfer reactions and have utilized chemically induced nuclear polarization (CIDNP) effects to gain an insight into the structure and reactivity of short-lived radical cations which can be generated in this type of reaction (1, 2). The CIDNP technique is based on the interpretation of greatly enhanced nmr signals in either absorption or emission, which may be observed during reactions proceeding via pairs of radicals or radical ions (3). According to the generally accepted radical pair theory the directions and intensities of these effects are determined by several parameters, including the spin multiplicity of the precursor, the magnetic properties (electron g factor, hyperfine coupling constants) of the radical intermediates, and the type of reaction by which the polarized product is formed.

In recent publications we reported evidence for the structure of radical cations derived from substituted cyclopropanes such as diphenylcyclopropane (4) and quadricyclane (5). In order to evaluate the potential structures of the cyclopropane radical cations it is useful to consider the nature of the highest occupied molecular orbitals (HOMO's) of cyclopropane (6–11). One of its degenerate HOMO's is symmetrical and has appreciable bonding only between one pair of carbon atoms. Removal of an electron from this orbital would place spin and charge on two carbon atoms and would weaken the bond between them. The resulting radical cation could be described as a trimethylene species with a one-electron bond between the terminal methylene groups ($^2A_1$). The second HOMO has C_s symmetry; it is antibonding between two carbons and bonding between either of these and the third one. Removal of an electron from this orbital would generate a species which may be described as a π complex between ethylene and a methylene cation ($^2B_2$). This radical cation would have considerable spin density on the third carbon atom. Two of its carbon–carbon bonds would be weakened whereas the third one would be strengthened. A recent *ab initio* calculation of the cyclopropane radical cation (12) suggests that the lowest energy surface has low lying saddle points corresponding to the general structure types $^2A_1$ and $^2B_2$. The minima are of lower symmetry and have geometries intermediate between $^2A_1$ and $^2B_2$. The two degenerate HOMO's and schematic representations of the radical cations derived from them are shown in Scheme 1.



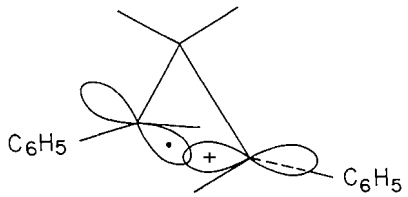
SCHEME 1

It is noteworthy that the lowest transition in the photoelectron spectrum of cyclopropane has been assigned to the ionization from the antisymmetrical orbital (8–11). However,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

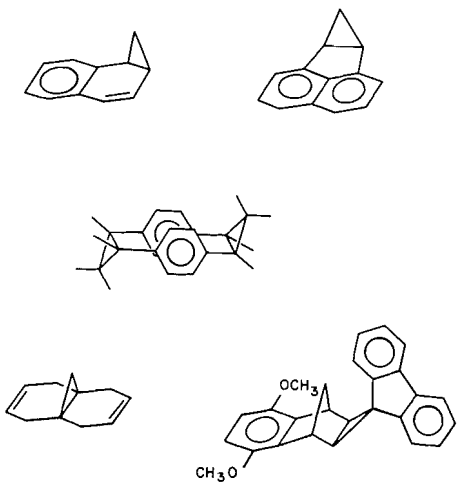
this conclusion does not necessarily have any bearing on the structure of the radical cations in solution. Photoelectron spectra reflect the energy differences of vertical transitions and do not reflect the energy differences between states. In addition, the relative energies of states in solution may be changed significantly by solvation. The generation of nuclear spin polarization effects requires radical (ion) pairs with lifetimes in the nanosecond range. This time scale is sufficient to allow the intermediates to dissipate excess energy. Accordingly, the CIDNP results can be expected to reflect the equilibrium geometry of the intermediates.

The general structure type which may be formed in cases of favorable interaction between aromatic/olefinic group and cyclopropane moiety is best illustrated for the isomers of 1,2-diphenylcyclopropane (4). The CIDNP results observed for these compounds suggest positive spin densities not only in the aromatic group but also on the benzylic carbons. These features are best accommodated in a structure in which the 3°−3° cyclopropane bond is broken or weakened, i.e. a structure of type $^2A_1$.



In continuing these studies we investigated the photoreactions of chloranil with several cyclopropane derivatives in which the three-membered ring is held in a well-defined position relative to olefinic and/or aromatic elements of unsaturation. These substrates should allow us to evaluate the factors influencing the interaction of the cyclopropane moiety with an unpaired spin in a π system and to identify the substitution patterns which would stabilize one structure type relative to the other. Among the factors likely to influence this interaction, we mention the relative ionization potentials of the two groups, the spatial relation between them, and the orbital symmetry of the aromatic/olefinic HOMO. The molecules to be discussed here were chosen primarily to evaluate geometric factors. The orbital symmetry effects will be discussed in a separate publication.

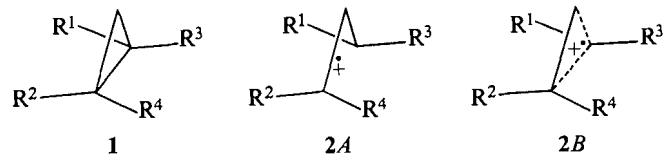
In some of the substrates to be discussed here, the cyclopropane ring is directly attached to the unsaturated moiety; in others the strained ring is separated from the unsaturated group by two or more single bonds. Further, the molecular architecture can force the 3°−3° cyclopropane bond into an orientation nearly parallel to the π orbitals of the element of unsaturation or into a position nearly orthogonal to them.



Molecules such as benzonorcaradiene or [9:10]methanoacenaphthene are examples for the orthogonal orientation whereas [1:2,9:10]bismethano[2.2]paracyclophane is an example for an essentially parallel orientation of π electrons and cyclopropane bond. Tricyclo[4.4.1.0^{1,6}]undeca-3,8-diene and a benzomethanonorbornene were chosen as examples for compounds in which cyclopropane moieties are held in a well-defined position relative to a π system but separated from it by more than one carbon−carbon bond. Finally, we studied a series of compounds, in which a cyclopropane ring is tetra-, tri-, or di-substituted without containing an element of unsaturation. We begin with a discussion of effects observed for two cyclopropanes which do not contain any element of unsaturation.

Methylsubstituted cyclopropanes

In an attempt to evaluate the donor potential of simple cyclopropane derivatives we studied the photoreactions of chloranil with a series of methylsubstituted cyclopropanes (13). These experiments failed to provide evidence for radical ion formation when dimethylcyclopropanes (**1***a*−*c*) were employed as substrates. However, in the case of 1,1,2-trimethylcyclopropane (**1***d*), pronounced CIDNP effects were found for all signals and in the case of 1,1,2,2-tetramethylcyclopropane (**1***e*) strong polarization was observed for the methyl groups and for the geminal cyclopropane protons. These results can



1 **2*A*** **2*B***

a R^1, R^2 = CH$_3$; R^3, R^4 = H
b R^1, R^4 = CH$_3$; R^2, R^3 = H
c R^1, R^3 = CH$_3$; R^2, R^4 = H
d R^1, R^2, R^3 = CH$_3$; R^4 = H
e R^1, R^2, R^3, R^4 = CH$_3$

be explained by a mechanism involving electron-transfer quenching of triplet chloranil by the cyclopropane derivatives, **1***d*,*e*. The resulting radical ion pairs can regenerate the reactants by reverse electron transfer after intersystem crossing. The finding that these simple cyclopropanes are electron donors is somewhat surprising. However, we note that the donor character is displayed only toward the excited state of a very strong electron acceptor and that it falls off rapidly with decreasing substitution. Thus, **1***d* shows only a small fraction of the effects observed for **1***e* (Fig. 1) and **1***a*−*c* fail to show any evidence for radical ion formation. In addition, neither uv nor nmr spectra showed any indication for charge transfer interactions in the ground state. These results characterize the cyclopropane moiety as only a marginal electron donor (13).

Evidence for the structure of the radical cations, **2**, derived from **1** is contained in the CIDNP pattern. The fact that the methyl groups at C-1 and the geminal cyclopropane protons at C-3 show the same signal direction (emission) and similar relative enhancements suggests that all protons occupy similar positions relative to the unpaired spin. The most likely structure

The gain for the spectra of **1***d* was 32 times as high as for the spectra of **1***e*.

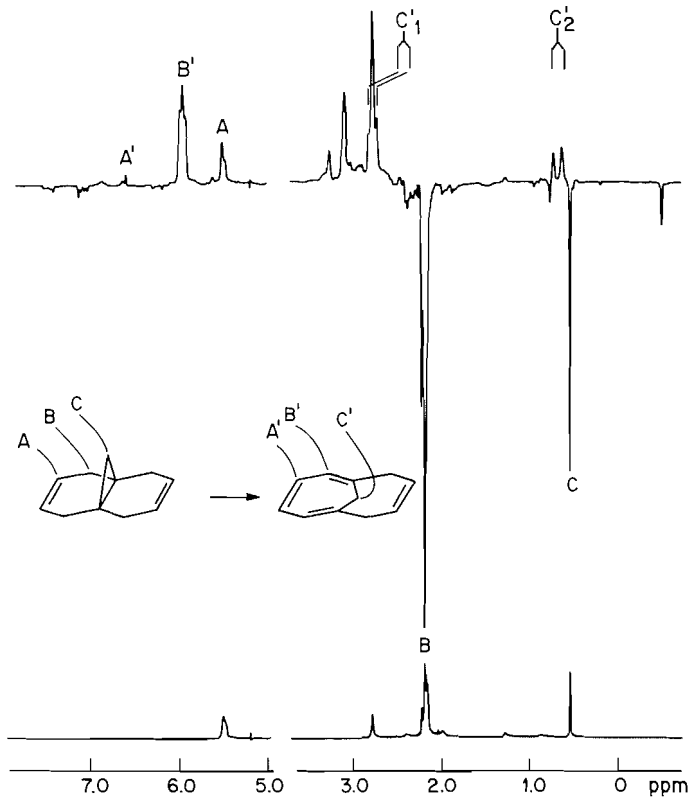

FIG. 2. The ^{1}H nmr spectra (90 MHz) of 0.02 *M* chloranil solutions in acetone-d_6 containing 0.02 *M* tricyclo[4.4.1.0^{1,6}]undeca-3,8-diene (**4**) in the dark (bottom) and during uv irradiation (top).

type is one in which the spin density is located on the quaternay cyclopropane carbons. This structure is related to the $^2A_1$ state of the cyclopropane molecular ion and is quite similar to the structure postulated for the diphenylcyclopropane radical cations.

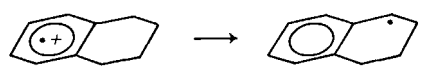
Norcarene derivatives

In the norcar-3-ene system, a three-membered ring is arranged in a well-defined position relative to an olefinic π system but separated from it by more than one carbon–carbon bond. Two substrates of this type, 1,6-dimethylbicyclo[4.1.0]-hept-3-ene (**3**) and tricyclo[4.4.1.0^{1,6}]undeca-3,8-diene (**4**), were chosen to allow a comparative evaluation of the donor properties of the cyclopropane ring versus an olefinic moiety (13).

3 **4**

The results observed in these systems allow an unambiguous assignment. For example, the chloranil photosensitized reaction of the tricyclic diene, **4**, resulted in strong emission for the cyclopropane and the allylic protons but did not produce any polarization for the olefinic protons. Analogous results were observed for the bicyclic olefin, **3**. The observed polarization patterns establish the cyclopropane function as the better donor and, at the same time, eliminate any interaction of the olefinic groups with the unpaired spin of the radical cations, e.g. **5**.

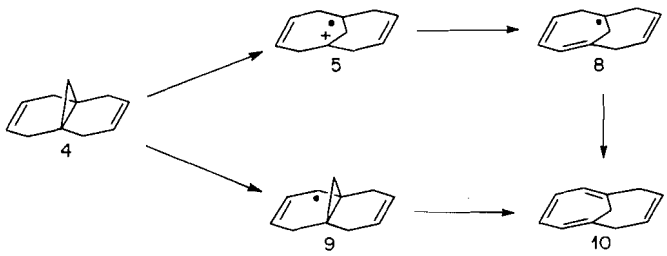
The norcarene derivatives, **3** and **4**, also proved to be useful substrates to probe the mechanism of the photosensitized dehydrogenation of hydrocarbons. This reaction could be initiated by either electron transfer or hydrogen abstraction. For aromatic or hydroaromatic substrates it is difficult to differentiate between these pathways because both routes involve the same neutral radical. The primary intermediate of electron transfer, e.g. **6**, can be converted to the primary intermediate of hydrogen abstraction, e.g. **7**, by a simple deprotonation process.



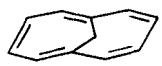
6 **7**

The substrates discussed here have the advantage that different radicals, e.g. **8** and **9**, are formed by the electron transfer/deprotonation route and by the dehydrogenation pathway, respectively. The hyperfine coupling patterns of these intermediates should be sufficiently different to allow an unambiguous assignment. Specifically, the olefinic protons are expected to have negligible hyperfine couplings in **8**, but sizeable couplings in **9**. The photoreaction of chloranil with **4** resulted in a characteristic polarization pattern for **10** (14); the bridge protons and the olefinic protons originating in the allylic position appeared in enhanced absorption but the remaining olefinic protons showed negligible polarization (Fig. 2). These results support the intermediacy of **8** and provide an unambiguous argument for the electron transfer induced mechanism.

A detailed examination of the CIDNP spectrum (Fig. 2) observed during this reaction also reveals the presence of a second dehydrogenation product. Emission multiplets near 7.2



and 7.6 ppm and an emission singlet at −0.5 ppm indicate the formation of bicyclo[4.4.1]undecapentaene (**11**) (15–17). The detailed mechanism by which this product is generated, specifically the identity of the paramagnetic intermediate that gives rise to the observed polarization pattern, is not immediately obvious.

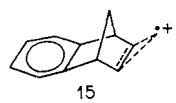


11

The [2.3]-benzo-[5:6]-methanonorbornene system

The bichromophoric compound, **12**, was originally synthesized to study the possibility of energy transfer between the fluorene and the dimethoxybenzene chromophores held in close propinquity but with orthogonal π systems (18, 19). Eventually, it was shown that energy transfer between the two π systems does occur readily (20). In the experiment described here, the radical cation of **12** is generated by reaction with photoexcited chloranil and the delocalization into the cyclopropane moiety is investigated. Of the two π systems contained in **12**, the dimethoxybenzene moiety is expected to be a better donor than the fluorene group because of the lower oxidation potential of the individual fragment.[1]

During the photoreaction, the two ^{1}H signals of the dimethoxybenzene moiety showed sizeable polarization: the aromatic singlet at 6.7 ppm appeared in enhanced absorption whereas the methoxy signal at 3.8 ppm appeared in emission (Fig. 3). In contrast, no polarization was observed for any signal of the fluorene subunit, confirming that the dimethoxybenzene group is the primary electron donor. The potential interaction between this radical cation and the cyclopropane ring can be evaluated on the basis of the polarization observed for the cyclopropane protons. During the photoreaction with chloranil, the signal near 2.0 ppm shows weak net emission. The relatively low intensity of this effect indicates a weak interaction. More importantly, the signal direction indicates a positive hyperfine coupling constant for the cyclopropane protons. This assignment rules out any delocalization of spin onto the tertiary cyclopropane carbons as in structure type **13** and is compatible



[1]The oxidation potential of dimethoxybenzene is 1.34 V vs. SCE (21), that of fluorene is 1.65 V vs. SCE (22).

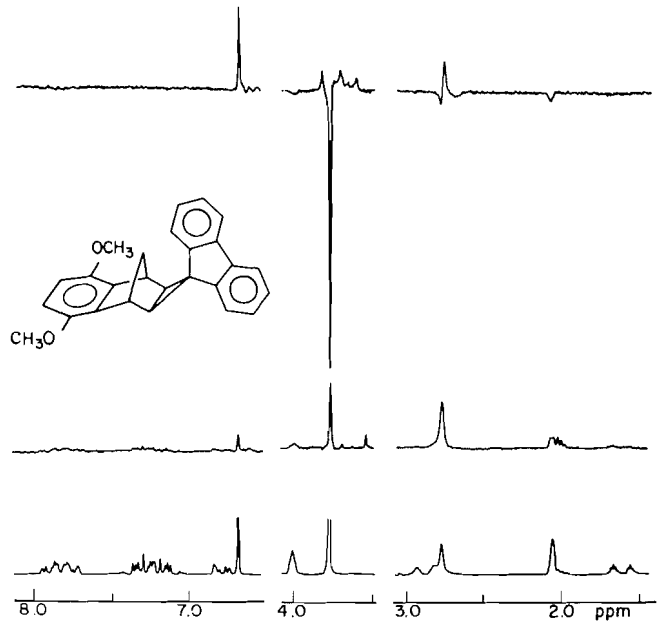


FIG. 3. The ^{1}H nmr spectra (90 MHz) of a concentrated acetone-d_6 solution (0.2 *M*) of the [1.2]benzo[5:6]cyclopropanorbornene, **12** (bottom) and net intensity changes ($I_{irr} - I_{dark}$) observed during uv irradiation of 0.02 *M* chloranil in an acetone-d_6 solution containing 0.02 *M* **12** (top).

either with a homohyperconjugative interaction (structure type **14**) or with a delocalization of spin onto the quaternary cyclopropane carbon (structure type **15**). The latter structure can be viewed as a π complex of a fluorenylidene radical cation with benzonorbornadiene, i.e. as a derivative of the $^2B_2$ structure (*vide supra*). The experimental results do not allow us to differentiate between structure types **14** and **15**.

As for the absence of delocalization of spin into the tertiary–tertiary carbon–carbon bond, a comparison with the polarization generated in the radical cation of benzonorbornadiene (**16**) is illuminating. In this molecule, the aromatic and olefinic π orbitals are in an orientation favoring delocalization. The polarization effects observed during the photoreaction of chloranil with **16** show identical signs and comparable magnitudes for olefinic and aromatic protons, indicating extensive delocalization of spin (and charge) into the olefinic moiety (Fig. 4). In contrast, the tertiary–tertiary bond of **12** is orthogonal to the aromatic π system. Hence the lack of delocalization.

Bismethanoparacyclophane

Having discussed several systems in which a cyclopropane group and an olefinic or aromatic π system are arranged in close proximity without being conjugated, we now proceed to compounds in which the two groups are conjugated. In principle, the two functionalities can be arranged so that the tertiary–tertiary cyclopropane bond is locked into a position nearly parallel to the normal axis of the aromatic π system or into a position nearly orthogonal to it. [1:2,9:10]Bismethano-[2.2]paracyclophane (**17**) is an interesting example for the parallel arrangement (23). This compound and its radical cation (**18**) obviously are highly strained. An insight into the spin density distribution of the intermediate might reveal how the strain is accommodated.

The CIDNP effects observed during the photoreaction of chloranil with **17** are, in principle, quite similar to those ob-

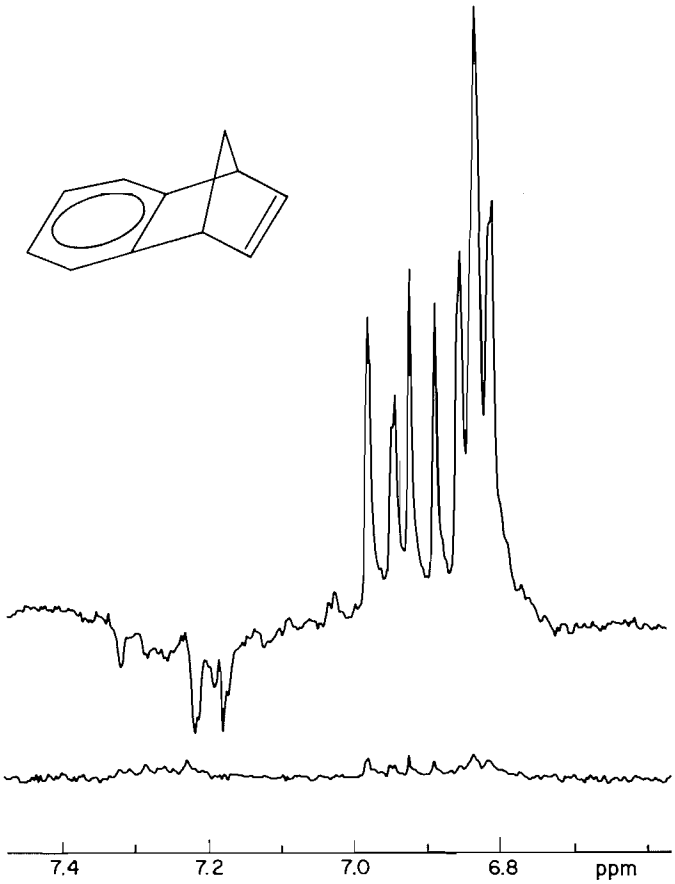

FIG. 4. The ^{1}H nmr spectra (90 MHz; olefinic/aromatic region) of a 0.02 *M* chloranil solution in acetone-d_6 containing 0.02 *M* of benzonorbornadiene (**15**) in the dark (bottom) and during uv irradiation (top).

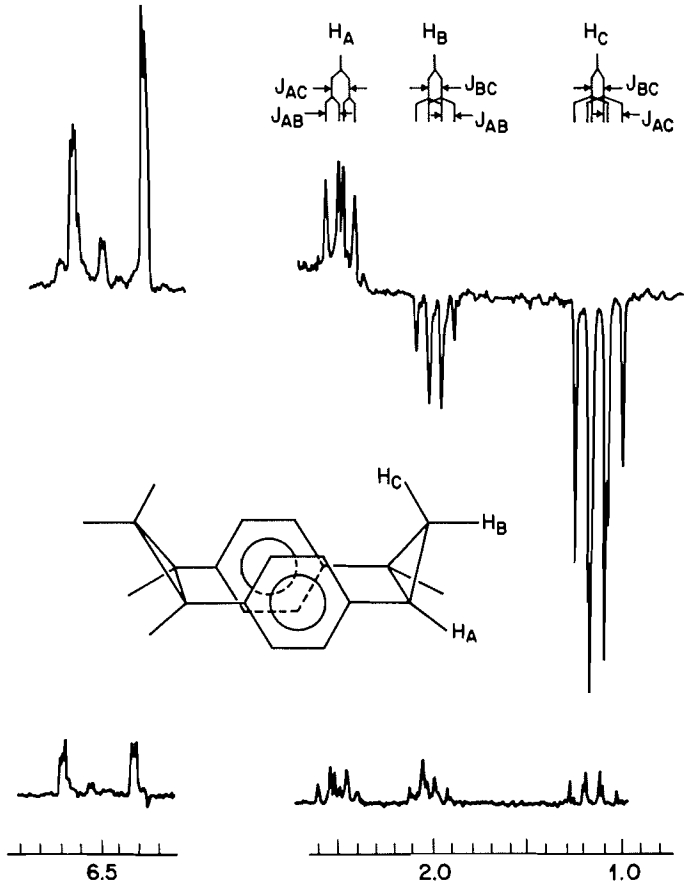

FIG. 5. The ^{1}H nmr spectrum (90 MHz) observed during the irradiation of chloranil (0.02 *M*) in acetone-d_6 solutions containing 0.01 *M* *syn*-[1:2.9:10]bismethano[2.2]paracyclophane. A dark spectrum of the hydrocarbon is shown as the lower trace.

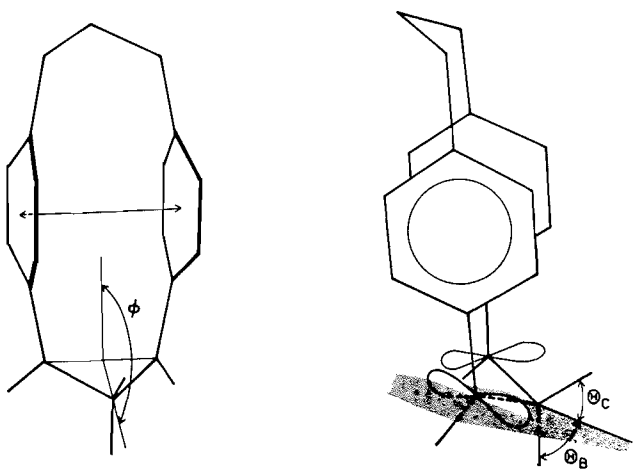
served for *cis*-diphenylcyclopropane (4), indicating an intermediate with an open, delocalized structure not unlike that assigned to the diphenylcyclopropane radical cations. However, the relative signal intensities are noticeably different (Fig. 5). The secondary cyclopropane multiplet assigned to the *endo* proton (1.2 ppm) shows a considerably stronger enhancement than does the multiplet of the *exo* proton (2.0 ppm). In addition, the benzylic multiplet is comparably weaker than in the case of diphenylcyclopropane. The different enhancement factors observed for the two secondary protons are ascribed to nonidentical hyperfine coupling constants. This implies that the



dihedral angles, θ_B and θ_C, between the singly occupied orbital and the two adjacent C—H bonds are different.

Nonidentical dihedral angles for the secondary cyclopropane protons can result if the angle, ϕ, between the plane of the three-membered ring and the plane defined by the benzylic and quaternary carbons, is increased in the radical cation relative to the parent hydrocarbon. The relative magnitude of the CIDNP effects and the chemical shifts of the corresponding protons are fully consistent with this interpretation. The *endo* proton, which in the diamagnetic molecule lies in the shielding cone of the aromatic moieties, has in the radical the smaller dihedral angle θ_C, with the benzylic π orbital and, therefore, the greater hyperfine coupling (24).

The comparably weak enhancement of the benzylic proton requires an additional explanation. This result, and the fact that ^{13}C polarization is observed only for the benzylic carbon signal, can be explained if the benzylic carbon adopts a pyramidal structure. Pyramidal carbon radicals are reasonably rare; most examples are derived from strained ring systems (25–28). For the radical cation discussed here, the change in the angle, ϕ, and the adoption of a pyramidal structure apparently relieve some of the strain in the carbon skeleton, yet maintain a reasonable degree of overlap between the benzylic carbons and the benzene rings (24).

The recent synthesis of [10:11]methano[3.2]paracyclophane (**19**)[2] allowed an extension of this study to a system which

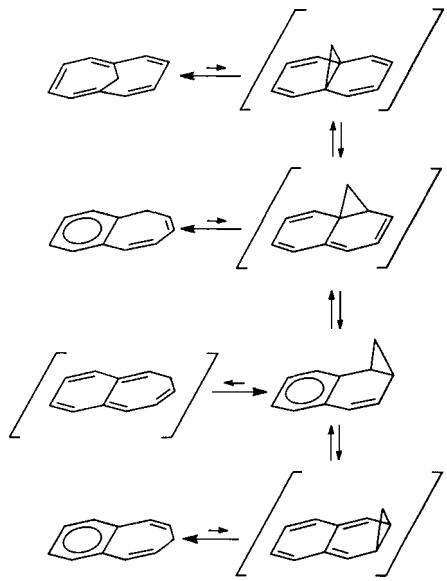
appears less strained than **17** yet more restricted than diphenylcyclopropane. The CIDNP effects observed for this hydrocarbon once again show different intensities for the two geminal cyclopropane protons. However, the enhancement pattern is closer to that of *cis*-diphenylcyclopropane than to that of **17** (Fig. 6). Obviously, a large fraction of the strain inherent in **17** is relieved by substituting a trimethylene bridge for one of the cyclopropane moieties (24).

Benzonorcaradiene

The final arrangement of cyclopropane ring and aromatic/olefinic group to be discussed in this paper is one in which the 3°−3° cyclopropane bond is essentially orthogonal to the π system. The benzonorcaradiene system (**20**) is a good example of this arrangement. This substrate is also of interest since its pattern of substitution may stabilize the alternative structure type for the cyclopropane radical cation. If spin and charge were localized on or near the methylene group, the remaining carbon frame would form a cyclic conjugated 10 π electron system whose stabilization may outweigh the potential lack of stability of the "methylene cation".

Benzonorcaradiene is one of four $C_{11}H_{10}$ hydrocarbons formally derived from naphthalene by addition of methylene to the four types of carbon−carbon bonds. Each of the hydrocarbons offers the possibility of an equilibrium between a bicyclic (cycloheptatriene) and a tricyclic (norcaradiene) valence isomer. However, the equilibria are decidedly one-sided: for three isomers the bicyclic structure is favored whereas for the fourth the tricyclic structure is preferred. The aromaticity of some of the valence isomers appears to be a key element in determining the preferred structure type: the four stable forms contain a cyclic conjugated system of either 6 or 10 π electrons whereas the unfavorable valence isomers are polyolefins. The four hydrocarbons can be interconverted through thermal, photochemical, or base-catalyzed reactions (29−31). Accordingly, the potential rearrangement of the radical cations cannot be neglected. Similarly, the deprotonation of the cations has to be considered, since it may play a role in the rearrangement of some of these radical cations.



Three structure types can be envisioned for the radical cation of benzonorcaradiene. The first structure is essentially a styrene radical cation in which charge and spin are delocalized over eight carbon atoms and in which the cyclopropane ring is unaffected (**21**). In the second structure, the 3°−3° cyclopropane bond is broken and charge and spin are delocalized over ten carbon atoms (**22**). This structure implies a thorough reorganization of the three cyclopropane carbon atoms and its formation may require a substantial activation energy. The third structure is one in which the secondary cyclopropane carbon bears spin density and in which the two 3°−2° bonds are weakened. This structure is essentially a linear combination of structure **21** and the structure formed by removal of an electron from the antisymmetrical cyclopropane HOMO (**23**) and is related to the $^2B_2$ state of the cyclopropane molecular ion.

All three structures lead one to expect qualitatively the same result for the aromatic and olefinic protons. The unpaired spin density could be positive throughout the π system or could

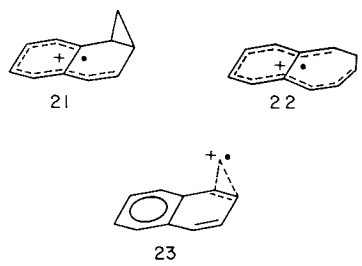
H_D		+	−	A



show an alternating pattern. The analogy with a related $C_{11}H_{10}$ system suggests the former spin density pattern. Benzocycloheptatriene (**24**) gives rise to a CIDNP spectrum in which essentially all aromatic/olefinic protons show enhanced absorption and in which the benzylic/allylic doublet shows strong emission (Fig. 7).

In contrast to the aromatic/olefinic protons, the four cyclopropane protons of **20** are expected to show characteristic differences. The polarization patterns expected for the first two structures are analogous to those discussed for the "closed" and

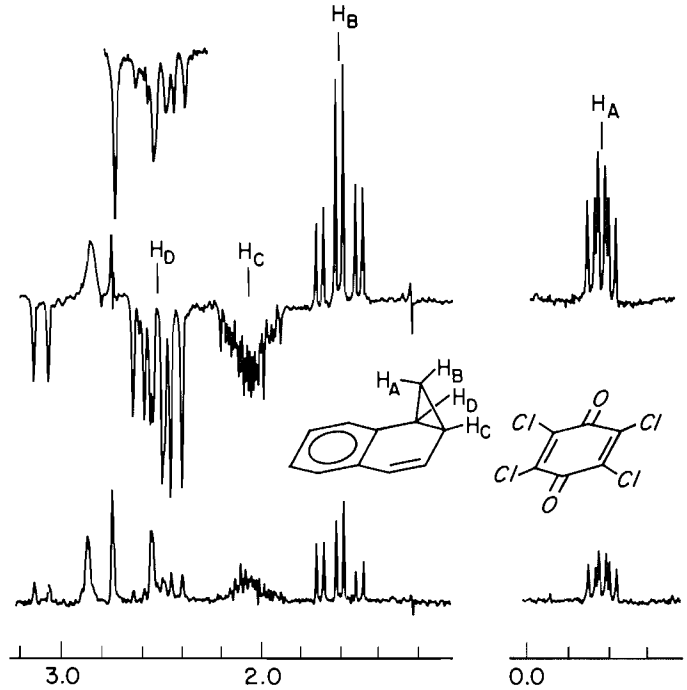


FIG. 8. The 90 MHz nmr spectra of 0.02 *M* chloranil solutions in acetone-d_6 containing 0.02 *M* benzonorcaradiene, **20**, in the dark (bottom) and during uv irradiation (center). The top trace (2.0−3.0 ppm) was recorded during the irradiation of 0.02 *M* chloranil in the presence of 0.002 *M* benzonorcaradiene.

"open" radical cation of diphenylcyclopropane (4). The third structure is unique since the secondary protons have negative hyperfine couplings whereas the tertiary ones have positive couplings. The hyperfine coupling patterns of these three structures are compared in Table 1.

The irradiation of chloranil in the presence of benzonorcaradiene results in substantial polarization for all ^{1}H signals of the substrate. The aromatic and olefinic protons appear in enhanced absorption as is expected for nuclei attached to carbons with positive spin density. Of the cyclopropane protons, the benzylic one (d of d of d; 2.5 ppm) and the allylic one (d of d of d of d; 2.1 ppm) appear in emission whereas the two geminal protons (d of t; 1.6 and −0.4 ppm) appear in enhanced absorption (Fig. 8). This polarization pattern is essentially that expected for the unique structure, **21** ↔ **23**, with spin density on the secondary carbon atom.

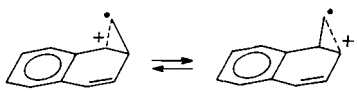
To make this assignment with confidence, an alternative explanation for the observed pattern must be eliminated. Nuclear spin polarization is occasionally observed for nuclei which do not possess a hyperfine coupling in the intermediate radial (ion). These effects are due to polarization transfer by dipolar or scalar cross relaxation (32−35). For the benzonorcaradiene radical cation, the polarization observed for the secondary protons (absorption) could be caused by dipolar cross relaxation of the tertiary protons (emission). Thereby, the radical cation of structure **21** would give rise to the same polarization pattern as that expected for **21** ↔ **23**.

Effects caused by cross relaxation can be identified by spin decoupling experiments. Closs and Czeropski have shown that primary polarization is not affected in these experiments but that secondary polarization vanishes when the nucleus with the primary polarization is irradiated (32, 33). For the system discussed here, the decoupling of the benzylic and the allylic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

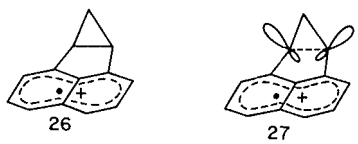
protons is crucial since they would be the logical source for any secondary polarization in the geminal protons. Accordingly, the transitions at 184 and 223 Hz and their average frequency were saturated while the photoreaction of chloranil with benzonorcaradiene was in progress. This caused the geminal multiplets to be simplified but did not cause the polarization of these multiplets to vanish. In the light of these results cross relaxation can be eliminated as an important contributor to the observed polarization and the structure **21** ↔ **23** is confirmed for the radical cation of benzonorcaradiene.

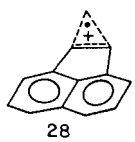
Further support for this assignment is derived from the observation of polarized 1- and 2-methylnaphthalene (emission, 2.7 and 2.5 ppm, respectively) at low benzonorcaradiene concentrations. The formation of these products is explained readily by transfer of a hydrogen atom from either the benzylic or the allylic position to the secondary cyclopropane carbon of **23**, followed by reverse electron transfer. The signal direction of the methyl groups is opposite to that of the geminal cyclopropane protons suggesting that the methylnaphthalenes are formed from the intermediate radical pair by a mechanism with a different electron spin dependence. This could be a mechanism involving the separation of the radical ions by diffusion or one involving triplet recombination of the intermediate pair. The information available at present does not permit us to identify the detailed chemical mechanism by which the methylnaphthalenes are formed.



[9:10]Methanoacenaphthene

Another substrate in which an aromatic π electron system is arranged in a position orthogonal to the 3°−3° bond of a cyclopropane ring is [9:10]methanoacenaphthene (**25**) (36, 37). The principal geometric features of this molecule are similar to those of benzonorcaradiene. There is, however, an important difference. The radical cation structure resembling a π complex (**28**) does not appear to have the same stabilization for the cation of **25** that it has for the cation of **20**. Accordingly, a naphthalene type radical cation, **26**, is a more likely structure than is the cyclopropane radical cation, **28**. The alternative structure, **27**, in which the cyclopropane ring is opened and in which the benzylic carbons have positive spin density is unlikely because of the unfavorable (orthogonal) orientation of the 3°−3° cyclopropane bond relative to the naphthalene π system.





The CIDNP effects observed for this substrate during the photoreaction with chloranil are weak and they are observed only at low substrate concentrations. The aromatic multiplets show enhanced absorption whereas the multiplet representing the tertiary (benzylic) protons appears in emission. These findings are compatible with an intermediate of structure **26**, and they rule out an intermediate of structure **27**. However, it should be noted that they do not completely eliminate a contribution from structure **28**. An intermediate of this structure is likely to have negative hyperfine coupling constants for the secondary cyclopropane protons and thus should give rise to enhanced absorption for the multiplets representing them. The magnitude of the hyperfine coupling constants (and the intensity of the CIDNP effects) will depend on the contribution of structure **28** to the radical cation.

The absence of significant polarization for these protons rules out a dominant contribution due to that structure. *However, the overall low level of polarization does not allow us to set a low upper limit for its involvement.* One argument against the participation of structure **28** lies in the failure to observe cyclopropane ring opening and formation of 9-methylacenaphthylene. In the reaction of benzonorcaradiene (*vide supra*), we considered the observation of methylnaphthalenes an important argument in favor of structure **23**, the equivalent of structure **28**.

Accordingly, we identify **26** as the intermediate derived from **25**. However, we emphasize that the observed effects are weak and that the comparison with the results observed for benzonorcaradiene is an important factor in this assignment.

Conclusion

The radical cations of a series of hydrocarbons containing a cyclopropane moiety can be generated as short-lived intermediates by photoinduced electron transfer to chloranil. In general, the radical cations tend to favor the trimethylene structure type in which one carbon−carbon bond is broken or weakened. Steric factors may induce special features such as the pyramidal structure of the radical cation of bismethanoparacylcophane. In other cases, an interaction of the 3°−3° cyclopropane bond with the unpaired spin may be prevented. For example the benzomethanonorbornene (**12**) forms a radical cation in which the 3°−3° bond is unaffected and in which only the protons interact with the unpaired spin (possibly by a homohyperconjugative mechanism). Special substitution patterns may favor a radical cation structure, which can be described as a π complex between a methylene radical cation and an appropriate π system. An example of such a structure is the radical cation of benzonorcaradiene. The stability of this structure is ascribed to the aromaticity of the ten-carbon complement to the methylene radical cation.

The finding that tri- and tetraalkyl-substituted cyclopropanes are marginal donors and that they surpass disubstituted olefins, makes it possible to probe the mechanism of photosensitized dehydrogenation of appropriate substrates. For tricyclo-[4.4.1.$0^{1,6}$]undeca-3,8-diene and bicyclo[4.1.0]hept-3-ene, the polarization of the dehydrogenation products identifies cyclopropane radical cations as primary intermediates in the dehydrogenation reaction.

The reaction of F atoms with CH_3SH. Vibrational spectroscopy and photochemistry of CH_3S and CH_2SH hydrogen-bonded to HF

MARILYN E. JACOX

Molecular Spectroscopy Division, National Bureau of Standards, Washington, DC 20234, U.S.A.

Received January 11, 1983

This paper is dedicated to Professor Harry E. Gunning on the occasion of his 65th birthday

MARILYN E. JACOX. Can. J. Chem. **61**, 1036 (1983).

When the products of the reaction between F atoms formed in a microwave discharge and methanethiol are frozen in a large excess of argon at 14 K, prominent absorptions of isolated and hydrogen-bonded HF appear, indicating that hydrogen abstraction occurs both in the deposition beam and in the solid. Secondary F-atom reactions play only a minor role. Studies of the partially deuterium-substituted methanethiols support the assignment of peaks at 3515 and 3672 cm^{-1} to the HF-stretching modes of HF hydrogen-bonded to CH_3S and CH_2SH, respectively, and indicate that CH_2SH is formed with enough excess energy to surmount the barrier for rearrangement to CH_3S. Although ground-state rearrangement of the thermochemically more stable isomer, CH_3S, to CH_2SH was not observed, when the sample was excited by radiation in the spectral region of a known electronic transition of CH_3S, isomerization to CH_2SH resulted. The present experiments cannot distinguish between direct isomerization and formation of CH_2SH by the cage recombination of CH_2S + H. Although peaks attributable to CH_3S isolated in solid argon are weak, the experiments provide some support for a recent assignment of vibrational fundamentals of CD_3S, based on photodetachment studies. A prominent, structured absorption at 424 cm^{-1} is assigned to the H_2CS "umbrella" deformation of CH_2SH, consistent with a recent *ab initio* calculation. The photodecomposition threshold of CH_2SH lies between 260 and 280 nm.

MARILYN E. JACOX. Can. J. Chem. **61**, 1036 (1983).

On observe des absorptions marquées dues au HF et au HF lié par des liaisons hydrogènes, lorsqu'on gèle dans un grand excès d'argon à 14 K les produits de la réaction entre les atomes de fluor issus d'une décharge de microonde, et le méthanethiol. Ces absorptions indiquent que l'élimination d'hydrogène se produit à la fois dans le faisceau de dépôt et dans le solide. La participation des réactions secondaires du fluor est minime. Des études portant sur le méthanethiol partiellement deutéré confirment l'attribution des pics à 3515 et à 3672 cm^{-1} aux modes d'élongation du HF des molécules de HF liées par des liaisons hydrogènes au CH_3S et au CH_2SH respectivement et indiquent que le CH_2SH formé a suffisamment d'énergie pour franchir la barrière de la transposition en CH_3S. Dans l'état stationnaire, on n'a pas observé la transposition de l'isomère le plus stable CH_3S en CH_2SH, cependant il s'isomérise en CH_2SH lorsqu'on excite un échantillon par une radiation de la région spectrale correspondant à la transition électronique du CH_3S. Ces expériences ne permettent pas d'établir une distinction entre l'isomérisation directe et la formation de CH_2SH par la recombinaison du CH_2S + H dans la cage. Bien que les pics attribuables au CH_3S isolé dans l'argon solide soient faibles, les expériences constituent un apport aux récentes attributions des vibrations fondamentales du CD_3S basées sur des études de photodétachement. On attribue une absorption marquée et structurée à 424 cm^{-1} à la déformation du H_2CS en "parapluie" en accord avec les récents calculs *ab initio*. Le désordre de la photodécomposition du CH_2SH se situe entre 260 et 280 nm.

[Traduit par le journal]

Introduction

Although an important role has been established for CH_3S free radicals in a variety of photolysis systems (1–3), their direct spectroscopic detection has been extraordinarily difficult. Flash photolysis studies by Callear *et al.* (4, 5) have provided chemical evidence for the assignment of a diffuse, unstructured absorption at 218.5 nm to the CH_3S free radical. Studies by Rosengren (6) and by Goldberg (7) had suggested that this radical should also have an electronic transition in the 400–370-nm spectral region. Their observations were confirmed by Tanaka and co-workers (8), who assigned an emission band system with origin near 378 nm to CH_3S and attributed a band spacing of 670 ± 75 cm^{-1} to the CS-stretching vibration. A similar band spacing was attributed to this fundamental of CH_3S in the photodetachment studies of Lineberger and co-workers (9), who assigned the CH_3 "umbrella" vibration at 1040 ± 80 cm^{-1}. In contrast, the photodetachment studies by Janousek and Brauman (10), which included studies of the deuterated molecule, suggested the assignment of these two fundamentals of CH_3S at 770 ± 50 cm^{-1} and 1360 ± 70 cm^{-1}, respectively.

The production of CH_3S in photolysis systems is complicated by the prevalence of secondary photodecomposition and by the multiplicity of the possible reactions of photodetached sulfur atoms. Such processes are important even for the mercury-arc photolysis of methanethiol isolated in inert solids at cryogenic temperatures (11). Recent studies by Dill and Heydtmann (12) and by Nesbitt and Leone (13) have provided evidence for the formation of both CH_3S and CH_2SH upon the reaction of fluorine or chlorine atoms with methanethiol. Although both of these studies were focused on the extent of vibrational excitation of the hydrogen halide product, the technique offers a promising route for generating the free radicals in sufficient concentration for direct spectroscopic characterization, without the complications which accompany photochemical generation of these species.

Recently, an experimental configuration has been developed in this laboratory which has permitted the trapping in solid argon at 14 K of a sufficient concentration of primary F-atom reaction products for study of their infrared spectra. In experiments on the F + CH_4 reaction (14), the principal product absorptions were assigned to isolated HF and CH_3 and to both

CH_3 and CH_3F hydrogen-bonded to HF. Although in a study of the F + CH_3OH system (15) only the lowest energy free radical, CH_2OH, was observed, in studies of the F + CH_3CHO reaction (16) infrared absorptions of both the acetyl and the vinoxy (formyl methyl) radical were prominent . These experiments also yielded photodecomposition thresholds and products for the free radicals formed in the primary reaction. The conduct of similar experiments on methanethiol not only may provide new spectral and photochemical data for the primary radical products but also may enhance our understanding of the dynamics of F-atom reaction. Although CH_2OH is thermodynamically somewhat more stable than is CH_3O, for the corresponding sulfur-containing radicals the reverse is true; CH_3S has been estimated (12) to be approximately 27 kJ/mol more stable than CH_2SH. This paper reports the results of such a study.

Experimental[1]

Samples of CH_3SH (Matheson Co., Inc.) and of CH_3SD, CD_3SH, and CD_3SD (Merck, Sharp, and Dohme of Canada, Ltd.) used for these experiments were freed of traces of relatively volatile impurities by pumping on the solid deposit at 77 K. Ar/CH_3SH-d_n samples of mole ratio 100 and 200 were prepared using standard manometric procedures. Ar/NF_3 samples of mole ratio 200 to 800 were used as F-atom sources. The Ar/NF_3 sample was introduced into the system through an Al_2O_3 tube with a pinhole having a diameter of between 1 and 2 mm. F atoms were produced in this discharge tube by microwave excitation, using 10 to 15% of the output of a 125-W, 2450-MHz microwave power supply. The Ar/CH_3SH-d_n sample was introduced into the system outside the discharge tube, in approximately the plane of the pinhole, and the reaction products were deposited on the cryogenic surface 2.5 cm downstream. The use of the Al_2O_3 tube completely eliminated SiF_4 from the reaction products, and there was no evidence for any aluminum-containing products. Studies in other experimental systems (14–16) have indicated that the primary hydrogen-abstraction reaction predominates under these experimental conditions, with a smaller yield, dependent on the F-atom concentration, of the product of the abstraction of a second hydrogen atom. There is no evidence for the participation of NF or NF_2 in secondary reactions; infrared absorptions of such species as HNF_2, HNF, *c*- and *t*-N_2F_2, and N_2F_4 have not been detected.

The cryogenic equipment and sample observation configuration (17) have previously been described. All observations were conducted at 14 K. After the infrared spectrum of the initial deposit had been recorded, the sample was subjected to the filtered radiation of a medium-pressure mercury arc in order to determine the threshold and products of secondary photodecomposition. Although observations were conducted with a variety of glass filters, the Corning filter of glass type 7740, with a short wavelength cutoff of 280 nm, was most useful for these studies.

Infrared spectra were recorded using a Beckman IR-9 spectrophotometer. Under the scanning conditions typical of these experiments, the relative and absolute frequency accuracies are estimated to be 1 cm^{-1} between 400 and 2000 cm^{-1} and 2 cm^{-1} between 2000 and 4000 cm^{-1}. The 275–400-cm^{-1} spectral region was also scanned for some of the deuterium-containing samples, using the CsI long wavelength interchange for this spectrophotometer. Because of the low signal level, the resolution and the relative and absolute frequency accuracies are estimated to be 5 cm^{-1} in this spectral region.

[1]Certain commercial instruments and materials are identified in this paper in order to specify adequately the experimental procedure. In no case does such identification imply recommendation or endorsement by the National Bureau of Standards, nor does it imply that the instruments or materials identified are necessarily the best available for the purpose.

Observations

In the previously reported (11) study of the photolysis of methanethiol in argon and nitrogen matrices, the most prominent product absorptions were those of H_2CS, CS, CS_2, and CH_4. However, several weaker absorptions which could not be definitively assigned may have been contributed by CH_3S or by CH_2SH. The positions and peak optical densities of the product absorptions in a typical study (designated as Experiment A) of the 121.6-nm photolysis of an Ar/CH_3SH = 200 sample are summarized in the first two columns of Table 1. Although the infrared spectrum of a previously unphotolyzed Ar/CH_3SH = 200 deposit was unchanged even on prolonged exposure of the sample to mercury-arc radiation of wavelength longer than 280 nm, marked changes occurred on exposure of the photolyzed deposit to radiation in this same spectral range. The peak optical densities which were observed at this stage of Experiment A are summarized in the third column of Table 1. There was little change in the intensities of the H_2CS and CH_4 absorptions under these photolysis conditions, but the absorption of CS diminished slightly in intensity and the 1479-cm^{-1} $^{13}CS_2$ peak and the 2180-cm^{-1} combination band of $^{13}CS_2$ grew, suggesting that some S-atom photodetachment occurred. Several unassigned absorptions diminished significantly in intensity, while a pair of relatively prominent absorptions at 424 and 431 cm^{-1} and a very weak absorption at 554 cm^{-1} grew substantially.

The peak optical densities of the product absorptions in a study (designated as Experiment B) of the reaction of a very low concentration of F atoms (Ar/NF_3 = 800) with CH_3SH are summarized in the fourth column of Table 1. Evidence for the occurrence of H-atom abstraction is provided by the appearance of infrared absorptions characteristic of HF isolated in solid argon (18) at 3886, 3922, and 3968 cm^{-1}. The moderately intense peak at 939 cm^{-1} corresponds to the strongest absorption of SF_6 in an argon matrix (19). Presumably this product results from the backstreaming of a small fraction of the methanethiol into the discharge region. There was little evidence for the infrared absorptions of other SF_n molecules (19) in the present series of experiments. The absorptions of CS and CS_2 which resulted from extensive secondary photodecomposition and S-atom reactions in Experiment A were completely absent from this and other F-atom reaction studies, and the most prominent peaks of H_2CS were diminished by a factor of approximately four. (The intensity of the 1056-cm^{-1} H_2CS absorption was relatively uncertain because of spectral interference by a nearby CH_3SH absorption.) A peak at 424 cm^{-1} was common to both systems. In the F-atom reaction study, its high-frequency satellite was shifted by 2 cm^{-1}, to 433 cm^{-1}. This peak is close to a band which has previously been attributed to HF aggregates in the solid (14), suggesting that their contribution may have led to the small but consistent frequency shift. Also common to both experimental systems was a weak absorption at 663 cm^{-1}. Because this peak lies very close to that of CO_2 isolated in solid argon, a contribution from a weakly absorbing photolysis or reaction product would be relatively uncertain. Prominent new absorptions appeared at 442, 569, 595, and 765 cm^{-1}, as well as between 3450 and 3700 cm^{-1}, the spectral region characteristic of the very strong HF-stretching absorptions of its hydrogen-bonded complexes.

Spectral regions in which major product absorptions appear are shown in the solid trace of Fig. 1 for an Ar/CH_3SH = 100 sample codeposited with a discharged Ar/NF_3 = 200 sample,

[a]Experiment A, $Ar/CH_3SH = 200$ deposited with concurrent hydrogen-discharge photolysis; Experiment B, $Ar/CH_3SH = 200$ codeposited with discharged $Ar/NF_3 = 800$; Experiment C, $Ar/CH_3SH = 100$ codeposited with discharged $Ar/NF_3 = 200$.

and the peak optical densities of all of the F + CH_3SH reaction product absorptions observed in this experiment (designated as Experiment C) are summarized in the fifth column of Table 1. Trace atmospheric impurities in the NF_3 sample lead to the appearance of prominent FNO absorptions in all of the discharge experiments. In the more concentrated F-atom experiments, peaks of FNO_2, FCO, and F_2CO are also present. These peaks have been included in Table 1 only when they changed in intensity on photolysis, suggesting that another product absorption may overlap. Although the peak optical densities of most of the product absorptions were somewhat greater than in Experiment B, the only new absorptions to appear were weak to moderately intense peaks at 462, 814, 1305, and 1310 cm^{-1}. The 814-cm^{-1} peak, which corresponds closely to a prominent product absorption in the photolysis experiments, was contributed at least in part by FNO_2. The 462-cm^{-1} peak can be assigned to $(HF)_n$ (14) and the 1305-cm^{-1} peak to CH_4. Since the intensities of the H_2CS absorptions were low in the F-atom reaction studies, it is concluded that secondary processes play a relatively minor role.

The presence of O atoms in the discharge suggests that products of their reaction with CH_3SH may be detectable. Tevault *et al.* (20) have attributed numerous infrared absorptions to incompletely characterized products of the O + CH_3SH reaction. In the present experiments, only the weak absorption at 1397 cm^{-1} could be assigned to such a product.

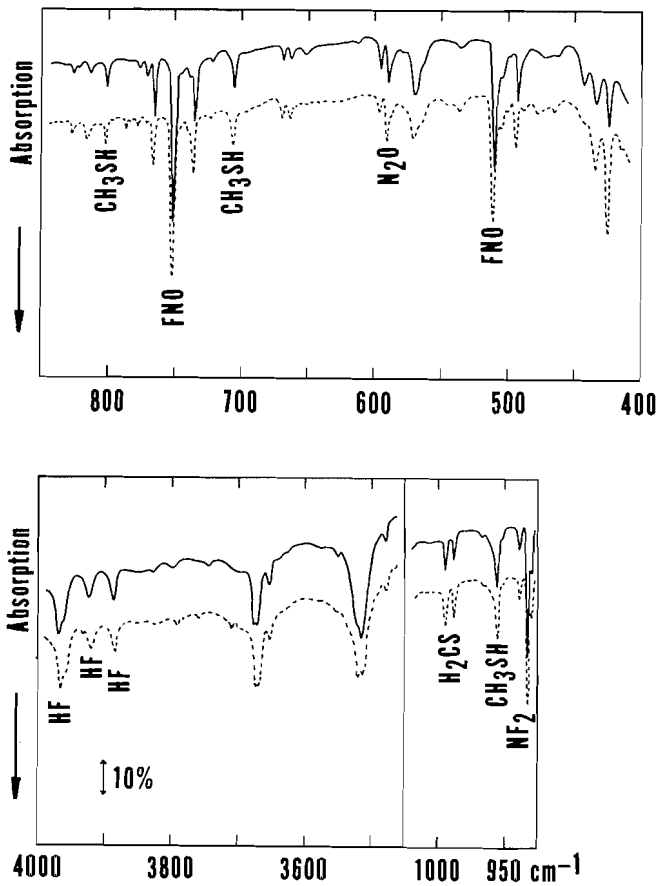

FIG. 1. Spectral regions for major product absorptions; ——— 4.71 mmol Ar/CH_3SH = 100 codeposited over period of 223 min with 3.21 mmol discharged Ar/NF_3 = 200. $[CH_3SH]/[NF_3]$ = 2.9; – – – – 120 min subsequent mercury-arc photolysis, $\lambda > 280$ nm.

When the sample of Experiment C was exposed to mercury-arc radiation with a 280-nm short wavelength cutoff, many of the product absorptions experienced changes in intensity. The spectrum observed at this stage of the experiment is shown in the broken-line trace of Fig. 1, for which the peak optical densities are summarized in the sixth column of Table 1. The marked growth in the intensity of the 424-cm^{-1} peak on 280-nm photolysis in both Experiment A and Experiment C supports its assignment to a common product. The more modest growth in the 433-cm^{-1} peak in the F-atom reaction system is consistent with spectral overlap by the absorption of $(HF)_n$. The 3672-cm^{-1} absorption also grew on 280-nm photolysis. The H_2CS absorptions grew somewhat, but absorptions of CS and CS_2 remained below the limits of detection. Within the experimental error, the intensities of the three absorptions of HF and of the weak CH_4 absorption were unchanged. The very prominent absorption at 3515 cm^{-1} diminished in intensity, as did the peaks at 442, 569, 595, 652, 765, 770, 1397, and 3478 cm^{-1}.

Two experiments were also conducted with the same samples used for Experiment C but with mercury-arc irradiation for a period of 1 to 3 h using a Type 7058 glass filter to give a photolysis cutoff of approximately 260 nm. After the 3-h irradiation, the peaks at 424, 433, 3652, and 3672 cm^{-1} were approximately halved in intensity, absorptions at 535 and 815 cm^{-1} grew to moderate intensity, broad, weak to moderately intense peaks grew in at 623 and 1380 cm^{-1}, the absorptions of H_2CS more than tripled in intensity, and weak to moderately intense absorptions of CH_4 and CS_2 appeared. While the peak optical density of the 3515-cm^{-1} absorption was almost unchanged, it was considerably broadened by the growth of one broad satellite absorption on the low frequency side and of two on the high frequency side.

The positions, peak optical densities, and direction of change on 280-nm photolysis of all of the product absorptions observed between 400 and 4000 cm^{-1} for Ar/CH_3SH-d_n = 200 samples codeposited with discharged Ar/NF_3 = 800 are summarized in Table 2, and the absorption patterns in the spectral regions typical of the HF- and DF-stretching vibrations of hydrogen-bonded complexes are shown in Fig. 2. The invariance of the 939-cm^{-1} peak on deuterium substitution is consistent with its assignment to SF_6.

Almost all of the product absorptions are common to both the Ar/CH_3SH study (Experiment B) and the Ar/CH_3SD experiment. Exchange of the deuterium atom at the walls of the vacuum system would lead to the formation of some CH_3SH in this latter experiment. However, a new, moderately intense peak at 2595 cm^{-1} which diminished in intensity on 280-nm photolysis has a frequency ratio of 0.74 to the 3515-cm^{-1} absorption, suggesting its assignment to the deuterium-stretching counterpart of the higher frequency peak. Furthermore, although in both systems the 424-, 433-, and 3672-cm^{-1} peaks grew significantly on photolysis, in the CH_3SD experiment a new pair of absorptions with a peak optical density of 0.038 appeared at 2700 and 2704 cm^{-1} in the spectrum of the photolyzed sample. (The spectrum was not scanned at this stage of the experiment for the CH_3SH sample of Fig. 2(a), but there was no absorption at this position in the spectra of other photolyzed CH_3SH samples.) The ratio of the mean frequency of this new absorption pair to the 3672-cm^{-1} absorption (which has a partially resolved component at 3666 cm^{-1}) is 0.74, appropriate for the assignment of the new doublet to the deuterium-stretching counterpart of the higher frequency absorption. A very weak absorption at 2898 cm^{-1} may be assigned to isolated DF. (Weak absorptions at 2854 and 2878 cm^{-1} were also present in the spectrum of a simple Ar/CH_3SD = 200 deposit.)

A supplementary experiment was conducted in which an Ar/CH_3SD sample codeposited with F atoms was successively photolyzed through glass filters with decreasing cutoff wavelengths, in order to determine the threshold for the growth in the 424–433-cm^{-1} absorptions on photolysis. The peak intensities of these two absorptions remained constant when filters with a short wavelength cutoff between 490 and 345 nm were used but grew significantly when a 300-nm cutoff filter was substituted.

In studies of the reaction of F atoms with CD_3SH and CD_3SD, the 424–433-cm^{-1} peaks were shifted below the range of the infrared scan with KBr optics. In supplementary experiments using the CsI optical interchange, a pair of product absorptions was reproducibly detected at 322–326 cm^{-1}. Unfortunately, the signal-to-noise ratio was too poor for meaningful comparison of the optical densities of these low frequency peaks before and after 280-nm photolysis. Since the frequency ratio of these two absorptions to that at 424 cm^{-1} is approximately 0.76, it is suggested that the vibration which contributes these absorptions is dominated by hydrogen-atom motion.

In the 430–2600-cm^{-1} spectral region, all of the F + CD_3SH and CD_3SD reaction product absorptions except a weak absorption at 447 cm^{-1} remained constant or diminished in intensity on 280-nm photolysis. The absorptions of both isolated DF and

[a]+, − indicate growth or decrease, respectively, on photolysis.

HF were observed in both systems; exchange of the sulfhydryl proton on the walls of the system led to the formation of CD_3SH in the CD_3SD experiments. The absorptions near 2600 and 2700 cm^{-1} and the 3515-cm^{-1} peak were prominent and had similar contours in both systems, but, as is shown in traces (c) and (d) of Fig. 2, the peaks at 2618 and 3672 cm^{-1} appeared with significant intensity only after 280-nm photolysis.

Discussion

F atoms may abstract either of the two different types of H atom from methanethiol:

[1] $F + CH_3SH \rightarrow CH_3SH + HF$

[2] $F + CH_3SH \rightarrow CH_2SH + HF$

While, as already noted, the first reaction is energetically somewhat more favorable, on the basis of stoichiometry the second reaction would be more probable. It has been estimated (21) that F atoms and the reactant molecule coexist in the beam for approximately 10^{-4} s before the sample reaches the cryogenic surface. At the concentrations used in these experiments, only one or two reactive collisions are likely to occur during this time. Products formed in the gas phase will generally be

trapped in isolated sites in the argon lattice. F atoms may also react with molecules on the surface of the deposit and, because of the exothermicity of the reaction, one or both of the product molecules may migrate from the site of the reaction, enhancing the probability for the trapping of the isolated species. Unreacted F atoms may diffuse through the argon lattice, where they may also react with methanethiol. However, HF formed in the solid cannot diffuse from the site of its production and will form a hydrogen bond with the free radical product:

[3] $F + CH_3SH\ (Ar) \rightarrow CH_3S\cdots HF$

[4] $F + CH_3SH\ (Ar) \rightarrow CH_2SH\cdots HF$

The six degrees of freedom lost by HF in forming the complex will contribute six new vibrational absorptions to the spectrum of the free radical (22). One of these, the H—F stretching mode, is generally very strongly infrared absorbing and appears at a somewhat lower frequency than the infrared absorption of isolated HF, often in the 3500–3800-cm^{-1} spectral region. The separation between these two absorptions provides a measure of the strength of the hydrogen bond in the complex. A pair of vibrational modes, doubly degenerate for a complex of cylindrical symmetry, is contributed by the H deformation motions in the hydrogen bond. These absorptions frequently have been observed in the 500–700-cm^{-1} spectral region, with a higher frequency associated with a stronger hydrogen bond. Three other vibrations appear in the far infrared, outside of the spectral region of these studies.

Secondary F-atom reactions may also occur. H-abstraction from either free radical product should lead to the formation of H_2CS. The strongest infrared absorptions of this product, observed at 988 and 993 cm^{-1} in an argon matrix (11), are of no more than weak to moderate intensity in these experiments, suggesting that such secondary F-atom reactions play a minor role. Secondary F-atom addition, forming CH_3SF or CH_2FSH, may also occur. The infrared spectrum of CH_3SF has not been reported. CH_2FSH should have a strong CF-stretching absorption in the 1000–1200-cm^{-1} spectral region. However, virtually no product absorption was present in this region. The conclusion that secondary F-atom reactions play a minor role under the conditions of these experiments parallels the similar conclusion drawn in the previously reported experiments (14–16, 21). On the basis of these earlier studies, it is also expected that the infrared spectra of products of the reaction of NF and NF_2 with methanethiol should be too weak to be detected in these experiments.

The presence of a rather prominent absorption of isolated HF indicates that reaction [1] and/or reaction [2] occur with significant probability, and the appearance of both isolated HF and isolated DF in the CD_3SH studies suggests that both occur. The relative prominence of the HF absorption in that experiment cannot be inferred to indicate that reaction [1] predominates, since the DF absorption is much weaker than is that of HF.

The appearance of very prominent absorptions at both 3515 and 3672 cm^{-1}, with differing photolysis behavior, suggests that both reaction [3] and reaction [4] also occur. In the CD_3SH study, the expected primary products should be $CD_3S\cdots HF$ and $CD_2SH\cdots DF$. The appearance of a single HF complex absorption at 3515 cm^{-1} supports the assignment of this peak to the complex of CH_3S-d_n with HF. However, in the CD_3SH experiments both DF complex absorptions appeared. The correlation of the lower frequency absorption with the complex of CH_3S suggests the assignment of the 2600-cm^{-1} absorption to $CHD_2S\cdots DF$. The 2700-cm^{-1} absorption would then be expected to be contributed by $CD_2SH\cdots DF$. Similarly, in the CH_3SD experiments, somewhat complicated by isotopic exchange, only the lower frequency DF-stretching absorption, assigned to $CH_3S\cdots DF$, was observed, but both HF stretching absorptions, assigned to $CH_2DS\cdots HF$ and $CH_2SD\cdots HF$, appeared. It is inferred that CH_2SH formed by reaction [2] or [4] possesses sufficient internal energy to surmount the barrier to its rearrangement to the thermochemically more stable CH_3S. However, the reverse rearrangement of CH_3S to form CH_2SH appears to be improbable under the conditions of these experiments.

The observed threshold for the appearance of the 2700-cm^{-1} absorption in the F + CH_3SD experiments and of the 3672-cm^{-1} absorption in the F + CD_3SH experiments, between 345 and 300 nm, lies within the expected absorption region for CH_3S-d_n corresponding to the emission band system reported for this molecule by Tanaka and co-workers (8). Therefore, it is suggested that photochemical rearrangement of CH_3S may occur:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

[5] $CH_3S + h\nu \rightarrow CH_2SH$

The threshold for the photodecomposition of CH_2SH, forming H_2CS, lies near 280 nm. Alternatively, the primary photodecomposition of CH_3S may involve detachment of an H atom, with a significant probability of its cage recombination to form CH_2SH. Generally, there is a slight growth in the H_2CS absorption on 300- or 280-nm photolysis and a more marked growth on 260-nm photolysis. It is concluded that, while the experiments suggest the occurrence of reaction [5], they do not definitively establish it.

The spectra of isolated CH_3S and CH_2SH may contribute to the pattern of absorptions observed in both the vacuum-ultraviolet photolysis and the F-atom reaction studies. Only the 424–431-cm^{-1} absorption pair and the peaks near 663 and 815 cm^{-1} satisfy this criterion. While a 663-cm^{-1} peak, to which CO_2 is the major contributor, would lie within the experimental error of the assignment proposed for the CS-stretching fundamental of CH_3S by Tanaka (8) and by Lineberger (9) and their co-workers, it is outside of the range of uncertainty of the assignment suggested by Janousek and Brauman (10). Moreover, there is no absorption near 1040 cm^{-1}, the position estimated by Lineberger for the CH_3 "umbrella" mode of CH_3S. On the other hand, the peaks at 815 and 1397 cm^{-1} lie within the experimental error of the assignment proposed by Brauman for these two fundamentals. Because in the F-atom studies FNO_2 contributed to the absorption at 815 cm^{-1} and a product of the O + CH_3SH reaction may have contributed to that at 1397 cm^{-1}, further studies are required for a definitive assignment.

Brauman has also assigned the CD_3 "umbrella" vibration of CD_3S at 1100 ± 50 and the CS-stretching fundamental at 660 ± 60 cm^{-1}. The estimate of 1560 ± 50 cm^{-1} for the first overtone of the degenerate DCS deformation fundamental would place this mode near 780 cm^{-1}. Only the peaks at 545, 620, and 815 cm^{-1} in the F-atom experiments on CD_3SD lie close to product absorptions in the earlier Ar/CD_3SH photolysis study (11), and the latter two of these peaks lie within the experimental uncertainty estimated by Brauman for CD_3S fundamentals.

The vibrational fundamentals of CH_3S and CD_3S which are hydrogen-bonded to HF or DF would be expected to be somewhat shifted from those of the isolated molecule. Prominent peaks at 593 and 796 cm^{-1} in the CD_3SH and CD_3SD + F studies may have been contributed by these fundamentals of perturbed CD_3S.

Since analogy with the pattern of the fundamental vibrations of the methyl and methyl-d_3 halides (23) indicates that the CS-stretching vibration should be the lowest frequency fundamental of CH_3S and of CD_3S, the 424–431-cm^{-1} absorptions, also common to the F-atom and photolysis experiments, could not reasonably be assigned to CH_3S. On the other hand, both the torsional vibration and the CH_2S "umbrella" deformation vibration of CH_2SH are expected to lie at low frequencies; a very recent *ab initio* calculation by Schlegel[2] at the HF/3-21G level, using the HF/3-21G optimized geometry, gave a value of 426 cm^{-1} for the "umbrella" vibration and of 211 cm^{-1} for the torsion. The close correspondence of the 424–431-cm^{-1} peaks to the calculated value for the "umbrella" vibration is to some extent fortuitous, since anharmonicity and the low barrier to inversion were not taken into account. There should also be only a small dependence of the frequency of the "umbrella" mode on whether an H or a D atom is substituted on the sulfur atom, but a large dependence of the torsional vibration on the isotope in this position. Thus, the isotopic data also favor the assignment to the "umbrella" mode.

The correlation of the photochemical behavior of the 424–433-cm^{-1} peaks with that of the 3672-cm^{-1} peak, which the isotopic substitution experiments have tied to the product of the attack of the F atom on a C—H bond, further strengthens the assignment of the 424–433-cm^{-1} absorptions to CH_2SH. Since no new peaks parallel their behavior in the F-atom experiments, it is concluded that this vibration of CH_2SH is only slightly perturbed by the formation of a hydrogen bond with HF.

Because the HF stretching frequency experiences a greater shift in the formation of a hydrogen bond with CH_3S than with CH_2SH, it is inferred that the hydrogen bond of CH_3S with HF is the stronger, suggesting the localization of the unpaired electron on the S atom. A recent study of the structure of the $H_2S\cdots HF$ complex (24) has determined that the HF bond is almost exactly perpendicular to the plane of the H_2S moiety, consistent with the tendency of the S atom to form bonds at angles of approximately 90°. Therefore, it is likely that the HF bond in $CH_3S\cdots HF$ is approximately perpendicular to the C—S bond, implying that the degenerate CH stretching and bending vibrations and the degenerate HF deformation mode should be split. Taken together, these arguments suggest that there should be four HF-deformation absorptions in the 500–700-cm^{-1} region in the F-atom reaction studies and that the two absorptions contributed by the relatively strongly bound HF complex with CH_3S should lie at higher frequencies than those of the complex with CH_2SH. Only the weak 535- and 776-cm^{-1} absorptions have the appropriate photolytic behavior for assignment to $CH_2SH\cdots HF$. Assuming a very small interaction with vibrations of the CH_2SH-d_n moiety, the corresponding vibrations of the DF complex should lie near 400 and 580 cm^{-1}. Several absorptions behave appropriately for assignment to the HF-deformation vibrations of $CH_3S\cdots HF$. Noteworthy is the invariance of a rather prominent absorption at 569 cm^{-1} in all of the isotopic studies. The frequency ratio of the 569-cm^{-1} peak to that at 765 cm^{-1} is 0.74 and of the 436- to the 569-cm^{-1} peak is 0.77, suggesting that both an HF- and a DF-deformation vibration may contribute to the 569-cm^{-1} absorption. However, the present data do not suffice for a definitive assignment.

The 260-nm photolysis experiments indicate that the threshold for the photodecomposition of CH_2SH to produce H_2CS lies between 260 and 280 nm. Quite possibly the broadening of the 3515-cm^{-1} absorption of $CH_3S\cdots HF$ on prolonged irradiation through the 260-nm cutoff filter results from the superposition of the growing absorption of $H_2CS\cdots HF$.

Conclusions

Both CH_3S and CH_2SH are formed in primary F-atom reactions with CH_3SH. In argon-matrix sampling studies, the very prominent absorptions at 3515 and 2600 cm^{-1} can be assigned to the HF and DF complexes, respectively, with CH_3S-d_n, while the peaks at 3672 and 2700 cm^{-1} can be assigned to the corresponding complexes with CH_2SH-d_n. Studies on partially deuterium-substituted methanethiol indicate that CH_2SH is formed with enough excess energy to surmount the barrier for rearrangement to the thermochemically more stable CH_3S. In contrast, CH_2S has a relatively small probability of rear-

[2]H. B. Schlegel, private communication.

rangement to CH_2SH. The experiments suggest that the threshold for the photoinduced rearrangement of CH_3S to CH_2SH lies between 345 and 300 nm, in the region of a previously identified electronic transition of CH_3S. However, the observed rearrangement may result at least in part from the cage recombination of initially-formed H_2CS and H atoms. The infrared data support, but do not establish, the recent vibrational assignment for CD_3S based on the photodetachment studies of Janousek and Brauman (10). A prominent, structured absorption at 424 cm^{-1} has been assigned to the H_2CS "umbrella" deformation of CH_2SH. The threshold for the photodecomposition of CH_2SH lies in the 260–280-nm spectral region.

ipso Halogenation. II.[1] Bromination of phenols, isomerization and disproportionation of bromophenols, and dienone–phenol rearrangement of bromodienones

ALFRED FISCHER AND GEORGE NARAYANAN HENDERSON
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received July 22, 1982

ALFRED FISCHER and GEORGE NARAYANAN HENDERSON. Can. J. Chem. **61**, 1045 (1983).

Bromination of *p*-cresol, 2-bromo-*p*-cresol, 3,4-dimethylphenol, and mesitol in trifluoromethanesulfonic acid gives as the main product the bromo derivative with bromine *meta* to hydroxyl, a result attributed to the intermediate formation of a bromodienone and its rearrangement. Phenol does not give *m*-bromophenol in trifluoromethanesulfonic acid. 4-Bromo-2,4,6-trimethylcyclohexa-2,5-dienone rearranges to 3-bromomesitol in trifluoromethanesulfonic acid and, similarly, 2,4,6-tribromo-4-methylcyclohexa-2,5-dienone rearranges to 2,3,6-tribromo-4-methylphenol. Under appropriate conditions debromination of bromodienones is competitive with rearrangement. Tetramethylammonium bromide in trifluoromethanesulfonic acid is an effective reagent for isomerization and disproportionation of bromophenols. Tetramethylammonium iodide in trifluoromethanesulfonic acid is an effective reagent for selective debromination of bromophenols at the *ortho* and *para* positions.

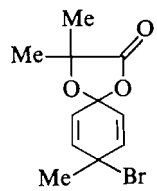
ALFRED FISCHER et GEORGE NARAYANAN HENDERSON. Can. J. Chem. **61**, 1045 (1983).

La bromation de *p*-crésol, du bromo-2-*p*-crésol, du diméthyl-3,4 phénol et du mésitol dans l'acide trifluorométhanesulfonique donne comme produit principal le dérivé bromé portant un brome en position *méta* par rapport à l'hydroxyle. On attribue ce résultat à la formation intermédiaire d'une bromodiénone qui subirait ultérieurement une transposition. Le phénol ne donne pas le *m*-bromophénol dans l'acide trifluorométhanesulfonique. La bromo-4 triméthyl-2,4,6 cyclohexadiène-2,5 one se transpose en bromo-3 mésitol dans l'acide trifluorométhanesulfonique et d'une façon analogue la tribromo-2,4,6 méthyl-4 cyclohexadiène-2,5 one se transpose en tribromo-2,3,6 méthyl-4 phénol. Dans des conditions appropriées, la débromation des bromodiénones entre en compétition avec la transposition. Le bromure de tétraméthylammonium dans l'acide trifluorométhanesulfonique est un réactif efficace pour l'isomérisation et la disproportionation des bromophénols. L'iodure de tétraméthylammonium dans l'acide trifluorométhanesulfonique est un réactif efficace pour la débromation sélective des bromophénols en position *ortho* et *para*.

[Traduit par le journal]

Aromatic electrophilic substitution reactions can lead to unexpected products as a result of *ipso* attack and subsequent reaction of the *ipso* intermediate so obtained (1). Chlorination of *p*-cresol gives 4-chloro-4-methylcyclohexa-2,5-dienone as well as the expected 2-chloro-4-methylphenol (2). Reaction of the chlorodienone in trifluoromethanesulfonic (triflic) acid gives 3-chloro-4-methylphenol (3). We have now investigated the bromination of *p*-cresol in an attempt to obtain the corresponding bromodienone, and have studied other reactions involving bromodienones as potential intermediates.

Bromodienones have been known for a long time. Phenol, on reaction with bromine water, gives a tetrabromo derivative, first isolated by Benedikt in 1879 (4). The debate on the structure of this product, alternatively identified as 2,4,6-tribromophenol hypobromite or 2,4,4,6-tetrabromocyclohexa-2,5-dienone (5) continued into recent times (6). The dienone structure is now well established. The most comprehensive studies of the formation and reactions of bromodienones are those of Ershov *et al.* (7) involving 2,6-dialkyl and 2,4,6-trialkylphenols as substrates. The notion that halodienones could be formed only from phenols fully substituted in the *ortho* and *para* positions was prevalent in the past (7*a*). With the exception of 4-bromo-2,6-di-*tert*-butylcyclohexa-2,5-dienone, all of the known bromodienones are derived from 2,4,6-trisubstituted phenols. However, the bromination of α-*p*-tolyloxyisobutyric acid to the bromodiene **1** (8) provides a close analogue to the bromination of *p*-cresol to the corresponding bromodienone and provides support for the expectation that the bromodienone should be formed.



1

Jacquesy *et al.* have investigated the bromination of phenol, methylphenols (including *p*-cresol), and dimethylphenols in antimony pentafluoride – hydrogen fluoride (9, 10). They observed that *p*-cresol, 2,4-dimethylphenol, and 3,4-dimethylphenol gave 3- (or 5-) bromo derivatives in which the bromine atom is *meta* to the hydroxyl group. On the other hand, phenol, *o*-cresol, and *m*-cresol gave 4-bromo derivatives. The hydroxyl group is strongly *ortho–para* directing and they suggested that the *meta* orientations observed in the first reactions, and also in the bromination of 2,6-dimethylphenol under the same conditions, could be accounted for if the oxonium ion conjugate acid of the phenol was the actual substrate brominated. They assumed that the protonated hydroxyl group is *meta* directing. We thought that an alterantive explanation for these observations could be that bromination of *p*-cresol and the 2,4- and 3,4-dimethylphenols would give, via *ipso* bromination, the corresponding 4-bromo-4-methylcyclohexa-2,5-dienone, or derivative, which would rearrange by an acid-catalysed 1,2 shift of the bromine to give, after deprotonation, the 3-bromophenol derivative. We had demonstrated the analogous reaction for chlorination of *p*-cresol (2, 3). During our study, de la Mare and co-workers (11) reported their observations on the bromination of *p*-cresol in triflic acid and sug-

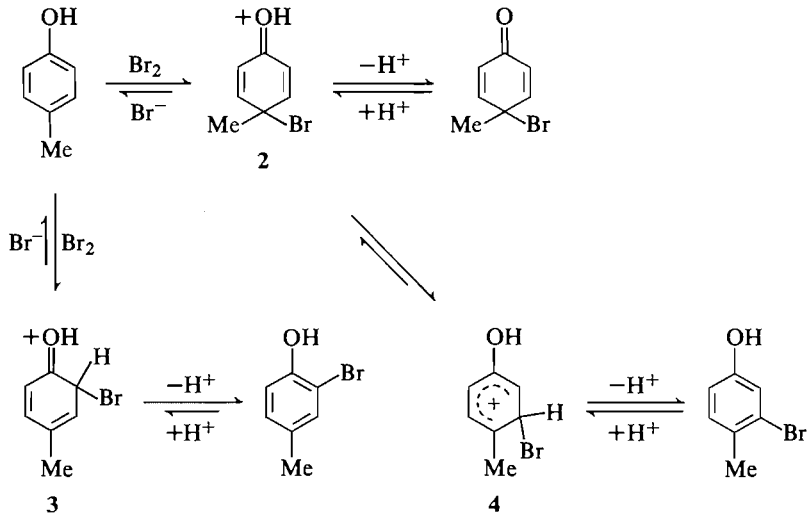

SCHEME 1. Bromination of *p*-cresol.

gested, amongst other possibilities, the pathway to 3-bromo-*p*-cresol involving the 1,2 bromine shift in the conjugate acid of 4-bromo-4-methylcyclohexa-2,5-dienone. De la Mare and co-workers have also investigated the polybromination of the cresols and of 3,4-dimethylphenol leading to the formation of tribromodienones (12, 13).

Results and discussion

Bromination of p*-cresol and 3,4,5-trimethylphenol*

p-Cresol was brominated under a number of different conditions in an attempt to detect the formation of 4-bromo-4-methylcyclohexadienone. Reactions were carried out, at 0°C or below, with bromine in deuteriochloroform containing pyridine, bromine in aqueous methanol, bromine in methanol, bromine in acetic anhydride, bromine in aqueous potassium bicarbonate, bromine in aqueous potassium carbonate, and bromine in ether. Only aromatic compounds were observed and no dienone was detected. 2-Bromo-4-methylphenol was the major product. Even at −50°C, under the conditions considered the most favourable for formation of bromodienones (ether–water–pyridine solvent), no dienone could be detected (7*h*).

Bromination of 3,4,5-trimethylphenol in ether containing a few drops of pyridine with a solution of bromine in aqueous potassium bromide gave only 2-bromo-3,4,5-trimethylphenol and no dienone was detected. Under the same conditions mesitol gave 4-bromo-2,4,6-trimethylcyclohexa-2,5-dienone in quantitative yield.

Bromination of phenols in acids

The products of bromination of *p*-cresol and of 2-bromo-*p*-cresol are shown in Table 1. Details of the results of bromination of other phenols are given in the experimental section. Sulfuric acid was unsatisfactory as a solvent for bromination of phenols since sulfonation occurred and no mono-brominated phenols were obtained. Bromination of *p*-cresol in methanesulfonic acid gave 2-bromo-*p*-cresol containing only small amounts of 3-bromo-*p*-cresol, and dibromo-*p*-cresol. In contrast, a substantial amount of *meta* bromination of *p*-cresol occurred in triflic acid, the amount increasing with reaction time.

De la Mare and co-workers have reported that bromination of *p*-cresol in triflic acid gives 3-bromo- as well as 2-bromo-*p*-cresol, the amount of the 3-bromo isomer increasing at the expense of the 2-bromo isomer on allowing the reaction mixture to stand (11). Our observations confirm and extend this report. We suggest, by analogy with the chlorination of *p*-cresol, that initial bromination can take place at both the 2-position and the 4-(*ipso*)position. The latter reaction would give 4-bromo-4-methylcyclohexa-2,5-dienone. Again by analogy with the chlorodienone, the conjugate acid of the bromodienone can rearrange by a 1,2 shift of bromine to give, after deprotonation, 3-bromo-*p*-cresol (Scheme 1). However, unlike chlorination, the *ipso* bromination is reversible, bromide ion being able to bring about the debromination of the bromodienone conjugate acid. In the very strongly acidic triflic acid the bromide ion concentration is low, as hydrogen bromide is only slightly dissociated. We suggest that, under this condition, the unimolecular rearrangement of the bromodienone conjugate acid **2** to **4** is able to compete with the bimolecular debromination to *p*-cresol and bromine and thus 3-bromo-*p*-cresol is obtained. In the less strong methanesulfonic acid, the bromide ion concentration is higher and the debromination reaction is favoured over the rearrangement. Although bromination at the (unsubstituted) 2-position is also reversible (Scheme 1) this would be expected to be much slower than debromination of the bromodienone. Protonation of the 2-bromo-*p*-cresol *ipso* to bromine, the first step of the reverse reaction, should be much less extensive than protonation of the bromodienone at the carbonyl oxygen atom. Thus on the time scale of the bromination–debromination at the *ipso* position, bromination at the unsubstituted 2-position is essentially irreversible. Hence bromination of *p*-cresol in methanesulfonic acid and in more weakly acidic conditions gives, essentially completely, 2-bromo-*p*-cresol, some of the *p*-cresol being cycled reversibly through the bromodienone before being converted into 2-bromo-*p*-cresol. In the stronger triflic acid debromination of 2-bromo-*p*-cresol is enhanced and, on standing, the 2-bromo isomer initially obtained isomerizes to 3-bromo-*p*-cresol and dibromo-*p*-cresols are also formed (see below).

Bromination of 2-bromo-*p*-cresol, 3,4-dimethylphenol, and mesitol in triflic acid, gave, in each case, the product of 3- (5-) substitution as the major (or only) component. As in the case of *p*-cresol, it is likely that these products are formed via *ipso* (4-) bromination followed by rearrangement of the bromine to the adjacent unsubstituted position. However, phenol gave only products of substitution at the 2- and 4-positions. Since it

[a]Bromine in methanesulfonic acid added over 10 min to *p*-cresol in methanesulfonic acid and the mixture worked up after further 10 min.
[b]Bromine solution added over 2.5 min and the mixture worked up after 0.5 min.
[c]Liquid bromine added rapidly and the mixture worked up after 5 min.
[d]Standard conditions described in the text of experimental section; bromine solution added over 15 min and worked up after 30 min.
[e]Liquid bromine added in a closed system to prevent the loss of HBr. Work-up after 24 h.
[f]The mixture of 2-bromo-*p*-cresol (1 mmol) and 48% HBr (10 cm^3) was heated under reflux in a closed system for 24 h. No reaction occurred when a similar mixture was stirred for 3 days at ambient temperature.
[g]Reaction time of 15 min.
[h]NMe_4Br added in 5 portions over 15 min; open system. Work-up after 30 min.
[i]Standard conditions described in the text of the experimental section; closed system. Work-up after 24 h.

lacks a methyl substituent, the *ipso* addition and rearrangement pathway is precluded. Again as expected, 3,4-dimethylphenol underwent bromination at only the 2- and 6-positions in aqueous acetic acid.

The above results do not rule out other pathways to *meta* brominated phenols that have been suggested. As mentioned in the introduction, Jacquesy and co-workers have proposed that it is the conjugate acid of the phenol that is substituted in strongly acidic conditions. However, de la Mare and co-workers observed that the OH_2^+ group should be *ortho*, *para* directing (11). Furthermore, bromination is extremely sensitive to substituent effects ($\rho = -12$ (14)) and it seems unlikely that the conjugate acid would be readily brominated. Indeed, we attribute the reduced reactivity of mesitol in the triflic acid to the fact that it is essentially completely protonated (probably at the ring rather than the hydroxyl group) and thus there is only a small amount of free mesitol available for reaction. Moreover, the fact that phenol does not give any 3-bromophenol on bromination in triflic acid is not readily explained if it is the conjugate acid that is brominated and if the OH_2^+ group is *meta* directing. De la Mare has also suggested that cation **3** can undergo a 1,2 bromine shift to give **4** (11). However, the same pathway should be available to phenol and should thus lead to the formation of 3-bromophenol.[2] An alternative pathway to the 3-brominated product would involve reversible *ipso* bromination followed by a slower but less reversible direct 3-bromination of the phenol. Bromination *meta* to the hydroxyl group is exceedingly slow. The difference between σ^+ for *p*-OH and σ ($= \sigma^+$) for *m*-OH is about -1, hence the relative rates of substitution in the *para* and *meta* positions of phenol are ca. 10^{12}:1. Such a calculation is at best crude and, moreover, in suitably substituted methylphenols the methyl groups can act in opposition to the directing effect of the hydroxyl. Nevertheless the reactivity difference is so great that it seems unlikely that direct *meta* substitution need be considered seriously. Experiments described in the next section involving a study of the reactions of the bromodienone from mesitol provide further evidence for ruling out this pathway.

Reaction of 4-bromo-2,4,6-trimethylcyclohexa-2,5-dienone with acids

When the dienone in deuteriochloroform at -20°C was treated with a few drops of triflic or sulfuric acid it immediately rearranged to 3-bromomesitol. This would appear to be an example of the acid-catalysed dienone–phenol arrangement observed for chlorodienones and illustrated for 4-bromo-4-methylcyclohexa-2,5-dienone in Scheme 1 (3). Reaction of the dienone in deuteriochloroform at -20°C with a solution of hydrogen bromide in ether gave, after 1 min, a mixture of 3-bromomesitol (78%) and mesitol (22%). The mesitol was slowly brominated to 3-bromomesitol, presumably via reformation of the dienone and its acid-catalysed rearrangement. Similar behaviour was exhibited when gaseous hydrogen bromide was passed into the bromodienone solution, and the characteristic colour of the liberated bromine was observed. Reaction with hydrogen chloride gave mainly 3-bromomesitol, while reaction with aqueous hydrogen iodide produced only mesitol. In the case of the reaction with iodide the iodine bromide formed in the debromination process reacts with excess iodide to form, irreversibly, iodine and bromide, thus preventing the rebromination reaction and leaving mesitol as the aromatic product.

The dienone did not react, within 10 min, with a solution of trifluoroacetic acid in deuteriochloroform (9% v/v) at 0°C. Evidently the acid is not strong enough to catalyse the 1,2 bromine shift under these conditions.

4-Methyl-2,4,6-tribromocyclohexa-2,5-dienone in deuteriochloroform gave 2,3,6-tribromo-*p*-cresol on treatment with a small amount of triflic or sulfuric acid. The same rearrangement in neat sulfuric acid has been reported by de la Mare and co-workers (13).

Methyl migration products were not observed in any of the reactions. Evidently migration of bromine is preferred over migration of methyl in the acid-catalysed dienone–phenol rearrangement, a result at least partially accounted for by the greater stabilizing effect of methyl than bromine on the positive charge developing in the transition state at the migration origin (cf. ref. 3).

Attempts were made to set up a competition between the 1,2-rearrangement reaction of 4-bromo-2,4,6-trimethylcyclohexadienone and the debromination to mesitol, by trapping the bromine released in the latter reaction. At -40°C no reaction occurred between the bromodienone and trimethoxybenzene in deuteriochloroform until hydrogen bromide was passed in, when rapid reaction to mesitol and bromotrimethoxybenzene ensued. Hydrogen bromide is a very effective debrominating reagent. However, addition of triflic acid (20% by vol) resulted in 78% of the bromodienone undergoing the rearrangement to 3-bromomesitol and 22% undergoing reaction to bromotrimethoxybenzene and mesitol. In strong acid and in the absence of a significant concentration of the bromide ion the rearrangement is faster than the debromination. The fact that in 20% triflic acid the 3-bromomesitol was formed in preference to bromotrimethoxybenzene from the bromodienone–trimethoxybenzene mixture indicates that the 3-bromomesitol is not formed by reversible debromination of the bromodienone followed by direct *meta* bromination, since bromination of trimethoxybenzene should be faster than *meta* bromination of mesitol.

The very ready debromination of bromodienones by the hydrogen bromide produced in the bromination accounts for the failure to observe the formation of bromodienones in the bromination of *p*-cresol and other simple phenols having at least one unsubstituted position *ortho* or *para* to the hydroxyl group. Thus bromination to bromodienone is rapidly reversible and the essentially irreversible bromination at the unsubstituted activated position is product determining.[3]

Isomerization and disproportionation of bromophenols

O'Bara *et al.* (16) showed that 4-bromo-*m*-cresol is converted into an equilibrium mixture of *m*-cresol, 2-, 4-, and 6-bromo-*m*-cresol, and 2,4-, 2,6-, and 4,6-dibromo-*m*-cresol on standing in chloroform saturated with hydrogen bromide, at 25°C, for several days. The same mixture was obtained when 2-bromo-*m*-cresol or when 6-bromo-*m*-cresol was used as substrate. O'Bara *et al.* proposed a reaction pathway involving the protodebromination of the bromocresol and the reversible rebromination of the resulting *m*-cresol and of the initial and

[2]Jacquesy and Jouannetaud (15) have recently demonstrated that direct rearrangement of **3** to **4** occurs in the superacid SbF_5–HF, but does not occur in triflic acid.

[3]Bromination at such a position is in fact reversible, but only on a time scale which is extremely long compared to the time of the forward bromination reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

product bromocresols. *p*-Bromophenol and 4-bromo-3,5-xylenol similarly isomerized and disproportionated. No *m*-bromophenols were detected in these reactions, in accord with the expectation that *meta* bromination of phenol is exceedingly slow compared to *ortho* or *para* bromination.

In preliminary experiments we established that solutions of hydrogen bromide or tetramethylammonium bromide in triflic acid provide a very effective means of bringing about isomerization and disproportionation of bromophenols. A solution of 2-bromo-*p*-cresol in deuteriochloroform saturated with hydrogen bromide was unreacted after 24 h at ambient temperature. Likewise 2-bromo-*p*-cresol was unchanged after stirring with 48% hydrobromic acid for 72 h at ambient temperature. In contrast, 16% of the 2-bromo-*p*-cresol had reacted after treatment with tetramethylammonium bromide in triflic acid for 15 min. *o*-Bromophenol isomerized and disproportionated on treatment with tetramethylammonium bromide in triflic acid but no *m*-bromophenol was formed, whereas 2-bromo-*p*-cresol gave a mixture of phenols in which 3-bromo-*p*-cresol predominated. A mixture of the same composition was obtained when 3-bromo-*p*-cresol was used as the substrate. This suggests that the mixture is close to an equilibrium or at least quasi-equilibrium distribution of components. When *p*-cresol was brominated in triflic acid in a closed system, to prevent the loss of hydrogen bromide, and the mixture stirred for 24 h, the product mixture had a similar composition. Clearly, the hydrogen bromide formed in the bromination had brought about the isomerization and disproportionation of the 2-bromo-*p*-cresol initially formed. Addition of tetramethylammonium iodide to the reaction mixture after the 24 h isomerization period resulted in the liberation of iodine. On work-up a mixture consisting mainly of 3-bromo-*p*-cresol was obtained from which pure 3-bromo-*p*-cresol could be obtained by preparative glc.

Further confirmation that bromine was liberated during the isomerization and disproportionation was provided by reacting 2-bromo-*p*-cresol with tetramethylammonium bromide in the presence of 3,4-dimethylphenol: 5-bromo-3,4-dimethylphenol was obtained in addition to 3-bromo-*p*-cresol. Again it is to be noted that the *m*-bromo isomers predominate.

Reaction of 4-bromo-2,6-dimethylphenol also gave mainly *meta* brominated products. In this case bromination occurs *ipso* to the 2-methyl group, followed by migration of the bromine to the adjacent 3-position. *o*-Bromination of 2,4,6-trisubstituted phenols to form 6-bromocyclohexa-2,4-dienones is a well established reaction (17). We have recently shown that 2,6-dimethylphenol, *o*-cresol, and other substituted *o*-cresols, are nitrated to form the corresponding 6-nitrocyclohexa-2,4-dienones.[4]

Experimental

Infrared spectra were obtained on Perkin–Elmer 283 and 1320 spectrometers. The ^{1}H nmr spectra at 90 and 250 MHz were determined using Perkin–Elmer R32 and Bruker WM250 spectrometers, respectively. The ^{13}C nmr at 15.1, 62.9, and 100.6 MHz were obtained on Nicolet-TT 14, Bruker WM250, and Bruker WH400 spectrometers, respectively. Mass spectra were obtained on a Hitachi Perkin–Elmer RMU 7 spectrometer. Combined gas chromatography and mass spectrometry was carried out on a Finnigan 3300 system. A Varian 5000 liquid chromatograph was used for analytical high pressure liquid chromatography. Analytical gas chromatography was performed on a Varian 3700 gas chromatograph, equipped with CDS 111 data system or Hewlett–Packard 3390A integrator. The 30 m glass capillary SE-54 and SP-2250 columns were from SUPELCO and the 25 m fused silica capillary SE30, OV-101, FFAP, and CW-20M columns from Varian. For preparative gas chromatography a Varian Aerograph 920 with a 3 m 3% SE-30 column was employed. Mixtures of bromo-*p*-cresol and of bromo-2,6-dimethylphenols were analysed on the SP-2250 and SE-54 or SE-30 columns. All other analyses, except that of the bromophenols, were carried out using the SE-54 column. In addition to the reported nmr data, appropriate infrared and mass spectral data, including the precise mass of the parent ion, were obtained for previously known bromophenols and methylbromophenols.

Phenol was obtained from British Drug Houses. 4-Bromo-, 4-methyl-, 2-bromo-4-methyl-, 2,6-dibromo-4-methyl-, 3,4-dimethyl-, and 2,4,6-trimethylphenol were from Aldrich, as were phloroglucinol dihydrate, methanesulphonic acid, and trifluoromethanesulphonic acid. 3-Bromo-, 2,4-dibromo-, 2,6-dibromo-, and 2,6-dimethylphenol were from Eastman. 2-Bromophenol was from Baker.

4-Bromo-2,6-dimethylphenol was obtained by bromination of 2,6-dimethylphenol in methylene chloride – pyridine. After recrystallization from ether it had mp 79°C (lit. (18) mp 79.5°C); ^{1}H nmr ($CDCl_3$) δ: 2.18 (s, CH_3), 4.55 (br s, O*H*), and 7.08 (s, 3-*H* and 5-*H*) ppm.

Addition of triflic acid (2 cm^3) to a stirred solution of 4-methyl-2,4,6-tribromocyclohexa-2,5-dienone (5.56 g) in methylene chloride (50 cm^3) at 0°C gave (<10 min) 2,3,6-tribromo-*p*-cresol. After crystallization from ether – methylene chloride the colourless crystals had mp 102°C (lit. (13, 19) mp 106°C, 101°C); ^{1}H nmr ($CDCl_3$) δ: 2.35 (s, CH_3), 5.87 (br s, O*H*), and 7.35 (s, 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 23.9 (*C*H$_3$), 107.8 (*C*-6), 113.7 (*C*-2), 126.2 (*C*-3), 132.3 (*C*-5), 132.6 (*C*-4), and 148.4 (*C*-1) ppm.

3-Bromomesitol was obtained by addition of triflic acid to a solution of 4-bromo-2,4,6-trimethylcyclohexa-2,5-dienone in $CDCl_3$ at −40°C. Crystallization of the worked-up product from pentane yielded colourless needles, mp 83°C (lit. (20–22) mp 81°C, 84.5°C, 82°C); ^{1}H nmr ($CDCl_3$) δ: 2.16 (s, 6-CH_3), 2.29 (s, CH_3), 2.33 (s, CH_3) 4.54 (s, O*H*), and 6.87 (s, 5-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 15.6 (6-*C*H$_3$), 16.3 (2-*C*H$_3$), 23.1 (4-*C*H$_3$), 121.8 (*C*-6), 123.8 (*C*-3), 125.2 (*C*-2), 129.5 (*C*-5), 129.7 (*C*-4), and 150.2 (*C*-1) ppm.

The literature procedure (12) for the preparation of 5-bromo-3,4-dimethylphenol was adapted for the preparation of 3-bromo-*p*-cresol. A mixture of 2,3,6-tribromo-*p*-cresol (3.5 g) and 54% HI (50 cm^3) was stirred and heated under reflux for 3 h. Work-up gave an oil (1.62 g) consisting of *p*-cresol (20%) and 3-bromo-*p*-cresol (80%). Preparative gc gave 3-bromo-*p*-cresol as a colourless oil which solidifed on standing, mp 55°C (lit. (23) mp 55.4°C); ^{1}H nmr ($CDCl_3$) δ: 2.28 (s, CH_3), 4.91 (s, O*H*), 6.17 (dd, J_{56} = 8 Hz, J_{26} = 2.5 Hz, 6-*H*), 7.03 (d, J_{26} = 2.5 Hz, 2-*H*), and 7.05 (d, J_{56} = 8 Hz, 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 21.7 (*C*H$_3$), 114.5 (*C*-6), 119.2 (*C*-2), 124.8 (*C*-3), 130.2 (*C*-4), 131.3 (*C*-5), and 153.3 (*C*-1) ppm.

Bromination of 3,4-dimethylphenol in aqueous acetic acid gave a mixture of 3,4-dimethylphenol (18%), and 6-bromo- (58%), 2-bromo- (14%), and 2,6-dibromo-3,4-dimethylphenol (10%). 6-Bromo-3,4-dimethylphenol crystallized and had mp 78–79°C (lit. (12) mp 79°C); ^{1}H nmr ($CDCl_3$) δ: 2.14 (s, 3-CH_3 and 4-CH_3), 5.21 (s, O*H*), 6.79 (s, 2-*H*), and 7.17 (s, 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 18.6 (3-*C*H$_3$) 19.5 (4-*C*H$_3$), 106.5 (*C*-6), 117.1 (*C*-2), 130.2 (*C*-4), 132.7 (*C*-5), 137.8 (*C*-3), and 150.0 (*C*-1) ppm.

1,3,5-Trimethoxybenzene was prepared by methylation of phloroglucinol with dimethyl sulfate. It had mp 53°C (lit.(24) mp 53°C); ^{1}H nmr ($CDCl_3$) δ: 3.72 and 6.06 ppm; ^{13}C nmr ($CDCl_3$) δ_C: 55.2 (O*C*H$_3$), 92.9 (*C*-2, *C*-4, *C*-6), and 161.6 (*C*-1, *C*-3, *C*-5) ppm. Bromination with *N*-bromosuccinimide in dimethylformamide gave 1-bromo-2,4,6-trimethoxybenzene, which was recrystallized from ether and had mp 98–99°C (lit.(25) mp 99°C); ^{1}H nmr ($CDCl_3$) δ: 3.79 (s, 4-OCH_3), 3.85 (s, 2- and 6-OCH_3), and 6.17 (s, 3-*H* and 5-*H*) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 55.4 (4-O*C*H$_3$), 56.2 (2- and

6-OCH_3), 91.6 (C-1, C-3, and C-5), 157.4 (C-4), and 160.5 (C-2 and C-6) ppm.

4-Bromo-2,4,6-trimethylcyclohexa-2,5-dienone (ref. 7a)

An ice-cold bromine solution prepared from bromine (1.6 g), potassium bromide (4.8 g), and water (to 20 cm^3) was added over 3 min, with stirring, to a solution of mesitol (1.36 g, 0.01 mol) and pyridine (5 drops) in ether (20 cm^3) at −15°C. The mixture was stirred for an additional 10 min, and allowed to warm to −10°C. The ethereal layer was extracted with aqueous sodium bicarbonate at −20°C, dried, and the ether evaporated at 0°C. Recrystallization of the residue from pentane at −25°C, followed by trituration with pentane, gave pale yellow crystals of the dienone which were dried under reduced pressure at 0°C. The purified dienone was dissolved at −20°C in $CDCl_3$ (5 cm^3) containing CH_2Cl_2 (50 mm^3). This gave a 0.71 mol dm^{-3} solution (calculated from the ^1H nmr spectrum using CH_2Cl_2 as internal standard) which was stored at −78°C and used in subsequent experiments. The solution was handled at −20°C or below. When the purified dienone was stored overnight as a solid at −20°C, it was found to have decomposed to 4-bromomethyl-2,6-dimethylphenol (74%), 3-bromomesitol (19%), and mesitol (3%), whereas the $CDCl_3$ solution at −20°C was stable for several days. 4-Bromo-2,4,6-trimethylcyclohexa-2,5-dienone had ^1H nmr ($CDCl_3$, −20°C) δ: 1.93 (s, 2- and 6-CH_3), 1.96 (s, 4-CH_3), and 6.89 (s, 3-H and 5-H) ppm; ^{13}C nmr ($CDCl_3$, −40°C) δ_C: 16.1 (2- and 6-CH_3), 30.7 (4-CH_3), 56.3 (C-4), 132.5 (C-2 and C-6), 146.2 (C-3 and C-5), and 186.2 (C-1) ppm. 4-Bromomethyl-2,6-dimethylphenol had ^1H nmr ($CDCl_3$) δ: 2.17 (s, 2- and 6-CH_3), 4.30 (br s, OH), 4.38 (s, CH_2Br), and 6.97 (s, 3- and 5-H) ppm.

2,4,6-Tribromo-4-methylcyclohexa-2,5-dienone

2,6-Dibromo-*p*-cresol (0.02 mol) was brominated in the presence of pyridine (2 cm^3), at −5°C, in a similar manner to mesitol. The bromine colour disappeared rapidly and a light yellow precipitate formed. After 10 min, the mixture was extracted with cold CH_2Cl_2, dried over $MgSO_4$, and the solvent removed at 10°C. The resulting yellow crystals (6.5 g), on recrystallization from CH_2Cl_2–ether at −20°C, gave pale yellow crystals of the dienone (4.6 g), mp 104°C (lit. (26, 27) mp 105°C); ir (KBr): 1673 (C=O), 1590, 1578, 1470, 1440, 1320, 1022, 910, and 690 (C—Br) cm^{-1}; ^1H nmr ($CDCl_3$, −20°C) δ: 2.02 (s, CH_3) and 7.54 (s, 3-H and 5-H) ppm; ^{13}C nmr ($CDCl_3$, −20°C) δ_C: 29.8 (CH_3), 54.3 (C-4), 121.0 (C-2 and C-6), and 150.4 (C-3 and C-5) ppm. The C-1 signal was not located.

Bromination of p*-cresol and 3,4,5-trimethylphenol (mild conditions)*

On a nmr scale, bromine solution (0.5 mmol in 200 mm^3) was added to the phenol solution (0.5 mmol in 200 mm^3) using the appropriate solvents. Some reactions were carried out on a larger scale (5 or 10 mmol). No dienone was observed in any of these reactions. Bromination of 3,4,5-trimethylphenol in ether–water–pyridine at −10°C gave only 2-bromo-3,4,5-trimethylphenol; ir (KBr): 3490 (OH), 1600, 1580, 1470, 1290, 1225 (C—O), 1200, 1155, 1100 1040, 990, and 900 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.15 (s, 4-CH_3), 2.20 (s, 5-CH_3), 2.35 (s, 3-CH_3), 5.66 (s, OH), and 6.73 (s, 6-H) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 16.0 (4-CH_3), 20.2 and 20.6 (3- and 5-CH_3), 111.1 (C-2), 114.6 (C-6), 128.0 (C-4), 135.5 (C-5), 136.7 (C-3), and 149.5 (C-1) ppm; ms m/e (relative intensity): 217 (12), 216 (97), 215 (25), 214.008 (100, M_r $^{12}C_9{}^1H_{11}{}^{79}Br^{16}O$: 213.999), 213 (18), 201 (55), 199 (53), 136 (13), 135 (59), 91 (27), 82 (11), 80 (13), 79 (14), and 77 (13).

Bromination of phenols in strong acids

Standard conditions of bromination, work-up, and analysis are described for *p*-cresol in triflic acid. Significant variations from these conditions are described in the text or in the footnotes to Table 1. Bromine (5 mmol) in triflic acid (10 cm^3) was added over 15 min, dropwise, with stirring, to a solution of *p*-cresol (0.54 g, 5 mmol) in triflic acid (5 cm^3). The bromine was immediately decolourized. After 30 min, the mixture was poured, with stirring, into ice-water (150 cm^3), neutralized with solid sodium bicarbonate (added in portions), saturated with solid NaCl, and extracted with ether (4 × 50 cm^3). After drying, evaporation gave an oil (0.88 g) which contained 3-bromo-*p*-cresol and other aromatic compounds. Analysis by temperature-programmed gc, using both 30 m SE-54 and 30 m SP-2250 capillary columns, and identification by both co-injection of authentic sample and by gc–ms (appropriate M + 1 peaks were obtained in all cases by chemical ionization) gave, in order of retention time in the indicated relative amount (mol%): *p*-cresol (26), 2-bromo-*p*-cresol (26), 3-bromo-*p*-cresol (28), 2,5-dibromo-*p*-cresol (14), 2,3-dibromo-*p*-cresol (1), 2,6-dibromo-*p*-cresol (5), and 2,3,6-tribromo-*p*-cresol (0.1). Identification of the 2,3-dibromo-*p*-cresol is tentative as an authentic sample was not available.

Bromine (5 mmol) in sulfuric acid (5 cm^3) was added dropwise over 5 min to a solution of *p*-cresol (5 mmol) in sulfuric acid (5 cm^3). The bromine decolourized slowly (1 h). The ^1H nmr spectrum showed that the isolated product (105 mg) was 56% 2,6-dibromo-*p*-cresol and 44% 2,3,6-tribromo-*p*-cresol.

Bromination of mesitol in sulfuric acid appeared to be incomplete even after 6 h at ambient temperature. Work-up gave 3,5-dibromomesitol (30%) mp 160–161°C; ir (KBr): 3370 (OH), 1563, 1375, 1300, 1240, 1183, 985, 955, and 810 cm^{-1}, ^1H nmr ($CDCl_3$) δ: 2.31 (s, 2- and 6-CH_3), 2.57 (s, 4-CH_3), and 4.72 (s, OH, disappeared on addition of D_2O) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 17.1 (2- and 6-CH_3), 25.1 (4-CH_3), 123.1 (C-3 and C-5), 125.3 (C-2 and C-6), 129.7 (C-4), and 150.2 (C-1) ppm; ms m/e (relative intensity): 296 (47), 295 (15), 294 (100), 293 (14), 291.910 (51, M_r $^{12}C_9{}^1H_{10}{}^{79}Br_2{}^{16}O$: 291.910), 215 (63), 213 (63), 134 (14) 109 (12), 106 (35), 105 (25), 103 (14), 97 (18), 95 (18), 91 (27), 83 (18), 82 (12), 81 (20), 80 (12), 79 (18), 78 (14), and 77 (27).

Bromination of phenol (5 mmol) in triflic acid gave an oil (0.80 g) which was composed of phenol (22) and 2-bromo- (4), 4-bromo- (60), 2,4-dibromo- (13), and 2,6-dibromophenol (1). *m*-Bromophenol and *p*-bromophenol were inseparable by gc on any of the columns listed above. The two phenols have characteristic ^1H nmr spectra and the tallest peak of *m*-bromophenol at δ 7.02 ppm is clearly separated from peaks of *p*-bromophenol. *m*-Bromophenol had ^1H nmr δ: 5.89 (s, OH), 6.75 (m, 6-H), and 7.02 (m, 2-H, 4-H, and 5-H) ppm. *p*-Bromophenol had ^1H nmr δ: 5.22 (br s, OH), 6.70 (d, $J_{23} = J_{56} = 8.5$ Hz, 2-H and 6-H), and 7.34 (d, 3-H and 5-H). The component of the third gc peak, identified as *p*-bromophenol, was separated by preparative gc and the ^1H nmr showed the absence of *m*-bromophenol. No *m*-bromophenol was detected by analytical hplc of the reaction product, using a Varian reverse phase MCH-10 column and methanol–water 25:75 v/v eluent. The *m*- and *p*-bromophenols were shown to separate under this condition.

2,5-Dibromo-*p*-cresol, from the products of bromination of 2-bromo-*p*-cresol in triflic acid, was collected by preparative glc and was crystallized from pentane as colourless crystals, mp 60–61°C (lit. (19) mp 61°C); ^1H nmr ($CDCl_3$) δ: 2.26 (s, CH_3), 5.37 (s, OH), 7.20 (s, 6-H), and 7.29 (s, 3-H) ppm.

Bromination of 3,4-dimethylphenol (5 mmol) in triflic acid yielded a colourless solid (0.98 g), consisting largely 5-bromo-3,4-dimethylphenol (by ^1H nmr). Analyses by gc with identification by co-injection of authentic samples and by gc–ms showed the following composition (mol%): 3,4-dimethylphenol (20) and 6-bromo- (2), 2-bromo- (2), 5-bromo- (69), 5,6-dibromo- (4), and 2,6-dibromo-3,4-dimethylphenol (3). Crystallization of the crude product from carbon tetrachloride at −20°C gave colourless needles of 5-bromo-3,4-dimethylphenol, mp 101–102°C (lit. (12, 28) mp 101°C, 103°C); ^1H nmr ($CDCl_3$) δ: 2.24 (s, 3- and 4- CH_3), 4.56 (s, OH), 6.60 (d, J = 2.5 Hz, 2-H), and 6.92 (d, J = 2.5 Hz 6-H) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 18.4 (3-CH_3), 21.5 (4-CH_3), 116.3 (C-2), 117.0 (C-6), 125.3 (C-5), 128.4 (C-4), and 139.3 (C-3) ppm.

Bromination of mesitol in triflic acid was carried out under the standard conditions except for an extended reaction time. After 3 h the solution was still reddish brown, indicative of the presence of unreacted bromine. Work-up gave a solid product (0.86 g) consisting of 3-bromomesitol (59%) and mesitol (41%) by ^1H nmr.

Reaction of bromodienones with acids

The formation of 2,3,6-tribromo-*p*-cresol, by addition of triflic acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

to 4-methyl-2,4,6-tribromocyclohexa-2,5-dienone, and of 3-bromomesitol by addition of triflic acid to 4-bromo-2,4,6-trimethylcyclohexa-2,5-dienone has been mentioned above. These reactions were also carried out for analytical purposes on a nmr scale. In a typical reaction five drops of triflic acid were added to a solution of 4-bromo-2,4,6-trimethylcyclohexa-2,5-dienone (61 mg, 0.28 mmol) in $CDCl_3$ (400 mm^3), containing as an internal nmr standard CH_2Cl_2, at −20°C. The solution turned reddish brown and a nmr spectrum recorded within 2 min showed that the dienone had aromatized completely to 3-bromomesitol. Work-up gave crystalline 3-bromomesitol (56 mg). A similar reaction with sulfuric acid (20 mm^3) as the reagent also gave 3-bromomesitol but no reaction occurred with trifluoroacetic acid (40 mm^3) over 10 min at 0°C.

When 2,4,6-tribromo-4-methylcyclohexa-2,5-dienone was used as substrate, 2,3,6-tribromo-*p*-cresol was obtained as the sole product on reaction with triflic acid and also with sulfuric acid.

A solution of hydrogen bromide (0.4 mmol) in ether (100 mm^3) was added to a solution of 4-bromo-2,4,6-trimethylcyclohexa-2,5-dienone (0.28 mmol) in $CDCl_3$ (400 mm^3) at −40°C. The mixture was warmed to −20°C and the reaction followed by nmr. All the dienone had disappeared when the first spectrum was measured (<1 min) to give ~22% mesitol and ~78% 3-bromomesitol. After 35 min there was 9% of mesitol and 91% of 3-bromomesitol and after 12 h only 3-bromomesitol was present.

Hydrogen bromide was passed for 10 s through a solution of the dienone at −40°C. The solution turned reddish brown. It was warmed to −20°C and ^1H nmr after 10 min showed 7% mesitol and 93% 3-bromomesitol. After 12 h at −20°C, the composition had changed to ~1% mesitol and ~99% 3-bromomesitol.

In a similar experiment in which hydrogen chloride was passed through the solution of the dienone at −55°C and the solution then warmed to −40°C for 10 min, the ^1H nmr spectrum showed that all of the dienone had reacted to give 3-bromomesitol (83%) and 3-chloromesitol (17%).

Aqueous hydroiodic acid (40 mm^3 of 55%) was added to a solution of the dienone in a nmr tube at −50°C and the mixture shaken well. The ^1H nmr spectrum, taken after 10 min at −50°C, showed that no dienone remained. Work-up gave mesitol, identified by ^1H nmr.

Reaction of 4-bromo-2,4,6-trimethylcyclohexa-2,5-dien-1-one with p-*cresol and 1,3,5-trimethoxybenzene*

p-Cresol (59 mm^2, 0.57 mmol) was added to a solution of the dienone (0.28 mmol) in $CDCl_3$ (400 mm^3) in a nmr tube at −40°C and the temperature then raised to −20°C. In 5 min the dienone was completely debrominated to give mesitol and 2-bromo-*p*-cresol.

1,3,5-Trimethoxybenzene (105 mg, 0.63 mmol) in $CDCl_3$ (300 mm^3) was added to a standard solution of the dienone (0.31 mmol in 400 mm^3) in a nmr tube at −40°C. The resulting solution was warmed to −20°C and the reaction was followed by ^1H nmr. Mesitol and 2-bromo-2,4,6-trimethoxybenzene were formed to the extent of ~45% in 10 min and 96% in 25 min.

A solution of 1,3,5-trimethoxybenzene (0.16 mmol) and the bromodienone (0.16 mmol) in $CDCl_3$ (400 mm^3) did not react in 30 min at −40°C. Hydrogen bromide was then passed for 15 s. The ^1H nmr spectrum measured within 5 min showed that complete reaction to give mesitol and bromotrimethoxybenzene had occurred. Similarly, addition of triflic acid (20 mm^3) in $CDCl_3$ (100 mm^3) to a solution of 1,3,5-trimethoxybenzene (0.53 mmol) and the bromodienone (0.31 mmol) at −50°C resulted in complete reaction to give mesitol and bromotrimethoxybenzene. 3-Bromomesitol was not detected by nmr. However, addition of triflic acid (150 mm^3) in $CDCl_3$ (150 mm^3) to a solution of the trimethoxybenzene 0.53 mmol) and the bromodienone (0.31 mmol) in $CDCl_3$ (500 mm^3) at −50°C resulted in part of the dienone (78%) rearranging to 3-bromomesitol and part of it debrominating (22%) to yield bromotrimethoxybenzene and mesitol.

The bromodienone did not react with trimethoxybenzene in $CDCl_3$ at −40°C. CD_3OD (75 mm^3) was added to a solution of trimethoxybenzene (59 mg, 0.35 mmol) and the dienone (0.23 mmol) in $CDCl_3$ (400 mm^3) at −50°C and the solution warmed to −40°C. In 30 min all of the dienone had reacted to give mesitol and bromotrimethoxybenzene.

Isomerization and disproportionation of bromophenols

Standard conditions of isomerization are described for 2-bromo-*p*-cresol. Significant variations from these conditions are described in the text or in the footnotes to Table 1. Tetramethylammonium bromide (309 mg, 2 mmol) was added to a stirred solution of 2-bromo-*p*-cresol (1 mmol) in triflic acid (5 cm^3) contained in a closed system to prevent the escape of HBr. After 24 h, the mixture was poured into ice-water (50 cm^3) and neutralized with solid $NaHCO_3$. The solution was saturated with NaCl and extracted with ether (3 × 50 cm^3). The combined extract solution was washed with saturated NaCl solution (50 cm^3) and dried ($MgSO_4$). Removal of solvent gave an oil (175 mg) whose composition (by gc and gc−ms) is listed in Table 1.

The reaction of 2-bromo-*p*-cresol was repeated in the presence of 3,4-dimethylphenol (2 mmol). Work-up after 24 h gave a product (412 mg) of composition (mol%): *p*-cresol (19), 3,4-dimethylphenol (62), 3-bromo-*p*-cresol (12), 5-bromo-3,4-dimethylphenol (4), plus unidentified products (total ~2%).

4-Bromo-2,6-dimethylphenol (1 mmol) was reacted with tetramethylammonium bromide in triflic acid and gave a solid product (196 mg) containing (mol%): 2,6-dimethylphenol (17) and 3-bromo- (56), 4-bromo- (5), and 3,5-dibromo-2,6-dimethylphenol (22). The components of the second and third peaks were separated by preparative gc. 3-Bromo-2,6-dimethylphenol (from the second peak) crystallized from pentane to give colourless needles, mp 61°C (lit. (18) mp 60−61°C); ^1H nmr ($CDCl_3$) δ 2.16 (s, 6-C*H*$_3$), 2.30 (s, 2-C*H*$_3$), 4.58 (s, O*H*), 6.81 (d, J = 8 Hz, 5-*H*), and 7.04 (d, J = 8 Hz, 4-*H*) ppm. The identity of 3,5-dibromo-2,6-dimethylphenol (from the fourth peak) was confirmed by mp, ^1H nmr, and ^{13}C nmr. Crystallization from $CHCl_3$ gave colourless crystals, mp 135°C (lit. (29) mp 132−133°C); ^1H nmr ($CDCl_3$) δ: 2.26 (s, 2- and 6-C*H*$_3$), 4.03 (br s, O*H*), and 7.39 (s, 4-*H*) ppm; ^{13}C nmr ($CDCl_3$, 100.6 MHz) δ_C: 15.8 (2- and 6-*C*H_3), 122.8 and 122.9 (*C*-2, *C*-3, *C*-5, and *C*-6), 127.7 (*C*-4), and 152.9 (*C*-1) ppm. 3,4-Dibromo-2,6-dimethylphenol has mp 86°C (ref. 30) and a less symmetrical ^1H nmr spectrum (ref. 31).

Reaction of 2-bromophenol (1 mmol) in triflic acid containing tetramethylammonium bromide gave product (162 mg) consisting of (mol%): phenol (24) and 2-bromo- (12), 4-bromo- (32), 2,4-dibromo- (29), and 2,6-dibromophenol (3). 4-Bromophenol was separated by preparative gc and found by ^1H nmr to contain no 3-bromophenol.

*Preparation of 3-bromo-*p*-cresol*

Liquid bromine (5 mmol) was added to a stirred solution of *p*-cresol (5 mmol) in triflic acid (5 cm^3) in a closed system. After 24 h, tetramethylammonium iodide (3 mmol) was added. After a further 30 min, work-up gave product (0.76 g) consisting of (mol%): 3-bromo-*p*-cresol (73), *p*-cresol (24), and dibromo-*p*-cresol (3). Pure 3-bromo-*p*-cresol was isolated from the mixture as a colourless solid by preparative gc.

Preparation of some deuterium labelled 9- and/or 10-oxygenated derivatives of geraniol, geranial, nerol, and neral[1]

J. BALSEVICH

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Sask., Canada S7N 0W9

Received October 26, 1982

J. BALSEVICH. Can. J. Chem. **61**, 1053 (1983).

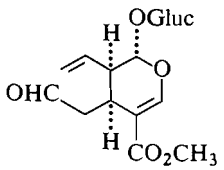
The preparation of various deuterium labelled 9- and/or 10-oxygenated derivatives of geraniol, geranial, nerol, and neral is described. Wittig reaction of the tetrahydropyranyl ethers of (*E*)- and (*Z*)-1,1-dideutero-6-(triphenylphosphonium)-3-methyl-2-hexen-1-ol iodides (**23** and **24**) with the tetrahydropyranyl ethers of hydroxyacetone and 1,3-dihydroxyacetone afforded, after deprotection, C-1 dideuterated 9-hydroxygeraniol, 9-hydroxynerol, 9,10-dihydroxygeraniol, and 9,10-dihydroxynerol of high isomeric purity. Selective oxidation of these products allowed for the preparation of the corresponding derivatives possessing an aldehyde functionality at C-9 or C-1 and C-9. Wittig reaction of **23** and **24** with pyruvaldehyde dimethyl acetal followed by acidic hydrolysis afforded C-1 dideuterated 10-oxogeraniol and 10-oxonerol, oxidation of which yielded C-1 deuterated 10-oxogeranial and 10-oxoneral. Wittig reaction of (*E*)- and (*Z*)-1,1-dideutero-6-(triphenylphosphonium)-3-methyl-2-hexen-1-ol iodides (**49** and **50**) with 1,1,3,3-tetraethoxyacetone afforded C-1 dideuterated 9,9,10,10-tetraethoxygeraniol and 9,9,10,10-tetraethoxynerol, oxidation of which provided C-1 deuterated 9,9,10,10-tetraethoxygeranial and 9,9,10,10-tetraethoxyneral.

J. BALSEVICH. Can. J. Chem. **61**, 1053 (1983).

On décrit la préparation de plusieurs dérivés oxygénés en position 9 et/ou 10 du géraniol, du géranial, du nérol et du néral marqués au deutérium. Une réaction de Wittig des éthers tétrahydropyrannyles des iodures du dideutéro-1,1 (triphénylphosphonium)-6 méthyl-3 hexène-2 ol-1 (*E*) et (*Z*) (**23** et **24**) avec les éthers tétrahydropyrannyles de l'hydroxyacétone et de la dihydroxy-1,3 acétone conduit, après déprotection, aux hydroxy-9 géraniol, hydroxy-9 nérol, dihydroxy-9,10 géraniol et dihydroxy-9,10 nérol dideutérés en C-1 en une grane pureté isomérique. L'oxydation sélective de ces produits permet de préparer les dérivés correspondants ayant une fonction aldéhyde en C-9 ou en C-1 et en C-9. La réaction de Wittig des composés **23** et **24** avec le diméthyle acétal de la pyruvaldéhyde, suivie d'une hydrolyse acide, conduit à l'oxo-10 géraniol et à l'oxo-10 nérol dideutérés en C-1. Par oxydation, ces composés donnent l'oxo-10 géranial et l'oxo-10 néral dideutérés en C-1. La réaction de Wittig des iodures de dideutéro-1,1 (triphénylphosphonium)-6 méthyl-3 hexène-2 ol-1 (*E*) et (*Z*) (**49** et **50**) avec la tétraéthoxy-1,1,3,3 acétone permet d'obtenir le tétraéthoxy-9,9,10,10 géraniol et le tétraéthoxy-9,9,10,10 nérol dideutérés en C-1 qui, par oxydation fournissent le tétraéthoxy-9,9,10,10 géranial et le tétraéthoxy-9,9,10,10 néral deutérés en C-1.

[Traduit par le journal]

In the biosynthesis of monoterpene indole alkaloids, the "monoterpene portion" of the alkaloids has been shown to arise from the seco-iridoid glucoside secologanin (**1**) (1, 2) which in turn arises, via the cyclopentanoid derivative loganin (**2**) (3), from the acyclic monoterpenes geraniol (**3**) and nerol (**4**)



1

3 R = CH_2OH, R' = H
4 R = H, R' = CH_2OH

(4–6). The exact pathway between geraniol/nerol and loganin, however, remains uncertain. Previously, tracer studies had established that 10-hydroxygeraniol (**5**) and 10-hydroxynerol (**6**) were incorporated into loganin and indole alkaloids in *Cathar-*

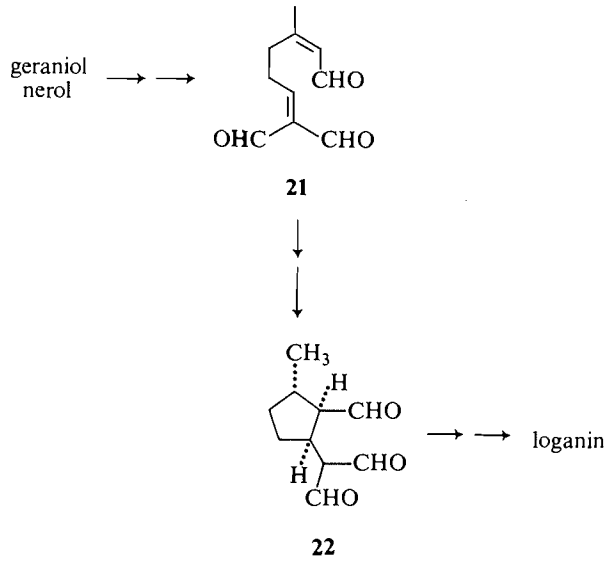
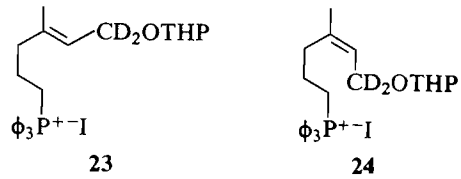


SCHEME 1

anthus roseus plants (7, 8). More recently, mixtures consisting of 10-oxogeraniol (**7**)/10-oxonerol (**8**), 10-hydroxygeranial (**9**)/10-hydroxyneral (**10**), and 10-oxogeranial (**11**)/10-oxoneral (**12**) were also shown to be incorporated (9), while such derivatives as 10-hydroxycitronellol (**13**), 10-hydroxycitronellal (**14**), 10-oxocitronellol (**15**), citronellol (**16**), citronellal (**17**), linalool (**18**), 10-hydroxylinalool (**19**), and iridodial (**20**) were not (7, 8, 10). These results coupled with the observation that an isotopic label at C-9 of geraniol becomes scrambled between C-9 and C-10 on conversion to loganin (3, 7, 11, 12) led to the hypothesis that the biosynthesis of loganin involves conversion of geraniol and nerol via several oxidative steps (and appropriate isomerizations) to 9,10-dioxoneral (**21**). Cyclization of **21** (to afford **22**) followed by further elaboration would then lead to loganin (Scheme 1) (7, 13).

In spite of the obtained evidence, however, definitive information regarding the importance of double bond geometries or direct evidence supporting the role of 9,10-oxygenated geraniol (nerol) derivatives is lacking. With the development of tissue culture methodology (which offers such advantages over the use of intact plants as having fewer problems associated with metabolite transport as well as greater control of experimental conditions) it was deemed that such questions could be resolved. Recently, it had been determined that 10-hydroxygeraniol and 10-hydroxynerol (labelled with deuterium) could be incorporated into indole alkaloids to the extent of 80% when a cell suspension culture of *C. roseus* was used for the tracer experiments (14). This incorporation was two orders of magnitude greater than that previously observed using intact plants, and augered well for further studies; however, a number of geraniol, geranial, nerol, and neral derivatives oxygenated at the 9 and/or 10 positions (i.e. hypothetical alkaloid precursors or analogs thereof) were required. Accordingly, the synthesis of these derivatives, possessing a deuterium label, was undertaken and the results presented here.

It was envisioned that the target compound could be conveniently prepared by Wittig reaction of isomerically pure phosphonium salts **23** and **24** with appropriately oxygenated derivatives of acetone (followed by deprotection and further functional group manipulation as required). To this end, 5-chloro-2-pentanone was coupled by Wittig–Horner reaction



with trimethylphosphonoacetate to yield a mixture of (*E*)- and (*Z*)-methyl 6-chloro-3-methyl-2-hexenoates (**25** and **26**, *E*/*Z* = 1.8:1) in 91% yield. The assignments of stereochemistry were achieved by examination of the proton magnetic resonance spectra which exhibited characteristic signals for the olefinic methyl groups at δ 2.16 for the (*E*)-isomer **25** and δ 1.87 for the (*Z*)-isomer **26** (7). Separation, by spinning band distillation, afforded the individual esters in >98% isomeric purity as determined by glc analysis. Reduction of **25** and **26**

25 R = CO_2CH_3
27 R = CD_2OH
29 R = CD_2OTHP

26 R = CO_2CH_3
28 R = CD_2OH
30 R = CD_2OTHP

with lithium aluminum deuteride furnished the allylic alcohols **27** and **28** in 96% and 93% yields respectively. Alcohols **27** and **28** were converted to the tetrahydropyranyl ethers **29** (98% yield) and **30** (95% yield) via standard means and then treated with triphenylphosphine and sodium iodide in refluxing acetonitrile to afford the desired phosphonium salts **23** (86% yield) and **24** (89% yield) as crystalline solids.

Having the desired phosphonium salts in hand, their Wittig reactions with various substrates were examined. Wittig reaction of **23** with the tetrahydropyranyl ether of hydroxyacetone under "salt free conditions" (15) yielded, after removal of the protecting groups, 1,1-dideutero-9-hydroxygeraniol (**31**) in 85% yield. Correspondingly, **24** yielded 1,1-dideutero-9-hydroxynerol (**32**) in 91% yield. The Wittig reactions were highly stereoselective with only 3% contamination by the 10-hydroxy isomers.

Oxidation of **31** and **32** with manganese dioxide gave, after purification by thin-layer chromatography, 1,1-dideutero-9-oxogeraniol (**33**) and 1,1-dideutero-9-oxonerol (**34**) contaminated with ca. 5% of the 10-oxo isomers. The chemical shifts of the aldehyde protons of **33** and **34** (δ 10.13 and δ 10.09)

31 R = CD_2OH, R' = CH_2OH
33 R = CD_2OH, R' = CHO
35 R = CDO, R' = CHO

32 R = CD_2OH, R' = CH_2OH
34 R = CD_2OH, R' = CHO
36 R = CDO, R' = CHO

were consistent with the 9-oxo assignments (8). The observed preference for oxidation of the C-9 over the C-1 hydroxy groups was likely the result of the deuterium isotope effect wherein the rate-determining step of the oxidation would be the breaking of the C—H (C—D) bond.

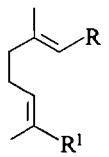
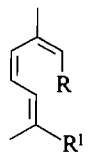
Further oxidation of **33** and **34** using barium manganate afforded dialdehydes **35** and **36** in 71% and 75% yields respectively. In the case of **35**, no significant isomerization was noted during this oxidation. In the case of **36** a small amount (ca. 2%) of isomerization of the 2,3 double bond was observed.

For the preparation of some 10-oxygenated derivatives, the phosphonium salts **23** and **24** were coupled by Wittig reaction with the dimethyl acetal of pyruvaldehyde. Although the 9-acetal derivatives were formed initially, acidic hydrolysis of the protecting groups was accompanied by isomerization to



37 R = CD_2OH, R' = CHO
39 R = CDO, R' = CHO

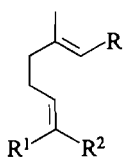


38 R = CD_2OH, R' = CHO
40 R = CDO, R' = CHO

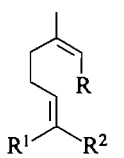
afford 1,1-dideutero-10-oxogeraniol (**37**) contaminated with 2% of the 9-oxo isomer and 1,1-dideutero-10-oxonerol (**38**) contaminated with 7% of the 9-oxo isomer. The chemical shifts of the aldehyde protons of **37** and **38** (δ 9.36 and δ 9.38) were consistent with the 10-oxo assignments (8).

Further oxidation of **37** and **38** employing barium manganate afforded the dialdehydes **39** and **40**. The isomeric purity of these derivatives was essentially unchanged.

For the preparation of some 9,10-oxygenated derivatives two approaches were utilized. In the first, phosphonium salts **23** and **24** were coupled by Wittig reaction with ditetra-



41 R = CD_2OH, R' = R^2 = CH_2OH
43 R = CD_2OH, R' = CHO, R^2 = CH_2OH
45 R = CD_2OH, R' = CH_2OH, R^2 = CHO

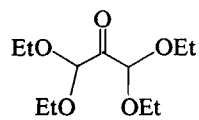


42 R = CD_2OH, R' = R^2 = CH_2OH
44 R = CD_2OH, R' = CHO, R^2 = CH_2OH
46 R = CD_2OH, R' = CH_2OH, R^2 = CHO

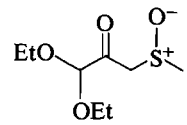
hydropyranyl ether of 1,3-dihydroxyacetone. After removal of the protecting groups 1,1-dideutero-9,10-dihydroxygeraniol (**41**) and 1,1-dideutero-9,10-dihydroxynerol (**42**) were obtained in 56% and 63% yields respectively.

Oxidation of triols **41** and **42** with manganese dioxide in tetrahydrofuran at 0°C was reasonably regioselective yielding 1,1-dideutero-9-oxo-10-hydroxygeraniol (**43**) contaminated with 12% of the 9-hydroxy-10-oxo isomer **45** and 1,1-dideutero-9-oxo-10-hydroxynerol (**44**) contaminated with 14% of the isomer **46**. The assignments of stereochemistry were based on the chemical shifts of the aldehyde protons. The major components of the two oxidations (i.e. **43** and **44**) exhibited resonances at δ 10.10 and δ 10.02 while the minor components (**45** and **46**) exhibited resonances at δ 9.41 and δ 9.37 (8). The yields of the oxidations were 72% and 66% respectively. Interestingly, when manganese dioxide in dichloromethane at ambient temperatures was used, poorer yields and lower regioselectivity were observed.

Attempted oxidation of **43** with barium manganate gave poor recovery of a complex mixture of products and was not further pursued, rather an alternative approach to other 9,10 oxygenated derivatives was employed. The second approach involved preparation of 1,1,3,3-tetraethoxyacetone (**47**) (16, 17) as the

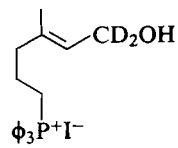


47

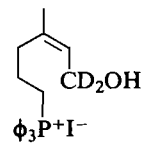


48

ketonic substrate for the Wittig reaction. Accordingly, ethyl diethoxyacetate was reacted with dimsyl sodium in dimethyl sulfoxide to furnish β-ketosulfoxide **48**. Treatment of **48** with mercuric oxide and boron trifluoride in refluxing ethanol effected Pummerer rearrangement and ethanolysis to yield **47**.[2]

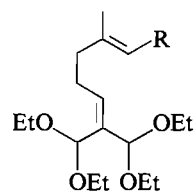


49

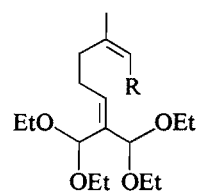


50

Wittig reaction of **47** (18) with phosphonium salts **49** and **50** (prepared from the chloroalcohols **27** and **28** by reaction with triphenylphosphine and sodium iodide in refluxing acetonitrile as before) furnished 1,1-dideutero-9,9,10,10-tetraethoxygeraniol (**51**) in 71% yield and 1,1-dideutero-9,9,10,10-tetraethoxynerol (**52**) in 55% yield.



51 R = CH_2OH
53 R = CDO



52 R = CH_2OH
54 R = CDO

Oxidation of **51** and **52** with barium manganate yielded the corresponding aldehydes **53** and **54**. Attempts to hydrolyse compounds **51** to **54** to afford the corresponding 9,10 dialdehydes were not successful, likely due to the instability of the vinyl dialdehyde system. This result, however, does not preclude the use of these derivatives for tracer experiments as the possibility of in vitro generation of the 9,10-dialdehyde functionality remains.

[2]The previous preparation of **47** (16, 17) involves reaction of pyruvaldehyde diethylacetal with ethyl nitrite in the presence of ethanolic hydrogen chloride, however, the product is generally contaminated with 5–10% of the corresponding ketal. The procedure employed gave essentially pure **47**.

Experimental

Melting points (mp) were obtained on a Koffler block and are uncorrected. Gas–liquid chromatography (glc) was carried out with a Hewlett–Packard model 5710A gas chromatograph equipped with an 8.6 meter capillary glass column containing OV-101. Ultraviolet (uv) spectra were obtained with samples in 95% ethanol using a Beckman model 35 spectrophotometer; absorption maxima are quoted in nanometers with log ϵ values in brackets. Infrared (ir) spectra were obtained with samples as neat films on sodium chloride plates using a Varian model 257B spectrophotometer; absorption maxima are quoted in centimeters^{-1}. Proton magnetic resonance (^{1}Hmr) spectra were obtained with samples in deuterochloroform (unless otherwise noted) using a Varian model EM-390 spectrometer. The position of peaks is listed in the δ scale relative to tetramethylsilane which was used as internal standard. Low resolution mass spectra (ms) were obtained on a Finnegan model 4000 spectrometer run at 70 eV. Microanalyses were performed by the Spang Microanalytical Laboratory, Eagle Harbor, Michigan, U.S.A. For thin-layer chromatography, Whatman PLK5F precoated silica gel plates were employed. For column chromatography, Aldrich silica gel, grade 12, 28–200 mesh was used.

Lithium aluminum deuteride and n-butyllithium were obtained from the Alfa Chemical Co. Manganese dioxide, barium manganate, and phenyllithium were obtained from the Aldrich Chemical Co. Potassium hexamethyldisilazide was prepared by the reaction of potassium hydride with hexamethyldisilazane in tetrahydrofuran. The tetrahydropyranyl ethers of hydroxyacetone (acetol) and 1,3-dihydroxyacetone were prepared from the alcohols via standard means. Anhydrous tetrahydrofuran was obtained by distillation from the sodium ketyl of benzophenone. Spinning band distillation was carried out with a Kontes model K-500400 spinning band micro still. Isomeric purities were determined from glc analyses or ^{1}Hmr spectra.

(E)-and (Z)-Methyl 3-methyl-6-chloro-2-hexenoates (25 and 26)

A suspension of sodium hydride (4.7 g of 50% NaH/mineral oil, 0.098 mol) in anhydrous tetrahydrofuran (150 mL) at 0°C was treated with a solution of trimethylphosphonoacetate (18.2 g, 0.099 mol) in dimethyl sulfoxide (25 mL) at a dropwise rate over 20 min. After a further 20 min 5-chloro-2-pentanone (10 mL, 0.087 mol) was added. The reaction mixture was stirred for 24 h at ambient temperature, diluted with petroleum ether (100 mL), and washed with 5% sodium bicarbonate solution (5 × 50 mL). The combined aqueous portion was back-extracted with petroleum ether (1 × 50 mL). The combined organic portion was dried (Na_2SO_4) and the solvent removed *in vacuo*. The residue was distilled at 10 Torr to afford a mixture of **25** and **26** (1.8:1, 13.92 g, 91%) as a colorless liquid; bp 112–119°C at 10 Torr. The two isomers were separated by spinning band distillation at 0.5 Torr (3×) yielding **25** and **26** in greater than 98% isomeric purity. (*E*)-Methyl 3-methyl-6-chloro-2-hexenoate (**25**); bp: 65°C at 0.5 Torr; glc retention time (80°C): 3.97 min; uv λ_{max}: 218 (4.41); ir ν_{max}: 1718, 1650, 1432, 1224, 1151, 1144; ^{1}Hmr δ: 5.67 (1H, bs), 3.65 (3H, s), 3.48 (2H, t, J = 6 Hz), 2.29 (2H, m), 2.16 (3H, d, J = 1.3 Hz), 1.96 (2H, m); ms m/e: 178 (^{37}Cl, M$^+$, 5%), 176 (^{35}Cl, M$^+$, 16%), 145 (39%), 127 (69%), 114 (100%), 95 (44%). (*Z*)-Methyl 3-methyl-6-chloro-2-hexenoate (**26**); bp: 61°C at 0.5 Torr; glc retention time (80°C): 3.07 min; uv λ_{max}: 217 (4.20); ir ν_{max}: 1716, 1648, 1430, 1224, 1152; ^{1}Hmr δ: 5.70 (1H, bs), 3.64 (3H, s), 3.52 (2H, t, J = 6 Hz), 2.73 (2H, m), 1.93 (2H, m), 1.87 (3H, d, J = 1.4 Hz); ms m/e: 178 (^{37}Cl, M$^+$, 7%), 176 (^{35}Cl, M$^+$, 20%), 145 (33%), 127 (100%), 114 (55%), 95 (72%). *Anal.* (mixture of *E* and *Z* isomers) calcd. for $C_8H_{13}O_2Cl$: C 54.39, H 7.42, Cl 20.07; found: C 54.43, H 7.42, Cl 20.10.

(E)-1,1-Dideutero-3-methyl-6-chloro-2-hexen-1-ol (27)

A solution of ester **25** (18 g, 0.10 mol) in anhydrous ether (150 mL) was treated with small portions of lithium aluminum deuteride (4.2 g, 0.10 mol) over a period of 30 min. After stirring for a further 4 h at ambient temperature, water (20 mL) was cautiously added over a period of 30 min. The reaction mixture was filtered and the solvent removed *in vacuo* to give **27** as a colorless liquid (14.5 g, 96%); ir ν_{max}: 3350, 2190, 2085, 1664, 1078; ^{1}Hmr δ: 5.44 (1H, bs), 3.51 (3H, t, J = 6 Hz), 2.3–1.7 (4H, m), 1.66 (3H, d, J = 1.3 Hz); ms m/e: 152 (^{37}Cl, M$^+$, 1.4%), 150 (^{35}Cl, M$^+$, 5.5%), 135 (15%), 133 (36%), 97 (15%), 83 (18%), 73 (100%). *Anal.* (of nondeuterated analog) calcd. for $C_7H_{13}OCl$: C 56.57, H 8.82, Cl, 23.85; found: C 56.32, H 8.77, Cl 23.75.

(Z)-1,1-Dideutero-3-methyl-6-chloro-2-hexen-1-ol (28)

A solution of ester **26** (13 g, 0.07 mol) in anhydrous ether (130 mL) was treated with lithium aluminum deuteride (3 g, 0.07 mol) as above to afford alcohol **28** as a colorless liquid (10.2 g, 93%); ir ν_{max}: 3350, 2190, 2082, 1664, 1078; ^{1}Hmr δ: 5.42 (1H, bs), 3.45 (3H, t, J = 6 Hz), 2.4–1.7 (4H, m), 1.71 (3H, d, J = 1.3 Hz); ms m/e: 152 (^{35}Cl, m$^+$, 0.9%), 150 (^{35}Cl, m$^+$, 3.1%), 135 (7%), 133 (13%), 97 (15%), 83 (30%), 73 (100%). *Anal.* calcd. for $C_7H_{11}D_2OCl$: C 55.83, Cl 23.54; found: C 55.11, Cl 23.25.

(E)-Tetrahydropyranyl ether 29

A solution of alcohol **27** (14.5 g, 0.096 mol) and *p*-toluenesulfonic acid monohydrate (300 mg, 1.6 mmol) in ether (100 mL) was treated with dihydropyran (11 mL, 0.13 mol) at a dropwise rate over a period of 2 h. The reaction mixture was stirred for a further 18 h at ambient temperature and then washed with 1 *N* sodium hydroxide solution (3 × 30 mL) and brine (2 × 30 mL). After drying (Na_2SO_4) the solvent was removed *in vacuo* to afford **29** as a colorless liquid (22 g, 98%); ir ν_{max}: 2155, 2075, 1662, 1020, 724; ^{1}Hmr δ: 5.39 (1H, bs), 4.59 (1H, t, J = 3 Hz), 3.9 (1H, m), 3.5 (1H, m), 3.49 (2H, t, J = 6 Hz), 2.4–1.4 (10H, m), 1.67 (3H, bs); ms m/e: 234 (M$^+$, 0.1%), 133 (33%), 85 (100%).

(Z)-Tetrahydropyranyl ether 30

A solution of alcohol **28** (9.5 g, 0.06 mol) and *p*-toluenesulfonic acid monohydrate (200 mg, 1.1 mmol) in ether (70 mL) was treated with dihydropyran (7.3 mL, 0.09 mol) as above to afford **30** as a colorless liquid (14 g, 95%); ir ν_{max}: 2158, 2074, 1661, 1020; ^{1}Hmr δ: 5.43 (1H, bs), 3.49 (1H, t, J = 6 Hz), 2.5–1.4 (10H, m), 1.75 (3H, bs); ms m/e: 234 (M$^+$, 0.1%), 133 (24%), 85 (100%). *Anal.* calcd. for $C_{12}H_{19}D_2O_2Cl$: C 61.39, Cl 15.12; found: C 61.73, Cl 15.02.

(E)-Phosphonium salt 23

A mixture of **29** (21.5 g, 0.092 mol), triphenylphosphine (25 g, 0.095 mol), and sodium iodide (27 g, 0.18 mol) in acetonitrile (60 mL) was heated at reflux. After 27 h the reaction mixture was cooled to 0°C, diluted with dichloromethane (130 mL), and filtered. The solvent was removed *in vacuo* and the resultant gum was washed with ether (3 × 50 mL), dissolved in acetone (50 mL), treated with ether (130 mL), and allowed to stand at 0°C for several days whereupon crystallization occurred. The solid mass was pulverized, filtered, further washed with ether and water, and dried *in vacuo* at 100°C to afford **23** as an off-white crystalline solid (48 g, 86%), mp 149–151°C (crystals soften at 119°C); ^{1}Hmr δ: 7.8 (15H, m), 5.35 (1H, bs), 4.55 (1H, m), 4.0–3.3 (4H, m), 2.73 (2H, t, J = 7.5 Hz), 2.2–1.3 (8H, m), 1.54 (3H, bs). *Anal.* calcd. for $C_{30}H_{37}D_2IOP$: C 61.23, I 21.57; found: C 61.40, I, 21.65.

(Z)-Phosphonium salt 24

A mixture of **30** (8 g, 0.034 mol), triphenylphosphine (9.4 g, 0.036 mol) and sodium iodide (10.2 g, 0.068 mol) in acetonitrile (25 mL) was heated at reflux. After 27 h the reaction mixture was cooled to 0°C, diluted with dichloromethane (100 mL), and filtered. The solvent was removed *in vacuo* and the resultant gum washed with ether (3 × 4 mL). The residue was treated with acetone (40 mL) and let stand at 0°C for 4 h whereupon cyrstallization occurred. The solid mass was pulverized, filtered, washed with ether, and dried *in vacuo* at 100°C to afford **24** as a white crystalline solid (17.8 g, 89%), mp 187–188°C; ^{1}Hmr δ: 7.8 (15H, m), 5.45 (1H, bs), 4.57 (1H, m), 4.0–3.2 (4H, m), 2.43 (2H, t, J = 7.5 Hz), 2.0–1.2 (8H, m), 1.59 (3H, bs). *Anal.* calcd. for $C_{30}H_{37}D_2IOP$: C 61.23, I 21.57; found: C 61.27, I 21.48.

1,1-Dideutero-9-hydroxygeraniol (31)

A suspension of phosphonium salt **23** (2.8 g, 4.76 mmol) in anhydrous tetrahydrofuran/hexamethylphosphoramide (10 mL/1 mL) under a nitrogen atmosphere was treated with a solution of potassium hexamethyldisilylazide in tetrahydrofuran (4.8 mL of 1 *M* solution, 4.8 mmol). After 15 min at ambient temperature the reaction mixture was cooled to −78°C and treated with the tetrahydropyranyl ether of hydroxyacetone (0.7 g, 4.7 mmol). The cooling bath was removed and the reaction mixture allowed to warm to ambient temperature. After a further 3 h at ambient temperature the reaction mixture was diluted with petroleum ether (10 mL) and filtered through a short column of silica gel using petroleum ether as eluent. After evaporation of the solvent, the residue was dissolved in methanol (50 mL), treated with *p*-toluenesulfonic acid monohydrate (80 mg), and stirred at ambient temperature for 18 h. Sodium hydroxide solution (2 *M*, 0.25 mL) was added and the solvent removed *in vacuo*. The residue was chromatographed on silica gel using ether as eluent to afford **31** (contaminated with 3% of the 10-hydroxy isomer) as a colorless liquid (690 mg, 85%); ir ν_{max}: 3340, 2180, 2090, 1080; ^{1}Hmr δ: 5.37 (1H, bs), 5.22 (1H, t, J = 7 Hz), 4.04 (2H, s), 2.70 (1H, bs), 2.2 (4H, m), 1.76 (3H, bs), 1.65 (3H, bs); ms m/e: 154 (M^+ − 18, 0.5%), 136 (3.2%), 121 (15%), 84 (28%), 70 (35%), 43 (100%). *Anal.* calcd. for $C_{10}H_{16}D_2O_2$: C 69.74; found: C 69.75.

1,1-Dideutero-9-hydroxynerol (32)

Reaction of phosphonium salt **24** (2 g, 3.4 mmol) with potassium hexamethyldisilazide (3.4 mL of 1 *M* solution in THF) and the tetrahydropyranyl ether of hydroxyacetone (0.5 g, 3.4 mmol) as above afforded **32** (contaminated with 3% of the 10-hydroxy isomer) as a colorless liquid (530 mg, 91%); ir ν_{max}: 3340, 2160, 2078, 1662, 1080; ^{1}Hmr δ: 5.40 (1H, bs), 5.26 (1H, t, J = 6.5 Hz), 4.02 (2H, s), 2.1 (4H, m), 1.77 (3H, bs), 1.71 (3H, bs); ms m/e: 154 (M^+ − 18, 0.3%), 139 (5%), 136 (5%), 121 (16%), 84 (27%), 70 (40%), 43 (100%).

1,1-Dideutero-9-oxogeraniol (33)

A solution of diol **31** (200 mg, 1.16 mmol) in dichloromethane (18 mL) at ambient temperature was treated with manganese dioxide (2.4 g). The resultant suspension was stirred for 1.5 h and filtered through Celite. The filtrate was concentrated *in vacuo* and the residue chromatographed on silica gel using ether/petroleum ether (1:1, v/v) as eluent to yield **33** (contaminated with 5% of the 10-oxo isomer) as a pale yellow oil (141 mg, 71%); uv λ_{max}: 237 nm (4.09); ir ν_{max}: 3420, 2180, 2078, 1672; ^{1}Hmr δ: 10.13 (1H, s), 6.48 (1H, t, J = 7 Hz), 5.43 (1H, bs), 2.71 (2H, q, J = 7 Hz), 2.18 (2H, t, J = 7 Hz), 1.88 (1H, s), 1.75 (3H, bs), 1.68 (3H, bs); ms m/e: 152 (M^+ − 18, 5%), 137 (9%), 123 (13%), 109 (11%), 95 (16%), 84 (35%), 82 (43%), 41 (100%).

1,1-Dideutero-9-oxonerol (34)

A solution of diol **32** (150 mg, 0.87 mmol) in dichloromethane (15 mL) was treated with manganese dioxide (1.5 g) as above to yield **34** (contaminated with 5% of the 10-oxo isomer) as a pale yellow oil (98 mg, 65%); uv λ_{max}: 237 (4.08); ir ν_{max}: 3420, 1674; ^{1}Hmr δ: 10.09 (1H, s), 6.46 (1H, t, J = 7 Hz), 5.47 (1H, bs), 1.74 (6H, bs); ms m/e: 170 (M^+, 0.1%), 152 (8%), 137 (12%), 109 (15%), 95 (30%), 84 (52%), 82 (94%), 42 (100%). *Anal.* calcd. for $C_{10}H_{14}D_2O_2$: C 70.55; found: C 70.05.

1-Dieutero-9-oxogeranial (35)

A solution of **33** (180 mg, 1.08 mmol) in dichloromethane (11 mL) was treated with barium manganate (1.9 g). The resultant suspension was stirred at ambient temperature for 2.5 days and filtered through Celite. The filtrate was concentrated *in vacuo* and the residue chromatographed on silica gel using ether/petroleum ether (1:1, v/v) as eluent to afford **35** as a pale yellow liquid (130 mg, 71%); uv λ_{max}: 237 (4.38); ir ν_{max}: 2100, 1663; ^{1}Hmr δ: 10.15 (1H, s), 6.43 (1H, t, J = 8 Hz), 5.89 (1H, bs), 3.0–2.2 (4H, m), 2.21 (3H, bs), 1.78 (3H, bs); ms m/e: 167 (M^+, 0.5%), 152 (7%), 149 (4%), 95 (36%), 82 (96%), 42 (100%). *Anal.* calcd. for $C_{10}H_{13}DO_2$: C 71.83; found: C 71.55.

1-Deutero-9-oxoneral (36)

A solution of **34** (120 mg, 0.71 mmol) in dichloromethane (8 mL) was treated with barium manganate (1.3 g) as above to afford **36** as a pale yellow liquid (88 mg, 75%); uv λ_{max}: 236 (4.35); ir ν_{max}: 2100, 1667, 1636; ^{1}Hmr δ: 10.11 (1H, s), 6.44 (1H, t, J = 7 Hz), 5.93 (1H, bs), 2.9–2.6 (4H, m), 2.00 (3H, bs), 1.77 (3H, bs); ms m/e: 167 (M^+, 0.4%), 152 (6%), 149 (4%), 95 (38%), 82 (96%), 42 (100%).

1,1-Dideutero-10-oxogeraniol (37)

A suspension of the (*E*)-phosphonium salt **23** (5.4 g, 9.2 mmol) in anhydrous tetrahydrofuran/hexamethylphosphoramide (30 mL/3 mL) under a nitrogen atmosphere was treated with a 1.9 *M* solution of phenyllithium in ether (5 mL, 9.5 mmol). After stirring for 10 min at ambient temperature the reaction mixture was cooled to −78°C and treated with pyruvaldehyde dimethyl acetal (1.05 g, 8.9 mmol). The reaction was allowed to warm to ambient temperature (ca. 30 min) and stirred for a further 3 h. Petroleum ether (30 mL) was added and the resultant mixture filtered through a short column of silica gel using ether/petroleum ether (1:1) as eluent. The filtrate was concentrated *in vacuo* and the residue dissolved in methanol (60 mL) containing *p*-toluenesulfonic acid monohydrate (50 mg). After stirring for 18 h at ambient temperature, water (70 mL) was added and stirring continued. After 30 min, the reaction mixture was concentrated *in vacuo* (to ca. one-half the original volume, made basic with 1 *N* sodium hydroxide, and extracted with ether (3 × 40 mL). The combined ether extract was dried and the solvent removed *in vacuo* to afford **37** (contaminated with 2% of the 9-oxo isomer) as a pale yellow oil (980 mg, 65%); uv λ_{max}: 229 (4.20); ir ν_{max}: 3400, 1683, 1640; ^{1}Hmr δ: 9.36 (1H, s), 6.46 (1H, t, J = 7 Hz), 5.43 (1H, bs), 2.7–2.0 (4H, m), 1.73 (3H, bs), 1.68 (3H, bs); ms m/e: 152 (M^+ − H_2O, 11%), 137 (26%), 123 (26%), 84 (60%), 42 (100%).

1,1-Deutero-10-oxonerol (38)

A suspension of the (*Z*)-phosphonium salt **24** (2.5 g, 4.3 mmol) in anhydrous tetrahydrofuran/hexamethylphosphoramide (13 mL/1.3 mL) under a nitrogen atmosphere was treated with a 1.9 *M* solution of phenyllithium in ether (2.4 mL, 4.6 mmol) as above to afford **38** (contaminated with 7% of the 9-oxo isomer) as a pale yellow oil (500 mg, 69%); uv λ_{max}: 229 (4.29); ir ν_{max}: 3400, 1672, 1644; ^{1}Hmr δ: 9.38 (1H, s), 6.48 (1H, t, J = 7 Hz), 5.48 (1H, bs), 2.4 (4H, m), 1.76 (6H, bs); ms m/e: 152 (M^+ − 18, 5%), 151 (6%), 137 (11%), 123 (16%), 109 (11%), 98 (26%), 95 (19%), 84 (76%), 55 (60%), 42 (100%). *Anal.* calcd. for $C_{10}H_{14}D_2O_2$: C 70.55; found: C 70.48.

1-Deutero-10-oxogeranial (39)

A solution of **37** (350 mg, 2.06 mmol) in dichloromethane (25 mL) was treated with barium manganate (3.3 g). The resultant suspension was stirred at ambient temperature for 3 days and then filtered through Celite. The solvent was removed *in vacuo* to give the dialdehyde **39** as a pale yellow liquid (272 mg, 80%); uv λ_{max}: 234 (4.42); ir ν_{max}: 2100, 1682, 1660, 1640; ^{1}Hmr δ: 9.39 (1H, s), 6.44 (1H, t, J = 7 Hz), 5.89 (1H, bs), 2.7–2.22 (4H, m), 2.22 (3H, bs), 1.76 (3H, bs); ms m/e: 167 (M^+, 0.2%, 166 (0.5%), 149 (8%), 121 (13%), 110 (33%), 82 (44%), 55 (100%). *Anal.* calcd. for $C_{10}H_{13}DO_2$: C 71.83; found: C 71.39.

1-Deutero-10-oxoneral (40)

A solution of **38** (114 mg, 0.67 mmol) in dichloromethane (8 mL) was treated with barium manganate (1 g) as above to afford the dialdehyde **40** as a pale yellow liquid (93 mg, 82%); uv λ_{max}: 229 (4.32), 235 sh (4.29); ir ν_{max}: 2100, 1681, 1662, 1638; ^{1}Hmr δ: 9.40 (1H, s), 6.45 (1H, t, J = 7 Hz), 5.93 (1H, bs), 3.0–2.4 (4H, m), 2.02 (3H, bs), 1.75 (3H, bs); ms m/e: 167 (M^+, 1%), 152 (3%), 149 (6%), 138 (12%), 122 (14%), 109 (27%), 95 (63%), 85 (66%), 82 (76%), 55 (100%).

1,1-Dideutero-9,10-dihydroxygeraniol (41)

A suspension of the (*E*)-phosphonium salt **23** (5.36 g, 9.1 mmol) in anhydrous tetrahydrofuran/hexamethylphosphoramide (30 mL/3 mL) under a nitrogen atmosphere was treated with a 1.9 *M* solution of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

phenyllithium in ether/hexane (4.7 mL, 8.9 mmol). After stirring at ambient temperature for 15 min the reaction mixture was cooled to −78°C and treated with a solution of the ditetrahydropyranyl ether of 1,3-dihydroxyacetone (2.3 g, 8.9 mmol) in ether (3 mL). The reaction mixture was allowed to warm to ambient temperature and stirred for a further 3 h. Petroleum ether (20 mL) was added and the resultant mixture filtered through a short column of silica gel using petroleum ether/ether as eluent. The filtrate was concentrated *in vacuo* and the residue was dissolved in methanol (230 mL) containing *p*-toluenesulfonic acid monohydrate (150 mg). After standing at ambient temperature for 17 h, sodium hydroxide (50 mg) was added and the solvent removed *in vacuo*. The residue was chromatographed on silica gel using ether/methanol (20:1 then 10:1) as eluent to afford **41** as a colorless oil (940 mg, 56%); ir ν_{max}: 3340, 1005; ^{1}Hmr δ: 5.47 (1H, t, J = 7 Hz), 5.30 (1H, bs), 4.22 (2H, s), 4.14 (2H, s), 2.4–2.0 (4H, m), 1.66 (3H, bs). *Anal.* calcd. for $C_{10}H_{16}D_2O_3$: C 63.80; found: C 63.75.

1,1-Dideutero-9,10-dihydroxynerol (42)

A suspension of the (*Z*)-phosphonium salt **24** (3.4 g, 5.8 mmol) in anhydrous tetrahydrofuran/hexamethylphosphoramide (20 mL/2 mL) was treated with phenyllithium (3 mL of 1.9 *M* solution, 5.7 mmol) and the tetrahydropyranyl ether of 1,3-dihydroxyacetone (1.5 g, 5.7 mmol) as above to afford **42** as a colorless oil (680 mg, 63%); ir ν_{max}: 3340, 1008; ^{1}Hmr δ: 5.53 (1H, t, J = 7 Hz), 5.39 (1H, bs), 4.16 (2H, s), 4.10 (2H, s), 2.2–1.9 (4H, m), 1.73 (3H, bs).

*Oxidation of **41** with manganese dioxide*

A solution of **41** (100 mg, 0.53 mmol) in tetrahydrofuran (14 mL) at 0°C was treated with manganese dioxide (1 g). After 30 min at 0°C the reaction mixture was filtered through Celite and the filtrate concentrated *in vacuo* to afford 1,1-dideutero-9-oxo-10-hydroxygeraniol (**43**), contaminated with 12% of the 9-hydroxy-10-oxo isomer **45**, as a pale yellow liquid (72 mg, 72%); uv λ_{max}: 233 (4.04); ir ν_{max}: 3368, 1670; ^{1}Hmr δ: 10.10 (1H, s), 6.69 (1H, t, J = 7 Hz), 5.41 (1H, bs), 4.21 (2H, s), 2.75 (2H, q, J = 7 Hz), 2.23 (2H, t, J = 7 Hz), 1.67 (3H, bs).

*Oxidation of **42** with manganese dioxide*

A solution of **42** (150 mg, 0.81 mmol) in tetrahydrofuran (20 mL) at 0°C was treated with manganese dioxide as above to afford 1,1-dideutero-9-oxo-10-hydroxynerol (**44**), contaminated with 14% of the 9-hydroxy-10-oxo isomer **46**, as a pale yellow liquid (98 mg, 66%); uv λ_{max}: 234 (4.01); ir ν_{max}: 3380, 1668; ^{1}Hmr δ: 10.02 (1H, s), 6.70 (1H, t, J = 7 Hz), 5.44 (1H, bs), 4.19 (2H, bs), 2.71 (2H, q, J = 7 Hz), 2.32 (2H, t, J = 7 Hz), 1.73 (3H, bs). *Anal.* calcd. for $C_{10}H_{14}D_2O_3$: C 64.49; found: C 63.94.

*β-Ketosulfoxide **48***

A suspension of sodium hydride (4 g of 50% NaH/mineral oil, 83 mmol) in dimethyl sulfoxide (80 mL) was heated at 70°C for 1 h, cooled to ambient temperature, and treated with a solution of ethyl 1,1-diethoxyacetate (7 g, 39.8 mmol) in ether (5 mL) at a dropwise rate over 2 h. The reaction mixture was stirred for a further 17 h, diluted with water (50 mL), and washed with petroleum ether (3 × 50 mL). The aqueous portion was made neutral with acetic acid (5 mL) and extracted with dichloromethane (4 × 50 mL). The combined dichloromethane extract was dried (Na_2SO_4) and the solvent removed *in vacuo*. The residue was chromatographed on silica gel (250 g) using ethyl acetate/ethanol (100:1 then 10:1) as eluent to afford **48** as a yellow liquid (5 g, 60%); ir ν_{max}: 1729, 1110; ^{1}Hmr δ: 4.60 (1H, s), 4.00 (2H, AB quartet), 3.6 (4H, m), 2.,67 (3H, s), 1.23 (6H, t, J = 7 Hz). *Anal.* calcd. for $C_8H_{16}O_4S$: C 46.13, H 7.74, S 15.39; found: C 46.19, H 7.66, S 15.38.

1,1,3,3-Tetraethoxyacetone (47)

A suspension of red mercuric oxide (6.5 g, 0.03 mol) in ethanol (60 mL) was treated with boron trifluoride etherate (3.6 mL, 0.03 mol). After stirring for 5 min, a solution of **48** (4.4 g, 0.021 mol) in ether (5 mL) was added. The resultant mixture was heated at reflux for 45 min, cooled to ambient temperature, and stirred for a further 2 h. Petroleum ether (50 mL) was added and the mixture filtered through Celite. The filtrate was washed with 1 *N* sodium hydroxide (4 × 50 mL). The combined aqueous portion was back-extracted with petroleum ether (2 × 40 mL) and the combined organic portion dried (Na_2SO_4). The solvent was removed *in vacuo* and the residue distilled at 0.7 Torr to give **50** as a colorless liquid (3.5 g, 71%); bp 82°C at 0.7 Torr; ir ν_{max}: 1763, 1070; ^{1}Hmr δ: 5.02 (2H, s), 3.65 (8H, m), 1.24 (12H, t, J = 7 Hz).

*Phosphonium salt **49***

A mixture of the (*E*)-chloroalcohol **27** (5.2 g, 34.6 mmol), triphenylphosphine (9.2 g, 35.1 mmol), and sodium iodide (6 g, 40 mmol) in acetonitrile (80 mL) was heated at reflux. After 30 h, the reaction mixture was cooled to 0°C, diluted with dichloromethane (60 mL), and filtered. The filtrate was concentrated *in vacuo*, treated with ether (100 mL), and allowed to stand until crystallization was complete. The solid mass was pulverized, washed with ether, recrystallized from aqueous ethanol, and dried *in vacuo* at 100°C to give **49** as a white crystalline solid (14.4 g, 83%); mp 180–181°C; ^{1}Hmr δ: 7.8 (15H, m), 5.50 (1H, bs), 3.48 (2H, m), 2.28 (2H, t, J = 7 Hz), 1.8 (2H, m), 1.50 (3H, bs). *Anal.* (of nondeuterated analog) calcd. for $C_{25}H_{28}IPO$: C 59.77, H 5.62, I 25.26; found: C 59.91, H 5.62, I 25.32.

*Phosphonium salt **50***

A mixture of the (*Z*)-chloroalcohol **28** (7.3 g, 48.5 mmol), triphenylphosphine (13.1 g, 50 mmol), and sodium iodide (9 g, 60 mmol) in acetonitrile (100 mL) was treated as above to give **50** as a white crystalline solid (20.3 g, 83%); mp 149–150°C; ^{1}Hmr δ: 7.8 (15H, m), 5.59 (1H, bs), 3.57 (2H, m), 2.44 (2H, t, J = 7 Hz), 1.8 (2H, m), 1.49 (3H, bs). *Anal.* calcd. for $C_{25}H_{26}D_2IPO$: C 59.53, I 25.16; found: C 59.64, I 25.22.

1,1-Dideutero-9,9,10,10-tetraethoxygeraniol (51)

A suspension of phosphonium salt **49** (2.2 g, 4.38 mmol) in anhydrous tetrahydrofuran/hexamethylphosphoramide (15 mL/1.5 mL) under a nitrogen atmosphere was treated with a 2 *M* solution of n-butyllithium in hexane (4.4 mL, 8.8 mmol). After stirring for 15 min at ambient temperature the reaction was cooled to −78°C and treated with a solution of 1,1,3,3-tetraethoxyacetone (1 g, 4.27 mmol) in ether (2 mL). The reaction was allowed to warm to ambient temperature and stirred for a further 3 h. Water (5 drops) and petroleum ether (20 mL) were added, and the resultant mixture filtered through Celite. The filtrate was concentrated *in vacuo* and the residue chromatographed on silica gel using ether/petroleum ether (1:1) as eluent to give **51** as a colorless liquid (1 g, 71%); ir ν_{max}: 3450, 1056; ^{1}Hmr δ: 5.79 (1H, t, J = 7 Hz), 5.40 (1H, bs), 5.01 (1H, s), 4.77 (1H, s), 4.0–3.3 (8H, m), 2.7–2.0 (4H, m), 1.67 (3H, bs), 1.19 (12H, t, J = 7 Hz).

1,1-Dideutero-9,9,10,10-tetraethoxynerol (52)

A suspension of phosphonium salt **50** (2.2 g, 4.38 mmol) in tetrahydrofuran/hexamethylphosphoramide (15 mL/1 mL) was treated with a 2 *M* solution of n-butyllithium in hexane (4.4 mL, 8.8 mmol) and a solution of 1,1,3,3-tetraethoxyacetone (1 g, 4.27 mmol) in ether (2 mL) as above to afford **52** as a colorless oil (780 mg, 55%); ir ν_{max}: 3450, 1060; ^{1}Hmr δ: 5.81 (1H, t, J = 7 Hz), 5.43 (1H, bs), 5.00 (1H, s), 4.78 (1H, s), 4.0–3.3 (8H, m), 2.6–2.0 (5H, m), 1.72 (3H, bs), 1.18 (12H, t, J = 7 Hz). *Anal.* calcd. for $C_{18}H_{32}D_2O_5$: C 65.03; found: C 64.95.

1-Deutero-9,9,10,10-tetraethoxygeranial (53)

A solution of **51** (180 mg, 0.54 mmol) in dichloromethane (15 mL) was treated with barium manganate (1.7 g). The resultant suspension was stirred at ambient temperature for 3 days, filtered through Celite, and concentrated *in vacuo*. The residue was chromatographed on silica gel using ether/petroleum ether (1:1) as eluent to give **53** (86 mg, 48%) as a colorless liquid; uv λ_{max}: 238 (4.06); ir ν_{max}: 2096, 1665, 1064; ^{1}Hmr (CCl_4) δ: 5.74 (1H, bs), 5.53 (1H, t, J = 7 Hz), 4.79 (1H,

s), 4.53 (1H, s), 3.4 (8H, m), 2.8–2.1 (4H, m), 2.13 (3H, bs), 1.14 (6H, t, J = 7 Hz), 1.11 (6H, t, J = 7 Hz). *Anal.* calcd. for $C_{18}H_{31}DO_5$: C 65.62; found: C 65.56.

*1-Deutero-9,9,10,10-tetraethoxyneral (**54**)*

A solution of **52** (200 mg, 0.60 mmol) in dichloromethane (18 mL) was treated with barium manganate (1.9 g) as above to afford **54** as a colorless liquid (89 mg, 45%); uv λ_{max}: 237 (4.07); ir ν_{max}: 2092, 1663, 1062; ^{1}Hmr (CCl_4) δ: 5.74 (1H, bs), 5.60 (1H, t, J = 7 Hz), 4.81 (1H, s), 4.56 (1H, s), 3.4 (8H, m), 2.9–2.1 (4H, m), 1.95 (3H, bs), 1.15 (6H, t, J = 7 Hz), 1.12 (6H, t, J = 7 Hz).

Tritium isotope fractionation between hydrogen sulphide and methanol

ANDRZEJ WAWER AND JERZY SZYDŁOWSKI[1]

University of Warsaw, Department of Chemistry, Zwirki i Wigury 101, 02-089 Warsaw, Poland

Received July 5, 1982

ANDRZEJ WAWER and JERZY SZYDŁOWSKI. Can. J. Chem. **61**, 1060 (1983).

Tritium isotope fractionation in the exchange reaction between methanol and hydrogen sulphide has been studied in the gaseous phase over the temperature range 283–373 K. It was found that the heavier isotope accumulates in methanol and that the tritium–protium isotope effect characterizing the exchange reaction studied reaches large values: from 2.70 at 373 K to 3.72 at 283 K. The temperature dependence can be described by the simple relation: $\ln \alpha = -0.1221 + 431.5/T$. Using observed vibrational frequencies, theoretical fractionation factors could be calculated and good agreement with the experimentally determined values was observed. The results presently obtained were also compared with those obtained for the CH_3SH-H_2S system.

ANDRZEJ WAWER et JERZY SZYDŁOWSKI. Can. J. Chem. **61**, 1060 (1983).

On a étudié le fractionnement isotopique du tritium dans la réaction d'échange entre le méthanol et le sulfure d'hydrogène en phase gazeuse dans l'intervalle de température allant de 283 à 373 K. On a trouvé que l'isotope le plus lourd s'accumule dans le méthanol et que l'effet isotopique tritium–protium caractérisant la réaction d'échange étudiée atteint de fortes valeurs qui vont de 2,70 à 373 K jusqu'à 3,72 à 283 K. On peut décrire l'effet de la température par la relation simple $\ln \alpha = -0,1221 + 431,5/T$. En utilisant les fréquences vibrationnelles observées, on peut calculer les facteurs de fractionnement théorique et on a observé un bon accord avec les valeurs déterminées expérimentalement. On compare également les résultats obtenus dans ce travail avec ceux du système CH_3SH-H_2S.

[Traduit par le journal]

In previous papers results of kinetic and thermodynamic studies on tritium isotope exchange between hydrogen sulphide and methyl thiol (1, 2) were reported. In this paper we present experimental and theoretical studies on tritium isotope fractionation between hydrogen sulphide and methanol in the gas phase. The knowledge of hydrogen isotope fractionation between compounds with OH and SH groups can play an important role in a better understanding of the physicochemical properties of biologically active structures containing OH and SH groups. Moreover, knowledge of the isotope effects in such exchange reactions may be interesting from a practical view point, especially in isotope enrichment technology.

Experimental

Reagents

Methanol used in the experiments was distilled over CaO, boiled with Mg + I_2, and redistilled. The water content in the alcohol was determined by means of the Fisher reagent; it did not exceed 0.02% (w/w).

The labelling, purification, and drying procedures for H_2S were the same as described earlier (1).

Procedure

Before each experiment the vacuum apparatus was carefully evacuated to a pressure of ca. 10^{-2} Pa. The reaction vessel was filled successively with hydrogen sulphide and methanol vapors. Exchange equilibrium was reached after 10 min. The reaction was quenched by condensation of the gas mixture at the temperature of liquid nitrogen. The components of the mixture were separated by vacuum distillation at 178 K (melting point of acetone). After distillation, the hydrogen sulphide contained less than 1% of methanol; this was verified by gas-chromatographic analysis. Furthermore, under the conditions of the vacuum distillation at 178 K no measurable isotope exchange between gaseous H_2S and liquid CH_3OH was observed.

The method of determination of tritium in H_2S was described previously (1, 3). However, in the present experiments the resolving time of the counter (2.0×10^{-4} s) was taken into account. This was done by standard method using the formula:

$$[1] \quad A_0 = A/(1 - A\tau)$$

where A_0 is the actual counting rate, A is the measured counting rate, and τ is resolving time of the counter.

The wall effect could be neglected as we are interested in the measurements of the relative specific radioactivities only. It should be added that the use of the isotope dilution method in the radioactivity measurements gave the same results.

Results and discussion

The tritium isotope fractionation in the gas phase exchange reaction:

$$[2] \quad H\overset{*}{S}H + CH_3OH = HSH + CH_3O\overset{*}{H}$$

can be defined as follows:

$$[3] \quad \alpha_{exp} = 2A_{m,\infty}/A_{s,\infty}$$

where $A_{m,\infty}$ and $A_{s,\infty}$ are the equilibrium specific radioactivities of methanol and hydrogen sulphide, respectively. $A_{m,\infty}$ was obtained from the material balance:

$$[4] \quad n_s A_{s,0} = n_s A_{s,\infty} + n_m A_{m,\infty}$$

where $A_{s,0}$ is the initial specific radioactivity of H_2S; n_m and n_s refer to the molar concentrations of methanol and hydrogen sulphide, respectively.

The tritium isotope fractionation factors α in the exchange reaction studied are presented in Table 1. The values listed in the second column are those obtained directly from experiments. In the third column the values with corrections for the resolving time of the counter are presented; the small corrections for the traces of radioactive CH_3OH in H_2S are also taken into account. Each separation factor reported represents the average of 5 to 7 separate determinations. The error limits cited in the table are the standard deviations of the measurements.

TABLE 1. The experimental fractionation factor in the tritium exchange reaction between CH_3OH and H_2S in the gas phase

T/K	α_{exp}	α_{corr}
283	3.58	3.78±0.10
293	3.40	3.59±0.08
308	3.22	3.39±0.10
323	3.02	3.18±0.10
339	2.84	2.99±0.08
353	2.70	2.85±0.12
373	2.56	2.70±0.08

It can be easily seen that the temperature dependence of the isotope effect is simple and that the experimental fractionation factors can be fitted by the least-squares method to the equation:

$$[5] \quad \ln \alpha = -0.1221 + 431.5/T$$

The molar enthalpy change of the exchange reaction [2] obtained from the relation [5] is equal to 3.6 kJ/mol.

It is worth noting that Khurma and Fenby (4) obtained similar values of the enthalpy change for the exchange reactions in the gas phase:

$$CH_3OD + CH_3SH = CH_3OH + CH_3SD$$

and

$$CH_3SH + HOD = CH_3SD + H_2O$$

They gave the values of 2.26 kJ/mol and 1.43 kJ/mol for the above reactions which gives approximately (5) 3.2 kJ/mol and 1.7 kJ/mol for the tritium exchange near room temperature.

Theoretical calculations of equilibrium constants for the isotope exchange reactions were initiated by Urey and Rittenberg (6) and developed further by Bigeleisen and Mayer (7) and Urey (8). Following the Bigeleisen and Mayer formulation (7) the isotope fractionation factor for the exchange reaction [2] can be expressed in terms of the reduced partition function ratios:

$$[6] \quad \alpha = (s/s')f_{CH_3OH}/(s/s')f_{HSH}$$

The equation for the isotopic reduced partition function ratio $(s/s')f$ in the harmonic approximation neglecting effects due to quantum-mechanical rotation is:

$$[7] \quad (s/s')f = \prod_i \left\{ \frac{u_i}{u_i'} \frac{1 - \exp(-u_i')}{1 - \exp(-u_i)} \exp \frac{u_i' - u_i}{2} \right\}$$

where $u_i = hc\omega_i/kT$, ω_i are the normal mode vibrational frequencies in cm^{-1}, and c, h, k, and T have their usual meanings; s is the symmetry number and the prime refers to the light isotopic species. The product is taken over all normal mode vibrational frequencies of the molecule. It is then evident that the reduced partition function ratio can be easily calculated by using the spectroscopic data of isotopic molecules.

The vibrational spectra of methanol and its isotopic species have been the subject of considerable interest. We mention here only the more recent experimental data and assignments; those by Falk and Whalley (9), Shimanouchi (10), Barnes and Hallam (11), Mallinson (12) and, the most important, those by Serrallach, Meyer, and Günthard (13). The assignments proposed in literature differ considerably from one another. In particular, the matrix data by Barnes and Hallam (11) showed

TABLE 2. Observed vibrational frequencies of gaseous CH_3OH and CH_3OD (13) used in the calculations of the reduced partition function ratios (frequencies in cm^{-1})

[a]Matrix frequency.
[b]Calculated frequency.

that parts of the spectra are still not very well understood. Most disagreements in assignment concern the modes of the methyl group. Such discrepancies are not surprising in view of the difficulties arising in the interpretation of the spectra. Indeed the gas and matrix spectra can provide reliable information on the CH_3OH molecules; however, some difficulties in locating the fundamentals in the gas spectra still arise from frequent overlapping due to the broad rotational and complicated torsional structure as well as to Coriolis or Fermi resonances. The liquid and solid state spectra are even more complicated due to strong hydrogen bonding. Keeping all this in mind the vibrational data were carefully examined and the most reliable set, based on the Serrallach, Meyer, and Günthard data (Table 2) (and one which is consistent with the vibrational data for CH_3SeH (14) and CH_3SH (15)), was used in the calculation of the reduced partition function ratio of methanol. The results of the theoretical calculation of vibrational frequencies by the SCF method have been omitted due to their relatively large uncertainties (16).

Excellent data for the H_2S and D_2S molecules are available (17). However, to our knowledge there are no precise experimental vibrational data for HDS available but only the very old and incomplete data cited by Herzberg (18). Therefore, the vibrational frequencies of HDS must be calculated using the known force field for the H_2S molecule or by the following procedure (19) which enables one to evaluate the vibrational frequencies of HDS directly from the very precise data obtained for H_2S and D_2S. Thus the observed HS and DS stretching frequencies of HSD were taken as the average of ν_1 and ν_3 for H_2S and D_2S, respectively, while ν_2 was obtained from the equation:

$$[8] \quad \nu_2^2(HSD) = \frac{1}{2}\left[\nu_2^2(H_2S) + \nu_2^2(D_2S)\right]$$

These approximations require, of course, a negligible mixing among internal coordinates but seem to be justified when comparing the calculated and observed frequencies for HDO where only small errors are noted.

The following frequencies (in cm^{-1}): 2614.6, 1182.7, 2627.5, and 2621.0, 1032.0, 1901.0 for H_2S (13) and HDS, respectively, were used to calculate deuterium partition function ratios or hydrogen sulphide. It should be added that in this case such a calculation can be performed including force field analysis and anharmonic corrections. It is also possible to carry out these calculations using the procedure outlined by Bron, Chang, and Wolfsberg (20). In this procedure various correction factors to the harmonic approximation have been included and the reduced partition function ratios calculated by this method have been found to be very reliable. There are, of

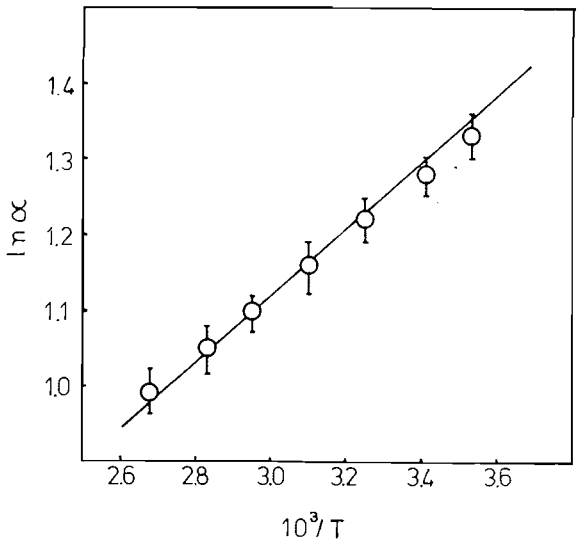

FIG. 1. Comparison of the calculated tritium isotope fractionation factors (solid line) with experimental results, α_{corr} (points) for the vapor phase exchange reaction: $CH_3OH + H\overset{*}{S}H = CH_3O\overset{*}{H} + HSH$. Uncertainties in the experimental values denoted by error bars are taken from Table 1.

course, some differences in the values of the partition function ratios calculated in this paper from the observed vibrational frequencies and resulting from the procedure mentioned above (20); thus at 283 K $(s/s')f(HDS/H_2S)$ is equal to 5.793 and 6.253 respectively. Taking into account that there is some cancellation in the correction factors to the harmonic approximation partition function ratios when equilibrium constants are obtained (20), and since in calculation of the deuterium reduced partition function ratio of methanol we used the observed vibrational frequencies without anharmonic corrections (the latter are not yet available), the same procedure was consequently applied in the case of H_2S. Hence the deuterium fractionation factor α_D for the reaction studied can be easily calculated. Then using the known relation of Swain (5*a*) and Bigeleisen (5*b*) we obtain the tritium fractionation factor characterizing the isotope effect in the exchange reaction studied. The values obtained are presented in Fig. 1 in comparison with the experimental results. It is seen that the agreement is good taking into account the approximations used in the calculations and the experimental error.

On the other hand, our experimental results can be correlated with those existing in the literature. Namely, from the known values of the fractionation factors for the exchange of hydrogen between H_2S and H_2O (21) and between CH_3OH and H_2O (22) we can calculate the fractionation factor for the $CH_3OH + H_2S$ reaction. Hence, the tritium isotope fractionation factor calculated in such a way (using also the Swain–Bigeleisen relation) is in the range of 3.46–3.65 at 298 K (these uncertainties arise from some scatter in the existing data). This result can be compared with our value at 298 K which is equal to 3.50 ± 0.08.

In conclusion it seems interesting to compare the two systems studied, i.e. CH_3SH/H_2S and CH_3OH/H_2S. It is immediately evident that there are pronounced differences in the values of the isotope effects accompanying above exchange reactions; thus at 293 K α is equal to 1.075 for the CH_3SH/H_2S and to 3.59 for the CH_3OH/H_2S systems. These differences can be explained taking into account the correlation between isotope effects and molecular structure. In particular we would like to emphasize here the role of the stretching vibrations and their contributions to the reduced partition function ratio. Thus in the case of CH_3SH/H_2S system the great similarity of SH bonds in the mercaptan and the sulphide and also similar values of the stretching vibrations frequencies result in a small value of the isotope effect.[2] On the other hand, in the CH_3OH/H_2S system the exchanging groups differ greatly and the frequencies of OH and SH stretching vibrations are far from each other. Consequently, we observe a large isotope effect in this exchange reaction. Such a behaviour is quite understandable, taking into account the discussion given by Bigeleisen on the relationship between the magnitude of isotope effects in polyatomic systems and bending and stretching force constants (23).

Finally, we should mention that considering the large value of the fractionation factor and its strong temperature dependence, as well as the acceptably rapid isotope exchange reaction, the system studied may be of some interest in the hydrogen isotope separation process.

Solvent and pH dependence of fluorescence spectra of 9-phenanthrylamine

MEENAKSHISUNDERAM SWAMINATHAN AND SNEH KUMAR DOGRA
Department of Chemistry, Indian Institute of Technology, Kanpur-208 016, U.P., India

Received July 27, 1982

MEENAKSHISUNDERAM SWAMINATHAN and SNEH KUMAR DOGRA. Can. J. Chem. **61**, 1064 (1983).

Fluorimetric titrations were carried out for various forms of 9-phenanthrylamine and pK_a^* values were determined. An unusual behaviour observed in the fluorimetric titration of the neutral form at moderate proton concentration is due to the quenching of the S_1 state of PNH_2 by H^+.

MEENAKSHISUNDERAM SWAMINATHAN et SNEH KUMAR DOGRA. Can. J. Chem. **61**, 1064 (1983).

On a réalisé des titrations par fluorométrie de différentes formes de la phénanthrylamine-9 et on a déterminé les valeurs du pK_a^*. On a observé un comportement inhabituel lors du titrage par fluorométrie de la forme neutre pour une concentration modérée en proton. Ceci est dû au piégeage de l'état S_1 du PNH_2 par H^+.

[Traduit par le journal]

Introduction

The information on the excited state pK_a^* values will be much more useful in understanding the mechanism of photoreactions (1) (photoreduction, photohydration etc.) if the excited state equilibrium constant (pK_a^*) is calculated with the help of fluorimetric titrations or time dependence fluorimetry. Tsutsumi *et al.* (2) have reported the excited state acidity constants of 2,3,4- and 9-phenanthrylamines, determined using the Förster cycle method and a semi-empirical SCF-MO-CI method for equilibrium [I]. The pK_a^*'s calculated using the Förster cycle method and the 0–0 transition energy, determined from absorption and fluorescence spectra, do not indicate whether the equilibrium in the excited state is actually attained. This information can be obtained from fluorimetric titration (3). Moreover, the technique also indicates the interactions of a proton with the molecules other than the simple proton transfer reaction in the excited state.

The present study was carried out to determine pK_a^* (S_1) using fluorimetric titrations for both the equilibria [I] and [II] of 9-phenanthrylamine (PNH_2). In addition we determined the influence of the solvent dependence on the absorption and the fluorescence,

[I] $PNH_3^+ \rightleftharpoons PNH_2 + H^+$

[II] $PNH_2 \rightleftharpoons PNH^- + H^+$

Experimental

PNH_2 was obtained from the Aldrich Chemical Co. and recrystallised from benzene. Analytical grade H_2SO_4 and NaOH were used to prepare acidic and basic solutions. A modified Hammett's scale (4) for H_2SO_4–H_2O mixtures and Yagil's basicity scale (5) for NaOH–H_2O mixtures were used for solutions below pH = 1 and above pH = 13, respectively. Methanol, acetonitrile, and hexane were of analytical grade and were purified further before use. Absorption spectra were recorded with a Cary 17D spectrophotometer and fluorescence measurements were made with a scanning spectrofluorimeter constructed in our laboratory. The details of the instrument are described elsewhere (6).

Results and discussion

Solvent effect on absorption and fluorescence spectra

Absorption and fluorescence spectra of PNH_2 were taken in different solvents and are shown in Figs. 1 and 2. The band

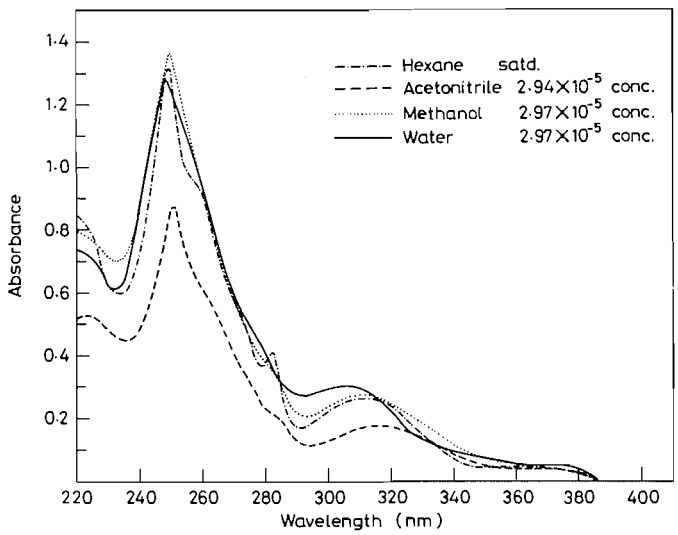

FIG. 1. Absorption spectra of 9-phenanthrylamine in different solvents.

maxima are listed in Table 1. The absorption and fluorescence spectra are structured in hexane and the structure is lost as the polarity and hydrogen bonding ability of the solvent increases. This structure loss is due to increased solute–solvent interaction.

A gradual blue shift in the absorption maxima was observed with an increase in the hydrogen bonding ability of the solvents with the exception of acetonitrile, whereas there is a continuous red shift in the fluorescence maxima for these conditions without exception.

An amino group attached to phenanthrene moiety can interact with a hydrogen donor solvent through its lone pair or it can interact with a hydrogen-acceptor solvent through its hydrogen atom. Due to this a blue shift in the former and a red shift in the latter relative to hexane are expected. The blue shifts in the absorption spectra in methanol and water relative to hexane show that only hydrogen–donor interaction of the solvent is taking place with the lone pair on the amino nitrogen atom. Acetonitrile, being a hydrogen-acceptor solvent, has little effect on the absorption spectra. But the red shift in the fluorescence maxima from hexane to water according to their hydrogen-acceptor capability shows that the availability of the

lone pair in the excited state is much reduced by a greater charge transfer interaction of the lone pair of the amino group with the ring.

Prototropic phenomena in the ground and excited states

Equilibrium [II] showed a peculiar behaviour in absorption as well as in fluorescence. The absorption spectra of PNH_2 at different pH/H_- are shown in Fig. 3. It is found that there is no clear isosbestic point in this case; i.e. when the pH is increased above 14, the absorption maxima changes but the isosbestic point is constant only for solutions below $H_- = 15$. On further increase in H_- (>15), the isosbestic point changes without much change in the maximum for each solution. Due to this irregular dependence of the absorption spectrum on pH/H_- and a very narrow range of H_- over which one type of equilibrium is present, the pK_a for this equilibrium could not be determined.

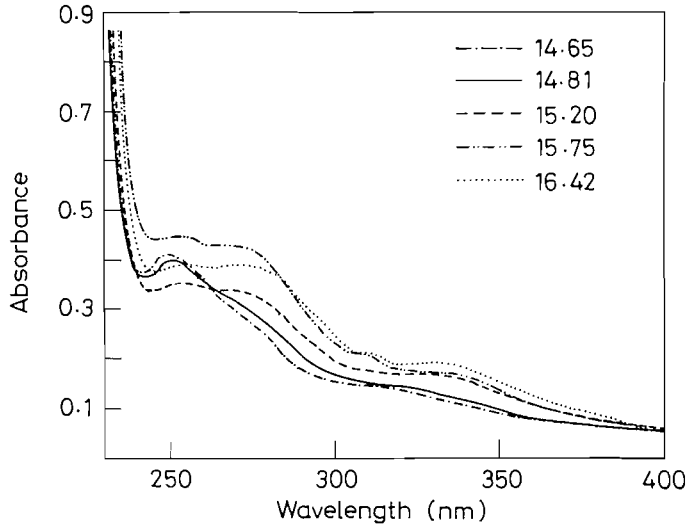

FIG. 3. Absorption spectra of 9-phenanthrylamine at different H values.

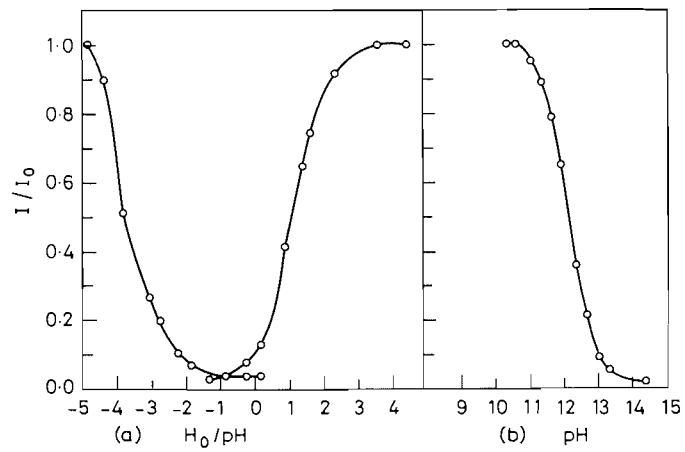

FIG. 4. Plot of relative fluorescence intensities of 9-phenanthrylamine versus pH/H_0; (*a*) cation and neutral form, (*b*) neutral form.

The fluorimetric titration curves are shown in Fig. 4 and the pK_a* values determined for different equilibria are reported in Table 2. It is clear from Fig. 4 that the fluorescence intensity of PNH_2 is quenched with a decrease in pH/H_0. The middle of this quenching occurs at pH 1.1 which could not be pK_a* [I] because PNH_3^+ starts fluorescing only from $H_0 \leq -1$ and its intensity increases with an increase in acidity. The mid-point of this rise occurs at $H_0 = -3.6$ which is in good agreement with the reported value of ($H_0 = -3.2$) (2). The sharp fluorimetric titration curve shows that the formation of PNH_3^+ is complete within the life time of the neutral species. The small difference of 0.4 units in the Förster cycle pK_a* might be due to the difference in the solvent relaxation of the excited conjugate acid – base pair in a highly concentrated acid solution. The lack of correspondence between quenching of fluorescence of PNH_2 and appearance of fluorescence of PNH_3^+ clearly indicates that the fluorimetric titration curves do not correspond to the simple two component (7) (i.e. conjugate acid – base pair) equilibrium in the lowest excited singlet state. Probably it is due to the proton-induced quenching of fluorescence of PNH_2^* at moderate H^+ concentration; it has been shown that this process competes with the proton transfer reaction (8). Similar behaviour has also been observed in many aromatic amino compounds. Under

[b]FT = fluorimetric titration.

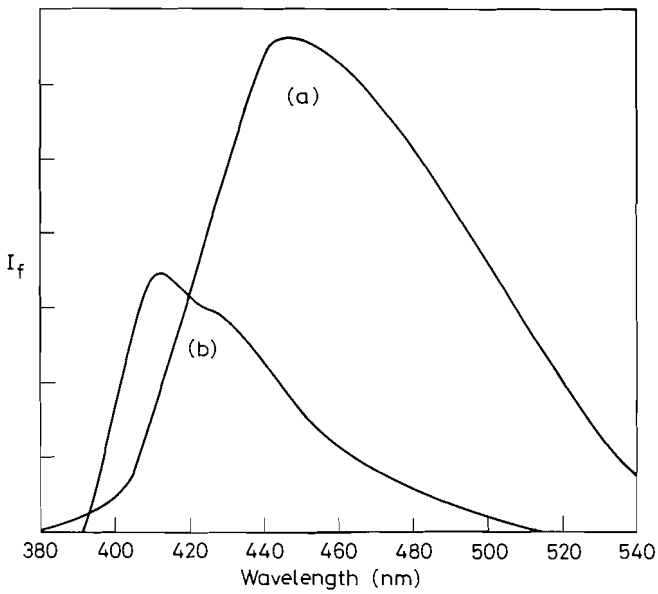

FIG. 5. Fluorescence spectra of 9-phenanthrylamine; (*a*) neutral form (pH ~ 7), (*b*) dianion (H_- 15.2).

such circumstances, accurate values of pK_a^*'s can only be calculated with the help of time-dependent fluorimetry; however, the mid-point of the rise of the PNH_3^+ fluorescence curve (9) will not be far from the true value.

The fluorescence of the neutral form is again quenched when the pH is increased above 10.5 due to the formation of the PNH^- anion. The mid-point of the quenching occurs at 12.8, which is the pK_a^* for the equilibrium between the neutral form and the anion. This indicates that PNH_2 has become more acidic in the excited singlet state as observed in other aromatic amino compounds (10, 11). When the pH is increased beyond 14, a new fluorescence peak appears at 410 nm which is blue-shifted relative to the neutral form. Figure 5 represents the fluorescence spectra of PNH_2 at pH 7 and at H_- = 16. This fluorescence could not be due to the monoanion of PNH_2 because (*i*) monoanions of other aromatic amines such as aminoquinolines (12), 5-aminoindazole (10), 2-aminobenzimidazole (11), etc. are nonfluorescent, and (*ii*) the maximum should be red-shifted relative to the fluorescence maximum of the neutral form as the amino group becomes more acidic in S_1. The intensity of this fluorescence increases up to H_- 16.75 (~8 *M* NaOH) and then decreases with further increase in concentration of NaOH. The appearance of this new fluorescence and the peculiar behaviour observed in the absorption spectra near this H_- range suggest the formation of a new fluorescent species which might be a dianion. α- and β-naphthylamines were also found to show a blue-shifted fluorescence under the similar conditions (10). Fluorimetric titration could not be used to calculate the pK_a^* for the equilibrium between the mono- and dianion because of the variation in the isosbestic point in this range. Similarly, the Förster cycle method cannot be used as the ground state pK_a is not known. But a blue shift in the band maxima when compared to the neutral form or PNH^- indicates qualitatively that PNH^- is a weaker acid in S_1 compared to S_0, i.e. the first dissociation of PNH_2 is strengthened in S_1 while the second dissociation is weakened.

Adsorption of cycloalkane and cyclopentanealkyl acids at the air/water interface

JAN J. SPITZER AND LOUIS D. HEERZE[1]

Department of Chemistry, University of Lethbridge, Lethbridge, Alta., Canada T1K 3M4

Received September 10, 1982

JAN J. SPITZER and LOUIS D. HEERZE. Can. J. Chem. **61**, 1067 (1983).

Surface tensions of aqueous solutions of cyclopropane, cyclobutane, cyclopentane, and cycloheptane carboxylic acids, and of cyclopentaneacetic and cyclopentanepropionic acids were measured at 25°C by the drop volume method. The Traube constants for calculation of standard free energies of adsorption were estimated from second and third degree polynomial least-squares analyses, from nonlinear least-squares analysis using the Szyszkowsky equation, and graphically.

The standard free energies of adsorption at the air/solution interface of cycloalkane and cycloalkanealkyl carboxylic acids are less negative than those of the corresponding straight chain acids, but not by a constant amount; the standard free energy of the CH_2 group in a cycloalkane ring is -2.5 kJ mol^{-1} as compared to a value of -3.3 kJ mol^{-1} for straight chain acids.

JAN J. SPITZER et LOUIS D. HEERZE. Can. J. Chem. **61**, 1067 (1983).

On a mesuré les tensions de surface de solutions aqueuses d'acides carboxyliques cyclopropane-, cyclobutane-, cyclopentane- et cycloheptane-carboxyliques et des acides cyclopentane-acétique et -propionique, à 25°C, utilisant la méthode du volume de la goutte. On a évalué les constantes de Traube nécessaires pour le calcul des énergies libres standard d'absorption à partir d'analyses, par la méthode des moindres carrés de polynomes du second et du troisième ordre, à partir d'une analyse non linaire, par la méthode des moindres carrés, en utilisant l'équation de Szyszkowsky et par une méthode graphique.

Les énergies libres standard d'absorption au niveau de l'interface air/solution des acides cycloalcane- et cycloalcanealkyle-carboxyliques sont moins négatives que celles des acides correspondants à chaîne linéaire mais la différence n'est pas constante; l'énergie libre standard du groupe CH_2 d'un cycloalcane est de $-2{,}5$ kJ mol^{-1} alors qu'elle est de $-3{,}3$ kJ mol^{-1} pour les acides à chaînes linéaires.

[Traduit par le journal]

Introduction

The relationship between interfacial activity and the structure of the hydrophobic part of a surfactant molecule has not been much studied (1). In particular simple cycloalkane hydrophobic structures do not seem to have been investigated, most of the literature data dealing with surface properties of molecules with single or double n-alkyl chains. Recently we have investigated the free energy of adsorption and micellization behaviour of cyclohexanealkyl carboxylic acids and their salts in connection with their occurrence in petroleum (2). In this paper we report our further measurements of the standard free energies of adsorption of other cycloalkane and cyclopentanealkyl carboxylic acids in order to find out quantitatively how much the standard free energy of adsorption of the CH_2 group depends on the cyclic closure of a straight aliphatic chain.

For straight chain paraffinic compounds the free enregy of adsorption has been described by Traube's rule (1, 3) as

$$[1] \quad \Delta G^0_{ad} = A + BN$$

where N is the number of carbon atoms in the chain. The constant A is thought to depend only on the kind of hydrophilic group that is attached to the chain (ref. 3 and ref. 1, Chapt. 11). The constant B has been ascribed a value of -2.6 kJ mol^{-1}/CH_2 (ref. 3 and ref. 1, Chapt. 11), while later results on fatty acids (4) indicated a value of -3.3 kJ mol^{-1}/CH_2. A value of -3.1_5 kJ mol^{-1}/CH_2 based on straight chain alcohols has also been cited recently (5). It thus appears that the free energy of adsorption of the CH_2 group is about -3.2 kJ mol^{-1} for straight aliphatic chains. In this paper we show that the standard free energy of adsorption of the CH_2 group depends on the hydrophobic structure in which the CH_2 group is located.

[1]Present address: Department of Chemistry, University of Alberta, Edmonton, Alberta.

Experimental

The surface tensions were measured by the drop volume method using the Gilmont ultra-precision syringe (± 0.0001 cm^3). The syringe was mounted in a jacketed cell through which water that was thermostatted at 25.0 ± 0.1°C was circulated. The outside wetted diameter of the stainless steel tube from which drops were formed was measured with a travelling microscope to be 0.272 ± 0.001 cm. The surface tension of the water obtained from the Gelman Water I System was determined to be 71.9 mN m^{-1}, and this water was used for making up the solutions. The densities of solutions were measured with a vibrating tube Sodev densitometer to ± 0.00005 g cm^{-3}. The calculations of surface tensions using Harkins' corrections were done according to equations given in ref. 6.

The carboxylic acids were purchased from Pfaltz & Bauer or from Aldrich with stated purity of 96–99%. The general procedure for purifying these acids was as follows. The acids were converted to their sodium salts with a 1 molar aqueous solution of NaOH (pH ≃ 10.5), and the resulting solutions were filtered through 0.22 μm millipore filters to remove insoluble nonacidic impurities. The salts were then isolated in the solid state on a steambath, and then extracted with ether in a Soxhlet appartus for 3–4 days. After the salts were dried in a vacuum desiccator, they were converted back to acids with aqueous HCl (ph ≃ 2.5). Depending on the solubility of the acids in water, they were isolated either by liquid/liquid extraction (ether) or with a separating funnel. The acids were then redistilled once or twice under vacuum and used as such. Infrared and nmr spectra did not indicate presence of impurities.

The total uncertainty of individual measurements is estimated to be ± 0.3 mN m^{-1} or less. This larger uncertainty is partly due to aging phenomena in the equilibration of the drops (7).

Results

The Traube constants were estimated from the surface tension data by four independent methods: (*i*) graphically from the data in the low concentration region; (*ii*) as a limit at zero concentration of second degree polynomial least-squares fit.

[2] $\gamma = a_{0(2)} + a_{1(2)}C + a_{2(2)}C^2$

where C is molarity and (2) refers to second degree polynomial. In this case the Traube constant, defined by

[3] $\alpha = \lim_{C \to 0} \left(-\frac{d\gamma}{dC}\right)$

is given by $\alpha = a_{1(2)}$; (*iii*) as a zero concentration limit using a third degree polynomial least-squares fit

[4] $\gamma = a_0 + a_{1(3)}C + a_{2(3)}C^2 + a_{3(3)}C^3$

where (3) refers to third degree polynomial. The Traube constant is now equal to $a_{1(3)}$; (*iv*) from nonlinear least-squares analysis using Szyszkowsky's equation[2]

[5] $\pi = a \ln (1 + bC)$

where π is surface pressure that is defined by $\pi = \gamma_0 - \gamma$ where γ_0 is the surface tension of pure water and γ is the surface tension of the solution. The Traube constant is given now by $\alpha = ab$.

[2]Fortran program to fit interfacial data to Szyszkowsky's equation is available from the authors.

In this paper we define the standard free energy of adsorption ΔG^0_{ad} by the relation (8, 9)

[6] $\Delta G^0_{ad} = -RT \ln \alpha$

This definition has been applied to data for fatty acids (2, 4) but other definitions involving different standard states are possible (5, 10). In eq. [6] the implied standard states are the ideal solution of unit molarity for the bulk phase and the standard surface pressure of 1 mN m^{-1} for the surface phase. The least-squares derived coefficients, the Traube constants, and the standard free energies of adsorption are given in Tables 1 and 2.

Discussion

The estimation of Traube constants

From Tables 1 and 2 it is seen that two sets of Traube's constants can be derived from the data. The graphical method and the second degree polynomial fit (Table 1) give standard free energies precise to ±0.2 kJ mol^{-1} and in agreement with each other. The 3rd degree polynomial fit and Szyszkowsky's equation (11, 12) give concordant standard free energies of adsorption precise to ±0.1 kJ mol^{-1}. However, these two sets

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

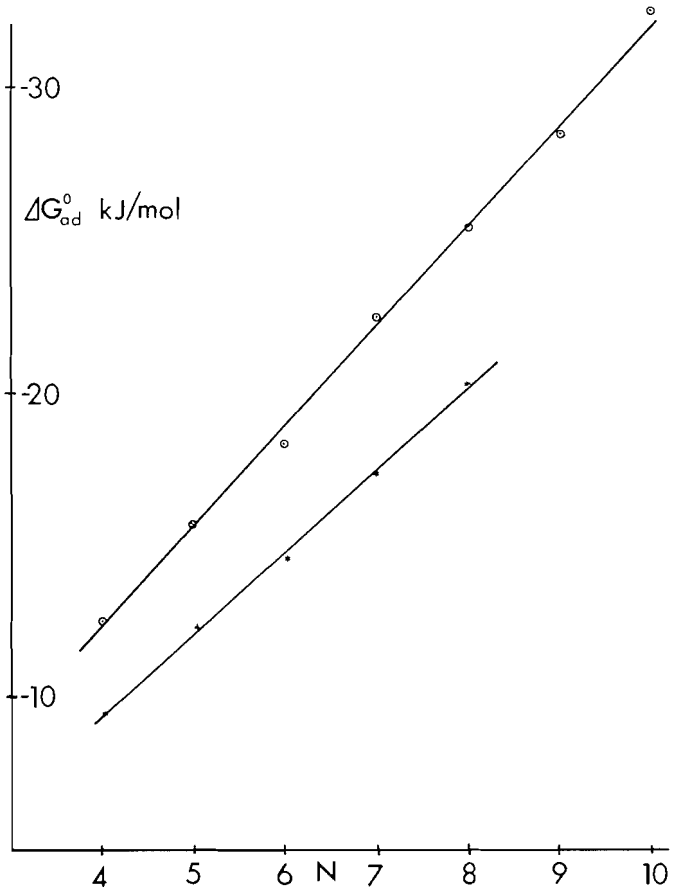

FIG. 1. Standard free energies of adsorption of straight chain paraffinic acids (○) and of cycloalkane carboxylic acids (*).

of data differ on average by 0.8 kJ mol^{-1}. For the purpose of the following correlations it does not matter which set of data is used since only the values of constant A in eq. [1] are affected. We have used the data from Table 1 for the sake of consistency for comparisons with previous work (2, 4).

The standard free energies of adsorption of CH_2 group

In Fig. 1 the standard free energies of adsorption of cycloalkane carboxylic acids are plotted against the number of carbon atoms, together with those for straight chain acids (2, 4). The standard free energies of adsorption of paraffinic acids were used to estimate the coefficients of the straight line (least-squares) as

[7] ΔG^0_{ad} (P.A.) = 0.7(±0.7) − 3.3(±0.1) N

where P.A. refers to straight chain paraffinic acids. The standard free energies of adsorption of cycloalkane carboxylic acids were found to obey eq. [8]

[8] ΔG^0_{ad} (C.P.A.) = 0.3(±0.7) − 2.5(±0.2) N

where C.P.A. refers to cycloparaffinic acids. The slope in eq. [8] is independent of the choice of the data given in Tables 1 and 2 within the experimental error. Clearly the free energy of adsorption of the CH_2 group (the slopes in eqs. [7] and [8] is by 0.8 kJ mol^{-1} less negative if the CH_2 group is located in a cycloparaffinic ring than if the CH_2 group is located in a straight paraffinic chain.

A further correlation is possible. The standard free energies of adsorption of cyclopentanealkyl and cyclohexanealkyl (2) carboxylic acids are shown in Fig. 2, where they are plotted against the number of carbon atoms. From these graphs the slope is estimated to be $-2.8(0.2_5)$ kJ mol^{-1} as the free energy of adsorption of the CH_2 group that is located in the alkyl portion of the cycloalkanealkyl moiety. These results may be summarized by saying that the standard free energy of adsorption of the CH_2 group located in a cycloalkanealkyl moiety is well described by the rule of three ($-RT$ ln 3), which gives -2.7 kJ mol^{-1}. The standard free energy of the CH_2 group in a straight paraffinic chain of alkanoic acids, however, does not follow this rule. The difference is likely to be due to the presence of a terminal methyl group in straight paraffinic chains and, since the slopes in Fig. 1 are different, the effect of the methyl group is not additive.

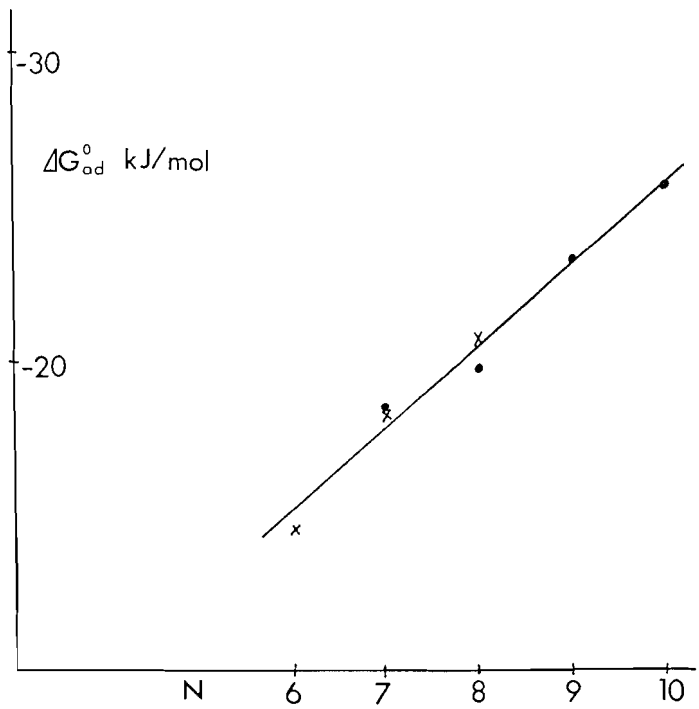

FIG. 2. Standard free energies of adsorption of cyclohexanealkyl carboxylic acids (●) and of cyclopentanealkyl carboxylic acids (×).

Received November 2, 1982

PAUL BIRD, MALCOLM SAINSBURY, and DAVID I. C. SCOPES. Can. J. Chem. **61**, 1071 (1983).

We find that the product from the interaction of 6,7-dimethoxy-3-isochromanone and hydrazine, followed by treatment of the intermediate hydrazide with mineral acid, is not 6,7-dimethoxy-1,3-dihydro-3-(2*H*)isoquinolone as stated in the literature, but rather bis-2,2-(6,7-dimethoxy-1,4-dihydro-3(2*H*)isoquinolonyl). An explanation of the formation of this product is provided.

PAUL BIRD, MALCOLM SAINSBURY et DAVID I. C. SCOPES. Can. J. Chem. **61**, 1071 (1983).

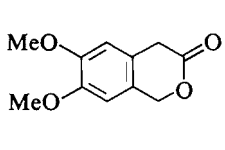
Nous avons trouvé que la réaction entre la diméthoxy-6,7 isochromanone-3 et l'hydrazine, suivie de l'action d'un acide minéral sur l'hydrazide intermédiaire, donne la bis-2,2 (diméthoxy-6,7 dihydro-1,4 (2*H*) isoquinolonyle-3) et non pas la diméthoxy-6,7 dihydro-1,3 (2*H*) isoquinolone-3 comme mentionnée dans la littérature. Nous expliquons la formation de ce produit.

[Traduit par le journal]

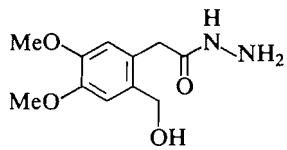
In 1969 Rosen and Popp claimed (1) to have prepared 6,7-dimethoxy-1,4-dihydro-3(2*H*)isoquinolone (**3**, R = H) by reacting the isochromanone (**1**) with hydrazine, followed by treatment of the intermediate hydrazide (**2**) with 10% hydrochloric acid. We have repeated this preparation and now find that the product of the reaction is a colourless crystalline solid, which when first formed contains water of crystallization; this is not removed by recrystallization from ethanol, but is eliminated by azeotroping with toluene. When dry, our compound does not contain any protons which exchange with deuterium atoms from deuterium oxide and, unlike Rosen and Popp's product, it does not exhibit a band at 3400 cm^{-1} in the infrared spectrum.

We observe a slightly lower melting point for our compound (~215°C) than that quoted by Rosen and Popp (277–228°C, ethanol) and there are also differences between the published ^1H nmr data and ours; for example, in our product the aromatic protons resonate at δ 6.87 and δ 6.84, whereas Rosen and Popp observe a signal at δ 7.3 in the same solvent (DMSO-d_6). Thus we cannot be sure that we are dealing with the same compound, yet our chemical shift values correspond very closely with those of authentic 6,7-dimethoxy-2-methyl-1,4-dihydro-3(2*H*)isoquinolone (**3**, R = Me) (2).[1]

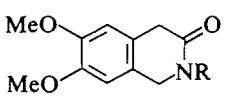
The mass spectrum of our product, recorded at an ionization potential of 70 eV, shows a weak molecular ion at m/z 412 (0.5%) which corresponds to $C_{22}H_{24}N_2O_6$ rather than to $C_{11}H_{13}NO_3$ (m/z 207) as required for the isoquinolone (**3**, R = H), but there are major fragmentation peaks at m/z 221 (30%), 208 (12%), 207 (26%), 206 (15%), 71 (30%), and 69 (100%). The molecular ion is further established by chemical ionization techniques (isobutane), which provide a $M + 1$ peak at m/z 413 (3%) and fragment ions at m/z 222 (7%), 208 (21%), and 71 (100%), and it is now clear that our compound is bis-2,2-(6,7-dimethoxy-1,4-dihydro-3(2*H*)isoquinolonyl) (**4**), i.e. the dehydrodimer of the isoquinolone (**3**, R = H). The low intensity of the molecular ion is readily understood in terms of scission of the N—N bond with transfer of a hydrogen atom via a cyclic transition state.



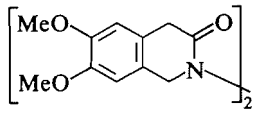
1



2

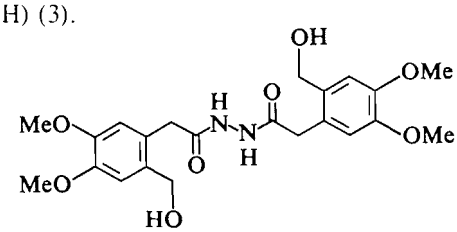


3



4

Both Rosen and Popp and ourselves have shown that under acidic conditions some of the hydrazide (**2**) is degraded back to the isochromanone (**1**), and it seems probable that these two compounds then react together to form the diacylhydrazide (**5**) which under the reaction conditions undergoes a double ring closure to the dehydrodimer (**4**). Such a sequence of reactions resolves the obvious difficulty which Rosen and Popp had in explaining why the least basic nitrogen in the hydrazine (**2**) was involved in the cyclization step, and also obviates the necessity to invoke a very unusual reductive N–N cleavage reaction in order to account for the formation of the "simple" isoquinolone (**3**, R = H) (3).



5

[1]*Note added in proof*: In the course of recent correspondence, Professor Popp confirms that the two samples are identical, and states that he has arrived at similar conclusions concerning the structure of the compound, although these observations have not been published.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

We have repeated the reaction several times and on each occasion we have obtained the same result.

The ^{1}H nmr spectrum of our crude reaction product shows signals at similar chemical shifts to those of the refined compound, although the peaks are broadened and there is a signal of variable intensity due to water. At no time have we isolated a product which corresponds to the monomeric structure (**3**, R = H) (3).

Experimental

*Bis-2,2-(6,7-dimethoxy-1,4-dihydro-3(2H)-isoquinolonyl) (**4**)*

The hydrazide (**2**) (5 g), prepared as described previously (1), was heated in 10% hydrochloric acid solution (200 cm^3) for two hours. After cooling, water (50 cm^3) was added, and the solid product filtered off and crystallized from ethanol. Since this product had an indefinite mp it was then recrystallized twice more from toluene, allowing some of the solvent to boil off on each occassion. This afforded the title compound as colourless prisms (3.1 g), mp ~215°C (dec.); ν_{max} ($CHCl_3$): 1660, 1610 cm^{-1}; ^{1}H nmr δ (DMSO-d_6): 6.87, 6.84 (2 × s, 4H, 5-H, 8-H, 5′-H, 8′-H), 4.58 (s, 4H, 2 × CH_2N), 3.76 (s, 12H, 4 × CH_3O), 3.67 (s, 4H, 2 × CH_2CO); ^{13}C nmr δ (CF_3CO_2H): 174.2 (s, C=O), 150.7, 150.0 (2 × s, 4 × C—OCH_3), 123.7, 123.4 (2 × s, 4a-C, 8a-C, 4a′-C, 8a′-C), 112.9 (d, 8-C, 8′-C), 111.1 (d, 5-C, 5′-C), 57.3 57.2, (2 × q, 4 × OCH_3), 53.2 (t, 1-C, 1′-C), 37.2 (t, 4-C, 4′-C); *m/z* (EI): 412 (0.5%), 410 (2%), 221 (30%), 208 (12%), 207 (26%), 206 (15%), 192 (16%), 188 (16%), 149 (20%), 71 (30%), 69 (100%). *Mol. Wt.* calcd. for $C_{22}H_{24}N_2O_6$: C 64.1, H 5.9, N 6.8%; found: C 63.8, H 5.9, N 6.65%.

Some alkali metal alkyl amides as alkyne isomerization reagents: selective isomerization of one triple bond of a diynol[1]

SUZANNE R. ABRAMS,[2] DONATO D. NUCCIARONE, AND WARREN F. STECK
Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Sask., Canada S7N 0W9

Received April 30, 1982[3]

SUZANNE R. ABRAMS, DONATO D. NUCCIARONE, and WARREN F. STECK. Can. J. Chem. **61**, 1073 (1983).

The lithium and sodium salts of 1,2-diaminoethane, 1,3-diaminopropane, n-butylamine, and the lithium salt of isobutylamine were studied as potential reagents for isomerization of triple bonds in alkyn-1-ols. The sodium salts of the diamines afforded high yields of the ω-alkyn-1-ol. Somewhat surprisingly, the sodium salt of n-butylamine also effects isomerization to the terminal position. The lithium salt of 1,3-diaminopropane gave the highest conversion of 2- to 3-alkyn-1-ol. A novel, selective rearrangement of one triple bond of a diynol, a 2,ω- to 3,ω-diyn-1-ol isomerization, was incorporated into a synthesis of the insect sex pheromone 3,13-octadecadienol acetate.

SUZANNE R. ABRAMS, DONATO D. NUCCIARONE et WARREN F. STECK. Can. J. Chem. **61**, 1073 (1983).

On a évalué l'utilisé des sels de sodium et de lithium du diamino-1,2 éthane, du diamino-1,3 propane, de la n-butylamine et du sel de lithium de l'isobutylamine en tant qu'agents potentiels d'isomérisation des triples liaisons des alcynols-1. Les sels de sodium des diamines donnent des rendements élevés en ω-alcynols-1. Par opposition le sel de sodium de la n-butylamine affecte aussi l'isomérisation vers la position terminale. Le sel de lithium du diamino-1,3 propane donne le plus fort pourcentage de transformation des alcyne-1 ols-1 en alcyne-3 ols-1. Dans le cadre de la synthèse de la phéromone sexuelle des insectes, l'acétate d'octadecadiène-3,13 ol, on a introduit une nouvelle transposition sélective d'une triple liaison d'un diynol à savoir l'isomérisation d'un 2,ω-diyne ol-1 en un 3,ω-diyne ol-1.

[Traduit par le journal]

Introduction

Isomerization of internal triple bonds of straight chain alkynes and alkyn-1-ols to the free terminus is effected by the sodium (1) and potassium (2) salts of 1,3-diaminopropane. This reaction is useful in synthesis as it makes α,ω-disubstituted long chain compounds readily available. We wish to report a study on the potential of some other alkali metal alkyl amides to isomerize triple bonds, and illustrate their application in a novel selective isomerization reaction.

Results and discussion

The isomeric linear decyn-1-ol system, which has been used in a previous study (3), was employed to compare potential isomerization reagents. The isomer with the triple bond furthest removed from the free terminus, 2-decyn-1-ol, was the starting material in this work. Four lithium reagents were prepared from 1,2-diaminoethane, 1,3-diaminopropane, n-butylamine, and isobutylamine. The sodio analogs of the two diamines and n-butylamine were also studied. Rearrangement reactions were carried out with 5.5 equivalents of reagent at 55°C. The reagents were formally 1.7 molar in the appropriate amine which also served as the solvent for the rearrangement reactions. In Fig. 1 is displayed the percentage of 9-decyn-1-ol, the isomer wherein the triple bond has migrated to the end of the chain, obtained with the lithium and sodium salts of 1,2-diaminoethane and 1,3-diaminopropane and with the sodium salt of n-butylamine. The lithium salts of n-butylamine and isobutylamine gave little 9-decyn-1-ol.

The sodium salts of 1,2-diaminoethane and 1,3-diaminopropane both prove to be excellent isomerization reagents. 9-Decyn-1-ol comprises over 95% of the total decyn-1-ol mixture after 0.5 hour and is obtained in 95% yield using the sodium salt of 1,2-diaminoethane for 1.0 hour. This reagent offers some practical advantages since it can be formed at a lower temperature and the solvent is dried by distillation at atmospheric pressure from BaO more conveniently. Solutions of both reagents can be stored in the freezer for over a month without loss of activity.

It is surprising that the sodium salt of n-butylamine is an effective isomerization reagent. The extremely fast reaction rates observed with the original isomerization reagents were attributed to a concerted, bimolecular mechanism involving the bidentate nature of the base (2). A cycle was postulated wherein the amide nitrogen would abstract a proton from the carbon next to the triple bond and the resultant allenic anion would abstract a proton from the other nitrogen of the base. The result obtained for the isomerization with sodium n-butylamide demonstrates that it is not necessary to invoke a concerted, cyclic mechanism.

While the rate of isomerization observed with the lithium salts is slower and thus not as useful for preparation of terminal acetylenes, it was thought that these milder reagents might be useful in selective rearrangements. Earlier work showed (3) that homopropargyl isomers are particularly stable and accumulate in rearrangement reactions even when the triple bond in the starting material was closer to the free terminus. It was hoped that high conversion of propargyl to homopropargyl compounds might be obtained. The rearrangement of 2- to 3-decyn-1-ol was studied with the different reagents at 10°C, just above the freezing point of 1,2-diaminoethane. In Table 1 is shown the maximum percentage of 3-decyn-1-ol observed. The lithium salts of the diamines gave the best conversions in the shortest times. The lithium salts of the monoamines reacted too slowly, while the sodium salts all led to further rearrangements to other products. The maximum conversion to the homopropargyl isomer is obtained with the lithium salt of 1,3-diaminopropane at −11°C.

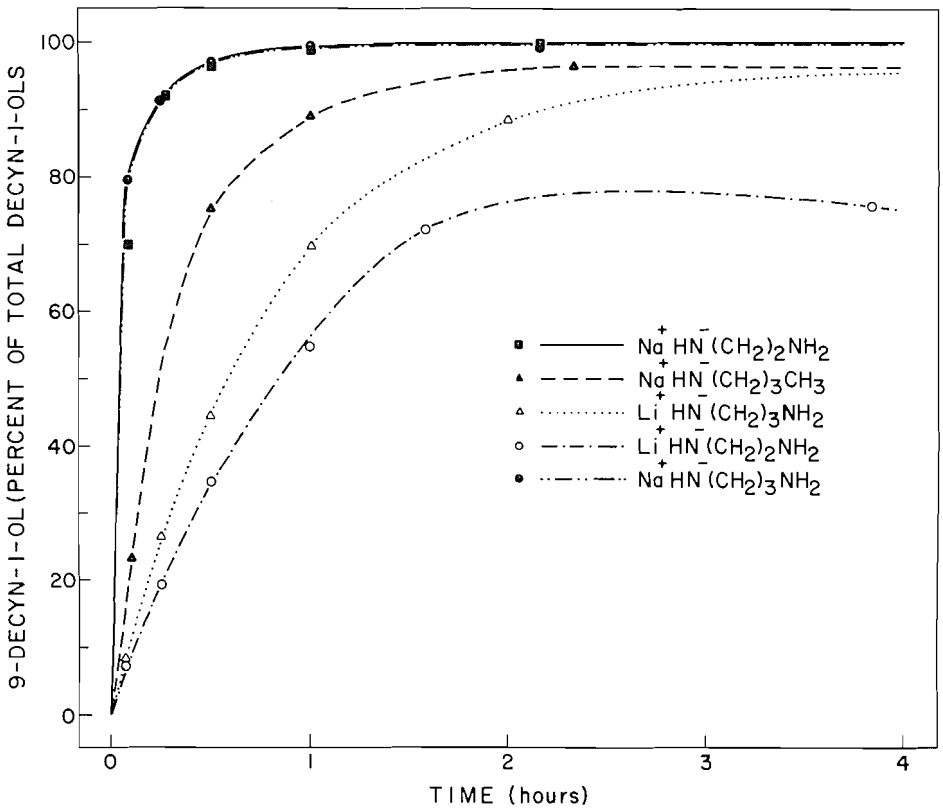

FIG. 1. Isomerization of 2-decyn-1-ol with some alkali metal amides at 55°C.[4]

TABLE 1. Rearrangement of 2- to 3-decyn-1-ol with alkali metal alkyl amides

Isomerization reagent	Reaction time (min)	Reaction temperature (°C)	% 3-Decyn-1-ol of total decyn-1-ols
Li^+ $H\bar{N}(CH_2)_2NH_2$	5	10	76
Li^+ $H\bar{N}(CH_2)_3NH_2$	5	10	78
	15	−11	82
Na^+ $H\bar{N}(CH_2)_3NH_2$	5	10	69
Na^+ $H\bar{N}(CH_2)_2NH_2$	5	10	47
Na^+ $H\bar{N}(CH_2)_3NH_2$	10	10	46
Li^+ $H\bar{N}(CH_2)_3CH_3$	60	10	55
Li^+ $H\bar{N}CH_2CH(CH_3)_2$	60	10	66

It was anticipated that, by employing a mild isomerization reagent, a unique selective isomerization of a one triple bond of a 2,ω-diynol might be possible. Such an isomerization has been incorporated as the key step in a new synthesis of *Z,Z*-3,13-octadecadienyl acetate (**5**) (Scheme 1), an insect sex pheromone of many clearwing moths including the cottonwood crown borer (4), the smaller clearwing moth (5), and the lesser peachtree borer (6). To our knowledge, this is the first report of a selective isomerization of one triple bond of a diyne independent of other acetylene groups in the molecule. Two triple bonds which are widely separated, as in α,ω-diynes, respond to base treatment as two separate monoacetylenes and diynes with triple bonds in close proximity tend to rearrange to give conjugated isomers (7, 8).

The synthesis is outlined in Scheme 1. The starting diyn-1-ol **2** was prepared by reaction of the monolithium salt of 1,12-tridecadiyne with paraformaldehyde. The selective rearrangement to **3** was carried out using 7.0 equivalents of isomerization reagent: 2 equivalents were employed to form the anion at each end of the molecule and 5 equivalents were available for the rearrangement reaction. With the lithium salt of 1,2-diaminoethane at ambient temperature, the ratio of **3** to **2** after 5 min was 7:1, and after 15 min was 12:1. By the latter time, some of the product had undergone further rearrangement, but still made up 61% of the total reaction mixture. Using the same conditions, but with the sodium salt of 1,2-diaminoethane, the ratio of **3** to **2** was only 1:1. To prevent side product formation the lithium salt of 1,3-diaminopropane at 0°C was used. The rearrangement proceeded more slowly: at 15 minutes the proportion of **3** to **2** was 3:1 but **3** made up 66% of the total diynol mixture. The propargylic and homopropargylic isomers were separable by silicic acid chromatography. The desired product was obtained in 53% isolated yield based upon consumed starting material.

[4]*Note added in proof*: The yields of 9-decyn-1-ol (glc) after 1.0 hour were greater than 70%. The lithium reagents gave lower yields: $LiNH(CH_2)_3NH_2$ (52%) and $LiNH(CH_2)_2NH_2$ (32%).

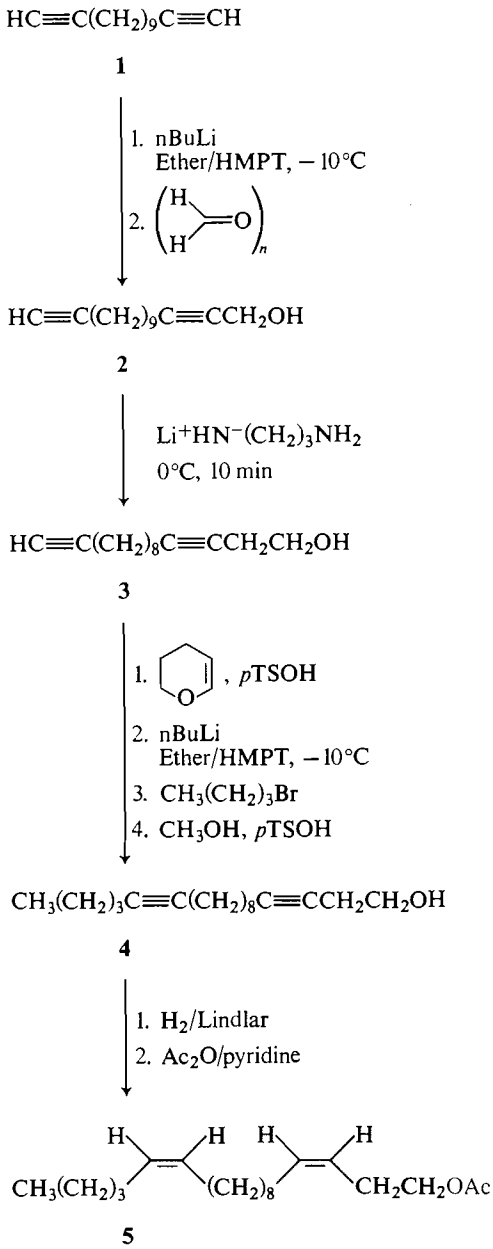

SCHEME 1

Alkylation of **3**, protected as the tetrahydropranyl ether, with butyl bromide and removal of the protecting group with methanol and *p*-toluenesulfonic acid gave **4** identical with authentic material (4, 9). Hydrogenation over Lindlar catalyst and acetylation gave the pheromone **5** (4).

Thus the sodium and lithium salts of amines can be useful isomerization reagents for different purposes. The sodium salts give high yields of terminal alkynes free of other isomers. The lithium salts can be employed in selective isomerizations as the reagents are strong enough bases to abstract the terminal acetylenic proton, trapping the triple bond at the end of the chain, and mild enough to effect the Δ2 to Δ3 rearrangement in good yield.

Experimental

The procedure for analysis of decyn-1-ol mixtures was the same as described in a previous paper: the alcohols were converted to the TMS ethers with *N,O*-bistrimethylsilylacetamide and analyzed by glc using a 30M SP 2100 capillary column. n-Decanol was added as internal standard in decyn-1-ol isomerization reactions. The amine solvents were distilled from BaO and stored over activated 4 Å molecular sieves. All reactions were carried out under a slight positive pressure of dry nitrogen in flame dried glassware.

Proton nmr spectra were recorded on an HA-100 spectrometer, with deuterochloroform as solvent and internal tetramethylsilane as reference. Carbon nmr spectra were recorded on an XL-100-15 spectrometer in the Fourier transform mode at 25.16 MHz with proton noise decoupling. Deuterochloroform served as solvent and internal deuterium lock.

Preparation of isomerization reagents

Lithium salt of 1,2-diaminoethane

According to the method of Reggel *et al.* (10), 1,2-diaminoethane (20 mL) was added to lithium wire (275 mg, 40 mmol). As the metal dissolved, the mixture turned blue and heat evolved as the salt formation began. Additional heating at 50°C was applied until the blue colour disappeared leaving a white suspension of the salt.

Lithium salt of 1,3-diaminopropane

The same procedure was used as for 1,2-diaminoethane.

Sodium salt of 1,2-diaminoethane

To sodium hydride (57% in mineral oil, 1.70 g, 40 mmol, washed free of oil with petroleum ether) was added 1,2-diaminoethane (20 mL). The mixture was stirred and heated to 50°C. After about a 5 min induction period, gas evolution was noted and the mixture turned to blue-grey and then to brown solution in 0.5 hour.

Sodium salt of 1,3-diaminopropane

The reagent was formed exactly as above except that heating to 70°C was required.

Sodium salt of n-butylamine

A mixture of sodium hydride (1.70 g, 40 mmol, washed free of oil) and n-butylamine (20 mL) was refluxed overnight to give a brown/purple mixture.

Lithium salt of n-butylamine

To n-butylamine (6.5 mL) at −10°C was added BuLi (in hexane, 0.6 *M*, 20 mL, 13 mmol). The hexane was removed by distillation at reduced pressure to give a yellow solution.

Lithium salt of isobutylamine

The lithium salt was prepared by reaction of isobutylamine (6.5 mL) with nBuli (in hexane, 0.6 *M*, 20 mL, 13 mmol) at −10°C. The hexane and isobutylamine were removed at reduced pressure and 6.5 mL isobutylamine added to the resultant solid.

General isomerization procedure

To the prepared reagent (nominally 40 mmol, in 20 mL solvent) at either 55° or 10°C was added a solution of 2-decyn-1-ol (900 mg, 6.0 mmol) and n-decanol (90 mg, 0.6 mmol) in solvent (4 mL). Samples of 1.0 mL were removed at intervals: 5 min, 15 min, 30 min, 1 h, 2 h, and 4 h; each was poured onto ice-water and extracted with ether (2×). The combined organic phases were washed with NaCl solution, dried over Na_2SO_4, filtered, and the solvent evaporated.

9-Decyn-1-ol

To the sodium of 1,2-diaminoethane (prepared from NaH (1.70 g, 40.0 mmol) and 1,2-diaminoethane, 20 mL) at 55°C was added 2-decyn-1-ol (925 mg, 60 mmol) in 1,2-diaminoethane (4.0 mL). After 1.0 h, the mixture was poured onto ice/water and extracted with ether (3×). The combined organic phases were washed with NaCl solution, dried over Na_2SO_4, filtered, and the solvent evaporated to yield 1.09 g crude product which was chromatographed over silica gel (Bio Rad 200–400 mesh), eluting with ether/hexane mixtures to separate residual mineral oil from the product 9-decyn-1-ol (880 mg, 95%).

2,13-Tetradecadiyn-1-ol (2)

To a solution of 1,12-tridecadiyne (1.0 g, 5.7 mmol) in diethylether (dry, 45 mL) and HMPT (dry, 5 mL) at −10°C was added n-butyllithium (5.7 mmol, 3.5 mL). After 0.5 h, paraformaldehyde (250 mg, 8.5 mmol) in ether (8 mL) was added. The mixture was stirred

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

and allowed to warm at room temperature overnight. Ice/water was added; the organic phase separated and the aqueous phase was extracted with ether (3×). The combined organic phases were washed successively with water and NaCl solution, then dried over Na_2SO_4, filtered, and the solvent evaporated. The crude product was chromatographed over silica gel, eluting with ether/hexane mixtures to give 1,12-tridecadiyne (500 mg) and desired product **2** (350 mg, 60%, based upon consumed starting material). The product was distilled (Kugelrohr oven temperature 110°C) at 0.1 Torr; ν_{max} (film): 3350 (s), 3280 (s), 2205 (w) and 2103 (w) cm^{-1}; ^1H ($CDCl_3$) δ: 4.21 (t, J = 1 Hz, 2H), 2.1–2.3 (m, 4H), 1.90 (t, J = 1.5 Hz, 1H), and 1.2–1.6 (m, 14H); ^{13}C ($CDCl_3$) δ: 86.56, 84.81, 78.45, 68.16, 51.38, 29.38, 29.09, 29.09, 28.87, 28.75, 28.65, 28.52, 18.78, and 18.44 ppm. *Anal.* calcd. for $C_{14}H_{22}O$: C 81.50, H 10.75; found: C 81.60, H 10.94%.

3,13-Tetradecadiyn-1-ol

To the lithium salt of 1,3-diaminopropane (prepared from lithium (150 mg, 21 mmol) and 1,3-diaminopropane, 12 mL) at 0°C was added a solution of **2** (600 mg, 3 mmol) in 1,3-diaminopropane (6 mL). The reaction was quenched after 10 min and worked up as usual to give 500 mg crude product which was chromatographed over silicic acid, eluting with ether/hexane mixtures to give recovered **2**, 80 mg, and **3**, 275 mg, 53% yield based upon consumed starting material. The product was distilled (Kugelrohr oven temperature 110°C) at 0.1 Torr; ν_{max} (film): 3350 (s), 3300 (s), and 2103 (w) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.61, (t, J = 6.5 Hz, 2H), 2.38 (tt, J = 6.5, 1.5 Hz, 2H), 2.0–2.25 (m, 4H), 1.91 (t, J = 1.5 Hz, 1H), and 1.2–1.6 (m, 12H); ^{13}C nmr ($CDCl_3$) δ: 84.76, 82.65, 76.42, 68.15, 61.42, 29.01, 29.01, 29.01, 28.84, 28.72, 28.50, 23.22, 18.77, and 18.43 ppm; analyzed as the *p*-nitrobenzoate. *Anal.* calcd. for $C_{21}H_{25}NO_4$: C 70.95, H 7.10, N 3.94; found: C 71.08, H 7.09, N 3.92.

3,13-Octadecadiyn-1-ol

To **3** (380 mg, 1.85 mmol), cooled to 0°C, was added dihydropyran (5 mL) and 50 mg *p*-toluenesulfonic acid. After 1.5 h K_2CO_3 was added, the mixture was filtered, and the solid washed with ether. The solvents were evaporated and the crude THP ether was alkylated immediately, by dissolving it in diethyl ether (dry, 20 mL) and HMPA (dry 5 mL) and cooling to −10°C. A solution of n-butyllithium (in hexane, 2.2 mmol, 1.4 mL) was added, followed by n-butylbromide (0.4 mL, 2.3 mmol, 1.25 equivalent). The reaction was stirred at ambient temperature overnight, then ice/water was added. The phases were separated and the aqueous layer worked up with ether 3×. The combined organic phases were washed with water, then NaCl solution, dried over Na_2SO_4, filtered, and the solvent removed to yield a yellow oil which was suspended in methanol (100 mL) and *p*-toluenesulfonic acid (50 mg). The mixture was refluxed for 3.5 h and then the methanol evaporated. The residue was partitioned between ether and $NaHCO_3$ solution. The aqueous phase was extracted with ether (3×) and the combined organic phases were washed with water and NaCl solution, then dried over Na_2SO_4 and evaporated to give a brown oil which was chromatographed over silicic acid, eluting with ether/hexane mixtures to give 120 mg **4** (9) and 120 mg **3**. The yield based upon consumed starting material was 40%. Semihydrogenation and acetylation were carried out as previously described (4).

A homoallyl radical rearrangement. Kinetics of the isomerization of the 2,2-dimethyl-3-buten-1-yl radical to the 1,1-dimethyl-3-buten-1-yl radical[1]

CHRYSSOSTOMOS CHATGILIALOGLU AND KEITH U. INGOLD[2]

Received September 1, 1982

CHRYSSOSTOMOS CHATGILIALOGLU, KEITH U. INGOLD, IRENE TSE-SHEEPY, and JOHN WARKENTIN. Can. J. Chem. **61**, 1077 (1983).

Rate constants for the overall rearrangement of the 2,2-dimethyl-3-buten-1-yl radical to the 1,1-dimethyl-3-buten-1-yl radical, $k^{C=C}$, have been measured from − 145°C to −101°C by kinetic epr spectroscopy and at 40°C by spin trapping with 1-methyl-4-nitroso-3,5-diphenylpyrazole. The temperature dependence can be represented by

$$\log (k^{C=C}/s^{-1}) = (12.5 \pm 0.6) - (6.6 \pm 0.4)/\theta$$

where $\theta = 2.3RT$ kcal mol^{-1}. This rearrangement, which must proceed via a 2,2-dimethylcyclopropylcarbinyl radical as an intermediate, is one of the fastest rearrangements involving a primary alkyl radical. At 25°C, $k^{C=C} = 4.3 \times 10^7$ s^{-1}, which makes this rearrangement about 10 000 times faster than the rearrangement of the simplest homoallyl radical, 3-buten-1-yl. This rate enhancement is attributed to steric acceleration of ring closure by the *gem* dimethyl groups (Thorpe–Ingold effect).

CHRYSSOSTOMOS CHATGILIALOGLU, KEITH U. INGOLD, IRENE TSE-SHEEPY et JOHN WARKENTIN. Can. J. Chem. **61**, 1077 (1983).

On a mesuré les constantes de vitesse de la transposition globale du radicale diméthyl-2,2 butène-3 yle-1 en radical diméthyl-1,1 butène-3 yle-1, $k^{C=C}$, de −145°C à −101°C en utilisant la spectroscopie de rpe cinétique et à 40°C par piégeage de spin avec le méthyl-1 nitroso-4 diphényl-3,5 pyrazole. On peut représenter l'effet de la température par:

$$\log (k^{C=C}/s^{-1}) = (12,5 \pm 0,6) - (6,6 \pm 0,4)/\theta$$

où $\theta = 2,3RT$ kcal mol^{-1}. Cette transposition qui ne peut se produire que par l'intermédiaire du radical diméthyl-2,2 cyclopropylcarbinyle est l'une des plus rapides impliquant un radical alkyle primaire. A 25°C, $k^{C=C} = 4,3 \times 10^7$ s^{-1}, ce qui rend cette transposition environ 10 000 fois plus rapide que la transposition du radical homoallyle le plus simple: le butène-3 yle-1. On attribue cette augmentation de vitesse à l'accélération stérique de la fermeture de cycle par les groupes *gem*-diméthyles (effet de Thorpe–Ingold).

[Traduit par le journal]

Introduction

Homoallylic rearrangements of free radicals, eq. [1], are well known and there is much evidence that cyclopropylcarbinyl radicals are discrete intermediates in the process, eq. [1].[3] Some of the evidence is direct, for cyclopropyl products can be isolated in a few cases (eq. [2] (2); eq. [3][4]), and some is indirect as, for example, in the *cis* ⇆ *trans*

[1] 
interconversion of eq. [4] (3), where there is no reasonable alternative mechanism.

[2] 
Although there is no longer any doubt about the mechanism of vinyl group transfer in free radical rearrangements, little is

[3] 
[4] 
known about the kinetics of such processes. The rate constant for ring-closure of 1,1-dideuterio-3-buten-1-yl (eq. [5]) has the value 4.9×10^3 s^{-1} at 25°C (4)[5] and that for the overall irreversible rearrangement of eq. [6] is estimated to lie between

[5] 
1×10^4 s^{-1} and 5×10^4 s^{-1} (5). These are the only known values for the overall process of vinyl migration, although a few rate constants for the ring opening step alone have been estimated (1).

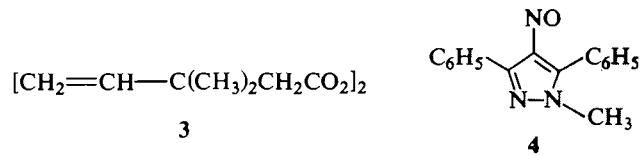
[6] 
We wish to report the kinetics of rearrangement of the 2,2-dimethyl-3-buten-1-yl radical (**1**) to the 1,1-dimethyl-3-buten-1-yl radical (**2**), eq. [7]). This rearrangement rate is of

[7] 
1 **2**

interest because of the question as to the magnitude of the "*gem* dimethyl acceleration factor" (cf. eq. [5]), which was found to be substantial in the analogous homopropargyl rearrangement (6). In addition, new "radical clocks" (7) are still required as aids to the quantitative study of free radical chemistry. That is, there is a need to increase the range of clock speeds, to fill in gaps in the existing range, and for clocks that are chemically compatible with as many reaction systems as possible.

Experimental

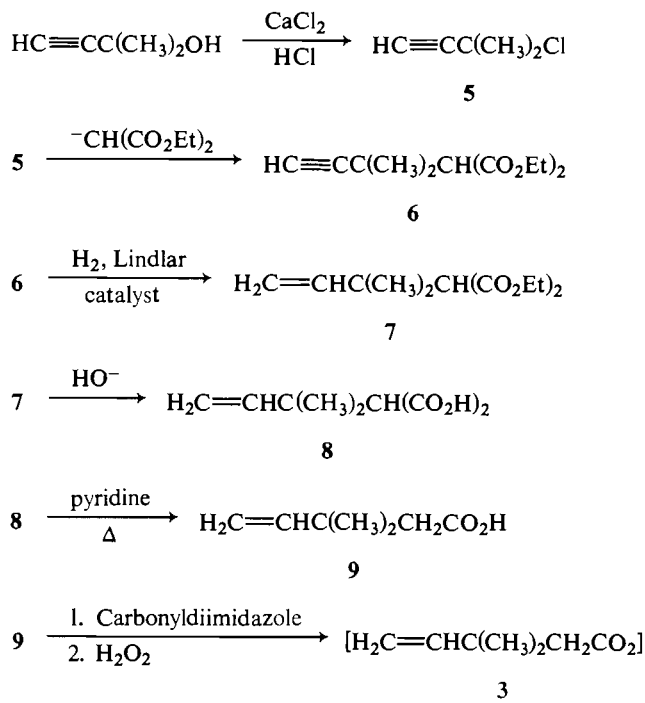
The steady state and kinetic epr techniques applicable to the study of radical rearrangements have been described (8–10). For direct epr studies, radicals **1** and **2** were generated by photolysis of 3,3-dimethyl-4-pentenoyl peroxide (**3**) in CF_2Cl_2 at low temperature. The region swept was 40 G wide and included lines of relative intensities 20, 30, 6, 15, and 12 from radical **2** and a line with relative intensity one from the 1:2:1 triplet spectrum of **1**. That line fell between the lines of relative intensity 20 and 30 from radical **2** (see parameters of Table 1) and was not well resolved from them. The total of these unresolved signals and the line of relative intensity 15 were doubly integrated. The latter integral was used to calculate the relative concentration of **2** and the former integral, corrected for the calculated contribution from **2**, was used to calculate the relative concentration of **1**. These relative concentrations were converted to absolute values in the usual way (8–10) through the use of the ruby signal and a solution of DPPH at a known concentration. For indirect epr studies, using the spin trapping technique, diacyl peroxide **3** was thermolyzed at 40°C in



3 **4**

benzene or dichloromethane solutions containing 1-methyl-4-nitroso-3,5-diphenylpyrazole (**4**). The buildup of nitroxide spin adducts from addition of **1** and **2** to **4** was monitored by recording repeatedly a part of the spectrum containing the outer and center lines of one of the wing triplets in the spectrum of the spin adduct of **1**. That center line overlapped with a wing line of the 1:1:1 triplet from the spin adduct of **2**. Double integration and simple calculation gave the relative concentrations of the two adducts. The rearrangement rate constant was then determined from the known rate constant for trapping of **1** by **4**, assumed to be the same as that for trapping of undecyl radicals by **4** ($1.5 \times 10^7 M^{-1}$ s^{-1} at 40°C) (18), and the known concentration of **4**.

Peroxide **3** was prepared by the sequence of steps below.



3-Chloro-3-methyl-1-butyne (5)

The published procedure (11) gave, from 84 g of 2-methyl-3-butyne-2-ol, 91.8 g of crude **5** which was distilled at 95–107 Torr, the fraction boiling at 27–30°C being collected. The distillate was redistilled at atmospheric pressure to afford, after a forerun boiling at 31–72°C, 37.4 g of pure **5**, bp 72–73°C (36% yield).

2,2-Dimethyl-3-butyne-1,1-dicarboxylic acid diethyl ester (6)

This compound was prepared from **5** by literature procedures (12,

[5]Barring large isotope effects, this means that the rate of overall rearrangement is $1/2 \times 4.9 \times 10^3$ s^{-1} (4).

13). From 24.96 g (243 mmol) of **5** was obtained 16.55 g (30%) of **6**, bp 63–68°C (0.2 Torr).

2,2-Dimethyl-3-butene-1,1-dicarboxylic acid diethyl ester (7)

Best results were obtained when **6** was hydrogenated over Lindlar catalyst at one atmosphere pressure in a solvent consisting of hexane and quinoline.

Lindlar catalyst (0.25 g) in 60 mL of hexane containing 0.3 mL of quinoline was exposed to H_2 at 1 atm for 30 min before **6** (4.55 g, 20.1 mmol) was added. When 20 mmol of H_2 had been taken up, the catalyst was filtered off and the hexane layer was washed with dilute acid and with dilute aqueous bicarbonate solution. It was dried over $MgSO_4$ and the hexane was evaporated to leave **7** as a colourless liquid (4.33 g, 94%).

2,2-Dimethyl-3-butene-1,1-dicarboxylic acid (8)

To diester **7** (4.27 g, 18.7 mmol) in ethanol (12 mL) was added 6 *N* NaOH (15 mL). The mixture was heated at 70°C for 2 h and at 85–90°C overnight. Hot water (40 mL) was added and the solution was concentrated on the rotary evaporator to remove ethanol. The aqueous solution was washed with CH_2Cl_2, acidified with 6 *N* HCl to pH = 1, and extracted with ethyl acetate. The extract was dried and evaporated to leave **8** as an off-white solid (3.11 g, 96%), mp 111–114.5°C.

3,3-Dimethyl-4-pentenoic acid (9)

Decarboxylation of **8** by heating it neat at 158°C for 3 min gave mostly β,β-dimethyl-γ-valerolactone, ir: ν_{CO} 1785 cm^{-1}. Cyclization could be avoided by heating **8** with pyridine at 145°C.

Diacid **8** (3.79 g, 22.0 mmol) was heated at 145°C with 374 μL of pyridine for 1 h. Distillation at 0.2 Torr, with the oil bath temperature between 94° and 100°C, gave **9** (2.81 g, 99%) as a colourless liquid; ^{1}H nmr ($CDCl_3$) δ: 1.20 (s, 6H), 2.37 (s, 2H), 4.82–5.22 (m, 2H), 5.78–6.30 (m, 1H), 11.9 (s, 1H).

3,3-Dimethyl-4-pentenoyl peroxide (3)

Acid **9** (1.72 g, 13.4 mmol) in 5 mL of dry tetrahydrofuran was added to a suspension of *N,N'*-carbonyldiimidazole in 15 mL of THF. After stirring for 1.5 h at room temperature, evolution of carbon dioxide had ceased. Hydrogen peroxide (0.77 mL of 30% solution, 6.8 mmol of peroxide) was added all at once and the resulting solution was stirred for 3 h at room temperature. The solvent was pumped off under vacuum, water and ether were added, and the ether extract was separated. It was washed with 5% H_2SO_4 and then with 5% $NaHCO_3$ before it was dried over $MgSO_4$. Evaporation of the ether without heating gave **3** (0.33 g, 19%) as a colourless oil; ^{1}H nmr ($CDCl_3$) δ: 1.20 (s, 6H), 2.37 (s, 2H), 4.80–5.17 (m, 2H), 5.67–6.17 (m, 1H).

Results and discussion

The epr parameters of **1** and **2**, as well as those of their spin adducts with **4**, are listed in Table 1. Table 2 gives measured concentrations of **1** and **2** and the rate data derived from the experiments carried out at low temperatures.

The observation of hyperfine splitting by just one of the δ-hydrogens in radical **1** was not unexpected, e.g. (14, 15), for the $CH_2{=}CHCH_2\dot{C}H_2$ radical, $a^H\gamma$ = 0.6 G and $a^H\delta$ (1H) = 0.35 G. Equivalence of the γ-H and δ-H splittings has also been observed previously in related radicals in the *cis* conformation, e.g. (16), for $RCH{=}CHCH_2\dot{C}H_2$ radicals, $a^H\gamma = a^H\delta$ (1H) = 0.7 G (R = CH_3) and = 0.61 G (R = c-C_3H_5 and OH).

Spectra of the spin adducts of **1** and **2** with **4** (Table 1) agree well with those of analogues (17, 18) and with those of the models which were prepared in this work (Table 1). This agreement provides assurance that the spin trapping reactions are not

complicated by competitive O-alkylation of the nitroso compound or by rearrangements other than that of eq. [7]. It should perhaps be added that although the adduct from **4** and the 2,2-dimethylcyclopropylcarbinyl radical might not be distinguished from that of the **1**/**4** adduct, the lifetime of this intermediate will be far too short for it to be spin trapped. That is, although the rearrangement of cyclopropylcarbinyl to yield 3-butenyl is a rapid process ($k^{298\ K} = 1.3\times 10^8$ s^{-1} (10*g*)), the cyclopropylcarbinyl radical can at least be observed by epr at temperatures below ca. 153 K (10*g*, 15, 19). In contrast, when cyclopropylcarbinyls having one (20) or two (16, 19) methyl groups at the 2-position are generated, the epr spectrum of only the ring-opened alkylcarbinyls can be observed even at much lower temperatures, i.e., methyl substitution on the cyclopropane ring enhances the rate of ring opening of cyclopropylcarbinyls.

The [**2**/**4** spin adduct]/[**1**/**4** spin adduct] ratio increased slightly with time (Table 3), probably because of the greater persistence of the spin adduct of the tertiary alkyl radical. This ratio was therefore extrapolated back to time zero (defined as one minute after the cold tube was inserted into the epr cavity), a value of 6 being obtained. Using this extrapolated value of the ratio of the concentrations of the two spin adducts and assuming that the rate constant for trapping of **1** by **4** is the same as that for the trapping of the undecyl radical (18) yields $k^{C=C} = 8.8_7\times 10^7$ s^{-1} at 40°C.

Combination of the data from Tables 2 and 3 leads to the following equation for the temperature dependence of $k^{C=C}$, where $\theta = 2.3RT$ kcal mol^{-1}.

$$\log (k^{C=C}/s^{-1}) = (12.5 \pm 0.6) - (6.6 \pm 0.4)/\theta$$

Examination of the tables of rate constants for the clock reactions (7) of primary alkyl radicals reveals that the rearrangement reported herein is among the fastest yet discovered. In particular, we note that at 25°C rearrangement of **1** to **2** is about 2×10^4 times faster than the analogous rearrangement of the homoallyl radical itself (eq. [5]). The very substantial driving force for formation of three-membered rings by free radicals when *gem* dimethyl groups are present (Thorpe–Ingold effect) is demonstrated once again (6).

Conformations of simple disulfides and L-cystine

RUSSELL J. BOYD,[1] JOHN S. PERKYNS, AND R. RAMANI
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received September 10, 1982

RUSSELL J. BOYD, JOHN S. PERKYNS, and R. RAMANI. Can. J. Chem. **61**, 1082 (1983).

ab initio Molecular orbital calculations at the STO-3G and STO-3G* levels on H_2S_2, $(CH_3)_2S_2$, $(CH_3CH_2)_2S_2$, and L-cystine show that the minimum energy conformation occurs at the angle at which the S—S overlap population is at a maximum. In agreement with experiment, the calculations favour a disulfide dihedral angle close to 90°. The variation of the S—S overlap population is essentially independent of substituents, whereas the *cis* barrier to rotation about the S—S bond increases relative to the *trans* barrier as the size of the substituents increases. These observations lead to the conclusion that electronic effects determine the disulfide dihedral angle and that both steric and electronic effects control the relative magnitude of the *cis* and *trans* barriers.

RUSSELL J. BOYD, JOHN S. PERKYNS et R. RAMANI. Can. J. Chem. **61**, 1082 (1983).

Les calculs *ab initio* d'orbitale moléculaire au niveau STO-3G et STO-3G* se rapportant au H_2S_2, au $(CH_3)_2S_2$, au $(CH_3CH_2)_2S_2$ et à la L-cystéine, montrent que la conformation d'énergie minimum s'établit à l'angle pour lequel la population de recouvrement S—S est maximum. En accord avec l'expérience, les calculs favorisent un angle dièdre pour le disulfure voisin de 90°. La variation de la population de recouvrement S—S est essentiellement indépendante des substituants alors que la barrière à la rotation autour de la liaison S—S du composé *cis* augmente avec la taille des substituants par rapport à la barrière du composé *trans*. Ces observations portent à conclure que les effets électroniques déterminent l'angle dièdre du disulfure et que les effets stériques et électroniques contrôlent l'amplitude relative des barrières des composés *cis* et *trans*.

Introduction

There are two major covalent linkages between amino acids in proteins: the peptide bond of the linear backbone and the disulfide bond of cystine. The latter serves in some proteins as a cross-link between two separate polypeptide chains or between loops of a single chain. Thus the conformation of the disulfide bond affects the tertiary structure of some proteins. In open-chain molecules, the disulfide bond is known to have a nonplanar structure, similar to that of hydrogen peroxide, with the torsional angle around the S—S bond being about ±90°.

The purpose of this paper is to report the results of *ab initio* molecular orbital (MO) calculations on the S—S bond in H_2S_2, $(CH_3)_2S_2$, $(CH_3CH_2)_2S_2$, and L-cystine, and to examine the relationship between the overlap population (1) along the S—S bond and the conformational potential energy. Previous theoretical work includes some semi-empirical calculations on the conformation of disulfides (2, 3) and *ab initio* calculations on H_2S_2 (4, 5). As in the case of our study of the *cis* and *trans* conformations of natural dipeptides (6), our calculations on L-cystine, which are the first *ab initio* MO calculations, provide some insight into the structure of proteins.

Method

Standard single determinant *ab initio* MO theory was used in this work. All calculations were carried out on a CDC CYBER 170-720 system by use of the GAUSSIAN 76 program (7) at the STO-3G (8) and STO-3G* (9) levels. In order to reduce the requirements for computer time the following assumptions were introduced: H_2S_2 was assumed to have at least C_2 symmetry, model methyl groups (r(CH) = 1.09 Å and ∠HCH = 109.5°) were assumed for dimethyl disulfide, and standard bond lengths and angles (10) were assumed for diethyl disulfide and L-cystine. Only rigid rotations, corresponding to geometric model B of Radom and Pople (11), were carried out.

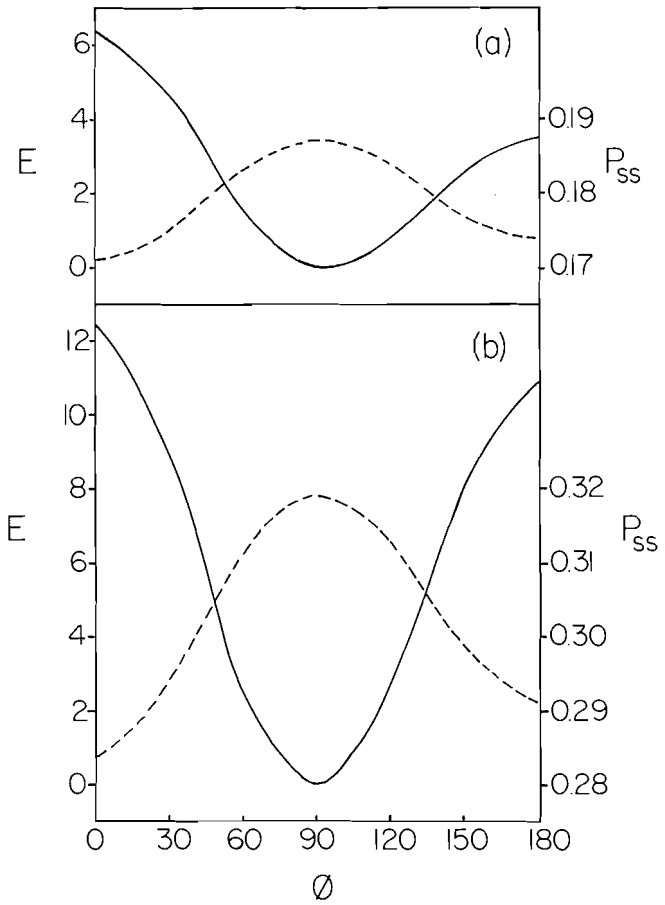

FIG. 1. One-dimensional cross-section of the conformational energy hypersurface for rigid rotation about the S—S bond of H_2S_2. The S—S overlap population, P_{SS}, is indicated by the dashed line. (a) STO-3G (b) STO-3G*.

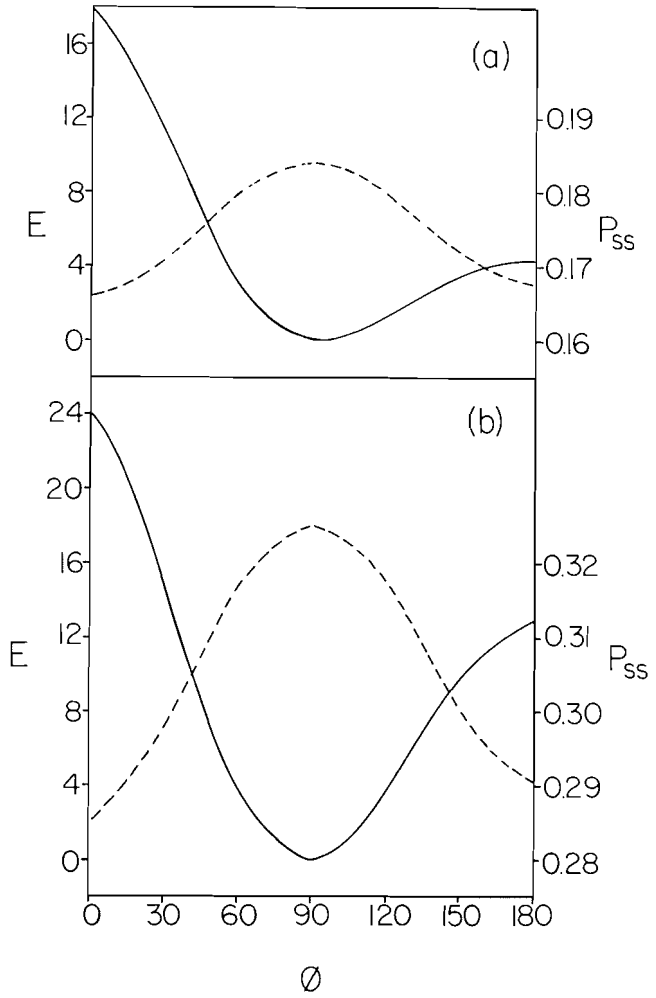

FIG. 2. One-dimensional cross-section of the conformational energy hypersurface for rigid rotation about the S—S bond of $(CH_3)_2S_2$. The S—S overlap population, P_{SS}, is indicated by the dashed line. (a) STO-3G (b) STO-3G*.

are excellent. In fact the STO-3G structure is in closer agreement with experiment than are the results obtained with split-valence basis sets (5). Adding polarization functions to the sulfurs leads to excessive shortening of the S—S bonds. The poor agreement between the STO-3G* and experimental S—S bond lengths stands in contrast to the results for hypervalent molecules containing sulfur. For the latter, the STO-3G* geometries are very much better than the STO-3G results (5, 9, 12, 13).

The one-dimensional cross-section of the conformational energy hypersurface for rigid rotation about the S—S bond of H_2S_2 is shown in Fig. 1. The variation of the overlap population as a function of the torsional angle is shown on the same graphs. Besides shortening the S—S bond by more than 0.1 Å, the addition of polarization functions to the basis set leads to larger barriers and overlap populations. Both basis sets lead to minimum energy conformations of about 90°, at which angle we note that the overlap population is at a maximum: 0.19 and 0.32[2] for STO-3G and STO-3G*, respectively. The *cis* and *trans* barriers obtained by rigid rotation are 6.4 and 3.5 kcal/mol, respectively, at the STO-3G level and 12.5 and 10.8 kcal/mol, respectively, at the STO-3G* level.

Similar results are shown in Fig. 2 for $(CH_3)_2S_2$. The overlap population is again a maximum at the minimum energy conformation. The effect of the methyl group is to raise the *cis* barrier relative to the *trans* barrier. The calculated barriers are 18.0 and 4.4 kcal/mol at the STO-3G level and 24.1 and 12.7 kcal/mol, respectively, at the STO-3G* level.

The asymmetry is even more pronounced in $(CH_3CH_2)_2S_2$ for which the *cis* and *trans* barriers are estimated to be 19.5 and 5.1 kcal/mol, respectively, at the STO-3G level (Fig. 3). Here we note that no geometry optimizations were carried out for diethyl disulfide and the CCSS dihedral angles were fixed at 180°C. Test calculations on H_2S_2 and $(CH_3)_2S_2$ indicate that the use of a model geometry will have only a very small effect on the results for $(CH_3CH_2)_2S_2$. Although the barriers in H_2S_2 have not been measured, Winneswisser *et al.* (14) have concluded that the two barriers are almost equal and that the barrier is much higher in H_2S_2 than in H_2O_2, for which the experimental value is 7.0 kcal/mol (15). From Fig. 1 it appears that the barrier is better described at the STO-3G* level than at the STO-3G level. Unfortunately the barrier in $(CH_3)_2S_2$ has not been studied experimentally, but the higher barrier for the *cis* conformation is readily attributed to a steric factor. In the absence of experimental values of the barriers, we can not decide which basis set provides a better description of internal rotation. Since the changes introduced into the hypersurfaces by replacing H by CH_3 are very similar for the two basis sets, we have not

[2]At the STO-3G equilibrium geometry, the STO-3G* overlap population between the sulfur atoms drops to 0.27 at the maximum.

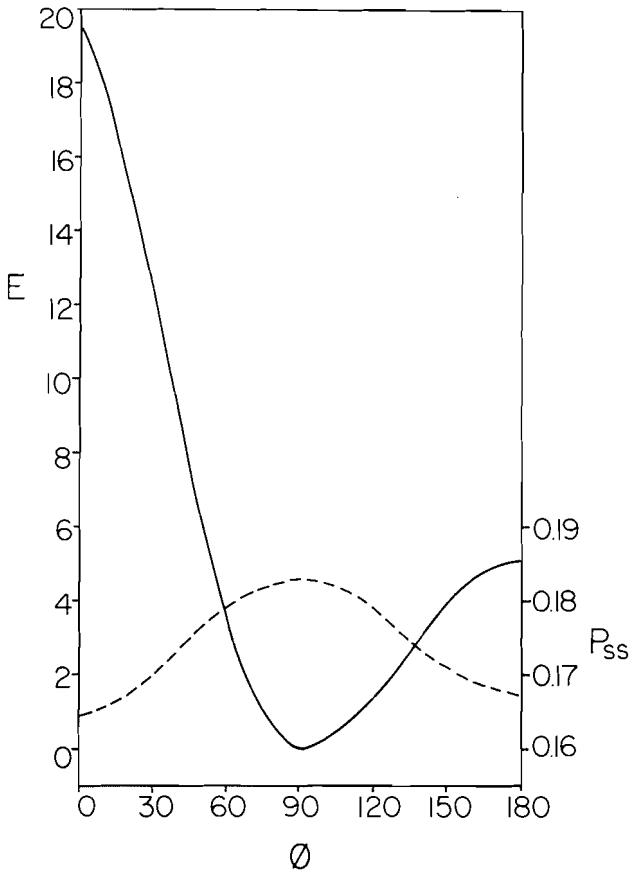

FIG. 3. One-dimensional cross-section of the conformational energy hypersurface for rigid rotation about the S—S bond of $(CH_3CH_2)_2S_2$. The S—S overlap population, P_{SS}, is indicated by a dashed line.

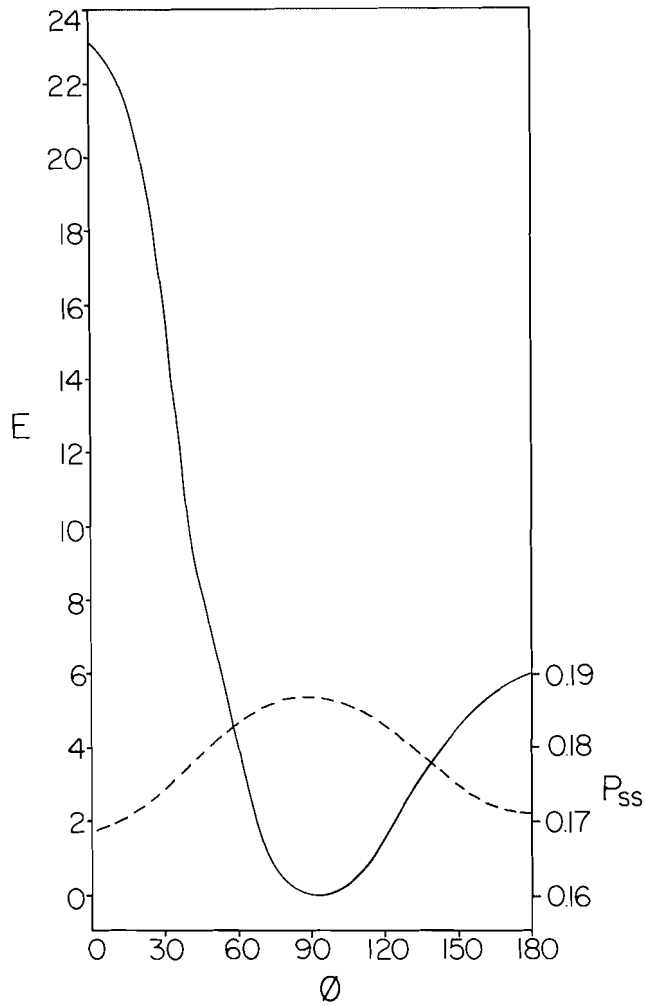

FIG. 4. One-dimensional cross-section of the conformational energy hypersurface for rigid rotation about the S—S bond of L-cystine. The S—S overlap population, P_{SS}, is indicated by a dashed line.

carried out the much more time-consuming STO-3G* calculations on diethyl disulfide.

The hypersurface for rigid rotation about the S—S bond of L-cystine is shown in Fig. 4. As in our previous studies of amino acids (6, 16), L-cystine was taken to be in the zwitterionic form (Fig. 5). With the CCSS dihedral angles fixed at 180°, as in diethyl disulfide,[3] the *cis* and *trans* barriers are 23.1 and 6.0 kcal/mol, respectively, at the STO-3G level. Thus, replacement of two hydrogens of the methyl groups by ammonium and carboxylate groups leads to a further increase in the barrier. Comparison of Figs. 1–4 reveals that the variation of the S—S overlap population is essentially independent of substituents in the disulfides, whereas the *cis* barrier increases relative to the *trans* barrier as the size of the substituent increases. In all cases the minimum energy and the maximum overlap population coincide at about 90°, which is the observed dihedral angle of the disulfide bond in the crystal structure of L-cystine.

Although only rigid rotations, corresponding to geometric model B of Radom and Pople (11), have been considered in this work, we would like to estimate the lowering of the barriers to be expected by allowing the molecule to undergo flexible rotations. Optimization of the CSS bond angles of the 0° and 180° conformations of $(CH_3)_2S_2$ at the STO-3G level leads to *cis* and *trans* barrier reductions of 7.4 and 0.7 kcal/mol, respectively, and optimized angles of 105.5° and 97.0°, respectively. At the STO-3G* level, the same procedure leads to reductions of 5.9 and 2.4 kcal/mol for *cis* and *trans* barriers, respectively, and

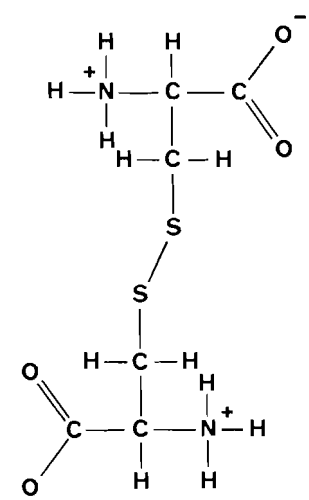

FIG. 5. Structural formula of cystine in the zwitterionic form.

[3]In both diethyl disulfide and L-cystine, the S—S bond was taken to be 2.06 Å and the C—S bond was fixed at 1.86 Å as observed in the crystal structure (see ref. 17).

optimized angles of 107.2° and 96.3°, respectively. Further relaxation of the structures, for example, by allowing the model methyl groups to distort or by re-optimization of the C—S and S—S bonds, would be expected to have only a secondary effect on the computed barriers. Even with the substantial reduction of the *cis* barriers due to relaxation of the CSS bond angles, the *cis* barriers are about 8 kcal/mol greater than the *trans* barriers at both the STO-3G and STO-3G* levels. From our inspection of molecular models, we expect the effect of optimizing the CSS bond angles in the larger disulfides to be comparable to the $(CH_3)_2S_2$ case. In summary, we suggest that the principal conclusions of this work would not be altered by carrying out completely flexible rotations rather than the rigid rotations illustrated in Figs. 1–4.

Conclusions

On the basis of the calculations reported in this paper, the following conclusions regarding the disulfide bond may be drawn.

1. The minimum energy conformation occurs at the angle at which the S—S overlap population is at a maximum. At the 6-31G** level (18) we have found the same conclusion applies to C_2H_6 and N_2H_4 but not to H_2O_2, in which the overlap population is at a maximum at about 90° but the energy minimum lies close to 115°.

2. All calculations favour an equilibrium dihedral angle close to 90° in agreement with microwave spectroscopic studies of small disulfides and an X-ray diffraction study of L-cystine dihydrobromide.

3. In contrast to the results for hypervalent sulfur moieties, the minimal STO-3G basis set leads to more accurate bond lengths than the STO-3G* basis set in which polarization functions are included in the sulfur basis set.

4. As the size of the substituents increases, the *cis* barrier to rotation about the S—S bond increases relative to the *trans* barrier. The variation of the S—S overlap population is essentially independent of substituents in the disulfides and is in fact lower in the *cis* conformation than in the energetically more favourable *trans* conformation. These observations suggest that the disulfide dihedral angle of the equilibrium conformation is determined by electronic effects, whereas the relative magnitudes of the *cis* and *trans* barriers are controlled by steric and electronic effects.

Heterogeneous processes in the pyrolysis of ethane in contact with surfaces of SiO_2, C, KCl, and PbO

PHILIP D. PACEY AND JAYANTHA H. WIMALASENA[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received August 19, 1982

PHILIP D. PACEY and JAYANTHA H. WIMALASENA. Can. J. Chem. **61**, 1086 (1983).

Heterogeneous termination reactions in the pyrolysis of ethane have been investigated by three methods, involving measurements of the reductions in the steady state rates of formation of C_2H_4 and C_4H_{10} and of the reduction in the induction period in the presence of active surfaces. Equations were developed for the approach of the concentration of C_2H_5 to its steady state value when both first and second order termination reactions occur. Experiments have been performed at about 904 K with from 2.8×10^{-4} to 2.3×10^{-3} mol L^{-1} of C_2H_6 in the presence of surfaces of SiO_2, PbO, KCl, and C. Data from the literature have been reinterpreted. The data may be most simply explained if the main surface termination on most surfaces is first order with respect to gaseous C_2H_5. Collisional termination probabilities, γ, for this reaction were calculated to be: KCl, 905 K, 3×10^{-4}; C, 903 K, 3×10^{-4}; SiO_2, 894 K, 6×10^{-5}; 823 K, 10^{-5}; PbO, 833 K, 6×10^{-5}; Pyrex, 833 K, 4×10^{-6}.

PHILIP D. PACEY et JAYANTHA H. WIMALASENA. Can. J. Chem. **61**, 1086 (1983).

Nous avons étudié la pyrolyse de l'éthane en écoulement vers 904 K à des concentrations initiales comprises entre 2.8×10^{-4} et 2.3×10^{-3} mol L^{-1}. Le traitement des parois du réacteur à carbone a diminué la période d'induction et le rendement en C_2H_4. Le traitement des parois à C, à KCl ou à PbO a diminué le rendement en C_4H_{10}-*n*. Nos résultats, et la plupart de ceux de la littérature, sont compatibles avec un mécanisme radicalaire, dont les chaînes sont partiellement terminées par la destruction de radicaux C_2H_5. On obtient les rendements suivants de disparition de C_2H_5 par choc avec les parois suivantes: KCl, 905 K, 3×10^{-4}; C, 903 K, 3×10^{-4}; SiO_2, 894 K, 6×10^{-5}, 823 K, 10^{-5}; PbO, 833 K, 6×10^{-5}; Pyrex, 833 K, 4×10^{-6}.

Introduction

Studies of the pyrolysis of ethane have made important contributions to our understanding of kinetics (1–9), but complete acceptance of the results has been hindered by the knowledge that minor, heterogeneous reactions play a role in the mechanism (1–3). The nature of these reactions is unknown; it is known that they are most important at low temperatures and pressures (1) and in reactors coated with NaOH or PbO (2). Marshall and Quinn developed a detailed theory (10, 11). Lin and Back (1) and Scacchi, Martin, and Niclause (2) obtained experimental data which showed that the heterogeneous process was a chain termination reaction.

In principle, any of the three radical species present could react at the wall. Several authors (1, 2, 10, 11) have favoured the recombination of hydrogen atoms, since these species could diffuse most rapidly to the wall.

The object of this work is to learn more about the heterogeneous reaction. Experiments have been performed in flow reactors with surfaces of quartz, pyrolytic carbon, KCl, and PbO. The latter surface is known to be active in this and other pyrolyses (2, 12) and the carbon surface results from the process of "conditioning", which is sometimes used to obtain reproducible results (13). It has been found that the surfaces other than quartz result in reductions in the steady state rates of formation of C_2H_4 and *n*-C_4H_{10}; for the carbon surface there is a reduction in the induction period for establishment of the steady state. In the next section, the theory of these three phenomena is presented for six hypothetical surface termination reactions, for which the rate laws are listed in Table 1. A reduction in the steady state rates of formation of C_2H_4 and *n*-C_4H_{10} is predicted for each termination reaction; a reduction in the induction period, for five of the six. The reductions in the induction periods and steady state rates are in quantitative agreement with each other only if the termination is first order in gaseous C_2H_5 or H. The pressure dependence of the steady state rates is found to be correctly predicted only if the surface termination is dominated by a reaction first order in C_2H_5.

TABLE 1. Predicted orders of measurable quantities for various surface reactions

Rate of surface termination reaction, X	Kinetic control	Diffusion control
	Predicted orders of $R_{CH_4}^{\circ\,1/2}$ $(1 - ([C_2H_5]_{5+X}/[C_2H_5]_5)^2) \times [C_2H_5]_5/[C_2H_5]_{5+X}$	
$k_6[C_2H_5]$	0.0	−1.0
$k_{19}[H]$*	−0.5±0.1	−1.5±0.1
	Predicted orders of $([C_2H_5]_5/[C_2H_5]_{5+X})^2 - 1$	
$k_{20}[CH_3]$	−1.0	−2.0
$k_{22}[C_2H_5]^2$	0.0	—
$k_X[C_2H_5][H]$*	−0.5±0.1	—
$k_X[H]^2$*	−1.0±0.2	—

*k_3 has been assumed to have an order of 0.5 ± 0.1 (1).

Theory

The main features of the homogeneous pyrolysis of ethane are consistent with the following mechanism (1–9):

[1] $C_2H_6 \rightarrow 2CH_3$

[2] $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$

[3] $C_2H_5 \rightarrow C_2H_4 + H$

[4] $H + C_2H_6 \rightarrow H_2 + C_2H_5$

[5*a*] $2C_2H_5 \rightarrow C_4H_{10}$

[5b] $2C_2H_5 \rightarrow C_2H_6 + C_2H_4$

We shall assume at first that the additional, surface termination reaction is:

[6] $C_2H_5 \rightarrow$ Products

a process first order with respect to gaseous C_2H_5, and later shall consider the changes that should be made if other processes occur.

Making the steady state assumption for all three radicals and solving for $[C_2H_5]_{5+6}$, where reactions [5a], [5b], and [6] are considered to contribute to termination, and for $[C_2H_5]_5$, where only [5a] and [5b] contribute, one obtains

$$[7] \quad [C_2H_5]_{5+6}/[C_2H_5]_5 = (1 + k_6^2/a^2)^{1/2} - k_6/a$$

where $a = 4(k_1k_5[C_2H_6])^{1/2}$ and the rate constant $k_5 = k_{5a} + k_{5b}$.

Making the long chain assumption, the rate of formation of C_2H_4, when the steady state assumption is valid but before any secondary reactions become significant, is given by

$$R^\circ_{C_2H_4} = k_3[C_2H_5]$$

The ratio of rates in the presence or absence of reaction [6] then equals the ratio in eq. [7]:

$$[8] \quad R^\circ_{C_2H_4,5+6}/R^\circ_{C_2H_4,5} = [C_2H_5]_{5+6}/[C_2H_5]_5$$

Similarly, assuming reaction [5a] is the only source of C_4H_{10}, one obtains

$$[9] \quad R^\circ_{C_4H_{10},5+6}/R^\circ_{C_4H_{10},5} = ([C_2H_5]_{5+6}/[C_2H_5]_5)^2$$

Provided that reaction [2] is the only source of CH_4 and the only reaction of CH_3, it has been shown elsewhere (1–3) that

$$[10] \quad R^\circ_{CH_4} = 2k_1[C_2H_6]$$

Combining this result with the definition of a and with eq. [7] and rearranging, one obtains

$$[11] \quad k_6/k_5^{1/2} = (2R^\circ_{CH_4})^{1/2}\{1 - ([C_2H_5]_{5+6}/[C_2H_5]_5)^2\} \times [C_2H_5]_5/[C_2H_5]_{5+6}$$

By measuring the rates of formation of CH_4 and either C_2H_4 or C_4H_{10} in the presence and absence of a surface reaction, it should be possible, therefore, subject to the above assumptions, to determine the quotient $k_6/k_5^{1/2}$.

Pyrolysis before $[C_2H_5]$ is steady

If the steady state assumption is dropped for C_2H_5 but retained for CH_3 and H (8, 9) the net rate of formation of C_2H_5 becomes

$$d[C_2H_5]/dt = 2k_1[C_2H_6] - 2k_5[C_2H_5]^2 - k_6[C_2H_5]$$

Integrating this equation (14), taking $[C_2H_5] = 0$ when $t = 0$, one obtains

$$[12] \quad [C_2H_5] = a'/(4k_5)\tanh\{a't/2 + \tanh^{-1}(k_6/a')\} - k_6/(4k_5)$$

Here $a' = (a^2 + k_6^2)^{1/2}$.

Making the long chain assumption, the rate of formation of C_2H_4 is

$$[13] \quad d[C_2H_4]/dt = k_3[C_2H_5]$$

Substituting eq. [12] into eq. [13] and integrating, taking $[C_2H_4] = 0$ when $t = 0$, one obtains

$$[14] \quad \frac{[C_2H_4]}{t} = \frac{k_3}{2tk_5}\ln\{(a/a')\cosh[a't/2 + \tanh^{-1}(k_6/a')]\} - \frac{k_3k_6}{4k_5}$$

If $k_6 = 0$, this reduces to

$$[15] \quad \frac{[C_2H_4]}{t} = \frac{k_3}{2tk_5}\ln\cosh(at/2)$$

which is algebraically identical with the expression given in ref. 8. If $k_5 = 0$, eq. [14] does not apply, but it can be shown by similar methods (15) that

$$[16] \quad \frac{[C_2H_4]}{t} = \frac{2k_1k_3[C_2H_6]}{k_6}\{1 - \frac{1}{tk_6}[1 - \exp(-tk_6)]\}$$

In eqs. [14] to [16], the chordal rate of formation of C_2H_4 increases from zero and then approaches the steady state rate, given by eqs. [8] and [7]. A plot of $[C_2H_4]$ against t would approach a straight line at long residence times. If this line were extrapolated back it would intersect the time axis at $t_i = 2(a' - k_6)^{-1}\ln[2a'/(a' + k_6)]$. The induction period, t_i, approaches k_6^{-1} as k_5 approaches zero and $2a^{-1}\ln 2$ as k_6 approaches zero.

Control by diffusion or chemical reaction

Marshall and Quinn (10) have numerically solved the diffusion equation for second order removal of radicals in the gas phase and first order removal at a spherical vessel wall. They also obtained an approximate analytical solution which agreed with the numerical results within 13% or better. The approximate solution is identical in form to eq. [11], but with k_6 replaced by $(k_C^{-1} + k_D^{-1})^{-1}$. Here k_C is the rate constant for control by surface reaction, given by (16)

$$[17] \quad k_C = \gamma c(S/V)/4$$

where γ is the probability of reaction on each collision, c is the average molecular velocity of the radicals, and S/V is the surface-to-volume ratio of the vessel. Also, k_D is the effective rate constant for control by diffusion, which for laminar flow in a cylinder, is given by (16)

$$[18] \quad k_D = 0.915(S/V)^2D$$

Here D is the diffusion coefficient for the radical. For reaction in a sphere (10), the numerical factor becomes 5/3. The diffusion coefficient and k_D are inversely proportional to pressure, so if diffusion controls the rate of surface reaction, k_6 would have an apparent order of -1.

Nature of the surface reaction

We will now consider the effect of replacing reaction [6] by each of the five other reactions whose rate expressions are listed in Table 1.

As shown for eq. [11] in ref. 10, if the surface termination is

$$[19] \quad H \rightarrow \tfrac{1}{2}H_2$$

k_6 in eqs. [11], [14], and [16] would be replaced by $k_{19}k_3/(k_4[C_2H_6])$. Similar substitutions apply if H replaces C_2H_5 in reactions considered later.

The radical with the second highest concentration is CH_3. If reaction [6] is replaced by the surface termination

$$[20] \quad CH_3 \rightarrow \text{Products}$$

eq. [11] would be replaced by

$$[21] \quad k_{20}/k_2 = [C_2H_6](([C_2H_5]_5/[C_2H_5]_{5+20})^2 - 1)$$

If reaction [20] is significant, the induction period would become longer, whereas surface terminations involving C_2H_5 or H would shorten the induction period.

If reaction [6] is replaced by the second order surface reaction

$$[22] \quad 2C_2H_5 \rightarrow \text{Products}$$

making the same assumptions as previously, eq. [11] would be replaced by the following equation,

$$[23] \quad k_{22}/k_5 = ([C_2H_5]_5/[C_2H_5]_{5+22})^2 - 1$$

In eq. [15] and the expressions for a and t_i, k_5 would be replaced by $k_5 + k_{22}$. The first and second order terminations, reactions [6] and [22], affect the steady state rate and the induction period in different ways.

The predicted orders of the right hand sides of eqs. [11] and [23] for various surface reactions, calculated as above, are summarized in Table 1.

Experimental

A general description of the apparatus and experimental techniques has been given elsewhere (3, 8, 17). Reactors were constructed of cylindrical quartz tubing, with an axial thermocouple well 4 mm in outside diameter and with outer walls of either 17 mm inside diameter (S/V = 3.1 cm^{-1}) or 8 mm inside diameter (S/V = 9.9 cm^{-1}). Reactors described herein as clean quartz reactors were allowed to stand in concentrated HNO_3 overnight, washed with distilled water, and evacuated. One 17 mm diameter reactor was coated with carbon by filling it with 2.5×10^{-3} mol L^{-1} of propane and pyrolyzing at 900 K for 30 h. An 8 mm diameter reactor was coated with carbon by pyrolyzing 6.7×10^{-3} mol L^{-1} of ethane at 900 K for 20 h. A 17 mm diameter reactor was rinsed with a 10% KCl solution, drained for 2 min, and was heated to 373 K while evacuating slowly. A 17 mm diameter reactor was rinsed with a 1 mol L^{-1} solution of $Pb(NO_3)_2$ and then heated slowly to obtain a PbO deposit.

Products were analyzed on a 4.75 m, 10% squalane on chromasorb P (100/120 mesh) column, operated at 273 K for analysis of CH_4 and C_2H_4 and at 313 K for analysis of C_4H_{10}.

Results

Butane

Measurements[2] of yields of *n*-butane and methane have been determined for the pyrolysis of ethane at temperatures close to 904 K, at concentrations from 5.0×10^{-4} to 2.3×10^{-3} mol L^{-1}, for residence times from 1 to 7 s, in reactors of S/V equal to 3.1 cm^{-1}.

Product concentrations have been divided by residence times to obtain chordal rates. Chordal rates for experiments at constant temperature and pressure but differing residence times have been extrapolated to a residence time of zero to find initial rates, $R^\circ_{CH_4}$ or $R^\circ_{C_4H_{10}}$, following the method of ref. 17. Some results are presented in Table 2.

It can be seen that, for a constant C_2H_6 concentration, the rate of formation of C_4H_{10} drops by 28 to 77% as the reactor surface is changed from clean quartz to a coated surface. The rate of formation of CH_4 also appears to decline, but by a lesser amount.

[2]Tables of data are available, at a nominal charge, from the Depository of Unpublished Data, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6.

TABLE 2. Initial rates of formation of CH_4 and C_4H_{10} in reactors with S/V = 3.1 cm^{-1}

T (K)	Surface	$10^8 \times R^\circ_{CH_4}$ (mol L^{-1} s^{-1})	$10^8 \times R^\circ_{C_4H_{10}}$ (mol L^{-1} s^{-1})
$[C_2H_6] = 0.5 \times 10^{-3}$ mol L^{-1}			
904	SiO_2	1.7	0.44
903	C	1.2	0.22
905	KCl	1.2	0.17
$[C_2H_6] = 1.0 \times 10^{-3}$ mol L^{-1}			
904	SiO_2	4.8	1.4
903	C	3.4	0.81
903	C	3.7	0.69
905	KCl	3.3	0.77
907	PbO	3.8	0.32
$[C_2H_6] = 2.3 \times 10^{-3}$ mol L^{-1}			
904	SiO_2	12.1	3.6
903	C	9.7	2.3
905	KCl	8.7	2.4
905	KCl	9.5	2.6
907	PbO	11.1	1.7

Experiments have also been performed with clean quartz vessels of different S/V. In some cases an increase in S/V resulted in a small decline in $R^\circ_{C_4H_{10}}$, in others, an increase, and in yet others, no change. Evidently, any termination reaction on the quartz surface is too slow to be measured reproducibly by the present technique. As an approximation, the rate of such a reaction has been assumed to be zero in analyzing the present results.

The ratios of $R^\circ_{C_4H_{10}}$ in a coated reactor to $R^\circ_{C_4H_{10}}$ in a clean reactor in Table 2 were assumed to be equal to $([C_2H_5]_{5+6}/[C_2H_5]_5)^2$ as in eq. [9]. $R^\circ_{C_4H_{10}}$ in the clean reactor was adjusted to the same temperature as in the coated reactor using the Arrhenius law with an activation energy of 368 kJ mol^{-1}. $([C_2H_5]_{5+6}/[C_2H_5]_5)$ and $R^\circ_{CH_4}$ were then substituted in eq. [11] to calculate the quantity $k_6/k_5^{1/2}$.

The related quantity $k_6V/(Sk_5^{1/2})$ is plotted logarithmically as a function of C_2H_6 concentration as open circles (C surface), squares (KCl), and triangles (PbO) in the upper part of Fig. 1. It can be seen that the rates of surface termination on the C and KCl surfaces are similar, whereas the rate on the PbO surface is about three times faster. The data do not exhibit any clear trend with C_2H_6 concentration.

The data for each surface in Fig. 1 have been fitted by a least-squares method to a straight line. The slopes or orders which were found are quoted in the first three lines in the third column in Table 3. The quoted uncertainties are standard deviations. Within experimental uncertainty, the order for each surface is zero. From the upper part of Table 1, it can be seen that this result is consistent with a mechanism in which the dominant surface reaction is reaction [6], kinetically controlled.

The right hand side of eq. [23] has also been calculated from the data of Table 2. The order of this quantity, listed in the first three lines of the fourth column of Table 3, was found to vary from surface to surface.

Ethylene

Yields of CH_4 and C_2H_4 were measured in experiments at 902 K with 2.8×10^{-4} mol L^{-1} of ethane and residence times from 0.09 s to 2.2. s. Two reactors of S/V equal to 9.9 cm^{-1} were used; one reactor was of clean quartz, the other was

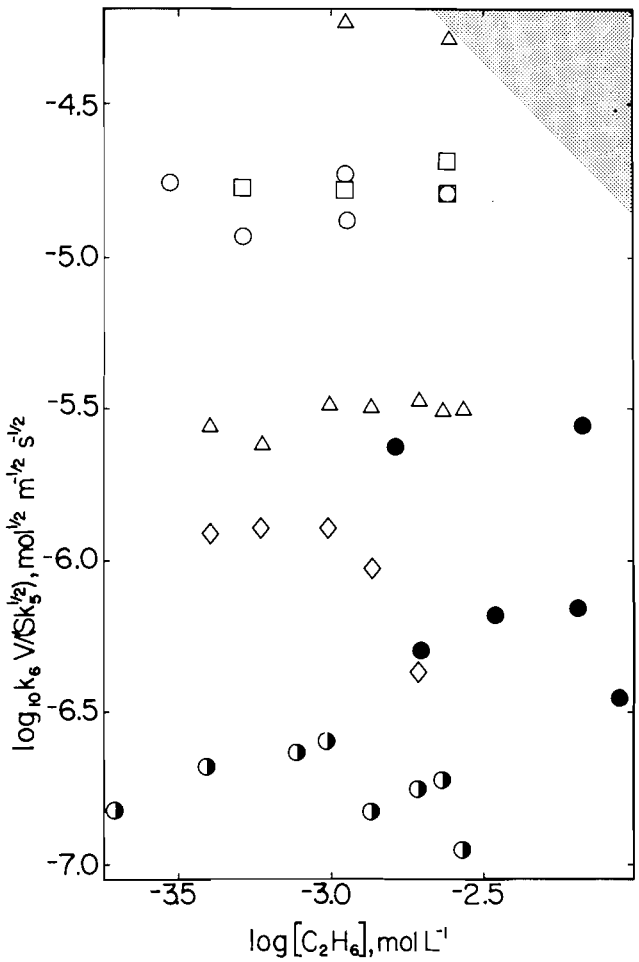

FIG. 1. Order plot for $k_6V/(Sk_5^{1/2})$: △, PbO surface, upper points, 907 K, this work, lower points, 833 K, ref. 2; □, KCl surface, 905 K, this work; ○, C surface, 903 K, this work; ●, SiO_2 surface, upper points, 894 K, lower points, 823 K, ref. 1; ◇, NaOH surface, 833 K, ref. 2; ◑, Pyrex surface, 833 K, ref. 2; the shaded area is above the limit set by diffusion for the conditions of this work.

coated with carbon. The results for C_2H_4 are shown in Fig. 2. In both reactors there is an initial increase in the chordal rate of formation of C_2H_4, followed by a plateau. This behaviour has been observed previously in clean quartz and Pyrex reactors (8, 9). In the C-coated reactor, however, the plateau is much lower and the leveling-out occurs at shorter residence times.

From the measured yields of CH_4, using eq. [10], k_1 was found to be 0.58×10^{-5} s^{-1} for the clean reactor and 0.68×10^{-5} s^{-1} for the C-coated reactor. These are within experimental uncertainty and may be averaged to obtain $k_1 = 0.63 \times 10^{-5}$ s^{-1}.

Equation [15] has been fitted by a nonlinear least-squares method (8) to the C_2H_4 data from the clean reactor; the results are shown as a smooth curve in Fig. 2. From the induction period, it was found that $4(k_1k_5[C_2H_6])^{1/2} = 19.7 \pm 1.2$ s^{-1} and hence that $k_5 = 1.43$ (± 0.17) $\times 10^{10}$ L mol^{-1} s^{-1}. From the plateau it was found that $k_3 = 810 \pm 110$ s^{-1}.

The other smooth curve in Fig. 2 shows the results of fitting eq. [14] to the data from the C-coated reactor. From the induction period, taking k_1 and k_5 as above, one finds $k_6 = 59 \pm 8$ s^{-1}. The ratio of the plateau rates in the two reactors, 0.155 ± 0.015, is equal, according to eq. [8], to $[C_2H_5]_{5+6}/[C_2H_5]_5$. From eq. [11], using the values of $R^\circ_{CH_4}$ and k_5 determined above, k_6 is found to be 62 ± 7 s^{-1}. These two values of k_6 are consistent. It was seen in the introduction that replacing reaction [6] by reaction [22] means that the establishment of the steady state is described by eq. [15], with k_5 replaced by $k_5 + k_{22}$. If the data for the C-coated reactor are fitted to this equation, one finds from the induction period that k_{22} would be 3.2 (± 0.5) $\times 10^{11}$ L mol^{-1} s^{-1} and from the plateau rate that k_{22} would be 6 (± 1) $\times 10^{11}$ L mol^{-1} s^{-1}. This discrepancy, a factor of two, is also found if other second order wall terminations are postulated.

The above values of k_5 and k_6 have been combined to obtain a value of $k_6V/(Sk_5^{1/2})$ of 1.6 (± 0.3) $\times 10^{-5}$ mol$^{1/2}$ m$^{-1/2}$ s$^{-1/2}$. This is in agreement with the average value obtained from the observation of C_4H_{10} yields with a C-coated surface, 1.5 (± 0.4) $\times 10^{-5}$ mol$^{1/2}$ m$^{-1/2}$ s$^{-1/2}$.

Discussion

Data from the literature

Lin and Back (1) have reported yields of C_4H_{10} from ethane pyrolysis in quartz vessels with S/V equal to 0.6 cm^{-1} and 9.4 cm^{-1}. The yields were found to be reduced in the vessel of larger S/V. Assuming negligible surface reaction in the vessel of smaller S/V and applying eq. [9], the right hand sides of eq. [11] and eq. [23] have been calculated. Values of $k_6V/(Sk_5^{1/2})$ from eq. [11] are plotted in Fig. 1 as the filled circles. Calculated orders are listed in Table 3.

Scacchi, Martin, and Niclause (2) studied the overall reaction rate in clean Pyrex vessels with S/V of 0.8 cm^{-1} and 10.5 cm^{-1} and in reactors of S/V of 10.5 cm^{-1}, coated with NaOH or with PbO. Taking the overall rate as approximately equal to $R^\circ_{C_2H_4}$, and calculating the reduction in $[C_2H_5]$ from eq. [8], the right hand sides of eq. [11] and eq. [23] have been calculated; the results are shown in Fig. 1 and Table 3.

Nature of the surface reaction

If one compares the orders of the right hand side of eq. [11] in Table 3 with the predicted orders in the upper part of Table 1, one finds all the results but one are in agreement with the hypothesis that reaction [6], kinetically controlled, is the principal surface reaction. The lone exception is the NaOH surface, for which the order is −1/2.

In contrast, the orders of the right hand side of eq. [23] in

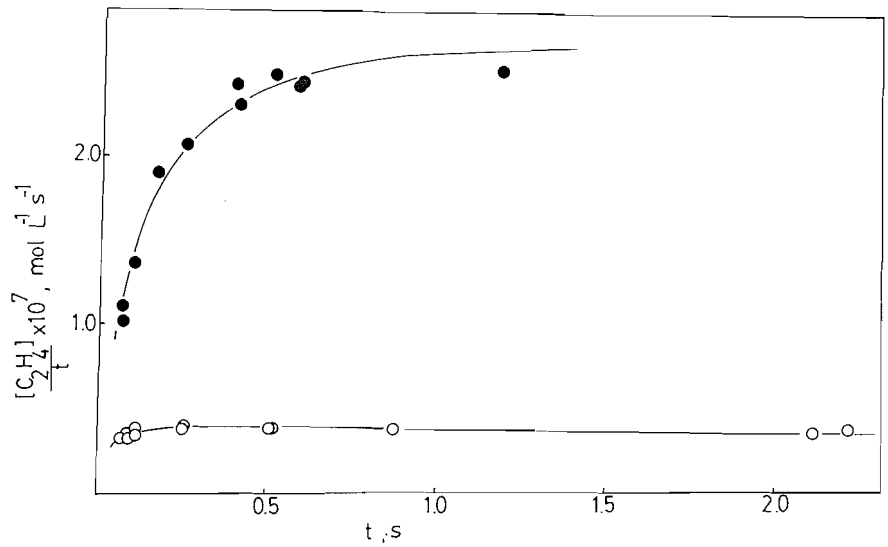

FIG. 2. Dependence of the chordal rate of formation of C_2H_4 on reactor residence time for pyrolysis of 2.8×10^{-4} mol L^{-1} of C_2H_6 at 902 K in reactors with $S/V = 9.9$ cm^{-1}: ●, SiO_2 surface; ○, C surface; —, least-squares fits to eqs. [15] and [14], respectively.

Table 3 vary considerably. It would be necessary to specify several different mechanisms to explain all the results by means of this equation.

A major contribution by reaction [21] can be ruled out because the induction period was observed to shorten in the presence of the C surface, instead of lengthening, as predicted in the Theory section. As seen in the Results section, if a second order wall termination is postulated, the rate constant, k_{22} or k_X, calculated from the induction period disagrees with that calculated from the plateau rate by a factor of two. The data in Fig. 2 can only be explained if reaction [6] or [19] is the principal heterogeneous termination.

Comparison of the predicted and observed orders in Tables 1 and 3 suggests that the reactions are kinetically controlled. This has been confirmed by calculating rate constants for diffusion control using eq. [18]. Diffusion coefficients were calculated using the methods of ref. 19. Lennard-Jones parameters for the radicals were assumed equal to those for the parent molecules. In all cases but one the diffusion rate was much faster than the observed reaction rate and hence could not be a limiting factor. The exception was the PbO surface at 907 K, for which k_D at 2.3×10^{-3} mol C_2H_6 L^{-1} was equal to the value of k_6 calculated from eq. [11] and for which, at 1.0×10^{-3} mol C_2H_6 L^{-1}, k_D was 50% greater than the value of k_6. This surface may exemplify combined kinetic and diffusion control.

It has been argued in the literature that H atoms may react at the wall, as they diffuse fastest (1, 2, 10, 11). However, it can be seen from the previous paragraph that C_2H_5 may also diffuse to the wall fast enough to account for the observed wall termination rates.

In predicting the orders in Table 1, only reactions first and second order in gaseous radical concentrations were considered. It would also be reasonable to consider intermediate, fractional orders or an inverse dependence on the concentration of reactant, which might absorb on the surface and block reaction sites. The observed orders for eq. [11] in Table 3 are randomly distributed about zero, so a fractional increase in order would not assist in interpreting the data with this equation. An inverse dependence on reactant concentration would have a similar effect to that shown in Table 1 for diffusion control. The predicted orders for diffusion control did not agree well with the experimentally observed orders.

For the above reasons, it is concluded that the simplest explanation of the data with all surfaces except NaOH is that the principal heterogeneous termination is reaction [6]. Using eq. [17], values of the collisional reaction probability, γ, have been calculated from the data of Figs. 1 and 2 and are listed in the final column in Table 3. These values may be compared with values of 5×10^{-4} at 843 K and 8×10^{-4} at 878 K which may be calculated from reported values of k_6 on a gold surface in very low pressure pyrolysis experiments (20). The values are smaller than some which have been quoted for hydrogen atom termination at similar temperatures (16), but the concentration of C_2H_5 is calculated to be several hundred times that of H at these conditions, allowing C_2H_5 to dominate the rate of surface termination.

The results of ref. 2 for the NaOH surface are more easily explained by first order termination by hydrogen atoms, reaction [19]. However, if the point furthest to the right for this surface in Fig. 1 were deleted, the order of $k_6V/(Sk_5^{1/2})$ would be -0.18 ± 0.14, similar to the values for the other surfaces in Table 3. Further work is necessary before the order of the termination on this surface can be established.

At the surface, C_2H_5 must react with species with unpaired electrons. Butane cannot be a major product of these processes as the rate of formation of butane was observed to decrease in the presence of active surfaces. Carbon is known to be formed when conversion is large, but no carbon deposition was observed in the experiments at small conversions. The detailed nature of the surface reactions cannot be determined from the present experiments.

Possible systematic errors

In this section we will consider certain assumptions which have been made and consider the influence they might have on our conclusions.

In our calculations, it has been assumed that only one reaction contributes to termination on each surface. In reality, several reactions probably contribute and the quoted values of γ for reaction [6] should be reduced.

In each calculation, it has been assumed that no surface reaction occurs in one reactor, used as a reference. Values of

γ calculated from the experiments of refs. 1 and 2 should be increased by 7 and 8%, respectively, to take surface reactions in the reference reactor into account. It is difficult to estimate the correction for the present experiments as the nature of the surface, not S/V, was changed. In Table 3, it can be seen that the value of γ for an SiO_2 surface at 894 K is about the same as the uncertainties in γ on the C and KCl surfaces at 903 and 905 K. This explains why we were unable to measure γ on SiO_2 in this work. If the value of γ for SiO_2 from the data of ref. 1, wherein the method of surface preparation was similar to that of the present work, is adjusted for the temperature difference and applied to the present work, values in Fig. 1 of $k_6V/(Sk_5^{1/2})$ for C and KCl surfaces from steady state measurements should be increased by about 25%. The value from the induction period measurement would not be significantly affected.

The long chain assumption would not introduce significant error. The shortest chain length, observed for the conditions of the lower curve in Fig. 2, was 25.

It has been assumed that C_4H_{10} is not formed at the surface. Calculations based on C_4H_{10} yields determined the rate of surface terminations forming products other than butane. Calculations based on C_2H_4 yields determined the total rate of surface termination.

Equation [10] will not be strictly true if the "atom-cracking" reaction (3) occurs. Reduction in the radical concentration by surface termination would be expected to reduce the influence of this process. Small reductions in $R^{\circ}_{CH_3}$ in the presence of active surfaces were observed in Table 1 but not in the experiments for Fig. 2 nor in refs. 1 and 2. If k_1 were reduced to allow for this reaction, values of k_6 calculated from steady state rates should be reduced but that from the induction period would be unchanged.

If a surface initiation occurs in parallel with the surface termination, the values of k_6 calculated from steady state rates should be increased, but that from the induction period would be unchanged.

A referee has suggested surface coating could affect radial heat transfer and hence gas temperatures. Flow rates have been kept to less than 5×10^{-5} mol s^{-1} to minimize this (21).

Elimination of some assumptions would increase the quoted surface rates, whereas elimination of others would decrease them. The values in Fig. 1 and Table 3 have not been adjusted, but the reader should be aware that the true uncertainties are greater than the quoted standard deviations and that the rates may depend on the method of surface preparation.

The preceding discussion illustrates the relative merits of static and flow systems for studies of surface effects. Static systems have the advantages that residence times are known precisely and that surface-to-volume ratios may be varied widely by packing reactors. In flow systems, packing reactors might create regions of stagnant gas, and residence times are less well known. Nevertheless, flow reactors do permit the use of shorter residence times, reducing the chance of reactions of products. In favourable circumstances, flow reactors enable the observation of induction periods. Rate parameters calculated from induction periods are subject to fewer of the foregoing assumptions than are those calculated from steady state rates.

It can be seen from eq. [7] that the ratio of heterogeneous to homogeneous termination is governed by the quantity $0.25k_6(k_1k_5[C_2H_6])^{-1/2}$. Ethane pyrolysis may be more influenced by surface effects than are other pyrolyses, because the initiation rate constant, k_1, is especially small.

We recommend that workers wishing to minimize surface termination use clean reactors of small S/V and keep conversion low so as to minimize carbon deposition. The opposite extreme, in which surface termination dominates, merits further study. Surface termination may be significant in industrial pyrolysis, in which conversions are large and carbon is known to be formed.

Photochemical rearrangement of acetanilide, benzanilide, and ethyl phenyl carbonate in the presence of β-cyclodextrin

ROBERT CHÊNEVERT[1] AND RAYMOND PLANTE

Département de chimie, Faculté des sciences et de génie, Université Laval, Québec (Qué.), Canada G1K 7P4

Received July 21, 1982[2]

ROBERT CHÊNEVERT and RAYMOND PLANTE. Can. J. Chem. **61**, 1092 (1983).

The photorearrangement of acetanilide, benzanilide, and ethyl phenyl carbonate is changed in the presence of β-cyclodextrin (cycloheptaamylose). Addition of β-cyclodextrin alters the *para/ortho* migration ratio in favor of the *para* position and improves the rearrangement yield. The production of phenol (in the case of carbonate) and aniline (in the case of amides) falls significantly when irradiations are carried out in the presence of β-cyclodextrin.

ROBERT CHÊNEVERT et RAYMOND PLANTE. Can. J. Chem. **61**, 1092 (1983).

Le réarrangement photochimique de l'acétanilide, de la benzanilide et du carbonate d'éthyle et de phényle est modifié par la présence de la β-cyclodextrine (cycloheptaamylose). L'addition de β-cyclodextrine améliore le rendement du réarrangement et favorise la migration en *para* par rapport à la position *ortho*. La formation du phénol (dans le cas du carbonate) ou de l'aniline (dans le cas des amides) diminue sensiblement lorsque la photolyse a lieu en présence de β-cyclodextrine.

Introduction

Cyclodextrins form inclusion compounds in aqueous solution with a variety of smaller molecules and can catalyse several chemical reactions (1). These systems are considered to be enzyme models (2, 3) and some interesting rate enhancements or selectivity effects have been found. This last area, selective stereochemistry, is one of the most neglected areas of cyclodextrin chemistry. Breslow *et al.* (4) have reported a striking example of the use of complexation to alter the course of a reaction. When anisole was chlorinated by hypochlorous acid, *para* and *ortho* isomeric chloroanisoles were produced in the ratio 1.48:1. This ratio increased to 21.6:1 when α-cyclodextrin was added to the reaction. Cyclodextrins also modified product distribution in the rearrangement of dibenzylmethylsulfonium tetrafluoroborate in alkaline medium (5) and changed the *para* to *ortho* formylated phenol ratio of the Reimer–Tiemann reaction (6). Ohara and Watanabe (7) reported that β-cyclodextrin alters the *para* to *ortho*-hydroxyacetophenone ratio of the photochemical Fries rearrangement of phenyl acetate. We report here the influence of β-cyclodextrin on the photorearrangement of acetanilide, benzanilide, and ethyl phenyl carbonate.

Experimental

Reagents

Acetanilide and benzanilide (Aldrich Co.) were recrystallized until no further improvement in melting point was observed and dried in vacuum before use. Ethyl phenyl carbonate (Alfred Bader collection, Aldrich Co.) was shown to be pure by gas chromatography.

Irradiation; general procedure

The anilide or carbonate was dissolved in 500 mL of the chosen solvent. Concentrations were 10^{-2} *M* (acetanilide), 1.8×10^{-2} *M* (benzanilide), and 10^{-2} *M* (carbonate). When β-cyclodextrin was used, the molal proportion was 0.5 mol cyclodextrin per mol of substrate. The solution was placed in a cylindrical quartz reactor and irradiated with an immersion-type, 450-watt Ace–Hanovia uv lamp (medium pressure mercury arc). Degassed solvents were used and nitrogen was bubbled through the solution during the irradiation. When organic solvents were used, the solution was concentrated under vacuum (rotary evaporator) before analysis. When water was the solvent, the aqueous phase was thoroughly extracted with ether and the ether phase was dried and concentrated under vacuum. It was found that no loss of products occurred during these operations.

Analysis

The reaction mixtures were analyzed by quantitative vapor phase chromatography with a "7620 Research chromatograph Hewlett Packard" instrument using a 6 ft × 1/8 in., 10% Dexil 300 column on 80/100 Chromosorb W AW/DMSC support. In all cases, the injector and flame ionization detector were set at 250°C and the helium rate flow was 20.1 mL/min. The relative yields were determined by using the relative response ratio method with sulfolane as the internal standard. The retention times of all photoproducts were compared to those of authentic samples.

Acetanilide photoproducts analysis

Temperature program: 6°C/min (60°C to 125°C), 10 min; isotherm at 125°C, 10°C/min. (125°C to 210°C). Retention times (minutes): aniline (7.2), *o*-aminoacetophenone (18.0), acetanilide (24.6), *p*-aminoacetophenone (26.8).

Benzanilide photoproducts analysis

Temperature program: 6°C/min (60°C to 125°C), 10 min; isotherm at 125°C, 10°C/min. (125°C to 225°C), isotherm at 225°C. Retention times (minutes): benzoic acid (12.0), *o*-aminobenzophenone (31.6), benzanilide (34.0), *p*-aminobenzophenone (37.2).

Ethyl phenyl carbonate photoproducts analysis

Temperature program: same as for acetanilide. Retention times (minutes): phenol (5.6), ethyl phenyl carbonate (12.4), ethyl salicylate (14.6), ethyl *p*-hydroxybenzoate (25.0).

Results and discussion

Irradiations of acetanilide, benzanilide, and ethyl phenyl carbonate were first performed under conditions previously reported in the literature in order to set up experimental conditions and analysis techniques. The irradiations were then completed using water as the solvent with and without β-cyclodextrin. The results are summarized in eqs. [1]–[3] and compiled in Tables 1–3.

The photolysis of acetanilide in isopropyl alcohol and benzanilide in ethanol gave results identical to those reported by Hageman (8) and by Elad *et al.* (9). In both cases, the *ortho/para* ratio is 1.1. In our hands, photolysis of ethyl

24.0	Water	79.8	20.2	—	0.3	4.0
24.0	Water β-cyclodextrin	58.1	41.9	—	2.0	1.4

[a] Contrarily to ref. 9, we found no trace of aniline.

phenyl carbonate in ethanol gave an *ortho*/*para* ratio of 0.45. This value is lower than the value reported by Pac and Tsutsumi (10).

As seen from Tables 1–3, the presence of β-cyclodexetrin had three effects on the photolysis of the title compounds. (1) Conversion is increased by about 2.4-fold for acetanilide, 7-fold for benzanilide, and 1.5-fold for ethyl phenyl carbonate. (2) The migration to *para* position is preferred over the *ortho*-migration. (3) Formation of phenol or aniline is decreased.

These data can be explained by assuming that the substrate penetrates the cyclodextrin cavity and reacts according to the mechanism proposed for the photo-Fries reaction and related rearrangements (Scheme 1).

The primary mechanism involves fragmentation to give free radicals which undergo extensive geminate recombination (11, 12). In this mechanism, the carbon–heteroatom (oxygen or nitrogen) bond is cleaved homolytically giving acyl and phenoxy (or nitrogen equivalent) radicals which are held in close

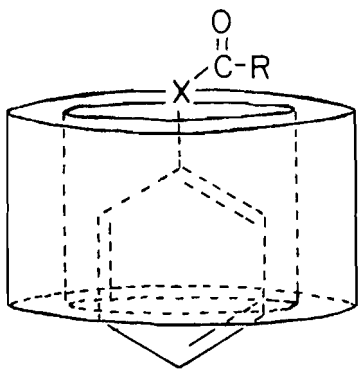

SCHEME 2

proximity to each other by the solvent cage. The lifetime of radical pairs should be very short in this solvent cage. Recombination of the two fragments by reestablishing the carbon–heteroatom bond would result in the regeneration of the starting material. On the other hand, recombination of the acyl radical at either *ortho* or *para* position of the aromatic radical would produce acyl cyclohexadienones (or nitrogen equivalent), tautomers of the final photoproducts. Alternatively, the radicals may escape from the solvent cage and diffuse to give separate products. Phenol (or aniline) is produced when the aromatic radical abstracts hydrogen from the solvent or otherwise.

During the photolysis in the presence of cyclodextrin, a substantial portion of substrate must react while bonded into the cavity of a cyclodextrin, otherwise no change in the aromatic substitution pattern would have been observed. The dissociation constants of cyclodextrin–aromatic complexes all lie close to 10^{-3} mol/L and are characteristic of weak intermolecular interactions (1). There is no correlation between the chemical properties (functional groups) of the guest molecules and dissociation constants. Thus, inclusion does not seem to depend primarily on the character of the substrate (13).

Better rearrangement yields in the presence of cyclodextrin can be explained by an increase in the solubility of the substances which are slightly soluble in water. It is a well-known fact that solubility of the guest component increases linearly with the amount of cyclodextrin added (1).

The change in the migration pattern in favor of the *para* position is the result of the geometric blocking role of the cyclodextrin. An aromatic nucleus bonded into the cavity of a cyclodextrin has its *ortho* and *meta* positions well shielded, while the *para* position is more accessible and might be involved in a reaction (Scheme 2). There is a well-known geometric requirement for binding aromatic compounds into the cavity, in which *para*-disubstituted aromatic compounds are well bound compared to *ortho*-disubstituted compounds (13).

Decrease in the formation of phenol or aniline can also be explained by the complex formation. The phenoxy radical (or

For personal use only.

its nitrogen equivalent) has first to depart from the cyclodextrin cavity before leaving the solvent cage and abstracts hydrogen. This supplementary requirement slows down the process.

We are presently studying the influence of cyclodextrins on regio and stereoselectivity of other organic reactions.

Tungsten carbonyl complexes of Main Group IV organometallic sulfides

C. Robert Lucas

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received September 7, 1982

C. Robert Lucas. Can. J. Chem. **61**, 1096 (1983).

Vibrational spectroscopic data from the literature and from seven new compounds is treated by the methods of Cotton and Kraihanzel and of Graham. The results are interpreted as evidence that in $(R_3MSPh)W(CO)_5$ (R = Me, Ph; M = Si, Ge, Sn) there are W → S $d\pi-d\pi$ and S → M $p\pi \rightarrow d\pi$ components to the bonding, the extent of the latter varying in the order Si > Ge > Sn. It is concluded that changes in the carbonyl stretching spectra reflect changes in electron density on sulfur. Thus, the carbonyl spectra are affected both by the electronegativity of groups bound to sulfur and by the extent of S → M π-bonding. The fact that changing M affects spectroscopic properties of a bond three atoms away represents long range transmission of effects via multiple bonds but in a manner quite unlike that in conjugated organic systems.

C. Robert Lucas. Can. J. Chem. **61**, 1096 (1983).

Faisant appel aux méthodes de Cotton et Kraihanzel et de Graham, on traite les données spectroscopiques de vibration répertoriées dans la littérature ainsi que celles relatives à sept nouveaux composés. On interprète les résultats comme une preuve du fait que, dans le composé $(R_3MSPh)W(CO)_5$ (R = Me, Ph; M = Si, Ge, Sn), il y a des composantes de liaison W → S $d\pi-d\pi$ et S → M $p\pi \rightarrow d\pi$ l'importance de la dernière variant dans l'ordre suivant: Si > Ge > Sn. On conclut que les variations des spectres d'élongation du carbonyle réflètent les variations de la densité électronique du soufre. Ainsi l'électronégativité des groupes liés au soufre et le taux de liaison S → M affectent les spectres du carbonyle. Le fait que le remplacement de M affecte les propriétés spectroscopiques d'une liaison entre trois atomes éloignés, représente une transmission à longue distance des effets par l'intermédiaire des liaisons multiples. Ce comportement est complètement à l'opposé de celui des systèmes organiques conjugués.

Introduction

Preparation and bonding studies of Main Group IV organometallic sulfides, R_3MSR' (M = C, Si, Ge, Sn, or Pb), have been undertaken by a variety of laboratories (1–4), as have studies of Group VI carbonyl complexes, $M(CO)_5L$ (M = Cr, Mo, or W), in which L is an organic sulfide (5, 6). Use of the organometallic sulfides as L, however, has been relatively infrequent (7–9). The purpose of this work, therefore, was to prepare a series of compounds $(R_3MSPh)W(CO)_5$ (R = Me, Ph; M = C, Si, Ge, or Sn) in which M is systematically varied in order to observe changes in the complexes as a function of M.

Experimental

All procedures were carried out under a nitrogen atmosphere and anhydrous conditions. Spectroscopic data (Tables 1 and 2) were obtained using the following instruments: ir, Perkin Elmer Model 283; Raman, Coderg laser; nmr, Varian EM-360 or Bruker WP 80 Fourier-transform; mass spectra, VG Micromass 7070 HS. Raman spectra were obtained from saturated hexane solutions of the complexes sealed *in vacuo*. Infrared spectra were obtained from dilute hexane solutions and are reproducible to ± 0.8 cm^{-1} on duplicate runs involving separate preparations of the same compound. Analyses were performed by Canadian Microanalytical Service Ltd. and by Analytical Laboratories, Elbach, West Germany.

(a) Preparation of ligands

Me_3CSPh was obtained in 58% yield by Ipatieff's method (16) involving addition of thiophenol to isobutene dissolved in cold 75% H_2SO_4.

Me_3SiSPh, Me_3GeSPh, and Ph_3CSPh were obtained in 65–85% yield using Abel's procedure (17) involving treatment of R_3MCl with $Pb(SPh)_2$ in refluxing benzene.

Me_3SnSPh, Ph_3GeSPh, and Ph_3SnSPh were prepared in 60–90% yield by Abel and Brady's method (18) of combining R_3MX with PhSH in presence of a base. (R = Me, M = Sn, solvent H_2O, base NaOH; R = Ph, M = Ge, Sn, solvent tetrahydrofuran, base pyridine.)

(b) Preparation of the complexes

Tungsten hexacarbonyl (4.6 g, 13 mmol) was dissolved in tetrahydrofuran (250 mL) in a Pyrex flask fitted with a double surface condenser, a magnetic stirrer, and a gas dispersion inlet tube. The top of the condenser was connected to an oil bubbler and the solution was irradiated with a 100 W uv lamp while stirring and passing a stream of N_2 bubbles. After 4 h, the lamp was switched off, the yellow solution chilled rapidly to 0°C, and ligand (13 mmol) added. The solution was stirred briefly, stored at −20°C in the dark overnight, filtered, and evaporated *in vacuo* at 40°C. The residue was extracted with hexane (3 × 100 mL) and the extracts were combined, concentrated, and placed on an Al_2O_3 column from which they were eluted with hexane. The yellow eluate was evaporated to dryness and the crystals that formed were ground to a fine powder, placed in a sublimer and the $W(CO)_6$ impurity sublimed at 40°C and 0.1 mm Hg. The residue was then recrystallized from hexane.

When the ligand was Me_3SiSPh the crude product was a yellow oil which was purified by distillation in a short path distillation apparatus at 0.01 mm Hg taking care that the heating bath temperature did not exceed 75°C.

$(Me_3CSPh)W(CO)_5$ mp 82°C (decomp.), yield 31%. *Anal.* calcd. for $C_{15}H_{14}O_5SW$: C 36.75, H 2.88, S 6.54, W 37.50; found: C 37.12, H 3.20, S 7.02, W 37.20.

$(Me_3SiSPh)W(CO)_5$ yield 18%. Decomposes in a few days at room temperature or rapidly above 75°C.

$(Me_3GeSPh)W(CO)_5$ mp 77°C (decomp.), yield 28%. *Anal.* calcd. for $C_{14}H_{14}GeO_5SW$: C 30.53, H 2.56, S 5.82; found: C 31.30, H 2.75, S 6.40.

Mass spectra

Molecular ions were not detected except for $(Me_3GeSPh)W(CO)_5$ which gave a spectrum of the ions $[Me_3GeSPh \cdot W(CO)_5]^+$, $[Me_3GeSPh \cdot W(CO)_3]^+$, $[Me_3GeSPh \cdot W(CO)]^+$, $[Me_3GeSPh \cdot W]^+$, $[Me_3GeSPh]^+$, and various ligand fragments. Spectra of the other complexes consisted of peaks corresponding to $[ligand]^+$, $[R_3M]^+$, $[PhS]^+$, $[W(CO)_n]^+$ (n = 1−4), and ligand fragments.

Results

The new complexes prepared in this work were examined in hydrocarbon solutions in the carbonyl stretching region of their ir and Raman spectra (Table 1). The data obtained were treated according to Cotton and Kraihanzel (10) in order to obtain approximate carbonyl stretching force constants and then by Graham's method (11) to obtain $\Delta\sigma$ and $\Delta\pi$ factors. Results from these treatments are also given in Table 1 and are displayed graphically in Fig. 1. Force constant variation as a function of ligand Lewis basicity is plotted in Fig. 2. Results of a ^1H nmr study of the methyl resonances in $(Me_3MSPh)W(CO)_5$ are in Table 2.

Discussion

The ir and Raman spectra appeared as predicted by theory and as found previously for other molecules of idealized C_{4v} symmetry (10), except for the occurrence of a weak B_1 mode in the ir and splitting of the E mode. These anomalies suggest that the symmetry is actually somewhat lower than C_{4v}, probably because of non-equivalence of the two groups attached to sulfur in the ligand or because of crowding which causes distortion of the $W(CO)_5$-group.

Although the absolute values of the force constants derived from the ir data may be disputed, differences between them for a series of compounds of closely related structure are generally accepted as meaningful (12) and such differences were used here to calculate $\Delta\sigma$ and $\Delta\pi$ factors. As discussed by Graham (11), the possible error in these factors can be taken as ±0.08 for $\Delta\pi$ and ±0.12 for $\Delta\sigma$ although probable errors are considered to be smaller due to the excellent reproducibility of the data and the fact that any systematic errors would be eliminated during calculation of $\Delta\sigma$ and $\Delta\pi$.

For all the complexes in Table 1 and especially for the series of structurally related ones (L = R_3MSPh, HSPh), frequencies of the ν_{CO} bands are relatively constant, indicating that there are no drastic changes in carbonyl bonding throughout the series. This suggests that tungsten−sulfur bonding is similar throughout the series too and one may therefore conclude that varying M causes no qualitative changes in bonding within the S—W—$(CO)_5$ part of the complexes. However, when the data in Table 1 are plotted (Fig. 1) it becomes apparent that there is a definite relationship between the nature of the ligand and bonding in the carbonyls and one may therefore conclude that varying M causes quantitative changes in bonding within the

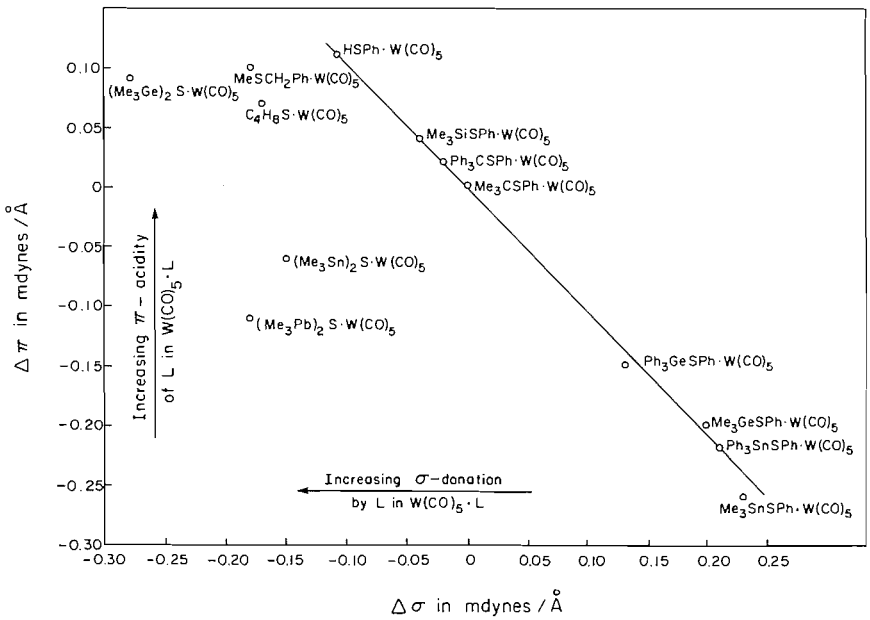

FIG. 1. Graham's $\Delta\sigma$ and $\Delta\pi$ factors.

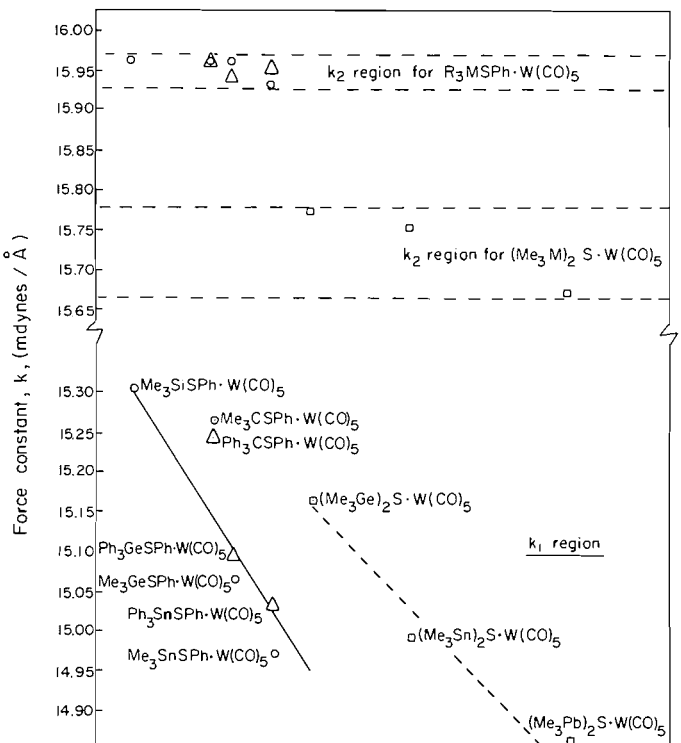

FIG. 2. Effect of ligand basicity on *cis* and *trans* CO bonding.

S—W—$(CO)_5$ part of the complexes.

It is generally accepted that the major route of influence on bonding in carbonyl ligands is the π-bond between the metal and CO (6). The effect of changing M could be transmitted by this route as a result of changes in either σ- or π-bonding (or both) between R_3MSPh and tungsten. The existence of a σ-bond between tungsten and sulfur, involving one of the unshared pairs of electrons on sulfur in the free ligand, is not a matter of dispute but the existence of a tungsten−sulfur π-bond is somewhat more contentious (5, 9). Observations on organic sulfide complexes and the results of this study are most conveniently understood, however, in terms of W → S, $d\pi-d\pi$ bonding of a type broadly similar to that already established for many other ligands (6). A similar question concerning π-bonding between M and sulfur in R_3MSPh has been addressed by several workers (1, 3, 13) and the evidence is again most readily interpretable in terms of multiple bonding involving some degree of S → M, $p\pi \rightarrow d\pi$ interaction. One must therefore acknowledge at least the possibility of a series of π-bonds in the complexes $(R_3MSPh)W(CO)_5$ extending from M to sulfur, from sulfur to tungsten, and from tungsten to the CO ligands. Conjugation, however, in the sense recognized in organic chemistry should not be assumed since different kinds of atomic orbitals are involved.

Notwithstanding the possibility of tungsten−sulfur $d\pi$-bonding, it is worthwhile to question whether the relationship displayed in Fig. 1 can be explained satisfactorily in terms of M—S—W σ-bond or inductive effects alone. Figure 2 is a plot of *cis*- and *trans*-carbonyl force constants in $W(CO)_5L$ as a function of Lewis basicity of L. (Lewis basicity is indicated by the shift, caused by the ligand, in ν(C—D) of $CDCl_3$ (2).[1]) Figure 2 demonstrates that changes in ligand basicity have a definite effect on the *trans*-carbonyl (k_1 region) but very little effect on those in *cis*-positions (k_2 regions). Furthermore, in Table 1 it may be noted that the largest changes in band position upon varying M are experienced by the A_1^2 mode which involves stretching of the *trans*-carbonyl. This effect can also be seen in values of k_1 (the *trans*-carbonyl force constant) which shows variation with M while k_2 (the *cis*-carbonyl force constant) remains relatively unchanged. These observations sug-

[1]Values of $\Delta\nu$ plotted for R_3MSPh are actually those for R_3MSMe because complete data for R_3MSPh are not available. Reference 2 indicates, however, that this practice will not change significantly the slopes of the lines in Fig. 2, although it would be expected to move entire lines left or right on the $\Delta\nu$ axis. Such horizontal movement of an entire line has no effect on arguments presented above since it is the slope, not the position, of a line which is significant in the present context.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

gest that the effects of changing M are transmitted more efficiently to the *trans*- rather than the *cis*-positions. Since a purely inductive effect on tungsten by the ligand should be transmitted equally to both *cis*- and *trans*-positions, it is unlikely that effects of changing M are being transmitted to tungsten through the σ-bond framework alone. On the other hand, if the ligand were interacting with tungsten through a π-bond, the *trans*-carbonyl should be more sensitive than the *cis*-carbonyls to changes in the ligand. This is due to the fact that there are two tungsten *d*-orbitals of appropriate symmetry to interact with the ligand π-system and the π*-system of the *trans*-carbonyl but only one tungsten *d*-orbital to interact with the *cis*-carbonyls. It seems therefore that effects of changing M are transmitted through an S—W—CO π-system, but in a manner unlike that in organic compounds. Accompanying changes must also be occurring in the σ-system due to electronegativity changes in neighbouring groups and synergistic response to the π-system.

Based on this hypothesis, the spectroscopic results and the role of the M—S bond can be understood. Taking $(Me_3CSPh)W(CO)_5$, in which M—S π-bonding is unlikely, as reference ($\Delta\sigma$ and $\Delta\pi = 0$), one could argue that upon substituting carbon by silicon, which is more electron-donating, the electron density on sulfur would be increased. This should raise the energy of the sulfur *d*-orbitals (19) and make them less suitable for overlap with tungsten *d*-orbitals. Thus, if inductive effects alone are considered Me_3SiSPh should be a poorer π-acid and a better σ-donor than Me_3CSPh and $(Me_3SiSPh)W(CO)_5$ should appear lower in Fig. 1 and to the left of $(Me_3CSPh)W(CO)_5$ while in Fig. 2 it should appear lower and to the right. This is not, however, what is observed.

Therefore, there must be some mechanism, such as S → Si $p\pi \rightarrow d\pi$ bonding, which removes electron density from sulfur to an extent that causes contraction of the sulfur *d*-orbitals so that they overlap more, rather than less, effectively with tungsten *d*-orbitals. This would make Me_3SiSPh a better π-acid and synergistically a better σ-donor than Me_3CSPh, as observed.

The position of $(Me_3GeSPh)W(CO)_5$ in Fig. 1 can be understood similarly. Thus, germanium is probably a better σ-donor to sulfur than even silicon (6) but unlike silicon, the efficiency of S → M $p\pi \rightarrow d\pi$ bonding is not adequate to remove the extra electron density on sulfur. The sulfur *d*-orbital energies are therefore raised making the ligand a poorer π-acid and synergistically a poorer σ-donor than either Me_3SiSPh or Me_3CSPh.

The key to understanding the spectroscopic results in Figs. 1 and 2 seems to be the energy of the sulfur *d*-orbitals or, in other words, the π-acidity of the sulfide ligand. This in turn appears to be determined by the extent of both σ-donation to sulfur and $p\pi \rightarrow d\pi$ bonding from sulfur. Thus, changing R in R_3MSPh from Me to Ph or changing R_3M to H (14) should both decrease σ-donation to sulfur, causing movement upward and to the left in both figures, as observed. It should be noted, too, that while changes in R have some effect on the σ and π characteristics of the ligand, larger changes are caused by varying M. Thus, replacing Ph in R_3MSPh by a second R_3Ge or R_3Sn makes the ligands stronger π-acids and better σ-donors, implying that R_3M delocalizes sulfur-3*p* electron density more efficiently than Ph and does so in the order $R_3Ge > R_3Sn$. The positions of the benzylmethyl sulfide and tetrahydrothiophene complexes in Fig. 1 are also consistent with the explanation based on sulfur *d*-orbital energies. In these cases, the energies would be affected mainly by inductive effects since S → C $p\pi \rightarrow d\pi$ bonding is presumably absent.

The nmr results in Table 2 and, in particular, the observation that coordination of Me_3CSPh caused no change in the shift of the methyl resonance whereas coordination caused varying shifts for all other Me_3MSPh, make it tempting to suggest that the shift is dependent on the extent of S → M $p\pi \rightarrow d\pi$ bonding. However, such correlation is only meaningful if the magnetic anisotropic contributions to the shift are known to be constant or, at least, to vary linearly throughout the series. Unfortunately this is not known to be true for these complexes. In fact, since Me_4M (M = Ge, Sn, Pb) are known to have variable anisotropic contributions to the methyl resonance shift (15), it is possible the same applies to Me_3MSPh. Thus, until the anisotropic contribution to the methyl resonance shift in these complexes is understood any correlation between shift and other molecular properties must be viewed as suspect.

The determination of the stoichiometry and stability constant of weak complexes in solution: a restatement of the "straight-line" method

AURELIO BELTRÁN-PORTER AND JOSÉ A. RAMÍREZ

Departamento de Química Inorgánica, Facultad de Ciencias Químicas, Universidad de Valencia, Burjasot (Valencia), Spain

Received August 10, 1982

AURELIO BELTRÁN-PORTER AND JOSÉ A. RAMÍREZ. Can. J. Chem. **61**, 1100 (1983).

Usually, to establish the degree of condensation of a complex species in solution, primarily when it is a weak complex, is more cumbersome than to determine the stoichiometric ratio itself. The present work describes a modification of the Asmus method in order to render it suitable for the determination of the actual stoichiometric coefficients and the stability constant of weak complexes whatever the degree of condensation may be.

AURELIO BELTRÁN-PORTER ET JOSÉ A. RAMÍREZ. Can. J. Chem. **61**, 1100 (1983).

La détermination du degré de condensation des complexes relativement faibles dans dissolution présente souvent plus de difficultés que la détermination de leurs relations stoechimétriques. La modification de la méthode classique d'Asmus qui nous montrons dans ce travail-ci la rend utilisable pour établir les paramètres stoechiométriques réels du complex et, de cette façon, son degré de condensation. Également il est démontré que cette méthode permet de calculer la valeur de la constant de stabilité conditionelle du complex.

Introduction

The "straight-line method" was proposed by E. Asmus (1) as a suitable procedure for fixing the stoichiometric ratio and stability constant of relatively weak AB_n complexes in solution. It constituted an alternative to other classic methods which lead to uncertain results when the complex is not completely formed at the equivalence point.

Nevertheless, K. S. Klausen and F. J. Langmyhr (2) emphasized that while the applicability of the Asmus method to mononuclear systems seemed obvious, it was not clear whether it could be used for determining the composition of polynuclear A_mB_n complexes. Accordingly, assuming the same approximations introduced by Asmus, they developed a general equation which, in agreement with their discussion, made it possible, in some cases, to distinguish between mono and polynuclear species. In addition, calculation of the stoichiometric ratio and stability constant of the complex was also possible.

The fact that in the experimental part of the Klausen–Langmyhr work there are some contradictory aspects which make the procedure unreliable was recoginized later and an alternative procedure has been proposed (3). This fact not withstanding, it is our opinion that leaving aside the Klausen–Langmyhr speculative considerations, the equation derived by them *must* lead to the correct *m and n* values when it is strictly considered. In practice, we have often found serious difficulties in selecting the most likely degree of condensation of the complex from graphical plots of the equation.

The work reported here tries to avoid these troubles and shows an improved technique for applying the "straight-line" method to weak complexes in solution whatever its degree of condensation may be. The conditional stability constant of the complex and its specific value for the physical property measured can also be evaluated easily.

Theory

Let us assume a general equilibrium

$$[1] \quad \delta A + n\delta B \rightleftharpoons A_\delta B_{\delta n}$$

describing the formation of a weak complex in solution. In this equation δ and $n\delta$ are integral numbers whereas n may also be a fraction.

According to the practical procedure of Asmus and Klausen–Langmhyr, a constant volume v_0 of a standard solution of A (initial concentration a_0) and varying volumes v of a standard solution of B (concentration b_0) are introduced into a series of volumetric flasks of volume V. The samples are prepared in such a way that the reagent B always is in a great excess in relation to A. In this way δ represents the degree of condensation of the complex with respect to the deficient reagent, A. An inert saline solution is added until volume V and the pH are adjusted. Then, the variations of a physical property proportional to the complex concentration (i.e. the validity of the Lambert–Beer law is assumed (4)) are measured.

In these conditions the mass action law can be written as

$$[2] \quad K' = K^{1/\delta} = \frac{[A]\,[B]^n}{[A_\delta B_{\delta n}]^{1/\delta}}$$

The equilibrium concentrations of the reactants are related to the initial concentrations through

$$[3] \quad [A] = a - \delta[A_\delta B_{\delta n}] \qquad \text{and}$$

$$[B] = b - \delta n[A_\delta B_{\delta n}] = b - n(a - [A])$$

where $a = a_0v_0/V$ and $b = b_0v/V$.

If the Lambert–Beer law is obeyed

$$[4] \quad [A_\delta B_{\delta n}] = Y/\epsilon$$

(in which Y = variation of the physical property due to complex formation and ϵ = molar coefficient of proportionality[1]) and assuming, according to Asmus, that for a weak complex $a - [A] \simeq 0$ (or $[A_\delta B_{\delta n}] << b$),

$$[5] \quad [A] = a - \delta[A_\delta B_{\delta n}] = a - \delta\, Y/\epsilon$$

$$[B] \simeq b$$

Thus, the equation [2] is transformed into

$$[6] \quad K' = (a - \delta Y/\epsilon)\, b^n/(Y/\epsilon)^{1/\delta}$$

[1]It can be easily shown that the specific value of the physical property of the complex, ϵ_C, is related to ϵ through $\epsilon_C = \epsilon + \delta n\epsilon_B$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

an expression that can be rearranged, after the substitution of a and b values, to yield

$$[7] \quad \frac{Y^{1/\delta}}{\nu^n} = \frac{a_0 b_0^n v_0}{V^{n+1}} \epsilon^{1/\delta} \frac{1}{K'} - \left(\frac{b_0}{V}\right)^n \cdot \delta \cdot \epsilon^{1/\delta - 1} \cdot \frac{1}{K'} \cdot Y$$

This equation, that easily can be transformed into that of Asmus when $\delta = 1$, will correspond to a straight line only if K' is truly a constant, that is to say when δ and δn values are the actual stoichiometric coefficients of the complex.

In this manner, from the graphical plots of $Y^{1/\delta}/\nu^n$ vs. Y we have the following relations.

(1) The correct δ and n values are those for which a plot of $Y^{1/\delta}/\nu^n$ vs. Y gives a straight line.

(2) For this straight line, (a) the abscissa at the origin (A.O.) provides us the ϵ value:

$$[8] \quad \text{A.O.} = (a_0 v_0/V)(\epsilon/\delta)$$

From this, ϵ_C is immediately calculated. (b) The K' value, and K consistently, can be calculated from:

$$[9] \quad \text{(i) slope} = -(b_0/V)^n \cdot \delta \cdot \epsilon^{1/\delta - 1} (1/K')$$

or

$$[10] \quad \text{(ii) ordinate at the origin} = (a_0 b_0^n v_0/V^{n+1}) \epsilon^{1/\delta} (1/K')$$

On the other hand, ϵ and K' can be simultaneously determined solving the system of eqs. [9] and [10].

In this way, contrary to Klausen and Langmhyr, a single experience is required in order to calculate the entire set of characteristic parameters of the complex. At the same time, eq. [8] enables us to check readily the reliability of our measurements: if only the $A_\delta B_{\delta n}$ complex has been formed in the solution the abscissa at the origin (A.O.) value must coincide with the upper limit value of the variation of the physical property measured.[2] In the same way, the fact that both ϵ and K' can be evaluated by two different means will allow us to estimate the meaning of our results.

Results and discussion

In order to demonstrate that the proposed technique can be used successfully to identify weak complexes in solution, studies were performed on previously well-characterized complexes.

Firstly we have considered it of interest to apply this procedure to the monomeric $[Fe(C_{13}H_{12}N_2)_3]^{2+}$ complex studied in the original work of Asmus. The experimental data used for our calculations are those tabulated in his paper.

When $(\text{absorbance})^{1/\delta}/\nu^n$ is plotted against (absorbance) for several δ and n values, a straight line is obtained only for $\delta = 1$ and $n = 3$. The coordinates at the origin of this straight line are:[3] abscissa $= 1.6 \pm 0.2$; ordinate $= 8.3 \pm 0.2 \times 10^4$. Its slope is equal to $-5.1 \pm 0.2 \times 10^4$. From these values, $\epsilon_C = 4.8 \pm 0.6 \times 10^3$ and $K = 4.6 \pm 0.4 \times 10^{-5}$ are calculated. As we see, our results are in excellent agreement with those reported by Asmus ($K = 4.3 \times 10^{-5}$, $\epsilon_C = 4.68 \times 10^3$).

TABLE 1. Mo(VI) – malic acid system pH = 4.00, excess of ligand

4.00	0.390	0.252	0.138
5.00	0.456	0.315	0.141

[a]All the samples are levorotatory at $\lambda = 436$ nm. Rotatory power values are expressed in degrees, $t = 30 \pm 0.05$°C.

Nevertheless, the main aim of the procedure described here lies in its applicability to polynuclear systems. In order to check this aim, the method has been applied, among others, to the system Mo(VI) – malic acid. When malic acid is in excess (reactant B), Mo(VI) (6), as well as W(VI) (7), gives rise to a dinuclear complex of stoichiometric ratio 1:1 which is stable in acidic medium.

A series of samples containing a constant amount of Na_2MoO_4 ($a = 2.00 \pm 0.01 \times 10^{-3}$ M) and varying concentrations of l(−)-malic acid (ν mL of a $b_0 = 1.2240 \pm 0.0001$ M solution) was prepared by dilution of the appropriate amounts of the standard solutions until $V = 25$ mL. All the solutions were made 1 M in $NaClO_4$ and their pH was adjusted to 4.00. The measured values of the rotatory power ($\lambda = 436$ nm, $t = 30 \pm 0.05$°C) of the solutions are summarized in Table 1.

In the Fig. 1 we show the plots of $(\text{rotatory power})^{1/\delta}/\nu^n$ vs. (rotatory power) as a function of δ and n values. The dimeric character of the complex ($\delta = 2$) and its stoichiometric ratio 1:1 ($n = 1$) are clearly inferred from it. The calculated values of the conditional stability constant, $K = 1.3 \pm 0.2 \times 10^{-6}$ (pH = 4.00), and specific molar rotation, $-(\delta)_{436}^{30°} = 1.5 \pm 0.2 \times 10^2$ agree (within experimental limits of error) with other values previously reported (8). On the other hand, the abscissa at the origin, A.O. $= 0.15 \pm 0.02$, is closer to the limiting value of the rotatory power.

Klausen–Langmhyr's equation could be applied in other ways, using the data in Table 1. It has the form

$$[11] \quad \frac{1}{\nu^n} = \frac{a_0^m v_0^m b_0^n}{V^{n+m} K} X_m - \frac{m^2}{K} \left(\frac{a_0 v_0}{V}\right)^{m-1} \left(\frac{b_0}{V}\right)^n$$

in which

$$[12] \quad X_m = \frac{1}{Y} + \left(\frac{m}{2}\right)\left(\frac{m}{a\epsilon}\right)^2 Y - \left(\frac{m}{3}\right)\left(\frac{m}{a\epsilon}\right)^3 Y^2 + \ldots + (-1)^m \left(\frac{m}{a\epsilon}\right)^m Y^{m-1}$$

m and n being the stoichiometric coefficients of the $A_m B_n$ complex. According to their considerations, the form and position of the curves obtained from eq. [11] varying m and n values are

[2]Occasionally, this limit value may be unaccessible in practice due to experimental hindrance (such as precipitation or a new complex formation, etc.). Equation [7] has the advantage that, unlike the Klausen–Langmhyr equation, previous knowledge of this value is not necessary.

[3]The line has been fitted according to the general method described by Lark *et al.* (5) and the confidence limits calculated at a 95% significance level.

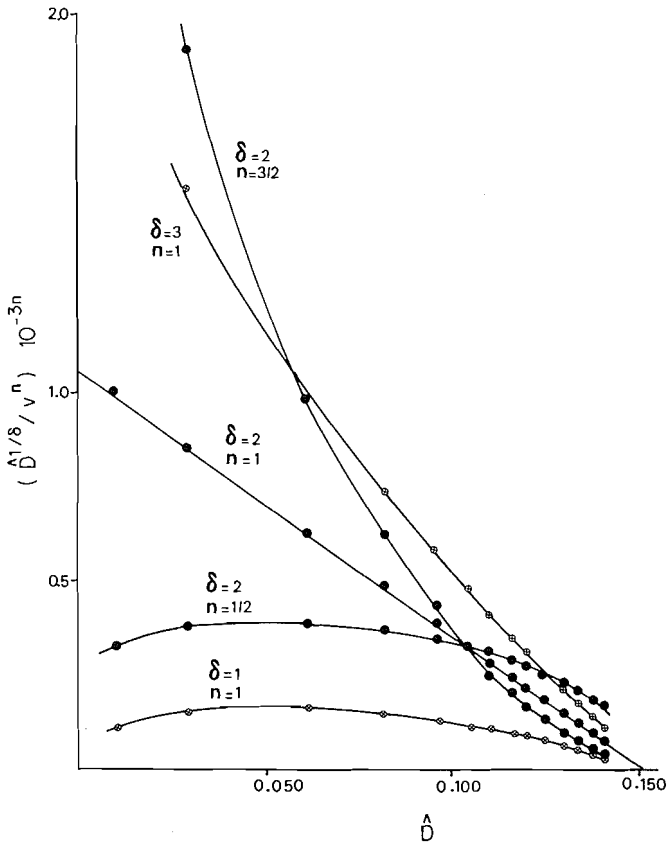

FIG. 1. Modified "straight-line" method for $[Mo_2O_5(C_4H_4O_5)_2(OH)_2]^{4-}$. $\hat{D}$ = rotatory power (Degrees). Curves have been plotted for some selected values of δ and n.

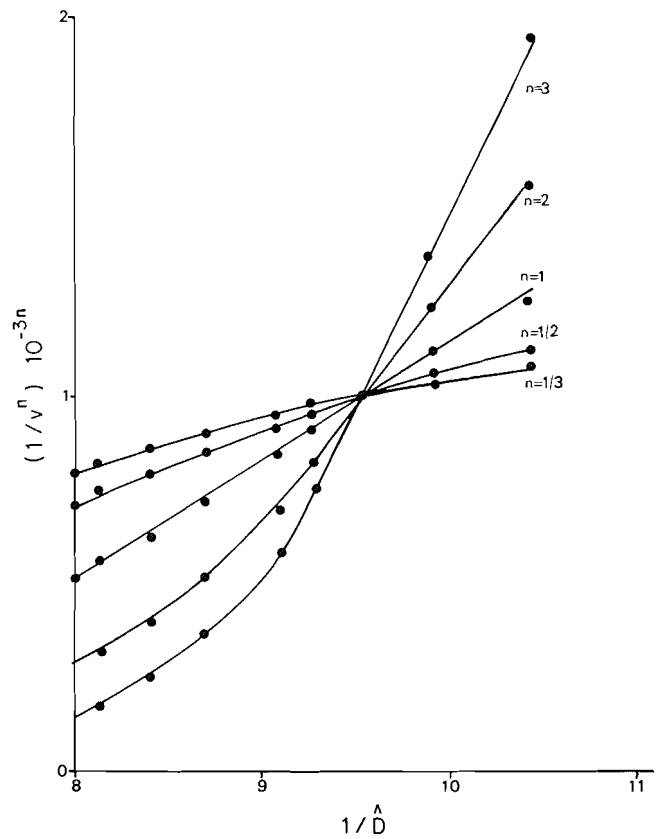

FIG. 2. Asmus "straight-line" method for $[Mo_2O_5(C_4H_4O_5)_2(OH_2)]^{4-}$.

determined mainly by the values of n. A straight line would be produced by the correct value of n irrespective of the value of m. Thus, the determination of m would require working with an excess of the reagent A.

However, it can be experimentally checked that this is not so. In agreement with our results, eq. [11] only leads to a straight line (through the entire interval of v considered) when $n = m = 2$, as expected if the approximations introduced hold. In spite of that, if we make $m = 1$, i.e. if we use an equation identical to that proposed by Asmus, the curves in Fig. 2 result. From these, it seems clear that a stoichiometry $m = n = 1$ might be erroneously deduced. This fact is an example of the statement made above: whereas the stoichiometric ratio of the complex can be inferred accurately from eq. [11], it does not seem equally obvious to distinguish its degree of condensation by visual examination of the graphs.

Conclusion

The modification of the straight-line method proposed here can be advantageously used in order to determine unambiguously the actual stoichiometric coefficients and the conditional stability constant of weak complexes in solution irrespective of their mono or polynuclear character.

A single experiment is required. When only one complex is formed, this experiment might be performed regardless of which reagent is in excess. If the composition of the prevailing species depends on the relation between concentrations of the reactants, this procedure could allow us to establish the stoichiometry of both species.

As it has been shown in Fig. 1, plotting *simultaneously* the curves[4] resulting from eq. [7] for different degrees of condensation (δ values) and stoichiometric ratios (n values), the possibility of getting an erroneous result is greatly lessened.

Experimental

The rotatory power of the samples has been measured with a Perkin–Elmer 141 digital reading photoelectric polarimeter. The precision of the measurements is ± 0.002 degrees.

The cell is thermostatically set at 30 ± 0.05°C and has a length of 10 ± 0.002 cm. The measurements can be taken at five different wavelengths (589, 578, 564, 436, and 365 nm). The results obtained for each one of these are comparable in all cases.

[4]The theoretical shapes of the curves obtained for wrong δ or n values may be predicted by working out the two first derivatives of eq. [7]. Although the procedure becomes tedious, it provides us a direct way to check the validity of our findings. Curves in Fig. 1 are as predicted.

Photolysis of polychlorinated benzenes in cyclohexane solution

NIGEL J. BUNCE,[1] PATRICK J. HAYES, AND MARY E. LEMKE
Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received October 15, 1982

NIGEL J. BUNCE, PATRICK J. HAYES, and MARY E. LEMKE. Can. J. Chem. **61**, 1103 (1983).

Quantum yields of dechlorination and of intersystem crossing have been measured in cyclohexane for a series of chlorinated benzenes. The results are compatible with the reactions occurring predominantly from the triplet excited state. The quantum yield of reaction shows a concentration dependence on [ArCl], but the dependence is less for the more heavily chlorinated members of the series.

NIGEL J. BUNCE, PATRICK J. HAYES et MARY E. LEMKE. Can. J. Chem. **61**, 1103 (1983).

On a mesuré dans le cyclohexane, les moments quantiques de déchloration et de croisement intersystème de divers benzènes chlorés. Les résultats sont compatibles avec les réactions qui ont lieu de façon prédominante à partir de l'état excité triplet. Le rendement quantique de la réaction montre une influence de [ArCl] sur la concentration, mais l'influence est moindre dans le cas des composés de la série la plus fortement chlorée.

[Traduit par le journal]

We recently reported a study of the photodehalogenation of chlorobenzene in cyclohexane solution (1). For this compound the identity of the reactive excited state is difficult to determine. Energetic considerations would seem to suggest that the triplet state is not reactive, unless it is postulated that the vibrational energy content of the molecule becomes available for bond cleavage. Conventional sensitization studies are ruled out for this system because of the lack of suitably high energy sensitizers. Quenching experiments were not completely conclusive; simple alkenes failed to quench the reaction as would have been expected for a triplet state process (cf. ref. 2). However, xenon did accelerate decomposition slightly (cf. ref. 3), and the effect of oxygen was greater for reaction quenching than for fluorescence quenching. On balance, therefore, it was concluded that the triplet is the predominant reactive state for chlorobenzene.

The uncertainties in the above arguments prompted us to extend our studies to other members of the chlorobenzene family. The strategy was to obtain quantum yields of both dechlorination (ϕ_r) and intersystem crossing, in the hope that a photon balance would allow us to draw conclusions about the identity of the reactive excited state. The problem was complicated somewhat by the fact that we had previously found (1, 4) that ϕ_r for chlorobenzene is concentration dependent, with the photoefficiency greater at lower concentrations. This effect was ascribed to the intervention of an unreactive excimer of chlorobenzene.

Photodechlorination of chlorobenzene derivatives has received considerable attention because of the importance of a number of these compounds as environmental pollutants (5). The present work is mainly oriented mechanistically rather than environmentally, and the photolyses have been carried out at 254 nm.

Experimental

Chlorinated benzenes were reagent grade materials; their purities were checked by glc, and they were purified where necessary. Biacetyl was freshly distilled before use and was kept in the dark. Spectral grade cyclohexane was used throughout as the solvent.

The intersystem crossing quantum yields were determined as described previously (1) with solutions that were degassed in the dark at pressures $\leq 10^{-3}$ Torr using the freeze–pump–thaw method. Solutions for dechlorination were similarly degassed at 10^{-2} Torr. The concentration dependence of ϕ_r was determined as follows. Solutions in which all the light was absorbed were prepared at different concentrations in the range 0.01 to 0.06 *M* and their relative quantum yields were determined using the relationship $\phi_r = M_0 \ln (M_0/M)/$(einsteins absorbed), where M_0 is the initial concentration of the chlorobenzene, and *M* its concentration after photolysis (6). Then $\phi_r/\phi'_r = (M_0 \ln (M_0/M))/(M'_0 \ln (M'_0/M'))$ when several solutions are irradiated simultaneously using a "merry-go-round". To convert these relative values to an absolute scale, ϕ_r was determined by azoxybenzene actinometry at [ArCl] = 0.02 *M*. The azoxybenzene actinometer has $\phi = 0.017$ at 254 nm.[2] The methodology for correcting for the light that was not absorbed by ArCl was decribed previously for chlorobiphenyls (7).

The results of these studies are given in Table 1. Uncertainties on the ϕ_{ISC} data are ±20%, those on the ϕ_r's are ±10%. Experimental information about the analyses is given in Table 2.[3] The expected dechlorination products were formed, but were not analysed quantitatively.

Discussion

The following points emerge from an examination of Table 1.

1. Among isomers, higher quantum yields of reaction are seen when *ortho* chlorines are present. Probably this is a steric effect (cf. refs. 1 and 7). Quite wide variations are observed when different values of ϕ_r are available for comparison. Not only solvent changes, but also differences in the concentrations of the solutions photolysed probably explain most of these differences, especially in those cases, such as *p*-dichlorobenzene and 1,3,5-trichlorobenzene, where the concentration dependence of ϕ_r is particularly strong.

2. If the assumption is made that the whole series behaves similarly mechanistically, the results are incompatible with exclusively singlet reactivity. Thus, the triplet has to be involved in the case of 1,2,3-trichlorobenzene ($\phi_{ISC} = 0.7$

[g]According to ref. 12, ϕ_r are in the order 1,2,4- > 1,2,3- ~ 1,3,5-Cl_3.

± 0.3, ϕ_r = 1.0) and in the case of 1,2,4,5-tetrachlorobenzene (ϕ_{ISC} = 1.0 ± 0.1). The only case where singlet reactivity would seem to be implicated definitely is that of *ortho*-dichlorobenzene (ϕ_{ISC} = 0.4 ± 0.1, $\phi_r \rightarrow$ 0.78). *o*-Dichlorobenzene is one of the two cases, together with hexachlorobenzene, where ϕ_{ISC} is unusually low; both values were rechecked, with the same result. However, the biacetyl quenching method is not easy to carry out; we found that many ampoules had to be discarded because they did not give the expected phosphorescence spectrum, either inexplicably, or because of the presence of traces of oxygen. Fortunately, this latter situation causes very clear-cut changes in the spectrum (a tailing at short wavelength). Thus the most economical explanation of the results is that most of the members of the series react predominantly from the triplet state.

Duality of mechanism, i.e. singlet and triplet reactivity, in the photodechlorination of aryl halides has been proposed previously. In the case of chlorobenzene, Augustyniak (13) has studied the direct and acetone sensitized photolyses. Despite an initial uncertainty as to what state was being sensitized by acetone, the current view is that triplet acetone acts as a triplet sensitizer although the rate constant is well below that for diffusion. Thus dechlorination can occur from the triplet state, in agreement with the present interpretation. Soumillion and De Wolf (14) likewise conclude that the dechlorination of chlorobenzene in methanol involves both states. They studied the competition between dechlorination and nucleophilic replacement of chlorine by CN^-, and found that acetone sensitization caused relatively more nucleophilic substitution. Consequently, both S_1 and T_1 must dechlorinate.

Both mechanisms also operate in the photodechlorination of 1,2,4-trichlorobenzene in methanol (11, 12). The direct and acetone-sensitized reactions give different proportions of *m*- and *p*-dichlorobenzene. The *m*-isomer arises predominantly from the triplet and most of the *p*-isomer comes from singlet excited trichlorobenzene.

3. The concentration dependence of ϕ_r drops off as the number of chlorine substituents increases, and is essentially lost for tetra-, penta-, and hexachlorobenzenes. Previously, we have explained this concentration dependence in terms of an unreactive excimer (4). The present results, if interpreted in the same way, suggest that excimer formation becomes less important with increasing chlorination. We cannot tell whether this is because of decreased excimer stability or perhaps because of an increased rate of intersystem crossing in more highly chlorinated benzenes. Among isomers, the concentration dependence is greater in the order *p* > *m* > *o* for dichlorobenzenes, and 1,3,5 > 1,2,4 for trichlorobenzenes. Perhaps this points to a steric factor affecting excimer stability, but we have no further information on this point.

Centro di studio sulla chimica e la struttura dei composti eterociclici e loro applicazioni, C.N.R., Istituto di Chimica organica, Universita de Firenze, 50121 Firenze, Italie

Reçu le 7 juillet 1982

Y. Y. C. Yeung Lam Ko, Robert Carrié, Francesco De Sarlo et Alberto Brandi. Can. J. Chem. **61**,1105 (1983).

Les ylures de nitriles **2** résultant de l'ouverture photochimique des azirines **1** s'additionnent aux diazaphospholes **3** et au diazaarsole **4** pour donner les adduits **6** et **7**. Le site d'addition et son orientation sont établis à l'aide de la rmn ^{1}H, ^{31}P et ^{13}C. La stéréochimie des adduits est discutée. Le triazole **5** ne réagit pas avec les ylures de nitrile **2**.

Y. Y. C. Yeung Lam Ko, Robert Carrié, Francesco De Sarlo, and Alberto Brandi. Can. J. Chem. **61**,1105 (1983).

Nitrile ylides **2** obtained by the photochemical ring-opening of azirines **1** react with diazaphospholes **3** and diazaarsole **4** yielding adducts **6** and **7**. The regiospecificity of the addition is established by nmr spectroscopy (^{1}H, ^{31}P, and ^{13}C). The stereochemistry of the adducts is discussed. The triazole **5** does not react with nitrile ylides **2**.

La chimie des composés du phosphore dicoordiné fait l'objet d'un intérêt croissant (1–3). Cependant la réaction des dipôles-1,3 avec la double liaison C=P a donné lieu à très peu de travaux. Deux études relativement ponctuelles ont été consacrées à l'addition de diazocomposés (4, 5) et récemment la cycloaddition de nitriles imines a été signalée (6). Par ailleurs, la réactivité de nitrones vis à vis de composés dicoordinés de l'arsenic a été aussi décrite (7).

Dans deux publications récentes nous avons étudié le comportement comparé des doubles liaisons N=C, P=C et As=C vis à vis des oxydes de nitriles (8, 9). L'objet du présent mémoire est de préciser la réactivité de diazaphospholes, d'un diazaarsole et du triazole correspondant avec les ylures de nitrile résultant de la photolyse d'azirine.

Resultats

Il est connu que l'ouverture photochimique des azirines **1** conduit d'une manière irréversible aux ylures de nitrile **2** qui ont été engagés dans de nombreuses cycloadditions (10).

Ces ylures de nitrile **2** s'additionnent sur la double liaison C=P et C=As des diazaphospholes **3** et du diazaarsole **4**. Les cycloadduits primaires **6** et **7** (schéma 1) sont isolés. Le triazole **5** ne réagit pas.

Les cycloadduits sont obtenus après irradiation d'une solu-

SCHÉMA 2

tion benzénique du composé **3** ou **4** et d'une azirine **1** dans un récipient en quartz (lampe Hanau HQ 80 ou Philips HPK 125 W). La chaleur dégagée par la lampe maintient la solution à l'ébullition. L'ylure de nitrile **2***a* dérivé de la phénylazirine **1***a* ($R^1 \neq R^2$) conduit avec les diazaphospholes **3** aux deux diastéréoisomères **6′***a* et **6″***a* (schéma 2) qui ont été complètement ou partiellement séparés.

Les points importants suivants doivent être soulignés.

(a) L'irradiation prolongée des composés **3***d*, **3***f* et **4** n'entraîne pas une dégradation sensible des dipolarophiles dans le benzène bouillant. Le composé **3***e* est plus sensible, il est complètement transformé après 18 h d'irradiation dans les mêmes conditions; cet inconvénient se trouve partiellement compensé par la réactivité plus grande de **3***e* (comparée à celle des autres dipolarophiles) vis à vis des ylures de nitrile.

(b) Les azirines donnent divers produits d'évolution lorsqu'elles sont irradiées (10*d*, 11). La formation de ces composés est d'autant plus importante que le dipolarophile est moins réactif et dépend de la nature de l'azirine (**1***b* est particulièrement sensible).

(c) Les adduits se dégradent d'une manière sensible sous l'influence du rayonnement ultra-violet. Ils ne sont pas thermiquement très stables et évoluent lentement à la température ambiante d'autant plus vite qu'ils sont moins purs.

Pour ces raisons, lors des réactions de cycloadditions, la proportion relative de l'azirine et du dipolarophile d'une part, la durée de la réaction d'autre part sont modulées en fonction de la stabilité des réactifs, de celle des produits formés et des difficultés rencontrées pour séparer l'adduit du mélange réactionnel. Les conditions opératoires et les résultats obtenus sont précisés dans la partie expérimentale. Les rendements sont en général faibles et la purification des adduits particulièrement difficile dans la plupart des cas.

Spectres de résonance magnétique nucléaire et structure des produits obtenus

Les principales caractéristiques de rmn ^1H et ^{31}P d'une part, ^{13}C d'autre part, figurent respectivement dans les tableaux 1 et 2. Les atomes d'hydrogène et de carbone sont référenciés comme il est indiqué dans le schéma 1.

(a) L'addition s'est effectuée sur la double liaision C=P ou C=As et non sur C=N. En effet, le phosphore des adduits **6** est considérablement blindé (δ ^{31}P 225 à 231, 4 pour les composés **3**), et la même observation est faite en ce qui concerne H_k et C_k (**3** et **4**: δ_{H_k} = 7,25 à 8,62, δ_{C_k} = 135,5 à 154,5). Les déplacements chimiques de H_i et C_j varient peu après la cycloaddition.

(b) Les observations suivantes permettent d'établir la structure des composés **6** et d'éliminer le sens inverse d'addition qui conduirait aux composés **8** (schéma 3). Le couplage entre $R^1 = R^2 = H$ et le phosphore (J = 2 à 7 Hz) est incompatible avec la structure **8**, le couplage $^2J_{PH_k}$ étant de l'ordre de 33 à 35 Hz; et le couplage entre le phosphore et le carbone 1 (J = 51 à 57 Hz) est en accord avec $^1J_{PC}$ et non avec $^2J_{PC}$. Nous avons trouvé des constantes du même ordre de grandeur lors de l'étude des composés **9** résultant de l'addition d'oxydes de nitrile à des diazaphospholes ($^1J_{PC_1}$ = 53 à 63 Hz) (8, 9).

La structure des composés **7** est attribuée par analogie avec les dérivés phosphorés **6** (déplacements chimiques, rmn ^1H et ^{13}C).

(c) La rmn donne également des renseignements intéressants quant à la stéréochimie des cycloadduits: la valeur élevée de $^2J_{PH_k}$ (32 à 36 Hz) indique que H_k est en *cis* de la paire libre du phosphore ($^2J_{PH_k}$ des composés **9** est nettement plus élevé: 44,2 à 50,0 Hz) (12). De plus il est possible de discuter la stéréochimie (schéma 4) des adduits phosphorés diastéréoisomères **6′***a* et **6″***a* obtenus à partir de l'azirine **1***a*.

Le méthyle i des composés **6′***a* est très blindé comparativement à ceux de **6″***a* (différence de déplacement chimique supérieure à 1 ppm); il est dans le cône de blindage du phényle substituant le carbone m. De ce fait, les hydrogènes k et m de **6′***a* sont en *cis* ($^3J_{H_kH_m}$ = 5 à 6,1 Hz). Ces deux hydrogènes sont en *trans* en ce qui concerne **6″***a*, la constante $^3J_{H_kH_m}$ est alors pratiquement nulle. La géométrie proposée est donc qualitativement en accord avec la relation de Karplus. On retrouve des résultats comparables avec les composés **6***b* ($R^1 = R^2 = H$) pour lesquels l'un des hydrogènes lié au carbone m est en *cis* de H_k et l'autre nécessairement en *trans*.

Un point intéressant doit être souligné. Lorsque H_m est en *trans* de la paire libre du phosphore, la constante de couplage $^3J_{PH_m}$ est de l'ordre de 6 à 7 Hz. Elle est nettement plus petite (0 à 2,5 Hz) si H_m est en *cis* de cette paire libre. Comme nous l'avons mentionné précédemment l'inverse est observé avec les constantes $^2J_{PH}$ des composés **6**.

Remarque

La spectrométrie de masse n'apporte pas de renseignements intéressants sur la structure (et donc l'orientation de l'addition du dipôle 1,3). La cycloréversion attendue est observée, l'ion moléculaire de l'azirine étant le pic de base dans la plupart des cas. On note également la fragmentation de l'ion moléculaire avec perte de benzonitrile (confirmée dans certains cas par l'étude de spectres MIKE).

Partie expérimentale

Les points de fusion sont pris au banc Kofler. Les spectromètres de rmn suivants sont utilisés: JEOL MH 100 (^1H, 100 MHz) et Bruker WP 80 DS (^1H: 80 MHz; ^{13}C: 20,115 MHz; ^{31}P: 32,38 MHz). Les spectres de masse sont enregistrés sur l'appareil Varian MAT 311 (géométrie Nier Johnson inversée) du Centre de Mesures Physiques de Rennes:[2] énergie des électrons 70 eV, intensité du faisceau électronique 300 μA, tension d'accélération des ions 3000 V, la température de la source T_s et celle de la sonde d'introduction directe T_i est précisée dans chaque cas, la détermination de la masse des ions moléculaires est effectuée à l'aide de la technique dite par "Peak Matching". Les spectres MIKE sont enregistrés sur le même appareil par balayage du champ électrique. Les analyses élémentaires ont été effectuées par le Service Central de Microanalyse du CNRS.

Préparation des azirines 1

Les azirines **1***a* et **1***b* d'une part, **1***c* d'autre part, sont préparées selon les méthodes décrites respectivement par Hassner et collaborateurs (13) et par Sato (14).

Ces méthodes ont été légèrement améliorées par Perrocheau (15).

[2]Les auteurs remercient P. Guenot pour l'enregistrement des spectres et ses remarques constructives.

[h] L'attribution de ces signaux n'est pas certain (C_j ou C_o).

Préparation des dipolarophiles

Les composés **3***a* et **3***c* sont préparés à l'aide de la méthode de Weinmaier *et al.* (16), **3***b* selon la réf. 17.

Le diazaarsole **4** est obtenu suivant la procédure de Märkl et Martin (18) modifiée (9). Le triazole **5** est préparé selon Henseke et Müller (19, 9).

Mode opératoire général utilisé pour les cycloadditions

Toutes les réactions sont réalisés sous gaz inerte (azote ou argon) et un solvant soigneusement séché. Après 15 minutes de dégazage une solution benzénique contenant $3,2 \times 10^2$ mol par litre des composés **3** ou **4** et 0,9 à 1,1 équivalents d'azirine **1** est irradiée. La lampe (Hanau HQ 80 (80 W) ou Philips HPK (125 W)) est placée dans un

plongeur en quartz. La chaleur dégagée maintient le benzène à reflux. Après irradiation, le benzène est distillé et les cycloadduits isolés par cristallisation, cristallisation fractionnée ou chromatographie sur colonne.

La purification par recristallisation des adduits solides a échoué dans de nombreux cas en raison de l'instabilité de ces composés.

Les résultats sont donnés dans le tableau 3.

Réactions de l'azirine **1**a *avec les composés* **3**

(a) Diazaphosphole **3**d

La réaction est effectuée avec 1,00 g de **3***d* et 1,00 g de **1***a* dissous dans 175 cm^3 de benzène. Après distillation de ce dernier, l'addition d'éthanol à 95°C provoque la cristallisation de l'adduit impur (0,31 g). Il est essoré, dissous dans le dichlorométhane et la solution filtrée sur silice (Merck 60). La distillation sous vide du solvant donne 0,26 g de **6'***ad* pur (F = 141−143°C; Rdt = 12%). *Anal.* calc. pour $C_{23}H_{20}N_3P$: C 74,80 H, 5,42, N 11,38; trouvée: C 74,9, H 5,6, N 11,3%. Spectre de masse (T_i = 110°C; T_s = 140°C); masse moléculaire calculée: 369,139; trouvée: 369,138; *m/z* (intensité relative %): 369 (2,1); 193 (100,0; $\mathbf{1}a^{]+}$); 192 (6,5); 176 (14,1; $\mathbf{3}d^{]+}$); 165 (9,5); 122 (8,1); 91 (7,7); 90 (18,8); 89 (11,4); 77 (11,8); 51 (5,0).

Lorsque le produit brut de la réaction est directement chromatographié sur une colonne de silice (Merck 60) en utilisant le dichlorométhane comme éluant, l'une des fractions d'élution (60 à 90 cm^3 de CH_2Cl_2) donne 0,19 g de cycloadduit **6"***ad* impur qui est purifié (contrôle rmn) après lavage avec 2 cm^3 de méthanol. On obtient 0,10 g de **6"** *ad* pur (F = 155−157°C; Rdt = 5%).

(b) Diazaphosphole **3**e

L'irradiation d'une solution benzénique (220 cm^3) de diazaphosphole (1,00 g) et d'azirine **1***a* (1,22 g) est effectuée. Après élimination du benzène, l'addition de méthanol anhydre permet d'obtenir 3 jets successifs qui sont des mélanges dans des proportions différentes des diastéréoisomères **6'***ae* et **6"***ae*. Le 1er jet (0,21 g) dissous dans CH_2Cl_2 donne après filtration sur silice (Merck 60) 0,15 g du mélange **6'***ae*/**6"***ae* = 30:70 (F = 172−173°C). Le 2ème jet fond à 139−142°C (**6'***ae*/**6"***ae* = 85:15). Le 3ème jet est un mélange 50:50 des deux diastéréoisomères (F = 129−130°C). Le rendement global du mélange d'isomères est de 17%. Il n'a pas été possible de séparer **6'***ae* et **6"***ae* caractérisés à l'aide de la rmn ^1H et ^{13}C. Spectre de masse (mélange d'isomères F = 172−173°C; T_i = 105°C; T_s = 130°C; l'ion moléculaire n'est pas mis en évidence), *m/z* (intensité relative %): 232 (1,2; M − $PhCN^{]+}$); 193 (100,0; $\mathbf{1}a^{]+}$); 192 (7,4); 191 (2,7); 190 (4,9); 189 (10,1); 165 (8,8); 147 (2,5); 144 (3,0); 103 (4,3); 100 (5,1); 90 (14,6); 89 (12,4); 77 (4,0).

(c) Diazaphosphole **3**f

On irradie une solution de 0,90 g de **3***f* et de 1,00 g de **1***a* dans 250 cm^3 de benzène. Le produit brut de la réaction est chromatographié sur une colonne de silice (Florisil) en éluant successivement par l'éther de pétrole et des mélanges d'éther et d'éther de pétrole 30:70 et 40:60.

On elue 0,20 g de **6"***af* huileux pour (rmn) avec le mélange 40:60; 0,29 g d'huile sont obtenus après élution avec le mélange 30:70; l'addition de 1 à 2 cm^3 d'éther fait cristalliser le cycloadduit **6'***af* (0,09 g; Rdt = 4%; F = 130−131°C). Les adduits évoluent relativement rapidement à la température ambiante.

Composé **6"***af*

Spectre de masse (T_i = 70°C; T_s = 140°C), masse moléculaire calculée pour $C_{18}H_{18}N_3P$: 307,124; trouvée: 307,122; *m/z* (intensité relative %): 307 (1,3); 204 (1,1; M − $PhCN^{]+}$); 203 (4,1); 193 (100,0; $\mathbf{1}a^{]+}$); 192 (7,0); 166 (3,4); 165 (9,3); 127 (2,9); 114 (6,2; $\mathbf{3}f^{]+}$); 113 (3,0); 104 (2,3); 103 (2,9); 90 (14,3); 89 (12,9); 77 (3,7); 60 (8,0).

Réactions de l'azirine **1**b *avec les composés* **3** et **4**

(a) Diazaphosphole **3**d

Solution irradiée: 1,00 g de **3***d* et 0,73 g **1***b* dans 80 cm^3 de benzène. Le benzène distillé sous vide, le résidue cristallise. Après lavage au benzène froid 0,35 g du cycloadduit **6***bd* pur (rmn) est isolé (F = 160−162°C; Rdt = 21%). Le composé peut être recristallisé dans le méthanol. *Anal.* calc. pour $C_{17}H_{16}N_3P$: C 69,62, H 5,46, N 14,33; trouvée: C 69,7, H 5,5, N 14,1%. Spectre de masse (T_i = 85°C; T_s = 140°C), masse moléculaire calculée: 293,108; trouvée: 293,108; *m/z* (intensité relative %): 293 (16,0); 190 (21,0); M − $PhCN^{]+}$); 189 (10,6); 176 (4,0); 122 (21,0); 117 (100,0; $\mathbf{1}b^{]+}$); 103 (4,2); 90 (5,6); 78 (8,5); 77 (27,8) 51 (7,7).

(b) Diazaphosphole **3**e

On irradie une solution de 1,15 g de **3***e* et de 0,85 g de **1***b* dans 250 cm^3. Après élimination du solvant, on ajoute 10 cm^3 du mélange éther − éther de pétrole (50:50). Le produit solide est essoré est lavé avec 2 à 3 cm^3 de méthanol anhydre froid. On obtient ainsi 0,31 g de cycloadduit **6***be* relativement pur. Le filtrat après élimination du solvant est chromatographié sur une colonne de silice Merck 60 en éluant successivement avec des mélanges éther − éther de pétrole (40:60 et 60:40) puis avec de l'éther pur; 0,07 g d'adduit pratiquement pur sont récupérés de l'éluant éthéré.

La totalité du produit obtenu (0,38 g) est recristallisée dans 50 cm^3 d'un mélange éther − éther de pétrole à −20°C. On isole ainsi 0,24 g de **6***be* pur (F = 127−128°C; Rdt = 11%). Ce composé évolue lentement à la température ambiante. Spectre de masse (T_i = 55°C; T_s = 120°C, masse moléculaire pour $C_{13}H_{14}N_3OP$: 259,087; trouvée; 259,089; *m/z* (intensité relative %): 259 (10,3); 232 (10,3); 156 (21,7; M − $PhCN^{]+}$); 118 (10,3); 117 (100,0; $\mathbf{1}b^{]+}$); 115 (7,8); 114 (39,5); 103 (6,0); 102 (8,0); 90 (7,6); 77 (15,9); 73 (8,4).

(c) Diazaphosphole **3**f

Solution irradiée: 0,90 g de **3***f* et 0,85 g de **1***b* dans 250 cm^3 de benzène. Après élimination du solvant, on obtient 1,60 g d'une huile rouge qui est chromatographiée sur une colonne de silice (Merck 60) avec l'éther comme éluant. On isole 0,33 g (Rdt = 18%) de l'adduit **6***bf* pur (rmn). Le composé est une huile qu'il n'a pas été possible de faire cristalliser. Spectre de masse (T_i = 75°C; T_s = 150°C), masse moléculaire calculée pour $C_{12}H_{14}N_3P$: 231,092; trouvée 231,092; *m/z* (intensité relative %): 231 (12,9); 172 (5,9); 171 (3,3); 128 (38,7; M − $PhCN^{]+}$); 127 (21,3); 117 (100,0; $\mathbf{1}b^{]+}$); 116 (3,7); 114 (7,1); 113 (8,0); 105 (2,8); 104 (3,2); 103 (5,1); 101 (2,7); 99 (2,4); 91 (3,7); 90 (7,1); 89 (5,9); 87 (5,9); 86 (4,3); 77 (20,0); 76 (3,1); 60 (24,0).

[a] Nombre d'équivalents d'azirine engagée par rapport au phosphole.
[b] C: cycloadduit, A: azirine, D: dipolarophile, rapports déterminés par analyse rmn du produit brut de la réaction.
[c] Rendement en produit pur (rmn) calculé par rapport au dipolarophile engagé.
[d] Mélange **6′***ae*/**6″***ae* = 85:15.
[e] Mélange **6′***ae*/**6″***ae* = 30:70.

L'examen du spectre MIKE montre que les ions m/z = 128 et 117 proviennent de la fragmentation directe de l'ion moléculaire (m/z = 231).

Diazaarsole **4**

Solution irradiée: 1,75 g de **4** et 0,85 g de **1***b* dans 250 cm³ de benzène. Après distillation du benzène sous vide, le résidu solide est lavé avec 50 cm³ d'éther. On isole 1,50 g de produit cristallisé dans le mélange chloroforme−éther à −20°C; 1,15 g de **7***b* (F = 175−177°C; cristaux jaunes; Rdt = 43%) sont obtenus. *Anal.* calc. pour $C_{17}H_{16}N_3As$: C 60,54, H 4,75, N 12,46; trouvée C 60,6, H 4,8, N 12,4%. Spectre de masse (T_i = 65°C; T_s = 130°C), masse moléculaire calculée: 337,056; trouvée: 337,056; m/z (intensité relative %): 337 (53,6); 234 (100,0; M − $PhCN^{\cdot+}$); 233 (41,1); 220 (10,0; $\mathbf{4}^{\cdot+}$); 219 (5,2); 193 (6,8); 192 (19,6); 168,5 (2,3; M^{2+}); 167 (4,6); 166 (51,8); 159 (13,4); 152 (3,0); 151 (2,9); 145 (4,6); 144 (2,1); 139 (4,6); 138 (2,3); 129 (4,6); 127 (2,5); 118 (14,1); 117 (96,4); $\mathbf{1}b^{\cdot+}$); 116 (6,2); 115 (2,9); 105 (8,2); 104 (6,8); 103 (9,1); 102 (2,3); 101 (3,4); 91 (7,0); 90 (10,2); 89 (6,8); 78 (6,8); 77 (97,1); 76 (4,6); 65 (3,2); 64 (2,9); 63 (2,7); 51 (10,2).

L'examen du spectre MIKE montre que l'ion m/z = 234 provient de la fragmentation directe de l'ion moléculaire m/z = 337.

Réactions de l'azirine **1**c *avec les composés* **3** *et* **4**

(a) Diazaphosphole **3**d

Solution irradiée: 1,00 g de phosphole et 0,90 g de **1***c* dans 80 cm³ de benzène. Après élimination du solvant le résidu cristallise lentement et partiellement. Le produit solide est essoré et lavé avec très peu de benzène. On obtient ainsi 0,19 g de l'adduit **6***cd*. Le filtrat est repris au benzène. La formation de gouttelettes huileuses non solubles est observée; la phase benzénique est décantée et le solvant distillé sous vide. Après addition de méthanol au résidu huileux ont obtient 0,13 g de **6***cd*. Rendement total 18%; F = 109−110°C. Le composé peut être recristallisé dans le méthanol. *Anal.* calc. pour $C_{19}H_{20}N_3P$: C 71,03, H 6,23, N 13,08; trouvée: C 70,8, H 6,2, N 13,0%. Spectre de masse (T_i = 75°C; T_s = 150°C), masse moléculaire calculée: 321,139; trouvée; 321,139; m/z (intensité relative %): 321 (6,0); 176 (8,9; $\mathbf{3}d^{\cdot+}$); 146 (12,7); 145 (100,0; $\mathbf{1}c^{\cdot+}$) 122 (8,2); 104 (38,5); 103 (7,3); 77 (12,7).

(b) Diazaphosphole **3**e

Solution irradiée: 0,90 g de **3***e* et 1,00 g de **1***c* dans 200 cm³ de benzène. Le résidu après distillation du benzène sous vide cristallise après addition de méthanol (0,40 g); un second jet (0,11 g) est obtenu après refroidissement de la solution méthanolique à −20°C. Rendement total 28%; F = 119−120°C. *Anal.* calc. pour $C_{15}H_{18}N_3OP$: C 62,72, H 6,27, N 14,63; trouvée: C 62,6, H 6,3; N 14,5%. Spectre de masse (T_i = 70°C; T_s = 125°C), masse moléculaire calculée: 287,119; trouvée: 287,117; m/z (intensité relative %): 287 (1,8); 184 (2,0; M − $PhCN^{\cdot+}$); 146 (14,3); 145 (100,0; $\mathbf{1}c^{\cdot+}$); 142 (2,0; $\mathbf{3}e^{\cdot+}$); 141 (15,2); 127 (10,5); 104 (49,5); 103 (10,0); 100 (7,4); 77 (7,7).

(c) Diazaphosphole **3**f

Solution irradiée 0,90 g de **3***f* et 1,00 g de **1***c* dans 250 cm³ de benzène. Le benzène est distillé sous vide et le résidu repris à l'éther. Un solide pateux insoluble (évoluant à l'air) est éliminé par filtration. Après refroidissement à −20°C de la solution éthérée on obtient 0,18 g de **6***cf* pur (rmn); F = 74−76°C; Rdt = 9%. Le produit évolue assez rapidement à la température ambiante. Spectre de masse (T_i = 30°C; T_s = 140°C) masse moléculaire calculée pour $C_{14}H_{18}N_3P$: 259,124; trouvée: 259,122; m/z (intensité relative %): 259 (3,8); 145 (100,0; $\mathbf{1}c^{\cdot+}$); 144 (6,2); 141 (10,6); 114 (8,2; $\mathbf{3}f^{\cdot+}$); 113 (3,0); 105 (5,6); 104 (4,7); 103 (9,5); 77 (7,1); 76 (2,4); 71 (2,6); 60 (8,0).

(d) Diazaarsole **4**

Solution irradiée: 1,00 g de **4** et 0,60 de **1***c* dans 150 cm³ de benzène. Après élimination du solvant, le résidu est chromatographié sur une colonne de silice (Merck 60) avec comme éluant un mélange éther − éther de pétrole (50:50). On obtient ainsi 0,25 g d'adduit **7***c* pur (rmn). Le composé est une huile rouge qu'il n'a pas été possible de cristalliser (Rdt = 15%). Spectre de masse (T_i = 65°C; T_s = 120°C), masse moléculaire calculée pour $C_{19}H_{20}N_3As$: 365,087; trouvée; 365,084; m/z (intensité relative %): 365 (5,1); 262 (2,6; M − $PhCN^{\cdot+}$); 247 (8,5); 220 (9,0; $\mathbf{4}^{\cdot+}$); 206 (2,4); 166 (8,0); 145 (100,0; $\mathbf{1}c^{\cdot+}$); 144 (6,0); 130 (2,0); 105 (4,9); 103 (8,5); 78 (12,0); 77 (12,4); 75 (3,1).

Le spectre MIKE montre que les ions m/z = 262 et 145 proviennent de la fragmentation directe de l'ion moléculaire m/z = 365.

The chemistry of thujone. VII.[1] Thujone as a chiral synthon for the preparation of sesquiterpenes. Synthesis of β-elemol

JAMES P. KUTNEY AND ASHOK K. SINGH

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received September 14, 1982

JAMES P. KUTNEY and ASHOK K. SINGH. Can. J. Chem. **61**, 1111 (1983).

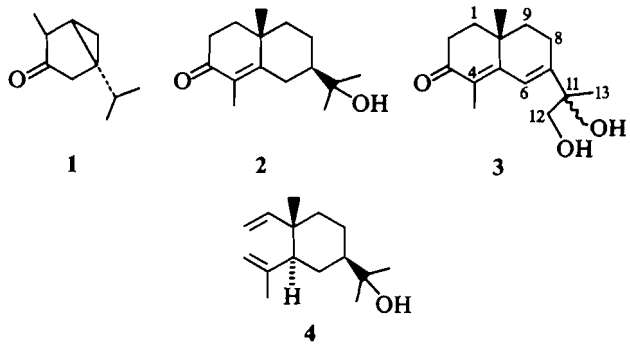
An efficient synthesis of β-elemol (**4**) from thujone (**1**) is described. The key intermediate **3** is readily prepared and described in previous studies within the synthesis of (+)-carissone (**2**).

JAMES P. KUTNEY et ASHOK K. SINGH. Can. J. Chem. **61**, 1111 (1983).

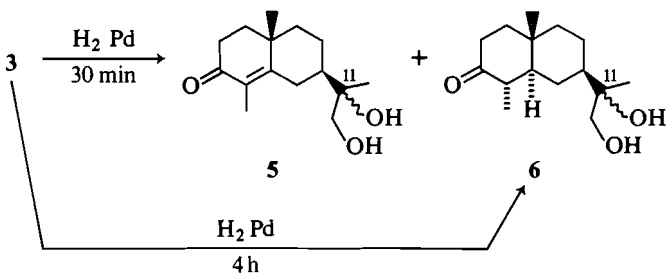
On décrit une synthèse efficace du β-élémol (**4**) à partir de la thujone. L'intermédiaire principal **3** se prépare facilement et il a été décrit antérieurement à la suite d'études sur la synthèse de la (+)-carissone (**2**).

[Traduit par le journal]

In previous studies from these laboratories, thujone (**1**)[2] has been shown to be a versatile synthon in the preparation of juvenoid (1, 2), pyrethroid (3), and steroidal (4) analogues as well as in the synthesis of the natural products (+)-β-cyperone (5) and (+)-carissone (**2**) (6). Here we wish to describe the synthesis of β-elemol (**4**) by elaboration of ring A in the intermediate **3** (mixture of C11 isomers) prepared earlier during our studies within the carissone synthesis (6).



Controlled hydrogenation of **3** (ethanol, KOH, Pd) for 30 min as described earlier (6) provides the partially reduced intermediates **5** (72% yield) as an inseparable mixture of C11 isomers, and the fully reduced diols **6** (C11 isomers) as minor components (24% yield). On the other hand, reduction of **3** for an extended period (4 h) affords **6** in quantitative yield. Again efforts to separate the C11 isomers of **6** proved fruitless but it was found very convenient to utilize this mixture directly in the synthesis of β-elemol as described below.

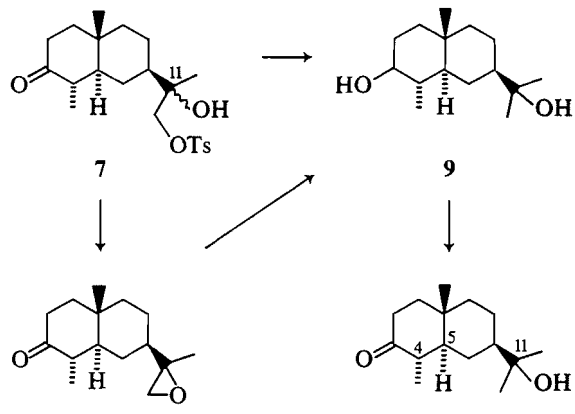


[1]For part VI, see ref. 4.

[2]Thujone is the major component (ca. 80%) of the steam distillate from the slash (waste) of Western red cedar.

Treatment of **6** with *p*-toluenesulfonyl chloride in pyridine provided the mixture of tosylates **7**. The latter on chromatography employing basic alumina (grade III) afforded the epoxyketone **8** in high yield. Direct reduction of **7** or **8** yielded a crystalline diol **9**. The preparation of **9** was more convenient from the tosylate **7** and this was the route selected for all subsequent studies.

Oxidation of **9** with chromium trioxide in pyridine afforded, in 92% yield, a crystalline product, mp 111−112°C, and with spectral characteristics identical with those published for (−)-*trans*-dihydrocarissone (**10**) (7).



It is indicated (7) that the reduction of **2** affords the *trans* product **6**. We have confirmed the stereochemistry at C4 and C5 by a detailed nmr study at 400 MHz and a brief discussion of these results is appropriate. The C4 methine proton appeared at δ 2.23 (1H, sextet, J = 6 and 12 Hz) while the C4 methyl group revealed a doublet at δ 1.01 (J = 6 Hz). These assignments were established from decoupling studies which showed that C4-H becomes a doublet (J = 12 Hz) upon irradiation at the C4-methyl group frequency while, in turn, the latter becomes a singlet when the C4-H is irradiated. The *trans* diaxial relationship between C4-H and C5-H is consistent with initial *cis* reduction of **2** from the α face of the molecule followed by base-catalyzed epimerization of the C4-methyl group to the more stable 4α-(equatorial) orientation.

Treatment of **10** with BF_3 and tosylhydrazine in benzene gave an inseparable mixture of the isomeric hydrazones (see

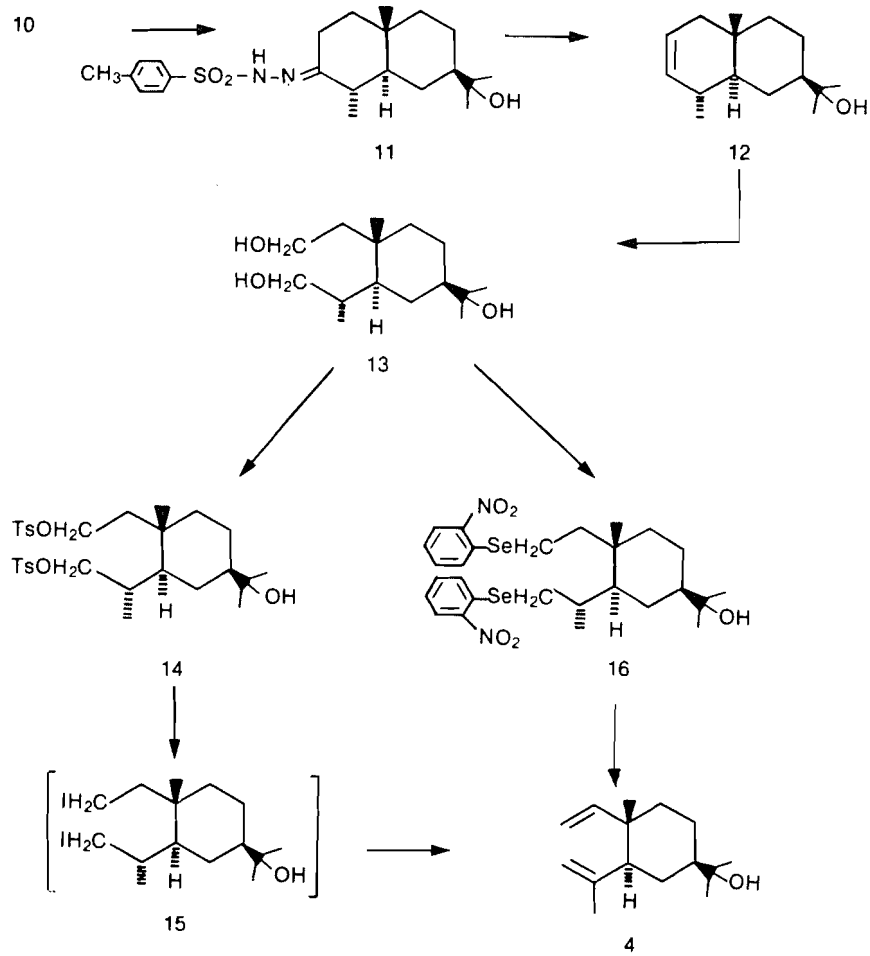

SCHEME 1

nmr data in Experimental) **11**, which was subjected directly to a modified Bamford–Stevens reaction (for a review of this reaction, see ref. 8) to provide the crystalline unsaturated alcohol **12** in 76% yield (Scheme 1).

Ozonolysis of **12** followed by treatment of the reaction mixture with sodium borohydride afforded the crystalline triol **13**, mp 117–118°C ($[\alpha]_D$ −9.4°) in 77% yield. The latter compound has been previously reported (9) as a glass ($[\alpha]_D$ −10°) and obtained from elemol.

Elaboration of **13** to the desired natural product **4** was considered via two synthetic routes as shown in Scheme 1. The initial study involved the sequence, **13** → **14** → **15**. Formation of ditosylate **14**, in 86% yield, proceeded without difficulty but unfortunately the intended conversion to di-iodide **15** and the subsequent elimination to **4** proceeded only in poor yield (see Experimental). The alternative sequence, **13** → **16** → **4** involving selenium intermediates is much preferred and is discussed in more detail.

Elimination of *o*-nitrophenylselenides to olefins is known (10) to proceed in excellent yields and this route was therefore evaluated with the triol **13**. The bis-*o*-nitrophenylselenide derivative **16** isolated as a crystalline product, mp 42–44°C (84% yield), was treated with sodium metaperiodate in an alkaline medium at room temperature and afforded β-elemol (**4**) in 72% yield. All the spectral data of the synthetic product are in acord with those published for the natural compound.

The previously reported syntheses of β-elemol (11, 12) provide low overall yields and/or racemic material. The present study affords a convenient route to optically active β-elemol in an overall yield of 35% from (−)-*trans*-dihydrocarissone (**10**).

Experimental

Melting points were determined on a Reichert hot stage apparatus and are uncorrected. Ultraviolet spectra were recorded on a Cary 15 spectrophotometer in methanol solution. Infrared spectra were measured on a Perkin–Elmer 710 spectrophotometer using chloroform as solvent. The ^{1}Hmr spectra were recorded on Bruker WH-400, Bruker WP-80, Varian XL-100, or Nicolet–Oxford H-270 instruments. Deuteriochloroform was used as the solvent with TMS as internal standard. Low resolution mass spectra were determined on either an AEI-MS-902 or an Atlas CH-4B spectrometer. High resolution mass measurements were made on an AEI-MS-50 spectrometer. Optical rotations were recorded on a Perkin–Elmer 141 polarimeter using a cell with a path length of 10 cm. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia. Column chromatography utilized Merck silica gel 60 (70–230 mesh). Preparative and thin layer chromatography utilized Merck silica gel GF_{254}. Petroleum ether refers to the fraction with boiling range 30–60°C.

Ketodiols 6

A mixture of dienone **3** (400 mg), potassium hydroxide (80 mg), and 10% palladium charcoal (560 mg) in ethanol (80 mL) was hydrogenated at room temperature and atmospheric pressure. Hydrogen absorption ceased after 4 h. The mixture was filtered and the filtrate evaporated, water (10 mL) was added to the residue, extracted with methylene chloride, and dried ($MgSO_4$). Evaporation of solvent at reduced pressure left ketodiols **6** (393 mg, 97%) which were identical with previously reported samples (6).

Tosylates 7

p-Toluenesulfonyl chloride (279 mg) was added to a solution of the diols **6** (186 mg) in dry pyridine (4 mL). The mixture was stirred at ambient temperature for 44 h, then poured into water (10 mL) and extracted with methylene chloride (3 × 20 mL). The extracts were combined, dried ($MgSO_4$), and concentrated *in vacuo* to give a colourless solid. Recrystallization from ether – petroleum ether gave tosylates **7** (270 mg, 91%): mp 99–101°C; ir ν_{max}: 3563, 1706, 1460, 1385, 1180, 995 cm^{-1}; uv λ_{max}: 225 (ε 13 562), 257 (573), 262 (672), 267 (600), 273 (537), 285 (30) nm; ^{1}Hmr δ: 0.94, 0.97 (3H, d, J = 7 Hz, two sets), 1.05 (3H, s), 1.13, 1.15 (3H, s, two sets), 1.18–1.83 (10H, m), 1.88 (1H, bs, D_2O exchangeable), 2.19 (1H, m), 2.36 (1H, ddd, J = 12, 8, 2 Hz), 2.47 (3H, s), 2.53 (1H, dt, J = 12, 8 Hz), 3.91, 3.93 (1H, d, J = 10 Hz, two sets), 3.99, 4.00 (1H, d, J = 10 Hz, two sets), 7.36 (2H, d, J = 8 Hz), 8.00 (2H, d, J = 8 Hz); ms *m/e*: 408 (M^+), 393, 390, 378, 236, 223. High resolution molecular weight determination, calcd. for $C_{22}H_{32}O_5S$: 408.1970; found: 408.1985. *Anal.* calcd. for $C_{22}H_{32}O_5S$: C 64.70, H 7.84; found: C 64.74, H 8.00.

Epoxy ketone 8

Compound **7** (260 mg) was filtered through basic alumina activity III (25 g), using ether to elute the product. Evaporation of the solvent left epoxyketone **8** (146 mg, 97%) as a viscous oil; $[\alpha]_D$ −8.6° ($CHCl_3$, *c* 0.1635); ir ν_{max} (neat): 1706 cm^{-1}; uv λ_{max}: 280 (ε 34) nm; ^{1}Hmr δ: 1.00 (3H, d, J = 7 Hz), 1.09 (3H, s), 1.29 (3H, s), 1.40–1.80 (7H, m), 2.00–2.50 (4H, m), 2.53 (1H, d, J = 5 Hz), 2.62 (1H, d, J = 5 Hz); ms *m/e*: 236 (M^+), 221, 203, 189, 179. High resolution molecular weight determination, calcd. for $C_{15}H_{24}O_2$: 236.1776; found: 236.1777. *Anal.* calcd. for $C_{15}H_{24}O_2$: C 76.27, H 10.16; found: C 75.90, H 10.13.

Diol 9

A mixture of **7** (460 mg) and LAH (88 mg) in dry ether (50 mL) under an atmosphere of argon was refluxed for 5 h. Excess LAH was destroyed by careful addition of water. The mixture was extracted with ether (3 × 50 mL), the combined organic extracts were dried ($MgSO_4$) and evaporated to leave a colourless solid. Recrystallization from ether – petroleum ether afforded the diol **9** (258 mg, 95%); mp 138–139°C; ir ν_{max}: 3450, 1461, 1395 cm^{-1}; ^{1}Hmr δ: 0.84 (3H, s), 0.98 (3H, d, J = 7 Hz), 1.03–1.13 (2H, m), 1.19 (3H, s), 1.20 (3H, s), 1.23–1.63 (10H, m), 1.77–1.86 (2H, m), 3.13 (1H, m); ms *m/e*: 240 (M^+), 225, 222, 207. High resolution molecular weight determination, calcd. for $C_{15}H_{28}O_2$: 240.2089; found: 240.2088. *Anal.* calcd. for $C_{15}H_{28}O_2$: C 75.00, H 11.66; found: C 74.55, H 11.71.

A solution of **8** (654 mg) in dry ether (10 mL) under argon was added to a stirred suspension of LAH (162 mg) in ether (20 mL). The mixture was refluxed for 12 h. Work-up as described above afforded **9** (622 mg, 94%).

Hydroxyketone 10

To a magnetically stirred solution of chromium trioxide (300 mg) in pyridine (4 mL) was added a solution of diol **9** (87 mg) in pyridine (3 mL). After stirring for 3 h at room temperature, the mixture was diluted with water (15 mL) and extracted with benzene–ether (100 mL, 1:1 v/v). The extracts were dried and evaporated. Chromatography of the residue on silica gel (ether – petroleum ether, 1:1 v/v) gave hydroxyketone **10** (80 mg, 92%); mp 111–112°C (lit. (7) mp 109–110°C); $[\alpha]_D$ −11.8° ($CHCl_3$, *c* 0.153) (lit. (7) $[\alpha]_D$ −11.7° (*c* 2.0)); ir ν_{max}: 3463, 1702, 1460, 1390 cm^{-1}; uv λ_{max}: 282 (ε 28) nm; ^{1}Hmr δ: 1.01 (3H, d, J = 6 Hz), 1.08 (3H, s), 1.10–1.19 (3H, m), 1.21 (3H, s), 1.22 (3H, s), 1.31 (1H, dt, J = 12, 4 Hz), 1.37 (1H, m), 1.49 (1H, dt, J = 14, 6 Hz), 1.59–1.69 (3H, m, including 1.66 (1H, bs, D_2O exchangeable)), 1.74 (1H, ddd, J = 14, 6, 2 Hz), 1.82 (1H, dt, J = 12, 4 Hz), 2.23 (1H, sextet, J = 12, 6 Hz), 2.36 (1H, ddd, J = 14, 6, 2 Hz), 2.53 (1H, dt, J = 14, 6 Hz); ms *m/e*: 238 (M^+), 223, 220, 205, 180. High resolution molecular weight determination, calcd. for $C_{15}H_{26}O_2$: 238.1933; found: 238.1929. *Anal.* calcd. for $C_{15}H_{26}O_2$: C 75.63, H 10.92; found: C 75.62, H 11.01.

Hydrazones 11

A solution of hydroxyketone **10** (436 mg) in benzene (50 mL) together with *p*-toluenesulfonyl hydrazide (358 mg) and a drop of boron trifluoride etherate was stirred under argon at ambient temperature for 4 h. The reaction mixture was evaporated under reduced pressure, the residue diluted with water (10 mL) and extracted with THF–ether (100 mL, 1:4 v/v). The extracts were dried ($MgSO_4$) and evaporated to leave hydrazones **11** which was crystallized from ether – petroleum ether, yield (435 mg, 99%); mp 116–118°C; ir ν_{max}: 3550, 1610, 1460, 1390, 1340, 1270, 1110 cm^{-1}; uv λ_{max}: 226 (ε 14 135), 260 (2257), 273 (1129) nm; ^{1}Hmr δ: 0.90 (3H, s), 1.01, 1.02 (3H, d, J = 7 Hz, two sets), 1.19, 1.21 (3H, s, two sets), 1.20, 1.22 (3H, s, two sets), 1.25–1.70 (7H, m), 1.74 (1H, ddd, J = 14, 6, 2 Hz), 1.81 (1H, m), 1.97 (1H, dt, J = 14, 6 Hz), 2.08 (1H, m), 2.24 (1H, m), 2.35 (1H, ddd, J = 14, 6, 2 Hz), 2.44, 2.46 (3H, s, two sets), 2.53 (1H, m), 5.56 (1H, bs), 7.32, 7.37 (2H, d, J = 8 Hz, two sets), 7.81, 7.87 (2H, d, J = 8 Hz, two sets); ms *m/e*: 406 (M^+), 391, 251, 233, 204. High resolution molecular weight determination, calcd. for $C_{22}H_{34}N_2O_3S$: 406.2289; found: 406.2282. *Anal.* calcd. for $C_{22}H_{34}N_2O_3S$: C 65.02, H 8.37, N 6.89; found: C 65.57, H 8.89, N 6.34.

Hydroxy olefin 12

To a solution of hydrazone **11** (708 mg) in THF (25 mL) at 0°C under argon was added ethereal methyllithium (15 mL of a 1 *M* solution). The mixture was stirred 20 min at the same temperature. The cooling bath was removed and the mixture was stirred at room temperature for 3 h. The reaction was quenched by the addition of water (10 mL) and extracted with petroleum ether (3 × 50 mL). The combined extracts were dried and evaporated to furnish 375 mg crude product. Chromatography on 50 g silica gel (ether – petroleum ether, 1:4 v/v) gave hydroxy olefin **12** (294 mg, 76%) as a white solid; mp 47–48°C; $[\alpha]_D$ −35.5° ($CHCl_3$, *c* 0.945); ir ν_{max}: 3463, 1660, 1470, 1390 cm^{-1}; ^{1}Hmr δ: 0.80 (3H, s), 0.97 (3H, d, J = 7 Hz), 1.17 (3H, s), 1.18 (3H, s), 1.23–1.35 (4H, m), 1.50–1.90 (8H, m), 5.43 (1H, dd, J = 8, 2 Hz), 5.54 (1H, ddd, J = 10, 5, 2 Hz); ms *m/e*: 222 (M^+), 207, 204, 189, 164. High resolution molecular weight determination, calcd. for $C_{15}H_{26}O$: 222.1983; found: 222.1968. *Anal.* calcd. for $C_{15}H_{26}O$: C 81.08, H 11.71; found: C 81.34, H 11.62.

Triol 13

A stirred solution of **12** (268 mg) in methanol and methylene chloride (20 mL, 1:1 v/v) was cooled to −77°C and treated with 50 mL of a precooled (−77°C) saturated solution of ozone in methylene chloride. After 20 min sodium borohydride (100 mg) was added at −77°C. At 15 min intervals additional portions (3 × 100 mg) of $NaBH_4$ were added. The reaction mixture was warmed to room temperature and the solvent was removed *in vacuo*. The residue was diluted with water and the product isolated by ether extraction. After drying, the solvent was removed to give a viscous material. Chromatography on alumina (activity III, methanol–ether, 1:20 v/v) afforded the triol **13** (241 mg, 77%) as a coloured solid; mp 117–118°C; $[\alpha]_D$ −9.4° (MeOH, *c* 0.384) (lit. (9) $[\alpha]_D$ −10° (*c* 4.2)); ir ν_{max}: 3413, 1480, 1420, 1390 cm^{-1}; ^{1}Hmr δ: 0.78 (3H, d, J = 6 Hz), 0.88 (3H, s), 1.15 (3H, s), 1.17 (3H, s), 1.21–1.62 (10H, m), 1.71 (1H, m), 2.07 (1H, m), 2.66 (2H, bs, D_2O exchangeable), 3.33–3.40 (2H, m), 3.65 (1H, m), 3.80 (1H, m); ms *m/e*: 240 ($M^+ - H_2O$), 225, 222, 210, 207. High resolution molecular weight determination, calcd. for $C_{15}H_{30}O_3 - H_2O$: 240.2089; found: 240.2092. *Anal.* calcd. for $C_{15}H_{30}O_3$: C 69.76, H 11.62; found: C 70.08; H 11.70.

Ditosylate 14

To a solution of triol **13** (200 mg) in pyridine (10 mL) was added *p*-toluene sulfonylchloride (590 mg). The solution was stirred for 3 days at ambient temperature. Work-up as described in **7** gave crude material, which was purified by column chromatography on alumina

For personal use only.

activity III. Elution with methanol – petrolcum ether – ether (1:4:5) gave pure **14** as a viscous oil, yield 376 mg (86%); $[\alpha]_D$ −5.8° ($CHCl_3$, *c* 0.651); ir ν_{max} (neat): 3475, 1600, 1460, 1360 cm^{-1}; uv λ_{max}: 225 (ε 24 553), 257 (958), 262 (1197), 267 (1117), 273 (1046) nm; ^{1}Hmr δ: 0.77 (3H, d, *J* = 6 Hz), 0.82 (3H, s), 1.01–1.08 (2H, m), 1.12 (3H, s), 1.14 (3H, s), 1.15–1.60 (8H, m, including 1.57 (1H, s, D_2O exchangeable)), 1.71 (1H, m), 2.03 (1H, m), 2.46 (6H, s), 3.74–3.78 (2H, m), 4.06–4.12 (2H, m), 7.36 (2H, d, *J* = 8 Hz), 7.37 (2H, d, *J* = 8 Hz), 7.79 (2H, d, *J* = 8 Hz), 7.81 (2H, d, *J* = 8 Hz); ms *m/e*: 548 ($M^+ - H_2O$), 376, 204, 189. High resolution molecular weight determination, calcd. for $C_{29}H_{42}O_7S_2 - H_2O$: 548.2266; found: 548.2282. *Anal.* calcd. for $C_{29}H_{42}O_7S_2$: C 61.48, H 7.42, S 11.30; found: C 61.43, H 7.48, S 11.15.

A mixture of compound **14** (71 mg) and NaI (160 mg) in dry acetone (6 mL) was heated to reflux in an oil bath for 5 h under argon. After removal of the acetone, the mixture was diluted with water and extracted with ether, and the ether layer was washed with water, dried ($MgSO_4$), and evaporated. The crude product **15** (55 mg) was used for subsequent reactions without further purification; ms *m/e*: 478 (M^+), 463, 420, 333. High resolution molecular weight determination, calcd. for $C_{15}H_{28}O^{127}I_2$: 478.0228, found: 478.0242.

The compound **15** (55 mg) was added to potassium *tert*-butoxide (300 mg) in DMSO (4 mL). The reactants were stirred for 12 h at room temperature and then poured into ice water. The mixture was extracted with ether (3 × 20 mL) and the combined ether extracts were washed with water, brine, and then dried over $MgSO_4$. Evaporation of the solvents left a semi-solid residue which was purified by preparative tlc on silica gel with ether – petroleum ether as the eluent. The yield was 1.2 mg (5%) of solid **4**.

Diselenide ***16***

A solution of triol **13** (61 mg), *o*-nitrophenyl selenocyanate (429 mg) (14) in THF (4 mL), and pyridine (4 mL) was treated with tri-*n*-butyl phosphine (338 mg). The mixture was stirred for 18 h at ambient temperature and concentrated *in vacuo*. The product was extracted with ether, dried ($MgSO_4$), evaporated, and chromatographed on silica gel (ether) to give diselenide **16** (125 mg, 84%) as a yellow solid; mp 42–44°C; $[\alpha]_D$ −32.1° ($CHCl_3$, *c* 0.461); ir ν_{max}: 3550, 1596, 1571, 1516, 1324, 1306, 1110, 870 cm^{-1}; uv λ_{max} ($CHCl_3$): 256 (ε 29 394), 272 (13 636) nm; ^{1}Hmr δ: 0.94 (3H, s), 1.05 (3H, d, *J* = 6 Hz), 1.20 (3H, s), 1.21 (3H, s), 1.30–1.73 (11H, m), 2.16 (1H, m), 2.74–2.84 (2H, m), 2.85–2.96 (2H, m), 7.18–7.30 (2H, m), 7.36–7.43 (4H, m), 8.11 (1H, d, *J* = 8 Hz), 8.25 (1H, d, *J* = 8 Hz); ms *m/e*: 628 (M^+), 426. High resolution molecular weight determination, calcd. for $C_{27}H_{36}N_2O_5{}^{80}Se_2$: 628.0953; found: 628.0934; *Anal.* calcd. for $C_{27}H_{36}N_2O_5{}^{80}Se_2$: C 51.59, H 5.73, N 4.45; found: C 51.65, H 5.83, N 4.63.

β-*Elemol* ***4***

The diselenide **16** (108 mg) was dissolved in a mixture of methanol (6 mL) and THF (6 mL), then water (0.9 mL), $NaHCO_3$ (51 mg), and $NaIO_4$ (258 mg) were added with vigorous stirring. After 6 h at room temperature, the reaction mixture was evaporated under *vacuo*, then diluted with saturated $NaHCO_3$ (5 mL), and extracted with ether (3 × 10 mL). The organic layer was washed with water, NaCl solution, and dried ($MgSO_4$). Solvent was removed and the residue chromatographed on alumina grade III (10 g) eluted with ether – petroleum ether (1:9, v/v) to give a crystalline solid (27.3 mg, 72%); mp 51–52°C (lit. (13) mp 51–52°C); $[\alpha]_D$ −4.6° ($CHCl_3$, *c* 0.5005) (lit. (13) $[\alpha]_D$ −4.5° ($CHCl_3$)); ir ν_{max}: 3438, 1643, 1473, 1448, 1383, 1116, 1011, 906, 891 cm^{-1}; ^{1}Hmr δ: 1.00 (3H, s), 1.22 (6H, s), 1.26–1.50 (5H, m), 1.55–1.70 (3H, m, including 1.56 (1H, bs, D_2O exchangeable)), 1.73 (3H, s), 1.98 (1H, dd, *J* = 12, 4 Hz), 4.62 (1H, bs), 4.83–4.96 (3H, m), 5.84 (1H, dd, *J* = 16, 12 Hz); ms *m/e*: 204 ($M^+ - H_2O$), 189, 163. High resolution molecular weight determination, calcd. for $C_{15}H_{26}O - H_2O$: 204.1878; found: 204.1887. *Anal.* calcd. for $C_{15}H_{26}O$: C 81.08, H 11.71; found: C 80.96, H 11.63.

Addition of 2 mol% of an alcohol to water or of 1 mol% of water to an alcohol increases the value of $G_{fi}\epsilon_{max}$ (e^-_s) above that in the pure solvent. The effect is attributed mainly to an increasing free ion yield G_{fi}. The increase of G_{fi} correlates with a "stiffening" of the solvent molecular rotational motions and a corresponding lower rate of energy loss by the epithermal electrons to dipole rotations. Thus the increase of G_{fi} is mainly attributed to a larger electron thermalization range b_{GP}. The value of $G_{fi}\epsilon_{max}$ passes through a maximum at 2 mol% of an alcohol in water; the maximum increases in the order methanol < ethanol < 1-propanol as additive. The solvent "stiffening" effect of these solutes increases in the same order.

Some of the published values of E_{Amax} and $W_{1/2}$ for solvated electrons in alcohols appear to be too low. A set of preferred values is reported herein.

AH-DONG LEU, KAMAL N. JHA et GORDON R. FREEMAN. Can. J. Chem. **61**, 1115 (1983).

L'addition de 2 mol% d'un alcool à l'eau ou de 1 mol% d'eau à un alcool augmente la valeur de $G_{fi}\epsilon_{max}$ (e^-_s) au dessus de celle du solvant pur. On attribue principalement cet effet à une augmentation du rendement de l'ion libre qui donne G_{fi}. L'augmentation de G_{fi} est en accord avec un raidissement des mouvements de rotation moléculaire du solvant et avec une vitesse correspondante plus faible de la perte d'énergie par les électrons épithermiques lors des rotations du dipole. Ainsi on attribue l'augmentation de G_{fi} principalement à un plus large distance de thermalisation de l'électron b_{GP}. La valeur de $G_{fi}\epsilon_{max}$ passe par un maximum à 2 mol% d'un alcool dans l'eau; le maximum augmentant dans l'ordre suivant: méthanol < éthanol < propanol-1 comme additifs. L'effet de raidissement du solvant de ces solutés augmente dans le même ordre.

Quelques unes des valeurs de E_{Amax} et de $W_{1/2}$ préférées pour les électrons solvatés dans des alcools semblent trop faibles. On rapporte qui ont été publié ici un ensemble de valeurs.

[Traduit par le journal]

Introduction

Addition of water to an alcohol has a large effect on the optical absorption energy and band shape of solvated electrons (1). The large effect of water was expected in tertiary and secondary alcohols, because the optical absorption energies, and presumably the electron trap depths, are greater in water than in these alcohols. However, water also has an unexpected, large effect on the spectra of solvated electrons in primary alcohols, where the absorption energies in the pure alcohols are greater than those in water. Furthermore, a distinct minimum in E_{Amax} exists at about 10 mol% water in a primary alcohol, which seems to imply that a particular solvent structure exists at that composition. No direct evidence about the nature of the structure is available, but speculation was offered about a hydrogen bonded cube of eight alcohol molecules reinforced by a water molecule at its center (1). Intermolecular solvent structure, rather than intramolecular structure by itself, has a dominating influence on the energy levels of solvated electrons.

The intensity of the e^-_s absorption, measured by $G\epsilon_{max}$, has now been found to display an unusual composition dependence in alcohol/water mixed solvents. The results are reported herein.

On a mundane level, there are significant discrepancies among reported values of E_{Amax} for solvated electrons in many alcohols at ~298 K (2–12). The discrepancies might be caused by the presence of impurities such as water in some of the alcohols. It seems less likely that the discrepancies, sometimes as much as 20% (5), were caused by malfunctioning monochromators. We present an internally consistent set of values of E_{Amax}, $W_{1/2}$, W_r, and W_b for $C_nH_{2n+2}O$, with $n = 0, 1, 2, ---, 8$.

Experimental

The materials and techniques were the same as those described earlier (1).

In brief, samples of purified alcohols and water in Spectrosil cells were given monitored 1.0 μs pulses of 1.8 MeV electrons (9×10^{16} eV/g). The optical absorbance at a given wavelength was measured as a function time after each pulse. The observed values of the absorbance A_{obs} at the end of a pulse were corrected for first order decay during the pulse to obtain A_e.

$$[1] \quad A_e = A_{obs}kt_p/[1 - \exp(-kt_p)]$$

where t_p is the pulse duration and $k = 0.69/t_{1/2}$ is the decay constant.

The pulse dose monitor was calibrated with 5 m*M* KCNS solution saturated with oxygen, using $G\epsilon_{max}$ = 21 000 (e^-_s/100 eV *M* cm) at 478 nm and 298 K.

Results and discussion

$G\epsilon_{max}$ and electron thermalization ranges

The value of $G\epsilon_{max}$ (e^-_s/100 eV *M* cm) was measured at 298 K in methanol, ethanol, and 1-propanol as functions of water concentration. There is a maximum in $G\epsilon_{max}$ at 98 mol% water in each system (Fig. 1). The height of the maximum increases in the order methanol < ethanol < 1-propanol, being 12, 16, and 24% greater than $G\epsilon_{max}$ in pure water. At the other end of the composition range, addition of 1 mol% water to alcohol also causes a significant increase of $G\epsilon_{max}$, by 6% in methanol, ~10% in ethanol, and 21% in 1-propanol.

The $G\epsilon$ curves in Fig. 1 show that the effects of water and alcohol are not additive. Between 10 and 98 mol% water the

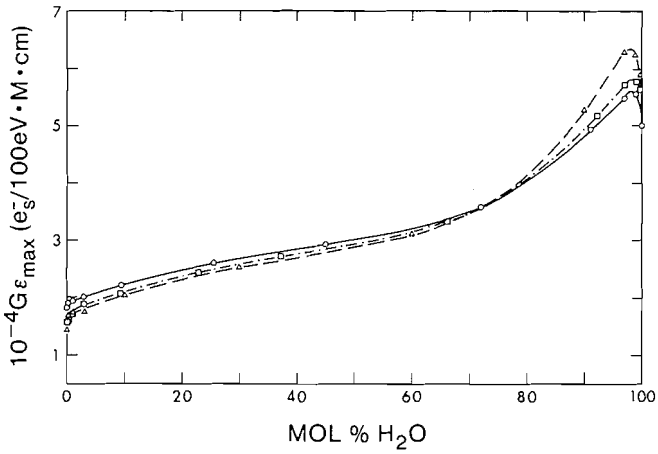

FIG. 1. Composition dependence of $G\epsilon_{max}$ in alcohol–water mixed solvents at 298 K. ○, methanol; □, ethanol; △, 1-propanol.

alcohols dominate the behavior of $G\epsilon$. This is the opposite of the effects on the optical band energy parameters, which were dominated by water (1).

The addition of 1 mol% of water to an alcohol or of 2 mol% of alcohol to water has greater relative effects on $G\epsilon_{max}$ than on the energy parameters of the absorption bands (Table 1). It is therefore probable that ϵ_{max} remained relatively constant for the small change of composition and that the increase of $G\epsilon_{max}$ was mostly due to an increase in G. The changes in G were analysed by the modified Onsager model (13, 14) to gain insight about electron behavior in the mixed solvents.

The approximate mechanism is as follows.

[2] $\mathrm{ROH} \rightsquigarrow [\dot{\mathrm{R}}\mathrm{OH}^+ + e^-]$

[3] $[e^- + n\mathrm{ROH}] \rightarrow [e^-_s]$

[4] $[\dot{\mathrm{R}}\mathrm{OH}^+ + m\mathrm{ROH}] \rightarrow [\mathrm{H}^+_s + \mathrm{RO}\cdot]$

[5] $[e^-, \dot{\mathrm{R}}\mathrm{OH}^+, e^-_s, \mathrm{H}^+_s] \rightarrow$ geminate neutralization

[6] $[e^-, \dot{\mathrm{R}}\mathrm{OH}^+, e^-_s, \mathrm{H}^+_s] \rightarrow e^-_s + \mathrm{H}^+_s$, free ions

Reaction [6] indicates that by the time electrons and ions have escaped from spurs the solvation processes [3] and [4] are complete (13). Under the conditions of the present measurements only the solvated electrons that had become free ions were measured.

The free ion yield in the single pair spur model is given by (13):

$$[7] \quad G_{fi} = G_{tot} \int_0^\infty F(y) \exp(-\xi^2/\epsilon_{ave} ykT)\, dy$$

where G_{tot} is the initial number of ionizations (reaction [2]) per 100 eV absorbed by the system, $F(y)dy$ is the fraction of electrons that travel distances between y and $y + dy$ from the parent ions during thermalization, ξ is the protonic charge, ϵ_{ave} is the average value of the time dependent dielectric constant during the competition between reactions [5] and [6], k is Boltzmann's constant, and T is the absolute temperature.

The $F(y)$ distribution function YGP (14), which has a Gaussian body and a power function tail, was used.

$$[8] \quad F(y)_1 = (3.84y^2/\pi^{1/2}b_{GP}^3) \exp(-y^2/b_{GP}^2), \quad y < 2.4\ b_{GP}$$

$$F(y)_2 = F(y)_1 + 0.48b_{GP}^2/y^3, \quad y > 2.4\ b_{GP}$$

A simple Gaussian would be adequate for alcohols and water because the power function tail is only needed to explain the electric field dependence of the small free ion yields ($G_{fi} < 0.2$) obtained in most hydrocarbons (14).

On the timescale of reaction [5] the dielectric constant of an alcohol, and probably that of water, is time dependent (13, 15, 16). Equation [7] would be more accurately represented as [7']:

$$[7'] \quad G_{fi} = G_{tot} \int_0^\infty \int_0^{t_{gn}(y)} F(y) \exp(-\xi^2/\epsilon(t) ykT)\, dy dt$$

where $\epsilon(t)$ is the dielectric constant of the medium between the ion and the electron as a function of time after the ionization event, and $t_{gn}(y)$ is the mean time required for geminate neutralization from an initial separation distance y. The value of $t_{gn}(y)$ is also a function of $\epsilon(t)$, so the complete calculation would be done iteratively. However, the range and relaxation parameters are not yet well enough known for such a treatment.

One can estimate crude values of ϵ_{ave} for use in eq. [7], for example, by assuming Debye-type relaxation with time constant τ (13):

$$[9] \quad \epsilon_{ave} = \epsilon_\infty + \frac{\epsilon_0 \tau}{t_{gn}} \ln\left(\frac{1 + [(\epsilon_\infty - \epsilon_0)/\epsilon_0] \exp(-\epsilon_\infty t_{gn}/\epsilon_0 \tau)}{1 + [(\epsilon_\infty - \epsilon_0)/\epsilon_0]}\right)$$

where ϵ_0 and ϵ_∞ are the values of ϵ at $t = 0$ and ∞, respectively. The values of τ and t_{gn} appear only as a ratio in eq. [9]. Addition of a small amount of alcohol to water or of a small amount of water to alcohol causes both τ (16) and the viscosity (17) to increase. Electron mobility in these liquids is ion like, so the mobilities are roughly inversely proportional to the viscosity and t_{gn} would be approximately proportional to the viscosity. These effects would tend to keep the ratio τ/t_{gn} constant.

Values of ϵ_∞ were obtained from ref. 18; the value for pure methanol in this reference was 3% low (17), so small corrections were applied for methanol containing <10 mol% water. The value of ϵ_0 changes negligibly upon the addition of a small amount of alcohol to water (16) or of water to alcohol (17).

The nitrogen yields from concentrated solutions (1–10 mol%) of nitrous oxide in water (19)[3] and the three alcohols (13, 20, 21) indicate that G_{tot} lies in the range 4.2–4.9. The value $G_{tot} = 4.6$ was used for all the liquids.

The free ion yields in water (22, 23) and the alcohols (13, 20, 24) were derived from scavenging yields, with the aid of models. The free ion yields in the mixed solvents were then estimated from the changes in $G_{fi}\epsilon_{max}$ (Table 1). Whether a bit of water was added to an alcohol or a bit of an alcohol was added to water, G_{fi} increased.

In our earlier study of electron scavenging in water by nitrous oxide we had added 3.3 mol% of ethanol to scavenge hydrogen atoms and hydroxyl radicals (19). The estimated free ion yield, 2.7, was therefore higher than would be obtained in pure water. For the present work we have chosen $G_{fi} = 2.6$, but the true value might be even lower.

It had been reported previously that addition of 2 mol% of ethanol to water increases G_{fi} (e^-_s) by 0.2 units, from 2.65 to 2.84 (23). The increase was attributed to the occurrence of reaction [10], thereby preventing reaction [11], and it was assumed that reaction [12] did not occur to an appreciable extent.

[10] $[\dot{\mathrm{O}}\mathrm{H} + \mathrm{RCH_2OH}] \rightarrow [\mathrm{H_2O} + \dot{\mathrm{R}}\mathrm{CHOH}]$

[3] $G_{tot} > 4.0$ because $G(N_2)$ did not reach a plateau (Fig. 1 of ref. 19).

Two mol% of alcohol in water corresponds to an alcohol concentration of 1 mol/dm^3. The values of the rate constant k_{10} (dm^3/mol s) in aqueous solution at ~295 K are ~9×10^8 for methanol, ~18×10^8 for ethanol, and ~27×10^8 for 1-propanol (25). The half-lives of reaction [10] in the 2% solutions are therefore ~1.1, ~0.6, and ~0.4 ns, respectively. Thus reaction [10] is negligible until well after the few ps required for reactions [3] and [4] to go to completion. However, reaction between the solvated intermediates in multipair spurs continues to be significant at several ns in water (26, 27), so [10] would influence the latter spur reactions. But reaction [12] should be included. It is probably exothermic, because gas phase radicals have positive electron affinities (28) and the solvation energy of the anion is probably greater than that of the electron.[4] The value of the rate constant k_{12} in the alcoholic aqueous solutions would be smaller than that of k_{11} in water solvent, because addition of an alcohol to water increases the viscosity η and the dielectric relaxation time τ of the system (16, 17). The diffusion coefficients of the radical and e^-_s (which is in a deeply localized state) in hydroxylic solvents decrease with increasing η and τ.

The decay rate of e^-_s during the time period 0.1–3.3 ns is 1.6-fold slower in 3 M ethanol/water than in pure water solvent (26). The value of η of the 3 M ethanol solvent is 1.7-fold larger than that of water (17), and the value of τ is ~1.5-fold larger (by comparison with the 1.74 factor for a 3 M 1-propanol aqueous solution, ref. 16). The values of k_{10} and k_{12} should therefore be about 1.6-fold smaller in the 3 M ethanol solvent than in water. This factor alone explains the difference between the e^-_s decay curves in water and 3 M ethanol shown in Figs. 2 and 3 of ref. 26. The 3 M ethanol curves superimpose the water curves if the times of the former are reduced 1.6-fold, taking the 0.1 ns normalization point as the zero of time. The signal heights, which are proportional to $G\epsilon(e^-_s)$, were normalized at 0.1 ns, so an increase of $G\epsilon$ caused by the addition of ethanol to water would not be observed. It therefore seems probable that the increase of $G_{fi}(e^-_s)$ reported by Fielden and Hart (23) was due mainly to events that occurred before 0.1 ns, namely, an increase of electron thermalization range.

Furthermore, reactions analogous to [10] could not explain the increase of $G_{fi}(e^-_s)$ caused by the addition of 1 mol% of water to the alcohols. The analogous reactions would be the reverse of reaction [10] and would be endothermic. Even if they did occur to an appreciable extent during the lifetime of the spur they would not cause $G_{fi}(e^-_s)$ to increase because the product $\dot{O}H$ radical is as efficient an electron scavenger as the $R\dot{C}HOH$ radical. The increase of $G_{fi}(e^-_s)$ when a little water is added to an alcohol is therefore due to something else.

The increase of $G_{fi}(e^-_s)$ caused by addition of 1 mol% of water to an alcohol, and at least a major portion of that caused by addition of 2 mol% of an alcohol to water, is attributed to an increase of the electron thermalization distance b_{GP}. The

[4] Dorfman and Taub reported that the lifetime of e^-_s was an order of magnitude smaller than that of $CH_3\dot{C}HOH$ in pulse irradiated 0.5 M ethanol in neutral water. They suggested that e^-_s and $CH_3\dot{C}HOH$ did not interact. The e^-_s lifetime would be dominated by reaction with H^+_s and H_2O_2 formed during the 5 μs (10 krad) pulse and possibly with H_2O_2 and acetaldehyde accumulated from previous pulses. The alcohol radicals would therefore be left to react mainly with each other. One cannot conclude from these results that $k(e^-_s + CH_3\dot{C}HOH)$ is small.

[a] Reference 16*a*.
[b] Estimated from eq. [13], using $\epsilon_{ir} = 5.5$ (16*a*), $d = 3.8 \times 10^{-8}$ cm, and $n = n_D = 1.333$ for each liquid.
[c] Table 1.
[d] Reference 33.
[e] See footnotes *d* and *e* in Table 1.

value of $\epsilon_{ave} b_{GP}$ for each of the liquids was calculated from eqs. [7] and [8] and is listed with the other pertinent data in Table 1. A lower limit for b_{GP} was estimated by taking $\epsilon_{ave} = \epsilon_\infty$; it is labelled $_{min}b_{GP}$ in Table 1.

The value of $_{min}b_{GP}$ increases progressively on going from methanol to ethanol to propanol as the 2% additive in water. The relative effect is greater for adding a bit of alcohol to water than for adding a bit of water to alcohol (Table 1). These changes correlate with the relative extents of changes in the liquid structures, as reflected by the viscosities (17). Furthermore, adding a few percent of an alcohol to water actually increases the partial molar volume of water, presumably due to enhancement of an icelike structure (29). At >10 mol% of alcohol the partial molar volume of water decreases, due to breaking of the icelike structure. There is a minimum in the partial molar excess volume of the alcohol in dilute aqueous solution. The minimum is deepest (-6.5 cm^3/mol) and lies at the lowest concentration (3 mol%) for 1-propanol, next deepest for ethanol (-5.7 cm^3/mol at 7 mol%), and shallowest for methanol (-3.3 cm^3/mol at 10 mol%) (29). Other thermodynamic parameters exhibit complex behavior that imply the existence of enhanced ordering of the liquid structure when a few mol% of an alcohol is added to water (30–32). For example, ethanol can form a clathrate $C_2H_5OH \cdot 17H_2O$, which is 6 mol% ethanol (31); there is a maximum in the velocity of sound and in the sound absorption coefficient around 7 mol% *t*-butanol in water (p. 55 of ref. 30); the critical micelle concentration of sodium dodecyl sulfate at 298 K has a minimum at 4 mol% *t*-butanol in water (30); in the hydrolysis of *t*-butyl chloride there are maxima in the enthalpy and entropy of activation for 3 mol% ethanol in water (32); and so on.

An increase of the icelike structure of water "hardens" the fluid and increases the rotational relaxation time τ (16). An increase in τ decreases the rate at which epithermal electrons lose energy W to dipole rotations (33):

$$[13] \quad \left(-\frac{dW}{dt}\right)_{dip} \approx \frac{\pi\xi^2(\epsilon_\infty - \epsilon_{ir})}{4dn^4\tau} \text{ erg/s}$$

where ϵ_{ir} = dielectric constant at frequencies sufficiently lower than the main infrared absorption frequency, d = intermolecular distance, and n = a suitable average optical refractive index; the units are ξ (esu) and d (cm). The thermalization time and therefore the value of b_{GP} is greater when τ is larger, other things being equal.

The liquid structure effect is also observed when comparing G_{fi} values in H_2O and D_2O (Table 2). The value of $G_{fi}(e^-_s)$ in D_2O is 11% greater than that in H_2O at ~298 K (34–36), which corresponds to a 25% greater value of $_{min}b_{GP}$ and correlates with the 27% larger τ in D_2O (Table 2 and ref. 37). The behavior in D_2O is similar to that in H_2O containing 2 mol% alcohol.

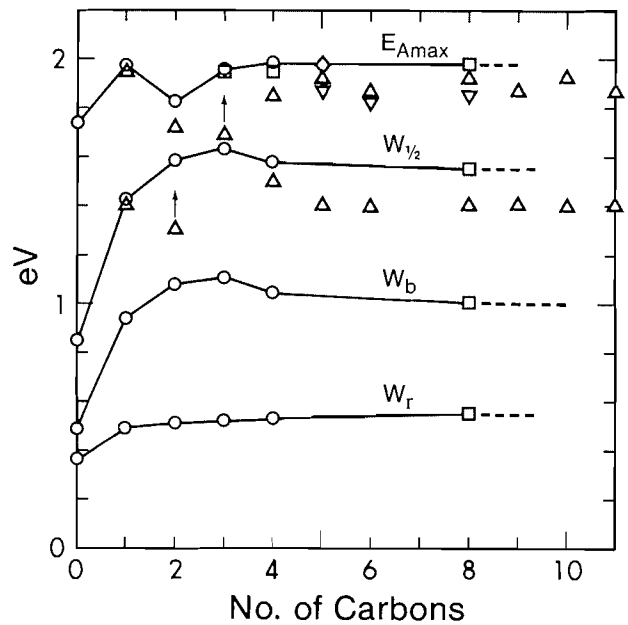

FIG. 2. Spectral parameter values as functions of the number of carbon atoms in 1-alcanols at 298 K. ○, this work; ◇, ref. 40; □, ref. 12; △, ref. 6; ▽, ref. 5. The E_{Amax} values from refs. 5, 6, and 12 were increased slightly to adjust to 298 K, using measured temperature coefficients for primary alcohols (40).

Critique

The preceding discussion is based upon a model in which there is only one ion–electron pair per spur (13). In reality, only about half of the ion–electron pairs are initially in single pair spurs; in water most of these become free ions. Most of the geminate reaction in water and much of it in alcohols occurs in spurs that initially contain more than one pair. Geminate neutralization yield calculations with an accurate multipair spur model are not yet possible (38). However, one may deduce that the above conclusions about structure effects in the mixed solvents and D_2O would be magnified in a multipair spur model. For example, the estimated increases of electron range would be larger.

Jonah and co-workers neglected solvent structure effects of solutes in their kinetic analysis of the e^-_s decay curves over the period 0.1–3.3 ns (26). Inclusion of the structure effects, which are large for the 1–3 mol/dm^3 that they used of ethanol, ammonia, sodium acetate, and sodium hydroxide, will greatly alter the diffusion coefficients and rate constants of the species. The conclusions drawn from the analysis will also be changed. In addition to those discussed above one might mention that

TABLE 3. Preferred values of $E_{\lambda max}$ and $W_{1/2}$ for e^-_s at 298 K

Solvent	$E_{\lambda max}$ (eV)	$W_{1/2}$ (eV)
Water	1.73	0.85
Methanol	1.97	1.43
Ethanol	1.82	1.59
1-Propanol	1.95	1.63
2-Propanol	1.52	1.45
1-Butanol	1.98	1.57
2-Methyl-1-propanol	1.97	1.61
2-Butanol	1.59	1.57
1-Pentanol	1.97	~1.57
1-Octanol	1.98	1.55

most of the effect of the sodium acetate at times up to 2 ns is attributable to the 1.4-fold increase of viscosity (39).

Reassessment of spectral parameter values in pure solvents

Recent measurements (1, 12, 40) indicate that some of the earlier reported values of $E_{\lambda max}$ and $W_{1/2}$ for solvated electrons in 1-alcanols (5, 6) are too low (Fig. 2). A possible cause of the low values, in addition to instrumental error, is the presence of a few mol% of water in the alcohols (1). Consistent with the wet alcohol interpretation is the relatively good agreement between the present and earlier (6) values for methanol, and the much smaller sensitivity to water of the parameters in methanol than those in other alcohols (1). Similar errors appear to exist for other alcohols as well (6), so preferred values are listed in Table 3.

Values of $E_{\lambda max}$ plotted against the number of carbon atoms in a 1-alcanol show a dip at ethanol (Fig. 2). In view of the discussion in the previous section, the dip is qualitatively attributed to a peculiarity of the liquid structure, without being able to say what it is.

Analogous plots show more variation in W_b than in W_r (Fig. 2).

Kinetics and mechanisms of the oxidation of ascorbic acid and benzene diols by nickel(III)tetraazamacrocycles in aqueous perchloric acid

A. McAuley,[1] T. Oswald,[2] and R. I. Haines

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received February 12, 1982[3]

A. McAuley, T. Oswald, and R. I. Haines. Can. J. Chem. **61**, 1120 (1983).

The kinetics of reaction of ascorbic acid, hydroquinone, and catechol (H_2A) with nickel(III) macrocycles (NiL^{3+}) (L = cyclam, *meso*-(5,12)-7,7,14,14-Me_6-14-ane-1,4,8,11-N_4 (tet-*a*), and *rac*-(5,14)-7,7,12,12-Me_6-14-ane-1,4,8,11-N_4 (tet-*c*):

$$2NiL^{3+} + H_2A \rightarrow 2NiL^{2+} + A + 2H^+$$

have been investigated in aqueous perchloric acid solutions using the stopped-flow technique. The data are consistent with a rate-determining one-electron transfer reactions:

$$NiL^{3+} + H_2A \xrightarrow{k_1} NiL^{2+} + H_2A^+$$

$$NiL^{3+} + HA^- \xrightarrow{k_4} NiL^{2+} + HA^\cdot$$

$$H_2A \rightleftharpoons HA^- + H^+ \ (K_a)$$

followed by a rapid oxidation of the radical formed. In the reaction with ascorbic acid, for Ni(cyclam)$^{3+}$, $k_1 = 250\ M^{-1}\ s^{-1}$ (25°C), $k_4K_a = 680\ s^{-1}$; Ni(tet-*c*)$^{3+}$, $k_1 = 2.52 \times 10^3\ M^{-1}\ s^{-1}$, $k_4K_a = 1.06 \times 10^4\ s^{-1}$; and Ni(tet-*a*)$^{3+}$, $k_1 = 2.85 \times 10^3\ M^{-1}\ s^{-1}$ (21.95°C), $k_4K_a = 1.26 \times 10^4\ s^{-1}$. With catechol, $k_1 = 6.98 \times 10^2\ M^{-1}\ s^{-1}$, $1.73 \times 10^4\ M^{-1}\ s^{-1}$, and $3.3 \times 10^4\ M^{-1}\ s^{-1}$ respectively in reactions with Ni(cyclam)$^{3+}$, Ni(tet-*c*)$^{3+}$, and Ni(tet-*a*)$^{3+}$. With hydroquinone, $k_1 = 1.09 \times 10^4\ M^{-1}\ s^{-1}$ (Ni(cyclam)$^{3+}$) and $2.49 \times 10^5\ M^{-1}\ s^{-1}$ (20.9°C) (Ni(tet-*c*)$^{3+}$). The reactions are considered to take place via an outer-sphere mechanism and rate constants are discussed in terms of the Marcus cross correlation. Use has been made of predicted rate constants to identify reaction pathways in the hydrogen-ion dependent systems.

A. McAuley, T. Oswald et R. I. Haines. Can. J. Chem. **61**, 1120 (1983).

Faisant appel à la méthode de flux stoppé, on a étudié, dans des solutions aqueuses d'acide perchlorique, la cinétique de la réaction de l'acide ascorbique, de l'hydroquinone et du catéchol (H_2A) avec les macrocycles de Ni(III) (NiL^{3+}) (L = cyclam, *méso*-(5,12)-7,7,14,14-Me_6-ane-14-N_4-1,4,8,11 (tét-*a*) et *rac*-(5,14)-7,7,12,12-Me_6-ane-14-N_4-1,4,8,11 (tét-*c*):

$$2NiL^{3+} + H_2A \rightarrow 2NiL^{2+} + A + 2H^+$$

Les données s'accordent avec une étape de transition impliquant des réactions de transfert à un électron:

$$NiL^{3+} + H_2A \xrightarrow{k_1} NiL^{2+} + H_2A^+$$

$$NiL^{3+} + HA^- \xrightarrow{k_4} NiL^{2+} + HA^\cdot$$

$$H_2A \rightleftharpoons HA^- + H^+ \ (K_a)$$

qui serait suivi par une oxidation rapide du radical formé lors de la réaction de l'acide ascorbique avec le Ni(cyclam)$^{3+}$, $k_1 = 250\ M^{-1}\ s^{-1}$ (25°C), $k_4K_a = 680\ s^{-1}$; avec Ni(tét-*c*)$^{3+}$ $k_1 = 2{,}52 \times 10^3\ M^{-1}\ s^{-1}$, $k_4K_a = 1{,}06 \times 10^4\ s^{-1}$ et Ni(tét-*a*)$^{3+}$, $k_1 = 2{,}85 \times 10^3\ M^{-1}\ s^{-1}$ (21,95°C), $k_4K_a = 1{,}26 \times 10^4\ s^{-1}$; dans le cas du catéchol, ces valeurs sont respectivement $k_1 = 6{,}98 \times 10^2\ M^{-1}\ s^{-1}$; $1{,}73 \times 10^4\ M^{-1}\ s^{-1}$ et $3{,}3 \times 10^4\ M^{-1}\ s^{-1}$ pour les réactions avec le Ni(cyclam)$^{3+}$, Ni(tét-*c*)$^{3+}$ et Ni(tét-*a*)$^{3+}$; avec l'hydroquinone $k_1 = 1{,}09 \times 10^4\ M^{-1}\ s^{-1}$ (Ni(cyclam)$^{3+}$) et $2{,}49 \times 10^5\ M^{-1}\ s^{-1}$ (20,9°C) (Ni(tét-*c*)$^{3+}$). On considère que ces réactions se font via un mécanisme hors sphère et on discute des constantes de vitesse en fonction de la corrélation croisée de Marcus. Dans les systèmes où il existe une influence des ions hydrogènes on a utilisé les constantes de vitesse prévues pour identifier les schémas de réactions.

[Traduit par le journal]

Introduction

A variety of metal complexes have been studied as oxidants (1–7) in reaction with ascorbic acid and there is evidence for both inner- and outer-sphere redox behaviour. Intermediate complexes have been identified in the reactions with vanadium(V) (8) and aquo-iron(III) (9) where the redox process involves the formation of an ascorbate radical ion rather than a two-electron transfer to yield the dehydroascorbic acid. Among other complexes of iron(III), for example, the reaction of tris(phenanthroline)iron(III) and its derivatives (2), and the reactions involving thioureapentacyanoferrate(III) (10), the dif-

ferences in oxidation rates have been discussed in terms of free energy changes as related to the Marcus theory (11).

In previous studies from our laboratory, we have investigated redox reactions of nickel(III) macrocyclic complexes. Complex formation has been observed in the reactions of nickel(III) cyclam (cyclam = 1,4,8,11-tetraazacyclotetradecane) with Cl^-, Br^-, and NCS^- (12) but with I^- (12) and aromatic diols (13) a redox process occurs. These nickel(III) macrocycles with various ring substituents offer a wide range of oxidising potentials, but relatively few studies have been made of the kinetics and mechanisms of reactions with reducing substrates. In the present paper we report the results of a kinetic study of the oxidation of ascorbic acid by Ni(III)L^{3+} (L = cyclam, tet-*a*, and tet-*c*), and of the latter two complexes as oxidants in reactions with hydroquinone and catechol.

Experimental

Nickel(II)L^{2+} (L = cyclam, tet-*a*, tet-*c*) were prepared as described in the literature (14). Cyclam (Strem) was recrystallised from ethanol before use. For the latter two complexes, the Me_6-4,11- and Me_6-4,14-N_4 diene intermediates prepared initially were reduced to tet-*a* and tet-*c* respectively using Ni/Al alloy at 70°C. Solid samples of the Ni(III) complexes $NiL(CH_3CN)_2(ClO_4)_3$ were prepared by electrolysis (0.01 *M* $NaClO_4$) of the corresponding Ni(II) species in rigorously anhydrous acetonitrile (P_2O_5/CaH_2) at 5°C in the dark under dry N_2. The solids were stored at −15°C in the dark.

L-Ascorbic acid was used as received (Sigma) while catechol and hydroquinone were recrystallised from ethanol. $LiClO_4$ was prepared by neutralisation of Li_2CO_3 with $HClO_4$ and recrystallised three times from distilled water. Care was taken to ensure the absence of SO_4^{2-} ion, which was removed by adding a slight excess of $Ba(ClO_4)_2$.

The stopped-flow apparatus and data acquisition system used have been described previously (15). For some runs a modified Applied Photophysics instrument was used. Both reservoirs and the drive syringes were thermostatted by circulating water (controlled to ±0.05°C). Absorbance data were collected at desired time intervals and processed using a PCM 12 minicomputer. In general, for each run, 200 points were used and rate constants quoted are the least squares slopes of log ($OD_\infty - OD_t$) vs. time curves.

Solutions were prepared immediately before starting the experiments, which were carried out with an excess of reductant. Ionic strength (1.0 *M*) was maintained constant with $LiClO_4$. Solutions of Ni(III)L^{3+} (L = tet-*a*, tet-*c*) were prepared by adding the required amount of solid to the thermostatted solution immediately prior to reaction. This is especially important at lower acid concentrations where decomposition of the (NiL^{3+}) in the absence of reductant was complete in 10−15 min. The disappearance of Ni(III)cyclam^{3+} was observed at 380 nm and that of Ni(III)L^{3+} (L = tet-*a*, tet-*c*) at 408 nm, yielding pseudo-first order plots which were linear over at least three half-lives.

Results and discussion

Spectrophotometric titration of the ascorbic acid and of the diols with the nickel complexes showed a stoichiometry of 2.0 mol of nickel(III) reacting per mole of reductant within experimental error (±4%). The overall reaction may thus be written as

$$[1]\quad 2Ni(III)L^{3+} + H_2A \rightarrow 2Ni(II)L^{2+} + A + 2H^+$$

where L = cyclam, tet-*a*, tet-*c*, and H_2A = ascorbic acid, catechol, or hydroquinone and A is dehydroascorbic acid or the corresponding quinone.

At constant $[H^+]$, the reactions were first order with respect to both oxidant and reductant as indicated by the pseudo first-order disappearance of Ni(III)L^{3+} and the linear dependence of the observed rate constant, k_{obs}, on reductant concentration (Fig. 1).

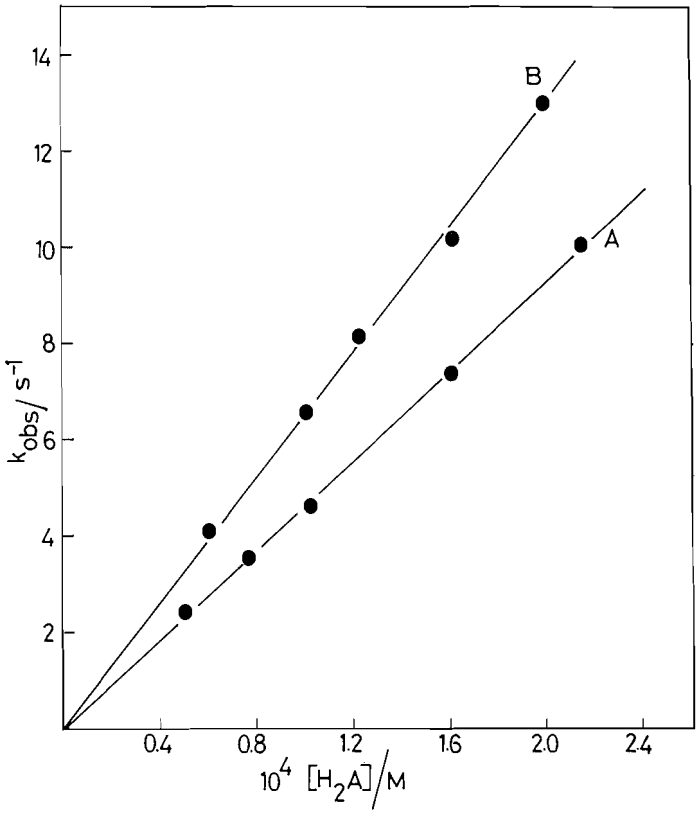

FIG. 1. First order substrate dependence: k_{obs} vs. [reductant]. (*A*) Nitet-c^{3+} + catechol, (*B*) Nitet-c^{3+} + ascorbic acid, T = 25°C, $HClO_4$ = 1.00 *M*.

Reaction with ascorbic acid

Hydrogen ion dependences of the rates were investigated for each oxidant. Although solutions of Ni(III) cyclam were sufficiently stable at pH 2 for kinetic measurements to be made, owing to the limited stability with respect to intramolecular decomposition of the tet-*a* and tet-*c* complexes at $[H^+] < 0.2$ *M*, hydrogen ion dependences for these species were studied over the range 0.2−1.0 *M*. Investigations were carried out in the temperature range = 5.1−31.1°C. For all three oxidants the rate of reaction was observed to be inversely dependent on $[H^+]$ with linear plots of the second order rate constant, k_2 (= $k_{obs}/2[H_2A]$) against $[H^+]^{-1}$ showing positive intercepts (Fig. 2).

These data are consistent with reaction of nickel(III) species with neutral and anionic forms of the ascorbic acid.

$$[2]\quad H_2A \rightleftharpoons H^+ + HA^- \quad (K_a)$$

$$[3]\quad Ni(III)L^{3+} + H_2A \xrightarrow{k_3} Ni(II)L^{2+} + (HA^\cdot + H^+)$$

$$[4]\quad Ni(III)L^{3+} + HA^- \xrightarrow{k_4} Ni(II)L^{2+} + (A^{\cdot -} + H^+)$$

followed by rapid oxidation of the radical intermediate

$$[5]\quad Ni(III)L^{3+} + A^{\cdot -}(HA^\cdot) \xrightarrow{fast} Ni(II)L^{2+} + A(+H^+)$$

An alternative mechanism, involving two-electron transfer reactions,

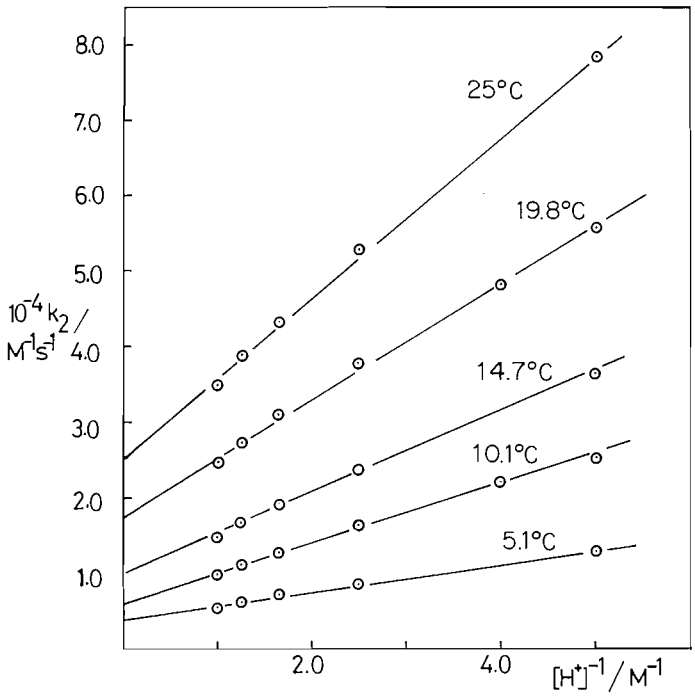

FIG. 2. Dependence of k_2 on $[H^+]^{-1}$ and temperature. Reaction of Ni tet-c^{3+} with ascorbic acid.

$$Ni(III)L^{3+} + H_2A \rightarrow Ni(I)L^{+} + A + 2H^{+}$$

$$Ni(I)L^{+} + Ni(III)L^{3+} \xrightarrow{fast} 2Ni(II)L^{2+}$$

is also consistent with the observed data. There is, however, no evidence for any concerted two-electron reduction of nickel(III). The redox potential for the couple

$$A + 2H^{+} + 2e \rightleftharpoons H_2A$$

has been determined as +0.39 V (30°C) in 1 *M* acid (16). For the reduction

$$Ni(II)tet\text{-}a^{2+} \rightarrow Ni(I)(tet\text{-}a)^{+}$$

in DMF, $E^0 = -1.295$ V (17*a*). Assuming a similar value in aqueous media, when combined with the reduction potential (1.23 V) for $Ni^{III/II}$ (17*b*), the overall Ni(III)L/Ni(I)L potential may be estimated at ~ -0.05 V, effectively ruling out any two-electron process. Using the data of Busch *et al.* (18), the $Ni^{III/I}$ potential is ~ -0.70 V (in CH_3CN versus a Ag/Ag^+ (0.1 *M*) reference electrode).

Although the reaction of the H_2A species (reaction [3]) may be assigned uniquely, there persists a "proton ambiguity" in the case of [4] since an equivalent representation, [7], may be presented:

[6] $$Ni(III)L(OH_2)_2^{3+} \rightleftharpoons Ni(III)L(OH)^{2+} + H^{+} \quad (K_h)$$

[7] $$Ni(III)L(OH)^{2+} + H_2A \xrightarrow{k_7} Ni(II)L^{2+} + HA^{\cdot}$$

There is evidence (19) for a pentacoordinate geometry of the hydroxo species for the tet-*a* and tet-*c* complexes whereas the cyclam complex has been shown (at pH ~10) to exist in the form $NiL(OH)_2^+$.

Using the reactions [3], [4], and [7] together with the associated equilibria, the rate expression is of the form

TABLE 1. Rate constants for reactions of ascorbic acid with Ni(III) macrocycles, $I = 1.00$ *M* ($HClO_4/LiClO_4$)

Oxidant	T/°C	$10^{-3}k_3/M^{-1}\,s^{-1}$	$10^{-3}(k_4K_a + k_7K_h)/s^{-1}$
Ni(III)cyclam^{3+}	11.5	0.15	0.26
	19.0	0.18	0.465
	25.0	0.25	0.68
	30.1	0.31	0.89
	$\Delta H^{\neq} = 6.5 \pm 0.8^a$		
	$\Delta S^{\neq} = -25.7 \pm 5^b$		
Ni(III)tet-c^{3+}	5.1	0.409	1.76
	10.1	0.72	3.92
	14.7	1.01	5.31
	19.8	1.83	7.65
	25.2	2.52	10.6

	21.9	2.85	12.6
	$\Delta H^{\neq} = 7.9 \pm 1.7^a$		
	$\Delta S^{\neq} = -11.4 \pm 5^b$		

[a] In kcal mol^{-1}.
[b] In cal deg^{-1} mol^{-1}.

[8] $$-d[Ni(III)]_{tot}/dt = \frac{2(k_3 + (k_4K_a + k_7K_h)/[H^+])[Ni(III)]_{tot}[H_2A]_{tot}[H^+]^2}{([H^+] + K_a)([H^+] + K_h)}$$

Since measurements were made in the range $[H^+] = 0.1-1.0$ *M* and $K_a \sim 10^{-4}$ *M* (1, 4, 20) and $K_h \sim 10^{-4}$ *M* (13, 21), the second order rate constant may be written as

[9] $$k_2 = k_3 + (k_4K_a + k_7K_h)/[H^+]$$

consistent with the experimental observations. There is no evidence for any $[H^+]^{-2}$ dependence attributable to the reaction of HA^- with $[Ni(III)L(OH)]^{2+}$ which may be expected at higher pH's. Rate data are shown in Table 1.

Nickel(III) species have been shown to form complexes with sulphate ions (21, 22). The reduction potentials associated with these systems are lower (by ~300 mV) than those for the aquo ions. We have examined the effect of sulphate on the reaction rates and find a marked decrease attributed to slower reactions of the sulphato complexes (Table 2). A similar effect has been observed previously in reactions of benzene diols (13) and in sulphate media an evaluation of the data based on reactions of nickel sulphate complexes as oxidants has been presented. In the present system, however, although the data are consistent with only monosulphato complexes reacting (as observed from the linear dependence of k_2^{-1} against $[SO_4^{2-}]_t$), the changes in rate with $[H^+]$ could not be assigned unambiguously and no extensive studies were therefore carried out.

Reactions with catechol and hydroquinone

Previous studies in these laboratories have dealt with the oxidation of these substrates by a variety of reagents (1, 13). In the present investigation we have extended the data on Ni(III) reactants to include the tet-*a* and tet-*c* complexes. Studies have been made at $[H^+] = 1.00$ *M* in order to limit reaction to only the $Ni(III)L^{3+}$ oxidant. In the range $[H^+] = 0.1-1.00$ *M* for reaction of these reductants, there is a fairly constant rate ob-

[a]Rate constants corrected for protonated reductant present under these reaction conditions.
[b]Assuming $k = 10^{11}e^{-\Delta G^{\ddagger}/RT}$.

served with a small, reproducible retardation in rate becoming increasingly more pronounced in the range [H$^+$] ≥ 0.6 *M*. This is attributable to the protonation of the organic substrate,

[10] $H_3Q^+ \rightleftharpoons H^+ + H_2Q \qquad K_{10}$

where H_2Q represents the quinol. Values of K_{10} have been shown to lie in the range 1−10 *M* for alcohols with the constant K_{10} = 3.9 *M* for phenol (23). In the case of hydroquinone and catechol, values of 4.5 ± 1.2 *M* and 3.3 ± 0.9 *M* have been determined from kinetic measurements, and interpolation into the data of Pelizzetti (24) on the oxidation of catechol by $IrCl_6^{2-}$ is consistent with K_{10} = 5.3 ± 2 *M* for this species. At [H$^+$] = 1.00 *M* some of the reductant will be in the protonated form. There is no evidence from any study to date of H_3Q^+ reacting. Assuming only H_2Q to react,

[11] $Ni(III)L^{3+} + H_2Q \xrightarrow{k_{11}} Ni(II)L^{2+} + HQ^{\cdot} + H^+$

[12] $Ni(III)L^{3+} + HQ^{\cdot} \xrightarrow{fast} Ni(II)L^{2+} + Q + H^+$

The second order rate constant may be expressed in the form

[13] $k_2 = k_{obs}/2[H_2Q]_t = k_{11}K_{10}/([H^+] + K_{10})$

k_{11} values are presented in Table 3. The first order dependence of the rate on [H_2Q] is shown in Fig. 1 (*T* = 25.6°C) and the other data quoted are the mean values of constants derived using at least two differing reductant concentrations. In the reaction of Ni(III)tet-*a*$^{3+}$ with hydroquinone, however, the rate was too rapid to be observed in our apparatus. (Using solutions of 5 × 10^{-5} *M* [H_2Q] and 5 × 10^{-6} *M* [Ni(III)], [H$^+$] = 1.00 *M*, *T* = 25°C, $t_{1/2}$ ~ 3 ms.)

Although attempts were made to identify intermediate complexes formed, there is no evidence in any of the systems studied for axially coordinated precursors, suggesting an outer-sphere mechanism.

The Marcus theory (11) affords the possibility of correlating free energy changes with the rate data, and its applicability to redox reactions involving organic substrates has been verified in the case of ascorbic acid (3, 10) and quinols (1, 24, 25) oxidised by a variety of Ir(IV), Fe(III), and Co(III) ions. The relationship may be expressed in the form

[14] $\Delta G_{12}^{\ddagger} = w_{12} + \lambda(1 + \Delta G_c^0/\lambda)^2/4$

where $\Delta G_c^0 = \Delta G_{12}^0 + w_{12} - w_{21}$, $\lambda = 2(\Delta G_{11}^{\ddagger} - w_{11} + \Delta G_{22}^{\ddagger} - w_{22})$, and $k_{12} = Z\exp(-\Delta G_{12}^{\ddagger}/RT)$. $\Delta G_{11}^{\ddagger}$ and $\Delta G_{22}^{\ddagger}$ are free energies of activation of the self-exchange process and w_{11} and w_{22} represent the associated work terms involved. w_{12} and w_{21} are the work terms required to bring together the reactants or products in the activated complex (26, 27). In many of the systems under study, since one of the reactants (or products) is uncharged, work terms are considered to reduce to zero.

The free energy of activation for the self-exchange process for Ni(cyclam)$^{3+/2+}$ has been measured recently (13, 28). Both direct measurements involving esr and cross reactions with Fe(LL)$_3^{3+}$ yield a value of $\Delta G_{11}^{\ddagger}$ = 10.9 ± 1.0 kcal mol^{-1}. There are no experimental data available for the self-exchange rates for H_2Q/H_2Q^+ or for H_2A/H_2A^+. Estimates for the quinols have been made from cross reactions with $IrCl_6^{2-}$ and $Mo(CN)_8^{3-}$, however, with a value in the range $\Delta G_{22}^{\ddagger\ddagger}$ ~ 6−7 kcal mol^{-1} (29). We have used a value of $\Delta G_{22}^{\ddagger\ddagger}$ = 6.0 kcal mol^{-1} (k_{22} ~4 × 10^6 *M*$^{-1}$ s^{-1}). The complexities of ascorbate as a reductant have been described recently (30). From an analysis of emf data derived for the $A^{\cdot}/A^{2-}$ couple (31), a value for $E^0(HA^{\cdot}/HA^-)$ = 0.68 V has been proposed, somewhat lower than that suggested previously. Using data for the reaction with Fe(LL)$_3^{3+}$, the self-exchange rate for the reaction is calculated as 10^2−10^4 *M*$^{-1}$ s^{-1}, consistent with that (10^4 *M*$^{-1}$ s^{-1}) derived from the Fe^{III}(cyt-*c*)/HA^- reaction (32). It is considered that barriers to the electron exchange process derive from differences in C=C and possibly C—C bond lengths in the various species. The data for H_2A/H_2A^+ are more tentative, however, owing to a lack of a measured value for the second pK_a of the ascorbate radical ($H_2A^+ \rightleftharpoons HA^{\cdot} + H^+$). Since the value for p$K_{a1}$ ($HA^{\cdot} \rightleftharpoons H^+ + A^{\cdot-}$) is negative (−0.45), using the data of Steeken and Neta (31) for the one-electron potentials $E^0(A^{\cdot-}/A^{2-})$ at higher pH's (11, 13.5), an approximate value for $E^0(H_2A/H_2A^+)$ may be calculated from known p*K*'s and an assumed value of pK_{a2}. If pK_{a2} lies in the range −1 to −4,

[e] Reference 13.

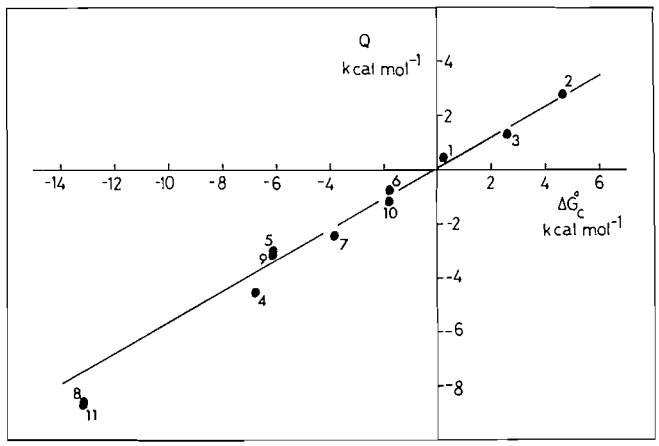

FIG. 3. Plot of Q against ΔG_c^0, eq. [15] for various systems. The numbers refer to reactions indicated in Table 4.

$E^0(H_2A/H_2A^+) = 0.98 \pm 0.10$ V. The rate of oxidation of H_2A by $Fe(LL)_3^{3+}$ (LL = 1,10-phenanthroline) has been measured recently (33) and from the observed rate ($1.73 \times 10^5\ M^{-1}$ s^{-1}) a self-exchange rate for H_2A/H_2A^+ of $\sim 10^2\ M^{-1}$ s^{-1} may be derived. We have used these data in our calculations. In the case of Ni(tet-c)$^{3+/2+}$ and Ni(tet-a)$^{3+/2+}$ we observed reasonable agreement with systems studied using a value $\Delta G_{11}^{**} = 14.0$ kcal mol^{-1} ($k_{11} \sim 2\ M^{-1}$ s^{-1}). Differences in ΔG_{11}^{*} have been observed previously with changes in ligand structure for the corresponding cobalt(III) complexes (34).

In Table 4, comparison is made of the calculated rate constants and those derived experimentally. In most cases the agreement is good when uncertainties in the self-exchange rates (~1 kcal mol^{-1}) are taken into account. Rearrangement of [14] leads to the expression

$$[15]\quad Q = \Delta G_{12}^{*} - w_{12} - \lambda/4 - (\Delta G_c^0)^2/4\lambda = 0.5\Delta G_c^0$$

and in Fig. 3 is shown a plot of ΔG_c^0 against Q. The least-squares slope (0.57) and intercept (0.03) are close to those predicted theoretically, with only the values for reaction of Ni(tet-c)$^{3+}$ and Ni(tet-a)$^{3+}$ with ascorbate ion (not included in the least-squares treatment) showing significant deviations. In these systems, however, very large free energy changes are involved and under such circumstances the Marcus approach may no longer hold. For other reactions, however, the agreement is consistent with an outer-sphere designation for these oxidations.

Adherence to the Marcus treatment enables some predictions to be made with respect to the relative rates of the hydrogen ion dependent pathways for ascorbic acid. Using $\Delta G_{11}^{*} = 9.55$ kcal mol^{-1} ($E^0 = 0.68$ V), the rate constants for the process $NiL^{3+} + HA^-$ (k_4) may be calculated (Table 4). In the reaction of Ni(cyclam)$^{3+}$ with HA^-, for example, k_4(calcd.) $= 1.3 \times 10^6\ M^{-1}$ s^{-1}. The composite constant observed, $(k_4K_a + k_7K_h) = 6.8 \times 10^2\ M^{-1}$ s^{-1}. If only the k_4 path is significant, using $K_a = 1.09 \times 10^4\ M$ (10), k_{obs} (= $6.2 \times 10^6\ M^{-1}$ s^{-1}) in reasonable agreement with the predicted value. It is known (35) that Ni(III)L(OH)$^{2+}$ is a weaker oxidant than Ni(III)L^{3+} so that the former species may be predicted to be less reactive. Also if the hydroxo species are pentacoordinated as seems likely, then an inner-sphere route may be a possibility in this instance. The hydrogen ion dependence of the reactions with ascorbic acid is therefore attributed to HA^- as the reducing ion. There are, in fact, very few instances where only the H_2A pathway predominates (36).

Further studies on redox reactions involving series of organic substrates such as those under consideration will be useful in providing a deeper insight into the use of the Marcus theory in the description of rate processes involved. Recently, data have been presented on the formation of nickel(III) complexes with a variety of polydentate (N_4 and N_5) macrocyclic ligands (37). Studies of the rates of redox reactions involving such species will be helpful in identifying contributions deriving from ligand effects on the metal centre. It is also inferred from the present study that significant changes in the rates of self-exchange reactions for the $NiL^{3+/2+}$ couples occur with ligand substitution. Electron spin resonance studies are planned to attempt to obtain a direct measure of these effects.

Synthetic approaches to haplophytine. 2. Synthesis of 4-methylamino-1-(2-furanyl)-2-phenyl-2-(2-pivaloylamidophenyl)butan-1-one[1]

DAVID AARON SCHWARTZ AND PETER YATES

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received November 9, 1982

DAVID AARON SCHWARTZ and PETER YATES. Can. J. Chem. **61**, 1126 (1983).

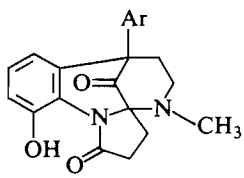
Approaches to the synthesis of compounds related to the 7-aryl-7-[3-(1-hydroxy-2-aminophenyl)]-9-methylamino-5,6-dioxononanoic acid moiety (**3**) of the alkaloid haplophytine and its dihydrobromide are described. Treatment of the dianion of phenyl (*o*-pivaloylamidophenyl)methane with 2-furancarboxaldehyde followed by oxidation of the resulting alcohol gives 1-(2-furanyl)-2-phenyl-2-(2-pivaloylamidophenyl)ethanone (**14**). This on allylation gives 1-allyloxy-1-(2-furanyl)-2-phenyl-2-(2-pivaloylamidophenyl)ethene (**20**), which on being heated at 80–95°C undergoes an intramolecular Diels–Alder reaction. Heating the resulting product or **20** at 165°C converts them to the C-allylation product of **14**, 1-(2-furanyl)-2-phenyl-2-(2-pivaloylamidophenyl)pent-4-en-1-one (**22**). Oxidation of **22** gives 4-(2-furoyl)-1,2,3,4-tetrahydro-4-phenyl-1-pivaloyl-2-quinolinol, which on Boreh reduction gives 4-methylamino-1-(2-furanyl)-2-phenyl-2-(2-pivaloylamidophenyl)butan-1-one (**24**) and 2-(2-furanyl)-1-methyl-3-phenyl-3-(2-pivaloylamidophenyl)pyrrolidine. Compound **24** is a potential advanced intermediate for the synthesis of compounds related to **3**. Experiments directed to the incorporation of a methoxyl or methylthio substituent at the C-5 position of the furan ring of **24** are also described.

DAVID AARON SCHWARTZ et PETER YATES. Can. J. Chem. **61**, 1126 (1983).

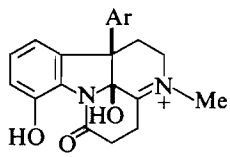
On décrit des méthodes de synthèse des composés apparentés à l'unité acide aryl-7 [(hydroxy-1 amino-2 phényl)-3] méthylamino-9 dioxo-5,6 nonanoïque (**3**) de l'alcaloïde halophytine et son dibromhydrate. Le dianion du phényl(*o*-pivaloylamidophényl) méthane réagit avec le furanne-2 carboxaldéhyde en donnant un alcool qui, par oxydation, conduit à la (furannyl-2)-1 phényl-2 (pivaloylamido-2 phényle)-2 éthanone (**14**). Cette dernière, par allylation, conduit à l'allyloxy-1 (furannyl-2)-1 phényl-2 (pivaloylamido-2 phényl)-2 éthène (**20**) qui, par chauffage à 80–95°C, subit une réaction de Diels–Alder intramoléculaire. Le chauffage du produit obtenu ou du composé **20** à 165°C les transforme en un produit C-allylé du composé **14**, la (furannyl-2)-1 phényl-2 (pivaloylamido-2 phényl)-2 pentène-4 one-1 (**22**). L'oxydation du composé **22** donne le (furonyl-2)-4 tétrahydro-1,2,3,4 phényl-4 pivaloyl-1 quinolénol-2 qui, par une réduction de Boreh, donne la méthylamino-4 (furannyl-2)-2 phényl-2 (pivaloylamido-2 phényl)-2 butanone-1 (**24**) et la (furannyl-2)-2 méthyl-1-phényl-3 (pivaloylamido-2 phényl)-3 pyrrolidine. Le composé **24** est un intermédiaire avancé potentiel pour la synthèse des composés apparentés au composé **3**. On décrit également des expériences portant sur l'incorporation d'un substituant méthoxyl ou méthylthio en position C-5 du cycle furanne du composé **24**.

[Traduit par le journal]

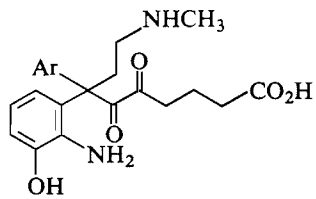
We have discussed in the previous paper in this series (1) the presence of the moieties **1** and **2** in the structures of the alkaloid haplophytine and its dihydrobromide, respectively, and the relationship of these to compounds of type **3**. In an approach to the synthesis of haplophytine we undertook studies of the synthesis of compounds of type **4**, which are closely related models of **3**, and have described the synthesis of compounds **5** and **6**. These contain the amino (X) and α-oxoglutaryl (Y) residues



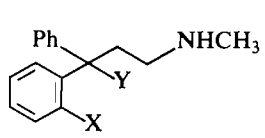
1

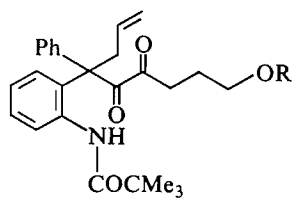


2



3





4 X = NH_2 equivalent
Y = $COCOCH_2CH_2CO_2H$ equivalent

5 R = H
6 R = Me

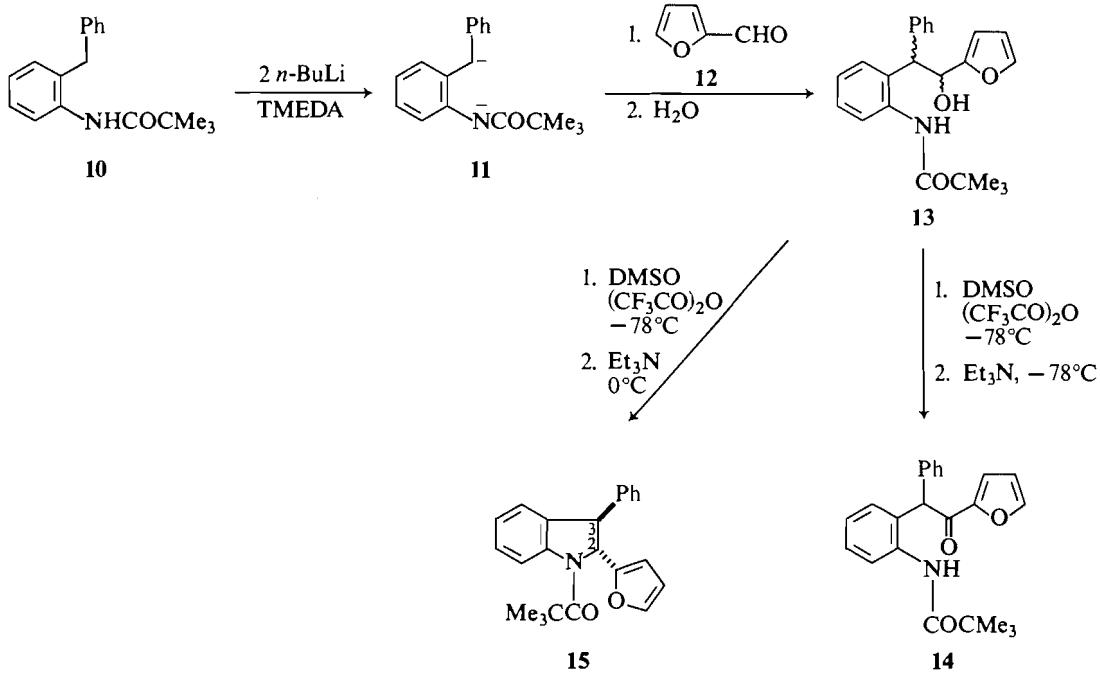
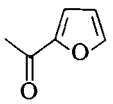


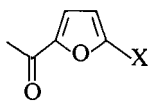
SCHEME 1

of **4**, but we were unable to convert the allyl group of **5** or **6** to the 2-(methylamino)ethyl group of **4**.

We now describe the synthesis of a compound of type **4** in which the group Y is an α-furoyl group **7**, which it is anticipated will serve as an equivalent of the -$COCOCH_2CH_2CHO$ group, itself an equivalent via oxidation of the α-oxoglutaryl group (Y).[2] We also discuss experiments directed towards the



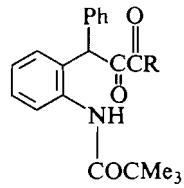
7



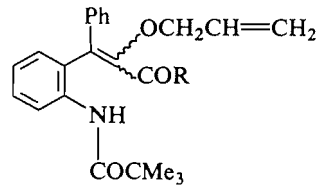
8 X = OMe
9 Y = SMe

incorporation of 5-substituted α-furoyl groups of type **8** and **9**, which would serve as α-oxoglutaryl equivalents without need of further oxidation.

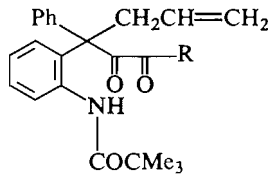
The dianion **11** was formed from *o*-pivaloylamidodiphenylmethane (**10**) and two equivalents of *n*-butyllithium/TMEDA or of lithium diisopropylamide in tetrahydrofuran at −20°C (1). Treatment with 2-furancarboxaldehyde (**12**) gave a 1:1 mixture of diastereomeric alcohols **13** in 98% yield (Scheme 1). The oxidation of **13** to the corresponding ketone **14** was attempted with silver carbonate on Celite (3) but this did not affect **13**. Success was achieved by addition of **13** to a solution of dimethyl sulfoxide and trifluoroacetic anhydride followed by addition of triethylamine, both at −78°C (4); the ketone **14** was thus obtained in 99% yield.[3] If the reaction mixture was allowed to warm to 0°C before addition of the triethylamine, the indoline **15** was formed as a single diastereomer, considered to have the *trans* configuration. The structural assignments **13**–**15** are based on spectroscopic data (see Experimental) as are those of other products discussed in the sequel. In the case of **15** some comment is appropriate. In its ^1H nmr spectrum two one-proton broadened singlets at δ 4.42 and 5.60 ppm are assigned to the C-2 and C-3 protons, respectively: the band widths indicate that they are coupled with $J = 1-1.5$ Hz. Anet and Muchowski (6) have observed that for 2,3-dimethylindoline $J_{2,3\text{-}cis} = 8.83$ Hz and $J_{2,3\text{-}trans} = 8.85$ Hz, but that on substitution of a conjugative group on the nitrogen, $J_{2,3\text{-}trans}$ decreases to 2.7–3.0 Hz while $J_{2,3\text{-}cis}$ is little changed (8.6–8.7 Hz); we therefore assign the *trans* configuration to **15** which is in accord with the following mechanistic proposal.



17



18



19

We interpret the formation of the indoline **15** as involving formation of the carbonium ion **16** from **13** (Scheme 2). This interpretation is substantiated by the fact that on addition of trifluoroacetic anhydride to a solution of **13** in deuteriochloroform the indoline **15** is formed as shown by ^1H nmr spectroscopy.

We have previously introduced an allyl group at the benzylic carbon of compounds of type **17** by reaction with allyl bromide and sodium carbonate in aqueous solution at 25°C to give an

[2]For example, cf. ref. 2.

[3]Another attempt to form the ketone **14** directly from the dianion **11** by treatment with methyl furan-2-carboxylate at −78°C led only to the recovery of starting materials, most probably because of deprotonation at the C-5 position of the furan by the dianion (5).

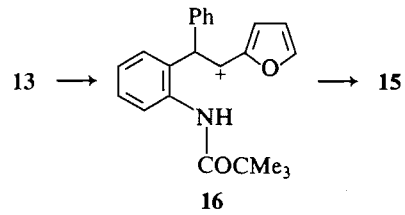
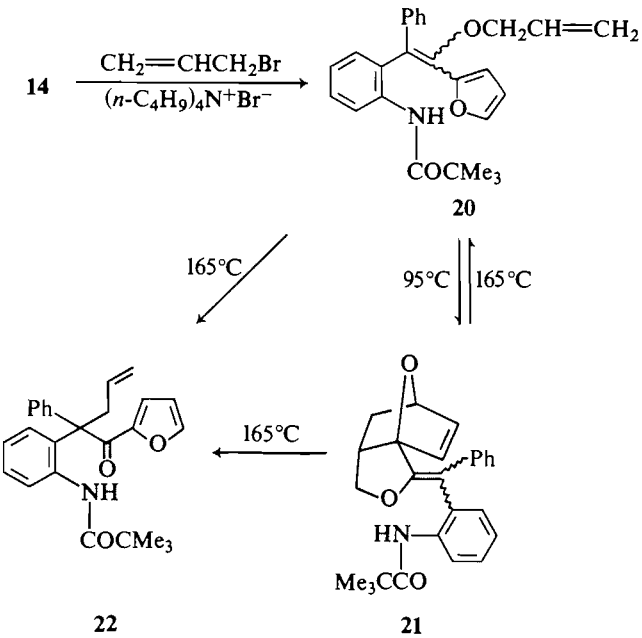


SCHEME 2



SCHEME 3

O-allyl vinyl ether of type **18** followed by thermolytic conversion of this to the C-allyl derivative **19** (1). In the case of **14** these reagents were ineffective for O-allylation, even at elevated temperatures. However, phase transfer alkylation (7) with tetra-*n*-butylammonium bromide as catalyst gave the O-allylation product **20** as a 7:3 mixture of geometrical isomers in 95% yield (Scheme 3). Thermolysis of **20** in toluene at 95°C led not to the desired C-allyl isomer but gave the intramolecular Diels–Alder adduct **21** as a mixture of stereoisomers; the same product was formed from **20** in boiling benzene. It was considered that this cycloaddition reaction would be reversible and that at higher temperatures such reversal might be followed by irreversible Claisen rearrangement to the desired C-allyl product. In fact it was found that heating of the mixture of stereoisomers **21** in mesitylene at 165°C gave the C-allyl product **22** in 95% yield; direct thermolysis of **20** under these conditions also gave **22**.

We next turned to the conversion of the allyl group to the 2-(methylamino)ethyl group. Attempted oxidative cleavage of the ethylenic double bond of **22** with ozone at −78°C led to degradation, but treatment with 2 equivalents of sodium periodate and a catalytic amount of osmium tetroxide (8) gave the hemiaminal **23** as a single diastereomer[4] in 91% yield (Scheme 4). Reaction of this with five molar equivalents of methylamine hydrochloride and one molar equivalent (three hydride equivalents) of sodium cyanoborohydride in methanol gave instead of the desired amine **24** a mixture of diastereomeric pyrrolidines **26**. This must have arisen via normal reductive amination (9) of **23** to **24** followed by a second reductive amination involving the intramolecular formation of the immonium ion **25**. In order to limit the occurrence of the second reductive amination, the hemiaminal **23** was treated with 25 molar equivalents of methylamine hydrochloride and 1.5 hydride equivalents of sodium cyanoborohydride. Under these conditions a 2:1 mixture of **24** and the diastereomeric pyrrolidines **26** was obtained from which the desired product **24** could be cleanly separated by chromatography.

Compound **24** represented our immediate synthetic goal since it contains the carbon skeleton of **4** with nitrogen and oxygen substituents appropriately situated. As noted earlier, the α-furoyl system is a latent α-oxoglutaryl group as required. However, its oxidation state is lower than that of the α-oxoglutaryl group and its successful utilization for further elaboration will require at some stage an increase in the oxidation state of the carbon atom corresponding to C-5 of the α-furoyl system. Of the several stages at which such a change might be effected, one could involve incorporating a suitable substituent at C-5 in the furan system before it is treated with the dianion **11**, and another could involve such incorporation immediately prior to manipulation of the allyl group. We conclude by describing approaches of these two types.

5-Methoxy-2-furancarboxaldehyde (**28**) was prepared from methyl 5-methoxy-2-furancarboxylate (**27**) (10) as outlined in Scheme 5. Reaction of **28** with the dianion **11** gave a mixture of diastereomeric alcohols **29**, the analogues of **13**, but oxidation of **29** under the conditions that had previously been used for the oxidation of **13** to the corresponding ketone **14** gave only the indoline **30**, as a single diastereomer (cf. **15**). The methoxyl group must sufficiently stabilize the carbonium ion analogue of **16**, which gives rise to **30** (cf. Scheme 2), to lead to formation of **30** even when the reaction is performed at −78°C. The synthesis of the ketone **31** was achieved in 50% yield by treatment of the ester **27** with the dianion **11**; here, in contrast to the case of methyl furan-2-carboxylate, the furan has no α hydrogen atom and proton exchange does not preempt attack of the dianion on the ester group. However, treatment of the ketone **31** under the phase transfer conditions that had previously been used successfully for the O-allylation of ketone **14** (Scheme 3) was ineffective in this case, as were the liquid–solid phase transfer conditions of Makosza and coworkers (11).

We were able to prepare an analogue of **22** with the C-5 carbon atom of the furan ring in a higher oxidation state by direct introduction of a methylthio substituent at this carbon as shown in Scheme 6. Compound **22** was converted to its dianion **32** and this was treated with dimethyl disulfide to give the methylthio derivative **33**. But we were unable to convert the allyl group of this to a 2(methylamino)ethyl group: attempted oxidative cleavage of the ethylenic double bond with osmium tetroxide and sodium periodate, as in the conversion of **22** to **23**, or with osmium tetroxide and *N*-methylmorpholine *N*-oxide (12) led to extensive destruction of the molecule presumably due to concomitant oxidation of the (methylthio)furan system.

Experimental

Melting points are uncorrected. Unless otherwise specified, the ir spectra were recorded for $CHCl_3$ solutions and the ^1H and ^{13}C nmr spectra for $CDCl_3$ solutions. Mass spectra were recorded at 70 eV and peak positions (m/e) are followed by relative abundances in parenthe-

[4]This is considered to have the phenyl group *trans* to the hydroxyl group as in the case of its 4-carbomethoxy analogue (1).

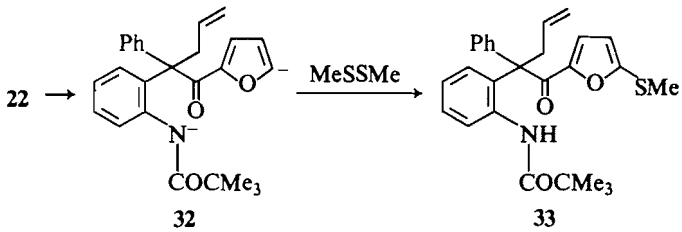

SCHEME 6

ses. Preparative thin layer chromatography was carried out on 20 × 20 × 1-mm or 20 × 20 × 2-mm Merck silica gel "60 PF_{254}" plates with uv visualization; the bands were extracted with MeOH, the residues obtained after filtration and evaporation were slurried with $CHCl_3$, and the solutions were filtered and evaporated to give the products. Solutions in organic solvents were dried over anhydrous $MgSO_4$ and evaporated by means of a rotary evaporator at water aspirator pressure.

*1-(2-Furanyl)-2-phenyl-2-(2-pivaloylamidophenyl)ethanol (**13**)*[5]

To a solution of dianion **11**, formed from amide **10** (4.00 g, 15 mmol), TMEDA (4.52 mL, 30 mmol), and 2.15 *M* *n*-BuLi in *n*-hexane (14.0 mL, 30 mmol) in THF (30 mL) at −30°C (1) was added 2-furancarboxaldehyde (**12**) (2.0 mL, 24 mmol) over 3 min. The color of the dianion was discharged upon completion of addition of the aldehyde. The reaction mixture was allowed to warm to room temperature. The standard work-up procedure (1) yielded 5.40 g (97%) of a crude mixture of diastereomeric alcohols **13** as a colorless oil. Crystallization from hexane–benzene yielded a single diastereomer, mp 127–128°C; ir λ_{max}: 3.00 (m), 6.00 μm; ^{1}H nmr δ: 1.27 (s, 9H), 3.2 (br s, 1H; D_2O exchangeable), 4.67 (d, J = 9 Hz, 1H), 5.43 (d, J = 9 Hz, 1H), 6.1 (m, 2H), 7.1–7.7 (m, 10H), 8.10 (br s, 1H); ^{13}C nmr δ: 27.6 (q), 39.4 (s), 51.1 (d), 70.5 (d), 107.6 (d), 110.2 (d), 125.5, 125.8, 126.8, 127.2, 128.4, 128.7, 128.8, 129.5, 134.3, 136.6, 140.1 (s), 141.7 (d), 155.2 (s), 177.4 (s); *m/e*: 363 (<1), 266 (100). *Anal.* calcd. for $C_{23}H_{25}NO_3$: C 76.00, H 6.93, N 3.85; found: C 75.62, H 6.93, N 3.70.

*1-(2-Furanyl)-2-phenyl-2-(2-pivaloylamidophenyl)ethanone (**14**)*[5]

To a solution of dimethyl sulfoxide (2.40 mL, 33.9 mmol) in dichloromethane (40 mL) cooled to −65°C was added dropwise with stirring a solution of trifluoroacetic anhydride (3.50 mL, 24.8 mmol) in dichloromethane (10 mL) at −60°C. After 15 min a solution of alcohol **13** (5.97 g, 16.4 mmol) in dichloromethane (10 mL) was added at −60°C. After a further 30 min trimethylamine (8 mL) was added at −60°C and stirring was continued for 5 min and the mixture

[5]This experiment was conducted under rigorously anhydrous conditions under a positive pressure of nitrogen.

was then allowed to warm to 23°C. Water (30 mL) was added, the phases were separated, and the organic layer was washed with saturated aqueous ammonium chloride (2 × 30 mL). The combined aqueous solutions were back-extracted with dichloromethane (30 mL). The combined organic extracts were dried and the solvent was removed to yield crude **14** (5.90 g, 99%) as a solid. Recrystallization from hexanes – ethyl acetate provided an analytical sample as colorless crystals, mp 176–177°C; ir λ_{max}: 3.00 (w), 5.99 μm; ^{1}H nmr δ: 1.00 (s, 9H), 5.98 (s, 1H), 6.53 (dd, J = 3.5–1.5 Hz, 1H), 7.0–7.5 (m, 9H), 7.6 (m, 1H), 7.9 (m, 1H), 8.5 (br s, 1H); ^{13}C nmr δ: 27.2 (q), 39.4 (s), 47.0 (d), 104.1 (d), 113.1 (d), 119.8, 125.1, 125.9, 127.3, 128.2, 128.7, 132.0, 136.9, 137.4, 147.8 (d), 152.5 (s), 177.0 (s), 189.3 (s); m/e: 361 (50), 266 (100). *Anal.* calcd. for $C_{23}H_{23}NO_3$: C 76.43, H 6.41, N 3.88; found: C 76.24, H 6.50, N 3.72.

*2-(2-Furanyl)-3-phenyl-1-pivaloylindoline (**15**)*[5]

Method A

A solution of trifluoroacetic anhydride (0.584 mL, 4.13 mmol) in dichloromethane (2 mL) was added dropwise to a stirred solution of dimethyl sulfoxide (0.390 mL, 5.51 mmol) in dichloromethane (10 mL) at −60°C. The reaction mixture was stirred at −60°C for 10 min and a solution of alcohol **13** (1.00 g, 2.75 mmol) in dichloromethane (7 mL) was added dropwise. The reaction mixture was stirred at −60°C for 10 min and allowed to warm to 0°C and then triethylamine (2 mL) was added. The reaction mixture was warmed to room temperature and washed with saturated aqueous ammonium chloride (2 × 10 mL). The organic solution was dried and concentrated to yield **15** (850 mg, 89%) as an oil; ir λ_{max}: 6.10 μm; ^{1}H nmr δ: 1.07 (s, 9H), 4.42 (br s, 1H), 5.62 (br s, 1H), 5.96 (d, J = 3 Hz, 1H), 6.15 (dd, J = 3, 2Hz, 1H), 6.9–8.2 (m, 9H), 8.27 (br d, J = 7 Hz, 1H); m/e: 345 (80), 255 (100). *Accurate mass* calcd. for $C_{23}H_{23}NO_2$: 345.1729; found: 345.1729.

Method B

A ^{1}H nmr tube was charged with alcohol **13** (50 mg) and deuteriochloroform containing 1% tetramethylsilane (~1 mL). Trifluoroacetic anhydride (0.25 mL) was added and the tube was shaken. The reaction mixture became deep blue in color. An ^{1}H nmr spectrum taken subsequently was identical to that of the product from Method A.

*1-Allyloxy-1-(2-furanyl)-2-phenyl-2-(2-pivaloylamidophenyl)ethene (**20**)*

A solution of ketone **14** (2.965 g, 8.2 mmol) and allyl bromide (1.0 mL, 11.6 mmol) in dichloromethane (25 mL) was added to a solution of sodium hydroxide (0.355 g, 8.88 mmol) and tetra-*n*-butylammonium bromide (0.55 g, 1.5 mmol) in water (25 mL). The heterogeneous mixture was stirred under nitrogen rapidly at 23°C for 18 h. The phases were separated and the aqueous phase was extracted with dichloromethane (15 mL). The combined organic solutions were concentrated to yield an oil. Treatment with ether (150 mL) effected precipitation of tetra-*n*-butylammonium bromide. Magnesium sulfate was added and the solution was filtered and concentrated to yield crude **20** (3.29 g, 99%) as an oil; ir λ_{max}: 2.90 (w), 5.96 μm; ^{1}H nmr δ: 1.08 and 1.18 (2 s, 9H), 4.15 and 4.33 (2 dd, J = 5, 1 Hz, 2H), 4.8–6.3 (m, 5H), 6.9–7.6 (m, 10H), 8.0–8.15 (m, 1H); m/e: 401 (26), 101 (100).

*6-[Phenyl(2-pivaloylamidophenyl)methylene]-5,10-dioxatricyclo-[4.2.1.0^{3,7}]dec-8-ene (**21**)*

A solution of allyl enol ethers **20** (600 mg, 1.5 mmol) in benzene was boiled under reflux under nitrogen for 26 h. The solution was allowed to cool to room temperature and the solvent was removed to yield an oil. The ^{1}H nmr analysis indicated the presence of three components. Compound **21** was isolated as a white crystalline solid (280 mg, 47%) by crystallization from hexanes – ethyl acetate; mp 156–158°C; ir λ_{max}: 2.95 (w), 5.96 μm; ^{1}H nmr δ: 1.20 (s, 9H), 1.3–2.6 (m, 2H), 3.83 (dd, J = 10, 8 Hz, 1H), 4.50 (t, J = 8 Hz, 1H), 5.22 (dd, J = 4, 2 Hz, 1H), 5.75 (d, J = 6 Hz, 1H), 6.20 (dd, J = 6, 2 Hz, 1H), 7.0–7.4 (m, 9H), 7.9 (br s, 1H), 8.15 (br d, J = 7 Hz, 1H); ^{13}C nmr δ: 27.5 (q), 30.4 (t), 39.5 (s), 45.9 (d), 74.7 (t), 81.2 (d), 90.0 (s), 121.9, 123.9, 127.0, 127.7, 128.3, 128.6, 129.8, 130.1, 130.7, 134.1, 135.4, 137.5, 176.3 (s); m/e: 401 (7), 180 (100). *Anal.* calcd. for $C_{26}H_{27}NO_3$: N 3.49; found: N 3.44.

*1-(2-Furanyl)-2-phenyl-2-(pivaloylamidophenyl)pent-4-en-1-one (**22**)*

A solution of allyl enol ethers **20** (5.37 g, 13.4 mmol) in mesitylene (55 mL) under nitrogen was immersed in an oil bath at 165°C for 3.5 h. The solution was then allowed to cool to room temperature and the solvent was removed to yield an oil. This was dissolved in hexanes – ethyl acetate (4:1) and eluted through a plug of silica gel (50 g) with hexanes – ethyl acetate. The eluate was concentrated to yield **22** as an oil (4.64 g, 86%), which crystallized on standing. Recrystallization from hexanes – ethyl acetate provided an analytical sample, mp 105–106°C; ir λ_{max}: 2.96, 6.00 μm; ^{1}H nmr δ: 0.90 (s, 9H), 3.38 (dd, J = 8, 2 Hz, 2H), 4.7–5.6 (m, 3H), 6.27 (dd, J = 4, 2 Hz, 1H), 6.75 (d, J = 4 Hz, 1H), 7.0–7.4 (m, 9H), 7.6–8.1 (m, 2H); ^{13}C nmr δ: 26.8 (q), 39.5 (s), 43.2 (t), 61.7 (s), 111.9 (d), 118.9, 119.9, 124.5, 125.2, 127.4, 128.0, 128.6, 128.9, 129.8, 130.4, 133.2, 137.5, 139.1, 145.8 (d), 151.6 (s), 176.4 (s), 187.9 (s); m/e: 401 (5), 180 (100). *Anal.* calcd. for $C_{26}H_{27}NO_3$: C 77.78, H 6.78, N 3.49; found: C 77.52, H 6.83, N 3.44.

*4-(2-Furoyl)-1,2,3,4-tetrahydro-4-phenyl-1-pivaloyl-2-quinolinol (**23**)*

To a stirred solution of olefin **22** (0.693, 1.72 mmol) in ether (15 mL) were added sequentially water (15 mL), osmium tetroxide (40 mg), and sodium periodate (0.734 g, 3.43 mmol) and the reaction mixture was stirred for 19 h at room temperature. The phases were separated and the ethereal solution was washed with water (10 mL). The combined aqueous solutions were back-extracted with ether (15 mL). The combined ethereal solutions were washed with aqueous 5% sodium hydroxide solution (2 × 15 mL), dried, and concentrated to yield **23** (635 mg, 91%) as a fluffy white solid, mp 147–149°C; ir λ_{max}: 2.70 (w), 6.00, 6.14 μm; ^{1}H nmr δ: 1.03 (s, 9H), 2.07 (dd, J = 13, 7 Hz, 1H), 3.50 (dd, J = 13, 7 Hz, 1H), 4.15 (br s, 1H; D_2O exchangeable), 5.75 (td, J = 7, 2.5 Hz, 1H), 6.35 (dd, J = 4, 2 Hz, 1H), 6.8–7.5 (m, 11H); ^{13}C nmr δ: 29.6 (q), 42.3 (s), 43.3 (t), 58.6 (s), 79.2(d), 112.0 (d), 119.8 (d), 125.5, 125.7, 126.9, 127.3, 127.6, 128.1, 128.3, 128.8, 136.4, 139.2, 146.0 (d), 152.4 (s), 185.2 (s), 187.0 (s); m/e: 403 (10), 306 (100). *Anal.* calcd. for $C_{25}H_{25}NO_4$: N 3.58; found: N 3.45.

*2-(2-Furanyl)-1-methyl-3-phenyl-3-(2-pivaloylamidophenyl)pyrrolidine (**26**)*

The general method of Borch *et al.* (9) was followed. A solution of hemiaminal **23** (0.052 g, 0.129 mmol), methylamine hydrochloride (0.045 g, 0.667 mmol), and sodium cyanoborohydride (0.009 g, 0.143 mmol) in methanol (5 mL) under nitrogen was allowed to stand overnight over 3 Å molecular sieves. The methanolic solution was decanted from the molecular sieves, the sieves were washed with methanol (3 × 5 mL), and the washings were decanted. The combined methanolic solution and washings were concentrated and the residue was treated with 1 *N* hydrochloric acid (5 mL) and extracted with ether (15 mL). The ethereal extract was extracted with 1 *N* hydrochloric acid (15 mL) and the combined acidic solutions were basified with powdered potassium hydroxide and extracted with ether (2 × 15 mL). The combined ethereal extracts were dried and concentrated to yield **26** (0.030 mg, 50%) as a colorless oil; ir λ_{max}: 2.92 (w), 5.97 μm; ^{1}H nmr δ: 0.90 and 1.08 (2 s, 9H), 2.18 and 2.45 (2 s, 3H), 2.0–3.4 (m, 4H), 4.25 and 4.662 (s, 1H), 5.15 and 5.80 (2 d, J = 3 Hz, 1H), 6.0 (dd, J = 3, 2 Hz, 1H), 6.6–8.0 (m, 11H); m/e: 402 (100). *Accurate mass* calcd. for $C_{26}H_{30}N_2O_2$: 402.2307; found: 402.2308.

*4-Methylamino-1-(2-furanyl)-2-phenyl-2-(2-pivaloylamidophenyl)-butan-1-one (**24**)*[5]

A solution of hemiaminal **23** (0.10 g, 0.25 mmol), methylamine hydrochloride (0.418 g, 6.19 mmol), and sodium cyanoborohydride (0.008 g, 0.127 mmol) in methanol (10 mL) was stirred overnight at room temperature. The reaction mixture was worked-up as in the case of **26** to yield an acid-soluble fraction as an oil that contained a 2:1 mixture of **24** and **26** by ^{1}H nmr spectroscopic analysis. Preparative thin-layer chromatography on silica gel with hexanes–ether (1:1) as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

eluant gave **24** (R_f = 0, 20 mg, 20%) as a pale brown oil; ir λ_{max}: 2.95 (w), 6.00 μm; ^{1}H nmr δ: 1.31 (s, 9H), 2.2–3.2 (m, 4H), 2.67 (s, 3H), 6.05 (dd, J = 3, 2 Hz, 1H), 6.40 (d, J = 4 Hz, 1H), 6.6 (m, 1H), 6.8–7.4 (m, 9H); m/e: 400 (M − H_2O; 14), 343 (100). *Accurate mass* calcd. for $C_{26}H_{28}N_2O_2$ (M − H_2O): 400.2151; found: 400.2152.

Methyl 5-methoxy-2-furancarboxylate (27)

This compound was prepared from methyl 5-bromo-2-furancarboxylate, sodium methoxide, and sodium iodide in methanol according to the method of Torii *et al.* (10). The crude product was sublimed in a Kugelrohr appratus at 90–100°C/0.025 Torr; mp 50–51°C (lit. (10) 51–52°C); ir λ_{max}: 5.80 μm; ^{1}H nmr δ: 3.80 (s, 3H), 3.94 (s, 3H), 5.29 (d, J = 4 Hz, 1H), 7.08 (d, J = 4 Hz, 1H).

5-Methoxy-2-furancarboxaldehyde (28)

5-Methoxy-2-furanmethanol was prepared in 61% yield by lithium aluminum hydride reduction of the ester **27** in ether according to the method of Manly and Amstutz (13). The crude product was used directly in the subsequent step; ^{1}H nmr δ: 3.20 (br s, 1H; D_2O exchangeable), 3.80 (s, 3H), 4.37 (s, 2H), 5.05 (d, J = 3.5 Hz, 1H), 6.08 (d, J = 3.5 Hz, 1H).

Activated manganese dioxide (9.0 g) was added to a solution of the alcohol (0.880 g, 7.86 mmol) in dichloromethane (80 mL) and the reaction mixture was stirred for 16 h at room temperature. Celite was added and the reaction mixture was filtered. The filtrate was concentrated to yield aldehyde **28** (600 mg, 69%) as a colorless oil. The oil was molecularly distilled; bp 110–120°C/15 Torr; ir λ_{max}: 5.95 μm; ^{1}H nmr δ: 4.04 (s, 3H), 5.48 (d, J = 4 Hz, 1H), 7.20 (d, J = 4 Hz, 1H), 9.30 (s, 1H).

1-(2-(5-Methoxy)furanyl)-2-phenyl-2-(2-pivaloylamidophenyl)ethanol (29)[5]

To a stirred solution of dianion **11**, formed from amide **10** (0.250 g, 0.936 mmol), TMEDA (0.285 mL, 0.93 mmol), and 2.20 *M* *n*-BuLi in *n*-hexane (0.85 mL, 0.93 mmol) in THF (5 mL) at −30°C (1) was added a solution of **28** (0.118 g, 0.936 mmol) in THF (1.5 mL). The reaction mixture was stirred at −30°C for 30 min and at room temperature for 1 h. The standard work-up procedure (1) yielded **29** (0.312 g, 85%) as a colorless oil; ir λ_{max}: 2.90 (w), 5.96 μm; ^{1}H nmr δ: 1.10 (2 s, 9H), 2.3 (br s, 1H), 3.68 (2 s, 3H), 4.4–5.5 (m, 3H), 5.84 (d, J = 4 Hz, 1H), 6.8–7.6 (m, 9H), 8.3 (br s, 1H); m/e: 393 (<1), 266 (100). *Accurate mass* calcd. for $C_{24}H_{27}NO_4$: 393.1940; found: 393.1940.

2-(2-(5-Methoxy)furanyl)-3-phenyl-1-pivaloylindoline (30)[5]

A solution of trifluoroacetic anhydride (0.030 mL, 0.21 mmol) in dichloromethane (1 mL) was added dropwise to a stirred solution of dimethyl sulfoxide (0.018 mL, 0.25 mmol) in dichloromethane (5 mL) at −60°C. The mixture was stirred for 10 min and a solution of alcohol **29** (50 mg, 0.13 mmol) in dichloromethane (1 mL) was added dropwise at −60°C. After 20 min triethylamine (0.5 mL) was added at −60°C. The reaction mixture was allowed to warm to room temperature and stirred for 10 min. It was then washed with water (10 mL) and saturated aqueous ammonium chloride (10 mL), dried, and concentrated to yield **30** (36 mg, 75%) as a yellow oil; ir λ_{max}: 6.10 μm; ^{1}H nmr δ: 1.10 (s, 9H), 3.80 (s, 3H), 4.40 (br s, 1H), 4.90 (d, J = 4 Hz, 1H), 5.45 (br s, 1H), 5.84 (d, J = 4 Hz, 1H), 6.9–8.4 (m, 9H).

1-[2-(5-Methoxy)furanyl]-2-phenyl-2-(2-pivaloylamidophenyl)-ethanone (31)[5]

A solution of dianion **11**, formed from amide **10** (0.200 g, 0.75 mmol), TMEDA (0.230 mL, 1.53 mmol), and 2.05 *M* *n*-BuLi in *n*-hexane (0.80 mL, 1.64 mmol) in THF (5 mL) at −30°C (1) was added dropwise by cannula to a stirred solution of ester **27** (0.215 g, 1.49 mmol) in THF (5 mL) at −70°C. The reaction mixture became red-brown and was then stirred for 15 min. Saturated aqueous ammonium chloride (10 mL) was added and the heterogeneous mixture was extracted with ether (2 × 20 mL). The combined ethereal extracts were washed with saturated aqueous ammonium chloride (10 mL), dried, and concentrated. The residue was chromatographed on silica gel with hexanes – ethyl acetate as eluant to yield **31** (0.146 g, 50%) as a yellow oil. Crystallization from hexanes – ethyl acetate gave an analytical sample, mp 136–138°C; ir λ_{max}: 3.00 (w), 6.00 μm; ^{1}H nmr δ: 0.98 (s, 9H), 3.93 (s, 3H), 5.43 (d, J = 4 Hz, 1H), 5.78 (s, 1H), 6.9–7.4 (m, 9H), 7.47 (d, J = 4 Hz, 1H), 7.95 (m, 1H); m/e: 391 (32), 125 (100). *Anal.* calcd. for $C_{24}H_{25}NO_4$: C 73.64, H 6.44, N 3.58; found: C 73.89, H 6.33, N 3.29.

1-[2-(5-Methylthio)furanyl]-2-phenyl-2-(2-pivaloylamidophenyl)pent-4-en-1-one (33)[5]

A 1.95 *M* solution of *n*-BuLi in *n*-hexane (0.970 mL, 1.89 mmol) was added dropwise to a stirred solution of diisopropylamine (0.263 mL, 1.88 mmol) in tetrahydrofuran (10 mL) at −20°C. The mixture was stirred at −20°C for 10 min and a solution of **22** (0.250 g, 0.623 mmol) in tetrahydrofuran was added dropwise, when the solution became brown. The reaction mixture was stirred at −20°C for 15 min and dimethyl disulfide (0.10 mL, 1.11 mmol) was added dropwise. The reaction mixture became light brown after standing for 30 min at −20°C and for 5 h at room temperature. Saturated aqueous ammonium chloride (10 mL) was added and the hetergeneous mixture was extracted with ether (2 × 15 mL). The combined ethereal extracts were washed with saturated aqueous ammonium chloride (10 mL), dried, and concentrated to give crude **33** (250 mg, 89%) as an oil; ir λ_{max}: 2.95 (w), 6.00 μm; ^{1}H nmr δ: 0.95 (s, 9H), 2.33 (s, 3H), 3.4 (br d, 2H), 4.75–5.80 (m, 3H), 6.20 (d, J = 4 Hz, 1H), 6.90 (d, J = 4 Hz, 1H), 7.0–8.2 (m, 10H); m/e: 447 (19), 141 (100). *Accurate mass* calcd. for $C_{27}H_{29}NO_3S$: 447.1868; found: 447.1853.

Synthesis and ^{31}P nmr spectra of the complex cations, *cis*-$[PtCl(L)(PEt_3)_2]^+$, L = theophylline, caffeine, or isocaffeine, and *cis*-$[Pt(isocaff)_2(PEt_3)_2]^{2+}$ are reported. The crystal structure of *cis*-$[PtCl(caffeine)(PEt_3)_2][BF_4]$ is determined, space group $P\bar{1}$, a = 1.1766(6), b = 1.4428(5), c = 0.9002(4) nm, α = 97.28(4)°, β = 97.69(4)°, γ = 100.96(5)°, D_m = 1.649 g cm^{-3}, the bond lengths are Pt—Cl = 233.4(4) pm, Pt—N = 215(1) pm, Pt—P = 225.4(5) pm (mean), and the residual R = 0.071. The crystal structure of *cis*-$[Pt(isocaffeine)_2(PEt_3)_2][BF_4]_2$ is orthorhombic, space group *Pbca*, a = 2.317(3), b = 1.717(3), c = 2.130(3) nm, D_m = 1.574 g cm^{-3}, with an opposing isocaffeine conformation, bond lengths Pt—N = 211(2) pm, Pt—P = 227.6(9) pm (mean), and R = 0.073. Both crystal structures contain approximately square planar Pt(II) coordination with the purine coordinated via an imidazole nitrogen. The structures are discussed as models for the possible involvement of N_7---O_6 chelation of guanine to platinum when platinum drugs act as antitumour agents, but there is no evidence that isocaffeine acts as an N_7---O_6 chelate.

GORDON WILLIAM BUSHNELL, RODERICK JAMES DENSMORE, KEITH ROGER DIXON et ARTHUR CHARLES RALFS. Can. J. Chem. **61**, 1132 (1983).

On rapporte la synthèse et les spectres de rmn du ^{31}P des cations complexes: $[PtCl(L)(PEt_3)_2]^+$ *cis*, L = théophylline, caféine ou isocaféine et $[Pt(isocaf)_2(PEt_3)_2]^{2+}$ *cis*. On a déterminé la structure du composé $[PtCl(caféine)PEt_3)_2][BF_4]$. Le cristal appartient au groupe d'espace $P\bar{1}$ avec a = 1,1766(6), b = 1,4428(5), c = 0,9002(4) nm, α = 97,28(4)°, β = 97,69(4)°, γ = 100,96(5)°, D_m = 1,649 g cm^{-3}. Les longueurs de liaison sont de Pt—Cl = 233,4(4) pm, Pt—N = 215(1) pm, Pt—P = 225,4(5) pm (moyenne) et la valeur conventionnelle de R est de 0,071. La structure cristalline du composé $[Pt(isocaféine)_2(PEt_3)_2][BF_4]_2$ *cis* est orthorhombique et appartient au groupe d'espace *Pbca* avec a = 2,317(3), b = 1,717(3), c = 2,130(3) nm, D_m = 1,574 g cm^{-3} avec une conformation isocaféine opposée. Les longueurs de liaison sont de Pt—N = 211(2) pm, Pt—P = 227,6(9) pm (moyenne) et R = 0,073. Dans chacune des deux structures cristallines, on retrouve du Pt(II) avec une coordination approximativement plan carrée avec la purine coordonnée au moyen de l'azote de l'imidazole. On discute des structures en tant que modèle pour l'implication de la chélation N_7---O_6 de la guanine sur le platine lorsque les drogues contenant du platine agissent comme agents antituméreux, mais il n'y a pas de preuve du fait que l'isocaféine agit comme un chélate N_7---O_6.

[Traduit par le journal]

Introduction

The use of platinum complexes as anti-tumour drugs is now well known and the subject has been extensively covered in recent reviews (1–5). One such complex, *cis*-$[PtCl_2(NH_3)_2]$, has passed into widespread clinical use (recent reports of the clinical status of the drug appear in a two-part issue (6)) but the design of more effective analogues, for example with greater solubility in body fluids and reduced toxicity, is hampered by the lack of detailed understanding of the mechanism of action of these drugs. It is widely accepted that the platinum becomes attached to DNA, most probably via coordination to the N_7 position of a guanine base, but the details of the attachment and the mechanism of its effect on the cancer cell are unknown. Several different models have been proposed (5, 7) and an especially important point is to account for the activity of *cis*-$[PtCl_2(NH_3)_2]$ relative to the corresponding *trans* isomer which is essentially inactive. An early proposal (8–12) which is still under discussion (5, 7, 13) involves chelation of the platinum by the N_7 and O_6 atoms of a guanine base attached to DNA. Assuming that it is the chloride ligands which are displaced by base coordination, such chelation is possible only for *cis*-$[PtCl_2(NH_3)_2]$ and not for the *trans* isomer (8–12).

Studies on model complexes have shown that unsubstituted purines normally coordinate to metals via the imidazole nitrogen atom which is protonated in the free, neutral ligand, i.e., N_9 for adenine, guanine, xanthine, and hypoxanthine and N_7 for theophylline. However, when N_9 is blocked, as it would be by the deoxyribose residue in DNA bound guanosine, N_7 is indeed the normal site of metal coordination (3).

any structural evidence for metal interaction with O_6 in addition to N_7, although chelation has been suggested several times from spectroscopic evidence (8–12). Indeed the only crystallographic demonstration of a direct O_6–metal interaction is in a copper complex of the theophyllinate anion and even here the bond is very weak, Cu—O = 292 pm (14). More definite chelate interactions have been observed in 6-thio-purine complexes of both copper, Cu—S = 242 pm (15), and palladium, Pd—S = 231 pm (16).

We have chosen to study this problem by a structural comparison of platinum complexes of the caffeine and isocaffeine molecules. Isocaffeine is a close model for the guanine base with the same possibilities for N_7—O_6 chelation but with the other sites blocked by methylation. Caffeine is isomeric but the different methylation pattern limits coordination to N_9 where no possibility of oxygen chelation exists. At the same time the presence of the methyl group on N_3 in caffeine permits a direct comparison of the Pt—O distance in the isocaffeine complex with the Pt—C(N_3) distance in the caffeine complex. This comparison is expected to reveal any shortening of Pt—O_6 or other geometrical distortions caused by Pt—O_6 bonding interactions.

Several crystallographic studies of transition metal caffeine complexes have been reported previously (17, 18). Structures of isocaffeine complexes are very few, but a recent paper (19) gives two crystal structures containing the ion $[Pt(en)(isocaff)_2]^{2+}$.

Results

(A) Synthesis and spectroscopy

The bridge cleavage reaction represented by eq. [1] is a convenient route to complexes of the general type [PtCl(L)(PEt_3)$_2$][BF_4], and under controlled conditions usually leads to exclusively *cis* stereochemistry (20).

[1] [$Pt_2(\mu\text{-}Cl)_2(PEt_3)_4$][$BF_4$]$_2$ + 2L → 2*cis*-[PtCl(L)(PEt_3)$_2$][BF_4]

Our preliminary results with a range of purines (L = guanine, hypoxanthine, adenine, and theophylline) indicated that crystals suitable for X-ray diffraction study were likely to be obtained only if L was highly substituted. Moreoever, ^{31}P nmr studies showed that complex mixtures, apparently involving coordination to several different nitrogen sites, resulted from reactions of unsubstituted purines. Even when L was theophylline several minor products were formed in addition to *cis*-[PtCl(theo)(PEt_3)$_2$][BF_4] which was identified as the main product by ^{31}P nmr (see Table 1). In view of these results we decided to focus our structural studies on the trimethylated purines, caffeine and isocaffeine.

Reaction of caffeine according to eq. [1] proceeded smoothly under mild conditions to yield *cis*-[PtCl(caff)(PEt_3)$_2$][BF_4] which was initially identified by microanalysis, and by infrared and nmr spectroscopy and finally by a full structure determination as described below. The infrared spectrum showed the expected caffeine, triethylphosphine, and fluoroborate absorptions together with ν(Pt—Cl) at 290 cm^{-1}. The ^{31}P nmr spectrum recorded at 24.3 MHz showed an AB quartet (δ_{AB} = 38.5 Hz) with ^{2}J(P—P), 20 Hz, typical of a *cis*-P_2Pt arrangement (21). Sidebands attributable to the 33.8% of molecules containing ^{195}Pt were also observed and, as is expected in this type of spin system (22), the sideband patterns were not identical to the centre-band. The effective chemical shifts introduced by the different phosphorus coupling constants to platinum ($\delta_{EFF} = \delta_{AB} \pm (1/2)\{^{1}J(Pt—P_A) - {}^{1}J(Pt—P_B)\}$) result in a low-field sideband which is essentially an AX double doublet, and an up-field sideband which is an AB system so closely coupled that only a single line is observed. The spectra of *cis*-[PtCl(theo)(PEt_3)$_2$][BF_4] and *cis*-[PtCl(isocaff)(PEt_3)$_2$]-[BF_4] which were identified only by nmr, were closely similar to that for the structurally characterised *cis*-[PtCl(caff)(PEt_3)$_2$]-[BF_4] complex and nmr parameters for all these molecules are collected in Table 1. The assignment of phosphorus resonances in this table is based on the assumption that the nmr *trans*-influence of nitrogen ligands is generally greater than that of chloride and hence the phosphorus *trans* to chloride will be the one with the larger ^{1}J(Pt—P) value (23). In the present case where the platinum–phosphorus coupling constants are fairly closely similar, the assignment should be treated with caution. The ^{1}H nmr of *cis*-[PtCl(caff)(PEt_3)$_2$][BF_4] showed the expected caffeine and triethylphosphine resonances in the correct relative intensities and is mainly notable for the ^{195}Pt sidebands observed on the caffeine H_8 resonance. The coupling constant (^{3}J(Pt—H) = 11.7 Hz) is a typical value for a proton α to a coordinated nitrogen (24) and confirms that the platinum is attached in the imidazole ring.

The reaction of isocaffeine with [$Pt_2Cl_2(PEt_3)_4$][BF_4]$_2$ was slightly more complex. ^{31}P nmr of the initial crude products showed the presence of a small amount of *cis*-[$PtCl_2(PEt_3)_2$] (δ_P −130.7 ppm, ^{1}J(Pt—P) 3509 Hz) together with two new compounds in an approximately 2:1 ratio. The more intense new

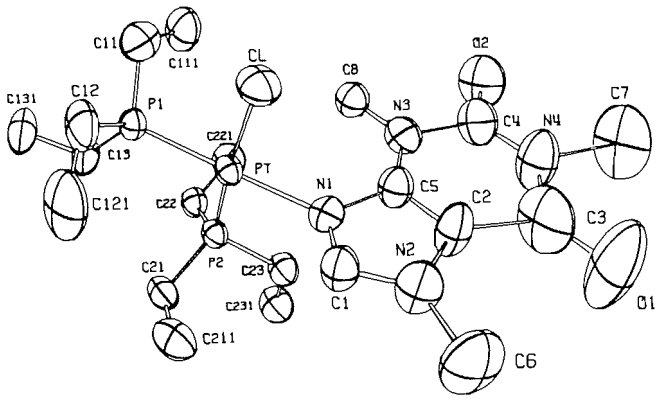

FIG. 1. The molecular structure of *cis*-[Pt(PEt$_3$)$_2$(caff)Cl][BF$_4$].

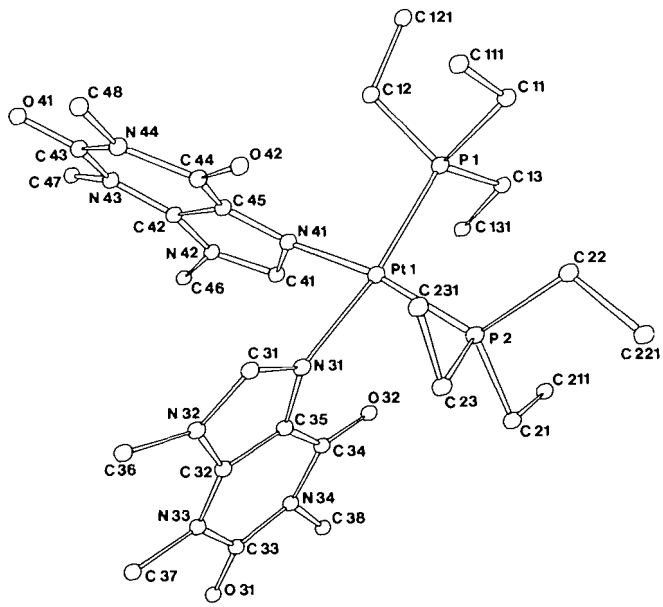

FIG. 2. The molecular structure of *cis*-[Pt(PEt$_3$)$_2$(isocaff)$_2$][BF$_4$]$_2$.

spectrum was very similar to that described above for the caffeine complex and is assigned to *cis*-[PtCl(isocaff)(PEt$_3$)$_2$]$^+$ while the less intense spectrum was a singlet with ^{195}Pt sidebands consistent with *cis*-[Pt(isocaff)$_2$(PEt$_3$)$_2$]$^{2+}$. An infrared spectrum of the mixture showed a ν(Pt—Cl) absorption at 275 cm^{-1}. However, various attempts at recrystallization to obtain high quality product for further analytical and crystallographic study resulted only in crystals of *cis*-[Pt(isocaff)$_2$(PEt$_3$)$_2$][BF$_4$]$_2$ and we were unable to obtain pure *cis*-[PtCl(isocaff)(PEt$_3$)$_2$]-[BF$_4$]. Mother liquors from these crystallizations contained no *cis*-[Pt(isocaff)$_2$(PEt$_3$)$_2$]$^{2+}$ but only *cis*-[PtCl(isocaff)(PEt$_3$)$_2$]$^+$ together with a much increased quantity of *cis*-[PtCl$_2$(PEt$_3$)$_2$]. Evidently *cis*-[PtCl(isocaff)(PEt$_3$)$_2$]$^+$ tends to disproportionate during crystallization and only the least soluble complex *cis*-[Pt(isocaff)$_2$(PEt$_3$)$_2$][BF$_4$]$_2$ is obtained.

(B) Description of structures

Both structures consist of discrete, essentially square planar cations and fluoroborate anions. The structures of the *cis*-[PtCl(caff)(PEt$_3$)$_2$]$^+$ and *cis*-[Pt(isocaff)$_2$(PEt$_3$)$_2$]$^{2+}$ cations are shown in Figs. 1 and 2 and the packing diagrams are given in Figs. 3 and 4. Fractional atomic coordinates, bond lengths, bond angles, and results of mean plane calculations are collected in Tables 2–9. Tables of anisotropic temperature parameters (Tables S12 and S13), mean plane coefficients (Tables S5 and S9), and bond lengths and angles of the BF$_4$ and PEt$_3$ groups (Tables S3, S4, S7, and S8) have been deposited for both structures.[2]

(i) cis-*[PtCl(caff)(PEt$_3$)$_2$][BF$_4$]*

The caffeine ligand is coordinated, as expected, through N$_9$ and is inclined at 97–98° (depending on the plane chosen for the ligand) to the coordination plane defined by the PtClP$_2$ unit. The platinum atom is significantly displaced (41.0 pm) from the plane of the imidazole ring. Similar displacements are not uncommon (e.g. [PtCl$_3$(caff)]$^-$, 4.9 pm (18), *cis*-[PtCl(naphthyridine)(PEt$_3$)$_2$]$^+$, 14.3 pm (25), and [CuCl$_2$(H$_2$O)(caff)], 31 pm (17)) but the present example seems unusually large. We have recently observed a similarly large displacement (34.8 pm) in a palladium pyrazole complex, *cis*-[PdCl(dimethylpyrazole)(PEt$_3$)$_2$]$^+$ (26). These displacements may simply be the result of steric factors such as interaction between the five-membered rings and the *cis*-PEt$_3$ ligands, but could also be indicative of some rehybridisation of the coordinating nitrogen. All the caffeine ligands in the crystal are parallel by symmetry and it may be seen in Fig. 3 that there is an intermolecular caffeine/caffeine contact halfway along the *b*-axis.

The bond lengths and bond angles within the caffeine ligand are essentially identical within experimental error with those reported previously in the complexes, [CuCl$_2$(H$_2$O)(caff)] (17) and [PtCl$_3$(caff)]$^-$ (18), the comparison with the latter being especially exact. The only slight discrepancy concerns the N$_7$—C$_8$—N$_9$ angle in the imidazole ring, where the present value of 109° is close to that found in [H(caff)]$^+$ (109.6°) rather than to the more usual value of 112–113° found in caffeine itself and in other N-bonded caffeine complexes (18). As in previous examples the caffeine shows significant departures from planarity, notably a slight dihedral angle (2.3°) between the 5- and 6-membered rings.

Within the platinum coordination sphere, the Pt—N distance is longer, 215 pm, in the present complex than in [PtCl$_3$(caff)]$^-$, 202 pm (18), reflecting the greater *trans* influence of phosphorus relative to chlorine. On the basis of *trans*-Pt—Cl bond lengths, the *trans* influence of caffeine itself has been suggested to be similar to that of simple nitrogen donors (18) and this view is confirmed by the Pt—P bond length *trans* to caffeine in the present complex. The value of 225.3 pm is very close to lengths observed *trans* to phenanthroline (27), naphthyridine (25), and phthalazine (28) ligands. Indeed, as Table 10 shows, the geometry of the *cis*-PtCl(PEt$_3$)$_2$ fragment remains very constant in a range of complexes and the *cis*-PdCl(PEt$_3$)$_2$ fragment in *cis*-[PdCl(dimethylpyrazole)(PEt$_3$)$_2$]$^+$ is also similar (26). The conformations of the triethylphosphine ligands are also the same in all these complexes.

(ii) cis-*[Pt(isocaff)$_2$(PEt$_3$)$_2$][BF$_4$]$_2$*

The two isocaffeine ligands are coordinated through N$_7$ and are inclined at 88.2 and 87.9° to the coordination plane defined by the PtP$_2$N$_2$ unit. The isocaffeines are arranged so that their 6-membered rings are away from each other, one above and one below the coordination plane. As in the *cis*-

[2]The structure factor tables for both **I** and **II** are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

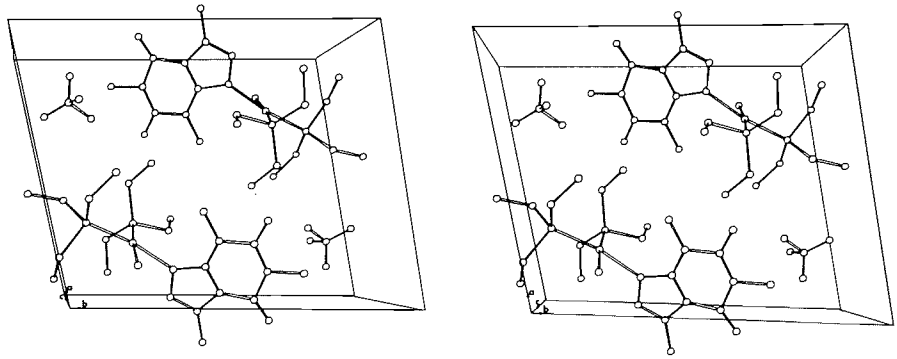

FIG. 3. The stereoscopic packing drawing for the caffeine complex, **I**.

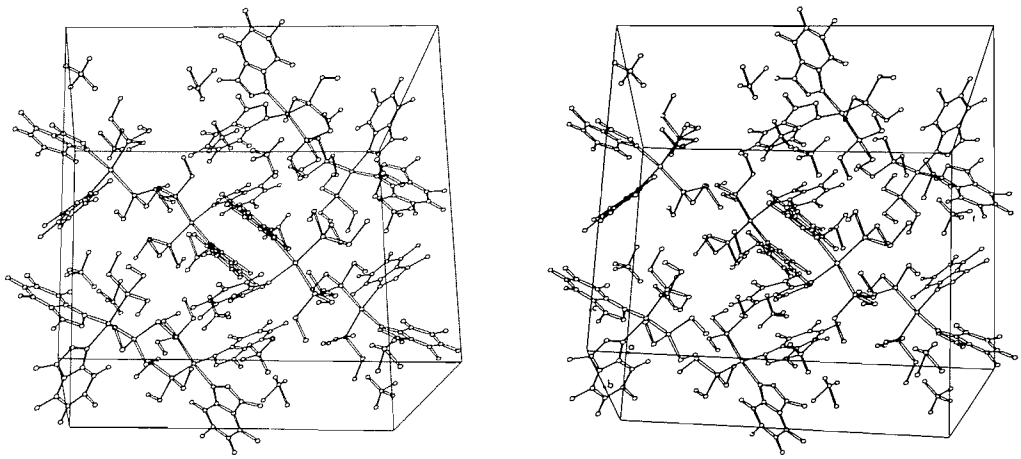

FIG. 4. The stereoscopic packing drawing for the isocaffeine complex, **II**.

$[PtCl(caff)(PEt_3)_2]^+$ structure the platinum atom is significantly displaced from the planes of the imidazole rings, by 22.6 pm from the more planar and by 44.7 pm from the less planar isocaffeine.

The bond lengths and bond angles in the isocaffeine ligands are generally similar within experimental error to those reported for the free ligand (29) but the puckering of the rings appears to be affected by coordination. One isocaffeine is fairly closely planar while the 5- and 6-membered rings in the other isocaffeine are inclined at ~8.9° to each other, possibly because of steric interactions with a PEt_3 ligand. Both base ligands of the complex are involved in intermolecular contacts with their planes parallel, as may be seen in Fig. 4. The hexafluorophosphate and nitrate salts of *cis*-$[Pt(en)(isocaff)_2]^{2+}$ studied by Orbell *et al.* (19) show structures similar to our isocaffeine complex in the general conformation of the *cis*-isocaffeine ligands and in departures of them from planarity, but differ in the base/base dihedral angles 70.6° (nitrate), 87.3° (hexafluorophosphate), 65.4° (this work). Hydrogen bonding cannot occur in our complex as it does in the structures containing ethylenediamine.

Within the platinum coordination sphere the Pt—N(isocaff) distances reported by Orbell *et al.* (19) are shorter than in *cis*-$[Pt(isocaff)_2(PEt_3)_2]^{2+}$ owing to the greater *trans* influence of PEt_3 over en, the mean values being 201.9(7) pm (19) and 211(1) pm (this work). The latter value is still slightly shorter than the corresponding distance, 215(1) pm, in the caffeine complex. If this is a reflection of greater donor strength towards platinum then it may explain the formation of the 2:1 complex in the isocaffeine/platinum case whereas we were able to obtain only the 1:1 complex for caffeine. Finally, we note that the geometry of the $Pt(PEt_3)_2$ unit in *cis*-$[Pt(isocaff)_2(PEt_3)_2]^{2+}$ is very similar to that in the complexes containing $PtCl(PEt_3)_2$ units (Table 10) and indeed the entire PtP_2N_2 geometry is closely comparable with other complexes containing $PtClNP_2$ and $PtCl_2P_2$ coordination spheres. The principal variable in these structures is the displacement of the coordinating nitrogen atom from the otherwise planar coordination geometry. In the phthalazine, naphthyridine, and phenanthroline complexes (Table 10), the displacement varies from 4 pm in *cis*-$[PtCl(phth)(PEt_3)_2]^+$ to 37 pm in *cis*-$[PtCl(phen)(PEt_3)_2]^+$. It correlates with the rate of metal shuttling between the two ligand nitrogens and serves as an index of potentially bidentate character (28). However, this does not appear to be a useful concept in the present case since the displacement (23 pm) in the caffeine complex, where there is no possibility of a chelate interaction, is larger than the displacements (+15 and −10 pm) in the isocaffeine complex.

Discussion

As noted in the Introduction, a primary motivation for this study was to seek evidence for or against the possibility of O_6—N_7 chelation in the isocaffeine complex. Two principal lines of evidence bear on this question.

Firstly, the Pt---O_6 distances in *cis*-$[Pt(isocaff)_2(PEt_3)_2]^{2+}$ are 334 pm and 322 pm. Szalda, Kirstenmacher, and Marzilli (14) have collected data for several 6-oxopurine complexes of copper in which they consider there is no Cu---O_6 interaction and the distances range from 328 to 383 pm. In contrast a complex with a weak Cu---O_6 interaction has a distance of 292 pm (14).

		N(2)—C(6)	149(2)

Orbell *et al.* (19) find Pt---O_6 distances of 341.3(6), 336.6(6), and 335.4(6) pm in two *cis*-[Pt(en)(isocaff)$_2$]$^{2+}$ salts, the hexafluorophosphate and the nitrate, and this is interpreted as indicating no significant participation of the 6-oxo group in the metal binding. The Pt---O_6 distance in our isocaffeine complex may also be compared with the corresponding non-bonding Pt---CH_3 distance of 338 pm in *cis*-[PtCl(caff)$(PEt_3)_2$]$^+$. Bearing in mind that the van der Waals radius (30) for a methyl group (200 pm) is larger than that for oxygen (140 pm), it is clear that the Pt---O_6 distance in *cis*-[Pt(isocaff)$_2(PEt_3)_2$]$^{2+}$ is too long to represent a bonding interaction.

Secondly, the various angles collected in Table 11 are expected to reflect the degree of interaction between M and X. For [$PtCl_3$(caff)]$^-$ we see that angle *b* is greater than angle *a* and that relative to caffeine itself *c* has increased in the complex while *d* has decreased. These observations have been interpreted as indicative of steric repulsion between (X = CH_3) and the metal coordination sphere (18). The argument may be extended by examination of the three copper theophylline complexes. In [Cu(theophyllinato)(SME)] (31) the O_6 atom of theophylline is involved in inter-ligand hydrogen bonding and $b > a$, in contrast to the situation in [Cu(theophyllinato)(BDE)] (14) where there is a weak Cu---O_6 bond and $a > b$. In the other theophylline complex, [$Cu(NO_3)(H_2O)_2$(theophylline)$_2$]$^+$, there are no special interactions involving O_6 and the angles *a* and *b* are approximately equal (32). In the 6-thiopurine complexes of copper and palladium in Table 11 there is a full coordinate bond between the metal and the S_6 atom and this introduces even more marked distortion with $a \gg b$ (15, 16). The other angles, *c*, *d*, and *e*, also show some changes which are correlated with the M---X interaction, especially in the thiopurine complexes which are genuine chelates. However, examination of all the data in Table 11 shows that the relative size of angles *a* and *b* is much the most sensitive criterion of interaction, either repulsive or bonding. On this basis it is clear that *cis*-[PtCl(caff)$(PEt_3)_2$]$^+$ has a repulsive Pt---CH_3 interaction similar to that in [$PtCl_3$(caff)]$^-$ and that *cis*-[Pt(isocaff)$_2(PEt_3)_2$]$^{2+}$ has essentially no Pt---O_6 interaction, similar to the case of [$Cu(NO_3)(H_2O)_2$(theophylline)$_2$]$^+$. Thus we find no evidence of any tendency for isocaffeine to act as a chelating ligand.

Experimental section

(A) Synthesis and spectroscopic studies

Data relating to the characterization of the complexes are given in the Results section and under individual preparations below. Microanalyses were by Schwarzkopf Microanalytical Laboratory, Woodside, NY. Infrared spectra were recorded from 4000 to 250 cm^{-1} with an accuracy ±3 cm^{-1} on a Beckman IR20 spectrophotometer calibrated against polystyrene film and water vapour. Solid samples were examined as Nujol mulls between caesium iodide plates. ^1H nmr spectra were recorded at 90 MHz on a Perkin-Elmer R32 spectrometer. ^{31}P nmr spectra were recorded in dichloromethane solution at 24.29 MHz on a Nicolet TT14 Fourier transform spectrometer using a Varian HA60 magnet. Protons were decoupled by broad band ("noise") irradiation at appropriate frequencies. [$P(OCH_3)_3$] was used as external reference and C_6D_6 as external lock. In all nmr spectra *positive* chemical shifts are *downfield* from the reference.

Caffeine and isocaffeine were commercially available and [$Pt_2Cl_2(PEt_3)_4$][BF_4]$_2$ was prepared as previously described (33).

(i) cis-*[PtCl(caff)$(PEt_3)_2$][BF_4]*

A solution of caffeine (0.083 g, 0.427 mmol) in dichloromethane was added dropwise to a stirred solution of [$Pt_2Cl_2(PEt_3)_4$][BF_4]$_2$ (0.237 g, 0.214 mmol) in dichloromethane under a nitrogen atmosphere at 25°C. After stirring for 3 h, the solution was evaporated to small volume under reduced pressure and diethyl ether slowly added to give *cis*-[PtCl(caff)$(PEt_3)_2$][BF_4] as a white precipitate (0.279 g, 0.373 mmol). Colourless crystals suitable for both X-ray study and microanalysis were grown by vapour diffusion of diethyl ether into a solution of the complex in dichloromethane. *Anal.* calcd. for

1	Pt, −0.15(5); Cl, 4.8(5); P(1), 0.4(4); P(2), 3.5(4); N(1), −23(1)
2	Pt, 40.96(5); C(3), −6(3); N(3), 6(1)
3	N(1), −8(1); N(2), 1(2); C(1), 2(2); Pt, 26.74(5)
4	Pt, 25.60(5); N(1), −10(1)

[a]Angles between planes: *1,2* = 97.3°; *1,3* = 98.3°; *1,4* = 98.0°; *2,3* = 2.3°; *2,4* = 2.2°; *3,4* = 0.3°.

$\chi^2 = \sum_i (P_i^2/\sigma^2(P_i))$ where P_i = the perpendicular distance of atom *i* from the plane (atom *i* belongs to the plane defining set of atoms).

$C_{20}H_{40}BClF_4N_4O_2P_2Pt$: C 32.1, H 5.39, N 7.49%; found: C 32.0, H 5.42, N 7.58%.

(ii) cis-*[PtCl(isocaff)$(PEt_3)_2$][BF_4] and* cis-*[Pt(isocaff)$_2$$(PEt_3)_2$]-[$BF_4$]$_2$*

A solution of isocaffeine (0.100 g, 0.515 mmol) in acetone (60 mL) was added dropwise to a stirred solution of [$Pt_2Cl_2(PEt_3)_4$][BF_4]$_2$ (0.285 g, 0.257 mmol) in acetone (15 mL) under a nitrogen atmosphere at 25°C. After stirring for 90 min, the solution was evaporated under reduced pressure to about 15 mL and diethyl ether slowly added to give a white precipitate (0.350 g). As detailed in the Results section, ^{31}P nmr showed this precipitate to be an approximately 2:1 mixture of *cis*-[PtCl(isocaff)$(PEt_3)_2$][BF_4] and *cis*-[Pt(isocaff)$_2$-$(PEt_3)_2$][BF_4]$_2$. Recrystallization by vapour diffusion of diethyl ether into a solution of the mixture in methanol resulted in colourless crystals, which were identified as *cis*-[Pt(isocaff)$_2$$(PEt_3)_2$][$BF_4$]$_2$ by ^{31}P nmr and then fully characterised by an X-ray diffraction study. *Anal.* calcd. for $C_{28}H_{50}B_2F_8N_8O_4P_2Pt$: C 33.9, H 5.07, N 11.3%; found: C 32.9, H 5.11, N 10.6%.

A ^{31}P nmr spectrum of the mother liquors from the recrystallization showed only *cis*-[$PtCl_2(PEt_3)_2$] and *cis*-[PtCl(isocaff)$(PEt_3)_2$][BF_4].

(B) Crystal measurements

Crystals of *cis*-[PtCl(caff)$(PEt_3)_2$][BF_4] (**I**) and *cis*-[Pt(isocaff)$_2$-$(PEt_3)_2$][BF_4]$_2$ (**II**) were prepared as described above and examined by photographic methods using CuK_α radiation and Weissenberg and precession cameras. For **I** a primitive unit cell was chosen and then changed by use of the Delaunay reduction procedure. Both crystals were mounted approximately along the *c*-axis. The crystals were then transferred to a Picker 4-circle diffractometer automated with a PDP-11 computer and the orientation matrices were refined by least squares

[a]Estimated standard deviations in parentheses.

Crystal data for **II** are as follows:

$C_{28}H_{50}B_2F_8N_8O_4P_2Pt$ mw = 993.40

Orthorhombic, space group *Pbca* (No. 61), a = 2.317(3), b = 1.717(3), c = 2.130(3) nm, cell volume 8.472(3) nm^3, D_m = 1.574 g cm^{-3}, D_c = 1.557, Z = 8.

Intensity measurements were obtained for the hemisphere $h \geq 0$ up to 48° in 2θ for **I** and up to 40° for **II**. Stepped scans with 50 steps of 0.04° in 2θ were used, counting for 1 s per step with a 25 s background count at each end. Each batch of 50 reflections was preceded by the measurement of three standard reflections (**I**: 4,0,0; 0,6,0; 0,0,4. **II**: 16,0,0; 2,5,0; 0,0,10). The Lorentz and polarisation factors were applied and each batch was scaled to maintain the sum of the standards constant. There was no marked decrease in the standard intensities during the measurements. An instrument instability constant of 0.020 was used to estimate σ(**I**). Absorption corrections were applied using numerical integration over 8×8×8 Gaussian grids with absorption coefficients 52.78 cm^{-1} (**I**) and 36.93 cm^{-1} (**II**) for MoK$_\alpha$ radiation. The crystal shapes were defined by perpendicular distances to seven crystal faces from central origins as follows: **I**, ±(1,0,0) 0.181 mm, ±(0,1,0) 0.087 mm, (0,0,1) 0.279 mm, (0,−1,−1) 0.104 mm, (0,1,−1) 0.145 mm; **II**, ±(1,0,0) 0,055 mm, ±(0,1,0) 0.105 mm, (0,0,−1) 0.350 mm, (0,1,1) 0.267 mm, (0,−1,1) 0.297 mm. The correction factors were in the ranges 0.16–0.43 (**I**) and 0.48–0.68 (**II**). The measurements were sorted and any duplicates averaged to give files containing 3749 (**I**) and 1893 (**II**) independent reflections.

(C) Crystal structure solution and refinement[2]

A set of programmes supplied by Penfold (34) was manly used. The programmes are based on ORFLS, ORFFE, ORTEP, and FORDAP. Platinum coordinates were found from the Patterson function and lighter atoms were located by means of difference maps. The refinement was by the method of least squares minimising $\Sigma w(|F_o| - |F_c|)^2$. The atomic scattering factors were corrected for dispersion (35).

[a]Angles between planes *1,2* = 88.2°; *1,3* = 87.9°; *1,4* = 92.3°; *2,3* = 65.4°; *2,4* = 62.0°; *2,5* = 66.0°; *4,5* = 8.9°. χ^2 has been defined in Table 5.

(i) cis-*[PtCl(caff)(PEt$_3$)$_2$][BF$_4$]*

The 35 non-hydrogen atoms were treated anisotropically and the refinement was done using alternate cycles which refined the heavy atoms and the caffeine ligands, then the heavy atoms, the fluoroborate group, and the triethylphosphine ligands. The weighting scheme finally used was of the form $w = [A + Bx + Cx^2 + Dx^3]^{-1}$ where $x = |F_o|$, with values $A = 57.82$, $B = -2.006$, $C = 4.793 \times 10^{-2}$, $D = -1.04 \times 10^{-4}$. This gave approximately constant $\Sigma w\Delta^2$ as a function of $|F_o|$, the summations being over subsets of reflections. At convergence the maximum change/error ratio was 1.16, the mean change/error ratio was 0.13, the larger ratios being associated with the BF_4 group. The final difference map gave no evidence for any further atoms, the major peaks and troughs being close to the Pt atom. The final R-value was 0.071 and $R_w = \sqrt{(\Sigma(w\Delta^2)/\Sigma wF_o^2)}$ was 0.087. $\Sigma w\Delta^2 = 822$ for 3749 observations and 316 variables, hence $\sqrt{(\Sigma(w\Delta^2)/(NO - NV)} = 0.489$.

(ii) cis-*[Pt(isocaff)$_2$(PEt$_3$)][Bf$_4$]$_2$*

Both BF_4 groups were subjected to the contraints B—F = 136 ± 10 pm, F—F = 222 ± 10 pm, which were significant but did not totally dominate the X-ray intensities. There were 1893 X-ray observations and 228 parameters in the refinement. The weighting scheme was $w = 0.3346/(\sigma(F)^2 + 0.0166F^2)$. The R-value was 0.0731 and $R_w = \sqrt{(\Sigma w\Delta^2/\Sigma wF_o^2)} = 0.1010$. The refinement converged and the maximum (shift/sigma) was 0.15 in the final cycle. The final difference map had a maximum of 2.3×10^{-6} e pm^{-3} close to the position of the Pt atom; there were only 4 peaks above 1.0×10^{-6} e pm^{-3} and these were unsuitable as positions of new atoms.

The reaction of trimethylamine in liquid hydrogen sulphide: an electrical conductivity study[1]

JAMES D. HALLIDAY AND PATRICK E. BINDNER

Physical Chemistry Branch, Atomic Energy of Canada Limited Research Company, Chalk River Nuclear Laboratories, Chalk River, Ont., Canada K0J 1J0

Received October 27, 1982

JAMES D. HALLIDAY and PATRICK E. BINDNER. Can. J. Chem. **61**, 1142 (1983).

The electrical conductivity of trimethylamine solutions (2.26×10^{-4} to 2.89×10^{-1} mol L^{-1}) in liquid hydrogen sulphide over the temperature range −72.5°C to +25.0°C has been measured. The data indicate that the trimethylamine behaves as a Brønsted base in liquid hydrogen sulphide [1] and is protonated to form trimethylammonium hydrogensulphide. The latter

[1] $(CH_3)_3N + H_2S \rightleftharpoons (CH_3)_3NH \cdot SH \rightleftharpoons (CH_3)_3\overset{+}{N}H + \bar{S}H$

behaves as a normal weak electrolyte in a solvent of low to medium dielectric constant ($\epsilon_{H_2S} = 9.05$ at −78.5°C). The conductance data as a function of temperature also show that trimethylamine exists both as a hydrogen bonded complex with H_2S and as an unassociated molecule in liquid H_2S.

JAMES D. HALLIDAY et PATRICK E. BINDNER. Can. J. Chem. **61**, 1142 (1983).

On a mesuré la conductivité électrique des solutions de triméthylamine ($2{,}26 \times 10^{-4}$ à $2{,}89 \times 10^{-1}$ mol L^{-1}) dans le sulfure d'hydrogène liquide dans un intervalle de température allant de −72,5°C à +25,0°C. Les données indiquent que la triméthylamine se comporte comme une base de Brønsted dans le sulfure d'hydrogène liquide [1]

[1] $(CH_3)_3N + H_2S \rightleftharpoons (CH_3)_3NH \cdot SH \rightleftharpoons (CH_3)_3\overset{+}{N}H + \bar{S}H$

et se protone pour former l'hydrogénosulfure de triméthylammonium. Ce dernier se comporte comme un électrolyte faible normal dans un solvant de constante diélectrique allant de faible à moyen ($\epsilon_{H_2S} = 9{,}05$ à −78,5°C). Les données de conductance en fonction de la température montrent également que la triméthylamine existe comme un complexe lié par des liaisons hydrogènes avec H_2S et comme une molécule non associée dans le H_2S liquide.

[Traduit par le journal]

Introduction

Relatively little information is available concerning the electrical conductivity of liquid H_2S and its solutions compared with that available from water and aqueous solutions. Even some of the physical properties of liquid H_2S such as the dielectric constant, ϵ, are not well documented as a function of temperature ($\epsilon_{H_2O,0°C} = 87.740$, $\epsilon_{H_2S,-78.5°C} = 9.05$). The dissociation of weak electrolytes in these two solvents is expected to differ due to the large difference in the magnitudes of their dielectric constants. The high dissociation of many electrolytes in water has allowed determinations of the limiting equivalent conductances, Λ_0, of these ions, but none have been determined for ions in liquid H_2S. However, trialkylamines are known to be protonated in liquid H_2S to yield conducting solutions (1, 2) (for example, trimethylamine, reaction [1])

[1] $(CH_3)_3N + H_2S \rightleftharpoons (CH_3)_3NH \cdot SH \rightleftharpoons (CH_3)_3\overset{+}{N}H + \bar{S}H$

Further evidence for this reaction is that trialkylammonium hydrogensulphides have been isolated and characterized from trialkylamine/H_2S reaction mixtures (e.g. $(CH_3)_3NH \cdot SH$, mp 28−30°C (3)). Earlier studies (1, 2) indicated that there was an abnormal electrical conductivity behaviour in these solutions in that the equivalent conductance, Λ, increased with increasing concentration of trialkylamine. This paper describes an electrical conductance study of the reaction of trimethylamine with liquid hydrogen sulphide, as a function of trimethylamine concentration and temperature, in an attempt to better understand the reaction of this base with hydrogen sulphide.

[1]AECL No. 7999.

Experimental

Variable temperature studies near ambient temperature with liquid H_2S require glass apparatus that can safely withstand the considerable vapour pressure of this liquid (2.1 MPa at 25°C) and handling techniques that take into consideration its very high toxicity (equivalent to that of HCN). For these reasons the conductance cells used in this study were hydrostatically tested to 5.0 MPa before use. Several failed this test, sometimes after being at high pressure for many hours. Cells containing liquid H_2S were kept behind scatter shields in a fumehood (air flow rate 52 L s^{-1}) whenever practical.

In addition to meeting the above pressure requirements the conductivity cell system was designed so that the concentrations of $(CH_3)_3N$ could be changed by direct transfer of the amine in the gas phase. This avoided the use of the large quantities of H_2S that would normally be required to dilute initial stock solutions. In addition the small volume of the cell itself (16.5 mL) minimized the total amount of H_2S being handled at any one time.

The final design of the conductivity cell is shown in Fig. 1. The walls are 3.8 mm thick Pyrex glass tubing with an ID of 23.5 mm. Construction was facilitated by the use of a glass cassette A that fitted snugly inside the cell and held the platinum electrodes B (18 × 18 × 0.5 mm, separated by a 2 mm glass spacer in the shape of a cross, C). Shiny platinum electrodes were used to minimize adsorption effects in the cell. The electrodes were held rigidly in the cassette by solid glass rods, D, ground flat on one side. The platinum electrode leads were spot-welded to short lengths of tungsten wire for passage through the cell walls. This enabled a good metal-to-glass seal to be made with the combination tungsten/uranium glass/Pyrex. A 4 mm Fischer and Porter flow control valve provided access to the solution containing approximately 6 mL of liquid H_2S.

The cell constant was determined as 0.08496 ± 0.00025 cm^{-1} at 25°C using a 0.000999 g equiv. L^{-1} aqueous KCl (Baker, Ultrex) solution, where Λ_{KCl} was obtained from the Fuoss equation (4).

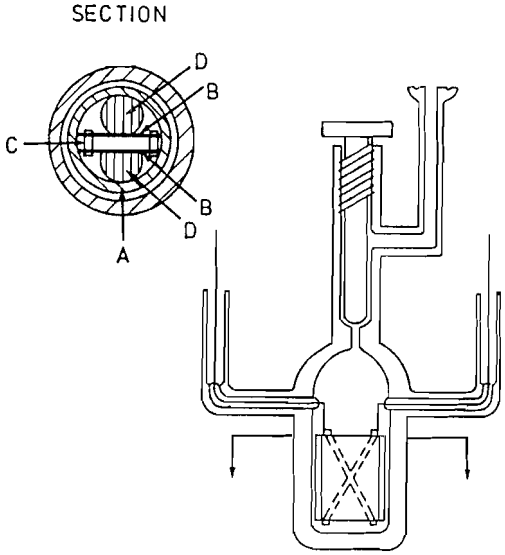

FIG. 1. Electrical conductance cell used for these experiments: wall (Pyrex) thickness 3.8 mm; platinum electrodes, 18 × 18 × 0.5 mm; cell constant, 0.08496 ± 0.00025 cm^{-1}. See text for description of the parts labelled with letters in the section view.

Conductance measurements were made using a Beckman RC-18A Conductivity Bridge at frequencies of 1 kHz and 3 kHz. The temperature of the cell was maintained to ±0.05°C by immersion in Neslab LT-9 and Haake FK2 constant temperature baths. The reagents were measured and transferred in the gas phase using a stainless steel/glass vacuum line equipped with calibrated gas volumes. Pressures were determined with either a 266 kPa (2000 Torr) Heise or an MKS Baratron 133 kla (1000 Torr) 170 Series pressure gauge. The reagents, H_2S (Matheson) and $(CH_3)_3N$ (Eastman), were purified by repeated cryogenic distillations on the vacuum line.

The solution concentrations were determined from the number of moles of trimethylamine added to the cell. Deviations due to solute in the vapour phase should be ≪1% since the trimethylamine was <0.012 mole fraction at the highest concentration. Changes in the H_2S liquid volume as a function of temperature were determined by an iterative technique using the following parameters: number of moles of H_2S in the cell, the vapour pressure (5) and density (6) of H_2S at each temperature, and the volume of the cell.

Results

The minimum measurable conductance value on our bridge with a 10 kΩ resistor in parallel with the cell is 9.9999×10^{-10} S. Conductances less than this, although they sometimes showed a small change in the bridge balance, could not be accurately determined. After repeated rinsings of the cell with liquid H_2S, the bridge consistently showed conductances $<9.9999 \times 10^{-10}$ S for the solvent at all the temperatures studied. This corresponds to a specific conductance for liquid H_2S of $<8.5 \times 10^{-11}$ S cm^{-1}.

Conductance data obtained from measurements made on solutions of $(CH_3)_3N$ in liquid H_2S are given in Table 1 and illustrated in Figs. 2 and 3. Small polarization effects were corrected for by taking measurements at 1 kHz and 3 kHz and then extrapolating the results to infinite frequency (by plotting frequency$^{-1/2}$ vs. resistance).

At the higher temperatures there was the possibility of solution decomposition since above 0°C polysulphide formation was reported (7) to occur in triethylamine solutions in liquid H_2S. The conductance data in this paper, even at 25°C, showed no changes over 24 h, which indicate that polysulphide formation was not a problem for trimethylamine solutions.

Discussion

As previously mentioned, few data have been reported from conductance measurements in liquid H_2S. The accepted literature values for the specific conductance of the pure liquid are given in Table 2. Our result of $<8.5 \times 10^{-11}$ S cm^{-1} for the specific conductance of liquid H_2S over the temperature range 25.0°C to −72.5°C is in good agreement with that of Satwalekar *et al.*, 3.7×10^{-11} S cm^{-1} (8). The conductance of pure H_2S would be expected to be low based on the self-dissociation constant of H_2S ($K = 2.5 \times 10^{-33}$ (2)) which is a factor of 10^{19} less than that of water. Higher literature values reported for the specific conductance of liquid H_2S are most likely due to trace impurities being present.

In aqueous solution trimethylamine behaves as a normal weak electrolyte (10) (dissociation constant, 5.45×10^{-5} (11)) in a solvent of high dielectric constant, i.e. the equivalent conductance initially decreases with increasing amine concentration. Cotton and Waddington (12) have shown for three concentrations of trimethylamine in liquid H_2S at −78.5°C a much different behaviour, in that the Λ appears to increase from the first addition of amine. Chipman and McIntosh (1) found similar behaviour for isopropylamine and *n*-butylamine in liquid H_2S, which led to Jander's (2) proposal that there was self-association of amine molecules in these solutions [2].

$$R_3NH\cdot SH + xR_3N \rightleftharpoons R_3\overset{+}{N}H + \bar{S}H + xR_3N$$

[2] $(x+1)R_3N + H_2S$ //

$$(R_3N)_x\cdot R_3NH\cdot SH \rightleftharpoons (R_3N)_x\cdot R_3NH^+ + \bar{S}H$$

R = alkyl

Such adducts have not been shown conclusively to exist but ammonium salts do coordinate H_2S loosely at low temperature (12, 13). For triethylammonium hydrogensulphide and tetramethylammonium hydrogensulphide the adducts have 2 and 3 moles of H_2S per mole of salt respectively at −78.5°C (13). These adducts do not form at significantly higher temperatures. Therefore an increase in Λ at higher concentrations may be interpreted as arising from the formation of triple ions and higher conducting agglomerates in solution, as predicted by the theory of Fuoss and Kraus (14).

However, our results, while confirming the increase in Λ at the higher concentrations, also show for the first time a minimum in Λ with decreasing trimethylamine concentration, Fig. 2. This behaviour is observed at all but the two highest temperatures studied. The minimum occurs at ~0.006 mol L^{-1} $(CH_3)_3N$. This implies that at the lowest concentrations $(CH_3)_3N$ in liquid H_2S is behaving like a normal weak electrolyte in this solvent of low to medium dielectric constant.

The conductances of a number of alkylammonium salts have been measured in liquid H_2S (15) and the Λ vs. concentration

curves nearly all show the Fuoss, Kraus (14) minimum in the same concentration range that we have observed for trimethylamine. However, no limiting equivalent conductance values, Λ_0, have been determined, even for solutions of tetraalkylammonium hydrogensulphides, which are among the most highly dissociated salts in liquid hydrogen sulphide (12). Even here though, unlike their analogues the tetraalkylammonium hydroxides in aqueous solution, these hydrogensulphide salts may not be fully dissociated due to the lower dielectric constant of liquid H_2S. A comparison of our Λ for trimethylammonium hydrogensulphide with those Λ available for tetramethylammonium hydrogensulphide from Cotton and Waddington (12) is given in Table 3.

This shows that the trimethyl compound is much less dissociated at the indicated concentrations. However, the Λ values need to be determined at concentrations $<2.26 \times 10^{-4}$ mol L^{-1} to allow fitting with the Fuoss−Shedlovsky equation (16) to determine Λ_0 and the dissociation constant for the ion pair accurately. Our lowest concentration was predetermined by the cell volume and the minimum transferable aliquot of $(CH_3)_3N$. To achieve lower concentrations much larger quantities of liquid H_2S would be required as a diluent. Handling such quantities in our apparatus would increase the safety hazards beyond an acceptable level.

Another interesting aspect to these solutions that illustrates the weak base character of this hydrogensulphide salt is the effect of temperature on Λ, Fig. 3. A decrease in Λ above −45.6°C was found, opposite to that expected if the dissociation constant increases with temperature. An analogy may be drawn here with the aqueous solutions of trialkylamines. Unlike the tetraalkylammonium hydroxides, which, as already mentioned, are strong bases in H_2O, the trialkylamines behave as very weak bases in aqueous solution. These amines, rather than forming highly ionized hydroxides, form unstable hydrates through hydrogen bonding (17). The amine can exist in two states, the more soluble hydrate and the unhydrated "free" amine. Triethylamine is 70% hydrated at 15°C, but less than 50% at 32.5°C (17). Thus hydrogen bonded and free tri-

3.7×10^{-11}	1.17×10^{-9}	$<8.5\times10^{-11}$

TABLE 3. Comparison of Λ for $(CH_3)_4NSH$ and $(CH_3)_3NHSH$

Compound	Concentration (mol L^{-1})	Λ (s cm^2 equiv.$^{-1}$)	
$(CH_3)_4NSH$	0.0150	2.2 (12)	(−78.5°C)
	0.0782	8.7 (12)	(−78.5°C)
$(CH_3)_3NHSH$	0.0150	0.032	(−72.5°C)
	0.0782	0.094	(−72.5°C)

methylamine species may be considered to exist in H_2S solutions. The ratio of free to hydrogen bonded species would be expected to increase with temperature. Since hydrogen bonding is much weaker in H_2S than in H_2O most of the amine in our solutions must be present in the free state. This is consistent with the very low Λ values measured.

To summarize, although the conductivity data do not allow us to calculate the limiting equivalent conductance values in H_2S solutions and consequently the dissociation constant for trimethylammonium hydrogensulphide in liqud H_2S, investigations have been furthered into the reactions of the triamines with liquid H_2S. We have been able to show that trimethylamine dissolved in liquid H_2S appears to behave as a normal weak electrolyte, contrary to previous reports (1, 2, 12). The increased Λ at the higher concentrations may be attributed to the formation of triple ions and higher conducting agglomerates in solution. At the lower concentrations the Λ also increase in the expected manner due to the decline in the ratio of ion-pairs to free ions in solution. Two effects of temperature on these solutions have been observed: firstly, the solutions have been found to be thermally stable up to 25°C with no signs of thermal decomposition to polysulphides; secondly, there appears to be a significant change in the hydrogen bonded to unassociated amine ratio at the higher temperatures, evidenced by the lowering of Λ. Over the temperature range studied there was no observed effect of $HS^- - H_2S$ hydrogen bonding.

Neutral and anionic derivatives of toluene-3,4-dithiolatocadmium(II); the crystal structure of di(tetraphenylarsonium) bis(toluene-3,4-dithiolato)cadmate(II)

LUIS BUSTOS, MASOOD A. KHAN, AND DENNIS G. TUCK
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received July 29, 1982

LUIS BUSTOS, MASOOD A. KHAN, and DENNIS G. TUCK. Can. J. Chem. **61**, 1146 (1983).

Cadmium(II) chloride reacts with toluene-3,4-dithiol (H_2TDT) to give Cd (TDT), which is apparently a homopolymer in the solid state. Adducts with neutral monodentate and bidentate donors have been prepared. The structure of the salt $(Ph_4As)_2[Cd(TDT)_2]$ was determined by X-ray crystallography. Crystals of this compound are monoclinic ($P2_1/c$), with a = 23.032(4) Å, b = 12.396(4) Å, c = 22.529(5) Å, β = 111.106(2)°. The structure was refined by least-squares methods to a final R-value of 0.0469 for 2523 "observed" reflections. The anion is a distorted tetrahedral, mononuclear species with Cd—S bond distances ranging from 2.488(5) Å to 2.531(4) Å. This anion is also a Lewis acid, forming complexes of the type $[Cd(TDT)_2L]^{2-}$ with neutral bidentate ligands.

LUIS BUSTOS, MASOOD A. KHAN et DENNIS G. TUCK. Can. J. Chem. **61**, 1146 (1983).

Le chlorure de cadmium(II) réagit avec le toluènedithiol-3,4 (H_2TDT) en donnant le Cd(TDT) qui est apparemment un homopolymère à l'état solide. On a préparé des adduits avec des donneurs monodentate et didentate neutres. On a déterminé la structure du sel $(Ph_4As)_2[Cd(TDT)_2]$ par crystallographie de rayons-X. Les cristaux de ce composé sont monocliniques et appartiennent au groupe d'espace ($P2_1/c$) avec a = 23,032(4) Å, b = 12, 396(4) Å, c = 22,529(5) Å, β = 111,106(2)°. On a affiné la structure par la méthode des moindres carrés jusqu'à une valeur finale de R = 0,0469 pour 2523 réflexions "observées". L'anion qui est une espèce mononucléaire a une géométrie tétraédrique déformée avec des longueurs de liaison Cd—S allant de 2,488(5) Å à 2,531(4) Å. Cet anion est également un acide de Lewis qui forme des complexes du type $[Cd(TDT)_2L]^{2-}$ avec les ligands bidentates neutres.

[Traduit par le journal]

Introduction

Complexes of cadmium with sulphur donor ligands have received some measure of attention recently, and one obvious reason is the interest in the biological activity of cadmium compounds. Studies of the stereochemistry of these molecules are important features of such investigations, and both solid state (1) and solution studies (2, 3) have been reported. A general review of the stereochemistry of cadmium complexes has appeared elsewhere (4).

The present paper reports the preparation of neutral and anionic derivatives of the cadmium salt of toluene-3,4-dithiol (H_2TDT). The compound Cd(TDT) forms a series of adducts with neutral ligands, and the anion $[Cd(TDT)_2]^{2-}$, which has been shown by X-ray crystallography to have a distorted tetrahedral CdS_4 kernel. This anion is itself a Lewis acid, giving rise to anions such as $[Cd(TDT)_2bipy]^{2-}$ (bipy = 2,2′-bipyridine) with bidentate nitrogen donors.

Experimental

General

All materials were of Reagent grade; solvents were appropriately dried and stored over drying agents. Toluene-3,4-dithiol (Eastman Kodak) was used as supplied.

Infrared spectra were recorded between 400–4000 cm^{-1} with Beckman IR-12 and/or Perkin-Elmer 180 instruments, using Nujol mulls, KBr or CsI discs as appropriate. Proton nmr spectra were recorded on a Varian EM-360 instrument operating at 60 MHz.

Cadmium analysis was carried out by atomic absorption spectroscopy, using an IL-250 atomic absorption emission spectrophotometer. Microanalyses (carbon, hydrogen, and sulphur) were carried out by Guelph Chemical Laboratories Ltd., Guelph, Ont., Canada. Analytical results are given in Table 1.

TABLE 1. Analytical results

Preparative

(a) Toluene-3,4-dithiolato cadmium(II): This compound has been prepared from the reaction between H_2TDT and cadmium nitrate in aqueous solution (3). In the present work, anhydrous cadmium chloride (4.3 g) dissolved in ethanol (30 mL) was slowly added to a mechanically stirred solution of H_2TDT (1.1 g) in ethanol (20 mL). This mixture was stirred for approximately 12 h at 55°C, yielding a yellow precipitate which was collected, washed twice with ethanol, and dried *in vacuo*. The product is toluene-3,4-dithiolato cadmium(II) (mp 225–227°C), which is soluble in dimethylsulphoxide (dmso), pyridine (py), ethylenediamine (en), and *N,N,N′,N′*-tetramethylethylenediamine (tmed), but insoluble in acetone, chloroform, or methanol. Yield 2.1 g, 34%.

(b) Bis(pyridine)(toluene-3,4-dithiolato) cadmium(II): Cd(TDT) (0.43 g) was dissolved in pyridine (5 mL), with stirring. Diethyl ether was added dropwise until the solution became cloudy; a further small quantity of pyridine was added to redissolve the precipitate, and the solution cooled at 0°C for 24 h. The resultant yellow precipitate was collected and dried *in vacuo*. Analysis and ir spectra showed this solid

to be Cd(TDT)(py)$_2$. Yield 0.87 g, 40%.

(c) Dimethylsulphoxide(toluene-3,4-dithiolato) cadmium(II): Cd(TDT) (0.65 g) was dissolved in 7 mL of dimethylsulphoxide, and the excess solvent removed under vacuum over several hours. A brown heavy oil was collected and redissolved in chloroform. Dropwise addition of diethyl ether precipitated Cd(TDT) (dmso) as a white powder, soluble in chloroform. Yield 0.24 g, 30%.

(d) Bis(1,10-phenanthroline) (toluene-3,4-dithiolato) cadmium(II): To a solution of 0.54 g of 1,10-phenanthroline(phen) in 40 mL of ethanol was added 0.25 g Cd(TDT). The solution slowly changed colour from pale yellow to orange on being stirred over a period of 6 h; the suspended solid was then collected, washed twice with ethanol, and dried *in vacuo*. This procedure was carried out for three different reaction times (6, 14, and 30 h) but the same product was obtained in each case, namely Cd(TDT) (phen)$_2$. Yield 0.36 g, 52%.

(e) 2,2′-Bipyridine(toluene-3,4-dithiolato) cadmium(II): The preparative method was exactly the same as that for the phenanthroline complex. The colour of the solution changed from pale yellow to deep yellow. This reaction was done twice for different reaction times, 7 h and 16 h, with the product being Cd(TDT) (bipy) in both cases. Yield 0.23 g, 50%.

(f) (N,N,N′,N′-Tetramethylethylenediamine) (toluene-3,4-dithiolato) cadmium(II): Cd(TDT) was dissolved in tmed and excess solvent pumped off over several hours. The dropwise addition of petrolcum ether precipitated a yellow powder, which was dissolved in chloroform, reprecipitated with petroleum ether, collected, and dried *in vacuo*.

(g) Di(tetraphenylarsonium)bis(toluene-3,4-dithiolato)cadmate-(II): Sodium hydroxide (0.8 g) dissolved in 30 mL of ethanol was mixed with a stirred solution of H_2TDT in 15 mL of ethanol at room temperature, Cd(TDT) (1.03 g) added slowly, and the mixture stirred until complete dissolution took place (approx. 16 h). An ethanol solution of tetraphenylarsonium chloride was then added, and after 5 min a yellow powder slowly precipitated. This material was collected, washed twice with ethanol, redissolved in EtOH/CH_3CN, and the solution cooled overnight at 0°C. The resultant yellow crystals were collected and dried *in vacuo* (mp 230−232°C). Yield 0.32 g, 6%.

(h) Di(tetraphenylarsonium)bis(toluene-3,4-dithiolato) (1,10-phenanthroline) cadmate(II): 1,10-Phenanthroline (0.08 g) in 10 mL ethanol was added to a stirred solution of $(Ph_4As)_2[Cd(TDT)_2]$ (0.6 g) in 30 mL of acetonitrile; the solution changed colour from yellow to orange. Diethyl ether was added dropwise until the appearance of cloudiness in the solution, the solid redissolved in acetonitrile, and the resultant solution cooled for approximately 15 h. The final yellow precipitate was filtered off, washed with ethanol, and dried *in vacuo* (mp 256−258°C). Yield 0.35 g, 51%. The corresponding $(Ph_4As)_2$-[Cd(TDT)$_2$ (bipy)] was prepared in 63% yield by a similar procedure.

(i) Di(tetraphenylarsonium)bis(toluene-3,4-dithiolato) (N,N,N′,-N′-tetramethylethylenediamine) cadmate(II): 3 mL of tmed was added to a solution of 0.3 g of $(Ph_4As)_2[Cd(TDT)_2]$ in 10 mL of acetonitrile. The volume of the solution was reduced to approximately 5 mL, yielding a white precipitate which was collected, washed with ethanol, and dried *in vacuo* (mp 215−217°C). Yield 0.27 g, 81%.

Spectroscopic studies

Infrared and nmr (^{1}H) spectra served to establish the presence of the relevant ligand and/or cation in the complexes listed in Table 1. Integration of the proton resonance was also used to confirm the stoichiometry. Because of the insolubility of the neutral complexes in common non-donor solvents, all nmr spectra were run in d_6-dmso. It seems very probable that dissolution in this solvent involves removal of the donor molecule, so that the species in solution are then free ligand and Cd(TDT) (dmso)$_n$, where the latter represents a solvated Cd(TDT) species. Under these circumstances, the resonance frequencies of TDT are essentially constant, with the toluene methyl group giving rise to a sharp singlet at 2.15 ppm from TMS, and the aromatic protons giving a multiplet centred at 7.31 ppm. These frequencies are shifted only slightly from those in the parent acid (2.05, 7.1 ppm), for which the thiol protons resonances are at 3.90 ppm. The resonance frequencies of bipy, phen, etc. released on dissolving the adducts in d_6-dmso are essentially those of the parent ligand in the same solvent. Spectra run in other solvents were of too low an intensity to be used for structural interpretation.

Crystallographic measurements

Pale yellow irregularly shaped crystals of $(Ph_4As)_2[Cd(TDT)_2]$ were obtained by the slow evaporation of ethanol/acetonitrile solutions (see above). An initial attempt to collect data using a crystal attached to a thin glass fibre failed because of crystal decomposition within 24 h. A second crystal (approximate dimensions given in Table 2) was sealed in a thin-walled glass capillary in random orientation and used for subsequent data collection on a Syntex P2$_1$ diffractometer. Details of the procedure for data collections and processing were described previously (5). The crystal was stable under these conditions, and the intensities of three monitor reflections decreased by only 8.0% during the data collection process; this was corrected for by applying an appropriate scaling factor. The space group $P2_1/c$ (No. 14) was determined from systematic absences ($h0l$, $l = 2n + 1$; $0k0$, $k = 2n + 1$). The data were corrected for Lorentz and polarization effects, but no absorption corrections were applied in view of the low absorption coefficient and crystal dimensions.

Solution and refinement of the structure

All calculations were performed on the IBM 3031 computer at the University of Windsor. Programmes used during the structural analysis include CHECK, PROC, XANADU, ORTEP (5), and SHELX 77 (6). Scattering factors for all the non-hydrogen atoms, including anomalous dispersion correction terms $\Delta f'$ and $\Delta f''$, were taken from ref. 7, and scattering factors for hydrogen atom were obtained from ref. 8.

The positions of Cd and As atoms were determined from a sharpened three-dimensional Patterson synthesis. The coordinates of the remaining non-hydrogen atom were obtained from the subsequent difference Fourier syntheses. The structure was refined by blocked matrix least-squares refinement; one matrix contained all the coordinates for the anion, with Cd and S atoms treated anisotropically, and the other contained all the coordinates of the cations, with As atoms being refined anisotropically. Six cycles of least-squares refinement gave an R-value of 0.09. At this stage a difference Fourier map showed two areas of electron density which could be attributed to disordered solvent molecules. The proton nmr spectrum confirmed the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

presence of two ethanol molecules in the crystal lattice, and since the two highest peaks in the difference map were ~3.0 e Å^{-3}, these were treated as the oxygen atoms of these C_2H_5OH units and were included in the least-squares refinement. Subsequent difference syntheses with various sin θ/λ cut-off values did not resolve the two carbon atoms of the ethanol molecules. From all the available evidence, we conclude that the two ethanol molecules are loosely held in the crystal lattice and are undergoing very high thermal motion. The S(4)—O(015) and S(1)—O(017) distances (see Table 4) are compatible with O—H---S bonding.[1]

No further attempt was made to resolve the carbon atoms, which were refined anisotropically in an averaged position to yield distances of 1.77(3) Å and 1.76(4) Å from the O(015) and O(017) atoms respectively. Eight cycles of block matrix least-squares refinement, with the coordinates of the solvent atoms being refined with the anion atoms coordinates, gave an R-value of 0.057. A difference Fourier synthesis then showed electron density maxima in some of the plausible hydrogen atom locations. All hydrogen atoms were subsequently included in idealized positions with C—H = 0.95 Å, HCH = 109.5°, and CCH = 120°; isotropic thermal parameters were refined for all the hydrogen atoms. After 10 more cycles of refinement, convergence was achieved, with the final R-value = 0.0469 and the final R_w = 0.0486 for the "observed" reflections. The function minimized during least-squares calculations was $\Sigma w(|F_o| - |F_c|)^2$. Unit weights were used in the initial stages of refinement, while in the final cycles of calculation a weighting scheme of the form $w = [1/\sigma^2(F) + pF^2]$ was employed, with a final p-value of 0.001. In the final cycle of refinement the largest shift/error ratio was ~0.2. The final difference map showed some features around the solvent molecules, with the largest peak being ~0.5 e$^-$ Å^{-3}. The function $\Sigma w(|F_o| - |F_c|)^2$ showed no appreciable dependence either upon (sin θ/λ) or upon $|F_o|$, so that the weighting scheme is satisfactory. There was no evidence for secondary extinction.

A table of observed and calculated structure factor amplitudes is available as supplementary data.[2] Positional and thermal parameters are given in Table 3, and interatomic distances and angles are listed in Table 4. Figure 1 shows the anion with the atomic numbering scheme, and Fig. 2 gives the cell packing; hydrogen atoms are excluded from both figures for the sake of clarity.

Results and discussion

The $[Cd(TDT)_2]^{2-}$ anion

The X-ray results show that the molecular structure of the $[Cd(TDT)_2]^{2-}$ anion is essentially distorted tetrahedral, with a mononuclear CdS_4 kernel. There is none of the intermolecular Cd—S interactions which are such a common feature of many other crystalline cadmium compounds (4), and this is presumably due both to the bulk of the cation and to the steric requirements of the TDT^{2-} ligand. The cation shows no unusual features which require comment.

The average Cd—S bond distance in the anion is 2.508(5) Å. By way of comparison, values in the range 2.51−2.62 Å have been reported for other four-coordinate CdS_4 species (4). The Cd—S distances in five-coordinate species lie in the same range (2.51−2.87 Å), but again any direct comparison is made difficult because of bridging, etc. The present value is thus one of the shortest Cd—S bonds reported to date. The S—Cd—S angle (average value 86.8(2)°) in the five-membered CdS_2C_2 ring is of course constrained by the nature of the bidentate ligand.

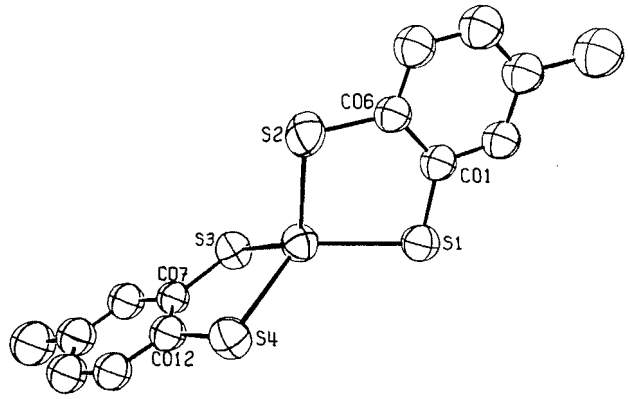

FIG. 1. The stereochemistry of the $[Cd(TDT)_2]^{2-}$ anion: ORTEP diagram, 50% probability for all atoms other than hydrogen. Hydrogen atoms omitted for clarity.

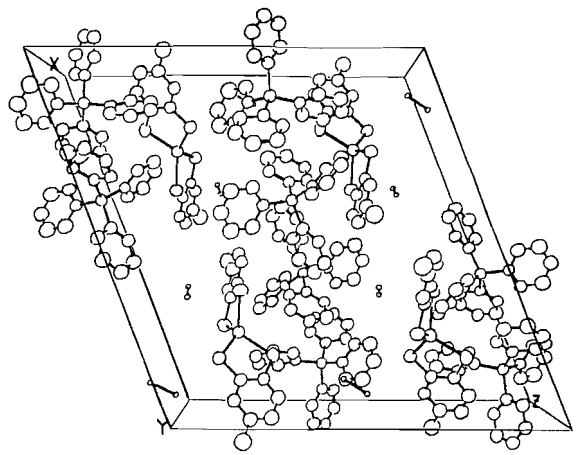

FIG. 2. Packing of Ph_4As^+ and $[Cd(TDT)_2]^{2-}$ in the unit cell. Hydrogen atoms omitted for clarity.

This anion is isoelectronic with $[In(TDT)_2]^-$ reported some years ago (9). One of the features of that complex is the easy conversion to $[In(TDT)_3]^{3-}$, but we were unable to obtain any analogous six-coordinate cadmium(II) species. It is also worth noting that the tetraphenylarsonium salt of $[Cd(TDT)_2]^{2-}$ was the only one which we were able to isolate. Attempts to synthesise a salt with the tetraethylammonium counterion, using procedures identical to those described above, were unsuccessful, since the product contained 29.8% cadmium; calcd. for $(Et_4N)_2[Cd(TDT)_2]$, $C_{30}H_{52}N_2S_4Cd$, Cd 16.5%. This result, together with the instability of $[Cd(TDT)_3]^{4-}$ in the solid state, appears to imply some special stability in the $Ph_4As^+/[Cd(TDT)_2]^{2-}$ lattice.

$[Cd(TDT)_2bipy]^{2-}$, and related anions

The tendency of indium(III) to expand its coordination number from four to six, as shown in the formation of $[In(TDT)_3]^{3-}$ from $[In(TDT)_2]^-$, is also evidenced in the formation of anionic species of the type $[In(TDT)_2(bipy)]^-$ (9). Exactly analogous behaviour is seen in the case of $[Cd(TDT)_2]^{2-}$, which readily forms 1:1 adducts with the bidentate ligands 2,2-bipyridine, 1,10-phenanthroline, and *N,N,N',N'*-tetramethylethylenediamine. These $[Cd(TDT)_2L]^-$ anions are formulated as mononuclear six-coordinate CdS_4N_2 species, isostructural with anionic indium(III) and neutral tin(IV) species (10−12) having this coordination kernel.

[1]We are grateful to a referee for pointing out this fact.

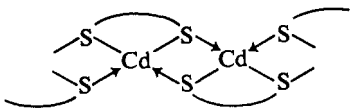
"Estimated standard deviations on average values are calculated by using the "scatter" formula $\delta = [\Sigma(d_i - \bar{d})^2/(N-1)]^{1/2}$ where d_i is the ith and $\bar{d}$ is the mean of N "equivalent" measurements.

Cd(TDT), and neutral adducts

The parent compound Cd(TDT) has many of the properties expected of a homopolymer, especially in that it is insoluble in all but donor solvents, with which it forms a series of adducts. A CdS_2 species would be a Lewis acid, and therefore prone to polymerise by sulphur-bridging. Examples of such bridging are to be found in many cadmium–sulphur compounds (4), and it is worth noting that the related $Sn(TDT)_2$ is also a polymeric solid, soluble only in donor solvents (10, 13). There are several forms which this bridging might take, and there is no evidence at present as to which form is preferred. For discussion purposes only, we can consider an idealised structure in which all dithiolate ligands participate in bridging.



Since the adducts are insoluble in non-donor organic solvents, it seems that the polymeric structure is retained after addition of neutral donors. The simplest mode of adduct formation would then involve coordination of the neutral ligand at the cadmium to expand the coordination sphere without rupture of the polymeric chain, although other structures in which the chain undergoes some reorganisation are also easily envisaged.

One unusual feature is the different coordination behaviour of 2,2′-bipyridine and 1,10-phenanthroline towards Cd(TDT), in that 1:1 and 1:2 adducts (respectively) are formed. A number of different factors might be responsible for this effect, including differing rearrangements of the polymeric structure. An interesting system relevant to this point involves the adducts of zinc ethylxanthate (14), for which the number of donor nitrogen atoms per zinc varies between one (i.e. $Zn(Etxanthate)_2py$) and six (i.e. $Zn(Etxanthate)_2(phen)_3$). A detailed discussion of the factors which might govern the stoichiometry of adducts in such polymeric systems is beyond the scope of the present paper.

Received April 21, 1982

JOHN F. READ, SANDRA J. AMIRAULT, YUK TONG CHAN, ALAN C. HIGGINS, DAPHNE G. IRVINE, VEDA C. STOREY, and B. MICHAEL WHELTON. Can. J. Chem. **61**, 1153 (1983).

The stoichiometric hydrogen–oxygen reaction has been studied in a static system over lanthanum oxide and europium oxide at an initial hydrogen pressure of approximately 200 N m^{-2} from 480 to 775 K, and at different initial hydrogen pressures from 70 to 750 N m^{-2} over the same temperature range. Nonstoichiometric reactions were conducted at five different temperatures over lanthanum oxide and four different temperatures over europium oxide, at hydrogen–oxygen ratios in the range 0.1 to 10. After detailed kinetic analysis it is shown that the results fit an equation of the form:

$$-\frac{dP_T}{dt} = \frac{k(b_{H_2}P_{H_2})^x b_{O_2}P_{O_2}}{(1 + b_{H_2}P_{H_2} + b_{O_2}P_{O_2})^{1+x}}$$

where k is a proportionality constant, b_{H_2} and b_{O_2} are the adsorption coefficients for hydrogen and oxygen, respectively, P_T is the total pressure of hydrogen plus oxygen, P_{H_2} and P_{O_2} are the partial pressures of hydrogen and oxygen, respectively, and x equals 2 for lanthanum oxide and 1 for europium oxide. The mechanism involves the competitive adsorption of molecular hydrogen and oxygen, with the rate-determining step involving the interaction between adsorbed hydrogen molecules and adsorbed oxygen or hydrogen peroxide (double hydroxide groups).

JOHN F. READ, SANDRA J. AMIRAULT, YUK TONG CHAN, ALAN C. HIGGINS, DAPHNE G. IRVINE, VEDA C. STOREY et B. MICHAEL WHELTON. Can. J. Chem. **61**, 1153 (1983).

On a étudié la réaction stoechiométrique hydrogène–oxygène dans un système statique sur de l'oxyde de lanthane et de l'oxyde d'europium à une pression initiale d'hydrogène de 200 N m^{-2} sur un intervalle de température allant de 480 à 775 K et à des pressions initiales variables d'hyrogène allant de 70 à 750 N m^{-2} pour le même intervalle de température. On a effectué des réactions nonstoechiométriques à 5 températures différentes sur de l'oxyde de lanthane et à quatre températures différentes sur de l'oxyde d'europium avec des rapports d'hydrogène–oxygène allant de 0,1 à 10. Après une analyse cinétique détaillée, on montre que les résultats s'ajustent à une équation de la forme:

$$-\frac{dP_T}{dt} = \frac{k(b_{H_2}P_{H_2})^x b_{O_2}P_{O_2}}{(1 + b_{H_2}P_{H_2} + b_{O_2}P_{O_2})^{1+x}}$$

où k est une constante de proportionnalité, b_{H_2} et b_{O_2} sont respectivement les coefficients d'adsorption de l'hydrogène et de l'oxygène, P_T est la pression totale (hydrogène + d'oxygène), P_{H_2} et P_{O_2} sont les pressions partielles d'hydrogène et d'oxygène respectivement; x égal 2 pour l'oxyde de lanthane et x égal 1 pour l'oxyde d'europium. Le mécanisme fait intervenir une adsorption compétitive de l'hydrogène et de l'oxygène moléculaire avec une étape déterminante impliquant une interaction entre les molécules d'hydrogène adsorbées et le peroxyde d'oxygène ou d'hydrogène adsorbé (groupes d'hydroxyde double).

[Traduit par le journal]

Introduction

Bakumenko (1) has studied the extreme nonstoichiometric hydrogen–oxygen reaction over lanthanum oxide at 2×10^3 N m^{-2} from 640 to 773 K. The activity decreased with time, with excess hydrogen having the greater deactivating effect; the activation energy in excess oxygen is 50 kJ mol^{-1} and in excess hydrogen is 70 kJ mol^{-1}. Barrett and Barry (2) investigated the adsorption of hydrogen and oxygen on europium oxide and the subsequent effect on the hydrogen–oxygen reaction. Hydrogen adsorption at 900 K and 133 N m^{-2} caused reduction to $EuO_{1.4928}$. Outgassing of this sample at 1100 K led to subsequent adsorption of oxygen down to 200 K, whereas after adsorption of oxygen on the pure oxide and outgassing at 1100 K, no further oxygen could be adsorbed. Hydrogen is strongly adsorbed and cannot be removed to any extent from the reduced oxide even after prolonged heating at 1100 K. This adsorption is weakened by re-oxidation. A cursory examination of the hydrogen–oxygen reaction at 3×10^4 N m^{-2} showed that pre-reduction in hydrogen increased the activity. The reaction on untreated europium oxide yielded kinetics which were first-order in hydrogen and zero-order in oxygen with an activation energy of 15 kJ mol^{-1}. Loginov *et al.* (3) studied the stepwise mechanism over lanthanum and europium oxides showing that the peroxide form of chemisorbed oxygen was an active participant.

A number of studies have been made, particularly on lanthanum oxide, concerning the nature of the active sites and the effect of pretreatment. Lanthanum oxide is one of the most basic lanthanide compounds, with the active reduction sites probably being O^{2-} surface ions, together with anion vacancies. These are produced by dehydration of the surface, which Rosynek and Fox (4) state is complete at 600 K; other workers give higher temperatures for this dehydration (5). Most studies, however, show that maximum activity is obtained after heating at higher temperatures than 600 K.

The reduction sites can be increased by exposure to hydrogen, eliminating hydroxyl groups and surface lattice oxygen, although extreme exposure can cause deactivation (6). Oxygen can adsorb as O_2^-, poisoning these sites (7), or creating lanthanum ion vacancies (8). The critical effect of pretreatment is illustrated by the two values obtained for the activation energy for the oxygen exchange reaction over lanthanum oxide of 46 kJ mol^{-1} (9) and 86 kJ mol^{-1} (10), where, in the latter case, the catalyst was heated in air at 900 K prior to the experiments. The acid sites on lanthanum oxide are generally considered to be the lanthanum ion, perhaps associated with an oxygen ion,

with hydrogen adsorbed in a polarised form (11).

For europium oxide, anion vacancies are readily produced (2), though they have a low mobility; the production of these sites increasing the activity towards the hydrogen–oxygen reaction. Ross and Delgass (12) showed, at 800 K, that oxygen adsorption was negligible but hydrogen adsorption considerable, causing surface reduction. Subba Rao *et al.* (8) have shown that, at low oxygen pressures and high temperatures, oxygen is lost from the surface and anion vacancies are produced giving rise to n-type characteristics, although under higher pressures, p-type characteristics result (8, 13).

Lanthanum oxide is one of the small group of lanthanide oxides with a stable hexagonal (A-type) structure whereas europium oxide has a cubic (C-type) structure (for example, ref 14). However, there is a tendency for europium oxide to transform to the monoclinic structure (B-type) (15) as the temperature increases, the change being slower in hydrogen than in oxygen atmospheres (16).

Experimental methods

The apparatus, experimental procedure, catalyst conditioning, method of analysis, and identification system for the reaction between hydrogen and oxygen are identical to those described in previous papers in this series (for example, ref. 17). The reaction was carried out in a batch reactor with a trap to remove water. The gas composition was analyzed by mass spectroscopy. Preliminary experiments excluded the possibility of transport domination. The catalysts were "specpure" grade lanthanum oxide and europium oxide (Johnson Matthey) each with a total surface area of 1.6 m^2 (determined by the BET method using krypton).

Twenty-six groups of experiments were conducted on lanthanum oxide. Groups 1 to 15 contain stoichiometric reactions at various temperatures in the range 480 to 775 K at an approximately constant initial hydrogen pressure in the range 185 to 239 N m^{-2}, three to five identical reactions being conducted in each group; groups 16 to 20 contain stoichiometric reactions at 474, 600, 776, 701, and 549 K, respectively, each group comprising from six to sixteen reactions at different initial hydrogen pressures from 70 to 742 N m^{-2}; groups 21 to 25 contain nonstoichiometric and standard stoichiometric (with an initial hydrogen pressure of approximately 210 N m^{-2}) reactions at 474, 599, 776, 698, and 548 K, respectively, and group 26 contains standard stoichiometric reactions at 598 K after pretreatment with hydrogen and oxygen (using the techniqc described previously (18)).

Similar experiments were performed on europium oxide. The first sixteen groups are stoichiometric at a constant initial pressure; groups 17 to 19 are stoichiometric at 624, 572, and 518 K, respectively, with varying initial pressures, and groups 20 to 23 are nonstoichiometric at 620, 544, 694, and 583 K, respectively.

Results

Analysis of data

The data were analyzed as before (for example, ref. 19) and are summarized below and in Tables 1, 2 and in the Depository of Unpublished Data.[1]

Summary of the results for the stoichiometric reactions

Reaction type

Three different types of log (rate) versus log (pressure) plots can be characterized (cf. ref. 19). Types *a* and *b* show three distinct regions: an inital section of short duration with a slope which is either greater than the second section (type *a*) or less than the second section (type *b*); a second linear section lasting for most of the reaction (the quoted orders with respect to time are calculated from this slope); and a third section with rapidly increasing slope. Type *c* does not show the "initial" section.

Most of the reactions over lanthanum oxide are type *c*. Type *a* appears at high initial pressures (>300 N m^{-2}) and *b* at low pressures. Type *b* also appears in some cases after exposure to excess of either gas. The reaction type over europium oxide is amost exclusively type *a*.

Catalyst activity

The initial rate and the time taken for 90% completion was calculated in all cases, as a measure of catalyst activity. For standard reactions over lanthanum oxide the initial rate is 1.5 ± 0.3 N m^{-2} s^{-1} with a negligible temperature effect. Over europium oxide the rate is 2.0 ± 0.3 N m^{-2} s^{-1} with a more marked temperature effect. Over both catalysts the rate decreases in runs preceded by nonstoichiometric reactions. The time taken for reactions to go to completion follows the expected pattern, with an average time of 700 s.

The rate of the central, linear portion increases with temperature and pressure for lanthanum oxide but is relatively constant over europium oxide with a value of 0.5 ± 0.2 N m^{-2} s^{-1}.

Orders with respect to time

These orders are calculated from the central, linear portion of each log (rate) versus log (pressure) plot and from the integrated *n*th order kinetic expression. For lanthanum oxide the order from groups 1 to 15 (with an initial hydrogen pressure of 210 ± 20 N m^{-2}) is 1.0 ± 0.4 and for the equivalent groups over europium oxide the order is 0.4 ± 0.1. The pressure dependent runs give orders which decrease to 0.2 for lanthanum oxide and 0 for europium oxide as the pressure increases. The temperature effect is more erratic, though for groups 16 to 20 over lanthanum oxide there is a definite decrease in order with a decrease in temperature. Pretreatment, or prior exposure to excess of either gas, does not affect the order.

Orders with respect to concentration

These orders, calculated from the pressure dependent runs, are 0.3 ± 0.2 for both oxides.

Temperature effects

Activation energies were calculated using zero-order and half-order rate constants. For lanthanum oxide there is a definite change with temperature giving activation energies of 13, 1, and 14 ± 2 kJ mol^{-1} in the temperature ranges 480–560, 560–650, and 650–770 K, respectively. For europium oxide the activation energy decreases from 8 ± 2 kJ mol^{-1} at low temperatures to a very low value above 550 K.

Summary of results for the nonstoichiometric reactions

Reaction type

For lanthanum oxide in hydrogen excess most reactions are of type *c*. In excess oxygen the pattern is more varied. At 474, 548, and 698 K, type *b* predominates under standard conditions (initial hydrogen pressure of approximately 200 N m^{-2}), with a tendency to give type *c* at 474 K, and type *a* at 548 and 698 K, when the initial hydrogen pressure is below 200 N m^{-2}. At 599 and 776 K most reactions are type *a*. The reaction type over europium oxide is almost exclusively type *a*.

Catalyst activity

For both oxides the initial rate generally decreases as the ratio becomes richer in hydrogen, and increases as the ratio

becomes richer in oxygen, except at extreme ratios.

For both oxides the average rates for the major portion of the reactions at an initial hydrogen pressure of approximately 220 N m^{-2} show a decrease in hydrogen excess as the mixture becomes richer in hydrogen, whereas in excess oxygen the rate increases slightly and then decreases as the mixture becomes richer in oxygen. The rate in excess oxygen is higher than the rate in excess hydrogen. There is little temperature effect. The rates range from 0.1 to 1.2 N m^{-2} s^{-1}.

Orders with respect to concentration

These orders, calculated from the initial rates of the pressure dependent runs, are 0.4 ± 0.2 for both oxides, with no consistent temperature effects.

Orders with respect to time

For lanthanum oxide the orders for oxygen are close to unity, especially as the ratio diverges significantly from stoichiometry. The orders for hydrogen are more varied, changing from a low of 0.2 at 698 K near the stoichiometric mixture to a high of 1.7 at 474 K at extreme ratios. For europium oxide the orders for oxygen increase from 0.5 to 1.2 as the ratio becomes more extreme, and the orders for hydrogen increase from zero near the stoichiometric ratio to approximately 1.5 at extreme ratios.

Isobars

In all cases plots of log (rate) versus log (pressure of hydrogen or oxygen) with oxygen or hydrogen pressure being constant are smooth curves exhibiting maxima.

For lanthanum oxide the hydrogen–oxygen ratio at the maxima for the hydrogen isobars is 1.0 ± 0.2 and for the oxygen isobars is 1.4 ± 0.2. There is a slight tendency for the maxima to decrease as temperature increases and pressure decreases. The slopes on the low pressure side of the isobars are 1.2 ± 0.4 for the hydrogen isobars and 1.8 ± 0.4 for the oxygen isobars. The slopes on the high pressure side are 1.4 ± 0.8 for the hydrogen isobars and 1.2 ± 0.5 for the oxygen isobars. There is a tendency for the slope to increase with pressure, and decrease with temperature.

For europium oxide the ratio at the maxima for the hydrogen isobars is 1.0 ± 0.1 and for the oxygen isobars is 1.2 ± 0.2 with no obvious temperature or pressure effect. The slopes of the isobars give a value of 0.9 ± 0.2 for the low pressure side of the hydrogen isobars and the high pressure side of the oxygen isobars, and 0.9 ± 0.2 for the other sides. There is no pattern to the variation of these values with temperature or pressure.

Discussion

The overall results for both oxides fit the general pattern described previously for other lanthanide oxides (for example, ref. 19) and will be discussed on the same basis.

General characteristics

Reaction type

Type *a* appears to be the standard form. Europium oxide exhibits this type of curve almost exclusively, whereas for lanthanum oxide, it only appears for nonstoichiometric reactions at 599 and 776 K, at low hydrogen initial pressures at 548 and 698 K, and at high pressures for stoichiometric reactions. Type *b* appears in oxygen excess reactions at 474, 548, and 698 K and in low pressure stoichiometric reactions. Also, prior exposure to excess of either gas can give rise to type *b* plots.

Most other reactions are type *c*, especially for most stoichiometric and hydrogen excess reactions.

Catalyst activity

Generally, the initial rate is decreased by prior exposure to excess of either gas, with the effect being greater for lanthanum oxide than for europium oxide. This parallels the change in reaction type discussed above and indicates that both gases can deactivate some or all of the very active sites available at the start of the reaction. Hydrogen-excess nonstoichiometric reactions also decrease the initial rate, indicating a deactivation process. Oxygen-excess nonstoichiometric reactions generally increase the initial rate which is in contradistinction to the appearance of type *b* plots in oxygen excess over lanthanum oxide at 474, 548, and 698 K.

The rate of the central, linear, portion is relatively independent of temperature except for a slight increase for lanthanum oxide. For nonstoichiometric reactions the rate decreases in hydrogen excess, and increases and then decreases as the ratio becomes more extreme in oxygen excess. This, again, shows a deactivating effect for hydrogen and a mixed effect for oxygen.

Active sites

The "standard" form of reaction curve is type *a*, indicating at least two different sets of sites: a hyperactive set available at the start of the reaction, and a less active set on which most of the reaction occurs.

The hyperactive set is always present for europium oxide and usually present for lanthanum oxide, though some of the sites can be blocked by prior exposure to either gas. For nonstoichiometric reactions sites are deactivated in excess hydrogen but activated in excess oxygen. It is assumed that these sites could result from the loss of hydroxyl groups during conditioning.

The second set of sites is probably associated with anion vacancies (cf. ref. 12 for europium oxide). Hydrogen adsorbs more extensively than oxygen, accounting for the rate decrease in excess hydrogen and rate increase in slight excess of oxygen. This deactivating effect was observed by Bakumenko (1), with the activation energy being greater in hydrogen excess reactions (70 kJ mol^{-1}) than in oxygen excess reactions (50 kJ mol^{-1}). The larger values for the activation energy obtained by Bakumenko over lanthanum oxide, and the slightly larger values of 15 kJ mol^{-1} obtained by Barrett and Barry (2) over europium oxide, are explained by prior deactivation of the surface sites.

Kinetics

Analysis of the data shows that the results (after the short initial period) fit a kinetic expression similar to that obeyed by this reaction over other lanthanide oxides, namely

$$[1] \quad \frac{-dP_T}{dt} = \frac{k(b_{H_2}P_{H_2})^x(b_{O_2}P_{O_2})^y}{(1 + b_{H_2}P_{H_2} + b_{O_2}P_{O_2})^{x+y}}$$

where k is a proportionality constant, b_{H_2} and b_{O_2} are the adsorption coefficients for hydrogen and oxygen, respectively, P_T is the total pressure of hydrogen plus oxygen, P_{H_2} and P_{O_2} are the partial pressures of hydrogen and oxygen, respectively, and x and y are integers.

Orders with respect to time

For stoichiometric reactions eq. [1] reduces to

$$[2] \quad \frac{-dP_T}{dt} = \frac{(A_m P_T)^m}{(1 + BP_T)^m}$$

where A_m and B are temperature-dependent constants, with B decreasing as temperature increases; $m = 1$, 2, or 3; and $B = (2b_{H_2} + b_{O_2})/3$.

The apparent order over lanthanum oxide is 1.0 and over europium oxide is 0.4. This indicates that $(2b_{H_2} + b_{O_2}) \times 100$ is of the order of unity, with the adsorption coefficients over lanthanum oxide being smaller than over europium oxide. The temperature and pressure effects are as expected from eq. [2].

For nonstoichiometric reactions the apparent orders are difficult to obtain accurately because the ratio of hydrogen to oxygen is continuously changing. The most accurate assessment of the order will be obtained when one gas is in extreme excess, so that the pressure will remain effectively constant. For lanthanum oxide the order is unity in oxygen, and low in hydrogen near the stoichiometric point.This agrees well with the stoichiometric results. The order in hydrogen increases up to 1.7. For europium oxide the order is approximately 0.5 in oxygen and zero in hydrogen near the stoichiometric point, again collaborating the stoichiometric results. The order in oxygen increases up to 1.2 and in hydrogen up to 1.5 as the ratio diverges from stoichiometry.

Isobars

If the kinetic expression shown in eq. [1] is differentiated with respect to change in pressure of oxygen or hydrogen, keeping the other pressure constant, a smooth curve exhibiting a maximum should result. The slopes of these isobars give an indication of the value for x or y, with the most accurate results being expected from the positive slopes. The position of the maximum allows b_{O_2} and b_{H_2} to be calculated.

Isobars are obtained as expected, further verifying eq. [1]. For both oxides an order close to unity in oxygen is obtained. This is in agreement with the results discussed above. For lanthanum oxide the average order in hydrogen is 1.8 with a high of 2.2. This, together with the results discussed above, indicates that the order is 2. The order in hydrogen is much lower over europium oxide, with an average of 0.9, indicating that the order is unity. This agrees with the preliminary value obtained by Barrett and Barry (2).

Approximate values for the hydrogen and oxygen adsorption coefficients can be calculated from the hydrogen−oxygen ratio at the maximum of the isobars. Some values are shown in Table 1. These results are of the correct order of magnitude, and the relative values between the two oxides support the conclusion that $x = 2$ for lanthanum oxide and $x = 1$ for europium oxide. The adsorption coefficient is expected to decrease with increasing temperature. This is seen over lanthanum oxide (with the values being particularly high at 474 K) but the values over europium oxide are abnormally high at 693 K.

The oxygen and hydrogen adsorption coefficients are approximately equal, indicating that both gases are adsorbed equally strongly although the coverage by hydrogen is higher than by oxygen. In general, the adsorption coefficients over lanthanum oxide are lower than those over europium oxide.

An approximate value for the proportionality constant, k, can be calculated and sample results are given in Table 2. The values obtained for lanthanum oxide are relatively constant at the lower temperatures and then increase at the higher temperatures, whereas, the values obtained for europium oxide are independent of temperature. These results, together with the adsorption coefficients, indicate a slight change in heat of adsorption with temperature.

Finally, once values are obtained in this manner for k, b_{O_2}, and b_{H_2} at each temperature, the results are shown to obey

eq. [1] with $y = 1$, and $x = 2$ for lanthanum oxide and $x = 1$ for europium oxide. The results do not fit any simple variation of this equation.

Mechanism

The general mechanism over both oxides appears to follow the pattern proposed before (e.g. ref. 18):

[3] $H_2(g) \leftrightharpoons H_2(ads)$

[4] $O_2(g) \leftrightharpoons O_2(ads)$

[5] $H_2(ads) + O_2(ads) \rightarrow H_2O_2(ads)$

[6] $H_2O_2(ads) + H_2(ads) \rightarrow 2H_2O(ads)$

[7] $H_2O(ads) \leftrightharpoons H_2O(g)$

From kinetic data the rate-determining step for europium oxide is [5], possibly associated with low oxygen adsorption. The rate-determining step for lanthanum oxide is [6], with [5] being reversible.

It has been shown that both lanthanum oxide and europium oxide are active catalysts for the hydrogen–oxygen reaction. The kinetic data were analyzed in detail and shown to obey a relationship of the form shown in eq. [1]. Therefore, for simplicity of presentation, it has been shown in this paper that the results are, indeed, consistent with this expression. A general overall mechanism has been proposed which is consistent with the kinetic information.

A total synthesis of (±)-biotin

RALPH ALLEN WHITNEY
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received November 15, 1982

RALPH ALLEN WHITNEY. Can. J. Chem. **61**, 1158 (1983).

A total synthesis of (±)-biotin **1** based on the photochemical cycloaddition reaction of 1,3-diacetylimidazolin-2-one **2** with 3,4-dihydro-2-methoxy-2*H*-pyran **3** is described. The photoadduct **4** was converted into the lactone **6**, which bears the complete carbon framework and all the requisite stereochemical features, via hydrolysis, Wittig olefination, and catalytic hydrogenation to the cyclobutanol **5** followed by oxidative rearrangement. Subsequent conversion of the lactone to (±)-biotin followed from literature precedent (5).

RALPH ALLEN WHITNEY. Can. J. Chem. **61**, 1158 (1983).

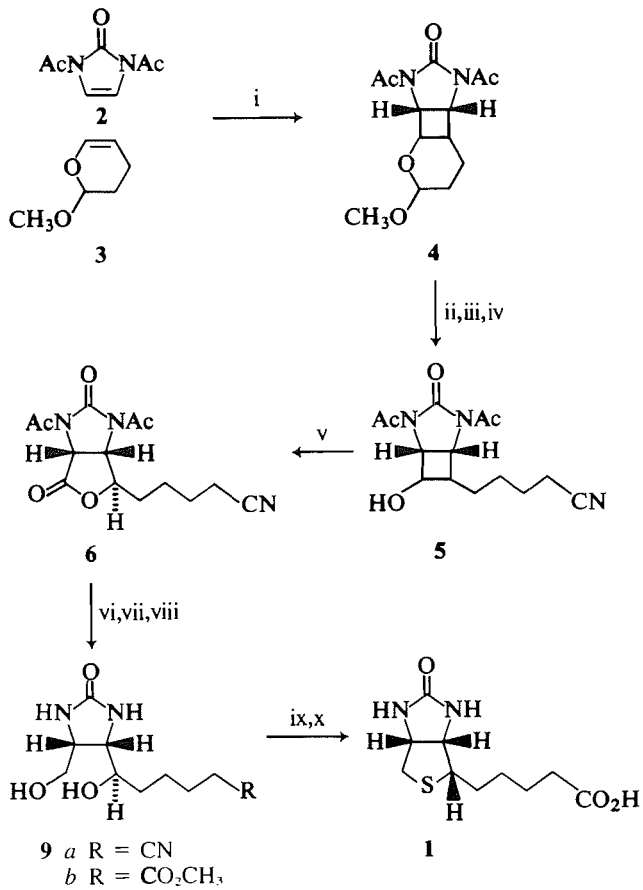
On décrit une synthèse totale de la (±) biotine **1** basée sur la cycloaddition photochimique de la diacétyl-1,3 imidazolinone-2 **2** sur le dihydro-3,4 méthoxy-2 2*H* pyranne **3**. On a transformé l'adduit photochimique **4** en la lactone **6** qui porte le squelette carboné complet et toutes les caractéristiques stéréochimiques requises en utilisant les étapes suivantes – hydrolyse, transformation en oléfine de Wittig et hydrogénation catalytique en cyclobutanol **5** suivie d'une transposition oxydante. On a transformé ensuite la lactone en (±) biotine selon la méthode décrite dans la littérature (5).

[Traduit par le journal]

Biotin, a vitamin of the B-complex, has been the goal of much synthetic activity (1) since its discovery in 1936 (2), particularly in the past decade. We have recently described a photochemical approach (3) to (±)-biotin **1** that gave an intermediate, n-pentyl biotin, which had previously been converted microbiologically to biotin itself (4). The purpose of this present report is to elaborate upon this photochemical route to provide directly a total synthesis of biotin that procedes via the previously described (5) 1,4-diol intermediate **9***b* as shown in Scheme 1.

1,3-Diacetylimidazolin-2-one **2** undergoes photochemical [2+2] cycloaddition with alkenes in acetone as solvent and sensitizer (6). Using commercially available 3,4-dihydro-2-methoxy-2*H*-pyran **3** as the alkene component, the photoadduct **4** was obtained in 75–80% yield, on chromatographic purification, as a mixture of four stereoisomers, presumably the two anomers of each of the *syn*- and *anti*-photoadducts, as evidenced by proton nmr. A single isomer was obtained by recrystallization for analytical purposes.

This readily available photoadduct required three basic modifications: exposure of the cyclobutanol portion of the compound, development of a five-carbon appendage functionalized at the terminal carbon, and oxidative rearrangement of the cyclobutanol to a fused butyrolactone suitable for elaboration to biotin. Liberation of the cyclobutanol portion of the photoadduct **4** was accomplished by the use of aqueous acetic acid to effect hydrolysis to the corresponding hemiacetal which was isolated by extraction and used without further purification. Treatment of the hemiacetal with cyanomethylenetriphenylphosphorane gave, via the isomeric hydroxyaldehyde, the α, β-unsaturated nitrile as the expected Wittig reaction product. Proton nmr indicated the product to be a mixture of (*E*)- and (*Z*)-alkene isomers so that, immediately upon chromatographic purification, the product was catalytically hydrogenated, then characterized as the saturated nitrile **5**. An overall yield of 54% from the photoadduct was obtained in accomplishing these modifications. The product was a mixture of two diastereomers as a consequence of the initial formation of *syn* and *anti* photoadducts. A single isomer was obtained for analytical purposes by recrystallization.



SCHEME 1. Reagents: (i) *hv*, CH_3COCH_3; (ii) CH_3CO_2H, H_2O; (iii) $Ph_3P{=}CHCN$, CH_2Cl_2; (iv) H_2, Pd/C, EtOAc; (v) $RuCl_3$, NaOCl, H_2O, CH_2Cl_2; (vi) $NaBH_4$, EtOH, H_2O; (vii) NaOH, H_2O; H_3O^+, (viii) CH_2N_2, Et_2O, CH_3OH; (ix) Na_2S, DMF; (x) NaOH, H_2O; H_3O^+.

Oxidative rearrangement of the cyclobutanol **5** to lactones was then examined under conditions similar to those previously employed (3). As expected, Jones oxidation gave rise to the

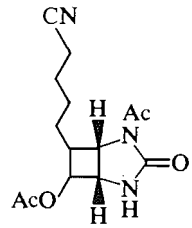
7



8

wrong regioisomeric lactone **7** as evidenced by proton nmr; the hydrogen at the γ-position of the lactone appeared at 6.35 δ (doublet, J = 7 Hz). Also present was a product **8** arising from acyl migration; the *N*-acetyl group appeared at 2.5 δ while the *O*-acetyl group appeared at 2.1 δ. As in our earlier experiences, the two-phase mixed oxidation system comprised of ruthenium tetroxide in the organic phase and sodium hypochlorite in the aqueous phase (7) again proved successful for obtaining the desired lactone. At moderate concentrations of hypochlorite (6–12%) in the aqueous phase, acyl migration was again observed so that the *N*-chloro derivative of **8** was obtained and converted to **8** upon bisulfite reduction. This problem was minimized by using low initial concentrations of hypochlorite, then adding additional hypochlorite only as necessary to regenerate the yellow ruthenium tetroxide. In this manner a mixture of rearrangement products was obtained from which the lactone **6** was recrystallized in 34% yield. A chemical shift of 5.38 δ for the hydrogen at the γ-position of the lactone ring indicated the correct regioisomer, while a coupling constant of 9 Hz between the hydrogens at the α- and β-positions indicated a *cis*-stereochemical relationship, and a negligible coupling (<0.5 Hz) between the hydrogens at the β- and γ-positions indicated a *trans*-stereochemical relationship. The structure of this important intermediate bearing the complete carbon framework and all the requisite stereochemical details was substantiated by other spectroscopic and analytical data. The structural assignment was verified by X-ray crystallographic analysis.[1]

Preliminary experiments designed to effect removal of the *N*-acetyl groups and reduction of the lactone in the presence of a nitrile were attempted using lithium borohydride (8) in ethereal solvents (tetrahydrofuran, diglyme). Products were obtained which, by proton nmr, appeared to include lactols arising from incomplete reduction of the lactone. Low solubility in ethereal solvents may have, in part, been responsible for the incomplete reduction. Complete reduction was achieved using sodium borohydride in aqueous ethanol (9) at reflux; however, the resulting dihydroxynitrile **9***a* proved difficult to purify so that conversion to the methyl ester **9***b* was effected to give, in 65% yield, material that could be purified by recrystallization and which was identical to that previously described (5).

Conversion of the diol **9***b* to biotin proceeded via the corresponding unstable bis-mesylate followed by treatment with sodium sulfide in dimethylformamide (5). Base hydrolysis followed by acidification then gave (±)-biotin **1**.

Experimental

General

Melting points were determined on a Fisher–Johns or a Thomas Hoover melting point apparatus and are uncorrected. Infrared spectra were recorded on either Perkin–Elmer 528 or Acculab 6 instruments. Proton and carbon magnetic resonance spectra were recorded on Varian EM 360, Bruker HX60, or Bruker CXP200 spectrometers. Chemical shifts are reported in δ values relative to tetramethylsilane. Column chromatography was performed with Merck silica gel 60 (70–230 mesh) while high performance liquid chromatography was performed on Merck Lobar columns. Unless otherwise stated, sodium sulfate was used as drying agent for organic solutions. Microanalyses were performed by Guelph Analytical Laboratories, Guelph, Ontario.

9,11-Diacetyl-4-methoxy-3-oxa-9,11-diazatricyclo[6.3.0.0^{2,7}] undecan-10-one ***4***

A solution of 1,3-diacetylimidazolin-2-one (3) (10 g, 59.5 mmol) in acetone (230 mL, distilled from $KMnO_4$) and 3,4-dihydro-2-methoxy-2*H*-pyran (70 mL) was placed in an immersion well photochemical reactor,[2] then deoxygenated with a stream of nitrogen for 0.5 h. The reaction mixture was then photolysed for 10 h with a 450 W Hanovia lamp filtered with Corex. Removal of the acetone by rotary evaporation under reduced pressure, drying overnight under high vacuum, then purification by column chromatography (hexanes – ethyl acetate) gave the photoadduct **4** (12.9 g, 77%) as a mixture of four stereoisomers; ^{1}Hmr ($CDCl_3$): 3.58, 3.40, 3.39, 3.33 (singlets, —OCH_3, four stereoisomers). One stereoisomer was obtained by recrystallization (ether – ethyl acetate), mp 128–129°C; ir ($CHCl_3$): 2930, 1750, 1700, 1360, 1270 cm^{-1}; ^{1}Hmr ($CDCl_3$): 4.88 (1H, m), 4.70 (1H, m), 4.47 (2H, m), 3.40 (3H, s, —OCH_3), 2.78 (1H, m), 2.61 (3H, s, —$COCH_3$), 2.60 (3H, s, —$COCH_3$), 1.95–1.42 (4H, m). *Anal.* calcd. for $C_{13}H_{18}N_2O_5$: C 55.3, H 6.4, N 9.9; found: C 55.5, H 6.4, N 10.1.

2,4-Diacetyl-7-(4-cyanobutyl)-6-hydroxy-2,4-diazabicyclo[3.2.0]-heptan-3-one ***5***

The photoadduct **4** (2.12 g, 7.45 mmol) was dissolved in acetic acid (10 mL) and water (30 mL), then heated on a steam bath for 1 h. Concentration by rotary evaporation under reduced pressure gave a residue that was dissolved in CH_2Cl_2 (100 mL), then the organic solution was washed with aqueous sodium bicarbonate, dried, filtered, and evaporated to dryness to give the crude hemiketal (1.9 g, 95%); ir ($CHCl_3$); 3600–3200 (OH), 3010, 2940, 1745, 1695, 1360, 1265 cm^{-1}.

The crude hemiketal (1.9 g, 7.1 mmol) was dissolved in CH_2Cl_2 (25 mL), then added to a solution of cyanomethylenetriphenylphosphorane (2.12 g, 8 mmol) in CH_2Cl_2 (25 mL) under a nitrogen atmosphere. The reaction mixture was stirred overnight at room temperature, then the organic solution was washed with water, dried, filtered, and evaporated to dryness. Column chromatography (Lobar, ethyl acetate) of the residue gave the unsaturated nitrile as a mixture of isomers; ir ($CHCl_3$): 3600–3200 (OH), 3000, 2940, 2220 (C≡N), 1760, 1700, 1370, 1275 cm^{-1}; ^{1}Hmr ($CHCl_3$): 6.90–6.45 (1H, m, —CH=CH—CN, (*E*)- and (*Z*)-isomers), 5.60–5.30 (1H, m, —CH=CH—CN, (*E*)- and (*Z*)-isomers), 4.85–4.23 (3H, m), 3.0–1.35 (12H, acetyl groups at 2.60–2.56).

The crude unsaturated nitrile was hydrogenated (5% Pd on charcoal, 150 mg, ethyl acetate) at atmospheric pressure, then filtered and the solution evaporated to dryness to give a mixture of isomeric nitriles (1.26 g, 3.8 mmol, 54% from the photoadduct) as a white solid. A single isomer was obtained by recrystallization (ether – ethyl acetate), mp 130–131°C; ir ($CHCl_3$): 3600, 2950, 2250 (C≡N), 1760, 1700, 1370, 1275 cm^{-1}; ^{1}Hmr ($CDCl_3$): 4.80–4.60 (3H, multiplet), 3.0–2.75 (1H, multiplet), 2.61 (3H, s, —$NCOCH_3$), 2.59 (3H, s, —$NCOCH_3$), 2.34 (2H, t, J = 6 Hz, —CH_2CN), 2.32 (1H, —OH), 1.8–1.1 (6H, multiplet); ^{13}Cmr ($CDCl_3$): 172.1, 171.2, 153.5, 119.8, 67.3, 53.0, 50.2, 43.5, 27.1, 25.4, 24.1, 24.0, 21.9, 17.1. *Anal.* calcd. for $C_{14}H_{19}N_3O_4$: C 57.3, H 6.5, N 14.3; found: C 57.4, H 6.5, N 14.4.

*(1*RS*,4*RS*,5*RS*)-6,8-Diacetyl-4-(4-cyanobutyl)-3-oxa-6,8-diazabicyclo [3.3.0]octan-2,7-dione* ***6***

To a mixture of CH_2Cl_2 (15 mL) and water (10 mL) containing

$RuCl_3 \cdot 3H_2O$ (100 mg) was added sufficient sodium hypochlorite solution (6%, commercial bleach) to generate a yellow RuO_4 solution in the organic phase. The cyclobutanol **5** (1.126 g, 3.8 mmol, mixture of stereoisomers) in CH_2Cl_2 (15 mL) was added dropwise to the rapidly stirred oxidizing solution; hypochlorite solution was added as required to maintain the yellow oxidizing solution. On completion of the addition the reaction mixture was stirred for 3 h, then the organic layer was separated, washed with dilute aqueous sodium metabisulfite, dried, filtered, and evaporated to dryness to give the crude product (1.01 g) as a mixture of rearrangement products. Recrystallization (ether − ethyl acetate) gave the desired lactone **6** (0.40 g, 1.3 mmol, 34%), mp 145−146°C; ir ($CHCl_3$): 3020, 2940, 2860, 2250 (CN), 1790 (lactone), 1770, 1705, 1370, 1350, 1310, 1270 cm^{-1}; ^{1}Hmr ($CDCl_3$): 5.38 (1H, d, J = 9 Hz), 4.65 (1H, d of d, J = 8 Hz, 5 Hz), 4.54 (1H, d, J = 9 Hz), 2.55 (6H, s, —$NCOCH_3$), 2.40 (2H, t, J = 6 Hz), 2.1−1.5 (6H, multiplet); ^{13}Cmr ($CDCl_3$): 171.4, 170.2, 169.0, 150.3, 119.1, 82.6, 56.3, 50.4, 33.5, 25.0, 24.1, 24.1, 23.9, 17.0. *Anal.* calcd. for $C_{14}H_{17}N_3O_5$: C 54.7, H 5.6, N 13.7; found: C 54.6, H 5.6, N 13.9.

*(4*RS,*5*SR,*6'*RS*)-5-Hydroxymethyl-2-imidazolidone-4-(6'-hydroxy)-hexanoic acid methyl ester 9*b

Sodium borohydride (800 mg, 21.1 mmol) was dissolved in aqueous ethanol, then the lactone (400 mg, 1.3 mmol) in ethanol was added. The reaction mixture was heated to reflux, then, after 2 h, additional sodium borohydride (300 mg, 8.4 mmol) in water was added. After an additional hour at reflux, the solution was cooled, acidifed to pH 2−3 with dilute sulfuric acid, then evaporated to dryness. The solid residue was triturated with absolute ethanol (3 × 30 mL), then the ethanol extracts were evaporated to dryness to give the crude diol contaminated with inorganic salts; ^{1}Hmr ($CDCl_3/CD_3OD$): 4.05−3.64 (5H, multiplet), 2.47 (2H, t, J = 6 Hz), 1.88−1.41 (m, 6H); ^{13}Cmr ($CDCl_3/CD_3OD$): 165.0 (C=O), 120.4 (C≡N), 69.3 60.8, 60.7, 57.5, 33.6, 25.7, 24.7, 17.1.

The crude product was dissolved in water, then sodium hydroxide (280 mg, 7 mmol) was added and the mixture refluxed for 6 h. After cooling, the solution was acidified with ion exchange resin (Amberlite IR-120H), then filtered and evaporated to dryness. The residue was dissolved in methanol, filtered, then treated with an excess of ethereal diazomethane. The resulting solution was concentrated by heating on a steam bath, filtered, and evaporated to dryness to give the methyl ester (221 mg, 65%), mp 165−168°C (chloroform−methanol) (lit. (5) mp 165−167°C); ^{1}Hmr ($CDCl_3/CD_3OD$): 3.98−3.45 (8H, multiplet, singlet located at 3.64), 2.33 (2H, triplet, J = 7.5 Hz), 1.8−1.2 (6H, multiplet); ^{13}Cmr ($CDCl_3/CD_3OD$): 175.2, 164.8, 69.4, 60.8, 60.6, 57.2, 55.1, 34.2, 34.0, 25.1, 25.0.

(±)-Biotin 1

To a solution of the diol **9***b* (200 mg, 0.77 mmol) in dry pyridine (5 mL), under a nitrogen atmosphere and cooled in an ice−salt bath, was added methanesulfonyl chloride (1.2 g, 10.5 mmol) dropwise with stirring. After 0.5 h the cooling bath was removed and the reaction mixture stirred at room temperature for 2.5 h. Evaporation to dryness and drying under high vacuum gave a residue that was dissolved in CH_2Cl_2 (50 mL), then washed with 1% aqueous HCl and 5% aqueous $NaHCO_3$, dried, filtered, and evaporated to dryness to give the crude bis-mesylate; ^{1}Hmr ($CDCl_3$): 6.2 (broad s, NH), 6.0 (broad s, NH), 5.0−3.6 (m), 3.63 (s, —CO_2CH_3), 3.10 (s, —OSO_2CH_3), 3.06 (s, —OSO_2CH_3), 2.32 (t, J = 7.5 Hz), 2.0−0.9 (m).

The crude mesylate was dissolved in dimethylformamide, then added to $Na_2S \cdot 9H_2O$ (0.25 g, 0.92 mmol) in dimethylformamide (5 mL) under a nitrogen atmosphere. The reaction mixture was heated to, then stirred at, 90°C for 2 h. The solution was cooled and the solvent removed under high vacuum, then the residue was heated at reflux in aqueous NaOH (2 *M*, 10 mL) for 3 h, decolourized with charcoal, and filtered. The filtrate was acidified with aqueous HCl, filtered, then concentrated under reduced pressure. The resulting residue was recrystallized from water to give (±)-biotin **1** (27 mg, 14%), mp 235−237°C (lit. (5) mp 236−237°C).

Acknowledgments

Financial assistance of the Aldrich Chemical Company, Queen's University, and the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged as is the technical assistance of the Heyding Magnetic Resonance Laboratory, Nuclear Division. The author is pleased to express his gratitude to Mr. Andrew Stuart Grant and Dr. Peter S. White, Department of Chemistry, University of New Brunswick for performing the X-ray crystallographic analysis.

The reaction of 1,6,6aλ⁴-trithiapentalenes with carbene and nitrene reagents

DAVID M. MCKINNON
Chemistry Department, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received October 12, 1982

DAVID M. MCKINNON. Can. J. Chem. **61**, 1161 (1983).

The reaction of some 1,6,6aλ⁴-trithiapentalenes with ethyl azidoformate provides 1:1 adducts, formulated as 4-thioacylmethylene-1,3,2-dithiazine-2-carboxylic esters; and with diphenyldiazomethane, 1:2 adducts, formulated as 4-(3-propenylidene)-1,3-dithiins. In some cases 4-diphenylmethylenethiopyrans are isolated. The products arise by insertion at a disulfide type bond, or on a thione function of an initial reaction product.

DAVID M. MCKINNON. Can. J. Chem. **61**, 1161 (1983).

Les trithia-1,6,6aλ⁴ pentalènes réagissent avec l'azidoformate d'éthyle en donnant des adduits 1:1 auxquels on attribue une formule d'esters d'acide thioacyl-4 méthylènedithiazine-1,3,2 carboxylique-2, la même réaction avec le diphényldiazométhane donne des adduits 1:2 que l'on a identifié comme étant des (propénylidène-3)-4 dithiins-1,3. Dans certains cas on a isolé des diphényl-4 méthylènethiopyrannes. Les produits proviennent de l'insertion du produit de la réaction initiale dans une liaison du type disulfure ou dans une fonction thione.

Introduction

The reactions of 1,6,6aλ⁴-trithiapentalenes (**1**) with various species have been described. Thus, nucleophilic attack occurs at the positions 2 or 5, and electrophilic substitution occurs at the positions 3 or 4, although alkylating agents react at 1 or 6 sulfur atoms leading to substituted 1,2-dithiolium cations (1). Also, certain radicals react with the trithiapentalenes **1** at position 1 or 6 to form substituted pentadienyl radicals (2). However, no reactions are reported for the attack of nitrene or carbene species on trithiapentalenes. Some 1,2-dithioles, with which the trithiapentalenes have some structural affinity, do react with nitrenes and carbenes to form insertion products (3, 4) in the disulfide bond.

Results and discussion

Accordingly, 2,5-diphenyl-1,6,6aλ⁴-trithiapentalene (**1***a*) was treated with ethyl azidoformate in refluxing carbon tetrachloride. A slow reaction was evident by the gradual disappearance of the typical deep red color of the trithiapentalene, and work-up gave a product whose analysis and nmr were consistent with a 1:1 trithiapentalene/nitrene adduct. Likewise, two other trithiapentalenes **1***b* and **1***c* also gave 1:1 adducts.

The adduct from **1***a* is assigned the structure **2***a* on the following basis; attack of the nitrene on other than a sulfur atom, whether on a heterocyclic ring carbon or on a carbon of an aryl substitutent, would produce a substituted trithiapentalene, with little change from the typical deep red color. A possible mechanism of formation is shown (Scheme 1).

The only other reasonable structure might be a thiaziridine, but such a structure would be expected to extrude sulfur rapidly to form an imine, as has been demonstrated for the attack of carbethoxynitrenes on thiones (4).

For the asymmetrical trithiapentalene **1***b* two monoadducts of the type above are possible, i.e. **2***b* and **2***c*. The latter is a thial. Although this has some structural resemblances to some thials which have been isolated (5), these types of compounds are notoriously unstable and may dimerize with subsequent elimination of sulfur (6, 7). On this basis the structure **2***b* is considered the more likely,

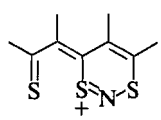
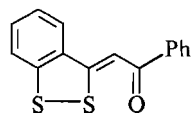
e $R^1/R^2 = -(CH{=}CH)_2-$, $R^3 = H$, $R^4 = Ph$



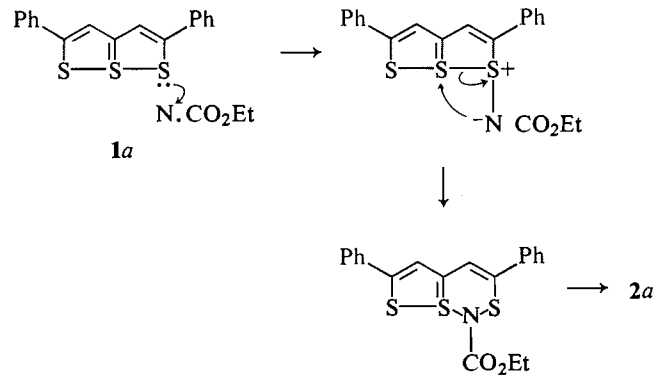
3



4

For the trithiapentalene **1***c*, again two monoadducts are possible, i.e. **2***d* and **2***e*. Compound **2***e* contains an *o*-quinonoid thione structure and is unlikely to exist as a monomer. Such types are related to intermediates in certain 1,2-benzodithiole reactions with amines (8), alkenes (9, 10), or trivalent phosphorus compounds (11). On this basis the structure **2***d* is considered the more likely and this formulation is in accord with carbene reactions described below. No differentiation could be made on the basis of mass spectrometry. In all of these products no ions corresponding to the parent were evident. They did however, exhibit $M - 73$ peaks, corresponding to loss of carbethoxy groups, i.e. the formation of ions of structure **3**.

The starting trithiapentalene **1***c* has been previously syn-



SCHEME 1

thesized from 1,2-benzodithiole-3-thione by condensation with benzoylacetonitrile and modification of the side chain (12) or in very low yield by direct reaction of dehydrobenzene with 5-phenyl-1,2-dithiole-3-thione (13), but an approach using reaction with phenacyl bromide, similar to that used for monocyclic 1,2-dithiole-3-thiones (14), was more convenient. The resulting 3-phenacylidene-1,2-benzodithiole (**4**) gave the trithiapentalene **1***c* on treatment with phosphorus pentasulfide.

The reaction of the trithiapentalene **1***a* with diphenyldiazomethane in the presence of copper acetylacetonate, to generate diphenylcarbene, gave a mixture from which was isolated tetraphenylethylene sulfide and a yellow oil which crystallized as yellow prisms. The properties of this were consistent with a trithiapentalene/carbene 1:2 adduct, less one atom of sulfur. This adduct is assigned the structure **5***a*. It could have been formed via a mechanism similar to that proposed for the nitrenes, with subsequent reaction at the thione function generated. The first stage is thus analogous to the insertion of carbenes in naphtho[1,8-*cd*]-1,2-dithiole (3) or 5-phenyl-1,2-dithiole-3-one (15), and the subsequent reaction is typical of thione functions in general (16–20).

When the reaction was performed with an excess of copper acetylacetonate, the thiopyran derivative **6***a* was obtained. Although trithiapentalenes may form complexes with various transition metals (21–23), treatment of the trithiapentalene **1***a* with only copper acetylacetonate gave no thiopyran products and therefore it may be that it is an initial carbene/trithiapentalene reaction product **7** that is the actual species undergoing rearrangement. Alternatively, a different reaction mechanism, e.g. attack of the carbene at carbon **3***a*, may be responsible.

The treatment of 2,4-diphenyl-1,6,6aλ^4-trithiapentalene (**1***b*) with diphenyldiazomethane and copper acetylacetonate gave a yellow oil which could not be crystallized, but had satisfactory analytical and spectral data for a 1:2 adduct, less one atom of sulfur. Two possible structures **5***b* and **5***c* must be derived from the 1:1 initial reaction products, **7***b* and **7***c* respectively. If the mechanism of the carbene reaction is similar to the nitrenes, then the former are favored, i.e. because **7***c* is a thial. It is possible that a metal carbenoid may be the actual attacking reagent (3), but this would also lead to the same intermediate **7***b*.

In these reactions the carbene (or carbenoid) may be considered as an electrophile, hence these reactions should have some parallels to the reactions of trithiapentalenes with electrophilic reagents, especially alkylating agents. In fact the trithiapentalene **1***b* reacts with methyl iodide at the 6 sulfur rather than the 2 sulfur atom (24).

From the reaction of 1,8,8aλ^4-2-phenylcyclopenta[*a*]indene (**1***c*) with diphenyldiazomethane, two yellow bands were separated by chromatography. One of these gave a satisfactory analysis and mass spectrum for a 1:2 adduct, minus one sulfur atom, and is assigned the structure **5***d* on the basis of the results for reaction of the trithiapentalene with ethyl azidoformate. This corresponds to an initial attack on the least hindered sulfur atom (24). The other material collected had the same mol. wt. (by mass spectrometry), but darkened rapidly on standing and could not be obtained sufficiently pure for analysis. This may be either a product **5***e* derived from an initial reaction at an alternate sulfur atom, or possibly a geometrical isomer of **5***d*. From the first band, a small amount of a yellow crystalline material separated on attempted crystallization. The analysis of

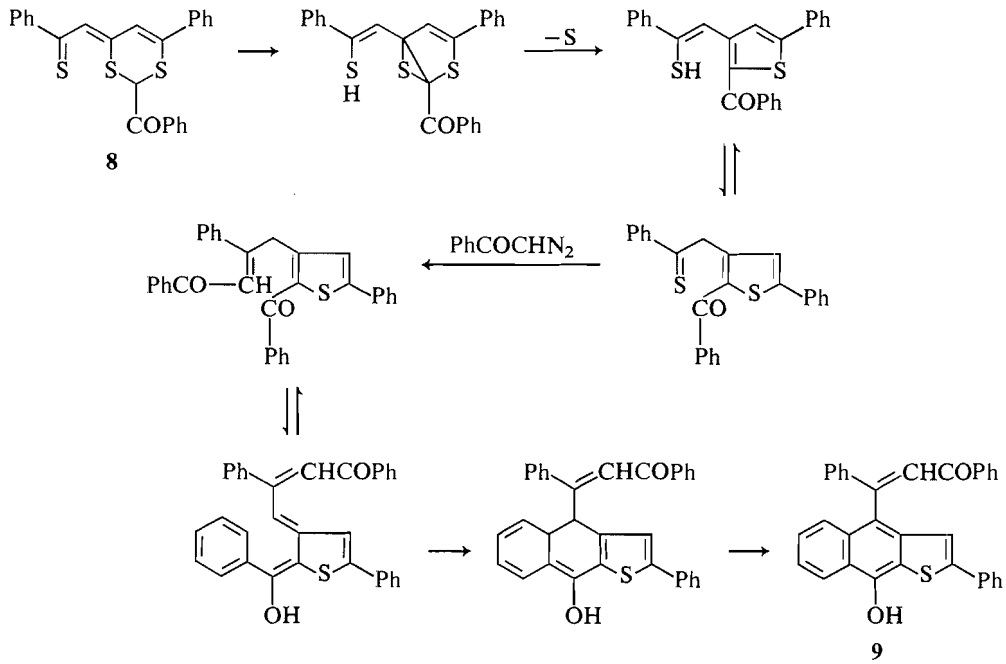

SCHEME 2

this was consistent with a 1:1 adduct minus two sulfur atoms. It was identified as the benzothiopyran structure **6***b*, and thus corresponds in type to the product **6***a* from the reaction of **1***a*, and may be formed by a similar mechanism. The compound **6***b* was made for reference by the reaction of 2-phenylbenzothiopyran-4-thione and diphenyldiazomethane, a typical reaction of thione functions (16–20).

The reaction of the trithiapentalene **1***a* with benzoyldiazomethane gave a pale yellow material whose data were consistent with a 1:2 adduct less two sulfur and two hydrogen atoms. This may arise by aromatization of an intermediate and the compound is tentatively assigned the structure **9**. An initial monoadduct of the type shown, **8**, in contrast to the products **2**, **5**, or **7** above, would possess an acidic hydrogen, and ready loss of a sulfur atom via an episulfide forming a benzoylthiophene is highly likely (Scheme 2). A plausible scheme for the eventual formation of a napththo[2,3-*b*]thiophene **9** by sequential tautomerism, electrocyclization, and aromatization is shown. Alternatively the monoadduct may form a diadduct prior to episulfide formation.

This reaction also gave traces of another product whose mass spectrum was consistent with a 1:1 adduct, minus one sulfur and two hydrogen atoms, indicating that at least the initial reaction product may lose sulfur readily.

The reaction of the other two trithiapentalenes **1***b* and **1***c* with benzoyldiazomethane gave only oily materials which could not be obtained sufficiently pure for analysis.

The nmr spectrum of the compound **2***a* exhibited two sharp single peaks at δ = 6.13 and 8.18 ppm respectively. Since the later is not much shifted from the heterocyclic proton peaks in the trithiapentalene **1***a* (1), it is assigned to the proton on the 1,3,2-dithiazine ring, and the former to the vinylic proton of the side chain. While the trithiapentalene **1***b* has the 3- and 5-heterocyclic protons at δ = 8.10 and 8.81 ppm respectively (26), the adduct **2***b* derived from it gave two apparent singlets at δ 6.60 and 7.13 ppm, the latter poorly resolved from aromatic protons. On the basis of the shift found from **1***a* to **2***a* above, the former is tentatively assigned to the proton on the thiophenacylidene side chain. The product **2** did not exhibit any proton in the range of 8.7 ppm (the heterocyclic proton of **1***c* (1)). An apparent single peak at 7.73 ppm cannot be discriminated from aromatic protons with certainty. No literature models of 1,3,2,-dithiazines are available and products from diphenylcarbene give only a complex series of aromatic peaks.

Experimental

Unless otherwise stated, ^{1}H nmr spectra were obtained in deuteriochloroform solution using tetramethylsilane as an internal standard, on a Varian model E. M. 360 spectrometer. Mass spectra were obtained on a Finnegan model 1015 spectrometer, and ir spectra on a Perkin–Elmer model 337 spectrophotometer. Thick-layer chromatography (tlc) was performed on "Camag" silica gel type D.S.F.S. supplied by Terochem Laboratories. All solutions were dried over anhydrous magnesium sulfate.

Preparation of 1,8,8aλ^4-2-phenylcyclopent[a]indene (1c)

1,2-Benzodithiole-3-thione (1.84 g, 10 mmol) and phenacyl bromide (2.39 g, 12 mmol) were intimately mixed and heated gently to form a homogenous red melt. This rapidly solidified to a yellowish solid which was triturated with tetrahydrofuran and filtered. The bright yellow salt was then heated in a mixture of tetrahydrofuran and propionic acid (2:1) (50 mL) until all solid material had dissolved and then for one further hour. The solution was poured into water and extracted with chloroform, washed with sodium bicarbonate solution, dried, and evaporated to give a yellow oil.

This was chromatographed on silica gel (60–200 mesh, Davison Chemical) in benzene. The second yellow band was collected and on evaporation gave a yellow oil which crystallized under ethanol. Recrystallization from nitromethane gave 3-phenacylidene-1,2-benzodithiole (**4**) as gritty orange prisms, mp 134–135°C (lit. (25) mp 135°C) (61%).

This compound was thionated in toluene to afford the trithiapentalene **3***c* (80%) as violet needles, mp 130–132°C (lit. (12) mp 130–132°C) (81%).

*Reactions of trithiapentalenes 1*a–c *with ethyl azidoformate*

Generally, the trithiapentalene (1 mmol) in carbon tetrachloride at reflux was treated with ethyl azidoformate (1 mL). Reflux was maintained 16 h, then a further 1 mL was added and reflux continued until a pale yellow solution resulted. The solutions were evaporated *in*

vacuo to give viscous yellow oils. The products **2***a* and **2***d* crystallized under a benzene/petroleum ether 1:1 mixture at −20°C. The compound **2***b* did not crystallize, even after further purification by thick-layer chromatography.

Data are summarized in Table 1.

*Reactions of trithiapentalenes **1** with diphenyldiazomethane*

The trithiapentalenes (1 mmol) in dry benzene (10 mL) were treated at reflux with freshly prepared diphenyldiazomethane (27) (~0.5 g) and copper acetylacetonate (25 mg). After a few minutes the color of the solution became dark yellow. The solutions were evaporated and the yellow oils examined by chromatography using a benzene/petroleum ether 1:3 mixture as an eluent. The fastest running band in each case gave tetraphenylthiirane, mp 175°C (lit. (28) mp 175°C); mixture mp 175°C. A bright yellow band running next corresponded to the 1:2 adducts produced in the reaction; a single band for reactions of **1***a* and **1***b*, and two bands for **1***c*. Other bands appear to be only reaction products of the diphenyldiazomethane decomposition, e.g. benzophenone azine.

The yellow bands gave thick oils or glasses on separation and evaporation, which in some cases slowly crystallized from mixtures of benzene and petroleum ether at −20°C as pale yellow solids. The compound **5***d* did not crystallize, but was accompanied by small amounts (5%) of a material which separated in a crystalline form. These were recrystallized from benzene/petroleum ether as yellow needles identical (mixture mp) with compound **6***b* reported below. Also **5***d* was accompanied by another material of close R_f value which did not crystallize and darkened rapidly on standing. Data are summarized in the table.

*Reactions of trithiapentalenes **1** with benzoyldiazomethane*

The trithiapentalenes (0.5 mmol) in boiling benzene (10 mL) containing copper acetylacetonate (25 mg) were treated with excess benzoyldiazomethane (0.4 g) and refluxed 16 h. The mixtures were filtered and examined by chromatography. A reasonable separation of components was obtained for only the reaction products from the trithiapentalene **1***a*. Two yellow bands both crystallized from benzene/petroleum ether mixtures at −20°C. The first eluted gave pale yellow prisms (51 mg), mp 152–154°C, tentatively assigned structure **9**. The ir spectrum: 1679 cm^{-1} (C=O str). The mass spectrum M^+ calcd.: 482 M^+; found: 482. *Anal.* calcd. for $C_{33}H_{22}O_2S$: C 82.16, H 4.56, S 6.64%; found: C 81.87, H 4.65, S 6.88.

Traces (~5 mg) of another material crystallizing as a pale yellow powder, mp 155–160°C, were obtained. The mass spectrum M^+ found: 396; M calcd. for $C_{25}H_{16}S_2O$ is 396.

*Reaction of trithiapentalene **1**a with diphenyldiazomethane and excess acetylacetonate*

The reaction performed as above, but with copper acetylacetonate (100 mg), gave a yellow oil on work-up. Separation by chromatography using a benzene/petroleum ether 1:4 mixture as an eluent gave initially a colorless crystalline material, identified (mixed up) as tetraphenylethene, and **6***a* as a golden yellow solid which crystallized from toluene as yellow plates, mp 252°C (lit. (29) mp 252°C) (41%). The reaction also gave a reddish oil which could not be crystallized.

*Reaction of 2-phenylbenzothipyran-4-thione with diphenyldiazomethane forming 2-phenyl-4-diphenylmethylenebenzothiopyran (**6**b)*

The thione (254 mg, 1 mmol) in benzene (10 mL) and copper acetylacetonate (25 mg) were treated at reflux with diphenyldiazomethane (250 mg). After a few minutes the dark yellow-green solution had become dark yellow. The mixture was filtered, evaporated, and chromatographed. The first bright yellow band, on work-up, gave a yellow oil which crystallized under ethanol as yellow prisms, mp 168°C (83%).

Enantiomeric synthesis of 9-hydroxy-(*E*)-2-decenoic acid, a queen honeybee pheromone

ALI A. KANDIL AND KEITH N. SLESSOR
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received August 25, 1982

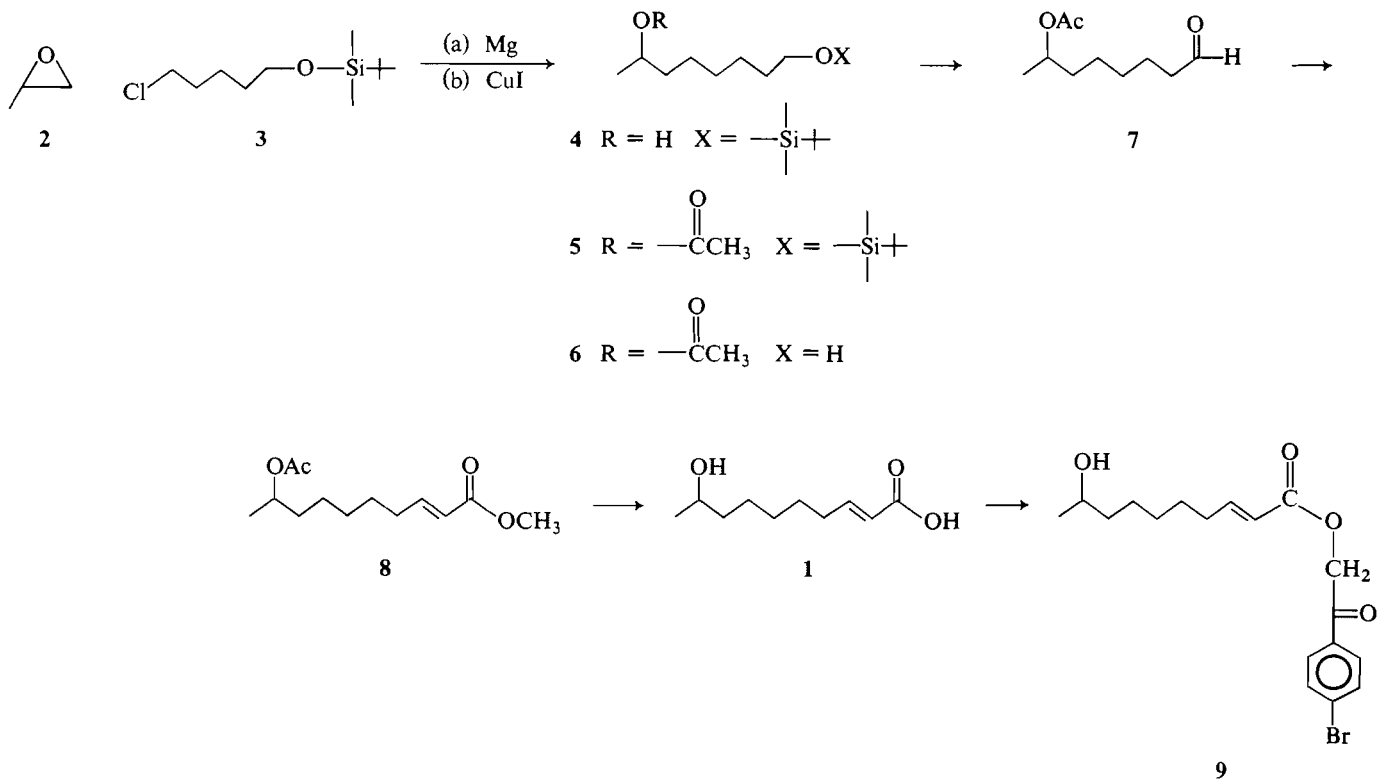
ALI A. KANDIL and KEITH N. SLESSOR. Can. J. Chem. **61**, 1166 (1983).

S-(+)-, *R*-(−)-, and (±)-9-hydroxy-(*E*)-2-decenoic acid have been synthesized by organocuprate-catalyzed opening of *S*-(−)-, *R*-(+)-, and racemic methyl oxiranes. This acid, of unknown chirality, is an important constituent of the honeybee queen's mandibular gland.

ALI A. KANDIL et KEITH N. SLESSOR. Can. J. Chem. **61**, 1166 (1983).

On a synthétisé les acides (*E*) décèn-2 oïques *S*-(+)-, *R*-(−)-, ainsi que l'acide hydroxy-9 (*E*) décen-2 oïque au moyen de l'ouverture des méthyloxyrannes racémiques, *S*-(−)- et *R*-(+)- catalysée par un organocuprate. Cet acide, de chiralité inconnue, est un constituant important de la glande mandibulaire de la reine des abeilles.

[Traduit par le journal]



SCHEME 1

Introduction

It has been known for some time that queen honeybees produce 9-hydroxy-(*E*)-2-decenoic acid in their mandibular glands (1). There has been considerable controversy regarding the bioactivity of synthetic (±)-9-hydroxy-(*E*)-2-decenoic acid, especially in its role as a swarm-settling pheromone. The purity of some of the synthetic preparations has been questioned (2) since they were prepared from the biologically-active 9-keto analogue. It was evident to us that the chirality of the 9-hydroxyl group may further complicate the recognition of the material by worker bees. Inhibition of pheromonal response by the opposite enantiomers has been documented in several insects (3). The chirality of the natural pheromone has not been determined and may well not be racemic in accord with the vast majority of known chiral pheromones (4).

It was of interest, then, to prepare pure 9-hydroxy-(*E*)-2-decenoic acid in a manner which did not involve the 9-keto intermediate and which permitted the chiral synthesis of the two enantiomers as well as racemate. The problem was facilitated by our earlier work on the chiral synthesis of 6-methyl-5-hepten-2-ol, the aggregation pheromone of the two sympatric northwestern timber pests, *Gnathotrichus retusus* and *G. sulcatus* (5). Advantage was taken of the CuI-catalyzed opening of the chiral methyl oxiranes, both readily derived from ethyl *S*-(−)-lactate from the chiral pool (6). With an appropriately functionalized alkylating agent, oxirane ring opening should provide a direct route to the desired chiral unsaturated acids **1**, as outlined in Scheme 1.

Discussion

The utility of copper-catalyzed Grignard oxirane openings is well documented (7). The very high regioselectivity and consequent stereoselectivity displayed by these reagents on methyloxirane provide an excellent entry into molecules containing a chiral 2-ol functionality (5, 8). The availability of methyloxiranes of high chiral purity is facilitated by the transformation of commercially available ethyl *S*-(−)-lactate into either oxirane enantiomer. Crystalline intermediates in the synthesis of the chiral oxiranes from commercial ethyl lactate (9) provided these materials in high enantiomeric excess, >95% for (−)-**2** and >99% for (+)-**2**, as determined by rotation.

5-Chloropentan-1-ol was prepared by the treatment of tetrahydropyran with acetyl chloride and anhydrous zinc chloride (10) followed by acid hydrolysis. The *tert*-butyldimethylsilyl group (11) was chosen as an appropriate blocking group due to its stability under the coupling conditions and its ease of removal, whereas the trimethylsilyl ether was found to be labile under these conditions. Difficulty in promoting the formation of the Grignard reagent was experienced when tetrahydropyranyl ether was utilized as a blocking group. The identity of the final product was verified by formation of the known racemic *p*-bromophenacyl ester (12).

Biological testing of the racemic and enantiomeric acids has begun and we have shown that 9-hydroxy-(*E*)-2-decenoic acid is indeed effective in swarm settling, with the *R*-(−)-isomer substantially more active than other formulations (13). Further work will establish the chirality of the natural acid and any role this material may have in the sex attraction of the drones.

Experimental

General procedures and instrumentation were as described earlier (5) except that nmr data were obtained on a Varian EM360 and the Si-methyl signals of the *tert*-butyldimethylsilyl were assigned a zero for compounds **3** − **5**. Purification of intermediates and analytical samples was carried out using flash chromatography (14). Analyses were performed by M. K. Yang, of Simon Fraser University, on a Perkin−Elmer elemental analyzer, Model 240. High resolution mass spectra were obtained by Dr. G. Eigendorf, Chemistry Department, The University of British Columbia, on a DS-50 mass spectrometer.

1-O-tert-*Butyldimethylsilyl-5-chloropentanol (**3**)*

5-Chloropentanol (5.8 g) was stirred with imidazole (5.9 g, 2.5 equiv.) and *tert*-butyldimethylsilylchloride (6.2 g, 1.2 equiv.) in *N*,*N*-dimethylformamide (15 mL) at 25°C for 12 h. The mixture was poured into ice-cold water (50 mL), extracted with ether (2 × 20 mL) washed with brine (50 mL), and dried over sodium sulphate. Evaporation of solvent under reduced pressure followed by vacuum distillation afforded **3** (9.18 g, 82% yield), bp 72−74°C (0.025 Torr); i.r. (film) ν_{max}: 2942, 1461, 1255, 1105 cm^{-1}; δ (CCl_4): 3.65 (t, 2H, J = 5 Hz, —CH_2—O), 3.41 (t, 2H, J = 6 Hz, —CH_2Cl), 1.56 (m, 6H, —$(CH_2)_3$), 0.81 (s, 9H, *tert*-butyl), 0.00 (s, 6H, $(CH_3)_2$Si—).

1-O-tert-*Butyldimethylsilyl-1,7-octanediol (**4**)*

A three-necked flask (50 mL), containing magnesium turnings (1.4 g, 61 mg-atoms) and a stirring bar, was dried in an oven at 100°C for 2 h and cooled to room temperature under a stream of dry N_2. A portion of a solution of 1-*O*-*tert*-butyldimethylsilyl-5-chloropentanol (8.0 g, 33 mmol) in anhydrous tetrahydrofuran (15 mL) was introduced, the reaction initiated with a small crystal of iodine, and the remaining solution added over 30 min. Stirring was continued for a further 1 h at room temperature and the mixture was cooled to −30°C. Freshly prepared CuI (15) (0.63 g, 3.3 mmol) was added and the mixture stirred for 30 min. Methyl oxirane **2** (1.56 g, 27 mmol) was added dropwise over a 15 min period, the mixture warmed to 0°C, and stirred for 3 h. The reaction was quenched by addition of saturated aqueous ammonium chloride (15 mL) and the product isolated by extraction with ether to yield a colorless liquid (8.1 g). Flash chromatography on silica gel with ether − petroleum ether (30−60°C) (1:1) afforded a pure product **4** (7.2 g, 25 mmol, 92% yield); i.r. (film) ν_{max}: 3316, 1462, 1359, 1257, 1109, 785 cm^{-1}; δ (CCl_4): 3.72 (m, 1H, CH), 3.52 (t, 2H, J = 6 Hz, —CH_2O—), 2.98 (b, 1H, OH), 1.35 (m, 10H, —CH_2—), 1.18 (d, 3H, J = 6 Hz, —CH_3), 0.87 (s, 9H, $(CH_3)_3$C—), 0.00 (s, 6H, $(CH_3)_2$Si—).

1-O-tert-*Butyldimethylsilyl-7*-O-*acetyl-1,7-octanediol (**5**)*

The hydroxy silyl ether **4** (0.8 g, 3.2 mmol) was acetylated in pyridine (8 mL), using acetic anhydride (8 mL), at room temperature for 12 h. The solution was poured into ice water (20 mL), extracted with methylene dichloride (2 × 30 mL) washed with ice-cold 1 *N* hydrochloric acid (2 × 5 mL) and water (2 × 25 mL), dried over anhydrous sodium sulphate. Evaporation of the solvent afforded **5** (0.72 g, 93% yield); ir (film) ν_{max}: 1747, 1248, 1105 cm^{-1}; δ (CCl_4): 4.82 (m, 1H, CH), 3.58 (t, 2H, J = 5 Hz, —CH_2O—), 1.94 (s, 3H, $COCH_3$), 1.37 (m, 10H, —CH_2—), 1.21 (d, 3H, J = 6 Hz, CH_3), 0.86 (s, 9H, $(CH_3)_3$C—), 0.00 (s, 6H, $(CH_3)_2$Si—).

7-O-*Acetyl-1,7-octanediol (**6**)*

A solution of **5** (1 g, 3.3 mmol), in acetic acid − water−tetrahydrofuran (3:1:1, 34 mL), was stirred at 25°C for 24 h. The reaction was poured into ice water (50 mL), extracted with methylene dichloride (2 × 30 mL), and washed with cold water (2 × 10 mL) and with cold 5% aqueous sodium hydrogen carbonate (2 × 5 mL). The extract was given a final water wash, dried over anhydrous sodium sulphate, and evaporated. Flash chromatography on silica gel, using ether − petroleum ether (30−60°C) (1:1) afforded **6** (0.52 g) in 84% yield, ir (film) ν_{max}: 3405, 1742, 1262, 1248 cm^{-1}; δ (CCl_4): 4.74 (m, 1H, CH), 3.74 (s, 1H, OH), 3.53 (t, 2H, J = 4 Hz, —CH_2O—), 1.91 (s, 3H, CH_3CO—), 1.39 (m, 10H, —CH_2—), 1.29 (d, 3H, J = 6 Hz, CH_3).

*7-Acetoxy-octanol (**7**)*

A solution of **6** (0.28 g, 1.48 mmol), in methylene dichloride (1 mL) was added to a stirred suspension of pyridinium chlorochromate (0.48 g, 2.23 mmol) in methylene dichloride (4 mL) under nitrogen atmosphere. After 2 h, at room temperature anhydrous ether (20 mL) was added and the supernatant decanted from the black gum. The insoluble residue was washed thoroughly with ether (3 × 50 mL) and the combined extracts filtered through a short column of Florisil. The eluent was evaporated to yield **7** (0.26 g) in 96% yield, ir (film) ν_{max}: 2982, 2735, 1752, 1728, 1378, 1248 cm^{-1}; δ (CCl_4): 9.83 (t, 1H, J = 2 Hz, CHO), 4.82 (m, 1H, —CH—), 2.37 (m, 2H, —CH_2—CHO), 1.93 (s, 3H, $COCH_3$), 1.42 (m, 10H, —CH_2—), 1.24 (d, 3H, J = 6 Hz, CH_3).

Methyl-9-acetoxy-(E)-*2-decenoate (**8**)*

Trimethylphosphonoacetate (0.46 g, 2.52 mmol) and sodium hydride (0.13 g of 50% dispersion) were stirred together in anhydrous tetrahydrofuran (10 mL), under N_2, at room temperature, for 40 min. A solution of **7** (0.47 g, 2.5 mmol), in tetrahydrofuran (2 mL) was added and the stirring continued for 1.5 h. Water (10 mL) was added to the reaction mixture and the mixture immediately neutralized with 2 *N* hydrochloric acid. The aqueous suspension was extracted with ether, the extract dried over anhydrous sodium sulphate and evaporated to a crude product (0.51 g). This material was subjected to flash chromatography on silica gel and elution with ether − petroleum ether (30 − 60°C) (1:4) yielded the diester **8** (0.41 g, 70%); ir (film) ν_{max}: 3005, 1745, 1718, 1655, 1240, 960 cm^{-1}; δ (CCl_4): 6.85 (d of t, J = 15 Hz, 6 Hz, CH_2—C*H*=CH—), 5.65 (d, 1H, J = 15 Hz, CH=C*H*—$COOCH_3$), 4.78 (m, 1H, —CH—), 3.92 (s, 3H, —$COCH_3$), 3.62 (s, 3H, —OCH_3), 2.22 (d, 2H, J = 7 Hz, CH_2—C=C), 1.38 (m, 8H, —CH_2—), 1.21 (d, J = 6 Hz, CH_3).

9-Hydroxy-(E)-*2-decenoic acid ((±)-**1**)*

The acetoxy ester **8** (0.8 g, 3.3 mmol) was stirred with 5% sodium hydroxide in methanol−water (1:1) (8 mL), at room temperature, for 12 h. Evaporation and dissolution in water (5 mL), washing with

*Difficulty was experienced obtaining consistent C, H analyses. High resolution mass spectrometry gave a weak, consistent $(M-1)^{\dagger\bullet}$ and a strong $(M—COCH_3)^{\dagger\bullet}$. Calcd. for $C_8H_{15}O_2$: 143.1072; found: 143.1070(±), 143.1066(+), 143.1072(−).

†The melting point of the racemate is lower than both enantiomers and in agreement with the reported melting point 73−74°C from hexane (cf. ref. 12).

methylene dichloride (2 × 5 mL), yielded an aqueous solution which was acidified with ice-cold 2 *N* hydrochloric acid (5 mL). Extraction with methylene dichloride (3 × 30 mL), washing with water (2 × 10 mL), and drying over sodium sulphate gave a solution which was evaporated to give the racemic 9-hydroxy-2-decenoic acid (0.42 g, 68% yield); ir (film) ν_{max}: 3385, 3005, 1705, 1662, 1425, 1292, 965 cm^{-1}; δ ($CDCl_3$): 7.21 (s, 2H, OH, COOH), 6.98 (d of t, 1H, J = 15 Hz, 6 Hz, CH_2—*CH*=CH), 5.77 (d, 1H, J = 15 Hz, C=*CH*—COOH), 3.89 (m, 1H, —CH—), 2.24 (d, 2H, J = 6 Hz, CH_2—C), 1.38 (m, 8H, —CH_2—), 1.22 (d, 3H, J = 6 Hz, CH_3).

p-*Bromophenacyl-9-hydroxy*-(E)-*2-decenoate* (***9***)

A sample of the hydroxy acid **1** (186 mg) was converted into its sodium salt with 5% aqueous sodium hydroxide to which 0.9 mmol of *p*-bromophenacyl bromide (286 mg) in ethanol (5 mL) was added. The solution was reflexed for 3 h, cooled, filtered, and recrystallized from hexane to give the derivative (215 mg).

S-(+)-*9-Hydroxy*-(E)-*2-decenoic acid* (*(±)-**1***)

The free acid was prepared as described for the racemic material, except for the substitution of anhydrous 1,2-dimethoxyethane as the solvent in the Wittig/Horner condensation. All physical properties of the intermediate enantiomeric materials were identical to those observed for the racemate (±)-**1** with the exception of the optical rotations and melting points of the derivatives. Table 1 summarizes the salient information.

R-*(−)-9-Hydroxy-(E)-Z-decenoic acid* (*(−)-**1***)

The laevorotatory isomer was prepared in a manner identical to the racemate (Table 1).

La synthèse totale de deux céphèmes diastéréomères est décrite avec trois étapes particulièrement originales: synthèse du cycle thiazinique-1,3 par cycloaddition (4+2), hydrogénations régiosélectives de la double liaison carbone–azote et lactamisation, en présence de BOP, avec d'excellents rendements.

JEAN-CLAUDE ROZÉ, JEAN-PAUL PRADERE, GUY DUGUAY, ANDRÉ GUEVEL, HERVÉ QUINIOU, and SERGE POIGNANT. Can. J. Chem. **61**, 1169 (1983).

The total synthesis of two diastereomeric cephems is described with three original steps in excellent yields: construction of the 1,3-thiazine ring via a (4+2) cycloaddition reaction, regioselective hydrogenation of the carbon–nitrogen double bond, and lactamization using BOP.

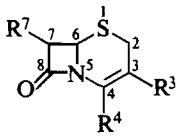
Introduction

L'accès aux céphèmes et céphalosporines par synthèse totale est conditionné par une double cyclisation: celle du β-lactame et celle du cycle thiazinique. Les deux cycles ont leurs difficultés de construction propres mais aussi relatives: l'ordre dans lequel il est préférable de les construire n'est pas évident.

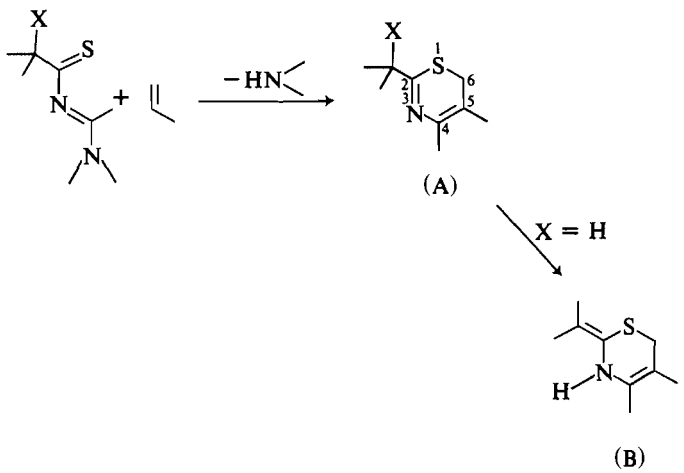


Céphèmes (céphalosporines: R^3 = substituant variable, R^4 = CO_2H, R^7 = RCONH)

Les travaux récents (2) ont généralement donné la préférence à l'ordre (*i*) lactame (*ii*) dihydrothiazine. Cette stratégie permet d'introduire au départ (et dans le meilleur des cas de conserver) la bonne stéréochimie autour des carbones 6 et 7. Elle exclut néanmoins, entre autre, l'usage ultérieur de réactifs nucléophiles susceptibles d'ouvrir le cycle lactamique. L'alternative, (*i*) dihydrothiazine (*ii*) lactame, a été suivie avec succès par Heymes *et al.* (3). Au total cette voie a été moins explorée sans doute en raison du caractère aléatoire prêté à une lactamisation placée à la fin d'une longue synthèse.

Nous avons eu l'occasion d'accéder aux thiazines par une réaction très générale de cycloaddition (4+2) (4).

A partir de ces thiazines convenablement substituées pour conduire aux céphèmes (et ultérieurement aux céphalosporines), il était tentant de mettre en oeuvre la seconde stratégie évoquée ci-dessus et notamment d'éprouver l'une des étapes qui pouvait sembler la plus délicate: l'hydrogénation



(B)

régiosélective de la thiazine sans ouverture de cycle. Un regain d'intérêt pour cette voie nous semblait aussi justifié par de nouvelles facilités offertes par le récent foisonnement des modes de couplage acide–amine que l'on relève en synthèse peptidique et que l'on peut espérer étendre aux lactames.

Les premiers essais d'hydrogénation pratiqués sur des modèles ont donné des résultats plus satisfaisants sur les structures de type (A) que sur les structures tautomères de type (B). Dans les réactions relatées ci-après nous avons donc maintenu les deux doubles liaisons dans le cycle en substituant le futur carbone 7 par un méthyle (A, X = CH_3).

Résultats

La nitrosation du cyanacétate de méthyle, obtenue avec un rendement de 85%, est suivie de l'hydrogénation de l'oxime **1** par l'amalgame d'aluminium dans le méthanol à 95% (Schéma 1). L'aminoester est traité par l'anhydride phtalique fournissant le cyano-2 phtalimido-2 acétate de méthyle **2**. Le rendement cumulé des deux étapes est de 50%. Les meilleurs rendements

[1]Mémoire précédent V, voir réf. 1.
[2]Auteur à qui adresser la correspondance.

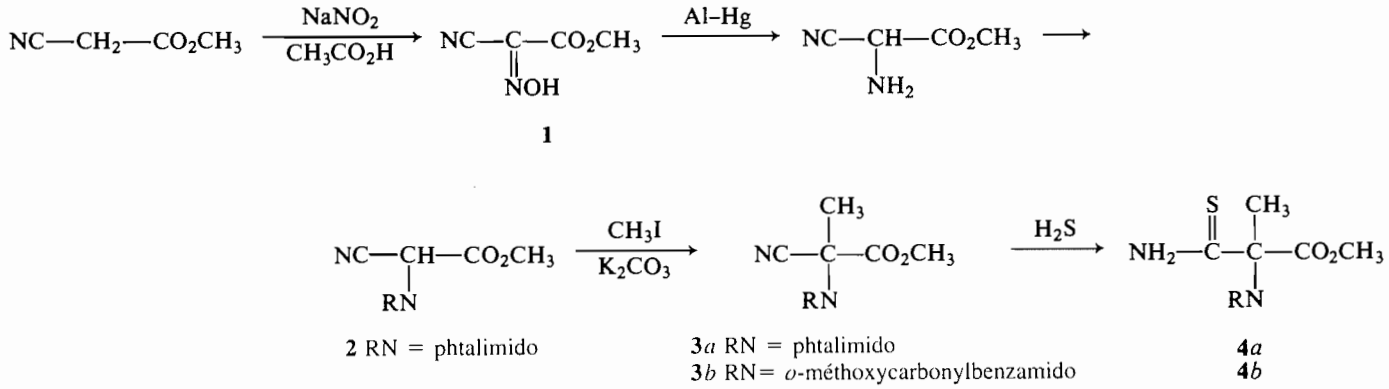


SCHÉMA 1

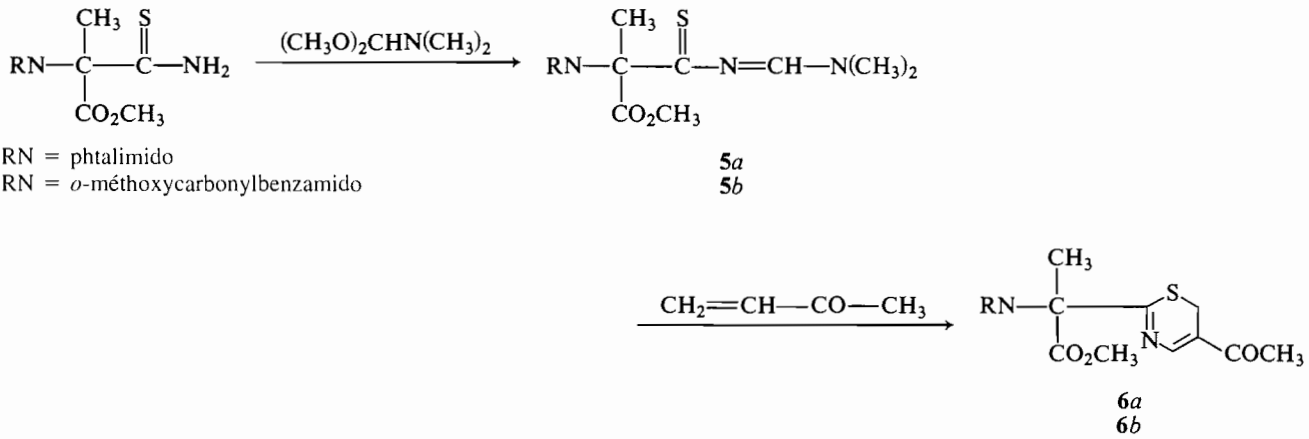

SCHÉMA 2

de méthylation (80%) sont obtenus en traitant par l'iodure de méthyle en excès l'ester-nitrile **2** en solution dans l'acétone anhydre, en présence de carbonate de potassium. A ce stade on peut provoquer l'ouverture du groupement phtalimido de **3***a* en dérivé *o*-méthoxycarbonylbenzamido **3***b* par action du méthanol en présence de triéthylamine. L'addition d'hydrogène sulfuré sur le groupement nitrile de **3***a* et **3***b* fournit les thioamides-esters correspondants **4***a* et **4***b* (80%).

La condensation de **4***a* sur le diméthylacétal du diméthylformamide, dans le benzène (Schéma 2) permet d'isoler la thioacylformamidine substitutée **5***a* (87%). A température ambiante, en solution benzénique, **5***a* réagit sur la méthylvinylcétone conduisant à la thiazine **6***a* (80%). Comme précédemment, la semi-alcoolyse de **6***a* par le méthanol, en présence de triéthylamine, convertit ce composé en son produit d'ouverture du groupement imide **6***b*. Ce produit **6***b* peut aussi être obtenu parallèlement à la voie précédente: réaction du thioamide **4***b* avec le diméthylacétal du diméthylformamide donnant **5***b* (87%) puis cyclisation de **5***b* sur la méthylvinylcétone aboutissant comme précédemment à **6***b* (80%).

La réduction de **6***a* par l'amalgame d'aluminium (Schéma 3) fournit trois composés. L'un d'entre eux **8** correspond à une double hydrogénation portant sur l'un des carbonyles du groupement phtalimido et sur la liaison C=N du cycle thiazinique. Les deux autres composés **9** (5) et **10** résultent vraisemblablement d'une élimination basique avant ou après réduction de l'un des carbonyles du groupement phtalimido. Ces complications nous avaient conduit à ouvrir le cycle phtalimido au niveau de **3***a* afin de rendre le carbonyle amidique restant moins réductible. Dans ce cas on observe effectivement la réduction régiosélective de **6***b* en **7***b* avec un rendement global de 95%. Nous avons séparé les deux racémates diastéréomères obtenus (*F* 112–114° et 182–184°C). La configuration de ces esters et des acides correspondants a été établie, comme il sera indiqué par la suite, à partir des lactames en dérivant.

Le cyanoborohydrure de sodium opposé à **6***a* et **6***b* apparaît comme un hydrogénant régiosélectif de la liaison C=N. Les composés **6***a* et **6***b* fournissent respectivement **7***a* et **7***b* (Schéma 4). Les rendements ne dépassent pas 45 à 50%. Dans les conditions expérimentales utilisées, il reste environ la moitié du composé initial qui n'as pas réagi quelle que soit la quantité d'hydrogénant. L'hydrogénation de **6***a* a aussi été effectuée par le triéthylsilane en présence d'acide trifluoroacétique: on obteint **7***a* avec un rendement de 86%.

A propos des saponifications décrites ci-après, on doit faire les remarques préliminaires suivantes. En plus de l'hydrolyse des fonctions esters de **7***a* et **7***b* (Schéma 5), on observe l'ouverture du groupement phtalimido de **7***a* (en *o*-carboxybenzamido) et une épimérisation au niveau du carbone 2. L'un ou l'autre des diesters **7***b* (ou leur mélange ou encore **7***a*) est saponifié par la lithine aqueuse 4 *N* dans le tétrahydrofuranne. Quel que soit le diester ou le monoester de départ, on obtient le mélange de deux diacides **11** approximativement dans le même rapport (Rdt global 95%).

Du mélange d'acides totalement solubles à chaud (acétone – acétate d'éthyle 50:50), le racémique *cis* (6*RS*, 7*RS*)[3] précipite

[3]Afin de faciliter l'exposition des résultats, la numérotation des atomes adoptée ici pour les esters et les acides est celle des céphèmes.

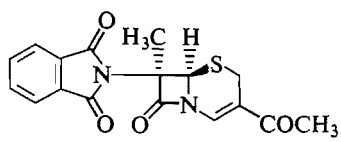
SCHÉMA 5

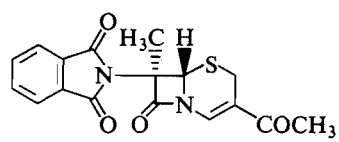
d'abord. En alcalinisant les eaux-mères, on peut provoquer une épimérisation partielle *trans*–*cis* et cristalliser, après acidification, une seconde fraction de racémique *cis*, etc...

La lactamisation des acides ci-dessus est accompagnée de la fermeture du substituant *o*-carboxybenzamido en groupement phtalimido. En opérant cette double cyclisation en présence de dicyclohexylcarbodiimide (DCC), dans une solution à parts égales de nitrométhane et de dichlorométhane, les rendements ne dépassent pas 20%. Les rendements ont été portés à 80% en employant l'hexafluorophosphate de benzotriazol-1-yl-oxy-tris(diméthylamino) phosphonium (BOP), agent de couplage intermoléculaire acide–amine utilisé en synthèse peptidique (6).

La lactamisation d'un mélange d'acides *cis*–*trans* (30:70) donne un mélange de céphèmes dans les mêmes proportions. L'acide *cis* pur donne un seul lactame **12** (6*RS*, 7*RS*) identifié comme étant l'isomère *cis* par effect nOe. L'irradiation du méthyle en position 7 produit un effect Overhauser nucléaire de



+ Enantiomère
12 "*cis*" (6*RS*, 7*RS*)



+ Enantiomère
12 "*trans*" (6*SR*, 7*RS*)

20% sur le proton lié au carbone 6. Le lactame diastéréomère **12** (6*SR*, 7*RS*) n'a pas été complètement purifié mais nous nous sommes assurés que son irradiation dans le mélange ne permettait pas de déceler d'effet nOe (7).

Comme on l'a remarqué, un diacide pur conduit par lactamisation à un céphème pur. L'autre diacide majoritaire dans un mélange conduit à l'autre céphème dans un mélange sous le même rapport. L'hypothèse d'une inversion complète de la configuration du carbone 6 en cours de lactamisation, inversion complète quelle que soit le configuration initiale *R* ou *S* étant peu vraisemblable, on a pu, à partir des céphèmes, attribuer les configurations des acides. Les attributions structurales (Tableau 1) ont été faites à partir d'enregistrements rmn du proton à 250 MHz en s'aidant du découplage homonucléaire.

En suivant la voie ascendante on peut aussi remarquer la similitude des déplacements chimiques des protons 6 du céphème *cis* et de l'ester **7***a* fondant à 195–200°C (5,19 ppm et 5,21 respectivement). Cet ester serait donc aussi *cis*. On peut faire la même observation relativement à leurs diastéréomères (5,36 ppm et 5,40 respectivement). L'ester **7***a* non isolé du mélange serait donc *trans*.

*Voir la note no. 3 en bas de page 1170.

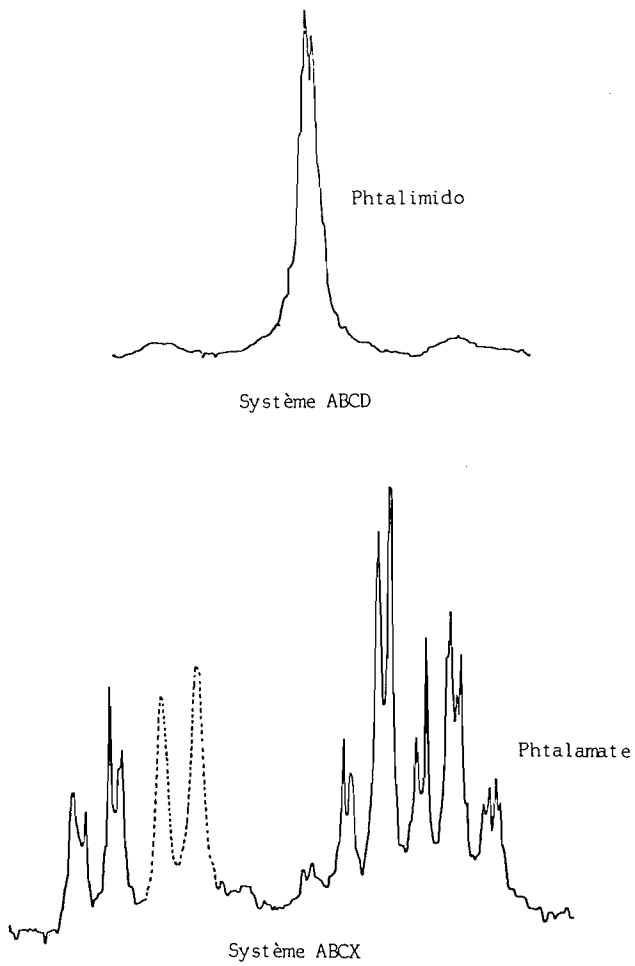

FIG. 1.

La similitude des couplages $J(5-6)$ entre les diacides et leurs diesters: 4 Hz d'une part permet d'attribuer la configuration *trans* à l'ester **7***b* fondant à 112–114°C, 3,4 Hz d'autre part permet d'attribuer la configuration *cis* à l'ester fondant à 182–184°C.

Notons aussi que l'ouverture du groupement phtalimido (méthanolyse et hydrolyse) est facilement repérée par rmn. La figure 1 montre les résonances comparées du cycle aromatique sous les deux formes: forme fermée phtalimido (système ABCD) et forme ouverte phtalamate N-substitué (système ABCX).

Conclusion

En résumé la rmn du proton (250 MHz) a permis d'établir les structures des précurseurs des céphèmes et des céphèmes eux-mêmes avec les configurations de leurs carbones asymétriques. La synthèse utilisée, originale à divers titres, peut être considérée comme stéréospécifique relativement à la production du racémique correspondant à la série naturelle active. En effet l'acide **11** *cis* moins soluble que son épimère peut être facilement isolé du mélange **11** *cis* + **11** *trans*. La solution acide, appauvrie en **11** *cis*, peut être rééquilibrée en milieu alcalin, une deuxième fraction de **11** *cis* précipite par acidification, etc... Finalement l'acide **11** *cis* est cyclisé en phtalimido-7 céphème, par l'intermédiare de BOP, avec de bons rendements et sans nouvelle épimérisation décelable.

Nous projetons d'utiliser les enseignements consignés dans ce mémoire à la synthèse de céphèmes méthoxylés en position 7 et des céphalosporines correspondantes (céphamycines). Les équivalents méthoxylés des composés **3**, inconnus à l'époque à laquelle nous avons commencé ce travail, ont été synthétisés dans l'intervalle dans notre laboratoire.

Reichert à platine chauffante Kofler. Les chromatographies ont été effectuées sur des colonnes d'alumine neutre Prolabo désactivée par 5% d'eau ou sur gel de silice Merck (Kieselgel 60, 70–230 mesh ASTM). Les spectres ir ont été enregistrés sur un spectrophotomètre Unicam SP 1100. Les mesures sont faites sur les substances dispersées dans le bromure de potassium. Les spectres de rmn ont été enregistrés sur des spectromètres Perkin–Elmer R-24-B (60 MHz), Varian XL 100 et Cameca 250 MHz. Les spectres de masse ont été enregistrés sur un spectromètre Varian-mat à double focalisation (énergie d'ionisation: 70 eV).

Cyano-2 oximino-2 acétate de méthyle ***1***

Ce composé a été préparé suivant le mode opératoire décrit dans l'une de nos publications (4). Après cristallisation dans le benzène, on obtient des cristaux blancs fondant à 124°C, Rdt = 85%. *Anal.* calc. pour $C_4H_4N_2O_3$: C 37,50, H 3,15, N 21,87; tr.: C 37,63, H 3,00, N 21,94.

Amino-2 cyano-2 acétate de méthyle et cyano-2 phtalimido-2 acétate de méthyle ***2***

L'amalgame d'aluminium nécessaire au traitement de 12,8 g (0,1 mol) d'oxime **1** est préparé à partir de 4 g de métal (0.15 mol) recouvert d'une solution aqueuse de 5% de chlorure mercurique. On laisse réagir 5 à 7 min puis on décante. L'amalgame obtenu est lavé deux fois par de l'eau puis deux fois par le minimum de méthanol. On y ajoute alors 150 cm^3 de méthanol, 12,8 g d'oxime et 5 cm^3 d'eau. L'agitation est maintenue jusqu'à refroidissement du mélange réactionnel (environ 30 min) puis on filtre. Le résidu solide est lavé par de l'acétate d'éthyle. Après concentration, le filtrat fournit environ 10 g d'une huile jaune. L'amino-2 cyano-2 acétate de méthyle obtenu, peu stable, est aussitôt dissous dans 100 cm^3 de toluène. On y ajoute 0,9 cm^3 de triéthylamine et 15 g d'anhydride phtalique (0,1 mol). Le mélange réactionnel est porté à reflux à l'aide d'un bain d'huile préalablement chauffé à 180°C. Le reflux est maintenu 15 min, on filtre le contenu du ballon encore chaud et on concentre le filtrat. Le précipité cristallin obtenu est traité par environ 200 cm^3 d'eau bouillante afin d'éliminer l'anhydride phtalique en excès. Après essorage, le produit est cristallisé dans le méthanol. On obtient des cristaux blancs fondant à 139–141°C, Rdt de 50% sur l'ensemble des 2 réactions; ir: 2270 (C≡N), 1780 et 1730 (C=O phtalimido), 1768 (C=O ester) cm^{-1}; rmn ($CDCl_3$) δ: 3,98 (s, 3H, OCH_3), 5,90 (s, 1H, CH), 7,93 (s, 4H, phtalimido); sm *m/e*: 244 $(M)^{\ddagger}$, 200, 185 ($Pht\overset{+}{N}{=}CH{-}C{\equiv}N$), 160 ($Pht\overset{+}{N}{=}CH_2$), 132, 104 ($C_6H_4{-}C{\equiv}\overset{+}{O}\cdot$), 76 (benzyne). *Anal.* calc. pour $C_{12}H_8N_2O_4$: C 59,02, H 3,30; tr.: C 59,50, H 3,55.

Cyano-2 phtalimido-2 propionate de méthyle ***3***a

Dans un ballon surmonté d'un réfrigérant à reflux et contenant 13,8 g (0,1 mol) de carbonate de potassium en suspension dans 100 cm^3 d'acétone anhydre, on ajoute 0,1 mol de composé **2** à méthyler. Après 15 min d'agitation à température ambiante, on ajoute un léger excès d'iodure de méthyle puis on chauffe sous reflux pendant 1 h. Après refroidissement, le mélange réactionnel est filtré. Le précipité est lavé par de l'acétone. Après évaporation du filtrat, le résidu est dissous dans le minimum de benzène que l'on filtre à travers une colonne de gel de silice (h = 20 cm, ϕ = 1,5 cm, éluant: benzène). Après cristallisation dans le méthanol, on obtient des cristaux blancs fondant à 113°C, Rdt = 80%; ir: 1782 et 1725 (C=O phtalimido), 1760 (C=O ester) cm^{-1}; rmn ($CDCl_3$) δ: 2,27 (s, 3H, CH_3—C), 3,93 (s, 3H, OCH_3), 7,99 (s, 4H, phtalimido); sm *m/e*: 258 $(M)^{\ddagger}$, 214, 199 ($Pht\overset{+}{N}{=}C(CH_3)CN$), 172 ($Pht\overset{+}{N}{=}C{=}CH_2$), 132, 104 ($C_6H_4{-}C{\equiv}\overset{+}{O}\cdot$), 76. *Anal.* calc. pour $C_{13}H_{10}N_2O_4$: C 60,46, H 3,90, N 10,85; tr.: C 60,45, H 3,91, N 10,96.

Cyano-2 o*-méthoxycarbonylbenzamido-2 propionate de méthyle* ***3***b

A 14,5 g (0,05 mol) de ***3a*** dissous dans 30 cm^3 de méthanol, on ajoute 0,8 cm^3 de triéthylamine. On chauffe le mélange sous reflux pendant 1 h. Après évaporation des solvants, le résidu est chromatographié sur gel de silice (éluant: éther de pétrole – acétate d'éthyle 75:25). On obtient des cristaux blancs (acétate d'éthyle – éther diéthylique) fondant à 104–106°C, Rdt = 79%. *Anal.* calc. pour $C_{14}H_{14}N_2O_5$: C 57,92, H 4,86, N 9,65; tr.: C 57,74, H 4,84, N 9,46.

Amino-3 méthyl-2 phtalimido-2 thioxo-3 propionate de méthyle ***4***a

On fait barboter pendant 4 h, à température ambiante, de l'hydrogène sulfuré dans une solution de 12 g (0,04 mol) de **3** dans 80 cm^3 de pyridine et 40 cm^3 de triéthylamine. L'hydrogène sulfuré en excès est éliminé sous le vide partiel de la trompe à eau. La solution est concentrée et reprise plusieurs fois par du toluène pour éliminer totalement la pyridine. Le précipité blanc-rougeâtre ainsi obtenu peut être purifié éventuellement sur une colonne de gel de silice (élimination de soufre). La cristallisation dans le benzène ou l'acétate d'éthyle fournit des cristaux blancs fondant à 194–199°C, Rdt = 80%; ir: 3350 et 3180 (NH_2 thioamide), 1782 et 1725 (C=O phtalimido), 1750 (C=O ester) cm^{-1}; rmn (DMSO) δ: 2,09 (s, 3H, CH_3—C), 3,75 (s, 3H, OCH_3), 7,85 (s, 4H, phtalimido), 9,40 et 10,04 (2s, 2H, NH_2); sm *m/e*: 292 $(M)^{\ddagger}$, 233 ($Pht\overset{+}{N}{=}C(CH_3){-}CSNH_2$), 201, 172 ($Pht\overset{+}{N}{=}C{=}CH_2$), 132, 104 ($C_6H_4{-}C{\equiv}\overset{+}{O}\cdot$), 76, 58, 50, 43. *Anal.* calc. pour $C_{13}H_{12}N_2O_4S$: C 53,41, H 4,14, N 9,58, S 10,97; tr.: C 53,44, H 4,15, N 9,60, S 11,00.

Amino-3 méthyl-2 o*-méthoxycarbonylbenzamido-2 thioxo-3 propionate de méthyle* ***4***b

A 11,3 g de ***4a*** dissous dans 25 cm^3 de méthanol, on ajoute 0,5 cm^3 de triéthylamine. Le mélange est chauffé sous reflux et agitation pendant 1 h. Après évaporation des solvants, le résidu est chromatographié sur gel de silice (éluant: chloroforme – éther diéthylique 50:50). Après cristallisation dans le méthanol, on obtient ***4b*** sous forme de cristaux blancs fondant à 150–154°C. Rdt = 70%. Le composé ***4b*** est aussi obtenu par addition d'hydrogène sulfuré sur ***3b*** selon le même mode opératoire que celui décrit pour la préparation du thioamide-ester ***4a***, Rdt 80%; ir: 3370, 3280, 3200 (NH amide et NH_2 thioamide), 1730 et 1705 (C=O ester), 1660 (C=O amide) cm^{-1}; rmn (DMSO) δ: 1,86 (s, 3H, CH_3—C), 3,71 et 3,80 (2s, 6H, 2 OCH_3), 7,70 (s, 4H, benzamide), 8,83 (s, 1H, NH), 9,25 et 10,30 (2s, 2H, NH_2); sm *m/e*: 324 $(M)^{\ddagger}$, 163, 102, 77, 76, 55, 44, 43, 42, 41. *Anal.* calc. pour $C_{14}H_{16}N_2O_5S$: C 51,84, H 4,97, N 8,64, S 9,89; tr.: C 52,08, H 4,75, N 8,67, S 9,84.

(N,N-diméthylaminométhylène)amino-3 méthyl-2 phtalimido-2 thioxo-3 propionate de méthyle ***5***a

Le mode opératoire utilisé est celui décrit par Weidinger et Eilingsfeld (8). Des quantités équimoléculaires du diméthylacétal du diméthylformamide et du thioamide-ester précédent ***4a*** dissous dans le chloroforme sont maintenues sous agitation, à température ambiante, pendant 2 h. Après évaporation de la majeure partie du solvant, on filtre sur colonne de gel de silice en éluant par un mélange benzène – acétate d'éthyle 80:20. La cristallisation dans le méthanol donne des cristaux jaunes fondant à 156–159°C, Rdt 87%; ir: 1770 et 1720 (C=O phtalimido), 1738 (C=O ester), 1622 (C=N) cm^{-1}; rmn ($CDCl_3$) δ: 2,31 (s, 3H, CH_3—C), 2,95 et 3,19 (2s, 6H, $N(CH_3)_2$), 3,80 (s, 3H, OCH_3), 7,75 (s, 4H, phtalimido), 8,49 (s, 1H, N=CH); sm *m/e*: 347 $(M)^{\ddagger}$, 199 ($Pht\overset{+}{N}{=}C(CH_3)CN$), 172 ($Pht\overset{+}{N}{=}C{=}CH_2$), 115 ($\overset{+}{S}{\equiv}C{-}N{=}CH{-}N(CH_3)_2$), 44. *Anal.* calc. pour $C_{16}H_{17}N_3O_4S$: C 55,32, H 4,93, N 12,10, S 9,23; tr.: C 55,51, H 4,93, N 12,22, S 9,13.

(N,N-diméthylaminométhylène)amino-3 o*-méthoxycarbonylbenzamido-2 méthyl-2 thioxo-3 propionate de méthyle* ***5***b

Ce composé est obtenu à partir de ***4b*** selon de mode opératoire ci-dessus. Il a été purifié par chromatographie sur gel de silice (éluant: éther diéthylique – acétate d'éthyle 50:50). Après cristallisation dans un mélange éther de pétrole – acétate d'éthyle, on obtient des cristaux jaunes fondant à 126–127°C, Rdt 87%; ir: 3300 (NH), 1755 et 1735 (C=O ester), 1665 et 1635 (C=O amide) cm^{-1}; rmn ($CDCl_3$) δ: 1,90 (s, 3H, CH_3—C), 3,08 et 3,20 (2s, 6H, $N(CH_3)_2$), 3,69 et 3,81 (2s, 6H, 2 OCH_3), 7,48 (m, 3H, benzamido), 7,71 (m, 1H, benzamido), 8,39 et 8,52 (2s, 2H, NH et N=CH); sm *m/e*: 379 $(M)^{\ddagger}$, 163, 115, 77, 44, 42. *Anal.* calc. pour $C_{17}H_{21}N_3O_5S$: C 53,81, H 5,58, S 8,45; tr.: C 53,90, H 5,60, S 8,31.

For personal use only.

*(Acétyl-5 6*H*-thiazine-1,3 yl-2)-2 phtalimido-2 propionate de méthyle* **6***a*

A 4 g de **5***a* en solution dans 30 cm^3 de benzène anhydre, on ajoute 0,1 g d'hydroquinone et 2 cm^3 de méthylvinylcétone fraîchement distillée. On chauffe sous reflux et agitation pendant 2 h puis on ajoute de nouveau un excès de diénophile (2 cm^3) en maintenant l'agitation et le chauffage. L'évolution de la réaction est contrôlée par chromatographie sur couches minces. On répète au besoin l'addition précédente jusqu'à disparition de **5***a*. L'évaporation du solvant sous pression réduite puis la chromatographie sur colonne de gel de silice, élution benzène – acétate d'éthyle 90:10, fournissent une huile jaune qui cristallise dans le méthanol ou l'éther diéthylique. On obtient des cristaux jaunes fondant à 155–157°C, Rdt 80%; ir: 1780 et 1723 (C=O phtalimido), 1760 (C=O ester), 1660 (C=O cétone), 1605 (cycle thiazinique) cm^{-1}; rmn ($CDCl_3$) δ: 2,21 (s, 3H, CH_3—C), 2,40 (s, 3H, CH_3CO), 3,66 (s, 2H, CH_2), 3,88 (s, 3H, OCH_3), 7,90 (s, 1H, CH en position 4 du cycle thiazinique), 7,90 (s, 4H, phtalimido); sm *m/e*: 372 $(M)^{\ddagger}$, 225 (M − PhtNH), 200, 193, 172 ($PhtN^{+}{=}C{=}CH_2$), 165, 145, 85, 71, 69, 57, 45, 43. *Anal.* calc. pour $C_{18}H_{16}N_2O_5S$: C 58,05, H 4,33, S 8,61; tr.: C 58,01, H 4,58, S 8,54.

*(Acétyl-5 6*H*-thiazine-1,3 yl-2)-2* o*-méthoxycarbonylbenzamido-2 propionate de méthyle* **6**b

Le mode opératoire est analogue au précédent mais on a procédé à température ambiante en 72 h d'agitation. Le produit brut a été chromatographié sur colonne de gel de silice (éluant: chloroforme – éther diéthylique 90:10). Le composé **6***b* est obtenu sous forme d'une huile jaune, Rdt 80%; ir: 3370 (NH), 1745 (C=O ester), 1675 (C=O amide) cm^{-1}; ir (CCl_4): 3400 (NH), 1745 (C=O ester), 1675 (C=O amide) cm^{-1}; rmn ($CDCl_3$) δ: 2,04 (s, 3H, CH_3—C), 2,40 (s, 3H, CH_3CO), 3,56–3,64 (m, 2H, CH_2), 3,84 et 3,86 (2s, 6H, OCH_3), 7,36–7,60 (m, 3H, benzamido), 7,72 (s, 1H, NH), 7,78–7,94 (m, 1H, benzamido et H en position 4); sm *m/e*: 404 $(M)^{\ddagger}$, 225, 163, 77, 43.

Hydrogénation de **6**a *par l'amalgame d'aluminium: (acétyl-5 dihydro-3,6 2*H*-thiazine-1,3 yl-2)-2 (hydroxy-3 phtalimidino)-2 propionate de méthyle* **8***, hydroxy-3 phtalimidine* **9** *et (acétyl-5 dihydro-3,6 2*H*-thiazine-1,3 ylidène-2)-2 propionate de méthyle* **10**

A 0,108 g (0,004 mol) d'aluminium décapé au préalable par le chlorure mercurique, on ajoute 0,372 g (0,001 mol) de **6***a* dissous dans 9 cm^3 de méthanol à 96% et 3 cm^3 de benzène. On agite 1 h à température ambiante. On filtre puis lave le précipité avec du méthanol. On évapore le filtrat puis on reprend le résidu par du benzène. Le composé **8** précipite déjà de cette solution benzénique. Le nouveau filtrat est chromatographié sur gel de silice (éluant: éther diéthylique – acétate d'éthyle 50:50).

8 (2 isomères) se présente sous forme de cristaux blancs; ir: 3360, 3250 (OH, NH), 1730, 1680, 1640 (C=O) cm^{-1}; sm *m/e*: 376 $(M)^{\ddagger}$, 235, 227, 217, 202, 186, *185*, 159, 158, 157, 143, 142, 133, 132, 130, 88, 77, 43.

9 se présente aussi sous forme de cristaux blancs (lit. (5) *F* 178°C); sm *m/e*: 149 $(M)^{\ddagger}$, 148, 132, 131, 130, 121, 105, 104, 103, 102, *77*, 76, 75, 74, 66, 65, 57, 52, 51, 50.

10 est une huile jaune; ir (CCl_4): 3190, 3130 (NH), 1665, 1640, 1585 (C=O, C=C) cm^{-1}; rmn ($CDCl_3$) δ: 1,93 (s, 3H, CH_3—C), 2,27 (s, 3H, CH_3CO), 3,60 (s, 2H, CH_2), 3,72 (s, 3H, OCH_3), 7,40 (d, J = 6,6 Hz, 1H, H en position 4), 11,44 (d, 1H, NH); sm *m/e*: 227 $(M)^{\ddagger}$, 195, 194, 184, 153, *152*, 124, 102, 99, 92, 91, 78, 71, 59, 45, 44, 43.

Hydrogénation de **6**b *par l'amalgame d'aluminium: (acétyl-5 dihydro-3,6 2*H*-thiazine-1,3 yl-2)-2* o*-méthoxycarbonylbenzamido-2 propionate de méthyle* **7**b

On ajoute 1,6 g de **6***b* (0,004 mol) dissous dans un mélange de 20 cm^3 de méthanol à 96% et de 20 cm^3 de benzène à 0,648 g (0,024 mol) d'aluminium décapé comme ci-dessus. On agite 2 h à température ambiante. Après filtration et lavage du précipité par du méthanol, le filtrat est concentré. Le résidu dissous dans le minimum d'acétate d'éthyle est chromatographié sur gel de silice. L'élution par de l'acétate d'éthyle fournit le mélange des deux isomères, séparés par cristallisation fractionnée. Une première cristallisation dans l'acétate d'éthyle conduit à un isomère fondant à 112–114°C (cristaux blancs). Les eaux mères concentrées sont reprises par du benzène et laissent déposer des cristaux blancs correspondant à l'isomère fondant à 182–184°C, Rdt global = 95%; ir: 3355 (NH), 1730 (C=O ester), 1655, 1635 (C=O amide et C=O cétone) cm^{-1}; rmn (CD_3COCD_3): voir Tableau 1; sm *m/e*: 406 $(M)^{\ddagger}$, 265 (M − cycle acétylthiazinique)$^+$, 227 (M − *o*-méthoxycarbonylbenzamido)$^+$, 173, 172, 163 ($CH_3OCOC_6H_4$—C≡O^+), 143, *142* (cycle acétylthiazinique)$^+$, 102, 98, 77, 56, 43. *Anal.* calc. pour $C_{19}H_{22}N_2O_6S$: C 56,14, H 5,46, S 7,89; tr.: C 55,98, H 5,50, S 7,75.

Hydrogénation de **6** *par le cyanoborohydrure de sodium: (acétyl-5 dihydro-3,6 2*H*-thiazine-1,3 yl-2)-2 phtalimido-2 propionate de méthyle* **7**a

On dissout 2,23 g (0,006 mol) de **6***a* dans 150 cm^3 d'éthanol bouillant. Après retour à la température ambiante, on ajoute 0,415 g (0,0066 mol) de cyanoborohydrure de sodium et quelques cristaux de vert de bromocrésol comme indicateur de pH. On maintient l'acidité en additionnant goutte à goutte de l'acide chlorhydrique concentré. L'agitation est maintenue 1,5 h. Après lavage à l'eau puis extraction par de l'acétate d'éthyle, une chromatographie sur gel de silice fournit un mélange de diastéréomères du produit attendu (éluant: benzène – acétate d'éthyle 80:20). Un échantillon cristallisé dans un mélange acétone – éther diéthylique puis recristallisé dans l'acétate d'éthyle fournit l'isomère ayant le point de fusion le plus élevé (195–200°C) sous forme de cristaux blancs. L'autre isomère, contenu dans les eaux-mères n'a pu être isolé à un degré de pureté suffisant, Rdt global = 45 à 50%; ir: 3415 (NH), 1782 et 1724 (phtalimido), 1745 (C=O ester), 1720 (C=O cétone), 1610 (C=C) cm^{-1}; rmn (CD_3COCD_3): voir Tableau 1; sm *m/e*: 374 $(M)^{\ddagger}$, 174 ($PhtN^{+}{=}CH{-}CH_3$), 143, *142* (cycle acétylthiazinique)$^+$, 132, 104, 98, 76, 43. *Anal.* calc. pour $C_{18}H_{18}N_2O_5S$: C 57,74, H 4,85, N 7,48, S 8,56; tr.: C 57,85, H 4,93, N 7,45, S 8,32.

Hydrogénation de **6**a *par le triéthylsilane: (acétyl-5 dihydro-3,6 2*H*-thiazine-1,3 yl-2)-2 phtalimido-2 propionate de méthyle* **7**a

On agite 1 h, à température ambiante, 0,372 g (0,001 mol) de **6***a* en solution dans 2,28 g (0,020 mol) d'acide trifluoroacétique. On ajoute ensuite 0,58 g (0,005 mol) de triéthylsilane. On maintient alors l'agitation 72 h à 60°C. On dilue par de l'eau puis neutralise par de la soude. Le composé hydrogéné **7***a* est extrait par du chlorure de méthylène puis chromatographié sur gel de silice (éluant: chlorure de méthylène-acétate d'éthyle 90:10), Rdt global des 2 isomères = 86%.

Sponification de **7**a *et* **7**b*: acides (acétyl-5 dihydro-3,6 2*H*-thiazine-1,3 yl-2)-2* o*-carboxybenzamido-2 propioniques* **11**

A 0,010 mol de **7***a* ou **7***b* en solution dans 50 cm^3 d'acétonitrile, on ajoute sous agitation 8 cm^3 de lithine 4 *N* (0,032 mol) à la température ambiante. On suit la réaction par chomatographie sur couches minces en effectuant périodiquement des prélèvements et l'on arrête la réaction lorsque tout l'ester a disparu. Après acidification du mélange réactionnel et extraction par l'acétate d'éthyle, l'acide obtenu est cristallisé dans l'acétate d'éthyle ou dans un mélange acétone – acétate d'éthyle. On obtient des cristaux blancs fondant à 158–160°C (décomposition), Rdt 95%; rmn (CD_3COCD_3): voir Tableau 1; sm *m/e*: 316 $(M - CO_2 - H_2O)^{\ddagger}$, *142* (cycle acétylthiazinique)$^+$. Ce composé est le seul parmi tous les composés décrits dans ce mémoire à ne pas présenter de pic moléculaire dans les conditions standard d'enregistrement. Les diacides subissent une décarboxylation et une déshydratation dans le spectromètre. *Anal.* calc. pour $C_{17}H_{18}N_2O_6S$: C 53,96, H 4,79, N 7,40, S 8,47; tr.: C 54,19, H 4,75, N 7,47, S 8,37.

Acétyl-3 méthyl-7 phtalimido-7 céphème **12***. Lactamisation en présence de DCC*

A 0,378 g (0,001 mol) d'acide **11** en suspension dans 20 cm^3 de chlorure de méthylène, sous agitation, on ajoute 0,3 g (0,015 mol) de dicyclohexylcarbodiimide (DCC). Le mélange réactionnel est agité à

température ambiante pendant 72 h. Après séparation de la majeure partie de la dicyclohexylurée qui a précipité, le filtrat est distillé sous pression réduite puis le résidu est repris par le minimum de chlorure de méthylène. On répète au besoin l'opération. Après chromatographie sur colonne de gel de silice (éluant: benzène – acétate d'éthyle 95:5), on cristallise dans le méthanol et l'on obtient ainsi **12** sous forme de cristaux blancs fondant à 227–229°C.

Lactamisation en présence de BOP

A 0,110 g (≃ 0,0003 mol) d'acide **11** *cis* en solution dans 9 cm^3 de chlorure de méthylène anhydre, on ajoute 0,12 g (0,0012 mol) de triéthylamine et 0,26 g (0,0006 mol) d'hexafluorophosphate de benzotriazol-1-yl-oxy-tris(diméthylamino) phosphonium (BOP). Le mélange réactionnel prend une coloration jaune. On agite à température ambiante pendant 4 h. On ajoute alors 9 cm^3 d'une solution aqueuse saturée de NaCl. On extrait ensuite trois fois par 30 cm^3 d'acétate d'éthyle. On lave trois fois par 10 cm^3 d'acide chlorhydrique 2 *N* puis trois fois par 10 cm^3 d'une solution aqueuse saturée de bicarbonate de sodium puis finalement deux fois par 10 cm^3 d'une solution aqueuse saturée de chlorure de sodium. La solution résultante est séchée sur sulfate de sodium puis distillée sous pression réduite. Le résidu est chromatographié (éluant: chlorure de méthylène). On obtient 0,080 g de lactame **12** *cis* (Rdt 80%) fondant à 227–229°C (méthanol); ir ($CHCl_3$): 1798 (C=O lactame), 1784 et 1726 (C=O phtalimido), 1664 (C=O cétone), 1617 (C=C) cm^{-1}; rmn (CD_3COCD_3): voir Tableau 1; sm *m/e*: 342 $(M)^{\ddagger}$, 218 $(PhtN(CH_3)CHC{\equiv}S^+)$, *201* $(PhtN(CH_3)C{=}C{=}O)^{\ddagger}$, 174 $(Pht\overset{+}{N}{=}CH{-}CH_3)$, 173 $(PhtN{-}CH{=}CH_2)^{\ddagger}$, 147 $(PhtNH)^{\ddagger}$, 132, 104 $(C_6H_4{-}C{\equiv}O)^{\ddagger}$, 76, 43 $(CH_3{-}C{\equiv}O)^+$. *Anal.* calc. pour $C_{17}H_{14}N_2O_4S$: C 59,63, H 4,12; tr.: C 59,51, H 4,18.

Received October 22, 1982

DENNIS G. GARRATT, MARIA PRZYBYLSKA, and MIROSLAW CYGLER. Can. J. Chem. **61**, 1176 (1983).

The electrophilic cleavage of a cyclopropane single bond in tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane by 2-nitrobenzenesulphenyl chloride in methanol and acetic acid has been studied using both nmr and single crystal X-ray structural determination techniques. The orientation of ring opening has been shown to be inversion as a result of electrophilic corner attack. The crystal structure of one adduct allowed the unambiguous assignment of *exo*-3-(2′-nitrophenylthio)-*exo*-5-methoxytricyclo[2.2.1.0^{2,6}]-heptane, $C_{14}H_{15}NO_3S$. This species crystallizes in space group $P2_1/a$ with unit cell dimensions a = 10.633(1), b = 13.637(1), c = 9.938(1) Å, β = 115.36(1)°, Z = 4. The structure was solved by MULTAN 78. The parameters were refined by block-diagonal least squares to a final R = 0.039 for 2445 observed reflections. Of particular interest is an interaction between the sulphur atom and the oxygen atom of the nitro group with an S...O distance of 2.694(2) Å and C—S···O = 175.5(1)°. The data presented in this paper show errors in previous assignments based on ^{13}C nmr spectroscopy made in this laboratory and indicate the danger of basing assignments of configuration in nortricyclenes entirely upon this technique.

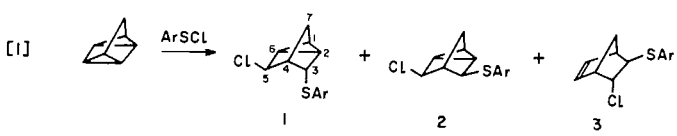
DENNIS G. GARRATT, MARIA PRZYBYLSKA et MIROSLAW CYGLER. Can. J. Chem. **61**, 1176 (1983).

Faisant appel à la détermination de structure par cristallographie de rayons-X sur un mono cristal et à la rmn, on a étudié le clivage électrophile d'une liaison simple du cyclopropane du tétracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane par le nitro-2 benzène chlorure de sulphényle dans le méthanol et l'acide acétique. On montre que l'orientation de l'ouverture du cycle est une inversion résultant d'une attaque électrophile par l'arête. La structure du cristal d'un adduit permet d'identifier sans ambiguité l'*exo*-(nitrophényl-2′ thio)-3 *exo* méthoxy-5 tricyclo[2.2.1.0^{2,6}]heptane $C_{14}H_{15}NO_3S$. Ce composé cristallise dans le groupe d'espace $P2_1/a$ avec a = 10,633(1), b = 13,637(1), c = 9,938(1) Å, β = 115,36(1)°, Z = 4. On a résolu la structure selon la méthode MULTAN 78 et on l'a affinée par la méthode des moindres carrés ("block-diagonal") jusqu'à une valeur finale de R = 0,039 pour 2445 réflexions observées. L'interaction entre l'atome de soufre et l'atome d'oxygène du groupe nitro avec une distance S···O de 2,694(2) Å et d'un angle C—S···O 175,5(1)° est d'un intérêt particulier. Les données que l'on présente ici révèlent les erreurs qui se sont glissées dans les attributions antérieures fondées sur la spectroscopie de la rmn du ^{13}C et mettent en évidence le danger d'utiliser uniquement cette technique pour établir la configuration des nortricyclènes.

[Traduit par le journal]

Introduction

In an earlier paper of this series, we reported the reactions of a series of arenesulphenyl chlorides with tetracyclo-[3.2.0.0^{2,7}.0^{4,6}]heptane to give two or all three of the adducts **1**–**3** (eq. [1]), when methylene chloride is used as solvent at



ambient temperature (1). Assignment of the nortricyclene adducts, **1** and **2**, was based upon previously defined criteria utilizing ^{1}H and ^{13}C nmr spectroscopy. For example, the ^{13}C nmr data for species **1** and **2** indicated three cyclopropyl methine carbons with characteristic high-field chemical shifts (2) and high $^1J_{^{13}C-^1H}$ values (3). The remaining carbon resonances, methine *geminal* to chlorine or sulphur and the lone methine, and methylene bridge, were readily identified on the basis of their respective chemical shifts and multiplicities. In addition we were able to compare these spectral data with those of authentic samples of **2** and **3** prepared during the analogous investigation using bicyclo[2.2.1]hepta−2,5-diene.

The structure of **1** was defined as the C(3) epimer of **2** on the basis of ^{13}C nmr analysis. The *endo* orientation of the arylthio moiety at C(3) follows from the observed paramagnetic shift of C(3) in **1** relative to **2**, and a diamagnetic shift of C(5), albeit a small one, in **1** relative to **2**. The small absolute value of this latter shift difference was unanticipated but presumably results from a combination of the expected γ−*gauche* interaction and an anisotropy effect from the phenyl ring operating in the opposite sense.

These assignments were further corroborated by the observations of Morrill *et al.* (4) that tetracyclo[3.2.0.0^{2,7}.0^{4,6}]-heptane-1,5-dicarboxylic acid **4***a* and its dimethyl ester **4***b*

react with benzenesulphenyl chloride (eq. [2]) to give *exo*-5-chloro-*endo*-3-phenylthiotricyclo[2.2.1.$0^{2,6}$]heptane-2-*exo*-3-dicarboxylic acid, **5***a*, the C(3) epimer **6***a*, and the corresponding dimethyl esters, **5***b* and **6***b*, in approximately equal amounts. Both Bredt and later Cristol and LaLonde substantiated these results in their studies of the analogous addition of 4-toluenesulphenyl chloride to **4** (5).

[2] 
4 a R = H
b R = CH_3 5 6

A recent paper by Zefirov *et al.*, however, brings all of these results into question (6). They have shown on the basis of a single crystal X-ray structure determination that the nortricyclene adduct isolated in the reaction of arenesulphenyl chlorides with bicyclo[2.2.1]hepta-2,5-diene is not **2** as previously reported (7), but is in fact the species: *endo*-3-chloro-*exo*-5-arylthiotricyclo[2.2.1.$0^{2,6}$]heptane, **7** (eq. [3]). Since species **7**

[3] 
7

corresponds spectroscopically to species **2** in our work with tetracyclo[3.2.0.$0^{2,7}$.$0^{4,6}$]heptane it is obvious that there exists an error in our assignments. This brings into question the methodology based upon the use of ^{13}C nmr for assignment of configuration in nortricyclene products. The importance of these data is clearly evident in that numerous papers from this laboratory and elsewhere have been based upon the utility and ease of ^{13}C nmr based assignments.

The importance attached to correctly establishing the stereochemistry of the nortricyclene adducts stems from the controversy surrounding the mode of interaction of an electrophile EN with a strained carbon–carbon single bond. Conceptually there exist two distinct mechanisms as shown in Scheme 1. For example, the electrophile and the strained bond may approach each other orthogonally, i.e. edge-on attack. In the case of cyclopropane, one would anticipate the maximum interaction of orbitals to occur when the electrophile approaches the single bond in the same plane as the three carbons which define the ring, i.e. for $\theta = 0°$. In the case of a substituted cyclopropane, as is found in the substrate used in this investigation, the best angle of approach with respect to this plane may be significantly different. The major point to be noted is that this type of interaction leads to retention of configuration at the carbon atom, wherein the new bond is formed with the electrophilic portion of the reagent (E of EN or ArS of ArSCl).

Alternatively, the electrophile may approach the corner of the strained bond along an extended axis joining two of the carbon atoms of the ring, that is to say, collinearly or end-on, the interaction ultimately resulting in inversion of configuration at the carbon atom forming the new bond with E (ArS). The presence of diastereomeric products in this latter case requires that the subsequent nucleophilic attack on the cationic intermediate be nonstereospecific, the relative proportions of each product being dependent upon steric or other electronic effects.

Earlier studies carried out in these laboratories suggested that arenesulphenyl halides react with tetracyclo[3.2.0.$0^{2,7}$.$0^{4,6}$]-

Edge-on attack
retention of configuration at carbon
in plane $\theta = 0°$

Corner or end-on attack
inversion of configuration at carbon
in plane $\theta = 0°$, equivalent to collinear attack

SCHEME 1

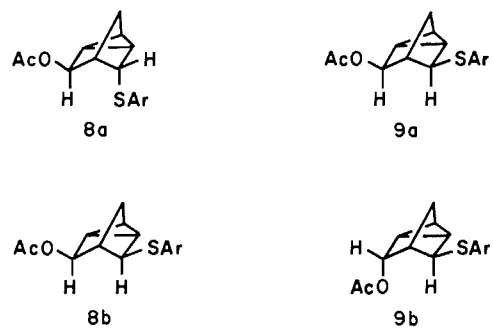
heptane by both pathways described above. If the original assignments were incorrect a new mechanistic scenario would be required.

Results and discussion

In order to study this problem in more detail an investigation was undertaken wherein 2-nitrobenzenesulphenyl chloride was reacted with tetracyclo[3.2.0.$0^{2,7}$.$0^{4,6}$]heptane in protic solvents, in particular, methanol and anhydrous acetic acid.

The reaction in acetic acid is quite complex, yielding in addition to two 3-arylthio-5-acetoxy nortricyclenes **8** and **9**, the two known 3-arylthio-5-chloro species **1** and **2**, the known olefinic species **3**, 3-acetoxytricyclo[2.2.1.$0^{2,6}$]heptane, presumably from addition of acetic acid upon the substrate, and two species which were shown to be 2-chloro-3-arylthio-5-acetoxy and 2-chloro-3-arylthio-6-acetoxy substituted norbornanes.

Of primary interest is the assignment of the two nortricyclenes **8** and **9**. On the basis of ^{13}C nmr criteria these species may be tentatively assigned as **8***a* and **9***a* respectively (see Table 1). On the basis of ^{1}H nmr data, however, Zefirov has chosen to assign the same species as **8***b* and **9***b*. In both



cases use has been made of the relative differences in chemical shifts. Thus, Zefirov and co-workers have argued for structures **8***b* and **9***b* on the basis of the observation that the ^{1}H nmr chemical shifts of the methine protons geminal to the acetoxy groups δ 4.9 and 4.7, respectively, indicate that the arylthio group in both isomers is found in the same position, whereas the difference in the proton chemical shifts of the methine protons geminal to the arylthio groups, δ 3.4 and 3.9, points to a difference in the configuration of the acetoxy group, the latter apparently being in the *endo* orientation in species **9**. On the basis of the greater probabililty of *exo* attack upon bicyclo-[2.2.1]hepta-2,5-diene, which yields the same two nortri-

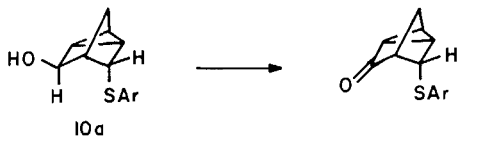
cyclene adducts, Zefirov ascribed an *exo* orientation to the arylthio moieties (6).

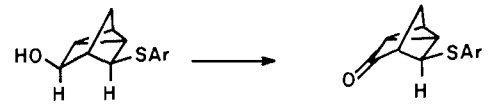
On the other hand, an examination of the ^{13}C nmr data in Table 1 shows that the chemical shifts of methine carbons bonded to sulpur in **8** and **9** are essentially identical (δ 50.0 and 50.3), whereas the chemical shifts of the methine carbons bonded to the acetoxy groups (δ 77.8 and 79.9) show a larger difference. If the adducts are epimeric at C(5) as per Zefirov's assignment one would expect, on the basis of the γ−*gauche* effect, to see little difference in the resonances at C(5) but a diamagnetic shift of the C(3) resonance in species **9***b* relative to **8***b*. If, however, the adducts are epimeric at C(3) as per the assignments **8***a* and **9***a*, the ^{13}C nmr data are readily interpretable.

Since both interpretations cannot be correct, another approach to the problem was necessary. Reduction of the two acetates **8** and **9** with sodium borohydride in the presence of lithium chloride in 2-propanol as solvent at reflux gave the corresponding alcohols **10** and **11**. An examination of the ^{13}C nmr parameters (Table 1) of these species indicates that no molecular rearrangements have occurred and that **8** yields clearly species **10**, while **9** yields species **11**. If the assignments as based on ^{13}C nmr are correct, oxidation of **10** and **11** should yield two different ketones. (eq. [4]). If, on the other hand,

[4]



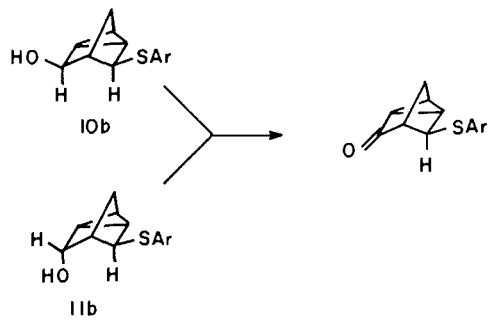
10a



11a

the species are epimeric at C(5) as per the ^{1}H nmr assignment only one ketone should be formed on oxidation (eq. [5]).

[5]



The reactions of **10** and **11** with Jones' reagent in acetone at room temperature yield a single ketone **12** which is readily converted to the known compound **13**: 3-arylthiotricyclo-[2.2.1.$0^{2,6}$]heptane by conversion first to its tosylhydrazone followed by reduction with sodium borohydride (eq. [6]) or 1 : 1 methyllithium and lithium bromide in diethyl ether. The

[6]

12 13

assignment is further corroborated by a comparison of the spectral parameters of **12** with those of **13** and species **14**: tricyclo[2.2.1.$0^{2,6}$]heptanone.

While this last series of experiments clearly shows that the assignments based on ^{13}C nmr spectroscopy are incorrect and that therefore the nortricyclene adducts are epimeric at C(5), the relative orientations of both the arylthio groups and the acetoxy groups are still in question.

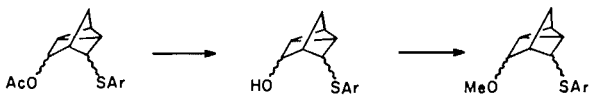
To solve this latter problem the reaction of 2-nitrobenzenesulphenyl chloride with tetracyclo[3.2.0.$0^{2,7}$.$0^{4,6}$]heptane in methanol has been used as a model since the reaction is much cleaner (only 3 species are formed) and the adducts may be isolated in a much more facile manner. As per the reaction in acetic acid, two solvent-incorporated nortricyclenes, **15** and **16**, are formed. The third species has been tentatively assigned as *exo*-2-methoxy-*syn*-7-(2′-nitrophenylthio)bicyclo[2.2.1]-hepta-2,5-diene, **17** (eq. [7]).

[7]

15 + 16 17

The relationship of **15** and **16** to the acetoxy nortricyclenes was, furthermore, established through conversion of the alcohols **10** and **11** to their respective methyl ethers with diazomethane, thereby showing that the orientation of arylthio groups and solvent-incorporated functionalities (methoxy, hydroxy, acetoxy) are similarly oriented in species **15**, **10**, and **8** and in species **16**, **11**, and **9** (eq. [8]).

[8]



8 or 9 — 10 or 11 — 15 or 16

A detailed analysis of the ^{1}H nmr (250 MHz) and ^{13}C nmr spectra (20 MHz) of species **15** and **16** did not allow us to make unambiguous assignments. In order to unequivocally establish the configurational specificity of this reaction, we therefore undertook a single crystal X-ray structural determination of adduct **15**. The molecular conformation, the numbering scheme, and the bond lengths of species **15** are shown in Fig. 1. The refined positional parameters and isotropic temperature factors are listed in Table 2.[4] The angles are listed in Table 3. The C—H bonds vary from 0.93 to 1.00 Å (mean = 0.96 and esd ≤ 0.03 Å).

The C—C bonds of nortricyclene are in the range of 1.500 to 1.519 Å with the exception of the bonds to C(4), which are appreciably longer (1.528(2), 1.540(2), 1.548(2) Å). The substitution by a methoxy group at C(5) leads to a significant shortening of the C(5)—C(6) bond (1.500(3) Å) and the lengthening of the C(4)—C(5) bond to 1.548(2) Å as compared with the equivalent bonds in this moiety. The angles of the three-membered ring give a mean of 60.0°, and those of the

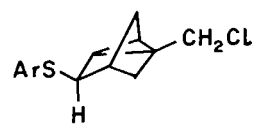
five-membered rings vary from 97.0 to 107.5° with the smallest at C(3), C(5), and C(7).

The dihedral angle between the plane of the benzene ring and that of the nitro group is 25.0°. This rotation of NO_2 about the C—N bond combined with the increase of the C(9)—C(10)—N angle (120.8° vs. 116.5° for C(11)—C(10)—N) gives rise to the S···O(2) distance of 2.694(2) Å. Since this distance is considerably smaller than the sum of O and S van der Waals radii (3.07 Å), a nonbonded interaction between these two atoms must be present, as otherwise a much larger rotation of the nitro group would be expected to lead to an adequate separation between them. Very large twists of the nitro groups to accommodate *ortho*-substituents have indeed been reported for 1-bromo-2,4-dinitrobenzene (40°) (9), 1,5-dinitronaphthalene (49°) (10), 9,10-dinitroanthracene (63.7°) (11), and nitromesitylene (66.4°) (12).

The C(3), S, and O(2) atoms are almost collinear with C(3)—S···O(2) = 175.5(1)°. This condition appears to ensure maximum hybridization utilizing empty *p*- and *d*-orbital participation in bonding. An examination of 69 structures containing divalent sulphur carried out by Rosenfield *et al.* (13) revealed that nucleophiles tend to make short contacts with S approximately along the extension of one of the covalent bonds to S.

A similar S···O interaction, although somewhat weaker, was observed in 1-chloromethyl-3-*endo*-(2′,4′-dinitrophenylthio)tricyclo[2.2.1.0^{2,6}]heptane (14), **18**, where S···O is 2.739(2) Å and C(3)—S···O = 166.3(1)°. This difference in strength is consistent with that found between S···O in other 2-nitrophenylthio compounds (15) (2.630, 2.634 Å) and 2,4-dinitrophenylthio derivatives (16) (2.657 Å).



18

Ar = 2, 4-dinitrophenyl

Somewhat stronger S···O interactions were reported in compounds in which complex alicyclic moieties were replaced by either a phenyl or a thiophenyl group (17). The S···O distances vary in these compounds from 2.588 to 2.636 Å and the C—N rotations are 1° to 18.6°. In general the S···O distances can be correlated with the variations in the rotations of the nitro groups. There is no doubt therefore that the strength of the interaction depends on the nature of the substituents on S. This was demonstrated clearly by Kálmán and Párkányi (18) who compared intramolecular X—S···O=Y interactions in 26 structures. The shortest S···O contact of 2.034(5) Å was reported in S—S···O=N with S—S···O = 174.1(1) Å (19).

The energetic favourability of the above interaction between sulphur and an oxygen atom of the *ortho*-nitro substituent is corroborated both here and elsewhere by use of carbon-13 nmr spectroscopy (18, 20–22) to exist in the solution phase and thus is not a manifestation of the conformational changes often required during crystallization to give the energetically most stable packing arrangement in the crystal stucture.

The S—C (sp^3) and S—C (sp^2) bonds in **15** are 1.812(2) and 1.758(2) Å, respectively. The bonds along the chain S—C(9)—C(10)—N—O(2) show an alternate shortening and lengthening similar to that observed in **18**, the corresponding values being in agreement within 0.002 Å. The torsion angles for the nortricyclene moiety also agree well with the values for **18**, as is shown in Table 4. The attachment of the chloromethyl group at C(1) in **18** caused only a slight increase in the

*Mean values for 1-chloromethyl-3-*endo*-(2′,4′-dinitrophenylthio)tricyclo[2.2.1.$0^{2,6}$]heptane (14).

†Calculated values for the envelope conformation with a puckering amplitude (q = 0.435 Å) determined from an electron diffraction study of cyclopentane (23).

(*b*) Exocyclic torsion angles

C(4)—C(5)—O(1)—C(8)	−81.9
C(4)—C(3)—S—C(9)	69.4
C(3)—S—C(9)—C(14)	14.7
C(9)—C(10)—N—O(2)	−24.5

mean value for the torsion angles along the C(1)—C(2), C(2)—C(6), and C(6)—C(1) bonds (1.7 vs. 0.7°).

The N—O(3) bond is 1.220(3) Å and the presence of a weak C(11)—H···O(3) intramolecular hydrogen bonding is indicated by the difference between the angles C(10)—C(11)—H(11, 1) and C(12)—C(11)—H(11, 1) (118.7(1.3)° vs. 121.6(1.3)°). O(3)···H(11, 1) = 2.41(2) Å and C(11)—H(11, 1)···O(3) = 97.9(1.4)°.

The benzene ring deviates significantly from planarity (χ^2 = 133) as C(9) is at −0.009 and C(14) at 0.011 Å from the plane calculated for the six atoms of the ring. S, N, and O(2) are situated at −0.049, −0.023, and −0.494 Å from that plane, respectively.

The molecules are held together by van der Waals forces. The shortest intermolecular O···H distance O(1)···H(12, 1) is 2.65(2) Å and the closest H···H contacts are 2.41(4) and 2.58(3) Å.

The use of the above X-ray structure data to assign **15** unambiguously as *exo*-3-(2′-nitrophenylthio)-*exo*-5-methoxytricyclo-[2.2.1.$0^{2,6}$]heptane allows us now to assign **8** as the di-*exo* species **8***b*. Since species **8** and **9** were shown to be epimeric at C(5), it is also clear that **9** must be *exo*-3-(2′-nitrophenylthio)-*endo*-5-acetoxytricyclo[2.2.1.$0^{2,6}$]heptane, **9***b*. Similarly, species **16** must be epimeric at C(5) and thus have an *endo*-5-methoxy moiety.

The question may now be raised as to the possible existence of an applicable heuristic method utilizing ^{13}C nmr spectroscopy for assigning configuration in 3,5-disubstituted tricyclo[2.2.1.$0^{2,6}$]heptanes. The behaviour of the compounds studied in this investigation is clearly anomalous relative to the normally anticipated γ−*gauche* effects of the model systems. Specifically, when the chemical shifts of the C(3) and C(5)

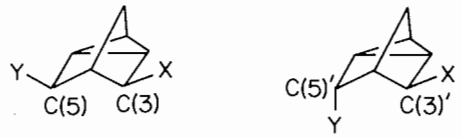
TABLE 5. A comparison of variations in the ^{13}C chemical shifts of C(3) and C(5) for various substituents



Substituents		Chemical shifts (δ, ppm)					
X	Y	C(5)	C(3)	C(5)′	C(3)′	$\Delta_{C(5)-C(5)'}$	$\Delta_{C(3)-C(3)'}$
ArS*	Cl	64.2	49.4	64.9	48.1	−0.7	1.3
ArS*	OAc	77.8	50.0	79.9	50.3	−2.1	−0.3
ArS*	OH	76.8	49.6	79.3	50.5	−2.5	−0.9
ArS*	OMe	84.5	47.8	86.5	47.7	−2.0	0.1
Br	Br	51.0	51.0	[54.3]†	[53.7]†	−3.3	−2.7
Br	OEt	80.3	53.1	83.7	55.2	−3.4	−2.1
Br	OMe	81.8	52.6	85.2	54.6	−3.4	−2.0

*ArS = 2-nitrophenylthio.
†Chemical shifts in brackets may be switched.

resonances are compared, a shift from *exo* to *endo* at C(5) uniformly gives rise to a diamagnetic shift of from 0.7 to 2.5 ppm, upon comparing **1**, **8**, **10**, and **15** to **2**, **9**, **11**, and **16**, respectively. The chemical shift difference of C(3) is generally smaller, being either slightly diamagnetic or paramagnetic. Comparing the chemical shift differences as per Table 5 indicates that as the variation in C(5) resonances becomes less negative, i.e. less diamagnetic, the variations at C(3) become more positive and paramagnetic.

While the behaviour of the arylthio systems seems quite general, its universality must still be tested. One possible set of compounds are the 3-bromo-5-substituted tricyclo[2.2.1.$0^{2,6}$]-heptanes prepared by the electrophilic cleavage of tetracyclo[3.2.0.$0^{2,7}$.$0^{4,6}$]heptane by molecular bromine and previously reported (24). Initial assignments were made on the basis of the γ-*gauche* effect which has now been shown to be inapplicable. If the bromination reaction is reinterpreted in terms of the model of Skell *et al.* (25), the variations in chemical shifts for C(3) and C(5) are as given in Table 5 and follow the observed behaviour of the arylthio compounds. The above correlations, while gratifying, do not, however, prove the universality of the new heuristic method, but suggest that further detailed studies in this area are warranted.

Summary

Our studies show that electrophilic cleavage of cyclopropane rings by arenesulphenyl chlorides in systems such as tetracyclo[3.2.0.$0^{2,7}$.$0^{4,6}$]heptane occurs by a single path leading to corner attack by the electrophile followed by proportioning between *exo* and *endo* attack by solvent in a second step. Previous work in this laboratory is thus in error and the preceding papers in this series must be reevaluated in terms of the new data. In particular, our work on the bromination of cyclopropanes (24) which questioned the interpretations of Skell *et al.* (25) must be reinvestigated in detail. If this system, too, can be shown to be epimeric at C(5), our data become compatible with those of Skell and will lead to a self-consistent theory of cyclopropane cleavage by bromine.

In conclusion, the assignment of configuration in nortricyclenes by use of ^{13}C nmr spectroscopy has been shown to be invalid in the absence of good models of known configuration. A heuristic method, utilizing ^{13}C nmr, based upon existing data has been suggested but requires further model compounds.

Experimental

General

The ^{1}H nmr spectra were recorded on a Bruker WM-250 spectrometer. The ^{13}C nmr spectra were recorded on a Bruker WP-80 spectrometer, using chloroform-*d* as an internal lock and reference. All spectral parameters are referenced to TMS as an internal standard.

Tetracyclo[3.2.0.0.^{2,7}.$0^{4,6}$]heptane was purchased from Aldrich and used without further purification. The purity was confirmed by nmr and glc.

2-Nitrobenzenesulphenyl chloride was purchased from Aldrich and recrystallized prior to use.

The general procedure for the reaction of tetracyclo-[3.2.0.$0^{2,7}$.$0^{4,6}$]heptane with sulphenyl chloride is as previously described (1). All reactions were carried out at 23°C, unless otherwise stated, on a 0.01 to 0.02 mole scale. When methanol was used as the solvent, recovery of the products was accomplished by distillation of the excess methanol under vacuum.

The resultant oil was separated into its components by preparative tlc on silica gel using in the first instance a 1:1 mixture of methylene chloride and 30−60 petroleum ether which yields six bands with R_f's of 0.71, 0.63, 0.53, 0.36, 0.27, and 0.16. No evidence for isomerization on the plates was observed. The combined fractions with R_f's of 0.53, 0.36, and 0.27 were rechromatographed on silica gel using a 1:4 mixture of ethyl acetate and toluene which yields three fractions with R_f's of 0.74, 0.56, and 0.47. The species with R_f's of 0.56 and 0.47 were shown by nmr to be the 5-methoxy-3-(2′-nitrophenylthio)-nortricyclenes.

Crystals of the species with R_f = 0.47 were obtained from a 1:1 mixture of ethyl acetate and chloroform. *Anal.* calcd. for $C_{14}H_{15}O_3NS$: C 60.63, H 5.45, N 5.05, S 11.56, O 17.31%; found: C 60.42, H 5.49, N 5.12, S 11.70%. Single crystal X-ray structural analysis showed this species to be exo-*3-(2′-nitrophenylthio)*-exo-5-*methoxytricyclo[2.2.1.$0^{2,6}$]heptane*, **15**. On the basis of spectral analysis, the species with R_f = 0.56 was shown to be exo-*3-(2′-nitrophenylthio)*-endo-*5-methoxytricyclo[2.2.1.$0^{2,6}$]heptane*.

When anhydrous acetic acid was used as solvent, recovery of the products was accomplished by distillation under vacuum using a liquid nitrogen condenser followed by dissolution in water, neutralization with sodium bicarbonate, and extraction with methylene chloride. The methylene chloride extracts were dried over anhydrous magnesium sulphate. Preparative tlc on silica gel using 1:3 ethyl acetate/65−110

petroleum ether gave six fractions with R_f's of 0.67, 0.62, 0.51, 0.37, 0.33, and 0.25, the latter two of which were identified by nmr as the 5-acetoxy-3-(2′-nitrophenylthio)nortricyclenes. Treatment of either acetoxynortricyclene with 1:1 sodium borohydride/lithium chloride in 2-propanol under reflux for 24 h gives the corresponding hydroxynortricyclene in 75–83% yields after standard work-up. Treatment of either hydroxynortricyclene with Jones' reagent in acetone at 25°C gives a single ketone with R_f = 0.27 on silica gel using 1:3 ethyl acetate/toluene. Yellow needles, mp 94–95°C, were obtained from 1:1 ethyl acetate/cyclohexane. *Anal.* calcd. for $C_{13}H_{11}NO_3S$: C 59.76, H 4.24, N 5.36, S 12.27%; found: C 60.02, H 4.35, N 5.02, S 12.31%.

The ketone was treated with one molar equivalent of tosylhydrazine in ethanol at reflux for 2 h to yield the corresponding tosylhydrazone in 78% yield. The tosylhydrazone was dissolved in anhydrous diethyl ether and reacted with 2 molar equivalents of 1:1 methyllithium/lithium bromide at 23°C for 4 h. Aqueous hydrolysis followed by extraction with methylene chloride gives 3-(2′-nitrophenylthio)-tricyclo[2.2.1.$0^{2,6}$]heptane in 69% yield based on the corresponding ketone.

X-ray structure determination

Crystal data are as follows.

$C_{14}H_{15}NO_3S$ fw = 277.3

Monoclinic, $P2_1/a$, a = 10.633(1), b = 13.637(1), c = 9.938(1) Å, β = 115.36(1)°, V = 1302.2 Å^3. Z = 4, ρ_c = 1.42 g cm^{-3}, λ(CuK$\bar{\alpha}$) = 1.54178 Å, μ(CuK$\bar{\alpha}$) = 22.0 cm^{-1}. Yellow prisms of **15** were obtained as described above. After establishing the space group from precession films, the data were collected at room temperature for a crystal of dimensions 0.34 × 0.34 × 0.39 mm with a Nonius CAD-4 diffractometer using Ni-filtered CuKα, at a take-off angle of 2.5°.

The intensities were collected by $\omega-2\theta$ scan techique using for ω scan angle 0.6° + 0.2 tan θ, with a maximum scan time of 90 s. Three standard reflections were used to monitor the intensity changes every 100 min of exposure time. Data were collected to 2θ limit of 152°. 2686 reflections were measured out of which 2445 (91%) were above threshold of $2\sigma(I_{net})$. The net intensities were corrected for Lorentz and polarization effects, but not for absorption.

The structure was solved by direct methods using the program MULTAN 78 (26). The E map revealed all the non-hydrogen atoms of the molecule.

Refinement was by block-diagonal least-squares with the weighting scheme:

$$\sqrt{w} = 1/\{1 + [(|F_o| - 10)/15]^2\}^{1/2} \text{ if } \sin^2\theta \geq 0.27$$

and

$$\sqrt{w} = [1/\{1 + [(|F_o| - 10)/15]^2\}^{1/2}](\sin^2\theta/0.27)$$

$$\text{if } \sin^2\theta < 0.27$$

The constants were chosen to make $\Sigma w(F_o - F_c)^2$ independent of $|F_o|$.

When R decreased to 0.07, the hydrogen atoms were located from a difference map. They were refined isotropically, but for all other atoms anisotropic temperature factors were used. The refinement was carried out only with the observed reflections, excluding three reflections which suffered form multiple diffraction ($\bar{2}56$, $\bar{2}75$, 407). Eight strongest reflections were corrected for extinction. In the final cycle, R = 0.039 and R_w = 0.040 and the mean and maximum parameter shifts for all atoms were 0.08σ and 0.48σ, respectively. The residual electron density distribution in the final difference map was within −0.41 (in the vicinity of S) to 0.22 e Å^{-3}. Scattering factors for non-hydrogen atoms were those of Hanson *et al.* (27) and for H those of Stewart *et al.* (28). Calculations were carried out with the NRCC system of programs by Ahmed *et al.* (29)

HANS KOENIG, RICHARD T. OAKLEY, A. WALLACE CORDES, and MARK C. NOBLE. Can. J. Chem. **61**, 1185 (1983).

The reaction of tetrasulphur dinitride with norbornadiene produces the 1:1 adduct $S_4N_2 \cdot C_7H_8$; X-ray crystallographic analysis of this compound reveals that olefin addition cleaves one of the sulphur–sulphur bonds of S_4N_2, yielding a novel eight-membered $C_2S_4N_2$ ring. Crystals of $S_4N_2 \cdot C_7H_8$ are monoclinic, space group $P2_1/c$, $a = 6.127(1)$, $b = 17.369(1)$, $c = 9.580(1)$ Å, $\beta = 106.74(1)°$, $V = 1003.8(5)$ Å^3, $Z = 4$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.039$. The S—S—N—S—N—S fragment of the $C_2S_4N_2$ ring is planar to within 0.15 Å. The S—C—C—S unit is folded out of this plane to produce a dihedral angle of 74.5°.

HANS KOENIG, RICHARD T. OAKLEY, A. WALLACE CORDES et MARK C. NOBLE. Can. J. Chem. **61**, 1185 (1983).

La réaction du dinitrure de tétrasoufre avec le norbonadiène donne l'adduit 1:1 $S_4N_2 \cdot C_7H_8$. L'analyse de ce composé par cristallographie de rayons-X révèle que l'addition d'oléfine clive une des liaisons soufre–soufre du S_4N_2 en donnant un nouveau cycle à 8 chaînons $C_2S_4N_2$. Les cristaux de $S_4N_2 \cdot C_7H_8$ sont monocliniques et appartiennent au groupe d'espace $P2_1/c$ avec $a = 6{,}127(1)$, $b = 17{,}369(1)$, $c = 9{,}580(1)$ Å, $\beta = 106{,}74(1)°$, $V = 1003{,}8(5)$ Å^3, $Z = 4$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à une valeur de $R = 0{,}039$. Le fragment S—S—N—S—N—S du cycle $C_2S_4N_2$ est plan à plus ou moins 0,15 Å. L'unité S—C—C—S est pliée hors de ce plan pour former un angle dièdre de 74,5°.

[Traduit par le journal]

Introduction

The orientation of the addition of 2*e*-olefins to tetrasulphur tetranitride S_4N_4 remained a controversial issue for many years (1). The correct mode of addition, in a 1,3-*S*,*S*-fashion, was finally confirmed by chemical degradation methods (2) and X-ray crystallography (3). A similar regiochemistry has since been observed for the addition of norbornadiene to phosphadithiatriazenes $R_2PS_2N_3$ (4). In the light of these findings and our recent report of the molecular and electronic structure of tetrasulphur dinitride S_4N_2 (5) we have investigated the reaction of S_4N_2 with olefins. In part, our work was stimulated by the observation that S_4N_2 forms a 1:1 adduct with dicyclopentadiene, for which the structure **1** was proposed (6). Esr spectroscopic analysis of the reaction suggested an alternative pathway, involving free radicals such as **2** (7). We report here that the reaction of S_4N_2 with norbornadiene produces an adduct of composition $S_4N_2 \cdot C_7H_8$. An X-ray crystal structure determination of this compound reveals that olefin addition cleaves the six-membered ring structure of S_4N_2, producing the novel eight-membered heterocycle **3**.

Experimental

Tetrasulphur dinitride was prepared in small quantities by the reaction of sulphur monochloride with aqueous ammonia (5). Ultraviolet–visible spectra were recorded on a Cary 219 spectrophotometer, and ^{1}H nmr spectra were recorded on an XL-200 NMR spectrometer. Chemical analyses were performed by Mr. Lada Malek.

Preparation of $S_4N_2 \cdot C_7H_8$ (3)

Equimolar solutions of S_4N_2 (freshly sublimed, 0.277 g, 1.78 mmol in 9 mL CS_2) and norbornadiene (0.166 g, 1.78 mmol in 9 mL CH_2Cl_2) were simultaneously added dropwise over a 10 h period (using a syringe pump) to a rapidly stirred reservoir of 200 mL of CH_2Cl_2. The resultant orange solution was evaporated to dryness and the residual oil eluted down a short (100 mm) silica column using 80:20 hexane:CH_2Cl_2 as eluting solvent. The orange–red band ($r_f \simeq 0.8$) was collected and the solvent removed from it to leave a semi-crystalline material which was further purified by chromatography down a 35 × 700 mm Bio-Beads S-X8 column using toluene as eluting solvent. Evaporation of the solvent from the orange–red fraction yielded orange crystals of $S_4N_2 \cdot C_7H_8$ **3** (68 mg, 0.276 mmol, 15%), which could be recrystallized from ether/toluene at −20°C as orange mica-like plates, mp 92–94°C. The compound is stable indefinitely in air as a solid and in solution (hexane). *Anal.* calcd. for $H_8C_7N_2S_4$: C 33.85, H 3.25, N 11.28; found: C 33.73, H 3.24, N 11.11. Ultraviolet and visible spectrum (CH_2Cl_2), λ_{max} (ϵ): 420 (2 × 10^3), 362 (3 × 10^3), 266 (4 × 10^3) nm (M^{-1} cm^{-1}). ^{1}H nmr ($CDCl_3$) δ: 6.45, 6.33 (m, $H_{5,6}$), 3.25, 3.21 (s, $H_{1,4}$), 2.81, 2.53 (d of d, $H_{2,3}$, J = 1.8, 6.6), 1.82, 1.68 (AB, $H_{7,7'}$, $J_{7-7'}$ = 9.5).

X-ray analysis of $S_4N_2 \cdot C_7H_8$ (3)

A small irregularly shaped crystal of $S_4N_2 \cdot C_7H_8$, mounted on a glass fiber, was used for data collection on an Enraf-Nonius CAD-4 diffractometer employing MoK_α ($\lambda = 0.71069$ Å) radiation. A least-squares calculation using the diffractometer settings for 25 carefully

centred reflections gave the following cell parameters (at 21°C):

$C_7H_8S_4N_2$ mw = 248.41

$a = 6.127(1)$, $b = 17.369(1)$, $c = 9.850(1)$ Å, $\beta = 106.74(1)°$, $V = 1003.8(5)$Å^3, $Z = 4$, $D_c = 1.64$ g cm^{-3}, $F_{000} = 512$, $\mu(MoK_\alpha) = 8.63$ cm^{-1}, space group $P2_1/c$.

Systematic absences of $h0l$ (l odd) and $0k0$ (k odd) uniquely indicated the space group $P2_1/c$. Reflections were measured using $\theta-\theta$ scans for 2θ from 4 to 50° (h = 0 to 7, k = 0 to 20, l = −11 to 11). The scan range was (1.3 + 0.35 tan θ) and the scan speed varied from 20 to 5 deg/min. Of the 1987 unique data collected, 399 reflections had $I < 3\sigma(I)$ and were considered unobserved. An empirical absorption correction based on psi scans gave correction factors which varied from 0.811 to 0.996. The intensities of three reflections (−1 13 −1, 2 5 −6, 3 5 −1) were measured periodically during the data collection; these varied by less than 4% and thus indicated crystal and electronic stability.

The structure was solved by direct methods (MULTAN80) (8) and refined by full-matrix least-squares techniques. The final cycle of refinement based on F^2 included 118 parameters (positional and anisotropic thermal parameters for all non-hydrogen atoms) and gave a parameter:reflection ratio of 1:13.5. Hydrogen atoms were included in the structure factor calculations at idealized positions (d(C—H) = 0.95 Å) with isotropic thermal parameters of 5.0 Å^2. The final R = 0.039 and R_w = 0.055. The weighting scheme used was $w = [\sigma^2(F) + 0.05F^2]^{-1}$ where $\sigma(F)$ was derived from counting statistics. The standard deviation of an observation of unit weight was 1.68. In the final cycle of refinement, the maximum shift/error was 0.42. The final difference map had maximum values of 0.6 e/Å^3. No secondary extinction correction was made. The atomic scattering factors for neutral atoms were those of Cromer and Waber (9) and the real and imaginary anomalous dispersion corrections were those of Cromer (10). The computer programs were those provided by the Enraf-Nonius SDP program package. Table 1 gives the atomic coordinates of all the atoms, and Table 2 provides the derived bond distances and valence angles. Table 3 (anisotropic thermal parameters) and the table of measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

[2]The structure factor table and Table 3 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and discussion

Reaction of S_4N_2 with 2e-olefins

The pericyclic reactions of conjugated sulphur–nitrogen rings provide an important means of analysing the nature of their frontier molecular orbitals. For example, the cycloaddition of 2e-olefins to S_4N_4 (11) and phosphadithiatriazenes (4) substantiates the theoretically predicted symmetries of their highest occupied and lowest unoccupied molecular orbitals. In contrast to these reactions, which afford virtually quantitative yields of $S_4N_2 \cdot$ 2olefin and $R_2PS_2N_3 \cdot$ olefin, the reaction of S_4N_2 with olefins (norbornadiene, dicyclopentadiene) is less specific, leading, primarily, to intractable polymeric materials of variable composition. However, soluble molecular species of formula $S_4N_2 \cdot$ olefin are also formed and, with appropriate preparative procedures, these compounds can be obtained in low to moderate yields.

The first such derivative was reported by Adkins and Turner, who were able to isolate and partially characterize a red–orange solid with the empirical formula $S_4N_2 \cdot C_{10}H_{12}$ from the reaction of S_4N_2 with dicyclopentadiene (6). On the basis of infrared and mass spectrometric results, they assigned to it a structure of the type **1**. They did not report the yield of the compound but, using their conditions, we have been unable to achieve yields better than 2–3%. We have focused our own synthetic work on the use of norbornadiene, in part because it affords an easily crystallizable product, but also because it avoids the possibility of a product which is a mixture of diastereomers (which appears to be the case for $S_4N_2 \cdot C_{10}H_{12}$). However, the major synthetic innovation involved not so much the choice of olefin as the method of mixing of the two reagents (S_4N_2 and norbornadiene). When high dilution addition techniques are employed instead of normal addition methods the proportion of intractable materials is markedly reduced. More importantly, the soluble fraction consists (based on tlc evidence) almost entirely of a single component, $S_4N_2 \cdot C_7H_8$ **3**, which can be purified by gel permeation chromatography and recrystallization to give yields of 15%.

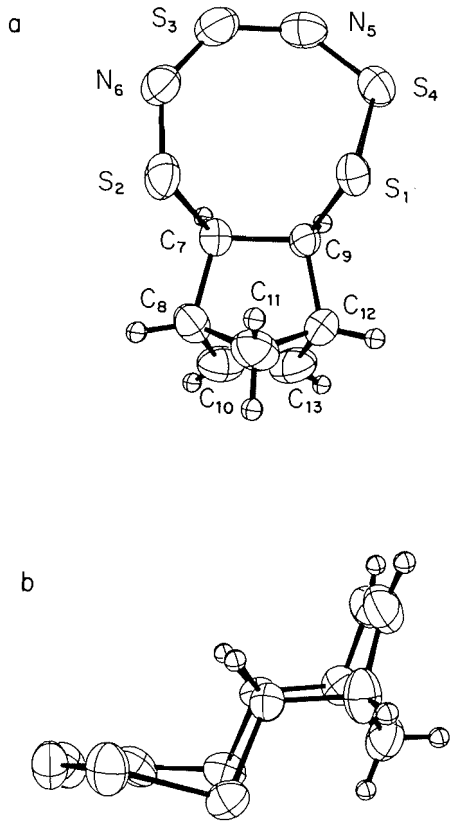

FIG. 1. (*a*) An ORTEP drawing of $S_4N_2 \cdot C_7H_8$ showing the atom numbering scheme, and (*b*) an alternative view illustrating the orientation of the C_7H_8 residue with respect to the S_4N_2 plane.

Some of the structural permutations possible for the cycloaddition of S_4N_2 and a 2*e*-olefin have been reviewed by Adkins and Turner (6). Many of these possibilities were immediately eliminated for $S_4N_2 \cdot C_7H_8$ by the appearance of its ^1H nmr spectrum, which shows a high multiplicity for the $H_{1,4}$, $H_{2,3}$, and $H_{5,6}$ resonances and thereby establishes an unsymmetrical mode of substitution for the norbornenyl group.[3] That the substituents are both sulphur is suggested by the δ-values of the $H_{2,3}$ signals (2.81, 2.53 ppm), which are quite different from those expected for *N*-substitution (ca. 4.5 ppm) (1*c*, 12). The relationship between **3** and the compound reported by Adkins and Turner cannot be established by ^1H nmr spectroscopy,[4] but can be inferred through a comparison of their uv–visible spectra. The dicyclopentadiene derivative exhibits an almost identical pattern of absorption bands (λ_{max} = 262, 350, and 420 nm) with the same relative extinction coefficients. Clearly the chromaphores in $S_4N_2 \cdot C_{10}H_{12}$ and $S_4N_2 \cdot C_7H_8$ are the same. However, while the spectroscopic information on the latter are consistent with the proposed structure **3**, absolute confirmation of this assignment has required the use of X-ray crystallography.

Molecular structure of $S_4N_2 \cdot C_7H_8$

Two ORTEP drawings of $S_4N_2 \cdot C_7H_8$ **3** are shown in Fig. 1. The structure (which exhibits no unusually short intermolecular contacts) reveals that the $S_4N_2 \cdot C_7H_8$ molecule is indeed formed via the *exo* addition of a S—S σ-bond of S_4N_2 across a π-bond of norbornadiene.[5] The molecule thus consists of an eight-membered $C_2S_4N_2$ ring. This ring possesses an approximately planar (to within 0.15 Å) S(1)—S(4)—N(5)—S(3)—N(6)—S(2) sequence with the S(1)—C(9)—C(7)—S(2) unit (which is itself planar to within 0.04 Å) folded out of this plane to produce a dihedral angle of 74.5°. Within the $C_2S_4N_2$ ring there are variations in the N—S distances which are reminiscent of those observed in S_4N_2 itself (5). Thus the bonds to S(3) (mean 1.536 Å) are significantly shorter than those to S(4) and S(2) (mean 1.662 Å). The S(1)—S(4) bond (2.017 Å) is slightly shorter than in S_4N_2 (2.061 Å). The S(1)—S(2) separation (3.156 Å) is shorter than expected for a normal non-bonded contact. The endocyclic angles at sulphur and nitrogen are all somewhat larger than in S_4N_2 itself, as would be expected following the expansion of the ring. The structural parameters of the norbornenyl residue are all normal.

Conclusion

The rupture of the cyclic skeleton of S_4N_2 by norbornadiene represents a surprising departure from other sulphur nitride/olefin electrocyclic reactions. Indeed the attack of the olefin at a sulphur–sulphur σ-bond is not easily rationalized on symmetry grounds; olefin addition across a disulphide linkage represents a forbidden $2_s + 2_s$ process. However, the generation of free radicals in the reaction (7) suggests that a non-concerted di-radical mechanism is involved. The need for high dilution addition techniques, which would suppress competitive bimolecular reactions and thereby favour ring closure, supports this conclusion. The intractable materials produced are probably the result of a radical polymerization.

[3] ^1H nmr assignments were confirmed by homonuclear decoupling experiments.

[4] The ^1H nmr spectrum of $S_4N_2 \cdot C_{10}H_{12}$ is uninterpretable because of the superposition of multiplets arising from different stereoisomers. By contrast, the uv–visible spectra of these isomers will be, to a first approximation, independent of the organic moiety, since the transitions are confined to the S_4N_2 fragment.

[5] Specific *exo* addition is also observed in the reaction of S_4N_4 (3) and $R_2PS_2N_3$ molecules (4) with norbornadiene.

Échelle d'acidité dans les mélanges eau–oxydipropionitrile. II. Cas des mélanges eau–oxydipropionitrile. Application à l'extraction

J. Y. GAL, M. PERSIN ET B. CASTELAS

Laboratoire de chimie analytique de l'université des sciences et techniques du Languedoc, Place Eugène Bataillon, 34060 Montpellier Cedex, France

Reçu le 26 avril, 1982[1]

J. Y. GAL, M. PERSIN et B. CASTELAS. Can. J. Chem. **61**, 1189 (1983).

L'étude des réactions acide–base dans les mélanges eau–oxydipropionitrile à l'aide des électrodes de verre et à hydrogène permet de déterminer les pK_a de quelques couples dans ces milieux. Il est alors possible de disposer de tampons susceptibles de fixer le niveau d'acidité dans les mélanges se séparant lors de la démixtion. L'extraction de divers acides, bases et chélatants par l'oxydipropionitrile montre que les rendements de celles-ci sont très influencés par la nature des ions présents dans la phase aqueuse. La connaissance des paramètres de transfert des diverses espèces présentes constitue une donnée importante permettant d'orienter la recherche des conditions d'extraction les plus favorables.

J. Y. GAL, M. PERSIN, and B. CASTELAS. Can. J. Chem. **61**, 1189 (1983).

The study of acid–base reactions in water–oxydiproprionitrile mixtures using glass and hydrogen electrodes allows for the determination of the pK_a for some couples in these media. It then becomes possible to develop buffers capable of fixing the acidity level in mixtures undergoing separation during demixtion. The extraction with oxydiproprionitrile of various acids, bases, chelating agents shows that the yields are greatly influenced by the nature of the ions present in the aqueous phase. Knowing the transfer parameters of the various species is an important factor in orienting the research for the most favorable extraction conditions.

Introduction

Dans un précédent mémoire (1) nous avons décrit les propriétés de quelques couples acide–base dans l'oxydipropionitrile[2] pur. Ce solvant est intéressant car il est fortement dissociant et moins basique que l'eau. On peut donc y titrer des bases relativement faibles. Les mélanges eau–oxydipropionitrile présentent une importante lacune de miscibilité comprise entre 0,018 et 0,6 en fraction molaire d'oxydiopropionitrile, il était naturel de tenter d'utiliser ce solvant en extraction liquide–liquide. Au cours du présent mémoire, nous avons tout d'abord étudié les propriétés acido-basique de quelques couples dans les mélanges eau–oxydipropionitrile afin de pouvoir disposer de tampons efficaces dans les deux phases se séparant à la démixtion. Cette étude préliminaire permet alors d'envisager la réalisation d'extractions sélectives en milieu de pH contrôlé. La seconde partie de notre mémoire est consacrée à l'étude de différents effets de sels sur l'extraction d'acides, de bases et d'un chélatant: la 1,10-phénanthroline; on y met en particulier en évidence l'influence de l'anion associé lors de l'extraction de certains cations. La connaissance des paramètres de solvatation de divers ions déjà étudiés par ailleurs (2) permet d'orienter de façon judicieuse la mise au point d'extraction quantitative.

Partie expérimentale

Synthèse et purification du solvant

L'établissement d'une échelle d'acidité dans les mélanges eau–oxydipropionitrile nécessite l'obtention d'un solvant particulièrement propre. Le solvant a été synthétisé au laboratoire selon le protocole décrit dans un précédent mémoire (1). L'usage d'un tel solvant n'est cependant pas envisageable directement, celui-ci contenant une impureté amphotère acide–base à concentration voisine de 10^{-3} *M*. Une chromatographie du solvant sur colonne d'alumine neutre permet d'éliminer totalement cette impureté; le solvant obtenu a une conductivité spécifique voisine de 10^{-7} Ω^{-1} cm^{-1}, il est alors conservé sur tamis moléculaire 4 Å.

Réactif

Les acides et les bases utilisés sont des produits pour analyse Prolabo, les sels de tétraalkylammonium sont des produits des établissements K et K. Les agents extractants tripyridyl-symtriazine, dipyridyle et 1,10-phénanthroline proviennent des établissements Merck.

Réalisation des mesures

Les titrages acido-basique ont été réalisés en utilisant une électrode de verre Tacussel ou une électrode à hydrogène constituée d'un carré de platine platiné de 1 cm^2 de surface. Les mesures des potentiels ont été effectuées à l'aide d'un millivoltmètre Tacussel type S6; la température était régulée à 25°C. Les bases ont été titrées avec de l'acide perchlorique 0,1 *M* préparé directement dans le milieu étudié, les acides ont été titrés par la butylamine 0,1 *M*. Les potentiels sont rapportés par rapport à une électrode de référence $Ag \downarrow / Ag^+$ 10^{-2} *M* fonctionnant dans le milieu étudié.

Pour les manipulations d'extraction nous avons déterminé les concentrations des espèces dans chacune des phases par spectrophotométrie à l'aide d'un spectrophotomètre Jean et Constant. Les volumes respectifs des deux phases mises en contact initialement sont egaux.

Résultats expérimentaux

Étude de l'acidité dans les mélanges eau–oxydipropionitrile

Les résultats présentés ont été obtenus en utilisant les électrodes à hydrogène et de verre qui sont indicatrices de l'activité du proton dans tous les mélanges. Le fonctionnement de l'électrode à hydrogène s'avère cependant plus délicat surtout dans les milieux riches en solvant organique par suite de la lenteur de l'établissement des équilibres. Nous l'avons surtout utilisée pour la corrélation des diverses échelles, les titrages classiques ont été effectués à l'aide de l'électrode de verre après étalonnage de celle-ci au moyen de solutions tampons préparées dans les divers milieux.

TABLEAU 1. Echelle d'acidité dans l'eau saturée d'oxydipropionitrile

Couple acide–base	pK_a $x = 0{,}018$	pK_a H_2O (4)
Acide perchlorique	Fort	Fort
Acide nitrique	Fort	Fort
Acide paratoluène-sulfonique	Fort	Fort
Acide benzoïque	4,2	4,2
Acide acétique	4,8	4,7
Ammoniaque	9,2	9,2
Pyridine	5,2	5,2
Butylamine	10,6	10,6

(a) *Cas des mélanges riches en eau*

L'ensemble des résultats expérimentaux montre que les pK_a mesurés dans les divers mélanges sont sensiblement identiques à ceux observés dans l'eau. Ceci s'explique avant tout par la nature très différente des deux cosolvants. Tous ces milieux présentent une basicité probablement voisine de celle de l'eau puisque les quantités ajoutées d'ODPN, solvant moins basique que l'eau, sont très faibles (1). L'espèce la plus acide se trouve pratiquement être toujours l'ion H_3O^+ et l'origine de l'échelle d'acidité est peu modifiée par rapport à l'eau. Dans le tableau 1 nous avons reporté les valeurs mesurées dans l'eau saturée d'oxydipropionitrile ($X_{ODPN} = 0{,}018$). En première approximation on peut donc utiliser les valeurs de $pK_a^{H_2O}$ pour estimer les pK_a dans l'eau saturée d'ODPN de nombreux couples acide–base (tableau 1).

Les comportements des acides et des bases dans les mélanges eau–oxydipropionitrile riches en eau sont voisins de ceux observés dans les mélanges similaires eau – carbonate de propylène de basicité sensiblement équivalente (3).

(b) *Cas des mélanges riches en solvant organique*

Au contraire du cas précédent les pK_a mesurés sont très dépendants de la quantité d'eau présente dans le mélange. Comme nous le verrons par la suite la basicité du milieu augmente avec la quantité d'eau ajoutée, l'origine de l'échelle d'acidité se déplace vers les milieux acides au fur et à mesure de la diminution de la concentration en eau du mélange. L'analyse de l'évolution du comportement des différents couples acide–base permet de formuler les remarques suivantes.

De tous les acides minéraux usuels étudiés seul l'acide perchlorique est toujours totalement dissocié quel que soit la composition du milieu ce qui est en bon accord avec la relativement bonne solvatation de l'anion perchlorate dans tous les mélanges (2). Pour les autres acides minéraux totalement dissociés dans l'eau (HCl, HNO_3, H_2SO_4) la dissociation n'est totale que pour les milieux les plus riches en eau, ce qui est également en accord avec la très faible solvatation des anions dans les mélanges H_2O–ODPN (2). L'ensemble des autres acides organiques se comportent de manière identique et présentent une élévation de leur pK_a au fur et à mesure de l'augmentation de la fraction molaire en ODPN (Tableau 2).

Pour les couples de type B/HB^+ la tendance est également à l'élévation du pK_a au fur et à mesure de la diminution de la teneur en eau. Nous avons examiné plus en détail les variations de la solvatation des espèces responsables de cette évolution des pK_a.

(c) *Corrélation des différentes échelles d'acidité*

La corrélation des échelles d'acidité de façon approximative n'est possible que par la connaissance du paramètre de solvatation $\gamma(H^+)$ du proton, celui-ci peut être obtenu en réalisant les piles suivantes dans l'eau et chacun des mélanges:

$$H^+/H_2 \mid \text{Pt platiné} \parallel Fc/Fc^+ \mid Pt$$

La mesure des potentiels normaux de cette pile dans chacun des milieux par rapport au couple de référence Ferrocène–Ferricinium permet de déterminer le coefficient d'activité de transfert $\gamma(H^+)$ du proton au moyen de la relation:

$$\log \gamma(H^+) = \frac{{}^{s}E^0_{H^+/H_2} - {}^{E}E^0_{H^+/H_2}}{0{,}059} \qquad \text{à } t = 25°C$$

ou ${}^{s}E^0_{H^+/H_2}$ est le potentiel normal apparent du couple H^+/H_2 dans le mélange et ${}^{E}E^0_{H^+/H_2}$ est le potentiel normal apparent du couple H^+/H_2 dans l'eau.

Nous avons pu vérifier le fonctionnement Nernstien de cette pile dans tous les milieux, cependant le temps de réponse est allongé à quelques minutes lorsque la fraction molaire en oxydipropionitrile augmente dans les milieux riches en solvant organique. L'ensemble des résultats est rassemblé dans le tableau 3.

Ceux-ci montrent que dans les milieux très riches en eau la présence d'oxydipropionitrile affecte peu log $\gamma(H^+)$. Par conséquent la basicité du mélange n'est pas modifiée par les traces d'oxydipropionitrile conformément à la faible basicité de ce solvant. Au contraire dans les milieux riches en oxydipropionitrile l'addition d'eau entraine une variation importante de log $\gamma(H^+)$ qui montre que la basicité du milieu augmente considérablement; le milieu de composition 0,6 correspondant à l'une des phases qui apparait à la démixtion présente une basicité très voisine de celle de l'eau pure. Il est dès lors possible de corréler entre elle les différentes échelles d'acidité; le décalage de chacune d'elles par rapport à l'eau étant donné par la valeur de log $\gamma(H^+)$, Fig. 1. On peut expliquer aisément l'affaiblissement général des acides HA ou HB^+ dans les milieux riches en oxydipropionitrile par la solvatation de plus en plus faible du proton.

L'ensemble des résultats mentionnés précédemment montre qu'il est possible de disposer de divers mélanges tampons dans une large gamme de pH. Nous allons maintenant étudier les possibilités d'utilisation de l'oxydipropionitrile pour réaliser des extractions à pH contrôlé; ce milieu est à priori intéressant car sa forte constante diélectrique rend possible l'emploi de méthodes électrochimiques d'analyse en phase organique, ce qui s'avère impossible lorsque l'on utilise des solvants comparables au chloroforme ou au tétrachlorure de carbone. Afin de préciser les conditions à réaliser nous aborderons dans ce mémoire le comportement de divers réactifs lors du processus d'extraction par l'oxydipropionitrile.

Extraction des acides et des bases par l'oxydipropionitrile

Une solution d'eau saturée d'oxydipropionitrile contenant un acide ou une base à la concentration C_0 est agitée avec le même volume de solution d'oxydipropionitrile saturé d'eau. Après séparation le dosage dans chacune des deux phases de l'acide ou de la base conduit au coefficient de distribution défini par

$$K_D = \overline{|A|}_s / |A|_E$$

(a) *Coefficient de distribution de quelques acides*

Les résultats du tableau 4 montrent que les acides sont plus ou moins extraits selon la nature de l'anion présent.

Dans le cas des acides totalement dissociés dans les deux phases de démixtion tel $HClO_4$, HNO_3, HCl ... l'équilibre d'extraction est du type:

$$H_E^+ + A_E^- \rightleftharpoons H_s^+ + A_s^-$$

Comme les données concernant la solvatation nous ont montré

0,998	−0,143	+3,95

que le proton est préférentiellement solvaté par la phase aqueuse on doit s'attendre à une extraction de l'acide d'autant plus prononcée que l'anion associé est mieux solvaté par la phase organique. Dans celle-ci l'ordre de solvatation a été déterminé (2):

$$ClO_4^- > NO_3^- > Cl^-$$

Ces données sont en bon accord avec l'importance des coefficients de distribution observés:

$$HClO_4 > HNO_3 > H_2SO_4 > HCl$$

On peut toutefois noter que parmi les acides minéraux usuels seul l'acide perchlorique est extrait de façon importante, la même conclusion s'applique à l'acide picrique dont l'anion très volumineux peut être relativement facilement solvaté par la phase organique, ces résultats sont en tous points analogues à ceux observés dans les mélanges eau – carbonate de propylène (5, 6).

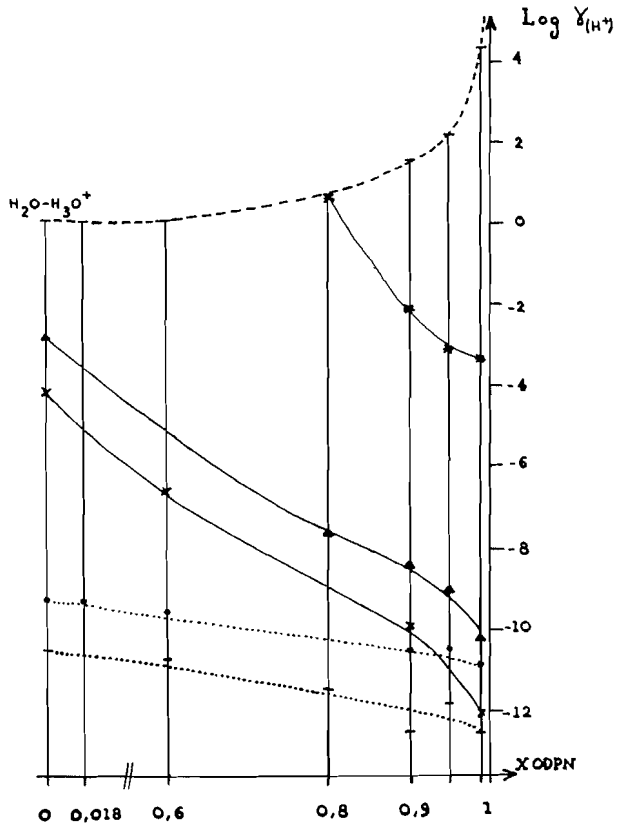

FIG. 1. Variation log $\gamma(H^+)$ et des pK_a de quelques acides dans les mélanges H_2O–ODPN; ● ammoniaque, × acide benzoique, – butylamine, *acide chlorhydrique, ▲ acide monochloracétique.

Dans le cas des autres acides peu dissociés dans les deux phases, ceux-ci sont extraits principalement à l'état de molécules, le coefficient de distribution rend compte de leur affinité pour chacune des deux phases. On peut remarquer que la pro-

Phosphorique	−1,83	98

TABLEAU 5. Effet de la présence de cation sur le rendement d'extraction des acides forts

Acide	Sel		Rendement %
HCl 0,1 *M*	—		2
HCl 0,01 *M*	Bu_4NCl	0,1 *M*	3,5
HCl 0,01 *M*	NaCl	0,1 *M*	3,5
HNO_3 0,1 *M*	—		7
HNO_3 0,01 *M*	$NaNO_3$	0,1 *M*	12,5
$HClO_4$ 0,1 *M*	—		39
$HClO_4$ 0,01 *M*	Et_4NClO_4	0,1 *M*	20
$HClO_4$ 0,01 *M*	$NaClO_4$	0,1 *M*	51

portion d'acide passant dans la phase organique et loin d'être négligeable.

(b) *Effet de sel sur l'extraction des acides forts*

Le tableau 5 montre que la présence d'un sel dont l'anion est commun à l'acide extrait modifie considérablement le rendement d'extraction de ce dernier. Ce résultat est particulièrement net dans le cas de l'acide perchlorique où le rendement passe de 39% en l'absence de sel, à 20% en présence de perchlorate de tétraéthylammonium et 51% en présence de perchlorate de sodium. On peut expliquer ce phénomène par une compétition entre l'extraction de l'acide et du sel. Dans le cas d'un sel présentant un cation ammonium quaternaire il y a abaissement du rendement de l'extraction de l'acide et extraction préférentielle du sel dont le cation ammonium se trouve mieux solvaté par la phase organique que le cation H^+; au contraire l'utilisation d'un sel contenant un cation minéral augmente le rendement par suite de la mauvaise solvatation de ce dernier par la phase organique. Pour l'acide nitrique et l'acide chlorhydrique ces variations sont bien plus faibles à cause de la mauvaise solvatation des ions nitrate et chlorure par la phase organique.

Extraction d'une substance chélatante: la 1,10-phénanthroline

(a) *Étude de l'influence du pH de la phase aqueuse*

La 1,10-phénanthroline (oph) est une base de pK_a 4,9 en phase aqueuse et 5,3 dans l'ODPN saturé d'eau. Il en résulte que selon le pH elle sera extraite soit à l'état de molécule oph ou d'ion $ophH^+$, dans ce dernier cas la présence d'anions doit modifier les conditions d'extraction. L'analyse du tableau 6 montre qu'en milieu tampon ammoniacal de pH 9,2 l'extraction est peu sensible à la nature de l'ion associé au cation NH_4^+; on extrait la molécule de 1,10-phénanthroline. En milieu acide le rendement de l'extraction dépend de l'acide utilisé pour imposer le pH. Le rendement est d'autant plus élevé que l'anion de l'acide présente d'affinité pour la phase organique.

(b) *Modification du rendement en présence de sels*

En milieu acide perchlorique le rendement est peu affecté par

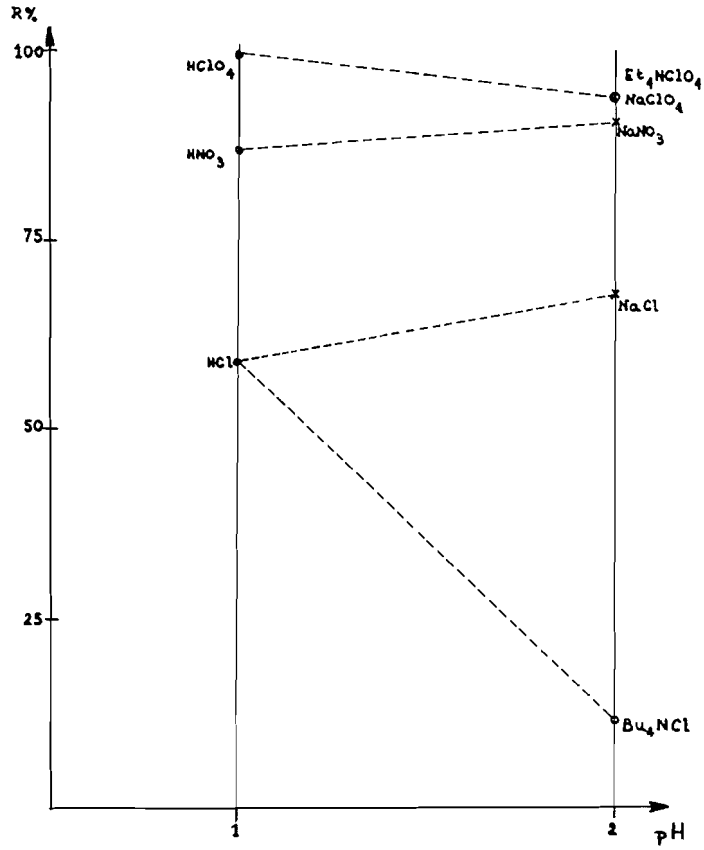

FIG. 2. Rendement d'extraction de la 1,10-phénanthroline en milieu acide en présence de divers sels à la concentration 0,1 *M*.

la présence de sels, les ions Et_4N^+ ou Na^+ ne perturbent pas l'extraction de $ophH^+$ ClO_4^-.

En milieu acide chlorhydrique la présence d'ion Bu_4N^+ diminue fortement le rendement d'extraction de $ophH^+$ Cl^- au profit de Bu_4N^+ Cl^-; la présence d'un petit cation Na^+ peu solvaté par la phase organique renforce au contraire l'extraction de $ophH^+$ Cl^- (Fig. 2). En milieu tamponné le rendement dépend de l'anion du sel ajouté si celui-ci présente un cation identique à celui de la base du tampon, ainsi en milieu tampon chloracétique on extrait le chloracétate de 1,10-phénanthrolinium, l'addition de perchlorate de sodium favorise l'extraction du perchlorate de 1,10-phénanthroline. Dans le cas d'un tampon imposant un pH en phase aqueuse supérieur au pK_a de la 1,10-phénanthroline les effets de sels sont moins nets, l'extraction s'effectuant à l'état de molécules.

Il apparait que l'incidence des cations ou anions parasites en solution peut être aisément prévue par la connaissance des grandeurs de transfert de ceux-ci entre les deux phases de démixtion, il est dès lors possible d'orienter les conditions optimales d'extraction de façon raisonnée. Les résultats obtenus constituent une bonne vérification des grandeurs de transfert de quelques anions déjà déterminées (1, 2).

Conclusions

Cette étude montre qu'il est possible d'utiliser certains couples acide−base comme substances tampons dans les deux zones de démixtion des mélanges eau oxydipropionitrile. L'étendue de l'échelle de pH utilisable dans les mélanges eau−oxydipropionitrile est réduite à une douzaine d'unités par suite de la basicité importante de l'eau par rapport à

l'oxydipropionitrile.

L'utilisation de l-oxydipropionitrile comme solvant d'extraction est intéressante par suite du caractère dissociant des milieux se séparant à la démixtion; ce qui constitue une originalité par rapport aux solvants inertes classiquement utilisés ($CHCl_3$, CCl_4). La possibilité d'extraire certaines substances sous forme ionique permet de jouer sur la nature du contre-ion extrait pour modifier les rendements d'extraction. Les prévisions de ces derniers à partir de la connaissance des paramètres de transfert γ sont vérifiées expérimentalement de façon satisfaisante. On dispose alors d'un paramètre supplémentaire qui permet d'orienter les séparations et de les rendre quantitatives dans certaines conditions par ajout d'un contre-ion bien solvaté par la phase organique se séparant lors de la démixtion.

A partial synthesis of aconosine[1]

O. E. EDWARDS, R. J. KOLT, AND K. K. PURUSHOTHAMAN[2]

Chemistry Division, National Research Council of Canada, 100 Sussex Drive, Ottawa, Ont., Canada K1A 0R6

Received November 30, 1982

O. E. EDWARDS, R. J. KOLT, and K. K. PURUSHOTHAMAN. Can. J. Chem. **61**, 1194 (1983).

The diterpenoid alkaloid cammaconine, with known structure and stereochemistry, was converted into a base with the same properties as those reported for the alkaloid aconosine.

O. E. EDWARDS, R. J. KOLT et K. K. PURUSHOTHAMAN. Can. J. Chem. **61**, 1194 (1983).

On a transformé l'acaloïde diterpénique cammaconine, dont la strueture et la stéréochimie sont connues, en une base possédant les même propriétés que cells rapportées pour l'alcaloïde aconosine.

[Traduit par le journal]

In 1972 Murav'eva *et al.* (1) described a new diterpenoid alkaloid from *Aconitum nasutum*, which they named aconosine. It had a C_{18} skeleton, the first of its class, and they proposed that it had structure **1** (but with a 1β methoxy group), lacking the usual alkyl or oxyalkyl group on C-4. We report a simple transformation of the alkaloid cammaconine **2***a* into **1**, with properties very similar to those reported for aconosine by the Russian workers.[3,4]
